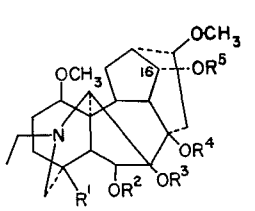
DELPHINIUM ALKALOIDS

THE STRUCTURES OF THE ALKALOIDS OF DELPHINIUM CARDINALE HOOK AND THE ALKALOID DELATINE

M. H. BENN

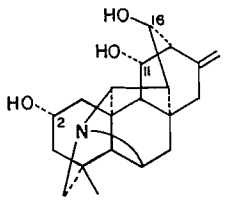
Department of Chemistry, University of Alberta, Calgary, Alberta

Received July 16, 1965



ABSTRACT

Browniine, dehydrobrowniine, lycoctonine, hetisine, and a dehydrohetisine were isolated from *Delphinium cardinale* Hook. Delatine, an alkaloid previously isolated from *D. elatum* L., was found to be hetisine. These are the first examples of the occurrence of the *Aconitum* alkaloid hetisine in *Delphinium* spp.



As part of a programme concerned with the chemotaxony of the genus *Delphinium*,[1] we have examined the alkaloids of *D. cardinale* Hook, a handsome, red-flowered species that sometimes exceeds 6 ft in height and is native to Southern and Baja California.

Extraction of the above-ground portion of the plant yielded an amorphous mixture of ester alkaloids which, on saponification, gave the parent alkaloids as a noncrystalline glass, together with benzoic and N-methylsuccinylanthranilic acids. Careful column chromatography of the mixed alkaloids on alumina initially yielded three crystalline alkaloids, one of which was recognized as lycoctonine. This alkaloid was first isolated as the (−)-N-(*o*-carboxyphenyl) methylsuccinimide ester,[2] methyllycaconitine, from *Aconitum lycoctonum*[3] (3, 4) and was subsequently found to be distributed quite widely in *Delphinium* spp. (2*a*). Lycoctonine has been shown to have the structure I (R^1 = OH, R^2 = CH_3, R^3 = R^4 = H, R^5 = CH_3) (6, 7). The other two crystalline alkaloids from the column chromatogram appeared to be unknown.

The first of these, m.p. 163–164°, was eluted from the column before lycoctonine and

I

II

[1]*Some 500 species of Delphinium that are almost exclusively native to the Northern Hemisphere and commonly blue flowered have been described (1). The genus has long been recognized by chemists as a rich source of alkaloids (2).*

[2]*The succinimide ring is easily opened by bases, hence the appearance of N-methylsuccinylanthranilic acid after saponification (4). We presume that lycoctonine is present in D. cardinale as methyllycaconitine.*

[3]*It has been suggested that this was actually A. vulparia Reichb. (5).*

had an infrared spectrum showing a strong resemblance to those of lycoctonine and the closely related alkaloid browniine[4] (I, $R^1 = OCH_3$, $R^2 = CH_3$, $R^3 = R^4 = R^5 = H$) (8), with, however, the additional feature of absorption in the carbonyl region at 1 750 cm^{-1}. Proton magnetic resonance spectroscopy (60 Mc/s) also revealed a striking similarity of the spectrum of the new alkaloid to those of lycoctonine and browniine, with signals caused by an ethyl group and four methoxyl groups as prominent features of the spectrum. However, in contrast to spectra of these two alkaloids, in which the methoxyl signals were completely resolved, in the spectrum of the new alkaloid two of the methoxyl signals overlapped to form a single, unresolved signal. The new alkaloid also showed low-intensity absorption in the ultraviolet at 288 mμ, while its optical rotatory dispersion curve exhibited a positive Cotton effect with extrema at 310 and 287 mμ.[5] All of these features seemed to be accommodated by dehydrobrowniine, in which the secondary hydroxyl at C-16 of browniine has been oxidized to give a cyclopentanone system. That this was, in fact, the correct structure of the alkaloid was readily shown by a sodium borohydride reduction, browniine being the only product formed. The stereospecific reduction of dehydroxobrowniine (to oxobrowniine) has already been described (8); in both cases shielding of one side of the carbonyl function results in exclusive formation of the 16α-alcohol.

The structure of the alkaloid of m.p. 163–164° was also established by a partial synthesis from browniine. Sodium dichromate in acetic acid[6] gave low yields of ketonic, basic material from which dehydrobrowniine was separated by chromatography and found to be identical with the naturally occurring alkaloid.

Thin-layer chromatography results had already suggested that browniine itself was probably present in the noncrystalline alkaloid fractions eluted before and together with dehydrobrowniine, and indeed browniine could be isolated as the crystalline perchlorate salt from these fractions, after all ketonic materials had been removed with Girard-T reagent.[7]

The second new crystalline alkaloid, m.p. 268–270°, eluted from the column after lycoctonine, had an infrared spectrum markedly different from that of lycoctonine (or browniine). In particular, the second new alkaloid exhibited absorption at 3 080, 1 650, and 900 cm^{-1} which suggested the presence of an exocylic methylene group, at 1 700 cm^{-1} which suggested a cyclohexanone, and at 1 050 cm^{-1} which suggested the presence of secondary hydroxyl functions. All these absorptions were absent in the spectra of lycoctonine and browniine, which in contrast had strong absorption bands at 2 820 and 1 085 cm^{-1}, caused by their methoxyl functions, which are not present in the spectrum of the unknown alkaloid. An analysis of the proton magnetic resonance spectrum of the unknown alkaloid confirmed that there were no methoxyl groups present, and also revealed the presence of one tertiary C-methyl group (and the probable absence of other simple alkyl groups) and two vinylic protons (as required for an exocyclic methylene function). The ultraviolet light absorption spectrum of the second new alkaloid showed low-intensity absorption at 290 mμ. The optical rotatory dispersion curve of the alkaloid dissolved in

[4]*This alkaloid was originally isolated from D. brownii Rydb. (synonym D. glaucum S. Wats.).*

[5]*Interestingly, in acid solution the optical rotatory dispersion curve shows a negative Cotton effect. A similar observation in the Lycopodium alkaloid series (9) has been interpreted as indicating that positively charged nitrogen has a large specific rotativity, like fluorine (10). We thank Dr. W. A. Ayer for drawing our attention to this observation (9).*

[6]*Oppenhauer oxidation failed to yield dehydrobrowniine, the starting material being recovered even under reasonably forcing conditions (cyclohexanone – aluminium t-butoxide in refluxing toluene for 8 h), presumably because of steric hindrance to the formation of the cyclic transition state required in this oxidation.*

[7]*Unless this was done, dehydrobrowniine perchlorate contaminated the product and could not be removed, even by repeated recrystallization.*

For personal use only.

methanol showed only the vestige of an inflexion at 325 mμ; however, when dissolved in acetic acid or 1 *N* aqueous sulfuric acid the alkaloid showed a weak positive Cotton effect with extrema at 310 and 330 mμ. The molecular weight, determined by mass spectrometry, was 327 which, combined with the analytical results, gave a molecular formula for the alkaloid of $C_{20}H_{25}NO_3 \cdot \frac{1}{2}H_2O$.

In 1943, Goodson (11) reported the isolation of three alkaloids, methyllycaconitine, delpheline (I, R^1 = H, R^2 = OH, $R^3 + R^4 = CH_2$, $R^5 = CH_3$) (12), and delatine, from the seeds of *D. elatum*.[8] Delatine was much less heavily oxygenated than the other two alkaloids and was ascribed the molecular formula $C_{19}H_{25}NO_3 \cdot H_2O$ by Goodson, who also reported it to have m.p. 148° (hydrate), 261–264° (anhydrous), $[\alpha]_D^{23}$ +13.5° in dilute hydrochloric acid, and to contain neither methoxyl nor N-methyl groups. No further work on delatine appears to have been reported in the literature.

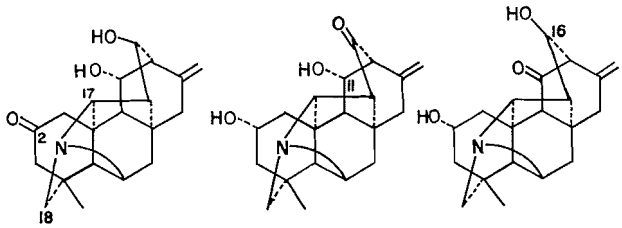
It appeared possible that our second alkaloid and delatine might be the same compound, and we obtained a sample of Goodson's delatine hydrochloride for comparative purposes. However, there was complete absence of carbonyl absorption in the infrared spectrum of delatine hydrochloride. There was, however, a striking similarity to the spectrum of hetisine hydrobromide, which we also had at hand.

Hetisine was first described in 1942, having been isolated from *Aconitum heterophyllum* Wall. by Jacobs and Craig (13), and its complete structure has very recently been established as that shown in II by X-ray crystallographic analysis of the hydrobromide (14). The physical constants reported by Jacobs and Craig for hetisine, m.p. 145° (effervescence), 253–256°, $[\alpha]_D^{25}$ +13.7° (ethanol), were suggestively similar to those of delatine, and indeed upon comparison of the alkaloids, as the free bases and hydrobromides, they were found to be identical. Thus delatine is in fact hetisine (II).

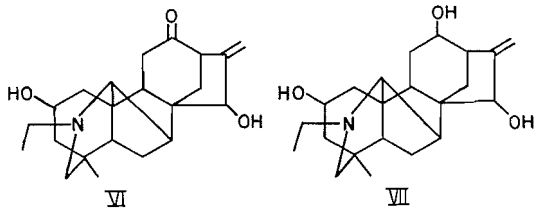
After this serendipitous outcome, we observed that there were certain general similarities in the infrared spectra of hetisine and our alkaloid. Acting on the premise that the second new alkaloid might be a dehydrohetisine, we therefore reduced it with sodium borohydride. The only product isolated was hetisine, which was characterized as the hydrobromide.

Our second alkaloid is therefore one of the three possible dehydrohetisines (III, IV, and V). High-resolution infrared spectroscopy[9] failed to reveal any shift (or splitting) of the carbonyl absorption band from the position expected for a simple cyclohexanone system, 1 707 cm^{-1}, i.e. there was no evidence for hydrogen bonding such as might have been expected had the keto function been at either C-11 (IV) or C-16 (V). There was also no sign of "abnormally" intense $n \rightarrow \pi^*$ ultraviolet light absorption at 290 mμ, such as would also have been anticipated had the keto function been in these positions, gamma to the exocylic methylene group.[10]

The remaining alternative of locating the keto function is at C-2, and this is not particularly attractive since one would have anticipated (octant rule) that this compound would have shown a large, negative Cotton effect in its optical rotatory dispersion spectrum. Furthermore, in this position, the stereospecific sodium borohydride reduction is much more unexpected than for the alternative positions (IV, V), where very pronounced shielding effects are apparent.[11] However, we tentatively advance the structure III for the alkaloid, m.p. 268–270°.



[8]*The seeds were those of a horticultural strain that was probably much crossed.*



[9]*In very dilute solution in chloroform, with a Beckman IR-7 spectrometer having scale expansion.*

[10]*Molecular models of III and IV show that there should be perceptible overlap of the orbitals of the carbonyl and exocylic methylenic double bonds, the required conditions for enhanced $n \rightarrow \pi^*$ absorption (15), although the overlap is not as good as that in songorine (VI), which has λ_{max} 290 mμ, ε 500 (16).*

[11]*Possibly the β-oriented hydrogens at C-17 and C-18 do screen the "rear-side" of the keto function in III, but exclusive "front-side" attack and formation of the 2α-ol, by sodium borohydride, seems rather surprising.*

Finally, we reexamined the noncrystalline alkaloids eluted after dehydrohetisine and, from the infrared spectra of these, we were able to deduce that hetisine was present. Upon rechromatography of these fractions, hetisine was isolated and characterized as the hydrobromide.

The co-occurrence of the dehydroalkaloids and their parent alkaloids raises the question of whether the dehydro compounds are of genuine natural occurrence, or are artifacts produced by oxidation during the processing of the plant material and isolation of the alkaloids. From the evidence at our disposal,[12] however, we believe that the dehydroalkaloids which we isolated do actually coexist in the plant with the corresponding alkaloids.

It is interesting to see another diterpenoid alkaloid, hetisine, common to *Aconitum* and *Delphinium* species, reflecting the very close phylogenetic relationship of these two genera. Presumably the lycoctonine and hetisine skeletons are closely related biosynthetically, possibly arising from some common diterpenoid precursor, e.g. by some modification of the common biogenetic derivation suggested for the lycoctonine and atisine skeletons (2*b*, 17).

EXPERIMENTAL

Unless otherwise stated, all melting points are corrected, infrared spectra are of KBr disks and were made with a Perkin–Elmer 337 grating spectrometer, proton magnetic resonance spectra were measured at 60 Mc/s in deuterochloroform with tetramethylsilane as standard (τ = 10), optical rotatory dispersion measurements were made with a Durrum–Jasco spectrometer, and ultraviolet light absorptions are of solutions in 95% (v/v) ethanol. The alumina used for column chromatography was Woelm, neutral, grade 4. Thin-layer chromatography was performed on silica gel G with chloroform–methanol (4:1 v/v) as solvent and iodine vapor for location of the alkaloids.

Isolation of the Alkaloids

D. cardinale plants, collected in and just before blossoming, were cut up and preserved under isopropanol–methanol. After 7 days, the plants were repeatedly macerated with methanol, in a Waring Blendor, until the extracts were almost colorless. The dry plant residue amounted to 0.8 kg. Rapid concentration of the

[12]*On prolonged exposure to the atmosphere, in solution or as solids, browniine and hetisine were discolored. Infrared examination of the "aged" alkaloids revealed the formation of only traces of carbonyl-containing products from hetisine and not a trace of such material from browniine. There is a previous example of the co-occurrence of an aconite alkaloid and its dehydro derivative. Napelline (VII) and songorine (VI) have been isolated from Aconitum napellus (16).*

methanol extracts (cyclone evaporator) yielded a dark-green syrup which was partitioned between petroleum ether and 1 *N* aqueous sulfuric acid. The petroleum ether layer was re-extracted with dilute sulfuric acid (4 × 200 ml) and the combined aqueous extracts washed with petroleum ether (4 × 100 ml). The aqueous solution was made strongly alkaline with sodium hydroxide solution and then extracted with chloroform (7 × 200 ml). The combined, dried ($MgSO_4$) chloroform extracts were concentrated under reduced pressure (to about 200 ml) and then extracted with 1 *N* aqueous sulfuric acid (5 × 100 ml). The combined aqueous extracts were backwashed with chloroform (1 × 100 ml), make alkaline with sodium hydroxide solution, and extracted with chloroform (5 × 100 ml) as before. The combined, dried ($MgSO_4$) chloroform extracts were evaporated under reduced pressure to a residual oil which was dissolved in acetone, and the solution was then reevaporated under reduced pressure to yield the ester alkaloids as an amorphous off-white solid (3.5 g, 0.44%, based on dry plant residue).

Saponification of the Ester Alkaloids

The ester alkaloids (2.5 g) were dissolved in methanol (50 ml) containing sodium hydroxide (300 mg) and water (10 ml). The solution was refluxed for 90 min and then the bulk of the methanol was removed under reduced pressure. The residual solution was diluted with water (40 ml) and extracted with chloroform (4 × 30 ml). The combined, dried ($MgSO_4$) chloroform extracts were evaporated under reduced pressure to yield the alkaloids as an off-white glass (2.5 g).

The aqueous alkaline extracts were adjusted to pH 5 with dilute sulfuric acid and extracted with chloroform (4 × 25 ml). Evaporation of the dried ($MgSO_4$) extracts yielded a little off-white solid, which was recrystallized from water to give colorless laths, m.p. 120–121°, undepressed on admixture with authentic benzoic acid. The infrared spectrum of the recrystallized material was also superimposable on that of benzoic acid.

The aqueous extracts remaining from the chloroform extraction were brought to pH 1 with sulfuric acid and extracted continuously with ether for 48 h. Evaporation of the ether extract yielded an oil which crystallized from concentrated ether or acetone. Recrystallization of this acid from water gave colorless needles, m.p. 162–163°. Thin-layer chromatography showed that this acid was indistinguishable from synthetic (±)-N-methylsuccinylanthranilic acid,[13] and the infrared spectra of the synthetic and isolated acids, in chloroform solution, were identical. The literature m.p. for (−)-N-methylsuccinylanthranilic acid is 163–164° (18) and 155° (11).

Column Chromatography of the Mixed Alkaloids

The mixed, saponified alkaloids (2.5 g) were chromatographed on a column of alumina (2.0 cm × 40 cm). Fractions of 25 ml were collected and evaporated individually under reduced pressure, and the residues were examined by thin-layer chromatography. The fractions were then appropriately grouped. Details of the column chromatography are given in Table I.

Fractions 19–38 were crystallized from ether to give small colorless prisms of an alkaloid, m.p. 161–163° (128 mg, 5%).

Fractions 49–52 were crystallized from acetone – petroleum ether to give colorless needles of lycoctonine hydrate, m.p. 115–125° (open capillary) (104 mg, 4%). Lit. m.p. 120–139° (19). The infrared spectrum of the isolated alkaloid was identical with that of an authentic specimen of lycoctonine hydrate.

Fractions 67–69 were rechromatographed on alumina, neat chloroform being used as eluant and 10 ml fractions being collected. Fractions 5–10 from this separation yielded a white glass (229 mg) which was crystallized from acetone to give colorless needles of an alkaloid, m.p. 265–270° (104 mg, 4%).

Fractions 73–81 and 82–85 and the tail fractions from the rechromatographed fractions 67–69 had infrared spectra which indicated that they were almost pure hetisine. The tail fractions (105 mg) were converted into the hydrobromide salt, m.p. 260–266° (decomp.), undepressed on admixture with authentic hetisine hydrobromide. Lit. m.p. 266–269° (14*b*). The infrared spectrum of the hydrobromide was also identical with that of authentic material.

Alkaloid, m.p. 161–163°

$[\alpha]_D^{27}$ +19°; optical rotatory dispersion, Cotton effect, $[\phi]_{300}^{27}$ +1 380°, $[\phi]_{260}^{27}$ +650° (*c*, 0.2); optical rotatory dispersion in 1 *N* aqueous H_2SO_4, Cotton effect, $[\phi]_{310}^{30}$ −372°, $[\phi]_{287}^{30}$ +1 320° (*c*, 0.15). The ultraviolet absorption had a slight inflexion on the end absorption curve at 288 mμ, ε 30. The infrared spectrum had prominent absorption bands at 3 500, 3 400, 2 970, 2 910, 2 855, 2 830, 1 750, 1 470, 1 350, 1 290, 1 215, 1 100 (broad), 990, 940, 730, 650, 630, and 590 cm^{-1}. The proton magnetic resonance spectrum contained prominent signals at τ 8.9 (t) (3H) (CH_3 of N-ethyl group) and at τ 6.7 (s) (6H), 6.65 (s) (3H), 6.58 (s) (3H) (four OCH_3 groups).

Alkaloid, m.p. 265–270°

Anal. Found: C, 71.20; H, 7.70; N, 4.17; mol. wt. 327 (mass spectrometer). $C_{20}H_{25}NO_3 \cdot \frac{1}{2}H_2O$ requires C, 71.40; H, 7.79; N, 4.15.

$[\alpha]_D^{28}$ +18°; optical rotatory dispersion, plain curve, $[\phi]_{600}^{29}$ +60°, $[\phi]_{280}^{29}$ +420° (slight inflexion), $[\phi]_{340}^{29}$

[13]*This acid was obtained by saponification of the ester prepared by the reaction of (±)-methylsuccinic anhydride with ethyl anthranilate.*

TABLE I

Fraction Nos.	Eluant composition (v/v)	Wt. eluted (mg)	Appearance	Composition
1–6	Benzene	14	Pale brown wax	Essentially alkaloid free
7–18	5% ether–benzene	14	Pale yellow oil	At least two alkaloids, one (the slower moving) indistinguishable from browniine
19–38	5–50% ether–benzene	329	Pale yellow glass	Similar to fractions 7–18, but fastest moving alkaloid now predominant
39–48	50% ether–benzene and ether	95	Off-white glass	A third alkaloid now present, indistinguishable from lycoctonine
49–52	Ether	153	Colorless glass	The third alkaloid now predominant
53–66	Ether and chloroform	267	Off-white glass	As fractions 49–52
67–69	5% methanol–chloroform	777	Off-white glass	A mixture of several alkaloids
70–72	5 and 10% methanol–chloroform	409	Off-white glass	Similar to fractions 67–69
73–81	10% methanol–chloroform	117	Lemon-yellow glass	A mixture with a predominant (slow-running) alkaloid
81–85	25% methanol–chloroform	75	Brownish-yellow glass	Similar to fractions 73–81

+210° (*c*, 0.16); optical rotatory dispersion in 1 *N* aqueous H_2SO_4, Cotton effect, $[\phi]_{343}^{30}$ +175°, $[\phi]_{316}^{30}$ +92° (*c*, 0.16); ultraviolet absorption, λ_{max} 290 mμ, ε 40. The infrared spectrum had bands at 3 350, 3 080, 2 960, 2 940, 1 700, 1 650, 1 430, 1 285, 1 070, 1 050, 900, and 875 cm^{-1}. The proton magnetic resonance spectrum had signals at τ 5.1 (1H) and 5.3 (1H) (two vinylic protons) and 8.85 (s) (3H) (CH_3—C(—)—).

Isolation of Browniine from the "Front" Fractions of the Main Column Chromatogram

Fractions 4–14 (105 mg) were dissolved in ethanol (5 ml) containing acetic acid (0.5 ml), Girard-T reagent (100 mg) was added, and the reaction mixture was then refluxed for 8 h. After having been kept at room temperature overnight, the reaction mixture was concentrated under reduced pressure, the residue diluted with ice water (40 ml), and the solution made alkaline with ammonia and extracted with chloroform (4 × 10 ml). Removal of solvent, under reduced pressure, from the combined, dried ($MgSO_4$) chloroform extracts left an off-white glass (72 mg). This material showed no carbonyl absorption in the infrared spectrum (chloroform solution). Part of this material (38 mg) was chromatographed on alumina and the alkaloid (21 mg) that was eluted with 25% (v/v) ether–benzene was converted into the crystalline perchlorate salt, m.p. 208–210°, undepressed on admixture with authentic browniine perchlorate. Lit. m.p. 212° (8). The infrared spectrum was also identical with that of browniine perchlorate.

Sodium Borohydride Reduction of the Alkaloid, m.p. 161–163°

Sodium borohydride (50 mg) was added during the course of 1 h to a solution of the alkaloid (38 mg) in methanol (8 ml) containing water (1 ml). After 2 h at room temperature, two drops of concentrated hydrochloric acid was added to the solution to destroy any excess borohydride, the reaction mixture was evaporated to a small volume under reduced pressure and diluted with water (5 ml), and the solution was made alkaline with 6 *N* aqueous sodium hydroxide solution (5 ml) and extracted with chloroform (4 × 10 ml). The combined, dried ($MgSO_4$) chloroform extracts were evaporated under reduced pressure to a residual oil (44 mg), which was converted into the beautifully crystalline perchlorate salt, m.p. and mixed m.p. with browniine perchlorate 212–214°. The infrared spectrum of the perchlorate of the reduced alkaloid was also superimposable on that of authentic browniine perchlorate.

Preparation of Dehydrobrowniine

Browniine (from 363 mg of perchlorate salt) was dissolved in acetic acid (5 ml) and to this, at room temperature, was added 1.5 ml of a solution of sodium dichromate (0.60 g) in acetic acid (50 ml).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Further 1.5 ml volumes of the sodium dichromate solution were added to the reaction mixture after 30, 90, and 150 min. After 18 h at room temperature, the reaction mixture was diluted with ice water (30 ml), made alkaline with sodium hydroxide solution, and extracted with chloroform (4 × 20 ml). (Centrifugation was necessary at this stage.) The combined, dried ($MgSO_4$) chloroform extracts were evaporated under reduced pressure to yield a yellow glass (288 mg). This glass was redissolved in chloroform (15 ml) and extracted with 1 *N* aqueous sulfuric acid (2 × 15 ml). The combined aqueous extracts were backwashed with chloroform (1 × 10 ml) and the combined, dried ($MgSO_4$) chloroform extracts evaporated under reduced pressure to yield neutral material (85 mg). Basification of the aqueous extracts with sodium hydroxide solution followed by chloroform extraction (3 × 15 ml) gave, after solvent had been removed from the combined, dried ($MgSO_4$) chloroform extracts, the basic material (195 mg). The infrared spectrum of this material in chloroform solution suggested about 30% ketone content, and when it was chromatographed on alumina the fractions that were eluted with benzene and 5% (v/v) ether–benzene were crystallized from concentrated ether solution as colorless prisms, m.p. 161–163° (37 mg, 12%). The infrared spectrum was superimposable on that of the alkaloid of m.p. 161–163° isolated from *D. cardinale*.

Anal. Found: C, 64.64; H, 8.73; N, 3.03. $C_{25}H_{39}NO_7$ requires C, 64.49; H, 8.44; N, 3.01.

Sodium Borohydride Reduction of the Alkaloid, m.p. 261–265°

A solution of the alkaloid (10.8 mg) in 90% ethanol was reduced with a total of 30 mg of sodium borohydride and the product isolated as described before. The reduction product was converted into the hydrobromide, which formed thin, colorless needles, m.p. 265–270° (decomp.), undepressed on admixture with authentic hetisine hydrobromide. The infrared spectra of the hydrobromides of the reduction product and of hetisine were also identical.

Delatine

The free base was prepared from a sample of Goodson's hydrochloride salt and converted into the hydrobromide salt, m.p. 262–266° (decomp.), undepressed on admixture with authentic hetisine hydrobromide. The infrared spectrum was also superimposable on that of the authentic hetisine hydrobromide.

ACKNOWLEDGMENTS

For assistance with the collection of plant material, we thank Professor T. A. Geissman, Chemistry Department, U.C.L.A., Dr. Peter Raven, Botany Department, Stanford University, Dr. T. Mosquin, Research Branch, Canada Department of Agriculture, Ottawa, Dr. R. C. B. Hartland-Rowe, Biology Department, and Dr. T. S. Sorensen and Mr. D. Meakin, Chemistry Department, University of Alberta.

We are indebted to Drs. Adamson and Wilkinson of the Wellcome Foundation, Beckenham, Kent, England, who supplied the authentic sample of Dr. Goodson's delatine hydrochloride, and to Dr. E. O. Edwards of the National Research Council, Ottawa, for a gift of hetisine hydrobromide.

Dr. W. A. Ayer of the Chemistry Department, University of Alberta, Edmonton, kindly arranged for the measurement of mass spectra (one of which was provided by Dr. D. B. McLean of McMaster University) and some initial optical rotatory dispersion spectra, on which he made some extremely helpful comments.

Finally, we thank the National Research Council of Canada for a grant which made possible the collecting expedition and subsequent chemical investigations.

CHARGE-TRANSFER COMPLEXES OF BIPHENYLENE

P. H. EMSLIE, R. FOSTER, AND R. PICKLES
Chemistry Department, Queen's College, University of St. Andrews, Dundee, Scotland
Received June 24, 1965

ABSTRACT

An attempt has been made to redetermine the enthalpy and entropy of formation of the charge-transfer complex between tetracyanoethylene and biphenylene in dichloromethane solution from measurements of the equilibrium constant at different temperatures. The results obtained under conditions where biphenylene is in excess differ from those previously published in which tetracyanoethylene was in excess. It is argued that the optimum condition for determining equilibrium constants of a 1:1 complex is when the reactants are mixed in solution in this ratio. Determinations under this condition yield $\Delta H = -2.6$ kcal mole^{-1} and $\Delta S = -4.1$ e.u.

The energies of the intermolecular charge-transfer transitions of biphenylene with several different acceptors suggest that the ionization potential of biphenylene is ~7.4 eV.

The association constant of the charge-transfer complex between biphenylene, D, and tetracyanoethylene, A, in dichloromethane has recently been measured by Farnum *et al.* (1). This constant was evaluated by the Benesi–Hildebrand method (2) from measurements of the optical absorption caused by the characteristic charge-transfer transition. Because of the limited supply of biphenylene, measurements were made on a series of solutions in which [D] was constant and small compared with [A]. From such determinations an association constant K_c was determined where

$$K_c = [AD]/[A][D] \text{ l mole}^{-1}, \quad [1]$$

which was converted to a dimensionless association constant K_x:

$$K_x = [AD]/x_A[D], \quad [2]$$

where x_A = mole fraction of A; hence for dilute solutions

$$K_x = K_c\,(1000d/M), \quad [3]$$

where d = density of solvent and M = molecular weight of solvent. Farnum *et al.* (1) obtained a value of $K_x = 80$ at 22°, and a molar extinction coefficient $\epsilon = 500$. From measurements of a single solution at various temperatures, the temperature variation of K_x was calculated on the assumption that ϵ is temperature independent. From van't Hoff plots, $\Delta H = -2.8$ kcal mole^{-1} and $\Delta S = -1.0$ e.u., the pure complex being used as the standard state.

An attempt has been made to redetermine these constants by using the condition [D] $\gg$ [A], in which K_c and ϵ are evaluated by a variant (3) of the Benesi–Hildebrand relationship. It may be shown (3) that

$$d/[D] = -Kd + K[A]\epsilon, \quad [4]$$

where, for a series of solutions of constant [A] and varying [D], and [A] $\ll$ [D], d represents the optical density of a 1 cm path length at a wavelength λ caused by absorption by the complex alone, at which wavelength the extinction coefficient is ϵ. A plot of $d/[D]$ against d should be linear, with a gradient of $-K_c$.

RESULTS AND DISCUSSION

Thermodynamic Constants of the Tetracyanoethylene Complex

Plots of $d/[D]$ against d, measured at the wavelength of maximum absorption (λ_{max} = 680 mμ) and 22° under the conditions described in the previous section, gave nonlinear correlations; the results of one such determination are shown in Fig. 1. Estimates of $K_c \approx 1.1 \pm 0.5$ l mole^{-1} (hence $K_x = 17 \pm 8$) and $\epsilon \approx 2\,300 \pm 1\,000$ are very different from the values obtained by Farnum *et al.* In contrast the values of the product $K_x\epsilon$ at a given temperature are equal within the admittedly large error.

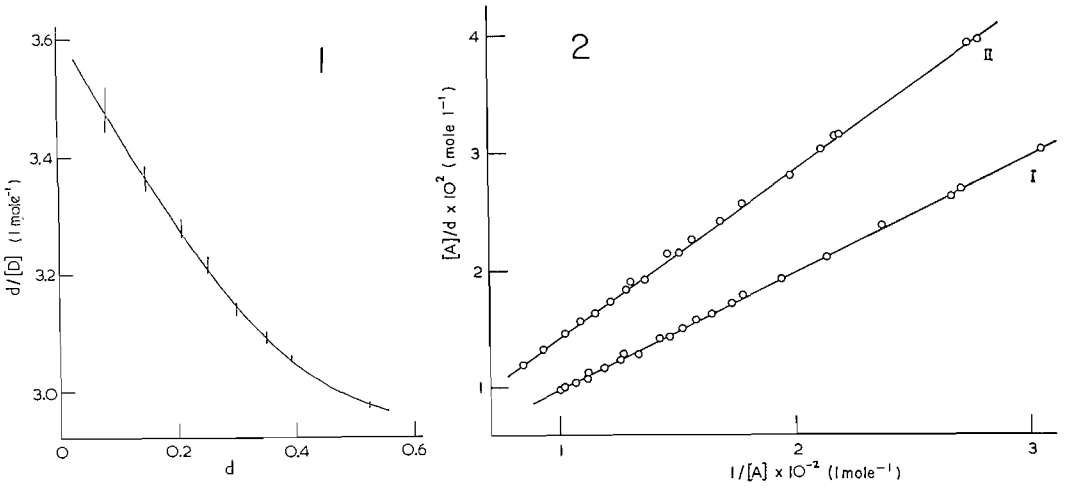

FIG. 1. Plot of $d/[D]$ against d for solutions of tetracyanoethylene, A, plus biphenylene, D, in dichloromethane, where [A] = 1.537 × 10^{-3} M, at 22.0°, with a 1 cm cuvette. The lengths of the lines marking the experimental points are measures of the error as reckoned in terms of the reproducibility of the measurements of d.

FIG. 2. Plots of $[A]/d$ against $[A]^{-1}$ for solutions of tetracyanoethylene, A, plus biphenylene, D, in dichloromethane, where [A] = [D], at 6.5° (I) and at 25.1° (II), with a 3 cm cuvette.

We consider (4) that these differences in K_x and ϵ and the nonlinearity of $d/[D]$ with d shown in the present determination are the results of the deviations from Beer's law shown by the optical absorption of the species AD. Both the method of evaluation used by Farnum *et al.* and that used by ourselves assume that Beer's law is strictly obeyed. The consequences of deviations have been discussed recently (4), where it was pointed out that the optimum condition needed to minimize such deviations is to use systems which involve a minimum *total* concentration of solute. To obtain maximum concentrations of complex under such conditions, [A] = [D] for a 1:1 complex. We have now used this condition to re-evaluate the association constant. It may be shown (5) that, when [A] = [D],

$$[5] \qquad \frac{[A]}{d} = \frac{1}{[A]K_c\epsilon} + \frac{2}{\epsilon}$$

for a 1 cm path length. For a 3 cm path length as used in the present determination,

$$[6] \qquad \frac{[A]}{d} = \frac{1}{[A]3K_c\epsilon} + \frac{2}{3\epsilon}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Hence a plot of $[A]/d$ against $[A]^{-1}$ should be linear, and from this plot K_c and ϵ may be evaluated. Such plots are shown in Fig. 2. The values of K_c and ϵ calculated by this method are given in Table I, together with the calculated values of K_x, ΔH, and ΔS, based on the same standard states as the values quoted by Farnum *et al.*

TABLE I

Values of equilibrium constants (K_c, K_x), extinction coefficient (ϵ), enthalpy (ΔH), and entropy (ΔS) of formation of the complex biphenylene–tetracyanoethylene in dichloromethane

Temp. (°C)	K_c (l mole^{-1})	K_x	ϵ	ΔH (kcal mole^{-1})	ΔS (e.u.)
6.5	$0.95_4 \pm 0.008$	$14.9_8 \pm 0.1$	$3\,540 \pm 30$	-2.6_5	-4.1_0

Ionization Potential of Biphenylene from Charge-Transfer Spectra

Farnum *et al.* have compared the value of the frequency of the maximum of the charge-transfer band (ν_{max}) with ν_{max} for other tetracyanoethylene complexes. From the empirical relationship described by Merrifield and Phillips (6) the value of ν_{max} for the biphenylene complex would correspond to an ionization potential (I_p) of 6.4 eV. Merrifield and Phillips suggested that for tetracyanoethylene complexes a better linear correlation exists between the free energy of formation of the complex and the I_p. From such a relationship, Farnum *et al.* obtained a value of $I_p = 7.37$ eV for biphenylene.

Tetracyanoethylene complexes give a poorer correlation of ν_{max} with I_p of the donor than do complexes with many other acceptors. It has recently been suggested that this may be the result of multiple overlapping charge-transfer bands (7). From an analysis of such spectra it is suggested (7) that eq. [7] provides a better correlation of I_p and ν_{ct} for tetracyanoethylene complexes.

$$\nu_{ct} = 0.83 I_p - 4.42, \qquad [7]$$

where ν_{ct} is the frequency of the charge-transfer bands and is measured in electron volts. The position of λ_{max} for the biphenylene complex (680 mμ) corresponds to $I_p = 7.5$ eV by eq. [7].

Although Mulliken (8) and others have emphasized the lack of a theoretical basis for such linear correlations, consistent and reasonable results may be obtained from them (9). ν_{max} for complexes of biphenylene with several acceptors have now been compared with ν_{max} for complexes of these acceptors with a series of donors. Dichloromethane was used as the solvent in most cases; otherwise 1,2-dichloroethane or chloroform was used. Recently, it has been shown that ν_{max} is virtually independent of the solvent for these particular solvents (10). The donors have been selected from those for which the ionization potential has been determined experimentally by the photoionization method (11). Plots of ν_{max} against I_p of the donor molecules (Fig. 3) suggest that I_p for biphenylene is ~7.35–7.45 eV.

EXPERIMENTAL

Analytical

Solutions were made up and measured as described previously (3, 12) with an Optica CF4 spectrophotometer. The spectra of complexes referred to in Fig. 3 were recorded with an Optica CF4DR spectrophotometer. For weaker complexes, concentrated solutions of the mixture of components were measured in cells having a short path length.

The best straight lines and root-mean-square deviations for the data depicted in Fig. 2 were obtained by using a standard root-mean-square program on a Stantec Zebra computer.

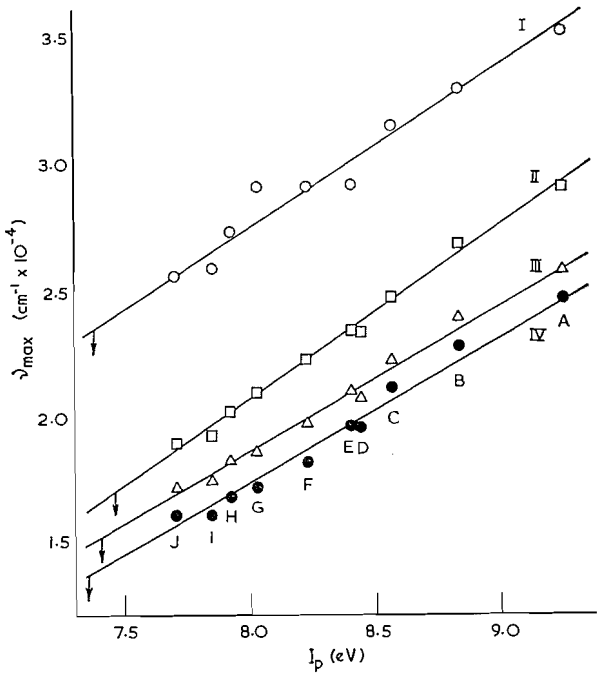

FIG. 3. Plots of the frequencies of the maxima (ν_{max}) of the charge-transfer bands for the complexes of the acceptors (I) 1,3,5-trinitrobenzene, (II) chloranil, (III) 2,3-dicyano-*p*-benzoquinone, (IV) 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, with the donors (A) benzene, (B) toluene, (C) *o*- and *m*-xylene, (D) *p*-xylene, (E) mesitylene, (F) anisole, (G) durene, (H) pentamethylbenzene, (I) hexamethylbenzene, (J) aniline, (↓) biphenylene, against the ionization potentials (I_p) of the respective electron donors A–J.

Materials

Tetracyanoethylene was prepared and purified as described previously (13). Biphenylene was prepared by the method of Baker *et al.* (14) by the pyrolysis of diphenyleneiodonium iodide (15). It was recrystallized three times from methanol. Dichloromethane was distilled three times from phosphoric oxide and then from anhydrous potassium carbonate, and finally redistilled; b.p. 40° at 760 mm.

ACKNOWLEDGMENTS

The authors thank the Department of Scientific and Industrial Research for a grant (to P. H. E.), and the Royal Society for the provision of cells of variable path length (to R. F.).

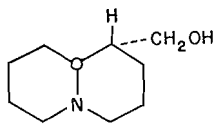
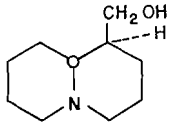
INVESTIGATION OF THE STRUCTURE OF 1,5-METHYLENE-QUINOLIZIDINIUM ION[1]



O. E. EDWARDS, GÁBOR FODOR,[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received November 3, 1964



ABSTRACT

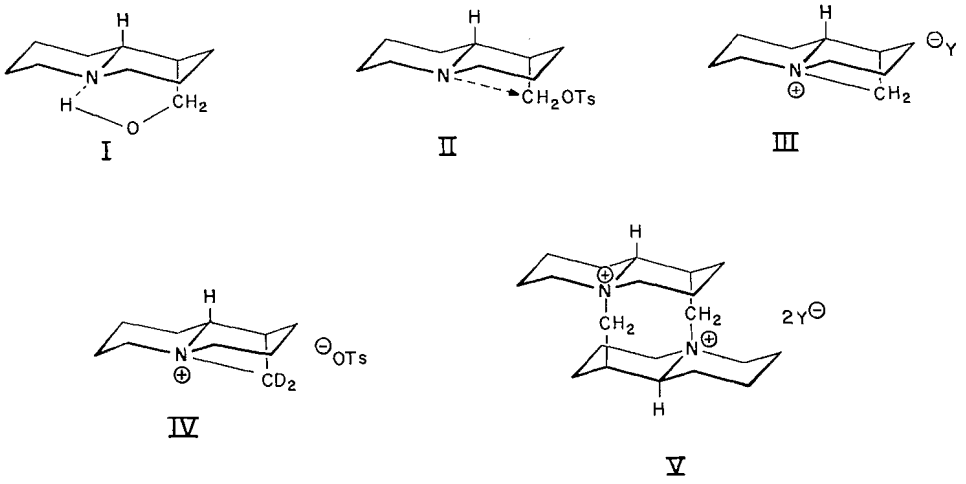
Galinovsky observed that O-tosyllupinine (II) readily isomerized to a quaternary tosylate. Without rigorous proof he assigned to this a monomeric azetidinium salt structure. A study of the infrared and nuclear magnetic resonance spectra and molecular weight of the compound confirms the 1,5-methylene-quinolizidinium salt structure III.

Galinovsky (1) demonstrated that the tosyl ester (II) of the alkaloid lupanine (I*a*) was isomerized on heating into a quaternary salt, in contrast to the thermal stability of the tosyl ester of epilupinine (I*b*). He interpreted this isomerization as an internal nucleophilic displacement to give the azetidinium salt (III*a*). The fact that the quaternary salt could be converted into lupinine by alkali confirmed that no skeletal rearrangement was involved in the thermal reaction.

Ia

Ib

The relative configurations of lupinine and its epimer have been demonstrated, by conformational analysis (2), infrared evidence for internal hydrogen bonding (3, 4), and dipole moment measurements (4), to be those illustrated in I*a* and I*b*, and the absolute configuration was proved by degradation of lupinine to (+)-4-methyl-nonane (5). Thus the stereochemistry of lupinine permits the formation of the internal salt III.



As pointed out recently by Leonard (6), however, Galinovsky produced no rigorous evidence for structure III, and a strain-free dimeric salt containing a diazaoctane system (V) would account equally well for his observations. Molecular models of the dimer V demonstrate the presence of bad hydrogen interactions and make this a priori unlikely. Nevertheless, a reexamination of the quaternary salt seemed desirable.

When completely dissociated, salt III should give an apparent molecular weight of 161.5, while IV should have one of 215.3. The salt was slightly associated in ethanol, but in methanol increasing dilution caused progressive dissociation. Extrapolation of the apparent molecular weight curve to infinite dilution in this solvent gave a value of 158.5 (Fig. 1), in excellent agreement with the requirement for III. Infrared spectral and nuclear magnetic resonance (n.m.r.) evidence supports this structure.

Infrared Evidence

Although the spectra of azetidinones have been investigated thoroughly because of interest in the penicillins, only limited data are available on the azetidines (7). Sheinker

[1]*Issued as N.R.C. No. 8672.*
[2]*Visiting scientist, National Research Council, Ottawa. Present address: Chemistry Department, Laval University, Quebec, Quebec.*

and Peresleni (8) studied the infrared and Raman spectra of cyclic imines to determine the influence of ring size on basicity. Later, Lippert and Prigge (9) assigned specific infrared and Raman absorption bands to symmetrical and antisymmetrical skeletal vibrations in the four-membered ring. A comparison is given in Table I between the infrared absorption frequencies for azetidine, piperidine, and (incomplete) 1-methyl-*trans*-quinolizidine (10) and the frequencies that we have observed for the quaternary bromide from lupinine (presumably *IIIb*) (Fig. 2).

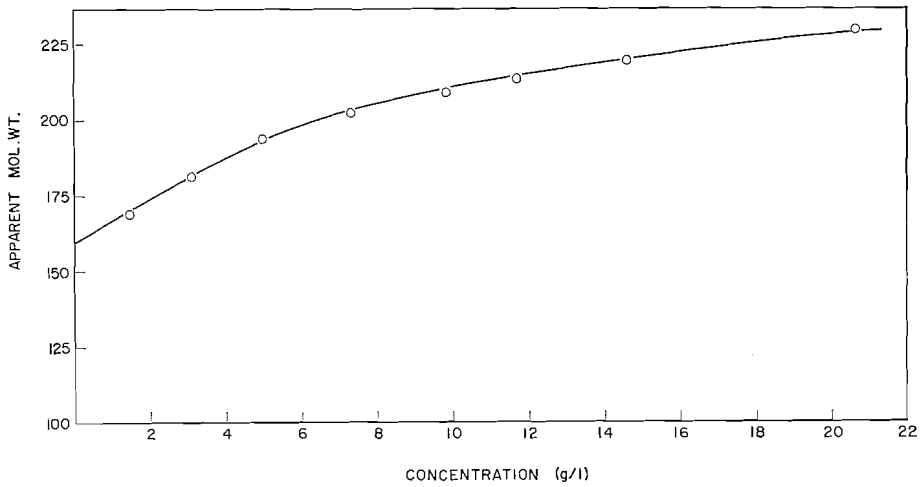


FIG. 1. Molecular weight determination.

The possible structures under consideration contain either (*a*) one four-membered and one six-membered ring, both strained, together with a less distorted six-membered ring, or (*b*) four six-membered rings and one eight-membered ring, all strainless. A significant absorption is found around 1 449–1 460 cm^{-1} in the spectrum of azetidine, which is ascribed by the Russian authors (8) to internal deformation vibrations of the methylene groups; comparable methylene groups in compounds having larger rings gave only

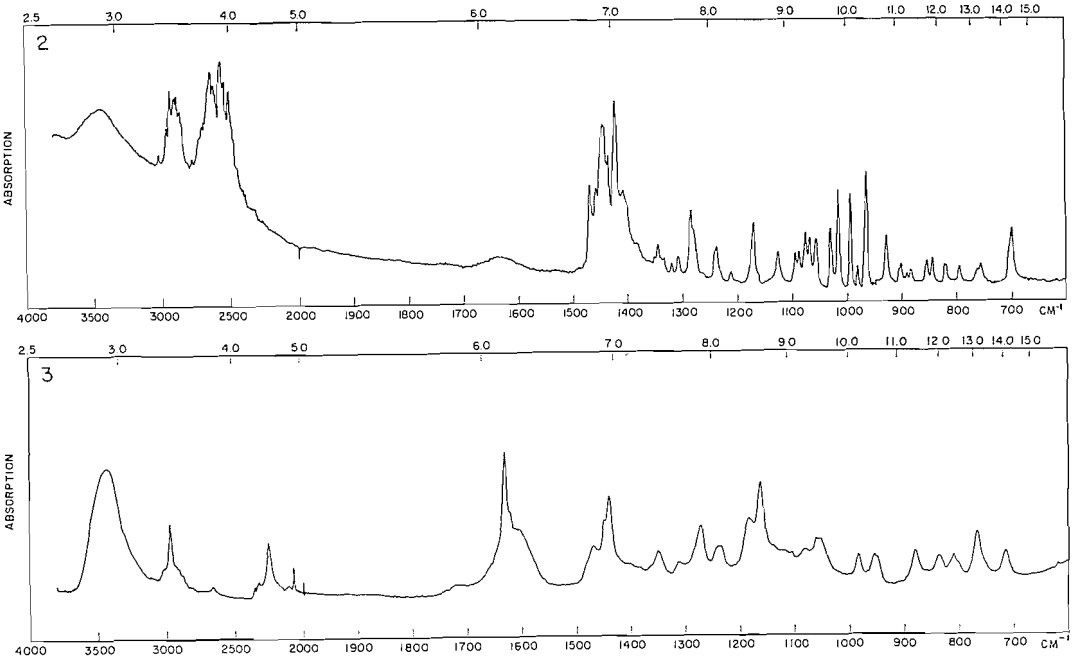

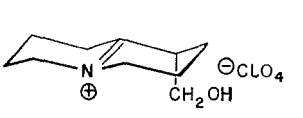

FIG. 2. Infrared spectrum of 1,5-methylene-quinolizidinium bromide.
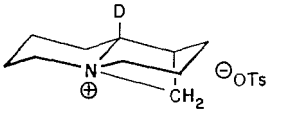
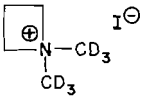
FIG. 3. Infrared spectrum of N,N-(dimethyl-d_6)-azetidinium iodide.



weak absorption in this region. The infrared spectrum of III*b* contains a very strong multiple peak between 1 425 and 1 468 cm^{-1}.

In their consideration of the effect of ring size on symmetrical and antisymmetrical skeletal vibrations Lippert and Prigge (9) ascribed to symmetrical skeletal vibrations a peak at 1 084 cm^{-1} in the spectrum of azetidine and one at 820 cm^{-1} in the spectrum of piperidine. The spectrum of III*b* shows a strong multiple peak between 1 050 and 1 090 cm^{-1} and a weak double peak at 820 cm^{-1}.



A maximum at 983 cm^{-1} in the spectrum of the imine having a four-membered ring and a maximum at 1 110 cm^{-1} in the imine having a six-membered ring were ascribed to antisymmetrical skeletal vibrations. The spectrum of III*b* shows a multiplet between 965 and 1 030 cm^{-1} and a single sharp peak at 1 125 cm^{-1}. These comparisons, together

with the general shape of the absorption curve, point to the close resemblance of III*b* to azetidine. It may be questioned whether it is justified to compare a quaternary azetidinium salt (with positively charged nitrogen) with a secondary amine of the same series. However, Sheinker and Peresleni (8) report only a slight change in spectra in going from the cyclic bases to their hydrochlorides. To meet this objection N,N-(dimethyl-d_6)-azetidinium iodide (VIII) was prepared and its infrared spectrum (see Table I and Fig. 3) compared with that of azetidine and with that of our quaternary bromide. The characteristic absorption near 1 465 and 1 084 cm^{-1} remained unaltered in the quaternary salt, and the medium peak attributable to antisymmetrical skeletal vibrations was only slightly displaced to 982 cm^{-1}, thus providing a close analogy to the spectrum of II*b*.

Nuclear Magnetic Resonance Spectra

The n.m.r. spectrum of Galinovsky's tosylate (III*a*) determined on a Varian A-60 instrument is reproduced in Fig. 4. The sharp signals at δ 7.20, 7.42, 7.68, and 7.80

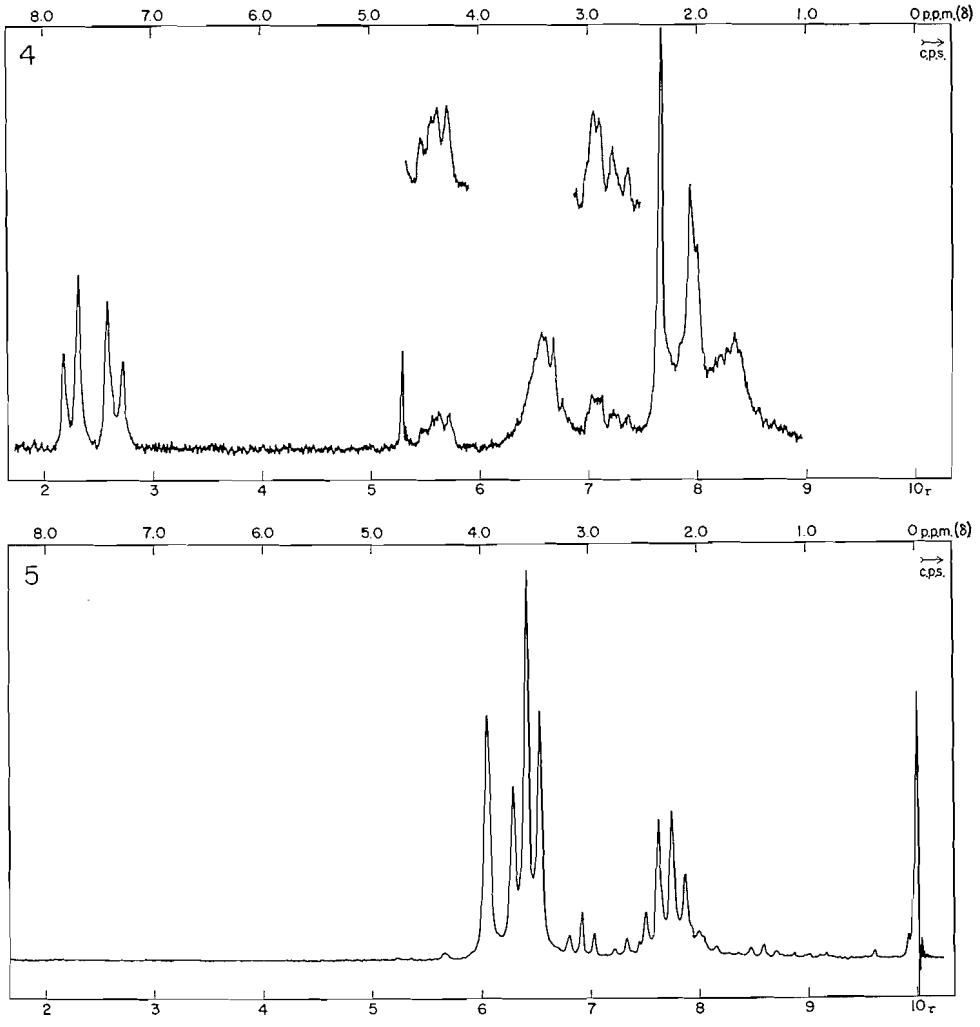

FIG. 4. Nuclear magnetic resonance spectrum of Galinovsky's tosylate.
FIG. 5. Nuclear magnetic resonance spectrum of azetidine.

correspond to four aromatic protons, and the methyl signal of the tosyl group is at δ 2.32. The remaining signals are rather complex and broadened. The quartet from 4.16 to 4.42 corresponds to one proton; the broad quartet at 3.20–3.32 corresponds to four protons, while the three peaks between δ 2.50 and 2.82 equal two protons. The higher field resonance corresponds to 11 protons.

In looking for n.m.r. criteria for the possible azetidinium ion structure of Galinovsky's salt, we noted that methylenes in four-membered rings are deshielded to an unusual extent. For example, cyclobutane methylenes resonate at δ 1.98 as contrasted with δ 0.22 for cyclopropane, 1.51 for cyclopentane, and 1.44 for cyclohexane; azetidine α-methylene protons resonate at δ 3.54 (cf. Fig. 5, also Table II), while those in ethyleneimine resonate

§Moynehan *et al.* gave τ values in their paper (10).

at δ 1.36, in pyrrolidine at δ 2.75, and in piperidine at δ 2.71 (11, 13). The signals at δ 3.20 in the spectrum of III*b* thus are very suggestive of the presence of the four-membered ring. It was surprising, however, if this were so, that the charge on the nitrogen had not produced further deshielding in the quaternary salt. Moynehan *et al.* (10) observed a downfield shift of 0.4–0.6 p.p.m. of the α-methylenes on quaternization of 1-methylquinolizidine (Table II). Indeed, the α-methylenes of N,N-(dimethyl-d_6)-azetidinium iodide (VIII) gave rise to a triplet centered at δ 4.3 (Fig. 6). In the n.m.r. spectrum of

III*a* the one-hydrogen signal at δ 4.1–4.38 seemed likely to be caused by the tertiary 10-hydrogen, provided it were linked to the alleged azetidinium ring; the 10-hydrogen in the quinolizidinium ion itself has no signal at such a low field (10). To assign the low-field hydrogen signals of III*a* with confidence, recourse was had to deuteration. The tosylate of lupinine-11,11-d_2 was prepared and converted into the d_2-salt of Galinovsky (IV). Its n.m.r. spectrum now lacked the signal at δ 4.16–4.42, and integration showed that the signal of a second proton was missing in the region δ 3.2–3.32. Three protons still resonated in the region δ 2.5–3.3 (Fig. 7). We conclude that the azetidinium ion is present but is somewhat twisted, so that the magnetic environment of the two methylene hydrogens is different, only one experiencing the strong deshielding characteristic of an azetidinium salt. Furthermore, the 10-proton resonates at higher field than one of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

11-methylene protons. To allocate it precisely, an attempt was made to replace the 10-hydrogen by deuterium, i.e. by synthesizing VII. Mercuric acetate converted (−)-lupinine into 5(10)-dehydrolupininium acetate, which was converted directly into the crystalline perchlorate (VI). This analyzed correctly and had the characteristic immonium ion absorption at 1 680 cm^{-1} (12). However, it had no optical activity at the D-line, and hence may have been racemized despite the attempt to avoid basic conditions under which $\Delta^{1(10)}$-enamine might be formed. Catalytic deuteration or reduction with lithium aluminium deuteride converted this into a high-boiling base. In the latter case this was shown to analyze correctly for 10-monodeutero-lupinine, and hence was probably racemic 10-deutero-epilupinine. As a consequence, these attempts were abandoned.

In summary, the evidence from molecular weight determinations and infrared and n.m.r. spectroscopy is consistent with the azetidinium salt structure for Galinovsky's product. The high percentage of internal quaternization in a melt is remarkable, especially since a strained ring is being produced. A large factor must be the shielding of the unshared pair in the all-*trans* conformation by the axial tosyloxymethyl group (thereby preventing bimolecular reaction) coupled with an entropy effect favoring the internal quaternization.

The tosylate III*a* is relatively stable and could not be reductively cleaved by sodium borohydride.

An X-ray crystallographic examination of the tosylate of III has been initiated in these laboratories.[3]

EXPERIMENTAL

All melting points were determined on a Kofler stage and were not corrected.

O-Tosyl-lupinine (II)

Lupinine I*a* (19.98 g, 0.118 mole) was dissolved in dry acetone (300 ml), and *p*-toluenesulfonyl chloride (11.3 g, 0.059 mole) dissolved in acetone (210 ml) was added. The pale yellow solution was stirred magnetically for 15 h at 25°. The separated lupinine hydrochloride was removed by filtration; m.p. 212° (10), wt. 10.9 g (yield 90%). The acetone was removed from the filtrate at 25° under 15 mm pressure in a rotatory evaporator, and the brownish oily residue was dissolved in 300 ml of *n*-heptane and 30 ml of water. After the solution was shaken, the two layers were separated. The aqueous layer was adjusted with 0.5 *N* sodium hydroxide to pH 9 and extracted 5 times with methylene chloride (total 200 ml). The combined heptane and methylene chloride extracts were dried over drierite, filtered, and evaporated as above. It left the product II as an oily residue (18 g). A small quantity was converted into the picrate, m.p. 165°; Galinovsky (1) reported m.p. 145°.[4]

Anal. Calcd. for $C_{23}H_{28}O_{10}N_4S$: N, 10.14. Found: N, 10.02.

Rearrangement of II to IIIa

Lupinine tosyl ester (17.8 g) was heated in a 500 ml round-bottomed flask fitted on a rotatory evaporator, in a boiling water bath under 15 mm pressure for 4 h. After 1 h most of the oil had formed a solid film-like layer on the wall of the flask. At this point, dry ether (100 ml) was added, whereupon crystallization was initiated. After completion of the reaction the white precipitate was filtered off, washed with dry ether (20 ml), finely ground under ether in a mortar, and filtered again. After it was allowed to dry in a desiccator, the tosylate III*a* thus obtained (16.2 g; 84.6% yield based on the lupinine) melted at 128–130°. For analysis and spectroscopic measurements a sample was crystallized twice from dry ethanol–ether (1:4); m.p. 139°. Galinovsky (1) reported the same melting point, as determined in an evacuated capillary tube.

Anal. Calcd. for $C_{17}H_{25}NO_3S$: C, 63.10; H, 7.79; N, 4.02. Found: C, 63.26; H, 7.97; N, 4.15.

1,5-Methylene-quinolizidinium Bromide (IIIb)

Via the Picrate

The tosylate III*a* was converted into the picrate III*c*, m.p. 208°, as described by Galinovsky (1). The picrate (691 mg) was treated with 0.2 *N* hydrobromic acid, and the picric acid was removed by extracting 10 times with a total of 1 l ether. The extracted aqueous solution was evaporated to dryness in a rotatory evaporator under 15 mm pressure, the oily residue was dissolved in absolute ethanol, dry benzene was added, and the solution was evaporated, this process of solution and evaporation being repeated several times to

[3]*C. Saunderson, unpublished.*

[4]*He prepared his tosyl ester in pyridine (1), which gives a less pure product than the method we used, with lupinine both as substrate and as proton acceptor.*

For personal use only.

drive off the water. Finally, the residue was crystallized from butanol–ether (1:2), wt. 50 mg, m.p. 167°, infrared spectrum shown in Fig. 2.

Because of some inorganic contamination the C and H values are usually low.

Via the Iodide

The tosylate III*a* (5.83 g, 0.01805 mole) was dissolved in dry ethanol (8 ml), and a solution of dry sodium iodide (2.70 g) dissolved in ethanol (5 ml) and dry acetone (20 ml) was added. The precipitated sodium tosylate was filtered off and washed with acetone, wt. 3.492 g (99.8%). The combined acetone–alcohol filtrate and washings were evaporated under reduced pressure in a rotatory evaporator, the residual crystalline iodide III*d* was dissolved in methylene chloride (25 ml), alcohol (1 ml) was added, the solution was filtered to remove the last traces of sodium tosylate, and the filtrate was evaporated to dryness. The residual iodide was dissolved in water (20 ml), silver bromide (5 g) added, and the mixture stirred for 14 h until no more iodide ion was present in a sample of liquid drawn from the mixture. After filtration the aqueous filtrate was evaporated to dryness and the residue crystallized from methylene chloride – *n*-hexane, wt. 0.100 g. The low yield is due to the tendency of the bromide to give a volatile product. This will be discussed in a forthcoming paper.

*Attempted Reductive Cleavage of the Tosylate III*a*

The tosylate (271.2 mg, 0.837 mmole) was dissolved in water (5 ml), sodium borohydride (380 mg, 10 mmoles) was added, and the solution was adjusted to pH 9 by the addition of a few drops of 0.2 *N* potassium hydroxide. After 3 days, seven extractions with a total of 500 ml of ether failed to remove any basic material. The aqueous solution was neutralized with 2 *N* hydrochloric acid and evaporated to dryness, and the residue was extracted with dry ethanol. Addition of dry ether to the ethanol extract caused the crystallization of the unchanged tosylate III*a*, m.p. 139°.

Azetidine

This was prepared by Kraut from tosylamide and 1-chloro-S-bromopropane according to Searles *et al.* (14), with subsequent cleavage of N-tosyl-azetidine with sodium and amyl alcohol (15).

The main problem consisted in the removal of the last traces of water from azetidine. Drying over barium oxide (16) alone proved unsufficient; so sodium–lead alloy was used thereafter, yielding a pure product after distillation, b.p. 72–73°, n.m.r. spectrum shown in Fig. 5.

N,N-(Dimethyl-d_6)-azetidinium Iodide (VIII)

Azetidine (0.5425 g) was dissolved in 10 ml of methanol; then 0.5167 g powdered sodium methoxide was added followed by 5 g deuteromethyl iodide, with cooling to maintain the temperature at 15°. Water (1 ml) was added and the solution was kept at 20° for 20 h, during which time the pH was kept near neutrality by addition of sodium methoxide. The filtered solution was evaporated in a vacuum, and the residue was extracted first with acetone to remove sodium iodide and then with absolute ethanol. The residue, after evaporation of the ethanol solution, crystallized on the addition of acetone. The needle-like crystals were collected by filtration, giving 0.502 g, m.p. 276°, n.m.r. spectrum shown in Fig. 6.

Anal. Calcd. for $C_5H_6D_6NI$: C, 27.4; H + D, 6.45; D, 6 atoms. Found: C, 27.13; H + D, 6.1; D, 5.6 atoms.

1,5-(Methylene-d_2)-quinolizidinium tosylate (IV)

Methyl lupininate (0.9272 g) dissolved in 5 ml dry ether was added over the course of 5 min to a stirred solution of lithium aluminium deuteride (0.5 g) in 25 ml anhydrous ether, while the solution was kept cool with ice. Stirring was continued for 30 min at 20°. After decomposition of excess lithium aluminium deuteride by 3 ml deuterium oxide (with cooling) the precipitate was removed by filtration and washed with a total of 30 ml ether. After removal of the ether the residual oil soon solidified to a white crystalline mass. The product was distilled under 0.001 mm pressure from an oil bath at 100–120° (yield: 577.5 mg (72.5%)), giving low-melting crystals of 1-hydroxymethyl-quinolizidine-d_3.

The compound has no signal for a hydroxyl at δ 5.2. It lacked the quartet at δ 3.6–3.8 present in lupinine, which corresponds obviously to the C—H protons in the CH_2OH group.

Lupinine-d_3 (5.775 mg) was dissolved in 5 ml dry acetone, tosyl chloride (322 mg) in dry acetone (5 ml) was added, and the solution was kept overnight at 20°. Lupinine-d_3-deuterochloride (129 mg; calcd. 300 mg), which separated, was filtered off.

Anal. Calcd. for $C_{10}M_{16}D_4ONCl$: D, 4.0 atoms. Found: D, 3.78 atoms.

The mother liquor was evaporated, and the residue was dissolved in 10 ml *n*-hexane and shaken with 2 ml 0.2 *N* NaOH. Then the alkaline layer was extracted several times with a total of 50 ml *n*-hexane. The combined hexane extracts were dried (K_2CO_3) and the solvent removed to give O-tosyl-lupinine-d_2 (506.7 mg; calcd. 554 mg). It was converted into the internal quaternary salt by heating for 3 h at 95° in a rotatory evaporator under a vacuum; yield, 330 mg, after washing with ether. When recrystallized from ethanol–ether (1:3), this gave 220 mg, m.p. 137–139°.

Anal. Calcd. for $C_{17}H_{23}D_2O_3NS$: D, 2 atoms. Found: D, 1.87 atoms.

Mercuric Acetate Oxidation of Lupinine to the 5(10)-Dehydrolupininium Salt

Mercuric acetate (75 mg) was dissolved in glacial acetic acid (30 ml) and to it was added a solution of lupinine (800 mg) in a minimum volume of glacial acetic acid. The reaction was heated under a reflux condenser for 2 h in an oil bath at 80°. The mercurous acetate formed (~85% of theory) was removed by filtration. The filtrate was diluted with water and the excess mercuric acetate precipitated by hydrogen sulfide. The mercurous sulfide was filtered off and the aqueous solution evaporated nearly to dryness. The residue was dissolved in water and evaporated once more to get rid of the acetic acid. It was then dissolved in methanol and the calculated amount of 1.63 *N* perchloric acid (2.8 ml) was added. The perchlorate VI crystallized as white leaflets. After one recrystallization from MeOH–H_2O it had m.p. 172–174°, $[\alpha]_D$ 0° ± 0.3° (*c*, 9.7 in dimethylformamide).

Anal. Calcd. for $C_{10}H_{18}O_5NCl$: C, 44.90; H, 6.72; N, 5.26. Found: C, 44.70; H, 6.25; N, 5.26.

Attempts to Deuterate 5(10)-Dehydrolupininium Perchlorate

Catalytic Deuteration of 5(10)-Dehydrolupininium Perchlorate VI

Crude 5(10)-dehydrolupininium perchlorate (231.9 mg) was reduced by deuterium gas over PtO_2 (30 mg) in glacial acetic acid (10 ml). Because of the presence of traces of sulfur in the substance the catalyst was being poisoned and had to be replaced at intervals. The deuteration was continued until the calculated amount of D_2 had been adsorbed. The resulting reduced material was recovered by removing the solvent, and the base was liberated. Its infrared and n.m.r. spectra showed that more than one atom had entered the molecule.

By Lithium Aluminium Deuteride

Lithium aluminium deuteride (200 mg) was dissolved in dry ether (20 ml), dehydrolupininium perchlorate (540 mg, 2 mmoles) was added with magnetic stirring, and the whole was refluxed for 3 h. The complex was decomposed by 2 ml of water, the ethereal layer was decanted and dried (K_2CO_3), and the solvent was distilled. A viscous oil (300 mg) remained in the flask, which could be driven over at 10^{-4} mm pressure from an oil bath at 190–200°. The nearly colorless oil gave analytical figures corresponding to lupinine-d_2.

Anal. Calcd. for $C_{10}H_{17}D_2ON$: C, 70.02; H, 11.19; N, 8.19. Found: C, 69.73; H, 10.72; N, 8.34.

ACKNOWLEDGMENTS

We thank Mr. H. Seguin, who carried out the molecular weight determinations as well as the microanalyses including deuterium determinations, Mr. R. Lauzon for measuring the infrared absorption spectra, and Mr. M. Lesage, who measured n.m.r. spectra and made the mercuric acetate oxidations of lupinine.

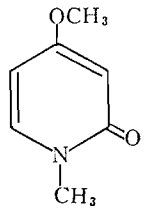
THE ROLE OF ASPARTIC ACID IN THE BIOSYNTHESIS OF RICININE[1]

S. R. JOHNS[2] AND LÉO MARION[3]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 27, 1965



ABSTRACT

Ricinine, isolated from *Ricinus communis* L. fed aspartic acid-3-^{14}C and aspartic acid-4-^{14}C, was degraded, and in each case the activity of all the carbon atoms was determined. The results obtained indicate that aspartic acid is incorporated into ricinine via the Krebs tricarboxylic acid cycle rather than directly as aspartic acid. Experiments with aspartic acid-^{15}N support this suggestion; they indicate that the ring nitrogen from ricinine is not derived directly from the nitrogen of aspartic acid, since both it and the nitrile nitrogen contain essentially the same abundance of ^{15}N.

Previous studies (1, 2) on the biosynthesis of ricinine (I) in *Ricinus communis* L. indicate that succinic acid or a closely related four-carbon dicarboxylic acid found in the Krebs tricarboxylic acid cycle is the source of carbon atoms 2, 3, and 7. The distribution of labelling in ricinine produced in feeding experiments with acetate-2-^{14}C is essentially the

I

II

same as that when succinate-2,3-^{14}C is fed to the plant, since acetate is converted into succinate via the Krebs cycle.

Aspartic acid has been shown to be incorporated into ricinine (3), nicotine (4, 5), and nicotinic acid (6). The question remained unsolved concerning whether the aspartic acid was incorporated as such, or whether the amino group was lost and the resulting four-carbon dicarboxylic acid was the true precursor. Schiedt and Boeckh-Behrens (3) found that, in ricinine isolated after aspartic acid-3-^{14}C had been fed to the plant, 42% of the total activity was at C-3 while C-2 was not radioactive. This result would indicate either that the aspartic acid is incorporated as a unit with the amino group attached or that the amino group is lost and the resulting dicarboxylic acid is incorporated without passing through the Krebs cycle. The work of Gross *et al.* (6) involving the feeding of aspartic acid-1,4-^{14}C,^{15}N to *Mycobacterium tuberculosis* (Stam BCG) and subsequent isolation of nicotinic acid further supports the view that aspartic acid is incorporated as a unit. These authors found the incorporation of ^{14}C and ^{15}N to be essentially the same and assumed that this implied no breakdown of the amino acid.

In contrast to the above results, Griffith *et al.* (4) report that aspartic acid-3-^{14}C is not a

[1]*Issued as N.R.C. No. 8712.*

[3]*Present address: Faculty of Pure and Applied Science, University of Ottawa, Ottawa, Canada.*

direct precursor of nicotine in *Nicotiana rustica*. Only approximately half of the ^{14}C activity of the pyridine ring is located at C-3. Similarly, Christman and Dawson (5) fed aspartic acid-^{15}N to excised tobacco (*Nicotiana tabacum* L.) roots in sterile culture and found that the nitrogen label was equilibrated during the culture period with the general nitrogen pool. The approximate mean excess of ^{15}N present in the tobacco roots and culture fluids was 2%; this was also the concentration in each ring of the nicotine produced.

The present work describes the results obtained in feeding aspartic acid-3-^{14}C, aspartic acid-4-^{14}C, and aspartic acid-^{15}N to *Ricinus communis* L. The ricinine isolated after the aspartic acid-3-^{14}C and aspartic acid-4-^{14}C feedings was diluted in each case with synthetic ricinine. The carbons were individually isolated as suitable derivatives and their activity determined. Carbon atoms 2, 3, and 7 were obtained by the method of Juby and Marion (2) respectively as benzoic acid and bromopicrin, and by difference between ricinine and 4-methoxy-N-methyl-2-pyridone (II), i.e. loss of the C-7 nitrile. Carbon atoms 4, 5, and 6 were isolated as described by Essery *et al.* (7) as benzoic acid, bromopicrin, and formaldehyde dimedone respectively. The methyl groups attached to oxygen and nitrogen were each isolated as tetramethylammonium iodide. All derivatives were converted by combustion into carbon dioxide which was precipitated as barium carbonate, and counted as thin layers on aluminium planchets.

The results obtained for aspartic acid-3-^{14}C and aspartic acid-4-^{14}C are shown in Table I.

TABLE I

Location of activity in ricinine

Incorporation of aspartic acid-3-^{14}C, 2.4%			Incorporation of aspartic acid-4-^{14}C, 0.66%		
Position	Activity (d.p.m./mg $BaCO_3$)	% of ricinine activity	Position	Activity (d.p.m./mg $BaCO_3$)	% of ricinine activity
OCH_3†	3.91	1.5	OCH_3‡	5.55	8.7
NCH_3†	3.33	1.3	NCH_3‡	4.75	7.5
C-2*	67.7	37.2			
C-3*	497	39	C-3‡	10.2	4.0
C-4†	0	0			
C-5†	8.0	0.8			
C-6	Not determined				
C-7*	150	18	C-7‡	7.75	78.2

*Activity of diluted ricinine used, 160 d.p.m./mg $BaCO_3$.
†Activity of diluted ricinine used, 127 d.p.m./mg $BaCO_3$.
‡Activity of diluted ricinine used, 32 d.p.m./mg $BaCO_3$.

These results indicate that aspartic acid-3-^{14}C is incorporated into ricinine to an extent comparable with the incorporation of labelled succinic acid (2). The distribution of activity among carbon atoms 2, 3, and 7 of ricinine in the ratio 2:2:1 is indicative of a precursor randomized in the Krebs tricarboxylic acid cycle. The percentage activities on carbons 2, 3, and 7 are similar to those observed when succinate-2,3-^{14}C and acetate-2-^{14}C are fed to the plant, and suggest that the amino group of aspartic acid is eliminated first, and that the resulting acid goes through the Krebs cycle before incorporation.

The results of feeding aspartic acid-4-^{14}C are in complete accord with such a mechanism, and the lower overall incorporation of the aspartic acid-4-^{14}C precursor further supports the breakdown to a symmetrical dicarboxylic acid similar to succinic acid. The labelling on the carboxylic acid group would then be distributed equally between carbon atom 7 of ricinine and the carbon atom of the acid lost by decarboxylation. An incorporation of approximately half that observed after aspartic acid-3-^{14}C had been fed to the plant would be expected in the aspartic acid-4-^{14}C experiment, but because of the possibility of a number of cycles through the Krebs cycle the figures are approximately in the ratio 1:3.

The ^{15}N content of the ricinine isolated from *Ricinus communis* L. after aspartic acid-^{15}N was fed was determined by mass spectrometric analysis. Nitrogen was isolated from ricinine and 4-methoxy-N-methyl-2-pyridone (II) by the method and apparatus of Rittenberg (8). The alkaloid was digested under Kjeldahl conditions for 18 h. The extended time of digestion was meant to remove all carbonaceous material and prevent carry through of any material with mass 28, 29, or 30. After the reaction mixture had been made basic, it was steam distilled into dilute hydrochloric acid. The ammonium chloride in the distillate was oxidized with sodium hypobromite and the resulting nitrogen analyzed in the mass spectrometer. Initially, contamination with oxygen gave inconsistent results. This oxygen could originate either from air contamination or from decomposition of the hypobromite solution. To prevent loss of oxygen from the hypobromite, the reagent was stabilized with 1% potassium iodide as suggested by Sims and Cocking (9). Further modification of the original Rittenberg procedure involved complete removal of solvent from the ammonium chloride solution, and repeated degassing of the hypobromite solution by freezing it and allowing it to warm to room temperature. Mass spectrometer analyses in which the 32 peak (O_2) content was greater than 2–3% of the 28 peak (N_2) were discarded as a result of the possibility of CO(28) contamination of the N_2 peak by reaction of the oxygen with the carbon filament in the mass spectrometer.

The results obtained from separate feeding experiments are given in Table II. The

TABLE II

^{15}N excess in nitrogen samples

	Feeding *i*	Feeding *ii*
Aspartic acid	71.9%	93%
Ricinine	0.50%	0.77%
4-Methoxy-N-methyl-2-pyridone	0.49%	0.82%

nitrogen isolated from ricinine originates from both the pyridine ring and the nitrile group. Removal of the nitrile group by hydrolysis and decarboxylation with 57% sulfuric acid (10) gave 4-methoxy-N-methyl-2-pyridone (II), from which the nitrogen was isolated and analyzed as before. This gives the value of the isotopic nitrogen content of the pyridone ring.

Again the results indicate that aspartic acid is not incorporated as such into the ricinine molecule. The ^{15}N abundance in both nitrogens of ricinine was the same, indicating that deamination of the aspartic acid has taken place and that the nitrogen was equilibrated with the nitrogen pool before incorporation into the alkaloid. If the pyridone nitrogen were derived from aspartic acid, it is unlikely that the incorporation into the ring would be the same as that into the nitrile group.

Our results are at variance with those reported by Schiedt and Boeckh-Behrens (3), but agree with those of Griffith *et al.* (4) and of Christman and Dawson (5). Although Mothes and his co-workers (6) claimed that aspartic acid was incorporated as such into nicotinic acid, they did their work with a microorganism, not a higher plant in which biosynthetic pathways are not necessarily the same. Hence, both in *Ricinus communis* and in the tobacco plant (4) aspartic acid is deaminated and goes through the Krebs cycle before incorporation.

With aspartate-4-^{14}C the label is found mostly in the nitrile group; this is in agreement with the observation of Waller and Henderson (11) after succinic acid-1,4-^{14}C had been fed to the plant.

EXPERIMENTAL

Melting points were determined on a Kofler hot stage and corrected. Radioactive samples were burned and counted as thin layers of barium carbonate on aluminium planchets in a Baird-Atomic Inc. end-window proportional counter using methane gas. Appropriate corrections were made for background count, counter efficiency, and sample self-absorption. Nitrogen mass spectrometric analyses were carried out on an analytical instrument.

Growth of Plants and Administration of Tracers

Seeds of *Ricinus communis* L. were planted just beneath the surface of moist vermiculite in wooden flats in a greenhouse kept at 20–25°. After approximately 14 days (depending upon the time of the year) when the plants were 15–20 cm high and the primary leaves were emerging, an aqueous solution of the precursor was introduced into the base of the stem of each plant by means of glass capillary tubes. The tubes were previously partly filled with the solution by capillary rise (2). The following precursors were administered by this method: (*a*) a solution of (±)-aspartic acid-3-^{14}C (1.79 mg, 1.77×10^8 d.p.m., California Corporation for Biochemical Research, Los Angeles) and (−)-aspartic acid-^{15}N (13.10 mg, 71.9% ^{15}N excess, Schwarz Bioresearch Inc., Orangeburg, New York) in 0.1 *N* aqueous sodium hydroxide (0.8 ml) to 31 plants; (*b*) a solution of (±)-aspartic acid-3-^{14}C (2.22×10^8 d.p.m., Merck, Sharpe and Dohme, Montreal) in 0.1 *N* aqueous sodium hydroxide (0.7 ml) to 26 plants; (*c*) a solution of (−)-aspartic acid-4-^{14}C (2.22×10^8 d.p.m., California Corporation for Biochemical Research, Los Angeles) and (−)-aspartic acid-^{15}N (10.31 mg, 71.9% ^{15}N excess) in 0.1 *N* aqueous sodium hydroxide (1.0 ml) to 35 plants; (*d*) a solution of (−)-aspartic acid-^{15}N (33.3 mg, 93% ^{15}N excess, Merck, Sharpe and Dohme, Montreal) in 0.5 *N* aqueous sodium hydroxide (0.5 ml) to 16 plants.

Isolation of Ricinine

Ricinine was isolated from the plant and purified as previously described (1, 2, 7).

In experiment 1, in which a mixture of (±)-aspartic acid-3-^{14}C and (−)-aspartic acid-^{15}N was fed, the ricinine isolated (147 mg, m.p. 202–203°) had an activity of 3.18×10^3 d.p.m./mg $BaCO_3$. This represents an incorporation of 2.4%.

After (±)-aspartic acid-3-^{14}C (experiment 2) had been fed to the plant the latter yielded ricinine (187 mg, m.p. 202°) with an activity of 3.08×10^3 d.p.m./mg $BaCO_3$. This represents an incorporation of 2.3%.

In experiment 3, in which a mixture of (−)-aspartic acid-4-^{14}C and (−)-aspartic acid-^{15}N was fed, the ricinine (201 mg, m.p. 202°) isolated from the plant had an activity of 9.02×10^2 d.p.m./mg $BaCO_3$, which shows an incorporation of 0.66%.

Degradation of Ricinine

Active ricinine was diluted with inactive synthetic ricinine prepared by the method of Schroeter *et al.* (12) as modified by Schiedt *et al.* (13). The procedures used for the isolation of the individual carbon atoms were essentially those previously reported (1, 2, 7). The N-methyl and methoxyl carbons were isolated as tetramethylammonium iodide by a modification of the Herzig–Meyer method. Carbon 2 was isolated as the carboxylic group of benzoic acid, and carbon 3 as bromopicrin (2). Also, carbon 4 was isolated as the carboxylic group of benzoic acid, and carbon 5 as bromopicrin by oxidation of 5-nitroricinine with calcium hypobromite (7). The activity of carbon 7 was determined by the difference between the activity of ricinine and that of 4-methoxy-N-methyl-2-pyridone (II), the product obtained by removal of the nitrile group. All isolated products were purified and burned to carbon dioxide, and the gas was converted into barium carbonate by absorption in a solution of barium hydroxide. The results are listed in Table I, in which the activity of a derivative of ricinine is given as disintegrations per minute per milligram of barium carbonate.

Samples for Mass Spectrometric Analysis

Nitrogen was determined from samples of aspartic acid, ricinine, and 4-methoxy-N-methyl-2-pyridone (II) by the modified method and apparatus described by Rittenberg (8, 9). To prevent contamination of the nitrogen samples by oxygen, the hypobromite solution used in the oxidation of the ammonium chloride was stabilized with 1% potassium iodide. Further precautions to prevent any contamination involved removal of the solvent from the ammonium chloride solution and prolonged degassing of the hypobromite solution by alternate freezing and warming at least three times. Mass spectrometric determinations in which the oxygen peak (32) was more than 3% of that of the nitrogen peak (28) were discarded. The results of the determinations of ^{15}N excess in the aspartic acid-^{15}N fed to the plant, of the isolated ricinine, and of the derived 4-methoxy-N-methyl-2-pyridone are recorded in Table II.

ACKNOWLEDGMENTS

The authors thank Mr. H. Séguin for carrying out the sample combustions, and Mr. R. Pilon for the mass spectrometric analyses. One of us (S. R. J.) acknowledges with thanks a travel grant from the Burroughs Wellcome Trust.

ALKALOIDS OF THE SEEDS OF ASPIDOSPERMA FENDLERI WOODSON

R. H. BURNELL[1] AND J. D. MEDINA

Received September 8, 1964

ABSTRACT

The structures of three new alkaloids from the seeds of *A. fendleri* have been elucidated and two of the bases have been converted into aspidolimidine. A fourth base has been shown to be present in small amounts but its nature remains unknown.

Extraction of the seeds of the Venezuelan tree *Aspidosperma fendleri* (1) has yielded four alkaloids, of which fendlerine, $C_{23}H_{30}N_2O_4$, is the most abundant; this alkaloid is also found in large quantities in the trunk and root bark. The structures of fendlerine and the minor base fendleridine have been discussed in preliminary reports (2, 3).

Fendleridine, $C_{19}H_{24}N_2O$, is the simplest of the bases present and, on the basis of its ultraviolet spectrum, belongs to the unsubstituted dihydroindole group of alkaloids. The infrared spectrum reveals peaks characterizing the dihydroindole imino group and the aromatic ring but gives no information concerning the nature of the oxygen atom, which is probably ethereal. The nuclear magnetic resonance spectrum confirms the presence of four aromatic protons (multiplet: 6.55 to 7.50 δ), but absorption typical of olefinic protons and of methyl groupings of any type is absent. A two-proton quartet (centered at 3.98 δ), which has also been observed in other dihydroindolic aspidosperma alkaloids, has been shown to be characteristic of the —O—CH_2— grouping as found in aspidoalbine (V) (4) and aspidolimidine (IV) (5). This region of the nuclear magnetic resonance spectrum of fendleridine is strikingly similar to that of O-methyl-N-despropionylaspidoalbine (6)

I R = R′ = R″ = R‴ = H
II R = H; R′ = OCH_3; R″ = OH; R‴ = $COCH_2CH_3$
III R = H; R′ = R″ = OH; R‴ = $COCH_3$
IV R = H; R′ = OCH_3; R″ = OH; R‴ = $COCH_3$
V R = R′ = OCH_3; R″ = OH; R‴ = $COCH_2CH_3$

(except for the methoxyl bands in the latter). A plausible structure for fendleridine is that shown by I; this is supported by the mass spectrometric fragmentation pattern (Fig. 1). Confirmation of the analytical figures was shown by the molecular ion peak at 296 *m/e*; the typical aspidospermine type M-28 peak (*a*) arising from the loss of ethylene is also present. Rupture of the C-10—C-11 bond (at *x* in *a*) gives rise to fragment *b*, which is responsible for the base peak at 138 *m/e*. This fragment has also been observed in the

[1]*Present address: Chemistry Department, Laval University, Quebec 10, Quebec.*

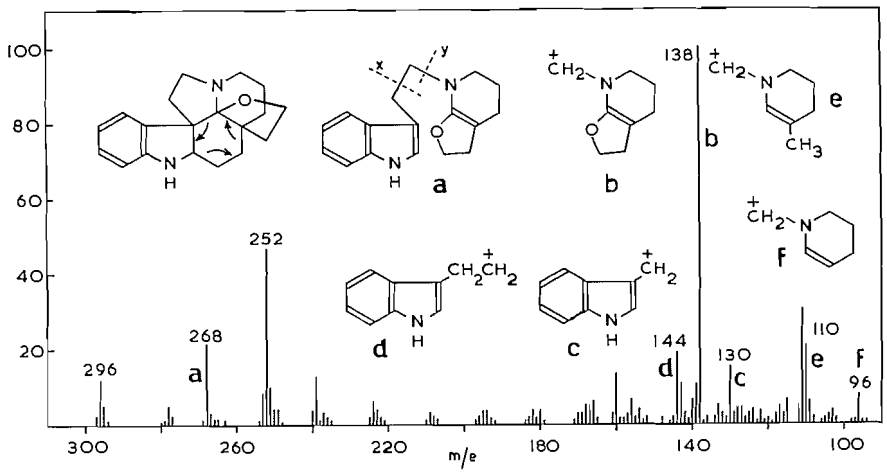

FIG. 1. Mass spectrum of fendleridine. Peaks with an intensity greater than 2% of the most intense peak are shown.

fragmentation of aspidoalbine (V) (4) and aspidolimidine (IV) (5). The indolic portion of the molecule gives rise to weaker peaks at 144 *m/e* (rupture at *y*) and 130 *m/e* (rupture at *x*). The other significant peaks in the mass spectrum arise from expulsion of the oxide bridge (intense peak at 252 *m/e*) and subsequent fragmentation as described above.

Fendlerine shows ultraviolet absorption attributable to a phenolic N-acyldihydroindole and, as expected, the spectrum changes in basic solution. The infrared spectrum confirms the presence of the N-acyl residue (1 635 cm^{-1}), which is presumably hydrogen bonded with the phenolic hydroxyl since virtually no absorption is observed in the hydroxyl-stretching region. From the nuclear magnetic resonance spectrum the N-acyl grouping was shown to be a propionyl residue (triplet and quartet centered at 1.24 δ and 2.53 δ respectively); this was confirmed by acidic hydrolysis of fendlerine and vapor phase chromatography of the volatile acid. Only propionic acid was detected. Other peaks in the nuclear magnetic resonance spectrum include a quartet from two aromatic protons (centered at 6.89 δ), one methoxyl residue (3.84 δ), and a one-proton peak at 12.42 δ attributable to the chelated phenolic hydroxyl. Since the nature of one of the oxygen functions remained obscure, the probability that fendlerine contained an ethereal moiety (other than the methoxyl) was a tempting assumption. This hypothesis was to some extent strengthened by the appearance of a peak in the hydroxyl region of the infrared spectrum of the product obtained by hydrogenating the base over platinum on charcoal. Under the conditions employed, most of the peaks in the mass spectrum of fendlerine were of low intensity, but the base peak was at 138 *m/e* (fragment *b*) as in the case of fendleridine (I). The analytical figures were confirmed by the molecular ion peak at 398 *m/e*; other peaks of importance were those associated with the loss of the N-propionyl residue. The most prominent indolic fragment (the dihydroxy derivative of *c*) gave rise to a peak at 161 *m/e*. Structure II was in all respects compatible with the spectral data on fendlerine; this was confirmed by the conversion of the latter into aspidolimidine (IV). Acid hydrolysis of fendlerine gave the des-N-propionyl derivative, which could not be crystallized but which was acetylated with acetyl chloride in pyridine. The product, a mixture of the N-acetyl and O,N-diacetyl derivatives, was hydrolyzed in methanolic sodium hydroxide under nitrogen to give the pure N-acetyl compound, which was in all respects identical with aspidolimidine

(IV). Since the number of bases with this same hexacyclic skeleton is increasing, it would seem logical to name them as derivatives of the simplest member. Preference is given to the name aspidoalbidine, which has already been used to describe this system (7). Thus fendlerine is N-propionyl-16-methoxy-17-hydroxyaspidoalbidine (II).

The small amount of the high-melting aspidofendlerine (m.p. 278° (decomp.)) was easily purified by fractional sublimation; analysis indicated the molecular formula $C_{21}H_{26}N_2O_4$. The ultraviolet spectrum is similar to that of fendlerine (II) and changes in basic ethanol and in the presence of buffered boric acid, thus suggesting a catechol residue (8). The infrared spectrum shows the presence of hydroxyl and N-acyl functions. Peaks in the nuclear magnetic resonance spectrum are interpreted as showing both bonded and unbonded phenolic hydroxyl groups (11.06 and 5.79 δ respectively), two adjacent aromatic protons (quartet centered at 6.84 δ), and a N-acetyl residue (2.30 δ). The mass spectrum gave peaks of extremely low intensity, with the exception of the base peak at 138 *m/e* (fragment *b* in Fig. 1), which confirmed the suspicion that this base was also of the fendleridine (I) skeletal type. On a small scale, aspidofendlerine, assumed to be N-acetyl-16,17-dihydroxyaspidoalbidine (III), was treated with diazomethane; aspidolimidine (IV) was isolated as the major product, thus confirming the structure.

The fourth base obtained from the extraction appears to be unrelated to the three already described. Absorption in the ultraviolet is similar to that of a dihydroindole, and the infrared spectrum suggests the presence of an ester residue. The mass spectrum is unlike that of a member of the hexacyclic aspidoalbidine series.

EXPERIMENTAL

Melting points are uncorrected. Unless otherwise stated ultraviolet spectra were measured in ethanol (ϵ values in parentheses) and infrared spectra in Nujol mulls. Nuclear magnetic resonance spectra were measured on 5–10% solutions in deuteriochloroform with a Varian Associates model HR-100 spectrometer. Tetramethylsilane protons were taken as 0 p.p.m. An AEI MS2-H mass spectrometer was used and the samples were introduced through a heated inlet system maintained at 200°.

Isolation of the Alkaloids

The dried seeds (480 g) of *A. fendleri* Woodson (1) were continuously extracted with methanol in a Soxhlet extractor. Concentration gave a brown tar which was dissolved in 2% hydrochloric acid; after filtration the non-basic material was removed by continuous extraction with chloroform. The aqueous solution was then basified with ammonia and the crude mixture of bases (14.8 g) was obtained by chloroform extraction. Shaking the chloroform containing the non-basic material with dilute hydrochloric acid, basification, and extraction yielded a further quantity of crude base (12.7 g; total = 27.5 g).

The crude base (27 g) was distributed between chloroform (stationary phase) and acetate buffer (pH 4.45) in a countercurrent distribution apparatus for a total of 20 transfers. The buffer entering the first tube of the apparatus was then replaced by acetate buffer of pH 4.0, and a further 20 transfers were completed. The mixture of stronger bases contained in the leading aqueous fractions (tubes 33 to 40; 917 mg) was chromatographed over type H alumina in benzene. The first eluate which contained alkaloid (benzene–chloroform, 3:1) gave white crystals of *fendleridine* (209 mg).

Fractions 15 to 32 yielded *aspidofendlerine* (135 mg), which was recrystallized from methanol.

Chromatography of fractions 1 to 12 over alumina in benzene gave the major base, *fendlerine* (12.6 g), as a thick, pale yellow oil which crystallized on contact with acetone.

Fractions 13 and 14 from the distribution contained, in addition to fendlerine, a small amount of another *base* which was purified by repeated preparative chromatography on Whatman 3MM paper. In this manner a total of 64 mg (m.p. 176–178°) was obtained but, apart from the ultraviolet spectrum (λ_{max} 240 (8 000) and 290 (3 100) mμ) and the infrared spectrum (no OH or NH bands, an ester carbonyl peak at 1 735 cm^{-1}), this base has resisted more positive characterization.

Fendleridine (Aspidoalbidine)

The base was recrystallized from acetone and then sublimed for analysis, m.p. 185–186°. Ultraviolet spectrum: λ_{max} 242 (7 300) and 293 (3 050) mμ. Infrared peaks at 3 300 (N—H) and 1 600 (aromatic) cm^{-1}.

Anal. Found: C, 77.3; H, 8.0; N, 9.4; O, 5.8. $C_{19}H_{24}N_2O$ requires C, 77.0; H, 8.2; N, 9.4; O, 5.4.

Fendlerine (N-Propionyl-16-methoxy-17-hydroxyaspidoalbidine)

After several recrystallizations from acetone the base melted at 179–181°. Ultraviolet spectrum: λ_{max} 225 (19 200) and 258 (3 560) mμ, $\lambda_{max}^{EtOH \cdot NaOH}$ 220 (17 200) and 300 (2 440) mμ. Infrared peaks at 1 635, 1 602, and 1 570 cm^{-1}.

Anal. Found: C, 69.1; H, 7.5; N, 7.2; O, 16.2; OMe, 7.7. $C_{23}H_{30}N_2O_4$ requires C, 69.3; H, 7.6; N, 7.0; O, 16.1; OMe (one), 7.8.

To confirm the presence of the N-propionyl group, the base (50 mg) was hydrolyzed in 20% sulfuric acid and a sample of the aqueous distillate was injected into a vapor phase chromatograph, yielding only propionic acid (by comparison with an authentic sample).

The *perchlorate*, m.p. 245–248°, was prepared by dissolving fendlerine in dilute aqueous perchloric acid and extracting with chloroform. The chloroform solution was dried over sodium sulfate and evaporated to give the crystalline salt, which was recrystallized from ethanol.

Anal. Found: N, 5.0; O, 26.6; Cl, 6.5. $C_{23}H_{30}N_2O_4 \cdot HClO_4 \cdot C_2H_5OH$ requires N, 5.1; O, 26.4; Cl, 6.5.

Aspidofendlerine (N-Acetyl-16,17-dihydroxyaspidoalbidine)

The small amount of base was sublimed twice and then recrystallized from ethanol, m.p. 278° (decomp.). Ultraviolet spectrum: λ_{max} 225 (11 500) and 259 (5 000) mμ, $\lambda_{max}^{buffered\ boric\ acid}$ 250 (broad plateau) and 290 (shoulder) mμ. Peaks in the infrared at 3 240 (OH), 1 635 (N-acyl), and 1 615 and 1 580 (aromatic) cm^{-1}.

Anal. Found: C, 67.9; H, 7.2; N, 7.5; O, 17.5. $C_{21}H_{26}N_2O_4$ requires C, 68.1; H, 7.1; N, 7.6; O, 17.3.

Aspidolimidine (from Fendlerine)

Fendlerine (330 mg) was hydrolyzed by refluxing it with 10% sulfuric acid for 4 h. The solution was cooled and, in an atmosphere of nitrogen, made basic with ammonia and then extracted with chloroform. The dried solution gave a glass (260 mg) which could not be induced to crystallize. The ultraviolet spectrum showed peaks at 215, 240 (shoulder), and 296 mμ; N-acyl absorption was absent in the infrared spectrum. The hydrolysis product (230 mg) was dissolved in pyridine (10 ml), acetyl chloride (0.5 ml) was added, and the mixture was shaken well for 10 min and then allowed to stand at room temperature for 2 h. After the mixture was poured into ice water and basified with ammonia, it was extracted with chloroform to give a brown foam (240 mg), which showed both N-acetyl and O-acetyl absorption in the infrared spectrum. Under nitrogen, the crude product was hydrolyzed with dilute methanolic sodium hydroxide (3 h) and then poured into water; a yellow foam was obtained by extraction with chloroform. Alumina chromatography of the latter gave the crystalline product (150 mg), which was recrystallized from ethanol and sublimed for analysis, m.p. 194–197°. The ultraviolet, infrared, and nuclear magnetic resonance spectra were identical with those of aspidolimidine, and a mixed melting point gave no depression.

Anal. Calcd. for $C_{22}H_{28}N_2O_4$: C, 68.7; H, 7.3; N, 7.3; O, 16.6. Found: C, 68.6; H, 7.3; N, 7.3; O, 16.6.

Aspidolimidine (from Aspidofendlerine)

Aspidofendlerine (35 mg) was dissolved in methanol and treated with ethereal diazomethane for 4 h. The volatile materials were removed at the pump and the residue triturated with acetone. An insoluble residue was shown to be unchanged aspidofendlerine (15 mg) and the soluble portion was repeatedly sublimed to give a crystalline product (17 mg), identical (melting point, mixed melting point, and infrared spectrum) with aspidolimidine.

ACKNOWLEDGMENTS

We thank Dr. B. Gilbert (Brazil) and Prof. C. Djerassi (Stanford University) for a sample of aspidolimidine.

THE SYNTHESIS OF D-*glycero*-L-*altro*-HEPTOSE, D-*glycero*-L-*allo*-HEPTOSE, AND *meso*-*glycero*-*altro*-HEPTITOL[1]

ROBERT YOUNG[2] AND G. A. ADAMS
Division of Biosciences, National Research Council, Ottawa, Canada
Received August 18, 1965

ABSTRACT

Condensation of D-talose with nitromethane in alkaline methanol gave the corresponding epimeric 1-deoxy-1-nitroheptitols which were converted into D-*glycero*-L-*altro*-heptose and D-*glycero*-L-*allo*-heptose (1.5:1) in 44% yield. Reduction of D-*glycero*-L-*altro*-heptose with sodium borohydride gave the hitherto unknown *meso*-*glycero*-*altro*-heptitol. The gas–liquid chromatography retention times of the 10 geometrically isomeric heptitol heptaacetates were determined. These data provide the necessary information for the key step in a procedure for the rapid identification of an unknown heptose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Structural investigations of the polysaccharides from *Serratia marcescens* showed the presence of L-*glycero*-D-*manno*-heptose and D-*glycero*-D-*manno*-heptose (1), which were identified initially by gas–liquid chromatography of the derived heptitol acetates (2). It was apparent that this latter method of analysis provided a facile and reliable method for identifying heptoses in polysaccharides of unknown composition. If one disregards enantiomorphs, since they have identical chromatographic mobilities, there are 10 possible heptitols. One of these, *meso*-*glycero*-*altro*-heptitol, has not yet been prepared (3); consequently to complete the reference standards for the gas–liquid chromatography of the heptitol acetates its synthesis was undertaken. Heptitols can be prepared by the reduction of aldoheptoses or heptuloses. The former route was followed in the present study as it had the added advantage of involving the synthesis of two hitherto unknown heptoses, D-*glycero*-L-*altro*-heptose and D-*glycero*-L-*allo*-heptose.

Heptoses have been prepared successfully from the corresponding aldohexose by condensation of nitromethane with the aldehydic group of the glycose (4) and subsequent acid hydrolysis (5) of the derived 1-deoxy-1-nitroheptitols. Since the two essential requisites of this process, high solubility of the hexose and low solubility of the alcohol products in the reaction medium, were both met, this method was used in the present work.

D-Talose was prepared from D-galactose, via D-galactal, by described procedures (6, 7). Nitromethane was condensed with D-talose in alkaline methanol solution and the precipitated sodium salts of the 1-deoxy-1-nitroheptitols were recovered. Hydrolysis of the epimeric mixture with sulfuric acid yielded the expected mixture of D-*glycero*-L-*altro*-heptose and D-*glycero*-L-*allo*-heptose in 44% yield, together with unreacted starting material, D-talose. This mixture was fractionated successfully by cellulose column chromatography to give pure samples of each heptose. The ratio of D-*glycero*-L-*altro*-heptose to D-*glycero*-L-*allo*-heptose obtained was 1.5:1, as estimated by gas–liquid chromatography (2) of the mixture before chromatographic separation; this was confirmed by the yields from chromatographic fractionation. It was noteworthy that the chromatographic mobility of the heptoses was the same as that predicted by Davies in 1957 (8).

Although the heptoses themselves failed to crystallize, crystalline acetates were prepared. D-*glycero*-L-*altro*-Heptose, on reduction with borohydride, gave the expected

[1]*Issued as N.R.C. No. 8730.*
[2]*National Research Council Postdoctorate Fellow, 1963–1965.*

optically inactive *meso-glycero-altro*-heptitol. This alditol was characterized by the formation of a crystalline acetate. D-*glycero*-L-*allo*-Heptose, when reduced, gave the crystalline alcohol D-*glycero*-L-*allo*-heptitol. This heptitol is already known by its synonym D-*glycero*-D-*altro*-heptitol, which has been prepared (9) from D-*glycero*-D-*altro*-heptose.

Final proof for the structure of the synthetic heptoses was provided by selective periodate oxidation. This method (10) involves the oxidation of methyl heptopyranosides with 1 mole of periodate, which cleaves the exocyclic C_6—C_7 glycol system. Reduction of the aldehyde group at C_6 followed by hydrolysis of the methyl glycosides gave the expected hexose. D-*glycero*-L-*allo*-Heptose yielded mainly allose and the unreacted heptose. Arabinose and altrosan were obtained from D-*glycero*-L-*altro*-heptose. Altrosan and not altrose is to be expected, since hydrolysis of methyl altroside produces the anhydro derivative as the predominant product (11). Glycosidation of altrose results in almost equal amounts of furanosides and pyranosides (12) together with a small amount of altrosan. It can be assumed that D-*glycero*-L-*altro*-heptose behaves in a similar fashion, and so the production of arabinose can be explained by oxidation of the methyl furanoside at the exocyclic C_5—C_6 glycol system.

The 10 heptitol acetates were examined by gas–liquid chromatography on two different column packings, and the retention times are given in Table I.

TABLE I

Retention times of heptitol heptaacetates relative to that of hexa-*O*-acetyl-galactitol (T_g)

Heptitol acetate	Column packing material	
	i	*ii*
meso-glycero-allo-Heptitol	1.61	1.47
D-*glycero*-L-*allo*-Heptitol D-*glycero*-D-*altro*-Heptitol	1.80	1.67
D-*glycero*-D-*manno*-Heptitol D-*glycero*-D-*talo*-Heptitol	1.98	1.90
meso-glycero-altro-Heptitol	2.05	1.93
D-*glycero*-D-*gluco*-Heptitol L-*glycero*-D-*talo*-Heptitol	2.11	1.93
meso-glycero-gulo-Heptitol	2.25	2.25
D-*glycero*-D-*ido*-Heptitol D-*glycero*-L-*gulo*-Heptitol	2.28	2.31
D-*glycero*-L-*manno*-Heptitol L-*glycero*-L-*galacto*-Heptitol	2.32	2.28
D-*glycero*-L-*gluco*-Heptitol D-*glycero*-L-*galacto*-Heptitol	2.47	2.41
meso-glycero-ido-Heptitol	2.66	2.66

NOTE: The brace denotes two synonyms for the same compound.

A procedure can now be given for the consecutive steps involved in identifying a heptose. The presence of heptose in the intact polysaccharide can be detected with the sulfuric acid – cysteine reaction (13), which gives a characteristic absorption maximum at 505 mμ as a result of aldoheptose constituents. Detection of aldoheptoses on paper chromatograms with the *p*-anisidine hydrochloride spray reagent (14) reveals these compounds as brown-black spots, which are quite different in color from those given by any other class of sugar. Examination by gas–liquid chromatography (2) of the alditol acetates derived from the polysaccharide hydrolysate, using the standard relative retention times given in Table I, will identify the heptitol. A meso heptitol can arise from one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

heptose precursor, and an optically active heptitol from one of two heptose precursors. Where one heptitol can be derived from two different heptoses, the latter are fortunately easily differentiated by the paper chromatographic mobilities (8) of the original aldoheptoses. Finally, after the heptose has been isolated the determination of the optical form can be made, and proof of structure can be obtained by means of selective periodate oxidation to the hexose with the same configuration as the upper six carbon atoms of the heptose (10).

EXPERIMENTAL

Paper chromatograms were run by the descending method on Whatman No. 1 filter paper with the following solvent systems (v/v): (*a*) ethyl acetate – pyridine – water (10:4:3), (*b*) butan-1-ol–ethanol–water (4:1:5), (*c*) butan-1-ol–pyridine–water (6:4:3), (*d*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4). Sugars were detected on the chromatograms with the *p*-anisidine hydrochloride (14) or alkaline silver nitrate (15) spray reagents. The rates of movement of the sugars are quoted relative to that of D-glucose (R_g).

Gas–liquid partition chromatography (16) was carried out on a Pye argon chromatograph fitted with an ionization detector by using straight glass columns (120 × 0.5 cm inside diameter) with the following packings: (*i*) 10% (w/w) neopentyl glycol succinate on 80–100 mesh nonacid-washed Chromosorb W (temperature 210°); (*ii*) 1:1 (w/w) mixture of 15% w/w butanediol succinate polyester on 100–120 mesh Chromosorb W and 15% w/w Apiezon M grease on 100–120 mesh Chromosorb W (temperature 205°).

The retention times of the acetylated polyols are quoted relative to that of hexa-*O*-acetyl-galactitol (T_g).

Melting points were determined on a Fisher–Johns apparatus and are corrected.

Specific rotations are reported as equilibrium values.

Condensation of D-*Talose with Nitromethane*

A solution of sodium (1.8 g) in dry methanol (40 ml) at 0 °C was added to a vigorously stirred solution of α-D-talose (4.00 g) in dry methanol (50 ml) and nitromethane (50 ml). The solution was clear immediately after the addition, but 10 min later a precipitate began to appear. Stirring was continued for 8 h at room temperature, and the solution gradually turned yellow. The mixture was kept at 0 °C overnight, and the precipitated sodium salts of the 1-deoxy-1-nitroheptitols (5.22 g) were removed by filtration and washed with cold methanol and finally with ether. The solid material was dissolved in 0.5 *M* sodium hydroxide (50 ml) and the solution was added dropwise, with stirring, to 12 *N* sulfuric acid (61 ml), which was cooled externally with ice. Stirring was continued for 1 h, water (110 ml) was added, and the solution was adjusted to pH 3 by the addition of saturated aqueous barium hydroxide (ca. 1 400 ml). The removal of sulfate ions was completed with 12% aqueous barium acetate solution (55 ml). Barium salts were removed by centrifugation and the supernatant was evaporated to a smaller volume (ca. 300 ml). Deionization was effected by stirring the solution with Rexyn 101 (H^+) and Duolite A4 (OH^-) ion-exchange resins. Evaporation of the deionized solution to dryness gave a syrup (3.2 g), which was shown by paper chromatography to contain the two heptoses with some unreacted talose.

A small portion of the mixture was reduced with sodium borohydride and acetylated with acetic anhydride and sulfuric acid, and the resulting polyol acetates were examined by gas–liquid chromatography (2) on column *i*. Three peaks were obtained corresponding to D-talitol, D-*glycero*-D-*altro*-heptitol, and an unknown heptitol acetate. The ratio of D-*glycero*-D-*altro*-heptitol to the unknown heptitol was 1.0:1.50, as assessed by measurement of the peak areas.

The rest of the syrup was fractionated on a cellulose column (60 × 3 cm) with butan-1-ol (¼ saturated with water) as eluent, and the following fractions were collected.

Fraction 1, D-*Talose*

This fraction (872 mg) was shown by paper chromatography and by gas–liquid chromatography of the derived polyol acetate (hexa-*O*-acetyl-D-talitol, T_g 0.88 on column *i* (2)) to be homogeneous and to be chromatographically indistinguishable from D-talose, R_g 1.45 in solvent *a*. The syrup was dissolved in boiling methanol and, when it was cooled, crystals of α-D-talose were obtained, m.p. 134 °C, $[\alpha]_D$ +21° (equilibrium) (*c*, 3.0 in water).

Fraction 2, D-*Talose and* D-*glycero*-L-*altro-Heptose*

Paper chromatography of fraction 2 (347 mg) showed that it contained D-talose and D-*glycero*-L-*altro*-heptose. The ratio of hexose to heptose in the mixture was 3:4, as assessed by gas–liquid chromatography of the polyol acetates (2). Chromatographic fractionation on filter paper in solvent *a* gave a pure sample of each component. The syrup (192 mg) containing D-*glycero*-L-*altro*-heptose was added to fraction 3.

Fraction 3, D-*glycero*-L-*altro-Heptose*

This fraction (332 mg) was shown to be homogeneous by paper chromatography. It had R_g 1.09 in solvent *a*, 1.08 in solvent *b*, and 1.02 in solvent *c*. Attempts to crystallize the heptose were unsuccessful. The colorless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

syrup had $[\alpha]_D$ −22° (*c*, 1.96 in water). Gas–liquid chromatography (2) of the derived heptitol heptaacetate indicated the presence of only one peak, T_g 2.05 on column *i*.

D-*glycero*-L-*altro*-Heptose (100 mg) was acetylated with acetic anhydride (10 ml) and sulfuric acid (0.1 ml), the solution being shaken at room temperature for 48 h. The mixture was poured onto ice, and extraction with chloroform yielded a syrup which gave crystals from methanol solution. Hexa-*O*-acetyl-D-*glycero*-L-*altro*-heptose was recrystallized from methanol, and the crystals were found to contain 2 moles of methanol of crystallization. The crystalline product had m.p. 221 °C and $[\alpha]_D$ +52° (*c*, 0.95 in chloroform).

Anal. Calcd. for $C_{21}H_{34}O_{15}$: C, 47.91; H, 6.47. Found: C, 47.92; H, 6.50.

The rest of the syrup yielded an isomeric crystalline product from ethyl ether – light petroleum (b.p. 30–60°) which, on recrystallization from the same solvent, gave hexa-*O*-acetyl-D-*glycero*-L-*altro*-heptose·$2CH_3OH$, m.p. 125 °C, $[\alpha]_D$ −25° (*c*, 1.01 in chloroform).

Anal. Calcd. for $C_{21}H_{34}O_{15}$: C, 47.91; H, 6.47. Found: C, 47.83; H, 6.46.

These two isomers could have different anomeric configurations or could have different ring sizes, and so no attempt is made to assign a definite structure to them.

D-*glycero*-L-*altro*-Heptose (100 mg) was dissolved in water (10 ml) and stirred with sodium borohydride (120 mg) for 2 h at room temperature. Amberlite IR 120 (H^+) ion-exchange resin was added to bring the pH of the solution to 5, and boric acid was removed by evaporation with methanol. The resulting *meso-glycero-altro*-heptitol failed to crystallize but the syrup had $[\alpha]_D$ 0° (*c*, 3.0 in water). A portion (70 mg) of the syrup was acetylated with acetic anhydride (20 ml) and concentrated sulfuric acid (0.15 ml), yielding crystalline hepta-*O*-acetyl-*meso-glycero-altro*-heptitol. The acetate, on recrystallization from ethyl ether – light petroleum (b.p. 30–60°), had m.p. 70 °C and $[\alpha]_D$ 0° (*c*, 3.0 in chloroform).

Anal. Calcd. for $C_{21}H_{30}O_{14}$: C, 49.80; H, 5.96. Found: C, 49.64; H, 5.68.

Fraction 4, D-*glycero*-L-*altro-Heptose and* D-*glycero*-L-*allo-Heptose*

Fraction 3 (329 mg) was shown by paper chromatography to contain the above two heptoses. Gas–liquid chromatography (2) indicated the relative proportions of D-*glycero*-L-*altro* heptose and D-*glycero*-L-*allo* heptose to be 3:1.

Fraction 5, D-*glycero*-L-*allo-Heptose*

Paper chromatography in several solvent systems showed that this fraction (448 mg) was homogeneous. It had R_g 0.77 in solvent *a*, 0.77 in solvent *c*, and 0.89 in solvent *d*. Attempts to obtain the sugar in a crystalline form were unsuccessful. D-*glycero*-L-*allo*-Heptose had $[\alpha]_D$ −10° (*c*, 1.90 in water). Gas–liquid chromatography of the derived polyol acetate on column *i* gave only one peak, T_g 1.80.

D-*glycero*-L-*allo*-Heptose was acetylated with a mixture of concentrated sulfuric acid, acetic anhydride, and acetic acid (17). Hexa-*O*-acetyl-D-*glycero*-L-*allo*-heptose was obtained in a crystalline form from ethyl ether – light petroleum and was recrystallized twice from the same solvent. The crystals had m.p. 142 °C and $[\alpha]_D$ +32° (*c*, 1.24 in chloroform).

Anal. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.33; H, 5.66. Found: C, 49.41; H, 5.73.

Reduction of D-*glycero*-L-*allo*-heptose (100 mg) with sodium borohydride (120 mg) in a manner analogous to the reduction of the other heptose gave D-*glycero*-L-*allo*-heptitol, already known by its synonym D-*glycero*-D-*altro*-heptitol. Recrystallization from ethanol gave a crystalline product (m.p. 131 °C, undepressed on admixture with an authentic sample) having $[\alpha]_D$ −0.7° (*c*, 3.0 in water) and $[\alpha]_D$ +53° (*c*, 0.7 in 5% ammonium molybdate) (9).

Selective Periodate Oxidation of the Heptoses (10)

Samples of D-*glycero*-L-*allo*-heptose (26.4 mg) and D-*glycero*-L-*altro*-heptose (27.4 mg) were heated with 2% methanolic hydrogen chloride at 100 °C for 17 h. After neutralization with silver carbonate, the solutions were evaporated to dryness, yielding syrups (24.4 mg and 21.7 mg respectively). The latter were dissolved in water (2.0 ml), the calculated amount of an aqueous solution of 0.015 *M* sodium metaperiodate (7.2 ml and 6.4 ml respectively) was added slowly at 0 °C, and the mixtures subsequently were shaken at room temperature overnight. A solution of sodium borohydride (30 mg) in water (5.0 ml) was added slowly to each and the mixtures again left overnight. After work-up in the usual way, hydrolysis was effected with *N* hydrochloric acid at 100 °C for 2 h. The neutralized products were examined by paper chromatography and by gas–liquid chromatography of the derived polyol acetates (2).

D-*glycero*-L-*allo*-Heptose gave equal amounts of the unreacted heptose and allose (R_g 1.05 in solvent *c*) together with smaller amounts of nonreducing sugars (R_g 1.17 and 1.38 in solvent *c*).

D-*glycero*-L-*altro*-Heptose yielded equal amounts of a reducing and a nonreducing sugar. The former was identified as arabinose and the latter as altrosan (R_g 1.41 in solvent *c*).

ACKNOWLEDGMENTS

The authors thank Dr. N. K. Richtmyer for a sample of D-*glycero*-D-*ido*-heptose, and our colleague, Dr. M. B. Perry, for several samples of heptitol heptaacetates and also for many valuable discussions.

NUCLEAR MAGNETIC RESONANCE STUDIES

VIII. DETERMINATION OF THE THERMODYNAMIC PARAMETERS GOVERNING ASSOCIATIONS OF SUBSTITUTED BENZALDEHYDES IN TOLUENE SOLUTION[1,2]

R. E. KLINCK[3] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received August 9, 1965

ABSTRACT

The temperature dependence of the proton chemical shifts of four substituted benzaldehydes in toluene solution has been measured. From these results, estimates have been made of the enthalpies and entropies of formation of the stereospecific solute–solvent complexes which were previously shown to exist in these systems. These calculations indicate that the ΔH and ΔS values are -0.9 ± 0.2 kcal/mole and -4.9 ± 1.3 e.u., respectively. No correlation with substitution is apparent; the results are compared with other available data.

INTRODUCTION

In an earlier paper, the pronounced effect of substituents on the solvent shift of formyl proton shieldings in benzaldehydes caused by aromatic solvents was described (1); subsequently, a more detailed examination of this phenomenon was reported (2). In the latter work, the solvent shift for each non-equivalent proton site in a series of *p*-substituted benzaldehydes, acetophenones, and toluenes was measured, and the results gave strong evidence for the existence of stereospecific solute–solvent interactions in a variety of aromatic solvents. At that time it was noted that measurements of the temperature dependence of these solvent shifts could, in principle, provide the necessary data with which to evaluate the thermodynamic parameters governing these associations. With this object in mind, we present the results of an investigation of the variation with temperature of the proton chemical shifts of four benzaldehydes in toluene solution.

For this study, *p*-substituted examples were chosen to permit a straightforward measurement of the chemical shifts of all solute protons without a detailed analysis. To compare the influence of an electron-withdrawing substituent with that of an electron donor, the *p*-nitro and *p*-N,N-dimethylamino derivatives were examined. Terephthalaldehyde was included to show the effects for a symmetrically substituted solute, and benzaldehyde itself was examined for comparison with the others, although only the temperature dependence of its formyl proton is readily determined. Toluene was selected as the solvent because of the relatively wide temperature range over which measurements are possible.

The existence of solute–solvent complex formation in a variety of systems involving aromatic solvents is well established and a number of discussions of the phenomenon have appeared (2–11). In general, these investigations have been carried out at a single temperature and, thus, the relative strengths of the complexes were not determined. Abraham (5), however, has examined the temperature variation of the solute proton shieldings of both chloroform and methyl iodide in toluene solutions, and the effect of temperature on pyrimidine–toluene solutions has been reported (10). The present results may be compared with the ΔH and ΔS values obtained for these cases.

EXPERIMENTAL

The solutes used in this work are commercially available and were purified by recrystallization or distillation before their spectra were recorded. Toluene-d_8 (98 atom % D minimum) was obtained from Merck, Sharp and Dohme, Montreal. To approximate infinite dilution conditions, 5 mole % solutions of each solute were examined in the first instance. To permit observations over a larger temperature range, and to examine the effects of further dilution, the *p*-NO_2 and *p*-N,N-$(CH_3)_2$ derivatives were studied at concentrations down to 0.5 mole %.

All spectra were obtained with a Varian DP-60 instrument and peak positions were determined by interpolation between audio side bands of an internal tetramethylsilane reference signal placed on either side of the peak to be measured. The precision is estimated to be ±0.5 c/s. The variable temperature studies were performed with a Varian V-4340 probe accessory which has been modified to allow operation over a much wider range.

TREATMENT OF EXPERIMENTAL DATA

The formation of the postulated stereospecific solute–solvent complexes may be considered in terms of a dynamic equilibrium of the type

[1] $$\text{aldehyde (A)} + \text{solvent (S)} \rightleftharpoons \text{complex (C)},$$

if one assumes a 1:1 solute–solvent molecular ratio. Since the energies of the unassociated aldehyde and the complex may be expected to differ, the equilibrium will be temperature dependent. As the temperature is lowered it is expected that the relative amount of complex present will increase. It follows that the observed shielding of a given solute proton will be temperature dependent, because any specific chemical shift measurement will reflect the average magnetic environment of that proton. On the basis of the earlier studies (1, 2), the shielding of the solute protons, therefore, will be increased as the temperature decreases, and, in the limit of very low temperatures, the observed chemical shift should be characteristic of the complex itself. An estimate of the shielding for the solute protons in unassociated molecules can be obtained from measurements in an "inert" solvent. From these two limiting values, one can determine an equilibrium constant for any temperature according to the following method.

For eq. [1], let the original concentrations be represented by n_A^0 and n_S^0, the number of moles of aldehyde and solvent initially present. At equilibrium, the number of moles of the various species are n_A, n_S, and n_C and, if fraction p of the solute is complexed, $n_C = pn_A^0$. In terms of mole fractions the equilibrium constant, K, is given by

[2] $$K = X_C/(X_A \cdot X_S) = \exp(\Delta S/R) \exp(-\Delta H/RT),$$

where $X_C = pn_A^0/n_A^0 + n_S^0 - pn_A^0$, etc. ΔH and ΔS are the enthalpy and entropy of formation of the complex. Substitution of the appropriate expressions gives

[3] $$K = \frac{p}{(1-p)}\left[1 + \frac{X_A^0}{X_S^0 - pX_A^0}\right],$$

where X_A^0 and X_S^0 are the initial mole fractions of aldehyde and solvent, respectively. The fraction p can be obtained from the chemical shift measurements for a specific solute proton such that ν is an observed shift and is the weighted mean of the shifts for the unassociated solute, ν_A, and for the complex, ν_C. Thus

$$p = (\nu - \nu_A)/(\nu_C - \nu_A),$$

which for convenience may be reduced to $p = \nu/\nu_C$ by taking ν_A as the reference point (i.e. $\nu_A = 0$).

To obtain values of ν_A for the various solute protons it seemed most reasonable to use the data for dilute solutions in carbon tetrachloride. Since all of the solutes employed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

are not sufficiently soluble to permit the determination of precise chemical shifts in this solvent, data for chloroform solutions were used for certain cases. For the latter, small corrections were made for the effects of hydrogen bonding between the solvent and the carbonyl group on the basis of our earlier results (1). All raw chemical shift measurements were made relative to that of internal tetramethylsilane and then converted, for purposes of calculation, to a scale having ν_A for a specific proton set as zero. Values for ν_C for the various solute protons were obtained by extrapolation to absolute zero of the curve defined by the chemical shift data over the experimentally accessible temperature range. From these figures, values for p are obtained from which, by using eq. [3], the equilibrium constants were calculated. From plots of $\log K$ vs. $1/T$, ΔH and ΔS are obtained in the usual fashion.

The principal feature of the approach employed in this study is the use of the chemical shift variation with temperature for more than one proton site in a given solute molecule. Previously, similar estimates have been made by an analogous analysis, but these have been confined to measurements of the shift variations of a single solute proton. The use of more than one set of experimental results for a given case should lead to a more reliable estimate of the ΔH and ΔS parameters as well as providing an internal check on the precision of the calculated results.

As a further test of the analysis, the calculated values of ΔH and ΔS may be used together with the value of ν_C to calculate the theoretical curve of chemical shift vs. temperature for a given solute proton.

RESULTS

To illustrate the approach employed in this study, the experimental results for p-nitrobenzaldehyde in toluene solution will be considered in detail. Four concentrations were examined for this particular case, namely, 10.0, 5.0, 2.5, and 1.0 mole %. The largest temperature range over which measurements were possible was the most dilute of these, and the analysis of these results is presented in the following paragraphs.

The variation with temperature of the chemical shifts of the formyl, ortho, and meta protons is illustrated by the points in Fig. 1 over the range -71.5 to $+100$ °C. Extrapolation of these curves to 0 °K gave the values 472 ± 20, 339 ± 20, and 377 ± 20 c/s (from tetramethylsilane) for these three non-equivalent proton sites, respectively. The corresponding values of ν_A for these protons were taken as 606.9, 481.9, and 499.9 c/s, respectively, from results for dilute carbon tetrachloride solutions. Thus, the ν_C values are found, by subtraction, to be 135 ± 20, 143 ± 20, and 123 ± 20 c/s for the formyl, ortho, and meta protons, respectively. By using eq. [3], the equilibrium constants were calculated for the various temperatures at which measurements were made. As an example of typical experimental results, the data for the meta protons of p-nitrobenzaldehyde are collected in Table I. Since the data for the other nuclei in this and the following examples are similar, only one case is presented in detail.[4] Plots of the results for $\log K$ vs. $1/T$ are illustrated in Fig. 2 for each of the three non-equivalent protons in p-nitrobenzaldehyde. Values for ΔH and ΔS obtained from the three lines in Fig. 2 are presented in Table II, together with the corresponding results for the other concentrations for which a reasonable interval could be examined. From the results for the 1 mole % solutions, the theoretical curves of temperature vs. chemical shift were calculated, and these are given in Fig. 1 as the solid lines.

[4]*The full experimental details for all other cases examined during the course of this investigation are available in ref. 12.*

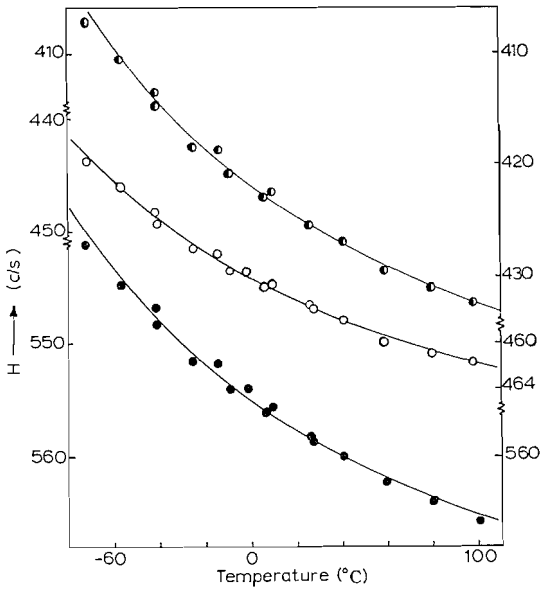

FIG. 1. Temperature dependence of the proton shieldings for 1 mole % solutions of *p*-nitrobenzaldehyde in toluene-d_8 (in cycles per second from tetramethylsilane at 60 Mc/s). Experimental points are shown for the formyl proton (●), ortho protons (◐), and meta protons (○); the full lines are the calculated temperature variations (see text).

TABLE I

Experimental data and results for meta protons in *p*-nitrobenzaldehyde (1 mole % in toluene-d_8)

Temp. (°C)	Chemical shift (c/s)		$1/T \times 10^{-3}$	K	$-\log K$
	Observed	ν

Although, in principle, the temperature dependence of four different proton chemical shifts in *p*-N,N-dimethylaminobenzaldehyde could be analyzed by the method outlined above, the temperature variation of the shielding for only two of these, the *N*-methyl and meta protons, is very pronounced. A series of equilibrium constants at various temperatures were calculated from the data for these two sites. From the results for the 1 mole % solutions, the plots shown in Fig. 3 were constructed. The average shielding (see the next paragraph) of the ortho protons is virtually independent of temperature

while that of the formyl proton changes by only 3 c/s over the interval −104 to +103 °C. Both of these observations are entirely consistent with our original ideas on the relative orientation of the solvent molecule in the complex (2). As in the previous case, several different concentrations were examined (10, 5.0, 2.5, 1.0, and 0.5 mole %), and the behavior was similar for all. The parameters obtained for each of these dilutions are collected in Table III and the temperature ranges are indicated.

At the lower temperatures (<−50 °C) the proton spectra for the p-N,N-$(CH_3)_2$ derivative become more complex because of the decreased rate of rotation of the formyl

group about the bond connecting it to the aromatic ring. This feature has been noted before (13) but, for the present case in an aromatic solvent, the relative shift between the two non-equivalent ortho proton sites is substantially increased (in the limit of slow rotation) such that the spectral changes characteristic of a slow exchange process are apparent at a temperature higher than that observed in the published account (13), for which vinyl chloride and methylene chloride were employed as solvents. We have determined the potential barrier to rotation in this and several closely related systems (12, 14) by a detailed study of the spectra at low temperatures; a full account of this work will be published in the near future.

Chemical shift measurements were carried out for the formyl and aryl protons of terephthalaldehyde with 5 mole % solutions over the rather limited temperature range 26 to 98.5 °C. For benzaldehyde, measurements were confined to the temperature dependence (over the range −35 to +100 °C) of the formyl proton shielding, since chemical shift data for the aryl protons are not so readily obtained. For these two examples, the $\log K$ vs. $1/T$ plots are presented in Figs. 4 and 5, respectively.

A summary of the calculated results for the ΔH and ΔS parameters found for all of the solutes included in this study is presented in Table IV. For those cases in which several different concentrations were examined, the results were averaged statistically

TABLE IV

Thermodynamic parameters for complex formation of substituted benzaldehydes in toluene-d_8

and the Chauvenet Principle (15) was employed to eliminate widely divergent values. The error limits given in the table are the standard deviations (σ). A reasonable estimate of the precision of the measurements may be set at about twice the standard deviation. It is important to note that the calculated ΔH for terephthalaldehyde is without doubt the least precise because of the relatively narrow temperature range examined.

DISCUSSION

From the values given in Table IV it is clear that the solute–solvent associations are very weak interactions indeed. The calculated ΔH values of -0.9 ± 0.2 kcal/mole are significantly smaller than those obtained from analyses of the results for either chloroform or methyl iodide in toluene solutions (5), which have been reported as -1.6 and -1.3 kcal/mole, respectively, but only slightly less than that given for the pyrimidine–toluene association (10). It is interesting that the observed solvent shifts (2) in aromatic as opposed to nonpolar aliphatic solvents are so marked for such weak interactions. The present results emphasize the sensitivity with which nuclear magnetic resonance techniques can detect the presence of such interactions. Although the basic assumption underlying the considerations presented in this paper has been that the complex has a 1:1 solute–solvent ratio, it should be stressed that the methods employed do not permit a clear distinction between this, the simplest model, and other more complicated forms. In fact, the magnitudes of the observed ΔH parameters show that the complex is a very loose one, and any conclusions regarding a more precise description would be unwise and unwarranted.

Although the estimates of the proton shieldings for the complex itself are crude because of the long extrapolation, and consequently are subject to rather large error, trial calculations show that a 10–15% error in the ν_C values produces changes of less than 5% in the calculated ΔH values. Another source of error inherent in the method employed is the inaccuracy of the values chosen for ν_A, which may be in error by a few cycles per second. There is little doubt that the solvent shift caused by the aromatic solvent is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

far greater than that arising from other mechanisms (2), and it seems reasonable to assume that the calculated ΔH values are within 0.2 kcal/mole of the correct magnitude.

A priori one may have expected the complex formed by *p*-N,N-dimethylaminobenzaldehyde to be more stable than the others, since the lone pair of electrons on nitrogen can interact directly with the carbonyl group by resonance and so give a more highly polarized solute molecule. It is clear, however, that no trends with substitution are revealed by the present results. There seems to be little doubt that specific solute–solvent associations do occur in these systems, and it is mildly surprising to find that the interactions are so weak. These results suggest that the problem of interpretation of solute proton shieldings in aromatic solvents should be approached cautiously, particularly in the case of large solute molecules for which a number of sites may be available for similar weak interactions. Potentially, the use of selective solvent shifts for unravelling subtle points of stereochemistry is most interesting but the way to a complete understanding of these may be difficult. In the meantime, careful studies using well-known model compounds offer a practical and valuable means of exploiting some of the more pronounced solvent shifts (9, 16).

NUCLEAR MAGNETIC RESONANCE STUDIES

IX. THE CHEMICAL SHIFT OF THE FORMYL PROTON IN ALIPHATIC ALDEHYDES[1]

R. E. KLINCK[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario
Received August 27, 1965

ABSTRACT

The effects of structure on the shielding of formyl protons of aliphatic aldehydes have been examined. The survey included examples of acyclic, alicyclic, and α,β-unsaturated aldehydes. The potential use of these results as an aid for structural elucidations is discussed, and the limitations are noted.

As part of a survey of the variation of the chemical shift of the formyl proton with structure in a variety of organic aldehydes (1), the nuclear magnetic resonance spectra of 36 aliphatic examples have been determined. These include aldehydes in which the formyl group is bonded to acyclic, alicyclic, and α,β-unsaturated carbon skeletons. Certain general trends which have potential application for structural elucidations are evident from these shielding results; these data constitute the subject of the present paper.

In an earlier paper (1), the major factors which could be expected to influence the shielding of formyl protons were considered in detail, and the present results are examined in light of these ideas. Briefly, these effects include (*a*) the deshielding influence of the carbonyl bond itself, (*b*) the shielding of the formyl proton by conjugative electron release to the carbonyl bond in suitable systems, and (*c*) the long-range effects attributable to neighboring anisotropic bonds. As before, it may be expected that only *b* and *c* will be variable throughout the series, since the orientation of the formyl proton with respect to the carbonyl bond is invariant. Support for these considerations has been provided by recent ^{13}C nuclear magnetic resonance studies (2–4), and some comparison of the ^{1}H and ^{13}C data is presented below.

For the purpose of intercomparing the results, all chemical shift values were determined in carbon tetrachloride solutions and, for most cases, concentrations of 20, 10, and 5% (w/v) were examined. In general, little effect of dilution was apparent over this range, since for most examples the total change is less than 0.01 p.p.m. The formyl proton chemical shifts for all compounds included in this study are listed in Table I for 5% solutions, and the shift observed upon dilution from 20% is indicated.

From the data for the first six entries in the table it can be seen that an increased chain length in the linear acyclic cases produces very small changes in the shielding of the formyl proton. A shift of 0.03 p.p.m. toward higher field is apparent upon substitution of an additional carbon to propionaldehyde but further extension of the chain is without effect. It is interesting that the ^{13}C shieldings of the carbonyl carbon nuclei of these simplest examples are also unaffected by chain extension (2), except for the significant change of ca. -2 p.p.m. from CH_3CHO to CH_3CH_2CHO. While this behavior is typical for methyl substitution in a variety of systems (5), the absence of a change in the formyl proton shielding for the same structural modification makes it difficult to

XX	Acrolein	9.54 (+0.01)	—				
XXI	Crotonaldehyde	9.43 (0.00)	7.6				

*From internal tetramethysilane. The quantity in parentheses is the shift (in p.p.m.) observed upon dilution of 20% solutions.
†Reported values (10): citral *a*, 9.84 p.p.m. (J = 7.8 c/s); citral *b*, 9.80 p.p.m. (J = 8.4 c/s).

offer an explanation for both experimental observations. In fact, a satisfactory rationalization of the methyl substitution effect on ^{13}C shieldings has not yet appeared but the problems involved have been discussed (5). In any event it appears that a proton chemical shift of 9.71 ± 0.02 p.p.m. is characteristic of the structure RCH_2CHO, since chain branching at the β-C (i.e. C-3) has no effect on the formyl shieldings (entries VII and VIII in the table). The appearance of a triplet pattern for the formyl absorption proves, of course, the presence of a monosubstituted α-carbon. For the examples included in the table, the observed coupling constants are listed, but no discussion of these is given since a careful examination and detailed interpretation of these spin–spin coupling interactions have been presented recently by Karabatsos and Hsi (6).

The effect of alkyl substitution at the α-carbon in the aliphatic series is illustrated by the results for entries IX–XV. Clearly the trend is toward higher field upon replacement of an α-C—H bond by a C—C bond. Presumably the origin of this shift is the diamagnetic anisotropy of the additional α-C—C bond since, according to the currently accepted view, the formyl proton lies in the shielding region of this bond (7). These protons absorb in the range 9.54 ± 0.03 p.p.m., with the exception of Δ^3-cyclohexene-1-carboxaldehyde (XV), and the fact that the latter compound exhibits formyl absorption at slightly lower field can be attributed to a long-range deshielding influence of the olefinic bond. Another feature of these results is that there is no apparent effect of ring size for the compounds having five-, six-, and seven-membered rings. While each of these undoubtedly exists as a mixture of conformations, it is interesting that the time-average shielding is similar for each. It is well known that rather larger chemical shift differences are observed between the protons of axial and equatorial formyl groups on six-membered rings in a number of natural products (8), but preliminary results in these laboratories indicate that the differences probably arise from more remote structural features than the cyclohexyl ring. We are currently engaged in a more detailed study of this particular aspect.

The shielding results for entries XVI–XIX exhibit an additional shift to higher field as a result of the replacement of the remaining α-C—H bond by a C—C bond. Presumably the reason for this is the same as that noted for the immediately preceding examples. It is expected that the effect of the β–γ double bond in XVII will be negligible, in contrast to the result for XV mentioned above, since free rotation is possible for the acyclic example so that a rapid interconversion among a host of conformers effectively averages the long-range influence of the olefinic bond to zero. These results indicate that, for structures of the type R_3CCHO, the formyl proton absorption occurs in the range 9.36 ± 0.03 p.p.m.

The next group of aldehydes listed have the common feature of an α,β-unsaturated structure. In the earlier paper (1), the notion was advanced that conjugation of the carbonyl group leads to a decreased polarization of the formyl C—H bond and hence an up-field shift of the formyl proton absorption. A considerable body of ^{13}C data for carbonyl compounds (2–4) also supports the original hypothesis (1). The present results are in complete accord with this view. For example, acrolein exhibits formyl absorption at 0.2 p.p.m. higher field than propionaldehyde, and a further shift of 0.1 p.p.m. is found for crotonaldehyde, as would be expected for the additional electron release by the β-methyl group. Thus it appears that the conjugative shielding effect outweighs the deshielding influence of the olefinic bond (9) in the α,β-unsaturated cases. Since a planar conformation will be preferred in these systems, it is not unreasonable that the formyl proton for *trans*-2,4-hexadienal (XXII) appears at slightly lower field than that for crotonaldehyde (XXI) as a result of the deshielding effect of the second olefinic bond

through space. Similarly, a low-field shift can be seen for the second double bond in XXXIII relative to that in XXXI. A detailed study of the two isomeric forms of citral has recently appeared (10) and the data in the table are in reasonable agreement with those published. It is somewhat surprising that these formyl protons appear at such low field, 9.80 and 9.85 p.p.m. These results are atypical for the α,β-unsaturated cases considered here with one other exception, which is discussed later. Dilution of the citral samples over the concentration range 20–2.5% (w/v) gives no change in the position of the formyl signals, and so it would appear that a self-association of solute molecules is not responsible for the low-field position of these peaks.

As in the saturated cases, α-alkyl substitution leads to shielding of the formyl proton, as indicated by the shift for 2-methyl-2-butenal (tiglaldehyde) as well as for the α-methyl and α-amyl derivatives of cinnamaldehyde relative to that for crotonaldehyde and cinnamaldehyde, respectively.

In our earlier paper (1), it was argued that the appearance of the formyl proton absorption for cinnamaldehyde (XXV) at 9.64 p.p.m. is consistent with the view that the ring-current effect of the aromatic ring is substantially reduced from that operative in the case of benzaldehyde (9.96 p.p.m.) while the conjugative shielding should be similar for each. Since the absorption position of a given formyl proton appears to be determined by the relative influence of these two opposing factors, we conclude that the conjugative contribution tends to dominate in XXV. The fact that the aryl ring still tends to deshield in this system, albeit to a lesser extent, can be seen by a comparison of the results for acrolein and cinnamaldehyde. Other evidence to support the interpretation is given by the chemical shift of 9.36 p.p.m. for the formyl proton of phenylpropynal (XXIX), a value which is at 0.27 p.p.m. higher field than that for cinnamaldehyde. Since the spatial effect of a triple bond caused by its magnetic anisotropy is approximately opposite to that of a double bond (11), one would expect the formyl proton in a structure of the type —C≡C—CHO to be shielded relative to one of the type —CH=CH—CHO, other things remaining essentially constant. Thus, the formyl shieldings for the series benzaldehyde, cinnamaldehyde, acrolein, and phenylpropynal are entirely consistent with our original interpretations.

Another example for which a ring-current contribution could be expected to be appreciable is furfural (XXXVII). The question of a possible ring current arising from the furan ring has received attention recently by several authors using both theoretical and experimental approaches (12, 13), and there is little doubt of the existence of this effect. Controversy has arisen, however, over its magnitude relative to that of the benzene ring. Some workers (12) have concluded that the ring-current effect of furan is significantly less than that of benzene whereas others (13) believe that they are comparable in magnitude. The results of the present study point to the conclusion that the ring-current effect of the furan nucleus is real but smaller than the benzene effect, since the formyl proton of furfural absorbs at 9.67 p.p.m.

Formyl proton shieldings have been shown to respond to the influence of polar substituents in conjugated systems (1), and the result for *p*-N,N-dimethylaminocinnamaldehyde provides another example of this trend. The change of 0.08 p.p.m. to higher field upon substitution of this substituent on the cinnamaldehyde skeleton, however, is significantly smaller than the 0.31 p.p.m. change found earlier (1) for the corresponding substitution in the benzaldehyde series.

In contrast to the saturated cases, the results for the 1-cycloalkene-1-carboxaldehydes show a pronounced change in chemical shift with ring size. The formyl proton for the

cyclopentenyl derivative absorbs at much lower field than that in the cyclohexenyl and cycloheptenyl systems. In fact, the shift for cyclohexene-1-carboxaldehyde (XXI) agrees well with the value for *trans*-2-methyl-2-butenal (tiglaldehyde) (XXIV), indicating that there is no special effect from the ring. The origin of this remarkable deshielding found for the compound with a five-membered ring is not evident, but some additional observations are pertinent to the problem. Dilution of the sample produces no change in the observed shift; therefore the possibility of self-association can be ruled out. It is interesting that the ultraviolet absorption of cyclopentene-1-carboxaldehyde (XXX) is unlike that of many other disubstituted α,β-unsaturated aldehydes (14), several of which absorb near 228 mμ while XXX absorbs at 237 mμ. The intensities of the absorption for these cases, however, are similar (ϵ_{max} 11 000 – 12 000), indicating no appreciable conformational differences. Another possible explanation for the low shielding in XXX, which could be considered, is the existence of a ring current for the nearly planar cyclopentenyl ring. It is conceivable that this might account for the observations, but examination of the 2-chloro derivatives of the cycloalkenylaldehydes (XXXIV–XXXVI) shows that the formyl protons absorb over a much narrower range, 10.03 ± 0.08 p.p.m., which appears to rule out a significant ring-current contribution for the cyclopentenyl ring. If all other factors were approximately constant, one would expect formyl absorption for 2-chloro-1-cyclopentene-1-carboxaldehyde (XXXIV) to be near 10.5 p.p.m. rather than the observed 9.95 p.p.m. position. The observed shift for XXX at 9.72 p.p.m., therefore, would seem to indicate that another, as yet undefined, influence is operative for this structure. This behavior, however, appears to be characteristic of the 1-formyl-1-cyclopentenyl system, since two other examples having this basic structure have been found. These are helminthosporal (15) and lycoctamone (16), which absorb at 9.90 and 9.75 p.p.m., respectively, in $CDCl_3$ solution.

In summary, it can be said that variations of the formyl proton shieldings of aliphatic aldehydes are, for the most part, qualitatively interpretable in terms of conjugative interactions involving the carbonyl group and anisotropic effects of neighboring groups. For structural studies, indications of the nature of the environment of specific formyl protons may be obtained from their resonance positions and multiplicities, but the narrow range of shifts encountered in this study shows that such data must be employed with caution.

EXPERIMENTAL

All spectra were determined with a Varian DP-60 spectrometer and the peak positions were measured by using audio modulation in the usual way. All chemical shift results are the average of at least 10 separate measurements.

Most of the compounds used in this study are commercially available and were purified by distillation or recrystallization before use. A sample of 2,2,4-trimethyl-3-pentenal was kindly provided by Dr. R. H. Hasek, Tennessee Eastman Co. The preparations employed for the other aldehydes are described below.

Cycloalkanecarboxaldehydes

Cycloheptanecarboxaldehyde (XIV)

Cycloheptyl chloride (10 g), prepared as described by Goering and McCarron (17), in dry ether (10 ml) was added to magnesium turnings (1.9 g) in dry ether (100 ml) under nitrogen and refluxed gently for 12 h. The Grignard reagent formed was treated with 10 g N,N-dimethylformamide and worked up in the usual way to give XIV (5.0 g, 53%), b.p. 75° at 25 mm, n_D^{20} 1.4698. Its semicarbazone had m.p. 154–155°. The reported physical constants are: XIV, b.p. 74° at 25 mm, n_D^{21} 1.4720 (18); semicarbazone, m.p. 155–156° (19).

Cyclopentanecarboxaldehyde (XII)

In a similar manner, cyclopentyl chloride gave XII (28%), b.p. 138°, n_D^{20} 1.4452; semicarbazone, m.p. 123–124°. The reported values are: XII, b.p. 41–42° at 18 mm, n_D^{25} 1.4470; semicarbazone, m.p. 123–124° (20).

1-Methyl-1-cycloalkanecarboxaldehydes

1-Methyl-1-cyclohexanecarboxaldehyde (XIX)

Cycloheptanol (11 g) treated with formic acid (1.77 g) and concentrated H_2SO_4 (60 ml) as described by Koch and Haaf (21) yielded 1-methyl-1-cyclohexanecarboxylic acid. The crude acid was reduced with $LiAlH_4$ (4.0 g) in ether (200 ml) to give the corresponding carbinol (3.8 g, 31%). Oxidation of the carbinol after the method of Barton *et al.* (22) gave XIX (1 g, 27%), b.p. 161–163°, n_D^{20} 1.4492; semicarbazone, m.p. 155–156°. The reported constants are: XIX, b.p. 120° at 54 mm, n_D^{21} 1.4490; semicarbazone, m.p. 154–155° (23).

1-Methyl-1-cyclopentanecarboxaldehyde (XVIII)

In a similar manner, cyclohexanol gave 1-methyl-1-cyclopentanecarboxaldehyde (29%), b.p. 140–141°, n_D^{20} 1.4557; semicarbazone, m.p. 165–166°. The reported values are: XVIII, b.p. 31–33° at 10 mm, n_D^{25} 1.4560; semicarbazone, m.p. 166–168° (20).

1-Cycloalkene-1-carboxaldehydes

A slight modification of the general method of Braude and Evans (24) was employed for these preparations.

1-Cycloheptene-1-carboxaldehyde (XXXII)

Freshly distilled 1-chloro-1-cycloheptene (15 g), prepared as described previously (25), was added slowly to a stirred suspension of finely cut lithium (2 g) in dry pentane (150 ml) under nitrogen and the mixture gently heated under reflux for 12 h. After the mixture was cooled to the ambient temperature, N,N-dimethylformamide (10 g) in dry ether (30 ml) was added dropwise. The mixture was stirred for 2 h and worked up as usual to give XXXII (3.0 g, 20%), b.p. 80° at 10 mm, n_D^{20} 1.4982, λ_{max} (hexane) 228 mμ (ϵ 11 500); semicarbazone, m.p. 205–206°, λ_{max} (EtOH) 268 mμ (ϵ 27 000). The reported constants are: XXXII, b.p. 82–83° at 9 mm, n_D^{20} 1.4983, λ_{max} 228 mμ (ϵ 12 000); semicarbazone, m.p. 310–311°, λ_{max} 268 mμ (ϵ 27 000) (24).

1-Cyclohexene-1-carboxaldehyde (XXXI)

In a similar manner, 1-chloro-1-cyclohexene (14 g), as prepared previously (26), gave XXXI (3.0 g, 23%), b.p. 70° at 13 mm, n_D^{20} 1.4924, λ_{max} (hexane) 227 mμ (ϵ 11 000); semicarbazone, m.p. 216–217°, λ_{max} (EtOH) 266 mμ (ϵ 25 500). The reported values are: XXXI, b.p. 72° at 15 mm, n_D^{20} 1.4920, λ_{max} 227 mμ (ϵ 11 000); semicarbazone, m.p. 217–218°, λ_{max} (EtOH) 266 mμ (ϵ 26 000) (24).

1-Cyclopentene-1-carboxaldehyde (XXX)

Similarly, XXX was prepared from 1-chloro-1-cylcopentane (27) in very low yield (~1%) and had b.p. 40° at 10 mm and λ_{max} 237 mμ (ϵ 12 000), which can be compared with the literature values (28): b.p. 45° at 16 mm and λ_{max} 237 mμ (ϵ 12 000).

2-Chloro-1-cycloalkene-1-carboxaldehydes

2-Chloro-1-cycloheptene-1-carboxaldehyde (XXXVI)

Cycloheptanone (5.6 g) was treated with phosphoryl chloride (15.7 g) and N,N-dimethylformamide (9.5 g) as described by Ziegenbein and Lang (29) to give XXXVI in 57% yield. The material had b.p. 92° at 11 mm and n_D^{20} 1.5223, while the literature values (29) are b.p. 108–111° at 19 mm and n_D^{20} 1.5215.

2-Chloro-1-cyclohexene-1-carboxaldehyde (XXXV)

In an analogous manner, cyclohexanone gave XXXV in 68% yield, having b.p. 87° at 11 mm and n_D^{20} 1.5201. The reported constants are b.p. 88–90° at 11 mm and n_D^{20} 1.5198 (29).

2-Chloro-1-cyclopentene-1-carboxaldehyde (XXXIV)

Cyclopentanone was employed in a similar manner to yield XXXIV in poor yield (5%). This material exhibited the following constants: b.p. 80–81° at 22 mm, n_D^{20} 1.5150, which may be compared with the reported values (29): b.p. 42–44° at 1 mm, n_D^{20} 1.5145.

6-Methyl-1,3-cyclohexadiene-1-carboxaldehyde (XXXIII)

Following the method described by Wichterle and Hudlicky (30) for the preparation of 1-acetoxy-1,3-butadiene, the higher boiling fractions yielded XXXIII, b.p. 62° at 5 mm; semicarbazone, m.p. 201° (decomp.); phenylhydrazone, m.p. 84–85°. The literature values (30) are: XXXIII, b.p. 62.5° at 5 mm; semicarbazone, m.p. 200°; phenylhydrazone, m.p. 83–84°.

ACKNOWLEDGMENTS

We thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, for generous support of this project, the National Research Council for support in the early stages of this work, and the Dow Chemical Co. for a fellowship granted to one of us (R. E. K.). We acknowledge the generosity of Dr. R. H. Hasek, Tennessee Eastman Co., for providing a sample of 2,2,4-trimethyl-3-pentenal, and thank Dr. G. J. Karabatsos for providing us with a preprint of his work before publication.

POLYOXYPHENOLS OF WESTERN RED CEDAR (THUJA PLICATA DONN)

III. STRUCTURE OF PLICATIC ACID

J. A. F. GARDNER,[1] E. P. SWAN,[2] S. A. SUTHERLAND,[3] AND HAROLD MACLEAN[2]

Department of Forestry of Canada, Forest Products Laboratory, Vancouver, British Columbia

Received August 24, 1965

ABSTRACT

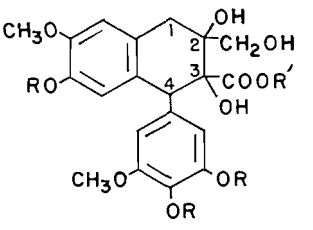
Periodate oxidation studies, nuclear magnetic resonance spectra of derivatives, and X-ray crystallographic data have shown that plicatic acid, the major component of the heartwood extractive of western red cedar (*Thuja plicata* Donn), is 2,3,6-trihydroxy-7-methoxy-2-hydroxymethyl-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-tetralin-3-carboxylic acid. The asymmetric configuration by X-ray data is 2R,3S,4R or its enantiomer, by Cahn–Ingold nomenclature.

Analytical and degradation studies described in previous papers (1, 2) provided a partial structure for plicatic acid, the reactive strong acid polyoxyphenol present in the heartwood of western red cedar. Plicatic acid, now shown to be I, forms a γ-lactone, termed plicatin, which also occurs in the heartwood, although in smaller quantities. To assist in the location of the alcoholic hydroxyls, the oxidation with sodium periodate of various crystalline methyl ether derivatives of plicatic acid was examined. The results are summarized in Table I.

The usual arsenite (3) technique for determining the periodate consumption, which involves treatment of aliquots with sodium bicarbonate solution, could not be used. The raising of the pH by the bicarbonate induced rapid over-oxidation in the aliquot solution, with the formation of yellow and then blue dyes, which are presently under investigation. It was therefore necessary to use the Malaprade (3) technique.

TABLE I

Periodate oxidation (pH 4) of plicatic acid derivatives



Derivative	Temperature (°C)	Time	Periodate consumed (moles)	Formaldehyde formed (moles)
Trimethyl ether, II	0	1 h	3.05	0.97
	0	6 h	3.30	0.97
Trimethyl ether methyl ester, III	20	1 h	2.30	0.98
	20	1½ h	2.52	—
	0	10 min	1.17	0.97
	0	1½ h	2.10	—
	0	4 h	2.40	0.97
Tetrol by $LiAlH_4$ reduction of III	20	15 min	2.90	—
	20	40 min	3.10	1.97
	20	1 h	3.15	—
	20	3½ h	3.30	1.98

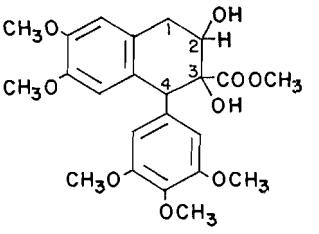
[3]*Assistant Professor, Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.*



The trimethyl ether II consumed 3 moles of sodium periodate in 1 h and formed 1 mole of formaldehyde. For the methyl ester III, however, only 2 moles of periodate were consumed rapidly and additional oxidation was slow. This behavior was consistent with the acid being an α-hydroxy acid (3), as indicated by its strong acidity and color reactions (1, 2). Following the oxidation carefully at 0 °C showed that the 1 mole of formaldehyde formed was produced during consumption of the first mole of periodate. These results and lactone formation were consistent with structure I for plicatic acid and structure III for its tri-O-methyl ether methyl ester.

I R = R′ = H
II R = CH_3, R′ = H
III R = R′ = CH_3

IV

V

The trimethyl ether γ-lactone and the monoacetate of the ester were inert to the periodate in the cold. In carbohydrates, the presence of an additional ring as in the 1,6-anhydrofuranoses confers stability (4); esterification of the primary alcohol removed the first point of attack and lack of reaction with the tertiary hydroxyls on carbons 2 and 3 indicated a sterically hindered *trans* configuration.

In further confirmation of structure III, a tetrol was formed by lithium aluminium hydride reduction of its ester carbonyl function. As expected, this tetrol rapidly consumed 3 moles of periodate while 2 moles of formaldehyde were formed. Furthermore, repeated attempts to form a podophyllotoxone analogue by manganese dioxide oxidation of III failed, indicating the absence of a hydroxyl group in the 1 position (5).

Presence of the tetrahydronaphthalene ring was supported by the ready formation of a crystalline naphthalene derivative by heating the trimethyl ether lactone (1) to 340 °C. The product had an ultraviolet absorption spectrum characteristic of a substituted naphthalene and gave a positive phenol test with anhydrous ferric chloride in chloroform. On the basis of analysis, infrared and ultraviolet spectra, nuclear magnetic resonance spectra of the product and its acetate, and the successful, although difficult, coupling reaction with diazotized sulfanilic acid (color test) (6), this compound appeared to be the β-naphthol IV. This structure was indicated further by its inability to be methylated with either diazomethane or dimethyl sulfate. Also, nitric acid oxidation in a Carius tube failed to yield any benzoic acid derivatives.

To fix the position of the hydroxymethyl and carboxylic acid group on carbon atoms 2 and 3 of the tetrahydronaphthalene ring, the oxidation of methyl tri-O-methyl plicatate (III) with periodate was limited to 1 mole to produce the ketone at carbon 2. Catalytic hydrogenation then gave the diol V, in which a new proton on the saturated ring replaced the hydroxymethyl group. Nuclear magnetic resonance (n.m.r.) spectra of III and V show the spin–spin coupling of this new proton with the two protons of carbon 1, thereby positioning the original hydroxymethyl group at carbon 2 and giving plicatic acid the structure I.

For personal use only.

The n.m.r. spectrum of III together with an integral curve summed for all proton species believed present was obtained, and agreed well with the proposed structure. Figure 1 (upper curve) shows the n.m.r. spectrum of III in deuteriochloroform containing deuterium oxide and trifluoroacetic acid to exchange the protons of the hydroxyl group.

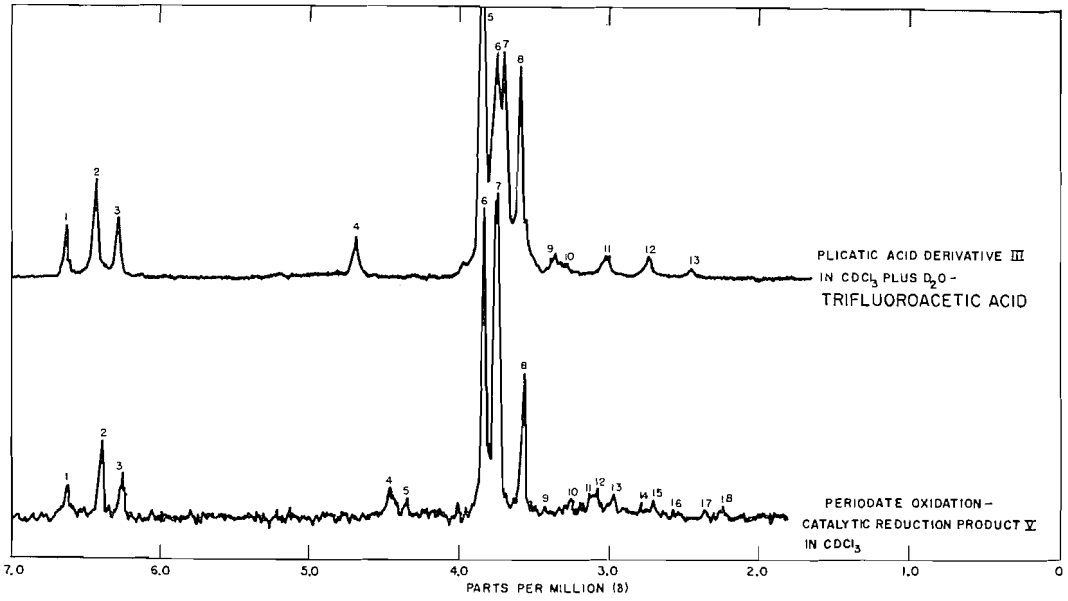

FIG. 1. Nuclear magnetic resonance spectrum at 60 Mc/s of methyl tri-O-methyl plicatate (III) and its periodate oxidation – catalytic reduction product (V).

Assignation of proton signals at the various numbered positions is given in Table II. Relatively few lignan n.m.r. spectra have been published but, of those available, the above assignations agree well with those of lyoniresinol and its derivatives (7).

Optimum reaction conditions for the periodate oxidation of III were studied by means of thin-layer chromatography. Preparative thick-layer chromatography was used to obtain a small yield of desired product with the correct infrared spectrum and analyses. This oxidation product, which was susceptible to further air oxidation, was readily reduced to the desired product (V), which was a mixture of two isomers. The major product was purified by preparative thick-layer chromatography to yield the desired product with an infrared spectrum very similar to that of III. The n.m.r. spectrum was taken as before but the solution was rather dilute, necessitating high amplification with consequent high noise level so that the integral curve was not obtained. After the n.m.r. spectrum was taken, the sample was reexamined by thin-layer chromatography to demonstrate that no changes had occurred.

The n.m.r. spectrum of the oxidation–reduction product V was similar to that from III and is shown in Fig. 1 (lower curve). The positions of the absorptions from the aromatic and methyl protons were unchanged. The signal from the C4 proton was unchanged but shifted by 0.22 δ, and was attributed to the removal of the hydroxymethyl group (by the periodate oxidation) which had given long-range shielding of this proton in III. The signal from the C1 proton was changed from the regular AB pattern to a poorly resolved complex pattern of the AB portion of an ABX spectrum. Similar poorly resolved spectra are found in the literature (9). The interpretation of the spectrum of V was facilitated by obtaining

‡See text for explanation.

and comparing it with the spectrum of the acetate of V, which showed that it was the monoacetate derivative. Acetylation of a secondary hydroxyl group shifts the attached proton downfield by about 1.0 δ (10). New signals appeared at 5.57, 5.65, and 5.80 δ for the C2 proton but it was not certain from what position they had shifted. By allowing for the difference in chemical shifts between V and its acetate, it was certain that the signals from C1 protons (peaks 9–18 except peak 11) were the same in both cases. Proton-exchange experiments, carried out by the addition of two drops of deuterium oxide to the n.m.r. tube, showed that the tertiary hydroxyl group α to the carbonyl was giving peak 11 and thus did not acetylate. The position of the remaining hydroxyl group was uncertain. Since peak 5 disappeared upon acetylation, it was either this hydroxyl group or the C2 proton; upon deuterium exchange it was uncertain whether the peak disappeared or not because of a low ratio of signal to noise.

The *p*-bromoanilide of tri-O-methylplicatic acid crystallizes in the orthorhombic system, space group $P2_12_12_1$, with unit cell dimensions $a = 21.08$, $b = 5.79$, $c = 23.08$ Å. There are four molecules of $C_{29}H_{32}O_9NBr$ in the cell. Three-dimensional X-ray data were collected on a Nonius equi-inclination Weissenberg camera, and intensities of the 1 778 observed reflections were estimated visually. The coordinates of the bromine atom were determined from a Patterson synthesis, and the calculated phase angles applied to a first three-dimensional Fourier synthesis. Bromine is not heavy enough to give optimum phase agreement, although it was possible to identify the basic ring skeleton. Addition of increasing numbers of light atoms to subsequent structure-factor calculations improved the phases until all atoms were clearly visible (Fig. 2). Refinement of the structure is continuing. Since X-ray data did not differentiate between this compound and its enantiomer, the asymmetric configuration is either 2R,3S,4R or 2S,3R,4S by Cahn–Ingold nomenclature (12), i.e. all carbons attached to the tetralin ring are *trans*.

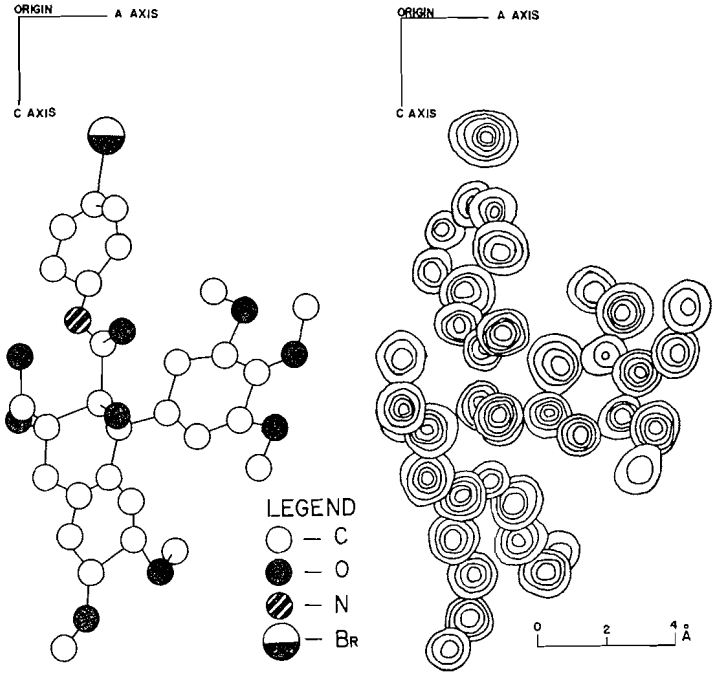

FIG. 2. X-ray crystallographic projection of *p*-bromoanilide of tri-O-methyl plicatic acid.

Plicatic acid is therefore 2,3,6-trihydroxy-7-methoxy-2-hydroxymethyl-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-tetralin-3-carboxylic acid. The nomenclature of Freudenberg and Weinges (11) does not allow for the naming of a free acid lignan. The proposed name by this system is 3,4,8,4′,8′,9′-hexahydroxy-5,3′-dimethoxy-9-cyclolignanoic acid. This lignan is novel in that it is the first to be known to have a monomethylated pyrogallol ring. It is also the first lignan to have a free carboxylic acid group in the side chain.

EXPERIMENTAL

All melting points are uncorrected. The n.m.r. spectra were run in deuteriochloroform on a Varian A-60 machine of the Chemistry Department, University of British Columbia, with tetramethylsilane as an internal standard. X-ray crystallographic calculations were performed on an IBM 7040 computer with programmes written by Dr. J. Trotter of the University of British Columbia. Analyses were performed by Clark Microanalytical Laboratories, Urbana, Illinois. Thin-layer and preparative chromatography was carried out on silica gel G with dichloromethane – acetone – acetic acid (80:20:1 v/v/v) as the developing solvent; the detecting reagent used was a concentrated nitric acid – sulfuric acid (1:1 v/v) mixture. Infrared spectra were taken as KBr disks.

Periodate Oxidations; Methylated Plicatic Acid Derivatives

The following example illustrates the reaction techniques used to obtain the data shown in Table I. Tri-O-methyl plicatic acid (II; 0.121 g) was dissolved in ethanol (1.5 ml) and water (35 ml), cooled to 0 °C, and added to 0.1 *M* aqueous sodium metaperiodate (10 ml), also at 0 °C. The total volume was adjusted to 50 ml with cold water and the solution stored at 0 °C. Periodate consumption was determined on aliquots (5 ml) at ½, 1, and 6 h intervals by the Malaprade (3) technique. Formaldehyde yields were determined colorimetrically by the chromotropic acid method of Lambert and Neish (13).

Pyrolysis Product V of Tri-O-methyl Plicatic Acid

Tri-O-methyl plicatic acid (II; 1.03 g) was intimately mixed with small glass helices in a glass tube and heated in a current of nitrogen gas in a muffle furnace at 290 °C, the temperature being increased to 340 °C over a period of 1 h. The yellowish solid that condensed on the tube walls outside the furnace was crystallized from benzene to yield pale yellow crystals (0.466 g), m.p. 202–204 °C, which on repeated recrystallization melted at 210–211 °C. Ultraviolet spectrum in ethanol ($m\mu$ (log ϵ)): 236 (4.82), 282 (3.82), 293 (3.79) shoulder, 321 (3.56), and 334 (3.68); in 0.002 *M* sodium ethylate: 238 (4.61), 253 (4.54) shoulder.

Anal. Calcd. for $C_{22}H_{24}O_6$: C, 68.7; H, 6.29; OCH_3, 40.3. Found: C, 68.6; H, 5.93; OCH_3, 39.6.

Kuhn–Roth oxidation showed 0.97 mole C-methyl (14). This product, after acetylation (15) and recrystallization from methanol–water, melted at 152–153 °C. Infrared spectral comparison showed complete acetylation by the disappearance of the phenolic hydroxyl band. Nuclear magnetic resonance spectra of both the pyrolysis product and its acetate indicated both the number and species of protons expected.

Preparation of Methyl Tri-O-methyl Plicatate; Oxidation–Reduction Product V

Methyl tri-O-methyl plicatate (III; 100 mg) was dissolved in ethanol (25 ml) and cooled to 0 °C. Sodium metaperiodate (672 mg) in water (75 ml) containing three drops of 0.1 *N* hydrochloric acid was cooled and added. The mixture was kept for 1 h in the dark at the same temperature and then extracted with chloroform (3 × 25 ml); the combined extracts were dried over anhydrous sodium sulfate, filtered, and evaporated under reduced pressure. The keto-ester product was purified by preparative thin-layer chromatography (R_f 0.8) and recrystallized from ether to give slightly green crystals, m.p. 69–70 °C, yield 47 mg. It had the expected infrared spectrum, showing in comparison with that of III a very much decreased hydroxyl absorption at 3 450 cm^{-1} and the appearance of another carbonyl absorption at 1 750 cm^{-1} for the six membered ring ketone.

Anal. Calcd. for $C_{23}H_{26}O_9$: C, 61.90; H, 5.87; OCH_3, 41.70. Found: C, 60.85; H, 5.97; OCH_3, 39.01.

The keto-ester product (40 mg) was dissolved in ethanol (10 ml), and hydrogenated at room temperature and 3 atmospheres pressure in a Parr apparatus for 1 h with platinum catalyst. The catalyst was recovered on the filter, the ethanol evaporated under reduced pressure, and the product purified by thick-layer chromatography. The main product (21 mg) had R_f 0.25 (slightly more than that of III) and after recrystallization from ethanol–ether melted sharply at 165 °C. The infrared spectrum was as expected, with only carbonyl absorption from the ester group.

Anal. Calcd. for $C_{23}H_{28}O_9$: C, 61.62; H, 6.29; OCH_3, 41.51. Found: C, 60.87; H, 6.23; OCH_3, 39.58.

After the n.m.r. spectrum of this product was obtained the recovered material was crystallized from benzene. The crystals were treated with pyridine (1 ml) and acetic anhydride (1 ml) at 40 °C for 1 h. The reagents were evaporated under high vacuum and the n.m.r. spectrum of the product was obtained.

p-Bromoanilide of Tri-O-methyl Plicatic Acid

Tri-O-methyl plicatic acid (II; 1 g) was mixed with *p*-bromoaniline (2 g), refluxed for 2 h at 140 °C, cooled overnight, dissolved in $CHCl_3$ (50 ml), and filtered. The solution was extracted with 10% HCl (3 × 15 ml), washed once with water (10 ml), re-extracted with 10% NaOH (3 × 15 ml), dried, and evaporated. The product, recrystallized from ethanol, melted at 247–248 °C (yield 57%). Infrared spectrum: carbonyl shifted to 1 672 cm^{-1} with additional amide absorption (16) at 3 325, 1 535, and 1 308 cm^{-1} when compared with the spectrum of methyl tri-O-methyl plicatate (III).

Anal. Calcd. for $C_{29}H_{32}O_9BrN$: C, 56.3; H, 5.21; N, 2.26; Br, 12.93. Found: C, 55.74, 56.01; H, 4.75, 4.91; N, 2.20, 2.17; Br, 12.76, 13.00.

Reduction of Methyl Tri-O-methyl Plicatate

Methyl tri-O-methyl plicatate (III; 3.0 g) was reacted with lithium aluminium hydride (1.86 g) in accordance with the procedure of Schrecker and Hartwell (17) and yielded, on three recrystallizations from ethyl acetate – hexane (1:2), a tetrol derivative, 2,3-dihydroxy-6,7-dimethoxy-2,3-dihydroxymethyl-4-(3′,4′,5′-trimethoxyphenyl)-tetralin (1.58 g). After this product was dried in a vacuum at 100 °C for 2 h it showed a partial melting, without gasification, at 150–155 °C, followed by recrystallization on the melting point stage and remelting at 164–164.5 °C. Recrystallization from methanol–water (1:10) and similar drying yielded crystals melting at 125–126 °C. Infrared spectra of both crystal forms were identical, showing enhanced hydroxyl and no acid carbonyl band when compared with the spectrum of the starting material.

Anal. Calcd. for $C_{23}H_{30}O_9$: C, 61.3; H, 6.72; OCH_3, 34.4. Found: C, 60.83; H, 6.87; OCH_3, 33.9.

ACKNOWLEDGMENTS

We thank Dr. L. D. Hall of the Chemistry Department, University of British Columbia, for many helpful discussions on the interpretation of the n.m.r. spectra; Dr. J. B. Armstrong, Department of Biochemistry, University of Wisconsin, for work on the crystallographic data; and the National Research Council of Canada for financial support to S. A. S. for the crystallographic study.

1,2,3,4-TETRAPHENYLDIAZETIDINE

A REEXAMINATION[1]

J. G. SMITH
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received August 13, 1965

ABSTRACT

The reported synthesis of 1,2,3,4-tetraphenyldiazetidine by treating the sodium adduct of N-benzylidene aniline with benzaldehyde or benzoate ester is reexamined. It is shown that the original report is in error. The products from the reaction are the two diastereomeric N-benzoyl-N,N′,1,2-tetraphenylethylenediamines and *dd,ll*-N,N′,1,2-tetraphenylethylenediamine. When diethyl ether was used as a reaction medium, another product, N-benzoyl-N,N′-diphenylstilbene-α,α'-diamine, was formed. An explanation is offered for the formation of these compounds and for the differences in reaction products caused by the two reaction media employed, diethyl ether and tetrahydrofuran.

In 1928 it was reported (1) that the treatment of the sodium addition product (I) of N-benzylidine aniline with either ethyl benzoate or benzaldehyde produced 1,2,3,4-tetraphenyldiazetidine (II), as shown in eq. [1]. Because of the rarity of compounds such as (II)

[1] $C_6H_5—CH=N—C_6H_5 \xrightarrow[(C_2H_5)_2O]{Na}$ $C_6H_5—CH(Na)—CH(Na)—C_6H_5$ (I) $\xrightarrow[C_6H_5—CO_2—C_2H_5]{C_6H_5CHO\ or}$ $C_6H_5—CH—CH—C_6H_5$ (II)

and the possibility that such a reaction may be a synthetic route to them, the reaction was reexamined.

RESULTS

Tetrahydrofuran was initially used as the preparative solvent and reaction medium because of the greater solubility of the organometallic compound in it. The addition of sodium to N-benzylidene aniline proceeded rapidly and smoothly to give the expected 2:2 adduct (I) (2, 3).

The reaction of this adduct with either benzaldehyde or esters of benzoic acid proceeded in a manner quite unlike that previously described. While the same compound was isolated from the two reactions, the melting point was some 30° higher than that reported.

On the basis of its analysis and its infrared spectrum, which showed a NH band at 3 380 cm^{-1} and an amide carbonyl band at 1 625 cm^{-1}, the compound was identified as N-benzoyl-N,N′,1,2-tetraphenylethylenediamine. Synthesis of the monobenzamides from the known diastereomeric N,N′,1,2-tetraphenylethylenediamines established its identity as the monobenzamide of the *dd,ll* diamine.

In addition to this, a second amide was isolated in low yield, which, on the basis of its analysis, infrared spectrum (NH band at 3 360 cm^{-1}, amide carbonyl at 1 635 cm^{-1}), and

mixed melting point, was shown to be the N-benzoyl derivative of meso-N,N′,1,2-tetraphenylethylenediamine. The *dd,ll*-N,N′,1,2-tetraphenylethylenediamine was also detected in the products arising from the reaction with benzaldehyde.

Thinking that the course of the reaction may have been influenced by the choice of solvent, we repeated the experiments with diethyl ether, the solvent originally employed (1, 2). With methyl benzoate, no change in the course of the reaction was noticed. The products isolated were *dd,ll*-N,N′,1,2-tetraphenylethylenediamine and again the N-benzoyl derivatives of the *dd,ll* and meso diamines. There was, however, a change in the relative amounts of the two diastereomeric benzamides. With diethyl ether as solvent approximately equal quantities were formed, whereas with tetrahydrofuran the benzamide was largely derived from *dd,ll*-N,N′,1,2-tetraphenylethylenediamine.

Benzaldehyde generated a new compound which appeared as a yellow precipitate when the reaction mixture was hydrolyzed with water. This material decomposed at its melting point, was oxidized in boiling solvents, and lost its yellow color on treatment with acids. Its infrared spectrum showed a NH band at 3 340 cm^{-1} and an amide carbonyl band at 1 645 cm^{-1}. The chemical properties matched closely those described (4) for N-benzoyl-N,N′-diphenylstilbene-α,α'-diamine. Its identity was established by synthesis, by comparison of its infrared spectrum, and by the mixed melting point of its picrate.

Table I summarizes the reaction products and yields obtained.

TABLE I

Summary of reaction products and yields

			Products and yields

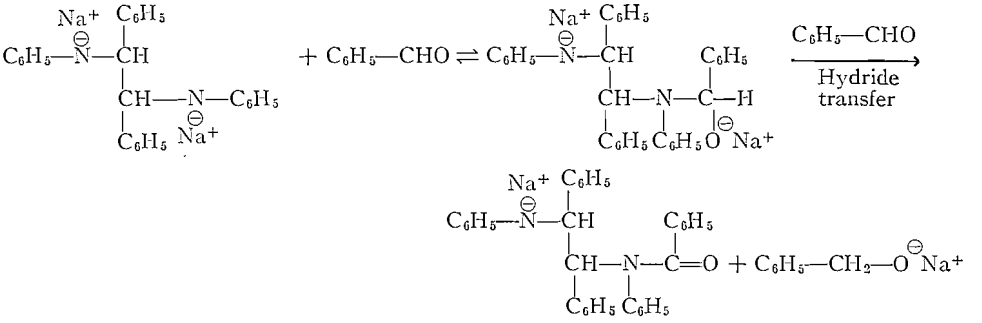
DISCUSSION

It must be concluded that 1,2,3,4-tetraphenyldiazetidine is not formed in any significant quantity in these reactions. The question remains concerning the identity of the compound isolated by Schlenk and Bergmann (1). Two pieces of evidence were offered for its identity, its analysis and its melting point, 153–154°, which differed markedly from that (136–139°) of the N,N′,1,2-tetraphenylethylenediamine obtained on hydrolysis of the organosodium compound.

At the time of the original work the fact was not appreciated that the hydrolysis product is actually a mixture of the meso and *dd,ll* diastereomers, whose individual melting points are 167° and 153° respectively (5). It seems likely that the reported compound was *dd,ll*-N,N′,1,2-tetraphenylethylenediamine, whose melting point and analysis agree with those reported. Its formation was probably due to premature hydrolysis of the reaction mixture.

Treatment of the sodium compound in ether with benzaldehyde results in the immediate formation of a yellow precipitate. Hydrolysis of the reaction mixture at this point produced only the diastereomeric mixture of the tetraphenylethylenediamines. It is only after the reaction mixture has been allowed to stand at room temperature for several hours before hydrolysis that appreciable quantities of benzoylated products are detected.

The formation of N-benzoylated derivatives with benzoate esters is to be expected. The interesting feature is the formation of only the monobenzamide. Possibly, after the formation of the monobenzamide, further reaction occurs intramolecularly to form (III),

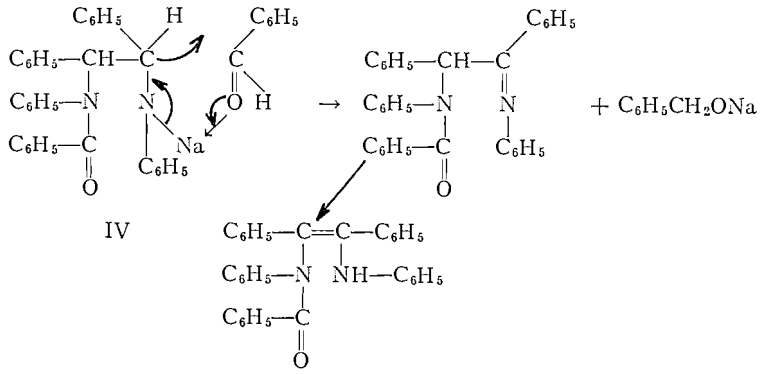


[2] 

III

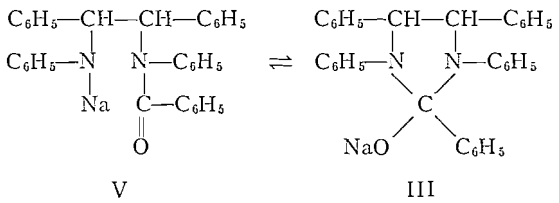
as shown in eq. [2]. Hydrolysis of the reaction product results in the ring opening of (III), thereby forming the N-benzoyl derivative.

Differences in the ratio of the monobenzamides of meso- and *dd,ll*-N,N′,1,2-tetraphenylethylenediamine formed in tetrahydrofuran versus those formed in diethyl ether are due to the difference in the ratio of the diastereomeric N,N′-disodio-N,N′,1,2-tetraphenylethylenediamines formed in the two solvents. It has been established (*5b*) that the ratio of the diastereomeric diamines formed by reductive dimerization of N-benzylidene aniline in wet ether is approximately 1:1. By using this published melting point – composition phase diagram, the diamine mixture obtained on hydrolysis of the sodium compound formed in tetrahydrofuran contained approximately 10% of the meso diamine.



In the case of the reaction with benzaldehyde, the substituted benzamide can arise from two sources. The amine anion can take part in a Cannizarro reaction, as shown in eq. [3],

[3] 



to produce the product and an alkoxide ion. This anion in turn can react with benzaldehyde in a Cannizarro reaction to produce benzyl benzoate, which acts as a second source of the benzamide.

Since the stilbene derivative arises in diethyl ether, it is a reasonable assumption that the meso-disodio compound, which is formed in large amounts in diethyl ether, is its source. Presumably it is formed by a hydride transfer within a cyclic complex (IV), as shown in eq. [4]. A similar hydride transfer has been noted in the reactions of lithium diethylamide with benzophenone (6).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

[4] 

The ability of the meso-disodio derivative to engage in this reaction is probably connected with the position of the equilibrium between the "open" mono-N-benzoyl compound (V) and the cyclic isomer (III), as shown in eq. [5]. It will be noted that the *dd,ll*

[5] 

isomer of (V) produces the *trans* arrangement of the two phenyl groups in (III) whereas the diastereomeric *dl,ld* isomer of (V) produces the *cis* arrangement. It would be anticipated that, in the latter case, a higher concentration of the open structure (V) would exist in the equilibrium because of the greater steric interaction of the phenyl groups in the corresponding stereoisomer of (III).

An increase in the benzaldehyde concentration increases the rate of the Cannizarro reaction much faster than it increases the rate of the cyclic hydride transfer. The benzyl benzoate so formed reacts with the sodium compound, producing the monobenzamide before the internal hydride transfer can occur within the complex to produce the stilbene derivative.

EXPERIMENTAL

Melting points are uncorrected and were determined in an open capillary in a Gallenkamp melting point apparatus. Infrared spectra were taken on a Beckmann IR9 or a Perkin–Elmer 421G.

All operations involving the organometallic compound were performed under a positive head of purified nitrogen (7). N,N′,1,2-Tetraphenylethylenediamine (TPED) was prepared by an aluminium amalgam reduction of N-benzylidene aniline in wet ether (5*b*). The diastereomers were separated by means of their complexes with N,N-dimethylformamide (5*a*); *dd,ll*-TPED had m.p. 150–153°, meso-TPED m.p. 167–168°.

The tetrahydrofuran and diethyl ether used in the experiments were purified by refluxing them under nitrogen over sodium metal until the addition of benzophenone produced the permanent blue color of the ketyl. The solvent was then distilled onto lithium aluminium hydride and stored in this fashion. When needed, the solvent was refluxed over the lithium aluminium hydride for 2 to 4 h and then distilled into the reaction vessel, a modified Schlenk tube (8).

Preparation of the Organosodium Compound

The Schlenk tube containing the freshly distilled solvent was transferred to a dry box where the N-benzylidene aniline and sodium metal (freshly cut) were weighed and added. The tube was removed from the dry box and shaken in a horizontal shaker. The reaction began at once, accompanied by the formation of an orange or orange-red color. The completeness of reaction was determined by permitting weighed amounts

For personal use only.

of the solution to flow into 50% aqueous ethanol. The solution was then titrated with standardized hydrochloric acid and phenolphthalein indicator. Under these conditions the TPED is not titrated. Table II demonstrates that the reaction is quite rapid.

Table III summarizes the properties of the mixed diastereomeric diamines isolated from the hydrolysis.

Preparation of Monobenzamide of Meso-N,N′,1,2-tetraphenylethylenediamine

Meso-N,N′,1,2-tetraphenylethylenediamine (1.09 g, 0.003 mole) was dissolved in 15 ml of benzene and 15 ml of pyridine. Benzoyl chloride (0.632 g, 0.0045 mole) was added and the solution refluxed for 18 h. To the cooled mixture, 15 ml of benzene and 15 ml of 10% aqueous potassium hydroxide was added. The aqueous phase was separated, and the organic phase was washed once with 10 ml of 10% potassium hydroxide and three times with 15 ml portions of water, and then dried over magnesium sulfate. Evaporation of the solution gave 1.332 g of solid, m.p. 170–182 °C. The material was dissolved in 30 ml of hot carbon tetrachloride, the solution was filtered hot, and when the solution was allowed to cool 1.133 g of a voluminous white precipitate separated, m.p. 188–192 °C. The infrared spectrum (Nujol mull) showed a NH band at 3 360 cm^{-1} and an amide carbonyl band at 1 635 cm^{-1}.

Anal. Calcd. for $C_{33}H_{28}N_2O$: C, 84.59; H, 6.02; N, 5.97. Found: C, 84.90; H, 5.92; N, 6.00.

Preparation of Monobenzamide of dd,ll-N,N′,1,2-Tetraphenylethylenediamine

dd,ll-N,N′,1,2-Tetraphenylethylenediamine (0.723 g, 0.002 mole) was dissolved in 25 ml of diethyl ether and 5 ml of benzene. Benzoyl chloride (0.912 g, 0.0021 mole) was added and the solution was allowed to stand at room temperature for 40 h. A white precipitate separated. The mixture was evaporated to dryness and the residue dissolved, with heating, in 15 ml of ethanol and 5 ml of water. Potassium hydroxide (0.40 g) dissolved in 10 ml of ethanol and 2 ml of water was added to the hot solution. The precipitate which formed was dissolved in 20 ml of benzene, and the organic phase was separated, washed twice with 10 ml of water, and dried over magnesium sulfate. Evaporation gave 0.882 g of a glassy residue. Treatment with 10 ml of diethyl ether effected crystallization. Filtration gave 0.349 g of derivative, m.p. 176.5–182 °C. Recrystallization from 5 ml of *n*-butanol gave 0.336 g, m.p. 180–183 °C. The infrared spectrum (Nujol mull) showed a NH band at 3 380 cm^{-1} and an amide carbonyl band at 1 625 cm^{-1}.

Anal. Calcd. for $C_{33}H_{28}N_2O$: C, 84.59; H, 6.02; N, 5.97. Found: C, 84.79; H, 5.97; N, 6.08.

Reaction in Tetrahydrofuran with Methyl Benzoate

The sodium adduct from 5.43 g (0.03 mole) of N-benzylidene aniline, 75.3 g of tetrahydrofuran, and 1.4 g (0.06 atom) of sodium was transferred to a 250 ml flask which was filled with dry nitrogen and which was equipped with a magnetic stirring bar. The solution was stirred, and 4.08 g (0.03 mole) of freshly distilled methyl benzoate dissolved in 15 ml of dry tetrahydrofuran was added all at once. A deep ruby-red color developed immediately. During the next 24 h, an orange-red precipitate formed and the color of the solution became orange. Water (25 ml) was then added and the precipitate dissolved.

The solution was transferred to a separatory funnel with 50 ml of benzene, and the aqueous phase was separated. The organic phase was washed three times with 25 ml portions of water, dried over magnesium sulfate, and evaporated, giving 6.84 g of residue. This was dissolved in 25 ml of hot benzene and treated with 40 ml of petroleum ether (b.p. 30–60°). A precipitate separated and (after 5 h) was filtered off, wt. 5.22 g, m.p. 163–175°. This material had an infrared spectrum identical with that of the N-benzoyl-*dd,ll*-TPED. However, the presence of a small amount of the diastereomer N-benzoyl-meso-TPED was demonstrated by allowing a solution of 0.6 g of the mixture in 50 ml of toluene–heptane (1:1) to evaporate to half volume spontaneously at room temperature over a period of 1 week. The crystals which separated consisted of small needles intermixed with relatively massive parallelopipeds. These were easily separated mechanically. The needles (0.05 g, m.p. 178–182°) had an infrared spectrum (Nujol mull) identical with that of the monobenzamide of the meso-TPED; the parallelopipeds (0.49 g, m.p. 165–182°) were similarly shown to be the monobenzamide of the *dd,ll* diamine.

The filtrate from the mixed monobenzamides was evaporated and the residual oil dissolved in 5 ml of methylene chloride and 25 ml of petroleum ether (b.p. 30–60 °C). The solution was chromatographed on 60 g of Woelm, grade I, basic alumina, elution being carried out with petroleum ether containing increasing amounts of methylene chloride. The first 350 ml of petroleum ether – 10% methylene chloride gave, on evaporation, 0.173 g of an amorphous solid. Crystallization from 5 ml absolute ethanol gave 0.018 g of N-benzylidene aniline, m.p. 50–54°.

The filtrate from this gave 0.086 g of the 2,4-dinitrophenylhydrazine derivative of benzaldehyde, m.p. 235–237 °C, on treatment with 2,4-dinitrophenylhydrazine reagent. An additional 0.104 g of this material was eluted with the next 200 ml of petroleum ether – 25% methylene chloride. After this, 300 ml of petroleum ether – 50% methylene chloride eluted 0.186 g of a solid which was recrystallized from 3 ml of ethanol. There was obtained 0.105 g of *dd,ll*-TPED, m.p. 148–150°, mixed melting point with an authentic sample 148–153°.

The next 275 ml of methylene chloride eluted 0.191 g of a solid which, on recrystallization from 3 ml of ethanol, gave 0.163 g of the monobenzamide of *dd,ll*-TPED, m.p. 170–176°, mixed melting point with an authentic sample 174–180°.

The yields obtained for the various compounds are: N-benzoyl-TPED (mixed isomers), 77%; *dd,ll*-TPED, 3%; N-benzylidene aniline, 5%.

Reaction in Tetrahydrofuran with Benzaldehyde (Mole Ratio 1:1)

The sodium adduct from 3.62 g (0.02 mole) of N-benzylidene aniline and 0.8 g (0.04 atom) of sodium in 62.2 g of tetrahydrofuran was transferred to a 125 ml flask which was filled with dry nitrogen and which was equipped with a magnetic stirring bar. The solution was stirred and 2.12 g (0.02 mole) of benzaldehyde was added all at once. A deep red color immediately developed. The solution was allowed to stand for 16 h, during which time a dark red precipitate formed.

Water (15 ml) was added with stirring. The color of the solution changed to orange and the precipitate dissolved. Diethyl ether (75 ml) was added, the aqueous phase was separated, and the ether layer was washed five times with 20 ml portions of water. After drying over magnesium sulfate, the solution was filtered and evaporated. The residue, a semicrystalline gummy solid, was dissolved in 20 ml of benzene and added to 50 ml of petroleum ether (b.p. 30–60°). The solid which separated was filtered off, washed with 1:1 benzene – petroleum ether, and dried; wt. 2.564 g, m.p. 174–180°. A comparison of the infrared spectrum with that of an authentic sample of N-benzoyl-*dd,ll*-TPED showed that the materials were identical.

The filtrate was evaporated, and the residue was dissolved in 20 ml of ether and 10 ml of benzene, and chromatographed on 60 g of Woelm, grade I, basic alumina. Elution with 50 ml of 1:1 petroleum ether – diethyl ether and then 100 ml of diethyl ether removed 1.02 g of *dd,ll*-N,N′,1,2-tetraphenylethylenediamine, m.p. 145–148°. Recrystallization from absolute ethanol raised the melting point to 150–153°; the mixed melting point with an authentic sample was 151–153°. The next 200 ml of ether containing 10% benzene eluted 0.161 g of N-benzoyl-meso-TPED, m.p. 180–186°, which after recrystallization from toluene melted at 186–192°; the mixed melting point with an authentic sample was 186–192°. The next 200 ml of ether containing 25% benzene, 150 ml of 1:1 ether–benzene, 200 ml of 1:1 ether–benzene containing 0.5% methanol, and 200 ml of 1:1 ether–benzene containing 2% methanol yielded a total of 0.25 g of N-benzoyl-*dd,ll*-TPED. The yields of these various compounds are: *dd,ll*-TPED, 28%; N-benzoyl-*dd,ll*-TPED, 60%; N-benzoyl meso-TPED, 3%.

Reaction in Tetrahydrofuran with Benzaldehyde (Mole Ratio 1:2)

This last experiment was repeated, except that only 1.06 g (0.01 mole) benzaldehyde was added. Evaporation of the solvent after washing gave a residue of 3.61 g. The infrared spectrum of this material showed only a weak band at 1 630 cm^{-1} characteristic of the amide carbonyl. The rest of the spectrum was identical with that of *dd,ll*-TPED.

Chromatography of the crude product as described above enabled 2.61 g (72% yield) of *dd,ll*-TPED, m.p. 141–153°, and 0.176 g (4% yield) of the monobenzamide, m.p. 173–184°, to be isolated.

Reaction in Tetrahydrofuran with Benzaldehyde (Mole Ratio 2:1)

The adduct prepared from 1.81 g (0.01 mole) of N-benzylidene aniline and 0.5 g (0.02 atom) of sodium in 43.6 g of tetrahydrofuran was transferred to a 125 ml flask which was filled with dry nitrogen. The solution

was stirred and 2.12 g (0.02 mole) of benzaldehyde was rapidly added. A red color developed at once and deepened when the solution was allowed to stand for 20 h. Addition of water (15 ml) caused the color to change to yellow. Diethyl ether (50 ml) was added, the aqueous layer was separated, and the organic layer was washed twice with 20 ml portions of water, twice with 20 ml portions of 10% sodium bisulfite solution, and twice with 20 ml portions of water. After drying over magnesium sulfate, the solution was filtered and evaporated, giving a yellow crystalline residue.

The material was dissolved in 10 ml of benzene and added to 30 ml of petroleum ether (b.p. 30–60°). A crystalline solid separated; wt. 2.113 g, m.p. 170–180°. The infrared spectrum showed that this material was N-benzoyl-*dd,ll*-TPED (90% yield). The filtrate was not examined further.

Reaction in Diethyl Ether with Methyl Benzoate

The sodium adduct from 3.26 g (0.02 mole) of N-benzylidene aniline, 0.9 g (0.04 atom) sodium, and 103 g of diethyl ether was transferred to a 250 ml flask which was filled with dry nitrogen. The solution was stirred with a magnetic stirrer and 2.72 g (0.02 mole) of methyl benzoate added all at once. An immediate orange color developed and, when the solution was allowed to stand overnight, a precipitate formed. On the addition of 25 ml of water the color changed to yellow and the precipitate dissolved. When the solution was allowed to stand, small needle-like crystals separated. After 24 h, the precipitate was filtered off, washed with ether, and dried. This solid amounted to 0.938 g, m.p. 190–193°, mixed melting point with an authentic sample of N-benzoyl-meso-TPED 189–193°.

The ether phase was separated from the filtrate, washed twice with 25 ml portions of water, dried over magnesium sulfate, and evaporated. The residue amounted to 2.985 g and melted at 122–152°. Its infrared spectrum (Nujol mull) revealed the presence of the two diastereomeric N-benzoyl-TPED's.

A sample of material (1.50 g) was dissolved in 50 ml of ether–benzene (3:1) and chromatographed on 60 g of Woelm, grade I, basic alumina. Elution with diethyl ether gave 0.341 g (100 ml) of *dd,ll*-TPED, m.p. 127–134°; recrystallization from absolute ethanol raised the melting point to 147–153°, no depression with an authentic sample. The next 50 ml gave 0.270 g of a mixture of *dd,ll*-TPED and N-benzoyl-meso-TPED. These were separated by treating the mixture with 20 ml diethyl ether, at which time the N-benzoyl compound crystallized, giving 0.032 g, m.p. 188–191°, no depression with an authentic sample. The filtrate was evaporated and the residue recrystallized from 4 ml of absolute ethanol, giving 0.130 g of *dd,ll*-TPED, m.p. 149–153°; the mixed melting point with an authentic sample was not depressed. The next 200 ml of ether eluted an additional 0.545 g of N-benzoyl-meso-TPED, m.p. 183–187°, identified by its infrared spectrum. The next 200 ml of ether–benzene (3:1) and 350 ml ether–benzene (1:1) eluted 0.369 g of N-benzoyl-*dd,ll*-TPED; its melting point after recrystallization from ethanol was 182–184°, not depressed by an authentic sample.

Correcting the isolated samples for the aliquot sample of crude material and dividing the one mixture in the ratio of the amounts isolated gives total yields of *dd,ll*-TPED of 1.12 g (30%), N-benzoyl-meso-TPED 2.14 g (46%), and N-benzoyl-*dd,ll*-TPED 0.735 g (16%).

Reaction in Diethyl Ether with Benzaldehyde (Mole Ratio 1:1)

The sodium adduct from 3.62 g (0.02 mole) of N-benzylidene aniline, 0.9 g (0.04 atom) of sodium, and 104 g of diethyl ether was transferred to a 250 ml flask. The solution was stirred with a magnetic stirrer and 2.12 g (0.02 mole) of benzaldehyde dissolved in 10 ml of ether was added all at once. An orange color immediately developed together with a dense yellow precipitate. The mixture was stirred for 6 h, during which time the color deepened to a dark red-brown and the precipitate partially dissolved, changing color to a dark red or brown. Water (25 ml) was added with stirring. The precipitate dissolved to give a clear yellow solution, and then after 5 min a yellow solid began separating. After standing overnight, the mixture was filtered, and the solid was washed with ether. After drying it amounted to 0.996 g, m.p. 212–214°.[2] Its infrared spectrum (Nujol mull) showed a NH band at 3 340 cm^{-1} and an amide carbonyl at 1 645 cm^{-1}. Comparison of the spectrum with that of an authentic sample (4) of N-benzoyl-N,N′-diphenylstilbene-α,α'-diamine showed that they were identical. The compound yielded a picrate, m.p. 274–277°, mixed melting point with the picrate of N-benzoyl-N,N′-diphenylstilbene-α,α'-diamine 273.5–278.5°.

The filtrate was chromatographed on 60 g of Woelm, grade I, basic alumina. Elution with 300 ml of petroleum ether – benzene (2:1) removed 1.207 g of *dd,ll*-TPED, m.p. 140–153°. The next 200 ml of 2:1:1 benzene – petroleum ether – methylene chloride removed 0.561 g of the N-benzoyl derivative of meso-TPED, m.p. 148–173°. The N-benzoyl derivative was dissolved in 1 ml of hot ethyl acetate, and 5 ml of ethanol was added. The material which crystallized had m.p. 180–197°, mixed melting point with an authentic sample 188–198°. The next 900 ml of petroleum ether – methylene chloride (1:1) and 400 ml of methylene chloride eluted 1.198 g of N-benzoyl-*dd,ll*-TPED, m.p. 173–180°; the mixed melting point with an authentic sample was undepressed. The combined yields of these materials are: *dd,ll*-N,N′,1,2-tetraphenylethylenediamine, 33%; N-benzoyl-N,N′-diphenylstilbene-α,α'-diamine, 21%; N-benzoyl-N,N′,1,2-tetraphenylethylenediamine (mixed isomers), 38%.

[2]*This material was degraded during the determination of the melting point. The reported value was obtained by inserting the sample in a melting point apparatus preheated to 205 °C.*

Reaction in Diethyl Ether with Benzaldehyde (Mole Ratio 1:2)

The sodium compound from 1.81 g (0.01 mole) of N-benzylidene aniline and 0.5 g (0.02 atom) of sodium in 61 g of diethyl ether was treated with 2.12 g (0.02 mole) of benzaldehyde. An immediate formation of a yellow precipitate occurred and the solution became orange. Over the next 12 h no change occurred in the appearance of the mixture. Water (13 ml) was added and the precipitate dissolved, accompanied by a color change from orange to yellow. A small amount of a granular white precipitate remained. This was filtered off (wt. 0.243 g, m.p. 188–290°), dissolved in benzene, filtered from the insoluble material, and evaporated to give 0.167 g of N-benzoyl-meso-TPED, m.p. 180–195°.

The ether filtrate was evaporated to 2.32 g of a gummy residue. This was dissolved in 20 ml of benzene and the solution was added to 50 ml of diethyl ether. The small amount of solid which separated was filtered off to give 0.058 g, m.p. 189–195°; the mixed melting point with an authentic N-benzoyl derivative of meso-TPED was not depressed.

An aliquot portion (1.35 g solids) of filtrate was then chromatographed on 65 g of Woelm, grade I, basic alumina, diethyl ether being used as the eluting agent. The first 150 ml of eluate removed 0.666 g of gum (A). The next 150 ml eluted 0.217 g of the N-benzoyl derivative of meso-TPED, m.p. 189–192°, undepressed by an authentic sample. The next 175 ml eluted 0.122 g of a mixture of the N-benzoyl derivatives of meso- and *dd,ll*-TPED. After this, 250 ml of 3:1 ether–benzene and 150 ml of 1:1 ether – methylene chloride eluted 0.240 g of the N-benzoyl derivative of *dd,ll*-TPED, m.p. 173–177°. When it was recrystallized from absolute ethanol it had m.p. 177–180°; the mixed melting point with an authentic sample was undepressed. No further material was eluted from the column.

The infrared spectrum of gum (A) showed a NH absorption band at 3 380 cm^{-1} and a carbonyl band at 1 725 cm^{-1} but no amide carbonyl band at 1 630 – 1 650 cm^{-1}. This material was treated with 10 ml of petroleum ether (b.p. 30–60°) and allowed to stand. A solid separated, 0.339 g, m.p. 139–141°. When this solid was recrystallized from cyclohexane it had m.p. 138–146°; the mixed melting point with authentic *dd,ll*-TPED was 144–150°. The petroleum ether filtrate, on evaporation, gave a mobile yellow oil whose infrared spectrum was identical with that of benzyl benzoate. The total yields, after they were corrected for the aliquot portion chromatographed, were: *dd,ll*-TPED (0.583 g), 32%; N-benzoyl-TPED (1.221 g), 52%. If the fraction of mixed diastereomers obtained during chromatography is arbitrarily assumed to be a 1:1 mixture of the two diastereomers, then the yield of N-benzoyl-meso-TPED is 30% and that of N-benzoyl-*dd,ll*-TPED is 22%.

ACKNOWLEDGMENTS

The author is indebted to Mr. I. J. Bastien (Dow Chemical of Canada, Limited) for the infrared spectra and Mr. L. E. Swim (The Dow Chemical Company, Midland, Michigan) for the microanalyses.

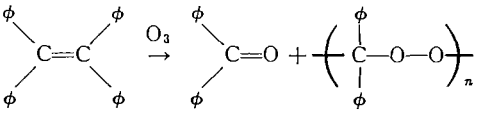
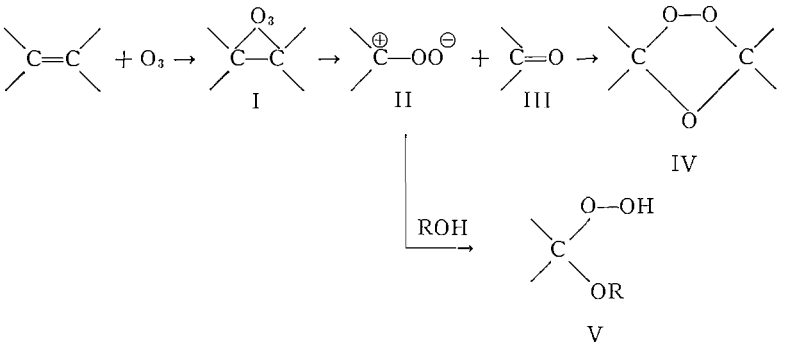
ÉTUDE QUANTITATIVE DES RÉACTIONS D'OZONOLYSE

I. OZONATION DU TÉTRAPHÉNYLÉTHYLÈNE



S. FLISZÁR, D. GRAVEL ET E. CAVALIERI
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 23 août 1965



RÉSUMÉ

L'étude quantitative de l'ozonation du tétraphényléthylène en solution dans du CCl_4 montre que l'ozonolyse de 1 mole d'oléfine engendre 1 mole de benzophénone, 0.57 mole d'oxyde de carbonyle sous forme de peroxyde cyclique et 0.43 mole d'oxyde de carbonyle sous forme de polymère (supposé en chaîne ouverte); ce bilan est indépendant du débit d'ozone et de la température, dans l'intervalle compris entre 0 et 45 °C.

Contrairement à ce qui se passe avec de nombreuses oléfines, l'ozonation du tétraphényléthylène ne conduit pas à la formation d'un ozonide mais engendre de la benzophénone et des peroxydes polymères (1).

La théorie de Criegee (2) sur le mécanisme de formation des ozonides rend bien compte de cette réaction: l'attaque de l'ozone sur la double liaison engendre un ozonide primaire[1] (I) qui se scinde en un zwitterion (II) plus un composé carbonylé (III) (aldéhyde ou cétone).

En absence d'un réactif (alcool ou acide, par exemple) amenant la destruction du zwitterion (II) en engendrant un hydroperoxyde (V), le zwitterion réagit soit avec le composé carbonylé (III) pour former l'ozonide (IV), soit se polymérise en formant un peroxyde. Sauf dans des cas particuliers où la fonction carbonyle est activée (2, 4) (esters α-cétoniques, par exemple) ou se trouve sur la même molécule que la partie zwitterion (5), il n'y aura généralement pas de réaction entre II et III avec formation de l'ozonide (IV) si III est une cétone;[2] alors, dans un solvant inerte, il n'y aura production que de peroxydes à

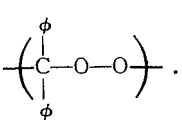
[1] *Pour plus de détails au sujet de la structure de I, c.f. réf. 3.*
[2] *La formation d'ozonides par réaction de zwitterions aldéhydiques avec de l'acétone (ce dernier en grand excès) est décrite dans réf. 6.*

différents degrés de polymérisation, en plus de la cétone engendrée lors de la scission de l'ozonide primaire (I) très instable. Par contre, si III est un aldéhyde, il y aura presque toujours formation de l'ozonide; ce cas sera discuté lors d'un prochain travail.

Les difficultés qui se présentent lors de l'interprétation quantitative des résultats d'ozonations ont trait particulièrement à une connaissance insuffisante (*a*) du sens de rupture de l'ozonide primaire et (*b*) du comportement du zwitterion, en relation avec un mécanisme de cage plus ou moins prononcé. Ces difficultés se reflètent dans les travaux établissant des bilans de production d'ozonides "naturels" et "non naturels" engendrés lors de l'ozonation d'oléfines non symétriques (7).

Le but de nos recherches est d'étudier plus en détail le comportement du zwitterion de Criegee. A cet égard l'ozonation du tétraphényléthylène offre l'exemple le plus simple, vu que cette oléfine n'engendre pas d'ozonide (1), du moins pas en quantité appréciable: le groupement carbonyle des cétones étant en général moins susceptible à une attaque nucléophile que celui des aldéhydes, et du fait de la grande facilité de formation de peroxydes à partir du zwitterion, la non-production d'ozonide est facilement expliquée.

Concernant la formation de peroxydes il importe de relever les faits expérimentaux suivants: (*i*) les solutions de tétraphényléthylène fraîchement ozonées libèrent rapidement de l'iode à partir d'une solution acétique de NaI (1*b*) et (*ii*) le peroxyde dimère (VI) isolé par Marvel et Nichols ne donne pas cette réaction; ceci suggère que nous aurons à tenir compte de deux types de peroxydes. Nous désignerons par peroxyde "actif" celui qui libère l'iode et par diperoxyde de benzophénone le produit connu (VI).



Des bilans[3] d'ozonation nous ont renseigné sur les quantités des différents produits engendrés par l'attaque de l'ozone sur le tétraphényléthylène. Les quantités d'oléfine consommée et de benzophénone formée ont été calculées d'après des mesures d'absorption infrarouge; le peroxyde "actif" a été déterminé par voie iodométrique (Tableau I); le diperoxyde de benzophénone a été calculé par différence et, dans d'autres expériences, mesuré par pesée.

TABLEAU I

Ozonation du tétraphényléthylène dans CCl_4 à 25°

[C=C]	Débit O_3	Durée	O_3 consommé	C=C consommée	>C=O formée	 formé
0.05	0.0178	15	0.19	0.21	0.20	0.09
	0.0205	60	0.71	0.75	0.72	0.32
	0.0325	20	0.46	0.45	0.46	0.18
	0.0310	30	0.58	0.69	0.64	0.29
	0.0365	40	0.90	0.90	0.91	0.42
	0.135	5	0.38	0.37	0.39	0.15
	0.140	10	0.66	0.67	0.66	0.33
0.085	0.152	5	0.43	0.42	0.43	0.18
	0.152	10	0.78	0.76	0.76	0.33

NOTONS: [C=C]: concentration (mole/l) de l'oléfine; débit: millimole/min; durée: min; O_3 et C=C consommés, C=O et (actif) formés: millimole. La quantité de diperoxyde de benzophénone se calcule en soustrayant le peroxyde "actif"de C=C consommée.

[3]*Dans ces bilans, les peroxydes seront comptés sous forme d'oxyde de carbonyle monomère*  .

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Une constatation importante se dégage de ces résultats: la quantité de benzophénone formée est, aux erreurs expérimentales près, égale à la quantité d'oléfine consommée; nous nous en sommes encore assurés par des ozonations poussées jusqu'à consommation complète de l'oléfine et avons confirmé ainsi que 1 mole d'oléfine ozonée engendre seulement 1 mole de benzophénone. On en conclut que, dans nos conditions expérimentales, il n'y a pas de décomposition d'oxyde de carbonyle avec formation de benzophénone.

En vue d'établir en quelle mesure le bilan d'ozonation dépend des conditions expérimentales, nous avons procédé à une confrontation des proportions de benzophénone et de peroxyde "actif" formés. La Fig. 1 rend compte des résultats obtenus par l'ozonation de 20 ml de solution d'oléfine dans CCl_4 à 25 °C (±0.3°) par un courant de gaz O_2–O_3.

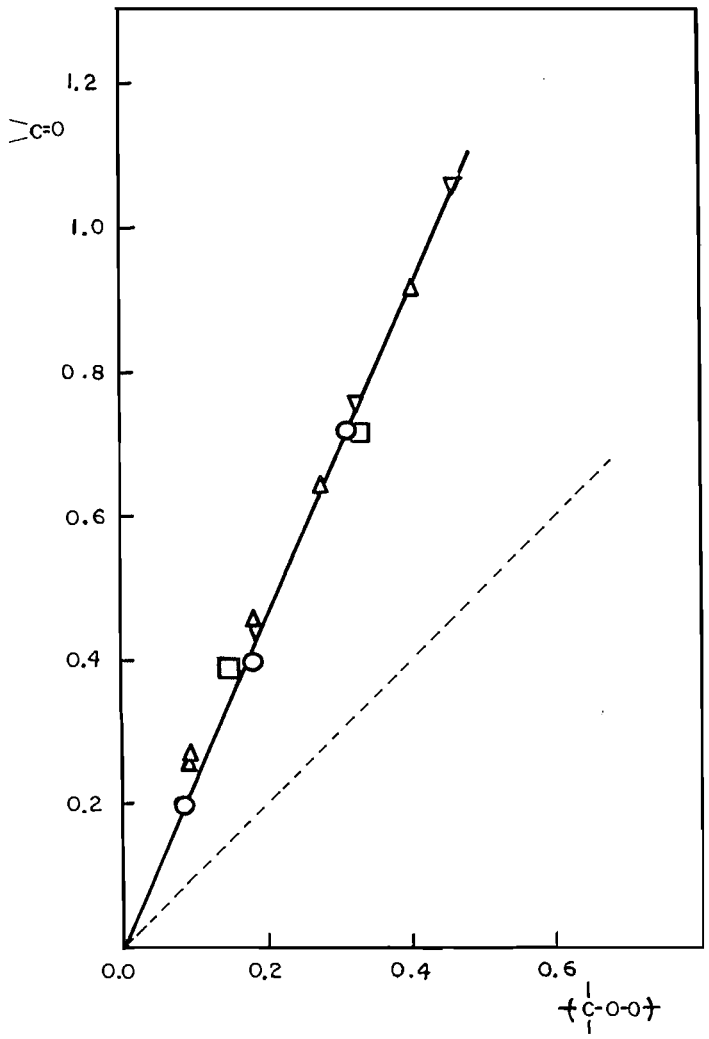


FIG. 1. Ozonation du tétraphényléthylène dans CCl_4 à 25 °C: millimoles de benzophénone et peroxyde "actif" produits. Concentration initiale de l'oléfine: 0.05 *M*; débit O_3: ○, 0.0175–0.0205 mmole/min; △, 0.0310–0.0370 mmole/min; □, 0.135–0.140 mmole/min; ▽, 0.152 mmole/min (concentration oléfine 0.085 *M*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Des valeurs rapportées dans cette figure il se dégage que le rapport r = (benzophénone formée/peroxyde "actif" formé) est indépendant du débit en O_3 et de la concentration en oléfine de la solution; on calcule, d'après ces valeurs, $r = 2.30$. La Fig. 1 montre clairement la constance de r jusqu'à un degré avancé de la réaction (environ 95%). La ligne en pointillé se rapporte à une formation équimolaire de benzophénone et d'oxyde de carbonyle. Notons encore que la valeur de r est indépendante de la température dans le domaine de 0 à 45 °C, ce qui est attesté par les valeurs reproduites dans la Fig. 2, I.

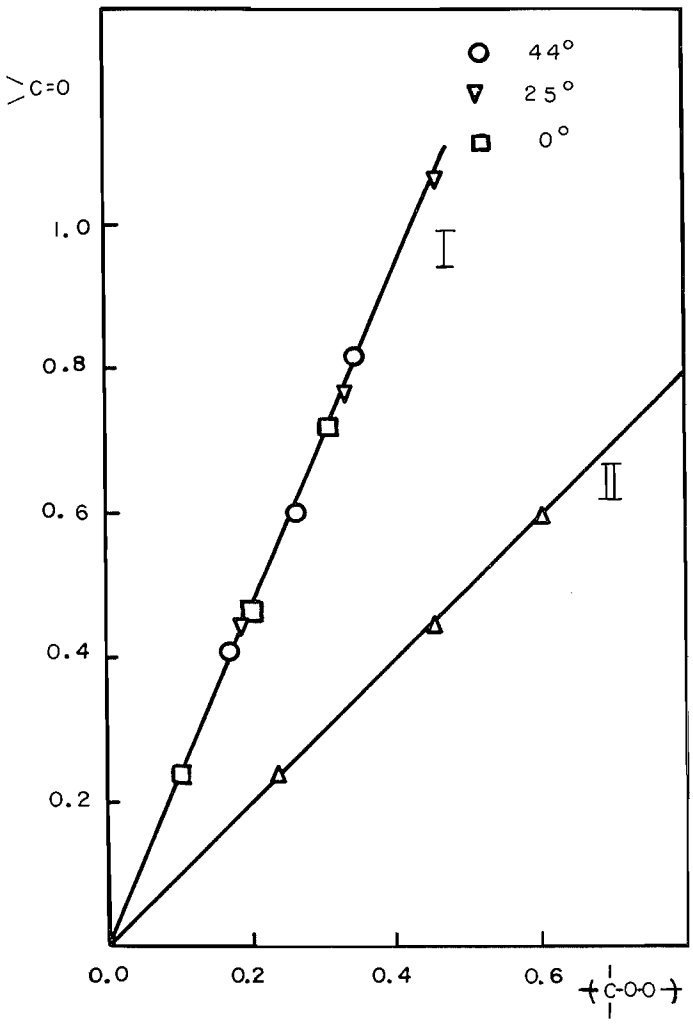

FIG. 2. I. Ozonation du tétraphényléthylène dans CCl_4 à différentes températures. LÉGENDE: ○ et ▽, concentration oléfine 0.085 M, débit O_3 0.128–0.153 mmole/min; □, concentration oléfine 0.05 M, débit O_3 0.068 mmole/min. II. Ozonation en présence de CH_3OH (0.3 M) dans CCl_4, à 0 °C.

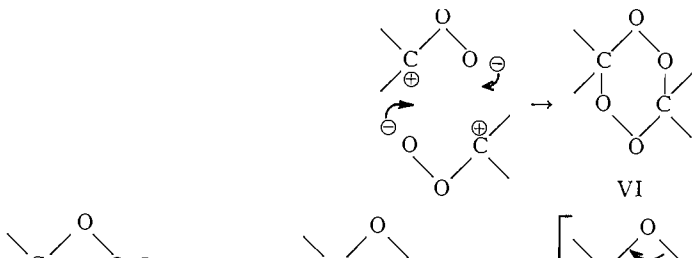
La constatation que la benzophénone formée est 2.30 fois plus abondante que le peroxyde "actif" formé ne pouvant s'interpréter par une scission d'un oxyde de carbonyle qui engendrerait de la benzophénone, la somme[3] peroxyde "actif" plus diperoxyde de benzophénone doit être égale à la quantité de benzophénone formée, soit égale à la quantité

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

d'oléfine consommée. Nous nous sommes d'ailleurs assurés que l'ozonolyse de 1 mole d'oléfine conduit bien à la formation de 1 mole de zwitterion en effectuant des expériences d'ozonolyse en présence de CH_3OH (Tableau II) et montrant qu'il se forme autant d'hydroperoxyde (V) que de cétone.

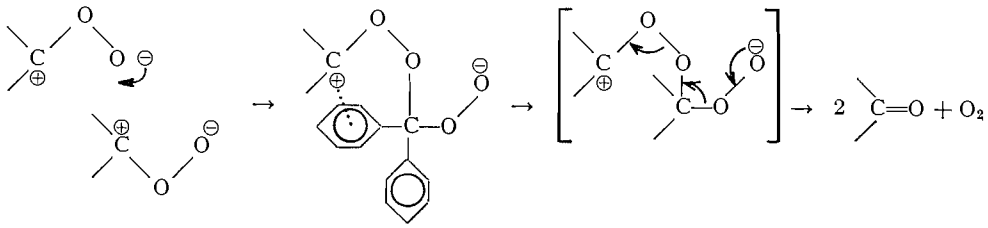
TABLEAU II

Ozonation d'une solution 0.05 *M* de tétraphényléthylène dans CCl_4 at 0 °C, en présence de 0.3 *M* de CH_3OH



Débit O_3	Durée	O_3 consommé	$>C{=}O$ formée	$-\overset{|}{C}-O-OH$ formé
0.068	5	0.20	0.23	0.24
0.079	10	0.44	0.44	0.46
0.077	15	0.60	0.59	0.61

NOTONS: Débit O_3: millimole/min; durée: min; O_3 consommé, $>C{=}O$ et $-\overset{|}{C}-O-OH$ formés: millimole.



Ce fait est bien démontré par la Fig. 2, II, la ligne tracée étant celle calculée pour la formation équimolaire de II et de III.

Dès lors le bilan d'ozonation du tétraphényléthylène en solution dans le CCl_4 s'établit comme suit aux températures comprises entre 0 et 45 °C: 1.0 mole d'oléfine engendre 1.0 mole d'ozonide primaire (I) qui se scinde en 1.0 mole de benzophénone plus 1.0 mole de zwitterion. C'est le processus de Criegee confirmé par les expériences effectuées en présence de CH_3OH. Le zwitterion engendre ensuite un peroxyde stable (57%), principalement sous forme de dimère cyclique (VI) n'oxydant pas l'ion iodure en I_2, le restant du zwitterion (43%) engendrant un polymère capable d'oxyder l'ion iodure en I_2.

Il paraît raisonnable d'admettre pour le polymère "actif" la forme en chaîne ouverte (VII), représentée ici par son dimère, sans pour autant présumer de la possibilité de polymérisation à un plus haut degré. On note en effet la possibilité d'interaction de l'ion $C^{\oplus}$ provenant d'une molécule zwitterion avec le système d'électrons π des noyaux benzéniques, comme le montre le schéma (VII). Une telle interaction pourrait, en quelque sorte, être comparée aux liaisons H intramoléculaires comme elles s'établissent, par exemple, dans les alcools benzylique et phényléthylique (VIII); une interaction similaire

For personal use only.

de carbocations avec des noyaux benzéniques a été décrite récemment par Cram et Goldstein (8). Cette stabilisation aurait pour effet d'empêcher la libre rotation autour de la liaison C—O avec cyclisation conséquente.

VIII

Pour confirmer que le produit libérant l'iode est composé uniquement de fragments d'oxyde de carbonyle nous avons dosé la benzophénone engendrée par la réaction du peroxyde "actif" avec I^-. Les solutions fraîchement ozonées ont été additionnées d'un peu de CH_3COOH; après mesure de l'intensité de la bande carbonyle de la cétone à 1 667 cm^{-1}, on ajoute un peu de NaI et procède (après $\frac{1}{2}$ h) à une nouvelle mesure de l'intensité de cette bande. Ces expériences montrent que par l'adjonction de I^- la quantité de benzophénone augmente de 1.43 fois par rapport à l'expérience faite en absence de I^-. Le fait qu'il se forme exactement 1 mole de benzophénone par mole d'oxygène actif titré iodométriquement confirme bien que le produit "actif" est uniquement constitué de fragments oxyde de carbonyle ce qui exclut la présence, du moins en quantité appréciable, d'ozonide.

Ainsi, par exemple, avons-nous obtenu les résultats suivants[3] (en millimoles) par l'ozonation à 25 °C de 70 ml d'une solution 0.085 *M* de tétraphényléthylène: O_3 consommé, 3.3; oléfine consommée, 3.3; benzophénone formée, 3.2; peroxyde "actif", 1.45; diperoxyde de benzophénone, 1.85 (dosé par voie spectrographique), 1.80 et 1.93 (par isolation et pesée). Bilan: obtenu 1.85 + 1.45 + 3.2 = 6.50 mmoles de produits, correspondant à 6.50/2 = 3.25 mmoles d'oléfine consommée. Après adjonction de 10% d'acide acétique glacial, la densité optique de la bande carbonyle, mesurée dans une cellule de 0.203 mm d'épaisseur, est de 0.137; la densité optique de cette bande mesurée dans les mêmes conditions, mais en présence de I^-, est de 0.197, soit 0.197/0.137 = 1.43 fois plus grande.

Pour terminer, nous avons encore étudié la stabilité du peroxyde "actif". En laissant reposer les solutions ozonées pendant 24 h à 25 °C on note une diminution d'environ 30% de la teneur en peroxyde "actif", sans pour autant déceler une augmentation de la quantité de benzophénone; par contre on note un accroissement de la teneur en diperoxyde de benzophénone, difficile à doser du fait que ce produit cristallise à partir du mélange réactionnel en raison de sa très faible solubilité. A l'ébullition, par contre, la diminution de la quantité de peroxyde "actif" est accompagnée d'une forte augmentation de la quantité de benzophénone. Ainsi, par exemple, la solution dont nous avons décrit ci-haut le bilan en détail donne, après 1 h de reflux (79–80 °C), 0.56 mmole de benzophénone, accompagnant une diminution de 0.60 mmole de peroxyde "actif".

PARTIE EXPÉRIMENTALE

Le débit d'ozone a été mesuré par le dosage de l'iode libéré par l'ozone dans une solution aqueuse de KI; la quantité d'ozone consommé par l'oléfine a été calculée par différence, en connaissant d'une part le débit d'O_3 et la durée d'ozonation et, d'autre part, en dosant l'iode libéré dans une solution de KI receuillant le gaz d'ozonation après son passage dans la solution d'oléfine. Les ozonations ont été effectuées en faisant barbotter le mélange gazeux O_2–O_3, avec un débit variant (selon les expériences) entre 4 et 7 l par heure, dans la solution d'oléfine dans du CCl_4 anhydre. Lors des expériences faites à 25° et à 45° la partie supérieure du récipient contenant la solution à ozoner, et notamment le tube d'évacuation du gaz d'ozonation, était refroidi afin de limiter les pertes de solvant. Chaque ozonation était suivie d'un balayage de la solution par de l'azote sec pendant 10 min.

La benzophénone et le tétraphényléthylène ont été dosés par voie spectrographique infrarouge d'après les densités optiques de la bande de vibration du groupement carbonyle à 1 667 cm^{-1} pour la benzophénone et la fine bande à 1 493 cm^{-1} du tétraphényléthylène. Le diperoxyde de benzophénone possédant également une bande faible à 1 493 cm^{-1}, nous en avons tenu compte lors de l'évaluation de la quantité d'oléfine consommée: pour ce faire nous avons établi un diagramme de calibration en admettant la validité de la loi de Lambert–Beer et en déterminant soigneusement les densités optiques (i) des solutions d'oléfine de départ et (ii) des mêmes solutions ozonées à 100%. Dès lors il est facile, à l'aide de tels diagrammes, de déterminer les concentrations d'olefine non consommée et, pour les réactions suffisamment avancées (ozonées à plus que 50%), d'estimer la quantité de diperoxyde de benzophénone formé. Ce dernier composé a également été isolé en suivant la méthode de Marvel et Nichols (1*a*) avec des rendements variant entre 52 et 59%, en bon accord avec le bilan proposé.[4] Le point de fusion, après recristallisation dans du benzène, était 205–206 °C.

Anal. Calc. pour $C_{26}H_{20}O_4$: C, 78.77; H, 5.09. Trouvé: C, 79.36; H, 5.03.

Quant aux corps peroxydiques libérant l'iode, nous avons recouru à leur dosage chimique selon Lohaus (9): une partie de la solution d'oléfine ozonée est ajoutée à une solution fraîchement préparée de NaI dans l'acide acétique glacial, en présence d'un peu de CO_2 solide; après un repos de 30 min à l'obscurité on titre l'iode libéré par une solution de thiosulfate de sodium. On opère parallèlement sur un témoin, constitué par un mélange de CCl_4, CH_3COOH et NaI, additionné de benzophénone et de tétraphényléthylène. Nous nous sommes d'ailleurs assurés que ces derniers corps n'influencent pas le dosage des peroxydes; on a vérifié d'autre part que les analyses effectuées après un repos du mélange réactionnel de 20, 30 et 40 min donnent les mêmes résultats, aux erreurs expérimentales près; après seulement 10 min de temps de réaction, les valeurs sont environ 5–10% trop faibles. Le dosage des hydroperoxydes engendrés lors des expériences faites en présence de méthanol a été effectué de manière identique.

REMERCIEMENTS

Nous sommes reconnaissants à M. le Professeur C. Sandorfy, Directeur du Laboratoire de Spectroscopie chimique, ainsi qu'à M. le Professeur J. C. Richer pour toutes les facilités qu'ils nous accordent dans nos recherches expérimentales. Nous remercions également M. G. Bélanger de son assistance technique précieuse et le Conseil National de Recherches du Canada pour une subvention qui a permise ces recherches.

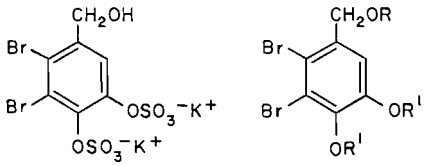
Received August 9, 1965

ABSTRACT

A new brominated phenolic compound, isolated in 5% yield from the red alga *Polysiphonia lanosa*, has been characterized as 2,3-dibromobenzyl alcohol 4,5-disulfate, dipotassium salt. The structural determination, synthesis, and properties of this compound and its derivatives are described.



INTRODUCTION

Evidence for the presence of brominated phenolic compounds in the Rhodomelaceae family of algae has been based principally on the results of paper chromatographs, and characteristic color reactions with ferric chloride (1). However, 5-bromo-3,4-dihydroxybenzaldehyde has been shown to occur in *Polysiphonia morrowii* (2), and two other compounds (believed to be brominated sulfonated hydroxybenzoic acids) with the empirical formulae $C_7H_2O_9S_2Br_2K_2$ and $C_7H_3O_9S_2BrK_2$ have been isolated from *Polysiphonia lanosa* (3).

The purpose of this communication is to report the isolation of 2,3-dibromobenzyl alcohol 4,5-disulfate, dipotassium salt (I), in high yield from *Polysiphonia lanosa* (L.) Tandy.

RESULTS AND DISCUSSION

A colorless compound (I), with the molecular formula $C_7H_4O_9S_2Br_2K_2$, crystallized from solution when aqueous–alcoholic extracts of *P. lanosa* were concentrated. The infrared spectrum (Fig. 1) of this compound indicated the presence of a hydroxyl group (3 320 cm^{-1}, broad), a benzene ring (3 055, 1 603, 1 572, and 880 cm^{-1}), a benzylic methylene group (2 970, 2 910, and 1 455 cm^{-1}), and the anion of a sulfate ester (1 250 and 1 030 cm^{-1}). Mild acid hydrolysis of I gave 2 moles of sulfuric acid per mole of compound, and a crystalline phenol (II*a*), molecular formula $C_7H_6O_3Br_2$. Proton magnetic resonance (p.m.r.) studies showed that this phenol contained a single aromatic hydrogen (τ 2.83), a methylene group (τ 5.38) of a benzyl alcohol, and three hydroxyl protons (broad signal centered at about τ 6.9).

I

Compound II*a* formed a triacetate (II*b*), molecular formula $C_{13}H_{12}O_6Br_2$, on acetylation with acetic anhydride in pyridine. The p.m.r. spectrum established the presence of two non-equivalent aromatic acetoxyl groups (τ 7.70 and 7.77), an aliphatic acetoxyl group (τ 7.92), a methylene group (τ 4.85) of a benzyl acetate, and a single aromatic hydrogen

[1]*Issued as N.R.C. No. 8754.*

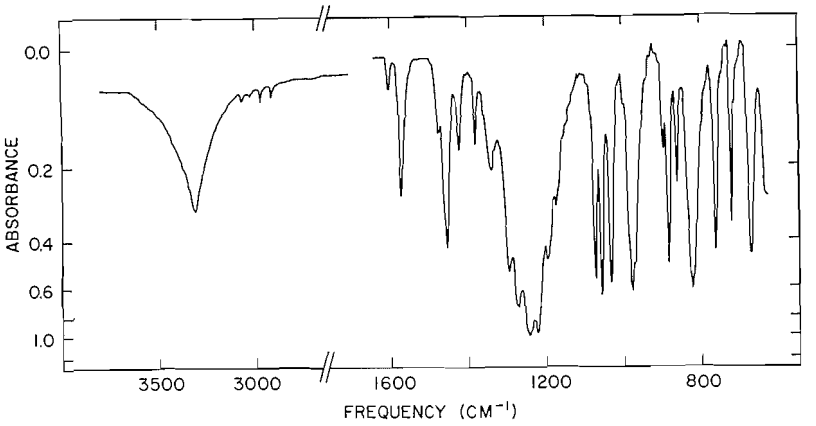

FIG. 1. The infrared spectrum of 2,3-dibromobenzyl alcohol 4,5-disulfate, dipotassium salt (KBr disk).

(τ 2.70). Moreover, "field sweep" double resonance experiments with a Varian V-6058 decoupler established that the aromatic hydrogen was coupled to the methylene group (4). Consequently, the phenol II*a* must contain two non-equivalent phenolic hydroxyl groups, a benzylic hydroxymethylene group, and a single aromatic proton.

Reduction of II*a* with Raney nickel in sodium hydroxide solution (5, p. 143) yielded a compound which was shown to be identical with an authentic sample of 3,4-dihydroxytoluene by p.m.r. and infrared examination. The phenolic hydroxyls in the parent compound must therefore occupy the 3- and 4-positions relative to the hydroxymethylene group, which was hydrogenolized to a methyl group (5, p. 127) during the reduction. The three structures for phenol II*a*, which are compatible with the above results, are 2,3-dibromo-4,5-dihydroxybenzyl alcohol (as shown), 2,5-dibromo-3,4-dihydroxybenzyl alcohol, and 2,6-dibromo-3,4-dihydroxybenzyl alcohol.

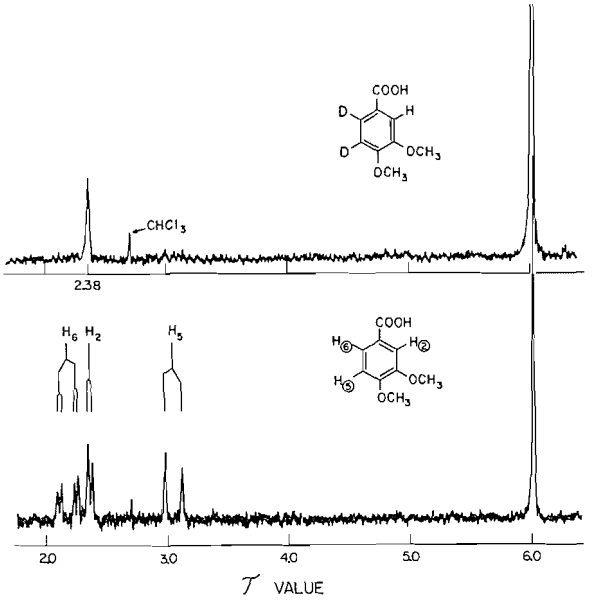

FIG. 2. The p.m.r. spectra of veratric acid and 5,6-dideuteroveratric acid in deuterochloroform with tetramethylsilane as an internal standard.

It was possible to determine the structure of the phenol by comparing the p.m.r. spectra of veratric acid with that of a dideuteroveratric acid (Fig. 2) prepared from II*a*. The isotopically labelled acid was obtained by methylation and oxidation of a deuterated 3,4-dihydroxytoluene that was produced from II*a* by reduction with Raney nickel (*vide supra*) in sodium deuteroxide solution. Proton magnetic resonance signals at average τ values of 2.38, 2.20, and 3.07 in the spectrum of veratric acid (Fig. 2) could be assigned to protons H_2, H_5, and H_6 on the basis of the ortho, meta, and para coupling constants ($J_{H_5H_6}$ = 8.2 c.p.s., $J_{H_2H_6}$ = 2.0 c.p.s., and $J_{H_2H_5} < 0.5$ c.p.s.). The presence of the single aromatic proton at τ 2.38 for the deuterated derivative (Fig. 2) is therefore proof that it is at the 2-position in the benzene ring, and establishes the structure of the compound as 5,6-dideuteroveratric acid. As the two deuterium atoms replaced the bromine atoms in II*a*, this compound must be 2,3-dibromo-4,5-dihydroxybenzyl alcohol. This structure is consistent with the fact that the two aromatic methoxyl and acetoxyl groups in II*c* and II*b* are in magnetically non-equivalent environments, as shown by p.m.r. (see Experimental section).

Final proof of the structure of II*a* was obtained when II*c* was shown to be identical with an authentic sample of 2,3-dibromo-4,5-dimethoxybenzyl alcohol that was synthesized from 5,6-dibromovanillin (6) by methylation and sodium borohydride reduction. Moreover, synthetic 5,6-dibromoveratraldehyde (7) and 5,6-dibromoveratric acid (8) were also shown to be identical with the products of the partial or complete oxidation of II*c*.

It is interesting to note that one of the phenolic hydroxyls in II*a* is much more acidic than the other because the reaction with 1 molecular equivalent of diazomethane produces a single monomethyl ether. This ether was not identical with synthetic 2,3-dibromo-4-hydroxy-5-methoxybenzyl alcohol, as shown by p.m.r., and consequently must be the other possible isomer, 2,3-dibromo-4-methoxy-5-hydroxybenzyl alcohol.

When compound II*a* was caused to react with sulfur trioxide – pyridine complex in aqueous potassium carbonate, it formed a disulfate dipotassium salt whose infrared spectrum was identical with that of the salt isolated from *P. lanosa*. Since aliphatic hydroxyl groups do not form sulfate esters under these conditions, the salt must be 2,3-dibromobenzyl alcohol 4,5-disulfate, dipotassium salt (I).

As far as the authors are aware, this is the first aromatic compound isolated from a natural source which contains bromine on contiguous carbon atoms. A knowledge of the mechanism of bromination of the aromatic ring by the organism would be of considerable interest to both the biochemist and the organic chemist. Studies have been initiated to investigate this matter.

EXPERIMENTAL

Melting points were carried out on a Kofler hot stage. Infrared spectra were determined on a Perkin–Elmer model 237 spectrometer as potassium bromide disks. Proton magnetic resonance spectra were obtained with a Varian A-60 spectrometer equipped with a V-6058 spin-decoupler accessory, and were determined as 5–15% solutions in deuterochloroform or deuterated acetone (where specifically indicated) with tetramethylsilane as an internal standard.

Isolation of the P. lanosa Salt (I)

Freshly harvested alga (17 kg) was blotted and then extracted for 3 h with boiling aqueous ethanol (40 l, 80%). The extract was filtered to remove debris, and the filtrate was concentrated under reduced pressure (to 4 l). The dark-brown crystals, which deposited as the filtrate cooled, were collected and washed with methanol until the wash solvent remained colorless. The yield of light-grey product was 77 g (4%, dry wt. basis). Similar extractions of material collected at different times of the year yielded between 1 and 5% of the crystalline product. The salt was purified by repeated recrystallization from water to yield fine colorless needles of I.

Anal. Calcd. for $C_7H_4O_9S_2Br_2K_2$: C, 15.74; H, 0.75; O, 26.96; S, 11.98; Br, 29.91. Found: C, 15.96; H, 0.85; O, 27.12; S, 11.76; Br, 29.77.

The determination of sulfate by gravimetric methods (9), after hydrolysis of I with dilute hydrochloric acid, indicated the presence of two sulfate groups per molecule.

Hydrolysis of the P. lanosa Salt (I)

The potassium salt (16 g) in dilute hydrochloric acid (500 ml, 0.1 *N*) was heated on a steam bath until the solution turned slightly milky (0.5 h). The reaction mixture was then cooled and continuously extracted with ether to yield phenol II*a* as a colorless solid (8 g). The product was crystallized from ethyl acetate to give fine needles, m.p. 123–125°; p.m.r. spectrum: 2.83 τ (1H, singlet), 5.38 τ (2H, singlet), $\approx$6.9 τ (3H, very broad singlet).

Anal. Calcd. for $C_7H_6O_3Br_2$: C, 28.22; H, 2.03; Br, 53.62. Found: C, 28.21; H, 2.27; Br, 53.67.

The phenol, on treatment with excess acetic anhydride in pyridine, formed a triacetate derivative (II*b*), which was crystallized from methanol as fine colorless prisms, m.p. 105–106°; p.m.r. spectrum: 7.70 and 7.77 τ (6H, two singlets), 7.92 τ (3H, singlet), 4.85 τ (2H, doublet, $J \simeq 0.4$ c.p.s.), 2.70 τ (1H, triplet, $J \simeq 0.4$ c.p.s.).

Anal. Calcd. for $C_{13}H_{12}O_6Br_2$: C, 36.83; H, 2.85; Br, 37.69. Found: C, 36.87; H, 3.12; Br, 37.18.

The phenol formed a dimethyl ether (II*c*) when it was allowed to stand for 16 h with excess diazomethane in ether. This derivative was crystallized from petroleum ether (b.p. 60–80°) as fine, colorless needles, m.p. 92°; p.m.r. spectrum (deuterated acetone): 6.21 and 6.11 τ (6H, two singlets), 5.38 τ (2H, singlet), 2.64 τ (1H, singlet).

Anal. Calcd. for $C_9H_{10}O_3Br_2$: C, 33.16; H, 3.10; Br, 49.02. Found: C, 33.28; H, 3.29; Br, 48.53.

The phenol II*a* also formed a monomethyl ether on treatment with approximately 1 mole of diazomethane, for 1 h. This was separated from the dimethyl ether and unchanged phenol by chromatography on alumina. The monomethyl ether, on crystallization from benzene, gave colorless needles, m.p. 160–162°; p.m.r. spectrum (deuterated acetone): 6.18 τ (3H, singlet), 5.41 τ (2H, broad singlet), 2.75 τ (1H, broad singlet).

*Reduction of Phenol II*a *with Raney Nickel*

(*i*) The phenol (0.81 g) was dissolved in 5% sodium hydroxide solution (100 ml) and Raney alloy (4 g) added in small portions, with shaking. The mixture was heated on a steam bath for 1 h, cooled, filtered, and then acidified with concentrated hydrochloric acid. The resulting solution was continuously extracted with ether to yield 3,4-dihydroxytoluene as a pale yellow oil (0.25 g), b.p. 65° at 0.3 mm. This was shown by p.m.r. and infrared spectra to be identical with an authentic sample synthesized from 3,4-dihydroxybenzaldehyde by reduction, first with sodium borohydride by the procedure of Vogel (10, p. 881) and then with Raney alloy (as above).

(*ii*) The phenol II*a* (0.97 g) was dissolved in sodium deuteroxide solution (5 g of sodium in 70 ml D_2O), Raney alloy (4 g) was added in small portions over 20 min, and the mixture was heated on a steam bath for 1 h (care being taken to exclude any water vapor). The solution was cooled, filtered, acidified with concentrated hydrochloric acid, and continuously extracted with ether to yield, on removal of the solvent, a light oil (0.32 g). This was immediately methylated with diazomethane in ether solution to yield a dideutero-3,4-dimethoxytoluene as a colorless oil (0.29 g). The dimethoxytoluene was then treated with potassium permanganate (0.5 g) in aqueous sodium carbonate solution (50 ml, 5%). The mixture was warmed on a steam bath for 1 h, cooled, and decolorized with acidic sodium metabisulfite solution. The solution was continuously extracted with ether and the solvent removed under vacuum. The resulting solid was purified by dissolving it in sodium bicarbonate, extracting the impurities with ether, and then reprecipitating the solid with acid and re-extracting it with ether. The material was recrystallized from water and sublimed under vacuum to give 2,3-dideuteroveratric acid (51 mg) as fine needles, m.p. 180°.

Preparation of 2,3-Dibromo-4,5-dimethoxybenzyl Alcohol

5,6-Dibromoveratraldehyde (0.46 g, prepared by the method of Raiford and Wittmer (7)) was dissolved in methanol (10 ml), and a solution of sodium borohydride (80 mg) in sodium hydroxide (7 ml, 0.1 *N*) was added, with stirring. The methanol was removed on a steam bath and the residue was diluted with water (20 ml) and extracted with ether. The ethereal solution was taken to dryness and the residue was crystallized from petroleum ether to give 2,3-dibromo-4,5-dimethoxybenzyl alcohol (II*c*) as fine needles, m.p. 91–92°. This was shown by p.m.r., infrared spectra, and mixed melting point to be identical with the dimethyl ether obtained from the natural phenol (II*a*). The oxidation products of the natural dimethyl ether (method of Vogel (10, p. 520)) were shown to be identical with synthetic 5,6-dibromoveratraldehyde (7) and 5,6-dibromoveratric acid (8) by p.m.r., infrared spectra, and mixed melting point. The melting point of our sample of synthetic 5,6-dibromoveratric acid was 194° (lit. m.p. 186–187° (8)).

*Sulfonation of Phenol II*a

The phenol (0.36 g) was dissolved in water (10 ml) containing potassium carbonate (0.5 g), and sulfur trioxide – pyridine complex (0.24 g) was added slowly, with stirring. The solution was then cooled to 5° for 24 h and the resulting crystals were collected and recrystallized from a small amount of water to give fine needles of 2,3-dibromobenzyl alcohol 4,5-disulfate, dipotassium salt (I) (0.33 g). This was shown by infrared spectra to be identical with the natural sulfate salt isolated from *Polysiphonia lanosa*.

SELECTIVE NUCLEOPHILIC SUBSTITUTION AND PREFERENTIAL EPOXIDE FORMATION

A. J. DICK[1] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received July 20, 1965

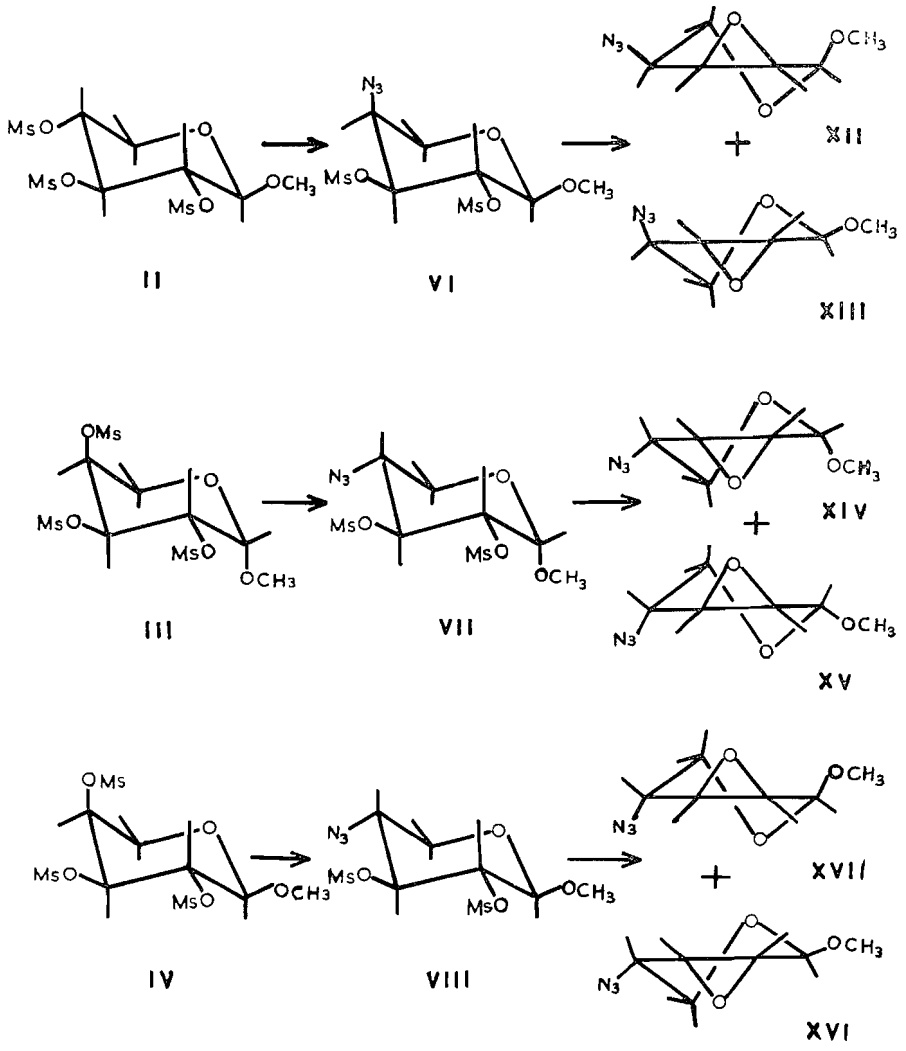
ABSTRACT

The tri-*O*-methanesulfonyl derivatives of methyl β-D-xylopyranoside, methyl β-L-arabinopyranoside, and methyl α-L-arabinopyranoside undergo selective substitution at C-4, when heated with sodium azide in *N*,*N*-dimethylformamide, to yield 4-azido derivatives with inversion of configuration at C-4. The resultant 4-azido-2,3-di-*O*-methanesulfonyl derivatives were converted, by reaction with sodium methoxide, into 2,3-anhydro compounds whose configurations were assigned by nuclear magnetic resonance analysis. The mechanism of epoxide formation is discussed.

INTRODUCTION

The many attempts to effect nucleophilic substitution of isolated sulfonate ester groups attached to furanoside and pyranoside rings have met with only limited success (1), although the replacement of 4-sulfonates of certain hexopyranosides has been achieved (2), as has also the replacement of the 3-toluene-*p*-sulfonyl-β-D-glucopyranose (3). The course of the reactions of tosyl derivatives of cyclitols with sodium benzoate in *N*,*N*-dimethylformamide has also been described (4). The present study is concerned with the competitive nucleophilic substitution of methyl 2,3,4-tri-*O*-methanesulfonyl-pentopyranosides with azide ion in *N*,*N*-dimethylformamide solution. This work was prompted by a related investigation of the reaction of methyl hexopyranoside tetrachlorosulfates with chloride ion (5), to which the results reported here are strictly analogous.

The 2,3,4-tri-*O*-methanesulfonyl derivatives of methyl α-D-xylopyranoside (I) (6), methyl β-D-xylopyranoside (II), methyl β-L-arabinopyranoside (III), and methyl α-L-arabinopyranoside (IV) were each caused to react with 1 mole of sodium azide in *N*,*N*-dimethylformamide at 130° to yield 4-azido-4-deoxy derivatives with inversion of configuration at C-4. Thus the 4-azido-4-deoxy-2,3-di-*O*-methanesulfonyl derivatives of methyl β-L-arabinopyranoside (V) (6), methyl α-L-arabinopyranoside (VI), methyl α-D-xylopyranoside (VII), and methyl β-D-xylopyranoside (VIII) were obtained from I, II, III, and IV, respectively. Of the four azido-di-*O*-methanesulfonyl derivatives described, only methyl 4-azido-4-deoxy-2,3-di-*O*-methanesulfonyl-β-D-xylopyranoside (VIII) could be substituted further in the presence of an excess of sodium azide; these results will be described in a later publication.



That V, VI, and VII were resistant to further substitution may be rationalized according to the arguments put forward by Jennings and Jones (5). The ester group on C-2 would be expected to be unreactive as compared with those on C-3 and C-4 because of their different electronic environments, that on C-2 being in the proximity of two β-oxygen atoms (ring oxygen and anomeric groups). Hindrance to attack at the rear side of the sulfonyloxy groups at C-3 of V and VII by the axial methyl glycosidic group would prevent further substitution in these compounds. To explain the unreactivity of the ester group at C-3 of VI it is necessary to invoke deactivation of the equatorial ester group by the vicinal axial substituent at C-4. Jennings and Jones referred to hindrance

of the attainment of the substitution transition state as a result of the eclipsing of the large substituents at C-3 and C-4 in the transition state. The ester group at C-3 of VIII, which is not subject to the types of interaction described above, would be expected to be replaced.

Reist *et al.* (7) observed a similar selective replacement reaction of methyl 2-*O*-acetyl-3,4-di-*O*-toluene-*p*-sulfonyl-β-L-arabinopyranoside with sodium azide in *N*,*N*-dimethylformamide, and thereby achieved the synthesis of 4-acetamido-4-deoxy-D-ribose. 4-Acetamido-4-deoxy-L-xylose has been synthesized from methyl tri-*O*-methanesulfonyl-α-D-xylopyranoside (I) (6).

It was shown that VI, VII, and VIII were 4-azido derivatives by conversion into 2,3-anhydro-4-azido-4-deoxy derivatives with sodium methoxide in methanol. It was also reported that V gave predominantly methyl 2,3-anhydro-4-azido-4-deoxy-β-L-ribopyranoside (IX) (6) on treatment with methanolic potassium hydroxide. The structural assignment of IX was made on the basis of its nuclear magnetic resonance (n.m.r.) spectrum

(Table I) and has since been confirmed by its further reaction with potassium hydroxide in methanol, but for a longer time. A crystalline mono-*O*-methyl derivative (X) was isolated from the reaction. Acetylation of this in pyridine yielded a syrupy acetate whose n.m.r. spectrum (Fig. 1) showed it to be methyl 2-*O*-acetyl-4-azido-4-deoxy-3-*O*-methyl-β-L-xylopyranoside (XI). The singlets caused by the methoxyl and *O*-acetyl hydrogens

are immediately assignable. The doublet at τ 5.75 ($J_{1,2}$ = 7.0 c.p.s.) was assigned to H-1, and since the triplet at τ 5.14 contained the same 7.0 c.p.s. spacing, it was therefore assigned to H-2. Because H-2 resonates at low field, the acetyl group must be on C-2. The relative intensities of the lines in the multiplets confirmed these assignments. The comparatively large couplings between H-1 and H-2 and between H-2 and H-3 indicated that these pairs of hydrogens are disposed *trans* diaxially, and since the configuration at C-1 is already known, the β-L-*xylo* configuration may be assigned to this compound. This 3-*O*-methyl-L-xylose derivative could only have been derived from a 2,3-anhydro-L-ribose precursor. The sequence of reactions (I → V → IX → X) leads to inversion of configuration, namely, at C-2, C-3, and C-4 (i.e. α-D-*xylo* to β-L-*xylo*).

The di-*O*-methanesulfonyl derivatives (VI, VII, and VIII), when treated with sodium methoxide, each gave a mixture of two 2,3-anhydro derivatives, namely, methyl 2,3-anhydro-4-azido-4-deoxy-α-L-ribopyranoside (XII) and methyl 2,3-anhydro-4-azido-4-deoxy-α-L-lyxopyranoside (XIII) from VI, methyl 2,3-anhydro-4-azido-4-deoxy-α-D-ribopyranoside (XIV) and methyl 2,3-anhydro-4-azido-4-deoxy-α-D-lyxopyranoside (XV) from VII, and methyl 2,3-anhydro-4-azido-4-deoxy-β-D-ribopyranoside (XVI) and methyl

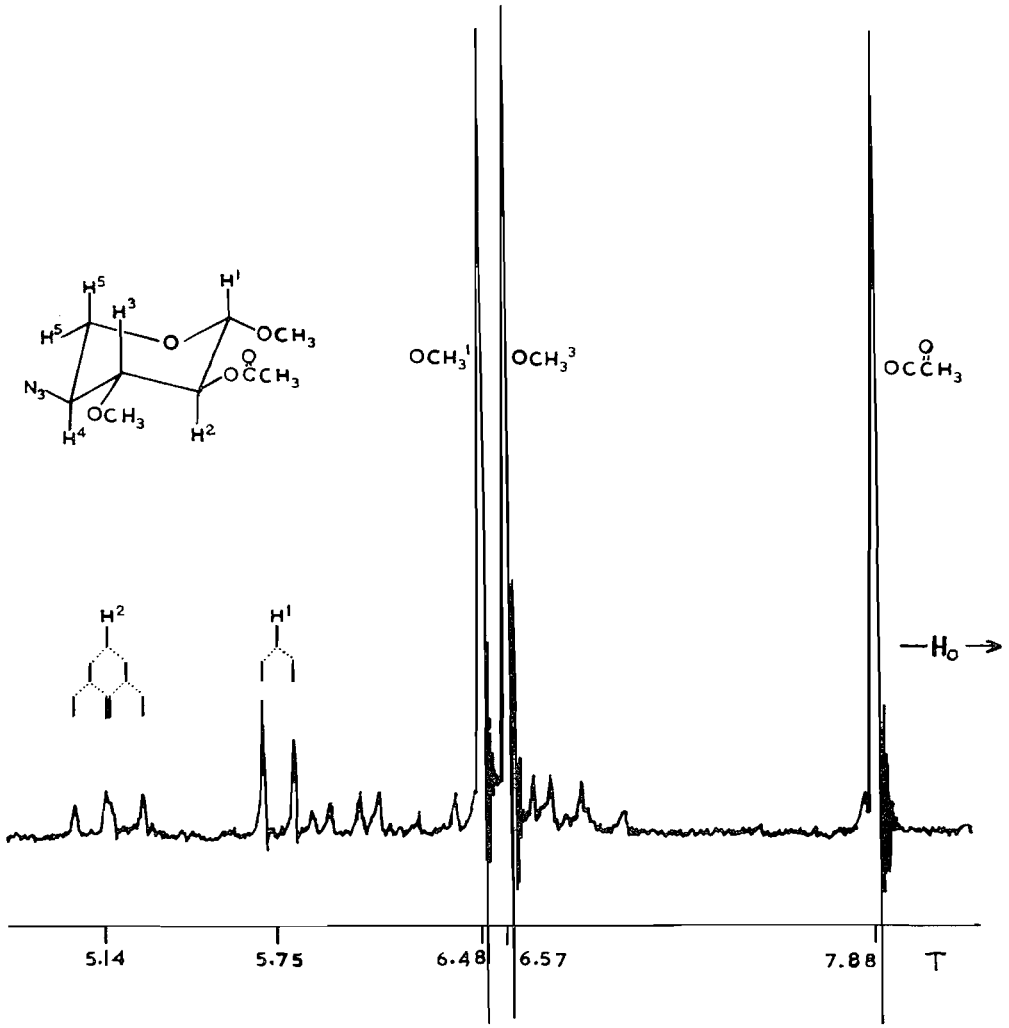

FIG. 1. Partial n.m.r. spectrum of methyl 2-*O*-acetyl-4-azido-4-deoxy-3-*O*-methyl-β-L-xylopyranoside.

2,3-anhydro-4-azido-4-deoxy-β-D-lyxopyranoside (XVII) from VIII. The anhydro-pyranosides from VI and VII were easily separated by column chromatography on silica gel, but it was necessary to separate those prepared from VIII by preparative thin-layer chromatography.

Structural assignments of the anhydro-pyranoside derivatives were made on the basis of partial analysis of their n.m.r. spectra. The chemical shifts and first-order coupling constants which were obtained for the ring protons of these compounds and which are collected in Table I are in sufficient agreement with those obtained by Buss *et al.* in their n.m.r. study of carbohydrate 2,3-epoxides (8) to assign the epoxide ring to the 2,3 position. For example, the spectrum of XIII (Fig. 2*b*) has a singlet (τ 5.17) assignable to H-1 and an "AB" quartet (centered at τ 6.77) assignable to H-2 and H-3. The very small couplings between H-1 and H-2 and between H-3 and H-4 indicate that these pairs of protons contain a *trans* relationship. In Fig. 2*a* is shown the spectrum of XII, which reveals a doublet at τ 5.12 ($J_{1,2} = 2.5$) assignable to H-1, thus indicating that H-1 and H-2 are *cis*.

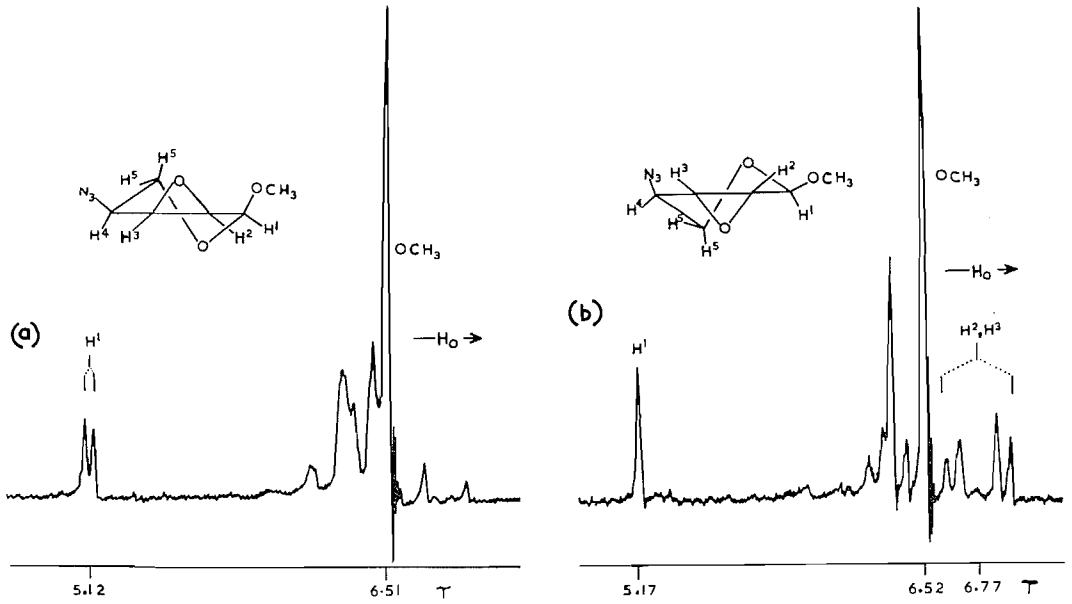

FIG. 2. Partial n.m.r. spectra of (*a*) methyl 2,3-anhydro-4-azido-4-deoxy-α-L-ribopyranoside and (*b*) methyl 2,3-anhydro-4-azido-4-deoxy-α-L-lyxopyranoside.

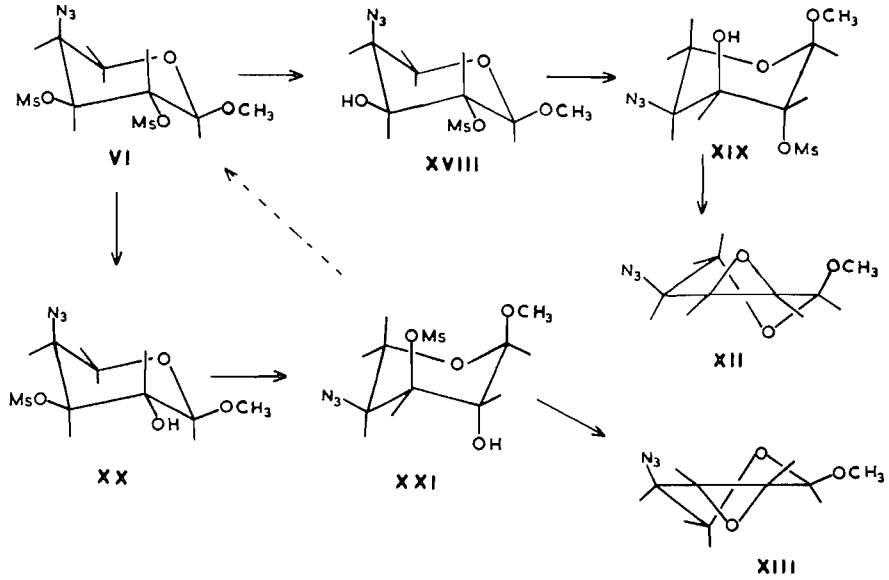
Also we noted in an earlier publication (6) the synthesis of methyl 4,6-diazido-4,6-dideoxy-2,3-di-*O*-methanesulfonyl-α-D-galactopyranoside (XXIII) from methyl 2,3,4,6-tetra-*O*-methanesulfonyl-α-D-glucopyranoside (XXII). The details of this preparation are now given. Proof of structure of XXIII was achieved by mesylating methyl 4,6-diazido-4,6-dideoxy-α-D-galactopyranoside (2), which gave a di-*O*-methanesulfonyl derivative identical in all respects with XXIII.



DISCUSSION

The mechanism of the sequence of reactions leading to epoxide formation is of interest in view of the relative yields of the two anhydro derivatives obtained. But the interpretation is complex. Angyal and Gilham, in their synthesis of anhydroinositols from vicinal *trans* di-*O*-tosylates (9), favored removal of one of the sulfonyl groups by *O*—*S* fission (S_N2_S type), a process that is facilitated by the inductive effect of the adjacent sulfonyloxy group, followed by participation of the free hydroxyl in the elimination of the neighboring sulfonyl group to give the epoxide. Although a preponderance of one anhydro-pyranoside over the other is obtained in most cases in the present study, it is difficult to imagine that one sulfonyloxy group is more accessible to hydrolysis than the other (e.g. C-2 of VII), because an equatorial substituent is equidistant from a vicinal equatorial or axial substituent. However, the inductive effect of the neighboring methoxyl and azido groups is probably a major influence. Moreover, the situation is complicated by the possibility of "transsulfonylation", since Cope and Shen (10) have obtained evidence that "transtosylation" is operating in the formation of 1,4:2,5:3,6-trianhydro-D-mannitol from the ditosylate of 1,4:3,6-dianhydro-D-glucitol. Our attempts to achieve transmesylation have, however, been unsuccessful. Methyl 4-azido-4-deoxy-β-L-xylopyranoside (6) and methyl 3,4-di-*O*-isopropylidene-2-*O*-methanesulfonyl-α-L-arabinopyranoside (11) were boiled under reflux in methanol solution containing sodium methoxide. Hydrolysis of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2-*O*-methanesulfonyl group occurred, but the formation of an anhydro derivative or a mono-*O*-methyl compound derived from the epoxide was not observed. Similarly, reaction of methyl 4-azido-4-deoxy-β-L-arabinopyranoside (6) with methyl 4,6-diazido-4,6-dideoxy-2,3-di-*O*-methanesulfonyl-α-D-galactopyranoside failed to yield an anhydro derivative from the *arabino* compound.

Nevertheless, the relative yields of anhydro-pyranosides that were obtained may be explained on purely conformational grounds. Initial hydrolysis, by *O*—*S* cleavage of the sulfonyloxy group, at C-3 of VI would give XVIII, which would have to undergo a change in chair conformations for the participating substituents to be *trans*-diaxial in the

transition state in order to yield the epoxide XII, which was obtained as the major product. On the other hand, if the sulfonyloxy group at C-2 of VI were hydrolyzed first, the chair conformation (XXI) would be formed to give *trans* coplanarity of the participating groups and subsequently would give the epoxide XIII.

If the two transition states are considered as approximating to XIX and XXI, the formation of the latter would be the least favored on conformational grounds because of the passing interaction of the methanesulfonyloxy group on C-3 with the axial azido group on C-4 when XX changes to that conformation (e.g. XXI) where the substituents on C-2 and C-3 are diaxial. In the case of XVIII, the same passing interaction involves a less bulky hydroxyl group. Also, there would be a larger 1,3-diaxial interaction in XXI than in XIX. Thus, although XVIII and XX may be formed with similar ease, the former would be the more reactive and the anhydro-pyranoside (XII) derived from it would predominate. Furthermore, transmesylation of XXI by VI followed by S_N2_S cleavage at C-3 would yield XVIII and thus increase the final yield of XII.

Similar considerations of passing interactions that are incurred when there is a change in conformation, and of transtosylation are useful in explaining the virtually exclusive formation of the *allo*-epoxide from methyl 4,6-*O*-benzylidene-2,3-di-*O*-toluene-*p*-sulfonyl-α-D-glucopyranoside (12) and of the *talo*-epoxide from methyl 4,6-*O*-benzylidene-2,3-di-*O*-toluene-*p*-sulfonyl-β-D-galactopyranoside (13).

EXPERIMENTAL

Solutions were concentrated under reduced pressure below 50° with a rotating vacuum-type evaporator, except *N,N*-dimethylformamide solutions which were evaporated at 60°. Melting points were determined on a Reichert melting point apparatus and are uncorrected. Optical rotations were measured at 23 ± 3° with a Hilger standard polarimeter. All infrared spectra obtained for the compounds described were consistent with the assigned structures. Thin-layer chromatograms (silica gel G, Merck) were irrigated with 4% v/v methanol in benzene and the spots located by spraying the chromatograms with a 5% solution of sulfuric acid in ethanol and heating the plates at 120°. Epoxides were also detected with a sodium iodide and methyl red reagent (14). Nuclear magnetic resonance spectra were measured in $CDCl_3$ solution with a Varian A60 spectrometer.

*Methyl 2,3,4-Tri-O-methanesulfonyl-β-*D*-xylopyranoside (II) and Methyl 2,3,4-Tri-O-methanesulfonyl-β-*L*-arabinopyranoside (III)*

Methyl β-D-xylopyranoside and methyl β-L-arabinopyranoside were methanesulfonylated as usual with 3 moles of methanesulfonyl chloride in pyridine solution. The respective trimethanesulfonates were isolated by pouring the reaction mixtures into ice water and were recrystallized from methanol to give II (78% yield), m.p. 147.5–148.5°, $[\alpha]_D$ −33.6° (*c*, 1.4 in chloroform), and III (92% yield), m.p. 127.5–128°, $[\alpha]_D$ +143° (*c*, 4.6 in chloroform).

Anal. Calcd. for $C_9H_{18}O_{11}S_3$: C, 27.1; H, 4.5; S, 24.1. Found for II: C, 27.3; H, 4.5; S, 23.8. Found for III: C, 26.9; H, 4.2; S, 24.1.

*Methyl 2,3,4-Tri-O-methanesulfonyl-α-*L*-arabinopyranoside (IV)*

A crystalline mixture (20 g) containing ca. 70% methyl α-L-arabinopyranoside (15) plus 30% of the anomer (calculated from the specific rotation) was dissolved in pyridine (250 ml), and methanesulfonyl chloride (3.2 moles) was added slowly, the temperature of the reaction mixture being kept below 0°. After the reaction mixture had been kept at room temperature for 3 h, it was poured into ice water (500 ml). The crystalline precipitate was collected and recrystallized from methanol to give 19.3 g of a solid which melted at 177–181°. Two further recrystallizations from methanol gave the pure α-anomer (IV), which melted at 190.5–191.5° and had $[\alpha]_D$ +34.3° (*c*, 1.02 in chloroform).

Anal. Calcd. for $C_9H_{18}O_{11}S_3$: C, 27.1; H, 4.5; S, 24.1. Found: C, 26.7; H, 4.8; S, 24.4.

*Methyl 2,3,4,6-Tetra-O-methanesulfonyl-α-*D*-glucopyranoside (XXII)*

Methyl α-D-glucopyranoside was treated with methanesulfonyl chloride (4 moles) as described above to give XXII, which melted at 146.5–147.5° and had $[\alpha]_D$ +91° (*c*, 1.76 in chloroform).

Anal. Calcd. for $C_{11}H_{22}O_{14}S_4$: C, 26.1; H, 4.34; S, 25.3. Found: C, 25.7; H, 4.0; S, 24.9.

Reaction of the Tri-O-methanesulfonyl Derivatives with Sodium Azide

A 10% solution of the methanesulfonyl derivative in *N,N*-dimethylformamide containing sodium azide (ca. 1.2 moles) was heated at 130°. The disappearance of starting material was followed by thin-layer chromatography, and the reaction mixture was cooled 2 h after starting material was no longer evident. The solution was then filtered to remove precipitated sodium methanesulfonate and the filtrate evaporated to dryness. The residue was partitioned between water and chloroform, and the chloroform layer was washed several times with water, dried ($MgSO_4$), and concentrated to a syrup which crystallized when it was allowed to stand. Recrystallization from methanol or ethanol gave the corresponding azido-deoxy-di-*O*-methanesulfonyl derivative.

*Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-α-*L*-arabinopyranoside (VI)*

Reaction of methyl 2,3,4-tri-*O*-methanesulfonyl-β-D-xylopyranoside (II) as above required 24 h for complete disappearance of the starting material and gave VI, isolated in 40% yield, which melted at 124.5–125.5° and had $[\alpha]_D$ +1.3° (*c*, 3.76 in chloroform).

Anal. Calcd. for $C_8H_{15}N_3O_8S_2$: C, 27.8; H, 4.35; N, 12.2; S, 18.5. Found: C, 27.5; H, 4.3; N, 12.4; S, 18.7.

*Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-α-*D*-xylopyranoside (VII)*

The reaction of methyl 2,3,4-tri-*O*-methanesulfonyl-β-L-arabinopyranoside (III) was essentially complete in 12 h and gave 84% yield of VII, which melted at 117.5–118° and had $[\alpha]_D$ +121° (*c*, 2.94 in chloroform).

Anal. Calcd. for $C_8H_{15}N_3O_8S_2$: C, 27.8; H, 4.35; N, 12.2; S, 18.5. Found: C, 27.5; H, 4.4; N, 12.5; S, 18.6.

When VI and VII were treated with sodium azide as above, no further substitution products were observed on thin-layer chromatograms after 24 h reaction, and only starting material was recovered.

*Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-β-*D*-xylopyranoside (VIII)*

Methyl 2,3,4-tri-*O*-methanesulfonyl-α-L-arabinopyranoside (IV), when caused to react with sodium azide (1.2 moles) for 36 h as described above, gave VIII in 38% yield. In addition to the desired monoazido derivative, several other components were observed on thin-layer chromatograms. Starting material (12%) was recovered by fractional crystallization from methanol. VIII remained in the mother liquors and was purified by evaporation of the solvent and crystallization of the residue from ethanol; it had m.p. 140–141° and $[\alpha]_D$ +1.4° (*c*, 3.55 in chloroform).

Anal. Calcd. for $C_8H_{15}N_3O_8S_2$: C, 27.8; H, 4.35; N, 12.2; S, 18.5. Found: C, 27.6; H, 4.4; N, 11.9; S, 18.3.

Reaction of Methyl 2,3,4,6-Tetra-O-methanesulfonyl-α-D-glucopyranoside with Sodium Azide

The methanesulfonyl derivative (XXII) (20 g) was heated in *N,N*-dimethylformamide solution (300 ml) containing sodium azide (7.7 g) at 115° for 40 h. The reaction was worked up as above and gave methyl 4,6-diazido-4,6-dideoxy-2,3-di-*O*-methanesulfonyl-α-D-galactopyranoside (XXIII) (12.8 g; 81%), which melted at 144–144.5° and had $[\alpha]_D$ +92° (*c*, 1.06 in chloroform).

Anal. Calcd. for $C_9H_{16}O_8N_6S_2$: C, 27.0; H, 4.0; N, 21.0; S, 16.0. Found: C, 26.9; H, 4.0; N, 21.2; S, 15.6.

Reaction of Methyl 4,6-Diazido-4,6-dideoxy-α-D-galactopyranoside with Methanesulfonyl Chloride

Methyl 4,6-diazido-4,6-dideoxy-α-D-galactopyranoside (2) (0.10 g) was treated with methanesulfonyl chloride (0.2 ml) as usual, in pyridine solution. A crystalline product was obtained which, after recrystallization from methanol, melted at 144–144.5°. The melting point was undepressed on admixture with methyl 4,6-diazido-4,6-dideoxy-2,3-di-*O*-methanesulfonyl-α-D-galactopyranoside.

Reaction of Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-pentopyranosides with Sodium Methoxide

A 5% solution of the 4-azido-4-deoxy-2,3-di-*O*-methanesulfonyl derivative in methanol containing ca. 2 moles sodium methoxide was boiled under reflux. The reaction was continued until the starting material had disappeared, as shown by thin-layer chromatography. Methanol was removed and the residue was partitioned between chloroform and water. The chloroform layer was dried ($MgSO_4$) and concentrated to a syrup from which a little starting material was removed by crystallization from methanol. The oily residue remaining after evaporation of the methanol was fractionated by chromatography on a column of silica gel (Davison). Elution with 4:1 v/v petrol (b.p. 40–60°) – ether gave a good separation of the anhydro derivatives obtained from VI and VII.

Anhydro Derivatives from Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-α-L-arabinopyranoside (VI)

After VI (5.52 g) was allowed to react for 4 h as described above, starting material (2.14 g) was recovered together with an oily mixture (1.35 g). When this oil was fractionated on silica gel (70 g), with benzene – 0.2% methanol as eluent, methyl 2,3-anhydro-4-azido-4-deoxy-α-L-lyxopyranoside (XIII) (12.5%) was eluted first as an oil, which had $[\alpha]_D$ −104° (*c*, 0.77 in chloroform), followed by methyl 2,3-anhydro-4-azido-4-deoxy-α-L-ribopyranoside (XII) (40.5%), which had $[\alpha]_D$ −252° (*c*, 0.43 in chloroform).

Anal. Calcd. for $C_6H_9O_3N_3$: C, 42.1; H, 5.3; N, 24.6. Found for XII: C, 42.3; H, 5.3; N, 24.1. Found for XIII: C, 42.4; H, 5.5; N, 24.2.

Anhydro Derivatives from Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-α-D-xylopyranoside (VII)

Reaction of VII (27 g) for 4 h as described above yielded starting material (VII) (16 g), methyl 2,3-anhydro-4-azido-4-deoxy-α-D-lyxopyranoside (XV) (0.40 g) (as an oil which had $[\alpha]_D$ +105° (*c*, 1.08 in chloroform)), and methyl 2,3-anhydro-4-azido-4-deoxy-α-D-ribopyranoside (XIV) (7) (3.33 g) (which melted at 43–44°).

Anal. Calcd. for $C_6H_9O_3N_3$: C, 42.1; H, 5.3; N, 24.6. Found for XV: C, 42.1; H, 5.4; N, 24.5.

Anhydro Derivatives from Methyl 4-Azido-4-deoxy-2,3-di-O-methanesulfonyl-β-D-xylopyranoside (VIII)

Treatment of VIII (3.22 g) with methoxide for 6 h as described above yielded starting material (1.55 g) and an oily product (0.78 g). Chromatography of the latter on silica gel gave a mixture (0.36 g) of two anhydro derivatives which were separated on thin-layer chromatograms, with 0.2% methanol in benzene as solvent, to give methyl 2,3-anhydro-4-azido-4-deoxy-β-D-ribopyranoside (XVI), m.p. 64–64.5°, $[\alpha]_D$ 0° (*c*, 0.30 in chloroform), and methyl 2,3-anhydro-4-azido-4-deoxy-β-D-lyxopyranoside (XVII) as an oil, $[\alpha]_D$ ca. −54° (*c*, 0.39 in chloroform). The relative amounts of XVI and XVII, obtained by estimation of the anomeric hydrogen from an integrated n.m.r. spectrum of the mixture, were 9:16 respectively.

Anal. Calcd. for $C_6H_9O_3N_3$: C, 42.1; H, 5.3; N, 24.6. Found for XVI: C, 42.4; H, 5.4; N, 25.1. Found for XVII: C, 42.1; H, 5.3; N, 24.1.

Methyl 4-Azido-4-deoxy-3-O-methyl-β-L-xylopyranoside (X)

A mixture of methyl 4-azido-4-deoxy-2,3-di-*O*-methanesulfonyl-β-L-arabinopyranoside (V) (6) (5.0 g), methanol–water (2:1) (125 ml), and potassium hydroxide (5.0 g) was boiled under reflux for 3 h. The solution was concentrated to remove methanol and was then extracted with ether. The ethereal extract was washed several times with water, and the aqueous washings were deionized by passage through Amberlite IR-120 (H^+ form) and Duolite A-4 (OH^- form) ion-exchange resins. Concentration of the aqueous solution gave a syrup (3 g) which was fractionated on a column of silica gel by elution with benzene containing 10% methanol. The first fraction obtained was methyl 4-azido-4-deoxy-3-*O*-methyl-β-L-xylopyranoside (X) (1.3 g) which, after recrystallization from petrol (60–80°), melted at 111–111.5° and had $[\alpha]_D$ −21.2° (*c*, 2.45 in chloroform).

Anal. Calcd. for $C_7H_{13}O_4N_3$: C, 41.4; H, 6.4; N, 20.7. Found: C, 41.1; H, 6.2; N, 20.8.

Methyl 2-O-Acetyl-4-azido-4-deoxy-3-O-methyl-β-L-xylopyranoside (XI)

Methyl 4-azido-4-deoxy-3-*O*-methyl-β-L-xylopyranoside (X) (0.20 g) was acetylated with acetic anhydride in pyridine solution in the usual manner and gave XI (0.22 g) as a colorless syrup which had $[\alpha]_D$ +25.7° (*c*, 4.1 in chloroform).

Anal. Calcd. for $C_9H_{15}O_5N_3$: C, 44.1; H, 6.1; N, 17.1. Found: C, 44.0; H, 6.2; N, 17.2.

STRUCTURES OF CHLOROBIUM CHLOROPHYLLS (660)[1]

A. S. HOLT, J. W. PURDIE,[2] AND J. W. F. WASLEY[3]
Division of Biosciences, National Research Council, Ottawa, Canada
Received June 2, 1965

ABSTRACT

The *Chlorobium* chlorophylls (660) consist of six different pigments, all of which are derivatives of δ-alkyl-2-desvinyl-2-α-hydroxyethylpyropheophorbide *a*. The six compounds differ in their substituents at C_4 (isobutyl, *n*-propyl, ethyl), C_5 (ethyl, methyl), and C_δ (ethyl, methyl).

INTRODUCTION

Initial studies (1–4) on the *Chlorobium* chlorophylls (660) established the presence of magnesium and a conjugated carbonyl group, and the absence of a methoxyl group. Removal of the magnesium by acid and hydrolysis of the product by hot, methanolic potassium hydroxide yielded crude "pheophorbide" and farnesol (5, 6). Oxidative degradation of the crude "pheophorbide" yielded *trans*-dihydrohematinic acid imide, methylethylmaleimide, and methyl-*n*-propylmaleimide. Crude "pheophorbide" was separated into six different fractions by column partition chromatography between ether and hydrochloric acid (6–8). These were designated 1 to 6 in the order of their decreasing acid numbers (order of elution). Their respective visible absorption spectra were not significantly different but resembled those of purpurins.

Fractions 1 and 2 yielded methylisobutylmaleimide; fractions 3 and 4, methyl-*n*-propylmaleimide; and fractions 5 and 6, methylethylmaleimide. All fractions possessed a hydroxyalkyl group (6, 7, 9) which could be oxidized to a conjugated carbonyl group (10) or dehydrated to an alkenyl group (11), the latter being converted into an alkyl group by catalytic hydrogenation to yield a "meso" derivative (12). The "meso" derivatives of fractions 3 and 4 yielded methylethylmaleimide in addition to methyl-*n*-propylmaleimide. This established the hydroxyalkyl group as an α-hydroxyethyl substituent. It was assumed to be at ring I by analogy with the *Chlorobium* chlorophylls (650).

The porphyrin that was obtained when fraction 5 was treated with hydriodic acid in acetic acid (65 °C) contained a conjugated carbonyl group, and an ethyl group in place of the hydroxyethyl group (7), and gave an "etio"-type visible absorption spectrum (13).

Oxidation of fraction 5 in alkaline dimethylformamide gave a diketone which was cleaved with hydrogen peroxide to yield a tricarboxylic acid. This, when decarboxylated at 185 °C in 1% HCl, gave a porphyrin with a "phyllo"-type absorption spectrum. It was concluded that the chlorophylls (660) possess a cyclopentanone ring, together with an alkyl substituent on a methine bridge carbon atom, and that it is this substituent which changes the effect of the cyclopentanone ring on the visible absorption spectrum of the porphyrin (13). The extra alkyl group was assigned to the δ methine bridge on the basis of nuclear magnetic resonance spectroscopy (7).

The purpose of the following work was to confirm the C_δ assignment and to identify the substituents at C_5 and C_δ in each fraction.

DISCUSSION

Comparison of the proton magnetic resonance spectra of the methyl esters of mesopyropheophorbide *a*, δ-chloromesopyropheophobide *a*, and the "meso" derivative of fraction 5 indicates that the alkyl group is at C_δ. Mesopyropheophorbide *a* has signals at $\tau = 0.67$ and 0.90 which are assigned to the α and β methine bridge protons, and a signal at $\tau = 1.53$ which is assigned to the C_δ proton (14). δ-Chloromesopyropheophorbide *a* has only two bridge proton signals, at $\tau = 0.69$ and 0.76. Similarly, the "meso" derivative of fraction 5 has only two signals in this region, at $\tau = 0.48$ and 0.65. The absence of a signal at about $\tau = 1.5$ indicates that there is an alkyl substituent on C_δ. This is supported by the fact that the "meso" derivative of fraction 5 of chlorophylls (660) does not give a chloro derivative when treated by the methods used to prepare δ-chloromesopyropheophorbide *a* (7). The nuclear magnetic resonance spectra of fractions 3 and 4 give only two methine bridge proton signals: fraction 3, $\tau = 0.23$ and 0.65; fraction 4, $\tau = 0.28$ and 0.70.

Rapoport and co-workers (15, 16) have also investigated the main fraction of the *Chlorobium* chlorophylls (660), presumably that designated fraction 5 in our work (7). On the basis of nuclear magnetic resonance studies, they concluded that the structure proposed by Holt *et al.* (7) was probably correct, except that the alkyl group was suggested to be at either the α or the β methine bridge. This conclusion is invalidated by assignment of the signal $\tau = 0.67$ to a δ-proton, which differs to an inadmissible extent from the assignments of δ-proton signals of chlorophylls *a* and *b*: $\tau = 1.85$ and 1.86, respectively.

In our studies it was found that fraction 5 has methine bridge proton signals at $\tau = 0.28$ and 0.61. Similarly, fraction 6 has signals at $\tau = 0.30$ and 0.85; its "meso" derivative has signals at $\tau = 0.63$ and 0.75. Thus, conversion of the 2-α-hydroxyethyl group into an ethyl group affects mainly the lower field signals. In fractions 5 and 6, respectively, $\tau = 0.28$ and 0.30 are provisionally assigned to the C_α protons, and $\tau = 0.65$ and 0.85 to the C_β protons. Treatment of fraction 5 with warm CH_3COOD removes the peak at $\tau = 0.28$, as observed by Rapoport and co-workers. The C_α proton appears to exchange in this compound.

The arrangement of the peripheral substituents was assumed to be analogous to the (650) *Chlorobium* chlorophylls so that only the groups at C_4 and C_5 remained to be determined. The C_5 substituents could have been determined by converting the "meso" derivative of each fraction into the corresponding δ-phylloporphyrin and oxidizing this derivative with chromic acid. The δ-phylloporphyrins gave only low yields. Oxidation of the porphyrins also gave low yields of the imide from ring III. On the other hand, chromic acid oxidation of the phyllochlorin from chlorophyll *a* gave a very good yield of citraconimide. Conversion of the (660) pheophorbides into chlorins with ring V removed (and the hydroxyethyl group still present) gave good yields by the following method (Fig. 1).

The pheophorbide (I) was oxidized by oxygen in dimethylformamide to a diketone (II), which was further oxidized with hydrogen peroxide to the tricarboxylic acid (III) with carboxyl groups on C_6 and C_γ. Refluxing the tricarboxylic acid in 10% HCl for 1 h caused the absorption maximum to shift from 672 mμ to 653 mμ, indicating removal of the γ-carboxyl group (IV). Further refluxing in a mixture of pyridine and acetic acid yielded V with an absorption maximum at 640 mμ.

Treatment of V with 1% HCl in a sealed tube at 185 °C gave VI, the corresponding porphyrin. Analyses of the esters from fraction 5 showed the presence of two methoxyl groups in IV and one in V. The tricarboxylic acid corresponding to III from the "meso" derivative of fraction 5 was described previously (7). The visible absorption spectrum of VI, after purification, was identical with that of the δ-phylloporphyrin prepared from fraction 5.

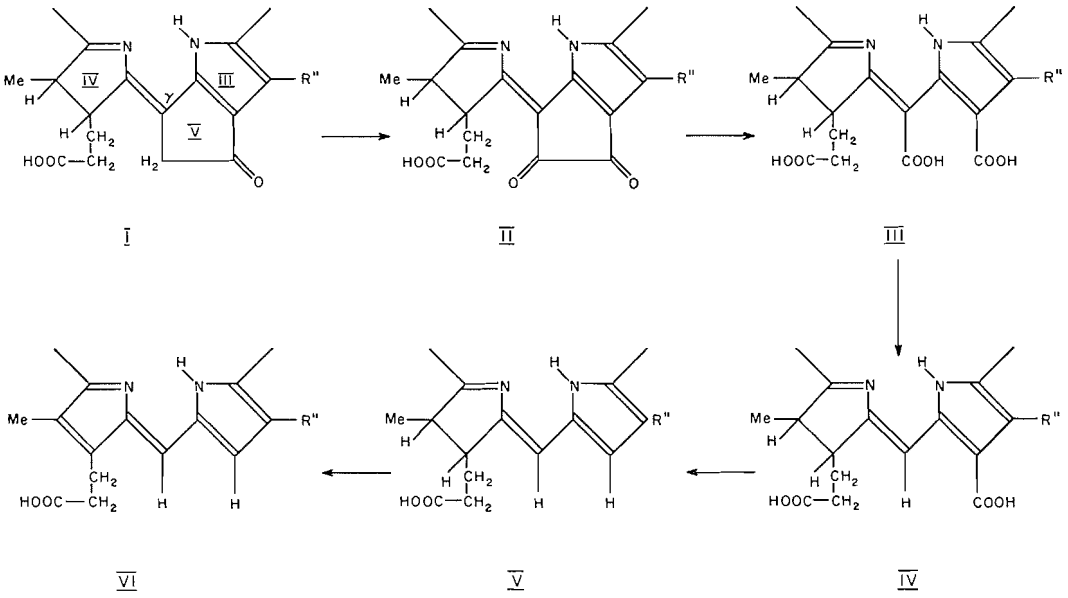

FIG. 1. Stepwise degradation of pheophorbides (660).

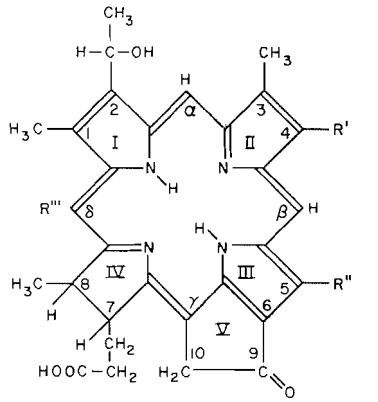
The chlorin derivatives (V) from fractions 1 to 6 (0.5–1 mg) were degraded with chromium trioxide in acetic acid by using a slight modification of the method described previously (9). The neutral imides produced were identified by comparison with synthetic imides by using gas–liquid partition chromatography on a column of polyphenyl ether, and the results were confirmed on a column of butanediol succinate. Fractions 1 to 5 all yielded ethylmaleimide, and fraction 6 citraconimide, from ring III, in addition to the expected imide from ring II, leaving only the δ-alkyl group undetermined.

TABLE I

Gas–liquid partition chromatography of the neutral imides from the oxidation of derivative V from fractions 1 to 6 (polyphenyl ether column; 175 °C; 100 ml argon per min)

Source of derivative V	Retention times relative to that of methylethylmaleimide
Mesopyropheophorbide *a*	0.535, 1.00
Fraction 1	0.53, 1.69
Fraction 2	0.81, 1.69
Fraction 3	0.81, 1.44
Fraction 4	0.81, 1.44
Fraction 5	0.81, 1.00
Fraction 6	0.53, 1.00
Synthetic imides	
Citraconimide	0.53
Ethylmaleimide	0.81
Methylethylmaleimide	1.00
Methyl-*n*-propylmaleimide	1.44
Methylisobutylmaleimide	1.69



Fractions 3 to 6 were converted into "meso" derivatives and then into δ-phylloporphyrins. In addition to the δ-phylloporphyrin, a small amount of the corresponding pyrroporphyrin (δ-alkyl group removed) was obtained from each fraction. This result was not unexpected, because the conditions used for decarboxylation were similar to those used by Fischer (19). The pyrroporphyrins obtained from fractions 3 and 4 were purified and compared with

For personal use only.

synthetic 1,3,8-trimethyl-2,5-diethyl-4-*n*-propylporphin-7-propionic acid (9, 17). The methyl esters of both pyrroporphyrins had m.p. 205–208 °C alone and 205–210 °C in admixture with the methyl ester of the synthetic compound (m.p. 207–211 °C). The pyrroporphyrin from fraction 4 was further shown to be identical with the synthetic compound by comparison of X-ray powder photographs. This confirmed that fractions 3 and 4 had identical peripheral substituents and that they therefore differed only at the δ-position.

MacDonald and co-workers (17, 18) prepared synthetic δ-phylloporphyrins and compared them with the phylloporphyrins from fractions 3, 4, 5, and 6. Fraction 5 phylloporphyrin was identical with synthetic 1,3,8,δ-tetramethyl-2,4,5-triethylporphin-7-propionic acid (17). Similarly, fraction 6 yielded δ-phylloporphyrin XV. This confirmed that, in fractions 5 and 6 at least, the order of the substituents in the *Chlorobium* chlorophylls (660) was the same as that found in the *Chlorobium* chlorophylls (650) (9), and that they possessed δ-methyl substituents.

Mass spectrometric molecular weight determinations were recently made of the methyl esters of fractions 2, 4, 5, and 6 (21). The values found for fractions 5 and 6 agree with those deduced from the degradative and analytical results. Those found for fractions 2 and 4 correspond to those of δ-methyl compounds. Consequently, previously proposed structures of fractions 1–4 (22) are here revised (Fig. 2).

4	*n*-Propyl	Et	Me
5	Et	Et	Me
6	Et	Me	Me

FIG. 2. Proposed structures of the pheophorbides from *Chlorobium* chlorophylls (660).

EXPERIMENTAL

Materials and Methods

Melting points (uncorrected) were measured on a Koffler hot stage. Imides were separated and identified as reported previously (4, 8). Nuclear magnetic resonance spectra were determined with a Varian V-4300 B spectrometer operating at 60 Mc/s. Visible absorption spectra were determined with a Cary model 14 spectrophotometer. Relative intensities of absorption bands are listed in parentheses.

Separation of Pheophorbides (660)

Initial separations by partition chromatography on a Celite column (8) were made with hydrochloric acid (8.5% w/w). Fractions 1 and 2 were purified with 11% hydrochloric acid; fractions 3 and 4, 9.5%; fraction 5, 8.0%; and fraction 6, 7.0%.

A large-scale preparation gave the following yields of pure pheophorbides from 13 g of *Chlorobium* chlorophyll (660): fraction 1, 25 mg; fraction 2, 30 mg; fraction 3, 84 mg; fraction 4, 715 mg; fraction 5, 3 150 mg; fraction 6, 462 mg. Thus fraction 5 accounted for 70% of the pure pheophorbides obtained.

Preparation of Tricarboxylic Acid Derivative (III); General Procedure

Fraction 5 (200 mg) was dissolved in dimethylformamide (100 ml), and oxygen was bubbled through for 5 min to saturate the solution. Aqueous potassium hydroxide (15%, w/v; 7 ml) was added and the mixture shaken for 3 min. Hydrogen peroxide (30%, 2 ml) was added and the mixture shaken for 30 s. It was then poured into a mixture of ether and water, and extracted into the ether layer by adding citric acid. The ethereal extract was washed well with water and the solvent was removed under reduced pressure. The residue was dissolved in a minimum of tetrahydrofuran and precipitated by addition to petroleum ether; yield 190 mg. Visible absorption spectrum (ether): λ_{max} 672 mμ (1.00); 620 mμ (0.12); 538 mμ (0.17); 507 mμ (0.24).

Preparation of Dicarboxylic Acid Derivative (IV); General Method

The tricarboxylic acid (III) from fraction 5 (200 mg) was dissolved in a minimum of acetic acid (80 ml), and hydrochloric acid (10%, 250 ml) was added. The mixture was refluxed for 1 h. The mixture was added to ether and neutralized. The ethereal extract was concentrated under reduced pressure, and the product (IV) was purified on a Celite column with 8% HCl; yield 140 mg. Visible absorption spectrum (ether): λ_{max} 653 mμ (1.00); 598 mμ (0.12); 540 mμ (0.17); 510 mμ (0.25).

A sample of IV was esterified (CH_2N_2), but the product failed to crystallize from ether.

Anal. Found: MeO, 10.15. $C_{34}H_{38}O_3N_4{\cdot}(OMe)_2$ requires MeO, 10.10.

Preparation of V; General Method

The dicarboxylic acid (IV) from fraction 5 (25 mg) was dissolved in a mixture of pyridine and glacial acetic acid (1:3, 80 ml) and refluxed for 8 h. The mixture was poured into ether and neutralized with sodium bicarbonate. The ethereal extract was washed well and the product (V) purified on a Celite column (hydrochloric acid, 8%); yield 5.8 mg. Visible absorption spectrum (ether): λ_{max} 640 mμ (1.00); 582 mμ (0.12); 527 mμ (0.15); 502 mμ (0.30).

Oxidative Degradation of Derivative V; General Procedure

The pigment (1.5 mg) was dissolved in glacial acetic acid (ca. 5 ml) and the solution cooled to 10 °C. Aqueous chromium trioxide (0.03 ml; 6.7%, w/v) was added to the cooled solution. Chromium trioxide (0.3 ml) was again added and the mixture was allowed to stand overnight. The isolation and the identification of the imides by gas–liquid partition chromatography has been described earlier (4, 8).

Preparation and Purification of "Meso" Derivatives; General Procedure

The "meso" derivatives of pheophorbides (660) were prepared by a method analogous to that used for the "meso" pheophorbides (650) (9).

The pheophorbide (50 mg) was dissolved in 100% phosphoric acid (20 ml) and maintained at 60 °C for 30 min, with vigorous stirring. The pigment was extracted with ether and chromatographed on a Celite column between ether and hydrochloric acid. The vinyl derivative separated as the lower band, leaving the unchanged material (which could again be treated with phosphoric acid to produce more of the vinyl derivative), and was hydrogenated (palladium black – H_2) in acetone; the "meso" derivative that was formed was purified by using hydrochloric acid that was 0.5% weaker than that required for the corresponding vinyl compound.

Preparation of δ-Phylloporphyrins; General Procedure

The "meso" compound was oxidized by oxygen to a tricarboxylic acid (Fig. 1). The product was dissolved in glacial acetic acid to which an equal volume of hydrochloric acid (1%) was added. The mixture was heated in a Teflon-lined brass bomb at 175° for 3½ h. After it had cooled, the solution was filtered to remove any decomposition products, and extracted with ether.

Hydrochloric acid (1%) extraction of the ether solution removed any δ-phylloporphyrin, and pyrroporphyrin that was formed as a by-product was obtained by a further extraction with hydrochloric acid (5%). The porphyrins obtained were then re-extracted with ether.

The δ-phylloporphyrins of fractions 3 to 6 of the pheophorbides (660) were prepared from the pure "meso" derivatives as outlined above, and were purified on acid-washed Celite with hydrochloric acid (1.5%). The pyrroporphyrins were purified (hydrochloric acid, 4.5%). Further purification was effected by crystallization from ether.

The purified free acids of the porphyrins were methylated with methanolic hydrogen chloride, and purified by chromatography on alumina (Shawinigan, reagent grade, deactivated with chloroform–methanol (95:5)) with chloroform as eluant.

The copper complexes of the phylloporphyrin methyl esters were also prepared, purified in the same way, and crystallized from chloroform–methanol.

Samples of the free acids, methyl esters, and copper complexes were all examined and compared with synthetic samples. The criteria used for identifying the natural samples with the synthetic materials were visible absorption spectra, melting and mixed melting points, and X-ray powder photographs.

Fraction 3.—δ-Phylloporphyrin (free acid), long needles from ether. δ-Phylloporphyrin methyl ester, needles from chloroform–methanol; m.p. 196–199°. Pyrroporphyrin methyl ester, needles from ether; m.p. 205–208°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fraction 4.—Pyrroporphyrin methyl ester, needles from ether; m.p. 205–208°. δ-Phylloporphyrin (free acid), long feathery needles from ether. δ-Phylloporphyrin methyl ester, small needles from chloroform–methanol; m.p. 195–197 °C (slight changes at 164 to 190 °C). δ-Phylloporphyrin methyl ester, copper complex, bright red prisms from chloroform–methanol; m.p. 174–179°.

Fraction 5.—δ-Phylloporphyrin (free acid), long needles from ether. δ-Phylloporphyrin methyl ester, from chloroform–methanol; m.p. 215–215.5°. δ-Phylloporphyrin methyl ester, copper complex from chloroform–methanol; m.p. 213.5–215°.

Fraction 6.—δ-Phylloporphyrin (free acid), long purple needles from ether. δ-Phylloporphyrin methyl ester, purple rods from chloroform–methanol; m.p. 209–213°. δ-Phylloporphyrin methyl ester, copper complex, small red purple needles from chloroform–methanol; m.p. 210–212.5°.

The δ-phylloporphyrins all possess almost identical visible absorption spectra; the pyrroporphyrins have spectra identical with that of pyrroporphyrin XV derived from chlorophyll *a*. Fraction 5 δ-phylloporphyrin: λ_{max} (ether): 629 mμ (0.10); 578 mμ (0.38); 535 mμ (0.39); 502 mμ (1.00). Bands II and III absorb almost equally, as compared with the same bands of γ-phylloporphyrin (II > III) (20).

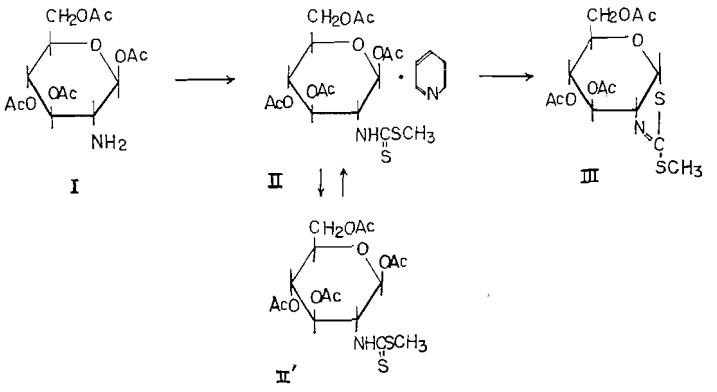
SYNTHESIS AND NUCLEAR MAGNETIC RESONANCE SPECTRUM OF 3′,4′,6′-TRI-O-ACETYL-2-(METHYLTHIO)-D-GLUCOPYRANO[2′,1′: 4,5]-2-THIAZOLINE

TEIICHIRO ITO
Research Laboratories, Meiji Seika Kaisha Ltd., Yokohama, Japan
Received June 15, 1965

ABSTRACT

1,3,4,6-Tetra-O-acetyl-2-deoxy-2-(dithiocarbomethoxy)-2-amino-β-D-glucopyranose, when it was treated with trifluoroacetic acid, gave 3′,4′,6′-tri-O-acetyl-2-(methylthio)-D-glucopyrano-[2′,1′:4,5]-2-thiazoline (III). Compound III showed a nuclear magnetic resonance spectrum capable of full interpretation. Long-range coupling between H_2 and H_4 was observed. The conformation of this compound in solution was discussed on the basis of the coupling constants for ring hydrogens.

Derivatives of amino sugars containing thiazoline rings have been prepared as intermediates for the synthesis of 2,3- and 3,2-thioamino sugars. In 1961, Goodman and Christensen (1) reported that a thiazoline ring was formed when a derivative of D-altropyranose 2-methanesulfonate with a dithiocarbomethoxyamino group at carbon 3 was heated in pyridine. Reckendorf and Bonner (2) synthesized a derivative of D-allopyrano-[3′,2′:5,4]-2-thiazoline by a similar reaction. The derivative of D-glucopyrano[2′,1′:4,5]-2-thiazoline, however, has not yet been described. As reported in a previous paper (3), N-benzyloxycarbonyl-tetra-O-acetyl-D-glucosamine, on treatment with trifluoroacetic acid, gave a glucose derivative containing an oxazolidone ring.



In this paper, application of the reaction using trifluoroacetic acid for the preparation of the derivative of D-glucopyrano-thiazoline, and the nuclear magnetic resonance (n.m.r) spectrum of this compound, will be described.

When 1,3,4,6-tetra-O-acetyl-2-deoxy-2-amino-β-D-glucopyranose (I) (4) was treated with carbon disulfide, triethylamine, and methyl iodide in pyridine, 1,3,4,6-tetra-O-acetyl-2-deoxy-2-(dithiocarbomethoxy)-2-amino-β-D-glucopyranose was isolated as needle crystals (II) which contained 1 mole of pyridine. The n.m.r. spectrum of compound II in $CDCl_3$ indicated the presence of a methylthio group (singlet, τ 7.40), O-acetyl groups (three peaks, τ 7.89, 7.91, and 7.96), and pyridine (multiplet, τ 1.3–1.5, 1.6–1.9, and 2.5–2.7).

The pyridine-free compound (II′) was obtained as an amorphous powder. In the n.m.r. spectrum (in $CDCl_3$), the peaks caused by ring hydrogens were identical in the spectra of compounds II and II′. The infrared spectrum (in Nujol) of compound II showed bands at 1 590, 1 578, and 1 564 cm^{-1}, while compound II′ showed bands at 1 545, 1 530, and 1 512 cm^{-1}.

When compound II was treated with trifluoroacetic acid at 70° for 12 min, the reaction product was obtained as a syrup which crystallized gradually when it was allowed to stand in a refrigerator. It showed m.p. 51–54°. Elemental analysis and infrared and n.m.r. spectra showed that the product was 3′,4′,6′-tri-O-acetyl-2-(methylthio)-D-glucopyrano-[2′,1′:4,5]-2-thiazoline (III).

The n.m.r. spectrum showed the presence of a methylthio group (τ 7.46) and O-acetyl groups (two peaks, τ 7.86 and 7.92; intensity 1:2). As shown in Fig. 1, the peaks caused by ring hydrogens gave such different chemical shifts that they were assigned readily from

their splittings. The observed first-order coupling constants (J) for ring hydrogens are shown in Table I. It is noteworthy that long-range coupling (J, 1 c.p.s.) between H_2 and H_4 is observed.

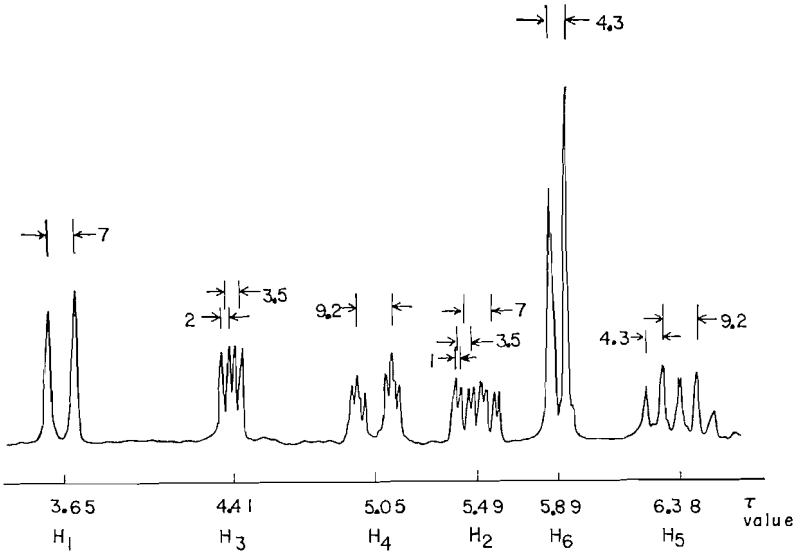


FIG. 1. The 60 Mc.p.s. n.m.r. spectrum of 3′,4′,6′-tri-O-acetyl-2-(methylthio)-D-glucopyrano[2′,1′:4,5]-2-thiazoline (III) in $CDCl_3$. The peaks caused by methylthio and O-acetyl groups are omitted.

Lemieux (5), Hall (6, 7), and their co-workers have observed the long-range interactions in numerous carbohydrates. It has been shown that the long-range couplings are highly stereoselective, occurring only between hydrogens possessing a critical relationship (6, 8).

Recently, a number of n.m.r. spectra of carbohydrates have been examined for information on their conformations through application of the relationships that appear to exist between the coupling constant and the dihedral angles defined by vicinal protons (7, 9–13). It has been recognized that the theoretical Karplus relation (9) has its own limitations (14).

However, it was thought to be of interest to show the dihedral angles of compound III, which were calculated from the Karplus equation (9). The calculated dihedral angles and the theoretical angles corresponding to the chair and skew-boat conformations are shown in Table I.

TABLE I

Coupling constants, calculated dihedral angles, and theoretical angles for chair and skew-boat conformations

	CH—CH					
	1,2	2,3	3,4	4,5	5,6	2,4
Coupling constant, J_{HH} (c.p.s.)	7	3.5	2.0	9.2	4.3	1.0
Dihedral angle calculated from Karplus equation*	22°	48° 129°	58° 119°	179°		
Theoretical angle						
Chair	60°	180°	180°	180°		
Skew-boat	30°	60°	90°	150°		

*$J = J_0 \cos^2 \phi - 0.28$ c.p.s., where $J_0 = 8.5$ for $0° \leqslant \phi \leqslant 90°$ and 9.5 for $90° \leqslant \phi \leqslant 180°$.

Since compound III contains a thiazoline ring fused to a pyranose ring, the dihedral angle for H_1–H_2 is expected to be less than 60°. The value of 22° calculated from the Karplus equation suggests that a partial flattening of the chair conformation occurs. The coupling constant of 9.2 c.p.s. for H_4 and H_5 suggests that the dihedral angle for H_4–H_5 is about 180° (15); thus this part of the pyranose ring remains virtually unaltered. The above data, including the small values for $J_{2,3}$ and $J_{3,4}$, indicate that the pyranose ring of compound III is somewhat distorted from the normal chair conformation.

Coxon and Hall (7) suggested a skew-boat conformation for 1,2-O-alkylidene-α-D-glucopyranoses. If we assume a skew-boat form for compound III, we find some differences between the calculated and theoretical angles for H_3–H_4 (Table I). Most likely, the observed spectra are time-averaged spectra of various half-chair and skew-boat conformations.

Recently, Williams and Bhacca (16) reported that, in the chair form of a cyclohexane ring, the variation of vicinal coupling constant with the orientation of an electronegative substituent such as —OH or —OAc is quite large. Therefore, to determine an exact conformation of the distorted pyranose ring, more experimental data must be available.

EXPERIMENTAL

Melting points are uncorrected. The n.m.r. spectra were measured with a Varian A-60 spectrometer, tetramethylsilane being used as internal reference.

1,3,4,6-Tetra-O-acetyl-2-deoxy-2-(dithiocarbomethoxy)-2-amino-β-D-glucopyranose

Crystals (II) Containing 1 Mole of Pyridine

To a chilled solution of 2.4 g of 1,3,4,6-tetra-O-acetyl-2-deoxy-2-amino-β-D-glucopyranose (I) in 8 ml of dry pyridine was added 1.5 ml of triethylamine and then 0.8 ml of carbon disulfide, with stirring. The temperature was maintained below 5°. The solution was stirred at the ice-bath temperature for 1.5 h, and then 0.8 ml of methyl iodide was added. After being stirred for an additional 30 min at 0°, the mixture was stored overnight at 5° and then poured into ice water. The separated crystalline precipitates were filtered off and washed with water; yield 3 g (72%). It was recrystallized from a mixture of ethyl acetate and hexane. The recrystallized compound has the following properties: m.p. 106–108°; $[\alpha]_D^{20}$ −44° (*c*, 0.5 in chloroform); $\lambda_{max}^{CH_3OH}$ 223 mμ (ε 4 100), 251 mμ (ε 13 100), 275 mμ (ε 5 100).

Anal. Calcd. for $C_{16}H_{23}NS_2O_9 \cdot C_5H_5N$: C, 48.82; H, 5.46; N, 5.42; S, 12.41. Found: C, 48.72; H, 5.37; N, 5.53; S, 12.57.

Pyridine-Free Compound (II′)

The above compound (II) (0.5 g) was dissolved in methylene dichloride, and washed with cold 1 *N* hydrochloric acid, cold sodium bicarbonate aqueous solution, and then cold water. The solvent layer was separated, dried, and evaporated to a white powder (300 mg).

Anal. Calcd. for $C_{16}H_{23}NS_2O_9$: C, 43.92; H, 5.29. Found: C, 43.91; H, 5.28.

Crystallization of compound II′ as such was unsuccessful; however, it was crystallized readily as crystals (II) by dissolving it in ethyl acetate and mixing the solution with hexane and a small amount of pyridine.

3′,4′,6′-Tri-O-acetyl-2-(methylthio)-D-glucopyrano[2′,1′:4,5]-2-thiazoline (III)

Compound II (700 mg) was dissolved in trifluoroacetic acid (5 ml) and the solution was refluxed for 12 min at 70°. It was evaporated *in vacuo*, and the resulting syrup was dissolved in chloroform and washed with cold sodium bicarbonate aqueous solution and then cold water. The chloroform solution was dried and evaporated to a syrup, which crystallized gradually when it was allowed to stand in a refrigerator. (The crystallization was very slow. It required about 1 week.) The crystalline product was recrystallized from a mixture of ether and petroleum ether; yield 320 mg (62%), m.p. 51–54°, $[\alpha]_D^{18}$ −70° (*c*, 0.3 in chloroform), $\lambda_{max}^{CH_3OH}$ 221 mμ (ε 9 600). The infrared spectrum (in Nujol) showed bands at 1 720 (O-acetyl), 1 570 (—N=C—), 1 220–1 200, 1 070, 1 030, 950, 880, 812, and 755 cm^{-1}.

Anal. Calcd. for $C_{14}H_{19}NS_2O_7$: C, 44.55; H, 5.07; N, 3.71; S, 16.99. Found: C, 44.88; H, 4.84; N, 3.92; S, 17.39.

ACKNOWLEDGMENTS

The author expresses his gratitude to Dr. T. Nishida, Kobayashi Institute of Physical Research, for the determination of the n.m.r. spectrum. The author is grateful to Dr. S. Inouye of this laboratory for his helpful suggestions regarding the interpretation of the n.m.r. spectrum.

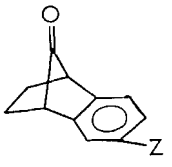
NOTES

POLAROGRAPHY OF 7-BENZONORBORNENONES[1]

HIROSHI TANIDA, HIROSHI MIYAZAKI, AND HIROYUKI ISHITOBI

Polarographic half-wave reduction potential distinguishes between aryl ketones and alkyl ketones. The reduction under neutral or acidic conditions is believed to involve a free radical process, followed by dimerization (pinacol formation) (1–3). As shown in previous papers (4), reactivity at the 7-position of benzonorbornenes demonstrated a typical homobenzylic conjugation; direct conjugate interaction was shown between the

C_7 carbonium ion formed in acetolysis of anti-7-benzonorbornenyl *p*-bromobenzenesulfonate and the aromatic ring. Interest in a radical reaction at this position led us to measure half-wave reduction potentials ($-E_{\frac{1}{2}}$) of benzonorbornen-7-one (I) and 4′-substituted derivatives (II–VI).



The Oppenauer oxidation of the 4′-substituted anti-7-benzonornenols (4) provided the materials used in this study. The $-E_{\frac{1}{2}}$'s measured under neutral conditions (see Experimental section), where a one-electron reduction process was observed for acetophenone, are summarized in Table I. For comparison, the results of benzonorbornen-2-one (VII), acetophenone, cyclohexanone, and cyclopentanone under the same conditions are also listed. The most significant result was that the $-E_{\frac{1}{2}}$ of the 7-ketones (I–VI) was almost the same as that of acetophenone; on the other hand, the 2-ketone (VII) did not yield a result similar to that of acetophenone, but instead resembled cyclohexanone and cyclo-

TABLE I

VII

pentanone. Therefore, one might be able to argue that the 7-ketones behave as a kind of aryl ketone. However, the limiting current of 7-ketones was very small for reasons that cannot be explained at present. No significant substituent effect was observed.

Absence of anchimeric assistance in the homolytic reactions of 2-norbornyl and 2-norbornenyl systems has recently been demonstrated by several workers (5). In this connection, the indication of phenyl participation in the polarographic reduction reported here may be of interest in considering a radical reaction at the 7-position of the norbornenyl system.

EXPERIMENTAL

Melting points were taken by capillary and are corrected; boiling points are uncorrected.

Materials

4′-Methoxy-, 4′-methyl-, 4′-chloro-, and 4′-bromo-benzonorbornen-7-one (II, III, IV, and V) were prepared by the Oppenauer oxidation of the corresponding anti-alcohols (4) according to the procedure of Bartlett and Giddings (6) which was used for the preparation of I. The cyano compound (VI) was prepared by refluxing a solution of V and cuprous cyanide in dimethylformamide (7). Properties and analyses of the new 7-ketones prepared in this study are listed in Table II.

TABLE II

*Bath temperature.

Polarography

The half-wave reduction potentials were measured on a Yanagimoto pen-recording polarograph, model 102. The dropping mercury electrode that was used had the following characteristics in distilled water under an open circuit: $m = 0.865$ mg/s; $n = 70$ cm; $t = 4.33$ s. The supporting electrolytic solution was prepared by mixing 10 ml of 95% ethanol, 0.01% gelatin solution, and 1 *N* lithium chloride solution, adjusted to a total volume of 20 ml. Dissolved oxygen was removed from the solutions by bubbling nitrogen gas through them for 10 min. A saturated calomel electrode was used as an external reference electrode and the measurements were made in triplicate at 25 ± 0.1 °C.

Under acidic conditions (supporting electrolytic solution prepared by mixing 10 ml of 95% ethanol, 0.01% gelatin solution, and 10 ml of pH = 3.59 buffer), the wave of I became blurred. For acetophenone, $E_{\frac{1}{2}} = -1.273$ V and $i_d = 7.16$ μA (5.64×10^{-3} mole/l) were observed.

GAS CHROMATOGRAPHY OF ESTRONE AND RELATED COMPOUNDS

RAFAEL MONTALVO AND OWEN H. WHEELER

Gas chromatography at high temperatures has been used widely for the analysis of mixtures of steroids (1). The liquid phases most generally used are the nonpolar SE-30 silicone gum (2) and the polar QF-1 fluorinated alkyl silicone (3). However, only a few measurements have been reported on estrone, estradiol, and estrone methyl ether (4, 5).

This note reports a study of the retention times of estrone and a series of its derivatives, principally those substituted in ring A, on QF-1 and SE-30 columns (Table I), both as the free compounds and as their trimethylsilyl ethers (4).

The retention times (R_t) on the QF-1 column depend on the polarity of the compound, and methylation in position-3 reduced the R_t values. Similarly, estrolactone showed a greatly increased R_t value, whereas 17-deoxyestrone gave a low retention time.

Hydroxylation in position-2 of estradiol increased the R_t value to about twice that of estradiol, as did hydroxylation at position-16, although a 4-hydroxyl substituent caused an increase of only about 70%. The retention time for 2-acetoxy substitution was also greater than that for the 4-isomer. These differences are probably steric in origin, since a 2,3-disubstituted compound can be absorbed more easily in a direction along the length of the steroid molecule.

The trimethylsilyl ethers had lower values of R_t on the QF-1 column (Table I) than did the corresponding free compounds. Estradiol gave two peaks, one of the monoether and the second of the diether. However, the derivatives of 4-hydroxyestradiol and 4-hydroxyestrone showed only one peak.

The usefulness of the QF-1 column in separating estrone derivatives was shown by the fact that a commercial sample of estradiol monoacetate was readily analyzed as estradiol (33%), estradiol 3-acetate (25%), estradiol 17β-acetate (22%), and estradiol diacetate (20%). A sample of Werbin's dilactone (6) showed the following peaks (and relative areas): 6.3 (2%), 7.5 (2%), 9.0 (6%), and 9.4 min (90%). The compound may be a mixture of isomers, as originally suggested (6), although the peaks of low retention time are probably the result of decomposition.

*At 255°; helium flow, 25 ml/min; 3% liquid phase on Chromosorb W in capillary column. R_t relative to cholestane = 1. R_t of cholestane = 4.2 min on QF-1 and 12.3 min on SE-30.
†TMSE = trimethylsilyl ethers, at 258°.

The data obtained with a column of silicon rubber (SE-30) showed much smaller differences in the retention times. This is consistent with the nonpolar nature of the liquid phase, and the retention times are usually lower than those obtained with a QF-1 column (5). Moreover, the order of retention times for different functional groups is different, that for QF-1 being deoxy < ether < alcohol < ketone < acetate, and that for SE-30 being deoxy < ether < ketone < alcohol < acetate. For the simple estrone derivatives, the small differences in R_t approximately follow the molecular weights (7). However, the

For personal use only.

polyhydroxy compounds, such as 2-hydroxyestradiol, estriol, and estrolactone, had R_t values much larger than those expected for their molecular weights (see also 2- and 4-nitro derivatives); some form of specific interaction with the liquid phase must occur in these cases.

The relative R_t values of the trimethylsilyl ethers on the SE-30 column are only slightly higher than those of the free derivative. In general, the same reduction in retention time that was obtained with trimethylsilyl ethers on a QF-1 column can be achieved by using a SE-30 column for the free compounds. Moreover, there seems to be no advantage in running compounds on a SE-30 column as their trimethylsilyl ethers.

The steroid numbers (k_x) of Clayton (7) and the factor (ΔR_{mg}) of Knights and Thomas (8, 9) ($\Delta R_{mg} = \log k_x$) have been calculated (Table II). The values reflect the differences

found in the retention times. Thus k_x is generally larger on the QF-1 column. However, compounds with two neighboring functional groups (k_x factor for acetylation at C-16α and hydroxylation at C-2 and C-4) showed larger values on the SE-30 column. These factors can be used to calculate the expected values of retention time of non-interacting functional groups (e.g. calculated R_t for estradiol diacetate, 16.2 min; experimental R_t, 16.4 min). However, the calculated values will be less accurate for the smaller k_x factors found with the SE-30 column (e.g. calculated R_t for estradiol 17β-acetate 3-methyl ether, 6.5 min; experimental R_t, 6.8 min).

EXPERIMENTAL

Apparatus

A Wilkens A-90 Aerograph was modified by incorporating small variable transformers, thermocouples, and a meter to control the temperature of the injector block. A hydrogen flame ionization detector was mounted in the column oven. The columns used were 3% QF-1 or 3% SE-30 on Chromosorb W, 60/80 mesh, 0.101 inch × 6 ft, prepared by Research Specialties. The gas flows were: helium and hydrogen, 25 ml/min; air, 250 ml/min. Samples of 1 μl of solution of the steroids of about 50 mg/ml were injected into the column. The detector response was linear for 20–75 μg of estrone, estradiol, and estradiol 3-methyl ether. The columns were saturated with 150 μg, and gave broad peaks. 2-Hydroxyestradiol and 4-hydroxyestradiol also gave broad peaks. The retention times were measured from the air peak. The QF-1 column had 500 and 1 020 theoretical plates for cholestane and estrone, respectively; the SE-30 column had 4 300 and 270 plates, respectively.

Steroids

Samples of analytical purity were used. Some were prepared as described elsewhere (10). 17-Desoxyestrone was prepared by Wolf–Kishner reduction of estrone (11). Estrolactone was synthesized by oxidizing estrone with hydrogen peroxide in aqueous sodium hydroxide (12). Nitration of estrone (13) yielded 2-nitro- and 4-nitro-estrone.

Trimethylsilyl Ethers

The steroid (30 mg) was dissolved in anhydrous tetrahydrofuran (0.2 ml), treated with trimethylchlorosilane (0.5 μl) and hexamethyldisilazane (2 ml), and left at room temperature overnight. The mixture was evaporated in a current of inert gas. The residue was extracted with tetrahydrofuran, the solution was centrifuged, and the upper layer was reevaporated. The residue that was left was dissolved in hexane, and this solution was used for chromatography.

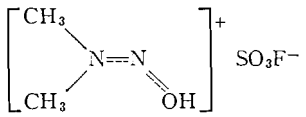
III. N.M.R. INVESTIGATION OF THE PROTONATION OF N,N-DIMETHYLNITROSOAMINE, N,N-DIETHYLNITROSOAMINE, AND N-NITROSOPIPERIDINE[1]



STEPHEN J. KUHN AND JOHN S. MCINTYRE

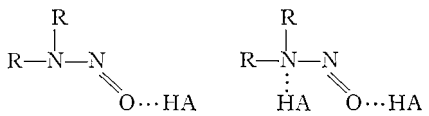
Dow Chemical of Canada, Limited, Exploratory Research Laboratory, Sarnia, Ontario

Received August 4, 1965

ABSTRACT

Protonation of N,N-dimethylnitrosoamine has been investigated by dissolving the nitrosoamine in different acids and recording the proton magnetic resonance spectra of these solutions. Concentrated sulfuric acid, sulfuric acid monohydrate, perchloric acid (72%), trifluoroacetic acid, and fluorosulfuric acid have been used in this study. Only in fluorosulfuric acid near 0 °C and lower was a new signal observed for the protonated nitrosoamine molecule. Integration of the peaks has shown that only one proton is captured by the nitrosoamine. The following structure is suggested for the protonated nitrosoamine.

The n.m.r. spectra of fluorosulfuric acid solutions of N,N-diethylnitrosoamine and N-nitrosopiperidine also show separate signals for the captured proton.



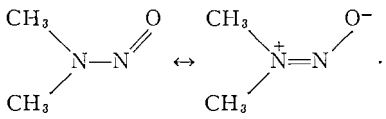
The n.m.r. spectrum of an equimolar solution of N,N-dimethylnitrosoamine, N,N-dimethylformamide, and trifluoroacetic acid in 2-nitropropane indicates that N,N-dimethylnitrosoamine is a weaker base.

INTRODUCTION

N,N-Dialkylnitrosamines with their four pairs of non-bonded electrons are potential Lewis bases. Recently Layne, Jaffe, and Zimmer (1, 2) have investigated the behavior of dialkylnitrosoamines and their interaction with acids in nonpolar and polar solvents by using ultraviolet spectroscopy. In a nonpolar solvent they found that two species are formed with trichloroacetic acid.

$$R_2N-NO\cdots HA \text{ and } HA\cdots R_2N-NO\cdots HA$$

The interaction is through hydrogen bonding and the structures suggested for the compounds are the following.



In aqueous sulfuric acid solution they observed a complicated series of changes rather than the expected simple change due to acid–base interaction. Assuming that some of the equilibria observed in more concentrated aqueous H_2SO_4 solution involved the formation of a

[1]*Contribution No. 135.*

conjugate acid, they attempted the isolation of these salts. By mixing pure dialkyl-N-nitrosoamines with concentrated sulfuric acid no precipitation of salts occurred. When the reaction was repeated with 70% aqueous perchloric acid, crystalline salts were obtained from di-*n*-heptyl-N-nitrosoamine and bis-(2-ethylhexyl)-N-nitrosoamine. The crystals slowly decompose above 30 °C and cannot be purified, but titration of the crude product suggested that their composition corresponded to a 1:1 molar adduct of the nitrosoamine and perchloric acid.

Looney, Phillips, and Reilly (3) have investigated the proton resonance spectra of nitrosoamines and have found that at room temperature the nuclear magnetic resonance (n.m.r.) spectrum of dimethylnitrosoamine consists of two sharp peaks of equal intensity which at higher temperature collapse into a singlet. The rotational barrier about the N—N bond in N,N-dimethylnitrosoamine is 23 kcal (considerably higher than in dimethylformamide ($\approx$ 7 kcal (4))), and probably arises largely from the partial double bond character of the N—N bond. Looney, Phillips, and Reilly conclude that the main contributors to the electronic structure of dimethylnitrosoamine are the two resonance forms:

The methyl protons occurring at higher fields are assigned as *cis* with respect to the oxygen and those at lower field as *trans* (5).

In the study reported here, the protonation of N,N-dimethylnitrosoamine was investigated in a number of protonating acids. N,N-diethylnitrosoamine and N-nitrosopiperidine were also examined in fluorosulfuric acid.

EXPERIMENTAL

All the nitrosoamines were obtained from Distillation Products and were used without further purification. Fluorosulfuric acid, obtained from Allied Chemical Corporation was distilled under vacuum before use; perchloric acid was obtained from Fisher Scientific Company.

Solutions of N-Nitroso Secondary Amines in Acids

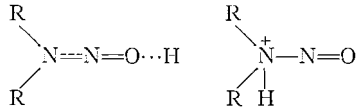
(*a*) The acid solutions of N,N-dimethylnitrosoamine were prepared by adding the nitrosoamine to the well-stirred cold acid. For fluorosulfuric acid solutions of N,N-dimethylnitrosoamine, N,N-diethylnitrosoamine, and N-nitrosopiperidine, the acid was cooled to −30 °C and the nitrosoamine added slowly with stirring. All solutions were 7.5 wt. % nitrosoamine.

(*b*) Solutions for the concentration study were prepared by diluting a 22% fluorosulfuric acid solution with fluorosulfuric acid to 18, 10, 7 and 1%.

(*c*) Solutions for investigating the basicity of N,N-dimethylnitrosoamine relative to N,N-dimethylformamide were prepared by adding CF_3COOH (0.1 mole) to solutions of N,N-dimethylnitrosoamine (0.1 mole) or N,N-dimethylformamide (0.1 mole) or both (0.1 mole each) in 80 g of 2-nitropropane.

Nuclear Magnetic Resonance

The n.m.r. spectra of the solutions were recorded on a Varian A-60 spectrometer. A capillary of tetramethylsilane (TMS) in the sample was used as an external reference. Low temperatures were obtained by the Varian Variable Temperature Controller Model C-6040; the temperature was determined by separation of the methyl and hydroxyl protons in methanol prior to and after the recording of the spectra.



RESULTS AND CONCLUSIONS

Solution of N,N-Dimethylnitrosoamine in Acids

The n.m.r. spectra of N,N-dimethylnitrosoamine in concentrated sulfuric acid, sulfuric acid monohydrate, trifluoroacetic acid, and 70% perchloric acid show that there is a strong interaction between the nitrosoamine and the acids, indicated by the shifts of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methyl proton signals. The results also indicate that the nitrosoamine retains its conjugated structure shown by the presence of two different methyl protons. This observation indicates that the protonation takes place on the oxygen atom of the nitroso group (I) and eliminates the possibility of the protonation on the nitrogen atom (II) of the dialkylamine group.

I II

No signal for the captured proton has been observed in any of these solutions. The relatively high freezing point of the acids prohibited using temperatures below −18°. The data obtained in these solutions is summarized in Table I.

TABLE I

N,N-Dimethylnitrosoamine in protonating acids*

Acid	Me position†	
	cis‡	*trans*‡
Neat	169	213
H_2SO_4	266	284
$H_2SO_4.H_2O$	256	276
CF_3COOH	215	239
$HClO_4$ (70%)	254	272

*These spectra were recorded at −18 °C, with the exception of H_2SO_4 which was determined at room temperature.

‡*cis* or *trans* to the oxygen atom (5).

Solutions of N,N-Dimethylnitrosoamine, N,N-Diethylnitrosoamine, and N-Nitrosopiperidine in Fluorosulfuric Acid

Fluorosulfuric acid is a convenient acid for protonation studies. It is a strong protonating acid with a low freezing point and is a good solvent for nitrosoamines. A solution of N,N-dimethylnitrosoamine in fluorosulfuric acid was investigated between 45 °C and −19 °C (Table II).

TABLE II

N,N-Dimethylnitrosoamine in fluorosulfuric acid: temperature effect

Temp. (°C)	Me position*		Proton*
	cis†	*trans*†	
45	253	269	—
Room temperature	248	264	—
10	243	259	850 broad
−5	242	259	854
−19	241	258	854

*Shifts are in c.p.s. relative to external tetramethylsilane.
†*cis* or *trans* to the oxygen atom (5).

At 10° there is a broad band appearing below the fluorosulfuric acid proton. At lower temperatures this becomes a well-resolved singlet (see Fig. 1). Integration of the peaks showed that only one proton was present in the lower peak. We have assigned this peak to the proton captured by the nitrosoamine molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

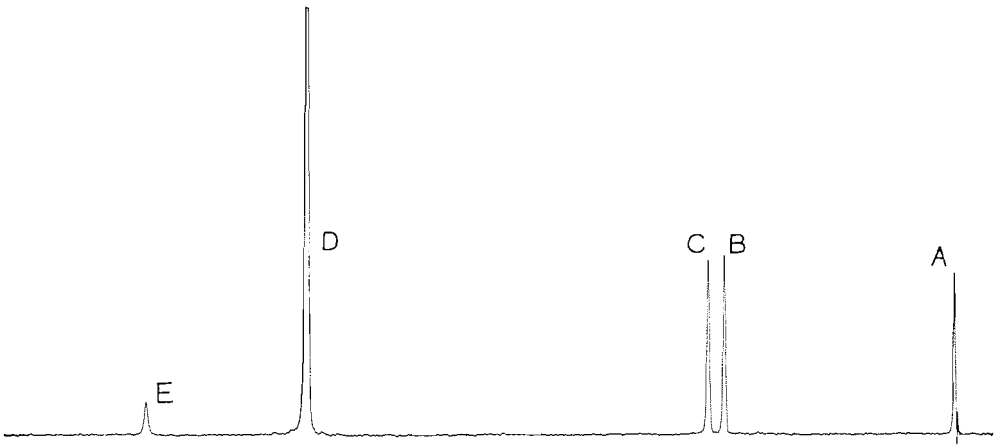

FIG. 1. N,N-Dimethylnitrosoamine in $HFSO_3$ at −19°. A, tetramethylsilane; B and C, methyls *cis* and *trans* with respect to the oxygen atom; D, $HFSO_3$; E, captured proton.

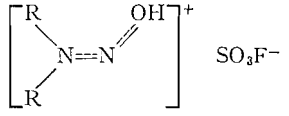
A solution of N,N-diethylnitrosoamine in fluorosulfuric acid at −5° showed a single peak at 837 c.p.s. The methyl peaks were centered at 100 and 106; the methylene at 269 and 276. The relative areas were 6 (combined methyl) and 4 (combined methylene). Also N-nitrosopiperidine in fluorosulfuric acid at −5° showed a singlet at 844 with area 1. The methylene peaks occurred at 134 (broad) and at 278 (multiplet) with relative areas of 6 and 4.

As expected the position of the single proton peak is concentration dependent whereas there is no appreciable change in the position of the methyl proton signals (Table III).

TABLE III



N,N-Dimethylnitrosoamine in fluorosulfuric acid at −17 °C: concentration effect

Concentration (% in $HFSO_3$)	Me position*		OH proton*
	cis†	*trans*†	
22	241	259	951
18	240	258	931
10	242	258	865
7	242	259	849
1	241	257	829

*Shifts are in c.p.s. relative to external tetramethylsilane.
†*cis* or *trans* to the oxygen atom (5).

In acid solution the N-nitrosoamine molecule with its four pairs of non-bonding electrons might be expected to interact with more than one molecule of acid. On the basis of the n.m.r. investigation of solutions of N,N-dialkylnitrosoamines in HSO_3F it seems clear that only one proton is captured by the nitrosoamine molecule. The spectra have also indicated that the site of protonation is on the oxygen atom of the molecule.

Formula III would be consistent with the n.m.r. results.

III

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The delocalization of the positive charge shown in the above structure would likely prevent further protonation of the molecule. Similar structures have been suggested for the adducts of N-nitroso secondary amines with alkyl carbonium ions (7) and boron trifluoride (8). Gillespie and Birchall (6) have found a fast exchange between the acid protons and the captured proton in fluorosulfuric acid solution of amides; a signal corresponding to the hydroxyl proton in the adduct separates only at −80 °C. The present study shows that in fluorosulfuric acid solutions of N-nitroso secondary amines the acid-OH proton exchange is relatively slow and the n.m.r. signal corresponding to the OH proton in the adducts already appears at slightly below room temperature.

Competitive Protonation of N,N-Dimethylnitrosoamine and N,N-Dimethylformamide

A yellow solution of N,N-dimethylnitrosoamine in 2-nitropropane gives a colorless solution when protonated with an equimolar quantity of trifluoroacetic acid. When N,N-dimethylformamide is added to the colorless solution, the yellow color returns suggesting that N,N-dimethylformamide is the stronger base. The competition of N,N-dimethylnitrosoamine and N,N-dimethylformamide for acid protons was also investigated by measuring the relative downfield shifts of their methyl proton signals (Table IV). A comparison of these shifts again indicates that N,N-dimethylnitrosoamine is a weaker base than N,N-dimethylformamide.

ORGANOPHOSPHORUS–URANYL COMPLEXES STUDIED BY NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY[1]

JANE L. BURDETT AND L. L. BURGER
Battelle Memorial Institute, Pacific Northwest Laboratory, Richland, Washington
Received July 27, 1965

ABSTRACT

The effect of extraction of uranyl nitrate on certain neutral organophosphorus compounds has been observed by nuclear magnetic resonance (n.m.r.) spectroscopy. Proton and phosphorus chemical shifts have been measured for the complexed and uncomplexed material. The effect of complexation on proton–proton and proton–phosphorus coupling constants has been noted.

INTRODUCTION

The metal-extracting ability of organophosphorus compounds has been investigated previously by many workers (1). Solvation complexes involving neutral organophosphorus compounds are formed with many salts, and of particular interest are the very strong complexes formed with uranyl nitrate and several other salts. These have the structure, $UO_2X_2(OP)_2$, where OP represents the phosphorus compound.

Numerous studies of the nuclear magnetic resonance of organophosphorus compounds have been published (2–8), but quantitative measurements of the effects of complex formation have not been reported. The present study has involved the effect of uranyl nitrate on the proton and phosphorus n.m.r. spectra of organophosphorus compounds. A series of compounds has been investigated, including phosphates, phosphonates, phosphinates, and phosphine oxides. Both the chemical shifts of ^1H and ^{31}P and the spin–spin coupling constants have been measured.

EXPERIMENTAL

Instrumental

Proton measurements have been made at 60.0 Mc on the Varian DP-60 and A-60 nuclear magnetic resonance spectrometers. Chemical shifts are reported within ±1 c.p.s. Phosphorus chemical shifts were measured at 24.3 Mc on the Varian DP-60 spectrometer and are reported within ±0.5 p.p.m. Proton–proton and proton–phosphorus coupling constants were measured on the Varian A-60 spectrometer and are reported to within ±0.1 c.p.s. All measurements have been made at room temperature (probe 33 ± 2 °C). Double resonance experiments have been performed using the Varian V-3521 integrator and inserting a 0.01 μF capacitor between the modulator output and the probe sweep coils, according to the technique developed by Johnson (9). Spectra were obtained using the first lower sideband.

Synthesis of Organophosphorus Compounds

Preparation of the compounds and their physical properties have been described elsewhere (10).

Preparation of Solutions

$UO(NO_3)_2.2H_2O$ was added to about 2 ml of the organophosphorus compound until the solution was saturated. The mixture was equilibrated with stirring for about 5 min and then was centrifuged. The supernatant was used to prepare carbon tetrachloride solutions of the complex. Concentrations of both complexed and uncomplexed material were 20% by volume.

RESULTS AND DISCUSSION

Chemical Shift Measurements

Proton chemical shifts are given in Table I for a series of organophosphorus compounds in c.p.s. from tetramethylsilane (TMS). Doubling of the β-alkoxy proton signal due to the

[1]*Work performed under contract AT(45-1)-1830 for the U.S. Atomic Energy Commission.*

presence of the phenyl ring in diisopropyl phenylphosphonate has been observed previously.

Representative proton spectra of the uncomplexed and complexed diethyl methylphosphonate are shown in Figs. 1*a* and 1*b*, respectively. Dissociation is negligible so that the spectrum does indeed represent that of the complex alone.

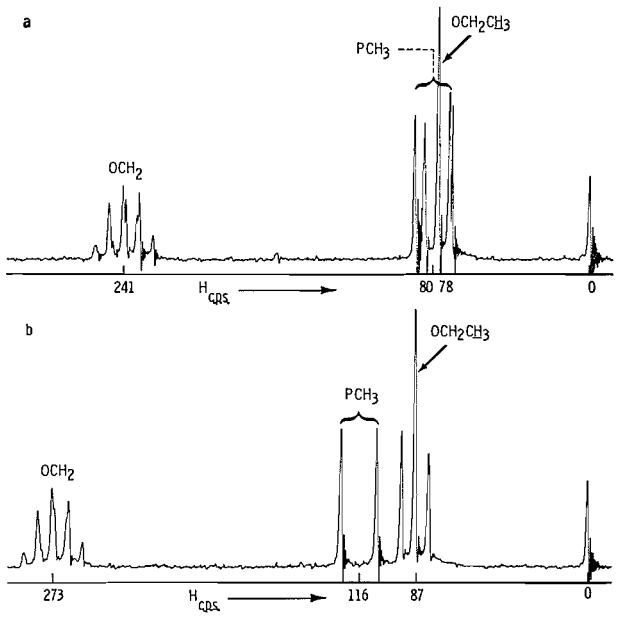

FIG. 1. (*a*) Proton magnetic resonance spectrum of diethyl methylphosphonate in carbon tetrachloride (20% v/v). (*b*) Proton magnetic resonance spectrum of diethyl methylphosphonate – uranyl nitrate complex in carbon tetrachloride (20% v/v).

The changes in chemical shift for protons in organophosphorus compounds on complexation with uranyl nitrate are seen in Table I. These changes are in the same order of magnitude as those observed in methylenediphosphonate complexes of uranyl nitrate (12). The greatest changes in chemical shift are observed for those protons closest to the phosphoryl group, i.e., the site of complexation. In every case the protons are effectively deshielded as a result of complexation. This is in agreement with the results of Ferraro for the α-protons of phosphoryl ligands in another uranyl complex, but not for the methyl protons which were more shielded in the complex (13). Presumably the structure of the complexed species is that of two bidentate nitrato and two phosphoryl groups as ligands in the plane perpendicular to the linear uranyl ion, similar to that for the trinitrato uranyl complex (14, 15). These paramagnetic shifts may be accounted for, at least in part, by the anisotropy of the uranyl group (12).

For the present series of compounds differences in chemical shifts *for protons* do not appear to be a sufficiently sensitive function of extracting ability. Apparently the major contribution to the chemical shift changes is the anisotropy of the uranyl group, and only a minor contribution is made by changes in the P—X bonds on complexation.

Phosphorus chemical shifts of carbon tetrachloride solutions are shown in Table II. As observed by earlier workers (3, 5), the substitution of stronger electron-donating groups on phosphorus results in less shielding of the quadruply-bound phosphorus nucleus. Recent

LCAO-MO calculations show that in quadruply connected phosphorus compounds the shielding of the phosphorus nucleus may be interpreted in terms of the polarity of the σ-bonds and the amount of π-character associated with the phosphorus (16, 17). An increase in ^{31}P shielding is accompanied by an increase in P=O bonding (16) or in π-electrons per phosphorus nucleus (17) in a series progressing from R_3PO to $(RO)_3PO$. The position of the phosphorus resonance of the dialkyl phenylphosphonates at higher applied fields than other phosphonates may also be explained in terms of an increase in the π-character of the P=O bond.

TABLE II

Phosphorus chemical shifts for organophosphorus compounds and their uranyl complexes*

Compound	Chemical shift (p.p.m.)		
	σ_{CCl_4}	$\sigma_{UO_2^{++},CCl_4}$	$\Delta\sigma$
$(CH_3CH_2O)_3PO$	−0.5	+0.2	+0.7
$[CH_3(CH_2)_3O]_2PO(OCH_3)$	+0.2	1.9	1.7

*Chemical shifts are given in p.p.m. and are relative to external 85% phosphoric acid. Positive values represent chemical shifts at lower applied field than the reference.

Molecular orbital calculations have not been attempted for the unsymmetrically substituted phosphoryl compounds in the present study because of their inherent complexity. Use of the results of Wagner (16) and of Letcher and Van Wazer (17) has been restricted to a qualitative interpretation because of uncertainties in the ZPZ′ angles, and because of the uncertain relative effect of ligands of differing electronegativities on the π-bonding. Both the ^{31}P shifts and the π-character associated with the phosphorus nucleus may be estimated roughly for unsymmetrical compounds, assuming that each substituent makes an additive contribution. Results obtained from these calculations based on the above assumptions give either increasing π-character of the P=O bond or greater π-bonds per phosphorus in the order of increased phosphorus shielding.

Of primary importance in complexation is the unshared electron pair on the phosphoryl oxygen which is available for covalent bonding. Phosphine oxide, which forms the strongest complex, presumably has the most negative oxygen of the compounds studied (16, 18, 19). As a second order effect, complexation results in phosphorus chemical shifts downfield from those of the free ligand. This paramagnetic shift may be seen to increase with increasing extracting ability of the organophosphorus compound to a maximum in the phosphine oxide. Undoubtedly changes in the nature of the P=O bond with complexation are reflected in this shift. Also the phosphorus nucleus is in the paramagnetic region of the uranyl ion.

Infrared Measurements

Infrared P=O stretching frequencies for several complexed and uncomplexed organophosphorus compounds are given in Table III. The P=O stretching frequency gives a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

linear correlation with extracting ability for these compounds (19). Thus a decrease in the stretching frequency is observed as extracting ability increases, i.e. phosphate < phosphonate < phosphinate < phosphine oxide. However, the change in stretching frequency on complexation, $\Delta_{P=O}$, does not correlate well with extracting ability (see Table III).

Spin–Spin Coupling Constants

Several proton–proton and proton–phosphorus coupling constants have been measured in the organophosphorus compounds (see Table IV). The very large J(P—H) coupling in the alkyl hydrogenphosphonates supports the structure in which hydrogen is directly attached to the phosphorus (2, 4, 5, 7). The alkoxy $^{31}P—^{1}H$ coupling forms an interesting series. Axtmann, Shuler, and Eberly (20) indicated an increase in J(P—O—C—H) coupling in trialkyl phosphates with increasing electron-withdrawing character of the alkyl group. In general the data in Table IV show that this picture may be extended to include phosphonates and phosphinates. Furthermore, comparison of J(P—O—C—H) in dimethyl methylphosphonate and diethyl methylphosphonate shows that the electron-withdrawing ability of an alkyl group affects the coupling in the alkoxy group of these compounds in the same manner.

Relative signs of coupling constants have been assigned in general from the literature (21–25). However, the relative sign of J(P—C—H) differs among several compounds (21, 23, 26–28). To determine its sign in the present organophosphorus compounds, proton double resonance experiments have been performed on diethyl ethylphosphonate and on the uranyl nitrate complex of this compound. In Fig. 2*a* is shown the normal proton spectrum for the diethyl ethylphosphonate – uranyl complex which has a doublet quartet (PCH_2) and a doublet triplet (PCH_2CH_3) whose lower triplet is masked by the ethoxy methyl protons. In Fig. 2*b* the upper triplet at 81 c.p.s. has been irradiated and, as a result, the lower quartet has collapsed, which indicates that J(P—C—H) and J(P—C—C—H) have unlike signs (29). Thus J(P—C—H) has a negative sign because J(P—C—C—H) has a positive sign (23). This negative sign for J(P—C—H) agrees with the conclusion of Duval and Koide (30, 31) that Hund coupling does make an important contribution to phosphorus–proton coupling.

The change in $^{31}P—^{1}H$ coupling constants on formation of uranyl complexes, although relatively small in most cases, is in the direction of increased coupling. In general the largest increase occurs for those protons closest to the phosphorus atom. Thus J(P—H) in

the dialkyl hydrogenphosphonates increases by as much as 61 c.p.s. There appears to be no marked trend relating the change in coupling constant to complexing ability of the parent compound, although J(P—O—C—H) increases from 0.4 c.p.s. in $(RO)_3PO$ to 0.7 c.p.s. in $(RO)_2PO(R')$. No change in proton–proton coupling constants is observed with complexation. The observed increases in coupling constant with complexation are in part a consequence of changes in the hybridization of the P—X bond orbitals. The effective withdrawal of electrons from the P=O bond is presumably accompanied by an increase in the amount of s-character in the P—X bonds.

ACKNOWLEDGMENTS

We wish to acknowledge assistance from the following people: Mrs. Thelma W. Lawell for infrared measurements, Mr. Earl C. Martin for synthesis of compounds, Mr. Bernard L. Nist for use of the Varian A-60 spectrometer, Mr. Ross Pitcher for obtaining 100 Mc spectra, Dr. E. Duval for a preprint of long-range spin–spin interaction between nuclei and saturated compounds, Dr. J. R. Van Wazer for a preprint of the theoretical interpretation of phosphorus chemical shifts, and Dr. E. L. Wagner for stimulating discussions.

KINETIC STUDIES OF PROTON TRANSFER FROM PHENOLS TO TRINITROBENZYL ANION

J. A. Blake, M. J. B. Evans, and K. E. Russell
Department of Chemistry, Queen's University, Kingston, Ontario
Received August 18, 1965

ABSTRACT

The rates of reaction of various phenols with the 2,4,6-trinitrobenzyl anion in the solvent ethanol have been determined by a spectrophotometric method. The rate constants at −40 °C are related to the dissociation constants of the phenols in water at 25 °C and the value of α in the Brönsted relation is 0.84 ± 0.07; α drops to 0.44 ± 0.05 if the results for the substituted acetic acids (1) are included. The rate constants for the phenols are also correlated by the Hammett relationship, the ρ value at −40 °C being 1.82 ± 0.2. The activation energies range from 9.4 to 10.9 kcal/mole.

The rate of reaction of trinitrobenzyl anion with 3-methylphenol at −30 °C is reduced by a factor of 12 if the phenol is deuterated at the OH group and the solvent is deuteroethanol. The large isotope effect confirms that the rate-determining step involves proton transfer from the OH group of the phenol. Substitution of lithium or potassium cations for the sodium cation does not affect the rate constant at −10 °C.

In the reaction with 3-methylphenol, a measurable concentration of trinitrobenzyl anion remains at equilibrium and the equilibrium constant for the reaction is 1.3 ± 0.2 at 25 °C. The heat and entropy changes are approximately −6.5 kcal/mole and −21 e.u./mole respectively.

INTRODUCTION

The broad objective of this work is to determine the factors which influence the rates of proton transfer from weak acids to carbanion bases. Caldin and Long have shown (1) that the purple anion produced by the reaction of sodium ethoxide with 2,4,6-trinitrotoluene (TNT) is probably the 2,4,6-trinitrobenzyl ion (TNT^-) and that the rates of reaction of this anion with substituted acetic acids can be determined by conventional means at temperatures of the order of −70 °C. An extension of this work to phenols is desirable because it is possible to study by appropriate choice of substituted phenols the influence of inductive, resonance, and steric effects on the rate of proton transfer. In this paper the influence of inductive effects is examined by determining the rates of reaction of the TNT^- ion with meta-substituted phenols.

EXPERIMENTAL

Apparatus

The absorbance of the TNT^- ion was determined using a modified Fisher electrophotomer with a 650 mμ filter. The glass cells were similar in design to those used by Caldin and Trickett (2). The volumes of the main cell and side chamber were 60 ml and 10 ml respectively and the corresponding values for the smaller cell used in the isotope work were 10 ml and 2 ml respectively. Each glass cell was sealed into the thermostat by means of a silicone rubber gasket which was held in place by a ring of high density polythene. Condensation on the windows was prevented by a stream of nitrogen produced by evaporation of liquid nitrogen; the temperature of the nitrogen was controlled by passing it over a heater in a glass flask.

The cell was sealed into a small brass tank surrounded by styrofoam. One side of the tank was removable to facilitate exchange of cells and the seal was made by an indium gasket. The bath liquid, methanol, was cooled using a tube of dry ice and acetone and the rate of cooling was adjusted by varying the extent to which the tube was immersed in the methanol. The temperature was maintained to better than ±0.1 °C using a 20 W heater controlled by a Yellow Springs Instrument Company thermistor unit. The temperature of the bath was determined by means of a multi-junction copper–constantan thermocouple calibrated against a platinum resistance thermometer.

Equilibria between phenols and ethoxide ion in ethanol solution were studied using a Beckmann DU spectrophotometer, the quartz cells being maintained at −10 °C by passing cooled ethanol through the modified cell holder (3).

Procedure

A solution of approximately 0.008 *N* sodium ethoxide in absolute ethanol was prepared and standardized in an atmosphere of nitrogen against 0.1 *N* hydrochloric acid using a pH meter. Forty-four milliliters of this ethoxide solution was placed in the main chamber of the cell and 5 ml of a solution of phenol in ethanol in the side chamber. When temperature equilibrium was attained, the electrophotometer was adjusted for 100% transmission. One milliliter of a 0.003 *M* solution of TNT in an ethanol–toluene mixture was added to the ethoxide solution and the solution stirred until the absorbance reached a maximum. For reaction temperatures below −30 °C it was more convenient to mix the TNT and ethoxide solutions outside the cell and cool the mixture before placing it in the cell; at −60 °C it was necessary to wait about half an hour before equilibrium was reached.

The phenol solution was forced into the reaction cell using a rubber bulb attached to the side chamber and complete mixing effected by forcing some of the reaction mixture back and forth between the two chambers. Readings of absorbance could be obtained within 20 s of mixing, and half-lives were generally in the range 2–30 min. Rates of disappearance of TNT^- anion were determined for a range of phenol concentrations at appropriate temperatures in the −10 °C to −60 °C region; for any one phenol the temperature range was 20 to 30 °C. Density corrections were made using the data of Smyth and Stoops (4) for pure ethanol.

The reaction of the TNT^- anion with deuterated 3-methylphenol was studied with deuteroethanol as solvent. The 3-methylphenol was dissolved in 1 ml deuteroethanol to obtain the deuterated phenol and this solution was mixed with 7 ml TNT^- anion solution in the small cell.

Lithium and potassium ethoxide solutions (0.008 *M*) were prepared by dissolving the metals in absolute ethanol and were standardized against hydrochloric acid. The reactions of 3-methylphenol with TNT^- anion prepared using these ethoxides were studied at −30 °C, −20 °C, and −10 °C.

Equilibria between sodium ethoxide and phenol, 3-methylphenol, and 4-chlorophenol were investigated at −10 °C and 25 °C. Sodium ethoxide was added to the phenol solution in an atmosphere of nitrogen and the degree of conversion of phenol to phenoxide determined using absorbance measurements at 290 mμ (305 mμ for 4-chlorophenol). The initial concentration of phenol was close to 0.003 *M* and the cell thickness was 1 mm.

The equilibrium constant of the reaction between TNT^- and 3-methylphenol was obtained by measurement of the concentrations of TNT^- at equilibrium with various concentrations of 3-methylphenol. The solutions initially contained TNT and 0.008 *M* sodium ethoxide, and 3-methylphenol was added until its equilibrium concentration was in the range 0.02–0.07 *M*. Under these conditions the reaction of 3-methylphenol with ethoxide ion goes virtually to completion so that the equilibrium concentration of 3-methylphenoxide ion is close to 0.008 *M* in each experiment. The maximum concentration of TNT^- is 6×10^{-5} *M* and variations in its value do not significantly affect the concentrations of phenol and phenoxide. The equilibrium concentration of TNT^- was estimated from the absorbance of the solution. The extinction coefficient of TNT^- was determined from separate measurements of absorbances of solutions containing 0.008 *M* sodium ethoxide and various amounts of added TNT.

RESULTS AND DISCUSSION

Caldin and Long (1) have shown that the reaction of ethoxide ion with TNT probably proceeds according to the equation

$$[1] \qquad TNT + OEt^- \rightleftharpoons TNT^- + HOEt$$

and that the proton is transferred from the methyl group of the TNT to the ethoxide ion. Equilibrium is rapidly reached at room temperature and at the low ethoxide concentrations used in this work the side reaction to give a brown complex (1) proceeds to a negligible extent. On addition of phenol almost all the ethoxide is removed by reaction [2]

$$[2] \qquad XOH + OEt^- \rightleftharpoons HOEt + XO^-$$

and the excess phenol reacts with the TNT^- ion by reaction [3].

$$[3] \qquad TNT^- + XOH \rightleftharpoons TNT + XO^-$$

The rate of disappearance of the TNT^- ion is given by

$$[4] \qquad -\frac{d[TNT^-]}{dt} = (k_3[XOH] + k_{-1}[EtOH] + k_f)[TNT^-] - (k_1[OEt^-] + k_{-3}[XO^-])[TNT]$$

where k_1 and k_3 are rate constants for the forward reactions of [1] and [3], k_{-1} and k_{-3} are rate constants for the corresponding reverse reactions and k_f is included to take account

of a very slow fade of the purple anion in the absence of added phenol. The concentration of TNT is given by its initial concentration less the TNT^- concentration; solutions of TNT^- obey Beer's law at the concentrations used. Thus upon integration, eq. [5] is obtained

$$[5] \quad \ln (D - D_e) = -(k_3[XOH] + k_1[OEt^-] + k_{-1}[EtOH] + k_{-3}[XO^-] + k_f)t + b$$

where D, D_e are the absorbances of the reacting solution at time t and at equilibrium and b is a constant. Fig. 1 shows a typical plot of ln D vs. time, t, for the reaction of 3-acetylphenol with TNT^- at -40 °C; the absorbance at equilibrium, D_e, is too small to be measured with this phenol. The slopes, s, of such plots are used to evaluate k_3.

$$[6] \quad s = -(k_3[XOH] + k_1[OEt^-] + k_{-1}[EtOH] + k_{-3}[XO^-] + k_f)$$

At a given temperature with a given ethoxide concentration, the last four terms of eq. [6] are either constant or small compared with $k_3[XOH]$ provided that reaction [2] proceeds almost to completion. Thus a graph of s vs. [XOH] gives a straight line for each phenol at constant temperature and the rate constant k_3 is determined from the slope of the graph. The second and fourth terms of eq. [6] vary appreciably when low concentrations of 3-methylphenol are used at -10 °C but the error in k_3 from this cause is small.

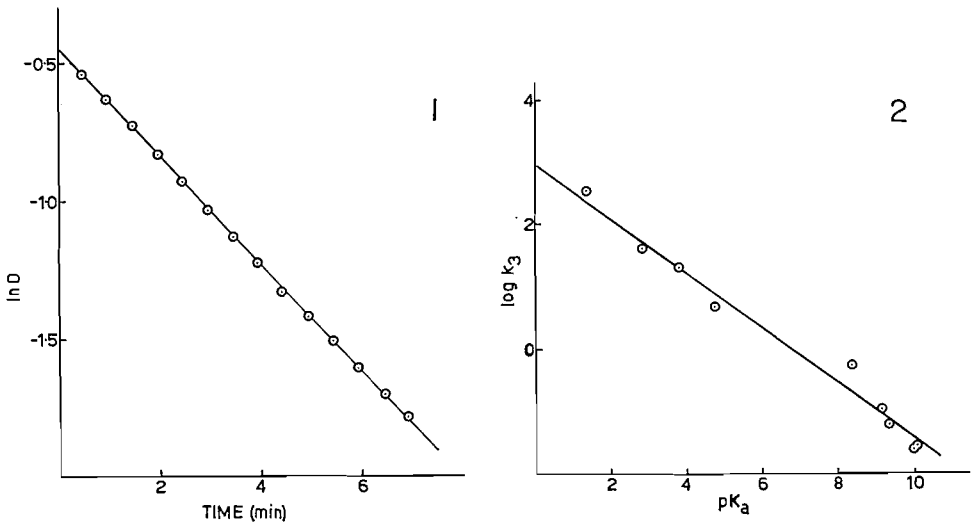

FIG. 1. Dependence of ln D on time for the reaction of TNT^- with 3-acetylphenol at -40 °C.
FIG. 2. Dependence of log k_3 (-40 °C) on pK_a in water.

The rate of reaction of TNT^- ion with deuterated 3-methylphenol in deuteroethanol is considerably less than that with 3-methylphenol in ethanol. The ratio of the rate constants k_3^H/k_3^D is 12 ± 2 at -30 °C. The rate constant may be affected by the change in solvent but the reduction in rate on deuteration is so great that it must be mainly due to a primary isotope effect. This confirms that the rate-determining step of the discharge of color of TNT^- ion by 3-methylphenol, and presumably other acids, is the proton transfer process of eq. [3]. The base strengths of the 3-methylphenoxide and TNT^- ions are not widely different and the transition state should be fairly symmetrical, so that a relatively large value of k_3^H/k_3^D is to be expected (5).

The kinetic results for phenol, 3-methyl-, 3-acetyl-, 3-cyano-, 3-nitro-, and 4-chlorophenol are summarized in Table I. The uncertainty in k_3 at -40 °C is estimated to be $\pm 8\%$, and the activation energies are probably correct to ± 0.8 kcal/mole; the resultant uncertainty in the values of log A at -40 °C is ± 0.9. The rate constants k_3 at -40 °C can be correlated by the Bronsted relation

$$[7] \qquad \log k_3 = \log G + \alpha \log K_a$$

where G and α are constants and K_a is the dissociation constant of the acid. Fig. 2 is a plot of log k_3 against pK_a in water at 25 °C for substituted phenols and acetic acids (1) showing that α is 0.44 ± 0.05 for acids whose pK_a values range from 1.4 to 10.1. This compares with a value of 0.54 observed by Bell and Higginson (6) in their study of the dehydration of acetaldehyde hydrate catalyzed by a wide variety of carboxylic acids and phenols. The rate constants of the meta-substituted phenols alone show a much more marked dependence on acid dissociation constant and the α value derived over the limited pK_a range 8.3–10.1 is 0.84 ± 0.07. The relatively high value of α may be due to solvation effects in the reactions of TNT^- with meta-substituted phenols. The rate constants for the more weakly acidic phenols are lower because of significantly lower A factors, rather than higher activation energies. This suggests that the formation of the activated complex in the reaction of TNT with phenol, for example, involves a larger increase in solvation than in the reaction with 3-nitrophenol.

TABLE I

Kinetic data for the reactions of phenols with TNT^- ion

Phenol	k_3 at -40 °C (l mole^{-1} s^{-1})	Activation energy (kcal/mole)	A factor (l mole^{-1} s^{-1})
Phenol	0.025	9.4	1.6×10^7
3-Methylphenol	0.029	9.8	4.4×10^7
3-Acetylphenol	0.108	10.1	3.2×10^8
3-Cyanophenol	0.30	10.9	4.9×10^9
3-Nitrophenol	0.55	10.9	9.1×10^9
4-Chlorophenol	0.066	10.0	1.6×10^8

The meta-substituted phenols were studied in an attempt to isolate inductive contributions of substituents to the reactivities of the phenols in this proton transfer reaction. The results are complicated by solvation effects but rate constants at -40 °C obey the Hammett relationship and a ρ value of 1.82 ± 0.2 is obtained. Only one para-substituted phenol, 4-chlorophenol, has been used as donor and the rate constant indicates that the resonance contribution to the reactivity of this phenol is small.

The effect on the rate of reaction of TNT^- with 3-methylphenol of varying the alkali metal cation from sodium to lithium or potassium was small. The rate constants with lithium, sodium, and potassium cations at -10 °C were 0.33, 0.33, and 0.32 l mole^{-1} s^{-1} respectively; although the rate constant for the reaction involving the lithium cation was somewhat greater than that for the reaction involving the potassium cation at -30 °C, the difference was not outside experimental error. Reactions of carbanions in solvents of fairly low dielectric constant, e.g. the addition of styrene to polystyrene anions in tetrahydrofuran (7), are frequently sensitive to the nature of the alkali metal counterion, and the lack of sensitivity in the reaction of TNT^- with 3-methylphenol in alcohol solution probably indicates that interaction between the TNT^- and the alkali metal cation is weak.

Equilibria in Proton-Transfer Reactions

Reaction [3] is reversible and the rate constant for the reverse reaction is dependent upon the base strength of the anion. Acetate ion (1) and 3-nitrophenoxide ion are relatively weak bases and reactions of TNT^- with their conjugate acids appear to proceed to completion. With 3-methylphenoxide ion, however, the rate of the reverse reaction is significant compared with that of the forward reaction. If the slow fade reaction which occurs even in the absence of added phenol is ignored, the equilibrium constant of reaction [3] can be derived from absorbance measurements at equilibrium of reaction mixtures containing 4 to 10×10^{-2} M excess 3-methylphenol. Equilibrium constants, K_3, at 25 °C and −10 °C are 1.3 ± 0.2 and 5.6 ± 1 respectively; the heat of reaction [3] is estimated to be −6.5 kcal/mole and the entropy change is approximately −21 entropy units (e.u.)/mole. K_3 can also be estimated from the equilibrium constants K_1 and K_2 of reactions [1] and [2], as $K_3 = K_2/K_1$. Interpolation of Caldin and Long's data (1) gives values of K_1 of 2 040 and 850 l/mole at 25° and −10 °C respectively; the concentration of ethanol is absorbed into the equilibrium constants K_1 and K_2. K_2, determined from absorbance measurements of mixtures of 3-methylphenol and ethoxide ion, was found to be 1 700 and 2 500 l/mole at 25 °C and −10 °C so that the derived K_3 values at these temperatures are 0.8 and 3.0. K_2 was determined for ionic concentrations an order of magnitude smaller than those used in the direct determination of K_3 and no account has been taken of activity coefficients in this work. In addition, it was observed that even with purified ethanol ethoxide ion at a concentration of 10^{-4} M was required to be added to the phenol solution before any appreciable conversion to phenoxide occurred. In these circumstances the agreement between the two sets of values of K_3 is satisfactory.

For the reaction of ethoxide ion with TNT the equilibrium constant at −10 °C is 850 l/mole and the heat and entropy of reaction are 3.6 kcal/mole and 27.2 e.u./mole (1) if the standard state of ethanol is taken as the pure liquid. The reaction of 3-methylphenoxide ion with TNT has an equilibrium constant at −10 °C of 0.18 and a heat and entropy of reaction of 6.5 kcal/mole and 21 e.u./mole. The lower equilibrium constant and higher heat of reaction reflect the weaker basicity of the 3-methylphenoxide ion as compared with ethoxide. In both reactions there appears to be considerable desolvation as the ethoxide or phenoxide ion in which the charge is relatively localized is converted to the TNT^- ion in which it is delocalized (1). The rate constant for the reaction of 3-methylphenoxide ion with TNT in ethanol solution can be estimated using the relationship $K_3 = k_3/k_{-3}$. At −10 °C k_{-3} is 0.06 ± 0.02 l $mole^{-1}$ s^{-1} and the activation energy is 16.3 ± 1.7 kcal/mole; the corresponding figures for the reaction of the more basic ethoxide ion with TNT are 3.8 l $mole^{-1}$ s^{-1} and 10.0 kcal/mole (1).

The equilibrium constant K_3 for the reaction of 3-methylphenol with TNT^- is relatively low and the dependence of the equilibrium concentration of TNT^- on phenol concentration is measurable. It was not possible to make comparable studies of the reaction of other phenols because the equilibrium concentration of TNT^- could not be determined with sufficient accuracy. K_3 for the reaction of phenol with TNT^- was estimated from the ratio K_2/K_1 to be 2.3 at 25 °C and the value for 4-chlorophenol is higher. These results suggest that equilibrium studies of reactions between TNT^- and dialkyl and trialkyl phenols would be fruitful, particularly at temperatures of the order of 25 °C. The occurrence of high equilibrium concentrations of ethoxide ion in reactions of TNT^- with such phenols will, however, complicate the interpretation of the kinetics of such reactions and it may be difficult to determine the exact magnitude of steric effects. Accurate quantitative studies of reactions with ortho-substituted phenols would be of considerable interest because the

proton transfer would be sterically hindered and might be susceptible to quantum mechanical tunnelling.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. F. Caldin for helpful discussions. They are grateful to the National Research Council for a grant and to Queen's University for a Milton Hersey fellowship (J.A.B.). The indium was a gift from Consolidated Mining and Smelting Co. Ltd.

SUR LES SPECTRES INFRAROUGES DES PHTALOCYANINES

H. F. SHURVELL[1] ET L. PINZUTI
Laboratoire de Physique P.C.B.1. et
Centre Technique de Spectrographie Infrarouge, Faculté des Sciences, Marseille, France

Reçu le 18 août 1965

RÉSUMÉ

Nous avons enrégistré les spectres infrarouges de la phtalocyanine sans métal, la phtalocyanine de cuivre (chlorée et non chlorée) et trois nouvaux derivés métalliques de la phtalocyanine: MoPc, Na_2Pc et AlOH—Pc (Pc = $C_{32}H_{16}N_8$). Nous proposons des interprétations pour la plupart des bandes des spectres infrarouges des phtalocyanines étudiées.

ABSTRACT

Infrared spectra of metal-free phthalocyanine, chlorinated and unchlorinated copper phthalocyanines, and three new metal derivatives of phthalocyanine: MoPc, Na_2Pc, and AlOH—Pc (Pc = $C_{32}H_{16}N_8$), have been recorded. Assignments have been suggested for many of the peaks in the infrared spectra of the phthalocyanines.

INTRODUCTION

Le spectre infrarouge de la phtalocyanine (H_2Pc*), Fig. 1*a*, a été étudié pour la première fois par Cannon et Sutherland (1). Par la suite, deux articles relatifs aux spectres infra-

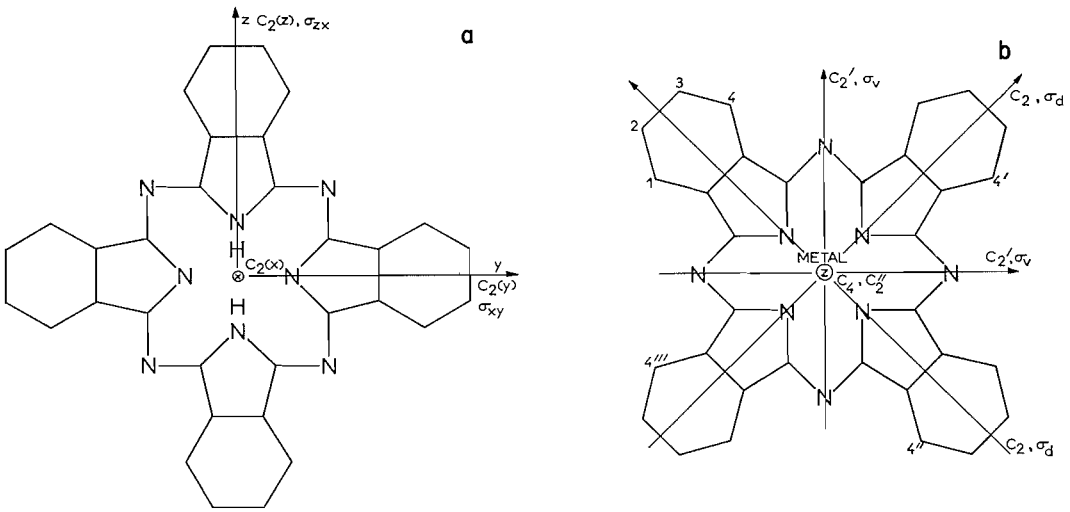

FIG. 1. Structure et symétrie des phtalocyanines: (*a*) H_2Pc (D_{2h}); (*b*) Metal–Pc (D_{4h}).

rouges des deux formes α et β de CuPc et d'autres phtalocyanines ont été publiés (2, 3). Terenin et Sidorov (4) ont étudié les effets produits par l'adsorption de vapeurs sur les spectres infrarouges de H_2Pc et de plusieurs dérivés métalliques, plus récemment Sidorov et Kotlyar (5) ont publié les spectres d'échantillons sublimés des deux variétés α et β

[1]*Adresse actuelle*: *Department of Chemistry, Queen's University, Kingston, Ontario.*
* *Le symbole Pc sera souvent utilisé ici pour représenter le noyau de la phthalocyanine*: $C_{32}H_{16}N_8$.

de H_2Pc (normale et partiellement *N*-deutériée) et des dérivés métalliques suivants: MgPc, ZnPc, CuPc, FePc, CoPc, NiPc et un dérivé de l'argent de composition non spécifiée. Ces auteurs ont trouvé plusieurs différences dans les spectres des formes α et β. Ils ont aussi donné quelques attributions. Très récemment les spectres infrarouges de plusieurs phtalocyanines de l'étain et du plomb ont été publiés (6).

Le présent article est une étude des spectres infrarouges de trois nouvelles phtalocyanines: MoPc, Na_2Pc et AlOH—Pc. Les spectres de toute une série de composés: H_2Pc, CuPc, 4,4′,4″,4‴-tétrachloro-CuPc et hexadécachloro-CuPc ont également été enregistrés. La comparaison de ces spectres entre eux et avec les spectres de molécules contenant des arrangements similaires d'atomes (benzènes ortho-disubstitués et pyrroles) peut permettre, avons nous pensé, de donner des attributions vibrationelles qualitatives.

Le Tableau I donne un résumé des changements attendus dans le spectre de H_2Pc quand les deux atomes d'hydrogène du groupement imine sont remplacés par un atome métallique puis quand, en plus, les hydrogènes des noyaux benzéniques sont substitués par des atomes de chlore.

TABLEAU I

Comportement prévu pour le spectre infrarouge de H_2Pc

Vibrations de H_2Pc	Changements du spectre attendus		
	Métal–Pc	Métal–Pc tétrachlorée	Métal–Pc hexadécachlorée
Vibrations des groupes N—H	Disparition	—	—
Vibrations des groupes C—H	Peu de changement	Quelques changements	Disparition
Vibrations des noyaux pyrroliques	Quelques changements dépendant du métal	Pas de changement	Pas de changement
Vibrations des noyaux benzéniques	Peu de changement	Peu de changement	Peu de changement

PARTIE EXPÉRIMENTALE

Les phtalocyanines étudiées ont été fournies par la S.A. Française des Matières Colorantes. L'échantillon d'hexadécachloro CuPc contient en réalité 15.5 atomes de chlore par molécule. Les fournisseurs ont signalé que les produits sont des produits techniques donc pas absolument purs.

Les spectres infrarouges (Figs. 2, 3 et 4) ont été obtenus avec un spectrophotomètre, Perkin-Elmer, modèle 125, à deux réseaux (300 et 60 traits/mm) et avant-prisme de KBr. L'étalonnage de l'instrument a été réalisé par l'enregistrement de spectres gazeux de: H_2O, NH_3 et CH_4, dont les fréquences sont connues avec une grande précision (7). Nous estimons que les fréquences figurant sur le Tableau IV ont une précision de ± 1.5 cm^{-1} dans la région de 3 000 cm^{-1} et une précision de ± 0.5 cm^{-1} dans les régions de plus grande longueur d'onde.

STRUCTURE ET SYMÉTRIE

Robertson (8) a étudié en détail le cristal et la structure moléculaire de H_2Pc (Fig. 1*a*). Plus tard Robertson et Woodward (9) ont publié la structure de NiPc (Fig. 1*b*). Ils ont montré que la structure du cycle de la phtalocyanine est peu perturbée par la substitution des deux hydrogènes iminiques par un atome métallique, à l'exception d'un glissement vers l'intérieur des quatre atomes d'azote pyrroliques (9).

Les symétries des phtalocyanines étudiées dans ce travail sont discutées dans les paragraphes qui suivent. Les nombres de vibrations normales de chaque type de symétrie appartenant aux différents groupes ponctuels sont donnés dans les Tableaux II (H_2Pc) et III (dérivés métalliques). Pour ces calculs nous avons utilisé les tableaux de Herzberg (10) et le choix des axes et plans de symétrie est conforme aux recommandations du "Joint Commission for Spectroscopy" (11).

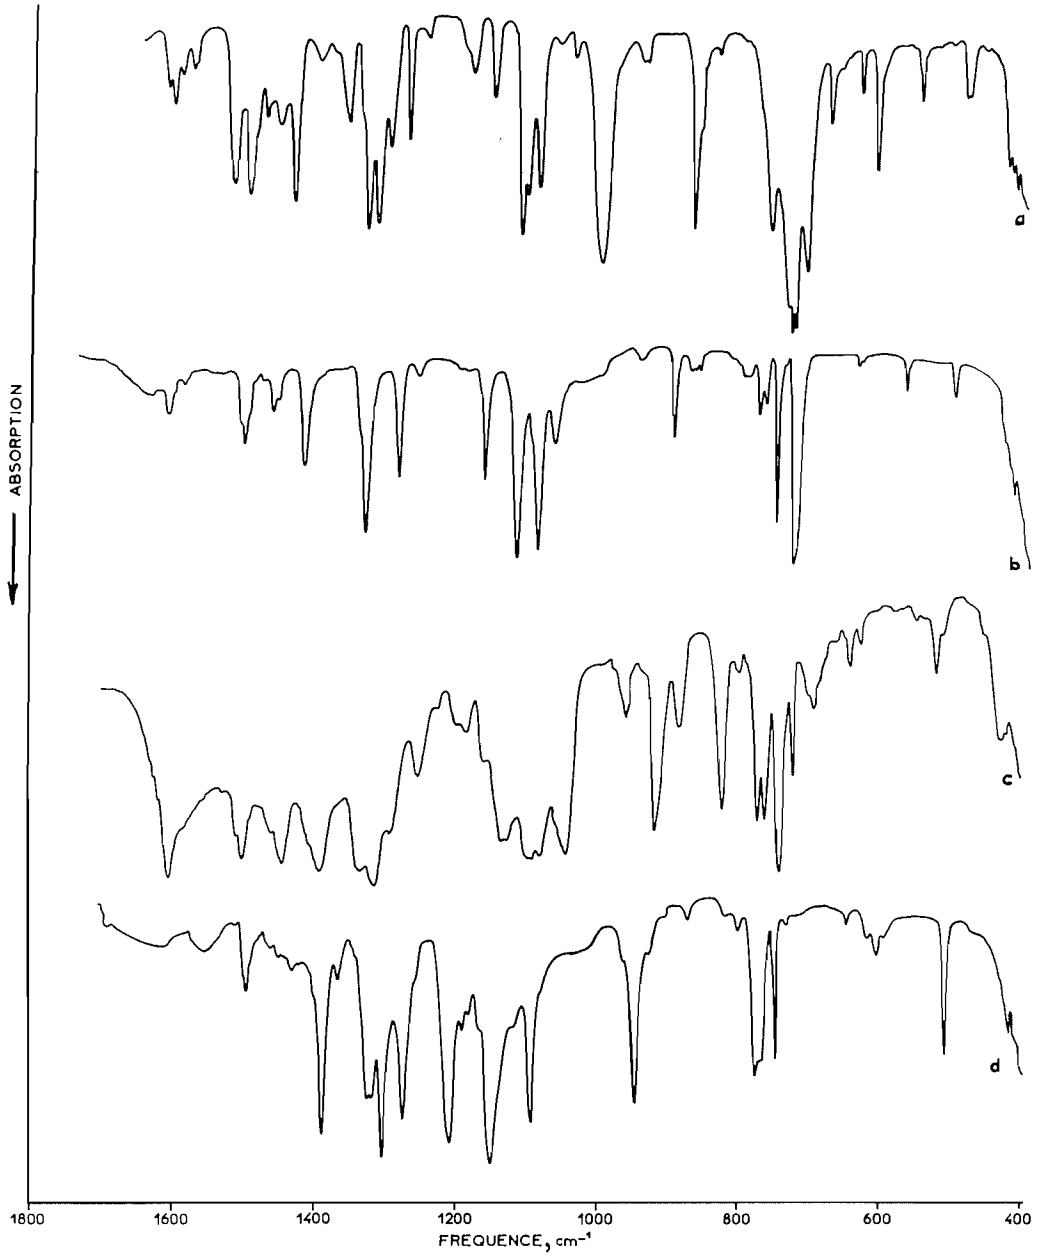

FIG. 2. Spectres infrarouges des phtalocyanines: (*a*) H_2Pc (0.5 mg); (*b*) CuPc (1 mg); (*c*) CuPc-4,4′,4″, 4‴-tétrachlorée (3 mg); (*d*) CuPc-hexadécachlorée (1 mg).

1. H_2Pc

La symétrie du noyau de phtalocyanine est sans doute voisine de D_{4h} (8) mais la présence de deux hydrogènes pyrroliques abaisse cette symétrie. Parmi les chercheurs précédents, plusieurs semblent avoir tacitement supposé que les hydrogènes pyrroliques sont dans le plan du noyau Pc sur un axe binaire (groupe ponctuel D_{2h}, Fig. 1*a*). Cependant, Linstead (12) et Lyons (13) ont indiqué que les hydrogènes pyrroliques pourraient être

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

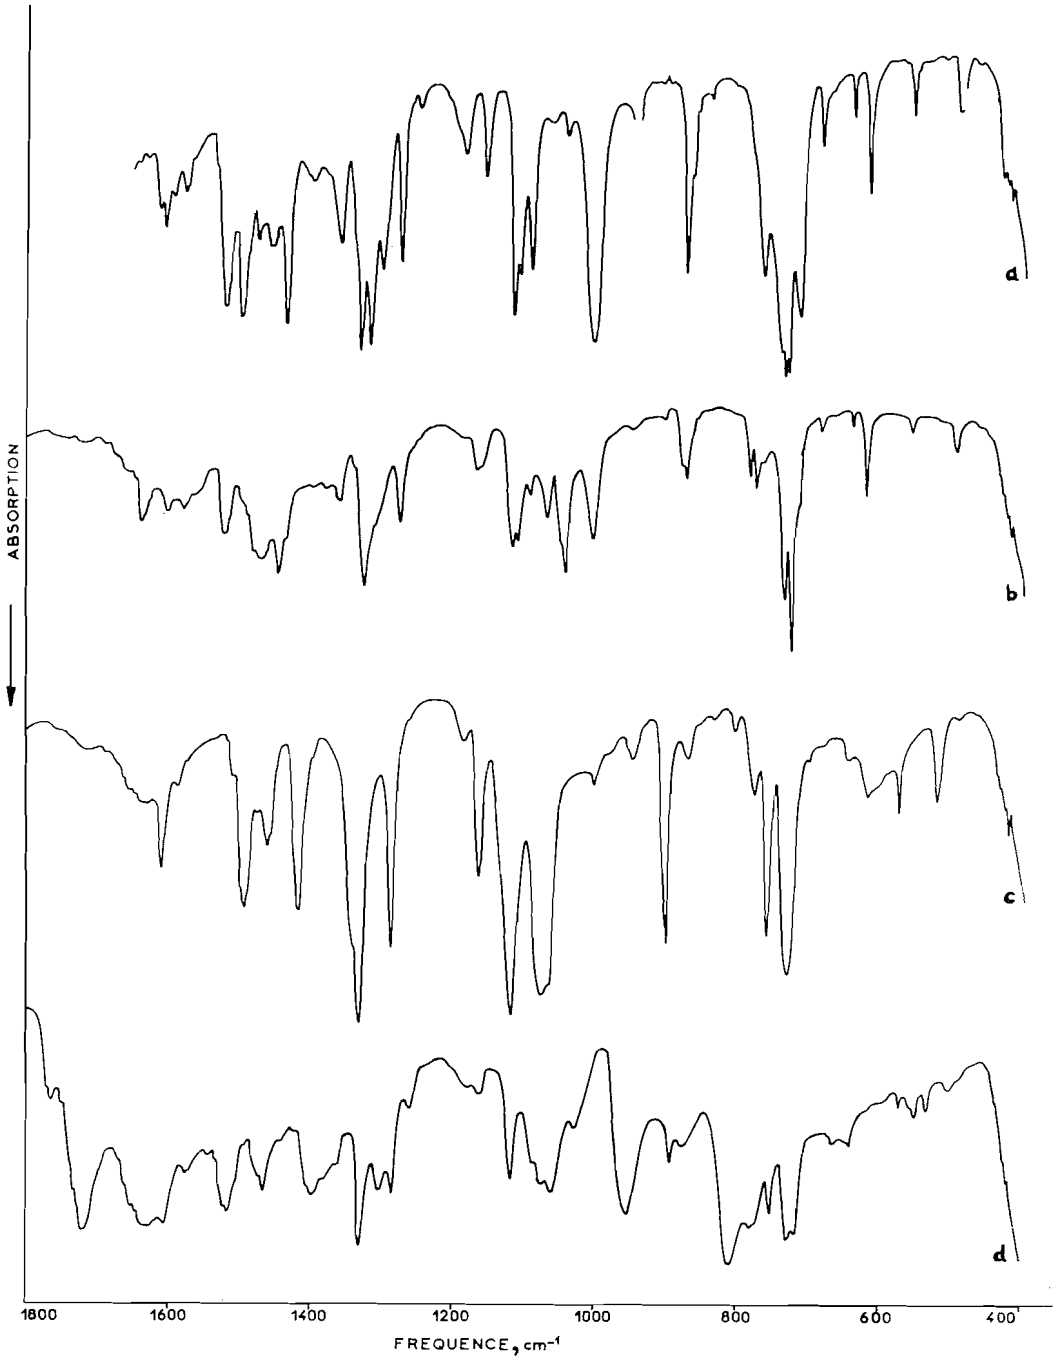

FIG. 3. Spectres infrarouges des phtalocyanines: (*a*) H_2Pc (0.5 mg); (*b*) Na_2Pc (1 mg); (*c*) AlOH—Pc (0.2 mg); (*d*) MoPc (1 mg).

extérieurs au plan du noyau Pc. De plus, en utilisant les valeurs fournies par Pauling (14) pour les longueurs des liaisons et des rayons de van der Waals, on s'aperçoit que les sphères de van de Waals des hydrogènes se recouvrent considérablement dans l'hypothèse d'une structure plane.

Si les atomes d'hydrogène en question sont situés de part et d'autre du noyau Pc dans un plan perpendiculaire au cycle et passant par les deux atomes d'azote pyrroliques, le groupe ponctuel est alors C_{2h}. Si les atomes d'hydrogène ne sont pas sur un tel plan, le groupe ponctuel est C_i; le seul élément de symétrie qui subsiste alors étant un centre de symétrie.

Le Tableau II dénombre les modes normaux de vibration de H_2Pc, actifs en infrarouge, (y compris les vibrations N—H), selon que le groupe est D_{2h}, C_{2h} ou C_i. On notera que, pour chacun de ces trois groupes, trois vibrations N—H, actives en infrarouge, sont prévues ce qui, malheureusement, ne permet pas de choisir entre les trois modèles à l'aide des spectres infrarouges.

2. CuPc, hexadécachloro-CuPc et MoPc

La symétrie de ces molécules est approximativement D_{4h}* (Fig. 1*b*). Le Tableau III donne l'analyse des vibrations normales, nous y avons inclus la molécule hypothétique Pc, sans rien au centre, pour montrer que les trois vibrations *N*-métal associées à l'atome central sont actives en infrarouge (un mode A_{2u} et un couple dégénéré E_u). La symétrie de MoPc est, elle aussi, probablement voisine de D_{4h}.

3. 4,4′,4″,4‴-Tétrachloro-CuPc

Quand on remplace par des atomes de chlore les hydrogènes en positions 4,4′,4″,4‴ (Fig. 1*b*) de CuPc, la symétrie est abaissée à C_{4h}.

4. AlOH—Pc

Nous suggérons, pour cette molécule, une symétrie C_{4v}, l'atome d'aluminium étant au centre du noyau Pc et le groupement O—H hors du plan du cycle.

5. Na_2Pc

Les atomes de sodium sont vraisemblablement situés de part et d'autre du noyau Pc de la même façon que dans le modèle C_{2h} de H_2Pc. Une similitude entre les spectres de Na_2Pc et H_2Pc impliquerait donc une similitude de structure entre ces deux molécules.

Formes α et β

Selon Kendall (3) les pigments commerciaux des phtalocyanines se présentent sous la forme β. Cependant, il y a dans la littérature une certaine confusion de notation entre les formes α et β. Si on compare entre les spectres infrarouges de CuPc produits par Kendall (3) et par Sidorov (5) on s'aperçoit que la form α de Kendall correspond à la forme β de Sidorov et vice versa.

Afin de savoir avec certitude quelle forme nous avons étudiée, nous avons enregistré les spectres des deux formes α et β de CuPc fournies par un autre producteur (Badische Anilin & Soda Fabrik A.G.). Ces spectres ont montré que notre échantillon était la variété β de Kendall (donc la forme α de Sidorov). En fait les spectres des deux variétés diffèrent peu et les attributions suggérées plus loin sont valables pour les deux variétés de H_2Pc et des dérivés métalliques.

La nature de la différence entre les formes α et β de H_2Pc et des dérivés métalliques n'est pas connue: seule la variété α a été étudiée aux rayons X (8, 9).† Kendall (3) a suggéré que la difference entre les spectres infrarouges, enregistrés pour les deux variétés α et β de CuPc, pourrait être due à un arrangement différent des molécules (régulier ou non), dans le cristal.

**Robertson et Woodward (9) trouvent, pour* NiPc, *de légères distorsions par rapport à une vraie symétrie D_{4h}.*
†Les composés étudiés par Robertson n'étaient pas des pigments commerciaux (forme β) mais des cristaux formés pas sublimation sous faible pression.

RÉSULTATS ET DISCUSSION

Les Figs. 2, 3 et 4 reproduisent les spectres. Le Tableau IV fournit les fréquences observées pour H_2Pc et les dérivés métalliques ainsi que les attributions que nous proposons.

Dans la discussion qui suit, nous avons parfois utilisé les abréviations suivantes; ν pour une vibration de valence, β pour une vibration C—H de déformation dans le plan, γ pour une vibration C—H de déformation hors du plan et ϕ pour une déformation du cycle benzénique exterieure du plan.

Allure générale des spectres

Le spectre dû au noyau Pc dans H_2Pc (en faisant abstraction des vibrations N—H) est assez voisin de celui de CuPc (comparer les Figs. 2*a* et 2*b*). Ceci indique que la symétrie du noyau de H_2Pc diffère peu de D_{4h}, puisque selon les Tableaux II et III, les règles de sélection permettent beaucoup plus de vibrations actives en infrarouge pour les groupes de plus basse symétrie. Ceci était d'alleurs prévisible puisque seuls les atomes d'hydrogène centraux ne respectent pas la symétrie D_{4h} et déterminent la symétrie exacte de la molécule.

L'éclatement des vibrations dégénérées E_u, ainsi que l'apparition de bandes supplémentaires interdits par les règles de sélection pour le groupe D_{4h}, permettent une évaluation de l'écart par rapport à cette symétrie D_{4h}. En fait, dans le spectre de H_2Pc plusieurs bandes d'absorption sont éclatées en doublets et on observe plusieurs maximums faibles qui ne se trouvent pas dans le spectre de CuPc.

Mises à part quelques différences d'intensité et de fréquences évidentes, le spectre de Na_2Pc ressemble beaucoup à celui de H_2Pc (voir Figs. 3 et 4).* La structure de Na_2Pc est donc vraisemblablement très voisine de celle de H_2Pc. Ceci confirme l'hypothèse d'une structure C_{2h} pour H_2Pc puisque les autres modèles sont moins raisonnables pour Na_2Pc. Malheureusement aucune étude de la structure de Na_2Pc n'a été publiée à ce jour.

Les fréquences du spectre de AlOH—Pc correspondent bien à celles de CuPc. Cependant, du fait de la différence de concentration, les intensités des bandes correspondantes sont entre 5 et 20 fois plus grandes dans le spectre de AlOH—Pc. Apparemment la présence du groupement O—H influe considérablement la variation de moment dipolaire mais n'affecte guère la symétrie du noyau Pc.

Le spectre de AlOH—Pc présente une bande floue vers 3 420 cm^{-1}, due sans doute à une vibration de valence ν O—H. La largeur et la position de cette bande, environ 200 cm^{-1} au dessous de la zone habituelle des vibrations ν O—H (15), indique une forte liaison hydrogène, qui est très probablement intermoléculaire.

En raison de l'excessive perte d'énergie infrarouge en traversant l'échantillon, le spectre de MoPc n'est pas aussi bien résolu que ceux des autres phtalocyanines. Il ressemble néanmoins grossièrement à celui de CuPc. Une forte bande, observée à 1 723 cm^{-1} ne se retrouve dans le spectre d'aucune des autres phtalocyanines étudiées. La seule interprétation que nous pouvons en donner est qu'elle est due à une impureté.

Attributions

On peut considérer que la molécule H_2Pc est construite à partir de quatre noyaux iso-indoles réunis par quatre atomes d'azote. Les noyaux iso-indoles eux mêmes sont composés d'un cycle benzénique et d'un cycle pyrrole. C'est pourquoi des travaux antérieurs sur les benzènes ortho-disubstitués et les pyrroles polysubstitués sont utiles pour attribuer les bandes observées dans le spectre de H_2Pc.

On peut supposer que les vibrations des cycles pyrroliques sont fortement couplées.

**Les bandes 3 290 cm^{-1} et 1 008 cm^{-1} dans le spectre de* Na_2Pc *sont dues à* H_2Pc *présent sous forme d'impureté.*

TABLEAU IV

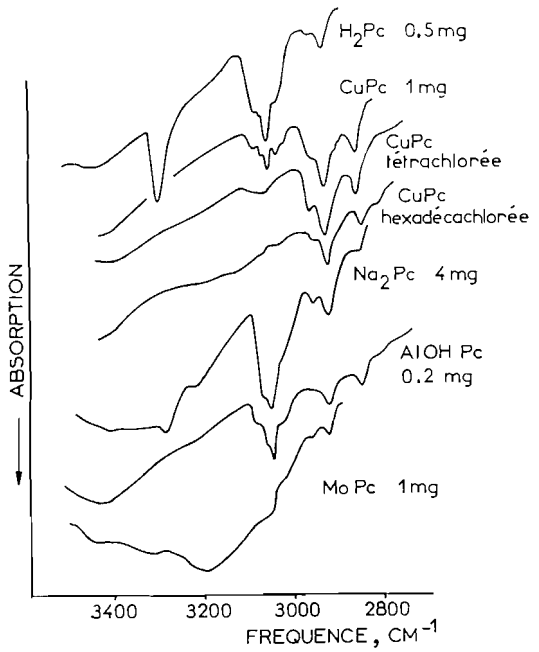

FIG. 4. Spectres infrarouges de quelques phtalocyanines entre 2 800 et 3 400 cm^{-1}.

D'autre part les vibrations du cycle benzénique seraient peu modifiées et les interactions entre les vibrations C—H des différents cycles benzéniques négligeables. Il nous est apparu que cette hypothèse est raisonnable, parce que les vibrations ν C—H ont été trouvées entre 3 000 et 3 100 cm^{-1}, les vibrations β C—H se trouvent entre 1 000 et 1 300 cm^{-1}, les vibrations γ C—H se trouvent entre 700 et 1 000 cm^{-1} et les vibrations ν C—C du cycle benzénique ont été trouvées entre 1 300 et 1 600 cm^{-1}. C'est à dire dans les régions ou on les observe pour un noyau benzénique substitué isolé.

Les spectres des molécules chlorées CuPc se sont révélés très utiles pour identifier les vibrations β C—H et γ C—H. Plusieurs vibrations propres au cycle benzénique ont été déterminées avec assez de certitude; mais il a été difficile d'identifier les vibrations provenant des liaisons C—N et du cycle pyrrolique.

(a) Vibrations N—H

Dans le spectre de H_2Pc, la bande forte à 3 290 cm^{-1} est sans doute une vibration de valence ν N—H. Cette vibration se manifeste vers 3 400 cm^{-1} dans les composés de l'indole (16) et dans la même région pour les pyrroles (17, 18). Cet abaissement de fréquence de l'ordre de 100 à 150 cm^{-1} par rapport aux indoles et aux pyrroles indique une forte liaison hydrogène dans H_2Pc. Mason (19) a trouvé un résultat analogue pour les porphines où les azotes et hydrogènes centraux sont arrangès de façon similaire. Cet auteur a également conclu que les liaisons hydrogènes étaient presque totalement intramoléculaire car les fréquences ν N—H étaient à peine changées quand on passe de l'état solide à la solution diluée dans CCl_4. Malheureusement aucun des solvants organiques connus ne dissout H_2Pc, ce qui nous a empêchés d'effectuer une expérience similaire.

On trouve les fréquences de déformation N—H à 716 et 1 006 cm^{-1}. Ces bandes étaient absentes des spectres de toutes les autres phtalocyanines étudiées (exception faite pour le spectre de Na_2Pc où on observe une bande à 1 008 cm^{-1}, mais cette bande est certainement due à H_2Pc présent sous forme d'impureté.

A la suite d'une étude sur des produits partiellement *N*-deutéries, Sidorov et Kotlyar (5) ont attribué deux bandes très faibles à 1 250 et 1 539 cm^{-1} à des vibrations de déformation N—H. Ces chercheurs ont suggéré qu'une bande à 753 cm^{-1} qui apparait seulement dans le spectre de la variété β est aussi liée aux fréquences de déformation des groupes imine. Mais d'autrepart, les recherches de Mason (19), montrent pour la porphine, que les déformations des groupes N—H ont lieu à 719 et 970 cm^{-1}; ceci vient donc à l'appui de notre attribution. Dans tous les cas, la théorie des groupes prévoit seulement deux fréquences de déformation N—H.

Il faut noter que la vibration N—H, 1 006 cm^{-1} de H_2Pc est inférieure de 140 cm^{-1} à la vibration correspondante du pyrrole (20). Ceci pourrait s'expliquer par l'existence d'une liaison hydrogène. Cependant, habituellement, les liaisons hydrogène augmentent plutôt la fréquence des vibrations de déformation (15). Pour la porphine, Mason (19) a expliqué cette anomalie en calculant le chevauchement des orbitales hybrides sp des quatre atomes d'azote pyrroliques avec les orbitales 1s d'un hydrogène. Ce calcul montre que la déformation de N—H dans le plan, devrait apparaître à une fréquence plus basse dans la porphine que dans le pyrrole. En fait ces calcules ne s'appliquent pas à H_2Pc puisque, pour les raisons indiquées plus haut, nous avons préféré adopter un modèle où l'arrangement des atomes d'hydrogène pyrroliques ne soit pas plan, avec une hybridation sp^3 des azotes iminiques. On peut alors imaginer une autre explication selon laquelle la vibration de déformation N—H serait couplée avec une vibration du cycle pyrrolique.

(b) Vibrations C—H

Pour les benzènes ortho-disubstitués on attend quatre vibrations de valence ν C—H entre 3 000 et 3 100 cm^{-1} (21, 22). Le spectre de la phtalocyanine H_2Pc présent quatre bandes d'absorption: 3 030, 3 050, 3 064 et 3 074 cm^{-1} qui correspondent pour CuPc aux fréquences: 3 030, 3 050, 3 059 et 3 082 cm^{-1}. Dans les spectres des autres phtalocyanines ces quatre pics ne sont pas résolus. Enfin, comme on pouvait le prévoir, la bande ν C—H est plus faible pour CuPc tétrachlorée et absente du spectre de CuPc hexadécachlorée.

D'après les spectres d'un certain nombre de benzènes ortho-disubstitués (21, 22, 23), on attend quatre vibrations β C—H dans les régions: 1 025 – 1 040 cm^{-1}, 1 070 – 1 130 cm^{-1}, 1 130 – 1 160 cm^{-1} et 1 250 – 1 290 cm^{-1}. Dans le spectre de H_2Pc on observe des bandes à 1 068 et 1 252 cm^{-1} ainsi qu'un doublet à 1 111, 1 120 cm^{-1} qui correspond aux sommets: 1 069, 1 121 et 1 260 cm^{-1} de CuPc. On observe des fréquences similaires pour les autres molécules métal–Pc sauf pour CuPc hexadécachlorée. Il est normal d'attribuer ces fréquences à des vibrations β C—H. Quant à la quatrième vibration β C—H de H_2Pc, elle est vraisemblablement mais avec moins de certitude située vers 1 045 cm^{-1}. Elle n'a pas été trouvée dans le spectre de CuPc mais ceci est peut être dû au fait que cette molécule a une plus haute symétrie. On observe une fréquence correspondante pour CuPc tétrachlorée mais cette absorption disparait de nouveau pour CuPc hexadécachlorée.

Le doublet 731, 736 cm^{-1} ainsi que la bande à 875 cm^{-1} du spectre de H_2Pc ont été attribués à des vibrations γ C—H. Pour CuPc il leur correspond les fréquences 730 et 871 cm^{-1}. Ces bandes sont absentes du spectre de CuPc hexadécachlorée.

Sidorov et Kotlyar (5) attribuent l'absorption à 716 cm^{-1} de H_2Pc à des déformations hors du plan des liaisons C—H des cycles benzéniques (γ C—H). Ils pensent que cette vibration donne lieu à une bande entre 719 et 739 cm^{-1} dans les spectres des phtalocyanines métalliques et n'existerait pas pour la CuPc chlorée. Ils affirment de plus que le doublet 731, 736 cm^{-1} du spectre de H_2Pc correspond aux bandes voisines de 755 cm^{-1} dans les spectres des phtalocyanines métalliques. Nous pensons qu'il parait beaucoup plus raisonnable de supposer que le doublet 731, 736 cm^{-1} correspond aux absorptions des métal–Pc

du massif ou de la bande situées entre 719 et 739 cm^{-1}. La bande à 716 cm^{-1} n'a d'équivalent ni dans les spectres des métal–Pc ni dans ceux des CuPc chlorées; cette bande serait donc due à une vibration du groupement N—H et on peut alors sûrement attribuer le doublet 731, 736 cm^{-1} à des vibrations γ C—H.

(c) Vibrations de l'ossature du cycle benzénique

Les trois modes ν C—C du benzène (1 594 cm^{-1} E_{2g}, 1 479 cm^{-1} E_{1u} et 1 309 cm^{-1} B_{2u}) (24) donnent, pour les benzènes ortho-disubstitués, cinq vibrations qui dépendent peu de la nature des substituants (21, 22, 23). La vibration dégénérée E_{2g} se sépare généralement en deux vibrations de fréquences voisines de 1 600 cm^{-1}. La vibration E_{1u} se sépare également, en donnant deux vibrations, plus espacées: entre 1 440 et 1 520 cm^{-1}; enfin le mode B_{2u} est généralement observé à une fréquence inférieure: entre 1 260 et 1 310 cm^{-1}. On observe dans les spectres de tous les composés étudiés des absorptions dans les régions 1 276 – 1 293 cm^{-1}, 1 391 – 1 438 cm^{-1}, 1 485 – 1 505 cm^{-1} et 1 605 – 1 616 cm^{-1}; nous suggérons d'admettre qu'elles proviennent de vibrations ν C—C du cycle benzénique.

On observe pour le benzène deux vibrations de déformation extérieures au plan du cycle ϕ C—C à 404 cm^{-1} (E_{2u}) et 707 cm^{-1} (B_{2g}) (24). La vibration 707 cm^{-1} ainsi qu'une des composantes du mode dégénéré 404 cm^{-1} sont assez peu sensibles aux substituants du cycle benzénique; on les trouve respectivement dans les régions 680–710 cm^{-1} et 400–450 cm^{-1} pour un grand nombre de benzènes mono- et disubstitués (21–23, 25). On observe dans les spectres de toutes les phtalocyanines étudiées, entre 420 et 421 cm^{-1}, une absorption qui correspond à la vibration 404 cm^{-1} du benzène. La bande 686 cm^{-1} du spectre de H_2Pc est peut être due à un autre mode ϕ C—C. On observe des absorptions correspondantes à 687 cm^{-1} pour Na_2Pc et 692 cm^{-1} pour CuPc-tétrachlorée, mais aucune bande analogue n'est observée dans les spectres de MoPc, CuPc et AlOH—Pc; encore une fois ceci est peut être dû à la plus grande symétrie de ces molécules.

(d) Autres bandes d'absorption caracteristiques

Plusieurs bandes apparaissant à des fréquences plus ou moins constantes dans les spectres de toutes les phtalocyanines étudiées n'ont pas été interprétées dans l'analyse précédente. Certains d'entre elles donnent lieu à des suites dans les spectres des divers composés étudiés (Tableau IV) on les observe dans le spectre de la H_2Pc à 642, 767, 1 095 et 1 160 cm^{-1}, et sous forme de doublets à 490, 494 cm^{-1} et 1 320, 1335 cm^{-1}. Nous pensons que ces absorptions sont dues à un couplage des vibrations de la partie centrale du cycle Pc considéré soit comme quatre cycles pyrroles reliés entre eux par quatre atomes d'azote soit comme un système continu de seize membres conjugués. Dans le premier cas, la bande 1 095 cm^{-1} pourrait être reliée à une vibration du cycle pyrrole trouvée à 1 144 cm^{-1} pour le pyrrole (20) et à 1 130 – 1 140 cm^{-1} pour les pyrroles substitués (17).

CONCLUSION

Il est évidemment hors de question d'interpréter complètement l'ensemble des fréquences de vibration d'une aussi grosse molécule que la phtalocyanine. Cependant, du fait du haut degré de symétrie de cette molécule particulière et des analogies de structure avec des molécules similaires dont les spectres sont assez bien connus, nous avons pu proposer des attributions pour de nombreuses bandes du spectre infrarouge.

Nos interprétations pour les vibrations N—H diffèrent de celles de Sidorov et Kotlyar (5) mais s'accordent avec celles de Mason pour les porphines (19). Les molécules CuPc chlorées se sont révélés utiles pour l'interprétation des vibrations C—H. Cependant, une étude des CuPc deutériées confirmerait mieux notre interprétation.

For personal use only.

Nous avons publié les spectres de trois nouvelles phtalocyanines: MoPc, Na_2Pc et AlOH—Pc. Un travail ultèrieur sur AlOH—Pc devrait servir à rechercher le rôle joué par les liaisons hydrogènes dans la structure de cette molécule. Il existe peut être une liaison hydrogène OH . . . N intermoléculaire entre molécules adjacentes qui aurait pu être étudiée à partir des spectres de solutions (15) mais ceci présente des difficultés experimentales considérables dues à l'insolubilité des phtalocyanines. Le composé sodé Na_2Pc est également intéressant du point de vue structural puisque, comme nous l'avons suggéré, les atomes de sodium de Na_2Pc et d'hydrogène de H_2Pc pourraient être disposés de façon similaire. Une étude aux rayons X de la structure de Na_2Pc, permettant de localiser avec précision les positions des atomes de sodium, serait très utile.

REMERCIEMENTS

Nous voudrions exprimer notre gratitude à Messieurs les Professeurs J. Chouteau et P. Pesteil qui ont mis leurs laboratoires à notre disposition. Nous remercions aussi Monsieur le Professeur A. Julg pour de fructueuses discussions. Nous sommes également reconnaissants aux S. A. Française des Matières Colorantes et Badische Anilin Soda Fabrik A.G. qui nous ont fourni gracieusement les échantillons étudiés. Nous exprimons enfin notre reconnaissance au Gouvernement français et au C.N.R.S. qui nous ont apporté leur soutien financier.

PREPARATION OF METAL NITRIDES BY THE EXPLODING WIRE TECHNIQUE[1]

MICHEAL J. JONCICH, JOE W. VAUGHN, AND BYRON F. KNUTSEN[2]
Michael Faraday Laboratories, Northern Illinois University, DeKalb, Illinois

Received July 6, 1965

ABSTRACT

An exploratory research program investigated the possibility of preparing metal nitrides by electrically exploding metal wires and foils in an atmsophere of (*a*) nitrogen, (*b*) ammonia, or (*c*) nitrogen and hydrogen. The explosions were carried out in an enclosed stainless steel pressure vessel. In a few cases, the wire was exploded while covered with liquid nitrogen in a stainless steel container maintained at liquid nitrogen temperatures.

The samples were analyzed using a modified Kjeldahl method for nitrogen. Greater yields of nitrides were obtained when a greater charge was given the oil-filled condensers used to supply the current, and when the pressure of gas surrounding the wire was increased. Yields as high as 50% were obtained in some cases. Clearly defined nitrides were obtained with magnesium, titanium, zirconium, tantalum, zinc, and aluminium. The metals iron, rhodium, platinum, copper, and cadmium did not appear to form stable nitrides under the experimental conditions.

A brief discussion of a mechanism by which a wire may explode is given.

INTRODUCTION

The exploding wire phenomenon (e.w.p.) is currently receiving considerable attention, particularly with regard to properties of the exploding wire, mechanism of the explosion process, and applications. The phenomenon was discovered in 1774 when Nairne (1) caused a wire to explode in his demonstration that the current in all parts of a series circuit is the same. Since shock waves may be produced during e.w.p. if the wire is confined, the exploding wire has been used recently to study shock waves in air and water. Chemical applications include the production of mirrors on the inside of vessels (2), the synthesis of inorganic compounds (3, 4), and the initiation of photochemical reactions (5, 6).

In 1964, Joncich and Reu (3) reported the preparation of sulfides, carbides, and iodides of aluminium and magnesium by electrically exploding a wire coated with the appropriate non-metal. Also, Mahieux (4) reported the formation of $PtXeF_6$ prepared by exploding platinum in an atmosphere of xenon and fluorine, although there appears to be some question as to the actual nature of the compound produced since no analysis for platinum was carried out. It was the purpose of this research to prepare various metallic nitrides by exploding the metal with an electrical discharge. The metal, in the form of wire or foil, was in an atmosphere containing nitrogen gas, ammonia, liquid nitrogen, or a mixture of hydrogen and nitrogen. There are several advantages in this method of chemical synthesis. (1) Preparation of very hygroscopic compounds can be accomplished since the system can be kept dry. (2) One of the reactants (nitrogen) can be removed easily from the products by evaporation. (3) Since considerable activation energy is available in e.w.p., it may be possible to synthesize new compounds, which under normal laboratory conditions cannot be prepared. (4) The equipment required is relatively simple.

For personal use only.

In addition to these four advantages, there are two aspects of this technique which are unique to e.w.p. (1) The reaction is completed within microseconds. (2) The reaction is rapidly quenched. This is particularly true when the explosion is carried out under liquid nitrogen.

The discussion of the results of the experimental work will cover three aspects: (1) the mechanism by which wires explode when subjected to a large electrical discharge, (2) the equipment used in e.w.p. technique, and (3) the results of the preparation of a number of different nitrides.

Figure 1, which shows an ideal current–time oscilloscope tracing, will be referred to in the discussion of the different stages in the mechanism of the exploding wire. Of course, the actual tracing will depend on inductance of the circuit, pressure of gas surrounding the wire, size of the wire, switch characteristics, charging voltage, spacing of the electrodes, etc. A more detailed description of the mechanism can be found in articles by Chace (7) and others (8).

At time t_0 the circuit is closed and current commences to flow through the wire. The maximum initial current surge may be as great as 250 000 A depending on the system used. The time duration of the surge is less than 100 μs. If a heavy metallic bar were placed in the position of the wire, the discharge curve would then have the shape of a damped sine curve. As the current increases, the wire is heated very rapidly and is converted to a liquid at its normal melting point. The temperature of the molten wire increases towards its boiling point; however, since there is no interfacial surface between the molten wire and the walls of the container, the metal does not boil at its normal boiling point. Because of the large current flowing through the conductor, the wire is surrounded by a very strong magnetic field. The effect of this field is to increase the normal boiling temperature of the molten wire. The wire becomes superheated until it finally flash boils at time t_1. The boiling is accompanied by a loud noise and a flash of light. The wire in the vapor state continues to expand while the current drops to a relatively low value, but remains appreciable. The current drops because the wire, in the vapor state, has a very high resistance. It has been found that a current of 50 – 500 A flows through the vaporized wire during the "dark" or "dwell" period beginning at t_2. As the distance between the vaporized metal atoms continues to increase, ionization occurs, followed by a "restrike" or second surge of current at t_3. The duration of the "restrike" is a function of the velocity of the metallic vapors.

The duration of the "dwell" period depends on the pressure of the atmosphere surrounding the wire (9) as well as on many other factors. Pressures below 6 mm Hg may cause the "dwell" time to decrease or disappear. In this case it is likely that a great deal of the current is bypassing the wire and is arcing through the air gap. Since there is a plasma state associated with the wire during its transitions in the vapor state, it would seem advisable to have the current pass through the wire in one initial surge. Although the mechanism given above may not agree with all other mechanisms, many workers in the field consider it to be fairly accurate.

EXPERIMENTAL

The diagram of the electrical circuit used in the experimental work is given in Fig. 3. The energy source for the synthesis was provided by ten 31-μF capacitors (C) connected in parallel. The total energy stored on the capacitors was 12 000 J when the capacitors were charged to 9 000 V by the d.-c. power supply (P). Prior to the explosion, switch (S) was connected to resistor (R) to protect the power supply. Switch (S′) was an air gap switch designed in our laboratory and used to discharge the condensers through the wire (W).

It is important that the condensers, switch, and connecting leads have as low an inductance as possible. The lower the inductance of the system, the more rapidly the current will rise when the switch is closed.

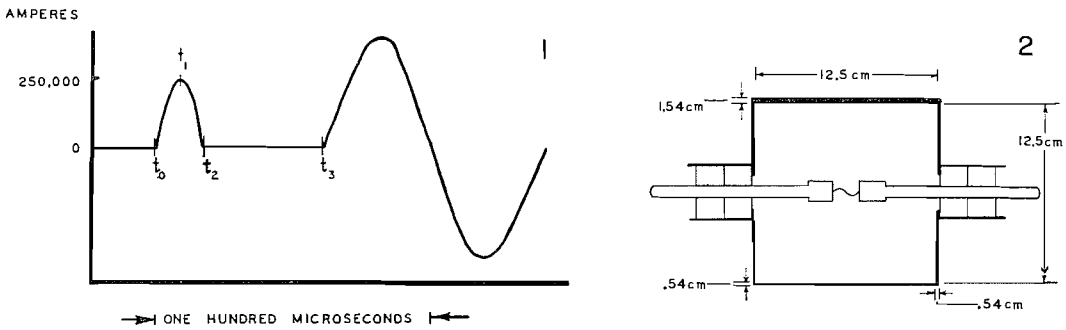

FIG. 1. An ideal current versus time oscilloscope tracing.
FIG. 2. Reaction vessel.

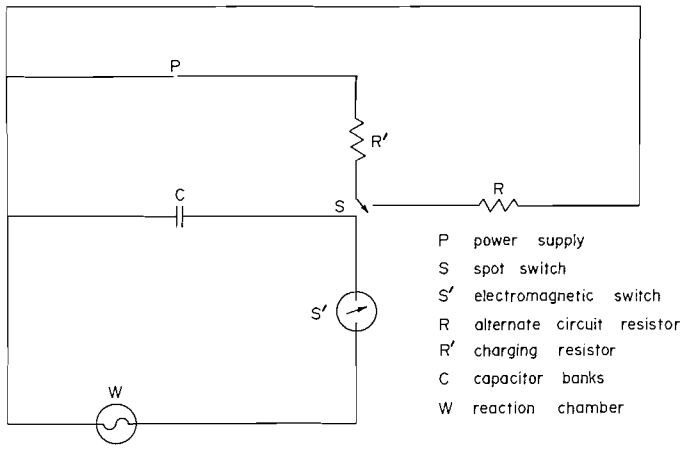

FIG. 3. Modified exploding wire circuit.

The investigations of Joncich and Reu (3) were performed in an evacuated glass reaction vessel, since the syntheses involved the reactions of two solids. The preparations of nitrides were carried out in a nitrogen atmosphere; a stainless steel cylindrical vessel was constructed to withstand the shock wave accompanying the explosion of the wire. Figure 2 is a side view of the 1 700 ml reaction chamber; a 500 ml reaction vessel was used in some experiments. In both cases, the top was removable and secured by heavy bolts with a Teflon gasket between the lid and the body of the vessel.

Various wire sizes were exploded and it was found that a wire weighing from 75–120 mg was the maximum weight that could be exploded without having large pieces of the unreacted wire in the collected sample. At a nitrogen pressure of 1 atm, the stoichiometric ratio of nitrogen to metal was approximately 1 000:1. After the explosion, it was necessary to wait 30 min before opening the chamber to prevent appreciable loss of the finely divided product.

The metals which were exploded in nitrogen were magnesium, iron, titanium, zirconium, tantalum, rhodium, platinum, copper, zinc, and aluminium. The products obtained for each element were grouped according to color and were analyzed for nitrogen by the Gunning modification of the Kjeldahl method. To test the analytical technique, it was found that 96% of the nitrogen in 20AlN·SiC* could be recovered by this method. Yields are reported as percentage nitride. Samples collected from wires exploded in gaseous ammonia were heated to 100 °C to drive off free ammonia prior to the determination of the nitrogen content.

RESULTS

Magnesium

Many samples of magnesium nitride (see Table I) were tan or white. These were predominately mixtures of the oxide and the metal and contained only a trace of nitrogen

**Available from Allis-Chalmers Co., Cerac Division, Milwaukee, Wisconsin.*

(0.2–0.5%). Magnesium exploded in an ammonia atmosphere under similar conditions gave a product with a nitride content of 6.4%. Increasing the charging voltages from 9 to 12 kV gave a product with a nitride content of 21.5%. Magnesium exploded in mixtures of hydrogen and nitrogen (1:1 molar ratio) showed a nitride content of 15.6%. Smaller wires were exploded in nitrogen; the product obtained had a nitride content of 6.23%. The use of smaller wires and a larger charge on the capacitors favors the production of the nitride. X-Ray powder photographs indicated the product contained Mg_3N_2 in all cases.

TABLE I

Results of explosions of wires in various atmospheres (condensers were charged to 9 kV)

Possible compound	Average weight of wire (mg)	Gas present	Total pressure of gas (mm Hg)	% yield of nitride	Total % metal in sample

§The nitrogen was passed over hot copper before filling the reaction vessel.
‖ND = no data collected.

Titanium

Titanium exploded in a 1:1 molar ratio of nitrogen to hydrogen gave a black product, corresponding to a 49.1% yield of nitride. Titanium was also exploded in a 1:2 mixture of ammonia and hydrogen; the yield of the nitride was 52.5%. Titanium nitride was prepared in 26.4% yield by exploding titanium under liquid nitrogen. The major product was TiN.

Zirconium

Rather large wires of zirconium (155 mg) were exploded in pure nitrogen at a pressure of 1 atm. This procedure gave the nitride in 24.8% yield. A smaller wire (78 mg) was exploded under the same conditions and the yield was increased to 41%. The yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the reaction was improved to 47.4% by increasing the pressure of the nitrogen to 976 mm Hg. X-Ray powder photographs confirmed the presence of ZrN in the samples.

Tantalum

Tantalum forms two nitrides, TaN, which is a metallic gray in color, and Ta_3N_5, which is red. Judging from the color of the samples, both forms were obtained. The red form was preferentially produced with small wires and large charge on the capacitors. However, the X-ray photographs of both forms were identical and showed the presence of TaN.

Iron

All explosions of iron except one gave a gray product which could be finely divided metal, Fe_2N, or the polymeric $(Fe_2N)_n$ which is also gray. However, the samples did not contain nitrogen and the X-ray data indicated the absence of any iron nitride.

Rhodium

Explosion of a rhodium wire in a nitrogen atmosphere produced a very dark green product, which did not contain nitrogen.

Platinum

Many attempts were made to prepare the unknown compound, platinum nitride. All attempts were unsuccessful. Nitrogen could not be detected in the samples, and chemical analysis as well as X-ray data indicated the product of the explosion was pure platinum.

Copper

Copper was exploded successfully but gave products which ranged in color from dark olive green to yellowish green and which contained a small amount of nitrogen. X-Ray data did not indicate the presence of Cu_3N in the sample. The product exhibited reactions characteristic of copper(I) compounds (10). However, chemical analysis indicated the presence of very small amounts of nitrogen, and X-ray diffraction patterns contained some lines characteristic of copper azide.

Zinc

A water soluble product was formed by the explosion of zinc in a nitrogen atmosphere. Kjeldahl analysis did not indicate the presence of nitrogen in the compound; however, it was later determined that the addition of concentrated sulfuric acid decomposes zinc nitride to the metal and free nitrogen. X-Ray data indicated the sample contained Zn_3N_2.

Aluminium

Aluminium foil exploded completely and gave the nitride in 17.5% yield. The color of the sample indicated the presence of the oxide. Since the nitrogen contained 0.3% impurity, which may have been oxygen, it was passed over hot copper before it was used in the exploding chamber. There is considerable evidence that when a metal is exploded in air, the oxide is formed in preference to the nitride (11). The presence of AlN in the sample was confirmed by X-ray data.

Cadmium

Cadmium exploded in a nitrogen atmosphere gave a product which had a nitrogen content of 0.39%. The cadmium content was 97.0%; the remainder was an acid insoluble residue. The nitride of cadmium may decompose into the metal and nitrogen upon the addition of acid; this possibility was previously pointed out in the case of zinc nitride.

It has been demonstrated that it is possible to prepare various nitrides using the techniques of e.w.p. Further work is needed to investigate the optimum conditions for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the preparation of the various nitrides. A conclusion from this exploratory work is that an increase in the voltage used to explode the wire and in the pressure surrounding the wire, accompanied by a decrease in the size of the wire, favors the formation of the nitride. In cases in which the nitride was not obtained, it is possible that the nitride will not form, or if formed, is unstable and rapidly decomposes to the metal and nitrogen. The results of these experiments are summarized in Table I.

ACKNOWLEDGMENT

The authors are grateful for helpful discussions concerning this work with Dr. Walter A. Yeranos. The aid received from Dr. Aubrey J. Serewicz on the X-ray diffraction studies is gratefully acknowledged.

EFFECT OF CO AND N_2 ON MERCURY-PHOTOSENSITIZED REACTIONS[1]

J. B. HOMER[2] AND F. P. LOSSING
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 25, 1965

ABSTRACT

The addition of CO is found to increase the rate of the mercury-photosensitized decomposition of certain compounds (ethylene, acetone, anisole) by a factor in excess of 2.5, but does not affect the rate with paraffin hydrocarbons. The addition of N_2, known to quench $Hg(^3P_1)$ to the metastable $Hg(^3P_0)$ state, does not produce an increase in rate. The results are discussed with reference to a possible HgCO* complex which contains most of the original excitation energy of $Hg(^3P_1)$ atom.

INTRODUCTION

This publication is concerned with some phenomena associated with the effect of foreign gases, particularly CO and N_2, on $Hg(^3P_1)$ photosensitized decomposition reactions at relatively low pressures. The effect was observed quite unexpectedly when the addition of moderate amounts of CO was found to give a twofold increase in the rate of decomposition of anisole by $Hg(^3P_1)$ atoms. Further investigation of this effect showed that addition of CO similarly increased the decomposition rates of ethylene and acetone, but left those of paraffin hydrocarbons unaffected. A possible explanation in terms of formation of metastable $Hg(^3P_0)$ atoms was quickly rejected when it was found that the addition of N_2, which also quenches $^3P_1$ atoms to the metastable $^3P_0$ state, gave no enhancement in the rates of decomposition. Further work on this unusual phenomenon was therefore felt to be justified.

A comprehensive review of the reactions of excited mercury atoms, summarizing the known cross sections and nature of such reactions has recently been published by Cvetanović (1), so that further background on such reactions need not be given here.

EXPERIMENTAL

The experimental arrangements were similar to those previously described (2, 3), but for the sake of clarity they are briefly described here. The reactor is shown in Fig. 1. A stream of helium at 12 mm pressure carried the reactant together with mercury vapor through a fused silica tube illuminated by an intense low pressure mercury lamp. The reactor, the lamp, and the supply of mercury to the stream were held at 55 °C by circulating water. The residence time in the illuminated zone was about 10^{-3} s. Directly after passing the illuminated zone the reaction stream passed over a small orifice through which a portion flowed directly into the ionization chamber of a mass spectrometer. The partial pressures of reactant and product gases in the reactor in the immediate neighborhood of the orifice can be measured with the mass spectrometer after appropriate calibrations. Changes in composition can be measured with 1–2% accuracy, at least for non-radical products. In the present experiments the extent of decomposition (in a constant residence time) was measured from the decrease in the parent peak of the compound brought about by turning on the mercury lamp. Isotopic corrections from interfering peaks were applied where necessary.

Some experiments were carried out using a static reactor. This consisted of a fused silica vessel 2 cm in diameter and 12 cm long containing a drop of mercury and irradiated by a U-shaped low pressure mercury lamp. The lamp and reactor were immersed in water at 25°. Illumination periods, controlled by a rotating electrical contact driven by a synchronous motor, varied from 0.6 s to 3 s. The reproducibility of measurement of C_2H_4 decomposed and C_2H_2 formed in identical repetitive runs was about 5%.

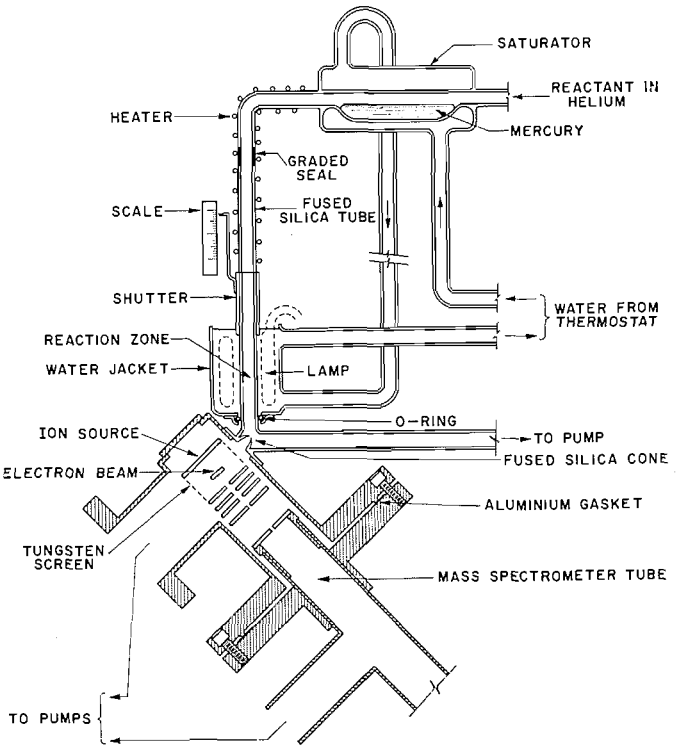

FIG. 1. Diagram of photochemical reactor.

RESULTS

Hg($^3P_1$) Photosensitized Decomposition of Ethylene

Although, as mentioned above, enhancement of the rate of photosensitized decomposition by CO was observed for several compounds, the effect was mainly studied with ethylene since this reaction is perhaps the most clearly understood, and the reaction products are mainly non-radical and therefore undergo a minimum of secondary reactions. The interaction of $Hg(^3P_1)$ atoms with ethylene leads to formation of an excited C_2H_4 which decomposes almost entirely through elimination of a H_2 molecule (4). A concurrent reaction giving $H + C_2H_3$ amounts to only 3–4% of the total reaction (2, 6) or lower (1, 5, 7). Moreover, the quantum yield of H_2 is close to unity at low pressures (8). Assuming the reaction sequence

[1] $$Hg + h\nu \rightarrow Hg(^3P_1)$$

[2] $$Hg(^3P_1) \rightarrow Hg(^1S_0) + h\nu$$

[3] $$Hg(^3P_1) + C_2H_4 \rightarrow Hg(^1S_0) + C_2H_2 + H_2$$

leads to a kinetic equation

$$-\frac{dt}{dP} = \frac{1}{I_a} + \frac{k_2}{I_a k_3[C_2H_4]}$$

where I_a is the rate of production of $Hg(^3P_1)$ by reaction [1], t = time, and P = partial pressure of ethylene. When the amount of decomposition is small

$$dt/dP = \Delta t/\Delta P$$

For personal use only.

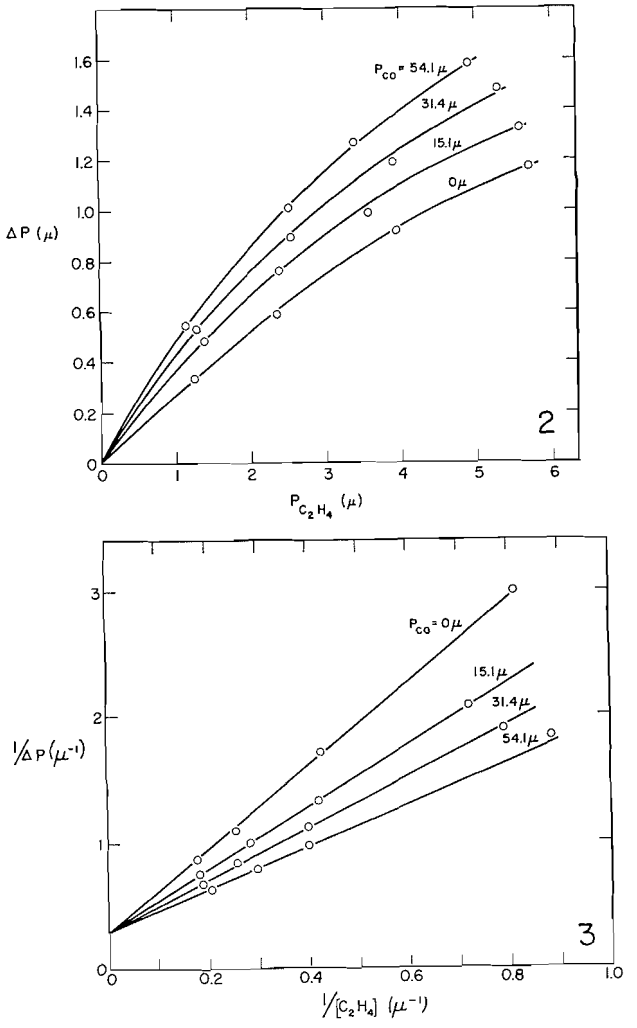

FIG. 2. Amount of ethylene decomposed as a function of its partial pressure.
FIG. 3. Reciprocal plot of data in Fig. 2.

where Δt is the residence time, and ΔP is the amount of ethylene decomposed. For the sake of simplicity, this is assumed to apply for decompositions of the order of 20%.

A plot of the amount of ethylene decomposed against the partial pressure of ethylene is shown in Fig. 2, and is transformed into a reciprocal plot in Fig. 3. When $P_{CO} = 0$, the intercept in Fig. 3 gives a value of $1/I_a\Delta t$; this and the slope of the line give k_2/k_3 to be 5.82×10^{-7} mole l^{-1}. The value of k_3 is known (1) to be 3.7×10^{11} l mole^{-1} s^{-1}, so that $k_2 = 2.15 \times 10^5$ s^{-1}. The effective lifetime of a quantum of 2 537 Å radiation in this system is therefore 4.65×10^{-6} s, which by comparison with the radiative lifetime of $Hg(^3P_1)$ of 1×10^{-7} s indicates the extent of radiative imprisonment in this reactor under the conditions employed.

Effect of Foreign Gas Addition

When CO was added to the reaction stream of ethylene and helium the amount of ethylene decomposed was greatly increased. The results obtained by varying the partial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pressure of both ethylene and CO are also shown in Fig. 2 and Fig. 3. The plots in Fig. 3 are a series of essentially straight lines fanning out from a common intercept on the $1/\Delta P$ axis. This shows, firstly, that the proportionality between $1/\Delta P$ and $1/[C_2H_4]$ is still retained in the presence of CO, and, secondly, that $I_a\Delta t$ is unchanged. Since the amounts of CO added were too small compared with the 12 mm of helium gas to affect the flow rate (and consequently Δt) significantly, the latter shows that no increase in the amount of chemically effective light occurred with the CO addition, either by pressure broadening or by absorption by CO itself.

At a partial pressure of ethylene of ~ 2 μ, the amount decomposed was about 20%. The change in this amount by the addition of CO, N_2, CO_2, and H_2O is recorded in Fig. 4 as a plot of Δ_2/Δ_1 against the partial pressures of the added gas. Here Δ_2 is the amount of decomposition in the presence, and Δ_1, in the absence, of the added gas. It can be seen that although CO greatly increases the extent of decomposition, N_2 shows practically no effect.

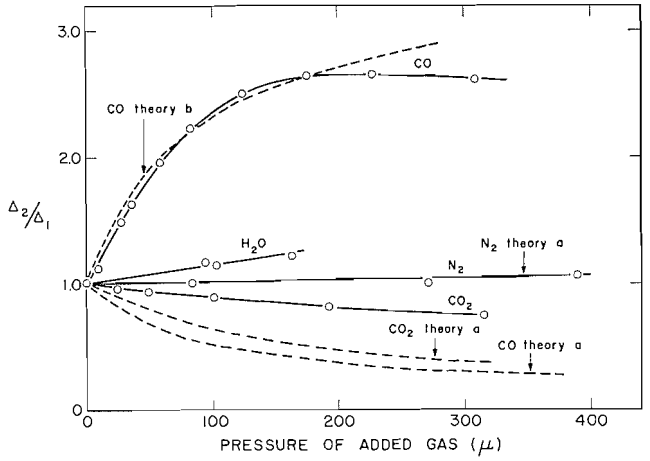

FIG. 4. Effect of added gas on the decomposition of ethylene. Δ_2 is the amount of decomposition in the presence, and Δ_1 in the absence, of the added gas.

From existing data it is possible to predict what effects the addition of CO and N_2 should have on the reaction of $Hg(^3P_1)$ with C_2H_4. CO and N_2 have no known electronic states low enough in energy to be excited by collision with $Hg(^3P_1)$ atoms. They can, however, absorb energy in internal and translational forms, thereby converting $Hg(^3P_1)$ to the metastable $^3P_0$ state or even to the $^1S_0$ ground state.

[4] $$Hg(^3P_1) + CO \text{ (or } N_2) \rightarrow Hg(^3P_0) + CO^* \text{ (or } N_2^*)$$

[5] $$\rightarrow Hg(^1S_0) + CO^{**} \text{ (or } N_2^{**})$$

Zemansky (9, 10) studied the quenching of the fluorescence of Hg 2 537 Å and found that CO was 20 times more efficient than N_2:

$$\text{i.e. } (k_4^{CO} + k_5^{CO})/(k_4^{N_2} + k_5^{N_2}) \approx 20.$$

This is a large difference for apparently similar molecules, and Zemansky proposed that $k_4^{CO} \gg k_4^{N_2}$ on the grounds that the energy discrepancy in reaction [4] was smaller for the formation of $Hg(^3P_0) + CO_{(v=1)}$ than for $Hg(^3P_0) + N_{2(v=1)}$. Scheer and Fine (11) showed this proposition to be false by measuring the amount of $Hg(^3P_0)$ atoms produced, concluding that, in fact, $k_4^{CO} = 1.35k_4^{N_2}$. In addition Callear and Norrish (12) have pointed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

out that if N_2 is added to a Hg resonance lamp, the decreased quantum output can be returned almost to normal by heating, an act that could easily reverse reaction [4] but not [5]. They inferred that $k_5^{N_2}$ is negligibly small.

From the values determined by Mitchell and Zemansky (10) the rates at 55 °C are:

$$k_4^{CO} + k_5^{CO} = 5.84 \times 10^{10}\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_4^{N_2} + k_5^{N_2} = 0.275 \times 10^{10}\ \text{l mole}^{-1}\ \text{s}^{-1}.$$

From the above arguments the separated rate constants are:

$$k_4^{CO} = 0.37 \times 10^{10}\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_4^{N_2} = 0.275 \times 10^{10}\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_5^{CO} = 5.47 \times 10^{10}\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_5^{N_2} = 0.$$

Although metastable $Hg(^3P_0)$ atoms decompose ethylene by a much lower rate of 0.7×10^{10} l mole^{-1} s^{-1} (1) compared with 37×10^{10} l mole^{-1} s^{-1} for $Hg(^3P_1)$ atoms, they have a much longer radiative lifetime, $\sim 4 \times 10^{-4}$ s. The presence of $Hg(^3P_0)$ atoms in the present reaction system could therefore be significant. If the additional reaction steps are then written

[6] $$Hg(^3P_0) \rightarrow Hg(^1S_0) + h\nu$$

[7] $$Hg(^3P_0) + C_2H_4 \rightarrow Hg(^1S_0) + C_2H_4 + H_2$$

and a steady state treatment is applied to $Hg(^3P_1)$ and $Hg(^3P_0)$ in this system, the following equation can be deduced.

$$\frac{-\Delta_2}{\Delta t} = \frac{I_a[C_2H_4][k_3k_6 + k_3k_7[C_2H_4] + k_4k_7[CO]]}{[k_6 + k_7[C_2H_4]][k_2 + k_3[C_2H_4] + (k_4 + k_5)[CO]]}$$

In the absence of CO

$$\frac{-\Delta_1}{\Delta t} = \frac{I_a k_3[C_2H_4]}{k_2 + k_3[C_2H_4]}$$

so that

$$\frac{\Delta_2}{\Delta_1} = \frac{1 + k_4k_7[CO]/k_3(k_6 + k_7[C_2H_4])}{1 + (k_4 + k_5)[CO]/(k_2 + k_3[C_2H_4])}.$$

If the values of the rate constants already evaluated are inserted in this equation, the theoretical dependence of Δ_2/Δ_1 on the pressure of added gas can be calculated for CO and N_2. The result is shown superimposed on Fig. 4 as theory *a*. Theory and experiment are identical for N_2, the small enhancement caused by the longer life of $Hg(^3P_0)$ being counterbalanced by its slower rate of reaction with ethylene. Theory predicts, however, that CO would *decrease* the amount of decomposition because of rapid deactivation of $Hg(^3P_1)$ to the ground state, whereas the experimental result shows an opposite effect. Indeed if, hypothetically, k_4^{CO} were infinite and all other rates remained the same, the maximum enhancement possible would still be much lower than that observed, that is, Δ_2/Δ_1 for the C_2H_4 concentration corresponding to Fig. 4 would reach a limit of 1.49.

It is evident that the formation of $Hg(^3P_0)$ is not the major factor in the observed effect of CO addition.

Dependence on Light Intensity

Wire gauze screens of known optical transmission were inserted between the lamp and the reactor, and the amount of decomposition of ethylene was measured with and without

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

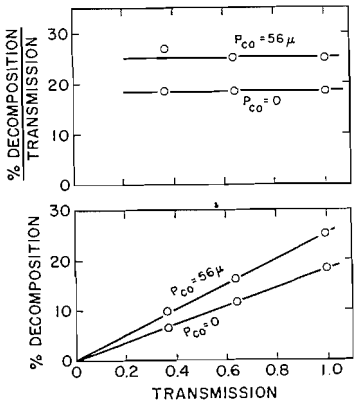

FIG. 5. Plot showing first-order dependence on light intensity with and without added CO.

the addition of 56 μ of CO to the stream. The results (Fig. 5) confirm that the dependence on light intensity was not greater than the first power. This immediately ruled out any stepwise excitation paths to excited species, for instance an electronically excited CO molecule.

A metal sleeve (shown in Fig. 1) was lowered in stages between the lamp and the reactor, thus varying the length of the illuminated zone. The amount of decomposition (Fig. 6) increased linearly with the length of the illuminated zone. No buildup of active species, as observed previously in the photosensitized decomposition of biacetyl (13), was therefore taking place along the reactor. This restricts all chemically active species to a lifetime much shorter than the time of transit along the reactor. The fact that both lines in Fig. 6 have the same extrapolated zero in terms of distance emphasizes this fact.

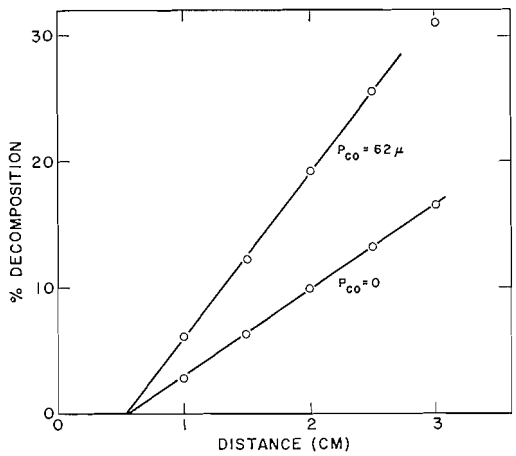

FIG. 6. Amount of decomposition as a function of the length of the illuminated zone.

Search for Abnormal Products

No products other than acetylene and hydrogen could be found at moderate pressures of ethylene ($\sim$ 20 μ) and high pressures of CO (200 μ). The additional decrease in ethylene caused by the addition of CO was as far as could be assessed ($\pm$2%) always equal to the increase in acetylene produced. A particularly close search was made for products such as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formaldehyde, acetaldehyde, or addition products of Hg and CO, but none was detected. A negative result was also obtained when N_2, CO_2, or H_2O were added.

In runs made in the static reactor system at higher pressures (see Experimental) no evidence for addition products of CO with ethylene could be found, in particular no acrolein, methyl ketene, or cyclopentanone. Butane, butene, and butadiene were produced in appreciable amounts, both in the presence and absence of CO. In order for CO to more than double the amount of decomposition of ethylene by the competition of reactions [6] and [7]

[6] $$C_2H_4^* + M \rightarrow C_2H_4 + M$$

[7] $$C_2H_4^* + CO \rightarrow \text{products}$$

the quantum yield for ethylene decomposition in the absence of CO would have to be <0.5. This seems unlikely in view of the probable inefficiency of 12 mm of helium as a medium for deactivation, and the observed high quantum yield for H_2 even at moderately high pressures (8).

Effect of CO on the Decomposition of Other Compounds

The extent of the photosensitized decomposition of *n*-butane, propane, and cyclopropane was unaffected by the addition of 100 μ of CO. Ethane showed a slight decrease and isobutane a slight increase, possibly larger than experimental error. Anisole and acetone, on the other hand, showed the same substantial increase as did ethylene. It would appear that the new active species formed by the CO addition has a preference for an attack on π-bonds.

Experiments with the Static Reactor System

It was thought that the enhancement of decomposition of ethylene in the presence of CO might result from some peculiarity of the fast-flow system or mercury lamp used in the mass-spectrometric experiments, or possibly from wall effects. It was found, however, that the enhancement effect of CO could be reproduced in the static reactor, in which the geometry and the lamp were quite different. For these experiments, a mixture of foreign gas and ethylene in the ratio of 10:1 was made up. Samples of this mixture at different pressures were irradiated in the reactor for times of 0.6 to 3 s, and analyzed for C_2H_4 and C_2H_2 with the mass spectrometer. The rates of decomposition were compared with those of pure ethylene under identical conditions. Variations in Δ_2/Δ_1 with total pressure are shown in Fig. 7 for the three foreign gases, CO, N_2, and He. At the lowest pressures, the effect of CO was to increase the rate of decomposition by a factor approaching that found in the flow reactor, while N_2 and He showed no effect. With increasing pressure, the special effect of CO vanished. This would be expected since the region of complete quenching is being approached, and the rate would be determined by the rate of absorption of quanta, i.e. by the useful output of the lamp, and the partial pressure of mercury in the reactor.

Consideration as to the Active Species Introduced by CO Addition

From the discussion above, it is apparent that the enhancement effect of CO cannot be attributed to the absorption of additional quanta. The explanation must therefore lie in the utilization of quanta which are, in the absence of CO, re-radiated from the reactor. This requires the introduction by CO of an active species with a large cross section toward ethylene. The high reactivity of the active species toward molecules decomposing by way of a triplet state (ethylene, acetone) compared with its inactivity toward paraffins would seem to define the species as being itself a triplet. The lowest triplet of CO, $A^3\pi$, lies over

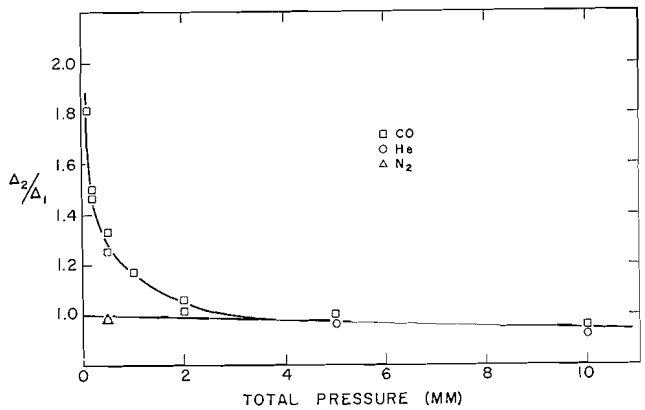

FIG. 7. Enhancement by CO of the rate of decomposition of ethylene in a static reactor system. Addition of He and N_2 has essentially no effect.

1 V above the $Hg(^3P_1)$ level, and could only be formed by stepwise excitation, or by collision with $Hg(^1P_1)$ atoms. Stepwise excitation has been ruled out on the grounds of first-order dependence on the light intensity. The formation of significant amounts of $Hg(^1P_1)$ atoms by 1 849 Å radiation present in the output of the lamp appears improbable, since this radiation would be greatly attenuated by the water surrounding the reactor. In any case the formation of $CO(A^3\pi)$ by $Hg(^1P_1)$ would be inefficient because of violation of the spin conservation rule.

The presence of vibrationally excited CO molecules, at levels up to $v = 8$ or higher, resulting from collision with Hg*, has been demonstrated by observation of the infrared emission (14). These observations suggested that a high vibrational state of CO was excited directly by collision with Hg* rather than by a stepwise excitation. Such vibrationally excited CO molecules could be the excited species responsible for the present observations, but this explanation runs into serious difficulties. Although the reaction $C_2H_4 \rightarrow C_2H_2 + H_2$ is only 41.7 kcal/mole endothermic, the photosensitized decomposition is extremely slow by $Cd(^3P_1)$ atoms (87.3 kcal/mole) and even, by $Zn(^3P_1)$ atoms (92.5 kcal/mole) (15). It seems reasonable, therefore, that vibrationally excited CO molecules with energies less than about 90 kcal/mole would be ineffective in exciting C_2H_4 to the required energy level, which is presumably a vibrationally excited triplet state. Even for CO molecules having vibrational energy in excess of this, the transfer in a single collision of such large amounts of vibrational energy to ethylene, as either vibrational or electronic excitation, seems most improbable.

It would appear that the proposal that $Hg(^3P_1)$ and CO form a complex with an appreciable lifetime, put forward by Scheer and Fine (11) to explain the large rate of reaction [5], might account for the presently observed effect. Such a complex has been further discussed by Polanyi (16) in relation to the vibrationally excited CO observed by Karl and Polanyi (14). If it is assumed that the HgCO* complex is a reasonably long-lived one, retaining essentially all the energy of $Hg(^3P_1)$ and decomposing to $Hg(^1S_0)$ and a vibrationally excited CO, reaction [5] can be replaced by

[8] $$Hg(^3P_1) + CO \rightarrow HgCO^*$$

[9] $$HgCO^* \rightarrow Hg(^1S_0) + CO^{**}$$

and a further reaction can be written:

[10] $$HgCO^* + C_2H_4 \rightarrow Hg(^1S_0) + CO + C_2H_2 + H_2.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Incorporation of these reactions into the previous scheme leads to the overall equation

$$\frac{\Delta_2}{\Delta_1} = \frac{1 + k_4k_7[CO]/k_3(k_6 + k_7[C_2H_4]) + k_8k_{10}[CO]/k_3(k_9 + k_{10}[C_2H_4])}{1 + (k_4 + k_8)[CO]/(k_2 + k_3[C_2H_4])}.$$

Now, if the rate formerly assigned to reaction [5] is assigned to reaction [8], values for the ratio k_{10}/k_9 can be evaluated from the experimental values of Δ_2/Δ_1. For the 80 μ CO point in Fig. 4, this leads to $k_{10}/k_9 = 1.10 \times 10^7$ l mole^{-1}.

The theoretical curve using this value is shown in Fig. 4 as theory *b*. While the fit to the Δ_2/Δ_1 vs. P_{CO} curve is fair, this theory leads to a slightly nonlinear plot between $1/\Delta_2$ and $1/[C_2H_4]$. The linearity can be improved on the assumption of other reactions leading to the loss of active species, e.g. the reverse of reaction [8] or an interaction between $Hg(^3P_0)$ and CO, but these considerations have to remain qualitative in the absence of the necesssary data. Moreover, it must be remembered that kinetic equations have been used which are ideally only applicable to small amounts of decomposition. It appears therefore that such a mechanism can approach correspondence with the experimental results. The assumption of a HgCO* complex remains the most plausible explanation of the observed effects.

Effect of CO_2 and H_2O Addition

CO_2 appears to quench $Hg(^3P_1)$ to the ground state only, no $Hg(^3P_0)$ atoms being formed (12). In the absence of other effects, the addition of CO_2 should reduce the amount of decomposition by competitive quenching. As seen in Fig. 4, a reduction was observed, but the reduction was smaller than predicted by the available quenching cross sections (1). It is not clear whether this should be regarded as evidence for a special effect of CO_2. The addition of H_2O slightly increased the amount of decomposition of ethylene (Fig. 4). It is known (12) that H_2O quenches $Hg(^3P_1)$ to $Hg(^3P_0)$ but the cross section for this reaction is not known. In this case also it is not clear whether a special effect of H_2O exists. Since these gases showed only minor effects compared with that found with CO, they were not investigated in detail.

CONCLUSION

The experimental results reported here concerning the interaction of $Hg(^3P_1)$ atoms and CO provide support for earlier evidence that this interaction involves the formation of a HgCO* complex of appreciable lifetime. Such a complex, if it had a cross section for reaction with ethylene the same as that for $Hg(^3P_1)$ atoms with ethylene, would need to have a lifetime of about 3×10^{-5} s (from the deduced value of k_{10}/k_9). A shorter lifetime would necessitate a corresponding increase in the reaction cross section. Such a large cross section is perhaps not incompatible with the known affinity of metallic carbonyls for π-bonds. Attempts to detect a HgCO* complex spectroscopically would appear to be worthwhile.

PROTON MAGNETIC RESONANCE LINE WIDTH AS A FUNCTION OF POLYMER TACTICITY[1]

S. BROWNSTEIN AND D. M. WILES
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received August 6, 1965

ABSTRACT

The high resolution proton magnetic resonance spectra of five samples of poly(methyl methacrylate) in chloroform solution have been measured with 100 Mc/s equipment. The widths of the absorption lines arising from the protons of the α-methyl and the methoxyl groups have been compared. The widths are greater when the polymer is predominantly syndiotactic than when it is predominantly isotactic. It is concluded that isotactic samples have the more extended conformation in chloroform solution. An analogy with dilute solution viscosity measurements is outlined in support of this conclusion. Differences between the widths of the lines of the methylene protons in a completely isotactic poly(methyl methacrylate) sample are attributed to long range spin coupling.

INTRODUCTION

High resolution proton magnetic resonance measurements have been used with considerable success in recent years to determine differences in stereoregularity for a number of different polymers. The method is applicable, at least in principle, whenever the resonance absorption for a particular proton exhibits a chemical shift, determined by the magnetic environment of that proton, which is unique to a particular steric configuration.

Poly(methyl methacrylate) (PMMA) was the first polymer to which the technique was applied. It was shown (1) that the chemical shift of the α-methyl group protons was determined by the configuration of substituents about the pseudo-asymmetric α-carbon atom in each unit of the polymer chain. The measurement of PMMA tacticities, based on this principle, is now considered routine.

It is the purpose of this communication to describe differences in proton absorption line widths, for different PMMA samples, which can be correlated with differences in polymer tacticities. These data will be related qualitatively to chain flexibility and relative conformational geometry. It also appears to be possible with 100 Mc/s apparatus to detect differences in line widths which may be due to proton spin coupling over longer distances than have been considered heretofore for these materials.

EXPERIMENTAL

One fraction from each of five polymer samples was used in this work. The conditions under which these polymers were prepared can be summarized as follows.

A.—This sample was prepared in tetrahydrofuran solution at −78 °C with magnesium diethyl initiator; [MMA] = 1 M; [$Mg(Et)_2$] = 45 mM. After removal of the petroleum ether soluble material, this sample was used without further fractionation.

B.—This polymer was prepared in benzene solution at 60 °C with 2,2′-azo-bis-isobutyronitrile initiator.*

C.—Polymerization was carried out in toluene solution at −30 °C with *n*-butyllithium initiator; [MMA] = 0.25 M; [BuLi] = 3.85 mM.

D.—This sample was prepared in toluene solution at −30 °C with *n*-butyllithium initiator in the presence of added lithium methoxide; [MMA] = 0.125 M; [BuLi] = [LiOMe] = 7.6 mM.

E.—Polymerization was carried out in toluene solution at 0 °C with phenylmagnesium bromide initiator; [MMA] = 0.5 M; [ϕMgBr] = 36 mM.

The anionic polymerizations (A, C—E) were carried out in an all-glass vacuum apparatus which could be prewashed with butyllithium solution. The monomer and solvents were rigorously purified on a vacuum line.

[1]*Issued as N.R.C. No. 8705.*

**Prepared by Dr. J. M. G. Cowie of these laboratories.*

The butyllithium was obtained in hexane solution from the Foote Mineral Company and the Grignard reagent as a diethyl ether solution from Peninsular Chemical Research, Inc. Details of the manipulation of reagents and of the polymerization procedure were similar to those described elsewhere (2).

The polymers (except A) were separated into fractions by a precipitation technique which has been published previously (3). The molecular weights of the fractions were derived from their viscosities measured in chloroform solution at 25 °C with Cannon–Ubbelohde dilution viscometers. One fraction, having a molecular weight of the order of 1 to 2×10^4, was to be selected from each polymer sample. The viscosity – molecular weight relationship used (3) is not particularly accurate below 2×10^4 but would certainly be adequate for this purpose.

The proton magnetic resonance spectra of the five selected polymer fractions were measured in chloroform solution (12%, w/v) at 70 °C (thermostatted probe) with a Varian HR100 spectrometer which had been modified to operate by a "time division pulsing scheme" (4). The spectra were calibrated with sidebands produced by audio modulation. Line widths were measured in cycles/s at half height. The widths quoted for the peaks arising from protons in the polymer molecules have had the value of the line width of the solvent peak subtracted from them. This was done to compensate for any slight difference in spectrometer resolution when obtaining the various spectra.

RESULTS AND DISCUSSION

A summary of the data obtained from the proton resonance spectra is shown in Table I. The tacticities were obtained in the usual way by measuring the relative areas of the peaks due to absorption by the protons of the α-methyl group. The half-height widths of the peaks in the spectra of fractions A/2 and B/F7 which arise from α-methyl group protons in syndiotactic configurations are significantly larger than the corresponding widths of the isotactic peak for fractions C/I2, D/H2, and E/9A. Similarly the widths of the methoxyl peaks for the former fractions are greater than for the latter, more isotactic fractions. It seems most reasonable to attribute the difference in peak widths to differences in freedom of molecular motion within the samples. There being no significant differences in fraction molecular weight or in solution concentration the peak width change with changing tacticity must arise because of differences in polymer chain segment flexibility. It is logical to suggest, therefore, that at a given temperature in chloroform as solvent, more isolated segmental motion can occur in an isotactic PMMA molecule in concentrated solution than in a syndiotactic molecule.

There is evidence from viscosity measurements in theta solvents (5, 6) that the unperturbed chain dimension for isotactic PMMA is greater than for atactic PMMA* in dilute solutions. In nitromethane solution the order of decreasing PMMA chain dimension is isotactic > atactic > syndiotactic (6). In a good solvent such as chloroform, viscosity measurements with dilute solutions indicate that the dimensional differences are much less pronounced but nevertheless an isotactic chain appears to be more extended than a syndiotactic chain.

It is reasonable to suppose that the relative order of chain dimensions for the tactic forms of PMMA remains the same in the more concentrated solutions used for proton magnetic resonance measurements. Qualitative observations show that, for comparable polymer molecular weights, a chloroform solution of isotactic PMMA is more viscous than a solution of syndiotactic PMMA in the 10–15% concentration range. An analogy appears to exist, therefore, such that in concentrated solutions an isotactic PMMA chain is more extended than a syndiotactic chain, as is found to be the case in dilute solutions. It would be expected that in the more extended conformation greater localized segmental motion can occur. This concept provides some support for the explanation of the narrower peak widths reported in Table I for the isotactic fractions.

**Atactic or "conventional" PMMA has by no means a random arrangement of configurations. Ordinarily it is prepared above room temperature with a radical initiator and has an appreciable content of syndiotactic triads (cf. Table I, fraction B/F7).*

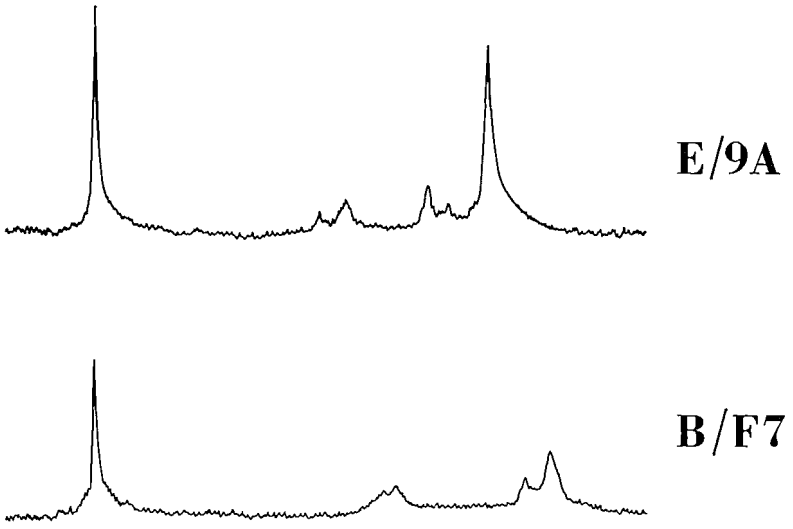

FIG. 1. The 100 Mc/s proton magnetic resonance spectra of two PMMA fractions with different tacticities.

In an isotactic sequence the methylene protons are magnetically non-equivalent. Therefore, a typical AB pattern of two non-equivalent, spin-coupled nuclei is obtained. Previously reported PMMA spectra were normally obtained at lower operating frequencies. Under these conditions the higher field peak of one of the methylene protons slightly overlapped the peak of the isotactic α-methyl group. By operation at 100 Mc/s it is possible to resolve clearly all the peaks from the isotactic methylene protons in fraction E/9A. Those at lower field are approximately 2.4 cycles/s wider than the ones at higher field (Table I). Since both methylene protons should experience the same freedom of motion the extra width for the low field protons may be attributed to a long range spin coupling to the protons of the α-methyl group.

It has generally been assumed, on the basis of spectra obtained at lower operating frequencies, that chemical shifts of methylene protons in syndiotactic and heterotactic sequences in the same polymer molecule are the same. From the proton resonance spectrum of fraction B/F7 it may be seen that separate peaks for each type are barely resolved. This slight difference in chemical shift may account for the unusually broad peak normally observed for the methylene group in largely syndiotactic and heterotactic samples. The spectra of polymer samples E/9A and B/F7 are shown in Fig. 1.

STEREOCHEMISTRY AND SEVEN COORDINATION[1]

T. A. CLAXTON[2] AND G. C. BENSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received August 11, 1965

ABSTRACT

A method is described to calculate the equilibrium configuration of any number of identical particles restricted to a spherical surface and interacting with forces derivable from an interparticle potential of the form r^{-n}. It is shown that distributions of symmetry C_2 are expected for seven particles when n is small. In certain cases, the model can be used to explain the shape of molecules of the type MX_m. The importance of directed valence in these molecules is considered and the structure of IF_7 discussed.

INTRODUCTION

Gillespie (1) has proposed that the arrangement of the electron pairs in the valency shell of a central atom of a polyatomic molecule can be predicted by considering the equilibrium configuration of similar particles on the surface of a sphere with an appropriate law of force between the particles. For numbers from two to eight it has been shown by Shütte and van der Waerden (2) that the arrangements predicted by maximizing the least distance between any two particles agree with those given by Föppel (3) for an interparticle potential of r^{-1} (i.e. an inverse square law of force), except for the case of seven particles. It is concluded that for any number of particles from two to eight, except seven, the minimum energy arrangement is independent of the force law. For the case of seven electron pairs we reproduce in Fig. 1 the three possibilities (D_{5h}, C_{2v}, C_{3v}) suggested by Gillespie as the force law is varied.

The most probable arrangement, for an interparticle potential proportional to r^{-n}, with large n is the C_{3v} structure. For $n = 1$ the D_{5h} structure is energetically more favorable. Gillespie suggests that the C_{2v} structure is an equilibrium arrangement for $1 < n < \nu$, where ν is large. Britton (4) has shown that the energy of the C_{2v} configuration is indeed less than both the C_{3v} and D_{5h} structures in the region $n = 4$. Thus Gillespie's suggestion is supported but since the energies of all the structures considered in this region are nearly equal it implies that less important forces obeying a different analytical form may be dominant in determining the structure.

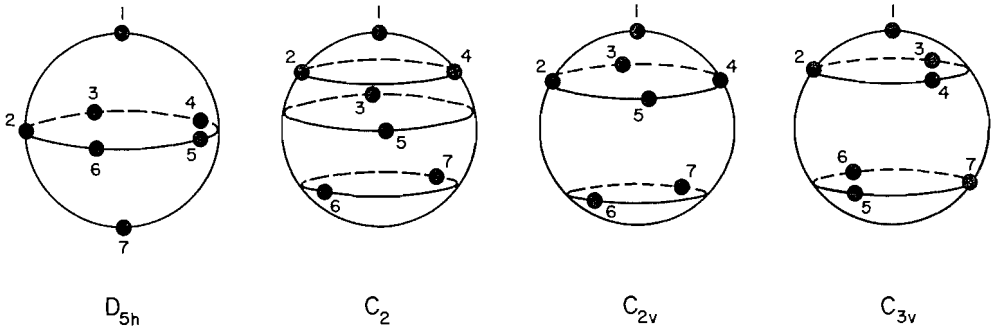

FIG. 1. Arrangements of seven particles on the surface of a sphere.

[1]*Issued as N.R.C. No. 8710.*
[2]*National Research Council of Canada Postdoctorate Fellow 1961–1963. Present address: Department of Chemistry, The University, Leicester, England.*

Since the three structures are not too different, it seems possible that the transition from one structure to another may occur through a complete spectrum of intermediate configurations. Indeed, it is reasonable to consider the C_{2v} structure as a perturbed form of either the C_{3v} or the D_{5h} structures. From Fig. 1 the similarity of the D_{5h} and C_{2v} structures can be appreciated by comparing the groups of particles 2;1,3,6,7;4,5 of D_{5h} with the groups 1;2,3,4,5;6,7 of C_{2v}. Also the groups 7;3,4,5,6;1,2 of C_{3v} are suitable for comparison with C_{2v}. The recent differences of opinion (5–8) concerning the structure of IF_7 may be attributed to this similarity especially since the molecule may be distorted (7). For this molecule, with identical ligands, it is somewhat surprising that the structure determined is not regular. As Gillespie and Nyholm (9) point out, the shapes predicted for molecules with electron pairs up to six are correct without exception. Any distortion incurred for systems with identical ligands is restricted to change in bond length along a unique axis (e.g. PCl_5). Such does not appear to be the case with IF_7. There does not seem to be any proof indicating that the D_{5h} structure is more stable than any other, except for $n = 1$. Britton has shown that both the C_{2v} and C_{3v} configurations have higher energies for $n < 4$, but did not prove that the D_{5h} structure has the lowest energy. From the comparison of the structures in Fig. 1 and the distorted form of IF_7, it would seem that intermediate structures of lower symmetry might be more favorable in the region of small n ($1 < n < 6$).

In order to investigate this possibility, a more general method than that of Britton is required. The latter restricts the number of degrees of freedom to those needed to specify configurations having a particular symmetry and then minimizes the energy. This approach is reasonable but becomes inadequate when the symmetry restrictions are removed.

A completely satisfactory solution of the problem calls for the determination of the configuration corresponding to an absolute minimum of the energy when the only condition imposed is that the particles must be located on a sphere. The method of calculation we have used falls somewhat short of the ideal goal since it provides a way only for finding relative minima of the energy and does not ensure the absolute stability of the configuration. However, it does offer a much more powerful approach than employed previously and merits brief description.

METHOD OF CALCULATION AND RESULTS

The location of each particle, of a set of m identical particles, is indicated by its Cartesian coordinates x_i, y_i, z_i (for the i-th particle). Restriction to a sphere of unit radius imposes the condition

$$x_i^2 + y_i^2 + z_i^2 = 1. \qquad [1]$$

The repulsive energy of interaction of the particles is assumed to be

$$E = \sum_{i=1}^{m-1} \sum_{j=i+1}^{m} r_{ij}^{-n} \qquad [2]$$

where r_{ij} is the distance between particles i and j and n is a constant (integer or non-integer).

Starting from any arbitrary configuration, an iterative procedure based on the method of steepest descent is used to displace the particles towards a minimum energy configuration. The latter is distinguished by the fact that the resultant tangential force on each particle is zero. This method of seeking a balance of forces, rather than attempting to minimize the energy directly, has the advantage of being more sensitive in situations where the energy surface is very flat near the minimum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The x-component of the force on the i-th particle is

$$[3] \qquad F_{xi} = n \sum_{j=1}^{m}{}' (x_i - x_j)\ r_{ij}^{-(n+2)}$$

where the prime on the summation indicates the omission of the term for $j = i$. Defining the other components (F_{yi} and F_{zi}) by similar equations, the magnitude of the force on the i-th particle is given by

$$[4] \qquad F_i = (F_{xi}^2 + F_{yi}^2 + F_{zi}^2)^{1/2}.$$

At any stage in the iterative calculation, each particle is allowed to move in the direction of the resultant force acting on it. Generally this will take the particle off the sphere and the distance from the center must be renormalized. The new x-coordinate of particle i is then

$$[5] \qquad x_i(\text{new}) = (x_i + \gamma F_{xi})/[(x_i + \gamma F_{xi})^2 + (y_i + \gamma F_{yi})^2 + (z_i + \gamma F_{zi})^2]^{1/2}$$

and similar expressions can be written for the y- and z-coordinates. The quantity γ is a scale factor which determines the extent of the displacement. Assignment of an optimum value to γ is difficult; small values lead to excessive numbers of iterations while too large a γ causes instability of the calculation. Experience has shown that a reasonable compromise can be obtained by setting

$$[6] \qquad \gamma = K/F_{\max}$$

where K is a constant and $F_{\max}$ is the largest value of F_i ($i = 1$ to m). In our calculations a value of K equal to 0.1 or 0.2 generally was satisfactory.

In effect, eqs. [5] and [6] correspond to displacing the particle experiencing the largest force by a vector of magnitude K (the vector being in the direction of the force) and altering the positions of the other particles by proportionally smaller vectors. Each particle is then moved along its new radius vector until it is again on the unit sphere.

The resultant force on any particle in a distribution of a particular symmetry must obey the operations of the symmetry point group. Hence if we let each particle move from one distribution to another along the directions of force, the symmetry of the distribution will be maintained. This is important since it means the general method can be used to determine the equilibrium configuration of specified symmetries. But it can also be a disadvantage since an arbitrary initial configuration (ideally containing only the identity symmetry element) may accidentally pick up undesired elements of symmetry during the process of the calculation. The consequences are obvious but it is assumed that they can be avoided by taking more than one starting configuration.

The treatment outlined above is well suited for calculation on a digital computer and, in our work, was programmed for an IBM 1620. A few initial calculations for the case of seven particles showed that distributions with lower energies than the configurations proposed by Gillespie did exist. We chose first to determine those values of n for which the configurations D_{5h} and C_{2v}, and C_{2v} and C_{3v} have identical energies. These situations occur for $n = 3.84165$ and 5.598 respectively. In the former case it is definite that a distribution of C_2 symmetry (see Fig. 1) has a lower energy. This finding prompted further calculations for other n, the results of which are summarized in Table I. These clearly indicate that the C_{2v} distribution never possesses the lowest energy uniquely. For the region $2 < n < 5.6$ a distribution with C_2 symmetry is favored. This configuration is illustrated in Table II where the polar coordinates (θ = colatitude, ϕ = azimuth) of the particles are given for calculations with $n = 2$, 4, and 5.6. For comparison, the corresponding C_{2v} and C_{3v} configurations are also listed.

DISCUSSION

The results show that for seven particles on a sphere the distribution of C_2 symmetry (1:2:2:2) is the most stable for $2 < n < 5.6$. On this basis, we expect seven-coordinated compounds to have similar structures with this symmetry. This conclusion is not strictly correct, since the distributions of particles are calculated using the condition that the tangential forces are zero. The perpendicular forces are not taken into account. For 2, 3, 4, and 6 particles on a sphere, the symmetry of the distributions require the perpendicular force to be the same for every particle. Such structures are found to be undistorted for molecules with the same number of equivalent ligands, unless the non-bonding electron distribution of the central atom is unsymmetrical, as it is in some transition metal ions. Five particles give a trigonal bipyramid. The two particles on the threefold symmetry axis belong to a different symmetry species from those on the twofold symmetry axes and

hence these two sets of particles may have different perpendicular forces. It is easily shown that the two particles on the threefold axis have a larger force for an interparticle potential r^{-1}. This explains the greater bond lengths along this axis for molecules such as PCl_5. Since for seven particles, we have suggested that the most probable symmetry is C_2, there are four different perpendicular forces possible, one for each of the groups 1:2:2:2 (corresponding to the particles 1;2,4;3,5;6,7 of the C_2 structure in Fig. 1). The restriction of the sphere is extremely important in this case. Possibly even for $n = 1$, the C_2 structure without the restraining influence of a sphere would be lower in energy than the D_{5h} structure, because of the higher number of degrees of freedom. Thus it is possible that the C_2 structure is the most favorable for a larger range of n than has already been suggested. Such an arrangement is shown later to be consistent with the structure of IF_7 (7). XeF_6 and $SbBr_6^{3-}$ can also be classified as having seven electron pairs in the valence shell. The structure of XeF_6 is unknown (10) but it behaves spectroscopically like a symmetrical molecule (11); $SbBr_6^{3-}$ is reported to be octahedral (12). Thus neither of these molecules appear to have the predicted distorted structure.* The basic arguments used by Gillespie and Nyholm (9), and later by Gillespie (1), require the use of directed valence orbitals which exist, in the same region of space as so-called lone pair orbitals, even when the orbital is not involved in bonding. This very useful picture has been extensively employed although (13) 'there is no causal relationship between the mathematical convenience of the orbital approximation and the occurrence of directed valences'. Evidence from theoretical studies of simple hydrides of elements in the first row of the periodic table is accumulating which indicates that it is very doubtful that a directed lone pair orbital occupies the same region of space as it would if it were a bonding orbital. Theoretical work, based on the Hellmann–Feynman theorem, has been interpreted as showing that (14) 'in hydride molecules which possess at least one lone pair of electrons the bond orbitals will be primarily of p character and the lone pair orbitals will contain close to the maximum amount of s character'. Possibly the importance of the concept of directed valence, especially regarding the spatial distribution of the lone pairs, has been overstressed (15). Gray and Pritchard (13) are of this opinion and suggest dividing compounds of the type MH_m into two classes: (*a*) where the nuclear repulsion term dominates, and (*b*) where the *net* electron attraction term is most important.

The ideas of Gillespie and Nyholm (9) and of Gray and Pritchard (13) lead to similar predictions for the shapes of molecules not containing lone pairs of electrons and in which the central atom is less than seven coordinated. Gillespie (1) showed that for these cases the molecular shape could be predicted by assuming the arrangement depended on an interparticle potential r^{-n}. Since the results were found to be independent of n, it can be concluded that either nuclear electrostatic repulsions or Pauli forces are the major factors in determining the shape. The presence of lone pairs in the valence shell will generally make the *net* electron attraction term dominant. Gray and Pritchard do not indicate the qualitative expectations in such cases but Nyholm and Gillespie have discussed them very convincingly. However, situations must arise where so many ligands are crowded around a central atom that the nuclear repulsion term is dominant whether or not the valence shell contains lone pairs. It seems reasonable to suggest that for molecules of the type MX_m, for $m \geqslant 6$, the shape may be determined solely by the repulsion between the ligands. As mentioned earlier, a symmetrical structure is reported for $SbBr_6^{3-}$. The

**Since the manuscript of this paper was submitted, preliminary results of an electron diffraction study of gaseous XeF_6 have been reported by Bartell, Gavin, and Thompson (J. Chem. Phys. 43, 2547 (1965)). These indicate a definite departure of the XeF_6 molecule from octahedral symmetry.*

valence shell of this molecule contains 14 electrons and if the structure is determined by nuclear repulsions, the bonding orbitals used are of secondary importance. However, for true octahedral symmetry the electron distribution must be compatible. It is sufficient to note that the 14 valence electrons can occupy the 4f shell to achieve spherical symmetry. This is more than enough to satisfy the minimum symmetry requirements.

In any set of molecules, say MX_m, for $m = 2, 4, 6$, only one of these, $m = 6$, can possibly have the nuclear repulsion term dominant. If the MX_4 structure were governed by this term it would be difficult to explain the stability of MX_6. In some molecules, for example SiF_4, it is unnecessary to know which term is more important since both arguments lead to the tetrahedral structure when no lone pairs are present. Since SiF_6^{2-} exists, the *net* electron attractive term is apparently dominant. This idea is supported by the failure of the nuclear spin–spin coupling constant in its reduced form (16) to give a linear dependence on the atomic number of the central atom in the series CF_4, SiF_4, GeF_4. The similarly reduced coupling constants for the series SiF_6^{2-}, PF_6^-, SF_6 vary linearly with atomic number (16, 17). It appears that the correlations obtained by Reeves (18) hold in every case where the nuclear repulsion term is expected to be dominant, and that the latter may be responsible for their existence.

Since IF_7 has no lone pairs in the valence shell, we cannot distinguish between Gillespie's model of seven particles on a sphere and that of Gray and Pritchard. However, there is no doubt that the structure is determined by the nuclear repulsion term. Let us assume that the valence electrons are distributed with an overall spherical symmetry. This allows us to consider the interaction of the central iodine atom with the fluorines to be a function of the radial distance only. Thus there is some justification for using a spherical surface for distribution of the particles. Possibly we should use an inverse square force law to describe the interaction but as already mentioned the C_2 distribution will probably be more stable than the D_{5h}, once we allow particles to move off the spherical surface. Although calculations have indicated that this is true it is not clear how to make an unequivocal comparison. For example, one basis for a fair comparison would be to insist that all the particles have in addition to a zero tangential force an identical perpendicular force. The difficulty with this approach is that an assumption has to be made about the nature of the central attractive force holding the molecule together. It is therefore clear that predictions of molecular structure derived from calculations for particles on a sphere are less reliable in the case of seven particles than when smaller numbers are considered.

As a check on these ideas we have taken the results for $n = 3$ to 5 and have calculated the perpendicular force on each particle in the C_2 configuration. It is found that particles 6 and 7 experience the largest forces and we would expect these to move out radially relative to the other particles. This is consistent with the observation of Burbank (7) that the fluorine atoms in these positions have the largest I—F bond distances in IF_7. However, Donohue (8) has recently questioned the conclusions of Burbank and suggests that 'it is not possible at the present time to demonstrate that the molecular symmetry is different from D_{5h}'. This uncertainty in the molecular structure does not affect our arguments, but emphasizes the similarity of the different symmetry types already discussed. It should be stressed that none of our results can be used to contribute to the present controversy (7, 8).

Although we cannot expect to calculate the structural details of any molecule (especially in cases of low symmetry) from the model of particles on a sphere, it appears that this approach does offer some help in understanding the factors governing molecular shape. The concept of the localized bond, which is very useful, especially for molecules without lone pair electrons, is unnecessarily rigid and does not explain the structure of IF_7 in the

natural way outlined above. It is appreciated that this model was proposed by Gillespie to represent the interaction of electron pairs in the valence shell, but we have chosen to identify the particles with atoms in those cases where the nuclear repulsion term is expected to be dominant. In this way the structure of $SbBr_6^{3-}$ can be discussed.*

ACKNOWLEDGMENT

We are indebted to Messrs. L. Marks and J. Taylor of the N.R.C. Computation Centre for suggesting the method of steepest descent used in this work and for programming assistance.

**A referee has kindly pointed out that Brown (Can. J. Chem. 42, 2758 (1964)) has shown that $TeBr_6^{2-}$, which is isoelectronic with $SbBr_6^{3-}$, is also octahedral. The fact that Brown has ascribed the symmetry of this ion to repulsions between the closed shells of the ligands rather than to nuclear repulsion is in our opinion merely a matter of emphasis. Thus considered along the lines outlined above, $TeBr_6^{2-}$ is clearly a case where the nuclear repulsion term dominates over the net electron attraction term. Brown attributes the repulsion specifically to the interactions between the closed shells of the bromines.*

THERMAL OXIDATION OF SARAN CARBON

PART I. STUDIES UNDER STATIC OXYGEN SYSTEM

R. G. BARRADAS, M. J. DIGNAM, AND D. D. CHADHA
Department of Chemistry, University of Toronto, Toronto, Ontario

Received April 26, 1965

ABSTRACT

Oxidation studies from 425 to 600 °C of porous carbons obtained from the pyrolytic decomposition of pure polyvinylidene chloride have been carried out in static oxygen systems. Measurements of weight change were made by means of a sensitive thermal microbalance. Empirical activation energies for the oxidation reaction were determined to be approximately 1 eV in magnitude, and comparison is made with previously published results for graphite. Carbon samples obtained from polymers compressed at different molding pressures showed somewhat different temperature and pressure rate dependence. An unusual pressure dependence was observed for the rate of reaction, and a tentative explanation is offered.

INTRODUCTION

Adsorption studies (1, 2, 3) and surface diffusion of gases (4, 5) on "Saran charcoal", a carbon obtained by the complete pyrolytic decomposition of pure polyvinylidene chloride, have been previously reported. Other adsorption studies on a similarly named Saran charcoal were published earlier on carbon prepared from a commerical copolymer of vinylidene chloride and vinyl chloride (6). An extensive investigation of the physicochemical properties of porous carbons is now being carried out in this laboratory, but the present paper is confined to reporting only the results of thermal oxidation studies of Saran charcoal under static conditions.

Saran carbon has been selected for this investigation because of its unique properties. It is a hard, strong, highly porous form of carbon with very regular surface and bulk properties (7, 8). In contrast, pyrolysis of many other polymers leads initially to tar formation and hence to carbon residues with non-uniform surfaces and irregular pore structures (3).

Interest in oxidation studies of this carbon stems in part from its possible development as a diffusion-type fuel cell electrode (9, 10) as well as in other electrode applications where oxidation of the carbon electrode can be of importance. Examples of the latter are electrochemical oxidations of organic compounds at carbon electrodes in strong oxygenated mineral acids where complex anodic chronopotentiometric behavior is observed (11) and the oxidative deterioration of carbon electrodes in the industrial manufacture of chlorine and chlorates (12).

EXPERIMENTAL

The apparatus, which is described in detail elsewhere (13), consists of an automatically recording Sartorius-Werke vacuum microbalance in conjunction with a vacuum furnace and associated vacuum equipment. The balance assembly has a load capacity in excess of 1 g and can detect weight changes as low as 3×10^{-7} g. The furnace temperature is maintained constant to ± 0.1 °C or better and uniform over 4 in. of the central portion to about ± 0.05 °C. The internal diameter of the furnace chamber is 4 cm, and the entire apparatus may be evacuated to pressures of about 3×10^{-6} Torr.

Saran carbon samples of approximately 0.5 g were prepared from pure polyvinylidene chloride powder, which was compressed into "flat" cylinders in a stainless steel die of 0.5 in. diameter by means of a Carver hydraulic press. Samples of the molded polymer were made by the application of 10 000 and 15 000 lb/in.^{2} pressures (referred to as type A and type B samples respectively in subsequent discussion). Before pyrolysis a small hole was drilled in each sample to facilitate its attachment (when fully carbonized) to the platinum

wire suspended from the microbalance beam. The complete pyrolytic decomposition of the polyvinylidene chloride samples and the subsequent determination of porosities by argon adsorption measurements were carried out according to previously described procedures (8). Oxygen was purified by liquefaction in a trap, using liquid nitrogen as refrigerant, followed by distillation; the middle fraction of the distillate was stored in a 2 l storage bulb for subsequent use.

The Saran carbon was introduced into the apparatus and manipulated until it hung centrally in the reaction chamber. After the sample was counterbalanced, the apparatus was evacuated, and the reaction chamber heated to 600 °C and kept at that temperature for 24 h to ensure that the carbon was outgassed. With this procedure, pressures of 5×10^{-5} Torr or better could be maintained at 600 °C. For an experimental run the temperature of the reaction chamber was set at the desired value, then oxygen was admitted to a known pressure. The initial oxygen pressure and subsequent total pressure were measured with an oil (dibutyl phthalate) manometer which could be read by a cathetometer to within ±0.015 Torr. The first measurement of weight changes, shown as positive increments in Figs. 1 and 2, were made not less than 30 s after the introduction of oxygen. The effect on the oxidation rate of varying the temperature and the oxygen pressure was followed in a systematic manner for the two sets of Saran carbons prepared by the different initial molding compression pressures.

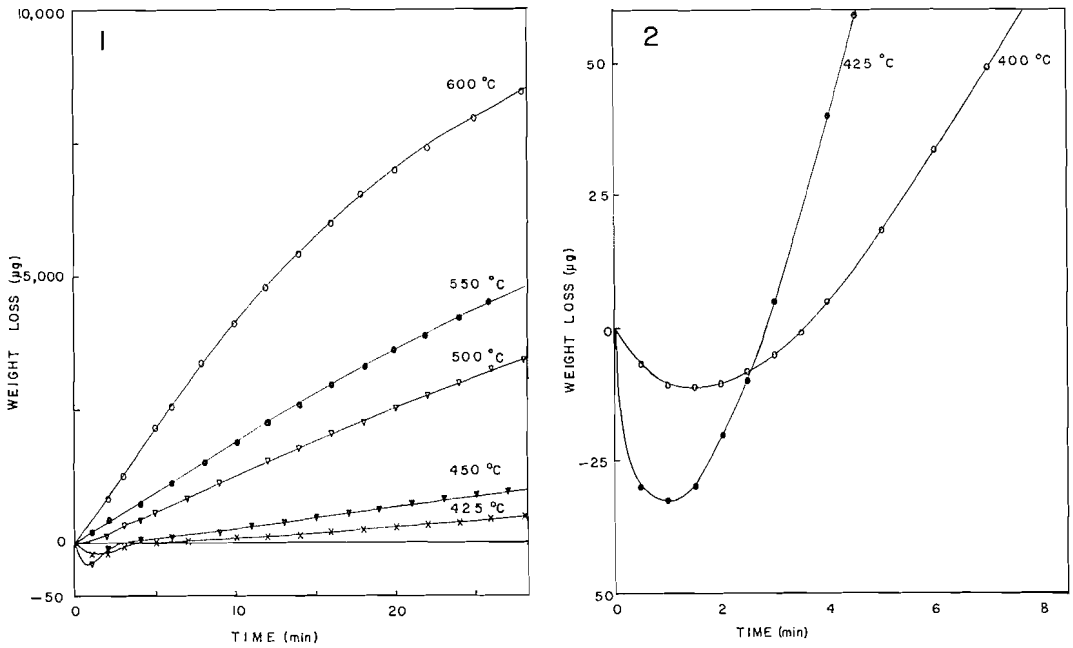

FIG. 1. Weight loss as a function of time for sample A for oxidation temperatures ranging from 425 to 600 °C and for an initial oxygen pressure of 4.5 Torr.

FIG. 2. Weight change as a function of time for sample A at 400 and 425 °C at an initial oxygen pressure of 19.7 Torr.

RESULTS

Outgassing at 400 °C for 24 h was inadequate to expel all sorbed species, and constancy in weight of the carbon could only be attained after heating the sample *in vacuo* at 600 °C for the same period of time.

The data for a sample of Saran carbon type A (pore volume 0.42 cm^3/g) are presented in Fig. 1. The weight scale in Fig. 1 has been expanded for positive weight changes to show the small initial weight increase which takes place at low temperatures (425–450 °C). A clearer illustration of this positive weight change is shown in Fig. 2. Although the detailed oxidation behavior at different pressures and for type B samples (pore volume 0.40 cm^3/g) is somewhat different, the qualitative features remain the same. The differences in their behavior can be inferred from Figs. 3 and 4. However, before pro-

ceeding to these data, it is worth noting that after a series of oxidation runs with a single sample, starting at 600 °C and finishing at 425 °C, a repeated run at 600 °C reproduces the results of the first run to within 10%. Although the rates of reaction at the respective temperatures are relatively constant, there appears to be no unequivocal evidence to suggest whether the internal pores have been significantly enlarged or not. Nevertheless, marked macroscopic changes in physical texture throughout the sample have been observed at the conclusion of a series of oxidation runs. The carbon then resembled "coke" in its ability to crumble easily on slight application of mechanical pressure, and inspection of the fragments showed that oxidation had taken place not only on the outer surface but also well within the interior of the sample.

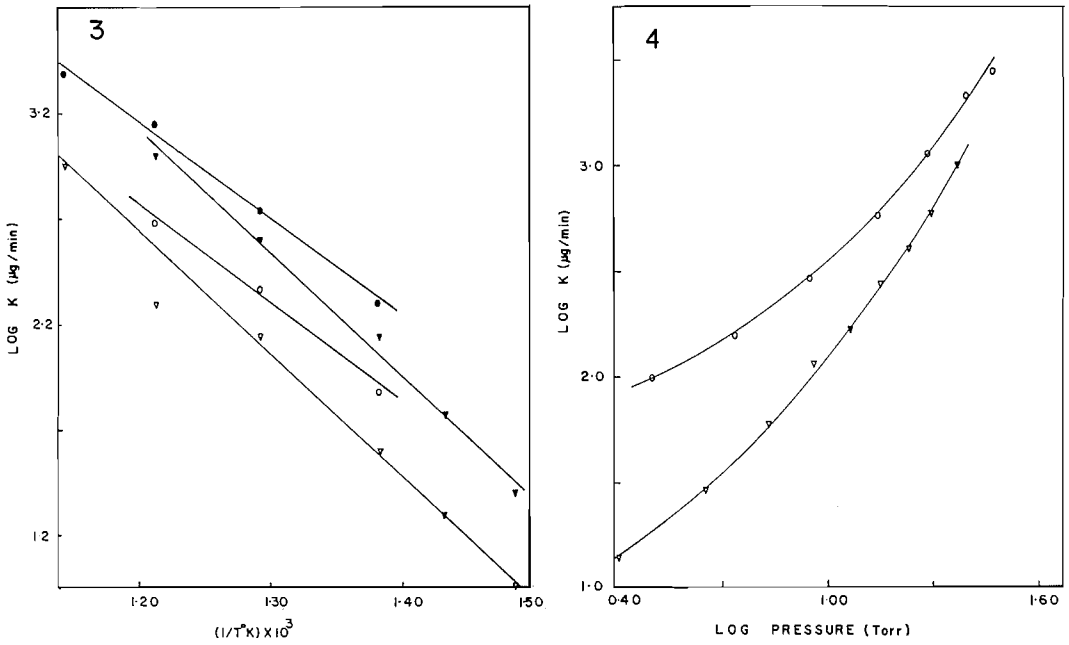

FIG. 3. Plot of logarithm of oxidation rate against reciprocal temperature in degrees absolute. Sample A: ○, 4.5 Torr (O_2); ●, 19.7 Torr (O_2). Sample B: ▽, 4.5 Torr (O_2); ▼, 19.5 Torr (O_2).
FIG. 4. Plot of logarithm of oxidation rate versus logarithm of initial oxygen pressure at 500 °C. ▽, Sample A. ○, Sample B.

The temperature dependence for oxidation of type A and type B Saran carbon is illustrated in Fig. 3 for two different initial oxygen pressures. The rates were calculated from the slopes of the initial linear regions of weight loss against time. The results for oxidation at 600 °C have been omitted from two of the curves of Fig. 1 as the pronounced curvature of the oxidation curves in conjunction with the rapid oxidation made the rate determination rather uncertain. In relation to the data shown in Fig. 1 we have calculated that the total amount of oxygen consumed at 425 °C is about 4% (on the basis that only CO is formed as the product) after 28 min of reaction. Higher oxygen consumption for the same period of reaction was obtained for each elevated temperature, and at 600 °C most of the oxygen appeared to have been consumed.

Figure 4 presents the pressure dependence of the rate for type A and type B samples at a temperature of 500 °C. Once again, the rates were determined from the linear region of the oxidation curves.

DISCUSSION

Dacey and Thomas (1) generally degassed their Saran carbons at 400 °C for several hours before carrying out adsorption studies. Our results indicate that this procedure is insufficient for the removal of more sorbed species. The decrease in oxidation rate with time at high temperatures (Fig. 1) undoubtedly arises from the consumption of oxygen and perhaps also from the formation of products* (presumably CO and (or) CO_2, cf. ref. 14 and the references contained therein).

The initial gain in weight at low temperatures (Figs. 1 and 2) is interesting as it can only result from chemisorption of oxygen or possibly from a pressure buildup within the porous carbon, which would be detectable if the diffusion constant for the reaction product(s) is sufficiently smaller than that for oxygen. In the present context, the diffusion constants are those for migration of the gases through the porous structure of the solid. It seems unlikely from the experimental conditions of our measurements that the initial gain in weight is caused by spurious effects resulting from "thermo-molecular flow" caused by thermal inhomogeneity or by various Knudsen Effects as reported by Poulis and Thomas (15). For the temperature and pressure ranges investigated in the present work, our calculations indicate that the mean free path of the oxygen molecules is well below the dimensions of the containing vessel (cf. ref. 15).

The relative constancy in the rates of reaction following a series of oxidation runs with a single carbon sample suggests that there may be a compensation between two operating parameters. If the surface area per unit volume of the carbon decreases (as porosity increases), this effect is balanced by a corresponding increase in the diffusion constants for the migration of the gases through the pores of the sample.

The linearity of the Arrhenius plots (Fig. 3) suggests a relatively simple interpretation of the temperature coefficient. Interpreting the slopes in terms of "activation energies" we obtain the values listed in Table I. These values are notably smaller than the 37

TABLE I

Energy of activation and oxygen pressure for type A and B samples

	Energy of activation (kcal/mole)	Oxygen pressure (Torr)
Saran carbon A	26.9	4.48±0.07
	26.9	19.74±0.06
Saran carbon B	21.5	4.54±0.17
	21.5	19.50±0.07

kcal/mole found by Gulbransen and Andrew (16) for the oxidation of artificial graphite in the same range of temperature and pressure. The activation energy for type A samples is significantly greater than that for type B samples, but this difference cannot be accounted for only on the basis of pore volume and density of the carbons. One cannot distinguish a carbon sample of pore volume 0.40 cm^3/g from another of 0.42 cm^3/g because the accuracy of measurement of porosities by argon adsorption is poorer than 0.02. Because of the difference in the initial molding compression pressures of the polymer, there is a good possibility that pore diameter and structure of the ultimate carbons may

**The apparatus is presently undergoing extensive modifications to allow oxidation studies to be carried out under dynamic flow conditions, thus enabling more precise control of the composition of the oxidizing environment. Modifications to permit monitoring of the product composition are also under way. The results of this complementary work under dynamic conditions will be communicated elsewhere later.*

be different. Saran carbon has been reported as being a system of uniform micropores, where the narrowest constrictions to flow are 10 to 15 Å wide (4). The observed differences in activation energy may arise as a result of different permeabilities of the samples to oxygen and (or) resultant products (cf. discussion which follows eq. [1] below).

A further interesting result concerns the unusual pressure dependence illustrated in Fig. 4. The slope of log (rate) versus log (oxygen pressure) is fairly close to 1 at low pressures, increasing to 2 or higher at high pressures. It might be supposed that the unusual pressure dependence could be explained simply by combining rate expressions for the interfacial reaction with conventional diffusion equations. This does not, however, appear to be the case. A detailed analysis of reaction kinetics in porous media will be presented by one of us (M. J. D.) in a subsequent publication. A brief summary of the pertinent results as they apply to the present static oxygen system will, however, be given below.

If the primary surface reaction rate is proportional to p^n where p is the oxygen pressure, and the diffusion constant for oxygen migration within the porous carbon is independent of the concentration of sorbed species, then the maximum possible pressure dependence for oxidation of the porous carbon will be given by p to the power of n or $(n + 1)/2$, whichever is greater. This postulate for the reaction of a gas in the pores of a solid is essentially the same as that derived by Wheeler from a somewhat different theoretical approach (17), and it has been applied by Blyholder and Eyring (18) to the interpretation of the kinetics of graphite oxidation. Furthermore, if diffusion plays a major role in the overall reaction kinetics, the empirical activation energy will be the mean of the activation energy for the primary reaction process and that for diffusion (*vide infra*).

In the present case it appears very unlikely that n is greater than 1. The data on graphite (16) would suggest a value between 0 and 1. It is extremely probable, therefore, that the observed pressure dependence arises as a result of an increase in the diffusion constant with increasing adsorbate concentration in the porous carbon. Although such a postulate appears somewhat contrary to expectation, a similar phenomenon has been observed by Dacey and Fendley (4) who measured the flow of non-reactive gases through Saran charcoal. They found that for certain samples the flow rate for a given pressure gradient increased linearly with increasing average pressure. The maximum dependence of the diffusion constant on pressure which may be inferred from their results is still insufficient to predict a p^2 dependence for $n \leqslant 1$. A more detailed examination of this problem will have to await the data obtained from the dynamic flow system.

It appears almost certain that diffusion of oxygen into the porous carbon plays a major role in the overall reaction kinetics. We may therefore write

$$[1] \qquad Q_{obs} = (Q_D + Q_R)/2$$

where Q_{obs}, Q_D, and Q_R are respectively the observed or empirical activation energy, the activation energy for diffusion, and that for the primary surface reaction (cf. ref. 18). Using the results in Table I, and noting that Q_R is probably not greater than the corresponding quantity for oxidation of graphite (37 kcal), we conclude that $Q_D \gtrsim 6$ kcal for type B samples, and $\gtrsim 14$ kcal for type A samples. The estimated value of Q_D for type B samples is in very good agreement with the activation energies of about 4 and 5 kcal/mole for diffusion of argon and methane as reported by Dacey and Fendley (4). This suggests that eq. [1] gives a good representation of the Q_D contribution, which arises from the permeability of the carbon to oxygen and (or) resultant gaseous products. The estimated value of Q_D for type A samples appears to be too large. One possible explanation for this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is that the permeability of type A samples is substantially greater than that of type B samples. If the type A permeability were sufficiently large, eq. [1] would not be valid in that Q_{obs} would be closer to Q_R than indicated by this equation. A further possibility is, of course, that Q_R differs for the two types of Saran carbons.

ACKNOWLEDGMENTS

We are indebted to the Defence Research Board and the University of Toronto for financial support of this work. One of us (M. J. D.) is grateful to the National Research Council for grants to construct the vacuum microbalance.

SOME HYDROGEN ABSTRACTION REACTIONS OF PERFLUOROETHYL RADICALS

G. O. PRITCHARD,[1] J. R. DACEY, W. C. KENT, AND C. R. SIMONDS
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario
Received August 19, 1965

ABSTRACT

With perfluoroazoethane as a photolytic source of C_2F_5 radicals, the hydrogen abstraction reactions of C_2F_5 with deuterium, ethane, cyclohexane, acetone, and trifluoroacetaldehyde have been studied, and the Arrhenius parameters derived. The H-atom abstraction reactions of the three perfluoroalkyl radicals, CF_3, C_2F_5, and C_3F_7, are discussed.

INTRODUCTION

Data on the H-atom abstraction reactions of perfluoroalkyl radicals (CF_3, C_2F_5, and C_3F_7) have recently been summarized (1, 2); they are quite limited, especially for C_2F_5 radicals, and the Arrhenius parameters obtained with a particular substrate RH show wide variations. The perfluoroketones have generally been used as a source of radicals, although some work has been done with the fluoroaldehydes, and hexafluoroazomethane has been used as a source of CF_3 radicals (3). Direct abstraction versus recombination data were not obtained in the last study because of the rapid addition of CF_3 radicals to —N=N—, which reduces their concentration so severely that the rate of formation of C_2F_6 cannot be accurately determined. However, perfluoroazo compounds can be photolyzed in the near ultraviolet, so that the range of compounds RH can be extended to aldehydes and ketones, without the latter being photolyzed. In contrast to hexafluoroazomethane, large yields of C_4F_{10} are obtained in the photolysis of perfluoroazoethane under comparable conditions (4), so that it has been used as the radical source in this work; and direct abstraction

[1] $$C_2F_5 + RH \rightarrow C_2F_5H + R$$

versus recombination

[2] $$2C_2F_5 \rightarrow C_4F_{10}$$

data have been obtained. Substrates RH were chosen so that comparison could be made with the available CF_3 and C_3F_7 radical data (see Table II).

EXPERIMENTAL

The beam from a high-pressure Hg arc was collimated and passed through a Corning 9863 blue-glass and $CuSO_4.5H_2O$ solution (100 g l^{-1}, 5 cm path). The cylindrical (5 cm diameter, 10 cm long) pyrex cell had a reaction volume of 192 cc, and it was fully illuminated. It was fitted with an outer jacket, and desired temperatures were obtained with refluxing liquids.

The perfluoroazoethane was prepared by the action of silver(I) fluoride on trifluoroacetonitrile (5); the contents of the bomb were bubbled through a KOH solution (twice) and then through a solution of Ag_2O suspended in water. The recovered gas was distilled on a Podbielniak column, the fraction between 18 and 21 °C being retained. After the gas was dried with P_2O_5, vapor density measurements gave a molecular weight (corrected) of 264 (calculated 266). Vapor phase chromatography indicated that the compound was >99.5% pure, although two trace impurities of greater volatility were detected. The more volatile of the two was found to be C_4F_{10} by vapor phase chromatographic characterization. Other possible impurities are C_2F_5Br and N-bromotetrafluoroethylidenimine, which are by-products of the preparation (5), although the purification technique was designed to remove them. Also, the mass spectrum of the perfluoroazoethane

[1]*Department of Chemistry, University of California, Santa Barbara, California.*

showed no conclusive evidence for Br^+, but spurious ion-peaks at *m/e* 30 and 46 were obtained. It is possible that these peaks are caused by NO_2 (b.p. 21°), which may be formed in some way in the preparation. The azo-compound was further purified by pumping at −110 to −115 °C, which completely removed the impurities from the chromatograms and the mass spectra. No variation in rate data was observed whether this final purification step was carried out or not.

The extinction coefficient (based on decadic logarithms) of perfluoroazoethane is 17.2 l mole^{-1} cm^{-1} at 3 840 Å (λ_{max}), and ϵ ranges from 12.4 to 15.6 l mole^{-1} cm^{-1} between 3 600 and 3 700 Å, showing the expected shift to the red when F atoms are substituted for H atoms (6). In azoethane, ϵ = 9.9 l mole^{-1} cm^{-1} at 3 550 Å (λ_{max}) (7).

At the completion of a run, N_2 could be collected at −190 °C and measured. Its purity was checked on the mass spectrometer. C_2F_5H was collected at −145 °C, and it was characterized and its purity established by vapor phase chromatography and mass spectrometry. A sample was then collected at −107 °C, and subjected to vapor phase chromatography on a 3% squalane on silica-gel column at 150 °C. The C_4F_{10} showed a retention time of 3½ min and the perfluoroazoethane 8½ min. The purity of the C_4F_{10} was checked on the mass spectrometer. When perfluoroazoethane, in which the final purification step had not been carried out, was used, the second impurity showed as a peak at 6½ min.[2] In runs above 220 °C, a small peak appeared at ~5 min, and tended to merge into the tail of the C_4F_{10} peak; the peak became slightly more pronounced at higher temperatures. It was observed when the azo-compound was photolyzed alone at these temperatures, but it was not formed in a dark reaction. Because of this peak, a slight correction (<3%) was made to the C_4F_{10} areas obtained above 220 °C. The retention time of the C_2F_5H, which sometimes contained a negligible quantity of C_4F_{10}, was 2½ min.

The compounds RH used were of spectroscopic or highest quality research grade. In the D_2 experiments, the D_2 was pumped off at −190°, together with the N_2. The D_2 used analyzed ~99% D_2, 1% HD, and < 0.3% H_2 on the mass spectrometer. The C_2F_5D produced in the reaction contained less than 2% C_2F_5H at the lowest temperature, as found by a comparison of *m/e* 51 and 52 (CF_2H^+ and CF_2D^+). In the ethane experiments, the excess ethane was pumped off the reaction mixture at −175°; attempts were made to identify $C_2F_5C_2H_5$ in the reaction products by vapor phase chromatography, but it was concluded that only trace amounts, if any, were formed.

Acetone and cyclohexane, and any other products formed in these systems, did not interfere with the analysis. In the experiments with CF_3CHO, after pumping off the N_2, a fraction was collected at −107° and subjected to vapor phase chromatography on the column at room temperature. Retention times were C_2F_5H 22 min, and C_4F_{10} 34 min. This procedure was adopted, since the excess CF_3CHO interfered with the Ward-still separation of C_2F_5H and C_4F_{10}.[3] Three small peaks at lower retention times were also observed, probably from CF_3H, C_2F_6, and C_3F_8 formed by the decomposition of the CF_3CO radical.

RESULTS AND DISCUSSION

The results for the five compounds studied are given in Table I. Pressures (measured at room temperature) of perfluoroazoethane used were: 1½–3 cm with D_2, ethane, and acetone; 3½–9 cm with cyclohexane; and 2–4½ cm with CF_3CHO. From the N_2 produced, it was calculated that about 10% of the perfluoroazoethane was photodecomposed in each experiment. The data give good Arrhenius plots, and $k_1/k_2^{1/2}$ in mole$^{-1/2}$ cc$^{1/2}$ s$^{-1/2}$ is: for D_2, $1.2 \times 10^6\ e^{-14100/RT}$; for ethane, $1.5 \times 10^5\ e^{-8700/RT}$; for cyclohexane, $1.5 \times 10^5\ e^{-6000/RT}$; for acetone, $5.1 \times 10^4\ e^{-8400/RT}$; and for CF_3CHO, $2.5 \times 10^5\ e^{-9700/RT}$. The value and limits of error for the D_2 activation energy are $E_1 - \frac{1}{2}E = 14.1 \pm 0.3$ kcal mole^{-1}. Including the low run at 232 °C, we obtain 13.8 ± 0.4 kcal mole^{-1}. The limits of error for the other activation energies are less than ±0.2 kcal mole^{-1}.

Table II shows all the available Arrhenius parameters on R_f(CF_3, C_2F_5, or C_3F_7) radical H-atom abstraction reactions.

[1] $$R_f + RH \rightarrow R_fH + R$$

[2] $$2R_f \rightarrow R_{f_2}$$

Two studies on the cross combination of perfluoroalkyl radicals, $CF_3 + C_3F_7$ (9), and $CF_3 + C_2F_5$ (10), yield ratios close to the collision theory value of 2, independent of the

[2]*This may suggest that the perfluoroazoethane exists to a small extent as two geometric isomers. An analysis of the infrared spectrum of hexafluoroazomethane has been presented (8), but it was not concluded whether the cis or the trans form predominated. It has been claimed that intensely yellow (cis) and colorless (trans) hexafluoroazomethane occur. (V. A. Ginsburg et al. Proc. Acad. Sci. USSR, Chem. Sect. Engl. Transl. 142, 34 (1962).*

[3]*The Ward-still separation used with the other compounds was as rapid, and the chromatograms were more accurate.*

temperature, showing that we may directly compare the values of $E_1 - \frac{1}{2}E_2$ in Table II, and the values of $A_1/A_2^{1/2}$ almost directly. The respective collision numbers at 400 °K for CF_3, C_2F_5, and C_3F_7 are 7.5×10^{13}, 1.1×10^{14}, and 1.3×10^{14} mole^{-1} cc s^{-1} ($\sigma_{CF_3} = 4.0$ Å, $\sigma_{C_2F_5} = 5.5$ Å, $\sigma_{C_3F_7} = 6.5$ Å). Very recent work (11) indicates that $E_2 = 0$ for CF_3 combination, so that we may equate $E_1 - \frac{1}{2}E_2$ with E_1 as an absolute value.

Limitations are put on the accuracy of the values of E_1 (and this applies to many radical abstraction studies) because additional R_fH (except in the aldehyde systems) may be formed by interaction of the R_f radical with the radical formed in reaction [1]

[3] $$R_f + R \rightarrow R_fH + R(-H)$$

*[R_fH] and [R_fD] divided by 2, see text. Parenthetical values considered less reliable. Data mainly obtained from the compilations in refs. 1 and 2, and this work. Other data taken from G. O. Pritchard and G. H. Miller. J. Chem. Phys. 35, 1135 (1961); W. G. Alcock and E. Whittle. Trans. Faraday Soc. 61, 244 (1965); R. L. Thommarson and G. O. Pritchard. To be published; and refs. 11, 14, and 19.

which competes with

[4] $$R_f + R \rightarrow R_fR.$$

In the C_3F_7 + ethane system, allowance was made for this from a knowledge of the C_4H_{10} ($R + R \rightarrow R_2$) and the $C_3F_7C_2H_5$ formed (12), but the value of E_1 was not affected whether the correction was made or not, although the reason for this is not apparent (13). In many systems the necessary product analysis to assess the extent of reaction [3] has not been or is not easily performed, and if only a partial analysis is carried out the possible temperature dependence of k_3/k_4 must be considered (14). A more complete review (15) of the problem will be presented.

In this respect the perfluoroazo-compounds may be preferable sources to the perfluoroketones, since a large fraction of the R radicals can easily add to —N=N—, rather than enter into reactions [3] and [4]. In the experiments with ethane we were not able to obtain measurable quantities of $C_2F_5C_2H_5$. Since k_3/k_4 for C_2F_5 and C_2H_5 is less than 0.4, based on k_3/k_4 for $C_3F_7 + C_2H_5$ (12, 14), any C_2F_5H formed in reaction [3] was negligible. The mass balance, $(\frac{1}{2}[C_2F_5H] + [C_4F_{10}])/[N_2]$, indicates an increasing loss of C_2F_5 radicals with temperature, from increasing addition at —N=N—, and reactions [3] and [4]. No analysis was attempted for C_2F_5–cyclohexyl and C_2F_5–acetonyl, but in experiments with cyclohexane above 200 °C, when $[C_2F_5H]/[N_2]$ approaches 2, the perfluoroazoethane consumed indicated the addition of cyclohexyl to —N=N—.

In the hydrogen (H_2 and D_2) systems the fate of the atom liberated

$$R_f + D_2 \rightarrow R_fD + D$$

poses a problem, since it may combine with an R_f radical

[5] $$R_f + D + (M) \rightarrow R_fD + (M)$$

to produce additional R_fD (this reaction may or may not have a third-body restriction) as well as another atom.

[6] $$D + D + M \rightarrow D_2 + M$$

This competition has been treated by Kutschke (16), who concludes that if both modes of removal of hydrogen atoms occur over the temperature range, a varying correction to $[R_fD]$ is necessary. Although this consideration is important in perfluoroketone systems, when C_3F_7CHO was used as the radical source (2), the HD enrichment of the D_2 that occurred during reaction indicated that the major fate of the D atoms was

$$D + C_3F_7CHO \rightarrow HD + C_3F_7CO$$

and no correction to $[C_3F_7D]$ was required. Similarly, no correction to the $[C_2F_5D]$ produced in this work is necessary, if we assume that the major fate of the D atoms is addition to —N=N—. This is substantiated by the pre-exponential ratio obtained, 120×10^4 mole$^{-1/2}$ cc$^{1/2}$ s$^{-1/2}$, which compares favorably with the aldehyde values, 158×10^4 ($C_2F_5 + H_2$), 72×10^4 ($C_3F_7 + H_2$), and 96×10^4 ($C_3F_7 + D_2$), all in mole$^{-1/2}$ cc$^{1/2}$ s$^{-1/2}$. The lower (asterisk) values (Table II) were obtained in perfluoroketone systems where it was considered that reaction [5] was the predominant fate of the hydrogen atoms, and the rates of production of R_fH and R_fD were divided by 2. The data imply that atom recombination (reaction [6]) predominates in these systems, but Kutschke (16) has pointed out that there are too many uncertainties to fully justify this conclusion.

Although limits of error have not been quoted in Table II, it will be assumed for the remainder of the discussion that the values of E_1 given, as derived from the Arrhenius plots, are good to ±0.5 kcal mole^{-1}, although much of the experimental data certainly appears to be more precise than this. Despite the experimental uncertainties, the values of

For personal use only.

E_1 for H_2 and D_2 with C_2F_5 and C_3F_7 show a pronounced increase over those with CF_3. Recent work (17) indicates that $D(CF_3—H)$ may exceed $D(C_2F_5—H)$, and $D(C_3F_7—H)$, which is identical with $D(C_2F_5—H)$ (1), by as much as 4–5 kcal mole^{-1}, so that the H_2 data could be explained in terms of the Evans–Polanyi relation, $E = \alpha\Delta H + c$, with $\alpha \simeq 0.6$.

Our previous conclusion, based on an assumed invariance for $D(R_f—H)$, that E_1 should remain constant for the three radicals for a particular substrate (1) is invalidated if one accepts the picture given for H_2 and D_2. Nevertheless, approximate constancy for E_1 is seen for methane, ethane, cyclohexane, and acetone in Table II. Any interpretation is further complicated by the greater than 10-fold variations in the $A_1/A_2^{1/2}$ ratios (acetone excepted), which in part is probably a result of internal compensation in the Arrhenius parameters. For instance, with the experimental value of $k_1/k_2^{1/2} = 24.7$ mole$^{-1/2}$ cc$^{1/2}$ s$^{-1/2}$ for CF_3 + ethane at 182 °C (18), if we assume $A_1/A_2^{1/2} = 10^5$ mole$^{-1/2}$ cc$^{1/2}$ s$^{-1/2}$ (rather than 10^4 as given in Table II), E_1 becomes 9.6 kcal mole^{-1}, which leads to a better correlation with the C_2F_5 and C_3F_7 + ethane data.

The variations in the Arrhenius parameters for the aldehydes are quite extreme. Based upon the value of $E_1 = 9.7$ kcal mole^{-1} that we have obtained for

$$C_2F_5 + CF_3CHO \rightarrow C_2F_5H + CF_3CO$$

it seems that the value of Dodd and Smith (19) of $E_1 = 8.2$ kcal mole^{-1} for

$$CF_3 + CF_3CHO \rightarrow CF_3H + CF_3CO$$

is experimentally justified, although it had previously seemed to be improbably high (20). Bromination studies (21) have demonstrated a marked deactivating effect for H abstraction when fluorine atoms are substituted for hydrogen atoms on the adjacent carbon atom. The values of E_1 for CF_3 + CF_3CHO and CH_3CHO are consistent with this.

The data on the ketones again suggest compensation in the Arrhenius parameters, although from steric considerations some attack at the primary rather than the secondary H-atoms could contribute to a real increase in E_1 for $C_3F_7 + C_2H_5COC_3F_7$.

Acetone shows very little variation for attack by the three radicals, which would lead one to conclude that the H_2 and D_2 data are best explained by compensation in the Arrhenius parameters, rather than by any real change in E_1. A complete interpretation must await further elucidation of all the factors involved, and at present it appears that it is only valid to compare the rate constant ratios, $k_1/k_2^{1/2}$, directly, and not the derived Arrhenius parameters.

REACTIONS OF ORGANOTIN COMPOUNDS

VI. THE REACTIONS OF TIN HYDRIDES WITH PERFLUOROVINYL TIN COMPOUNDS

A. D. BEVERIDGE, H. C. CLARK,[1] AND J. T. KWON
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received July 30, 1965

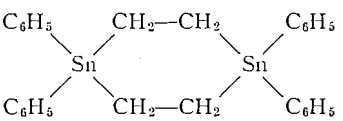
ABSTRACT

The reactions of methyltin hydrides with methylperfluorovinyltin compounds have been examined under heat or ultraviolet irradiation. In no case is there evidence of addition to the C=C bond. Instead, extensive reduction of the vinyl group occurs to give *cis*-1,2-difluorovinyltin derivatives as the principal products, with smaller amounts of the *trans*-1,2-difluorovinyltin isomers, 2,2′-difluorovinyltin compounds, and products containing one or more $-C_2H_2F$ groups. Trimethyl- or dimethyl-tin fluoride is formed quantitatively from the corresponding hydride. In the reaction of dimethyl bis(perfluorovinyl)tin with dimethyltin dihydride, vinyl-hydrogen exchange occurs at 60° in the dark to give dimethylperfluorovinyltin hydride, while under ultraviolet irradiation partially fluorinated vinyltin compounds are formed. On the other hand, no reaction takes place between dimethyl bis(perfluorovinyl)tin and 2 moles of trimethyltin hydride in the dark at 50°, but under ultraviolet irradiation at 25°, partial vinyl-hydrogen exchange occurs, accompanied by reduction, to yield both trimethyl and dimethyl partially fluorinated vinyltin compounds. The infrared and proton magnetic resonance spectra of the products are discussed.

INTRODUCTION

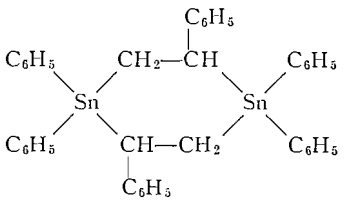
In earlier papers in this series (1–3), we examined the addition reactions of dimethyltin dihydride to a series of olefins, some partially fluorinated. It was concluded that such additions most probably occur by a free radical mechanism in which the formation of radicals from the tin dihydride may be the rate-determining step. A secondary and somewhat unexpected result from these studies centered about the apparent instability of groups such as $>Sn(C_2F_3H_2)_2$ or $>Sn(C_2F_3BrH)_2$. The latter should constitute part of the reaction product from dimethyltin dihydride and trifluorobromoethylene, but the reaction in fact proceeded chiefly according to the equation

$$(CH_3)_2SnH_2 + 2CF_2{=}CFBr \rightarrow (CH_3)_2SnBr_2 + 2CF_2{=}CFH.$$



To gain further information about the reactivity of the C=C bond towards tin hydrides, and about the stability and decomposition of the fluoroalkyl group bonded to tin, we have now investigated the reactions of tin mono- and di-hydrides with some tin–perfluorovinyl compounds.

DISCUSSION



By analogy with the ready addition of tetrafluoroethylene to dimethyltin dihydride, one might anticipate a smooth reaction between trimethyltin hydride and trimethyl(perfluorovinyl)tin to give the product $(CH_3)_3SnCF_2CFHSn(CH_3)_3$. It is, however, well established (4) that such additions to the vinyl C=C bond do not occur readily for vinyltin compounds, although exceptions are observed. Thus diphenyltin dihydride and diphenyldivinyltin do not form the 1,4-distannacyclohexane compound (I), although a related product (II) has been obtained by reaction of diphenyltin dihydride with phenylacetylene (5). However, triphenyltin hydride and triphenylvinyltin, when heated under nitrogen at 70°, formed 1,2-bis(triphenyltin)ethane in 50% yield (6). It is noticeable that those

[1]*To whom correspondence concerning this paper should be sent. Present address: Department of Chemistry, University of Western Ontario, London, Ontario, Canada.*

cases in which addition to the vinyl C=C bond does occur are largely confined to triphenylvinyltin, and the suggestion has been made that this is a result of the activation

(I)

(II)

of the double bond by a conjugative $d\pi$–$p\pi$ mechanism (6). In one instance there is evidence of vinyl-hydrogen exchange. In the reaction of tri-*n*-butyltin hydride with triethylvinyltin at 90°, the products[2] were a mixture of tri-*n*-butyltin hydride and tri-*n*-butylvinyltin, triethyltin hydride, and 1,2-bis(tri-*n*-butyltin)ethane.

In general the perfluorovinyltin compounds are less stable thermally and kinetically than their vinyltin analogues, and their chemical behavior is often quite different. For example, the only reaction so far reported of a perfluorovinyltin compound with a tin hydride (7) appears to be a double decomposition reaction and not an addition.

$$(C_6H_5)_3SnCF{=}CF_2 + (C_6H_5)_3SnH \rightarrow CF_2{=}CFH + (C_6H_5)_3SnSn(C_6H_5)_3$$

This is in contrast to the addition to triphenylvinyltin described above. Clearly, the extension of our previous studies with fluoro-olefins to similar reactions of perfluorovinyltin compounds allows a number of possibilities.

Trimethyltin hydride and trimethylperfluorovinyltin do not react at 25° in the dark, and raising the temperature to 70° caused only 3% reaction. This is in contrast to the smooth reaction of the triphenyltin compounds described above, and perhaps emphasizes the importance of $d\pi$–$p\pi$ interactions in the latter case. Very ready reaction of the trimethyltin compounds, however, does occur under ultraviolet irradiation at 25°. Addition to the C=C bond does not take place, and in fact the vinyl group is reduced, accompanied by the quantitative formation of trimethyltin fluoride. The principal volatile product is trimethyl (*cis*-1,2-difluorovinyl)tin; smaller amounts of the *trans*-1,2-difluorovinyl compound, trimethyl (2,2′-difluorovinyl)tin, and a product of empirical composition $(CH_3)_3SnC_2H_2F$ are also formed. The principal reaction is therefore described by the equation

$$(CH_3)_3SnCF{=}CF_2 + (CH_3)_3SnH \rightarrow (CH_3)_3SnCF{=}CFH \text{ (}cis\text{ and }trans\text{ in ratio 3:1)} \; [+ (CH_3)_3SnCH{=}CF_2] + (CH_3)_3SnF.$$

To obtain a compound with a monofluorovinyl group, $-C_2H_2F$, however, a secondary reaction must be postulated. All the above products have been characterized by their infrared and proton magnetic resonance spectra (*vide infra*), and by hydrolysis with trifluoroacetic acid. Thus, for example, trimethyl (*cis*-1,2-difluorovinyl)tin quantitatively forms 1,2-difluoroethylene on treatment with trifluoroacetic acid.

$$(CH_3)_3SnCF{=}CFH\ (cis) + CF_3COOH \rightarrow CFH{=}CFH + (CH_3)_3SnOOCCF_3$$

It was found that under ultraviolet irradiation with a twofold excess of the hydride, the conversion of trimethylperfluorovinyltin to protonated vinyl derivatives was complete, and also that the yield of $(CH_3)_3SnC_2H_2F$ increased threefold. Although there were

[2]*D. Seyferth and M. A. Weiner, quoted in ref. 4, p. 226.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

indications of other secondary products, further reaction of the 1,2-difluorovinyl compounds gives principally $(CH_3)_3SnC_2H_2F$. This is confirmed by the fact that trimethyl (*cis*-1,2-difluorovinyl)tin could be further reduced, by ultraviolet irradiation with trimethyltin hydride, to form $(CH_3)_3SnC_2H_2F$. Interestingly, in this reaction some of the *cis*-1,2-difluorovinyl compound is converted to the *trans* isomer.

$$(CH_3)_3SnCF{=}CFH\ (cis) + (CH_3)_3SnH \rightarrow (CH_3)_3SnC_2H_2F\ [+ (CH_3)_3SnCF{=}CFH\ (trans)] + (CH_3)_3SnF$$

The configuration of the SnC_2H_2F group is uncertain, although the spectra of the products always gave the same coupling constants for the $-C_2H_2F$ group, clearly establishing that only the one isomer was always formed, although three are possible. The most reasonable assignments are in terms of the configuration shown in Table I, but this requires a fluorine–proton coupling constant for the *trans* —HC=CF— group of 100 c.p.s., at least twice as great as any known value (8). Other configurations cannot be correlated with the other observed coupling constants.

In the reaction of dimethyl bis(perfluorovinyl)tin with 2 moles of trimethyltin hydride, there exist such possibilities as reduction to form either protonated vinyl products such as $(CH_3)_2Sn(CF{=}CFH)_2$ bis-*cis*, or mixed products such as $(CH_3)_2Sn(CF{=}CF_2)(CF{=}CFH)$, or vinyl-hydrogen exchange to form trimethylperfluorovinyltin, or addition. Although no reaction was apparent even after 35 h at 50° in the dark, some vinyl-hydrogen exchange and reduction were observed after heating for 24 h at 60° in the dark, followed by exposure to daylight for 24 h. Under ultraviolet irradiation at 25°, complete reaction was achieved, and both vinyl-hydrogen exchange and reduction were observed. The principal products of the reaction were trimethyl *cis*-1,2-difluorovinyltin, trimethylperfluorovinyltin, trimethyl *trans*-1,2-difluorovinyltin, dimethyl bis(*cis*-1,2-difluorovinyltin), smaller amounts of trimethyl 2,2-difluorovinyltin, and dimethyl bis(2,2-difluorovinyltin), and still lesser amounts of the secondary products $(CH_3)_3SnC_2H_2F$ and $(CH_3)_2Sn(C_2H_2F)_2$.

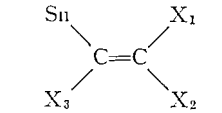
Therefore, it is clear that the two initial competing reactions must be

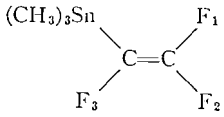
$$[a] \qquad (CH_3)_2Sn(CF{=}CF_2)_2 + 2(CH_3)_3SnH \rightarrow 2(CH_3)_3SnCF{=}CF_2 + (CH_3)_2SnH_2$$

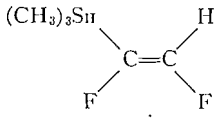
$$[b] \qquad (CH_3)_2Sn(CF{=}CF_2)_2 + 2(CH_3)_3SnH \rightarrow (CH_3)_2Sn(CF{=}CFH)_2\ (cis) + (\text{others})$$

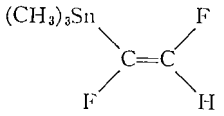
with the exchange reaction dominant. Extensive reduction of the fluorinated vinyl species by trimethyltin hydride, and dimethyltin dihydride (from [*a*]), must then ensue. This was completely borne out by identification of a white solid produced in the reaction as a mixture of trimethyltin fluoride and dimethyltin difluoride, with the latter present in higher yield. There was no evidence for addition.

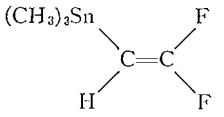
Finally, the reaction of dimethyltin dihydride with dimethyl bis(perfluorovinyl)tin was examined, and here markedly different results were obtained according to the conditions employed. At 60° in the dark, although products from the decomposition of the starting materials and from reduction were formed in small amounts, the only major product was dimethylperfluorovinyltin hydride, $(CH_3)_2SnH(CF{=}CF_2)$. This was identified unambiguously by its proton magnetic resonance and infrared spectra. Although one other example of vinyl-hydrogen exchange has been reported[2] in addition to that described in the preceding reaction, this appears to be the only compound so far known which contains simultaneously the Sn—C=C and Sn—H groups. This demonstrates in a unique way the lack of reactivity of the C=C bond in perfluorovinyltin compounds towards addition. The basic reaction under these conditions is therefore the following:

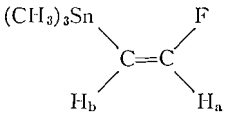












$$(CH_3)_2Sn(CF{=}CF_2)_2 + (CH_3)_2SnH_2 \rightarrow 2(CH_3)_2SnH(CF{=}CF_2).$$

From the infrared and proton magnetic resonance spectra of the reduction products, mixed products of the type $(CH_3)_2Sn(CF{=}CF_2)(CF{=}CFH)$ were clearly not formed, as was also the case in the reaction with trimethyltin hydride. For example, only one C=C stretching vibration could be assigned to each component (Table II), confirming that only one type of vinyl group was present in each dimethyltin product. Dimethyl bis(*cis*-1,2-difluorovinyl)tin was again the major product, and minor products were $(CH_3)_2Sn(CF{=}CFH)_2$ *trans*, $(CH_3)_2Sn(CH{=}CF_2)_2$, and $(CH_3)_2Sn(C_2H_2F)_2$ formed in the ratio 2:1:4. Trimethylperfluorovinyltin and trimethyl *cis*-1,2-difluorovinyltin were also detected in small amounts, presumably formed by the formation of trimethyltin hydride from dimethyltin dihydride (1), followed by vinyl-hydrogen exchange and partial reduction. Other unidentified compounds were also formed in small amounts. When the ultraviolet irradiation was prolonged (6 h) decomposition was extensive, and from the color and air sensitivity of the resulting involatile solid, it appeared that polymeric forms of dimethyltin (9) were also formed. The complex variation of the course of this reaction with the experimental conditions is thus well illustrated.

Meaningful conclusions about the mechanism by which perfluorovinyl groups are converted to fluorovinyl groups, because of reaction with a tin hydride, are difficult to draw. Clearly, ultraviolet light greatly accelerates this process, although vinyl-hydrogen exchange may also occur under such conditions. One is tempted to suggest that free radical formation from the tin hydride is again the determining factor, but there is no obvious reason for the favored formation of the *cis*-1,2-difluorovinyltin compound, and equally acceptable alternatives based on a four-center mechanism, or on an addition followed immediately by trimethyl or dimethyltin fluoride elimination, can be suggested. It should also be noted that vinyl-hydrogen exchange could occur undetected in the reactions of trimethylperfluorovinyltin and trimethyltin hydride, and dimethyl bis(perfluorovinyl)tin and dimethyltin dihydride.

The characterization of the fluorovinyl products of these reactions is based to a considerable extent on their proton magnetic resonance spectra. These are not discussed in detail, since all the observed spectra could be readily interpreted in terms of the fluorine – vinyl proton couplings, by comparison with previously reported (8) and other (10) values. Sidebands arising from coupling of the methyl protons with ^{119}Sn, ^{117}Sn, and ^{13}C were observed in all spectra, but complete assignments could not be made in all cases because of overlapping with similar bands due to other components in inseparable mixtures. Coupling constants, together with other data, are presented in Table I, and may be compared with earlier data (11, 12).

Since the C=C frequencies in the infrared spectra of the vinyltin compounds also provide a useful means of characterization, the variations in these frequencies are listed in Table II.

EXPERIMENTAL

Standard high vacuum techniques were used for most reactions, except where stated. Reactions involving heat only were carried out in pyrex glass Carius tubes, whereas those involving ultraviolet irradiation were carried out in silica tubes. Infrared spectra were recorded on model 137 sodium chloride and potassium bromide, and model 21 double-beam, Perkin–Elmer spectrophotometers, while nuclear magnetic resonance spectra were obtained with Varian A 60 and H.R. 60 spectrometers. Gas chromatographic separations were carried out on a Beckman GC – 2A instrument with a dinonyl phthalate column at 147°, and helium carrier gas (10 p.s.i.g.).

Dimethyl bis(perfluorovinyl)tin and trimethyl(perfluorovinyl)tin were prepared essentially according to the method of Kaesz, Stafford, and Stone (13) in 52% and 50% yields respectively. Both were characterized by their infrared spectra, molecular weights, elemental analyses, and nuclear magnetic resonance spectra (see Tables I and II).

Trimethylperfluorovinyltin, which had previously been reported by Seyferth *et al.* (14) as having been obtained in 64% yield from the reaction between perfluorovinyllithium and trimethyltin bromide, was prepared by the reaction of trimethyltin bromide and perfluorovinylmagnesium bromide in anhydrous tetrahydrofuran. The product (b.p. 110.5°) was separated from the tetrahydrofuran (b.p. 66°) by distillation at 760 mm with a Vigreaux column. Final purification was achieved by vacuum fractionation and gas chromatography.

Dimethyltin dihydride and trimethyltin hydride were obtained by the procedure described by Finholt *et al.* (15), and characterized by the above methods.

Reactions of Trimethyltin Hydride with Trimethylperfluorovinyltin

(*a*) Trimethyltin hydride (0.944 g, 5.70 mmoles) and trimethylperfluorovinyltin (1.41 g, 5.73 mmoles) were condensed into an evacuated Carius tube and left for 250 h in the dark at 25°. Fractional condensation of the volatile products in the vacuum system gave trimethyltin hydride (0.933 g, 5.67 mmoles) and trimethylperfluorovinyltin (1.29 g, 5.27 mmoles). A small amount of involatile white solid remained in the tube.

(*b*) Trimethyltin hydride (0.738 g, 4.46 mmoles) and trimethylperfluorovinyltin (1.09 g, 4.46 mmoles) were sealed in a pyrex Carius tube, and kept at 50° in the dark for 66 h. Fractionation of the reaction mixture gave unreacted hydride (0.692 g, 4.20 mmoles) and a fraction composed almost entirely of unchanged trimethylperfluorovinyltin (1.05 g, 98% recovery). However, this contained a small amount of a new compound which gave characteristic infrared bands at 1 649 (C=C stretch), 1 106, 1 065, 1 045 cm^{-1} (C—F stretch). A new, minor peak was observed in a gas chromatographic analysis of the recovered perfluorovinyltin. The new component was identified as trimethyl (*cis*-1,2-difluorovinyl)tin (*vide infra*). A small amount of involatile white solid remained in the reaction tube.

(*c*) In a reaction similar to *b*, equimolar amounts of trimethyltin hydride and trimethylperfluorovinyltin were allowed to react at 70° in the dark for 18 h. Vacuum fractionation led to a 97% recovery of the reactents, although again the trimethylperfluorovinyltin was shown by gas chromatography to contain not more than approximately 1% of trimethyl (*cis*-1,2-difluorovinyl)tin.

(*d*) Trimethyltin hydride (1.65 g, 10.00 mmoles) and trimethylperfluorovinyltin (2.45 g, 10.00 mmoles) were allowed to react in a silica Carius tube at 25° under ultraviolet irradiation (100 watt Henovia lamp) for 18 h. After 3 h, a white solid was visible in the tube, and at the conclusion of the experiment, the inside walls were coated with this solid. When the tube was opened, No non-condensable gas was observed, and the volatile products were separated by trap-to-trap distillation into fractions which condensed at −23° (1.44 g), −36° (0.283 g), −46° (0.421 g), −78° (0.059 g), and −196° (0.009 g).

The involatile white solid remaining in the reaction tube was washed out with ether, and, by comparison of its infrared spectrum and X-ray powder photograph with those of an authentic sample, was identified as trimethyltin fluoride. Yield 1.84 g, 100% based on trimethyltin hydride.

The −23° to −78° fractions contained at least three components in addition to unreacted trimethylperfluorovinyltin, determined on the basis of additional bands in the C=C stretching vibration and C—F stretching vibration regions in their infrared spectra (vapor state). Repeated trap-to-trap distillation eventually gave a fraction at −23° which showed only one C=C stretching frequency. This was identified by elemental analysis, its proton magnetic resonance spectrum, and by quantitative hydrolysis with trifluoroacetic acid, as trimethyl (*cis*-1,2-difluorovinyl)tin, obtained in 49% yield.

Anal. Calcd. for $C_5H_{10}F_2Sn$: C, 26.5; H, 4.41. Found: C, 26.7, H, 4.21.

Trimethyl (*cis*-1,2-difluorovinyl)tin (0.222 g, 0.98 mmole) was allowed to react with trifluoroacetic acid (0.264 g, 2.6 mmoles) at room temperature. Vacuum fractionation gave unreacted trifluoroacetic acid (0.142 g; amount calculated for 100% reaction 0.152 g) and 1,2-difluoroethylene (0.0605 g, 0.95 mmole), identified by its infrared spectrum (16) and molecular weight (calcd. 64, obs. 64).

The proton magnetic resonance spectrum of trimethyl (*cis*-1,2-difluorovinyl)tin consists of a quartet centered at −5.93 p.p.m., with methyl resonance at −0.26 p.p.m., with respect to internal tetramethylsilane. The infrared spectrum of this compound (vapor phase) showed absorption at 3 002 (m), 2 925 (m) (CH stretch); 1 649 (vs) (—CF=CFH (*cis*) stretch); 1 295 (w), 1 198 (vw) (CH_3 symmetric deformation); 1 125 (w,sh), 1 113 (vs), 1 068 s, 1 045 s (C—F stretch); 800 (sh); 779 (s) (CH_3—Sn rock); 715 (m); 537 (vs), 516 (m) (Sn—C stretch). In the liquid phase, absorption was observed at 3 125 w, 3 000 m, 2 925 m, 2 894 w, (C—H stretch); 1 645 s (CF=CFH stretch); 1 296 w, 1 195 w; 1 086 s, 1 058 s, 1 038 s (C—F stretch); 795 vs,sh; 780 vs (CH_3—Sn rock); 723 w, 540, 518 (Sn—C stretch).

The remaining volatile material, after this separation of some pure trimethyl(*cis*-1,2-difluorovinyl)tin, could not be separated into other pure components by further vacuum fractionation, and was split into three fractions by passage over a dinonyl phthalate column.

The first fraction eluted, present in only a small amount, was hydrolyzed with trifluoroacetic acid to give 1,1-difluoroethylene, identified by its infrared spectrum, suggesting that the original compound could only have been trimethyl(2,2-difluorovinyl)tin. Its infrared spectrum showed absorption at 3 015 (w), 2 970 (w), (C—H stretch); 1 683 (vs) ($CH=CF_2$ stretch); 1 266 (s), (C—F stretch); 1 200 (w,sh); 1 103 (s), 930 (s) (C—F stretch); 778 (s) (CH_3—Sn rock); 724 (w).

The second and largest fraction to be eluted was recycled through the chromatograph three times to remove the last traces of $(CH_3)_3SnCH=CF_2$ and $(CH_3)_3SnCF=CFH$ (*cis*) The infrared spectrum (vapor) of the remaining material showed it to contain unreacted trimethylperfluorovinyltin together with at least two other components. Qualitative hydrolysis with trifluoroacetic acid gave a mixture of fluoro-olefins, whose infrared spectrum contained all the expected bands for $CF_2=CFH$, CFH=CFH (16), and $CFH=CH_2$ (17). The following conclusions were therefore drawn: (i) The formation of $CF_2=CFH$ on hydrolysis confirms the infrared observation that unreacted $(CH_3)_3SnCF=CF_2$ was present. (ii) the formation of CFH=CFH shows the presence of $(CH_3)_3SnCF=CFH$ in the original volatile mixture. Since the *cis* isomer was quantitatively removed as the third fraction to be eluted from the chromatogram, this species must be trimethyl (*trans*-1,2-difluorovinyl)tin. (iii) the formation of $CH_2=CFH$ indicates the presence of reduction product(s) of composition $(CH_3)_3SnCH=CFH$ (*cis* or *trans*) or $(CH_3)_3SnCF=CH_2$.

These conclusions were further supported by the proton magnetic resonance spectrum of this second chromatographic fraction. The spectrum showed six doublets and two CH_3 peaks, of which, from the integrals, the former could be grouped as one set of four doublets, and a separate set of two doublets. The set of four doublets was consistent with a reduced vinyl group containing two protons, and the other set of two doublets with a reduced vinyl group containing one proton. Of the CH_3 peaks, that at −0.20 p.p.m. (with respect to internal tetramethylsilane) must be associated with the set of four doublets since, from the integrals, the ratio of CH_3 protons to vinyl protons was 1:4.2. The ratio expected for $(CH_3)_3SnC_2H_2F$ was 1:4.5. The other CH_3 peak at $\delta = -0.33$ p.p.m. was clearly due to unreacted $(CH_3)_3SnCF=CF_2$, and also to CH_3 groups which associated with the pair of doublets. The latter were at −7.60 p.p.m. with coupling constants of 78 c.p.s. and 15 c.p.s. These values were consistent (9) with C=CFH and CH=CF— (*cis*) couplings respectively, which confirmed the existence of $(CH_3)_3SnCF=CFH$ (*trans*). Since the observed ratio, obtained from the integrals, of vinyl proton (CF=CFH):methyl proton was 1:20, in contrast to the ratio of 1:9 expected for $(CH_3)_3SnCF=CFH$ (*trans*), the ratio of the latter compound to $(CH_3)_3SnCF=CF_2$ must be approximately 9:11. The four doublets could be grouped in two sets having $\delta = -4.97$ and −6.91 p.p.m. respectively and coupling constants of 76 and 5.5 c.p.s., and 100 and 5.5 c.p.s. respectively. To explain the 5.5 c.p.s. value, the occurrence of CH=CH— (*cis*) must be advanced. The value of 76 c.p.s. could then arise from the coupling in —CH=CFH. However, 100 c.p.s. is at least twice as great as any known value for the coupling of —CH=CF— (*trans*). The assignment is therefore uncertain, and the compound is just referred to as $(CH_3)_3SnC_2H_2F$.

From the infrared spectrum of this three-component mixture, and the spectra of $(CH_3)_3SnCF=CF_2$ and $(CH_3)_3SnC_2H_2F$ (see later), the following bands were assigned to $(CH_3)_3SnCF=CFH$ (*trans*): 1 637 (CF=CFH *trans*, stretch), 1 105 (C—F stretch), and 812 cm^{-1}.

(*e*) Trimethyl(perfluorovinyl)tin (1.08 g, 4.40 mmoles) and trimethyltin hydride (0.725 g, 4.40 mmoles) were allowed to react under conditions identical to experiment *d* above. To determine the relative yield of each species, the proton magnetic resonance spectrum of the total volatile products was recorded. From the integrated spectrum, the values in Table III were obtained, from a total of 0.972 g volatile material, this

TABLE III

	Weight (g)	Mole % (based on $(CH_3)_3SnCF{=}CF_2$)
$(CH_3)_3SnCF{=}CF_2$ (recovered)	0.209	19
$(CH_3)_3SnCF{=}CFH$ (*cis*)	0.509	51
$(CH_3)_3SnCF{=}CFH$ (*trans*)	0.170	17
$(CH_3)_3SnCH{=}CF_2$	0.01	1
$(CH_3)_3SnC_2H_2F$	0.044	5

being 54% of the total weight of reactants. Note that the yield of the *cis* isomer agrees well with the value obtained in the previous experiment. Trimethyltin fluoride (0.762 g, 4.2 mmoles, 95.4% yield) was also isolated.

(*f*) Trimethyltin hydride (1.59 g, 9.66 mmoles) and trimethylperfluorovinyltin (1.15 g, 4.70 mmoles) were allowed to react in a silica Carius tube at 25° under ultraviolet irradiation for 18 h. The volatile products were then transferred to a nuclear magnetic resonance sample tube, leaving a trace of an unidentified involatile liquid together with an involatile solid. The latter was washed out with ether, dried, and identified as trimethyltin fluoride (1.66 g, 9.09 mmole, 94.3% yield).

The proton magnetic resonance spectrum showed the presence of $(CH_3)_3SnCF{=}CFH$ (*cis*), $(CH_3)_3SnCF{=}CFH$ (*trans*), $(CH_3)_3SnH$, and $(CH_3)_3SnC_2H_2F$, but not of $(CH_3)_3SnCF{=}CF_2$. Some additional peaks, not observed in previous experiments and which could not be satisfactorily assigned, were also seen. From the integrated spectrum, the percentage yields and calculated weights shown in Table IV were obtained.

TABLE IV

	% of volatiles	Weight (g)	Mole % (based $(CH_3)_3SnCF{=}CF_2$)
$(CH_3)_3SnCF{=}CFH$ (*cis*)	52	0.429	40.2
$(CH_3)_3SnCF{=}CFH$ (*trans*)	11	0.091	8.5
$(CH_3)_3SnCH{=}CF_2$	—	—	—
$(CH_3)_3SnC_2H_2F$	18	0.148	15.1
$(CH_3)_3SnH$	9	0.074	4.6 (of original hydride)
Others (unidentified)	10	0.082	~10

Reactions of Trimethyltin Hydride with Trimethyl(cis-1,2-difluorovinyl)tin

(*a*) The vinyltin compound (0.175 g, 0.773 mmole) and trimethyltin hydride (0.165 g, 1.00 mmole) were irradiated with ultraviolet light for 15 h at 25°. The volatile products were separated chromatographically to give unreacted trimethyl(*cis*-1,2-difluorovinyl)tin and slightly impure $(CH_3)_3SnC_2H_2F$. The infrared spectrum (vapor) showed absorption at 3 090 (w), 3 000 (m), 2 093 (m); 1 608 (s); 1 190 (w), 1 160 (m), 1 100 (s), 973 (s); 800 (m,sh); 775 (vs); 725 (m,w).

Anal. Calcd. for $C_5H_{11}FSn$: C, 28.6; H, 5.24. Found: C, 27.7; H, 5.03. Molecular weight calcd. 209; found 209, 212.

The fraction identified as $(CH_3)_3SnC_2H_2F$ (0.228 g, 0.109 mmole) gave immediate reaction with excess trifluoroacetic acid in a Carius tube at 25°. The resulting olefin was trapped at −196° and shown by its infrared spectrum to contain $CFH{=}CH_2$ and a little $CFH{=}CFH$ (0.0475 g, molecular weight 55.0; molecular weight calcd. for $CFH{=}CH_2$, 46; for $CFH{=}CFH$, 64). The impurity was thus $CFH{=}CFH$, from trimethyl(*trans*-1,2-difluorovinyl)tin.

(*b*) Trimethyl(*cis*-1,2-difluorovinyl)tin (1.25 g, 5.49 mmoles) and trimethyltin hydride (0.904 g, 5.49 mmoles) were allowed to react under the conditions of the last experiment. The volatile products (1.00 g) were then transferred to a nuclear magnetic resonance sample tube, and, from an analysis of the spectrum and from the values of the integrals, the proportions shown in Table V were calculated.

TABLE V

	% of volatiles	Weight (g)	Mole %
$(CH_3)_3Sn(CF{=}CFH)$ (*cis*)	50	0.5	40
$(CH_3)_3SnCF{=}CFH$ (*trans*)	10	0.1	8
$(CH_3)_3SnC_2H_2F$	30	0.3	24
Others (unassigned peaks)	10	0.1	—

Reactions of Dimethyl Bis(perfluorovinyl)tin with Trimethyltin Hydride

(*a*) Trimethyltin hydride (1.06 g, 6.44 mmoles) and dimethyl bis(perfluorovinyl)tin (1.00 g, 3.22 mmoles) were kept at 50° in the dark for 35 h. Approximately 94% of the hydride as well as 78% of the unchanged perfluorovinyl compound, was recovered. A trace of an involatile solid and a small amount of CF_2=CFH were also formed.

(*b*) Trimethyltin hydride (2.15 g, 13.0 mmoles) and dimethyl bis(perfluorovinyl)tin (2.04 g, 6.55 mmoles) were heated to 70° in a Carius tube for 17 h and then left in daylight for a further 24 h. Hydrogen (0.009 g) was observed on opening the tube, and a white solid (0.85 g), identified as mainly dimethyltin difluoride, but containing traces of metallic tin and other species, remained in the tube after removal of all volatile products. The latter were separated into a −23° fraction (1.34 g), a −45° fraction (0.18 g), a −78° fraction (1.43 g) shown to be unreacted trimethyltin hydride, and a −196° fraction (0.065 g) identified as CF_2=CFH. Gas chromatographic examination of the −23° and −45° fractions showed them to consist largely of unreacted dimethyl bis(perfluorovinyl)tin, along with trimethylperfluorovinyltin and trimethyl *cis*-1,2-difluorovinyltin, with lesser amounts of the *trans* isomer.

(*c*) Trimethyltin hydride (0.566 g, 3.44 mmoles) and dimethyl bis(perfluorovinyl)tin (0.536 g, 172 mmoles) were allowed to react at 25° under ultraviolet irradiation for 11 h. The resulting involatile white solid (0.635 g), washed out with ether, was refluxed with toluene to remove soluble impurities. It was identified by its X-ray powder photograph as largely dimethyltin difluoride, along with some trimethyltin fluoride. The volatile products (0.380 g) were separated chromatographically into several fractions, which from their nuclear magnetic resonance and infrared spectra were shown to be: 1. $(CH_3)_3SnCH$=CF_2 (minor); 2. $(CH_3)_3SnCF$=CF_2, $(CH_3)_3SnCF$=CFH (*trans*), $(CH_3)_3SnC_2H_2F$ (major); 3. $(CH_3)_2Sn(CH$=$CF_2)_2$ (minor); 4. $(CH_3)_2Sn(CF$=$CF_2)_2$ (minor); 5. $(CH_3)_2Sn(CF$=CFH$)_2$ (*cis*), $(CH_3)_3SnCF$=CFH (*cis*) (major); 6. Unidentified species (minor). A very negligible amount of unreacted hydride, and a little CF_2=CFH were also observed.

(*d*) Trimethyltin hydride (0.425 g, 2.58 mmoles) and dimethyl bis(perfluorovinyl)tin (0.40 g, 1.29 mmoles) were reacted as in *c*. The involatile white solid (0.42 g), which was isolated and purified as in *c*, consisted of a mixture of dimethyltin difluoride and trimethyltin fluoride, with the difluoride in excess. The volatile products (0.36 g) were transferred to a nuclear magnetic resonance sample tube, after removal of CF_2=CFH by vacuum fractionation. From analysis of the proton spectrum, and from the integrated spectrum, the proportions shown in Table VI were obtained.

TABLE VI

	% of volatiles	Weight (g)	Mole %*
$(CH_3)_3SnCF$=CFH (*cis*)	49	0.18	30
$(CH_3)_3SnCF$=CF_2	17	0.060	9.5

*Taken with respect to trimethyltin hydride for the trimethyltin species, and with respect to dimethyl bis(perfluorovinyl)tin for the dimethyltin species.

Reactions of Dimethyltin Dihydride with Dimethyl Bis(perfluorovinyl)tin

In these reactions complete separation of the vinyl products from involatile residues was not always achieved, so that accurate yields cannot be given. According to the infrared spectra, however, recovery of unreacted hydride and of other hydride species was complete.

(*a*) Dimethyltin dihydride (1.247 g, 8.29 mmoles) and dimethyl bis(perfluorovinyl)tin (1.996 g, 5.67 mmoles) were heated to 60° in a sealed tube in the dark for 2 h. Removal of most of the volatile products left a white solid, and the following fractions were separated: (i) A −16° (0.042 g) fraction identified spectroscopically as unreacted perfluorovinyl compound. (ii) A −45° fraction (1.19 g) of which 87% was dimethyl (perfluorovinyl)tin hydride, $(CH_3)_2SnH(CF$=$CF_2)$. Molecular weight: calcd. 251; obs. 248. The infrared and proton resonance spectra support this characterization. The former shows absorption at 3 010 (m), 2 920 (m), (C—H stretch); 1 872 (s) (Sn—H stretch); 1 718 (s) (C=C stretch); 1 285 (s), 1 120 (s), 1 010 (s), (C—F stretch); 775 (s) (Sn—CH_3 rock); 725 (m), 576 (m), and 522 (s). The proton spectrum shows the Sn—H peak at −5.46 p.p.m. This is a broad, partially resolved multiplet, where for the proton attached to tin in $(CH_3)_2SnH(CF$=$CF_2)$, 56 components are expected. The methyl protons are seen as a doublet at −0.37 and −0.41 p.p.m. with the ^{119}Sn and ^{117}Sn sidebands at −0.93 and −0.89, and −0.90 and −0.86 p.p.m. respectively. The proton spectrum also showed that this −45° fraction contained approximately 7% of the $(CH_3)_2Sn(CF$=CFH$)_2$ bis-*cis* isomer, and 4% of the corresponding bis-*trans* isomer. (iii) A −64°

fraction (0.77 g, molecular weight 250) identified as pure $(CH_3)_2SnH(CF{=}CF_2)$. The total yield of $Me_2SnH(CF{=}CF_2)$ was thus 1.21 g, 4.82 mmoles. (iv) A −125° fraction (0.375 g, 2.50 mmoles) shown by its infrared spectrum and molecular weight (150) to be unreacted dimethyltin dihydride (95.4% of the excess). (v) A −196° fraction (0.02 g) identified spectroscopically as trifluoroethylene.

As further confirmation of the characterization of dimethyl(perfluorovinyl)tin hydride, a sample was reacted at 50° in the dark for 40 h with excess tetrafluoroethylene. Much of the product was separated as a fraction of molecular weight approximately 340 (calcd. for $(CH_3)_2Sn(CF{=}CF_2)(CF_2CF_2H)$, 330) and with an infrared spectrum which showed the presence of both $-CF{=}CF_2$ and $-C_2F_4H$ groups (1).

(*b*) Dimethyl bis(perfluorovinyl)tin (2.357 g, 6.73 mmoles) and dimethyltin dihydride (1.113 g, 7.38 mmoles) were exposed to ultraviolet irradiation for 1 h at 25–30°. When the tube was opened to the vacuum line, hydrogen (0.045 mmole) was evolved. The volatile products (0.900 g) were removed *in vacuo*, and a yellow solid was left in the tube. An infrared spectrum of the yellow solid showed the presence of $-CF{=}CF_2$, $-CF{=}CFH$, and $-C_2H_2F$ groups. When the solid was refluxed with toluene for 2 h, a white residue formed which was found by spectroscopy to contain no vinyl groups, and whose powder photograph was identical with that of an authentic sample of dimethyltin difluoride. The volatile products were transferred to a nuclear magnetic resonance sample tube, and from the proton spectrum, the integrated spectrum, and the known values of coupling constants, species containing $-CF{=}CFH$ (*cis*), $-CF{=}CFH$ (*trans*), and $-CH{=}CF_2$ groups were identified as well as dimethyltin dihydride and some unassigned peaks. It was concluded from the integral values that the volatile dimethyltin products were unreacted dimethyl bis(perfluorovinyl)tin (30%), $(CH_3)_2Sn(CF{=}CFH)_2$ (*cis*), $(CH_3)_2Sn(CF{=}CFH)_2$ (*trans*), $(CH_3)_2Sn(CH{=}CF_2)_2$, and $(CH_3)_2Sn(C_2H_2F)_2$, the last four in the approximate ratio 10:2:1:4, and an unidentified component. In addition, small amounts of trimethylperfluorovinyltin and trimethyl-1,2-difluorovinyltin were also detected. The latter presumably arose from decomposition of dimethyltin dihydride (1), followed by vinyl-hydrogen exchange, and partial reduction.

(*c*) Dimethyltin dihydride (0.82 g, 5.41 mmoles) and dimethyl bis(perfluorovinyl)tin (1.847 g, 5.26 mmoles) were irradiated at 25° for 6 h. When the tube was opened, hydrogen (1 mmole) was evolved, and only 14% of the total weight of reactants was recovered as volatile products, mainly as the unreacted perfluorovinyl compound. There remained a brightly colored, air-sensitive solid.

^{60}Co γ-RADIOLYSIS OF HYDROGEN HALIDES AT 77 °K[1]

R. C. RUMFELDT[2] AND D. A. ARMSTRONG
Department of Chemistry, University of Alberta, Calgary, Calgary, Alberta

Received August 31, 1965

ABSTRACT

Yields of hydrogen formed in the ^{60}Co γ-radiolyses of pure polycrystalline samples of HBr and HCl at 77 °K decrease with increasing dose in the range 0 to 1×10^{18} eV per g. The true initial yields are $G(H_2)_{\text{solid HCl at 77°K}} = 6.3 \pm 0.2$ and $G(H_2)_{\text{solid HBr at 77°K}} = 12.3 \pm 0.3$. Within experimental error these are the same as the respective liquid-phase yields at −79 °C. For doses in excess of 2×10^{18} eV per g the dose dependence is no longer significant and the yields tend toward plateau values of 3.2 ± 0.1 and 10.3 ± 0.1 for HCl and HBr respectively. The dose dependence of the hydrogen yields is attributed to the scavenging of a reactive intermediate by the halogen atoms and molecules which accumulate in the solid matrix as the dose increases.

In independent experiments with an apparatus of the Klein–Scheer type it was shown that hydrogen atoms react readily with films of HBr at 77 °K. There is, however, no evidence of a significant reaction with HCl at this temperature. The difference in behavior of the two hydrogen halides may be explained by their different activation energies for reaction with hydrogen atoms. The results of the γ-radiolyses are discussed in the light of these experiments and it is suggested that the dose dependence may be a result of the scavenging of an ionic intermediate rather than a thermal hydrogen atom.

INTRODUCTION

Earlier publications (1–3) from this laboratory have dealt largely with the γ-radiolysis of liquid and gaseous hydrogen halides. The present study was designed to investigate the radiolysis of solid polycrystalline HCl and HBr at 77 °K. Since it seemed that hydrogen atoms might be formed within the irradiated solids, an independent experimental technique was employed to investigate their reactivity toward HCl and HBr at this temperature.

EXPERIMENTAL

Materials

The hydrogen halides were purified and stored prior to irradiation as previously described (1, 3).

Apparatus

The apparatus and technique for the ^{60}Co γ-irradiations were essentially the same as in the earlier work. In this study the use of much larger samples (up to 5 g) of hydrogen halide and very careful experimental technique permitted the measurement of yields to within ±3% at doses as low as 2×10^{17} eV per g.

A number of experiments were performed in an apparatus of the type developed by Klein and Scheer (4) for studying hydrogen atom reactions at liquid nitrogen temperature. A uniform polycrystalline film of about 1 g of hydrogen halide was deposited on the inner wall of an evacuated 500 ml vessel immersed in a liquid nitrogen bath. Hydrogen atoms were produced by admitting a small pressure of hydrogen gas (50–100 μ of Hg) and dissociating the hydrogen molecules on an incandescent tungsten filament. At the pressures used most of these atoms diffuse to the walls of the vessel, where they may recombine or react with molecules in the hydrogen halide film to form hydrogen molecules, viz:

$$[1] \qquad H + HX \rightarrow H_2 + X.$$

Two different experimental arrangements were employed. In the first arrangement the apparatus consisted of a spherical bulb with the tungsten filament situated at its center. With this geometry the hydrogen halide film was exposed to the direct radiation from the incandescent filament as well as to the hydrogen atoms. In the second arrangement the filament was situated in a tube 2 cm in diameter attached to the cylindrical reaction vessel as shown in Fig. 1. The hydrogen atoms were carried into the vessel by convection and diffusion, and the film was shielded from the direct photon irradiation of the filament by an aluminium shield. In both arrangements the entire apparatus was immersed in liquid nitrogen.

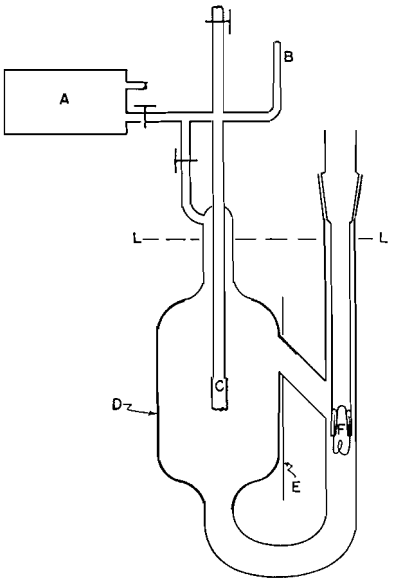

FIG. 1. Reaction vessel for the study of H-atom reactions with hydrogen halide films at 77 °K. (A) Equibar pressure meter coupled to recorder. (B) Palladium thimble for introducing pure gaseous hydrogen. (C) Sintered glass plug used to control deposition of the HX film on the surface of the reaction vessel. (D) Reaction vessel; double thickness indicates area in which the film is deposited. (E) Aluminium sheet to shield the film from direct visible radiation from F. (F) Tungsten filament and mercury pools for electrical contact. (L) Liquid nitrogen level.

The course of reaction [1] at 77 °K was followed by observing the pressure of hydrogen in the reaction vessel. In initial experiments this was done with a pirani gauge. In later work the pressure was monitored continuously with a Transonics type 120 equibar pressure meter coupled to a recorder.

RESULTS AND DISCUSSION

The hydrogen yields from pure polycrystalline hydrogen chloride are plotted against absorbed dose in Fig. 2. There is an obvious dependence on dose at doses less than 2×10^{18} eV per g. The true initial yield, obtained by extrapolation of the curve through the experimental points, is $G(H_2)^0_{\text{solid HCl at } 77°K} = 6.3 \pm 0.2$. Within experimental error this is the same as the liquid-phase yield of 6.5 ± 0.1 (1, 3). The hydrogen yields from pure polycrystalline HBr show a similar dependence on dose (see Fig. 2) and the experimental points also extrapolate to the liquid-phase yield (data have been included in Fig. 2 for comparison).

The liquid-phase yields in Fig. 2 show no evidence of a dose dependence. In control experiments no hydrogen was found: (*a*) in empty cells which had been subjected to the usual degassing procedure, sealed off under vacuum, and then subjected to irradiation at 77 °K, or (*b*) in cells filled with hydrogen halide and left unirradiated for periods equivalent to the duration of the average irradiation. From these observations and the fact that the G values were independent of sample size (and quantity of hydrogen determined), it may be concluded that the dose dependence is not an artifact of the experimental procedure or analytical technique.

The dose dependence of the hydrogen yields indicates that some product of the radiolysis accumulates in the solid hydrogen halides and scavenges reactive intermediates which under other circumstances react to form hydrogen molecules. It is apparent that the scavenger must consist of halogen atoms trapped in the HX matrix or halogen molecules

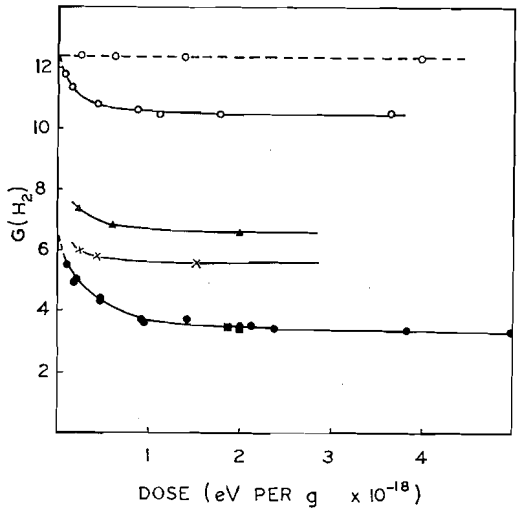

FIG. 2. Plots of $G(H_2)$ vs. dose for polycrystalline samples of hydrogen halides irradiated at 77 °K with ^{60}Co γ-rays. ○, Pure HBr; ●, pure HCl; ■, pure HCl, intermittent irradiations (see text); ×, 0.017 mole % HBr in HCl; ▲, 0.076 mole % HBr in HCl; the points on the broken line at the top represent corresponding yields in liquid HBr.

formed by atom recombination in the radiation tracks, or a combination of both. If a G value of 6.3 for the initial splitting of the H—Cl bond is assumed, it can be shown that approximately 2×10^{16} Cl atoms will have been formed per g of HCl when the hydrogen yield from the HCl has fallen halfway between 6.3 and the "plateau yield" (see below) of 3.3. This concentration corresponds to an average distance between Cl atoms of 300–400 Å. With the realization that these atoms would in fact be distributed in clusters and that some would probably have recombined, it is obvious that the species being scavenged must on the average traverse distances greater than 400 Å before reacting to form hydrogen molecules. Similar considerations apply in the case of HBr.

The value of $G(H_2)$ from solid HCl at a dose of 2 to 3 $\times$ 10^{18} eV per g is $3.3_6 \pm 0.1_0$, in good agreement with an earlier result (3). Beyond this dose range the dose dependence is very small for both hydrogen halides. Values of $G(H_2)$ in the dose range 2 to 3 $\times$ 10^{18} eV per g are therefore referred to as plateau yields.

Since the plateau yields in Fig. 2 are all much greater than zero it is clear that only a fraction of the total hydrogen formation from HCl and HBr is dependent on dose. In the case of HCl the remainder of the hydrogen may be attributed largely to a species, $H_{(s)}''$, the reactions of which are insensitive to the radical scavengers Cl and Cl_2 in the concentrations produced during the irradiations. Further evidence for such a reactive species comes from an earlier observation of the effect of chlorine added to the HCl prior to freezing and irradiation (3). A concentration of 2×10^{-4} mole of chlorine per g of HCl caused $G(H_2)$ to decrease from the plateau yield of 3.3 to 2.7. An increase of the chlorine concentration to 6×10^{-4} mole per g had no additional effect. The value of $G_{H(s)}''$ must therefore be 2.7. It is to be noted, also, that there is considerable evidence for corresponding species in both the liquid- and gas-phase radiolysis of HCl (1, 2, 3). The data for the gas-phase radiolysis of HBr (5) indicate that an analogous species is formed in this hydrogen halide, its yield ($G_H'' = 9$ to 10) being much greater than in HCl (cf. refs. 1, 5). The plateau yield of $G(H_2) = 10.3$ in solid HBr at 77 °K is in accord with these observations.

The reactive species responsible for the dose-dependent portion of the hydrogen yield from solid hydrogen halides (hereafter designated as $H_{(s)}'$) should be related to the species H′ observed in the liquids at −79 °C. The latter has the kinetic properties of a hydrogen atom (1) and is thought to be formed in the dissociative capture of electrons by suitable constellations of hydrogen halide molecules (1). This capture process must give rise to X—H—X⁻ as well as H. If capture occurred at 77 °K, $H_{(s)}'$ would have the kinetic properties of a thermal hydrogen atom (H) and two situations might arise. In the first, H atoms would be mobile and undergo reactions [1] and [2]

$$H + X + M \rightarrow HX + M \qquad [2]$$

in the solid hydrogen halides. In the case of HBr it can be shown on the basis of $A_1 \simeq A_2$, $E_2(H + Br) = 0$ kcal per mole, and $E_1(H + HBr) = 2$ kcals per mole activation energy (cf. ref. 1) that k_1/k_2 has a value of the order of 10^{-6} at 77 °K. Thus a relatively large concentration of Br atoms (10^{-5} per molecule of HBr or 10^{17} per g of HBr) would have to accumulate in the solid HBr before reaction [1] were suppressed. Depending on the yield of trapped bromine atoms (which has an upper limit of G(trapped Br) = 24) this would occur at an absorbed dose of 10^{18} to 10^{19} eV per g. Hence, although the approach to the plateau yield in Fig. 2 might have been expected at a somewhat higher dose than was observed, it is conceivable that this situation could be tenable in solid HBr. In contrast the corresponding value of k_1/k_2 for HCl at 77 °K based on $E_1(H + HCl) = 4.7$ kcals per mole (cf. ref. 1) would be about 10^{-13}. Thus as little as 10^{-12} Cl atoms per molecule of HCl (or 2×10^{10} per g of HCl) should serve to virtually suppress reaction [1] in HCl. If for example G(trapped Cl) $\geqslant 1$, it can be shown that this atom concentration would have been reached at a dose $\leqslant 2 \times 10^{12}$ eV per g. With allowance for an increase in $k_1(H + HCl)$ of up to 10^3 to take account of the enhanced contribution of quantum mechanical tunneling at 77 °K and other uncertainties in the calculation, the upper limit on this dose may be set at 2×10^{15} eV per g. This is some three orders of magnitude smaller than the dose at which the limiting plateau yield was attained in Fig. 2, and the discrepancy is sufficient to exclude the first situation in HCl.

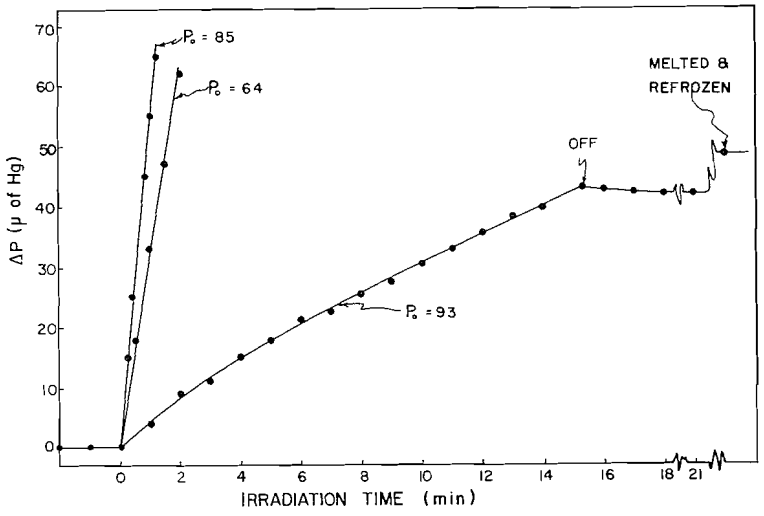

FIG. 3. Reaction time curves for H-atom reactions with HBr films at 77 °K. The tungsten filament was lighted at time zero. The curve for $P_0 = 93$ μ of Hg pressure was obtained with a film in the apparatus shown in Fig. 1. The apparatus used to obtain the other curves is described in the text.

In view of the foregoing considerations additional information about the reactivity of H atoms toward HCl and HBr at 77 °K was desirable. The application of the Klein–Scheer technique appeared to be the best method of obtaining this. Typical results are shown in Fig. 3, where the increase in the pressure of hydrogen in the reaction bulb has been plotted against the time elapsed after heating the tungsten filament. With an HBr film on the surface of the reaction bulb there was a pressure rise (see Fig. 3) with both of the experimental arrangements (described in Experimental). Although the reaction rate was much faster in the reaction vessel with the filament at its center, the second apparatus was considered more satisfactory for observing reaction [1] at 77 °K. In addition to eliminating the direct irradiation of the film, which might have caused a temperature rise of several degrees at the film surface, it ensured that all hydrogen atoms were brought to kinetic energies characteristic of 77 °K by collisional deactivation before they reached the film. The pressure increase observed in this vessel may therefore be regarded as a true indication of thermal hydrogen atom reactions with an HBr film at 77 °K. The slight decrease in the rate of the pressure rise as the reaction proceeded is to be expected, since the bromine atoms formed in reaction [1] will accumulate in the crystal lattice with the consequent occurrence of reaction [2]. The effect of this competition would have been alleviated to some extent by the increase in the rate of hydrogen atom formation, which would have accompanied the rise in the pressure of molecular hydrogen. Nevertheless the fact that the system did not rapidly approach a steady state indicates that the reaction does not proceed only at the crystal surfaces, and that the hydrogen atoms are able to penetrate to considerable depths. As a corollary, the observed pressure increase shows that hydrogen molecules are also mobile in the film, since the majority of them must escape very rapidly. However, a significant fraction of them appear to be formed too deep within the crystal to escape during the time of reaction. They are only observed on melting the film (see Fig. 3, the increase in pressure of hydrogen after melting and refreezing).

In the case of an HCl film in the first apparatus, which provides the optimum conditions for reaction [1], there was no increase in pressure over a prolonged period of exposure. Increasing the filament temperature and doubling the initial pressure also failed to initiate any reaction. It can be shown that $k_1(H + HCl)/k_2(H + Cl)$ would have to have approximately the same value as $k_1(H + HBr)/k_2(H + Br)$ to explain the dose dependence on the basis of hydrogen atom scavenging. Thus the above observations strongly support the arguments previously used against the occurrence of reaction [1] in solid HCl irradiated at 77 °K.

The second situation which must be considered is that H atoms would remain trapped in the hydrogen halide matrices at 77 °K and become mobile during the "warm-up" period before the bulkier halogen atoms could recombine. This situation is untenable in HBr in view of the foregoing observations. In addition it should be noted that Mitchell, Green, and Spinks (6) failed to find definite evidence for the presence of trapped H atoms in their electron spin resonance study of γ-irradiated HBr at 77 °K. For HCl the second situation would require that reaction [1] be in competition with [2] during the "warm-up" period at temperatures where the ratio k_1/k_2 was higher than 10^{-13}.* The dose dependence could be explained on this basis since, the larger the dose received prior to melting, the larger the concentration of chlorine atoms would be, and hence the greater the suppression of reaction [1]. In two experiments the HCl samples were successively irradiated to a dose of 0.24 $\times$

**In contrast to the value of 10^{-13} at 77 °K, $k_1(H + HCl)/k_2(H + Cl)$ would have a value of about 10^{-6} at the melting point of HCl (−114.3 °C). At this temperature $k_1(H + HCl)/k(H + Cl_2)$ would have a value of $\simeq 8 \times 10^{-4}$. Note that these and all similar calculations are based on the kinetic data given in ref. 1.*

10^{18} eV per g, melted to convert the accumulated chlorine atoms to molecules, refrozen, and reirradiated until a total final dose of about 1.9×10^{18} eV per g had been attained. If hydrogen formation took place on melting, one would expect the yields from these intermittent irradiations to be higher than those from a continuous irradiation to the same total dose. To be precise, they should have corresponded to the G value for a dose of 0.24×10^{18} eV per g. In fact the observed G values (see the squares in Fig. 3) corresponded to those for the total accumulated dose of 1.9×10^{18} eV/g. This indicates that the second situation is an extremely unlikely one in HCl. In this connection it is also to be noted that few crystalline solids are able to trap hydrogen atoms at 77 °K (cf. their behavior in ice (7)). Furthermore an electron spin resonance study of samples of HCl irradiated at 77 °K was carried out in this laboratory, and failed to reveal the presence of trapped hydrogen atoms (8).

The foregoing arguments show that reactions of thermal hydrogen atoms do not provide an acceptable explanation for the dose dependence of the hydrogen yields from solid HCl. Thus it appears that in crystalline HCl at 77 °K electrons may undergo processes other than the capture reaction referred to above. The low temperature phases, in which HCl and HBr exist at 77 °K, consist of orthorombic crystal lattices, and Hornig and his co-workers (9) have concluded that the hydrogen halide molecules are arranged in the form of zig-zag hydrogen-bonded chains. The component molecules are coupled in their infrared modes, and there is no evidence of rotation of the molecules in the spectroscopic sense of the term. In ordered crystalline solids of this type the rate of energy loss of sub-excitation electrons is much less than in liquids (10). Furthermore the regular lattice structure may provide preferred paths for electron and charge transfer. As a result, electrons are extremely mobile in such solids (11). Trapping and capture are most likely to occur at crystal defects present initially or created by radiation damage. Two alternative reactions of electrons are therefore probable: (*a*) reaction with H_2Cl^+ positive ions to form hydrogen molecules or atoms

[3]* $$H_2Cl^+ + e \rightarrow H_2 + Cl \text{ (or } H + Cl) + \text{energy}$$

and (*b*) reaction with the trapped Cl atoms which accumulate in the HCl matrix. Since these are probably formed in the reactions of $H_{(s)}''$ as well as in reaction [3], their concentrations should increase much more rapidly than that of H_2Cl^+, thus providing for eventual repression of reaction [3]. It should be noted that this electron-trapping mechanism is not subject to the objections encountered previously for hydrogen atom reactions in HCl. Furthermore electron trapping at crystal sites occupied by Cl_2 (or Br_2 in HBr) would probably also be a highly efficient process, since it should result in the formation of Cl_2^-, which is stable at 77 °K.† On this basis it is possible to explain the fact that the molecular chlorine which was formed on melting the samples in the intermittent experiments described above was essentially as effective in suppressing the hydrogen yield as the Cl atoms which it replaced. This would certainly not have been the case for hydrogen atom scavenging at 77 °K.

Although a hydrogen atom mechanism is not entirely excluded in the case of HBr, the electron-trapping mechanism could also explain the effects observed in that hydrogen halide.

**If* H *atoms were formed they should possess sufficient kinetic energy to undergo reaction [1] without further activation.*

†*The molecular halogen ions* Cl_2^- *and* Br_2^- *have been observed in the* γ*-radiolysis of sulfuric acid glasses containing* Cl^- *and* Br^- *at 77 °K (12), and in the corresponding crystalline alkali halides after* γ*-irradiation (13). Both* Br_2^- *and* Cl_2^- *exhibit strong absorption maxima in the region 3 300 to 3 900 Å (12, 13) and in the halide crystals there is evidence of an additional maximum at about 7 500 Å (13). It is to be noted that the formation of these ions could also explain the fact that both* HCl *and* HBr *exhibit a grey-green color after irradiation.*

Spectroscopic techniques (9) have confirmed that HCl and HBr form homogeneous solid solutions as would have been expected. Several experiments were performed with solid solutions prepared by rapidly freezing homogeneous liquid solutions of HBr in HCl. The hydrogen yields from these showed a much less marked dependence on dose than did those from pure HCl (see Fig. 2). $G(H_2)$ values for a dose of 2×10^{18} eV per g (i.e. plateau yields) are given in Table I as a function of HBr concentration.

TABLE I

Hydrogen yields from solid solutions of HBr in HCl at 77 °K

HBr (mole fraction)	$G(H_2)$	HBr (mole fraction)	$G(H_2)$
0.00_0	3.3_6	0.01_7	5.7_0
0.001_5	4.0_6	0.03_8	6.2_1
0.006_5	4.7_2	0.05_1	6.4_7
0.01_7	5.4_4		

It can be seen that the hydrogen yields from HCl are extremely sensitive to minute traces of HBr. For example, 0.001_5 mole % HBr enhanced $G(H_2)$ by 0.7 G units. This sensitivity confirms the fact that long range chemical or physical interactions precede the actual process of hydrogen formation. It is not clear at present whether these involve energy transfer along the chains of HCl molecules to isolated HBr molecules (cf. ref. 14) or the capture of positive charges or radicals (including e) at HBr sites on the crystal lattice. It is possible that all these processes occur.

THERMODYNAMIC AND ELECTROCHEMICAL PROPERTIES OF ZIRCONIUM CHLORIDES IN ALKALI CHLORIDE MELTS

B. SWAROOP[1] AND S. N. FLENGAS
Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario

Received June 4, 1965

ABSTRACT

The liquidus curves in the binary equilibrium phase diagrams of the systems, $ZrCl_2$–MCl, and $ZrCl_3$–MCl, where M is potassium or sodium, have been determined where possible. The electrochemical properties of the dilute solutions of zirconium di-, tri-, and tetra-chlorides, in the temperature range 670 °C to 750 °C, were investigated by reversible electromotive force measurements. From the results various equilibria between zirconium metal and the solutions of zirconium tri- and tetra-chlorides, respectively, were determined. Activity calculations indicate that zirconium tetrachloride is heavily complexed in these melts.

INTRODUCTION

Measurements of the "apparent standard potentials" of several metal – metal chloride systems in dilute solutions in fused alkali chlorides have been reported in previous investigations (1, 2, 3). Such measurements provide data on activities, help determine the equilibrium constants of chemical reactions in fused salts, and provide some of the necessary information for the recovery of metals by fused salt electrolysis. An equimolar melt of potassium and sodium chlorides was used as the solvent melt in all these studies, and a silver – silver chloride electrode developed earlier in this work (1) was the reference electrode.

In this investigation, the technique has been applied to the determination of the reversible potentials of the zirconium chlorides in the temperature range 670 °C to 750 °C. Three zirconium chlorides are known to exist at room temperature: zirconium dichloride, zirconium trichloride, and zirconium tetrachloride.

Pure solid zirconium trichloride disproportionates at high temperatures by the reaction:

[1] $$2ZrCl_{3(s)} = ZrCl_{2(s)} + ZrCl_{4\ vap.}$$

Turnbull and Watts (4) have shown that the reaction pressure of zirconium tetrachloride vapor in equilibrium with the two solid phases reaches 1 atm at about 450 °C. Solutions of zirconium trichloride in alkali chloride melts have also been considered to be thermally unstable and recent measurements of the zirconium potential have been conducted in melts containing zirconium tetrachloride (5, 6).

Preliminary experiments in this laboratory have indicated that at 700 °C zirconium metal is soluble in an equimolar melt of potassium and sodium chlorides containing either zirconium trichloride or zirconium tetrachloride. Solidified material from these solutions had a dark blue color, indicating the presence of reduced zirconium species.

In the experimental work reported herein, the thermal stabilities of zirconium dichloride and of zirconium trichloride in solution were investigated by cryoscopic measurements and by X-ray analysis.

The liquidus curves of the binary systems MCl–$ZrCl_2$ and MCl–$ZrCl_3$, where M is potassium or sodium, were determined. The potentials of a zirconium electrode immersed in a solution containing zirconium dichloride and the redox potentials of the systems $ZrCl_2|ZrCl_3$ and $ZrCl_3|ZrCl_4$ were also investigated. From the results, the equilibrium

[1]*Present address: Department of Metallurgy, Northwestern University, Evanston, Illinois, U.S.A.*

constants for the reactions between zirconium metal and zirconium tri- or tetra-chlorides in solution were obtained and the mechanism of the reversible deposition of zirconium metal by electrolysis from a melt containing zirconium tetrachloride is predicted.

EXPERIMENTAL

The preparations of anhydrous zirconium dichloride and of zirconium trichloride of purity better than 98% by weight have been described in previous publications (7, 8). Zirconium tetrachloride was used as the stable complex compound K_2ZrCl_6. The preparation of this compound has also been reported in a previous publication (9). Zirconium di- and tri-chlorides are hygroscopic and oxidize readily in air; the potassium hexachlorozirconate compound is only hygroscopic. Accordingly, handling of these materials was done in a dry box filled with purified argon.

The liquidus curves of the binary systems $MCl–ZrCl_2$ and $MCl–ZrCl_3$, where M is sodium or potassium, were established by freezing point measurements. The mixtures were contained in heart-shaped quartz ampoules, with a thermocouple well blown in the center, sealed under vacuum. The cooling curves were recorded on a 1 mV full-scale deflection recorder. The cooling rate was automatically regulated to between 0.75 to 1.5 deg per min. Undercooling was generally below 1.5 deg. Calibrated platinum – platinum – 13% rhodium thermocouples were used for these measurements and the reproducibility of the measured freezing points on the same sample was ±1 °C. Potentials were measured with the cell shown in Fig. 1.

The cell was constructed from quartz glass and was operated under an atmosphere of purified argon. The melt was contained in a platinum crucible connected to a platinum lead wire. The crucible itself represented

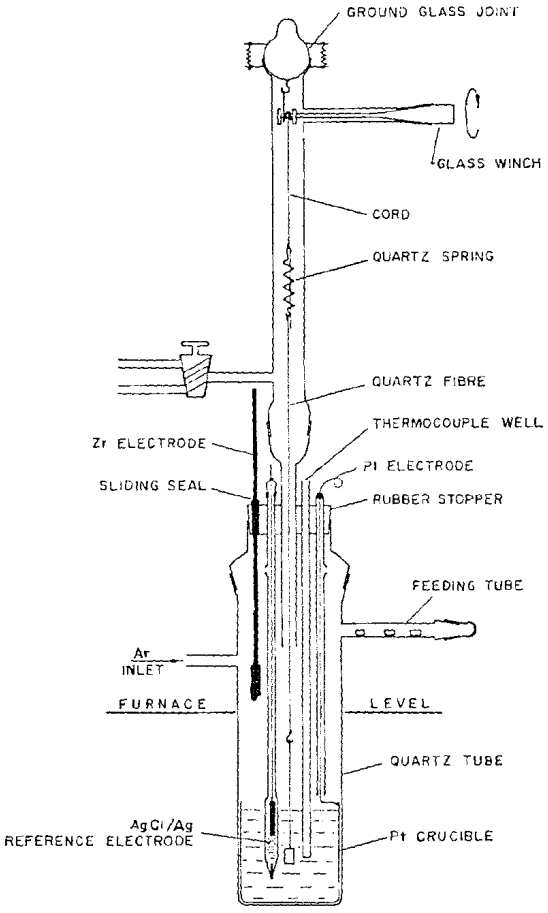

FIG. 1. Cell design.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the inert platinum electrode for the redox potential measurements of the systems $Zr^{2+}|Zr^{3+}$ and $Zr^{3+}|Zr^{4+}$. The potentials of the zirconium electrode were obtained with a solution containing zirconium dichloride. The electrode was of reactor-grade zirconium metal, containing less than 400 p.p.m. of metallic impurities. It could be lowered into the system using a sliding seal. The reference electrode in all these measurements was a silver – silver chloride electrode of a design given in a previous publication (1). The solutions in the two electrode compartments were separated by an asbestos fiber sealed at the tip of the reference electrode. Thermoelectric potentials caused by these electrodes were measured separately and the appropriate corrections were applied to the measured electrode potentials.

Solutions of zirconium dichloride were also prepared *in situ* by the direct reaction between zirconium metal and zirconium trichloride in solution:

$$[2] \qquad Zr_{(s)} + 2(ZrCl_3)_{solution} = 3(ZrCl_2)_{solution}.$$

For this purpose a quartz spring balance was incorporated in the cell. A zirconium rod, 1/2 in. long by 1/4 in. in diameter, was suspended from the lower end of the balance and dipped into a melt containing a known amount of zirconium trichloride. The loss of weight of zirconium in reaction [2] could then be followed by measuring the spring extension with a cathetometer. By this method 0.1 mg of reacted metal corresponding to the production of 0.53 mg of zirconium dichloride could be detected. A mixture of divalent and trivalent zirconium of any desired ratio could also be obtained by withdrawing the metal from the solution and thus interrupting the reaction at any given time prior to its completion. These solutions were then used for measurements of the redox potentials of the $Zr^{2+}|Zr^{3+}$ system.

Solutions of zirconium dichloride and mixtures containing known amounts of either zirconium di- and tri-chlorides, or zirconium tri- and tetra-chlorides were also prepared by adding weighed pellets of the pure anhydrous materials from the sidearm feeding tube shown in Fig. 1.

RESULTS AND DISCUSSION

(*a*) *Phase Diagram Determinations*

The liquidus curves for the binary systems KCl–$ZrCl_2$ and NaCl–$ZrCl_2$ were investigated and the results are given in Figs. 2 and 3.

The diagrams are of the simple eutectic type. The melting point of pure zirconium dichloride was found at 722 ± 1 °C. In the KCl–$ZrCl_2$ system, the eutectic is found at 698 ± 1 °C and 53.5 mole % zirconium dichloride. In the NaCl–$ZrCl_2$ system the eutectic lies at 695 ± 1 °C and at 69 mole % zirconium dichloride. X-ray patterns of material cooled from eutectic composition on the NaCl–$ZrCl_2$ system showed the same positions of the lines and the same order of relative intensities as found in pure zirconium dichloride (8) and sodium chloride, indicating that solid solubility is slight if it occurs.

X-ray patterns taken on KCl–$ZrCl_2$ samples cooled from a liquid of eutectic composition showed only a slight displacement in the position of the potassium chloride peaks, indicating the existence of solid solubility in this system. Disproportionation products such as zirconium metal, zirconium trichloride, or any of the hexachlorozirconate compounds could not be detected in these systems. Repeated freezing point determinations on the same sample were fully reproducible to within 1 °C, thus indicating the thermal stability of these solutions. The liquidus curve on the KCl-rich side of the system KCl–$ZrCl_3$ is shown in Fig. 4.

The melting point of pure zirconium trichloride could not be obtained because of disproportionation. The X-ray analysis of a solidified sample of zirconium trichloride included sharp lines for zirconium dichloride, a medium strong line for zirconium tetrachloride, and a weak line for zirconium trichloride. Similarly the $ZrCl_3$-rich solutions in this system indicated that disproportionation had taken place. On the potassium chloride side of the diagram, X-ray analysis on quenched samples obtained from a liquid solution containing 59.6 mole % zirconium trichloride showed very sharp lines for the trichloride. It appeared, however, that the lines were slightly displaced and their order of relative intensities had changed. The potassium chloride lines were also displaced, thus indicating solid solubility. The eutectic temperature was found at 581 ± 2 °C. The liquidus freezing

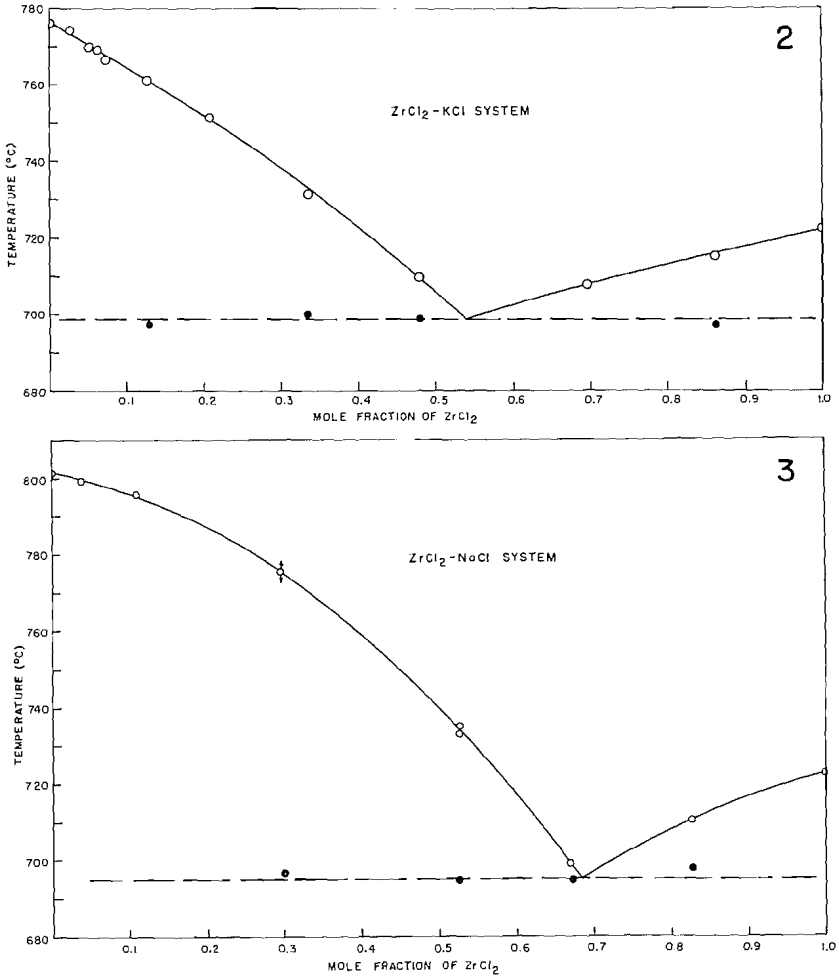

FIG. 2. Phase diagram of the $ZrCl_2$–KCl system.
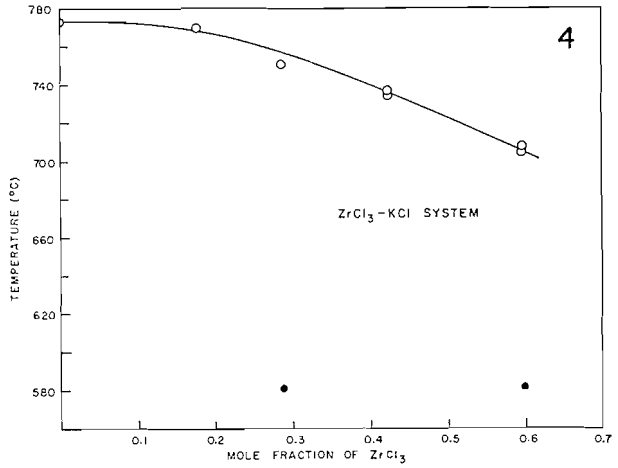
FIG. 3. Phase diagram of the $ZrCl_2$–NaCl system.



points were found to be lowered by 3 deg after the cooling curve had been repeated on the same sample.

Attempts to determine the phase diagram for the $ZrCl_3$–NaCl mixtures failed because of excessive disproportionation in this system.

In conclusion the phase diagram investigation indicates that zirconium dichloride is stable in its solutions with either potassium or sodium chlorides. On the other hand, zirconium trichloride is stable only in the presence of potassium chloride. It is probable that the formation of complex species with potassium chloride in the melt causes the shift of the equilibrium of disproportionation reaction [1] on the reactant side.

The stability of zirconium trichloride in the equimolar melt of potassium and sodium chlorides was also investigated by taking the X-ray diffraction patterns of a sample containing 15 mole % zirconium trichloride. The sample was raised to 750 °C, kept at that temperature for 24 h, and then quenched. The X-ray patterns showed clearly only the sharp lines for zirconium trichloride, along with those for potassium and sodium chlorides. The latter were slightly displaced because of the existence of solid solubility, as expected.

(b) Solubilities of Zirconium Metal in Zirconium Trichloride Solutions

The reaction between zirconium metal and zirconium trichloride in solution in the equimolar melt of potassium and sodium chlorides was investigated by the quartz spring balance apparatus. Typical solubility curves at 700 °C as a function of time are given in Fig. 5. The vertical dotted lines represent the weight loss of zirconium metal corresponding to the formation of zirconium dichloride from the initial amount of zirconium trichloride present in the melt. It was found that when all the trichloride had been reduced to the dichloride the zirconium rod continued to lose weight slowly. After periods of 96 h, amounts to the order of 5×10^{-5} to 10^{-4} mole fraction excess metal in solution were obtained. Zirconium metal did not dissolve in the equimolar melt of potassium and sodium chlorides. However, slow dissolution was evident when zirconium dichloride was added to this melt. The mechanism of metal dissolution in molten salts is not too well understood at present. Particularly in this case, the observed excess solubility cannot be associated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the existence of a species of a lower valence than divalent zirconium. From the potential measurements, to be discussed subsequently, it appears that the valence and the activity of divalent zirconium in solution are not affected by the presence of excess metal.

From the curves in Fig. 5 it is evident that at 700 °C the relative rate of metal dissolution is rather slow, and increases with increasing concentration of zirconium trichloride in solution, as expected.

(*c*) *Electromotive Force Measurements*

The reversible potentials of the cell,

$$\begin{array}{c|c||c|c} \text{Zr} & \text{ZrCl}_2\,(X_2) & \text{AgCl}\,(X_1) & \text{Ag} \\ (-) & \text{KCl} + \text{NaCl}\ ((1/1)\ \text{mole}) & \text{KCl} + \text{NaCl}\ ((1/1)\ \text{mole}) & (+) \end{array} \qquad \text{(cell A)},$$

were measured, at various concentrations of zirconium dichloride, as a function of temperature. At each concentration level, the potentials reached their equilibrium values within 3 to 4 h and remained constant thereafter. The results of these measurements are given in Fig. 6. Each curve corresponds to a complete temperature cycle in the range 670 °C to 750 °C. The readings were fully reproducible. During a temperature cycle that lasted 24 to 48 h, the potential drift on returning to the original temperature was less than ±2 mV. At temperatures higher than 750 °C readings became unstable and were not taken.

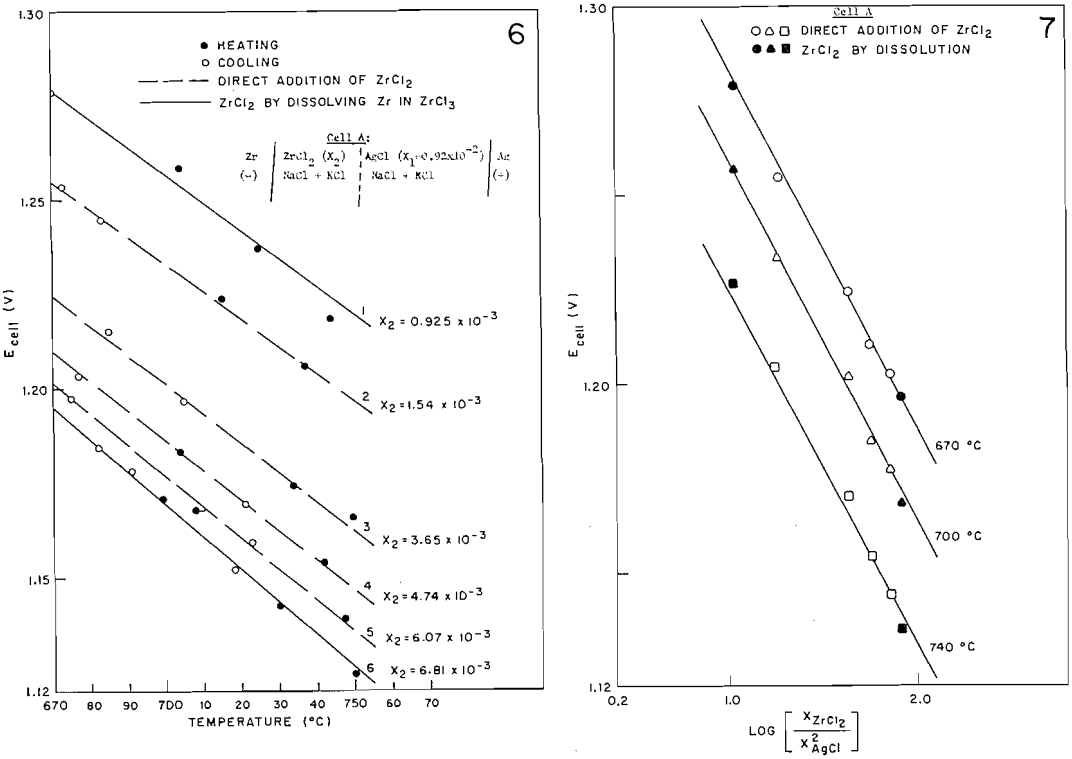

FIG. 6. Potentials of the $Zr|Zr^{2+}$ system as a function of temperature.
FIG. 7. Plot of the potentials of the $Zr|Zr^{2+}$ system against the logarithm of mole fractions.

In Fig. 6, the solid lines represent compositions of zirconium dichloride prepared by the dissolution method, and the dotted lines represent additions of pure zirconium dichloride. The reaction in cell A is given as

[3] $$Zr_{(s)} + 2(AgCl)_{solution} = (ZrCl_2)_{solution} + 2Ag_{(s)}$$

and the Nernst equation corresponding to this reaction is

[4] $$E_{cell} = (E_{ZrCl_2}{}^0 - E_{AgCl}{}^0) - \frac{RT}{2F} \ln \frac{\gamma_{ZrCl_2}}{\gamma_{AgCl}{}^2} - \frac{RT}{2F} \ln \frac{X_2}{X_1{}^2}$$

where, E_{cell} is the experimentally measured cell potential, and $E_{ZrCl_2}{}^0$ and $E_{AgCl}{}^0$ represent the formation potentials of the pure constituents. The formation potentials may be calculated from thermodynamic data available in the literature and will be referred to as "standard potentials" in all subsequent discussions. The X's and γ's are mole fractions and activity coefficients, respectively. The standard states of reference for the activity calculations are the pure compounds at the temperature of the experiment.

The plot of the cell potentials against log $(X_2/X_1{}^2)$ of eq. [4] is given in Fig. 7. Isotherms at the selected temperatures of 670 °C, 700 °C, and 740 °C are shown. The curves are linear indicating that the activity coefficients of zirconium dichloride and silver chloride are constant at constant temperature, and independent of concentration. Accordingly, the solutions obey Henry's law and the data may be used for the calculation of an "apparent standard cell potential", $E_{app}{}'^0$, given as

[5] $$E_{app}{}'^0 = E_{ZrCl_2}{}^0 - E_{AgCl}{}^0 - (RT/2F) \ln \gamma_2.$$

The activity coefficient for silver chloride has been neglected in eq. [5] since these solutions are known to be ideal (1).

The "apparent standard cell potential" defines the free energy of reaction [3] in hypothetical solutions of unit concentration, with reactants and products in their states at infinite dilution. The cell reactions for the two redox cells

Pt	$ZrCl_2$ (X_2)		AgCl (X_1)	Ag	
(−)	$ZrCl_3$ (X_3)	||	KCl + NaCl ((1/1) mole)	(+)	(cell B)
	KCl + NaCl ((1/1) mole)				

and

Pt	$ZrCl_3$ (X_3)		AgCl (X_1)	Ag	
(−)	$ZrCl_4$ (X_4)	||	KCl + NaCl ((1/1) mole)	(+)	(cell C)
	KCl + NaCl ((1/1) mole)				

are, respectively,

[5] $$(ZrCl_2)_{in\ solution} + (AgCl)_{in\ solution} = (ZrCl_3)_{in\ solution} + Ag_{solid}$$

and

[6] $$(ZrCl_3)_{in\ solution} + (AgCl)_{in\ solution} = (ZrCl_4)_{in\ solution} + Ag_{solid}$$

The appropriate forms of the corresponding Nernst equation are

[7] $$E_{cell} = [3E_{ZrCl_3}{}^0 - 2E_{ZrCl_2}{}^0 - E_{AgCl}{}^0 - (RT/F) \ln (\gamma_{ZrCl_3}/\gamma_{ZrCl_2})] - (RT/F) \ln (X_{ZrCl_3}/X_{ZrCl_2})$$

and

[8] $$E_{cell} = [4E_{ZrCl_4}{}^0 - 3E_{ZrCl_3}{}^0 - E_{AgCl}{}^0 - (RT/F) \ln (\gamma_{ZrCl_4}/\gamma_{ZrCl_3})] - (RT/F) \ln (X_{ZrCl_4}/X_{ZrCl_3})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

where E^0's represent the standard potentials of the pure constituents, and γ's and X's are the corresponding activity coefficients and mole fractions. The quantities in brackets are the "apparent standard potentials" for the two redox systems.

The redox potentials of di- and tri-, and of tri- and tetra-valent zirconium were measured in the mole fraction range 10^{-3} to 10^{-4} and in the temperature range 670 °C to 750 °C. These potentials reached steady values in 3 to 6 h. Accordingly, at each concentration level, the potentials were measured as a function of time. When steady readings were obtained, the system was observed for at least another 3 h to ensure that true equilibrium had been reached. The equilibrium potentials as a function of temperature for these two systems are shown in Figs. 8 and 9. The results correspond to complete temperature

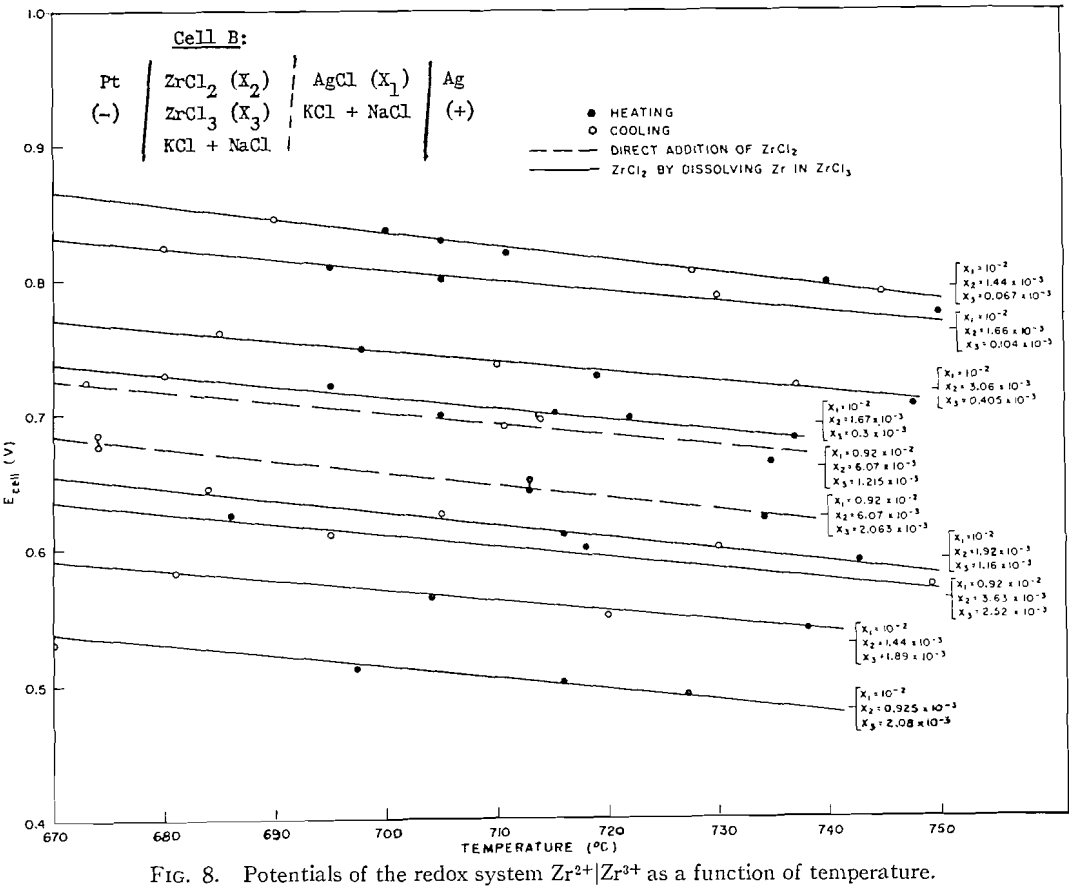

FIG. 8. Potentials of the redox system $Zr^{2+}|Zr^{3+}$ as a function of temperature.

cycles and were quite reproducible. Thus, during a temperature cycle, on cooling the potentials returned to the original values to within ±3 mV.

The corresponding Nernst isotherms for the two systems are given in Figs. 10 and 11. The curves are linear with a slope corresponding to a one-electron electrode process, as expected. The linearity of the curves also indicates that the solutions of trivalent and tetravalent zirconium follow Henry's law.

The "apparent standard" potentials of these three systems were calculated, at each concentration level, with eqs. [4], [7], and [8], and the arithmetic means of these values are given in Table I.

†Parentheses indicate components in solution.

The potentials in this table refer to the chlorine electrode as the zero potential reference. For the calculation, the known potentials of the silver – silver chloride electrode measured against a chlorine electrode (1) were added to the measured potentials. From these data the "apparent standard" potentials of the systems $Zr|Zr^{3+}$, and $Zr|Zr^{4+}$ were also calculated and are included in Table I.

"Apparent standard" potentials given in this table refer to the reactions between zirconium metal and chlorine gas at 1 atm to produce 1 gram mole of the corresponding chloride at a thermodynamic state having the properties of the solution at infinite dilution. From the data the mole fraction equilibrium constants for various reactions involving the zirconium chlorides were also calculated and are summarized in Table II.

*Parentheses indicate components in solution.

The high positive values of the equilibrium constants indicate that zirconium metal should reduce any tetra- or tri-valent zirconium present to the divalent species. The reduction in both cases should be almost quantitative. Thus the observed solubility of zirconium metal in a melt containing zirconium tetrachloride is supported by the thermodynamic calculations. It can also be predicted from these results that the potential of a zirconium electrode in a solution of zirconium tetrachloride cannot be interpreted in a simple manner. Measurements of this type represent nonequilibrium potentials which are not representative of the initial composition of the melt.

To provide further evidence on this matter, the potentials of a zirconium electrode immersed in a solution containing only zirconium tetrachloride were measured. The cell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was of the same design as before, including a zirconium and an inert platinum electrode. The potentials of these two electrodes were measured against the silver – silver chloride reference. Potential versus time curves were obtained and two such curves are plotted in Fig. 12. It is seen that the potential of the zirconium electrode appears to change rather

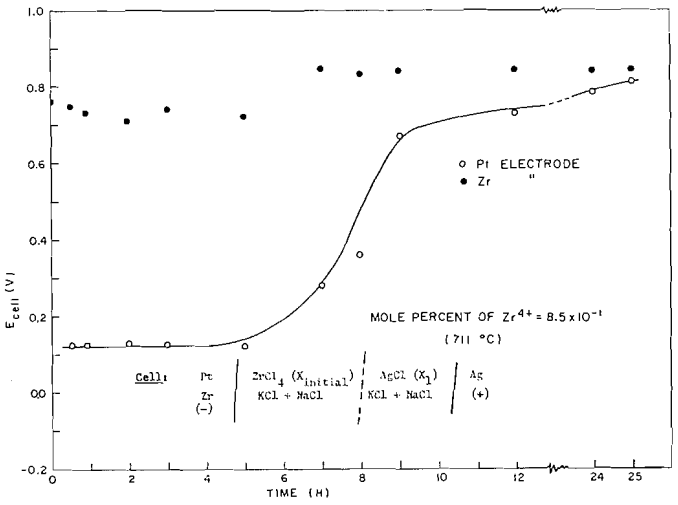

FIG. 12. Nonequilibrium potential measurements of zirconium and platinum electrodes immersed in a solution of zirconium tetrachloride.

slowly with time. However, the potential of the platinum electrode changes more rapidly. The shape of the potential versus time curve of the platinum electrode is characteristic of a redox titration. The behavior of such a reacting electrode may be predicted thermodynamically. For example, for the equilibrium between zirconium metal and zirconium tetrachloride, the final redox potential of the cell

Pt	$Zr^{4+} \rightleftharpoons Zr^{3+}$	Ag^+	Ag	(cell D)
(−)	(as $ZrCl_4$ and $ZrCl_3$)	(as AgCl)	(+)	

corresponds to an overall cell reaction which may be written as:

[9] $$(ZrCl_3) + (AgCl) = (ZrCl_4) + Ag_{(s)}$$

For this reaction $(ZrCl_3)$ and $(ZrCl_4)$ represent the equilibrium concentrations of tri- and tetra-valent zirconium in the presence of zirconium metal. Evidently, the concentration of tetravalent zirconium at equilibrium is entirely different from its initial concentration.

For reaction [9], the change in free energy is given as

[10] $$\Delta G_R = \bar{G}_{ZrCl_4} + G_{Ag_{(s)}}{}^0 - \bar{G}_{ZrCl_3} - \bar{G}_{AgCl} = -E_{cell}F$$

where $\bar{G}_{ZrCl_4}$ and $\bar{G}_{ZrCl_3}$ are the chemical potentials of these species at their equilibrium concentrations. These are determined by the reaction:

[11] $$Zr_{(s)} + 3(ZrCl_4) \rightleftharpoons 4(ZrCl_3).$$

At equilibrium $4\bar{G}_{ZrCl_3} - 3\bar{G}_{ZrCl_4} - G_{Zr}{}^0 = 0$ and

[12] $$\bar{G}_{ZrCl_4} - \bar{G}_{ZrCl_3} = (\bar{G}_{ZrCl_4} - G_{Zr}{}^0)/4.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Substituting this expression in eq. [10], we obtain the following relationship:

$$[13] \qquad 4\Delta G_R = \bar{G}_{ZrCl_4} - G_{Zr}{}^0 - 4\bar{G}_{AgCl} + 4G_{Ag}{}^0 = -4E_{cell}{}'F.$$

The chemical reaction corresponding to the free energy change above is

$$[14] \qquad Zr_{(s)} + 4(AgCl) = (ZrCl_4) + 4Ag_{(s)}$$

and may be realized in a galvanic cell containing a zirconium electrode immersed in a solution of zirconium tetrachloride at the previously established equilibrium concentration. It is evident that when the solution reaches its equilibrium composition, the platinum and the zirconium electrodes should indicate the same potential, i.e. $E = E'$. It may be shown in a similar manner that this potential is characteristic of *all* the possible redox combinations in the system and of *all* the various zirconium ions in solution.

The convergence of the two potential curves in Fig. 12 supports the theoretical interpretation. The initial differences in the two potentials are indicative of concentration changes occurring at the electrode solution interface as the result of the various competing reactions prior to equilibrium. The reliability of such measurements is therefore subject to the attainment of chemical equilibrium between all the possible species in the system. From the curves in Fig. 12, it is seen that the reduction processes at 711 °C are quite slow. During these measurements the potentials did not reach equilibrium even after a period of 25 h.

Potential measurements in the $Zr|Zr^{4+}$ system have been reported by Yang *et al.* (6). The measurements were obtained at 450 °C with solutions of zirconium tetrachloride in the eutectic melt of potassium and lithium chlorides. The reference electrode was a chlorine electrode (5). However, when these potentials are plotted against the concentration of zirconium tetrachloride on a logarithmic scale, a straight line is obtained with a slope indicating an electrode reaction corresponding only to 0.9 electron. In a later publication by Yang *et al.* (6), the measurements were repeated with a silver chloride reference electrode. Again the Nernst plot from these results gave a curve with a slope changing between one to three electrons. It appears that the system was reacting during the measurements. The "apparent standard" potentials could not be calculated from these results.

The potentials of the $Zr|Zr^{4+}$ system have also been measured recently by Smirnov *et al.* (11), with respect to a chlorine reference electrode. The measurements were taken in the solvent melt of potassium and sodium chlorides and in the temperature range 670 °C to 970 °C. The Nernst isotherms obtained from these measurements showed an appreciable curvature and were interpreted as implying the presence of divalent zirconium in the reaction:

$$[15] \qquad Zr_{(s)} + (Zr^{4+})_{solution} \rightleftharpoons 2(Zr^{2+})_{solution}.$$

From the mathematical analysis of the potential isotherms, the apparent standard potentials for the two systems $Zr|Zr^{2+}$ and $Zr|Zr^{4+}$ were calculated, and the results are in complete disagreement with the present values. Thus, at 700 °C, the apparent standard potentials for the two systems $Zr|Zr^{2+}$ and $Zr|Zr^{4+}$ are given as 1.927 V and 2.000 V, respectively. The corresponding values found in the present investigation are 2.200 V and 1.863 V. The equilibrium potential for a reacting electrode, representing reaction [15], is given by Smirnov as

$$[16] \qquad E_{cell} = (E_{app}{}'^0)_{ZrCl_2} - (RT/2F)\ln x[Zr]_t = (E_{app}{}'^0)_{ZrCl_4} - (RT/4F)\ln (1-x)[Zr]_t$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where, $E_{app}{}'^{0}$'s are the apparent standard potentials for the two systems $ZrCl_2$ and $ZrCl_4$, x is the fraction of Zr^{2+} ions computed with respect to the total soluble zirconium content in the electrolyte, and $[Zr]_t$, is the ionic-fraction concentration of total zirconium, equal to $[Zr]_t = [Zr^{2+}] + [Zr^{4+}]$

The fraction x of divalent zirconium ions is then calculated from the *slope* of the isotherm representing the plot of E_{cell} vs. log $[Zr]_t$. It is readily seen that the fraction x changes continuously with the total zirconium content in the melt; the apparent standard potential $E_{app}{}^{0'}$ is the only true constant in the system at any given temperature. It is evident that from the slope of this curve only the ratio of the x's at two different compositions may be obtained. The authors do not indicate whether other limiting conditions were considered in order to solve eq. [16]. It appears, therefore, that the method used in calculating the potentials of the two systems by Smirnov *et al.* (11) is highly questionable.

In a later publication, Smirnov and co-workers (12) reported potential versus current curves obtained during the electrolysis of solutions of zirconium tetrachloride in the equimolar melt of potassium and sodium chlorides at 700 °C. Molybdenum cathodes were used in these experiments, and the polarization curves showed quite clearly three distinctive steps at about 1.1, 1.7, and 2.1 V. In spite of this observation, the results were interpreted as a two-step reduction during which tetravalent zirconium was first reduced to the divalent species at about 1.7 V. This was followed by the reduction of the divalent zirconium to metal at about 2.1 V. The latter value is in agreement with the reversible potential of divalent zirconium obtained in the present work (Table I). (The first step, at 1.1 V, was attributed to the deposition of molybdenum ions produced *in situ* in the melt by the direct reduction of zirconium tetrachloride by molybdenum metal.) However, from the results obtained in this investigation (Table I), it is indicated that the polarization plateaux at 1.1 and 1.7 V should correspond to the reactions $Zr^{4+} \rightarrow Zr^{3+}$ and $Zr^{3+} \rightarrow Zr^{2+}$, respectively. Furthermore, it appears that molybdenum ions deposited either at a much lower potential or at a potential similar to that required for the reduction of tetravalent zirconium.

From the magnitude of the equilibrium constants given in Table II, it may be predicted that zirconium trichloride in solution does not disproportionate to any significant extent. Furthermore, the reaction between zirconium di- and tetra-chloride to produce trivalent zirconium proceeds almost to completion. Therefore, these calculations substantiate the thermal stability of zirconium trichloride in these melts found by the X-ray investigation.

ACTIVITY CALCULATIONS

The "apparent potentials" given in Table I may be used for the calculation of the activity coefficients of the various zirconium species in solution. For the calculation, accurate data on the free energies of formation of the pure zirconium chlorides are required. Unfortunately, the data given by various authors are entirely contradictory. For example, the free energies of formation of zirconium trichloride given by Wicks and Block (13) and by Turnbull and Watts (4) differ by about 25 kcal. Similarly, the data available (4, 13) for the zirconium dichloride differ by about 9 kcal. The data for zirconium tetrachloride are slightly better. Free energies of formation of pure zirconium tetrachloride given by Kubaschewski and Evans (14) differ by about 5 kcal from those found in tabulations given by Wicks and Block (13), or Hamer *et al.* (15). The difference is due to the uncertainty in the heat of formation of solid zirconium tetrachloride at 298 °K.

Because of such discrepancies, the partial molar properties for zirconium di- and trichlorides were not calculated. For zirconium tetrachloride, the data given by Kubaschewski

and Evans (14) appear to be the most reliable as they are also substantiated by Turnbull and Watts (4). Accordingly, the approximate activity coefficients for zirconium tetrachloride were calculated from the equation

$$[17] \qquad E_{app}'^{0} = E_{ZrCl_4}{}^{0} - (RT/4F) \ln \gamma_{ZrCl_4}$$

where $E_{app}'^{0}$ is the "apparent standard" potential for zirconium tetrachloride obtained experimentally, and $E_{ZrCl_4}{}^{0}$ is the corresponding "standard" potential calculated from the available thermodynamic data (13). The Henrian activity coefficients of zirconium tetrachloride, γ_{ZrCl_4}, obtained from these calculations at the selected temperatures of 670 °C, 700 °C, and 740 °C are 4.67×10^{-3}, 6.08×10^{-3}, and 8.49×10^{-3}, respectively. The activity coefficients are of the order of 10^{-3} to 10^{-2} and increase with increasing temperature, as expected. These values should be compared to the activity coefficients for zirconium tetrachloride in alkali chloride melts obtained by direct vapor pressure measurements (16). For the KCl–$ZrCl_4$ system at 800 °C, the activity coefficient is about 0.5×10^{-4}, while for NaCl–$ZrCl_4$, the activity coefficient is only 0.4×10^{-3}. The values which are found from the potential measurements in the equimolar melt of potassium and sodium chlorides are higher and change from 5×10^{-3} at 670 °C to 8×10^{-3} at 740 °C. This difference of one to two orders of magnitude in the activity coefficients obtained by the two methods could be explained by an uncertainty in the free energy of formation of zirconium tetrachloride of about 4.5 kcal. Such a difference is well within the limits of accuracy of the thermodynamic data given in the literature.

An additional source of error could be the calculation of the apparent standard potential of zirconium tetrachloride from the combined results of the electromotive force measurements on three different cells. It should also be realized that the activity coefficients obtained in these two investigations represent measurements on three different systems; therefore, some difference due to the solvent effect should be expected. In any case, the pronounced negative deviations from ideality of zirconium tetrachloride indicate the formation of the complex $ZrCl_6^{2-}$ anions in the melt, as suggested previously (16).

CONCLUSIONS

The results of this investigation indicate that zirconium trichloride does not disproportionate in molten solutions containing an excess of potassium chloride. The mechanism of the electrolytic deposition of zirconium metal from a melt of potassium and sodium chlorides containing zirconium tetrachloride is predicted from the combined results of the potential measurements. The latter indicate a three-step reduction:

$$Zr^{4+} \rightarrow Zr^{3+} \rightarrow Zr^{2+} \rightarrow Zr^{0}.$$

The approximate deposition potentials are 1.2, 1.8, and 2.2 V, respectively. The final step corresponding to the deposition of zirconium metal occurs at about 2.2 V, well below the deposition potentials (~3.5 V) of the alkali metal cations in the solvent melt.

Furthermore, the solubility of zirconium metal in a melt containing zirconium tri- or tetra-chlorides indicates that the deposition process should be carried out preferably from a melt containing reduced zirconium species.

THEORIES OF INHIBITION BY NITRIC OXIDE

MARGARET H. BACK AND KEITH J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received August 9, 1965

ABSTRACT

Theories of the inhibition by nitric oxide of pyrolysis and other reactions, proposed by Voevodsky, by Wojciechowski and Laidler, and by Norrish and Pratt, are critically discussed in this paper with reference to the experimental results. The Voevodsky scheme, involving the suppression by nitric oxide of a heteorgeneous initiation process, is shown to be inconsistent with the observed results for ethane pyrolysis. The Norrish–Pratt scheme, involving oxime formation and NO-induced oxime decomposition, is shown to be unsatisfactory in failing to predict nonintegral orders and in leading to activation energies that are much too high. It is concluded that it is necessary to postulate H abstraction by NO, as in the Wojciechowski–Laidler mechanisms.

INTRODUCTION

In recent years there has been considerable interest in the mechanisms of organic pyrolyses in the presence of inhibitors such as nitric oxide. It was originally thought that the sole effect of nitric oxide was to remove radicals from the system, but a number of studies of isotopic mixing have shown that free-radical chain processes are still important in the maximally inhibited reactions; this has been demonstrated for propane (1), ethane (2), butane (3), and dimethyl ether (4).

Three general schemes have recently been proposed to explain the kinetics of pyrolyses in the presence of nitric oxide. Voevodsky (5, 6) has suggested that initiation and termination both take place on the surface of the vessel, and that both irreversible and reversible surface initiation occurs, the former being suppressed by nitric oxide and other inhibitors. Wojciechowski and Laidler (7, 8) suggested that nitric oxide brings about an additional initiation reaction in which there is abstraction of a hydrogen atom.

$$M + NO \rightarrow R + HNO$$

Termination was suggested to occur by reaction between an organic radical R and either HNO or RNO. At higher NO concentrations termination becomes mainly RNO + RNO or HNO + HNO; under these circumstances the rate increases with NO concentration, as found experimentally.

Norrish and Pratt (9) have more recently put forward an alternative scheme which places emphasis on the reactions of oximes. They do not consider that nitric oxide abstracts hydrogen atoms; it adds on to radicals with the eventual formation of an oxime, e.g.

$$C_2H_5 + NO \rightarrow C_2H_5NO \rightarrow CH_3CH{=}NOH.$$

These oximes undergo decomposition in two ways, by reaction with an additional molecule of NO, and by direct unimolecular decomposition. Norrish and Pratt apply their scheme in a general way to the decomposition of *n*-pentane, and show that it can account qualitatively for the variation of rate with nitric oxide concentration. They also obtain quantitative agreement by making a plausible choice of rate constants.

The object of this paper is to discuss critically these schemes with reference to the experimental data. It will be seen that recent results on the ethane pyrolysis are at variance with Voevodsky's proposals. With the Norrish–Pratt scheme two serious difficulties arise. In the first place, the scheme is incapable of predicting fractional orders

for the maximally inhibited reactions; secondly, it does not account for the activation energies observed in the regions of maximal inhibition and accelerated reaction.

THE VOEVODSKY PROPOSAL

Several recent investigations, by Quinn (10), Gordon (11), and Back and Lin (12), have been concerned with the rate of production of methane in the ethane pyrolysis. The main initiation process is

$$C_2H_6 \rightarrow 2CH_3,$$

and the rate of production of methane, by the reaction

$$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

is therefore a measure of the rate of initiation. All three investigations have led to the conclusion that an increase in surface/volume ratio has a very small effect on the rate of initiation. For Voevodsky's suggestion to be applicable the heterogeneous initiation would have to be about 90% of the whole, since at maximal inhibition the rate is reduced to approximately one-tenth of the uninhibited value. The actual contribution of the surface initiation is very much less than this.

It might be argued that the surface brings about an alternative initiation process, namely

$$C_2H_6 \rightarrow C_2H_5 + H$$

and that it is this process that is suppressed by nitric oxide. This proposal also leads to difficulty, however. Back and Lin's results (12) show that the rate of production of butane by the reaction

$$2C_2H_5 \rightarrow C_4H_{10}$$

is not increased by packing the reaction vessel. If this is the main termination process the net rate of initiation must be unaffected by surface, since rates of initiation and termination must be equal. The possibility remains that there is an additional termination process

$$C_2H_5 + H \rightarrow C_2H_6$$

which occurs on the surface. This would require, however, that there would be an *equilibrium* concentration of C_2H_5; this being so, nitric oxide, by reducing the rate of formation of C_2H_5, could not affect the concentration of C_2H_5, since it would equally affect the rate of its removal. The results for ethane therefore cannot be reconciled with Voevodsky's proposal. His suggestions might, of course, be valid for other reactions.

THE WOJCIECHOWSKI–LAIDLER MECHANISMS

The Wojciechowski–Laidler proposals, which have been applied in detail to the decompositions of ethane (13), propane (14), butane (15), dimethyl ether (4), diethyl ether (16), acetaldehyde (17), and propionaldehyde (18) involve the following main features:

(i) Addition of nitric oxide leads to an *additional* initiation process, the abstraction of a hydrogen atom from the substrate molecule.

$$RH + NO \rightarrow R + HNO$$

(*ii*) There are formed species such as HNO and RNO, the latter becoming converted into the oxime which may break down further.

(*iii*) In the presence of nitric oxide there is an *additional* chain-ending step involving the reaction of a radical with HNO, RNO, or the oxime.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The most likely chain-ending step in the presence of nitric oxide is the one involving the predominant radical or radicals in the particular chain mechanism. Table I summarizes the situation with the various pyrolyses that have been investigated in detail. In each case the most probable chain-ending step leads to the correct order for the maximally inhibited reaction.

TABLE I

Wojciechowski-Laidler mechanisms for inhibition by nitric oxide. Initiation: RH + NO → R + HNO

Decomposition of:	Predominant radicals	Postulated chain-ending step	Overall order of maximally inhibited reaction	Ref.
C_2H_6	C_2H_5, H	$C_2H_5 + HNO \rightarrow C_2H_6 + NO$	1	13
C_3H_8	C_3H_7, H	$C_3H_7 + HNO \rightarrow C_3H_8 + NO$	1.5	14
C_4H_{10}	C_2H_5	$C_2H_5 + C_2H_4NOH \rightarrow C_4H_{10} + NO$	1.5	15
CH_3OCH_3	CH_3	$CH_3 + CH_2NOH \rightarrow C_2H_6 + NO$	1.5	4
$C_2H_5OC_2H_5$	C_2H_5	$C_2H_5 + C_2H_4NOH \rightarrow C_4H_{10} + NO$	1–1.5	16
CH_3CHO	CH_3	$CH_3 + CH_2NOH \rightarrow C_2H_6 + NO$	1.5	17
C_2H_5CHO	C_2H_5	$C_2H_5 + CH_3CH{=}NOH \rightarrow C_4H_{10} + NO$	1.5	18

Voevodsky (6) has recently objected to the Wojciechowski–Laidler scheme as applied to the ethane pyrolysis, mainly on the grounds that the chain length for the uninhibited reaction is "not large"; if the chain length in the uninhibited reaction were indeed short it would be impossible to explain inhibition on the basis of a mechanism which increases the rate of initiation. Voevodsky quotes the mass-spectrometric studies of Eltenton (19) as indicating short chains. The latest work (12), however, on the rate of methane production, leads to the result that the chain length is about 100. Wojciechowski and Laidler (13) concluded that the chain length is about 5 in the maximally inhibited reaction. A tenfold inhibition would therefore be produced if the addition of nitric oxide doubled the rate of initiation; there is therefore no difficulty along these lines.

Support for the suggestion that the main initiation reaction in the maximally inhibited reactions is the abstraction of a hydrogen atom by nitric oxide is provided by the behavior in the region in which the rate increases linearly with the nitric oxide concentration. Activation energies for the reaction in this region are given in the last column of Table II; the values for the paraffins are calculated from the rates measured by Blackmore and Hinshelwood (20), assuming a frequency factor of 10^{11} l mole^{-1} s^{-1}, while those for the ethers and acetaldehyde were measured directly by Laidler *et al.* (4, 17, 18). It is to be noted that the activation energies are consistent with the endothermicities of the postulated initiation reactions, listed in the next to last column of Table II.

TABLE II

Activation energies in the region of acceleration by nitric oxide

Decomposition of:	D(R—H) (kcal/mole)	Endothermicity of RH + NO → R + HNO	Activation energy of accelerated reaction (kcal/mole)
C_2H_6	98	50	52
C_3H_8	97	49	48
n-C_5H_{12}	95	47	52
iso-C_5H_{12}	94	46	45
neo-C_5H_{12}	96	48	48
CH_3OCH_3	92	44	43
$C_2H_5OC_2H_5$	93	45	45
CH_3CHO	85	37	39

THE NORRISH–PRATT PROPOSAL

The general scheme proposed by Norrish and Pratt (9) is

[1] $$M \rightarrow R_L + R_S$$

[2] $$R_S + M \rightarrow P_1 + R_L$$

[3] $$R_L \rightarrow P_2 + R_S$$

[4] $$R_L \rightarrow \text{products (chain ending)}$$

[5] $$R_L + NO \rightarrow R_LNO \rightarrow Ox$$

[6] $$Ox + NO \rightarrow R_S + \text{products}$$

[7] $$Ox \rightarrow \text{products}$$

where M is the substrate molecule, P_1 and P_2 are product molecules, Ox is an oxime, and R_L and R_S are large (μ) and small (β) radicals respectively. Reaction [4] is written as a first-order reaction for simplicity; this reaction is in any case unimportant in the presence of much nitric oxide.

Norrish and Pratt applied their scheme only to the *n*-pentane decomposition; we will now apply it to a number of other pyrolyses.

Pyrolysis of Ethane

A number of investigations (13, 21–25) have shown that small amounts of nitric oxide reduce the rate of the ethane pyrolysis to a limiting value; higher concentrations bring about an acceleration, the rate in this region being proportional to [NO] and to $[C_2H_6]$. In the maximally inhibited region the order with respect to ethane is unity at higher pressures and 3/2 at lower pressures. In the region of maximal inhibition the activation energy is 77.3 kcal per mole, whereas it is 52 kcal per mole in the region where the rate is proportional to [NO].

On the basis of the Norrish–Pratt proposals the mechanism would be*

[1] $$C_2H_6 \rightarrow 2CH_3$$

[2] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[3] $$C_2H_5 \rightarrow C_2H_4 + H$$

[4] $$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

[5] $$C_2H_5 + NO \rightarrow C_2H_5NO$$

[5′] $$C_2H_5NO \rightarrow CH_3CH{=}NOH$$

[6] $$CH_3CH{=}NOH + NO \rightarrow C_2H_4 + 2NO + H$$

[7] $$CH_3CH{=}NOH \rightarrow \text{products } (CH_3CN + H_2O?)$$

Application of the steady-state treatment to this scheme leads to

[*a*] $$[Ox] = \frac{k_1[C_2H_6]}{k_7}$$

[*b*] $$[C_2H_5] = \frac{k_1k_7 + k_1k_6[NO]}{k_5k_7[NO]}[C_2H_6]$$

[*c*] $$v = \frac{d[C_2H_4]}{dt} = k_3[C_2H_5] + k_6[Ox][NO]$$

**In the Norrish–Pratt scheme it is postulated that* NO *reacts with* $CH_3CH{=}NOH$ *to form* $CH_3 + HNO_2 +$ HCN, *in addition to reaction [6];* CH_3 *would produce* C_2H_5 *and then* H. *The essential feature of their scheme is the regeneration of* R_S *(in this case* H*) from the oxime. The* HNO_2 *is involved in the chain-branching processes at higher* NO *concentrations.*

$$[d] \qquad = \frac{k_1k_3}{k_5}\frac{[C_2H_6]}{[NO]} + \frac{k_1k_3k_6}{k_5k_7}[C_2H_6] + \frac{k_1k_6}{k_7}[C_2H_6][NO].$$

This equation is of the right form, in that it explains a reduction in rate at low NO concentrations, a flat region, and an acceleration at high NO concentrations.

A difficulty arises with this scheme when one considers the activation energies. The activation energy in the region of maximal inhibition would be

$$[e] \qquad E_{max} = E_1 + E_3 + E_6 - E_5 - E_7$$

and the experimental value is 77 kcal. E_1 is about 85 kcal and E_3 about 40 kcal. It follows that if the scheme is correct

$$[f] \qquad E_5 + E_7 - E_6 = 48 \text{ kcal.}$$

E_5 must be small, and it seems impossible that E_7 could be 48 kcal greater than E_6. In the region of acceleration by NO

$$[g] \qquad E_{ind} = E_1 + E_6 - E_7$$

or

$$[h] \qquad E_{max} - E_{ind} = E_3 - E_5.$$

Experimentally E_{max} is 77 kcal and E_{ind} is 52 kcal; therefore $E_3 - E_5 = 25$ kcal. Since E_3 is about 40 kcal, E_5 must be 15 kcal, which is unreasonably large.

The Wojciechowski–Laidler scheme, on the other hand, leads to a square-root relationship in the rate constants, and has no difficulty in explaining the experimental value of E_{max}, as explained in detail in the original paper (13). At high NO concentrations the Wojciechowski–Laidler mechanism predicts that the activation energy should be that of the initial abstraction reaction

$$C_2H_6 + NO \rightarrow C_2H_5 + HNO$$

This reaction is endothermic by about 50 kcal, so that an activation energy of 52 kcal is entirely reasonable.

The Norrish–Pratt scheme further predicts that the rate of the accelerated reaction will equal the rate of the maximally inhibited reaction when $[NO] = k_3/k_5$. With Bywater and Steacie's value (25) for $k_3 = 10^{13}\, e^{-39500/RT}\, s^{-1}$ and the value for k_5 of 3×10^{10} cc mole^{-1} s^{-1}, as suggested by Norrish and Pratt, $k_3/k_5 = 4.5$ mm at 900 °K and 1.0 mm at 850 °K. These estimates are upper limits since k_3 is probably no longer unimolecular in this region and k_5 is unlikely to be smaller. With ethane, however, these pressures of NO are barely sufficient to cause maximum inhibition, and much larger pressures are required to cause acceleration (20).

Furthermore, the accelerated reaction would be expected to occur at low pressures of NO when k_3, the rate constant for the decomposition of R_L, is small or when E_3 is large. In fact the opposite trend is observed. The accelerated reaction sets in earliest with acetaldehyde, for which R_L is one of the least stable radicals. Much larger pressures of NO are required to accelerate the reaction with hydrocarbons (26) and the greatest pressure of NO is required with ethane for which R_L is the most stable, i.e. E_3 is the argest.

Dimethyl Ether Pyrolysis

The effect of nitric oxide on the pyrolysis of dimethyl ether (4) is similar to that on ethane; there is again a flat region, followed by a region of acceleration. The order at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

maximal inhibition is 3/2, and the activation energy is 64.6 kcal per mole. At higher concentrations of NO the rate is proportional to $[CH_3OCH_3]$ and to [NO], and the activation energy is 43.4 kcal per mole.

The Norrish–Pratt mechanism would be

[1] $$CH_3OCH_3 \rightarrow CH_3 + CH_3O$$

[2] $$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3$$

[3] $$CH_2OCH_3 \rightarrow CH_2O + CH_3$$

[4] $$CH_3O \rightarrow CH_2O + H$$

[5] $$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3$$

[6] $$NO + CH_3OCH_2 \rightarrow CH_3OCH_2NO \rightarrow CH_3OCH{=}NOH$$

[7] $$CH_3OCH{=}NOH + NO \rightarrow 2NO + CH_2O + CH_3$$

[8] $$CH_3OCH{=}NOH \rightarrow \text{products } (CH_3OCN + H_2O?)$$

The steady-state equations lead to

[*i*] $$[Ox] = (2k_1/k_8)[CH_3OCH_3]$$

[*j*] $$[CH_3OCH_2] = \frac{2k_1[CH_3OCH_3]}{k_6[NO]} + \frac{2k_1k_7[CH_3OCH_3]}{k_6k_8}$$

[*k*] $$v = k_3[CH_3OCH_2] + k_7[Ox][NO]$$

[*l*] $$= \frac{2k_1k_3[CH_3OCH_3]}{k_6[NO]} + \frac{2k_1k_3k_7}{k_6k_8}[CH_3OCH_3] + \frac{2k_1k_7}{k_8}[CH_3OCH_3][NO].$$

Again the equation is of the right general form, leading first to inhibition and then to catalysis. The mechanism does not, however, account for the 3/2 order at maximal inhibition. It is to be noted that since in the Norrish–Pratt mechanisms the chain-ending steps are always first order, the steady-state equations are linear in free radical concentrations and cannot lead to nonintegral orders.

The experimental activation energies again present a difficulty for the mechanism. At maximal inhibition

[*m*] $$E_{max} = E_1 + E_3 + E_7 - E_6 - E_8 = 64.6 \text{ kcal (expt.)}.$$

$E_1 = 87$ kcal and $E_3 = 19$ kcal so that

[*n*] $$E_6 + E_8 - E_7 = 41 \text{ kcal}.$$

Such a high value seems impossible. At high NO concentrations

[*o*] $$E_{ind} = E_1 + E_7 - E_8 = 43 \text{ kcal (expt.)}.$$

With $E_1 = 87$ kcal

[*p*] $$E_8 - E_7 = 44 \text{ kcal}$$

which requires an impossibly high activation energy for the decomposition of the oxime.

Alternatively it might be suggested that since the CH_3 radicals are more plentiful than the CH_3OCH_2, the oxime will be formed from CH_3 by the reaction

[6′] $$CH_3 + NO \rightarrow CH_3NO \rightarrow CH_2{=}NOH$$

followed by

[7′] $$CH_2{=}NOH + NO \rightarrow 2NO + CH_3$$

[8′] $$CH_2{=}NOH \rightarrow \text{products } (HCN + H_2O?)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The result is now

$$[q] \qquad v = \frac{d[CH_2O]}{dt} = k_3[CH_2OCH_3]$$

$$[r] \qquad = \frac{2k_1k_2}{k_{6'}}\frac{[CH_3OCH_3]^2}{[NO]} + \frac{2k_1k_2k_{7'}}{k_{6'}k_{8'}}[CH_3OCH_3]^2 + k_1[CH_3OCH_3][NO].$$

This mechanism again fails to explain the 3/2 order at maximal inhibition, and is inconsistent with the experimental activation energies.

MODIFIED NORRISH–PRATT MECHANISMS

It is clear on the basis of the foregoing discussion that an important difficulty with the Norrish–Pratt mechanisms arises from their suggestion that the chain-ending steps are unimolecular, involving only the oxime molecule. As a result of this the steady-state equations are linear and not quadratic in radical concentrations, so that no explanation is provided for 3/2 kinetics, as found in the dimethyl ether pyrolysis. Furthermore, the rate expressions involve k_1 and not $k_1^{1/2}$, and therefore lead to much too high a value for the activation energy.

In view of this it is natural to modify the Norrish–Pratt proposals by replacing their unimolecular chain-ending step by a bimolecular one. For ethane pyrolysis, if we replace reaction [7] above by

$$[7'] \qquad Ox + C_2H_5 \rightarrow \text{products}$$

the result is

$$[l] \qquad v = \frac{d[C_2H_4]}{dt} = k_3\left(\frac{k_1k_6}{k_5k_{7'}}\right)^{1/2}[C_2H_6]^{1/2} + \left(\frac{k_1k_5k_6}{k_7}\right)^{1/2}[C_2H_6]^{1/2}[NO].$$

In the region of maximal inhibition the scheme therefore leads to an order slightly higher than 1/2 (since the order of reaction [3] is somewhat greater than unity); experimentally the order is somewhat larger than unity (~1.1). A further difficulty is that the scheme leads to a dependence on $[C_2H_6]^{1/2}$ at higher NO pressures, whereas the experimental dependence is on $[C_2H_6]$.

For the dimethyl ether pyrolysis, replacement of reaction [8] by

$$[8'] \qquad Ox + CH_3 \rightarrow \text{products}$$

leads to

$$[m] \qquad v = \frac{d[CH_4]}{dt} = k_2\left(\frac{k_1k_7}{k_6k_{8'}}\right)^{1/2}[CH_3OCH_3]^{3/2}$$

This mechanism correctly predicts the 3/2 order behavior, but fails to account for acceleration at high NO pressures.

CONCLUSION

The general conclusion of this analysis is that the H-abstraction reactions by NO must be important in the pyrolyses occurring in the presence of nitric oxide. The oxime decompositions may also be important, but do not have a very large effect on the overall kinetic behavior.

ADDENDUM: Gowenlock (27) has recently reviewed inhibition mechanisms, and has raised some objections to the Wojciechowski–Laidler proposals:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*a*) *The Wojciechowski–Laidler mechanisms do not account for nitric oxide consumption, which has been shown to occur in some cases.* The main feature of the mechanisms is that in the region of maximal inhibition there is a chain reaction that is zero order in nitric oxide. It is possible to introduce reactions leading to removal of nitric oxide, but these do not modify the explanation of the kinetic behavior. Undoubtedly such reactions are important, particularly at high nitric oxide concentrations, and should certainly be considered in a more detailed treatment.

(*b*) *The Wojciechowski–Laidler mechanism for the ethane pyrolysis "implicitly excludes methyl radical participation and methane production from the inhibited decomposition, although these appear in the uninhibited decomposition".* This is not the case; the uninhibited initiation process ($C_2H_6 \rightarrow 2CH_3$) is unaffected by nitric oxide addition.

(*c*) *The proposed termination steps are improbable.* The chemical evidence, however, nearly all relates to much lower temperatures than used in the pyrolysis experiments. This criticism may have validity, but still remains to be substantiated.

(*d*) *The proposals have the weakness that they attempt to produce a general mechanism for inhibited decompositions.* In fact, the Wojciechowski–Laidler mechanisms are significantly different for the various pyrolyses. The mechanisms resemble one another only in postulating the *same types* of initiation and termination steps.

Undoubtedly the Wojciechowski–Laidler mechanisms will have to be modified, but the discussion of the present paper strongly suggests that H-atom abstraction by NO must be included as an important step in inhibited decompositions. Work is at present being carried out in these laboratories to establish the nature of the subsequent processes.

A PERTURBATION CALCULATION OF THE EFFECT OF ELECTRIC INTERACTION ON PROTON MAGNETIC SHIELDING

T. YONEMOTO[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received February 19, 1965

ABSTRACT

The effect of electric interaction of molecular systems on proton magnetic shielding is calculated by a perturbation method, and a general expression of this effect is obtained. It is shown that the effect consists of three parts. Two of them are dependent on the time average of the field at the proton, and correspond to the linear and the square terms of Buckingham's equation of the (external) electric field effect. The third part is proportional to the van der Waals interaction energy between the hydrogen and the interacting object. The magnitude of the former two terms is calculated for a polarized hydrogen atom and a hydrogen molecule. The van der Waals deshielding caused by halogen atoms is also estimated.

I. INTRODUCTION

The theoretical treatment of the electric field effect on proton magnetic shielding was first taken up by Marshall and Pople (1). They obtained the perturbed wave function of a hydrogen atom in a uniform external electric field, and from this wave function they calculated the change of the magnetic shielding constant. Because of the spherical symmetry of the hydrogen atom, the effect of the electric field depends on the square of the field strength. In molecules, the electron distribution around a proton is not spherically symmetric, so that the shielding will also be expected to depend linearly on the field. Buckingham (2) showed, by application of the equation of Marshall and Pople, that such a linear term could arise if the hydrogen atom were in two constant fields, one external and one molecular. His formula proved to be successful in the explanation of the solvent effect in a polar solute (3). Buckingham's equation has been used also for the interpretation of the proton chemical shift in other cases (4, 5).

Bloembergen (6) pointed out that a linear variation of the nuclear quadrupole interaction with applied field can be obtained from the second-order perturbation energy which is bilinear in the nuclear quadrupole interaction and in the field. The same approach was made by Musher (7) to calculate the linear effect on the proton magnetic shielding. He used an approximate third-order perturbation formula and variation function method, and found that the linear change is of the same order of magnitude as that given by Buckingham. However, the square term was discarded in Musher's calculation, as he was interested in only the linear effect.

The van der Waals (dispersion) interaction, also an electric interaction, contributes an important part to the solvent shift (3, 8). The effect of this interaction has been calculated for a two-hydrogen atom system (9). Recently Schaefer *et al.* (10) proposed that shielding of this type could also operate on an intramolecular basis. In terms of this concept, an interpretation of the anomalous low shift in some halogen compounds and mesitylene derivatives was given (10, 11), although no exact information on the magnitude of this effect was available. Thus it was hoped to derive it by a quantum mechanical treatment of a molecular system in general.

In this paper, a general formulation of the effect of electric interaction is carried out with certain approximations in the fourth-order perturbation calculation. The electric

[1]*N.R.C. Postdoctorate Fellow, 1962–1964. On leave of absence from the Electrotechnical Laboratory, Nagatacho, Chiyoda-ku, Tokyo, Japan.*

interaction of the molecular system is included as another perturbation term in the problem of finding the magnetic shielding (12). In the expression of the shielding change that results from this interaction, the first-order term with respect to the electric perturbation is found to correspond to the linear term of Buckingham's equation, and the second-order term to correspond to the square term of Buckingham's equation and the so-called van der Waals effect. The magnitude of these terms is estimated for some cases.

II. PROCEDURE OF CALCULATION AND APPROXIMATIONS

Interaction Energy

Consider the interaction of a group of charged particles (electrons and (or) nuclei) with a hydrogen atom in a molecule. This group will be called group A. It may be either a part of the molecule which contains the proton in question (intramolecular case), or a molecule, or a part of a molecule to which the proton does not belong (intermolecular case). We assume that group A is close enough to the proton to perturb the wave function of the shielding electron, but not so close that there is appreciable overlap between the density distribution of the shielding electron and that of the group-A electrons. Thus the exchange repulsion is excluded. The interaction energy can then be approximated by the dipole–dipole interaction term, when we are interested in the effect of neutral molecules or group of atoms and there is no quadrupole moment in it. The generalization of the theory by the inclusion of these terms can be applied in a straightforward way.

The magnetic shielding in a molecule in liquid is given by averaging over the situations where the magnetic field is parallel and perpendicular to the proton – group A direction denoted by a vector $\boldsymbol{R}$. In the intramolecular case, the direction of the H—X bond axis (X is the atom to which the hydrogen is bonded) is fixed with respect to $\boldsymbol{R}$. We take the z'-axis of the external (laboratory) coordinates (x', y', z') along the direction of the magnetic field, and the molecular coordinates (x, y, z) on the proton with the z-axis along and opposite to the H—X bond direction. Two typical cases will be investigated, i.e. $\boldsymbol{R} \parallel z$ and $\boldsymbol{R} \perp z$. The interaction energy is

$$[1] \qquad \begin{aligned} U &= (e/R^3)(xX + yY - 2zZ) \equiv U_{\parallel} \qquad (\boldsymbol{R} \parallel z) \\ &= (e/R^3)(xX - 2yY + zZ) \equiv U_{\perp} \qquad (\boldsymbol{R} \perp z) \end{aligned}$$

where

$$[1a] \qquad X = \sum_i q_i x_i \text{ etc.},$$

and x_i is the x-component of the i-th charge (q_i) of the group A referred to its electric center. The summation in [1*a*] extends over all the charges in the group. The interaction U is of the form of the van der Waals interaction Hamiltonian, but in case there is a permanent dipole moment in A, the interaction includes dipolar field interaction as well as the so-called van der Waals interaction. In this case, the expectation values $\langle X \rangle$, etc. are non-zero and are related to the steady dipolar field F of the group A at the proton, as

$$[2] \qquad F_x = (1/R^3)\langle X \rangle \text{ etc.}$$

Hamiltonian

The perturbation Hamiltonian is

$$[3] \qquad \mathscr{H}' = U + \mathscr{H}_{\mathrm{H}},$$

$$\begin{aligned} \mathscr{H}_{\mathrm{H}} &= -\frac{ie\hbar}{2mc}\left(H + \frac{2\mu}{r^3}\right)\frac{\partial}{\partial \phi} + \frac{e^2}{8mc^2}\left(H + \frac{2\mu}{r^3}\right)^2 (x'^2 + y'^2) \\ &= AH + B\mu + CH\mu + D(H^2, \mu^2) \end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where H is the external magnetic field, μ is the nuclear magnetic moment of the proton, and ϕ is the azimuthal coordinate around the z'-axis. $\mathscr{H}_{\mathrm{H}}$ is the interaction of the magnetic field with the shielding electron, which can be written as a sum of linear and bilinear terms in H and μ. Other notations have the usual meanings. It should be mentioned here that the magnitude of the electric perturbation is of the order of one-tenth of the total electronic energy under conditions where the concept of the electric field effect is ordinarily applied. $\mathscr{H}_{\mathrm{H}}$ is many orders smaller than U, so that the first-order field effect on the magnetic shielding is obtained from the second- and the third-order perturbation energy, and the second-order field effect from the third- and the fourth-order perturbation calculation.

Perturbation Energy

The perturbation energy in the fourth-order approximation can be obtained by the ordinary procedure (13). As in most perturbation calculations, use is made of the mean excitation energy approximation. This approximation may be good when the discrete energy levels lie within a narrow range (14). The weight of the states in the continuum of energy levels is expected to be small. At any rate, the results should be valid as to the order of magnitude.

The explicit form of $\mathscr{H}'$ given in eqs. [3], [1], and [2] is brought into the energy expression, which is then expanded in terms of H and μ, and as in Ramsey's theory, terms proportional to $H\mu$ are picked out. The introduction of U in $\mathscr{H}'$ gives rise to more terms of different types other than those that appear in Ramsey's theory. However, from the fact that U is of the order of one-tenth of the excitation energy ΔE, it is easily shown that only terms proportional to $H\mu U/\Delta E$ and $H\mu U^2/\Delta E^2$ are significant. All the other terms are negligible or are independent of the nuclear transition energy. The sum of these $H\mu$-terms thus represents the interaction energy of the nuclear spin – electron system with the external magnetic field, i.e. the term additional to the nuclear Zeeman energy. The magnetic shielding of the proton is the coefficient of $H\mu$ in this additional energy, averaged over random orientation of the molecule.

Result

The calculation of the matrix elements that appear in the above-mentioned energy formula is made possible by the assumption of no overlap between the wave function of the hydrogen part and that of the group A. The operators X, X^2, etc. are thus replaced by their expectation values for the unperturbed state of the group A. Using [2] and

$$[4] \qquad \langle X^2\rangle = \langle \sum_i q_i x_i\rangle^2 + [\langle \sum_i q_i^2 x_i^2\rangle - \sum_i \langle q_i x_i\rangle^2]$$

$$\equiv R^6 F_x^2 + a_0^2 e^2 Q_x \text{ etc.}$$

which holds when the Hartree approximation is made for the wave function of the group A, we obtain

$$[5] \qquad \Delta\sigma = (e^2/3mc^2a_0)(A_1 + A_2 + B_1 + B_2 + C_1 + C_2),$$

where

$$A_1 = (a_0 e/\Delta E)a_1 F_z,$$

$$A_2 = (a_0^2 e^2/\Delta E^2)a_2 F_z,$$

$$B_1 = (a_0 e^2/\Delta E^2)[b_{11}(F_x^2 + F_y^2) + (b_{12} + b_{13})F_z^2],$$

$$B_2 = (a_0^2 e^4/\Delta E^2)[(b_{21} + b_{23})(F_x^2 + F_y^2) + (b_{22} + b_{24})F_z^2],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for both $\boldsymbol{R} \parallel z$ and $\boldsymbol{R} \perp z$, and

$$\left.\begin{aligned} C_1 &= (a_0^3e^4/R^6\Delta E^2)(b_{11}Q_x + b_{11}Q_y + 4b_{12}Q_z) \\ C_2 &= (a_0^4e^6/R^6\Delta E^3)(b_{21}Q_x + b_{21}Q_y + 4b_{22}Q_z) \end{aligned}\right\} \quad (\boldsymbol{R} \parallel z),$$

$$\left.\begin{aligned} C_1 &= (a_0^3e^4/R^6\Delta E^2)(b_{11}Q_x + 4b_{11}Q_y + b_{12}Q_z) \\ C_2 &= (a_0^4e^6/R^6\Delta E^3)(b_{21}Q_x + 4b_{21}Q_y + b_{22}Q_z) \end{aligned}\right\} \quad (\boldsymbol{R} \perp z).$$

The expressions for a_1, a_2, b_{11}, etc. are given in the Appendix. In the derivation of the above results, it was assumed that the wave function for the hydrogen part is axially symmetric about the z-axis. We shall later choose the form of the wave function for actual calculation of the matrix elements. However, this assumption was made beforehand, because it simplifies the result to a great extent.

In the above expressions, $A_1 + A_2$ and $B_1 + B_2$ are dependent respectively on the time average of the field and the square of its components at the proton. Thus we obtained incidentally the expression for intramolecular and (or) external field effect, by solving a van der Waals type perturbation problem. When the interacting group has no net dipole moment, terms A_1 to B_2 all vanish and the shielding change is of pure van der Waals effect, represented by $C_1 + C_2$.

III. TWO-HYDROGEN ATOM SYSTEM

The system of two slightly interacting hydrogen atoms, which is the simplest example of a perturbed hydrogen, has already been dealt with by a variational method (9). This problem is studied in this section, because the result of the present treatment can be compared with the former, and also because it affords an insight into more complex systems.

As the ground state wave function of a hydrogen atom is spherically symmetric, the effect is of the van der Waals type:

$$\Delta\sigma = \Delta\sigma_{HH} = -\frac{e^2}{3mc^2a_0}\left(9\frac{a_0^4e^4}{\Delta E^2} + 4\frac{a_0^3e^6}{\Delta E^3}\right)R^{-6}. \qquad [6]$$

For example, a hydrogen atom at 4 Bohr radius from another one is desheilded by 0.3 p.p.m. if the ionization energy of a hydrogen atom (2.2×10^{-11} erg) is adopted as ΔE. This result is three times larger than that found by the variational method (10^{-7} for $R = 4$ Bohr radius (9)). When the interatomic distance is 3 Å, $\Delta\sigma_{HH}$ is -0.025 p.p.m. Since only electric interaction is considered, no R^{-3} term appears in this treatment.

The van der Waals interaction energy between two hydrogen atoms, calculated by the second-order perturbation energy is (15)

$$\epsilon_{HH} = -6a_0^4e^4/R^6\Delta E.$$

Thus the shielding change in the two-hydrogen atom system is written as

$$\Delta\sigma_{HH} = \frac{e^2}{3mc^2a_0}\frac{\epsilon_{HH}}{\Delta E}\left(\frac{3}{2} + \frac{2}{3}\frac{e^2}{a_0\Delta E}\right). \qquad [7]$$

IV. VAN DER WAALS DESHIELDING BY A HALOGEN ATOM

The result of the calculations in the preceding section, that the field effect caused by the van der Waals interaction between two hydrogen atoms is proportional to the interaction energy, suggests that there will be a larger deshielding when a hydrogen interacts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with heavier atoms with which the van der Waals interaction is larger. This has been pointed out by Marshall and Pople (9) and by Musher (16). In proton resonance of organic molecules, there are many cases where a halogen atom is near a proton. These are the examples (intramolecular case) of the situation mentioned above.

A precise calculation of this effect is difficult because no accurate molecular wave function is available that describes the state of ionization, hybridization, or state of inner and lone pair electrons, etc. of a halogen in a bond. Thus we are obliged to estimate it from a calculation of the effect of a slightly interacting halogen atom on the shielding of a proton.

TABLE I

$\langle \sum_i x_i^2 \rangle / a_0^2$ values of halogen atoms and ions

Atoms or ions	F	F^-	Cl^-	Br	Br^-
$\langle \sum_i x_i^2 \rangle / a_0^2$	3.1	3.6	12.5	14	18

The spherical symmetry of these two atoms is the same as in the case of the two-hydrogen atom system, so that the result of the calculations in the preceding section can be applied to the present problem if Q for a hydrogen atom ($=1$) is replaced by that of the halogen value. The magnitude of Q ($=\langle \sum_i x_i^2 \rangle / a_0^2$ in this case) is calculated for some halogen atoms and ions by the use of the Hartree–Fock wave functions (17–20). The results are shown in Table I. These values are multiplied into [6] to obtain the deshielding by the van der Waals interaction of the halogens. The effect of a fluorine atom at 3 Å from a proton is not significant, but a chlorine atom at the same distance may deshield the proton by about 0.3 p.p.m.

V. POLARIZED HYDROGEN ATOM

The wave function for a hydrogen in a bond may in some cases be approximated by a function made up of the ground and the excited states. This approximation is not good at distances far from the proton, but in the region near the proton, where the main contribution to the shielding arises, the electron distribution will be expanded in terms of excited states wave functions. Thus

$$\psi_0 = C_0(1s) + C_1(2s) + C_2(2p) + \ldots .$$

The simplest form of this approximation is

[8] $$\psi_0 = (1 + C^2)^{-1/2}[(1s) + C(2p_{-z})]$$

where C is a small combination constant. By the directional character of the bond, the 2p-function is the hydrogen $2p_z$-orbital in the $-z$-direction, which is denoted as $2p_{-z}$. For simplicity, the 2s-function was omitted. This does not change the essential feature of the results.

The wave function [8] is actually that of a polarized hydrogen atom. Although this is a very crude model for a hydrogen in a molecule, it is worthwhile to examine the nature of the electric field effect on this model, because as long as we use a one-center wave function approximation, in which the calculation of the matrix elements is simple, the essential characteristics of any wave function of this type are contained in this form.

The result is

[9] $$\Delta\sigma = -6.3C \times 10^{-12}F_z - 0.68(1 + 5.9C^2) \times 10^{-18}F^2 - 1.25C^2 \times 10^{-18}F_z^2 + \Delta\sigma_W,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for $\Delta E = 2.2 \times 10^{-11}$ erg. It is shown that the linear dependence of the field effect is a result of the polarization of the shielding electron, or of the interaction of the field with the atomic dipole at the proton. The first and the second term of eq. [9] correspond to the two terms of Buckingham's equation, and the third term can be regarded as the correction to the first. The fourth term is the van der Waals contribution. When the interacting object has spherical symmetry, it can be written in a simple form. Using the mean excitation energy as mentioned above, but writing it as $e^2/2a_0$ rather than its magnitude, we get

$$\Delta\sigma_W = -(1\,204)(1 + 11.6C^2)Q(a_0/R)^6 \times 10^{-6} \quad [10]$$

for $\boldsymbol{R} \parallel z$. The coefficient to C^2 in [10] becomes 5.6 for $\boldsymbol{R} \perp z$ and 7.6 for the intermolecular case, if the mutual orientation of the two molecules is completely random. As in the two-hydrogen atom system, $\Delta\sigma_W$ is proportional to the corresponding interaction energy. For both $\boldsymbol{R} \parallel z$ and $\boldsymbol{R} \perp z$,

$$\Delta\sigma_W = 50(1 - 1.4C^2)(\epsilon/\Delta E) \times 10^{-6}. \quad [11]$$

It should be mentioned that, although eq. [9] was derived on the basis of the dipolar interaction between a hydrogen and a charge group, it holds also for a steady external field (in this case, of course, the van der Waals term does not appear). One can derive from [9] the equation of the external electric field effect on a hydrogen atom. However, this gives the average value over random direction of F, because eq. [5] is already in the averaged form. When F is an external field, the direction of it is fixed with respect to the magnetic field. The shielding in this case can be obtained from equations similar to [5] but for specific mutual direction of F and H, the average of which leads to [5]. The result is

$$\Delta\sigma = -(e^2/3mc^2a_0)[8.4(a_0^4/e^2)F^2] \qquad (F \parallel H), \quad [12]$$

$$= -(e^2/3mc^2a_0)[12.8(a_0^4/e^2)F^2] \qquad (F \perp H).$$

These equations are very close to the results of Marshall and Pople (1), in which the numerical coefficients in the square bracket are 439/40 and 193/15 for $F \parallel H$ and $F \perp H$, respectively.

VI. HYDROGEN MOLECULE

It is desirable to calculate the field effect with better wave functions than the polarized hydrogen atom model. A LCAO-molecular orbital is nearer reality. The use of this wave function, however, requires carrying out bi-central integrations, which is not always easy. It was found that the calculation for a hydrogen molecule is workable: the integrations were performed on the surface of an ellipsoid with the two nuclei as foci.

A simple form of the localized LCAO-MO

$$\psi_0 = (2 + 2S)^{-1/2}(\psi_1 + \psi_2) \quad [13]$$

was used, taking into account the approximate nature of the present treatment. ψ_1 and ψ_2 are the Slater type hydrogen atomic 1s orbitals (21) for the two nuclei, and S is the overlap integral between ψ_1 and ψ_2. Internuclear distance is 0.74 Å (22). As the procedure of the integration is tedious, only the result is given here. For $\Delta E = 2.2 \times 10^{-11}$ erg,

$$\Delta\sigma = -4.5 \times 10^{-12}F_z - 1.16 \times 10^{-18}F^2 + 1.02 \times 10^{-18}F_z^2 + \Delta\sigma_W \quad [14]$$

and when the charge distribution in the group A is isotropic,

$$\Delta\sigma_W = -(2\,369)Q(a_0/R)^6 \times 10^{-6}. \quad [15]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The van der Waals interaction energy can be calculated with the LCAO-MO given above. An equation of the form of [11] with a factor 37.5 in place of $50(1 - 1.4C^2)$ is valid in this case.

VII. SUMMARY OF THE RESULTS AND DISCUSSION

The results of the above calculation are summarized as follows:

(*a*) By the use of the fourth-order perturbation theory and mean excitation energy approximation, the general formula for the electric field effect on the proton magnetic shielding is obtained. This is

$$\Delta\sigma = \Delta\sigma(1) + \Delta\sigma(2) + \Delta\sigma_W \qquad \text{(eq. [5])}.$$

In this equation, $\Delta\sigma(1)$ is the part proportional to the steady field strength at the proton, $\Delta\sigma(2)$ is dependent on the square of the steady field and its z-component, and $\Delta\sigma_W$ is the van der Waals contribution.

(*b*) The field effect on a proton in a molecule, estimated with the polarized hydrogen atom model and a localized LCAO-MO for a hydrogen molecule, is given by eqs. [9] and [14], respectively. Although the magnitude of C is not certain, the linear term of [9] nearly coincides with that of Buckingham's equation when $C = 0.3$. The result for a hydrogen molecule is somewhat larger.

(*c*) Calculation of the van der Waals contribution $\Delta\sigma_W$ is in general difficult. However, it is possible to calculate it for a simple case of a two-hydrogen atom system (eq. [6]). It is also possible to estimate the effect of a heavy atom. This is $\Delta\sigma_{HH}$ (given by eq. [6] for the hydrogen – heavy atom distance R) times a factor such as given in Table I. In general, if the value of Q is obtained, $\Delta\sigma_W$ can be calculated by eq. [10] or [15]. The van der Waals contribution is shown to be proportional to the interaction energy. A heavy halogen near a halogen gives rise to a considerable amount of the van der Waals low shift.

There have been some experimental studies to determine the magnitude of the linear and the square terms of the field effect. The experimental values of the former for some molecules as obtained by different methods are in the range of $1.3\text{–}3.4 \times 10^{-12}\ F_z$ (23–25), and the square terms have been found to be $0.8\text{–}1.0\ (\pm 0.3) \times 10^{-18}\ F^2$, except for hydrogen chloride (26). In view of the approximations made, the agreement of the present results with the experimental findings is satisfactory both for the polarized hydrogen atom model with $C \simeq 0.3$ and for the LCAO-MO calculation for H_2. It should be noted also that $\Delta\sigma$ contains functions of the derivatives of the wave function, which may change greatly with the choice of the latter. Thus we encounter the same difficulty as that found in calculating the paramagnetic part of the magnetic shielding, if we attempt to obtain an exact value of the field effect. The exceptionally large effect found in HCl is either caused by the strong ionic character of the bond, namely, a very large atomic dipole at the hydrogen, or attributable to an interaction other than the dipole–dipole term that contributes much to the shielding change in this case.

The intermolecular field effect is the statistical average of $\Delta\sigma$ over the mutual orientations of the molecule. If it is completely random, one obtains the isotropic average, and the linear term vanishes in this case. The system of two hydrogen atoms, or solutions in which symmetric solute molecules are dispersed among symmetric solvent molecules, represents this case. In general, however, there exists the reaction field on which experiments to determine the linear field effect are based. In complex molecules, there will be specific interactions between different parts of the two (or more) molecules, which will result in non-isotropic orientation and different reaction fields on different parts of a molecule (27).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The constant C in the polarized hydrogen atom model has so far been assumed to be positive. This means that the electron cloud is shifted towards the atom to which the hydrogen is bonded, and this is a reasonable postulate. In the present treatment of the polarized hydrogen atom, C can be taken as the parameter which determines the atomic dipole moment $\mathbf{p}$ of the hydrogen. It is clear from the procedure of the present calculation that the linear term originates in the interaction of the form $-\mathbf{p}\cdot\mathbf{F}$, so that the direction of $\mathbf{p}$ with respect to the electric field determines the sign of the linear term. If $\mathbf{p}$ is in the direction H to X, the linear term reverses the sense. This is not found in proton resonance, but in fluorine resonance it has been found in the CHF_3 molecule, from a study of the medium effect (26).

A theoretical calculation of the electronic state in a HF molecule (28, 29) reveals that the atomic dipole on the fluorine is in the direction from the fluorine nucleus away from the bond, although the net dipole moment of the HF molecule is in the opposite direction. Presumably this holds also for a C—F bond, so that the direction of $\mathbf{p}$ on the fluorine atom with respect to the bond is the same as in the case of hydrogen in a C—H bond. On the other hand, the mean field remaining along the C—F bond is from F to C, because the bond moment of the C—F bond is C^+—F^- (26). The energy $-\mathbf{p}\cdot\mathbf{F}$ thus becomes opposite in sign, leading to the apparent positive effect (shielding rather than deshielding), when it is obtained from the medium effect. However, the coefficient of the linear term of the field effect equation for fluorine should have the same sign as in the proton. This may be verified by a study of an intramolecular field effect on the fluorine chemical shift.

ACKNOWLEDGMENTS

The author expresses his thanks to Professor T. Schaefer of the University of Manitoba for his interest in and valuable discussion on this work. He also thanks Dr. M. Shibuya of the Electrotechnical Laboratory (Tokyo) and the referees for their comments, and the National Research Council of Canada for a fellowship.

APPENDIX

$$a_1 = -8\langle r^{-1}\rangle\langle r\cos\theta\rangle + 4\langle\cos\theta\rangle$$

$$a_2 = -4\langle r^{-2}\cos\theta\rangle + 6\left\langle r^{-2}\cos\theta\frac{\partial^2}{\partial\theta^2}\right\rangle - 12\langle r\cos\theta\rangle\left\langle r^{-3}\frac{\partial^2}{\partial\theta^2}\right\rangle$$

$$b_{11} = -6\langle r^{-1}\rangle\langle r^2\sin^2\theta\rangle + 3\langle r\sin^2\theta\rangle$$

$$b_{12} = -12\langle r^{-1}\rangle\langle r^2\cos^2\theta\rangle + 6\langle r\cos^2\theta\rangle$$

$$b_{13} = \langle r\cos\theta\rangle[48\langle r^{-1}\rangle\langle r\cos\theta\rangle - 24\langle\cos\theta\rangle]$$

$$b_{21} = -5\langle r^{-1}\sin^2\theta\rangle + 6\langle r^{-1}\cos^2\theta\rangle + 6\left\langle r^{-1}\sin^2\theta\frac{\partial^2}{\partial\theta^2}\right\rangle - 8\langle r^2\sin^2\theta\rangle\left\langle r^{-3}\frac{\partial^2}{\partial\theta^2}\right\rangle$$

$$b_{22} = 6\langle r^{-1}\sin^2\theta\rangle - 16\langle r^{-1}\cos^2\theta\rangle + 12\left\langle r^{-1}\cos^2\theta\frac{\partial^2}{\partial\theta^2}\right\rangle - 16\langle r^2\cos^2\theta\rangle\left\langle r^{-3}\frac{\partial^2}{\partial\theta^2}\right\rangle$$

$$b_{23} = -32\langle r\cos\theta\rangle\langle r^{-2}\cos\theta\rangle$$

$$b_{24} = \langle r\cos\theta\rangle\left[32\langle r^{-2}\cos\theta\rangle - 48\left\langle r^{-2}\cos\theta\frac{\partial^2}{\partial\theta^2}\right\rangle + 80\langle r\cos\theta\rangle\left\langle r^{-3}\frac{\partial^2}{\partial\theta^2}\right\rangle\right]$$

In these equations, $\langle K\rangle$ represents $\pi\int\phi_0{}^*K\phi_0 r^2\sin\theta\,dr\,d\theta$ where ϕ_0 is the r–θ part of ψ_0. r, θ, and φ are the molecular polar coordinates on the proton.

KINETIC STUDIES OF CHLORO COMPLEXES OF RHODIUM AS HYDROGENATION CATALYSTS

B. R. JAMES AND G. L. REMPEL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received August 23, 1965

ABSTRACT

The anionic complexes $[RhCl_6]^{3-}$, $[Rh(H_2O)Cl_5]^{2-}$, and $[Rh(H_2O)_2Cl_4]^-$ activate molecular hydrogen for the reduction of ferric ion in aqueous acid solution; the catalytic activity increased with increasing number of chloride ligands present. Cationic and neutral chloroaquorhodium(III) complexes did not homogeneously catalyze the reduction of ferric ion, the complexes themselves being reduced to metallic rhodium, a powerful heterogeneous catalyst.

Chloro complexes of rhodium(III) and rhodium(I) were not effective catalysts in aqueous solution for the homogeneous hydrogenation of the olefinic bond in maleic acid. Anionic chlororhodate(III) complexes were reduced by hydrogen to the univalent state, this state being stabilized against further reduction to the metal by complexing with the maleic acid present. Preliminary studies indicate that in dimethylacetamide solution rhodium(III) trichloride is an effective homogeneous catalyst for the reduction of maleic acid to succinic acid by hydrogen, the reaction proceeding through a rhodium(I) – maleic acid complex.

INTRODUCTION

Previous workers (1) in this laboratory had found that rhodium(III) trichloride in aqueous 3 *M* HCl solution homogeneously activated molecular hydrogen for the reduction of a substrate such as ferric ion. It seemed likely that the species predominantly present was $[RhCl_6]^{3-}$, although there was no direct experimental evidence for this. More recently data have been published giving the absorption spectra and stability constants of the Rh(III)–chloride complexes (2). In the present investigations the kinetics of the $Rh(III)/H_2/Fe(III)$ system were studied in aqueous solution over a wide range of chloride concentration in an attempt to find correlation between catalytic activity and the nature of the Rh(III) chloride species present. This paper describes these studies.

The use of chloro complexes of rhodium as possible catalysts for the homogeneous hydrogenation of olefinic bonds is also considered in this paper. Most metal ions and complexes which activate molecular hydrogen homogeneously in solution and catalyze the reduction of inorganic substrates (3) are not effective catalysts for the hydrogenation of olefin bonds. Acid aqueous solutions containing chlororuthenate(II) complexes, however, did successfully hydrogenate, under homogeneous conditions, several olefinic compounds including maleic acid (4), and it seemed worthwhile to study the reactions of chloro complexes of rhodium under similar conditions. We have also started some studies on the $Rh(III)/H_2$/maleic acid system in dimethylacetamide solution. Recent publications have reported that certain rhodium(III) complexes can activate molecular hydrogen to give hydrogenation of olefinic bonds under homogeneous but nonaqueous conditions (5, 6). Hex-1-ene can be converted into *n*-hexane by ethanol—benzene solutions of tertiary phosphine and arsine complexes such as 1,2,3-tris-(triphenylphosphine)trichlororhodium (III) and by ethanolic solutions of rhodium(III) trichloride or 1,2,6-trichlorotripyridine rhodium(III). These reports are short communications and little detail is given. However, the reactions are probably complex, e.g. hex-1-ene is catalytically isomerized by ethanolic rhodium trichloride (7). It is also known that reaction with ethanol of the triphenylphosphine- and arsine-type complexes of the platinum transition metal ions can give

For personal use only.

hydrido- and hydridocarbonyl-type complexes with the metal in a reduced valency state (8, 9) and so the hydrogenation systems described are likely to be complex kinetically. A very recent communication describes a more well-defined system in which a hydride intermediate has been detected during the catalyzed hydrogenation of olefins and acetylenes by the complex $(Ph_3P)_3Rh^{I}Cl$ in benzene solutions (10). In view of the recent activity in the field of catalysis by rhodium complexes we have included in this paper results of some preliminary studies carried out in dimethylacetamide solutions.

EXPERIMENTAL

The H_2 was obtained from Canadian Liquid Air Co. and was passed through a deoxo catalytic purifier to remove O_2 before use. $Fe(ClO_4)_3$ and $TiCl_3$ were reagent grade products obtained from Alpha Inorganics Inc. The titanium salt was dissolved in 3 *M* HCl to give a solution about 2 *M* in Ti(III); this was stored in a burette in the absence of air. Maleic acid was obtained as C.P. grade from Eastman Kodak and was recrystallized before use. A stock 9.0 *M* $HClO_4$ solution was obtained by dilution of reagent grade 60% $HClO_4$ solution obtained from Nichols Chemical Company. B.D.H. concentrated HCl was diluted to give stock HCl solutions which were standardized against alkali solutions prepared from B.D.H. standard NaOH ampuls.

Rhodium(III) trichloride was obtained as the trihydrate $RhCl_3.3H_2O$ from Platinum Chemicals; $Na_3RhCl_6.12H_2O$ was a product of K and K Laboratories. These solids were dissolved in HCl to give stock rhodium solutions. The method of Pantani (11) was used to estimate the concentration of Rh in these solutions, the Rh(III) being oxidized by hypochlorite at pH 11.2 to a violet color, probably Rh(VI), with a characteristic absorption at 530 mμ (ϵ = 1 270); the results indicated concentrations within 10% of those expected for solutions made by the weighing out of the salts as pure compounds. Because of the strict conditions of concentrations, pH, and time required for the full development of the violet color it seemed that the rhodium compounds were essentially pure and could be weighed out as such to give standard Rh(III) solutions. A 0.2 *M* solution of $Na_3RhCl_6.12H_2O$ in 6 *M* HCl exhibited absorption spectrum maxima at 411 mμ (ϵ = 85) and 518 mμ (ϵ = 100) corresponding closely to the reported spectrum of the $[RhCl_6]^{3-}$ species (2). The spectrum of a freshly prepared solution of $RhCl_3.3H_2O$ in 3 *M* HCl exhibited a single absorption peak at 505 mμ (ϵ = 80); it has been suggested (12, 13) that this solution contains polynuclear species and complexes with both chloride ions and water molecules coordinated, both cationic and anionic Rh(III) species being present. The absorption spectrum very slowly changes when the solution is left at room temperature for several weeks, a second peak developing in the region of 400 mμ. This spectrum change can be accomplished rapidly by heating the initial solution. The final constant spectrum showed maxima at 404 mμ (ϵ = 67) and 511 mμ (ϵ = 74) and comparison with the data of Wolsey and co-workers (2) suggests that the major species present is $[Rh(H_2O)Cl_5]^{2-}$ with small amounts of the 6:1 chloro complex. A solution of the $[Rh(H_2O)_6]^{3+}$ species was made by digestion of $RhCl_3.3H_2O$ in strong $HClO_4$, the chloride being distilled off as HCl. The spectrum of the final solution corresponded to that of the fully aquated species (2) and showed maxima at 310 mμ (ϵ = 57) and 396 mμ (ϵ = 53); this solution was diluted to give a standard solution 6.0 *M* in $HClO_4$ and was used to prepare other solutions containing Rh(III) chloro complexes by the method described by Wolsey (2). In these solutions the chloride concentration was varied from 0.01 *M* to 3.25 *M* by the addition of HCl solution, the total acid strength and ionic strength always being 6.0 *M*: the solutions were made up in pyrex tubes which were subsequently sealed and maintained at 120° for 2 weeks. This period of time was necessary for the attainment of equilibrium among the complex species.

Kinetic measurements were made by following the uptake of H_2 at constant pressure by the procedure described earlier by Halpern and co-workers (14, 15). Gas uptake is indicated by a difference in levels of a liquid of negligible vapor pressure (e.g. butyl phthalate) in a capillary manometer thermostated with a gas burette at 25°. H_2 is then added to the system through a needle valve, a constant pressure being maintained by the resulting rise of mercury in a calibrated tube of the burette. The height of the mercury column is followed with a travelling microscope.

Visible and ultraviolet absorption spectra were measured on a Cary 14 recording spectrophotometer with matched Beckman standard silica cells of 1 cm optical path length.

RESULTS

Hydrogen Solubility from Kinetic Measurements

The kinetics of the reduction by H_2 of ferric ion in the presence of rhodium(III) chloride were of the form

$$-d[H_2]/dt = k[H_2][Rh^{III}] = k'[Rh^{III}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

where $k' = k[H_2]$, as previously found by other workers (1). Since the concentrations of Rh^{III} and H_2 remain constant while the ferric species is being reduced, the kinetics are pseudo zero order. When all the Fe^{III} had been reduced to Fe^{II} reduction of Rh^{III} to metallic rhodium occurred, and was marked by an increase in the rate of H_2 uptake caused by autocatalysis by the metal. Figure 1 shows typical H_2 uptake plots at 80° for some of the experiments summarized in Table I; this shows results for the $RhCl_3/H_2/FeCl_3$ systems over a range of chloride concentration from 0.43 *M* to 5.57 *M* at a constant acidity. The chloride concentration was varied by the addition of HCl, the total acid strength and ionic strength in the series always being 5.57 *M*; the Rh^{III} and initial Fe^{III} concentrations were the same throughout. Values of k' were calculated from the slopes of the zero order H_2 uptake plots.

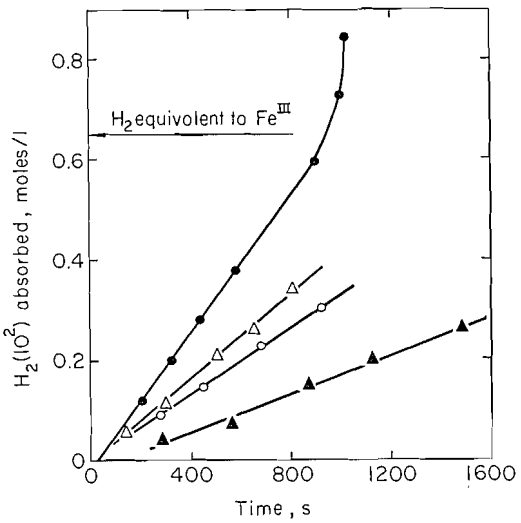

FIG. 1. Typical rate plots at 80°, 450 mm H_2, 0.011 *M* $RhCl_3$, 0.013 *M* $FeCl_3$; various media with $[HCl] + [HClO_4] = 5.57$ *M*: (●) 0.43 *M* HCl; (△) 3.00 *M* HCl; (○) 3.86 *M* HCl; (▲) 5.57 *M* HCl.

The spectra of the Rh^{III} solutions used in the two extreme concentrations (0.43 *M* and 5.57 *M* chloride) were measured near the end of the hydrogenation experiments and were found to be very similar, exhibiting peaks in the regions of 405 mμ ($\epsilon \sim 70$) and 510 mμ ($\epsilon \sim 80$), indicating that the chlororhodate(III) species present in the two solutions are essentially the same; comparison with the published data (2) shows that both solutions contain predominantly the $[Rh(H_2O)Cl_5]^{2-}$ species with smaller amounts (~20%) of the 6:1 chloro species. The available formation constant data (2) at 120° for the Rh(III)-chloride complexes indicate that the 5:1 chloro species would predominate in the 0.43 *M* $[Cl^-]$ conditions and the 6:1 species in the 5.57 *M* $[Cl^-]$ conditions. The hydrogenation experiments were carried out at 80° over a period of about 30 min; the slow equilibration of the species during this time must account for the perseverance of the 5:1 species at the higher $[Cl^-]$,

The relatively large variation in rate of H_2 uptake for this series of experiments is not then due to the presence of different chloro species but must be principally due to variation in the H_2 solubility in the different media. The concentration of H_2 in 5.57 *M* HCl was estimated as 5.3×10^{-4} mole atm^{-1} from the solubility data of Weibe and Gaddy (16), correcting for the effect of HCl (17); this gives a rate constant k of 0.60 l

0.43	5.14	7.11	6.46	0.60	10.8

$mole^{-1}$ s^{-1} in this medium. The solubility of hydrogen in the varying media can then be calculated approximately, assuming a rate constant of 0.60 l $mole^{-1}$ s^{-1} throughout the series. These data are included in Table I. The variation of H_2 solubility with media is shown in Fig. 2. The solubility of noble gases such as Kr increases by a factor of about two on going from pure H_2O to 6 M $HClO_4$ (18) and this together with the known decrease in H_2 solubility with increasing HCl strength (17) suggests that the magnitude of the solubility variation shown in Fig. 2 is reasonable.

Catalytic Reduction of Ferric Ion by the Complexes $[Rh(H_2O)_{6-n}Cl_n]^{(n-3)-}$

Kinetic results at 80° for two experiments with solutions of Na_3RhCl_6 at high and low chloride concentration and for the series of experiments with the prepared $Rh(H_2O)_6^{3+}/HCl/HClO_4$ solutions are summarized in Table II. Absorption spectra were measured before and, when possible (with the anionic complexes), after the hydrogenation experiment; the spectra of the Rh^{III} species were unaffected by the catalytic reduction. The principal species present were again determined by comparison with the spectroscopic data of Wolsey and co-workers (2). In the 0.64 M HCl, 5.14 M $HClO_4$ medium, Na_3RhCl_6 dissociated principally into the 5:1 chloro species. The hydrogen solubilities were estimated from the data shown in Fig. 2.

TABLE II

Kinetic data at 80° for Rh(III)/H_2/Fe(III) systems. $[Fe^{III}] = 0.013\ M$; $H_2 = 450$ mm. The number given for the species present represents the number of coordinated chloride ions*

The two experiments with the hexachloro salt indicate that the 6:1 chloro species is more active catalytically than the 5:1 species, the estimated rate constants being compatible with the data of Table I. The experiments with the complexes prepared from the $[Rh(H_2O)_6^{3+}]$ solution confirm this and demonstrate that the activities of the anionic complexes decrease in the order

$$[RhCl_6]^{3-} > [Rh(H_2O)Cl_5]^{2-} > [Rh(H_2O)_2Cl_4]^{-}$$

The rate constants determined in this series of experiments are about 25% lower than might be expected in comparison with those obtained with the $RhCl_3/HCl$ and Na_3RhCl_6/HCl systems. However, in consideration of the somewhat uncertain H_2 solubility corrections and the slight variations in ionic strength from one series of experiments to another, this is not too unreasonable. There is no doubt in the order of activity of the complexes.

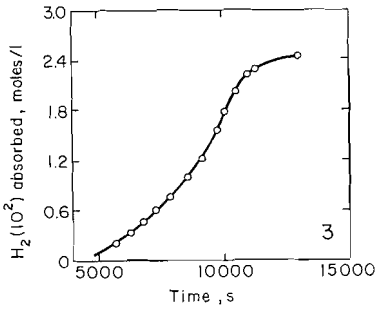

FIG. 2. Solubility of H_2 in $HCl/HClO_4$ media.
FIG. 3. Rate plot for cationic species $Rh(H_2O)_5Cl^{2+}$ at 80°, 450 mm H_2, 0.0087 *M* Rh^{III}, 0.025 *M* Fe^{III}, 6.0 *M* $HClO_4$, 0.01 *M* HCl.

Homogeneous hydrogenation of Fe^{III} was not observed when the $[Rh(H_2O)_6]^{3+}$, $[Rh(H_2O)_5Cl]^{2+}$, $[Rh(H_2O)_4Cl_2]^{+}$, and $Rh(H_2O)_3Cl_3$ complexes were initially present in solution. Figure 3 shows the H_2 uptake plot for a $[Rh(H_2O)_5Cl]^{2+}$ system. There was no gas uptake or change in species present (confirmed spectrophotometrically) for about 5 000 s; a slow autocatalytic uptake of H_2 was then observed, metallic rhodium being precipitated from solution. The uptake at the end point corresponded exactly to complete reduction of Fe^{III} to Fe^{II} and Rh^{III} to Rh^0. The other cationic and neutral Rh(III)–chloride complexes gave similar rate plots.

In the absence of Fe^{III} substrate, acid solutions containing $[Rh(H_2O)_{6-n}Cl_n]^{(n-3)-}$ species where $n = 0$ to 6 were all rapidly reduced by H_2 in an autocatalytic manner to the metal at temperatures above 40°, the final H_2 uptake corresponding to reduction of Rh^{III} to Rh^0.

Rh^{III}/H_2/Maleic Acid Systems

Excess maleic acid in 3 *M* HCl solution was added to the solution of $RhCl_3$ in 3 *M* HCl which contained principally the 5:1 chloro species and hydrogenation was attempted in the usual way at 80°. H_2 was taken up as shown in Fig. 4. The rate of uptake falls off with time and becomes very slow after about 16 000 s. At this stage the uptake corresponded to reduction of Rh(III) to Rh(I).

$$Rh^{III} + H_2 \xrightarrow{k} Rh^{I} + 2H^{+}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Spectrophotometric measurements showed that the Rh(III) chloro complexes did not complex with maleic acid. The Rh^{I} state must be stabilized by complexing with the maleic acid in a rapid step which prevents further reduction to the metal.

$$Rh^{I} + \text{maleic acid} \xrightarrow{\text{fast}} \text{complex.}$$

A rate law of the form

$$-d[H_2]/dt = -d[Rh^{III}]/dt = k[Rh^{III}][H_2]$$

indicates that at constant $[H_2]$ the reaction becomes one of pseudo first order. A good linear plot of $\log [Rh^{III}]$ versus time was obtained from the rate data, assuming the decrease in $[Rh^{III}]$ is proportional to the H_2 uptake (Fig. 4). From the slope of the rate plot the pseudo first order rate constant can be evaluated and, taking the solubility of H_2 as 6.1×10^{-4} mole atm^{-1} in this medium, the bimolecular rate constant k was calculated (Table III). The values obtained for two different initial Rh^{III} concentrations, 0.51 and 0.59 l $mole^{-1}$ s^{-1}, confirm that the reaction is first order in rhodium and agree with the values obtained for the catalytic reduction of Fe^{III} under similar conditions (1). This indicates that the rate-determining step is the same for both systems (see Discussion).

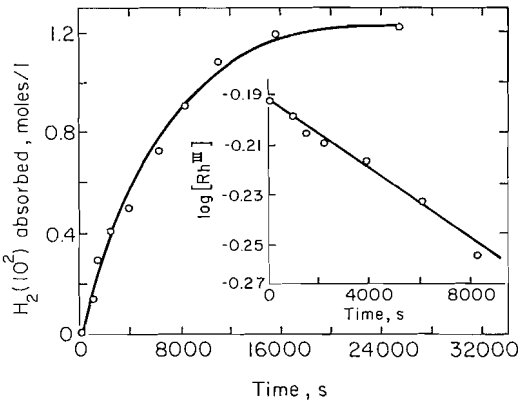

FIG. 4. Rate plot at 80°, 450 mm H_2, 0.011 M $RhCl_3$, 0.10 M maleic acid, 3 M HCl. Inset: plot of $\log [Rh^{III}]$ against time.

The original reddish Rh(III) solution gradually became light yellow during the course of the reaction; the spectrum of the final solution (Fig. 5) exhibited absorption maxima at 353 mμ ($\epsilon = 400$) and 425 mμ ($\epsilon = 180$). The same yellow species in solution was formed by reducing the Rh(III)/maleic acid/3 M HCl solution with Ti^{III} (in the absence of maleic acid, Ti^{III} rapidly reduced Rh^{III} to the metal). The solution certainly contains a complex of maleic acid with rhodium in a reduced valency state and the stoichiometry of the reaction with H_2 indicates a Rh^{I} complex.

Table III also summarizes results obtained for the maleic acid systems with the complexes prepared from the $Rh(H_2O)_6^{3+}/HCl/HClO_4$ solutions. With the cationic species $[Rh(H_2O)_6]^{3+}$ and $[Rh(H_2O)_4Cl_2]^{+}$ in solution a rapid uptake of H_2 was observed and reduction to Rh^{0} occurred with a resulting heterolytically catalyzed H_2 reduction of the maleic acid. With the solution containing predominantly the 5:1 chloro species reduction to the Rh^{I} – maleic acid complex again occurred, but there was also slight

reduction to the metal; the resulting heterogeneous hydrogenation complicated the H_2 uptake plot. The $RhCl_6^{3-}$ solution was also reduced to the same yellow species but the H_2 uptake did not level off and continued at a very slow rate, suggesting some further reaction, possibly heterolytic, might be involved. Because of this irreproducibility of the aqueous Rh^{III}/H_2/maleic acid systems, which probably resulted from slight reduction of Rh^{III} to the metallic state, a detailed kinetic study was not carried out.

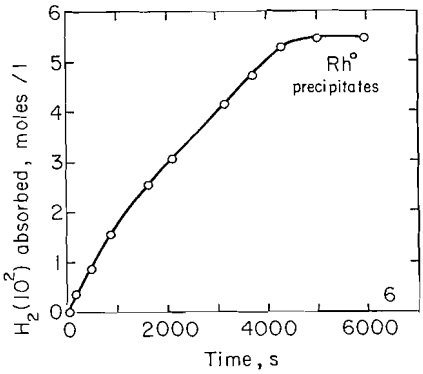

FIG. 5. Absorption spectrum of Rh^I – maleic acid complex in 3 *M* HCl.
FIG. 6. Rate plot at 80°, 730 mm H_2, 0.005 *M* $RhCl_3$, 0.05 *M* maleic acid in dimethylacetamide solution.

Preliminary experiments in dimethylacetamide solution have given reproducible results. The experiments consist of adding excess maleic acid to a neutral solution of $RhCl_3.3H_2O$ in dimethylacetamide; hydrogenation is carried out in the usual way. Figure 6 shows a typical H_2 uptake plot. In contrast to the aqueous system complete homogeneous hydrogenation of the maleic acid occurs, the total H_2 uptake being equivalent to the sum of that required for reduction of the olefinic bond and reduction of Rh^{III} to Rh^I. The initial more rapid rate of H_2 uptake, which is first order in both Rh^{III} and H_2, is concerned with the production of a Rh^I – maleic acid complex as in the aqueous system. The later linear uptake could be explained by the reactions

$$Rh^I - \text{maleic acid} + H_2 \xrightarrow{k} Rh^I + \text{succinic acid}$$

$$Rh^I + \text{maleic acid} \xrightarrow{\text{fast}} Rh^I - \text{maleic acid}.$$

At the end point in these systems metallic rhodium is precipitated. These systems are being more fully studied.

DISCUSSION

It has been found that in acid solution only anionic chlororhodate(III) complexes will activate molecular H_2 for the homogeneous reduction of ferric ion. The activity of the species increases with increasing number of chloride ligands attached to the metal ion, i.e.

$$[RhCl_6]^{3-} > [Rh(H_2O)Cl_5]^{2-} > [Rh(H_2O)_2Cl_4]^{-}$$

A common feature of the mechanisms of many homogeneously catalyzed hydrogenation reactions appears to be a rate-determining heterolytic splitting of H_2 by the catalytic species with the formation of a metal hydride complex which reduces the substrate in a subsequent fast step (1, 3). For the present reactions, for example,

[1] $$RhCl_6^{3-} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} HRhCl_5^{3-} + Cl^-$$

[2] $$HRhCl_5^{3-} + 2FeCl_3 \xrightarrow[\text{fast}]{k_2} RhCl_6^{3-} + HCl + 2FeCl_2.$$

Harrod and Halpern (1) had carried out their studies with $RhCl_3$ in 3.0 M to 5.0 M HCl solutions; they had suggested that $[RhCl_6]^{3-}$ was likely to be the predominant species in solution, but the present results show that the 5:1 chloro species persists over this range of HCl concentration. The rate constants we obtained are in excellent agreement with those obtained earlier under comparable conditions (1).

Reaction [1] is essentially the replacement of chloride ion by hydride ion; easier removal of chloride ion would be expected with increasing negative charge in agreement with the observed activities of the complexes. This factor is also reflected in the stepwise formation constants of the complexes $K_1 > 10^3$, $K_2 > 10^3$, $K_3 \sim 10^3$, $K_4 \sim 250$, $K_5 \sim 25$, $K_6 \sim 0.56$ (2); increasing strength of the metal chloride bonding in the lower species makes removal of the chloride or its replacement by hydride increasingly difficult. A similar trend has been reported for the catalytic hydrogenation of dichromate by chloro complexes of Cu^{II} (19). The catalytic activity increases with increasing concentration of chloride ion in solution, levelling off to a maximum when the $CuCl_4^{2-}$ species is fully formed.

In the absence of ferric substrate cationic, neutral, and anionic rhodium(III)–chloride complexes are all rapidly reduced to the metal by H_2 at 80° in acid solution. The equilibrium represented by reaction [1] must still exist but the hydride complex is rapidly converted by some process to metallic rhodium, i.e.

[3] $$Rh^{III} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Rh^{III}H^- + H^+$$

[4] $$Rh^{III}H^- \xrightarrow{k_3} Rh^0$$

where k_3 is likely to be $> k_{-1}$. The experiments involving the maleic acid systems indicate that process [4] goes via the Rh^I state. The rate-determining step for the formation of the Rh^I – maleic acid complex is again governed by reaction [3] since the determined rate constant is the same as that determined for the H_2-catalyzed reduction of Fe^{III}. Production of Rh^I must proceed by the rapid step

[5] $$Rh^{III}H^- \rightarrow Rh^I + H^+.$$

Rhodium metal could then be produced by further reduction of Rh^{I} by H_2 or by a disproportionation reaction. (It is of course possible that the reduction of ferric species involves a Rh^{I} species rather than the postulated hydride $Rh^{III}H^{-}$; this will depend on the relative rates of the two fast steps shown in reactions [2] and [5].)

There is stabilization of the Rh^{I} state by complexing with maleic acid only when anionic chlororhodate(III) complexes are initially present; with the cationic complexes present metal was precipitated. More information is required about the nature of the Rh^{I} – maleic acid complex; the d acceptor orbitals of the chloride ion might be important for stabilizing the low valency state of the metal, the stabilization increasing with the number of chloride ligands present. A simple dimer olefin complex of Rh^{I}, μ-dichlorotetraethylenedirhodium(I) $(C_2H_4)_4Rh_2^{I}Cl_2$ has recently been isolated by Cramer (20) by reacting ethylene with an aqueous methanolic solution of $RhCl_3$.

The cationic and neutral chlororhodium(III) complexes do not act as hydrogenation catalysts for the homogeneous reduction of ferric ion; metallic rhodium was always precipitated from solution. From the reaction schemes listed above this suggests that for these systems k_3 is $> k_2$, i.e. the dissociation of the $Rh^{III}H^{-}$ species for the cationic and neutral species is more rapid than its reaction with Fe^{III}; for the anionic species k_2 must be $> k_3$. Cationic and neutral complexes of Rh^{III} are like their Co^{III} analogues, usually kinetically inert whereas the anionic complexes are generally labile (21).

Rhodium – chloride complexes, with rhodium in the tri- or uni-valent state, in aqueous acid solutions are not effective catalysts for the homogeneous hydrogenation of the olefinic bond in maleic acid. An olefin complex is formed with Rh^{I}, but this shows no reaction with H_2. This is in contrast somewhat with the corresponding ruthenium systems: Ru^{III} chloro complexes have been shown to be ineffective as catalysts for the homogeneous hydrogenation of olefinic bonds, but Ru^{II} complexes were active (4). A 1:1 complex of Ru^{II} with maleic acid is formed, but this reacted with H_2 to yield again succinic acid and free Ru^{II}.

The preliminary experiments in the dimethylacetamide solvent, however, indicate that the Rh^{I} – maleic acid complex does react at measurable rates with H_2 in neutral solutions to produce succinic acid in a homogeneous catalytic reaction. Wilkinson and co-workers (10) have reported that a solution of $(Ph_3P)_3Rh^{I}Cl$ in benzene takes up molecular H_2 to give an intermediate hydride stable enough for the Rh—H bond to be detected by nuclear magnetic resonance; this hydride rapidly reduces olefins such as hex-1-ene and acts as a catalytic intermediate in the homogeneous hydrogenation of the olefin. In our studies, solutions of $RhCl_3.3H_2O$ in dimethylacetamide take up molecular H_2 to give the Rh^{I} valence state which rapidly complexes with the olefin present; the Rh^{I}–olefin complex then reacts further with H_2 to give the catalytic reduction. The kinetics of this system will be reported in a later paper.

NOTES

THE RADIOLYSIS OF TRIFLUOROETHANOL

J. C. RUSSELL[1] AND K. J. MCCALLUM

Information is being gathered on the radiolysis of related simple halogenated compounds. Woods and Spinks (1, 2) have studied the radiolysis of aqueous solutions of trichloroethanol, tribromoethanol, and dibromoethanol, as well as the trisubstituted acetaldehydes fluoral hydrate, chloral hydrate, and bromal hydrate. With the exception of fluoral hydrate, aqueous solutions of all the above compounds gave yields of the corresponding halogen acid in the range $G_{HX} = 25$–400. The size of the acid yields and the dose rate dependence that were found indicate that these compounds undergo chain reactions forming the halogen acids.

The radiation chemistry of ethanol, both pure and in aqueous solution, has been investigated in detail (3–5). No chain reaction was found and a detailed mechanism has been proposed by Adams and Sedgewick (4) and Myron and Freeman (5).

The present note reports an investigation of the ^{60}Co γ-radiolysis of trifluoroethanol, both as the pure alcohol and in aqueous solution. The halogen acid was formed in moderate yield; hydrogen and products similar to those found in ethanol radiolysis were also formed.

RESULTS

Most of the results are shown in Figs. 1 and 2 and Table I. All values except those for the vicinal glycol and gas analyses (for which duplicate determinations were made) represent at least four separate irradiations. Most values represent the average of eight or

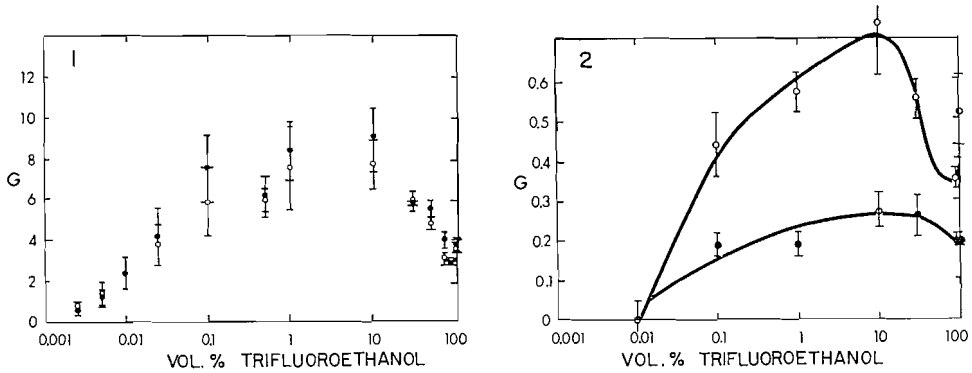

FIG. 1. The yield of acid and fluoride vs. concentration of trifluoroethanol. (●) Acid, (○) fluoride.
FIG. 2. The yield of carbonyl and formaldehyde vs. concentration of trifluoroethanol. (○) Total reactive carbonyl, (●) formaldehyde.

more separate irradiations. The vertical bars in Figs. 1 and 2 represent experimental standard deviations.

Trifluoroethanol samples containing 0.408% and 0.093% water by weight gave the same yield of acid and fluoride on irradiation.

[1]*Present Address*: *Department of Chemistry, University of Alberta, Edmonton, Alberta.*

TABLE I

Trifluoroethanol (moles/l)	Volume % trifluoroethanol	G					
		Vicinal glycol	H_2	CO_2	Organic acid	Unreactive carbonyl	Reactive carbonyl
11.4	99.6	0.10±0.02	3.2±0.2	<0.004	<0.05	0.4±0.2	0.52±0.1
1.14	10	0.27±0.02	2.4±0.2	0.016±0.002	0.5±0.2	0.9±0.4	0.75±0.1

Samples of pure irradiated trifluoroethanol were analyzed with a gas chromatograph equipped with a Carbowax column. Nine significant peaks were found, six of which could be considered to be large enough to indicate organic products of some importance. None of these compounds corresponded to known non-fluorinated aliphatic compounds. No identification could be made, since no authentic samples of the possible compounds were available.

The yields of acid and fluoride were measured for pure trifluoroethanol and 1.1 *M* trifluoroethanol in water at the dose rates 2×10^{18} eV/g h and 2×10^{17} eV/g h. The yields were found to be independent of the dose rate.

The yield of HF from aqueous solutions of trifluoroethanol is relatively small, being slightly larger than that found by Woods and Spinks (1) for fluoral hydrate ($G_{HF} = 7.1$). It is very much lower than the $G_{HCl} = 27$ found by Woods and Spinks for trichloroethanol and the $G_{HBr} = 89$ found for tribromoethanol. The yield of $G_{HF} = 7.9$ is, however, larger than the sum of the yields of free radicals and solvated electrons in γ-irradiated water (6). This might indicate that there is some contribution from a chain reaction, but that this is too small to give a detectable dose rate effect over the dose rate range studied.

Three distinct types of carbonyl compounds were found. These were formaldehyde, another reactive carbonyl which has not been identified, and an unreactive carbonyl (believed to be fluoral hydrate).

The radiolysis of pure trifluoroethanol gives products which are analogous to those found for ethanol. The yield of HF is small and there would appear to be little or no contribution from a chain reaction. The sum of the yields of HF and H_2 is only slightly larger than the radiolytic yield of H_2 from ethanol (5).

The radiolysis of trifluoroethanol is very similar to that of ethanol, but quite different from that of the related halogenated compounds. Trifluoroethanol is thus best regarded as a modified ethanol, rather than as an analogue of the other halogenated compounds.

EXPERIMENTAL

Materials

Trifluoroethanol, $CF_3—CH_2—OH$, was obtained from K and K Laboratories, Jamaica, N.Y. The trifluoroethanol was analyzed by gas chromatography. The total impurities were estimated to be less than 1%. The content of water was found by Karl Fisher titration (7) to be 0.408% by weight. This was not objectionable when making up aqueous solutions. A small quantity of trifluoroethanol was dried by fractional distillation through a 6 in. glass column, packed with glass helices. This material contained 0.093% water. Efforts to dry trifluoroethanol with silica gel and barium oxide were not successful. The dried trifluoroethanol gave the same yields of acid and fluoride on irradiation as trifluoroethanol containing 0.408% water. The undried material was used for subsequent irradiations of pure trifluoroethanol.

All water used in making up solutions which were irradiated was triply distilled. Ordinary distilled water was distilled from an alkaline permanganate solution and then redistilled from an acid solution of potassium dichromate.

All irradiations were performed in capped 10 mm × 75 mm polypropylene test tubes supplied by Nalgene Company Inc., Rochester, N. Y. The tubes were chosen on the basis of their inertness towards trifluoroethanol and the radiolysis products. One of the products, HF, attacks glass, giving low yields if glass vessels are used.

Experimental Methods

All samples were deoxygenated with a flow of dry oxygen-free nitrogen before irradiation. The irradiations were performed with a 50 curie ^{60}Co source. This gave a dose rate of 2×10^{18} eV/g h, and doses in the range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

0.26–1.6 $\times$ 10^{20} eV/g were used. The dose rates were measured with a "Fricke" dosimeter (8) and a Farmer Baldwin X-ray dosimeter MkII made by the Baldwin Instrument Company, Dartford, Kent, England. For the "Fricke" dosimeter $G_{Fe^{3+}}$ was taken as 15.5 and $\epsilon_{Fe^{3+}}$ as 2 201 at 25 °C and 304 mμ (8). The dose rates as measured by the two methods agreed within the experimental error of 2%.

The acid yields were determined by visual microtitration with 0.1 *N* NaOH and chlorophenol red indicator. The fluoride yields were determined by reaction with thorium chloranilate to give a colored complex. The concentration of the complex was measured spectrophotometrically at 304 mμ wavelength. The procedure followed was adapted by Fisher Scientific Company (9) from that of Fine and Wynne (10). The yields of hydrogen and carbon dioxide were determined by a gas chromatographic technique on a silica gel column.

The analytical method used to determine the total carbonyl yield was that of Lappin and Clark (11). The unreactive carbonyl (possibly fluoral hydrate) was estimated by a modification of the total carbonyl analysis of Lappin and Clark. Under the conditions of analysis by this procedure fluoral hydrate does not react with the 2,4-dinitrophenylhydrazine reagent. It was found that if the heating time at 80 °C was extended from 5 min to 60 min, approximately 20% reaction could be achieved. In this way the yield of such unreactive carbonyl compounds was estimated by comparison with known amounts of fluoral hydrate dissolved in trifluoroethanol.

The analytical method of Tanenbaum and Bricker (12) was used to determine the formaldehyde yields. The "chromotropic acid" (4,5-dihydroxy-2,7-naphthalene disulfonic acid) method of Bricker and Johnson (13) for the determination of formaldehyde was investigated and found to be unsuitable in the system of trifluoroethanol and water used. The method gave higher values for the formaldehyde concentration in irradiated samples than the total carbonyl concentration. The presence of trifluoroethanol also caused large negative errors in the analysis.

The analytical method of Siggia (14) was used for the determination of the yields of vicinal glycol. The yields of organic acid were estimated by treating the samples with diazomethane after the trifluoroethanol and water had been evaporated. The resulting methyl glycollate was then detected and the amount present estimated by gas chromatography. Known amounts of glycollic acid in trifluoroethanol were used for reference.

COMMENT: DEFINITION OF A BIRADICAL

G. R. Freeman

It is evident from the literature of the past few years that there is disagreement or lack of clarity about the meaning of the term "biradical". The concept of a biradical is of sufficient importance in several types of reaction that it should be clarified, even if arbitrarily. The purpose of the present note is to suggest a better definition of the term

For personal use only.

"biradical" and to discuss several aspects of biradicals, some of which are frequently ignored.

An often used definition of biradical is—a molecule with two unpaired electrons (1). This definition is inadequate because it restricts biradicals to triplet species and those that contain a pair of doublets. A better definition is—*a biradical is an atom or molecule that reacts as though it has two monoradical functions.** The latter definition includes electronically excited singlet species such as $O(^1D)$ atoms and singlet carbenes.

There is no difficulty with the concept of biradicals when speaking of their reacting in bimolecular reactions. However, part of the controversy over whether certain unimolecular isomerization and decomposition reactions occur via biradical intermediates or via concerted mechanisms seems to contain a lack of clarity about the concept of biradicals. For example, tests which are frequently applied to detect monoradicals, such as the addition of a scavenger, cannot easily be used to detect biradicals that can combine or disproportionate internally. Two radical groups in one molecule corresponds to a local monoradical concentration of the order of 10 M. If both the intra-biradical disproportionation and combination reactions are not sterically hindered, the concentration of even a very efficient scavenger would have to be $\gtrsim 10$ M to intercept the intra-biradical reactions. In reaction systems where radical scavengers, such as oxygen or olefins, have been used to detect monoradicals, the monoradical concentrations have usually been less than micromolar. Conveniently low scavenger concentrations have therefore been adequate to intercept inter-monoradical reactions. Similar reasoning shows that the lifetime of this type of biradical is many orders of magnitude shorter than that of monoradicals in most systems, so it would be extremely difficult to detect the biradicals by electron spin resonance spectroscopy. In spite of the difficulty of detection of this type of biradical, the concept is useful when one is trying to visualize the precise mechanism of certain isomerization and decomposition reactions. The controversy over whether these reactions occur via concerted or biradical mechanisms is not trivial. A concerted mechanism is one in which the transition state does not have free radical character.

At what point does a vibrationally excited ring (cyclic molecule) become a biradical? Consider the following sequence of events in a hydrocarbon molecule: (*a*) energy is absorbed by the molecule; (*b*) sufficient energy becomes localized in a C—C bond that it can break; (*c*) the groups involved in the bond in question move away from each other and as they become more and more separated in space, the correlation between the spins of the odd electrons in the free-radical ends decreases.

The probability of occurrence of a spin change during the collision of two doublet atoms is large when the change of internal energy is small compared with the energy of relative motion (2, 3). The energy of relative motion, E_{rm}, of the two ends of a biradical will be somewhere between the excess vibrational energy in the biradical (i.e. the amount of vibrational energy in excess of that required to break the bond in the molecule) and the thermal energy of the surrounding medium. Thus, if the ends of the breaking bond can become sufficiently separated that the difference in energy between the triplet and singlet states, $|E_t - E_s|$, is less than E_{rm}, then the species can be considered to be a biradical rather than an excited molecule.

The foregoing discussion is consistent with recent observations of Hammond (4).

The results of crude calculations indicate that a low-lying "pair of doublets" electronic state of the trimethylene biradical cannot exist in a vibrational ground state because the tetrahedral separation distance between the two end carbon atoms is too small (2.5 Å).

**This particular choice of words was partly suggested by one of the referees.*

It would very rapidly form cyclopropane (singlet). A vibrationally excited trimethylene biradical would also have a considerable amount of singlet or triplet character mixed with its "pair of doublets" character. This is in agreement with the product distributions obtained by Crawford *et al.* (5) from substituted trimethylene biradicals produced by the decomposition of pyrazolines.

NOTE ADDED IN PROOF: The 8.2 kcal/mole activation energy for ring closing of the trimethylene biradical calculated by Benson (6) is probably too high, for the following reasons.

(*a*) The primary C—H bond dissociation energies in propane are higher than those in ethane (7). The recalculated value of ΔH_f^0 ($\dot{C}H_2CH_2\dot{C}H_2$ at 25° and 1 atm) is 69 kcal/mole, as opposed to 67 kcal/mole used by Benson. Benson (6) removed a hydrogen atom from each end of a propane molecule and assumed that the two radical ends were independent of each other. The same procedure was used in the present calculation.

(*b*) The value 64.2 kcal/mole reported by Rabinovitch (8) and used by Benson (6) as the activation energy for opening the cyclopropane ring is too high by the amount of the activation energy for rotation of a CH_2 group in the biradical. The calculated activation energy for ring closure is also too high by this amount.

(*c*) All the hydrogens in cyclopropane are in the eclipsed conformation, so the biradical formed initially upon C—C cleavage might also be mainly in this conformation. Since the eclipsed conformation of ethane is 3 kcal/mole higher in potential energy than is the staggered conformation (10), the totally eclipsed conformation of the trimethylene biradical would have a ΔH_f^0 a bit less than 73 kcal/mole, calculated by the same method as before.

Thus the activation energy for ring closure in an eclipsed trimethylene biradical should be 2–3 kcal/mole.

A skew trimethylene biradical would tend to form "π-cyclopropane" (10), which is equivalent to an electronically excited state of cyclopropane.

THE PROTON MAGNETIC RESONANCE SPECTRA AND TAUTOMERIC EQUILIBRIA OF ALDOSES IN DEUTERIUM OXIDE[1]

R. U. LEMIEUX AND J. D. STEVENS[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 6, 1965

ABSTRACT

The proton magnetic resonance spectra of D-xylose, D-lyxose, D-arabinose, D-ribose, D-glucose, D-mannose, and D-galactose were determined at 100 Mc.p.s. in deuterium oxide. The chemical shifts and structures of a number of ring protons in these compounds were determined either by spin-decoupling experiments or by synthesis of specifically deuterated compounds. The proton magnetic resonance parameters are shown to provide considerable information on the conformations and tautomeric equilibria for the sugars in aqueous solution. It is concluded that, for aldopyranoses in a chair conformation, the chemical shift of equatorial protons at a given position is virtually independent of configurational changes at other positions. However, an axial proton is shielded about 0.3 p.p.m. less by an axial hydroxyl group at a neighboring position than when the hydroxyl group is in an equatorial orientation. An axial hydroxyl group leads to deshielding of an opposing axial proton by about 0.35 p.p.m. By using the chemical shifts of the ring protons of β-D-xylopyranose and β-D-glucopyranose as reference point, the chemical shifts of protons in other pyranose structures could be anticipated to within a useful degree of accuracy.

Evidence was obtained that D-ribose and 2-deoxy-D-ribose exist in aqueous solution both in the pyranose and in the furanose forms. None of the other pentoses showed readily detectable amounts of the furanose forms at equilibrium. Although D-allose does not give readily detectable amounts of the furanose forms when at equilibrium in aqueous solutions, D-altrose does. D-Talose showed only two forms, one of which was the β-pyranose structure.

Lenz and Heeschen (1) examined the nuclear magnetic resonance (n.m.r.) spectra of D-glucose, D-mannose, 2-deoxy-D-glucose, and D-xylose with deuterium oxide as solvent. Only the signals of the anomeric protons were readily observed, and the spacings of these signals were used as coupling constants to estimate conformational features for these sugars in aqueous solution. The observed spacings were undoubtedly strongly influenced by virtual long-range coupling (2, 3) and, therefore, were not a direct measure of the coupling constants involved. Also, it is now evident (4, 5) that the relationship between the coupling constant and the dihedral angle defined by neighboring protons (the Karplus relationship) is subject to parameters other than the dihedral angle. Therefore, attempts to relate the spacings of the doublet signals for the anomeric protons of sugars to precise molecular geometry are without either a theoretical or an empirical basis. Although coupling constants between neighboring protons cannot be used to predict precise conformational features, their use in appropriate instances for establishing configurational features (6) remains unchallenged.

Use has also been made of chemical shifts for establishing the configurations of sugars

and their derivatives. To our knowledge, there is no exception to the rule that an equatorial proton will produce its signal to lower field than a chemically similar but axial proton (7), when the compounds considered are epimeric and both in the same chair conformation, and when the protons considered are not at the α-position to a carbonyl group (8). However, as will be seen later, this rule may not apply, for example, to the anomeric forms of D-altropyranose in the C1-conformation.

It has long been recognized that important shielding effects can arise from positions other than the neighboring positions (3, 9, 10), so that any rationalization of chemical shift must take into consideration the total structure of the molecule. We have demonstrated (3) that the chemical shifts of the ring protons of acetylated sugars are strongly dependent on configurational changes at positions other than the neighboring positions. Also, it is clearly apparent that chemical shifts are subject to specific solvent effects which cannot, as yet, be predicted. Nevertheless, it proved possible to establish simple empirical rules for correlating chemical shift measured under standard conditions with the configurational and conformational properties of acetylated sugars (3), and the purpose of this communication is to report a similar success for free sugars dissolved in deuterium oxide. Furberg (11) has commented on the use of n.m.r. to establish points of configuration and on its application to reducing sugars dissolved in deuterium oxide. Both Lenz and Heeschen (1) and Hall (12) have commented on the diamagnetic anisotropy of the C—O bond and have rationalized the chemical shifts of axial anomeric protons in sugars (glucose and mannose) differing in the configuration of the 2-position. Lenz and Heeschen considered the chemical shifts of protons at positions other than the anomeric center, but had no experimental evidence to support the "intuitive" rationalizations. This effort was premature since, for example, it took no cognizance of the strong deshielding influence of an axial hydroxyl on an opposing axial proton (10). We have now determined the chemical shifts of a number of protons at positions other than the anomeric center for sugars in deuterium oxide by employing both double irradiation and specific deuteration techniques.

The procedure used in these investigations was to dissolve the sugar in deuterium oxide and to determine the n.m.r. spectrum on the Varian A60 spectrometer with tetramethylsilane as the external standard. Normally, the course of the mutarotation was readily followed in the spectrometer. The 100 Mc.p.s. spectra of the solutions at equilibrium were measured. The line positions were established relative to calibration side bands and placed on the scale in parts per million from tetramethylsilane using the positions for the anomeric protons found in the A60 spectra. The spin-decoupling experiments were obtained as described by Johnson (13) with the Varian H.R. 100 spectrometer (10).

A freshly prepared solution of α-D-xylopyranose in deuterium oxide showed a sharp, one-proton doublet at 5.26 p.p.m. The rest of the spectrum was a fairly narrow band in the region 3.5–3.9 p.p.m. When it was allowed to stand the solution mutarotated to equilibrium and at 35° showed signals (Fig. 1A) for anomeric protons at 5.26 and 4.65 p.p.m. with spacings of 3.1 and 7.4 c.p.s.; these signals were assigned to the α- and β-anomers, respectively. Integration of these signals showed that the mixture contained 67% of the β-anomer.

Spin decoupling at 1.63 p.p.m. to higher field from the signal for H_1^α collapsed the doublet; therefore, the chemical shift for H_2^α is at 3.63 p.p.m. The quartet at 4.00 p.p.m. with spacings of 4.3 and 10.4 c.p.s. was assigned to the 5-proton in an equatorial orientation, H_{5e}^β, in view of its intensity and structure. The intensity of the quartet was equal to that of the signal for H_1^β and, as the small coupling constant can only arise from H_4^β to H_{5e}^β coupling, this signal must belong to H_{5e}^β, since the signal for H_4^β should be more complex. The assignment of the H_{5e} signal was confirmed by examination of the spectrum of the

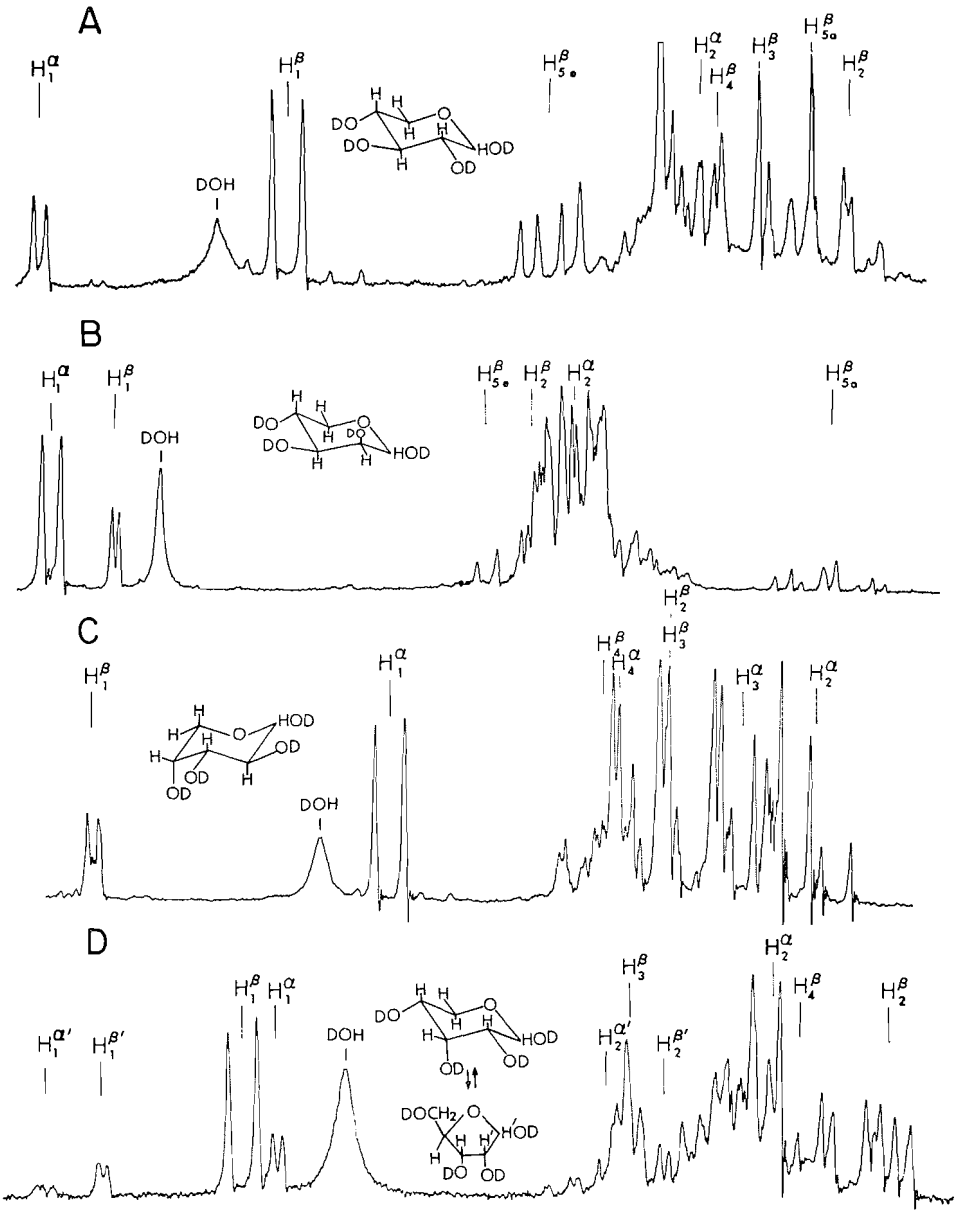

FIG. 1. Nuclear magnetic resonance spectra at 100 Mc.p.s. of aldopentoses at tautomeric equilibrium in deuterium oxide at 35°. LEGEND: A, D-xylose; B, D-lyxose; C, D-arabinose; D, D-ribose.

5-deuterio-D-xylose prepared by Lemieux and Howard (14). The quartet was now a doublet with an intensity corresponding to that expected from the composition of the compound. Irradiation at 42 c.p.s. to higher field than the signal for H^{β}_{5e} caused the quartet to collapse to a doublet with the larger spacing. Therefore, the signal for H^{β}_{4} is centered at about 3.58 p.p.m. The intensitites of the signals to higher field than 3.5 p.p.m. corresponded to three protons, based on the intensity of H^{β}_{1}. It was apparent, therefore, in view of the spectrum of the α-anomer, that H^{β}_{2}, H^{β}_{3}, and H^{β}_{5a} gave their signals in this region. Since irradiation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of H^{β}_{5e} caused extensive collapse of the signal at 3.36 p.p.m., it was most likely that the signal for H^{β}_{5a} was near this position. Irradiation of H^{β}_{1} caused the quartet with spacings of about 7.4 and 8.5 c.p.s. at 3.26 p.p.m. to collapse to a doublet. Therefore, the chemical shift of H^{β}_{2} is 3.26 p.p.m. and $J^{\beta}_{3,2} = 8.5$ c.p.s. The spectrum resulting from this double irradiation experiment showed clearly the triplets for H^{β}_{3} at 3.49 p.p.m. and for H^{β}_{5a} at 3.36 p.p.m. The spacings require $J^{\beta}_{3,4} = 8.5$ and $J^{\beta}_{4,5a} = 10$, and confirmed $J^{\beta}_{5a,5e} \simeq 10$ c.p.s.

The spacings observed in the spectrum for β-D-xylopyranose (see Table I) require that the compound exist in a near C1-chair conformation as anticipated from conformational analysis. All that can be said for the α-form is that the spacing from the H_1 signal agrees with that for a gauche interaction between H_1 and H_2. Also, as will be seen below, the chemical shift for H_2 is in the region expected for the compound in the chair conformation.

A freshly prepared solution of α-D-lyxopyranose showed a one-proton signal at 5.08 p.p.m. with a spacing of 4.2 c.p.s.; this signal was assigned to H^{α}_{1}. The rest of the spectrum was a rather narrow band in the region 3.7–4.1 p.p.m. On equilibration at 35°, a doublet appeared at 4.94 p.p.m. with a spacing of 1.5 c.p.s.; this signal was assigned to H^{β}_{1} (see Fig. 1B). An octet appeared that was centered at about 3.32 p.p.m. and had an intensity corresponding to that of the signal for H^{β}_{1}. This signal is provisionally assigned to H^{β}_{5a}. The signal collapsed to a much narrower complex multiplet on irradiation at 4.07 p.p.m. It seems most probable, in view of the chemical shift for H^{β}_{5e} of D-xylose, that the quartet centered at 4.09 p.p.m. is the signal for H^{β}_{5e}. The spacings suggest $J^{\beta}_{4,5e} \simeq 5$ c.p.s. and $J^{\beta}_{5a,5e} \simeq 10$ c.p.s. Irradiation at 3.90 p.p.m. collapsed the signal for H^{α}_{1} to a singlet, and it is concluded, therefore, that the chemical shift for $H^{\alpha}_{2} = 3.90$ p.p.m. Irradiation of H^{β}_{1} caused the quartet centered at 4.04 p.p.m. to collapse to a doublet. Therefore the chemical shift for $H^{\beta}_{2} = 4.04$ and $J^{\beta}_{2,3} \simeq 3$ c.p.s. Integration of the anomeric signals showed that the mixture contained 71% of the α-anomer at 35°.

A freshly prepared solution of β-D-arabinose in deuterium oxide gave a one-proton doublet signal at 5.34 p.p.m. with a spacing of 2.7 c.p.s.; this signal was assigned to H^{β}_{1}. The crystalline sugar is known by X-ray analysis (15) to have the pyranose ring in the 1C-conformation, wherein H_1 is in the equatorial orientation. On mutarotation, the solution produced a signal for H^{α}_{1} as a doublet with a spacing of 7.2 c.p.s. at 4.60 p.p.m. (see Fig. 1C). Although the DOH signal was reduced to an intensity of about that of H^{α}_{1} at equilibrium, no other signals for anomeric protons were observed. The shape of the signal for H^{β}_{1} showed the presence of second-order effects from virtual long-range coupling and, therefore, a small chemical shift for H^{β}_{2} and H^{β}_{3} (3). Irradiation at 3.93 p.p.m. collapsed the signal for H^{β}_{1}; therefore the signal for H^{β}_{2} is at this position. The signal for H^{α}_{1} is a sharp doublet and, therefore, H^{α}_{2} and H^{α}_{3} must be well shifted chemically. Double irradiation showed that H^{α}_{2} gave its signal at 3.58 p.p.m. The chemical shifts of the 3- and 4-protons in both the β- and α-forms were determined by examining the n.m.r. spectra of the 2,5,5-trideuterio derivatives. These compounds were prepared from D-glucurone as described in the Experimental section. The spectra measured at 60 Mc.p.s. are reproduced in Fig. 2B for both the freshly prepared solution of exchanged crystalline 2,5,5-trideuterio-β-D-arabinopyranose and the equilibrated solution. Figure 2A shows the corresponding spectra for ordinary D-arabinose. The two doublets for H^{β}_{3} and H^{β}_{4} seen on the spectrum of the freshly prepared solution of the deuterated compound must be at 3.93 and 4.07 p.p.m., respectively, in view of the strong second-order effects noted in the signal for H^{β}_{1} and the fact that the chemical shift for $H^{\beta}_{2} = 3.93$ p.p.m. The spacings of the signals require $J^{\beta}_{3,4} = 3.4$ c.p.s. Mutarotation caused the appearance of two new doublets at 3.75 and

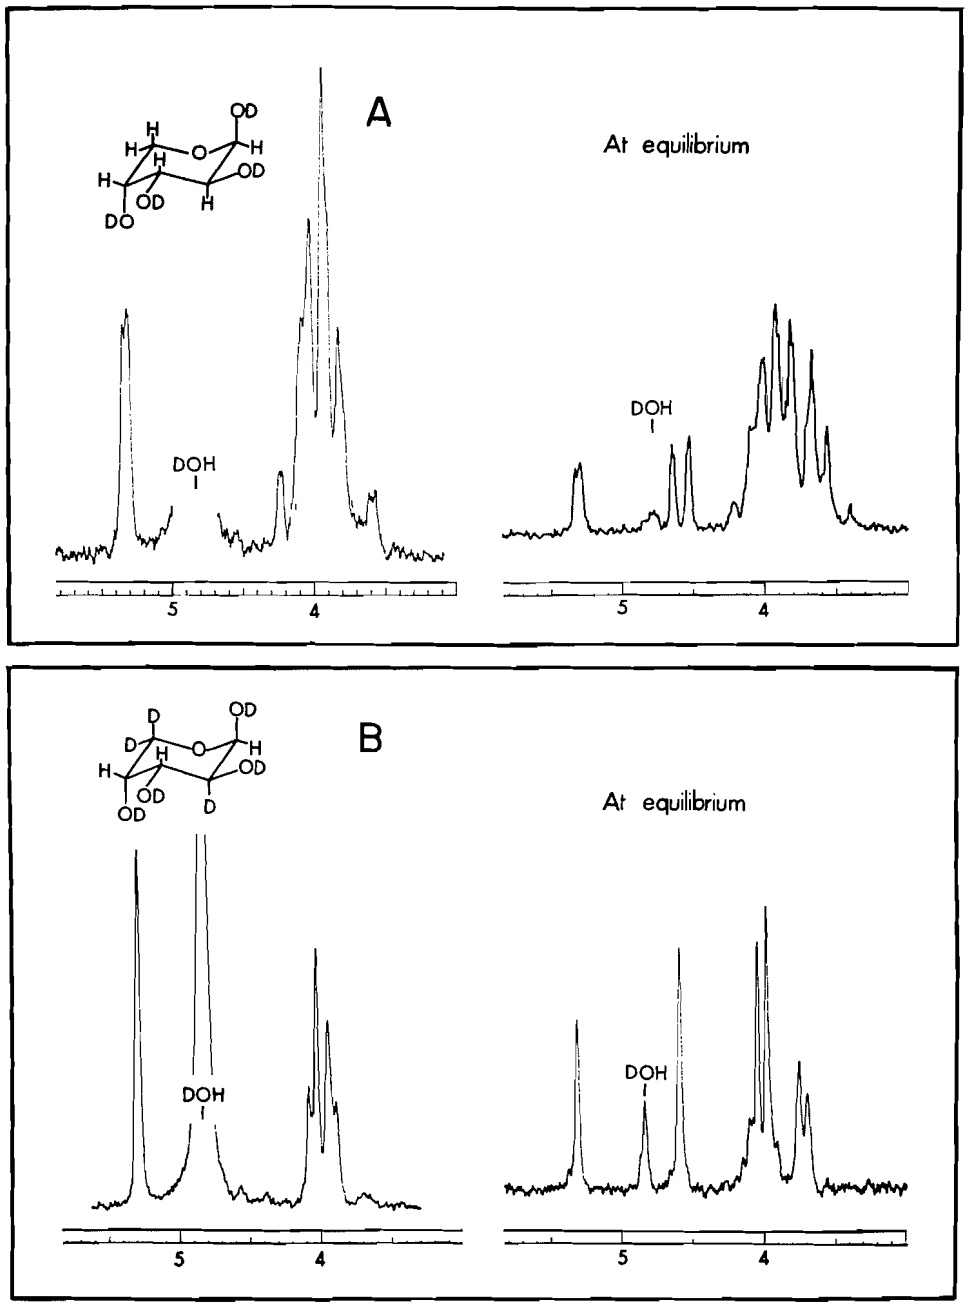

FIG. 2. Nuclear magnetic resonance spectra at 60 Mc.p.s. in deuterium oxide at 35°. LEGEND: A, β-D-arabinopyranose within a few minutes of dissolution and at tautomeric equilibrium; B, 2,5,5′-trideuterio-β-D-arabinopyranose within a few minutes of dissolution and at tautomeric equilibrium.

4.04 p.p.m. which are assigned to H_3^α and H_4^α, respectively. This assignment is based mainly on the rule that the anomerization from the β- to the α-form will lead to a greater shielding of the 3-proton. This effect is discussed in detail below. The spacings of the signals require $J_{3,4}^\alpha = 3.6$ c.p.s. The spectrum of this equilibrated solution substantiates the evidence discussed above that only the α- and β-forms of arabinopyranose are in appreciable concentration at 35°. Integration of the signals for the anomeric protons requires 63% of the α-anomer. The signal for H_2^α appears as a well-defined quartet at 3.58 p.p.m., from which it can be concluded that $J_{2,3}^\alpha = 9.9$ c.p.s. The coupling constants observed for $J_{1,2}$, $J_{2,3}$, and $J_{3,4}$ for the α-form are clearly in accord with the 1C-chair conformation for this compound in aqueous solution. It will be seen below that the observed chemical shifts also agree with this conclusion.

A freshly prepared solution of β-D-ribose in deuterium oxide showed rapid mutarotation, and it was not possible to obtain a spectrum of the crystalline material in a virtually unchanged condition. The mutarotation at 35° gave rise to a solution the n.m.r. spectrum (Fig. 1D) of which had four readily discernible signals of total intensity one at 5.42, 5.30, 4.99, and 4.91 p.p.m. The relative intensities were 6:18:56:20. When the sample was heated to 80°, the signal for DOH moved upfield from 4.75 p.p.m. to 4.3 p.p.m. No further signals for anomeric protons were observed and the integration showed that the total of the intensities for anomeric protons was one-fifth of those of the other protons in the molecule. It was therefore clearly apparent that only four of the tautomeric forms for D-ribose are at appreciable concentrations in water in the temperature range 35–80°. Only the position of the signal for the high-field doublet changed appreciably from 4.91 to 4.83 p.p.m. when the solution was heated to 80°. The relative intensities of the signals changed to 11:19:47:23.

The doublet at 4.99 p.p.m. with a spacing of 6.4 c.p.s. was evidently from H_1^β of the pyranose form. Irradiation at 3.60 p.p.m. caused collapse of the H_1^β signal and therefore corresponds to the chemical shift for H_2^β. Irradiation of H_2^β collapsed the signal for H_3^β at 4.13 p.p.m. This signal was also collapsed by irradiation at 3.79 p.p.m., the signal for H_4^β. It was apparent, therefore, that $J_{2,3}^\beta = 3.1$ c.p.s. and $J_{3,4}^\beta = 3$ c.p.s. The quartet signal for H_4^β suggests that $J_{4,5}^\beta \simeq 10$ c.p.s. The coupling interactions for the vicinal protons of β-D-ribopyranose leave no doubt that the compound has a C1-chair conformation. The axial 3-hydroxyl group probably has caused some distortion, which has decreased the dihedral angle defined by H_1 and H_2.

The n.m.r. spectrum of 5-*O*-methyl-D-ribose was determined to provide a basis for the assignment of the signals for the anomeric proton. Unfortunately, at the time the compound was available, it was not possible to apply heat to move the DOH sample upfield. Nevertheless, the DOH signal was reduced to a very low level, and only two signals for anomeric protons were observed at 5.40 and 5.51 p.p.m. with spacings of 1.5 and 3 c.p.s., respectively. The signals for the two protons at the 5-position in this compound occurred as a band centered at about 3.75 p.p.m. with an intensity double that of the total intensity of the two signals for anomeric protons. Also, a band centered at about 4.2 p.p.m. had an intensity of three, as expected for the total signals for H_2, H_3, and H_4 protons. Only two methoxy-group signals were observed at 60 Mc.p.s. It seems probable, therefore, that 5-*O*-methyl-D-ribose does not exist to any appreciable extent in more than two tautomeric forms (either the two furanose forms or a furanose form and the open-chain form). In view of the equilibrium between the methyl D-ribosides in 1% methanolic hydrogen chloride at 35° and the apparent absence of dimethyl acetal (16), it is most probable that the signals at 5.40 and 5.51 p.p.m. correspond to those of the anomeric protons for the anomeric D-ribofuranoses. The ratio of the intensities of these signals was 2.6:1,

For personal use only.

respectively. The signals are assigned to the β- and α-furanose forms, respectively, since, in general, derivatives of β-ribofuranose have $J_{1,2}$ of about 1 c.p.s. as compared to 4–5 c.p.s. for the α-anomers. Also, it can be expected that the 1,2-*trans*-β configuration will provide the more stable anomer in aqueous solution. For these reasons, the signals at 5.30 and 5.42 p.p.m. in the spectrum of D-ribose are assigned to the anomeric protons of the β- and α-furanose forms, respectively. Bishop and Cooper (16) found that the methyl ribosides at equilibrium contained 5.2% α-furanoside, 17.4% β-furanoside, 11.6% α-pyranose, and 65.8% β-pyranosides. The close correspondence between these values and those now estimated for the mutarotation of ribose at 35°, namely, 6% α-furanose, 18% β-furanose, and 56% β-pyranose, supports the above assignments and suggests that the signal with a spacing of 2.1 c.p.s. at 4.91 p.p.m. arose from the α-D-pyranose form which was present to an extent of 20%. The observed coupling of H_1 with H_2 for the open-chain form would be expected to be the weighted average of the coupling constants for the staggered conformations and, on this basis, to have a value substantially greater than 3 c.p.s. On this basis, the signal at 4.91 p.p.m. cannot have arisen from the open-chain form. This argument can also be applied to the signals at 5.30 and 5.42 p.p.m. There seems to be no alternative, therefore, to the conclusion that the signal at 4.91 p.p.m. arose from the α-D-ribopyranose form. The rather well defined doublet for this signal would be in keeping with the expectation of a substantial chemical shift between H_2 and H_3. It is noteworthy that the signal assigned to the anomeric proton of the α-furanose (H_1^{α}, Fig. 1D) seems to be too complex and, therefore, part of this signal may have arisen from the 1-proton of the hydrated open-chain form. On the other hand, the complexity of the signal may be caused by either long-range coupling or virtual long-range coupling, or both. Certainly, the indications are that the open-chain form is present at much lower concentrations than the 8.5% suggested by the results of a polarographic investigation (17).

Inspection of the chemical shifts for the ring protons of the pentopyranoses shows that there exists a good correlation of the shifts with the configuration of the sugar. This correlation is most readily appreciated by using the chemical shifts for β-D-xylopyranose as reference point and adjusting these shifts according to the following empirical rules. (*i*) If the proton under consideration is in an equatorial orientation, add 0.60 p.p.m. (3, 10). (*ii*) If the proton under consideration is in an axial orientation, (*a*) add 0.30 p.p.m. for each neighboring axial hydroxyl group and (*b*) add 0.35 p.p.m. for each axial hydroxyl group which is in opposition to the axial proton.

The results of these calculations are presented in Table I for the protons of known chemical shift. It is seen that the agreement is reasonably good, if one considers the inaccuracies in determining the chemical shifts by spin decoupling (at least ±0.05 p.p.m.) and the fact that at least some of the rings must be distorted appreciably from the perfect chair form. Certainly, the agreement is sufficiently good to support the conformations assigned above and to indicate that the empirical rules deal with the main configurational effects on chemical shift in the n.m.r. spectra of the sugars. The main discrepancies are in the values for the chemical shifts of the anomeric protons for α-D-lyxopyranose, β-D-arabinopyranose, and α-D-ribopyranose, compounds which, in chair conformations, have two of the four hydroxyl groups in an axial orientation.

As was seen above, H_1 for α-D-ribopyranose gives its signal at 4.91 p.p.m., which is much to higher field than that, 5.25 p.p.m., expected for the compound in the C1-conformation. On the other hand, this chemical shift is in good agreement with that, 4.95 p.p.m., expected for the compound in the 1C-conformation. The chemical shift for H_2 agrees with that expected for the compound in either of the chair conformations. Thus, as

is also concluded by Rudrum and Shaw (18), the indications are that α-D-ribopyranose strongly prefers the 1C-conformation.

α-D-Lyxopyranose has an anomalously high value for $J_{1,2} = 4.2$ c.p.s. when compared to that, 1.7 c.p.s., for the configurationally related α-D-mannopyranose. Also, the chemical shifts for H_1 calculated for α-D-lyxopyranose in either the 1C- or C1-conformations are in poor agreement (see Table I) with the experimental value. However, the n.m.r. parameters are well rationalized by assuming that the compound exists in about equal amounts in the two chair conformations. Thus, by using the spacings for the signals of H_1 in β-D-ribopyranose and α-D-mannopyranose as those to be expected for α-D-lyxopyranose in the 1C- and C1-conformations, respectively, a value for $J_{1,2} = 0.5(6.4 + 1.7) = 4.1$ c.p.s. is obtained. The chemical shift for H_1 would be expected, on this basis, to be $0.5(5.25 + 4.99) = 5.12$ p.p.m., which agrees well with the experimental value of 5.08 p.p.m. Also, on this basis, the chemical shift for H_2 is expected to be 3.89 p.p.m., in good agreement with the observed value of 3.90 p.p.m. Thus, it can be concluded that crystalline α-lyxose is in the pyranose ring form and exists in both chair forms in about equal amounts when dissolved in water. This conclusion was also reached by Rudrum and Shaw (18).

The values for $J_{1,2}$ and $J_{3,4}$ determined for β-D-arabinopyranose do not distinguish between the 1C- and C1-conformations for this compound. It is seen in Table I that the observed chemical shifts for protons 1 to 4 are in as good agreement with those calculated on the basis of the 1C-conformation as with those calculated on the basis of the C1-conformation. In fact, the agreement, especially for H_3 and H_4, is not at all good. Furthermore, the signal for H_1 is at a rather anomalously low field and, therefore, the n.m.r. data would not have sufficed to establish the pyranose ring form. Since it is known (15) that the compound is in the pyranose form, perhaps the conformations are rather seriously distorted from the chair forms. A knowledge of $J_{2,3}$ would shed light on the problem of the chair–chair equilibrium for this compound, but this was not available since the 2- and 3-protons are not appreciably shifted chemically. This lack of chemical shift is to be expected for the compound in chair forms, since these protons are in very similar environments in both chair conformations. Rudrum and Shaw (18) assigned the 1C-conformation to the compound in aqueous solution, but this conclusion must obviously be held in reservation.

It is of interest to note that, as was to be expected, the configurational effects on chemical shift are much simpler for the free sugars than for their acetylated derivatives (3). A consideration of a molecular model of an acetoxy group in axial orientation on a six-membered ring and the anisotropy of the carbonyl group of the acetoxy group (9) makes evident the fact that the carbonyl group should strongly deshield the geminal proton but tend to shield equatorial protons at the neighboring and next to neighboring positions. Thus, whereas an axial hydroxyl group has no appreciable effect on the chemical shifts of these protons, an axial acetoxy group leads, in both cases (3), to a shielding of about 0.2 p.p.m. relative to that when the acetoxy group is in an equatorial orientation.

As seen in Table II, the chemical shifts for the 1- and 2-protons of β-D-glucopyranose are in close agreement with those found for β-D-xylopyranose. Therefore, the introduction of the hydroxymethyl group has little effect on these chemical shifts. By using the observed values for β-glucose as reference point and the foregoing empirical rules, the chemical shifts of protons in the other hexoses were calculated; the results are given in Table II. It is seen that the agreement is quite good and the trends excellent. That is, for example, the same chemical shift for the 2-hydrogens of the anomeric mannopyranoses was predicted. Also, although the absolute chemical shifts for the 2-hydrogens of the α- and

*The chemical shift for H_3^β was 4.28 p.p.m. with $J^\beta_{2,3} \simeq J^\beta_{3,4} \simeq 2.5$ c.p.s.

†Spin-decoupling experiments showed H_3^β and H_5^β to differ little in chemical shift at about 24 c.p.s. to higher field (3.73 p.p.m.) than H_4^β which gave a rough doublet at 3.97 p.p.m. with $J_{3,4}$ about 3 c.p.s.

β-forms of galactopyranose were not estimated with precision, the difference in the chemical shifts was the same as that found by experiment. It is quite evident, therefore, that these simple rules should find widespread application for determination of structure. For example, if the chemical shifts of the 2-hydrogens of a pyranose structure, as determined by spin decoupling of the signals for the anomeric hydrogens, are nearly the same, then it can be concluded that the 2-hydroxyl group is in an axial orientation. It should prove possible to extend this method to rules for differentiating between pyranose and furanose structures, and this matter will be examined primarily in an attempt to establish the ring forms of the rare hexoses in aqueous solution. In the case of D-ribose, the chemical shifts of the 2-protons for the α- and β-furanose forms were 4.19 and 4.07 p.p.m., respectively. These chemical shifts are to substantially lower field than those for the α- and β-pyranose forms, 3.85 and 3.60 p.p.m., respectively. It is to be expected that the ring protons of furanose structures will, in general, have chemical shifts intermediate to chemically similar protons in an axial and equatorial orientation. Also, the long-range configurational effects on chemical shift should be diminished in furanose structures.

The spectra of allose, talose, and altrose were determined but not subjected, as yet, to extensive investigation. The spectrum for allose at equilibrium clearly required the compound to exist virtually entirely in the β-D-allopyranose form. It was apparent that some mutarotation occurred, since the signal for the anomeric proton diminished in intensity as compared with the signal for the 3-proton at 4.28 p.p.m. when the solution was allowed to come to equilibrium. However, the signal of no other anomeric proton was readily observable. It is therefore apparent that the anchoring effect of the hydroxymethyl group for the chair conformation destabilizes the α-pyranose form by forcing a strong interaction between the axial 1- and 3-hydroxyl groups. Also, it is apparent that the introduction of a hydroxymethyl group on C-5 of the ribose structure leads to substantial destabilization of the furanose rings relative to that of the β-pyranose ring. The intensities of the signals attributable to anomeric protons found in the spectrum of D-talose require the compound to exist almost entirely in two tautomeric forms. If talose assumed either one of the furanose forms, then the 1-hydrogen would be in very much the same environment as in the corresponding ribofuranose. For this reason, the signal at 4.88 p.p.m. appears to be at too high a field to be assigned to H_1 of a furanose form. Instead, this signal likely arises from the β-pyranose structure in a distorted-chair or twist-boat conformation. The form of talose which gives a signal for H_1 at 5.37 p.p.m. could be either α-pyranose or β-furanose

(19). The spectrum for D-altrose in deuterium oxide at 35° showed four signals attributable to anomeric protons with a total intensity of one proton. The chemical shifts were 5.00, 5.13, 5.26, and 5.32 p.p.m. with spacings of 4.0, 1.5, 2.0, and 4.5 c.p.s., respectively. The relative intensities were about 29:37:11:23. Obviously, therefore, altrose exists in aqueous solution to a large extent in the furanose forms. This is not surprising in view of the axial hydroxyl groups at the 2- and 3-positions of the pyranose forms (especially the axial group at the 3-position) and the favorable all-*trans* configuration of the furanose form (17). Although it is possible to speculate on the origin of the signals, this matter seems best to be reserved for a future publication when more detailed information will be available. It may be noted, however, that, according to the above rules for the correlation of chemical shift with the configuration of sugars, the chemical shift of H_1 (equatorial) for α-D-altropyranose in the C1-conformation is expected to be at 5.34 p.p.m. and that for the β-anomer (H_1 axial) in the same conformation to be at 5.39 p.p.m.

Experiments with 2-deoxy-D-ribose conducted with L. Anderson confirmed the X-ray evidence (20) for the β-pyranose form in the crystals, m.p. 77–84°, $[\alpha]_D^{22}$ −97° → −48° after 20 min (*c*, 2 in water). The mutarotation was readily followed in the n.m.r. spectrometer at 0° and found to lead to a mixture of four tautomers. The α- and β-pyranose forms were present in about equal amounts at equilibrium and comprised about 70% of the mixture at 60°. The quartet signal for the anomeric proton of the α-anomer was at 4.90 p.p.m. with spacings of 2.5 and 8.2 c.p.s., and requires the 1C-conformation for this compound. The anomeric proton of the β-form gave a triplet signal at 5.36 p.p.m. with a spacing of 3.5 c.p.s. Certainly, therefore, the compound must exist, at least to a substantial extent, in the C1-conformation which is present in the crystalline solid (20). The furanose forms gave signals for the anomeric protons of about equal intensity at 5.69 p.p.m. (triplet with spacing of 4.5 c.p.s.) and 5.63 p.p.m. (quartet with spacings of 2.1 and 5.5 c.p.s.), which for obvious reasons likely arose from the α- and β-forms, respectively.

Since this manuscript was first submitted for publication, a paper appeared on the same subject by Rudrum and Shaw (18). In general, the conclusions are the same as those we communicated in 1962 from spectra measured at 60 Mc.p.s. The generally larger "coupling constants" reported herein are no doubt caused by a greater absence of second-order effects resulting from reduced virtual long-range coupling. A comparison of the spacings in these two publications further emphasizes (3) the hazard of using spacings as coupling constants. In the absence of knowledge related to this effect, Rudrum and Shaw (18) assigned the 1C-conformation to β-D-arabinopyranose. This conclusion was based on the belief that an equatorial orientation was required to account for the chemical shift of H_1. The present data indicate that the agreement between the observed and expected values would be even better with the compound in the C1-conformation. Thus, as was found for the acetylated sugars (3), the simple rule that equatorial protons give their signals to lower field than chemically similar but axial protons can have exceptions depending on the chemical nature and orientation of nearby substituent atoms or groups.

Finally, it is of interest to compare the amounts of the anomeric forms found by integration of the signals for the anomeric protons with the values obtained by other methods. The results given in Table III show excellent agreement for xylose, glucose, mannose, and galactose. The values for lyxose and arabinose agree well with Angyal's calculated values (21) but definitely differ from those determined by rotation and bromine oxidation (22) to an extent greater than the experimental error (about ±2%). Perhaps these pentoses exist to a small extent in the furanose form. The signal for the anomeric proton of β-talose was directly under the DOH signal; therefore, the n.m.r. value is only a rough estimate.

EXPERIMENTAL

The physical measurements were made as described previously (10).

6,6′-Dideuterio-1,2:5,6-di-O-isopropylidene-α-D-glucofuranose

1,2-*O*-Isopropylidene-α-D-glucofuranurono-6,3-lactone, m.p. 120–122°, was prepared from D-glucurone according to the directions described by Owens *et al.* (23). The compound, 32.5 g, was dissolved in 200 ml of tetrahydrofuran freshly distilled from lithium aluminium hydride, and the solution was added dropwise to a stirred solution of 5.06 g of lithium aluminium deuteride (Metal Hydrides Inc., 96.3%) in 600 ml of the tetrahydrofuran. The addition took 3.5 h and the reaction mixture was refluxed for a further 1 h. Water, 15 ml, was then carefully added and this was followed by the addition of 10 ml of 15% aqueous sodium hydroxide and 55 ml of water (24). The precipitated aluminium hydroxide was removed by filtration with Celite as a filter aid. The filtrate was deionized with Amberlite IR 120, H^+, and evaporated to dryness *in vacuo*. The residue was triturated with acetone and ethanol to provide 30.5 g of a product which was dissolved in 900 ml of dry acetone. The solution was cooled to 0° and 36 ml of concentrated sulfuric acid was added dropwise to the stirred solution. After the mixture had been kept at about 15° for 4.5 h, it was cooled to below 10° and neutralized with a solution of 54 g of sodium hydroxide in 60 ml of water. The precipitated salts were removed by filtration and the filtrate was evaporated under reduced pressure. A chloroform solution of the syrupy residue was extracted with water, and the material in the aqueous extract was dried and retreated with acetone and sulfuric acid as described above. The combined chloroform solutions were evaporated and the residue recrystallized from benzene – petroleum ether. The total yield was 16.7 g (41.4% based on the lithium aluminium deuteride) of 6,6′-dideuterio-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, m.p. 108–110°, in agreement with the melting point of the undeuterated compound prepared in a similar manner (25).

The compound, 1.0 g, was dissolved in 50 ml of 50% aqueous methanol, and 0.2 ml of concentrated sulfuric acid was added. The solution was heated at 100° for 3 h and then neutralized with barium hydroxide. Removal of solvent left a syrup which was acetylated with acetic anhydride and sodium acetate in the usual manner to provide 6,6′-dideuterio-β-D-glucopyranose pentaacetate, m.p. 132–133°, in 0.69 g yield. Treatment of a sample of this product with a 1:1 mixture of acetic acid – acetic anhydride containing sulfuric acid provided 6,6′-dideuterio-α-D-glucopyranose pentaacetate, m.p. 111.5–112.5°. The n.m.r. spectra of these two pentaacetates are reported in a separate communication (3).

2-O-Benzyl-D-arabinose

3-*O*-Benzyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (26), 201 g, was dissolved in a mixture of 400 ml of ethanol and 200 ml of *N* sulfuric acid. The solution was heated at 75° for 7.5 h, and then evaporated *in vacuo* to a light syrup which was dissolved in about 500 ml of water. This solution was heated at 90° for 1.5 h. The cooled solution was extracted twice with chloroform and then neutralized with barium hydroxide. Evaporation of the filtered solution and crystallization of the residue from acetone–benzene gave 128 g (95% yield) of 3-*O*-benzyl-D-glucopyranose (27), m.p. 134–136°.

The procedures (28) for the conversion of this compound into 2-*O*-benzyl-D-arabinose were modified (29) as follows. Sodium metaperiodate, 45 g, was dissolved by heating in 150 ml of water, and the rapidly cooled solution was added to 54 g of 3-*O*-benzyl-D-glucose in 150 ml of water. The resulting solution was cooled in ice water and then left at room temperature. The mass of crystals which formed in 15 min was collected and washed with cold water. The yield was 37 g of 2-*O*-benzyl-4-*O*-formyl-D-arabinose, m.p. 124–130°. Methanol, 500 ml, was added to the filtrate and the mixture was refrigerated for 2 h. The precipitated salts were removed by filtration and washed with methanol. The combined filtrates were evaporated to a syrup which was dissolved in 25 ml of water. On cooling, a further crop of the formyl ester, 11.3 g, was deposited. The total yield was 90% of material of sufficient purity for the next stage in the preparation.

The above compound was saponified in aqueous solution with sodium hydroxide. The solution was deionized with Amberlite IR 120, H^+, and then evaporated to a light syrup which deposited crystals after refrigeration for several days. These crystals, plus a second crop obtained from the mother liquors, were recrystallized from ethyl acetate. The yield was 83% of 2-*O*-benzyl-D-arabinose (28), m.p. 111–113°, $[\alpha]_D$ −73° after 0.5 h (*c*, 2.1 in water).

2-Deuterio-β-D-arabinose

2-*O*-Benzyl-D-arabinose, 12.0 g, was dissolved in 8 ml of deuterium oxide and the solvent was removed by freeze-drying. This procedure was repeated and the product was then dissolved in 30 ml of deuterium oxide which had been treated with 550 mg of sodium. After standing at room temperature for 7 days, the solution was neutralized with *O*-deuterated acetic acid and extracted three times with 300 ml volumes of ethyl acetate. The combined extracts were evaporated to dryness *in vacuo* and the residue was crystallized from ethyl acetate to give 3.4 g of 2-deuterio-2-*O*-benzyl-D-arabinose, m.p. 108–109.5°, $[\alpha]_D$ −71.5 (*c*, 1.7 in water).

The compound was dissolved in ethanol for hydrogenolysis at atmospheric pressure with 10% palladium-on-charcoal catalyst. The yield of 2-deuterio-β-D-arabinose isolated in the usual manner and crystallized from 80% aqueous methanol (30) was nearly quantitative.

2,5,5'-Trideuterio-β-D-arabinose

The compound was prepared from the above described 6,6'-dideuterio-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose by the same procedures as described for the preparation of 2-deuterio-β-D-arabinose from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose. The overall yield of material melting at 151–153° was 8%.

ACKNOWLEDGMENTS

The authors thank the Corn Products Refining Company for a generous gift of D-glucurone. The n.m.r. spectra at 60 Mc.p.s. were determined by R. Swindlehurst and Mrs. G. Conway, and those at 100 Mc.p.s. by G. Bigam of this department. The research was supported in part by the National Research Council of Canada through grant T172 to R. U. Lemieux.

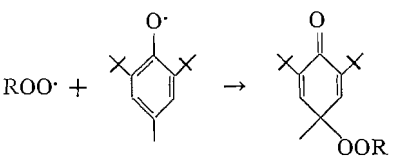
THE OXIDATION OF PHENOLS

I. THE OXIDATION OF 2,6-DI-*t*-BUTYL-4-METHYLPHENOL, 2,6-DI-*t*-BUTYLPHENOL, AND 2,6-DIMETHYLPHENOL WITH PEROXY RADICALS[1]

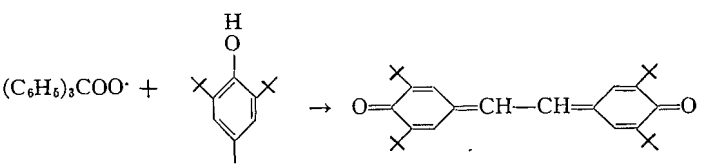
E. C. HORSWILL AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada



Received September 24, 1965

ABSTRACT

Previous work on the oxidation of alkyl phenols with peroxy radicals is summarized. The yields of the peroxy-cyclohexadienones formed from 2,6-di-*t*-butyl-4-methylphenol in the α,α'-azo-bis-isobutyronitrile-initiated oxidation of tetralin at 40 °C have been measured quantitatively. The results suggest that not all the oxidation chains are initiated by isobutyronitrile peroxy radicals.



The products from the oxidation of 2,6-di-*t*-butylphenol and 2,6-dimethylphenol with *t*-butyl peroxy radicals are found to be mainly dialkyl-*p*-benzoquinones and tetraalkyl diphenoquinones.

Although the kinetics of the phenol – peroxy radical reaction[2] have been investigated intensively in recent years, comparatively little attention has been paid to the products of this reaction. About 10 years ago the products from 2,4,6-trialkyl phenols were examined by several groups of workers (1–6), but there has been very little activity in this field since that time. Peroxy radicals generated by the cobalt-catalyzed decomposition of hydroperoxides (1, 2) or by the thermal decomposition of compounds such as α,α'-azo-bis-isobutyronitrile (AIBN) in the presence of oxygen (2, 3) generally gave mainly 4-peroxy-cyclohexadienones (1–3), the yields of which depended upon the phenol, the peroxy radical, and the experimental conditions. Extremely high yields approaching 100% were obtained with 2,6-di-*t*-butyl-4-methylphenol (BMP) and *t*-butyl peroxy radicals. After the initial abstraction of the phenolic hydrogen (cf., however, ref. 7), the reaction can be represented, for example, as

I

Under certain conditions phenols containing a *p*-methyl group gave stilbenequinones (e.g. see ref. 2),

II

This product is formed from two phenoxy radicals by a very complicated sequence of reactions (8). The less highly oxidized dihydroxy bibenzyl dimers have been isolated after

[1]*Issued as N.R.C. No. 8757.*
[2]*That is, the kinetics for the inhibition of hydrocarbon autoxidation by phenols.*

the high-temperature air oxidation of hydrocarbons retarded with phenols containing a *p*-methyl group, e.g. 2,6-di-*t*-butyl-4-methylphenol (4, 5), 2-*t*-butyl-4,6-dimethylphenol (5), and 2,4,6-trimethylphenol (5). With a *n*-alkyl group in the para position trialkyl phenols generally give 4-hydroxyaryl ketones (6).

In contrast to the wealth of information on trialkyl phenols only two di- and one mono-alkyl phenol have been examined. When cumene was oxidized, Moore and Waters (5) identified traces of 2,2′-dihydroxy diphenyls from *p*-cresol and 2,4-dimethylphenol, while 2,6-dimethylphenol gave the tetramethyl 4,4′-dihydroxy diphenyl and 4,4′-diphenoquinone (see also ref. 9).

Our interest in this subject arose from our studies of the kinetics of the inhibition of hydrocarbon autoxidation by phenols (10). In particular, we felt that more information on the products from phenols other than trialkyl phenols would be a great help in further elucidating the overall mechanism of this reaction. The present paper describes the products formed by the *t*-butyl peroxy radical oxidation of two dialkyl phenols, 2,6-di-*t*-butyl- and 2,6-dimethyl-phenol. In addition, the development of a thin-layer chromatographic (t.l.c.) method for separating and tentatively identifying oxidation products prompted us to look for a compound having structure I under the conditions actually employed in kinetic studies of inhibition. That is, no compound of this structure in which R is derived from an oxidizing hydrocarbon RH has ever been identified. The actual formation of such a product is of importance in connection with the assumptions involved in determining rates of chain initiation by the induction-period method of Boozer *et al.* (3). That is, rates of chain initiation in hydrocarbon autoxidation are generally determined by measuring the induction period produced by small quantities of BMP (3, 10), it being assumed that each molecule of the phenol reacts with just *two* peroxy radicals (see, however, ref. 11). This plausible assumption is based on the identification of 2,6-di-*t*-butyl-4-methyl-4-peroxy-isobutyronitrile-2,5-cyclohexadiene-1-one (I, R = $(CH_3)_2(CN)C$, hereafter referred to as IBN-1) after the decomposition of AIBN in chlorobenzene containing BMP in the presence of oxygen (3).

A somewhat better justification for this assumption is provided by the present results on the products formed from BMP during the oxidation of tetralin at 40 °C under conditions fairly typical of those normally used in induction-period studies. The reaction mixture in these experiments consisted of 3 ml of tetralin and 10 ml of chlorobenzene with 2.7×10^{-4} mole/l BMP and 0.66 g (2.94×10^{-1} mole/l) AIBN. The oxygen absorption curve is shown in Fig. 1. The induction period is 2 760 s, giving an efficiency of chain initiation, e, equal to 0.64. (The rate constant, k_1, for AIBN decomposition at 40 °C was taken to be 5.2×10^{-7} s^{-1}.) The reaction was stopped at various times between 3 600 and 5 500 s, since all the BMP should by now be consumed as the oxidation rate is equal to its uninhibited value. Work-up of the reaction mixtures for t.l.c. analysis is described in the Experimental section. The t.l.c. plates showed three well-resolved spots travelling ahead of a long streak which started at the origin and is due to residual AIBN and tetralin hydroperoxide. The spot with the largest R_f is formed from AIBN and chlorobenzene rather than from BMP or tetralin. The second spot corresponded in position to the expected α-tetralyl peroxy derivative of BMP (hereafter referred to as TET-1). Positive identification was achieved by extracting this spot (from a large sample) with CCl_4 and comparing its infrared spectrum with that of an authentic sample prepared by the method of Bickel and Kooyman (2). The third spot, which was relatively weak, corresponded in position to IBN-1. There was no spot corresponding to the stilbenequinone nor to either its di- or tetra-hydro derivatives. The yield of TET-1 was estimated by running the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture and several standard solutions on the same thin-layer sheet. The chromatogram was photographed and analyzed with a photodensitometer, as this proved to be more satisfactory than direct measurement on the chromatogram (see Experimental section). There was an excellent straight-line relation between the sample weight and the area under the densitometer curve in the range of concentrations from 5 to 40 g/l. From this calibration line the best estimate of the yield of TET-1 (based on the starting phenol) was 86 ± 10% (standard deviation) at 3 600 s and 84 ± 5% at 5 500 s. The IBN-1 spot was too faint for this method to be applied. Its yield was estimated to be 10 ± 3% by visual comparison with spots from solutions of known strength. The overall yield of compounds with structure I is, therefore, ~95 ± 10%. This provides a sound justification for the assumption that each molecule of BMP reacts with two peroxy radicals under normal kinetic conditions.

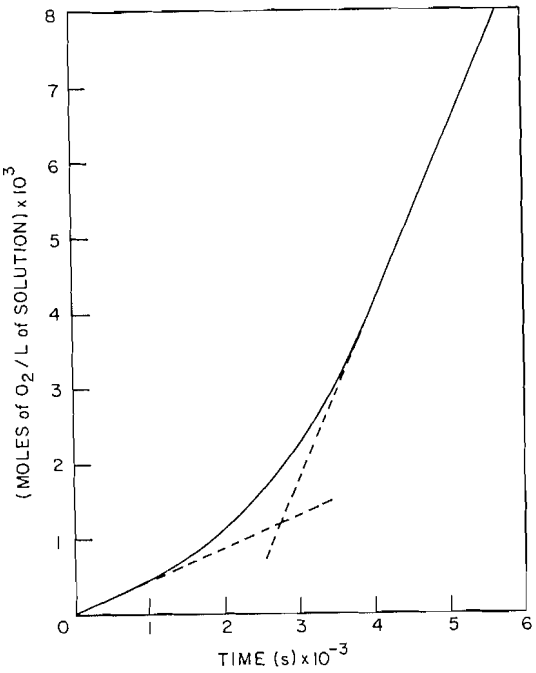


FIG. 1. Oxygen absorption by 3 ml tetralin in 10 ml chlorobenzene with 0.66 g AIBN and 2.7×10^{-4} mole/l BMP at 40 °C.

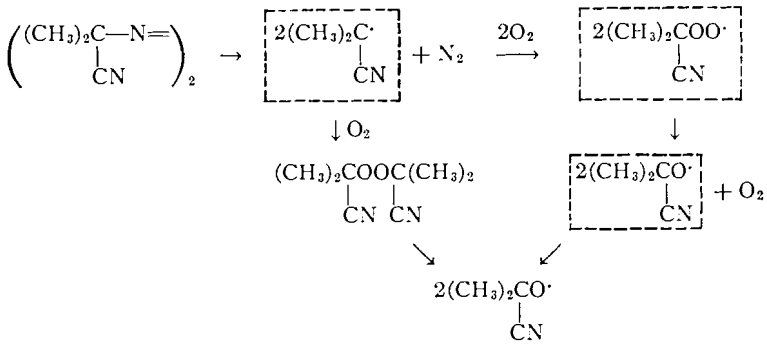

The relative yields of IBN-1 and TET-1 can roughly be predicted by comparing the rate of chain initiation ($2ek_1$[AIBN] = 2×10^{-7} mole/l s) with the amount of oxygen absorbed at the point where the rate reaches its uninhibited value (i.e. 3.10×10^{-3} mole/l at 3 600 s).[3] If the rate of isobutyronitrile peroxy radical production is equal to the rate of chain initiation, then $2 \times 10^{-7} \times 3\,600 = 7.2 \times 10^{-4}$ mole/l of these radicals was formed by the end of the induction period. Since 3.1×10^{-3} mole/l of α-tetralyl peroxy radicals was formed in this time, the expected yield of TET-1 is (3.1/3.1 + 0.72) × 100 = 81%, and of IBN-1 (0.72/3.82) × 100 = 19%. The fact that only about half the expected IBN-1 was formed indicates that fewer isobutyronitrile peroxy radicals

[3]*The measured change in gas volume amounts to* 3.25×10^{-3} *mole/l. This must be corrected for nitrogen evolution by the AIBN and oxygen absorption by the initiator radicals (10). This correction is* $-(2e - 1)k_1$[*AIBN*] $\times$ 3 600 $= -0.15 \times 10^{-3}$ *mole/l.*

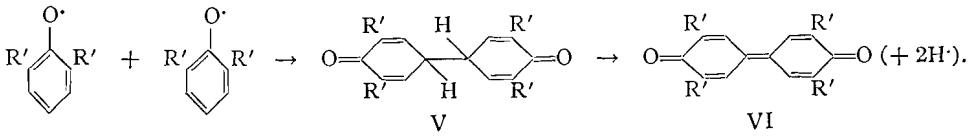
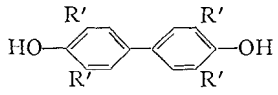
are involved in the main reaction sequence than is suggested by this simple calculation, since it seems unlikely that these radicals would add to the phenoxy radical any less readily than α-tetralyl peroxy radicals. A possible explanation for the low yield of IBN-1 is that two isobutyronitrile peroxy radicals can frequently be formed while they are still in the same solvent cage in which their precursors were produced. Mutual interaction would give two tertiary alkoxy radicals, which could both initiate oxidation but probably could not add to the phenoxy radical (cf. the reaction of *t*-butoxy radicals with this phenol (12)). An alternative possibility would be the formation of an unstable peroxide from a single molecule of oxygen and its subsequent decomposition to the same two alkoxy radicals. That is,

In this connection, the yield of IBN-1 in the absence of tetralin, but otherwise under the same experimental conditions, was only 62 ± 4% at 3 600 s and 71 ± 4% at 5 500 s, which also suggests that BMP is a relatively ineffective trap for the radicals formed from AIBN and oxygen.



The 2,6-di-*t*-butylphenol and 2,6-dimethylphenol were oxidized by the method of Bickel and Kooyman (2). That is, 0.1 mole of *t*-butyl hydroperoxide in 50 ml of benzene containing 0.05 mole of the phenol was catalytically decomposed by the slow addition of powdered cobalt toluate, the temperature being kept below 30 °C. Unfortunately, this simple procedure does not give very reproducible product yields. However, this disadvantage is more than offset when unstable products are formed by the low temperature of the reaction. After all the hydroperoxide had been decomposed, the products were separated by column chromatography on silica gel, mixtures of hexane, benzene, and ethyl acetate being used as eluents. Every fraction was checked for purity by t.l.c. on silica before being worked up for the products.

The principal products from 2,6-di-*t*-butylphenol and 2,6-dimethylphenol result from two competing radical coupling reactions. That is, the initially formed phenoxy radical can react with either a peroxy radical



III

or a second phenoxy radical

V VI

The 2,6-dimethylphenol–hydroperoxide solution turns the deep red color characteristic of diphenoquinones (VI) almost immediately after the addition of the cobalt catalyst. In contrast, the 2,6-di-*t*-butylphenol–hydroperoxide solution turns only light yellow, which is characteristic of *p*-benzoquinones (IV), although gas chromatography shows that all the starting phenol has been consumed. This yellow color very gradually darkens and finally becomes a deep red after several hours. This suggests that the tetra-*t*-butyl VI is not formed by the direct oxidation of V under these conditions.[4] Instead, this keto compound must first rearrange to its enol tautomer, the bis-phenol V*a*.

V*a*

This rearrangement is catalyzed by the *t*-butanol formed in the oxidation (cf. refs. 13 and 14). The bis-phenol is then oxidized to VI by the peroxy radicals. The rearrangement of V to V*a* must be a much faster process for the methyl than for the *t*-butyl compound. It is therefore not surprising that, although tetra-*t*-butyl V was a minor product (~1%) from 2,6-di-*t*-butylphenol, none of the tetramethyl compound was isolated or identified from 2,6-dimethylphenol. Compound III was not identified in either case, but its similarity to I provides a logical path for the production of the *p*-benzoquinone IV.

The relative importance of IV and VI in the products depends on the nature of the alkyl group. The dimethylphenol yields approximately 12% IV[5] and up to 75% VI, whereas the dibutylphenol yields approximately 59% IV and 31% VI. The higher yield of IV in the latter case can probably be attributed to the greater stability of the 2,6-di-*t*-butyl phenoxy radical. Both phenols also gave some brown polymeric material and a few additional crystalline products that were not isolated in sufficient quantity for identification.

EXPERIMENTAL

2,6-Di-t-butyl-4-methylphenol

When the oxidation was stopped after the rate had reached its uninhibited value, the reaction mixture was placed overnight in a freezer at −30 °C to crystallize the unreacted AIBN. After filtration the tetralin and chlorobenzene were removed under high vacuum with gentle warming. The semisolid residue, which consisted mainly of unreacted AIBN and tetralin hydroperoxide, was extracted with 5–10 ml of cold *n*-hexane (in which both these compounds are very insoluble). The hexane was removed under vacuum, and the very small oily residue was dissolved in toluene and made up to 0.1 ml. Handling losses were probably not more than 2–3% unless some compound was strongly adsorbed on the surface of the AIBN crystals.

A 1 μl sample of the toluene solution was spotted on an Eastman Chromagram sheet (with fluorescent indicator) along with the same volumes of three known concentrations of TET-1 (e.g. 5, 10, and 20 g/l). After t.l.c. was carried out in trichloroethylene, a transverse strip of the TET-1 spots was excised and evaluated on a Spinco model R Analytrol. This instrument was modified by using the ultraviolet light source to excite the fluorescent strip and the visible-sensitive photocell as the detector. To reduce the visible light from

[4]*However, the tetra-t-butyl V does inhibit the α,α′-azo-bis-isobutyronitrile-initiated oxidation of cumene at 65 °C. This inhibition may be due to the promotion by the higher temperature of either an isomerization to V*a* or a direct reaction of V with peroxy radicals.*

[5]*All product yields are based on the percentage conversion of the starting phenol.*

the source a Corning 7-54 filter was used between the light and fluorescent strip. The sensitivity of this method was later increased by photographing the uncut fluorescent chromatogram under ultraviolet light. An enlarged positive transparency was then prepared, cut into strips lengthwise, and evaluated in the Analytrol in visible light, to which the machine is more sensitive.

The average of triplicate (three t.l.c.) determinations of the yield of TET-1, based on the starting phenol concentration, was 86 ± 10% after 3 600 s and 84 ± 5% after 5 500 s. In the absence of tetralin the yield of IBN-1 (t.l.c. in benzene) was 62 ± 4% after 3 600 s and 71 ± 4% after 5 500 s.

The IBN-1 and TET-1 were both prepared by the methods of Bickel and Kooyman (2). The purified materials melted at 92–93.5° (lit. m.p. 92.5° (2) and 91–92° (3)) and 105–106.5° (lit. m.p. 104°(2)) respectively.

2,6-Dimethylphenol

The precipitate of reacted cobalt and of most of the deep red compound VI was filtered and weighed. Benzene was removed from the filtrate under vacuum. The residue was eluted through a 4 ft silica column with mixtures of benzene and ethyl acetate; the fractions were automatically collected in the order IV, VI, and *p*-toluic acid from the cobalt catalyst. Compounds IV and VI were identified by comparison with authentic samples of these compounds by means of melting point, mixed melting point, and X-ray powder pattern. The yield of IV was confirmed by gas–liquid chromatography on a polyester succinate column at 185 °C.

2,6-Di-t-butyl-phenol

The cobalt precipitate was filtered off and the benzene removed under vacuum. The products were eluted in the order V, VI, IV, and *p*-toluic acid. The products were identified by comparison with authentic samples by means of melting point, mixed melting point, X-ray powder pattern, and infrared spectra. Authentic V was prepared by the oxidation of 2,6-di-*t*-butylphenol with silver oxide (14). The melting point is 152–156° (lit. m.p. 151–152° (13, 14)); at 156° there is a sudden dendritic growth of red crystals of VI which do not melt until 249°. In separate experiments, it was shown that, at its melting point, V decomposed to VI and 2,6-di-*t*-butylphenol. The infrared spectrum of V shows the doublet characteristic of *p*-quinolides at 1 637 and 1 661 cm^{-1}, and the nuclear magnetic resonance spectrum of V shows protons with chemical shifts (in parts per million to low field of tetramethylsilane) of 1.18 (*t*-butyl), 3.36 (4H), and 6.33 (3H and 5H).

THE OXIDATION OF PHENOLS

II. THE OXIDATION OF 2,4-DI-*t*-BUTYLPHENOL WITH PEROXY RADICALS[1]

E. C. HORSWILL AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received September 24, 1965

ABSTRACT

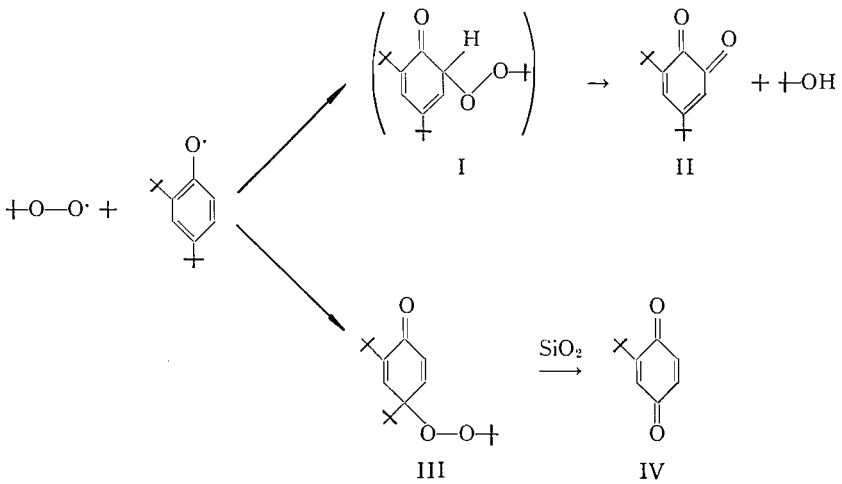
Ten products from the oxidation of 2,4-di-*t*-butylphenol with *t*-butyl peroxy radicals have been identified. They can be subdivided into three groups, depending on the type of radical–radical coupling reaction by which they are produced or in which their precursors are formed: (*i*) phenoxy–peroxy coupling, (*ii*) phenoxy–phenoxy coupling at the 6 positions, and (*iii*) phenoxy–phenoxy coupling through the oxygen atom of one radical and the 6 position of the second radical. Products resulting from still other phenoxy–phenoxy coupling reactions are undoubtedly formed in minor amounts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

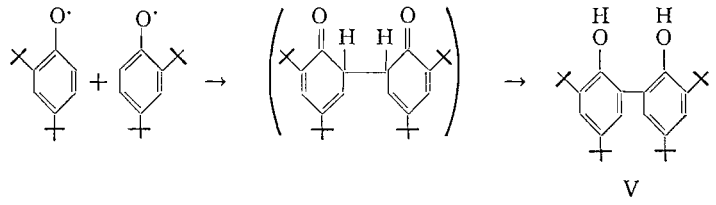
The products from the oxidation of 2,4-di-*t*-butylphenol with *t*-butyl peroxy radicals have been studied as a part of our general investigation into the oxidation of phenols (1). This compound was chosen as a representative 2,4-dialkyl phenol which might be expected to give a simpler mixture of products than a phenol containing a methyl group, since products coupled through the methyl group (such as dihydroxy bibenzyls and stilbenequinones) would not be formed. In spite of this simplification no less than 10 products were identified, and the thin-layer chromatographic (t.l.c.) plates showed that many others were present. The products were separated by column chromatography on silica (1). Their relative yields depended not only on the exact conditions of the reaction but also on the speed with which they were separated. The latter variation is due to the fact that many of the initial products are unstable peroxides which decompose on exposure to light and heat and even to the mildly acidic silica column itself.

By analogy with 2,6-dialkyl phenols (1) we may expect to get products resulting from phenoxy–peroxy and phenoxy–phenoxy radical coupling reactions. However, in the present case, the existence of a hydrogen atom in the 6 position leads to products of increased complexity because of the rapid rearrangement of those intermediates with an *o*-quinolide structure. For convenience, the overall reaction is divided into three parts.

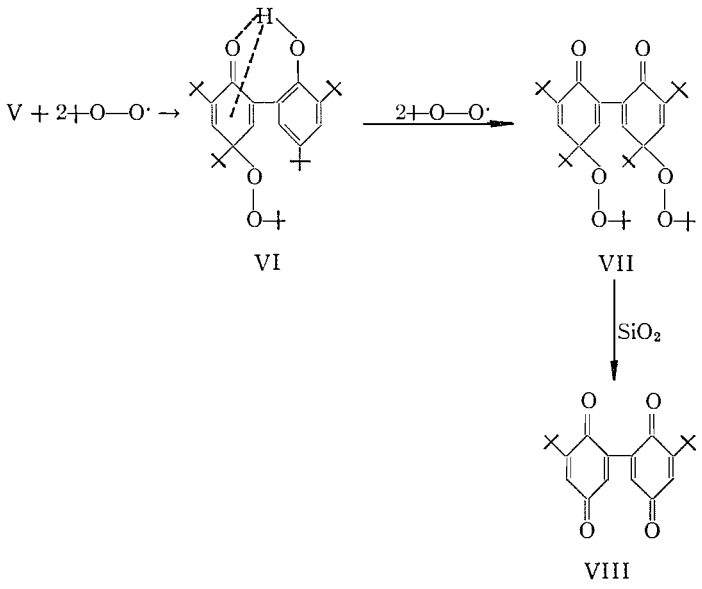
Firstly, combination of the initially formed phenoxy radical with a *t*-butyl peroxy radical.



3,5-Di-*t*-butyl-*o*-benzoquinone (II) was one of the major products (~10%), but its probable precursor (I) was not identified. The conversion of I into II may occur either directly (cf. ref. 1) or after rearrangement to an *o*-peroxy phenol. The 4-peroxy-cyclohexadienone, III, found in 5–10% yield, is similar to the major products formed from 2,4,6-trialkyl phenols (1). Compound III decomposed slowly on the t.l.c. plates to give 2-*t*-butyl-*p*-benzoquinone (IV) and other unidentified products. No compound corresponding to the addition of the peroxy radical at the 2 position of the original phenol was identified, nor was its expected decomposition product, 4-*t*-butyl-*o*-benzoquinone, detected.



Secondly, combination of two phenoxy radicals through their carbon atoms in position 6.



The biphenol V and its precursor were not identified among the products under the standard experimental conditions, that is, with a ratio of not less than 2 moles of hydroperoxide per mole of phenol. However, in a separate experiment with only 1 equivalent

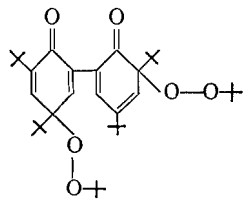
of hydroperoxide, compound V was isolated in 37% yield. The yield of VI varied from about 12% for a 2:1 hydroperoxide–phenol ratio to less than 1% for a 3:1 ratio, there being a corresponding increase in the yield of VII and, hence, VIII. These variations suggest that the phenolic hydrogen in VI is much less readily abstracted by peroxy radicals than is the first phenolic hydrogen in V or the hydrogen in the starting phenol. This conclusion is supported by the infrared spectrum of VI, which indicates that the hydroxyl group is not "free" but is involved in *two* intramolecular hydrogen bonds. That is, the spectra in the OH fundamental stretching region shows two bands, the frequencies of which correspond to the formation of hydrogen bonds with the cyclohexadienone ring and with the quinone oxygen (see Experimental section). A hydrogen-bonded OH group is much less readily attacked than a "free" OH group (2); therefore, VI is a relatively unreactive phenol. The maximum yield of VII (slightly less than 10%) was isolated from a reaction with a 3:1 hydroperoxide–phenol ratio. This compound decomposes rather readily on the silica column to give VIII. For instance, in the course of one experiment where a product initially containing ~10–12% VII remained on a column for several weeks, the separated products contained less than 1% VII but over 10% VIII. No attempt was made to identify or to isolate the corresponding decomposition product from VI, but it is undoubtedly present and responsible for one of the many unidentified spots on the t.l.c. analytical plates.

The basic carbon skeleton in VI and VII was confirmed by their preparation in high yield by the cobalt-catalyzed oxidation of V with 2 moles and 4 moles of *t*-butyl hydroperoxide, respectively. The biphenol itself was prepared by the oxidative coupling of 2,4-di-*t*-butylphenol in the presence of sodium hydroxide (3). The two tautomers, IX and X, resulting from the removal of only the two phenolic hydrogen atoms, were also prepared from V by its oxidation with silver oxide. Compound IX was not isolated from

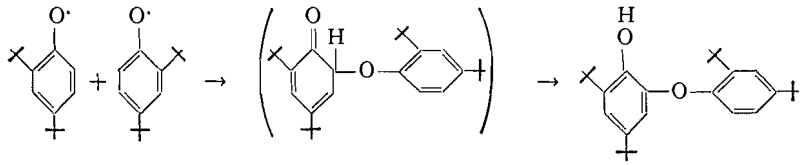
IX



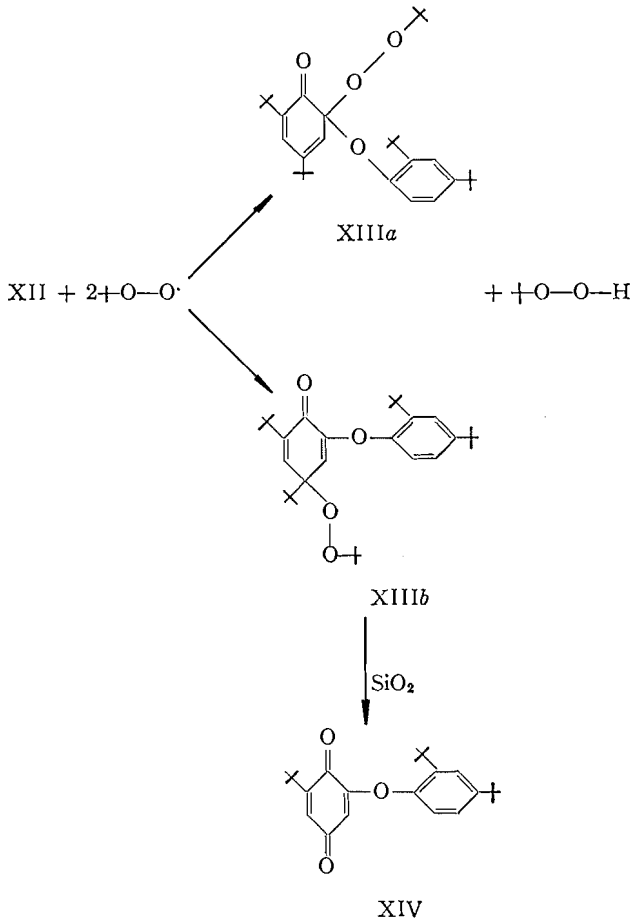
X

solution, but its presence was inferred by the rather stable, deep blue color of the products (cf. refs. 4 and 5). It rearranges to X slowly in ether or benzene but extremely rapidly in methanol or ethanol. The preparation of X by the oxidation of V with $K_3Fe(CN)_6$ and with 2,6-di-*t*-butyl-4-cyanophenoxy radicals has been described by Müller *et al.* (5). The absence of IX (by color) and X (by a spot test comparison on a t.l.c. plate) from the peroxy radical oxidation products of 2,4-di-*t*-butylphenol under the usual experimental conditions emphasizes the fundamental difference between oxidation with reagents that can add to the initial phenoxy radical and those which cannot.

Compound VIII was shown to be identical with the product obtained by the oxidation of 4,4′-dimethoxy-6,6′-di-*t*-butyl-*o*,*o*′-biphenol with chromium trioxide (6) and nitric acid (7). This dimethoxy biphenol was prepared by the oxidative coupling of 2-*t*-butyl-4-methoxyphenol with silver oxide.



A product which appears to be isomeric with VII, except that the two rings are not equivalent, was also isolated in extremely small yield. Although it was not detected on the t.l.c. plates on which the raw product mixtures from the reaction of V with *t*-butyl peroxy radicals were run, its nuclear magnetic resonance spectrum suggests that it probably has



XI

structure XI. The apparent absence of XI from these t.l.c. plates could be due to its low yield in the reaction, since minor products are, in general, not readily detected by thin-layer chromatography of raw products because of the streaking of the major components when the sample is heavily spotted.

Thirdly, combination of two phenoxy radicals through the oxygen atom of one of them to give a 2-hydroxy diphenyl ether (XII).

XII

XIV

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

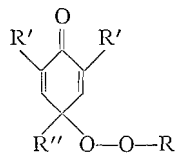
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

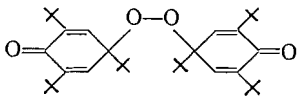


The phenol XII and its precursor were not identified, but its oxidation product XIII appears to be one of the major components in the reaction mixture (~20%). The yield of XIV was less than 5%. There is a slight doubt about whether the peroxy radical in XIII is in the *a* (ortho) or *b* (para) position, since this compound does not have a double band at around 1 667 cm^{-1} (6 μ) in its infrared spectrum. This doublet has generally been considered to be a characteristic feature in the spectra of *p*-quinolides (see below), so that its absence would seem to favor structure XIII*a*. However, most of the remaining evidence, including the nuclear magnetic resonance spectrum, certain other infrared bands, and the conversion of XIII into XIV thermally or on the silica column, favors structure XIII*b*. The detailed evidence relating to the structure of these and other products is given below. An attempt to synthesize XII by an Ullman condensation of 2,4-di-*t*-butyl-6-bromophenol or 2,4-di-*t*-butyl-6-bromoanisole with 2,4-di-*t*-butylphenol was unsuccessful, yielding V as the only crystalline product (cf. ref. 8).

The reaction schemes given above provide an obvious explanation for the occurrence of many spots on the t.l.c. plates which were not correlated with any particular compound. It is obvious, for example, that the peroxy radicals in VI and VII could also add to either ortho position or, alternatively, phenoxy radicals could add to V to give similar types of addition compounds. Even if we neglect all the products formed by the decomposition of the primary peroxides and all the products resulting from the combination of V and XII via their phenoxy radicals, we can calculate that over 40 primary products could be formed in the reaction. We have identified only seven of these (i.e. II, III, V, VI, VII, XIII, and, tentatively, XI), together with three secondary products (i.e. IV, VIII, and XIV).

Assignment of Structure

Structural assignments were based mainly on a comparison of the nuclear magnetic resonance, ultraviolet, and infrared spectra of the products with those of model compounds.



The nuclear magnetic resonance spectra of a number of model compounds were examined in carbon tetrachloride solution containing tetramethylsilane as an internal reference. A Varian Associates high-resolution spectrometer was used at an operating frequency of 100 Mc. The magnitudes of the chemical shifts for the *t*-butyl group (in parts per million to low field of tetramethylsilane) are as follows: (*a*) in six phenols the *t*-butyl group at the 2 or 2 and 6 positions was in the range 1.30–1.50, and at the 4 position was in the range 1.20–1.37; (*b*) in two *o*- and two *p*-quinones 1.20–1.30; (*c*) in *t*-butyl peroxide and hydroperoxide 1.18–1.24; (*d*) in 4-alkyl-4-peroxy-cyclohexadienones with the structure

XV

for R′ = *t*-butyl, 1.15–1.25, for R″ = CH_3 and R = $(CH_3)_2(CN)C$, α-tetralyl, and *t*-butyl, (1.16). The shift for the CH_3 group changes from 2.20 in the original phenol to 1.25–1.40 in these three dienones. For R′ = R″ = R = *t*-butyl, the assignments were 1.25, 0.95, and 1.22, respectively. These four compounds were all prepared by the method of Bickel and Kooyman (9).

We also attempted to prepare bis(1,3,5-tri-*t*-butyl-2,5-cyclohexadien-4-one) peroxide (XVI) by the oxidation of 2,4,6-tri-*t*-butylphenol with silver oxide in the presence of oxygen (10). Recrystallization of the raw product from methanol gave yellowish crystals,

XVI

m.p. 142–148° (lit. m.p. 148–149° (10, 11)). This melting point was not improved by a further recrystallization from ethanol. The nuclear magnetic resonance spectrum showed three peaks in the *t*-butyl region, the main one at 1.25 and two smaller bands at 0.85 and 0.79 present in a ratio of roughly 5:2:1, respectively. The ultraviolet spectrum had a maximum in the absorption at 317 mμ as well as the expected maxima at 385 and 238 mμ (see below). The band at 317 mμ suggested the presence of a compound with an *o*-quinolide structure (9). Thin-layer chromatography showed that three products were present. These correspond, in order of importance, to products coupled at the 4,4′; 4,2′; and 2,2′ positions (12). These products were not separated in bulk for complete characterization.

The data given above show that there is considerable overlap in the range of chemical shifts for *t*-butyl groups in different positions in these types of compounds. However, the results do suggest that a shift of 1.10 or less will generally be due to a *t*-butyl-peroxy-cyclohexadienone in which the *t*-butyl group and the peroxy group are both attached to the same carbon atom[2] (e.g. XV with R″ = *t*-butyl). The small shifts for CH_3 groups in this position also support this generalization.

In agreement with the results of Bickel and Kooyman (9), the ultraviolet spectra of all four model 4-peroxy-cyclohexadienones showed a distinctive, though rather weak ($\epsilon \sim 25$), absorption band at around 365 mμ and a much stronger absorption at ~235 mμ. In contrast, the oxidation products rarely showed a distinctive band at 365 mμ, although there was often a hump or shoulder on the side of a much stronger absorption. Several products also showed a maximum or a shoulder at ~280 mμ characteristic of an aromatic ring. None of the products had an absorption maximum at ~310 mμ which is probably characteristic of 2-peroxy-cyclohexadienones (9), although XI does have a band at 296 mμ which is fairly near this frequency.

The infrared spectra of many compounds with a *p*-quinolide structure show a characteristic double band at about 1 667 cm^{-1} (6.0 μ), generally with a separation of about 20 cm^{-1} between the bands. There are many examples of this feature in the literature both for 4-peroxy-cyclohexadienones (e.g. refs. 9, 14, 15) and, chiefly as a result of the extensive investigation into phenol oxidation by Müller, Ley, Rieker, and co-workers, for 4-oxy-cyclohexadienones (e.g. refs. 7, 13, 16, 17).[3] These workers also noted that bands at ~1 250 and ~1 000 cm^{-1} seemed to be characteristic of this structure (16). We have confirmed the presence of the 6 μ doublet in each of our four model 4-peroxy-cyclohexadienones, but the bands at ~1 250 and ~1 000 cm^{-1} were too variable in frequency and intensity to be very useful diagnostically. However, XV, with *t*-butyl groups at R, R′, and R″, had a strong absorption band at 975 cm^{-1} which was not present in the other

[2]*This rule is not always obeyed, as the nuclear magnetic resonance spectrum of the trimer of 2,5-di-t-butyl-4-methoxyphenol (13) has a t-butyl group with a shift of only 0.97. We are deeply indebted to Dr. Anton Rieker for a generous sample of this trimer.*

[3]*Only one exception to this general rule has so far been observed. That is, 2,6-di-t-butyl-4-triphenylmethyl-4-pentachlorophenoxy-2,5-cyclohexadien-1-one has only a single band at 1 680 cm^{-1}. However, it is possible that this compound was actually the o-quinol ether (17).*

For personal use only.

three compounds with structure XV. A strong band at 977 cm^{-1} is also present in XVI, and we therefore attribute this band to the 4-*t*-butyl-4-(per)oxy-cyclohexadien-1-one structure.

Although the presence of only a single 6 μ band in XIII (at 1 655 cm^{-1}) argues against the *b* structure, the presence of a fairly strong band at 993 cm^{-1} favors this structure. Structure *b* is also supported by the small shift (1.05) for one of the five *t*-butyl bands in the nuclear magnetic resonance spectrum of XIII and by its ultraviolet spectrum (shoulders at 382 and 365 mμ and maxima at 289 and 242 mμ). These results suggest that the 6 μ doublet is not a required feature in the infrared spectra of *p*-quinolides.[4]

The structure of XI is very uncertain. The small chemical shifts (1.00 and 1.08) for two of the six *t*-butyl groups suggest that the peroxy radicals have added to carbon atoms with *t*-butyl substituents. This is also suggested by the strong band at 965 cm^{-1} in the infrared spectrum of XI. However, it is rather surprising that there is only one moderately strong band in the 6 μ region, the one at 1 700 cm^{-1}. The ultraviolet spectrum of XI is quite similar to the spectra of a number of *p*-quinol ethers derived from 2,4,6-tri-*t*-butylphenol (16). Structure XI is suggested here mainly because the carbon and hydrogen analyses and molecular weight data are virtually the same as those for compound VII, while the nuclear magnetic resonance spectrum shows that the *t*-butyl groups on the two rings are not equivalent.

EXPERIMENTAL

The cobalt-catalyzed decomposition of *t*-butyl hydroperoxide in the presence of phenols has been described previously (1). The products were eluted from a silica column with hexane, benzene, and ethyl acetate in the following order: V, VI, XIII, XI, XIV, VII, III, VIII, II. Unless otherwise stated the infrared spectra were measured in KBr pellets. The molecular weights were measured in benzene on a Mechrolab vapor pressure osmometer. All melting points were measured on a Kofler hot stage.

3,5-Di-t-butyl-o-benzoquinone (II)

Formed in about 10% yield based on the amount of 2,4-di-*t*-butylphenol reacted. Dark red needles from benzene, m.p. 116.5–117°. Identical (by mixed melting point and X-ray powder crystallography) with an authentic sample prepared by oxidizing 3,5-di-*t*-butylcatechol with Ag_2O.

2,4-Di-t-butyl-4-t-butylperoxy-2,5-cyclohexadien-1-one (III)

Formed in 5–10% yield. White needles from MeOH, m.p. 60.8–61.3°, decomposition with evolution of gas at 140°. This compound can be sublimed without decomposition under high vacuum. Infrared spectrum: bands at 1 672, 1 645, and 975 cm^{-1}. Ultraviolet spectrum: shoulder at 365 mμ, maximum at 230 mμ. Nuclear magnetic resonance spectrum: *t*-butyl groups at 0.97 (1) and 1.17 (2), several aromatic protons between 5.90 and 6.72. Gives IV on decomposition on the silica t.l.c. plates.

Anal. Calcd. for $C_{18}H_{30}O_3$: C, 73.43; H, 10.27; mol. wt. 294.4. Found: C, 73.37; H, 10.27; mol. wt. 293.

2-t-Butyl-p-benzoquinone (IV)

An authentic sample was prepared by oxidizing 2-*t*-butyl hydroquinone with Ag_2O. Yellow needles from hexane, m.p. 58.5–59°.

4,4',6,6'-Tetra-t-butyl-o,o'-biphenol (V)

Synthesized by the air oxidation of the sodium salt of 2,4-di-*t*-butylphenol (3). White needles from MeOH, m.p. 200–201°.

This compound was also prepared by the cobalt toluate catalyzed decomposition of 0.09 g of *t*-butyl hydroperoxide in 0.4 ml benzene containing 0.2 g 2,4-di-*t*-butylphenol. Recrystallization from methanol yielded 74 mg (37%) V, m.p. 199–200.5°.

2,4-Di-t-butyl-4-t-butylperoxy-6,6'-(2,4-di-t-butylphenol)-2,5-cyclohexadien-1-one (VI)

The yield depends on the initial hydroperoxide–phenol ratio (see text). Yellow needles from MeOH, m.p. 136–139° (decomp.). These yellow crystals turn green in a few minutes on exposure to light. Infrared spectrum: bands at 1 657, 1 630, and 980 cm^{-1}. There is also a strong hydrogen-bonded OH band at about

[4]*The absence of the doublet is not simply due to the presence of an aryloxy group in the ortho position, since the 2,5-di-t-butyl-4-methoxyphenol trimer has the usual type of spectrum with bands at 1 663 and 1 677 cm⁻¹.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

3 230 cm^{-1} and a much weaker hydrogen-bonded band at about 3 500 cm^{-1}. In CCl_4 the bands are at 3 495,[5] 3 224, 1 658, 1 635, and 970 cm^{-1}. The ratio of the intensities of the two OH bands in CCl_4 is unaffected by a change in the concentration of VI from 0.005 to 0.025 *M*. Both bands therefore involve intramolecular hydrogen bonds. Ultraviolet spectrum: shoulder at ~365 mμ, maximum at 270 and 230 mμ. Nuclear magnetic resonance spectrum: *t*-butyl groups at 1.07 (1), 1.29 (3), and 1.39 (1), other protons at 6.82–8.09. This compound is identical in all respects with the product obtained by catalytically decomposing 0.1 g *t*-butyl hydroperoxide in 1 ml benzene containing 0.2 g V.

Anal. Calcd. for $C_{32}H_{50}O_4$: C, 77.06; H, 10.10; mol. wt. 498.7. Found: C, 77.07; H, 10.18; mol. wt. 500.

6,6′-Bis-2,4-di-t-butyl-4-t-butylperoxy-2,5-cyclohexadien-1-one (VII)

The yield depends on the initial hydroperoxide–phenol ratio. White needles from MeOH, m.p. 144–147° (decomp.). Infrared spectrum: bands at 1 662, 1 650, and 981 cm^{-1}. Ultraviolet spectrum: band maxima at 365 and 236 mμ. Nuclear magnetic resonance spectrum: *t*-butyl groups at 1.05 (1), 1.19 (1), and 1.23 (1), the only other protons are at 6.73. To judge by its X-ray powder pattern, this compound appears to exist in two polymorphic forms, depending on whether it is recrystallized from MeOH or benzene. It is identical with the product obtained in over 60% yield by causing V to react with an excess of *t*-butyl peroxy radicals.

Anal. Calcd. for $C_{36}H_{58}O_6$: C, 73.68; H, 9.96; mol. wt. 586.9. Found: C, 73.41; H, 9.84; mol. wt. 586.

6,6′-Bis-2-t-butyl-p-benzoquinone (VIII)

Formed from VII on the silica column (see text). Orange-yellow needles from carbon tetrachloride – hexane, m.p. 161–162°. Infrared spectrum: single band at 1 658 cm^{-1}. Ultraviolet spectrum: band maxima at 430 and 254 mμ. Nuclear magnetic resonance: *t*-butyl at 1.30, other protons at 6.50 and 6.58. This product is identical in all respects with that obtained by the chromic acid oxidation in acetone (6) of 6,6′-di-*t*-butyl-4,4′-dimethoxy-*o,o′*-biphenol. This dimethoxy biphenol was prepared by the oxidative coupling of 2-*t*-butyl-4-methoxyphenol with silver oxide in ether. The resultant deep purple solution was reduced with sodium iodide in acetic acid. Recrystallization from benzene gave white needles, m.p. 232° (lit. m.p. 228° (4)). To a solution of 0.1 g of this biphenol in 5 ml acetone was quickly added 1.0 ml chromic acid prepared according to Bowden *et al.* (6). The addition of excess water after 1 min precipitated fine yellow needles, which were extracted with ether, washed with 1% sodium bicarbonate solution, and dried over magnesium sulfate. Filtration and evaporation gave 70 mg of yellow crystals, m.p. 149–160°, which did not contain any of the starting material. Recrystallization fron carbon tetrachloride – hexane gave 42 mg of orange needles of VIII, m.p. 161–162 °C. Compound VIII was also prepared from the dimethoxy biphenol by oxidation with nitric acid (cf. ref. 7). A sample was purified by vacuum sublimation for analysis.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79; mol. wt. 326.4. Found: C, 73.26; H, 7.08; mol. wt. 324.

2,2′,4,4′-Tetra-t-butyl-o,o′-diphenoquinone (IX)

The deep purple color of an *o,o′*-diphenoquinone (4, 5) is produced in a very short time when 0.5 g V (or 2,4-di-*t*-butylphenol) are mixed, with shaking, with 0.3 g Ag_2O in 20 ml absolute ether containing 1 g of anhydrous Na_2SO_4. The color is fairly stable in ether or benzene but is rapidly destroyed by adding methanol or ethanol. This purple color is only transiently observed when 2,4-di-*t*-butylphenol is oxidized with $K_3Fe(CN)_6$ by the method of Müller *et al.* (5). We did not attempt to isolate IX.

The Spirocyclic Quinolide Ether (X)

The deep purple solution of IX was filtered, a few drops of MeOH was added to effect the interconversion of IX into X, and the solvents were removed under vacuum. Recrystallization from MeOH gave yellow crystals, m.p. 154.0–155.5° (lit. m.p. 152–154° (5)). Infrared spectrum: relatively weak bands at 1 656, 1 638, and 1 607 cm^{-1}. Ultraviolet spectrum: shoulder at 310 mμ, maximum at 275 mμ, and the absorption increases from 260 to 220 mμ without any maximum. Nuclear magnetic resonance spectrum: four *t*-butyl groups of equal intensity at 1.19, 1.25, 1.34, and 1.46, other protons at 5.39–7.03. These data support structure X, which was originally proposed by Müller *et al.* (5).

2,4-Di-t-butyl-4-t-butylperoxy-6-(3,5-di-t-butyl-3-t-butylperoxy-4,6-cyclohexadien-2-one)-2,5-cyclohexadienone (XI)

A very minor product. White crystals from MeOH, m.p. 123.0–123.5°. Infrared spectrum: bands at 1 700 and 965 cm^{-1}. Ultraviolet spectrum: an increase in absorption from 400 to 350 mμ; the absorption then remains constant to 325 mμ, after which it rises to a maximum at 296 mμ. This is followed by a strong increase in the absorption with shoulders at ~240 and ~220 mμ. Nuclear magnetic resonance spectrum: six *t*-butyl groups at 1.00, 1.08, 1.18, 1.20, 1.24, and 1.32, other protons at 5.64 and 7.25.

Anal. Calcd. for $C_{36}H_{58}O_6$: C, 73.68; H, 9.96; mol. wt. 586.9. Found: C, 73.50; H, 9.27; mol. wt. 587.

[5]*This frequency is too low to represent a "free" phenolic hydroxyl group in* CCl_4 *(18), which suggests that it is bonded to the π electrons of the cyclohexadienone ring (see ref. 19). The* OH *stretching fundamental in V is also at about this frequency (i.e. 3 527 cm⁻¹). This suggests that each of the* OH *groups in V is hydrogen bonded to the π electrons of the opposite aromatic ring. The main* OH *band in VI at 3 224 cm⁻¹ must correspond to a hydrogen bond with the quinonoid oxygen.*

2,4-Di-t-butyl-4-t-butylperoxy-6-(2,4-di-t-butylphenoxy)-2,5-cyclohexadien-1-one (XIIIb)

One of the most important products of the reaction (~20%). White needles from MeOH, m.p. 161–164° (decomp.). Infrared spectrum: bands at 1 665 and 993 cm^{-1}. Ultraviolet spectrum: maxima at 289 and 242 mμ, shoulders at 382 and 365 mμ. Nuclear magnetic resonance spectrum: five *t*-butyl groups at 1.05, 1.10, 1.28, 1.36, and 1.46, other protons at 6.58, 7.18, and 7.98.

Anal. Calcd. for $C_{32}H_{50}O_4$: C, 77.06; H, 10.10; mol. wt. 498.7. Found: C, 77.01; H, 10.05; mol. wt. 501.

2-t-Butyl-6-(2,4-di-t-butylphenoxy)-p-benzoquinone (XIV)

A very minor product produced by the decomposition of XIII on the silica column. It is also formed by the thermal decomposition of XIII. Yellow needles (which can be sublimed under vacuum) from MeOH, m.p. 181–183°. Infrared spectrum:[6] bands at 1 679 and 1 669 cm^{-1}. There are also strong bands at 1 584 and 1 145 cm^{-1}. The last band may be connected specifically with the 2,6-disubstituted-*p*-benzoquinone structure, since VIII and 2,6-di-*t*-butyl- and 2,6-dimethyl-*p*-benzoquinone have strong bands at 1 161, 1 160, and 1 185 cm^{-1}, respectively. Ultraviolet spectrum: maxima at 380, 287, and 240 mμ, and shoulders at 262 and 247 mμ. Nuclear magnetic resonance spectrum: three *t*-butyl groups at 1.38, 1.42, and 1.54.

Anal. Calcd. for $C_{24}H_{32}O_3$: C, 78.91; H, 8.48; mol. wt. 380.5. Found: C, 78.77; H, 8.22; mol. wt. 370.

ACKNOWLEDGMENTS

The authors thank Mr. D. A. Lindsay for his help with the t.l.c. and column chromatographic separation of the products. Our thanks are also due to Dr. S. K. Brownstein for the nuclear magnetic resonance spectra, to Mr. R. Ironside for the infrared spectra, to Mr. G. R. Duval for the ultraviolet spectra, to Dr. L. D. Calvert for numerous X-ray powder photographs, and to Mr. A. E. Castagne and Mr. J. R. H. Seguin for the carbon and hydrogen analyses. We are also grateful to Dr. I. E. Puddington for his continued interest in, and encouragement of, this work.

STEREOCHEMICAL STUDIES

V. REARRANGEMENTS ACCOMPANYING ATTEMPTS TO EPIMERIZE 4-OXA-3-OXO-5α-CHOLESTANE AND 4-OXA-3-OXO-5β-CHOLESTANE BY BREWSTER AND KUCERA'S METHOD

W. H. LUNN[1] AND J. T. EDWARD
Department of Chemistry, McGill University, Montreal, Quebec

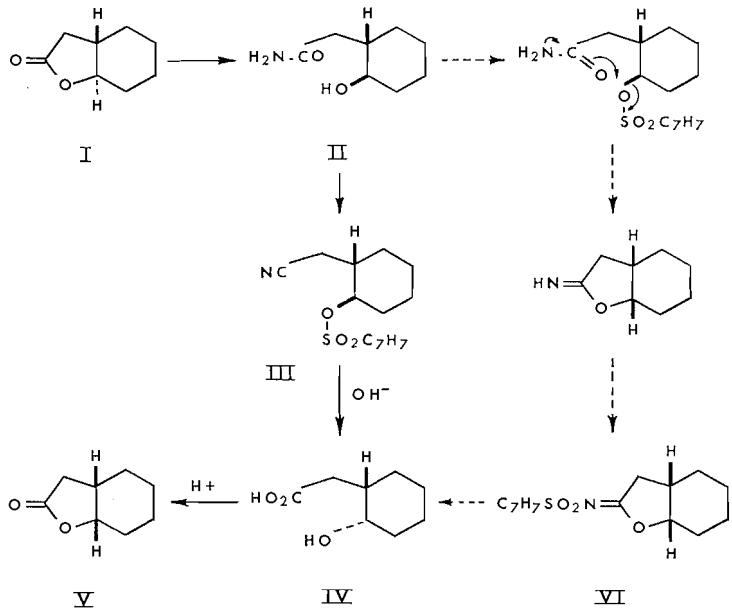
AND

SEYMOUR MEYERSON
Research and Development Department, American Oil Company, Whiting, Indiana

Received August 5, 1965

ABSTRACT

Epimerization of 4-oxa-3-oxo-5α-cholestane by Brewster and Kucera's method gave only a 23% yield of the 5β-lactone; several other compounds were formed, apparently via skeletal rearrangement during hydrolysis of the tosylate. The attempted epimerization of 4-oxa-3-oxo-5β-cholestane gave mainly unsaturated acids, but no 5α-lactone (a small amount of skeletal rearrangement also occurred). Both epimers undergo rearrangement to γ-lactones when treated with trifluoroacetic acid.



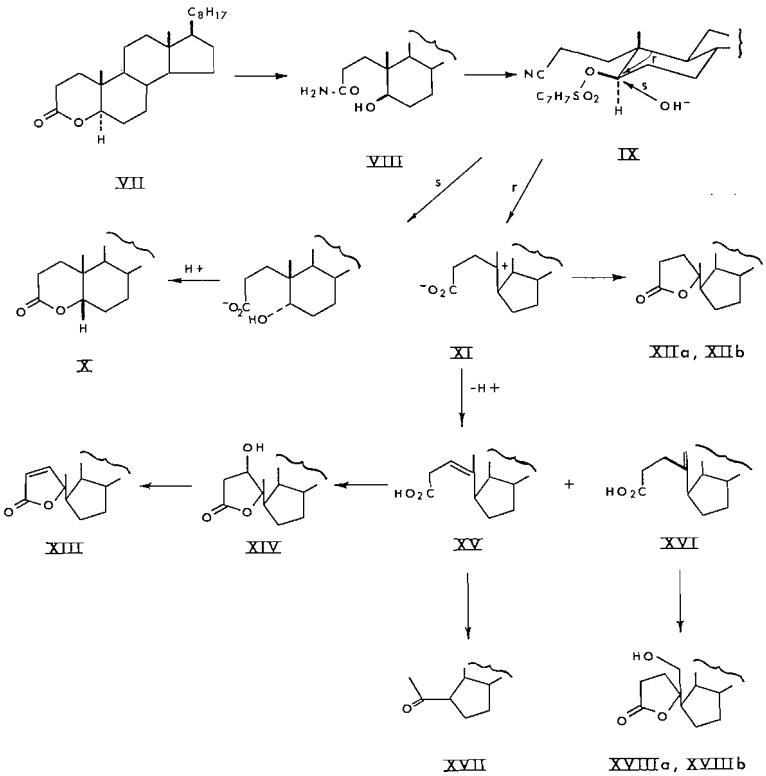
Mass spectra, used in conjunction with infrared and nuclear magnetic resonance spectra and other data to make structural assignments, were found to be highly sensitive to certain structural features. In particular, they can usually distinguish sharply between molecules that contain a pendant ring structure and those that do not.

Brewster and Kucera (1) epimerized the *trans*-fused lactone I, as shown in Reaction Scheme 1, by converting it with ammonia into the hydroxyamide II, transforming II with *p*-toluenesulfonyl (tosyl) chloride in pyridine into a compound having the molecular formula $C_{15}H_{19}NO_3S$, hydrolyzing this compound with aqueous sodium hydroxide to the hydroxyacid IV, and cyclizing IV with acid to the *cis*-fused lactone V. In accord with our own experience in applying this procedure to other lactones, as well as other evidence (2) that hydroxyamides react with tosyl chloride in pyridine to form nitriles, the intermediate $C_{15}H_{19}NO_3S$ is formulated here as the cyanotosylate III rather than VI, which was postulated (1) to arise via the steps shown by broken arrows. The cyanotosylate structure is supported by a nitrile band at 2 249 cm^{-1} in the infrared spectrum (3, p. 263).

In an attempt to obtain large quantities of the *cis* lactone X, which was required in another connection, we have applied Brewster and Kucera's epimerization procedure to the readily available *trans* lactone, 4-oxa-3-oxo-5α-cholestane VII (4, 5), as shown in Reaction Scheme 2. However, alkaline hydrolysis of the cyanotosylate IX gave a complex mixture from which the *cis* lactone X was obtained in only 23% yield. By contrast, Brewster and Kucera obtained relatively pure lactone V from the cyanotosylate III in 75% yield. It accordingly became of interest to identify other products of the hydrolysis of IX, in an attempt to discover the cause of the divergent behavior of the cyanotosylates III and IX. We also applied Brewster and Kucera's procedure to the isomeric *cis* lactone X (Reaction Scheme 3). The use of isomeric lactones in this procedure permitted us to discern the effect of differing stereochemistry in the hydrolysis of the cyanotosylates IX and XXV (Reaction Scheme 3).

Fractionation of the mixtures obtained by hydrolysis of the cyanotosylates proved to be a formidable task. In addition to adsorption chromatography, a technique that we term "split crystallization" proved to be highly useful. This consists of watching under a magnifying glass the shape of the crystals being formed, and filtering the mixture as

[1]*Holder of National Research Council Studentships, 1959–1961.*



REACTION SCHEME 1.

soon as a second crystalline form appears, thereby indicating a second compound. Concentration of the filtrate often leads to preferential crystallization of the second compound, the mixture being filtered as soon as crystals of the first compound become visible. Further concentration of the filtrate leads to crystallization of one or the other of the two compounds; the various crops are combined on the basis of crystalline shape and recrystallized to complete purification. In many instances this technique proved to be more successful than chromatography. Thus reduction of 5-oxo-3,5-seco-A-norcholestan-3-oic acid with sodium borohydride gave a mixture from which the lactones VII and X were obtained in yields of 37% and 4.5% by crystallization and chromatography; split crystallization from ethanol raised the yields to 64% of VII (needles) and 17.5% of X (plates).

Products from Applying the Epimerization Procedure to 4-Oxa-3-Oxo-5α-cholestane

Fractionation of the mixture obtained from the hydrolysis of the cyanotosylate IX yielded, besides the δ-lactone X, two crystalline isomeric γ-lactones XII*a* and XII*b*, an oily mixture of unsaturated acids, and several intractable oily fractions. From the unsaturated acid fraction, the acid XVI was obtained in a crystalline form; evidence for the presence of the isomeric acid XV comes from the products XIII, XIV, and XVII obtained by various chemical treatments of the fraction, as described below. The structures postulated for the different products, shown in Reaction Scheme 2, rest mainly on spectral evidence which is described below and which in aggregate seems reasonably convincing. These structures indicate that hydrolysis of the cyanotosylate IX (reaction *s*) is accompanied by a competing solvolysis (reaction *r*) in which Wagner–Meerwein shift of the antiparallel 9–10 bond synchronous with the loss of tosylate ion gives the carbonium ion XI. Rearrangements of this stereoelectronic character are common in ring A of triterpenes, and lead to its contraction to a five-membered ring (6). In these cases, as well as in that now under consideration, the rearrangement is made possible by *gem*-dialkyl substitution of the carbon atom next to the developing carbonium ion, because the alkyl shift then gives a relatively stable tertiary carbonium ion. The cyanotosylate

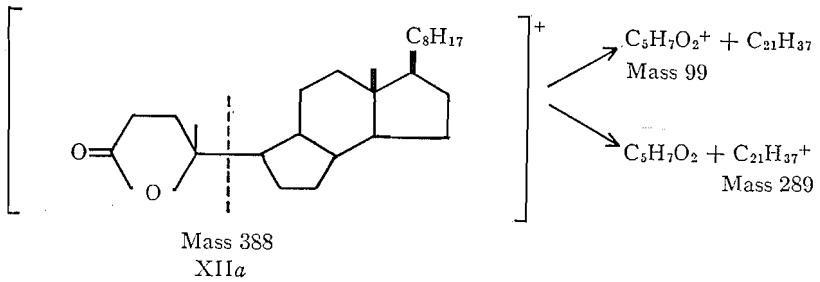
For personal use only.



REACTION SCHEME 2.

III will have less tendency to undergo rearrangement, because this would provide a secondary carbonium ion. Hence, it would be expected to give a better yield of epimerized lactone.

γ-Lactones XIIa and XIIb

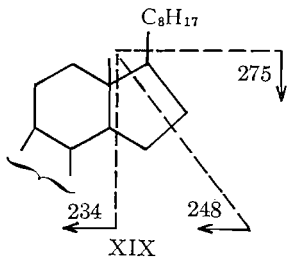
A crystalline product $C_{26}H_{44}O_2$, obtained in about 7% yield, appeared to be compound XII*a* for the following reasons. The infrared spectrum (ν_{max} 1 769 cm^{-1}; cf. ref. 3, p. 179) indicates a γ-lactone and, in contrast to X, the compound is extremely resistant to ring opening by hydroxide ion or ammonia, as would be expected for a *gem*-disubstituted γ-lactone (7). The pendant lactone structure is indicated by the mass spectrum of the compound, which shows the most intense peaks at masses 99, 287, and 289 (Table I). Those at masses 99 and 289 correspond to the complementary products from the expected bond cleavage in the parent ion of XII*a*:

Mass 388
XII*a*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fission of the single bond joining the pendant lactone to the rest of the molecule should be a highly preferred process, both because the bond is β to an oxygen atom (8), and because it joins two branched carbon atoms (8*d*, 9). When the lactone group is not joined by a single bond to the rest of the molecule, as in the isomeric spiro-γ-lactone XXVI*a*, the genesis of which is discussed later (Reaction Scheme 3), the intense peaks at masses 99, 287, and 289 are missing (Table I).

TABLE I



Partial mass spectra of lactones XII*a* and XXVI*a*

	Relative intensity*		
Mass	XII*a*	XXVI*a*	Loss†
388	26.0	100.0	(Parent ion)
373	7.3	13.2	CH_3
370	6.9	7.4	H_2O
331	0.4	9.2	C_3H_5O
289	34.0	0.8	$C_5H_7O_2$
287	64.6	1.3	$C_5H_9O_2$
275	15.0	25.6	C_8H_{17}
248	6.2	18.6	$C_8H_{17}CHCH_2$
234	9.8	42.0	$C_8H_{17}CHCH_2CH_2$
99	100.0	3.1	$C_{21}H_{37}$

*The scale of relative intensities was defined by assigning a value of 100.0 to the most intense peak of mass greater than 90 in each spectrum; this is also the strongest peak in the entire spectrum of XII*a*, XXVI*a*, XVIII*b*, and XIV, except for a peak of mass 43.

†Probable composition of neutral particle(s) lost from parent ion.

The other peaks in the mass spectrum are also consistent with the structure XII*a*. That at mass 287 corresponds to the loss of the pendant lactone group plus two hydrogen atoms. The mechanism of this reaction is not known; no evidence is available to pinpoint the source of the two extra atoms. Precedents for such double-hydrogen migration are known, although the most familiar ones, those of alkyl esters of oxygen acids (8*c*, 10), are not directly analogous to the present case. Peaks at masses 275, 248, and 234 correspond to characteristic cleavages of the cholestane skeleton leading to loss of C_8H_{17}, $C_8H_{17}CHCH_2$, and $C_8H_{17}CHCH_2CH_2$ from ring D (11):

XIX

Loss of C_3H_5O, as evidenced by the peak at mass 331 in the spectrum of XII*a*, occurs also in γ-valerolactone (12). The low intensity at mass 331 in the spectrum of XII*a* contrasts with that in the spectrum of XXVI*a*, and suggests that this reaction is too slow to compete effectively with other, more favored reactions in the former compound.

The nuclear magnetic resonance (n.m.r.) spectrum of $C_{26}H_{44}O_2$ confirms the structure of the lactone moiety of XII*a*. At high field it shows, as do all the other reaction products mentioned below, the spectrum characteristic of cholestane derivatives (13). The protons associated with the lactone moiety appear at lower field as multiplets centered at 7.45

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and 8.00 τ, corresponding to the α- and β-protons, respectively; the areas under the peaks indicate two α- and two β-protons. For comparison, γ-butyrolactone shows peaks at 7.69 and 7.92 τ for α- and β-protons (14). The absence of any peaks below 7 τ is significant, because a proton at the γ-position of the lactone would give a signal at about 5.5 τ (15, spectrum No. 63). Evidently, the γ-position is disubstituted. One of the substituents must be a methyl group, because a sharp, unsplit peak (area: three protons) appears at 8.61 τ; the γ-methyl groups of 3,3,4,4-tetramethylbutyrolactone give a signal at 8.67 τ (15, spectrum No. 214). This is well below the field at which the signals from the methyl groups of cholestane are observed (13).

Concentration of the mother liquors from the crystallization of the lactone XII*a* yielded very small quantities of another compound $C_{26}H_{44}O_2$, having the probable structure XII*b* and differing from XII*a* only in the configuration at C-10. The infrared spectrum of this product above 1 400 cm^{-1} is superimposable on that of XII*a* (Fig. 1), and the n.m.r. spectrum is similar, with a sharp peak at 8.65 τ.

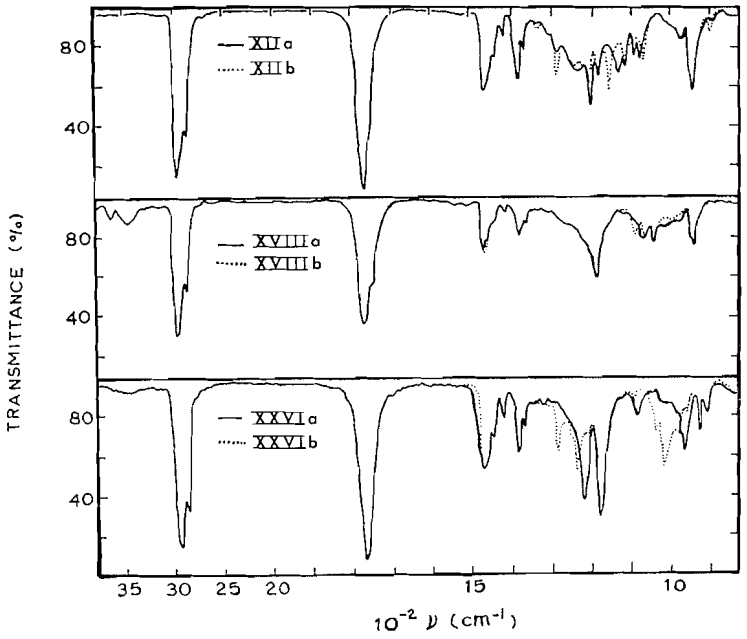


FIG. 1. Infrared spectra of some lactones (presumed to be epimeric).

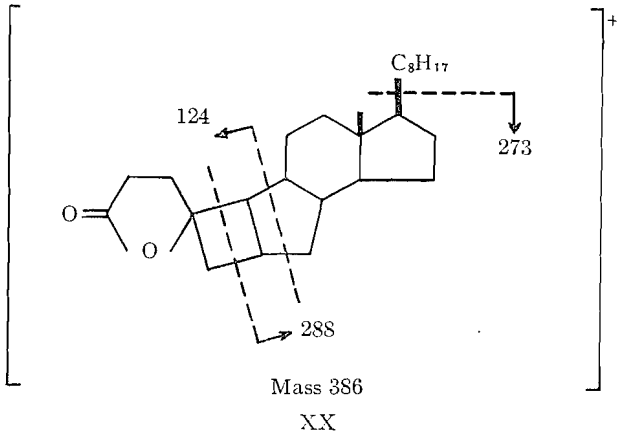
Unsaturated Acids XV and XVI and Products Derived from Them

The crude mixture from the hydrolysis of IX contained acids (ν_{max} 1 710 cm^{-1}) (3, p. 162). A small quantity of crystalline acid $C_{26}H_{44}O_2$, for which the structure XVI is suggested, was obtained after considerable manipulation. The terminal olefinic methylene of this structure was indicated by infrared peaks at 3 078, 1 638, and 885 cm^{-1} (3, p. 34), and its presence in the unsaturated acid fraction was confirmed by oxidizing a portion of the fraction with osmium tetroxide and sodium metaperiodate in aqueous dioxane (16) and identifying formaldehyde among the oxidation products.

Because no other unsaturated acid could be isolated in a crystalline state from this fraction, a portion of the fraction was oxidized with osmium tetroxide in the hope of obtaining more crystalline products. Chromatography of this reaction mixture on alumina

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



gave two hydroxylactones having the properties to be expected of the isomeric compounds XVIII*a* and XVIII*b*, produced by the two possible approaches of the oxidizing agent to the double bond of XVI. The infrared spectra of the two compounds are closely similar (Fig. 1) and show asymmetric peaks at 1 771 cm^{-1} (cf. ref. 17). The mass spectra (Table II) are also remarkably similar. In a manner characteristic of primary alcohols, which lose H_2O readily (18), the compounds give essentially no parent peaks, but show prominent

TABLE II

Partial mass spectra of hydroxylactones XVIII*a* and XVIII*b*

	Relative intensity		
Mass	XVIII*a*	XVIII*b*	Loss
404	0	0.02	(Parent ion)
386	59.5	59.4	H_2O
371	18.0	12.0	H_2O and CH_3
358	5.1	5.1	H_2O, and CO or CH_2CH_2
288	5.5	8.7	H_2O and $C_5H_6O_2$
273	31.2	31.4	H_2O and C_8H_{17}
124	100.0	100.0	H_2O and $C_{19}H_{34}$

peaks at the parent mass less 18. In *n*-hexanol, 91% of the hydrogen lost with hydroxyl as water comes from C-4, and considerable evidence indicates that 1,4-elimination is general in primary alcohols (19). In the present case, such elimination might plausibly give rise to the ion XX which can, by further fragmentation as shown, account for the peaks of masses 124, 273, and 288.

XX

As would be expected for the formulae XVIII*a* and XVIII*b*, the n.m.r. spectra of the lactones lack the peak at about 8.6 τ caused by a γ-methyl group on the lactone ring; instead, low-field peaks appear at 6.33 τ for XVIII*a* and at 6.34 τ (two protons) for XVIII*b*. These values are slightly lower than the usual value of 6.44 τ for the methylene protons of $—CH_2OH$ (20), but are reasonable when the deshielding effect that is to be expected from the lactone ring is taken into account.

A third compound obtained from the osmium tetroxide oxidation of the unsaturated acid fraction is most plausibly formulated as the hydroxylactone XIV. The infrared spectrum shows hydroxyl (3 620, 3 459 (broad) cm^{-1}) (3, p. 96) and carbonyl (1 776 cm^{-1}, with an inflection at 1 758 cm^{-1}) (3, p. 179) peaks. The mass spectrum (Table III) shows

For personal use only.

TABLE III

Partial mass spectrum of hydroxylactone XIV

Mass	Relative intensity	Loss
404	0.5	(Parent ion)
386	52.8	H_2O
371	5.0	H_2O and CH_3
360	3.4	CO_2 or, more likely, CH_2CHOH
289	100.0	$C_5H_7O_3$
288	43.7	$C_5H_8O_3$
232	17.6	H_2O and $C_8H_{17}CHCH_2CH_2$
175	24.4	$C_5H_8O_3$ and C_8H_{17}
149	73.5	$C_5H_7O_3$ and $C_8H_{17}CHCH_2$
135	62.4	$C_5H_7O_3$ and $C_8H_{17}CHCH_2CH_2$
134	43.9	$C_5H_8O_3$ and $C_8H_{17}CHCH_2CH_2$

a small peak for the parent ion and a strong peak at mass 386 for the parent ion less H_2O, as expected for a secondary alcohol (18). The most intense peak, at mass 289, corresponds to cleavage of the pendant hydroxylactone group ($C_5H_7O_3$) from the parent ion; the peak at mass 288 arises presumably by the same cleavage accompanied by migration of a hydrogen atom. The peak at mass 360 probably arises by loss of CH_2CHOH from the lactone ring. Other prominent peaks can be accounted for by further characteristic cleavages at ring D (as shown in XIX) of the ions of masses 288, 289, and 386.

In agreement with the structure XIV, the n.m.r. spectrum of this compound shows a sharp unsplit peak at 8.72 τ caused by a γ-methyl group on the lactone ring (cf. structure XII*a* above). A weaker, more diffuse band centered at 5.29 τ (one proton) may be attributed to the single β-hydrogen of the lactone (20). Again, the n.m.r. spectrum indicates that the lactone contains no γ-hydrogen.

A fourth compound isolated after the oxidation of fraction A may be the α,β-unsaturated γ-lactone XIII, produced by dehydration of XIV or of a more reactive isomer. Such dehydration should take place easily (21). The infrared (ν_{max} 1 758 cm^{-1}) (17) and ultraviolet (λ_{max} 206 mμ, ϵ_{max} ~11 000, in ethanol) (22) spectra indicate an α,β-unsaturated γ-lactone, and the most abundant ion in the mass spectrum (Table IV), which occurs at mass 97, almost certainly consists of the γ-methyl-α,β-unsaturated lactone moiety ($C_5H_5O_2$). Loss of this group as a radical from the parent ion accounts for the complementary ion of mass 289; other prominent peaks can be accounted for by further breakdown of this ion at ring D.

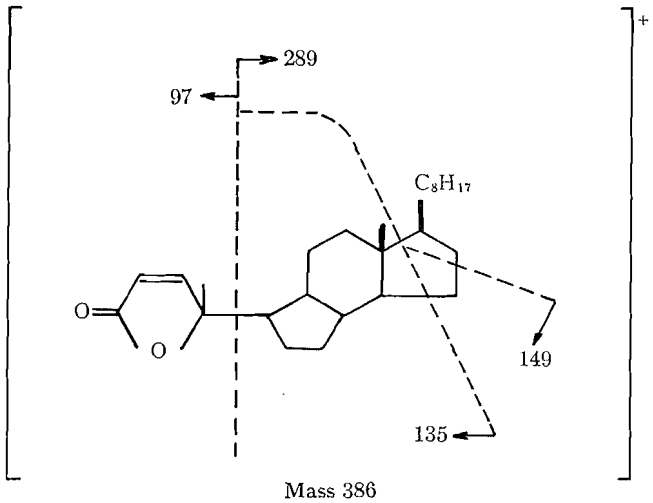

TABLE IV

Partial mass spectrum of unsaturated lactone XIII

Mass	Relative intensity	Loss
386	60	(Parent ion)
371	58	CH_3
289	87	$C_5H_5O_2$
149	85	$C_5H_5O_2$ and $C_8H_{17}CHCH_2$
135	62	$C_5H_5O_2$ and $C_8H_{17}CHCH_2CH_2$
97	100*	$C_{21}H_{37}$

*To facilitate handling the very small quantity of lactone available, it was introduced into the spectrometer in hexane solution. The peak at mass 97 was the strongest peak in the spectrum free of interference from hexane.

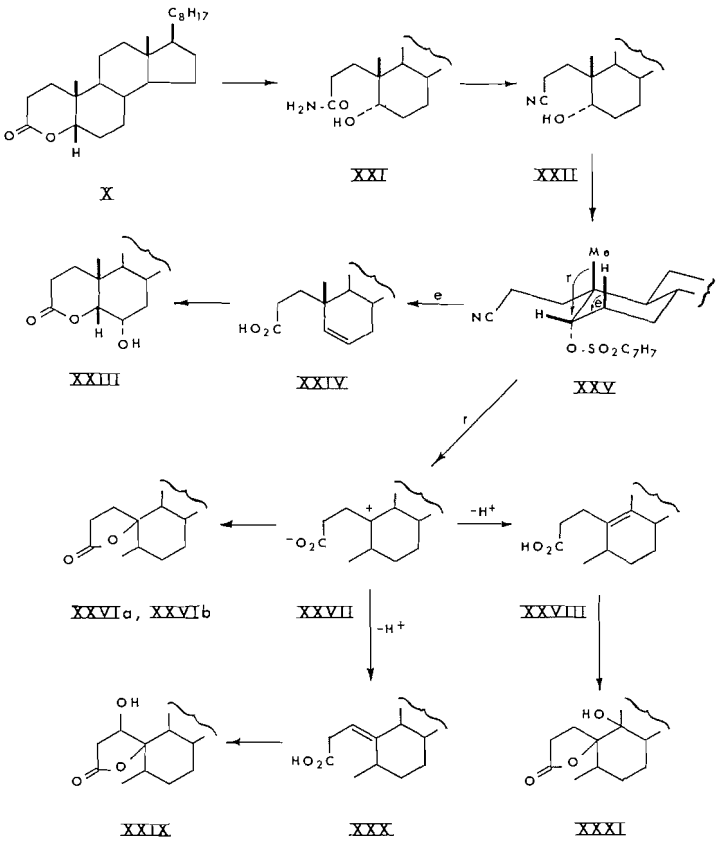
Mass 386
XIII

The oxidation products XIII and XIV point to the presence of XV in the unsaturated acid fraction. Further evidence for this acid was obtained by oxidizing another portion of the fraction with the Lemieux–Rudloff reagent (23). The mixture of carbonyl compounds thus formed gave two 2,4-dinitrophenylhydrazones whose analyses and ultraviolet (24) and n.m.r. spectra (25) were consonant with their being isomeric derivatives (possibly geometrical isomers) of the methyl ketone XVII.

Products from Applying the Epimerization Procedure to 4-Oxa-3-oxo-5β-cholestane



The results of applying the epimerization procedure to 4-oxa-3-oxo-5β-cholestane X are shown in Reaction Scheme 3. The hydroxyamide XXI (5) reacted with *p*-toluenesulfonyl chloride in pyridine to give the hydroxynitrile XXII. Under the same conditions, the equatorial hydroxyl group of VIII is tosylated, but evidently the axial hydroxyl of XXI is less reactive. However, at a higher temperature we were able to tosylate this hydroxyl group and obtain the cyanotosylate XXV.

Alkaline hydrolysis of this compound under the conditions specified by Brewster and Kucera gave a gum, which was separated into an unsaturated acid fraction and minute quantities of two crystalline compounds G and H, probably the isomers XXVI*a* and XXVI*b*. The unsaturated acids could not be obtained in a crystalline form, but appeared to consist chiefly of XXIV, with small amounts of XXVIII and XXX, as evidenced by the crystalline compounds XXIII, XXIX, and XXXI (the latter two formulations very tentative) obtained by oxidation of the mixture. The δ-lactone VII, which has a prominent peak at 1 740 cm^{-1} (5), could not be detected in the reaction mixture. A hydroxide ion approaching the top face of the cyanotosylate XXV is apparently prevented by the angular methyl group from attacking at C-5 and displacing the tosylate ion (as in reaction *s*, Reaction Scheme 2), and instead attacks the axial hydrogen at C-6 to give the elimination reaction *e*. The competing solvolysis to give the rearranged carbonium ion XXVII (reaction *r*), from which XXVI*a*, XXVI*b*, XXVIII, and XXX could arise, would be governed by the same stereoelectronic factors that govern the rearrangement IX → XI.

γ-Lactones XXVIa and XXVIb

The two crystalline products G and H were obtained in only minute amounts, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

REACTION SCHEME 3.

fortunately product H, $C_{26}H_{44}O_2$, was readily available by the acid-catalyzed rearrangement of X as described later. It appears to be a γ-lactone (ν_{max} 1 769 cm^{-1}), and has a n.m.r. spectrum similar in many respects to that of XII*a*. Thus, it shows multiplets at 7.43 τ (two protons) and 8.06 τ (two protons), which can be assigned to the α- and β-protons of a γ-lactone. These multiplets are symmetrical about their common center, the fine detail resembling that of A_2B_2 systems (e.g. β-propiolactone (26)) having J_{AB} and J_{AB}' equal. The absence of a proton from the γ-position is clear, because this would give an unsymmetrical A_2B_2C spectrum; confirmation comes from the absence of a peak at about 5.5 τ. The γ-position, hence, must be disubstituted and, because neither substituent is methyl (no sharp peak at about 8.6 τ), the spiro formulation XXVI*a* is suggested.

This spiro formulation is supported by the mass spectrum (Table I), which gives no evidence for a pendant lactone ring. The parent ion makes up a far larger part of the total ion yield than does that of XII*a*, and relatively strong peaks correspond to cleavages in ring D (cf. structure XIX) and loss of C_3H_5O (12); these processes are overshadowed in XII*a* by rupture of the pendant bond.

The structure XXVI*b*, epimeric at the spiro position, is tentatively suggested for product G on the basis of the very close similarity of its infrared spectrum to that of product H (Fig. 1). It was obtained in too small an amount (4 mg) for more extensive investigation.

Unsaturated Acids XXIII, XXVIII, and XXX and Products Derived from Them

The unsaturated acids that were the chief products from the solvolysis of the tosylate XXV could not be obtained in a crystalline form. Consequently, the fraction containing them was oxidized with osmium tetroxide. The major product from this reaction was a hydroxy-δ-lactone (ν_{max} 3 596, 1 742 cm^{-1}), for which the structure XXIII was suggested by the close similarity of the infrared spectrum below 1 060 cm^{-1} to that of the lactone X. The mass spectrum of the hydroxylactone (Table V) shows a weak peak for the parent

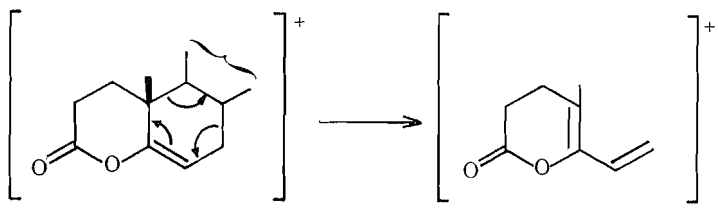

TABLE V

Partial mass spectrum of hydroxylactone XXIII

Mass	Relative intensity	Loss
404	0.8	(Parent ion)
389	0.6	CH_3
386	15.7	H_2O
371	100.0*	H_2O and CH_3

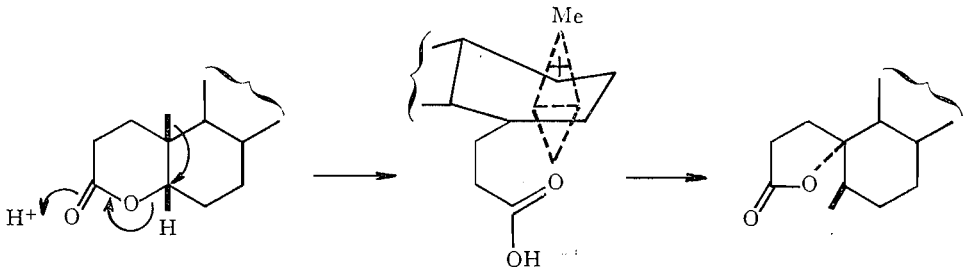
315	2.5	
291	0.4	C_8H_{17}
273	3.1	H_2O and C_8H_{17}
264	0.1	$C_8H_{17}CHCH_2$
248	1.2	
247	4.5	
246	1.4	
138	94.2	H_2O and $C_{18}H_{32}$

*Strongest peak in the entire spectrum.

ion and a strong one corresponding to loss of H_2O, as expected for a secondary alcohol. The intense peak at mass 138 suggests a reverse Diels–Alder reaction (27) via an intermediate that arises by primary loss of H_2O, either by 1,2-elimination or by 1,4-elimination followed by isomerization (19*a*). Other features of the mass spectrum seem to be consistent with the structure XXIII.

Mass 138

Osmium tetroxide would be expected to attack the unsaturated acid XXIV on the α-face (28, p. 14). An α-configuration for a 6-hydroxyl group of the hydroxylactone is indicated by its molecular rotation (−35°), as compared with that of the parent lactone X (+72°); the shift caused by introducing the hydroxyl group (−107°) is close to that expected for a 6α-hydroxyl group in the coprostane series (−100°) (28, p. 179).



Besides the hydroxy-δ-lactone XXIII, minute amounts of hydroxy-γ-lactones are formed by oxidation of the unsaturated acid fraction. Tentative structures XXIX and XXXI may be assigned to these compounds on the basis of their infrared spectra (ν_{max} 3 617, 3 440, 1 772 cm^{-1}; and 3 580, 1 772 cm^{-1}, respectively) and their possible genesis as shown in Reaction Scheme 3. The spectrum of the second lactone showed no bonded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydroxyl peak, unlike the spectra of all of the other hydroxylactones encountered in this study. This indicates a highly hindered hydroxyl group, as in XXXI.

Rearrangement of 4-Oxa-3-oxo-5α-cholestane and 4-Oxa-3-oxo-5β-cholestane in Acid

The low yields of the lactones G and H from alkaline hydrolysis of XXV because of the competing elimination reaction led us to attempt to prepare the compounds by treatment of the lactone X with acid. With hot formic (4 days) or trifluoroacetic acid (10 h), lactone H was obtained in 60–70% yield, together with starting material and small amounts of uncrystallizable products, which were indicated by their infrared spectra to be unsaturated acids. Selective formation of the single epimer H suggests that, in this reaction, the carbonium ion is the bridged ion XXXII, and that the stereochemistry of lactone H is as shown in XXVI*a*.

X XXXII XXVI*a*

The *trans*-δ-lactone VII was more stable in acid. After it had been heated under reflux for 13 days in trifluoroacetic acid, it was converted into a complex mixture, from which two uncrystallizable gums (each showing a single strong infrared absorption band in the carbonyl region) were separated by protracted chromatography. The first gum had an infrared spectrum very similar to those of XII*a* and XII*b*, and may possibly be a mixture of these lactones and of others epimeric at C-5. The second gum was yellow, and had an ultraviolet absorption suggesting an unsaturated ketone (28, p. 19); such compounds have been reported from the treatment of δ-lactones with acid (29 and references therein).

EXPERIMENTAL

All melting points are corrected. Unless otherwise stated, optical rotations were measured in chloroform solution, infrared spectra in carbon tetrachloride, and nuclear magnetic resonance spectra in chloroform or deuteriochloroform. Mass spectra were measured with 70 V electrons on a modified (30) Consolidated model 21-103*c* instrument, with the sample-introduction system heated to 250°. Woelm alumina was used for chromatography. Proportions indicated for solvent mixtures are by volume.

trans-1-Cyanomethyl-2-tosyloxycyclohexane (III)

This compound, m.p. 84.6–85.6°, was prepared according to the method described by Brewster and Kucera (1).

Anal. Calcd. for $C_{15}H_{19}NO_3S$: C, 61.40; H, 6.53; N, 4.77; S, 10.93. Found: C, 61.62; H, 6.45; N, 4.97; S, 11.04.

4-Oxa-3-oxo-5α-cholestane (VII) and 4-Oxa-3-oxo-5β-cholestane (X)

5-Oxo-3,5-seco-A-norcholestan-3-oic acid (40 g) (31) was reduced with sodium borohydride (5). The reaction products were split crystallized from 95% ethanol, successive crops being obtained by concentration of the solution until finally only an oil was obtained. The various crops were combined according to crystal shape and recrystallized three times to give pure 5α-lactone (VII) (24.5 g; 64% yield) and 5β-lactone (X) (6.73 g; 17.5%).

5β-Tosyloxy-3,5-seco-A-norcholestan-3-nitrile (IX)

4-Oxa-3-oxo-5α-cholestane (12.5 g) was converted into the corresponding hydroxyamide VIII (5). The crude dried product was dissolved together with vacuum-dried, recrystallized *p*-toluenesulfonyl chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(60 g) in dry pyridine (900 ml), and left in a stoppered flask for 24 h at room temperature. Slow addition of water, with stirring, and cooling gave a crystalline precipitate which was collected by filtration, washed with water until it was pyridine-free, dried under vacuum, and recrystallized from 95% ethanol to give white needles of cyanotosylate IX (13.65 g), m.p. 165.2–166°. Concentration of the mother liquors provided a second crop which, after being recrystallized twice (0.64 g), melted at 165–166°. Further concentration of the resultant mother liquors yielded the lactone VII (0.45 g; 4%), m.p. 114–115.2°. The total yield of the cyanotosylate IX amounted to 82%.

Recrystallization of the cyanotosylate, $[\alpha]_D^{26}$ +1° (*c*, 2.98), m.p. 165.2–166°, did not raise its melting point. Infrared: ν_{max} 2 250 (w) cm^{-1}.

Anal. Calcd. for $C_{33}H_{51}NO_3S$: C, 73.13; H, 9.51; N, 2.58; S, 5.92. Found: C, 73.08; H, 9.48; N, 2.62; S, 5.79.

In a previous pilot experiment the cyanotosylate was crystallized in the form of plates, m.p. 156.7–157.1°, whose infrared spectrum was identical with that of the material melting at 165.2–166°.

5α-Hydroxy-3,5-seco-A-norcholestan-3-nitrile (XXII)

Similar treatment of crude 5α-hydroxy-3,5-seco-A-norcholestan-3-amide (XXI) (5), prepared from 4-oxa-3-oxo-5β-cholestane (X) (11.54 g), with *p*-toluenesulfonyl chloride (58 g) in dry pyridine (950 ml) for 24 h gave a solid which was recrystallized three times from aqueous ethanol. Colorless plates of 5α-hydroxy-3,5-seco-A-norcholestan-3-nitrile (XXII) (7.83 g) were obtained; m.p. 153–153.7°; $[\alpha]_D^{26}$ +45° (*c*, 2.02); ν_{max} 3 665, 2 254 cm^{-1}.

Anal. Calcd. for $C_{26}H_{45}NO$: C, 80.56; H, 11.70; N, 3.61. Found: C, 80.30; H, 11.67; N, 3.82.

Concentration of the mother liquors gave a solid which, after three recrystallizations from aqueous ethanol, produced a second crop (0.44 g), m.p. 152.8–153.7°, thereby raising the yield to 72%. The final residue, after five recrystallizations from aqueous ethanol, gave 4-oxa-3-oxo-5β-cholestane (X) (0.24 g), m.p. 107.2–108°, equivalent to 2.1% of the starting material.

5α-Tosyloxy-3,5-seco-A-norcholestan-3-nitrile (XXV)

A solution of the 2-cyano-5α-hydroxy compound (XXII) (8.23 g) and vacuum-dried, recrystallized *p*-toluenesulfonyl chloride (47 g) in dry pyridine (470 ml) was kept at 67–71°. Infrared examination of the solid that was precipitated by dilution of small samples with water at 6 h intervals showed that the concentration of the tosyloxy compound reached a maximum in 96–102 h. After 102 h a large volume of water was slowly added to the reaction mixture, with stirring, the temperature being maintained below 5° by external cooling. The mixture was extracted with ether, and the ether extract was washed thoroughly with water and with saturated sodium chloride solution and then dried over magnesium sulfate. Evaporation of the extract to dryness at reduced pressure yielded a semicrystalline mass (9.48 g), which was chromatographed on alumina (285 g, 10% water). Evaporation of the fractions eluted with hexane gave an oil (3.92 g), which was proved by its infrared spectrum (ν_{max} 3 010 (w sh), 2 254 (w), and 1 650 (w) cm^{-1}) to be an unsaturated nitrile. Benzene–ether (9:1) then eluted a gum (4.55 g), which was crystallized three times from methanol–ether to give crystals of 5α-tosyloxy-3,5-seco-A-norcholestane-3-nitrile (XXV) (1.67 g), m.p. 91.3–92.8°, $[\alpha]_D^{29}$ +44° (*c*, 3.06), ν_{max} 2 247 cm^{-1}.

Anal. Calcd. for $C_{33}H_{51}NO_3S$: C, 73.13; H, 9.51; N, 2.58; S, 5.92. Found: C, 73.02; H, 9.58; N, 2.64; S, 5.80.

Concentration of the mother liquors at reduced pressure gave a solid which, after four crystallizations from methanol–ether, yielded a second crop (0.95 g), m.p. 92–92.6°.

The benzene–ether (8:1) eluates (0.96 g), after two recrystallizations from aqueous ethanol, gave starting material (0.75 g), m.p. 153–153.7°. A further crop (0.1 g), m.p. 152.8–153.6°, was obtained when the mother liquors were concentrated and the solid that was obtained was recrystallized three times from aqueous ethanol. The yield of cyanotosylate XXV was 22.5%, and the recovery of starting material was 10%.

Hydrolysis of 5β-Tosyloxy-3,5-seco-A-norcholestan-3-nitrile (IX)

The tosyloxy compound (14.2 g) was heated under reflux in a solution of sodium hydroxide (225 g) in 83% aqueous ethanol (2.8l) for 9 h. The tosylate had completely dissolved after 1 h. The bulk of the ethanol was removed at reduced pressure, and the mixture was acidified with cooling and extracted with ether. The ether extract was washed with water until the washings were neutral to litmus, washed with saturated sodium chloride solution, dried over magnesium sulfate, and evaporated to dryness at reduced pressure. The infrared spectrum of the resultant oil showed peaks at 1 770 (s), 1 735 (s), and 1 710 (s) cm^{-1}. The presence of a broad, rather weak band from 3 660 to 2 500 cm^{-1} indicated that the 1 710 cm^{-1} absorption could be attributed to carboxylic acids (3, p. 162); however, attempts to remove these acids from the ether solution by extraction with aqueous sodium hydroxide failed.

The hydrolysis products were dissolved in anhydrous ether (50 ml) and treated with an ether solution (50 ml) of diazomethane which had been obtained by the action of 50% potassium hydroxide (30 ml) on N-nitroso-N-methyl-N′-nitroguanidine (8 g). After 2 h, the excess diazomethane was destroyed with 0.1 *N* hydrochloric acid, and the ether solution was washed with water until it was acid free and then with saturated sodium chloride solution, dried over magnesium sulfate, and evaporated at reduced pressure. The infrared spectrum of the oil (10.14 g) thus obtained showed maxima at 1 700 (s) and 1 737 (m) cm^{-1}, the 1 710 and 3 660 – 2 500 cm^{-1} bands having disappeared.

The oil was chromatographed on alumina (315 g; 6% water) and the following fractions, clearly defined by their infrared spectra, were collected: A, an oil (3.75 g; 37% of material placed on column), eluted with hexane and hexane–benzene (9:1); B, an oil (0.38 g; 3.8%), eluted with hexane–benzene (7:1, 6:1, and 5:1); C, crystals (0.93 g; 9.2%), eluted with benzene; D, an oil (0.80 g; 7.9%), eluted with benzene–ether (4:1); E, crystals (3.04 g; 30%), eluted with ether – water – acetic acid (94:1:5). The total recovery amounted to 89%, a further 3% of mixed fractions being discarded.

Fraction A

The infrared spectrum (peaks at 3 080, 1 735, 1 655 – 1 635, and 890 cm^{-1}) showed that this fraction was probably a mixture of the methyl esters of unsaturated acids. Portions were treated as described below, yields being calculated on the assumption that fraction A has the approximate composition $C_{26}H_{44}O_2$.

Acid XVI

A part (200 mg) of the oil was heated under reflux for 2 h in a 1 *N* solution of sodium hydroxide in ethanol–water (9:1) (7 ml). The reaction mixture was then cooled, acidified with 1 *N* hydrochloric acid, diluted with water, and extracted with ether. The ether extract was washed with water until the washings were neutral, washed with aqueous saturated sodium chloride, dried over magnesium sulfate, and evaporated to dryness at reduced pressure. A solution of the resultant oil (192 mg) in 95% ethanol was made just alkaline to phenolphthalein by the addition of 0.01 *N* sodium hydroxide, and a hot solution of S-benzylisothiuronium chloride (0.8 g) in 95% ethanol (4 ml) was added. After 10 min, the organic salts were precipitated with water and collected by filtration as a whitish powder, m.p. 127.5–130°. Eight recrystallizations from aqueous ethanol raised the melting point to 144.8–145.3°. The purified salt was dissolved in 95% ethanol (5 ml), and the resultant solution was acidified with 1 *N* hydrochloric acid and then diluted with water. The oily solid that was precipitated was recrystallized three times from aqueous ethanol to give white crystals of XVI (10 mg; 5% yield), m.p. 90.5–92.3°. Infrared: ν_{max} 3 660 – 2 500 (m w), 3 078 (m sh), 2 870 (s sh), 1 745 (w), 1 710 (s), 1 638 (w), and 885 (m) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41. Found: C, 80.45; H, 11.28.

Oxidative Production of Formaldehyde

A solution of fraction A (0.5 g) and osmium tetroxide (50 mg) in dioxane (24 ml, freshly distilled from lithium aluminium hydride) and water (5 ml) was stirred for 30 min at room temperature. Finely ground sodium metaperiodate (0.8 g) was then slowly added over a period of 15 min and the tan-colored slurry agitated for a further 3 h. The mixture was steam-distilled until the distillate gave a negative reaction with Brady's reagent. The addition of a 6% solution (10 ml) of dimedone in 50% ethanol to the steam distillate (150 ml) resulted in the separation of white crystals after about 20 min, though the whole mixture darkened with time. After the mixture was allowed to stand overnight in the refrigerator, it was filtered. The grey crystalline solid was dissolved in boiling 95% ethanol and filtered through carbon, which was washed with more boiling 95% ethanol. The clear colorless filtrate and washings were concentrated to a small volume (10 ml) and diluted with water (30 ml). On refrigeration the solution deposited white crystals of the dimedone derivative of formaldehyde (73.8 mg), m.p. 190.5–191°.

Oxidation of Fraction A with Osmium Tetroxide

A solution of fraction A (1 g) in dry ether (50 ml) and dry pyridine (1.2 ml) was treated with osmium tetroxide (0.8 g) and left at room temperature in the dark for 10 days. Removal of the ether and pyridine at reduced pressure gave a brown oil, which was added to a solution of sodium sulfite (5 g) in 57% aqueous ethanol (65 ml). The solution was heated under reflux for 2 h, then sodium hydroxide (1 g) was added, and heating under reflux was continued for 1 h. The hot solution was filtered and the insoluble residue washed thoroughly with hot 95% ethanol. The bulk of the ethanol was removed from the filtrate and washings by distillation at reduced pressure. The concentrated solution was acidified with 5 *N* hydrochloric acid and extracted with ether. The ether extract was washed with water until it was free from acid, then washed with saturated sodium chloride solution, and dried over magnesium sulfate. Evaporation of the solution to dryness left an oil (844 mg). This oil was chromatographed on alumina (36 g, 10% water) and the following fractions were collected.

(*i*) Elution with hexane–benzene (2:1) gave crystals which, after two recrystallizations from aqueous methanol, yielded fine needles of XIII (6 mg), m.p. 119–120.2°, $[\alpha]_D^{29}$ +20° (*c*, 0.15), $\lambda_{max}^{CHCl_3}$ 206 mμ (ϵ ~11 000), ν_{max} 1 758 (s) cm^{-1}.

Anal. Calcd. for $C_{26}H_{42}O_2$: C, 80.76; H, 10.95. Found: C, 80.61; H, 11.14.

Recrystallization of the solid that was obtained by evaporating the mother liquors yielded a second crop (7 mg), m.p. 118.7–119.8°.

(*ii*) Elution with benzene–ether (9:1 and early 8:1 fractions) provided crystals (289 mg), which, on one split crystallization from petroleum ether (b.p. 60°), gave fine needles. These were recrystallized from hexane to produce XVIII*a* (13 mg); m.p. 172–173°; $[\alpha]_D^{29}$ −11° (*c*, 0.61); $\nu_{max}^{CHCl_3}$ 3 617 (w), 3 424 (w b), 1 771 (s), 1 753 (s i) cm^{-1}; $\nu_{max}^{CHCl_3}$ 3 570 (w), 3 350 (w b), 1 756 (s) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.18; H, 10.96. Found: C, 76.62; H, 10.87.

Concentration of the mother liquors from split crystallization gave a solid. After three recrystallizations from hexane this was obtained in long plates of XVIII*b* (60 mg); m.p. 159.2–161°; $[\alpha]_D^{26}$ +28° (*c*, 3.20); ν_{max} 3 617 (w), 3 424 (w b), 1 771 (s), 1 753 (s i) cm^{-1}; $\nu_{max}^{CHCl_3}$ 3 591 (w), 3 380 (w b), 1 755 (s) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.18; H, 10.96. Found: C, 77.03; H, 10.61.

The mother liquors from XVIII*b* gave more solid on concentration. On recrystallization from petroleum ether (b.p. 60°) this gave a crop of needles which was recrystallized twice from hexane to give a second crop of XVIII*a* (7 mg), m.p. 171.8–173°.

(*iii*) Elution with benzene–ether (8:1, 7:1, and 6:1) gave crystals (132 mg). These were recrystallized four times from aqueous methanol to give flat rhombs of XIV (36 mg); m.p. 189.4–190.2°; $[\alpha]_D^{26}$ +31° (*c*, 1.96); ν_{max} 3 620 (w), 3 459 (w b), 1 776 (s), 1 758 (s i) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.18; H, 10.96. Found: C, 76.97; H, 10.64.

Concentration of the mother liquors and recrystallization from aqueous methanol of the solid thus obtained yielded a second crop (24 mg) of the same product, m.p. 188.2–189.9°.

The yields of pure XIII, XVIII*a*, XVIII*b*, and XIV were 0.6, 1.9, 5.7, and 5.7%, respectively. However, the weights of the crude fractions from the chromatogram before the wasteful crystallizations indicate that the yield of XVIII*a* and XVIII*b* together was about 28%, and that that of XIV was 10%.

(*iv*) Elution with ether – water – acetic acid (94:1:5) gave an oil (270 mg), which could not be crystallized. The infrared spectrum showed bands attributable to a hydroxy-δ-lactone.

Oxidation of Fraction A with the Lemieux–Rudloff Reagent (23)

Potassium carbonate (0.25 g) in water (14 ml) was added, with vigorous stirring, to a solution of another portion (1.2 g) of fraction A in *t*-butanol (62 ml), followed by a portion (28 ml) of a solution prepared from sodium metaperiodate (4.1 g) and water (55 ml), and then 1% aqueous potassium permanganate solution (0.7 ml). The rest of the periodate was added over the next 30 min, permanganate solution (0.8 ml) being added when necessary to maintain the permanganate color throughout the next 3 h. Stirring was continued overnight, after which time the excess oxidant was destroyed with sodium bisulfite and the *t*-butanol removed by distillation at reduced pressure. The resultant mixture was extracted with ether. The ether layer was washed with water and then with saturated sodium chloride solution, dried over magnesium sulfate, filtered, and treated with an ether solution of diazomethane that was prepared from N-nitroso-N-methyl-N′-nitroguanidine (1.4 g). The excess diazomethane was destroyed with 0.1 *N* hydrochloric acid, and the solution was washed with water and then with saturated sodium chloride solution, dried over magnesium sulfate, and evaporated to dryness. The resultant oil (1.11 g) was chromatographed over alumina (34 g, 10% water). The initial hexane fractions gave a light oil (344 mg), the infrared spectrum of which indicated that it consisted primarily of ketonic material. It was dissolved in boiling ethanol (8 ml) and mixed with a hot solution of 2,4-dinitrophenylhydrazine (0.8 g) in sulfuric acid (2 ml) and 70% ethanol (20 ml). Yellow crystals were obtained which, on a single split crystallization and three recrystallizations from 95% ethanol containing a little ethyl acetate, produced small yellow needles of the 2,4-dinitrophenylhydrazone of XVII (224 mg); m.p. 142–142.5°; $[\alpha]_D^{26}$ +32° (*c*, 2.20); $\lambda_{max}^{CHCl_3}$ 367 mμ (ε 22 000); ν_{max} 3 312 (w), 3 095 (w), 1 618 (s) cm^{-1}; n.m.r. unsplit peak at 7.95 τ (methyl adjacent to C=N; cf. ref. 25).

Anal. Calcd. for $C_{29}H_{44}N_4O_4$: C, 67.92; H, 8.65; N, 10.92. Found: C, 67.75, 67.92; H, 8.86, 8.95; N, 10.94, 10.88.

Concentration of the filtrate from the split crystallization gave a solid which, after one recrystallization from 95% ethanol – ethyl acetate (4:1), was obtained as orange-yellow crystals, m.p. 118–120.4°. Two subsequent recrystallizations from hexane gave orange plates of an isomeric 2,4-dinitrophenylhydrazone of XVII (25 mg); m.p. 125.7–126.8°; $[\alpha]_D^{29}$ +18° (*c*, 1.60); $\lambda_{max}^{CHCl_3}$ 367 mμ (ε 22 500); ν_{max} 3 304 (w), 3 084 (w), 1 618 (s) cm^{-1}; n.m.r. peaks at 7.93 and 8.01 τ.

Anal. Calcd. for $C_{29}H_{44}N_4O_4$: C, 67.92; H, 8.65; N, 10.92. Found: C, 67.53; H, 8.99; N, 11.07.

Concentration of the mother liquors and two recrystallizations from hexane of the solid residue thus obtained gave a second crop (13 mg), m.p. 124.2–125.9°.

The residue that was obtained by allowing the mother liquors from all the recrystallizations of the two isomeric 2,4-dinitrophenylhydrazones to evaporate to dryness at room temperature was recrystallized three times from 95% ethanol to give pale yellow needles of a third 2,4-dinitrophenylhydrazone (23 mg); m.p. 125.6–126.7°; $[\alpha]_D^{31}$ −19° (*c*, 0.87); $\lambda_{max}^{CHCl_3}$ 367 mμ (ε 23 000); ν_{max} 3 313 (w), 3 087 (w), 1 618 (s) cm^{-1}.

Anal. Calcd. for $C_{31}H_{48}N_4O_4$: C, 68.85; H, 8.95; N, 10.36. Found: C, 68.76; H, 8.53; N, 10.52.

Fraction B

This material exhibited a maximum at 1 735 (s) cm^{-1} and no peaks in the 1 700 – 1 600 cm^{-1} region; it was not attacked by osmium tetroxide or the Lemieux–Rudloff reagent, and so lacked an olefinic double bond. It (350 mg) was saponified for 2 h with a solution (under reflux) of 0.5 *N* sodium hydroxide in 90% aqueous ethanol (12 ml). After the usual extraction procedure, the resultant oil was chromatographed on Davison silica gel (11.5 g). The material (157 mg) from the benzene–ether (9:1) fractions was collected and rechromatographed on Davison silica gel (140 g), giving a series of fractions from benzene–ether (92:8 to 8:1) which could not be crystallized. These gave identical infrared spectra (ν_{max} 3 500 (w), 3 500 (w), 3 500 – 2 300 (w m), 1 746 (m sh), 1 705 (s) cm^{-1}); spectra and analysis suggested that these fractions consisted of impure ethoxyacids derived from XI by reaction with ethanol.

Anal. Calcd. for $C_{28}H_{50}O_3$: C, 77.36; H, 11.60. Found: C, 76.83; H, 11.36.

Fraction C

This crystalline fraction, on two recrystallizations from aqueous ethanol, gave colorless needles of XII*a* (474 mg), m.p. 114.5–115.5°, $[\alpha]_D^{29}$ +14° (*c*, 2.72).

Anal. Calcd. for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41. Found: C, 80.34; H, 11.34.

Concentration of the mother liquors gave a solid which, after three recrystallizations from aqueous ethanol, produced a second crop (88 mg), m.p. 112.5–113.8°.

Fraction D

This oily fraction (ν_{max} 3 630 (m), 3 405 (w b), 1 724 (s), 1 709 (m i), 1 656 (m) cm^{-1}) could not be crystallized; treatment with sodium hydroxide in aqueous ethanol or with acetic anhydride in pyridine gave gummy products.

Fraction E

Three recrystallizations of this solid fraction from aqueous ethanol gave 4-oxa-3-oxo-5β-cholestane (X) (1.07 g), m.p. 107.2–108°, identified by mixed melting point and infrared spectrum. The residue (1.97 g) from the mother liquors was chromatographed on alumina (60 g, 10% water). The fractions eluted with hexane–benzene (6:1 to 1:6) yielded crystalline material (284 mg) which, after two recrystallizations from aqueous methanol, gave colorless needles (127 mg), which were identified by infrared spectrum, melting point, and mixed melting point as XII*a* (described above). Concentration of the mother liquors gave, after one split crystallization and five recrystallizations from the same solvent, long colorless plates of XII*b* (20 mg), m.p. 88.6–90.2°, $[\alpha]_D^{29}$ +1° (*c*, 2.40), ν_{max} 1 768 (s) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41. Found: C, 80.44; H, 11.44.

A second crop (32 mg), m.p. 88.5–90.2°, was obtained by further concentration of the mother liquors and five subsequent recrystallizations.

The fractions (1.53 g) eluted with ether – water – acetic acid (94:1:5) gave, on two recrystallizations from aqueous ethanol, a further crop of X (1.23 g), m.p. 107–107.8°.

Hydrolysis of 5α-Tosyloxy-3,5-seco-A-norcholestan-3-nitrile (XXV)

A solution of the cyanotosylate (2.4 g) and sodium hydroxide (37.5 g) in 83% aqueous ethanol (465 ml) was heated under reflux for 7 h (the tosylate had dissolved completely within 10 min). Removal of the bulk of the ethanol at reduced pressure and the usual ether-extraction procedure gave a gum (1.75 g), the infrared spectrum of which showed a large peak at 1 705 cm^{-1} (acid) and a small inflection at 1 770 cm^{-1} (γ-lactone). Relative values of the optical densities of these peaks, that of the C—H stretching peak at 2 939 cm^{-1} being taken as unity, were 1.02 and 0.04, respectively, minor corrections being made for band overlapping. Treatment of an ether solution of the gum with an ether solution of diazomethane (derived from N-nitroso-N-methyl-N′-nitroguanidine (1.4 g)) and the usual work-up produced an oil (1.75 g), which was chromatographed on alumina (53 g, 6% water).

Elution with hexane gave a series of fractions having almost identical infrared spectra, with bands at 3 010 (w sh), 1 736 (s), and 1 650 cm^{-1} characteristic of unsaturated esters. The fractions were combined as fraction F (1.46 g) and oxidized as described below.

Benzene–ether (9:1) eluted an oil (35 mg) which, after three crystallizations from aqueous methanol, gave long needles of compound G (probably XXVI*b*) (4 mg), m.p. 97.5–99.5°, ν_{max} 1 770 (s).

The next eluate with benzene–ether (9:1) gave a gum (29 mg) which, after three crystallizations from aqueous methanol, yielded needles of a γ-lactone (12 mg) (compound H), m.p. 153.1–153.8°. This product was proved, by mixed melting point and infrared spectrum, to be identical with the compound obtained by the acid-catalyzed rearrangement of 4-oxa-3-oxo-5β-cholestane (X), described below, and was assigned the structure XXVI*a*.

Elution with ether – water – acetic acid (96:1:3) removed some ill-defined oils from the column; in no fraction was there any evidence, from the infrared spectrum, of 4-oxa-3-oxo-5α-cholestane. Total recovery from the column amounted to 102%.

Oxidation of Fraction F with Osmium Tetroxide

Fraction F was heated under reflux in 1 *N* sodium hydroxide in 90% aqueous ethanol for 2 h, and the solution was worked up by the usual acidification, ether-extraction, and drying procedures. Part (525 mg) of the uncrystallizable acidic material thus obtained was left in the dark at room temperature for 10 days in a solution of osmium tetroxide (0.8 g) in anhydrous ether (40 ml) containing dry pyridine (1.6 ml). Removal of the ether and pyridine at reduced pressure then gave a brown oil, which was treated for 1½ h with sodium sulfite (6 g) in boiling 57% aqueous ethanol (60 ml). The hot solution was filtered, the insoluble residue washed thoroughly with hot 95% ethanol, and the bulk of the ethanol removed at reduced pressure. The solution was acidified and extracted with ether. The extract was dried and evaporated, yielding a gum (489 mg), which was chromatographed on alumina (15 g, 12.5% water).

Hexane–benzene (1:1) eluted crystalline material (16 mg), m.p. 199–202°, which, after two recrystallizations from hexane, was obtained as fine needles (XXXI?) (8 mg); m.p. 202–203°; $[\alpha]_D^{31}$ −23° (*c*, 0.44); ν_{max} 3 580 (m), 1 772 (s) cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.18; H, 10.96. Found: C, 77.12; H, 11.18.

Elution with benzene gave crystalline material (9 mg), m.p. 218–220°, which yielded, after two recrystallizations from hexane, heavy needles (XXIX?) (3 mg); m.p. 223–225°; ν_{max} 3 617 (w), 3 440 (w b), 1 772 (s) cm^{-1}.

The bulk of the material (385 mg) was recovered as a semicrystalline gum from the ether – water – acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

acid (96.5:0.5:3 to 93:2:5) eluates. It was rechromatographed on Davison silica gel (19 g), from which was eluted, by ether–methanol (9:1), crystalline material (283 mg). Three recrystallizations from hexane gave plates of XXIII (118 mg), m.p. 123.8–124.5°, $[\alpha]_D^{29}$ −9° (*c*, 3.07).

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.18; H, 10.96. Found: C, 77.47; H, 11.22.

Concentration of the mother liquors gave a solid which, after two recrystallizations from hexane, yielded a second crop (41 mg), m.p. 122.7–124°.

The amounts of XXIX, XXXI, and XXIII that were obtained correspond to respective yields for XXX, XXVIII, and XXIV of 0.5%, 1.2%, and 24.3% from the solvolysis of the cyanotosylate XXV. However, the high retention of XXIII on the columns suggests that this estimate is far too low for XXIV; an estimate based on the recovery of crude XXIII from the first column would be 59%.

Treatment of 4-Oxa-3-oxo-5α-cholestane (VII) with Trifluoroacetic Acid

A solution of the lactone (6.2 g) in trifluoroacetic acid (65 ml) was heated under reflux with the exclusion of moisture. Small samples were taken each day, and after removal of the trifluoroacetic acid at reduced pressure, their infrared spectra were measured. The peak at 1 740 – 1 737 cm^{-1}, attributable in part to the starting material, approached a minimum after 13 days, and other peaks appeared at 1 770, 1 706, and 1 649 cm^{-1}. At this time the bulk of the trifluoroacetic acid was removed by distillation, and the residue was diluted with water and extracted with ether. The ether solution, after washing and drying, was evaporated to give a heavy dark brown oil (5.9 g), which was chromatographed on Davison silica gel (230 g).

Hexane eluted a colorless oil (311 mg), the infrared spectrum of which showed C—H bands (2 910 (s), 2 850 (s sh), 1 463 (m), 1 380 (m), 1 368 (m sh) cm^{-1}) and no C=O band. Hexane–benzene (7:1) next eluted a light yellow oil (330 mg) having an additional peak at 3 022 (s sh) cm^{-1}. Benzene–ether (99:1 to 6:1) eluted the bulk of the material as a brown oil (fraction I) (3.94 g) with bands at 1 771 (m), 1 739 (m), 1 708 (m), and 1 649 (s) cm^{-1}. Benzene–ether (4:1), followed by pure ether, eluted an oil (fraction J) (0.82 g) which absorbed strongly at 1 649 cm^{-1}, with only smaller peaks in the 1 800 – 1 700 cm^{-1} region.

Rechromatography of fraction I on Davison silica gel (158 g) yielded, from the eluates with benzene–ether (98:2), a yellow oil (2.05 g) showing bands at 1 771 (s) and 1 708 (m) cm^{-1}. This oil was rechromatographed on alumina (72 g, 6% water). Elution with hexane–benzene (4:1) followed by benzene gave an oil (0.66 g) which showed a strong band at 1 771 cm^{-1} and a small band at 1 670 cm^{-1}. Further rechromatography on Florisil gave, on elution with benzene–ether (9:1 to 8:1), an almost colorless oil (0.55 g) showing only the 1 771 cm^{-1} peak between 1 800 and 1 600 cm^{-1}. However, rechromatography of this material on alumina (27.5 g, 10% water) again yielded an uncrystallizable oil (0.43 g), although the infrared spectrum was essentially changed.

Fraction J from the initial chromatogram was rechromatographed on Davison silica gel (35 g). The eluates with benzene–ether (92:8 to 6:1) yielded an oil (462 mg), which was further chromatographed on alumina (14 g, 12.5% water). From this, hexane to hexane–benzene (1:1) eluted a yellow oil (147 mg), the infrared spectrum of which was almost devoid of any absorption between 1 800 and 1 600 cm^{-1}, except for a strong band at 1 649 cm^{-1}. Ultraviolet: λ_{max} 323 mμ (ε 9 900) in 80% aqueous ethanol; in a 0.5 *N* solution of sodium hydroxide in 80% aqueous ethanol, after the solution had been allowed to stand overnight, λ_{max} 300 mμ (ε 7 500).

Treatment of 4-Oxa-3-oxo-5β-cholestane (X) with Formic Acid

A solution of the lactone (1 g) in formic acid (17 ml) was heated under reflux with the exclusion of moisture for 4 days. Removal of the bulk of the formic acid by distillation at reduced pressure and the usual ether extraction gave a white crystalline material which, after two recrystallizations from methanol, was obtained as long needles of compound H (320 mg), m.p. 153.2–153.8°, $[\alpha]_D^{29}$ +8° (*c*, 4.16 in chloroform).

Anal. Calcd. for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41. Found: C, 80.05; H, 11.32.

The solid from the concentration of the mother liquors, on three recrystallizations from methanol, gave a second crop (60 mg), m.p. 152.7–153.7°. The residue from the evaporation of the mother liquors was dissolved in ether (20 ml) and treated with an ethereal solution of diazomethane derived from nitrosodimethylurea (1 g), and the product was chromatographed on Woelm alumina (18 g, 6% water).

Hexane–benzene (7:1 to 2:1) eluted a semicrystalline material (231 mg), which was recrystallized three times from methanol to give a further crop of compound H as needles (189 mg), m.p. 152.8–153.6°. Ether – water – acetic acid (95:2:3) eluted an oil which solidified. This, after two crystallizations from aqueous ethanol, gave starting material (8.3 mg), m.p. 106.8–107.8°. The total yield of rearranged product was 61%, and the recovery of starting material was 0.8%.

Treatment of 4-Oxa-3-oxo-5β-cholestane (X) with Trifluoroacetic Acid

A solution of the lactone (1.95 g) in trifluoroacetic acid (14 ml) was heated under reflux and anhydrous conditions for 10 h. Removal of the trifluoroacetic acid at reduced pressure, followed by the usual ether-extraction procedure, gave oily crystals (1.89 g). Three recrystallizations from methanol produced needles (510 mg), which were proved by mixed melting point and infrared spectrum to be identical with the product from formic acid treatment. The residue from the evaporation of the methanolic mother liquors was dried and chromatographed on alumina (40 g, 6% water), as described above, to give more crystals of compound H (529 mg), m.p. 153.2–153.8°, and starting material (182 mg), m.p. 106.7–107.8°. The total yield of compound H was 71%, and the recovery of starting material was 9%.

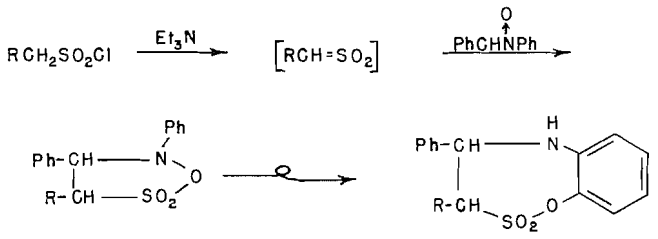
SULFONATE ESTERS OF α-CHLOROALDOXIMES, ALDOXIMES, AND AMIDOXIMES VIA "SULFENE" ADDITION



W. E. Truce and A. R. Naik
Department of Chemistry, Purdue University, Lafayette, Indiana

Received September 7, 1965

ABSTRACT

Reaction of aromatic nitrile oxides with methanesulfonyl and benzylsulfonyl chlorides in the presence of triethylamine yielded sulfonate esters of α-chloroaldoximes ($R-\overset{Cl}{\overset{|}{C}}=NO_3SCH_2R'$). Under the same reaction conditions, aldoximes yielded sulfonate esters, which decomposed to nitriles, and amidoximes yielded amidoxime O-sulfonates, which were also prepared by the action of ammonium hydroxide on $R-\overset{Cl}{\overset{|}{C}}=NO_3SCH_2Ph$. Chemical as well as nuclear magnetic resonance spectroscopic evidence confirms the formula $R-\overset{NH_2}{\overset{|}{C}}=NOH$ for amidoximes.

Inasmuch as cycloadditions of "sulfenes" to certain nucleophilic olefinic compounds to give products with four-membered rings have been realized (1), it became of interest to determine whether "sulfenes" would also cyclize with 1,3-dipolar systems. In fact, Truce *et al.* (2) have found that methanesulfonyl chloride reacts with C,N-diphenylnitrone in the presence of triethylamine to give a seven-ring aza-sultone, presumably via the sequence of steps shown in Reaction Scheme 1.

Reaction Scheme 1.

The present report concerns the behavior of another 1,3-dipolar system, nitrile N-oxides (3, 4), under "sulfene"-producing conditions. When an ethereal solution of benzonitrile oxide containing triethylamine was treated with benzylsulfonyl chloride, a crystalline product was obtained. Analysis of that product suggested the empirical formula $C_{14}H_{12}NO_3Cl$, indicating the presence of 1 mole of hydrogen chloride over that expected of a cycloadduct. The infrared spectrum showed bands at 1 180 cm^{-1} and 1 380 cm^{-1} ($\rangle SO_2$). The nuclear magnetic resonance spectrum showed a singlet at 4.7 p.p.m. (relative area 1) and aromatic protons at 7.4–8.2 p.p.m. (relative area 5). The singlet is nearly in the same position as the singlet for the benzylic protons (4.78 p.p.m.) in benzylsulfonic anhydride (5). From these limited data the product was assigned the structure α-chlorobenzaldoxime benzylsulfonate.

$$Ph-C\equiv N\rightarrow O + PhCH_2SO_2Cl \xrightarrow[Et_2O]{Et_3N} Ph-\overset{Cl}{\overset{|}{C}}=NO_3SCH_2Ph$$

Similar compounds were obtained by like reactions of benzylsulfonyl chloride (Et_3N) and methanesulfonyl chloride (Et_3N) with *p*-chlorobenzonitrile N-oxide and *m*-nitrobenzonitrile N-oxide. However, the structurally hindered 2,4,6-trimethylbenzonitrile N-oxide yielded only 2,4,6-trimethylphenylisocyanate.

Nitrile oxides are prepared by dehydrohalogenation of α-chloroaldoximes ($R-\overset{Cl}{\overset{|}{C}}=NOH$, hydroxamic acid chlorides) with triethylamine (3). However, the reverse can be effected, i.e. nitrile oxides add hydrogen chloride (6) and thiols (7). This suggests the occurrence of the following equilibrium under the above reaction conditions.

$$R-\overset{Cl}{\overset{|}{C}}=NOH + Et_3N \rightleftharpoons R-C\equiv N\rightarrow O + Et_3NHCl$$

Thus, there may be present a small but significant amount of α-chloroaldoxime in the medium, and this α-chloroaldoxime may be adding to "sulfene" to give the ester, with the equilibrium shifting to the left as the reaction proceeds.

$$R-CH_2SO_2Cl \xrightarrow{Et_3N} [R-CH=SO_2] \xrightarrow{R'-\overset{Cl}{\overset{|}{C}}=NOH} RCH_2SO_3N=\overset{Cl}{\overset{|}{C}}-R'$$

I–VI

I	R = C_6H_5, R′ = C_6H_5	(m.p. 105–107°)
II	R = C_6H_5, R′ = *p*-ClC_6H_4	(m.p. 102–103°)
III	R = C_6H_5, R′ = *m*-$NO_2C_6H_4$	(m.p. 144–146°)
IV	R = H, R′ = C_6H_5	(m.p. 110–111°)
V	R = H, R′ = *p*-ClC_6H_4	(m.p. 80°)
VI	R = H, R′ = *m*-$NO_2C_6H_4$	(m.p. 98–100°)

In fact, benzylsulfonyl chloride reacts with nitrile oxides in ether in the presence of triethylammonium chloride to give the corresponding esters. But, it adds to neither benzonitrile oxide nor *p*-chlorobenzonitrile oxide in the absence of triethylammonium chloride (the highly reactive *m*-nitrobenzonitrile oxide did give a small quantity of ester under the latter conditions). The maximum yield of ester was obtained when triethylamine was added to a mixture of α-chloroaldoxime and sulfonyl chloride in benzene or ether (Table I) at room temperature or ice-bath temperature.

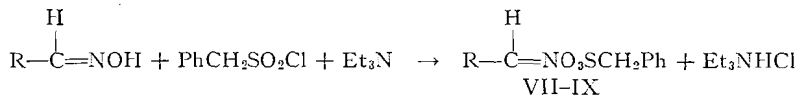


TABLE I

Yield of $R-\overset{Cl}{\overset{|}{C}}=NO_3SCH_2Ph$ in the reaction of $R-C\equiv N\rightarrow O$ with $PhCH_2SO_2Cl$

	R = C_6H_5 (I)	R = *p*-ClC_6H_4 (II)	R = *m*-$O_2NC_6H_4$ (III)
Ether + Et_3N	36%	37%	63%
Benzene + Et_3N	50%	43.6%	76%
Chloroform + Et_3N	24%	33.4%	
Ether	0%	0%	24%
Ether + $Et_3N\cdot HCl$	22%	39%	
Addition of Et_3N to a mixture of $RC(Cl)=NOH$ and $PhCH_2SO_2Cl$	57%	75%	81%

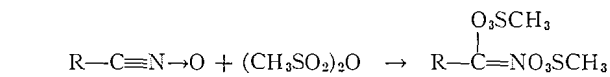
Also, *syn*-benzaldoxime, *syn*-*p*-chlorobenzaldoxime, and *anti*-*m*-nitrobenzaldoxime gave the corresponding sulfonic acid esters when treated under phenylsulfene-generating conditions.



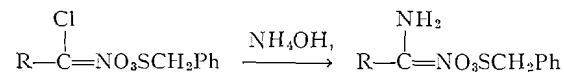
VII–IX

VII R = C_6H_5 (m.p. 77–79°)
VIII R = *p*-ClC_6H_4 (m.p. 103°)
IX R = *m*-$O_2NC_6H_4$ (m.p. 90–92°)

Under identical reaction conditions benzaldoxime did not react with *p*-toluenesulfonyl chloride.

Not many sulfonate esters of aldoximes are known (8, 9), because they are very unstable. *syn*-Aldoxime sulfonates decompose to nitriles spontaneously or when they are passed through an alumina column (8*a*). Such facile dehydrosulfonation was substantiated in this work and provided a simple and clean method for the overall dehydration of aldoximes to nitriles. The strained mesitaldoxime ester was too unstable to isolate, and decomposed to nitrile immediately.

It has been observed that methanesulfonic and benzylsulfonic anhydrides do generate "sulfenes" on reaction with triethylamine (5). Therefore, it was hoped that methanesulfonic anhydride might react with nitrile oxides as follows.



However, treatment of *p*-chlorobenzonitrile oxide and *m*-nitrobenzonitrile oxide with methanesulfonic anhydride in ether or chloroform in the presence of triethylamine yielded only starting nitrile oxide or its dimer.

In conclusion, the above facts do not clearly preclude a reaction sequence involving initial addition of "sulfene" to the nitrile oxide ($R'C\overset{+}{N}O_3\overset{-}{S}CHR$) followed by addition of hydrogen chloride, as against initial addition of hydrogen chloride to the nitrile oxide followed by addition of "sulfene".

Attempts were made, without success, to replace the "carbonyl" hydrogen of benzaldoxime benzylsulfonate and *p*-chlorobenzaldoxime benzylsulfonate with chlorine.

The esters I and II, on treatment with alcoholic KOH, gave benzonitrile and *p*-chlorobenzonitrile and, under more vigorous conditions, benzamide and *p*-chlorobenzamide, respectively. The ester III, on reaction with triethylamine, gave only *m*-nitrobenzonitrile. Presumably these reactions involve initial attack by the base on chlorine, with expulsion of the sulfonate anion to give the nitrile, which may be hydrolyzed further to the amide.

A cursory look at the structures of the esters indicates that there is a reactive chlorine atom, which should be replaced easily. The esters did not react with gaseous ammonia at room temperature. However, reaction with ammonium hydroxide in acetone at room temperature or higher yielded the corresponding amidoxime esters.

X–XII

X R = C_6H_5 (m.p. 102° (decomp.))
XI R = *p*-ClC_6H_4 (m.p. 89–90° (decomp.))
XII R = *m*-$NO_2C_6H_4$ (m.p. 127° (decomp.))

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The amidoxime esters were also prepared by the reaction of amidoximes with benzylsulfonyl chloride in the presence of triethylamine. The required amidoximes were prepared by the reaction of nitriles with hydroxylamine or by the action of gaseous ammonia on α-chloroaldoximes.

$$R{-}C{\equiv}N + NH_2OH \rightarrow R{-}\overset{\overset{NH_2}{|}}{C}{=}NOH$$

$$R{-}\overset{\overset{Cl}{|}}{C}{=}NOH + NH_3 \rightarrow R{-}\overset{\overset{NH_2}{|}}{C}{=}NOH$$

$$R{-}\overset{\overset{NH_2}{|}}{C}{=}NOH + [PhCH{=}SO_2] \rightarrow R{-}\overset{\overset{NH_2}{|}}{C}{-}NO_3SCH_2Ph$$

Amidoximes theoretically could exist in two tautomeric forms *a* and *b*.

$$R{-}\overset{\overset{NH_2}{|}}{C}{=}NOH \qquad (a)$$

$$R{-}\overset{\overset{NH}{\|}}{C}{-}NHOH \qquad (b)$$

Although structure *a* has been accepted as the correct structure of amidoximes, this preference was based on infrared spectroscopy (10 and references therein). However, more definitive support for structure *a* was provided by nuclear magnetic resonance spectroscopy (10, 11). Our synthesis of these compounds not only provides a proof for the structures of the sulfonate esters of α-chloroaldoximes but also provides chemical evidence for the structure of amidoximes.

Infrared spectra of the amidoximes that were studied showed asymmetric and symmetric NH_2 stretching modes as two weak but sharp bands at 3 400 – 3 500 and 3 300 – 3 400 cm^{-1} and a broad band at 3 200 cm^{-1} caused by an associated OH function (11). On esterification only the band caused by OH disappeared. The amidoximes as well as their sulfonate esters exhibited strong bands at 1 630 – 1 675 cm^{-1} caused by C=N (11).

The nuclear magnetic resonance spectra of the amidoximes and amidoxime sulfonates have been studied (Table II). The singlets at 9.6–10.0 p.p.m. are caused by N—OH (10, 11). The aromatic proton bands appear as a complex at 7.00 to 8.6 p.p.m., depending on the substitution on the aromatic ring. The NH_2 band appears as a singlet at 5.7 to 6.1 p.p.m. in amidoximes, a little higher than the literature values (10, 11). In the amidoxime sulfonate esters the singlet caused by OH disappears, and the singlet caused by NH_2 now shifts to the aromatic region and is not readily distinguished from the aromatic protons. However, the integration values support this conclusion. In the ester there is another band caused by benzylic protons at 4.78–4.80 p.p.m. as expected. The type of band shift observed for NH_2 has been reported (10) for oxamidoxime and its diacetate.

Variations in the chemical shifts observed and reported in the literature may be due to different solvents employed, e.g. it was observed that singlets caused by N—OH and NH_2 of benzamidoxime appear at 9.64 p.p.m. and 5.74 p.p.m. in dimethyl sulfoxide, but in deuterated chloroform they appear at 9.57 p.p.m. and 4.9 p.p.m., respectively.

EXPERIMENTAL*

Materials

The oximes were prepared according to the standard procedure. The α-chloroaldoximes were prepared by the action of chlorine on oximes in chloroform (12) or in 8 *N* HCl (4, 13) at ice-bath temperature. The solution first turns deep blue and finally slight orange. α-Chlorobenzaldoxime, m.p. 45–47° (lit. (4) m.p. 45°), is unstable and appears to be hydrolyzed to aldehyde when it is allowed to stand. *p*-Chloro(α-chloro)-benzaldoxime, m.p. 88–89° (lit. (4) m.p. 82–86°); *m*-nitro(α-chloro)benzaldoxime, m.p. 96–98° (lit. (4) m.p. 96°). Nitrile N-oxides were prepared *in situ* in most cases by the action of triethylamine on α-chloro-aldoximes in ether. However, *p*-chlorobenzonitrile oxide, m.p. 68–70° (lit. (14) m.p. 82–83°), was isolated for characterization. Triethylamine (Matheson, Coleman and Bell) was dried over KOH. Mallinckrodt anhydrous diethyl ether was used as obtained. Benzene was Baker spectrophotometric grade.

α-Chlorobenzaldoxime Benzylsulfonate (I)

To a continuously stirred solution of 1.55 g (0.01 mole) of α-chlorobenzaldoxime in about 100 ml of ether, maintained in an ice bath, was rapidly added 2 g (0.02 mole) of triethylamine. After 5 min, 2 g (slightly over 0.01 mole) of benzylsulfonyl chloride dissolved in about 15 ml of ether was added, dropwise, during a period of ½ h. After the solution was stirred for an additional hour, it was filtered and evaporated to dryness, and the residue was dissolved in benzene. Dilution with hexane and cooling yielded 0.5 g of 3,4-diphenylfuroxan, which, on further crystallization, had m.p. 112–114° (lit. (14) m.p. 114°). The mother liquor was evaporated to dryness and the residue was crystallized from alcohol to yield 1.1 g (36%) of the benzylsulfonate of α-chlorobenzaldoxime (I), m.p. 103–105° (raised to 105–107° after several crystallizations).

Anal. Calcd. for $C_{14}H_{12}ClNO_3S$: C, 54.28; H, 3.88; Cl, 11.45; N, 4.51; S, 10.32; mol. wt. 309.5. Found: C, 54.21; H, 4.13; Cl, 11.18; N, 4.71; S, 10.63; mol. wt. 313.

Infrared spectrum: 1 180 cm^{-1} (vs), 1 380 cm^{-1} (vs). Nuclear magnetic resonance spectrum: multiplets at 7.4–8.2 p.p.m. (relative area 5), singlet at 4.7 p.p.m. (relative area 1).

p-Chloro(α-chloro)benzaldoxime Benzylsulfonate (II)

To an ethereal solution containing 1 g of *p*-chlorobenzonitrile oxide and 1 g of triethylamine was added an ether solution of 1.5 g of benzylsulfonyl chloride as above. The residue remaining after the ether had been evaporated was dissolved in benzene, and the solution was filtered, diluted with hexane, and cooled. The precipitate was filtered off to give 0.6 g (37%) of the ester, m.p. 92–97°; after crystallization from benzene–hexane, m.p. 102–103°.

Anal. Calcd. for $C_{14}H_{11}Cl_2NO_3S$: C, 48.84; H, 3.20; Cl, 20.64; S, 9.30; mol. wt. 344. Found: C, 49.15; H, 3.56; Cl, 20.33; S, 9.71; mol. wt. 341.

The infrared spectrum was practically identical with that of I.

**All melting points are uncorrected. Microanalyses were performed by Dr. C. S. Yey and staff of the Microanalytical Laboratory, Purdue University. Nuclear magnetic resonance spectra were recorded on a Varian A-60 high-resolution spectrometer.*

Mesitonitrile N-Oxide

An aqueous basic solution of 12.7 g of the sodium salt of mesitaldoxime was added, while it was being filtered, to a stirred solution of sodium hypobromite (at 0 to 10°) prepared by adding 7 ml of bromine to 100 ml of 20% aqueous NaOH at 0 to 10°. The precipitate was filtered off, and the residue was washed with water and crystallized from hexane (first crop, m.p. 107–110°, yield 9.2 g; second crop, m.p. 104–106°, yield 2.1 g (lit. (6) m.p. 114°)).

Reaction of Mesitonitrile N-Oxide with Benzylsulfonyl Chloride in the Presence of Triethylamine

To an ether solution of 1.6 g (0.01 mole) of mesitonitrile oxide (m.p. 107–110°, lit. m.p. 114°) and 1 g of triethylamine was added an ethereal solution of 2 g of benzylsulfonyl chloride, as above. Evaporation of ether left a liquid residue, which was crystallized from hexane to give 1.1 g of 2,4,6-trimethylphenylisocyanate, m.p. 44–46°.

Anal. Calcd. for $C_{10}H_{11}NO$: C, 74.53; H, 6.83; N, 8.70. Found: C, 74.64; H, 6.93; N, 8.55.

In the infrared spectrum there was a very strong band at 2 260 cm^{-1}. In the literature (15) the isocyanate has been reported as a liquid. The urea derivative was prepared by treating the isocyanate with aniline, and had m.p. 240–242° (lit. (6) m.p. 245°).

m-Nitro(α-chloro)benzaldoxime Benzylsulfonate (III)

To an ice-cooled ethereal solution of 2 g (0.01 mole) of *m*-nitro(α-chloro)benzaldoxime was slowly added 1 g of triethylamine. After 5 min, 2 g of benzylsulfonyl chloride was added followed by the addition, over a ½ h period, of 1 g of triethylamine dissolved in ether. The residue obtained when the reaction mixture was filtered contained jelly-like material besides triethylammonium chloride. The residue was extracted with boiling benzene and the benzene solution evaporated to yield 1.65 g of the ester, m.p. 132–138°. The original ether mother liquor was evaporated to yield 550 mg of the ester, m.p. 135–140°; total yield 2.2 g (63%). After the product was crystallized from ether, it had m.p. 145–146°.

Anal. Calcd. for $C_{14}H_{11}ClN_2O_5S$: C, 47.46; H, 3.10; Cl, 10.00; N, 7.91; S, 9.00. Found: C, 47.73; H, 3.29; Cl, 10.28; N, 7.93; S, 8.72.

Although it is reported in the literature (14) that *m*-nitrobenzonitrile oxide is fairly stable, we could not isolate it in a pure form. On concentration it invariably turned to jelly-like material, possibly a dimer or trimer of the nitrile oxide. Therefore, the required nitrile oxide was always prepared *in situ* in dilute solution.

Reaction of Nitrile N-Oxides with Benzylsulfonyl Chloride in the Presence of Triethylamine in Benzene

The reactions in benzene were carried out the same as those in ether at a temperature of 10 to 15°. The yields of esters were: I, 50%; II, 43.6%; III, 76%.

Reaction of Nitrile N-Oxides with Benzylsulfonyl Chloride in the Presence of Triethylamine in Chloroform

The reactions in chloroform were carried out the same as those in ether at room temperature. The products could not be purified by crystallization and therefore were separated on acid-washed alumina columns. From the columns a 33.4% yield of compound II and a 24% yield of compound I were isolated.

Reaction of Nitrile N-Oxides and Benzylsulfonyl Chloride in Ether

Reaction of *p*-chlorobenzonitrile N-oxide with benzylsulfonyl chloride in ether yielded a white solid (after the solution had been stirred for 2 h at ice-bath temperature and the ether evaporated), which, when it was crystallized from benzene–hexane, yielded 1.55 g (75%) of benzylsulfonyl chloride and 0.9 g of crude nitrile oxide dimer.

Benzonitrile oxide which had similarly been treated with benzylsulfonyl chloride in ether yielded a white solid, which on work-up offered 1.9 g (95%) of benzylsulfonyl chloride.

After *m*-nitrobenzonitrile N-oxide had been treated with benzylsulfonyl chloride in ether as above, a small quantity (24%) of ester III (m.p. 140–143°) separated from the ether solution on concentration and cooling.

Reaction of Nitrile N-Oxides with Benzylsulfonyl Chloride in Ether in the Presence of 1 Equivalent of Triethylammonium Chloride

Without filtering off the triethylammonium chloride from the reaction of the α-chloroaldoxime and triethylamine (1 mole each) in ether, we treated the reaction mixture with 1 equivalent of benzylsulfonyl chloride, stirred it for 2 h at ice-bath temperature, and worked it up as before. When the ether was evaporated off, a liquid residue remained, in contrast to the preceding experiments. *p*-Chlorobenzonitrile oxide yielded 39% of ester II, and benzonitrile oxide yielded 22% of ester I.

Addition of 1 Equivalent of Triethylamine to a Mixture of 1 Mole of α-Chloroaldoxime and 1 Mole of Benzylsulfonyl Chloride

To an ether solution of a mixture of α-chloroaldoxime and benzylsulfonyl chloride (1 equivalent each) was added an ether solution of 1 equivalent of triethylamine at ice-bath temperature as before to yield: I, 57%; II, 75%; III, 81%.

α-Chlorobenzaldoxime Methanesulfonate (IV)

To an ether solution of 1.6 g of α-chlorobenzaldoxime was added 2 g of triethylamine at once at ice-bath

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

temperature followed by the addition of an ethereal solution of 1.2 g of methanesulfonyl chloride as before. From the residue, obtained after the ether had been evaporated, was isolated 0.8 g (33%) of ester IV (m.p. 106–109°), which, on further crystallization from benzene–hexane, had m.p. 110–111°.

Anal. Calcd. for $C_8H_8ClNO_3S$: C, 41.20; H, 3.43; Cl, 15.23; N, 6.01; S, 13.73. Found: C, 41.53; H, 3.46; Cl, 15.33; N, 5.94; S, 13.59.

p-Chloro(α-chloro)benzaldoxime Methanesulfonate (V)

Prepared as above, m.p. 80°.

Anal. Calcd. for $C_8H_7Cl_2NO_3S$: C, 35.82; H, 2.61; Cl, 26.50; N, 5.22; S, 11.94. Found: C, 35.76; H, 2.72; Cl, 26.35; N, 5.25; S, 12.21.

m-Nitro(α-chloro)benzaldoxime Methanesulfonate (VI)

Prepared as above with benzene as solvent (10 to 15° bath temperature); 1.4 g (50%) of crude ester VI was obtained (m.p. 91–95°), which, on further crystallization from benzene, had m.p. 98–100°.

Anal. Calcd. for $C_8H_7ClN_2O_5S$: C, 34.40; H, 2.51; Cl, 12.70; N, 10.03; S, 11.50. Found: C, 34.67; H, 2.51; Cl, 22.82; N, 9.96; S, 11.26.

syn-Benzaldoxime Benzylsulfonate (VII)

By using the method described for I, compound VII was prepared. The crude product, when it was dissolved in benzene and diluted with hexane, had m.p. 67–73°, and on further crystallization had m.p. 77–79°. The ester is unstable and decomposes to nitrile at room temperature in a couple of days. The infrared spectrum showed typical $\diagup\!\!\diagdown SO_2$ stretching bands at 1 175 cm^{-1} and 1 370 cm^{-1}.

The α-hydrogen of the aldoxime in the ester was not successfully replaced by chlorine as follows. (*a*) Dry chlorine was passed through a solution of 0.5 g of the ester at ice temperature for 20 min. When the solvent was evaporated, unchanged ester was recovered. (*b*) The same reaction was conducted at room temperature without success. (*c*) The ester was suspended in 8 *N* HCl and chlorine was passed through at room temperature, but only the unchanged ester was recovered.

syn-p-Chlorobenzaldoxime Benzylsulfonate (VIII)

The ester was prepared as above, m.p. 103°. The ester could not be chlorinated further.

Anal. Calcd. for $C_{14}H_{12}ClNO_3S$: C, 54.20; H, 3.87; N, 4.51; Cl, 11.42; S, 10.32; mol. wt. 310. Found: C, 54.29; H, 4.01; N, 4.42; Cl, 11.49; S, 10.19; mol. wt. 311.

The ester, when it was passed through an alumina column, decomposed to nitrile, m.p. 92° (lit. (16) m.p. 93–94°).

anti-m-Nitrobenzaldoxime Benzylsulfonate (IX)

The ester was prepared as above. The yield was quantitative (m.p. 90–92°).

Anal. Calcd. for $C_{14}H_{12}N_2O_5S$: C, 52.50; H, 3.75; N, 8.75; S, 10.00. Found: C, 52.48; H, 3.79; N, 8.55; S, 10.19.

Attempted Preparation of syn-2,4,6-Trimethylbenzaldoxime Benzylsulfonate

The same method was employed as described above, 3.26 g of oxime being used. The ester was a white solid at ice temperature. When it was dissolved in benzene at room temperature it decomposed spontaneously. Next day the solution was chromatographed on acid-washed alumina and the following compounds were isolated: 2,4,6-trimethylbenzonitrile (2 g), m.p. 49–51° (lit. m.p. 54°); *syn*-2,4,6-trimethylbenzaldoxime (100 mg), m.p. 125°; 2,4,6-trimethylformanilide (100 mg), m.p. 177–178° (lit. (17) m.p. 177°).

Hydrolysis of I and II

The esters (500 mg each) were hydrolyzed with 1 g of KOH dissolved in 50 ml of ethanol at room temperature (1 h) or at reflux temperature (½ h). The solution was diluted with water and the ethanol was removed under vacuum. The remaining solution was extracted with chloroform, dried over sodium sulfate, and evaporated to dryness. II at reflux temperature yielded 110 mg of *p*-chlorobenzamide, m.p. 172–174°, which, on further crystallization, had m.p. 176–177°; mixed melting point with an authentic sample, 175–176°. The same ester, on hydrolysis at room temperature, yielded a few milligrams of amide and 110 mg of crude *p*-chlorobenzonitrile, m.p. 80–87°. Hydrolysis of I at reflux temperature yielded 30 mg of benzamide, m.p. 125–126°, and at room temperature about 100 mg of crude benzonitrile.

Reaction of III with Triethylamine in Benzene

To a solution of 1.6 g of ester III in 50 ml of dry benzene was added 10 ml of triethylamine, and the solution was heated under reflux for 1 h. The solution was concentrated and added to an acid-washed alumina column prepared in hexane. Elution with benzene gave 340 mg of *m*-nitrobenzonitrile, m.p. 115–116° (lit. (18) m.p. 117–118°).

Reaction of m-Nitrobenzonitrile N-Oxide with Methanesulfonic Anhydride in Ether in the Presence of Triethylamine

To an ether (50 ml) solution of 1.75 g of methanesulfonic anhydride was added at ice-bath temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

an ether solution of 1.65 g of *m*-nitrobenzonitrile oxide. To the stirred solution was added, dropwise, an ether solution of 1 g of triethylamine (20 min). The solution was evaporated and the residue was treated with benzene, from which 0.4 g of the dimer of *m*-nitrobenzonitrile oxide was isolated. The residue was an orange liquid, which could not be identified further. However, the liquid did not show any characteristic $\rangle SO_2$ stretching bands in the infrared spectrum.

Reaction of p-Chlorobenzonitrile N-Oxide with Methanesulfonic Anhydride in the Presence of Triethylamine

The reaction was conducted as above, 1.9 g of *p*-chloro(α-chloro)benzaldoxime being used. The residue (after the ether had been evaporated) was treated with water and filtered to yield only *p*-chlorobenzonitrile oxide, as determined from its infrared spectrum (band at 2 300 cm^{-1} (vs)). The product was dissolved in benzene and worked up the next day to yield 1.1 g of the dimer of the nitrile oxide (m.p. 139–142°).

In a similar reaction in chloroform at room temperature 0.9 g of the dimer of the nitrile oxide (m.p. 139–142°) was obtained; the remaining residue was also a solid which showed a weak band at 2 300 cm^{-1} in its infrared spectrum caused by nitrile oxide but no bands caused by $\rangle SO_2$ stretching.

m-Nitrobenzamidoxime

Gaseous ammonia was passed through a benzene (50 ml) solution of 2.5 g of *m*-nitro(α-chloro)benzaldoxime for 15 min. The benzene solution was evaporated to dryness, and the residue was treated with water to remove ammonium chloride and crystallized from aqueous ethanol. The first crop was orange, m.p. 164–167°. The infrared spectrum showed two sharp bands at 3 500 – 3 400 cm^{-1} (vw) and 3 400 – 3 300 cm^{-1} (vw), a broad band at 3 200 cm^{-1}, and a sharp peak at 1 675 cm^{-1}. The second crop was greyish white, m.p. 167–170°, and there was a depression in the mixed melting point of the two. The first crop, on further crystallization, had m.p. 169–170°, yield 0.9 g (lit. (19) m.p. 174°).

When a similar experiment was done in ethanol at room temperature, a large amount of solid precipitated from the ethanol solution, m.p. 179–181°, which was not the dimer of the nitrile oxide. The yield of *m*-nitrobenzamidoxime was about the same as above. When ammonia was passed through the alcoholic solution at *ice-bath* temperature, the yield of *m*-nitrobenzamidoxime was doubled.

m-Nitrobenzamidoxime was also prepared by the reaction of *m*-nitrobenzonitrile and hydroxylamine, and the product was crystallized from water.

Nuclear magnetic resonance spectrum: singlet at 9.96 p.p.m. (relative area 1), multiplets at 7.4–8.6 p.p.m. (relative area 4), singlet at 6.1 p.p.m. (relative area 2).

p-Chlorobenzamidoxime

Gaseous ammonia was passed through an ethanol solution of 1 g of *p*-chloro(α-chloro)benzaldoxime at ice-bath temperature for 5 min. The solution was diluted with water and filtered. The clear solution was concentrated and cooled to give 740 mg of *p*-chlorobenzamidoxime, m.p. 127–130°. On further crystallization from water it melted at 132–133° (lit. (20) m.p. 134°). The infrared spectrum showed two sharp bands at 3 400 – 3 500 cm^{-1} (vw) and 3 300 – 3 400 cm^{-1} (vw), a broad band at 3 200 cm^{-1}, and a strong band at 1 650 cm^{-1}. Nuclear magnetic resonance spectrum: singlet at 9.64 p.p.m. (relative area 1), multiplets at 7.2–7.8 p.p.m. (relative area 4), singlet at 5.8 p.p.m. (relative area 2).

p-Chlorobenzamidoxime was also prepared by heating under reflux overnight a clear aqueous alcoholic solution of *p*-chlorobenzonitrile and hydroxylamine.

Benzamidoxime

A clear aqueous alcoholic solution of 0.1 mole of hydroxylamine and 0.1 mole of benzonitrile was gently heated under reflux overnight, concentrated, and cooled. The oil which separated out was poured on a porous plate, where it solidified. The solid was dissolved in benzene and crystallized, m.p. 76–78° (lit. (21) m.p. 78°). Infrared spectrum: two sharp bands at 3 400 – 3 500 cm^{-1} (vw) and 3 300 – 3 400 cm^{-1} (vw), a broad band at 3 200 cm^{-1}, and a band at 1 640 cm^{-1} (vs). Nuclear magnetic resonance spectrum: singlet at 9.64 p.p.m. (relative area 1), multiplets at 7.2 to 7.8 p.p.m. (relative area 5), singlet at 5.74 p.p.m. (relative area 2).

m-Nitrobenzamidoxime O-Benzylsulfonate (XII)

To an acetone (30 ml) solution of 1.75 g (0.005 mole) of the ester III was added 5 ml of ammonium hydroxide, and the mixture was stirred for ½ h at room temperature. Most of the acetone was removed under vacuum and diluted with water. A brown oil separated which soon solidified. The solid was dissolved in chloroform and diluted with hexane to give 1.1 g of crude XII (m.p. 117–120°). The mother liquor, on further concentration, gave a second fraction (m.p. 135–141°) which was mainly III. The first fraction, on further crystallization from benzene, had m.p. 127° (decomp.).

Anal. Calcd. for $C_{14}H_{13}N_3O_5S$: C, 50.15; H, 3.91; N, 12.53; S, 9.55. Found: C, 50.40; H, 3.95; N, 12.36; S, 9.72.

Infrared spectrum: two sharp bands at 3 400 – 3 500 cm^{-1} (vw) and 3 300 – 3 600 cm^{-1} (vw), a band at 1 640 cm^{-1} (s). Nuclear magnetic resonance spectrum: multiplets at 6.8–8.6 p.p.m. (relative area 11), singlet at 4.8 p.p.m. (relative area 2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

When ammonia was passed through the solution of the ester III in benzene at room temperature, only the starting material was recovered quantitatively.

m-Nitrobenzamidoxime O-benzylsulfonate was also prepared by the reaction of *m*-nitrobenzamidoxime with benzylsulfonyl chloride in the presence of triethylamine in tetrahydrofuran at ice-bath temperature. The solution was evaporated to dryness under reduced pressure and water was added to remove *m*-nitrobenzamidoxime. The ester was crystallized from benzene. The yield was quantitative, m.p. 126–127° (decomp.). The mixed melting point with the above ester was 125–126° (decomp.) and the infrared spectra of the two were identical.

p-Chlorobenzamidoxime O-Benzylsulfonate (XI)

The reaction was done as above with 1 g of II, except that the solution was gently heated under reflux for ½ h. The crude product (510 mg) was crystallized from benzene–hexane, m.p. 89–90° (decomp.).

Infrared spectrum: two sharp bands at 3 400 – 3 500 cm^{-1} and 3 300 – 3 400 cm^{-1}, a band at 1 640 cm^{-1}.

Compound XI was also prepared from *p*-chlorobenzamidoxime in ether as above. The white residue obtained after the ether had been evaporated was shaken with water to remove unreacted *p*-chlorobenzamidoxime, and the residue (90%) was crystallized. The first fraction (1 g) was pure XI, m.p. 87–89° (decomp.). The infrared spectrum was identical with that of the above material and there was no depression in the mixed melting point. The second fraction melted at 87–89°, but left a residue. The third fraction, m.p. 139–140°, had an infrared spectrum which indicated that it was a quaternary ammonium salt; also present were characteristic $\rangle SO_2$ stretching vibrations, indicating that the ester might be unstable and might decompose in the process of purification.

Anal. Calcd. for $C_{14}H_{13}ClN_2O_3S$ (m.p. 87–89°): C, 51.45; H, 4.01; Cl, 10.8; N, 8.6; S, 10.00. Found: C, 51.61; H, 3.97; Cl, 10.97; N, 8.40; S, 9.60.

Benzamidoxime O-Benzylsulfonate (X)

The reaction was done as above with 1 g of ester I, except that the reaction mixture was kept (well corked) for 2½ h at room temperature; 440 mg of crude X was obtained, m.p. 94° (decomp.). The compound is slightly soluble in benzene and ether. On crystallization from ether it had m.p. 98° (decomp.).

Infrared spectrum: two sharp bands at 3 400 – 3 500 cm^{-1} and 3 300 – 3 400 cm^{-1}, a strong band at 1 629 cm^{-1}.

Compound X was also prepared from benzamidoxime in ether as above. When the crude product was crystallized from ether, the ester had m.p. 102° (decomp.). The infrared spectrum was identical with that of the above material and a mixed melting point of the two was 98° (decomp.).

Anal. Calcd. for $C_{14}H_{14}N_2O_3S$: C, 57.93; H, 4.82; N, 9.6; S, 11.03. Found: C, 57.82; H, 5.00; N, 9.39; S, 10.84.

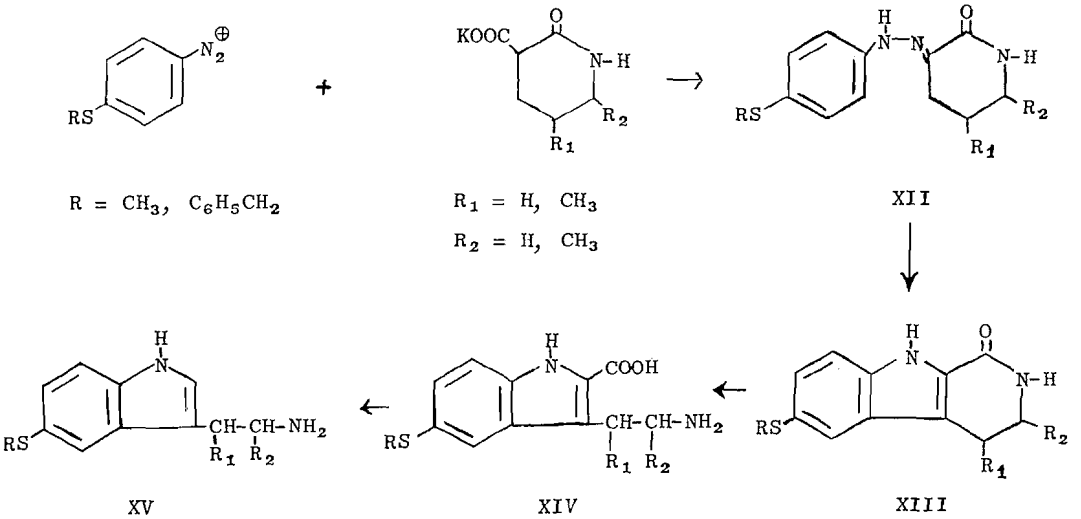
Received August 9, 1965



ABSTRACT

The Japp–Klingemann reaction has been employed to prepare six new tryptamines. Data on the intermediate phenylhydrazones, β-carbolines, and tryptamine carboxylic acids are presented. Syntheses of 5-methyl-, 6-methyl-, 5,5-dimethyl-, and 5,6-dimethyl-2-oxopiperidine-3-carboxylates are described.

Analogues of tryptamine have aroused considerable interest because of the implication of serotonin in the etiology of certain psychotic disorders. In a recent paper (1) we described the synthesis of the thiol analogue of serotonin. As an extension of this work we have now prepared some 5-alkylthio, branched-chain tryptamines.

The preparation of the various 5-alkylthiotryptamines was based on the piperidone procedure first introduced by Abramovitch and Shapiro (2). This route obviates the use of difficultly obtained indoles as starting materials and has been employed by several authors (1–5) for the synthesis of nuclear-substituted tryptamines. It was recently extended by Russian workers to include α-methyltryptamines (6, 7) and α,β-dimethyltryptamines (8). Abramovitch and Muchowski (9) further expanded the method to prepare β-methyltryptamines. An attempt by us to apply the method for the synthesis of 5-methylthio-β,β-dimethyltryptamine was unsuccessful when we were unable to hydrolyze the intermediate oxo-β-carboline (XIII-G; Table II). The general synthetic route is outlined in Reaction Scheme 1.

Utilizing the versatile Japp–Klingemann reaction, we prepared substituted 2,3-piperidione-3-(4′-alkylthio)phenylhydrazones (XII) from the various methyl-substituted

REACTION SCHEME 1.

3-carbethoxy-2-piperidones. The phenylhydrazones XII were cyclized in acid to the substituted 6-alkylthio-1,2,3,4-tetrahydro-1-oxo-β-carbolines (XIII). All β-carbolines underwent alkaline hydrolysis to the corresponding 3-aminoalkyl-5-alkylthio-2-indole carboxylic acid (XIV), except 4,4-dimethyl-6-methylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (XIII-G). With this compound, only starting material was isolated under a variety of alkaline hydrolytic conditions.

Infrared, ultraviolet, and nuclear magnetic resonance spectra were obtained for 6-methylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline and for the 3-methyl-, 4-methyl-, and 4,4-dimethyl-6-methylthio-1,2,3,4-tetrahydro-1-oxo-β-carbolines. In each case the spectra were inspected in an effort to find some difference in the 4,4-dimethyl compound which would account for its stability to basic hydrolysis. Enolization of the amide moiety of the lactam would confer alkaline stability upon the molecule, but infrared data failed to show any indication of C=N absorption in the critical 5.75–6.05 μ region in any of the β-carbolines. Ultraviolet spectra were unchanged when run in neutral and alkaline media, again indicating a lack of enolization. Nuclear magnetic resonance data on the four compounds, obtained on a 100 Mc instrument, showed the expected peaks and frequency shifts, except for those protons in the 5-positions. The 5-proton was found at 7.56 p.p.m. in both the non-methylated β-carboline and the 3-methyl β-carboline spectra. The 4-methyl spectrum showed a shift downfield of 0.11 p.p.m., and the 4,4-dimethyl a downfield shift of 0.22 p.p.m., for the 5-proton.

Menon and Simonson (10) reported that 4,4-dimethyl-2-piperidone was not hydrolyzed in base, while Kuhn and Jerchel (11) reported that 6-methyl-2-piperidone was opened under the same conditions. This retardation of ring-opening reactions by geminal substitution is well known, and Bordwell and co-workers (12) have theorized that the stabilizing effect is due to decreased ability of the departing atoms to move away from each other in the transition state. In our case nuclear magnetic resonance data have indicated interaction between the *gem*-dimethyls and the 5-proton. Molecular models suggest that there would also be rotational restriction between the *gem*-dimethyls and the carboxylate ion in the lyate species. These conditions would promote rapid reclosure to the lactam ring.

The 5-alkylthio, branched tryptamines (XV) were obtained in good yield by facile decarboxylation of the carboxylic acids (XIV) in a mixture of aqueous hydrochloric and acetic acids. Physical and analytical data for the compounds obtained by the above sequence are listed in Tables I–IV.

Except for ethyl 2-oxo-5,5-dimethylpiperidine-3-carboxylate (XI), the carbethoxypiperidones used in this work were prepared by modified versions of previously described procedures. These modifications along with references to the original methods are described in the Experimental section. The synthesis of ethyl 2-oxo-5,5-dimethylpiperidine-3-carboxylate (XI) was achieved by a three-step procedure starting with diethyl methylene malonate (13). The vinyl ester was allowed to react with 1-piperidino-2-methylpropene (14) to yield the formyl diester IX. The oxime X was prepared as described previously and hydrogenated over Raney nickel to yield piperidone XI, as shown in Reaction Scheme 2.

EXPERIMENTAL

Ethyl 2-Oxo-6-methylpiperidine-3-carboxylate (III)

A mixture of 1.2 g of ethyl 2-carbethoxy-4-acetylbutyrate (I) (15), 1.2 g of hydroxylamine hydrochloride, 6 ml of pyridine, and 6 ml of ethyl alcohol was refluxed for 3 h. The colorless solution was evaporated to dryness *in vacuo* and the residual syrup was partitioned between 15 ml of ether and 15 ml of water. The aqueous portion was extracted with another 15 ml of ether and the combined ether extracts were washed with 10 ml of water. The ether was dried and evaporated *in vacuo* to leave 0.98 g of syrup; λ_{max}^{film} 2.9–3.0 μ

REACTION SCHEME 2.

(NH, OH), 5.7–5.8 μ (ester C=O), 6.0 μ (C=N). The material was not purified further and was used directly in the next reaction.

A mixture of 185.7 g of ethyl 2-carbethoxy-4-acetylbutyrate ketoxime (II), 6 teaspoonfuls of W-2 Raney nickel, and 150 ml of ethyl alcohol was shaken under 3 atmospheres of hydrogen at 80°. The absorption of gas was complete after 98 h. The catalyst was removed by filtration and the filtrate was evaporated *in vacuo* to leave 117 g (84%) of off-white crystals. A portion was recrystallized from cyclohexane to yield an analytical sample, m.p. 71–73° (lit. m.p. 73° (7)). A more direct method (16) for the preparation of III has recently appeared.

Ethyl 2-Carbethoxy-4-acetylvalerate (IV)

To a solution of 0.2 g of sodium in 135 ml (0.84 mole) of diethyl malonate was added 18.0 g (0.21 mole) of methyl isopropenyl ketone over 15 min. The temperature rose to 45° and was maintained there by an external cold water bath. The mixture was stirred for 20 min, neutralized with acetic acid, and distilled *in vacuo* through a short Vigreux column. Excess diethyl malonate (95 g) was collected at 60–100° and 1.2 mm, and 39.7 g (76%) of product was collected at 122–132° and 1.2 mm. Redistillation of the latter fraction gave 32.2 g (62%), b.p. 116–122° at 1.0 mm.

In larger runs, the methyl isopropenyl ketone was distilled from a 50% monomer solution (K & K Chemical Co.) directly into the sodiomalonate solution. Yields of 70–75% were obtained by this procedure.

The analytical sample boiled at 124–125° and 1.7 mm.

Anal. Calcd. for $C_{12}H_{20}O_5$: C, 59.0; H, 8.25. Found: C, 59.1; H, 8.24.

Ethyl 2-Oxo-5,6-dimethylpiperidine-3-carboxylate (VI)

Ethyl 2-carbethoxy-4-acetylvalerate ketoxime (V) was prepared from the keto ester IV by the same procedure used to prepare oxime II.

A mixture of 126.8 g of oxime V, 2.5 teaspoonfuls of W-2 Raney nickel, and 150 ml of ethyl alcohol was shaken with hydrogen at 4 atmospheres and 100° for 66 h, thereby consuming 91% of the theoretical amount of gas. The catalyst was removed, and the solvent was evaporated to leave 96.3 g (99%) of the piperidone VI; λ_{max}^{film} 3.10 μ (NH), 5.75 μ (ester C=O), 5.99 μ (lactam C=O), *no* 10.69 μ band as seen in oxime V. The analytical sample was prepared by dissolving the oil in benzene and filtering the solution to separate a small amount of free acid. The benzene was concentrated and the residue was heated at 100° under reduced pressure. The residual oil did not crystallize. Reference 8 listed m.p. 67–68°.

Anal. Calcd. for $C_{10}H_{17}NO_3$: C, 60.3; H, 8.60; N, 7.03. Found: C, 60.0; H, 8.53; N, 7.10.

Ethyl 2-Oxo-5-methylpiperidine-3-carboxylate (VIII)

This compound was prepared essentially by the method of Abramovitch and Muchowski (9). The procedure involved the Michael addition of diethyl malonate and methacrylonitrile. The resulting ethyl 2-carbethoxy-4-cyanovalerate (VII) was hydrogenated to yield the piperidone VIII. We were able to effect this reduction over platinum oxide at low pressure, while the above authors utilized Raney nickel at high pressure.

Ethyl 2-Carbethoxy-4-formylisovalerate (IX)

To 88.0 g (0.63 mole) of 1-piperidino-2-methylpropene (14) was rapidly added 110.0 g (0.63 mole) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

diethyl methylene malonate (13). The resulting warm solution was cooled to room temperature and allowed to stand for 1 h. Ice water (100 ml) was added, and the mixture was adjusted to pH 3–4 with 6 *N* hydrochloric acid and stirred for 15 min. The acidic mixture was extracted with two 250 ml portions of ether. The ether was washed twice with 250 ml portions of water, and then with 100 ml of saturated sodium bicarbonate. The ethereal solution was dried and evaporated *in vacuo* to leave 110 g of a colorless syrup, which was distilled at 114–120° and 1.3 mm to give 71.5 g (46%). An analytical sample had b.p. 95–96° at 1.0 mm; λ_{max}^{film} 3.60 μ, 3.70 μ (aldehyde, C—H), 5.7–5.8 μ (ester, aldehyde C=O).

Anal. Calcd. for $C_{12}H_{20}O_5$: C, 59.0; H, 8.25. Found: C, 58.8; H, 8.39.

Ethyl 2-Oxo-5,5-dimethylpiperidine-3-carboxylate (XI)

Ethyl 2-carboxy-4-formylisovalerate aldoxime (X) was prepared from the formyl ester IX by the same procedure used to prepare the oxime II.

A mixture of 59.0 g of the oxime X, 5 teaspoonfuls of W-2 Raney nickel, and 150 ml of ethyl alcohol was shaken for 48 h under 3 atmospheres of hydrogen at 60°. The catalyst was removed and the solvent evaporated to leave 46.7 g (98%) of a syrup which crystallized after 2 weeks. A portion was triturated with cyclohexane to yield white crystals, m.p. 44–47°.

Anal. Calcd. for $C_{10}H_{17}NO_3$: C, 60.3; H, 8.60; N, 7.03. Found: C, 60.0; H, 8.55; N, 7.00.

2,3-Piperidione-p-alkylthiophenylhydrazones (XII)

All phenylhydrazones (XII-A–XII-G) listed in Table I were prepared by the same general procedure, which is described here for the preparation of 6-methyl-2,3-piperidione-3-(4′-methylthio)phenylhydrazone (XII-A).

Ethyl 2-oxo-6-methylpiperidine-3-carboxylate (III) (9.7 g, 0.05 mole) was dissolved in 25 ml of warm ethyl alcohol, cooled to 0°, and diluted with a solution of 3.5 g (0.05 mole) of potassium hydroxide in 75 ml of water. This clear solution was chilled overnight and diluted with 200 g of a mixture of cracked ice and water. The cold solution was stirred while a suspension of 4-methylthiobenzene diazonium chloride was added in one portion followed by the immediate addition of 6 g of sodium acetate. The diazonium salt was prepared from 0.05 mole of 4-methylthioaniline in 30 ml of 4 *N* hydrochloric acid and 0.05 mole of sodium nitrite. In the formation of this diazonium salt it was necessary to stir the reactants for 1–2 h at 0° to ensure complete reaction. The mixture was stirred at 0° for 6 h, and the tan solid was collected by filtration and washed well with water. The crude material was washed with ether, and then with cold ethyl alcohol, and was sufficiently pure for further reactions.

An analytical sample, m.p. 215°, was prepared by recrystallizations from 2-methoxyethanol and then from dilute ethyl alcohol.

All crystalline phenylhydrazones XII had infrared absorption spectra with these approximate values; λ_{max}^{Nujol} 3.10 μ, 3.15 μ (NH), 6.00 μ (amide C=O), 6.23 μ (aryl), 6.44 μ (amide II). The three benzyl-substituted hydrazones (XII-B, XII-D, and XII-F) showed 1,4-disubstituted benzene absorption near 12.1 μ.

5-Alkylthio-1,2,3,4-tetrahydro-1-oxo-β-carbolines (XIII)

The phenylhydrazones XII were cyclized to the β-carbolines (XIII-A–XIII-G) listed in Table II by a general method with either hydrogen chloride and glacial acetic acid or 88–90% formic acid. The preparation of 3-methyl-6-methylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (XIII-A) is described below. The acetic acid modification follows.

A solution of 9.5 g (0.035 mole) of 6-methyl-2,3-piperidione-3-(4′-methylthio)phenylhydrazone (XII-A) in 80 ml of 88–90% formic acid was refluxed for 1 h, cooled to 25°, and concentrated *in vacuo*. The residue was washed with ice and water, then separated, and triturated with ethyl alcohol to give a tan solid. This solid was collected and used in the next reaction without further purification. An analytical sample, m.p. 214°, was prepared by recrystallizations from butyl chloride – ethyl alcohol mixtures and finally from isopropyl alcohol.

In the preparation of the six β-carbolines XIII-C–XIII-G the phenyl hydrazones XII-C–XII-G were dissolved in glacial acetic acid either at 25° or by slight warming, and then hydrogen chloride was passed into the solutions for 15 min. To obtain maximum yields and to avoid decomposition, the resulting suspensions were heated for varying periods of time and at different temperatures: C, 15 min on a steam bath; D, 15 min at reflux; E, 10 min on a steam bath and 40 min at reflux; F, 1 min at reflux and 40 min at 25°; G, 15 min at reflux. These acetic acid solutions were then cooled, concentrated to approximately one-third volume under reduced pressure, and diluted with ice water. The aqueous portion was decanted and the gums were crystallized from hot isopropyl alcohol.

The β-carbolines XIII showed comparable infrared absorption spectra; λ_{max}^{Nujol} 2.90 μ, 3.07 μ (NH), 5.97 μ (amide C=O). Ultraviolet spectra: λ_{max}^{EtOH} XIII-A, 231 mμ (ϵ = 14 000); XIII-C, 248 mμ (ϵ = 16 000); XIII-G, 233 mμ (ϵ = 16 000). Nuclear magnetic resonance spectra were run in deuterated chloroform. Locations of the peaks for the 5-proton were: XIII-A, 7.56 p.p.m.; XIII-C, 7.67 p.p.m.; XIII-G, 7.78 p.p.m.

5-Alkylthiotryptamine-2-carboxylic Acids (XIV)

The tryptamine carboxylic acids XIV-A–XIV-F listed in Table III were prepared by the following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

general procedure, which is described for the preparation of 3-(2′-aminopropyl)-5-methylthio-2-indole carboxylic acid (XIV-A). One β-carboline XIII-G did not yield an amino acid under these alkaline hydrolytic conditions.

A solution of 3.8 g (15 mmoles) of 3-methyl-6-methylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (XIII-A) in 75 ml of ethyl alcohol was mixed with a solution of 12 g (0.18 mole) of potassium hydroxide in 20 ml of water and heated under reflux for 12 h. The solution was cooled, concentrated to half volume *in vacuo*, and diluted with water. The alkaline aqueous solution was passed through filter aid and charcoal, and then adjusted to pH 5 with acetic acid. The resulting solid was isolated by filtration and was of sufficient purity for use in further reactions. An analytical sample, m.p. 253° (decomp.), was prepared by recrystallizations from dilute ethyl alcohol.

The solid tryptamine carboxylic acids XIV showed similar infrared absorption spectra; λ_{max}^{Nujol} 2.94 μ (NH), 3.10 μ (NH, OH), 5.90 μ (acid C=O), 6.20 μ (aryl).

5-Alkylthio, Branched Tryptamines (XV)

The acidic decarboxylations of the tryptamine carboxylic acids XIV-A–XIV-F to the corresponding tryptamines XV-A–XV-F were run as described below in the preparation of 3-(2′-aminopropyl)-5-methylthioindole (XV-A). The substituted tryptamines are listed in Table IV.

A solution of 2.0 g (7.6 mmoles) of 3-(2′-aminopropyl)-5-methylthio-2-indole carboxylic acid (XIV-A) in 30 ml of acetic acid and 40 ml of 2 *N* hydrochloric acid was heated under reflux for 15 h. The clear solution was concentrated to near dryness and diluted with water. The acidic solution was passed through filter aid and charcoal, and adjusted to pH 10. The separated oil was extracted with ether; the ethereal solution was dried and concentrated to yield the free crystalline tryptamine XIV-A. Recrystallization from dilute ethyl alcohol gave an analytical sample, m.p. 108°.

The remaining tryptamines XV-B–XV-F were oils. For analytical purposes they were either converted into the picrate salts and recrystallized from 2-methoxyethanol–water (XV-B, XV-E), or converted into the hydrochloride salts in 6 *N* hydrochloric acid and recrystallized from dilute hydrochloric acid (XV-C, XV-D). One tryptamine (XV-F) was evaporatively distilled in a short-path tube for analysis.

All of the tryptamines that were prepared showed closely related infrared absorption spectra; λ_{max}^{Nujol} 3.00 μ (indole NH), 6.20 μ, 6.25 μ (NH_2, aryl). The benzyl derivatives had monosubstituted benzene absorption at 12.9 μ and 14.2 μ.

A GENERAL METHOD FOR SELECTIVE N-METHYLATION OF SUBSTITUTED TRYPTAMINES[1]

J. KENNETH HORNER AND W. A. SKINNER

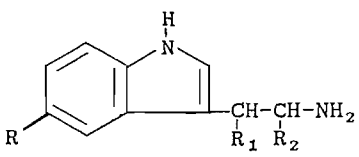
Department of Pharmaceutical Chemistry, Life Sciences Research, Stanford Research Institute, Menlo Park, California

Received August 16, 1965

ABSTRACT

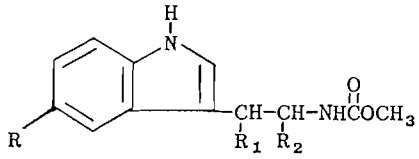
A general method for selective N-methylation of substituted tryptamines is described. The method involves the lithium aluminium hydride reduction of an intermediate carbamate. Eleven new tryptamines and 11 new carbamoyltryptamines are described.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



While preparing structural analogues of serotonin and bufotenin in this laboratory, we needed N-monosubstituted tryptamines (III) and N,N-disubstituted tryptamines (V). Until recently the method of choice for preparing N-substituted tryptamines was N-tosylation followed by N-alkylation with an alkyl halide and then reductive cleavage of the protective tosyl group with sodium in ammonia (1). This scheme, however, cannot be used if N,N-disubstitution is desired or if other functional groups sensitive to reductive cleavage are present on the molecule. In our laboratory 5-benzylthiotryptamine (I, R = $C_6H_5CH_2S$, $R_1 = R_2 = H$) was prepared and reduced to 5-mercaptotryptamine with sodium in ammonia (2); therefore, a different method of preparing 5-benzylthio-N-alkyltryptamines had to be found which would not cleave or reduce the labile benzylthio group.

While aryl tosylamides are sufficiently reactive to allow cleavage by hydrolysis with mineral acids (3), alkyl tosylates either are unaffected or polymerize. N,N-Dimethyl-5-aminoindole has been prepared by demethylation of the quaternary ammonium salt with sodium propoxide (4). In our laboratory the quaternary ammonium salt of N,N-dimethyltryptamine could not be demethylated by this procedure; the reaction only yielded material containing no amine function. A general method of converting β-phenethylamine into N,N-dimethylphenethylamine (5) by the Eschweiler–Clarke reaction yielded polymeric material when applied to tryptamines. Preparation of N-formyltryptamine followed by reduction with lithium aluminium hydride produced no identifiable product. N-Methyl-N-tosyltryptamine was not cleaved by boiling concentrated hydrochloric acid, nor was it reduced with lithium aluminium hydride.



The method which yielded N-methyltryptamines (III) and N,N-dimethyltryptamines (V), and which we report here, involved preparation of the appropriate carbamates (6) (II and IV) with methyl chloroformate followed by reduction with lithium aluminium hydride. Physical properties and elemental analyses of the substituted tryptamines prepared by this procedure are summarized in Table I.

To explore the applicability of the method, commercial-grade tryptamine hydrochloride was used as a model compound. The reaction of tryptamine and methyl chloroformate yielded the only crystalline carbamate in the series of tryptamines, methyl 2-(3′-indolylethyl)-carbamate (II, $R = R_1 = R_2 = H$), which was recrystallized from ethyl alcohol – water to give the analytical sample melting at 79°. This sample gave a good elemental analysis and was insoluble in dilute acid; its infrared spectrum showed amide carbonyl

IV

V

absorption at 5.9 μ. All other carbamates that were synthesized were oils which decomposed upon attempted distillation. Their infrared absorption spectra and solubility behavior corresponded favorably with the characterized carbamate of tryptamine, and in all cases they were reduced without further purification.

The attempted preparation of the quaternary ammonium derivative of 5-methylthio-3-(2′-dimethylaminopropyl)indole (IX) by reaction with methyl iodide yielded a crystalline compound XVII having the stoichiometry $C_{16}H_{28}I_2N_2SO$. This elemental analysis was not consistent with that of a monomethiodide; however, the analysis agreed quite well with that of a dimethiodide monohydrate of IX. In the proof of the suspected sulfonium–ammonium structure, ultraviolet and infrared spectral data were inconclusive. The nuclear magnetic resonance spectrum of the starting amine IX in carbon tetrachloride (with tetramethylsilane as an internal standard) revealed that the singlet absorption of the methylthio proton occurs at 2.41 p.p.m. (three protons) and that the singlet of the dimethylamino proton occurs at 2.30 p.p.m. (six protons).

The nuclear magnetic resonance spectrum of the uncharacterized product XVII in deuterated dimethyl sulfoxide (with tetramethylsilane as an external standard) showed six protons at 3.45 p.p.m. and nine protons at 3.57 p.p.m. Tiers (7) locates the methyl proton peaks of the tetramethylammonium ion at 3.33 p.p.m. and the methylene proton peaks of the tetraethylammonium ion at 3.40 p.p.m. Comparison of the nuclear magnetic resonance spectra of ethyl octadecyl sulfide and ethyl methyloctadecyl sulfonium iodide[2] in deuterated chloroform (with tetramethylsilane as an internal standard) showed that the

GENERAL EXPERIMENTAL

Methyl N-(5-Benzylthio-3-indolylpropyl-2′)-carbamate (II, R = $C_6H_5CH_2S$, R_1 = H, R_2 = CH_3)

All of the intermediate carbamoyltryptamines (II) and N-methylcarbamoyltryptamines (IV) were prepared by the following general procedure.

To a solution of 5.0 g (15.0 mmoles) of 3-(2′-aminopropyl)-5-benzylthioindole (8) in 150 ml of chloroform was added a solution of 0.1 mole of sodium hydroxide in 150 ml of water. The mixture was cooled in an ice bath and stirred while 30.0 mmoles of methyl chloroformate was added. The mixture was stirred, while cold, for 1 h, then acidified with 6 *N* hydrochloric acid, and stirred at 25° for 0.5 h. The layers were separated and the aqueous portion was extracted with chloroform. The organic portions were combined, washed with water, dried, and concentrated *in vacuo* to yield 4.4 g of the oily carbamate. The oil was insoluble in dilute hydrochloric acid and the infrared spectrum did not contraindicate the desired structure.

5-Benzylthio-3-(2′-methylaminopropyl)indole (XV)

All the N-methyltryptamines (III) and N,N-dimethyltryptamines (V) listed in Table I were prepared by the following general procedure.

To a stirred suspension of 3.8 g (0.1 mole) of lithium aluminium hydride in 100 ml of tetrahydrofuran was added a solution of 4.4 g (12.4 mmoles) of methyl N-(5-benzylthio-3-indolylpropyl-2′)-carbamate in 100 ml of tetrahydrofuran. The mixture was refluxed for 24 h and then cooled, and the excess reagent was decomposed either by careful addition of a few milliliters of a saturated ammonium chloride solution or by careful addition of a small amount of ethyl alcohol followed by water. The hydrolyzed mixture was concentrated *in vacuo* and extracted either with butyl alcohol – water (in the case of the aqueous ammonium chloride neutralization) or with ether–water (in the case of the ethyl alcohol – water neutralization). The butyl alcohol or ether portion was separated, washed with water, dried, and concentrated. The residual oil was dissolved in dilute hydrochloric acid; the solution was filtered, if necessary, and was then made basic with dilute sodium hydroxide. The free base was extracted with ether, dried, and concentrated under reduced

For personal use only.

pressure to give 4.3 g of free amine XV (80% yield). For analytical purposes a small amount was evaporatively distilled in a short-path tube at 200° and 0.2 mm.

Tryptamines VII and XI were solids and were recrystallized from dilute ethyl alcohol and butyl chloride. All other alkylated tryptamines in this series were oils. Some were converted into picrates and recrystallized from alcohol–water. One tryptamine (XIV) was converted into the hydrochloride by rubbing the free amine in 6 *N* hydrochloric acid; the hydrochloride was recrystallized from 2 *N* hydrochloric acid. One substituted free amine (XII) quickly formed a bicarbonate salt when left in the air for a short period of time. This salt was water soluble and high melting, and showed the characteristic NH_2^+ stretching vibration absorptions at 3.70 μ in the infrared. The salt was recrystallized from ethyl alcohol for analytical purposes.

5-Methylthio-3-(2′-dimethylaminopropyl)indole Dimethiodide (XVII)

The reaction of 5-methylthio-3-(2′-dimethylaminopropyl)indole (IX) with an excess of methyl iodide in acetone gave a solid which was purified by recrystallizations from ethyl alcohol. Elemental analysis of the water-soluble analytical sample, m.p. 130° (decomp.), was inconsistent with a monomethiodide structure but did correspond to the dimethiodide monohydrate of the starting amine IX.

Anal. Calcd. for mono CH_3I: C, 46.2; H, 5.94; N, 7.18. Found for XVII: C, 35.0; H, 4.90; N, 5.17. Calcd. for $(CH_3I)_2 \cdot H_2O$: C, 34.9; H, 5.13; N, 5.09.

That XVII was the dimethiodide monohydrate in the sulfonium–ammonium form was proved by nuclear magnetic resonance.

THE NUCLEAR MAGNETIC RESONANCE SPECTRUM OF VINYLENE CARBONATE

K. A. McLauchlan[1]
Basic Physics Division, National Physical Laboratory, Teddington, Middlesex, England

AND

T. Schaefer
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received August 16, 1965

ABSTRACT

The H and ^{13}C spectra of vinylene carbonate have been studied by double-resonance techniques. It was found that $J(^{13}C—H) = \pm 220.15 \pm 0.15$ c/s, $J(^{13}C—C—H) = \pm 17.47 \pm 0.12$ c/s, and $J(H—C—C'—H') = \pm 1.47 \pm 0.03$ c/s. A long-range coupling of 9.26 ± 0.10 c/s was observed between the carbon nucleus of the carbonate group and the vinyl protons. The magnitudes and signs of the geminal $^{13}C—C—H$ couplings are discussed in terms of the molecular orbital theory of Pople and Bothner-By.

INTRODUCTION

Early studies (1) of enriched samples of ethane, ethylene, and acetylene showed that the magnitude of the geminal couplings between ^{13}C and H nuclei varied considerably. Spectral analysis showed that the coupling in acetylene was of the same sign as the directly bonded $^{13}C—H$ coupling, and was therefore positive, while those in ethane and ethylene were negative. Freeman (2), using double-resonance techniques, discovered that the corresponding geminal coupling in *sym*-tetrabromoethane was positive and that couplings of both signs occurred in acrylonitrile (3). Studies of propene (4) and acetaldehyde (5) also demonstrated couplings of both signs, as did an investigation of vinyl bromide (6). The work reported here was initiated to discover the sign of the large geminal coupling constant observed in vinylene carbonate (structural formula given in Table I, No. 4).

EXPERIMENTAL

The sample of vinylene carbonate was obtained from the Koch-Light laboratories. Homonuclear double-resonance experiments were performed at "tickling" radio-frequency field strengths (7) in the frequency–sweep mode of a Varian H.A.100 spectrometer. Heteronuclear "tickling" experiments were carried out on a modified field–frequency stabilized V4300B spectrometer operating at 56.4 Mc/s in the proton region and with its transmitter coil double-tuned to the H and ^{13}C resonant frequencies. The ^{13}C irradiating field was derived from a Rohde and Schwarz frequency synthesizer.

RESULTS

The proton spectrum of vinylene carbonate showed three sets of satellite transitions caused by molecules containing ^{13}C nuclei. Two of these originated in the normal geminal and directly bonded coupling between ^{13}C and H nuclei of the ethylenic group. The third set, a doublet showing no H—H coupling, was derived from a long-range coupling between the carbon nucleus of the carbonyl group and the protons. This coupling, a *trans* one through oxygen and carbon, had a magnitude of 9.26 ± 0.10 c/s. Its sign could not be determined but its existence was confirmed by "tickling" experiments in the ^{13}C region.

A schematic representation of the spectrum caused by molecules containing a ^{13}C nucleus in one of the ethylenic positions is given in Fig. 1, the central proton peak caused

[1]*Present address: Physical Chemistry Laboratory, South Parks Road, Oxford, England.*

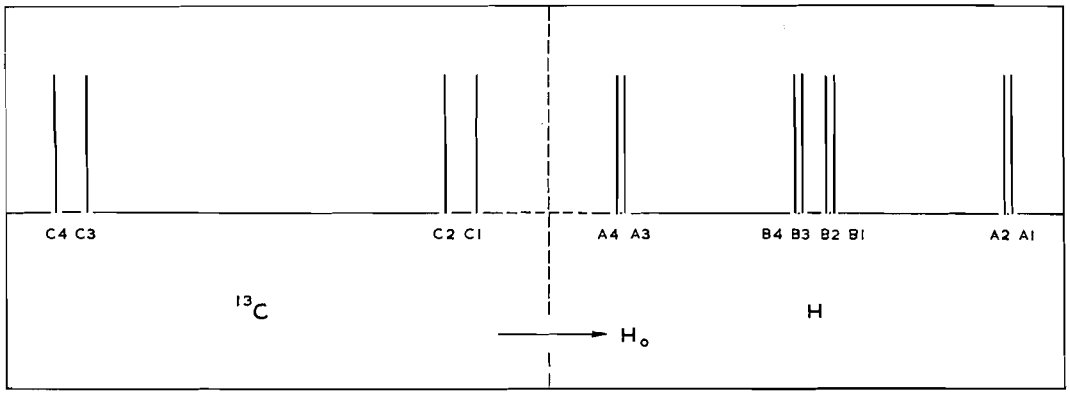

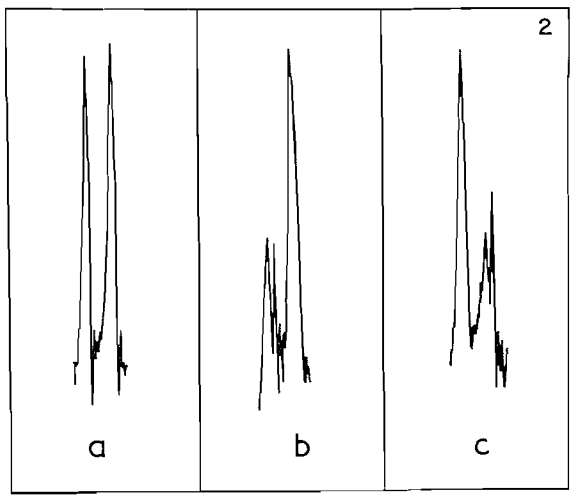

FIG. 1. A schematic diagram of the coupled spin system of molecules containing one ^{13}C nucleus in the vinyl group. Resonances caused by one of the carbons being ^{12}C are omitted for clarity. The numbering is in the order of increasing absolute frequency.

by the presence of a ^{12}C nucleus in the second ethylenic position being omitted to focus attention on the coupled spin system. Direct measurement of the proton spectrum gave the magnitudes of $J(^{13}C—H)$, $J(^{13}C—C—H)$, and $J(H—C—C'—H')$ quoted below, together with the standard deviations of the measurements. The relative signs of these coupling constants were obtained by "tickling" experiments. Figure 2 shows the results of one such experiment where the low-field satellite peaks A3 and A4 are shown while the proton transition B4 is irradiated (Fig. 2*b*) and while B3 is irradiated (Fig. 2*c*). Figure 3 shows the results of a further experiment performed with "tickling" in the ^{13}C region. Figure 3*a* shows the high-field doublet A1 and A2 while Fig. 3*b* shows the effect on this

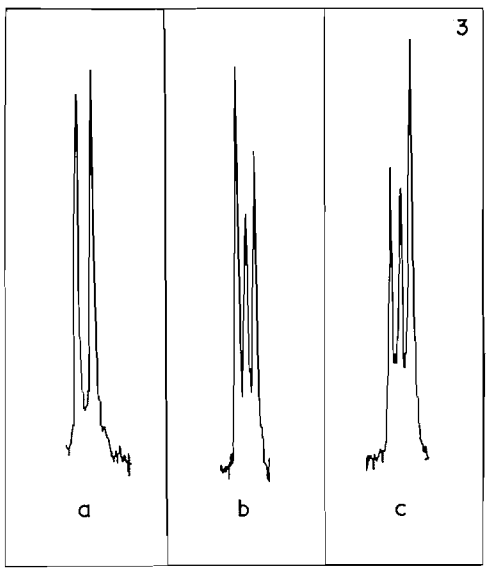

FIG. 2. (*a*) The low-field proton doublet A3 and A4, with (*b*) irradiation of the proton line B4 and (*c*) irradiation of B3.

FIG. 3. (*a*) The high-field proton doublet A1 and A2, with (*b*) irradiation of the ^{13}C transition C1 and (*c*) irradiation of the ^{13}C transition C2.

doublet of irradiating ^{13}C transition C1 and Fig. 3*c* shows the effect of irradiating C2. The observations are consistent only when all the couplings have like sign (2). The magnitudes and signs of the coupling constants are thus: $J(H—C—C'—H') = \pm 1.47 \pm 0.03$ c/s, $J(^{13}C—H) = \pm 220.15 \pm 0.15$ c/s, and $J(^{13}C—C—H) = \pm 17.47 \pm 0.12$ c/s.

A chemical shift of 23.07 p.p.m. was observed between the ethylenic and carbonyl ^{13}C resonances, the carbonyl ^{13}C nucleus being observed at the higher frequency, i.e. at low field. This result is consistent with other observations (8).

DISCUSSION

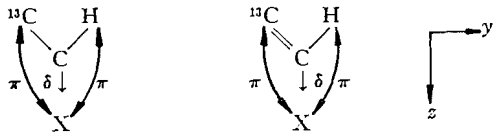
Proton–Proton Coupling

The coupling $J(H—C—C'—H')$ between the olefinic protons in cyclic compounds depends on ring size (9–12). Theory (13) agrees that it is inversely dependent on angles θ and θ' ($\theta = \angle HCC'$, $\theta' = \angle CC'H'$) of the HCC'H' fragment. $J(H—C—C'—H') = 5.3 \pm 0.1$ c/s in cyclopentene (11, 12). Replacement of the hydrogen atoms in ethylene by more electronegative atoms induces a rehybridization of the carbon atoms in the HCC'H' fragment (13) and decreases $J(H—C—C'—H')$. The observed decrease (14) in $J(H—C—C'—H')$ in substituted ethylenes is $11.7(1 - 0.34\Delta E)$, where $\Delta E = E_X - E_H$ (X = substituent). Replacement of two hydrogen atoms by carbon atoms would therefore result in $J(H—C—C'—H') = 8.5$ c/s, leaving 3.2 c/s as the decrease caused by ring closure, i.e. caused by increases in θ and θ'. Finally, if one writes $J(H—C—C'—H') = 5.3(1 - 2 \times 0.34\Delta E)$, where $\Delta E = E_0 - E_C = 1$, there results $J(H—C—C'—H') = 1.6$ c/s as the predicted value for vinylene carbonate, in satisfactory agreement with the experimental value of $+1.5$ c/s.

Geminal Carbon–Proton Coupling

General

In their theory of nuclear spin coupling between geminal hydrogens, Pople and Bothner-By (15) have indicated that the positive trend in $J(H—C—H)$ in going from ethane to ethylene arises because, with rising s character of the carbon atom, the lowest energy transition between a bonding antisymmetrical orbital and an antibonding symmetrical orbital is favored (the methylene group is described in terms of four molecular orbitals delocalized over both C—H bonds). Furthermore, inductive withdrawal of electrons from these orbitals is predicted to lead to a positive change in $J(H—C—H)$, while hyperconjugative withdrawal is predicted to lead to a negative change. The opposite predictions apply to a donation of electrons. These predictions are in qualitative agreement with experiment (15).



The positive trend of $J(H—C—H)$ with rising s character is also observed for $J(^{13}C—C—H)$ in ethane, ethylene, and acetylene (1). Now, it often happens that a linear relationship exists between s character in the bonding carbon orbital and $J(^{13}C—H)$ (16–19). On the assumption (16) that both $J(^{13}C—H)$ and $J(^{13}C—C—H)$ tend to reflect the s character in the carbon bonding orbitals, an increase is expected in both as the s character of the carbon atom in the C—H or C—C bonds increases. It is also normally accepted that the s character depends on inductive withdrawal or donation of electrons by the substituent (19). If it is now further assumed that hyperconjugative withdrawal or donation by the substituent does not affect $J(^{13}C—H)$ and that the theory of Pople and Bothner-By can be qualitatively extended to $^{13}C—C—H$ systems, then there exists a basis

$$\begin{array}{c} | \\ X \end{array}$$

for the semiquantitative discussion of the sign and magnitude of $J(^{13}C—C—H)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

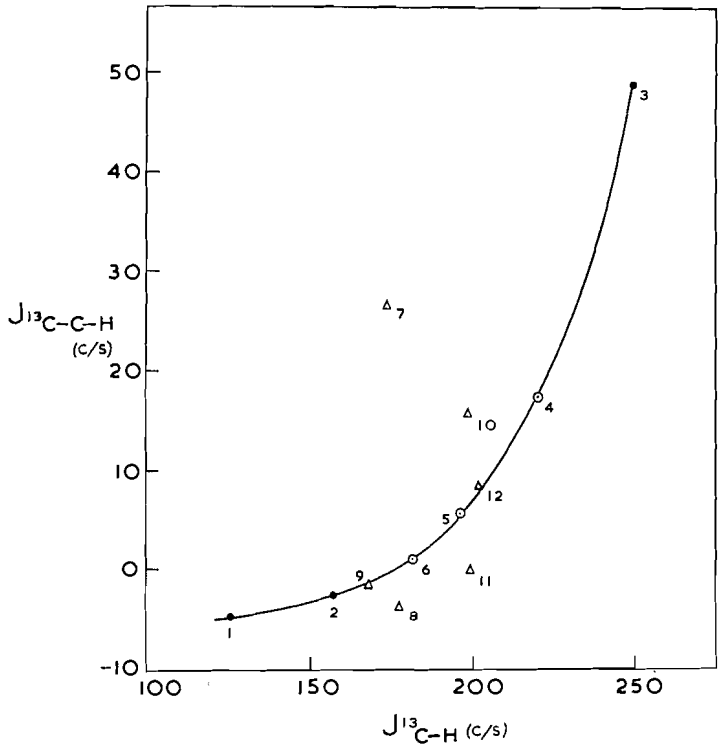
Assume that in structures I and II the approach of Pople and Bothner-By (15) can be

I II

qualitatively utilized. The electronegative substituent X withdraws δ electrons (straight arrow in I and II) from the C—C and C—H bonds, thus leading to a positive increase in $J(^{13}C—C—H)$. At the same time, by the theory of Juan and Gutowsky (19), the s character of the carbon-bonding orbital in C—H increases, leading to an increase in $J(^{13}C—H)$. If the substituent X is also able to donate or withdraw electrons in a hyperconjugative way (curved arrows in I and II), this will further increase or decrease, respectively, the value of $J(^{13}C—C—H)$ without affecting $J(^{13}C—H)$ very much.[2] Hence, a plot of $J(^{13}C—C—H)$ versus $J(^{13}C—H)$ should reflect hyperconjugative effects on $J(^{13}C—C—H)$ in a semi-quantitative way.

Application to Experimental Data

In Fig. 4 are plotted $J(^{13}C—C—H)$ values versus $J(^{13}C—H)$ values for the molecules listed in Table I. The solid circles represent ethane, ethylene, and acetylene. The points for vinylene carbonate, vinyl bromide, and *sym*-tetrabromoethane are represented by open circles. A smooth line is drawn through these six points. Deviations from this line are now discussed for individual compounds.



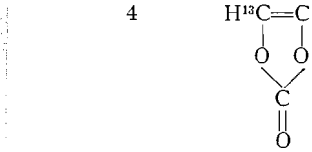


FIG. 4. $J(^{13}C—C—H)$ is plotted versus $J(^{13}C—H)$. The numbering corresponds to that in Table I. A smooth line is drawn through points 1 to 6.

[2]*There is some evidence that there are small contributions to* $J(^{13}C—H)$ *by* π *electrons (20).*

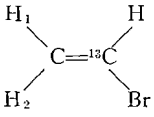
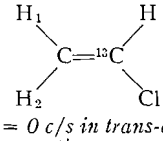
12	$Cl_2{}^{13}C=CHCl$	±8.4	201.2‡±1	27

*Sign relative to $J(^{13}C—H)$.

†Note that the value given refers to the carbon to which the substituent is attached, e.g. in acrylonitrile (point 8) $J_\alpha(^{13}C—H)$ = 176.7 c/s.

‡Reference 28 gives $J(^{13}C—H)$ = 220.1 and 201.2 c/s for vinylene carbonate and trichloroethylene, respectively.





Acetaldehyde (point 7).—The greatest deviation of any is found for this compound in Fig. 4. Inductive electron withdrawal by the oxygen from the C—C and C—H bonds leads to an increase in both $J(^{13}C—H)$ and $J(^{13}C—C—H)$. However, hyperconjugative back donation of electrons (from the oxygen p_y orbital) is expected to increase $J(^{13}C—C—H)$ further. The effects reinforce one another to give $J(^{13}C—C—H)$ = +26.6 c/s. A similar explanation holds for the very large positive value of $J(H—C—H)$ in formaldehyde (15).

Vinyl cyanide (point 8).—Here the cyano group, being more electronegative than hydrogen, increases $J(^{13}C—H)$[3] to 176.7 c/s; however, it can also withdraw electrons from the $^{13}C{=}C—H$ fragment by hyperconjugation, and this is expected to lead to a negative change in $J(^{13}C—C—H)$. From Fig. 4 it appears that the hyperconjugative effect outweighs the inductive effect, and the net result is a negative deviation from the line. A similar shift in $J(H—C—H)$ is noted for the cyanomethanes (15).

In diethyl maleate (point 9) hyperconjugative withdrawal by the carbonyl group is hindered by the geometry of the system (combined steric hindrance and rotation), and no deviation is present *if* it is assumed that $J(^{13}C—C—H)$ is *negative*.

The chloroethylenes (points 10, 11, and 12).—If $J(^{13}C—C—H)$ for trichloroethylene (point 12) is assumed to be positive, it falls very near the line in Fig. 4. However, both 1,2-dichloroethylenes (points 11 and 12) deviate strongly, and the deviations, probably of opposite sign,[4] cannot be explained in terms of the concepts presented above. In this

[3] *$J(^{13}C—H)$ involves the substituted carbon whereas $J(^{13}C—C—H)$ involves the unsubstituted carbon; see structures I and II.*

[4] *In the molecule*  *, $J(^{13}C—C—H_1)$ = +7.5 c/s while $J(^{13}C—C—H_2)$ = −8.5 c/s (21). If a similar situation holds in*  *, then $J(^{13}C—C—H)$ in cis-dichloroethylene is positive. Furthermore, the values $J(^{13}C—C—H)$ = 0 c/s in trans-dichloroethylene and $J(^{13}C—C—H)$ = +8.4 c/s (assumed positive) are consistent with this assumption.*

connection it may be noted that the hybridization parameters calculated from $J(^{13}C—H)$ values in the methyl halides (18, 19) are among the most "unacceptable" (22). Doubt has recently been expressed (23, 24) about the validity of the rehybridization theory for $J(^{13}C—H)$. In any case, the deviations noted here may well indicate the presence of an important factor which has been neglected in this discussion. Further determinations of both the size and sign of $J(^{13}C—C—H)$ in model compounds are needed.

The Coupling $J(^{13}C—O—C—H)$

The only other values in the literature are ± 3.1 and ± 4.0 c/s and are for compounds (alkylesters) where ^{13}C is sp^2 hybridized (25). The higher value in vinylene carbonate may partly be the result of the second oxygen atom bonded to $^{13}C{=}O$, since it is known (23) that $J(^{13}C—C—C—H)$ increases slightly as the electronegativity of the substituent on ^{13}C increases. However, there appear to be a number of other factors involved in determining $J(^{13}C—C—C—H)$, in addition to the s character of the ^{13}C atomic orbital (23). The largest value found to date for $J(^{13}C—C—C—H)$ is ± 6.4 c/s in trimethylacetylbromide (23).

CHOLLA GUM

I. STRUCTURE OF THE DEGRADED CHOLLA GUM

V. M. PARIKH[1] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received September 16, 1965

ABSTRACT

Purified cholla gum (*Opuntia fulgida*) contains L-arabinose (51.6%), D-galactose (31.7%), D-xylose (15.0%), L-rhamnose (2–3%), and D-galacturonic acid (11.2%). Partial hydrolysis of the gum by cold acid produced a polymer which contained only D-galactose and D-galacturonic acid in the proportion 9:2. Methylation and hydrolysis of the degraded gum produced 2,3,4,6-tetra-*O*-methyl-D-galactose (2 moles), 2,3,4-tri-*O*-methyl-D-galactose (1 mole), 2,4,6-tri-*O*-methyl-D-galactose (2 moles), 2,4-di-*O*-methyl-D-galactose (4 moles), and 2,3,4-tri-*O*-methyl-D-galacturonic acid (2 moles). Smith-type degradation of the degraded gum produced D-galactose (6 moles), glycolaldehyde (? moles), glycerol (2.5 moles), and glyceronic acid (2.5 moles).

Hydrolysis of the undegraded gum produced an aldobiouronic acid, which was proved to be 3-*O*-(β-D-galactopyranosyl uronic acid)-D-galactose by its reduction, methylation, and the identification of the methylated sugars obtained by the hydrolysis of the octamethyl galactobioside.

Based on these results, a possible structure for the average chain length of the degraded gum has been proposed.

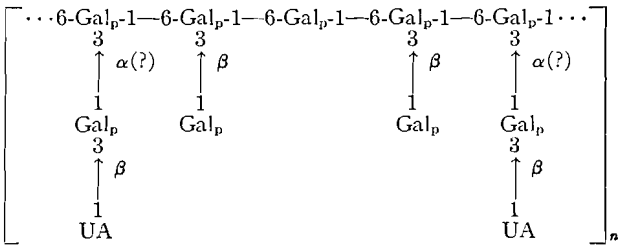
The sample of the cholla gum (*Opuntia fulgida*) that was investigated was obtained through the kindness of Dr. B. A. Erukoff and Dr. K. Folkers of the New York Botanical Garden. The gum was earlier investigated by Anderson *et al.* (1) and by Sands and Klass (2), who reported D-galactose, D-galacturonic acid, L-rhamnose, and L-arabinose as constituent units. They also isolated an aldobiouronic acid and identified it as *O*-(D-galactopyranosyl uronic acid)-L-rhamnose. In a later investigation Brown *et al.* (3) detected significant quantities of D-xylose residues in it, but reported that their sample of gum contained only trace quantities of L-rhamnose. They also carried out the methylation of the gum and were able to isolate, from the hydrolysate of the methylated gum, the following sugars: (*i*) 2,3,5-tri-*O*-methyl-L-arabinose, (*ii*) 2,3,4-tri-*O*-methyl-D-xylose, (*iii*) 2,3-di-*O*-methyl-L-arabinose, (*iv*) 2,4-di-*O*-methyl-D-galactose, (*v*) L-arabinose (unsubstituted), and (*vi*) 2-*O*-methyl-D-galacturonic acid. In the present investigations a beginning has been made on a study of the detailed molecular architecture of the repeating unit of the gum.

Partial hydrolysis of the gum with 3% sulfuric acid on a boiling water bath produced an aldobiouronic acid, viz. 3-*O*-(β-D-galactopyranosyl uronic acid)-D-galactose, which, after formation of its ester glycoside, was reduced with lithium aluminium hydride to a neutral galactobioside and then completely methylated; the product was hydrolyzed to produce 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose. The two methylated sugars were identified by conversion into their respective *N*-phenylglycosylamines. Partial hydrolysis of the gum with cold 6 *N* sulfuric acid for 21 days, on the other hand, produced a degraded gum, containing D-galactose and D-galacturonic acid only, together with a series of neutral oligosaccharides and monosaccharides. The pure degraded gum was obtained, as a barium salt, by removal of the mono- and oligo-saccharides by dialysis and the repeated precipitation of the undialyzable material from ethanol. A detailed report on the isolation and identification of the oligosaccharides

[1]*Present address: Department of Chemistry, Notre Dame University, Nelson, British Columbia.*

thus obtained will be published in a subsequent paper. However, it may be mentioned here that two of the major components were 6-*O*-β-D-galactopyranosyl-D-galactose and 3-*O*-β-D-galactopyranosyl-D-galactose. (The barium salt of the degraded gum was obtained as a white powder, and had $[\alpha]_D^{23}$ +46.5° (*c*, 1.5 in water).) The equivalent weight of the degraded gum acid was found to be 920, this amounting to a uronic acid anhydride content of 19.1%. On hydrolysis it gave mainly D-galactose and D-galacturonic acid in the approximate ratio of 9:2, together with trace quantities of L-arabinose (ca. 1%) and L-rhamnose (ca. 2–5%).

Polymers containing a high percentage of uronic acid residues are frequently very difficult to methylate by Haworth's method (4, 5). The degraded gum was, however, very rapidly methylated by the procedure described by Srivastava and co-workers (6). Methylation was completed by two treatments with Purdie's (7) reagents. Methanolysis and hydrolysis of the methylated degraded gum produced a mixture of partially methylated sugars, which were separated and identified as (i) 2,3,4,6-tetra-*O*-methyl-D-galactose (2 moles), (ii) 2,3,4-tri-*O*-methyl-D-galactose (1 mole), (iii) 2,4,6-tri-*O*-methyl-D-galactose (2 moles), (iv) 2,4-di-*O*-methyl-D-galactose (4 moles), 2,3,4-tri-*O*-methyl-D-galacturonic acid (2 moles), and trace quantities of a di-*O*-methyl (?) derivative of L-rhamnose. The average chain length of the degraded gum, which contains two D-galacturonic acid residues, was calculated to be 11 anhydrohexose units or a multiple of this. Isolation of 2 moles of tetra-*O*-methyl-D-galactose and 2 molecules of tri-*O*-methyl-D-galacturonic acid suggested that, out of a total of 11 hexopyranose residues constituting the average chain length of the degraded gum, 4 formed nonreducing terminal residues and that therefore the degraded gum must also be a highly branched molecule.



When subjected to periodic acid oxidation, the degraded gum consumed 0.93 mole of the oxidant and liberated 0.47 mole of formic acid per mole of anhydrohexose unit. As the average chain length of the degraded gum is believed to be composed of 11 anhydrohexopyranose units, the above results can be interpreted as the consumption of 10.2 moles of the oxidant and the liberation of 5.2 moles of formic acid per average repeating unit of the degraded polymer. During the methylation studies, 4 moles of 2,4-di-*O*-methyl-D-galactose and 2 moles of 2,4,6-tri-*O*-methyl-D-galactose residues were obtained. Thus, 6 moles of a total of 11 moles of the average repeating unit were not expected to consume any oxidant. The remaining five hexopyranose residues, resulting in the production of 2,3,4,6-tetra-*O*-methyl-D-galactose (2 moles), 2,3,4-tri-*O*-methyl-D-galactose (1 mole), and 2,3,4-tri-*O*-methyl-D-galacturonic acid (2 moles), were expected to consume 2 moles of the oxidant and to produce 1 mole of formic acid per hexose unit, thus accounting for a total consumption of 10 moles of the oxidant and production of 5 moles of formic acid per average repeating unit in the polymer.

The degraded gum was subjected to a Smith-type degradation (8, 9), whereby the polymer was oxidized by periodic acid and the polyaldehyde thus obtained was reduced to a polyol by sodium borohydride. The hydrolysate of the polyol, on chromatographic examination, was found to contain four components, viz. D-galactose (approximately 55–60%), glycolaldehyde (ca. 15–25%), and glycerol and glyceronic acid (almost equal proportions). (All estimations were visual.) D-Galacturonic acid was not detected in the mixture; similarly, L-arabinose and L-rhamnose, which formed trace quantities in the degraded polymer, were also absent from the hydrolysate. It is possible to compare these results with those expected from the methylation experiments. On the basis of the preceding methylation data 6 moles of galactose would be expected to be resistant to periodate oxidation and should be recovered after a Smith-type degradation. The

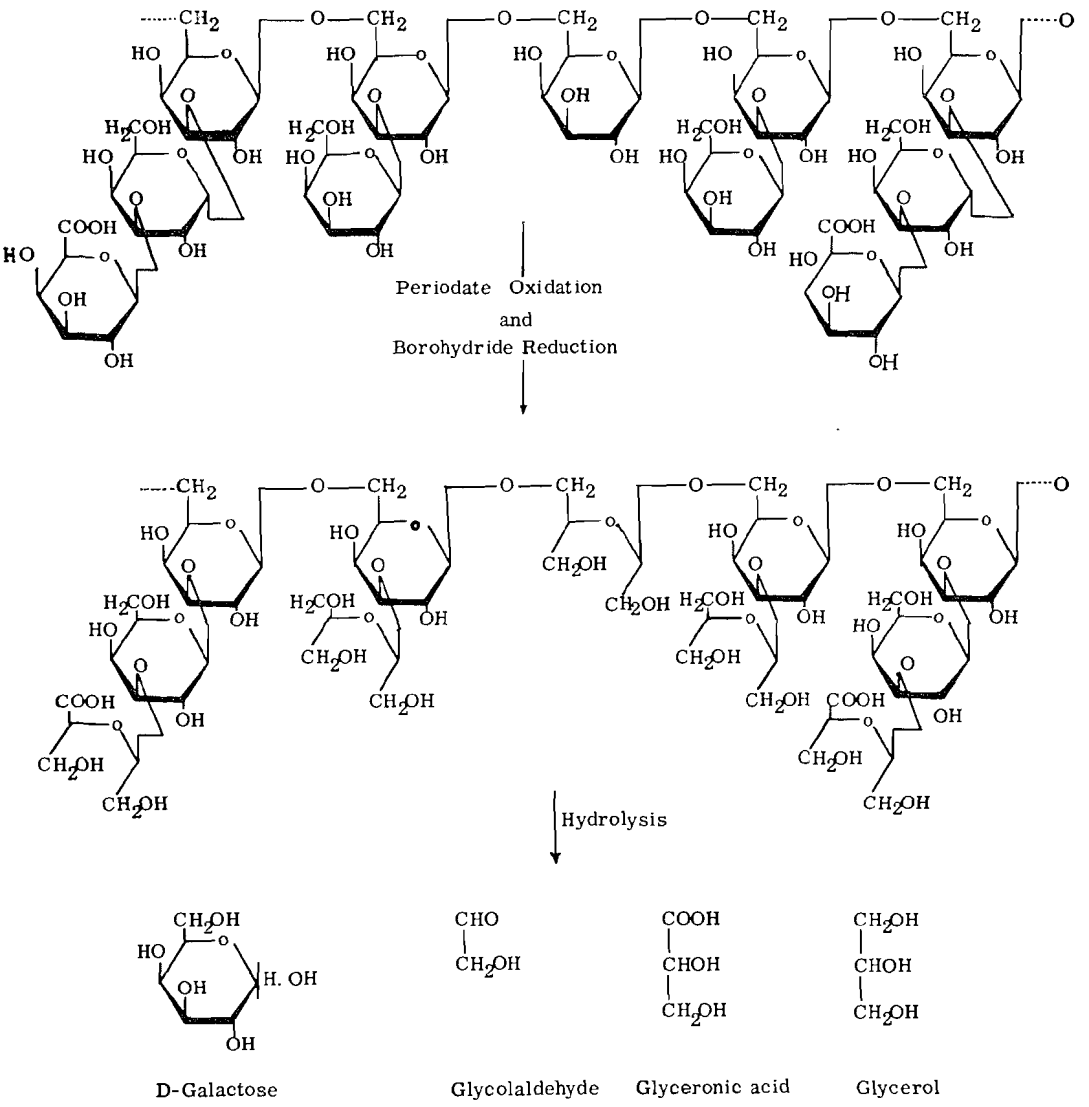
For personal use only.

remaining 3 moles of D-galactose were each expected to produce 1 mole of glycerol and 1 mole of glycolaldehyde (Formula 2). The two D-galacturonic acid residues, which produced 2,3,4-tri-*O*-methyl-D-galacturonic acid on methylation, were each expected to give rise to 1 mole of glyceronic acid and 1 mole of glycolaldehyde. Thus, the hydrolysate was expected to contain a total of 6 moles (57.8%) of D-galactose, 5 moles (16.1%) of glycolaldehyde, 3 moles (14.7%) of glycerol, and 2 moles (11.4%) of glyceronic acid.

On the basis of these results, the degraded polymer is believed to be composed predominantly of $1 \rightarrow 6$ and $1 \rightarrow 3$ linked galactose residues. It is not possible, as yet, to assign a unique structure to this polymer, but a simple structure which can accommodate all the above facts can be written as shown in Formula 1.

FORMULA 1. A probable structure of the degraded cholla gum. A comparison of experimental results with those calculated on the basis of the proposed structure as given above. LEGEND: Gal$_p$, D-galactopyranose; UA, D-galacturonic acid.

The unexpectedly high positive rotation ($[\alpha]_D$ +46.5°) of the degraded polymer (the original gum had $[\alpha]_D$ −86.2°) could be attributed to the presence of some α-linkages in the polymer, although all the neutral oligosaccharides, as well as the aldobiouronic acid, isolated from the gum were found to be β-linked. If the two aldobiouronic acid residues are assumed to be α-linked (shown with a question mark in Formula 1) to the 3 position of the galactose residues in the main chain (the linkage between D-galacturonic acid and D-galactose being much more stable in comparison with the rest of the linkage in the polymer), isolation of the $1 \rightarrow 3$ α-linked disaccharide may not be possible. Furthermore, if Hudson's rules (10) of isorotation are used to calculate the approximate optical rotation of the degraded gum, the value obtained ($[\alpha]_D$ +30.4°) on the assumption of the presence of two α-linkages is closer to the experimental value ($[\alpha]_D$ +46.5°) than that calculated on the assumption that all the linkages are of the β-type ($[\alpha]_D$ −1.7). Therefore, in Formula 2, these two linkages are shown as α-linkages, and Smith-type degradation results of the degraded gum are explained.



EXPERIMENTAL

Methods

Unless otherwise stated, all specific rotations are equilibrium values recorded at 23 ± 3°, and all solutions were concentrated under reduced pressure at 40–45°. All infrared spectra were made in chloroform solutions (6%) on a Perkin–Elmer model 21 infrared spectrophotometer. Whatman No. 1 papers were used for partition chromatography with the following solvent systems (by volume): (*a*) butan-1-ol–ethanol–water (3:1:1); (*b*) butan-1-ol–ethanol–water (5:1:4), top layer cleared by the addition of a minimum of ethanol; (*c*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*d*) butan-1-ol–pyridine–water–benzene (5:3:3:1); (*e*) ethyl acetate – pyridine – water (10:4:3); (*f*) butan-1-ol–ethanol–water (1:1:1); (*g*) benzene–ethanol–water (169:47:15). The spray reagents that were used were alkaline silver nitrate (11) and *p*-anisidine hydrochloride (12).

Whatman 3 MM paper and columns packed with Whatman cellulose powder by the wet method were used for the separation of sugar mixtures. All melting points are uncorrected.

FORMULA 2. Proposed structure of degraded cholla gum, and its Smith-type degradation.

Isolation and Purification of the Gum

The crude gum (120 g), which was dark brown and had a characteristic odor, was purified by dissolving the powdered material in warm, dilute sodium hydroxide (0.1 *N*), during which process some ammonia was evolved. The dark brown solution, after filtration, was cooled and then added slowly to ice-cold ethanol containing 1% hydrogen chloride. The precipitated product was washed twice by decantation, filtered off, dissolved in cold water, and reprecipitated by adding the solution to ice-cold ethanol containing 1% hydrogen chloride. The process was repeated three more times, after which the pale cream colored powder was separated by filtration, washed with acetone and ether, and dried *in vacuo* over silica gel for several days (yield, 58 g). The pure gum had: moisture, 4.8%; ash, 0.7%; $[\alpha]_D$ −86.2° (*c*, 1.8 in water); equivalent weight, 1 734 (acidimetry); uronic acid anhydride, 10.15% (acidimetry); L-arabinose, 51.6%; D-galactose, 31.7%; D-xylose, 15.0%; L-rhamnose, 2–3%; nitrogen, nil; methoxyl, nil. The uronic acid was identified as D-galacturonic acid (see below).

Examination of a sample of a gum by free-boundary electrophoresis in a Tiselius apparatus, with 0.05 *M* sodium borate buffer at 11 mA and 175 V, indicated that the polysaccharide was either homogeneous or inseparable under these conditions.

Isolation and Characterization of the Aldobiouronic Acid

The gum (15 g) was suspended in dilute sulfuric acid (3%, 400 ml), and the suspension was shaken vigorously overnight and then heated on a boiling water bath for 10 h. After neutralization ($BaCO_3$) and filtration, concentration of the hydrolysate gave a light brown, viscous syrup, which was poured slowly into ethanol (90%, 300 ml) to precipitate the barium salts of the uronic acid as a gummy mass. The precipitate was extracted several times with boiling ethanol (90%) until a dry, pale brown powder, free from monosaccharides, was obtained; yield, 1.85 g; $[\alpha]_D^{22}$ +56.2 (*c*, 1.0 in water); Ba, 14.9%. It was obviously a mixture, in the main, of the barium salts of the aldobiouronic (Ba, 16.1%) and aldotriouronic (Ba, 11.68%) acids. Chromatographic examination of the powder in solvent *c* gave one major spot (probably of the aldobiouronic acid) with a considerable trailing throughout the entire length of the chromatogram.

Complete hydrolysis of a portion of the above mixture and chromatographic examination, in solvent *c*, of the hydrolysate revealed the presence of D-galacturonic acid and D-galactose only in the hydrolysate, along with trace quantities of L-rhamnose. Unsuccessful attempts were made to convert the aldotriouronic acid into aldobiouronic acid by mild hydrolysis with 0.1 *N* sulfuric acid. The aldobiouronic acid was therefore purified by converting its barium salt into the free acid, by passage of the mixture through IR-120 ion-exchange resin, and by separation by partition chromatography of the mixture of acids on a cellulose column (80 × 4 cm), butan-1-ol fully saturated with water being used as the solvent phase. The aldotriouronic acid appeared to be adsorbed irreversibly on the column and could not be recovered even after the column had been eluted with distilled water.

The pure acid (equiv. wt. 340) was converted into its methyl ester methyl glycoside, which was reduced with lithium aluminium hydride to a neutral bioside, a small portion of which, on hydrolysis with 2 *N* sulfuric acid, gave only galactose. The methyl bioside was fully methylated by Haworth's procedure followed by Purdie's method to give a colorless syrup; OMe, 53.7%; η_D^{22} 1.4672; $[\alpha]_D$ +2.6° (*c*, 0.85 in water). This, on hydrolysis, gave a mixture of two methylated sugars (R_g 0.89 and 0.67 in solvent *b*), which were separated on Whatman 3 MM filter sheets and identified as 2,3,4,6-tetra-*O*-methyl-D-galactose (m.p. 74°; $[\alpha]_D$ +144 → +119° (in water) (13, 14)) and 2,4,6-tri-*O*-methyl-D-galactose (m.p. 98–104°; $[\alpha]_D$ +120 → +91 (in water) (15)). Both sugars were converted into their respective *N*-phenylglycosylamines. Found: *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 195–196° (16); *N*-phenyl-2,4,6-tri-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 178–180°, $[\alpha]_D$ −90 → 37° (24 h) (*c*, 0.8 in acetone) (17).

Hydrolysis of the Gum and Isolation of the Degraded Gum

The gum (100 g), once precipitated from its aqueous solution with ethanol, was suspended in dilute sulfuric acid (6 *N*, 1 200 ml); this suspension was left on a rotary shaker at room temperature (20–23°) for a period of 23 days. The dark brown solution was then filtered to remove some light, gelatinous residue (ca. 3–4 g), the filtrate was neutralized with barium carbonate, and the solution was again filtered. The filtrate was concentrated to a suitable volume (ca. 600 ml) and dialyzed against distilled water (3 × 4 l). The dialysate, on concentration, gave a mixture of mono- and oligo-saccharides (58 g); the undialyzed material, after further dialysis against running water and precipitation with ethanol, gave the barium salt of the degraded gum. The product was dissolved in cold water and reprecipitated with ethanol, the process being repeated four times until a chromatographically homogeneous, oligosaccharide-free white powder was obtained; yield, 26.4 g; $[\alpha]_D$ +46.5° (*c*, 1.5 in water); Ba, 7.13% (equivalent to an equiv. wt. 899). A portion of the barium salt was converted into the acidic degraded gum by passing its aqueous solution through a column of IR-120 ion-exchange resin, and the equivalent weight of the acid so obtained was determined by titration against standard alkali and found to be 920, equivalent to a D-galacturonic acid anhydride content of 19.1%.

Hydrolysis of the degraded gum by 2 *N* sulfuric acid and chromatographic examination of the hydrolysate revealed only two major spots, corresponding to D-galactose and D-galacturonic acid in an approximate ratio of 9:2. Trace quantities of L-rhamnose (ca. 2–3%) and L-arabinose (ca. 1% or less) were also present.

Methylation of the Degraded Gum (6)

Methylation of the degraded gum was carried out with ease by Srivastava's method (6), in which the dry polymer (3.5 g) was dispersed in warm, dry dimethyl sulfoxide, the suspension was cooled to 20°, and barium oxide (15 g) and methyl iodide (60 ml) were added to it. The mixture was stirred mechanically for 48 h at 30°, during which time it turned dark brown (as a result of the liberated iodine). The inorganic salts were then precipitated by addition of a large amount of chloroform, and the solution was centrifuged. The reddish brown colored organic phase was then washed with a small quantity (2 × 30 ml) of an aqueous solution of sodium thiosulfate (15%), followed by distilled water (25 ml). It was dried (Na_2SO_4) and concentrated to a brown mobile liquid (5–6 ml) containing dimethyl sulfoxide, which could not be removed by evaporation without some decomposition of the polysaccharide.

The mobile solution of partially methylated degraded gum in dimethyl sulfoxide was treated twice with Purdie's reagents (CH_3I and Ag_2O) (7), and the light yellow, syrupy product was examined by infrared spectrometry. It showed no absorption in the hydroxyl region (3 400 – 3 600 cm^{-1}) and in the region between 800 and 900 cm^{-1} which usually indicates the absence of α-linkages in the polymer.

Anal. Found: OMe, 41.6.

Methanolysis and Identification of Methylated Sugars of the Methylated Degraded Gum

A solution of the methylated degraded gum (0.95 g) in methanolic hydrogen chloride (7%, 50 ml) was heated to 100° in sealed tubes for 6 h. The solution was then diluted with 0.5 *N* hydrochloric acid (50 ml) and the mixture heated (4 h) on a boiling water bath to hydrolyze the glycosides. The cooled solution was then neutralized (silver carbonate) and filtered, and hydrogen sulfide was bubbled through the filtrate, which was again filtered. The filtrate, on evaporation under reduced pressure, gave a brown syrup (0.72 g). Chromatographic examination of the syrup in solvents *a*, *b*, *c*, *d*, and *f* showed it to be a mixture of at least five components, which were separated chromatographically on Whatman 3 MM filter sheets with solvent *b* as eluant. Table I shows the different fractions that were isolated from the mixture.

TABLE I

Components isolated from the hydrolysate of the methyl ether of degraded cholla gum

Fraction No.	Methylated sugar	Yield (approximate mole ratio)	R_g in solvent *b*	Color to *p*-anisidine
1	2,3,4,6-Tetra-*O*-methyl-D-galactose	114 mg (2 moles)	0.89	Reddish brown
2	2,3,4-Tri-*O*-methyl-D-galactose	60 mg (1 mole)	0.65	Yellowish brown
3	2,4,6-Tri-*O*-methyl-D-galactose	103 mg (2 moles)	0.67	Reddish brown
4	2,4-Di-*O*-methyl-D-galactose	189 mg (4 moles)	0.40	Yellow
5	2,3,4-Tri-*O*-methyl-D-galacturonic acid	102 mg (2 moles)	—	Pink
6	Not identified, probably a dimethyl-L-rhamnose	Trace	0.99	Yellow

Fraction 1, 2,3,4,6-Tetra-O-methyl-D-galactose

The syrup was crystallized from methanol–acetone; the crystals had m.p. 74°; $[\alpha]_D$ +142 → 118° (in water). It was chromatographically homogeneous, had R_g 0.89, and gave a reddish brown spot on chromatograms sprayed with *p*-anisidine hydrochloride. It was converted into *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine; m.p. and mixed m.p. 195–196°; $[\alpha]_D$ −82° (*c*, 1.2 in acetone) (18).

Fraction 2, 2,3,4-Tri-O-methyl-D-galactose

Fraction 2 (60 mg), on chromatographic examination, was found to contain ca. 10–15% of fraction 3. Similarly, chromatographic examination of fraction 3 revealed the presence of ca. 5% of fraction 2. The two fractions were therefore mixed together and purified by chromatographic separation on Whatman 3 MM paper with solvent *d*.

Fraction 2 so obtained (42 mg) was chromatographically pure and had $[\alpha]_D$ +138° (*c*, 0.4 in water). When its solution in ethanol (5 ml) was heated under reflux with redistilled aniline (22 mg) for 8 h, the *N*-phenyl-2,3,4-tri-*O*-methyl-D-galactosylamine was formed, which crystallized out, when the solution was kept for several days, in the form of large brown plates; these were washed with ice-cold ethanol – diethyl ether (9:1 v/v) and had m.p. 163–167°; $[\alpha]_D$ −58 → 46° (6 days) (*c*, 0.4 in methanol) (19).

Fraction 3, 2,4,6-Tri-O-methyl-D-galactose

The pure syrup (79 mg) obtained after the second chromatographic separation moved parallel, on chromatograms, to the 2,4,6-tri-*O*-methyl-D-galactose which had been obtained earlier from the aldobiouronic acid, and crystallized when seeded with it. When it was recrystallized from ethanol–acetone it gave fine needles, m.p. and mixed m.p. 103–104°; $[\alpha]_D$ +121 → 92° (*c*, 0.6 in water). Its *N*-phenyl glycosylamine had m.p. and mixed m.p. 178–180° (undepressed on admixture with an authentic specimen); $[\alpha]_D$ −90 → +37° (24 h) (*c*, 0.6 in acetone) (17).

Fraction 4, 2,4-Di-O-methyl-D-galactose

This component (189 mg) crystallized readily, and on recrystallization from benzene–ethanol–water had m.p. 103°; $[\alpha]_D$ +123 → +86° (*c*, 0.98 in water). Smith (19) gives m.p. 103°; $[\alpha]_D$ 122 → +86° (in water). It was further characterized as 2,4-di-*O*-methyl-D-galactose through its crystalline *N*-phenyl glycosylamine which, on recrystallization from benzene–methanol (1:2), had m.p. and mixed m.p. with authentic *N*-phenyl-2,4-di-*O*-methyl-D-galactosylamine 216–217°; $[\alpha]_D$ −182° (*c*, 1.2 in pyridine) (20).

Fraction 5, 2,3,4-Tri-O-methyl-D-galacturonic Acid

This component (102 mg) crystallized spontaneously, and on recrystallization from methanol–water (9:1 v/v) had m.p. 100°; $[\alpha]_D^{23}$ +128 → +106° (*c*, 0.88 in water).

Anal. Calcd. for $C_9H_{16}O_7 \cdot H_2O$: equiv. wt. 259. Found: equiv. wt. 254 (21).

The acidic sugar was oxidized by bromine water and converted into its dimethyl ester by boiling the product (8 h) with methanolic hydrogen chloride (1%, 25 ml). The resultant pale yellow syrup crystallized on trituration with a small amount of diethyl ether. Recrystallization from petrol – diethyl ether (1:1) gave the crystalline dimethyl ester of 2,3,4-tri-*O*-methyl-D-galactosaccharic acid, m.p. 101°; $[\alpha]_D$ +31° (*c*, 0.34 in water) (21).

Periodate Oxidation of the Degraded Gum

The ash-free degraded gum (60 mg dry wt) was dispersed in water (75 ml) and oxidized by shaking the suspension with 0.03 *M* periodic acid solution (25 ml) in the dark at 25°. The amount of periodic acid consumed and the formic acid liberated (after correction for the titratable acidity of the gum and of periodic acid) during the progress of the reaction were estimated in the usual way (22) at regular time intervals. The molar periodate consumption and formic acid liberation per mole of anhydrohexose unit were as shown in Table II.

TABLE II

Periodate oxidation of the degraded cholla gum (moles of periodate consumed and formic acid liberated per mole of anhydrosugar $C_6H_{10}O_5$)

Time (h)	1	4	8	12	24	28	32	48	72
Periodate	0.39	0.59	0.72	0.80	0.95	0.99	1.00	1.05	1.10
Formic acid	0.12	0.24	0.37	0.40	0.48	0.49	0.50	0.52	0.54

Extrapolation of the flat portions of the curves to zero time gave 0.93 mole of periodic acid consumed and 0.47 mole of formic acid liberated per $C_6H_{10}O_5$ unit.

Smith-Type Degradation of the Degraded Gum (8, 9)

The degraded gum (250 mg) was odixized by periodic acid for 24 h under conditions identical with those described above, after which excess oxidant was destroyed by ethylene glycol (25 ml) and the mixture was dialyzed against running distilled water. The undialyzed polyaldehyde solution was concentrated and the polyaldehyde was reduced by addition of aqueous sodium borohydride solution (1%, 25 ml) to the polyalcohol, which was obtained as a white powder (201 mg) on concentration of the solution. Hydrolysis of the polyol with 1 *N* sulfuric acid on a boiling water bath and concentration of the neutralized hydrolysate gave a syrup which, on chromatographic examination in various solvents, showed the presence of D-galactose (ca. 55–60%), glycolaldehyde (ca. 15–25%), and glycerol and glyceronic acid (almost equal proportions). (All estimations were visual.)

ACKNOWLEDGMENTS

The authors thank Drs. B. A. Erukoff and K. Folkers for the gift of cholla gum. They also thank the National Research Council for a grant (N.R.C. T-19) and Queen's University for financial assistance.

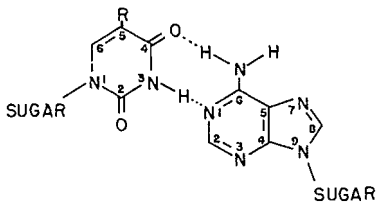
PROTONATED CARBONYL GROUPS

VIII. ALKYLURACIL SALTS

DENYS COOK

Department of National Health and Welfare, Food and Drug Directorate, Ottawa, Canada

Received July 29, 1965



ABSTRACT

With 1,3-dimethyluracil and 1,3,6-trimethyluracil as models for nucleic acid bases, it was found by infrared spectroscopic methods that the site of protonation is a carbonyl group. Analysis of other evidence makes it likely that it is the carbonyl group in position 4. In 1,3,6-trimethyluracil salts, activation of the 5 position under acid conditions permits ready hydrogen–deuterium exchange.

Some anomalous 2 base – 1 acid salts with complex acids are considered in the light of base pairing errors in nucleic acids.

INTRODUCTION

Uracil and thymine (5-methyluracil) are two of the pyrimidine bases found in the nucleic acids. Thymine (I) is thought to be paired with adenine in deoxyribonucleic acid (DNA) (1), and uracil (II) with adenine in ribonucleic acid (2).

I R = CH_3 THYMINE...

II R = H URACIL...

These pyrimidines are weak bases, and are capable of forming salts although no pK values seem to have been published. It is of interest to find the site of protonation in simple dioxypyrimidines of this type, and methods previously found to be satisfactory have presently been employed (3). To simplify the interpretation of the spectra of the salts the 1,3-dialkyl derivatives have been used. The N-monoalkyl derivatives will be considered later.

RESULTS

Tables I and II show the absorption bands in the salts of 1,3-dimethyluracil and 1,3,6-trimethyluracil; Table III shows the bands caused by the protonated group.

DISCUSSION

There are four basic atoms in the N-alkyluracils, and the molecule resulting from protonation of each site in turn is depicted in structures III–VI. The salt spectra show a broad strong band in the 2 000 – 2 500 cm^{-1} region which is attributed to the protonated group, but neither its position nor its structure helps in the determination of the protonation site, and any of structures III–VI could equally well give rise to such a band. The deuteration shifts and isotopic ratios are normal.

A consideration of the bands in the 1 700 cm^{-1} region leads to rejection of structures III and IV. N-Aroyltrialkylammonium ions (VII*a*) (4), N-acyltrialkylammonium halides (VII*b*) (5), and 2,2-dimethylquinuclid-6-one salts (VIII) (6), all possessing a quaternary nitrogen atom adjacent to a carbonyl group, have carbonyl stretching frequencies in the 1 780 – 1 810 cm^{-1} region. Even when the quaternary nitrogen atom has a trigonal sp^2 configuration, as in N-aroylpyridinium (IX*a*) (7) and N-acylpyridinium (IX*b*) (5) salts, the carbonyl stretching frequencies are in the region of 1 785 and 1 800 cm^{-1} respectively.

This shows that delocalization of the positive charge around the carbon atoms in the pyridinium ring is present but small.

Since the highest frequency band in the carbonyl stretching region is near 1 715 cm^{-1}, no similarity in structure between uracil salts and VII, VIII, or IX can be assumed.

A further argument can be advanced to rule out structures III and IV. In tertiary (sp^3) amine salts the NH deformation mode has been found near 1 402 cm^{-1}, and this value has been suggested as a diagnostically useful group frequency (3). No band near 1 402 cm^{-1} showing a deuteration shift has been found in the uracil salts.

Oxygen protonation is thus proposed in uracil salts, and the chief source of confirmation comes from the in-plane hydrogen-bending mode. This has been found hitherto (3) to

give an absorption band in protonated carbonyl groups near 1 257 cm^{-1}. There is indeed a band in all the uracil salts in the appropriate region (see Table III) which moves, on deuteration, to near 980 cm^{-1}, thereby giving normal isotopic ratios. In addition, this band is the only one (with the exception of the ~750 cm^{-1} band caused by the out-of-plane hydrogen-deformation γ_{OH}) which shifts on deuteration, thus unambiguously identifying it as δ_{OH}.

The other characteristic of protonated carbonyl groups is a lowered carbonyl frequency. These have previously been located near 1 500 cm^{-1}, except for that at ~1 400 cm^{-1} in the vibrationally coupled amides, with some reservations about the preciseness of the description as a result of possible mixing of the ring modes with carbonyl stretching modes.

Protonated uracils have a pattern of bands which is quite similar in each salt but which is very different from that of the free base. In the latter there are two bands, at ~1 700 and ~1 650 cm^{-1}, which are probably associated with carbonyl stretching vibrations (8–10). The ~1 650 cm^{-1} band is often overlapped by ring modes, so that it is quite broad. In the salts this region becomes nicely resolved into bands near 1 715, 1 615, 1 575, and 1 510 cm^{-1}. The highest and lowest bands are assigned to carbonyl group vibrations,

the lowest being caused by the protonated group. The middle two bands would then be assigned to ring modes ν_{8a} and ν_{8b}.* The 1 510 cm^{-1} band is in a position quite close to that seen in many protonated C=O bonds in heterocyclic ring systems, and the fact that it shows little movement in the deuterated salt has been taken as a sign that little or no mixing of C=O stretching vibrations and OH in-plane bending occurs. In peri-methoxyanthraquinone salts changes of ~20 cm^{-1} occur on deuteration, and other factors, too, have indicated coupling (11). On the other hand, α-pyridones (12) have shown changes in ν_{CO} and δ_{OH} similar to those observed in uracil salts. This is not too surprising in view of the similarity of the lactam grouping in each compound.

The question now arises as to which of the two carbonyl groups in the uracils is protonated. Nothing is known of the relative basicity of the two carbonyl groups in terms of pK values. Pullman and Pullman (13) have calculated bond orders and charge distribution in the uracil nucleotide, and give 0.770 and 1.501 for C_4O and 0.802 and 1.471 for C_2O respectively. Attempts to regard each C=O group as a prototype of a simpler system, e.g. C_2O as a part of $R_2N—CO—NR_2$ and C_4O as a part of an α-pyridone system, seem unsatisfactory. Since there is some structural evidence from crystallographic studies that C_4O is more basic than C_2O, this evidence will be examined; then an a posteriori justification of the spectra will be attempted.

TABLE IV

Systems exhibiting the $N_3H\cdots C_4O$ hydrogen bonds

	R_1	R_5
1-Methyluracil (14)	CH_3	H
1-Methylthymine (15)	CH_3	CH_3
Adenine–thymine pair in DNA (1)	Deoxyribose	CH_3
Adenine–uracil pair in RNA (2)	Ribose	H
1-Methylthymine–9-methyladenine complex (22)	CH_3	CH_3
1-Methyluracil–9-ethyladenine complex (31)	CH_3	H
Uracil (32)*	H	H
5′-Bromo-5′-deoxythymidine (33)†	Deoxyribose	CH_3

*N_1H also forms a hydrogen bond to C_4O, but there are no hydrogen bonds to C_2O.
†In the monoclinic form (A) N_3H and C_4O form hydrogen bonds to the appropriate part of the CH_2OH group in the sugar.

The crystal structures of 1-methyluracil (14) and 1-methylthymine (15) show that two molecules form a hydrogen-bonded dimer related by a center of symmetry (see partial structure in Table IV). The hydrogen bonds are formed between N_3H and C_4O. NR_1 cannot, and C_2O does not, form a hydrogen bond. These hydrogen-bonded dimers are arranged in a plane, and all other contacts in this plane, except for the hydrogen bonds, are weak van der Waals forces. Forces between planes are probably limited to van der Waals interactions, though there may be some weak dipole–dipole forces between

See ref. 12 for nomenclature.

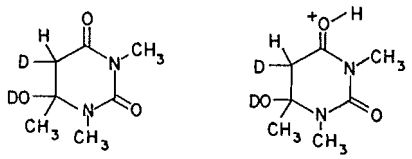
the polar parts of molecules in different layers. If one now considers the 1-methylthymine molecule, a rotation of 180° about the 3,6 axis would give a configuration which has merely exchanged the N_1CH_3 group for the C_5CH_3 group, and transposed the carbonyl groups. The spatial requirements of N_1CH_3 and C_5CH_3 are so similar that their interchange should have an imperceptible effect on the crystal lattice. The effect of charge distribution, particularly the π-electron distribution, is more subtle (15). From this point of view the effect of interchanging N_1CH_3 and C_5R might make more difference to the interlayer forces and might modify arrangements in a direction perpendicular to the plane of the dimer. It is considered, therefore, that C_4O is more basic than C_2O, since the $N_3H\cdots OC_4$ hydrogen bonds are maintained in the structures in Table IV, even though reversal of the hydrogen bonds to $N_3H\cdots OC_2$ would give rise to no additional instability. The acidity of N_3H does not enter into the discussion, as it is common to both arrangements.

What has been said of 1-methylthymine applies to the same extent to 1-methyluracil. R_5 in this case is hydrogen, so that interchange of N_1CH_3 and C_5H will make a larger difference. Since the interdimer and interlayer forces are van der Waals forces of low directional specificity, slight rearrangement to accommodate an altered methyl group would make small differences.

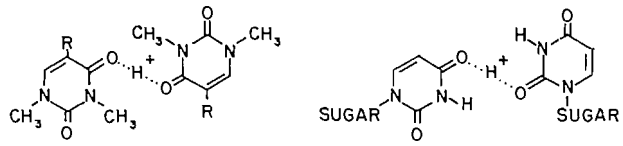
Additional information can be derived from carbonyl group bond lengths in certain molecules. Although the C_4O distances are larger than the C_2O distances in 1-methylthymine and 1-methyluracil, this may be due in part to the hydrogen bond. In 1,3,7,9-tetramethyluric acid (16), in which no hydrogen bonds are possible, C_6O, which is the carbonyl group equivalent to C_4O in the pyrimidines, is 0.03 Å longer than C_2O (same numbering in both bases). The same situation occurs in caffeine (0.07 Å) (17) and in theophylline hydrate (0.03 Å) (18), though in the latter the N_7H bond may interfere. The longer carbonyl groups are associated with more $C^+—O^-$ character and greater donor activity.

This evidence makes it seem likely that C_4O is the more basic site, and that the structure of the cation would therefore be that shown by VI. In the hydrohalides a hydrogen bond in $C{=}O^+—H\cdots X^-$ would be preferred, and not $C{=}O^+—H\cdots O{=}C$, since ν_{OH} does vary with X^-. But in the $HSbCl_6$ salt the low value of ν_{OH} might be taken as evidence for the latter type of hydrogen bond, especially as the protonated carbonyl group stretching frequency is shifted from 1 720 to 1 682 cm^{-1}.



The vibrational behavior of VI can now be interpreted in terms of the assignments of the 1 510 cm^{-1} band to C_4O stretching and the 1 715 cm^{-1} band to C_2O stretching. The two intermediate bands at 1 615 and 1 575 cm^{-1} are then assigned to ν_{8a} and ν_{8b}, and the 1 550 and 1 460 cm^{-1} bands to ν_{19a} and ν_{19b}. The N-methyl and C-methyl group asymmetric deformation vibrations would give rise to the absorption band near 1 423 cm^{-1}, whereas the symmetric deformation band would be obscured by the strong 1 380 cm^{-1} band, which seems to be too strong to assign to $\delta_{CH_3}{}^s$. The 1 380 cm^{-1} band would be assigned to ν_{14}; its intensity in heterocyclic compounds is much greater than in homocyclic compounds (12).

The exchange experiments with D_2O provided some interesting information on the reactivity at the 5 position. 1,3,6-Trimethyluracil·HCl, on treatment with excess D_2O and evacuation, did not give the deuterated salt. Instead the free base was recovered, but it was found to have exchanged the hydrogen at position 5 for deuterium. It was thus possible to relate bands at 3 088, 1 226, 1 040, and 845 cm^{-1} to the C_5H bond. Corresponding bands in the C_5D compound were at 2 302 (1.34), 1 070 (1.14), 778 (1.33), and 632? (1.33) cm^{-1}. Since only three absorption bands should occur (ν_{CH}, δ_{CH}, and



γ_{CH}), it is likely that some mixing of δ_{CH} with a ring mode occurs. The nuclear magnetic resonance spectrum of the deuterated material lacked the resonance at 338 c.p.s.

Two interesting points are raised with respect to this observation. One is concerned with the mechanism of exchange, whether by electrophilic substitution at position 5 or by covalent hydration across the 5:6 bond followed by dehydration to give the 5-d_1 derivative. The second one, which is independent of the mechanism, has to do with the protonation state during the reaction, for it will be recalled that no exchange took place with only D_2O (see Experimental section) or D_2O at pD > 7.

In view of the known ability of 1,3-dimethyluracil to add H_2O across the 5:6 double bond to give the 6-hydroxy derivative (19, 20), an intermediate of this nature (X) might be considered in the carbon deuteration of 1,3,6-trimethyluracil. The hydrogen atom at position 5 would be expected to be quite acidic and, upon isotopic exchange and subsequent D_2O elimination, would be replaced by deuterium. This acidity may only be generated in the protonated base XI. It is difficult to justify the exchange process without the acidic H_5 atom, since D_2O addition and elimination would be expected to follow the same stereochemical pathway. Some idea of the configuration of XI would be of value in these arguments, but unfortunately this is not known.

X XI

XII XIII

2 Base – 1 Acid Salts

The infrared spectra of the 2:1 salts show the usual broad strong band centered near 900 cm^{-1} with several deep transmission windows (21). The band near 1 700 cm^{-1} is thought to be caused by the carbonyl stretching vibration of position 2, though again there is no conclusive evidence about which carbonyl group is concerned in the hydrogen bond. A possible structure XII is indicated.*

The relevance of such structures to errors in base sequence in polynucleotides is determined by the geometry of the base pair. The distance between the 1′ carbon atoms of the deoxyribose sugar molecule attached to the base pairs was 11.1 Å in the Watson–Crick model (1) (see Table V). Calculations suggest that the corresponding distance in the 2:1 salts shown in XII may be close to 12.3 Å. This figure is large, but not unreasonably so. Just as Hoogsteen (22) has shown that a slightly distorted double-helix DNA model

**The structure of some of these 2:1 salts, their dimensions, and the question of the centrosymmetric hydrogen bond are being investigated by Dr. J. C. Speakman at the University of Glasgow, Scotland.*

9-Ethyladenine–1-methyluracil complex (31)	7.5
9-Ethylguanine–1-methylcytosine complex (34)	10.55
9-Methyladenine–1-methylthymine complex (22)	8.65
Watson–Crick model	11.1

can be built incorporating the anomalous hydrogen-bonded system in the 1-methylthymine–9-methyladenine complex, in which the distance between the methyl carbon atoms is 8.645 Å, then it is likely that a model having a larger distance could be built involving similar distortions but in the opposite sense.

However, XII is not the only model that can be considered. As has been shown above, although the C_4O carbonyl group is probably more basic than the C_2O carbonyl group, the difference is slight, and other factors may override this. Thus in the non-centrosymmetric structure XIII, where the short hydrogen bond between C_4O and C_2O is energetically very similar to that in XII, the C—C distance is 9.8 Å. Other similar structures are listed in Table VI. This distance is much closer to the one probably existing in the nucleic

NOTE: i = center of symmetry; σ = mirror plane.

acids. The symmetry of the hydrogen-bonded partners in the 2:1 salts was formerly thought always to involve a center of symmetry (23, 24), but recently an exception was noted. The mesitaldehyde – perchloric acid 2:1 complex (25) was found to have a plane of symmetry through the carbonyl oxygen atoms and the shared proton perpendicular to the molecular plane. This precedent makes more plausible some of the structures in Table VI which do not have a center of symmetry. Another possibility for the introduction of errors in base sequence would arise if a uracil–sugar bond was formed at N_3 of the pyrimidine molecule. Many other additional structural arrangements could then be made for the incorporation of such nucleosides into a nucleic acid by proton sharing. Some of these are also shown in Table VI.

The number of structural types known to form 2:1 salts is quite large, but they have one thing in common. The basic atoms forming the bond are usually of low pK_a; for example, amides, α-pyrones, α-pyridones, γ-pyridones, aromatic aldehydes, and heterocy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

clic amine oxides have pK_a values less than about 3.3. Most compounds of higher basicity form conventional salts. It is significant that, of the nucleic acid bases, uracil and thymine probably have the lowest pK_a values: cytosine, 4.6; adenine, 4.25; guanine, 3.0; uracil, no listed value, but probably slightly higher than that of 2-thiouracil, −4.16 (26).

Finally, the source of the proton accommodated between the bases is not hard to find. The secondary phosphate linking two sugar molecules has one OH group remaining which could, under the appropriate circumstances, yield the proton to be shared by the bases. There are precedents for this behavior: in polyadenylic acid (27) the proton is transferred from the POH group to the N_1 position on the base; and in polycytidylic acid (28) a form is known to exist at pH 5.5 in which the cytosine NH_2 groups form hydrogen bonds to the carbonyl groups, and the protonated N_3 atom forms a hydrogen bond to the unprotonated N_3 atom in the second molecule. It is very unlikely that this bond could be a symmetrical one because of the large distance involved.

EXPERIMENTAL

Materials

1,3-Dimethyluracil and 6-methyluracil were obtained from the Aldrich Chemical Company. 6-Methyluracil was dimethylated according to the method published by Davidson and Baudisch (29).

1,3-Dimethyluracil Salts

HCl Salt

The base, dissolved in a small amount of $CHCl_3$ and then excess CCl_4, was treated with anhydrous HCl to give a white hygroscopic solid, m.p. 105–106°.

Anal. Calcd. for $C_6H_8N_2O_2 \cdot HCl$: HCl, 19.2. Found: HCl, 18.7.

HBr Salt

The same treatment gave a white hygroscopic solid, m.p. 179–180°.

Anal. Calcd. for $C_6H_8N_2O_2 \cdot HBr$: HBr, 36.6. Found: HBr, 36.7.

HI Salt

Equimolar portions of aqueous (50%) HI and the base gave long needles after 24 h, m.p. 163–165 (decomp.).

Anal. Calcd. for $C_6H_8N_2O_2 \cdot HI$: C, 26.88; H, 3.38; N, 10.45. Found: C, 26.75; H, 4.03; N, 10.48.

When $CHCl_3$ solutions were used the 2:1 salt $(C_6H_8N_2O_2)_2 \cdot HI$ was found.

$HAsF_6$ Salt

Aqueous (~60%) $HAsF_6$ (4.0 g) and 2.01 g base gave long needles about 0.5 h after mixing, m.p. 172–174.

Anal. Calcd. for $(C_6H_8N_2O_2)_2 \cdot HAsF_6$: C, 30.65; H, 3.64; N, 11.92. Found: C, 30.65; H, 3.45; N, 11.46.

Infrared (Nujol and fluorolube): 3 095 m, 3 068 m, 1 710 s, 1 642 s, 1 580 s, 1 430 m,b, 1 380 m, 1 337 s, 1 258 m, 1 225 m, 1 148 m, 1 062 m, 1 050 m,sh, 960 m,b, 925 m,b, 822 m, 806 s, 788 s, 770 s, 700 vs (AsF_6^-).

The two following salts are similar.

HPF_6 Salt

Aqueous (~60%) HPF_6 (2.30 g) and 2.86 g base gave a solid immediately after mixing, m.p. 129–133.

Anal. Calcd. for $(C_6H_8N_2O_2)_2 \cdot HPF_6$: C, 33.81; H, 4.02; N, 13.15. Found: C, 33.37; H, 4.06; N, 13.44.

$HSbF_6$ Salt

Aqueous (~60%) $HSbF_6$ (3.61 g) and 2.77 g base developed crystals after mixing, m.p. 155 (decomp.).

Anal. Calcd. for $(C_6H_8N_2O_2)_2 \cdot HSbF_6$: C, 27.87; H, 3.31; N, 10.84. Found: C, 28.06; H, 3.20; N, 10.53.

HBF_4 Salt

Attempts to prepare this salt have been described previously (30); only the BF_3 complex resulted.

1,3,6-Trimethyluracil Salts

HCl Salt

Same as above, m.p. 127–129.

Anal. Calcd. for $C_7H_{10}N_2O_2 \cdot HCl$: HCl, 18.6. Found: HCl, 18.2.

HBr Salt

As above, m.p. 194–195.

Anal. Calcd. for $C_7H_{10}N_2O_2 \cdot HBr$: HBr, 34.0. Found: HBr, 34.0.

HI Salt

Equivalents of the aqueous acid and base yielded a hydrate. Attempts to remove water required conditions so vigorous that some decomposition into 2:1 salts occurred.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

H_2SnCl_6 Salt

The salt precipitated as a white solid when a $CHCl_3$ solution of the base was saturated with HCl and then treated with $SnCl_4$, m.p. 131–133°. Analytical figures for this and the following salt were difficult to obtain because of their hygroscopic nature; argentimetric titrations were usually low.

H_2SnBr_6 Salt

Same method as with HBr and $SnBr_4$, m.p. 138–139°.

$HSbCl_6$ Salt

A $CHCl_3$ solution of the base gave a pale yellow solid on treatment with dry HCl and $SbCl_5$, which was recrystallized from ethanol, m.p. 227–228°.

Anal. Calcd. for $(C_7H_{10}N_2O_2)_2 \cdot HSbCl_6$: C, 26.11; H, 3.29; N, 8.70. Found: C, 26.37; H, 3.28; N, 8.11.

Infrared (Nujol and fluorolube): 1 695 s,sh, 1 685 s, 1 632 s, 1 555 m,sh, 1 503 m, 1 426 m, 1 412 m, 1 378 m, 1 266 m, 1 215 m, 1 182 m, 1 125 m, 1 068 m, 1 046 m, 1 000 m, 895 m, 810 s, 805 s,sh, 794 s,vb, 759 vs, 688 s, 642 m.

Deuterated salts were prepared by exchange with D_2O. 1,3,6-Trimethyuracil·HCl gave 5-deuterio-1,3,6-trimethyluracil under these conditions, but neither the free base in D_2O nor a NaOD–D_2O solution of the base exchanged in this manner.

Spectra

The conditions under which the spectra were recorded have been described before (12).

ACKNOWLEDGMENTS

Most of the work reported here was done in the Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario; the assistance of Mrs. R. H. Veach in preparing many of the compounds and recording their spectra, and of Dr. J. S. McIntyre in recording the nuclear magnetic resonance spectra is gratefully acknowledged. The microanalytical data were obtained through the courtesy of Mr. L. E. Swim and his associates (The Dow Chemical Company, Midland, Michigan, U.S.A.).

THE SYNTHESIS OF PORPHYRINS DERIVED FROM CHLOROBIUM CHLOROPHYLLS[1,2]

J. L. ARCHIBALD,[3,4] D. M. WALKER,[3,5] K. B. SHAW,[3,6] A. MARKOVAC,[3] AND S. F. MACDONALD

Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received September 23, 1965

ABSTRACT

The proofs of the structures proposed for the *Chlorobium* pheophorbides 650, fractions 1–5, and for the *Chlorobium* pheophorbides 660, fractions 5 and 6, are completed and the degradational evidence, where parallel, confirmed through the synthesis of derived porphyrins.

The photosynthetic bacteria *Chlorobium thiosulfatophilum*, strain L and strain VN, contain *Chlorobium* chlorophyll 650 and *Chlorobium* chlorophyll 660 respectively, the numbers indicating the wavelength of their absorption maxima in the red. These are magnesium complexes of farnesyl (not phytyl) esters of the *Chlorobium* pheophorbides 650 and 660. Like ordinary chlorophyll, both these chlorophylls are mixtures, for their pheophorbides can be resolved into several components, which are termed fractions: *Chlorobium* pheophorbide 650, fractions 1–6, and *Chlorobium* pheophorbide 660, fractions 1–6.

These fractions (pheophorbides) are more closely related to the pyrropheophorbide *a* than to the pheophorbide *a* from chlorophyll *a*, for they lack the 10-carbomethoxy group of the latter. All were shown to be homologues of 2-(α-hydroxyethyl)-2-desvinyl-pyrropheophorbide *a* (I, R^1 = Et, R^2 = Me, R^3 = H) (Reaction Scheme 1) and were formulated (2, 3) as shown in Table I, wherein the structures of the related porphyrins as well as some chlorophyll *a* derivatives are also indicated. It will be noted that some trivial names such as pyrroporphyrin (strictly pyrroporphyrin 15), phylloporphyrin, and desoxo-phylloerythrin are used in two senses. Without qualification, they refer to the prototypes derived from chlorophyll *a*; otherwise, they refer to the homologues of these, derived from the *Chlorobium* chlorophylls.

The analytical and degradational evidence (2, 3) did not completely prove these structures for, in the absence of special features, it could only reveal the pairs of substituents on positions 1–8 but not their order. In both the 650 and 660 series other structures in which the substituents on any of the pyrrole rings 1, 2, or 4 were reversed in order (e.g. 7-methyl-8-propionic acid) were equally compatible with it. The indicated structures were preferred, because they were more obviously related to pheophorbide *a*.

In the 650 series, there was no direct evidence concerning the nature of R^2 in fractions 3, 5, and 6, for citraconimide had not been detected among their oxidation products.

In the 660 series, improved analytical methods revealed the natures of R^2 in all fractions. However, in the absence of adequate models, the nuclear magnetic resonance evidence which placed the R^3 groups on the δ-positions was not conclusive (3, 4). Further, as

REACTION SCHEME 1. *Chlorobium* pheophorbides and derived porphyrins.

TABLE I
Pheophorbides and derived porphyrins

	Structure (Reaction Scheme 1)	R^1	R^2	R^3
Derivatives of pheophorbide *a* (from chlorophyll *a*)				
Pyrropheophorbide *a*	I ($CH{=}CH_2$ for CH(OH)Me)	Et	Me	H
Mesopyrropheophorbide *a*	I (Et for CH(OH)Me)	Et	Me	H
Phylloerythrin	II*a*	Et	Me	H
Desoxo-phylloerythrin	II*b*	Et	Me	H
Pyrroporphyrin 15	III*a*	Et	Me	H
γ-Phylloporphyrin 15	III*a* (Me for H on γ)	Et	Me	H
Chlorobium pheophorbide 650				
Fraction 1	I	CH_2CHMe_2	Et	H
Pyrroporphyrin from fraction 1	III*a*	CH_2CHMe_2	Et	H
Fraction 2	I	$CH_2CH_2CH_3$	Et	H
Pyrroporphyrin from fraction 2	III*a*	$CH_2CH_2CH_3$	Et	H
Fraction 3	I	CH_2CHMe_2	Me	H
Pyrroporphyrin from fraction 3	III*a*	CH_2CHMe_2	Me	H
Fraction 4	I	Et	Et	H
Pyrroporphyrin from fraction 4	III*a*	Et	Et	H
Fraction 5	I	$CH_2CH_2CH_3$	Me	H
Desoxo-phylloerythrin from fraction 5	II*b*	$CH_2CH_2CH_3$	Me	H
Fraction 6	I	Et	Me	H
Chlorobium pheophorbide 660				
Fraction 1	I	CH_2CHMe_2	Et	Et
Fraction 2	I	CH_2CHMe_2	Et	Me
Fraction 3	I	$CH_2CH_2CH_3$	Et	Et
Fraction 4	I	$CH_2CH_2CH_3$	Et	Me
Pyrroporphyrin from fractions 3 and 4	III*a* (cf. 650, fraction 2)	$CH_2CH_2CH_3$	Et	H
Fraction 5	I	Et	Et	Me
δ-Phylloporphyrin from fraction 5	III*b*	Et	Et	Me
Fraction 6	I	Et	Me	Me
δ-Phylloporphyrin from fraction 6	III*b*	Et	Me	Me

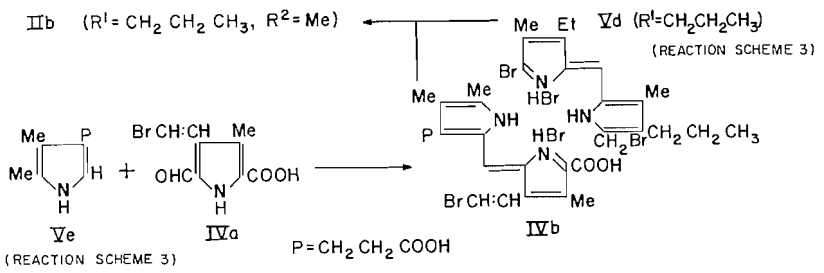
definite evidence about the nature of the R^3 groups was lacking, the 660 fractions were formulated by assuming the R^3 groups to be the simplest possible: R^3 = Me in all fractions except either 1 and 3 or 2 and 4, wherein R^3 = Et. The molecular weights of fractions 2, 4, 5, and 6, determined since the synthetic work was completed, are consistent only with the former alternative.

In the case of *Chlorobium* pheophorbide 650, fraction 6, the structure was subsequently confirmed and the assumptions validated by converting it into pyrropheophorbide *a* (3), wherein the order of the substituents and the 5-methyl group was known through Fischer's syntheses of related porphyrins. In the present work, the synthesis of the degradation products listed in Table I provides similar confirmation of the structures of the remaining *Chlorobium* pheophorbides 650, fractions 1–5, and of the *Chlorobium* pheophorbides 660, fractions 5, 6, and (in part) 3 and 4. This also supports the assumptions upon which these and the remaining structures were based. All the identities were established through the melting points, the mixed melting points, and the X-ray powder photographs of both the methyl esters and their copper complexes.

In the 650 series, the pyrroporphyrins from fractions 1–4 and the desoxo-phylloerythrin from fraction 5 were identified with synthetic specimens.

In the 660 series, not enough of fractions 1 and 2 were obtained for the degradations to be attempted. The two phylloporphyrins III*b* (R^1 = $CH_2CH_2CH_3$, R^2 = Et, R^3 = Me) and III*b* (R^1 = $CH_2CH_2CH_3$, R^2 = R^3 = Et) were synthesized for comparison with those from fractions 3 and 4, without prejudice about which should correspond to which. It was initially concluded from the X-ray powder photographs of the esters that the synthetic δ-methyl- and δ-ethyl-porphyrins might correspond with those from fractions 3 and 4 respectively, but the limited amounts of material were used before either of these identities had been established. Further, in view of the polymorphism of the specimens, none of the possible identities can be excluded on this evidence. Other difficulties here were the low yields in the syntheses, the relatively high solubilities, and the relative difficulty with which fractions 3 and 4 are separated. As these two synthetic δ-phylloporphyrins were neither well characterized (see Experimental) nor identified with material of natural origin, they are omitted from Table I. However, both fractions 3 and 4 were also degraded to one pyrroporphyrin which was shown (3) to be identical with the synthetic pyrroporphyrin corresponding to the 650 pheophorbide, fraction 2. This confirmed the structures of fractions 3 and 4 except for the nature and position of R^3. The δ-phylloporphyrins from fractions 5 and 6 were identified with synthetic specimens. That corresponding to fraction 6 (δ-phylloporphyrin 15) had been synthesized by Fischer (5), but none of his specimen remained. When his synthesis was repeated in a considerably modified form, we found that the melting point of its methyl ester – copper complex had been reported incorrectly.



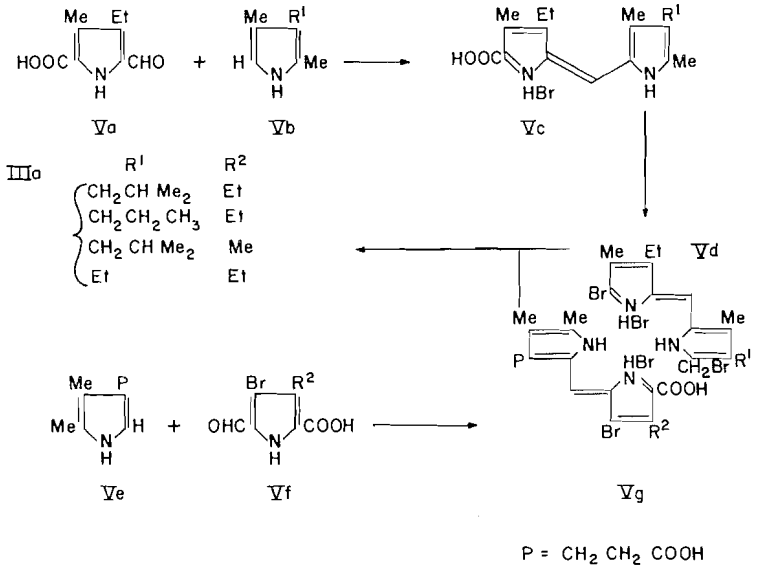
Porphyrins of the 650 Series

The obvious attack was to synthesize pyrroporphyrins for comparison with those obtained by degradation. This degradation seemed to be impracticable for, in contrast to that of pheophorbide *a*, the isocyclic ring of pyrropheophorbide *a* is not easily oxidized by Fischer's methods. In the first instance (fraction 5), this difficulty was avoided by comparing a synthetic desoxo-phylloerythrin with analytical ones. This confirmed the isocyclic ring, but the synthesis of desoxo-phylloerythrins is more laborious than that of pyrroporphyrins and is probably unsuited to 5-ethyl derivatives, for which the pyrrole intermediate providing ring 3 is reportedly unstable (6). Later, methods were found by which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the pheophorbides 650 were degraded to pyrroporphyrins, or the pheophorbides 660 to δ-phylloporphyrins and pyrroporphyrins (3). It was then possible to compare synthetic and analytical pyrroporphyrins, as was done with fractions 1–4.

The synthetic work was done concurrently with the analytical, before the potential of the developing analytical methods was known. A structure tentatively suggested for fraction 2 required it to be degraded to 2- or 4-*n*-propyl-2- or -4-desethyl-desoxophylloerythrin. Because the required pyrromethenes were known, the second of these was synthesized (Reaction Scheme 2) by the method which Fischer had used for desoxophylloerythrin itself (7, 8). All the intermediates were obtained by the reported methods or by modifications thereof (see Experimental).



REACTION SCHEME 2. The synthesis of 4-*n*-propyl-4-desethyl-desoxo-phylloerythrin (II*b*, $R^1 = CH_2CH_2CH_3$, R^2 = Me).

The synthetic 4-*n*-propyl-4-desethyl-desoxo-phylloerythrin (II*b*, $R^1 = CH_2CH_2CH_3$, R^2 = Me) differed from that obtained when fraction 2 was degraded. Later analytical work showed that, in both fractions 2 and 5, R^1 was indeed *n*-propyl and was on ring 2 rather than on ring 1. However, it also showed that R^2 was ethyl in fraction 2, and thus was probably methyl in fraction 5. Fraction 5 was then degraded to a desoxo-phylloerythrin which was shown to be identical with the synthetic one.

Some work on the above degradations should be mentioned. In model experiments, the degradation of pyrropheophorbide *a* with hydrogen iodide in acetic acid to phylloerythrin, and of the latter to desoxo-phylloerythrin by the Wolf–Kishner method (9), was repeated. This gave an initially low melting desoxo-phylloerythrin ester (m.p. ca. 255°) which required extensive purification. The same method was used to degrade fraction 2. Further model experiments showed that the Wolf–Kishner reduction of mesopyrropheophorbide *a* gave a mixture of desoxo-phylloerythrin and desoxo-mesopyrropheophorbide *a* (10), and the latter gave more desoxo-phylloerythrin when heated with dilute acid. Here a high-melting product (ester m.p. 262–264°) resulted directly, so this method was used to degrade fraction 5.

The four pyrroporphyrins were synthesized by the scheme used by Fischer for one synthesis of pyrroporphyrin 15 (11) (Reaction Scheme 3). Unlike two possible alternatives, it utilized some pyrromethenes which could also be used in the synthesis of δ-phylloporphyrins (see below); also, one methene (V*d*, $R^1 = CH_2CH_2CH_3$) had already been prepared. Further, and unlike the fourth alternative, this scheme used the more easily available pyrroles, derivatives of 2,4- rather than 2,3-dimethyl-pyrrole, to construct rings 2 and 3 on which R^1 and R^2 varied. All the pyrroles and pyrromethenes in Reaction Scheme 3 were obtained essentially by the reported methods, or by standard ones (see Experimental). However, there had been no satisfactory preparation of V*b* (R^1 = isobutyl), and the following are new: V*c* (R^1 = isobutyl), V*d* (R^1 = isobutyl), V*f* (R^2 = Et), and V*g* (R^2 = Et).

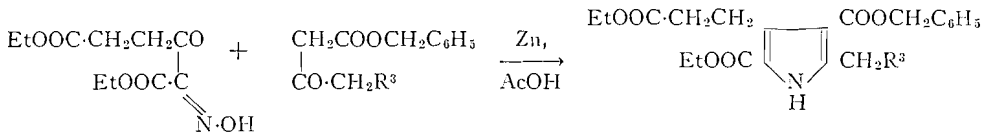
REACTION SCHEME 3. The synthesis of the pyrroporphyrins (V*d* (R^1 = Et)) is obtained directly by brominating 2,4-dimethyl-3-ethyl-pyrrole.

Porphyrins of the 660 Series



The syntheses of the δ-phylloporphyrins was undertaken by the method indicated in Reaction Scheme 4, for reasons mentioned in connection with the analogous synthesis of pyrroporphyrins. The 5-ethyl-5-desmethyl-δ-phylloporphyrin corresponding to fraction 5 was thus obtained. The δ-phylloporphyrins presumably corresponding to fractions 3 and 4, III*a* (R^1 = $CH_2CH_2CH_3$, R^2 = Et, R^3 = Me) and III*a* (R^1 = $CH_2CH_2CH_3$, R^2 = R^3 = Et), were also obtained, but, as mentioned above, were inadequately characterized. The data here (see Experimental) gave some misleading indications of identities, whereas the usual problem has been that of polymorphism obscuring identities (cf. 650, fraction 4, and 660, fraction 6); in both cases the criteria are near the limits of their usefulness. By using V*d* (R^1 = Et) and VI*b* (R^2 = R^3 = Me), this method failed to give δ-phylloporphyrin itself (III*a*, R^1 = Et, R^2 = R^3 = Me), which corresponds to fraction 6; the spectrum of the product suggested that it was the corresponding pyrroporphyrin.

REACTION SCHEME 4. The synthesis of homologues of δ-phylloporphyrin.

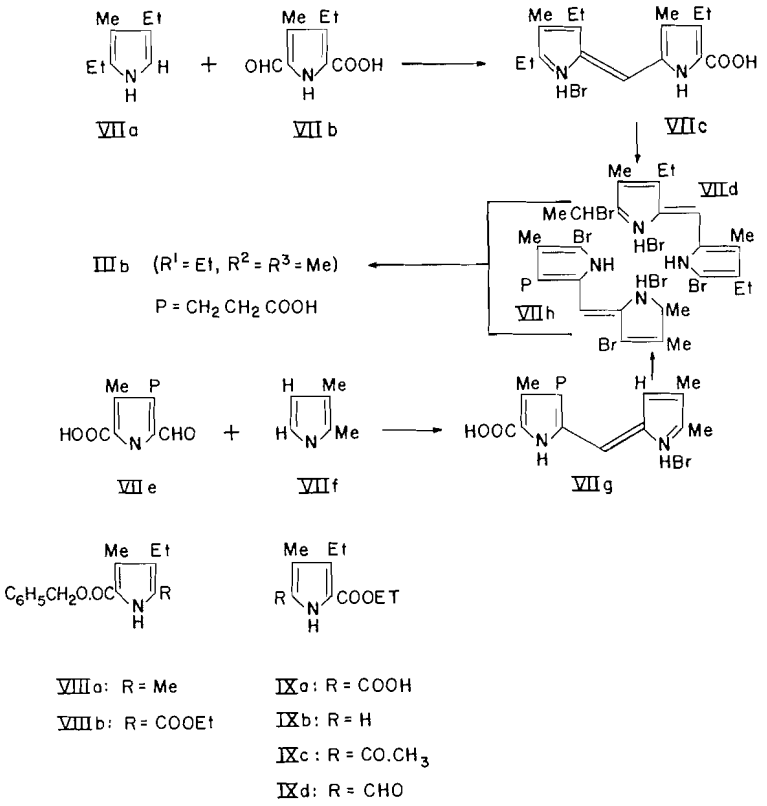
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The syntheses of the pyrroles VI*a* (R^3 = Me and R^3 = Et) were analogous to a synthesis of VI*a* (R^3 = H) (12):

followed by $COOCH_2C_6H_5 \rightarrow COOH \rightarrow H \rightarrow CHO \rightarrow CH_3$, and then hydrolysis and decarboxylation. Here, as in analogous cases, the acids produced by hydrogenating the benzyl esters are most smoothly decarboxylated by heating the crude acids containing Raney nickel, a small amount first being decarboxylated to wet the walls of the flask with the product. We have since found that homologues such as the above are more readily obtained through the reaction of α-bromomethyl-pyrroles with Grignard reagents (13).

The benzyl propionyl acetate and benzyl *n*-butyryl acetate required in the above pyrrole syntheses were obtained, as was benzyl acetoacetate (14), by heating the ethyl esters with benzyl alcohol. The ethyl esters were obtained by boiling ethyl propionyl malonate and ethyl *n*-butyryl malonate with water (cf. refs. 15, 16). This may be the most generally useful method for preparing ethyl acyl acetates. The yields by a standardized procedure are competitive, consistent, and insensitive to the size of the run. Acyl malonic esters (17, 18) have also been split less reliably (19) by heating them with sulfonic acids (18), less conveniently by cold concentrated sulfuric acid (16) (see also Experimental), in low yield by steam distillation (20), and (together with undesirable by-products) by heating them with acid and a catalyst (21). When the product is not readily separated from the by-product (diethyl malonate) by distillation, it can be purified as its bisulfite complex or, if it does not form one, as its magnesium derivative (cf. ref. 22). Related methods employing ethyl acyl acetoacetates as intermediates give ethyl acetoacetate as the by-product, the separation of which, other than by distillation, requires more specialized methods. Although ethyl propionyl acetate is conveniently obtained from ethyl cyanoacetate and ethyl magnesium iodide, this method is less general and requires 2 moles of the Grignard reagent.

As δ-phylloporphyrin (III*a*, R^1 = Et, R^2 = R^3 = Me) was not obtained as above, we repeated Fischer's synthesis (5) (Reaction Scheme 5). Accordingly, the pyrroles VII*e* and VII*f*, obtained by more recent methods (see Experimental), were converted into VII*g* and hence into VII*h*. The preparation of VII*d* was modified, VII*b* being used instead of 3-methyl-4-ethyl-pyrrole, for it is doubtful that the latter always condenses under the methyl group (23). The two known pyrroles VII*a* and VII*b* were obtained by a method which was particularly convenient, because both were required: VIII*a* was converted through VIII*b*, IX*a*, and IX*b* into IX*c* and IX*d*; the latter gave VII*a* and VII*b* respectively. In effect, this sequence converts a pyrrole into its isomer with the β-substituents reversed, or into higher homologues thereof. Another alternative though unsatisfactory synthesis of VII*a* was found in the modified Knorr synthesis (cf. ref. 24) of its α-carbethoxy derivative from isonitroso-acetoacetic ester and 4-methyl-3,5-heptanedione.



EXPERIMENTAL

Pyrroles

*2-Formyl-3-(ω-bromovinyl)-4-methyl-5-carboxy-pyrrole (IV*a*) (25)*

The reported yield and melting point of the intermediate, 2,4-dimethyl-3-(ω-bromovinyl)-5-carbethoxy-pyrrole, were only realized when the crude product (from ether) was recrystallized by extraction (thimble) successively with benzene (5 parts), with hexane (10 parts), and then with benzene.

REACTION SCHEME 5. The synthesis of δ-phylloporphyrin 15.

Only when the corresponding ester was hydrolyzed by heating it for 2 h under reflux (mantle) was the expected yield obtained.

2-Formyl-3-ethyl-4-methyl-5-carboxy-pyrrole (Va) (26)

2,4-Dimethyl-3-ethyl-5-carbethoxy-pyrrole (27) was oxidized in varying yield to the 2-aldehyde (28) (purified to m.p. ⩾ 90° from aqueous ethanol by high vacuum distillation or by extraction with pentane), and the latter was hydrolyzed (26), the product (m.p. ⩾ 200°) being precipitated by acetic acid. A specimen, m.p. 210° (lit. (26) m.p. 199°), was analyzed.

Anal. Calcd. for $C_9H_{13}O_3N$: C, 59.00; H, 7.15; N, 7.65. Found: C, 59.13; H, 6.88; N, 7.55.

2,4-Dimethyl-3-n-propyl-pyrrole (Vb, $R^1 = CH_2CH_2CH_3$) (29, p. 60)

The method developed for the 3-ethyl homologue (30) gave a 65% yield from 2,4-dimethyl-3-propionyl-5-carbethoxy-pyrrole (29, p. 200).

2,4-Dimethyl-3-isobutyl-5-carbethoxy-pyrrole

The corresponding 3-isobutyryl-pyrrole (31) (colorless prisms, 55%, m.p. 111–113° (lit. (31) m.p. 108°)) was isolated by extraction with ether, distillation (bath temperature 160° at 0.1 mm), and crystallization from aqueous ethanol. This was hydrogenated for 6 h in 2.5 parts of ethanol over Raney nickel (1 900 p.s.i., 160°), more nickel added, and the hydrogenation repeated. The product was filtered off and dissolved in ether. Ether was removed from the filtered solution and the residue crystallized from aqueous ethanol as colorless needles (52%), m.p. 116–117°.

Anal. Calcd. for $C_{13}H_{21}NO_2$: C, 69.92; H, 9.48; N, 6.27. Found: C, 70.03; H, 9.34; N, 6.31.

2,4-Dimethyl-3-isobutyl-pyrrole (Vb, $R^1 = CH_2CHMe_2$) (31)

The above 5-carbethoxy derivative (5 g) was heated under reflux for 3 h with 3 g of sodium hydroxide, 10 ml of water, and enough ethanol to maintain solution. It was taken to dryness *in vacuo*, the residue extracted with 150 ml of water, and the insoluble ester recycled. Acidifying the aqueous extracts with 10% hydrochloric acid to pH 6 precipitated the α-carboxy-pyrrole (92%), which decomposed at 92°. This was distilled *in vacuo* at 110° to give the product (87%) as a colorless oil.

Anal. Calcd. for $C_{10}H_{17}N$: C, 79.40; H, 11.34; N, 9.27. Found: C, 79.74; H, 11.12; N, 8.98.

The one-step method from 2,4-dimethyl-3-isobutyryl-5-carbethoxy-pyrrole was unsatisfactory by either the original (31) or the modified (30) Wolf–Kishner procedures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2,3-Dimethyl-pyrrole-4-propionic Acid (Hemopyrrole-carboxylic Acid, Ve)

This (12) was always recrystallized just before use as yellow needles, m.p. 132–133°, by extraction with 50 parts of hexane (thimble) over 12 h while protected from light.

2-Formyl-3-bromo-4-methyl-5-carboxy-pyrrole (Vf, R^2 = Me)

2,4-Dimethyl-3-bromo-5-carbethoxy-pyrrole (29, p. 92) was chlorinated in chloroform (not ether (cf. ref. 11)), the chloroform removed at 20°, and the residue converted into the 2-aldehyde which was obtained as colorless needles (65–80%). This was hydrolyzed (11) under nitrogen and the product recrystallized as microneedles (60%) from aqueous acetone.

Ethyl Propionyl Acetate (with D. K. Dougall)[7]

Ethyl propionyl malonate was prepared (18) on a 5 *M* scale in a 5 l flask, the ether layer containing the crude product being further washed with dilute $NaHCO_3$ and then water before stripping. The combined undistilled residues from two such runs were gently boiled under a 12 inch Vigreux column with 2 l of water for 9 h, with vigorous stirring (cf. ref. 16). The combined ester layers in the flask and distillate were extracted with 10 × 350 ml of aqueous $NaHSO_3$ (4 lb). The extract was washed with pentane, and then stirred in an ice bath while the solution was being neutralized at 25° with 35% NaOH, ice being added as necessary. The mixture was extracted with benzene; the extract was washed with aqueous $NaHCO_3$ and then with water, dried (Na_2SO_4), and filtered; the benzene was removed. Distillation gave 543 g (38% overall), b.p. 89.5–91° at 20 mm, n_D^{25} 1.4213, copper complex m.p. 142–143° (lit. (32) m.p. 144–145°). Gas–liquid chromatography showed about 4% of a second component.

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.31; H, 8.39. Found: C, 59.61; H, 8.41.

In preliminary experiments on a 1.25 *M* scale, the above method and the sulfuric acid method (cf. ref. 16) both gave 28% yields. When the purification with bisulfite was omitted, a 51% yield was reported by the above method (33). Using gas–liquid chromatography, we found a commercial specimen to be 50% pure.

Benzyl Propionyl Acetate

Ethyl propionyl acetate (432 g) and benzyl alcohol (324 g) were heated with a few boiling stones in a 1 l flask in a mantle under a 12 inch Vigreux column until thermometers in the liquid and at the top of the column registered 176° and 91° respectively. The rest was distilled to 83° (0.05 mm). The distillate was recycled by heating to 183° and then distilling to 83° (0.05 mm), this second distillate being recycled again. The three residues were combined and distilled to give the product (575 g, 93%), b.p. 80–85° or higher at 0.5 mm depending on the rate of distillation, n_D^{25} 1.5050.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84. Found: C, 69.23; H, 6.42.

2-Methyl-3-carbobenzoxy-4-ethyl-5-carbethoxy-pyrrole

This was prepared by the Knorr synthesis according to our usual procedure (compare the corresponding 4-(2′-carbethoxyethyl)-pyrrole (23)), ethyl propionyl acetate (see above) being nitrosated with amyl nitrite and the product being condensed with benzyl acetoacetate. The crude pyrrole was washed with 50% ethanol and crystallized from ethanol, m.p. 126–127° (51%). For analysis it was recrystallized to m.p. 127–129°.

Anal. Calcd. for $C_{18}H_{21}O_4N$: C, 68.55; H, 6.71. Found: C, 68.10; H, 6.67.

2-Methyl-3-bromo-4-ethyl-5-carbethoxy-pyrrole (29, p. 93)

The corresponding 3-carbobenzoxy-pyrrole (above) was reduced in 3 parts of ethanol over Raney nickel (1 000 p.s.i., 100°) to the 3-carboxylic acid (29, p. 257) (90%). This was decarboxylated at 260° and the resulting 3-free pyrrole (29, p. 240) was distilled at 15 mm and then twice crystallized from aqueous ethanol (69%). A solution of this (19 g) in 60 ml of carbon tetrachloride was stirred and protected from moisture while 5.8 ml of bromine was dropped in. Stirring was continued for ½ h, and the solution was concentrated *in vacuo* to one-half volume and then refrigerated overnight. The crystals were washed with ether and recrystallized from aqueous ethanol as needles (63%), m.p. 127–129° (lit. (29, p. 93) m.p. 124°).

2-Formyl-3-bromo-4-ethyl-5-carbethoxy-pyrrole (34)

Sulfuryl chloride (10.3 ml) was added over 20 min to a stirred solution of the corresponding 2-methyl pyrrole (above, 16.3 g) in 250 ml of chloroform (ethanol free). Next day the solvent was removed *in vacuo*. The residue was twice crystallized from 70% ethanol at 0° to give nearly colorless needles (68%), m.p. 96–97° (lit. (34) m.p. 93–95°).

Anal. Calcd. for $C_{10}H_{12}NO_3Br$: C, 43.81; H, 4.41; N, 5.11; Br, 29.16. Found: C, 43.99; H, 4.28; N, 5.06; Br, 28.69.

2-Formyl-3-bromo-4-ethyl-5-carboxy-pyrrole (Vf, R^2 = Et)

The corresponding ester (above, 11.74 g) was heated in the steam bath under nitrogen for 3 h with 36 ml of 5% NaOH. The cooled solution was diluted to 300 ml, filtered, acidified with HCl, and refrigerated. The nearly colorless precipitate (96%) was recrystallized from acetone as needles which decomposed above 230°.

Anal. Calcd. for $C_8H_8O_3NBr$: C, 39.05; H, 3.29; N, 5.69; Br, 32.48. Found: C, 39.07; H, 3.40; N, 5.71; Br, 32.11.

2-Ethyl-3-carbobenzoxy-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

This was prepared from ethyl β-keto-adipate (16), amyl nitrite, and benzyl propionyl acetate (above) on a

[7]*National Research Council Postdoctorate Fellow, 1956–1957.*

1.5 *M* scale exactly as was its 2-methyl homologue (23). It formed colorless prisms (58%) when it was crystallized from ethanol, m.p. 92–93°.

Anal. Calcd. for $C_{22}H_{27}O_6N$: C, 65.82; H, 6.78; N, 3.49. Found: C, 66.03; H, 6.91; N, 3.10.

2-Ethyl-3-carboxy-4-(2-carbethoxyethyl)-5-carbethoxy-pyrrole

The corresponding 3-carbobenzoxy-pyrrole (above) was hydrogenated in ethanol over Raney nickel for 6 h at 125° and 1 500 p.s.i. Ethanol was removed and the residue extracted with ice-cold 0.1 *N* sodium carbonate, from which the product was precipitated with acetic acid. When it was crystallized from 50% ethanol it formed colorless prisms, m.p. 186–188.5°.

Anal. Calcd. for $C_{15}H_{21}O_6N$: C, 57.86; H, 6.80; N, 4.50. Found: C, 57.81; H, 6.91; N, 4.84.

2-Ethyl-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

The corresponding 3-carbobenzoxy-pyrrole (above, 50 g) was hydrogenated as above and the crude acid was slowly distilled at 15 mm from a 250 ml flask heated in a mantle with the neck wrapped in heating tape. The distillate was redistilled from a Vigreux flask to give an oil (78%), b.p. 150° at 0.5 mm, solidifying to colorless prisms, m.p. 40–41°, unstable to air and light.

Anal. Calcd. for $C_{14}H_{21}O_4N$: C, 62.90; H, 7.92; N, 5.24. Found: C, 63.17; H, 7.89; N, 5.13.

2-Ethyl-3-formyl-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

The corresponding 3-free pyrrole (above, 17.5 g) was stirred with dimethylformamide (35 ml, distilled over P_2O_5), while 8.8 ml of phosphorus oxychloride was dropped in. The mixture was heated on the steam bath for 40 min, cooled, and poured into 300 ml of water containing 52 g of sodium acetate. The oily layer solidified when the solution was allowed to cool. It was recrystallized by extraction with 1 600 ml of hexane (thimble) to give colorless needles (79%), m.p. 85–86°.

Anal. Calcd. for $C_{15}H_{21}O_5N$: C, 61.00; H, 7.17; N, 4.74. Found: C, 60.79; H, 6.80; N, 5.08.

2-Ethyl-3-methyl-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

The corresponding 3-formyl pyrrole (above) was reduced in ethanol over Raney nickel at 180° and 1 300 p.s.i. for 4 h. After the catalyst had been separated and the ethanol removed, the residue was crystallized from aqueous ethanol to give colorless needles (82%), m.p. 80.5–81.5°. For analysis, it was recrystallized to m.p. 81–82°.

Anal. Calcd. for $C_{15}H_{23}O_4N$: C, 64.03; H, 8.29; N, 4.98. Found: C, 64.21; H, 8.19; N, 5.18.

2-Ethyl-3-methyl-pyrrole-4-propionic Acid (VIa, R^3 = Me)

The corresponding 5-carbethoxy ester (above, 21.4 g) was heated under reflux for 3 h on the steam bath with 100 ml of water, 30 ml of ethanol, and 22 g of sodium hydroxide. Ethanol was boiled off, more water added, and the solution saturated with sulfur dioxide under a layer of ether and extracted twice with ether. The ether layer was washed with water and dried (Na_2SO_4), and the ether was removed. The residual solid was heated on the steam bath for 5 min with 15 ml of water. The whole was quickly dried (oil pump) and the residue crystallized from 1 200 ml of hexane. The colorless needles (86%) that were initially formed rapidly turned pink, m.p. 85–88°, sensitive to air and light.

Anal. Calcd. for $C_{10}H_{15}O_2N$: C, 66.27; H, 8.34; N, 7.73. Found: C, 66.08; H, 7.95; N, 7.91.

Ethyl n-Butyryl Acetate

Crude ethyl *n*-butyryl malonate was prepared in two 4.1 *M* runs in the same manner as ethyl propionyl malonate was (above), and boiled with water in the same way for 6.5 h. Combining the ester layers in the flask and distillate gave 1 270 ml of crude product. Magnesia mixture (850 ml) (from 330 g of $MgCl_2 \cdot 6H_2O$, 420 g of NH_4Cl, 1 500 ml of water, and 450 ml of ammonium hydroxide), 800 ml of water, and 400 ml of ice were stirred vigorously at 10°, 110 ml of the crude ester was added, and stirring was continued for 20 min. The filtered precipitate was twice slurried (Waring Blendor) and filtered with 60 ml of magnesia mixture which had been diluted with 500 ml of ice water, and then dried to 0.02 mm. The magnesium complex from 310 ml of crude ester (194 g, m.p. 152.5–154° (lit. (22) m.p. 156–157°)) was shaken with 600 ml of ether, 110 ml of hydrochloric acid, and 800 ml of ice water. The ether layer was washed with 10% HCl and both acid layers washed in turn with ether. The combined ether layers were washed with water, aqueous disodium phosphate, and water, and then dried (Na_2SO_4) and the ether removed. The residue was distilled at 14 mm to give 14 g, b.p. 86–91°, $n_D^{16.5}$ 1.4265; 122 g, b.p. 91–92.5°, $n_D^{16.5}$ 1.4275; and 18 g, b.p. 92.5–93°, $n_D^{16.5}$ 1.4275; total 49% overall.

All three fractions were suitable for conversion into the benzyl ester (see below). The middle fraction (copper complex m.p. 126–126.5° (lit. (35) m.p. 125–126°)) appeared on gas chromatography to be homogeneous and indistinguishable from the product which was obtained from ethyl *n*-butyryl acetoacetate (29, p. 405), but both gave a carbon analysis which was 2.5% high.

Benzyl n-Butyryl Acetate

As in the preparation of benzyl propionyl acetate (above), 116.3 g of the above ethyl *n*-butyryl acetate and 93 ml of benzyl alcohol were heated to 195° and distilled to 95° (0.01 mm) through three cycles. Distillation of the combined residues gave 145 g (89%), b.p. (0.02 mm) 89–93° or higher depending on the rate of distillation, n_D^{15} 1.5040.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32. Found: C, 71.05; H, 7.41.

2-n-Propyl-3-carbobenzoxy-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

This was obtained from ethyl β-keto-adipate (16), amyl nitrite, and the above benzyl *n*-butyryl acetate in the same manner as its 2-methyl homologue was (23), except that more acetic acid was used to maintain solution and prevent foaming. It formed colorless prisms (42%) when it was crystallized from aqueous ethanol, m.p. 84.5–85.5°.

Anal. Calcd. for $C_{23}H_{29}O_6N$: C, 66.49; H, 7.04; N, 3.37. Found: C, 66.36; H, 6.96; N, 3.31.

2-n-Propyl-3-methyl-5-carbethoxy-pyrrole-4-propionic Acid Ethyl Ester

The corresponding 3-carbobenzoxy derivative (above), in the same manner as its 2-ethyl homologue above, was converted successively into the 3-carboxy pyrrole (colorless plates from ethanol, m.p. 178–180°, or changing at 160° to needles, m.p. 184–185°), the 3-free pyrrole (prisms from pentane at −10°, m.p. 35.5–36.5°), the 3-formyl pyrrole (needles from hexane, m.p. 87.5–88.5°), and the 3-methyl pyrrole (ca. 20% overall). The latter formed colorless needles when it was crystallized from aqueous ethanol, m.p. 77–79°.

Anal. Calcd. for $C_{16}H_{25}O_4N$: C, 65.06; H, 8.53; N, 4.74. Found: C, 65.33; H, 8.50; N, 4.78.

2-n-Propyl-3-methyl-pyrrole-4-propionic Acid (VIa, R^3 = Et)

This was obtained, in the same manner as its 2-ethyl homologue (above), from the corresponding 5-carbethoxy ester (above). It separated from hexane when the solution was allowed to stand under nitrogen, finally at 10°, as long colorless needles (68%), m.p. 80.5–81.5°.

Anal. Calcd. for $C_{11}H_{17}O_2N$: C, 67.66; H, 8.78; N, 7.17. Found: C, 67.43; H, 8.58; N, 7.42.

4-Methyl-3,5-diethyl-2-carbethoxy-pyrrole

Ethyl acetoacetate (48 g) in 200 ml of acetic acid was nitrosated at 8° with 28 g of sodium nitrite in 50 ml of water, and excess nitrite was destroyed the next day with ammonium sulfamate. This solution, zinc dust (150 g), and 4-methyl-3,5-heptanedione (36) (51 g) were added in 5 portions over 10 min to a stirred solution of ammonium acetate (40 g) in acetic acid (100 ml) maintained at 60–70°. More zinc dust was added at this temperature over 1 h. The mixture was then kept for 1 h at 105° and then decanted into ice water. The product was separated from 2,4-dimethyl-3,5-dicarbethoxy-pyrrole by extraction with pentane, distillation to 90° (1×10^{-4} mm), and crystallization from pentane at −20°. It formed large colorless prisms (7 g, 9%), m.p. 62–63°.

Anal. Calcd. for $C_{12}H_{19}NO_2$: C, 68.86; H, 9.15. Found: C, 68.77; H, 9.07.

References to this in the literature (5; 29, p. 57) refer to 4-formyl-3,5-diethyl-2-carbethoxy-pyrrole.

3-Methyl-2,4-diethyl-pyrrole (VIIa)

(*a*) 4-Methyl-3-ethyl-2-carbethoxy-5-acetyl-pyrrole (IX*c*, see below, 13 g) was heated for 16 h at 160° in an autoclave with 12 ml of hydrazine and 7 g of sodium dissolved in 220 ml of absolute ethanol. Ethanol was then distilled off through a column and 30 ml of water added to the residue, which was then extracted with ether. The extract was dried (potassium carbonate) and the ether distilled off through a column. A drop of hydrazine was added to the residue, which was distilled through a small column (95–98°, 12 mm) to give 7.5 g (94%) of a pale oil, picrate m.p. 110° (lit. (5) m.p. 110°). It is stable in an evacuated sealed tube protected from light.

Anal. Calcd. for $C_9H_{14}N$: C, 78.77; H, 11.02; N, 10.21. Found: C, 78.47; H, 10.76; N, 10.15.

(*b*) 4-Methyl-2,4-diethyl-2-carbethoxy-pyrrole (see above, 1 part) was heated for 5 h at 170° in a Teflon-lined metal tube with 8 parts of ethanolic potassium hydroxide (10% w/v). Ether was then added and the product (82%) isolated as above, picrate m.p. and mixed m.p. with the above picrate 109–110°.

Anal. Found: C, 78.64; H, 11.22; N, 10.01.

4-Methyl-3-ethyl-2-carboxy-pyrrole-5-aldehyde (VIIb)

The corresponding ester (IX*d*, see below, 9.5 g) was boiled for 5 min with 20 ml of 10% sodium hydroxide. The clear solution was cooled, filtered with Darco, and acidified with hydrochloric acid. The crystalline precipitate was separated and recrystallized from 60% ethanol, m.p. 176° (7.5 g, 91%). For analysis it was recrystallized three times from 70% ethanol as long needles, m.p. 180–181° (lit. (37) m.p. 174°).

Anal. Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.38; H, 5.98; N, 7.67.

2-Formyl-4-methyl-5-carboxy-pyrrole-3-propionic Acid Diethyl Ester

(*a*) A solution of 10.7 g of 2,4-dimethyl-5-carboxy-pyrrole-3-propionic acid diethyl ester (24) in 50 ml of chloroform (dried over calcium chloride) was stirred in an ice bath and protected from moisture while 7.2 ml of sulfuryl chloride was added over 1 h. Next day the chloroform was removed *in vacuo* and the residue was boiled for 5 min with 15 g of sodium acetate in 100 ml of water. The insoluble oil was washed by decantation and dissolved in ether. The washed (aqueous sodium carbonate and then water) and dried ether solution was evaporated and the residue distilled in high vacuum. The product (8 g, 71%) solidified when the solution was allowed to cool, m.p. 62–67°. For analysis it was recrystallized from pentane as pale yellow prismatic needles, m.p. 64.5–65.5° (lit. (38) m.p. 62–66°).

Anal. Calcd. for $C_{14}H_{19}NO_5$: C, 59.77; H, 6.81. Found: C, 59.95; H, 6.84.

(*b*) The corresponding half ester (free propionic acid (39)) was esterified at 20° in ethanolic hydrogen chloride and crystallized from pentane to give prismatic needles, m.p. and mixed m.p. with the above diethyl ester 64.5–65.5°.

For personal use only.

2-Formyl-4-methyl-5-carboxy-pyrrole-3-propionic Acid (VIIe)

Either the above diethyl ester or the monoethyl ester (39) was hydrolyzed in ethanolic potassium hydroxide, crystallized from formic acid as colorless needles (39), and dried (63°, 1×10^{-4} mm).

Anal. Calcd. for $C_{10}H_{11}NO_5 \cdot HCOOH$: C, 48.71; H, 4.83; N, 5.16; equiv. wt. 90.4. Found in the product from the diethyl ester: C, 48.45; H, 4.73; N, 5.16; equiv. wt. 80.6. Found in the product from the monoethyl ester: equiv. wt. 79.4.

After recrystallization from water, the former melted at 220–235° (decomp.) (lit. (38) m.p. 232–234° (decomp.)) with intervening phase changes.

2,3-Dimethyl-pyrrole (VIIf)

2-Methyl-3-carbethoxy-pyrrole (40) was reduced by lithium aluminium hydride (41).

4-Methyl-3-ethyl-5-carbobenzoxy-pyrrole-2-carboxylic Acid (cf. VIIIb)

Sulfuryl chloride (6.6 g) was dropped into a stirred solution of 2,4-dimethyl-3-ethyl-5-carbobenzoxy-pyrrole (42) (VIII*a*, 3.6 g) in 50 ml of absolute ether at 10–15°. Next day the ether was removed *in vacuo*, hot aqueous sodium acetate (7 g in 30 ml) added to the residue, and the mixture boiled for 5 min. After the solution was allowed to cool, the insoluble material was dissolved in 10% sodium hydroxide, and the solution was washed with ether and then acidified with hydrochloric acid. The precipitate was separated, washed with water, and crystallized from ethanol (thimble) to give 2.5 g (62%), m.p. 166°. For analysis it was recrystallized from ethanol as colorless prisms, m.p. 175°.

Anal. Calcd. for $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88. Found: C, 67.02; H, 5.95; N, 5.02.

4-Methyl-3-ethyl-2-carbethoxy-5-carbobenzoxy-pyrrole (VIIIb)

As in the preparation of the corresponding carboxylic acid (above), 26.7 g of 2,4-dimethyl-3-ethyl-5-carbobenzoxy-pyrrole in 250 ml of ether was treated with 40.8 g of sulfuryl chloride. Ethanol (150 ml) was added to the residue that was left after the ether had been evaporated. Water (200 ml) was added to the clear solution, and the mixture extracted with ether. The extract was washed with 5% sodium hydroxide, with saturated sodium bisulfite, and with water, and then dried (sodium sulfate) and the ether evaporated. Crystallizing the residue from *n*-hexane gave 28 g (92%), m.p. 51°. For analysis it was recrystallized from *n*-hexane as colorless needles, m.p. 53°.

Anal. Calcd. for $C_{18}H_{21}O_4N_2$: C, 68.55; H, 6.71; N, 4.44. Found: C, 68.39; H, 6.66; N, 4.65.

4-Methyl-3-ethyl-2-carbethoxy-pyrrole-5-carboxylic Acid (IXa)

The corresponding benzyl ester (VIII*b*, see above, 15.75 g) in 250 ml of ethanol was hydrogenated at atmospheric pressure over 500 mg of palladium black (uptake 1 100 ml, calcd. 1 180 ml). The mixture was heated to dissolve the precipitate, filtered, and cooled. The colorless product (10.2 g, 91%) separated, m.p. 230°. For analysis it was recrystallized from ethanol as colorless elongated prisms, m.p. 233° (lit. (37) m.p. 218°).

Anal. Calcd. for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22. Found: C, 58.74; H, 6.68; N, 6.43.

4-Methyl-3-ethyl-2-carbethoxy-pyrrole (IXb)

The corresponding acid (IX*a*, see above) was decarboxylated (37) to give the distilled product (53%), m.p. 69–70°. For analysis it was recrystallized from *n*-hexane as colorless plates, m.p. 75° (lit. (37) m.p. 76°).

Anal. Calcd. for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73. Found: C, 66.09; H, 8.25; N, 7.90.

4-Methyl-3-ethyl-2-carbethoxy-5-acetyl-pyrrole (IXc)

Anhydrous aluminium chloride (21 g) was added, in portions, to a cooled and stirred solution of the corresponding α-free pyrrole (see above, 14 g) in 150 ml of carbon disulfide and 10 ml of acetyl chloride. The mixture was heated under reflux for 15 min, cooled, and poured into ice water. The product was extracted with ether; the extract was washed with 5% sodium hydroxide and then with water, and dried (sodium sulfate); the solvents were removed *in vacuo*. The residue was crystallized from *n*-hexane (thimble) to give 13 g (75%) of colorless needles, m.p. 107°.

Anal. Calcd. for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.68; N, 6.27. Found: C, 64.30; H, 7.51; N, 6.04.

4-Methyl-3-ethyl-2-carbethoxy-pyrrole-5-aldehyde (IXd)

The corresponding α-free pyrrole (IX*b*, see above, 10 g) was converted into the aldimine hydrochloride (37). When this was dissolved in 50 ml of ice water (much less than suggested (37), the aldehyde being appreciably soluble), the aldehyde crystallized (9.5 g, 82%), m.p. 55°. For analysis it was crystallized from 60% ethanol, m.p. 65–66° (lit. (37) m.p. 68°).

Anal. Calcd. for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69. Found: C, 63.33; H, 7.39; N, 6.88.

Pyrromethenes

4,4',5'-Trimethyl-3-(ω-bromovinyl)-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (IVb) (8)

After washing with ethyl acetate until the washings were very pale, and then with ether, the product (57%) decomposed at about 105°.

5-Bromo-4,3'-dimethyl-5'-bromomethyl-3,4'-diethyl-pyrromethene Hydrobromide (Vd, R^1 = Et) (43)

The reported yield of a stable product was only obtained when *freshly* distilled cryptopyrrole was brominated; the resulting mixture of pyrromethenes was washed with a little acetic acid and then thoroughly with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

much petrol ether (30–60°), and dried over KOH at 0.02 mm; then the methenes were separated. More of the desired product was obtained by boiling "methene II" with 15 parts of acetic acid for 5 min.

5-Carboxy-4,3',5'-trimethyl-3-ethyl-4'-n-propyl-pyrromethene Hydrobromide (Vc, $R^1 = CH_2CH_2CH_3$) (44)

2-Formyl-3-ethyl-4-methyl-5-carboxy-pyrrole (1.25 g) was finely ground in an agate mortar and then mixed with 0.95 g of freshly distilled 2,4-dimethyl-3-*n*-propyl-pyrrole in a 10 ml beaker which was cooled in ice. Acetic acid (0.7 ml) was added, with stirring, followed by 0.7 ml of hydrobromic acid (48%). The syrup was stirred and rubbed (5 to 15 min) until the whole solidified to orange prisms (ca. 70%). These were filtered on sintered glass and washed with ether until the washings were light yellow.

5-Bromo-4,3'-dimethyl-5'-bromomethyl-3-ethyl-4'-n-propyl-pyrromethene Hydrobromide (Vd, $R^1 = CH_2CH_2CH_3$) (44)

The intermediate 5-carboxy-pyrromethene (above) (1 g) was powdered and stirred with 0.5 ml of acetic acid, the solution being cooled with ice, while bromine (1 g) in 1 ml acetic acid was added dropwise. After the reaction had subsided, the mixture was heated for 40 min in the steam bath. Next day the product was filtered off, and washed with a little acetic acid and then with ether until the washings were colorless. It formed purple prisms (50–60%) which decomposed above 190°. For analysis it was recrystallized as violet rods from acetic acid.

Anal. Calcd. for $C_{17}H_{23}N_2Br_3$: Br, 48.44. Found: Br, 46.89.

5-Carboxy-4,3',5'-trimethyl-3-ethyl-4'-isobutyl-pyrromethene Hydrobromide (Vc, $R^1 = CH_2CHMe_2$)

This was obtained from 1.165 g of freshly redistilled 2,4-dimethyl-3-isobutyl-pyrrole, 1.42 g of 2-formyl-3-ethyl-4-methyl-5-carboxy-pyrrole, 0.8 ml of acetic acid, and 0.8 ml of 48% hydrobromic acid exactly as was the 4'-*n*-propyl homologue (above). It formed yellow crystals (66%).

Anal. Calcd. for $C_{19}H_{27}O_2N_2Br$: C, 57.70; H, 6.89; N, 7.09. Found: C, 57.34; H, 6.88; N, 7.16.

5-Bromo-4,3'-dimethyl-5'-bromomethyl-3-ethyl-4'-isobutyl-pyrromethene Hydrobromide (Vd, $R^1 = CH_2CHMe_2$)

This was obtained from the above 5-carboxy-pyrromethene (2.52 g), just as was the 4'-*n*-propyl homologue (above), by using 1.3 ml of acetic acid and then 1.05 ml of bromine in 2.6 ml of acetic acid, except that heat was applied for 1.5 h. It formed red crystals (69%).

Anal. Calcd. for $C_{18}H_{25}N_2Br_3$: C, 42.25; H, 4.95; N, 5.50. Found: C, 42.38; H, 4.89; N, 5.37.

3-Bromo-4,4',5'-trimethyl-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (Vg, $R^2 = Me$) (11)

Hemopyrrole-carboxylic acid (1.67 g) and 2.32 g of 2-formyl-3-bromo-4-methyl-5-carboxy-pyrrole were ground together in an agate mortar, transferred to a 10 ml beaker, and stirred without cooling with 1 ml of acetic acid and then 2 ml of 48% hydrobromic acid. The orange product (96%) which rapidly separated was filtered off, washed with 150 ml dry ether, and dried.

3-Bromo-4',5'-dimethyl-4-ethyl-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (Vg, $R^2 = Et$)

This was obtained, exactly as was its 4-methyl-5'-ethyl isomer (above), from hemopyrrole-carboxylic acid (1.42 g), 2-formyl-3-bromo-4-ethyl-5-carboxy-pyrrole (2.09 g), 0.25 ml of acetic acid, and 2 ml of 48% hydrobromic acid. It formed orange prisms (70%) which decomposed above 200° without melting.

Anal. Calcd. for $C_{17}H_{20}O_4N_2Br_2$: C, 42.87; H, 4.25; N, 5.89; Br, 33.56. Found: C, 42.79; H, 4.25; N, 5.82; Br, 33.38.

3-Bromo-4,4'-dimethyl-5'-ethyl-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (VIb, $R^2 = R^3 = Me$)

2-Ethyl-3-methyl-pyrrole-4-propionic acid (0.91 g) and 2-formyl-3-bromo-4-methyl-5-carboxy-pyrrole (1.16 g) were ground in an agate mortar. Acetic acid (0.25 ml) was added and rubbing continued. In this case the intermediate may crystallize. Hydrobromic acid (1 ml of 48%) was added slowly, and rubbing gave a syrup from which the product crystallized, on further vigorous rubbing, as orange prisms (99%). These were filtered off on sintered glass, thoroughly washed with much dry ether, and dried *in vacuo* over sodium hydroxide.

Anal. Calcd. for $C_{17}H_{20}O_4N_2Br_2$: C, 42.87; H, 4.25; N, 5.89; Br, 33.56. Found: C, 42.73; H, 4.03; N, 5.51; Br, 33.41.

3-Bromo-4'-methyl-4,5'-diethyl-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (VIb, $R^2 = Et$, $R^3 = Me$)

This was obtained, exactly as was its 4-methyl-5'-ethyl homologue (above), from 2-ethyl-3-methyl-pyrrole-4-propionic acid (1.45 g), 2-formyl-3-bromo-4-ethyl-5-carboxy-pyrrole (1.97 g), 0.25 ml of acetic acid, and 2 ml of 48% hydrobromic acid, with rubbing for about 15 min to induce crystallization. The product (75%) formed orange prisms which decomposed at about 200°. It decomposed when its recrystallization was attempted.

Anal. Calcd. for $C_{18}H_{22}O_4N_2Br_2$: C, 44.11; H, 4.53; N, 5.72; Br, 32.60. Found: C, 44.16; H, 4.86; N, 5.89; Br, 32.97.

3-Bromo-4'-methyl-4-ethyl-5'-n-propyl-5-carboxy-pyrromethene-3'-propionic Acid Hydrobromide (VIb, $R^2 = R^3 = Et$)

This was obtained, exactly as was its 4-methyl-5'-ethyl homologue (above), from 2-*n*-propyl-3-methyl-pyrrole-4-propionic acid (0.9 g), 2-formyl-3-bromo-4-ethyl-5-carboxy-pyrrole (1.2 g), 0.85 ml of acetic acid,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and 1.5 ml of 48% hydrobromic acid, with rubbing for 0.5 h; then seed was obtained by rubbing a portion on a glass plate. The product (80%) formed orange prisms.

Anal. Calcd. for $C_{19}H_{24}O_4N_2Br_2$: C, 45.25; H, 4.79; N, 5.56. Found: C, 44.98; H, 4.55; N, 5.61.

5-Carboxy-3,4'-dimethyl-4,3',5'-triethyl-pyrromethene Hydrobromide (VIIc)

This was obtained, exactly as were its analogues above, from 1 g of 4-methyl-3-ethyl-2-carboxy-pyrrole-5-aldehyde, 0.75 g of 3-methyl-2,4-diethyl-pyrrole, 0.7 ml of acetic acid, and 0.7 ml of 48% hydrobromic acid in a cooled 10 ml beaker, the product being washed with 10% methanol in ether and then with ether. A sample of the red crystals (1.2 g, 57%) was recrystallized from methanol–ether as orange-red needles, m.p. 120–124° (decomp.).

5-Bromo-3,4'-dimethyl-4,3'-diethyl-5'-bromoethyl-pyrromethene Hydrobromide (VIId) (5)

The corresponding 5-carboxy-pyrromethene above (VII*c*, 1.2 g) was suspended in 2 ml of acetic acid, 0.4 ml of bromine added, and the mixture heated for 5 min in the steam bath. The red crystalline product (1.4 g, 89%) was filtered off from the cooled mixture and washed with ether. A sample for analysis was dissolved in acetone, heated for 10 min, filtered off the next day, and crystallized twice from acetic acid to give red prisms which decomposed above 280°.

Anal. Calcd. for $C_{17}H_{23}N_2Br_3$: C, 41.19; H, 4.68; N, 5.66; Br, 48.46. Found: C, 41.05; H, 4.16; N, 5.50; Br, 48.29.

5,3'-Dibromo-4,4',5'-trimethyl-pyrromethene-3-propionic Acid Hydrobromide (VIIh)

This was obtained from 2,3-dimethyl-pyrrole (VII*f*, see above) and 2-formyl-4-methyl-5-carboxy-pyrrole-3-propionic acid (VII*e*, see above) over the 5-carboxy-pyrromethene VII*g*, as reported (5); it decomposed above 220°.

Anal. Calcd. for $C_{15}H_{17}O_2N_2Br_3$: C, 36.23; H, 3.42; N, 5.63; Br, 48.24. Found: C, 36.57; H, 3.50; N, 5.37; Br, 48.04.

Porphyrins (Ordered as the Corresponding "650" Fractions 1–5 and then "660" Fractions 3–6)

4-Isobutyl-5-ethyl-4-desethyl-5-desmethyl-pyrroporphyrin 15 Methyl Ester (1,3,8-Trimethyl-2,5-diethyl-4-isobutyl-porphin-7-propionic Acid Methyl Ester (IIIa, $R^1 = CH_2CHMe_2$, $R^2 = Et$))

5-Bromo-4,3'-dimethyl-5'-bromomethyl-3-ethyl-4'-isobutyl-pyrromethene hydrobromide (V*d*, $R^1 = CH_2CHMe_2$, 2.1 g), 3-bromo-4',5'-dimethyl-4-ethyl-5-carboxy-pyrromethene-3'-propionic acid hydrobromide (V*g*, $R^2 = Et$, 2.93 g), and 5 g of methylsuccinic acid were ground together, dried at 20° in high vacuum, and then heated, with stirring, in a test tube at 160° and then (10 min after melting) at 180° for 2 min. The partially cooled melt was poured into 1.5 l of warm water. The pH was brought to 5 with disodium phosphate, and the mixture was heated for 1 h on the steam bath and then allowed to cool overnight. The solid was filtered off, well washed with water, dried, powdered, and extracted with 3 l of ether for 3 days (thimble). The ether was repeatedly extracted with 100 ml portions of 0.5% hydrochloric acid until neither colored impurities were extracted nor precipitates formed. The acid porphyrins were precipitated as their sodium salts by shaking the ether with 10% sodium hydroxide (4 × 25 ml). These were filtered off, dissolved in concentrated hydrochloric acid, and brought into 1.5 l of ether with sodium acetate. The pyrroporphyrin was extracted from the washed ether solution with 4% hydrochloric acid, leaving bromoporphyrins in the ether. The pyrroporphyrin was returned to fresh ether by using sodium acetate. Its ether solution was washed, dried, concentrated, and chromatographed on a column of 6% hydrochloric acid on Celite 545, development being carried out with equilibrated ether (45). The large lower band was cut out, leaving three small red, yellow, and brown ones. The pigment in it was eluted with 2% hydrochloric acid in acetone and brought into ether by using water. When this ether solution was washed, dried, and concentrated, most of the product (13 mg) crystallized; visible spectrum in ether (relative density in parentheses): maxima at 622 (0.46), 595 (0.09), 568 (0.48), 526 (0.70), 497 (1.00), and 493 (0.98) mμ, with shoulders at 613, 573, and 471 mμ.

The crystalline acid was left overnight in 5% hydrogen chloride in methanol, and the product brought from this into chloroform by using water. The washed and dried (sodium sulfate) chloroform solution was filtered through a column of alumina (grade V, made up with the 5% methanol in chloroform that was also used for the elution), and concentrated. The chloroform was removed by boiling it off while methanol was being added. Part of the product (4 mg, m.p. 223–226°) crystallized. The rest (5.6 mg, m.p. 222.5–225.5°) was obtained by evaporating the mother liquors and crystallizing the residue from ether (final volume 2 ml) at 0°. The whole was recrystallized slowly from ether to give 5 mg of needles; visible spectrum in ether (relative density in parentheses): maxima at 622 (0.47), 596 (0.09), 568 (0.49), 526 (0.72), 496 (1.00), and 493 (1.00) mμ, with shoulders at 613, 573, and 470 mμ.

Anal. Calcd. for $C_{35}H_{42}O_2N_4$: C, 76.33; H, 7.63. Found: C, 75.95; H, 7.43.

It melted at 225.5–227.5°. The mixed melting point with the "pyrroporphyrin" ester from *Chlorobium* pheophorbide 650, fraction 1 (m.p. 229.5–231° (2)), was 226–230° with softening from 224°; the X-ray powder photographs of these two specimens were identical.

Copper Complex of the Methyl Ester

About 0.2 mg of the ester in 0.5 ml of chloroform was boiled in a 3 × $\frac{3}{8}$ inch test tube; copper acetate (0.5 mg), in methanol (0.5 ml) containing a trace of acetic acid, was added. Half the solvent was boiled off (a glass boiling stick made from melting point tubing being used), and replaced by methanol; this was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

repeated three times as the product crystallized out. After a final concentration to ca. ¼ ml, the product was separated and washed with methanol (centrifuge). It formed a felt of hair-like crystals, m.p. 229–231.5°, mixed m.p. with the "pyrroporphyrin" ester copper complex from *Chlorobium* pheophorbide 650, fraction 1 (m.p. 230–232.5° (2)), 229–232.5°; the X-ray powder photographs of these two specimens were identical.

4-n-Propyl-5-ethyl-4-desethyl-5-desmethyl-pyrroporphyrin 15 Methyl Ester (1,3,8-Trimethyl-2,5-diethyl-4-n-propyl-porphin-7-propionic Acid Methyl Ester (IIIa, $R^1 = CH_2CH_2CH_3$, $R^2 = Et$))

5-Bromo-4,3′-dimethyl-5′-bromomethyl-3-ethyl-4′-*n*-propyl-pyrromethene hydrobromide (V*d*, $R^1 = CH_2CH_2CH_3$, 2.62 g), 3-bromo-4′,5′-dimethyl-4-ethyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (Vg, $R^2 = Et$, 2.5 g), and 5 g of methylsuccinic acid were heated together and the melt worked up exactly as in the synthesis of the 4-isobutyl homologue above. The Celite column was eluted for 4 h to separate the single slow-moving porphyrin band from dark material at the top. The intermediate free acid (40 mg) crystallized when its ether solution (3 ml) was allowed to stand; visible spectrum in ether (relative densities in parentheses): maxima at 622 (0.47), 597 (0.09), 567 (0.47), 525 (0.71), 497 (1.00), and 493 (0.99) mμ, with shoulders at 613, 573, and 471 mμ.

The methyl ester (30 mg) was prepared exactly as was the 4-isobutyl homologue above. It crystallized from methanol displacing chloroform, as long glistening needles; visible spectrum in ether (relative density in parentheses): maxima at 622 (0.48), 595 (0.09), 568 (0.47), 525 (0.71), 497 (1.00), and 493 (1.00) mμ, with shoulders at 613, 573, and 470 mμ.

Anal. Calcd. for $C_{34}H_{40}O_2N_4$: C, 76.09; H, 7.51. Found: C, 75.93; H, 7.59.

It had m.p. 210–213°. The mixed melting point with the "pyrroporphyrin" ester from *Chlorobium* pheophorbide 650, fraction 2 (m.p. 207–210° (2)), was 207–211°. The X-ray powder photographs of these synthetic and analytical specimens were identical.

The copper complex of the ester formed needles, m.p. 211–213°, mixed m.p. with the "pyrroporphyrin" ester – copper complex from *Chlorobium* pheophorbide 650, fraction 2 (m.p. 208.5–211.5° (2)), 209–213°; the X-ray powder photographs of these two specimens were identical.

The synthetic porphyrin has also been identified (3) with the pyrroporphyrins from *Chlorobium* pheophorbide 660, fractions 3 and 4.

The Desoxo-phylloerythrin Methyl Ester from Chlorobium Pheophorbide 650 Fraction 2 (4-n-Propyl-5-ethyl-4-desethyl-5-desmethyl-desoxo-phylloerythrin Methyl Ester (IIb, $R^1 = CH_2CH_2CH_3$, $R^2 = Et$))

The corresponding phylloerythrin methyl ester (cf. II*a*) (38 mg, m.p. 249–251° from chloroform–methanol after chromatography on sucrose; this had been obtained from *Chlorobium* pheophorbide 650, fraction 2, with hydrogen iodide in acetic acid (46)) was reduced by the Wolf–Kishner method as in the reduction of phylloerythrin itself (9). The crude product was extracted with ether, purified on a column of Celite – 3.5% hydrochloric acid, esterified, and crystallized as usual. It formed needles (15 mg), m.p. 221–222°, unchanged after hydrolysis, refractionation, and reesterification; visible spectrum in tetrahydrofuran–ether (relative density in parentheses): maxima at 620 (0.52), 594 (0.08), 566 (0.38), 531 (0.22), and 498 (1.0) mμ, with shoulders at 613 and 572 mμ.

Anal. Calcd. for $C_{36}H_{42}O_2N_4$: C, 76.83; H, 7.52; N, 9.96. Found: C, 76.41; H, 7.85; N, 10.14.

The copper complex formed needles, m.p. 233–235°.

This was compared with the synthetic desoxo-phylloerythrin (see below) corresponding to fraction 5.

4-Isobutyl-4-desethyl-pyrroporphyrin 15 Methyl Ester (1,3,5,8-Tetramethyl-2-ethyl-4-isobutyl-porphin-7-propionic Acid Methyl Ester (IIIa, $R^1 = CH_2CHMe_2$, $R^2 = Me$))

5-Bromo-4,3′-dimethyl-5′-bromomethyl-3-ethyl-4′-isobutyl-pyrromethene hydrobromide (V*d*, $R^1 = CH_2CHMe_2$, 2 g), 3-bromo-4,4′,5′-trimethyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (Vg, $R^2 = Me$, 2 g), and 5 g of methylsuccinic acid were heated together and the melt worked up exactly as in the synthesis of the 5-ethyl homologue above. On the Celite column, the pyrroporphyrin was in a dense bluish red band which was easily separated from two slower and weaker ones. The free acid did not crystallize from ether (3 ml), so the ether was evaporated and the residue esterified and crystallized from methanol displacing chloroform, as was its 5-ethyl homologue. The methyl ester formed prisms (2 mg); visible spectrum in ether (relative density in parentheses): maxima at 623 (0.47), 596 (0.09), 568 (0.47), 525 (0.71), 497 (1.00), and 493 (1.00) mμ, with shoulders at 614, 573, and 470 mμ. It melted at 224–226° after changing to needles at 220–221.5°. The mixed melting point with the "pyrroporphyrin" ester from *Chlorobium* pheophorbide 650, fraction 3, of m.p. 220–222° which has been analyzed (2) was 220–222.5°; the X-ray powder photographs of these two specimens were identical.

The copper complexes of these two esters, synthetic and of natural origin (2), both formed sheaves of needles, m.p. and mixed m.p. 222–223.5°; their X-ray powder photographs were identical.

The mixed melting point with synthetic 1,3,8-trimethyl-2,5-diethyl-4-isobutyl-porphin-7-propionic acid methyl ester (m.p. 225.5–227.5°) was 217 to ca. 223°.

5-Ethyl-5-desmethyl-pyrroporphyrin 15 Methyl Ester (1,3,8-Trimethyl-2,4,5-triethyl-porphin-7-propionic Acid Methyl Ester (IIIa, $R^1 = R^2 = Et$))

5-Bromo-4,3′-dimethyl-5′-bromomethyl-3,4′-diethyl-pyrromethene hydrobromide (V*d*, $R^1 = Et$, 1.5 g) and 3-bromo-4′,5′-dimethyl-4-ethyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (Vg, $R^2 = Et$, 1 g) were heated with 5 g of methylsuccinic acid, etc., as usual to yield the washed ether extract of the melt. Part of the product was extracted from the ether with 2% hydrochloric acid and worked up as under *a*; the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

balance was precipitated as the sodium salt and worked up as under *b*; etioporphyrin I (145 mg) remained in the ether.

(*a*) The pigment was returned to ether, and the product was separated from a faster band on Celite – 5% hydrochloric acid (5 × 12 cm), then esterified, and crystallized from methanol displacing chloroform. The product formed purple prisms (20 mg), m.p. 185–205°; visible spectrum in chloroform (relative intensities in parentheses): maxima at 619 (0.336), 566 (0.466), 534 (0.685), and 498 (1.00) mμ, with shoulders at 591 and 532 mμ and inflexions at 573, 526, 501, and 572 mμ. This ester (2 mg) was chromatographed three times in 4% chloroform – petrol (30–60°) on icing sugar (m.p. then 186–190°) and then in ether on successively Celite – 6.5% hydrochloric acid and then Celite – 7% hydrochloric acid (m.p. then 188–191°, remelt 208–210°). The balance was recrystallized for analysis, prisms m.p. 187–210°, remelt 205–210°.

Anal. Calcd. for $C_{33}H_{38}O_2N_4$: C, 75.83; H, 7.33; N, 10.72. Found: C, 75.91; H, 7.48; N, 10.61.

(*b*) The sodium salts were dissolved in hydrochloric acid. The pigment was brought from this into ether, extracted with 4% hydrochloric acid (the bromo-pyrroporphyrin being left in the ether), returned to ether, and re-precipitated as the sodium salt; these steps were repeated. The residue left when the final ether solution had been evaporated was esterified and crystallized from methanol displacing chloroform to give prisms (19 mg), m.p. 187–189°, resolidifying to needles, m.p. 205–211°. The mixed melting point with the analytical pyrroporphyrin from *Chlorobium* pheophorbide 650, fraction 4 (see below), was 210–216.5°, remelt 212–217°; the X-ray powder photographs of these analytical and synthetic materials differed only in that the former had a few extra lines.

The high-melting form of the synthetic porphyrin ester was obtained by heating it, in a tube sealed off at 1×10^{-4} mm, from 180 to 205° over 3 h and then 1 h at 205°; m.p. 213–216.5°, mixed m.p. with the pyrroporphyrin ester from fraction 4 (as originally crystallized, see below) 212.5–217°. After both specimens had been heated *in vacuo* to 205°, their X-ray powder photographs were consistent, with each being a mixture of two forms, with one predominant form in common.

The synthetic and analytical (from fraction 4) esters were recrystallized again in the same way as prisms, and now gave identical X-ray powder photographs (synthetic, m.p. 189–193°; analytical, m.p. 191–194°). These changed to, or when they were cooled resolidified to, needles (synthetic, m.p. 207–214°; analytical, m.p. 211–214°) or sheets (synthetic, m.p. 213–216°; analytical, m.p. 213–216.5°). The analytical specimen sometimes resolidified, when it was cooled, to crystals of uncertain form which changed to the above needles at 185–190°; here a fourth form sometimes appeared as prismatic needles, m.p. 215.5–216.5°. The mixed melting point of the synthetic and analytical prisms was 189–193°, resolidifying to needles, m.p. 206–214.5°.

The synthetic specimen – copper complex formed fine red needles, m.p. 220–226°, mixed m.p. with the analytical complex (m.p. 220–226°) 219–227°. The X-ray powder photographs of these two specimens were identical.

The mixed melting point with the copper complex of synthetic 1,3,5,8-tetramethyl-2-ethyl-4-isobutylporphin-7-propionic acid methyl ester (m.p. 222–223.5°) was 201 to ca. 213°.

The "Pyrroporphyrin" Methyl Ester from Chlorobium Pheophorbide 650 Fraction 4 (1,3,8-Trimethyl-2,4-5-triethyl-porphin-7-propionic Acid Methyl Ester (IIIa, $R^1 = R^2 = Et$))

The "pyrroporphyrin" free acid (2) in ether was chromatographed on Celite – 4.8% hydrochloric acid (2 × 10 cm). The single broad red band was eluted with ether. The pigment was esterified, its chloroform solution filtered through alumina, and the product crystallized from chloroform–methanol as purple prisms (4.6 mg), m.p. 214.5–216.5°, with some signs of a solid phase change at 180°; visible spectrum in chloroform (relative intensities in parentheses): maxima at 618 (0.335), 566 (0.461), 534 (0.672), and 497 (1.00) mμ, with shoulders at 592 and 532 mμ and inflexions at 573, 525, 500, and 472 mμ.

The copper complex formed fine red needles, m.p. 220–226°.

4-n-Propyl-4-desethyl-desoxo-phylloerythrin Methyl Ester (IIb, $R^1 = CH_2CH_2CH_3$, $R^2 = Me$)

Essentially as in the analogous synthesis of desoxo-phylloerythrin itself (7), 18 g of 5-bromo-4,3′-dimethyl-5′-bromomethyl-3-ethyl-4′-*n*-propyl-pyrromethene hydrobromide (Vd, $R^1 = CH_2CH_2CH_3$) and 18 g of 4,4′,5′-trimethyl-3-(ω-bromovinyl)-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (IVb) were heated in succinic acid at 190–220°. The 18 melts, freed of succinic acid with hot water at pH 4 (disodium phosphate), were powdered, dried, and extracted for 3 days with 1 l of chloroform (thimble). The extract was poured into 20 volumes of ether, and the acidic porphyrins (1.66 g) were precipitated by shaking the filtered solution with 2% sodium hydroxide. A portion (0.5 g) was dissolved in acetic acid – hydrochloric acid and the pigments were brought into 3.5 l of ether by using sodium acetate. The washed and clarified ether solution was concentrated to 800 ml, shaken with 1% hydrochloric acid, and applied to a column of Celite 545 (9.5 × 42 cm, made up with 3.5% hydrochloric acid). Elution with ether separated the main band from much slower and much faster ones. It was extruded and eluted with 50% acetone, from which the pigment was brought into ether. The washed ether solution was evaporated and the residue esterified, crystallized, and recrystallized in the usual way. The product (48 mg, 0.8%) formed plates (occasionally needles), m.p. 235–237.5° after sintering and apparently a solid phase change from 234°; visible spectrum in tetrahydrofuran–ether (relative density in parentheses): maxima at 621 (0.54), 595 (0.07), 567 (0.37), 531 (0.22), and 498 (1.0) mμ, with shoulders at 613 and 573 mμ.

Anal. Calcd. for $C_{35}H_{40}O_2N_4$: C, 76.61; H, 7.35; N, 10.21. Found: C, 77.02; H, 7.15; N, 10.55.

Its mixed melting points with the desoxo-phylloerythrin esters from *Chlorobium* pheophorbide 650,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

fractions 2 (see above) and 5 (see below), were respectively 213–216° and 235–237.5°. Its X-ray powder photograph was identical with that of the latter desoxo-phylloerythrin ester from fraction 5, and these two specimens had identical visible spectra in chloroform: λ_{max} (relative density in parentheses) 619 (0.41), 567 (0.40), 536.7 (0.24), 502 (1.0) mμ.

Its copper complex formed needles, m.p. 245–247.5°.

Anal. Calcd. for $C_{35}H_{38}O_2N_4Cu$: C, 68.89; H, 6.28; CuO, 13.04. Found: C, 68.56; H, 6.34; CuO, 12.39.

Its mixed melting points with the copper complexes of the desoxo-phylloerythrin esters from *Chlorobium* pheophorbide 650, fractions 2 and 5, were respectively 220–228° and 245.5–247°. Its X-ray powder photograph was identical with that of the latter complex from fraction 5.

1,3,5,7-Tetramethyl-2,6-diethyl-4,8-di-n-propyl-porphin

The chloroform–ether solution, from which the above synthetic desoxo-phylloerythrin had been precipitated as its sodium salt, was evaporated. An aliquot was dissolved in chloroform and passed through an alumina column (alkaline, grade II, made up with 5% methanol in chloroform). The eluate was concentrated and the pigment passed through a similar column. It was crystallized from chloroform–methanol as long prisms (17%) which decomposed at about 310°.

Anal. Calcd. for $C_{34}H_{42}N_4$: C, 80.59; H, 8.36; N, 11.06. Found: C, 80.72; H, 8.55; N, 11.54.

The Desoxo-phylloerythrin Methyl Ester from Chlorobium Pheophorbide 650 Fraction 5 (4-n-Propyl-4-desethyl-desoxo-phylloerythrin Methyl Ester (IIb, $R^1 = CH_2CH_2CH_3$, $R^2 = Me$))

The mesopyropheophorbide (2) (24 mg from *Chlorobium* pheophorbide 650, fraction 5), 0.4 g of sodium in 6 ml of absolute ethanol, and 0.3 ml of 95% hydrazine were frozen in a bomb tube, which was then sealed after it had been evacuated to 0.1 mm. The tube was warmed, shaken, and heated for 5 h at 170° in a rocking oven. The pigment was brought into ether by using acetic acid and the desoxo-phylloerythrin extracted with 2% hydrochloric acid. Evaporating the ether layer left the corresponding meso-desoxo-pyrropheophorbide, which was heated with 4 ml of acetic acid and 2 ml of 3% hydrochloric acid in a sealed tube, which had been deaerated as above, for 5 h at 180°. The resulting pigment was brought into ether and more of the product extracted with 2% hydrochloric acid. The pigment in the hydrochloric acid extracts was brought into ether with sodium acetate, and purified on a column of Celite – 5% hydrochloric acid, the single band being eluted with acetone after extrusion and the pigment being returned to ether. When the washed ether solution was concentrated, the product separated as needles of the free acid (7.7 mg). This was esterified and crystallized to give the product as plates, m.p. 235–237° after sintering and an apparent solid phase change at 234–235°.

The copper complex formed needles, m.p. 246–247°.

4-n-Propyl-5-ethyl-4-desethyl-5-desmethyl-δ-phylloporphyrin Methyl Ester (1,3,8,δ-Tetramethyl-2,5-diethyl-4-n-propyl-porphin-7-propionic Acid Methyl Ester (IIIb, $R^1 = CH_2CH_2CH_3$, $R^2 = Et$, $R^3 = Me$))

5-Bromo-4,3′-dimethyl-5′-bromomethyl-3-ethyl-4′-*n*-propyl-pyrromethene hydrobromide (V*d*, $R^1 = CH_2CH_2CH_3$, 2.75 g), 3-bromo-4′-methyl-4,5′-diethyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (VI*b*, $R^2 = Et$, $R^3 = Me$, 2.6 g), and 5 g of methylsuccinic acid were heated together and stirred at 160–170° for 15 min and then at 180° for 5 min. The crude product was isolated and extracted with ether as in the case of the 4-isobutyl-5-ethyl-pyrroporphyrin (above). The ether was washed with 0.1% hydrochloric acid, and the acidic porphyrins were then separated as their sodium salts by shaking the ether with 10% sodium hydroxide. They were returned to fresh ether, extracted with 4% hydrochloric acid, again brought into ether, and passed through a column of Celite – 2% hydrochloric acid. Elution for 5 h removed a little porphyrin, leaving a blue band and, near the top, a black one. The blue band was separated, and the pigment was eluted with 2% hydrochloric acid in acetone and then transferred to ether. The residue that was left when the ether was evaporated was esterified and brought into chloroform. The solution was passed through a column of alumina, filtered, and then concentrated to 2 ml while methanol was being added to displace the chloroform.

The product (5 mg) separated overnight; visible spectrum in ether: λ_{max} (relative density in parentheses): 629 (0.10), 576 (0.35), 534 (0.35), and 501 (1.00) mμ. Recrystallization from methanol gave prisms melting from 173° to 190°, with partial solidification at 180° followed by intervening remelting at 183–187°. Recrystallization from ether then gave needles, m.p. 191–194°, with the suggestion of a phase change at 190°.

X-ray powder photographs showed that the forms from methanol and from ether were different. The photograph of the latter was almost identical with that of the δ-phylloporphyrin ester (3), m.p. 196–199°, from *Chlorobium* pheophorbide 660, fraction 3, there being small differences in the intensities of a few lines. The photographs of the synthetic ester had nothing in common with those of the δ-phylloporphyrin ester from fraction 4.

1,3,8-Trimethyl-2-5,δ-triethyl-4-n-propyl-porphin-7-propionic Acid Methyl Ester (IIIb, $R^1 = CH_2CH_2CH_3$, $R^2 = R^3 = Et$)

5-Bromo-4,3′-dimethyl-5′-bromomethyl-3-ethyl-4′-*n*-propyl-pyrromethene hydrobromide (V*d*, $R^1 = CH_2CH_2CH_3$, 1.88 g) and 3-bromo-4′-methyl-4-ethyl-5-*n*-propyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (VI*b*, $R^2 = R^3 = Et$, 2.3 g) were fused with methylsuccinic acid, and the product was isolated exactly as was the δ-methyl analogue above; a single blue band appeared on the Celite column. The product (3 mg) formed poorly defined prisms, m.p. 140–156°; visible spectrum in ether (relative density in parentheses): λ_{max} 628 (0.10), 574 (0.34), 534 (0.32), and 502 (1.0) mμ.

It was recrystallized from methanol as prisms, m.p. 151–170°, with intervening darkening at 120° and partial phase changes to glistening prisms at 130–131°, to small needles from 151°, and to long needles at 164°.

The analytical δ-phylloporphyrin from *Chlorobium* pheophorbide 660, fraction 4 (3), had m.p. 195–197°, with the suggestion of phase changes at 164–190°. X-ray powder photographs showed that it existed in two (or more) forms, neither of which was identical with that of the synthetic material. The analytical and synthetic copper complexes, m.p. 174–179° and 172–180° respectively, mixed m.p. 172–180°, did not give identical X-ray powder photographs.

5-Ethyl-5-desmethyl-δ-phylloporphyrin 15 Methyl Ester (1,3,8,δ-Tetramethyl-2,4,5-triethyl-porphin-7-propionic Acid Methyl Ester (IIIb, $R^1 = R^2 = Et$, $R^3 = Me$))

Methylsuccinic acid (6.6 g), 3-bromo-4′-methyl-4,5′-diethyl-5-carboxy-pyrromethene-3′-propionic acid hydrobromide (VI*b*, $R^2 = Et$, $R^3 = Me$, 1 g), and 5-bromo-4,3′-dimethyl-5′-bromomethyl-3,4′-diethyl-pyrromethene hydrobromide (V*d*, $R^1 = Et$, 5.6 g) were ground together and heated in six portions at 160° for 20 min. The melt was freed of methylsuccinic acid, dried, powdered as usual, and then heated under reflux for 2 h in 200 ml of 5% methanolic hydrogen chloride. The pigment in the filtered solution was then brought into chloroform. The chloroform solution was filtered through deactivated alumina, washed with 45% aqueous resorcinol (10 × 50 ml subsequently backwashed), washed with water, dried, and again filtered through alumina; then the solvent was evaporated. The residue was stirred for 2 h with 500 ml of ether, and undissolved etioporphyrin separated. The pigments in the ether were chromatographed twice on Celite – 2% hydrochloric acid and once on Celite – 1.8% hydrochloric acid, in each case the blue band of the product being eluted with ether. The pigment in the final eluate was extracted with 2% hydrochloric acid and returned to ether. The solution was concentrated to 5 ml and left at 10° overnight. The product separated as needles, m.p. 209–211°, raised to 210–211.5° and then 214–215.5° (7.4 mg) when recrystallized from chloroform–methanol and then from ether; visible spectrum in ether (relative density in parentheses): maxima at 629.5 (0.11), 577 (0.39), 534 (0.40), and 502 (1.00) mμ.

Anal. Calcd. for $C_{34}H_{40}O_2N_4$: C, 76.09; H, 7.51; N, 10.44. Found: C, 76.27; H, 7.21; N, 10.61.

The mixed melting point with the phylloporphyrin ester from *Chlorobium* pheophorbide 660, fraction 5 (see below), was 214–215°, and the X-ray powder photographs of the two specimens were identical. The mixed melting point of the synthetic ester with synthetic δ-phylloporphyrin 15 methyl ester (m.p. 212–213.5°) (see below) was 202 to ca. 208°.

The copper complex formed needles, m.p. 212.5–215°, mixed m.p. with the copper complex of the above analytical phylloporphyrin 213–215°. The X-ray powder photographs of these two specimens were identical. The mixed melting point of the copper complex of the analytical phylloporphyrin with that of synthetic δ-phylloporphyrin 15 methyl ester (m.p. 206–209.5°) was 199 to ca. 206°.

The "Phylloporphyrin" Methyl Ester from Chlorobium Pheophorbide 660 Fraction 5 (1,3,8,δ-Tetramethyl-2,4,5-triethyl-porphin-7-propionic Acid Methyl Ester)

The analytical "phylloporphyrin" (free acid) (3) was left overnight in 5% methanolic hydrogen chloride, the ester brought into ether, and the solution chromatographed on Celite – 2% hydrochloric acid (2 × 12 cm). Two narrow brown bands followed a blue one. The pigment in the latter was eluted and its ether solution concentrated to 0.5 ml. The product (1.3 mg) separated as needles, m.p. 215–215.5°; visible spectrum in ether (relative density in parentheses): maxima at 629 (0.10), 578 (0.38), 535 (0.39), and 502 (1.00) mμ.

The copper complex formed needles, m.p. 213.5–215.5°.

δ-Phylloporphyrin 15 Methyl Ester (1,3,5,8,δ-Pentamethyl-2,4-diethyl-porphin-7-propionic Acid Methyl Ester (IIIb, $R^1 = Et$, $R^2 = R^3 = Me$)) (5)

5-Bromo-3,4′-dimethyl-4,3′-diethyl-5′-bromoethyl-pyrromethene hydrobromide (VII*d*, 4 g), 5,3′-dibromo-4,4′,5′-trimethyl-pyrromethene-3′-propionic acid hydrobromide (VII*h*, 4.01 g), and 16 g of methylsuccinic acid were heated together in portions, and the crystalline δ-phylloporphyrin free acid (40 mg) was isolated exactly as reported (5). This was dissolved in concentrated hydrochloric acid, brought into ether by using sodium tartrate, and chromatographed as usual on Celite – 2% hydrochloric acid. The pigment in the single red slow-moving band was eluted with acetone – 2% hydrochloric acid, and brought into ether; then the ether was evaporated. The residue was esterified and crystallized as usual from methanol displacing chloroform to give red needles (35 mg) of the ester, m.p. 210–212° (lit. (5) m.p. 214°), 212–213.5° after one or more recrystallizations from methanol displacing chloroform.

Anal. Calcd. for $C_{33}H_{38}O_2N_4$: C, 75.83; H, 7.33; N, 10.72. Found: C, 75.59; H, 7.54; N, 10.54.

X-ray powder photographs showed that it crystallized in either of two forms or in mixtures of the two. The usual pure form was obtained from both boiling and cold (20°) solutions; the other form was obtained pure only once, from a boiling solution. When the usual form was heated, a solid phase change at about 200° was sometimes apparent.

The phylloporphyrin ester from *Chlorobium* pheophorbide 660, fraction 6 (3) (m.p. 211–214°, mixed m.p. with the above 211–213°), separated sometimes as a mixture of these two forms and sometimes in a form giving an X-ray powder photograph identical with that of the usual form of the synthetic ester. The visible spectra of the two specimens in chloroform were identical; λ_{max} (relative density in parentheses): 628 (0.08), 576 (0.42), 539.5 (0.39), and 505 (1.0) mμ.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The copper complexes of these esters, synthetic and of natural origin, formed needles, m.p. 206–209.5° and 205.5–208° after sintering from 205.5 and 205° respectively (lit. (5) m.p. 189°), mixed m.p. 206–209.5° after sintering from 205.5°. The X-ray powder photographs of these two specimens were identical.

It has been reported (5) that the spectrum of the synthetic δ-phylloporphyrin 15 is identical with that of γ-phylloporphyrin 15, in which the intensity of band 2 is significantly greater than that of band 3. Elsewhere (47) these two bands in the spectrum of δ-phylloporphyrin 15 are reported to be nearly equal in intensity, as they are in the spectra of all the synthetic and degradational δ-phylloporphyrins mentioned above.

δ-Phylloporphyrin 15 (Free Acid)

Some of the synthetic ester was hydrolyzed at 20° overnight in acetic acid – hydrochloric acid (1:1) (alkaline hydrolysis apparently resulted in decomposition). The acid was brought into ether, precipitated by 5% sodium hydroxide as the sodium salt, and returned to ether with acid. Concentrating the ether gave the product as needles. The X-ray powder photographs of this and of the phylloporphyrin free acid (3) derived from the above *Chlorobium* pheophorbide 660, fraction 6, were identical.

ACKNOWLEDGMENTS

The authors thank Dr. A. S. Holt and his colleagues for their generous cooperation, and Dr. Maria Przybylska for the interpretation of the X-ray powder photographs.

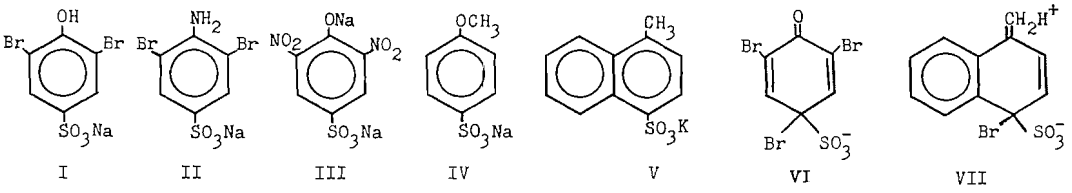
KINETIC SULFUR ISOTOPE EFFECTS IN AROMATIC BROMODESULFONATION[1]

B. T. BALIGA[2] AND A. N. BOURNS
Department of Chemistry, McMaster University, Hamilton, Ontario

Received October 7, 1965

ABSTRACT

Both bromodeprotonation and bromodesulfonation occur during aqueous bromination of sodium *p*-methoxybenzenesulfonate, A, and potassium 1-methylnaphthalene-4-sulfonate, B. Whereas for A the bromodeprotonation increases appreciably in amount as the bromide ion concentration is raised, this reaction takes place to a relatively small extent for the less reactive B. A reinvestigation of the kinetics of bromination and a determination of sulfate yields for both of these compounds over a range of bromide ion concentration of 0 to 0.5 *M* have been made to evaluate the individual rates of these two competing reactions. The kinetic data for the bromodesulfonation of A favor a two-step mechanism with Br_2 as the brominating species, but are not considered to eliminate completely a one- or two-step process involving Br^+ (or H_2OBr^+). For B, the kinetics allow either a one- or two-step mechanism with molecular bromine as the brominating agent.



Kinetic sulfur isotope effects (k^{32}/k^{34}) have been measured for the bromodesulfonation of A at different bromide ion concentrations. The observed effects are: at $[Br^-] = 0$, 0.3%; at $[Br^-] = 0.03$ *M*, 1.3%; at $[Br^-] = 0.5$ *M*, 1.7%. These results confirm the two-step mechanism favored by kinetics and allow the rejection of the alternate mechanism with Br^+ (or H_2OBr^+) as the brominating species. A similar study of B gave the following results: at $[Br^-] = 0$, 0.2%; at $[Br^-] = 0.25$ *M*, 0.3%; at $[Br^-] = 0.5$ *M*, 0.4%; at $[Br^-] = 2.0$ *M*, 0.8%. These results establish the two-step mechanism for this compound and completely eliminate the alternate one-step process.

INTRODUCTION

The direct replacement by bromine of the sulfonate group in aromatic sulfonates in aqueous medium, known as bromodesulfonation, is a reaction generally shown by aromatic

$$Ar—SO_3^- + Br_2 \rightarrow Ar—Br + SO_3 + Br^-$$

sulfonates in which the sulfonate group is activated by powerful electron-releasing groups situated in a position ortho or para to the sulfonate group in the aromatic nucleus. Cannell (1, 2) in 1957 reported for sulfonates I to V a rather thorough investigation of the kinetics of bromodesulfonation in aqueous solution. For the highly reactive I, both kinetic and spectral studies provided evidence for the existence of a relatively long-lived quinoid-type intermediate VI, whose decomposition is the rate-determining step in bromodesulfonation.

I II III IV V VI VII

For the less highly activated sulfonates II, III, and IV, whose bromodesulfonation rates are suppressed by bromide ion, over and above that which can be attributed to tribromide ion formation

[1]*Issued as N.R.C. No. 8789.*

[2]*To whom all correspondence should be made. Present address: Division of Applied Chemistry, National Research Council, Ottawa, Canada.*

$$Br_2 + Br^- \overset{K}{\rightleftarrows} Br_3^-,$$

he proposed the following mechanism (mechanism A), in which $Ar\overset{+}{\underset{SO_3^-}{\overset{Br}{}}}$ is a metastable intermediate.

$$Ar{-}SO_3^- + Br_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} Ar\overset{+}{\underset{SO_3^-}{\overset{Br}{}}} + Br^-$$

$$Ar\overset{+}{\underset{SO_3^-}{\overset{Br}{}}} \xrightarrow{k_3} Ar{-}Br + SO_3$$

The rate expression for this mechanism has the form

$$[1] \qquad k_{obs} = \frac{k_1 k_3}{k_2[Br^-] + k_3} \cdot \frac{1}{1 + K[Br^-]},$$

where k_{obs} is the observed rate constant and K is the equilibrium constant for the tribromide ion formation.

For the least activated sulfonate, V, he found no sufficient depression in rate by added bromide ion beyond that which could be accounted for by the equilibrium between Br_2 and Br_3^-. The author drew no conclusion from this about the mechanism, and simply stated that "the kinetics require only a transition state and it is not necessary to propose a reaction intermediate". It is important, however, to note that his kinetic data for V can be accounted for either by mechanism A with $k_3 \gg k_2[Br^-]$ or by a one-step process. The latter possibility exists because the quinoid configuration VII, stabilized only by hyperconjugation, would be expected to possess a higher energy than in the case of the more highly activated systems I to IV and might, therefore, not correspond to a potential energy minimum along the reaction coordinate curve. Kinetic sulfur isotope effect measurements might be expected to shed some light on this question of mechanism for the bromodesulfonation of V. If the reaction takes place according to mechanism A with $k_3 \gg k_2[Br^-]$, then from eq. [1] may be obtained

$$[2] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = \frac{k_1^{32}}{k_1^{34}}.$$

In this case, the formation of the intermediate (VII) being rate determining, the isotope effect should be zero or very close to it (at the most a few tenths of a percent). On the other hand, if the reaction takes place in a single step, then of course the C—S bond is being ruptured in the process and a sulfur isotope effect should result. It is true that the magnitude of this effect would be determined by the extent of bond rupture in the transition state and, conceivably, this could be such as to give rise to only a very small effect. If this result were observed, then no distinction could be drawn between the two mechanisms, although one would have gained a valuable insight into the extent to which bond rupture has proceeded in the highest energy state along the reaction coordinate. On the other hand, if a normal sulfur isotope effect, e.g. of the order of 1 to 2%, were to be found for this system, this result would clearly eliminate mechanism A and provide strong evidence in support of the one-step process.

To use kinetic sulfur isotope effects as a criterion to distinguish between these possibilities, it was felt necessary *first* to test this tool by applying it to the bromodesulfonation of a

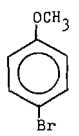
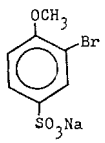
For personal use only.

compound which appeared on the basis of Cannell's kinetic results to proceed through mechanism A. Of the three compounds, II, III, and IV, whose bromination rates are suppressed by bromide ion beyond that attributable to Br_3^- formation, sodium *p*-methoxybenzenesulfonate (IV) seemed to be the most suitable for this test for the following reasons. Firstly, its reaction rate in the absence of bromide ion is sufficiently low to permit the use of reactant concentrations convenient for the isotope effect experiments and, furthermore, the bromide ion developed during the course of the reaction does not significantly affect the constancy of the rate constant, at least during the extent of reaction chosen for this study. Secondly, the ratio k_2/k_3 is of reasonable magnitude, namely 22 (as found by Cannell), to achieve the required condition $k_2[Br^-] \gg k_3$ at an attainable concentration of bromide ion. From the kinetic eq. [1] derived for mechanism A, which involves Br_2 as the brominating species, the ratio of the rate constants for the light and heavy sulfur isotopes, k^{32}/k^{34}, is given by eq. [3].



$$[3] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = \frac{k_1^{32}}{k_1^{34}} \cdot \frac{k_3^{32}}{k_3^{34}} \cdot \frac{k_2^{34}[Br^-] + k_3^{34}}{k_2^{32}[Br^-] + k_3^{32}}$$

At zero or very low bromide ion concentration ($k_2[Br^-] \ll k_3$) this can be reduced to the form shown in eq. [2]. The observed isotope effect is, therefore, a measure of the relative rates with which the two isotopic species form a quinoid intermediate. Since this step does not involve the rupture of a C—S bond, the isotope effect can be expected to be small or zero ($k_1^{32}/k_1^{34} \simeq 1$). At a bromide ion concentration sufficiently high that $k_2[Br^-] \gg k_3$,



$$[4] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = \frac{k_1^{32}}{k_1^{34}} \cdot \frac{k_2^{34}}{k_2^{32}} \cdot \frac{k_3^{32}}{k_3^{34}} = \frac{K^{32}}{K^{34}} \cdot \frac{k_3^{32}}{k_3^{34}},$$

in which K^{32}/K^{34} is the equilibrium isotope effect for the formation of the quinoid intermediate. Equation [4] now includes a rate constant ratio, k_3^{32}/k_3^{34}, for the step in which a C—S bond is being ruptured, and the isotope effect (a primary one) should be of normal magnitude (1 to 2%). Thus, it can be seen that for reaction by mechanism A the isotope effect should vary from zero to normal magnitude as the concentration of bromide ion changes. In other words, the isotope effect should be dependent on the concentration of bromide ion.

Initially, we assumed that Cannell's kinetic data on sodium *p*-methoxybenzenesulfonate were reliable and hence provided sound evidence for mechanism A. However, preliminary quantitative experiments, which involved the determination of sulfate yield (as related to the amount of bromine consumed) in the partial bromodesulfonation, disclosed the surprising fact that this yield is considerably less than that expected on the basis of the quantity of bromine consumed. This suggested that the bromination of sodium *p*-methoxybenzenesulfonate results in two competing reactions, bromodesulfonation and bromodeprotonation, the latter being the ordinary halogenation of the benzene ring in a position ortho to the methoxy group. This was further confirmed by product analysis: by isolating separately from the reaction mixture compounds VIII and IX, these being, respectively,

For personal use only.

the bromodesulfonated and bromodeprotonated products. Furthermore, it was established that these two competing reactions are of the same kinetic order, namely, first order with respect to sulfonate and first order with respect to bromine. The individual rate constants can therefore be evaluated from a knowledge of the rate constant for total bromination and the yield of sulfate. When the new kinetic data for the bromodesulfonation of compound IV were analyzed, it was found that, although the results favor mechanism A, a one- or two-step mechanism with Br^+ (or H_2OBr^+) as the brominating species cannot be eliminated completely. It now became apparent that the isotope effect study on compound IV was desirable to confirm the mechanism of bromodesulfonation, and was not, as originally intended, simply a test of reaction mechanism criterion.

When our attention was turned to compound V, again it was found that bromination results in two competing reactions, bromodesulfonation and bromodeprotonation. Also, there were strong indications that Cannell's salt was far from being of sufficient purity for reliable kinetic measurements. Consequently, with this compound also, the isotope effect investigation was preceded by a careful kinetic study involving the determination of total bromination rates and sulfate yields at different bromide ion concentrations. These results revealed that the product $k_{obs}(1 + K[Br^-])$, contrary to Cannell's findings, decreases somewhat as the bromide ion concentration increases, although not to an extent that cannot reasonably be attributed to a salt effect. Nevertheless, this result suggested the desirability of studying the kinetic isotope effect, not just at one bromide ion concentration, as had been originally planned, but at different concentrations, with the view to obtaining strong supporting evidence for mechanism A.

EXPERIMENTAL

Reagents

Anisole (Eastman Kodak, white label) was dried and fractionally distilled. α-Methylnaphthalene (99%) was obtained from L. Light and Co., England. Chlorosulfonic acid (British Drug Houses, laboratory reagent grade) was twice distilled before use. Carbon tetrachloride (Mallinckrodt, analytical reagent) was dried and fractionally distilled. All inorganic chemicals were analytical reagent grade.

Preparation of Sodium p-Methoxybenzenesulfonate

Anisole was sulfonated at −20 °C with chlorosulfonic acid by using carbon tetrachloride as solvent (3). The sulfonic acid that was formed was converted into its sodium salt, which was crystallized twice from water and twice from aqueous ethanol.

Cannell's kinetic experiment on the rate of bromination (expt. 26, p. 2935 of ref. 2) was repeated on this sulfonate. A steady rate constant, 0.0253 l mole^{-1} s^{-1}, compared with Cannell's value, 0.0254 l mole^{-1} s^{-1}, was obtained. The purity of the sulfonate was further established by estimating the yield of sulfate, gravimetrically, on complete bromodesulfonation. In several experiments, yields in the range 99.6–99.9% were obtained, in remarkable agreement with the theoretical yield of 100%.

Preparation of Potassium 1-Methylnaphthalene-4-sulfonate

For this preparation, direct sulfonation of α-methylnaphthalene by means of chlorosulfonic acid as used by Cannell (2) was first tried. The sulfonate that was obtained showed, however, after several recrystallizations unsteady rate constants when the rate of bromination was measured, and hence was impure. It was necessary, therefore, to employ a different method for purifying this sulfonate. Of the two purification methods tried for this purpose, only one proved to be successful.

The unsuccessful method was to convert the sulfonate into the *p*-toluidine salt, repeatedly recrystallize the *p*-toluidine salt to constant melting point, and then convert it back into the sulfonate. Although this method yielded a *p*-toluidine derivative of m.p. 234.8–235.8 °C, much higher than that reported by Cannell (227–229 °C), the material, after its conversion into the sulfonate, still showed unsteady rate constants.

In the second method the sulfonate was converted into the sulfonyl chloride by reaction with PCl_5, and the sulfonyl chloride that was formed was recrystallized repeatedly to constant melting point (melts very sharply at 81 °C; lit. (4) m.p. 81 °C) from benzene – petroleum ether (m.p. of anilide derivative, 157.5–158 °C; lit. (4) m.p. 158 °C). The sulfonyl chloride was then converted back into the sulfonate by refluxing with alcoholic KOH. The separated sulfonate was recrystallized twice from aqueous ethanol.

The question of the purity of this material and of the material prepared initially by the method used by Cannell is worth discussing. A number of kinetic experiments were first performed on material prepared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and purified by Cannell's method, the conditions used being identical with those of expts. 29 and 30 reported in his paper (p. 2935, ref. 2). It was found that, although the rate constants obtained from initial rates agreed fairly closely with Cannell's values, there was a serious fall off in the values of the rate constants as the reaction progressed. Nor could satisfactory results be obtained with material "purified" through the *p*-toluidine salt. On the other hand, the product obtained from the sulfonyl chloride purification procedure gave perfectly steady rate constants throughout the course of a kinetic run. It is of interest to note that the rate constant obtained for this material under the conditions of Cannell's expt. 29 was 0.0511 l mole^{-1} s^{-1}, which is to be compared with Cannell's reported value of 0.0985 l mole^{-1} s^{-1}. Since there seems to be little doubt that the salt used in the present study was of considerably higher purity than that used by Cannell, it is our view that no reliance can be placed on his rate constant for this compound.

Despite this elaborate purification procedure, the purity of the salt used in our work left something to be desired. The yields of sulfate obtained by "complete" bromodesulfonation in the presence of excess bromine at room temperature ranged from 92.6 to 93.1% of the theoretical amount, suggesting that the salt contained approximately 7% impurity. Since the same reactions carried out in a sealed tube at 210 °C for 8 days yielded sulfate in yields of 99.4–99.9%, it would appear that the impurity is an unreactive isomer, probably potassium 1-methylnaphthalene-5-sulfonate. Its presence, although introducing some error in the rate studies, should have no effect on the kinetic isotope effect results.

Product Analysis in the Bromination of Sodium p-Methoxybenzenesulfonate

Two separate aqueous solutions of 400 ml each, one containing the sulfonate (0.064 mole) and the other bromine (0.064 mole) and sodium bromide (0.4 mole), were cooled to 0 °C and then thoroughly mixed. The resulting solution was maintained at this temperature for about 3 h to permit the bromination to proceed to completion. At the end of the reaction, the bromodesulfonated product, *p*-bromoanisole, was extracted with carbon tetrachloride. After the latter had been distilled off, crude *p*-bromoanisole (2.45 g; 0.013 mole) was obtained in a yield corresponding to about 20% of the initial sulfonate. The product was identified by converting it into a derivative, *p*-methoxybenzoic acid (m.p. 183.5–184 °C), which gave no depression in melting point on admixture with an authentic sample of this acid (m.p. 183.5–184 °C).

After *p*-bromoanisole had been removed, the clear aqueous solution containing sodium 3-bromo-4-methoxybenzenesulfonate (the bromodeprotonated product) was first neutralized with solid sodium carbonate to a pH of 7. The solution was concentrated to about 125 ml by heating it at its boiling point and, when still hot, was saturated with sodium chloride before being allowed to cool. The separated solid weighed 15.1 g (0.051 mole), which corresponded in yield to about 80% of the initial sulfonate on the assumption that only one nuclear position is substituted by bromine. After recrystallization twice from water, it was converted into the sulfonamide via sulfonyl chloride. The melting point of the sulfonamide (139.5–140 °C) agreed with the literature value (139–140 °C (5)) for 3-bromo-4-methoxybenzenesulfonamide. The identity of the compound was further established by its infrared spectrum and by the lack of any melting point depression on admixture with an authentic sample of the sulfonamide prepared from *o*-bromoanisole.

Kinetics of Bromination

The rate of bromination was measured by following the rate of disappearance of bromine iodometrically. The technique was essentially the same as that adopted by Cannell (2). The aliquots (10 ml) of the reacting solution, withdrawn from time to time by means of a fast-delivery pipette (calibrated before use), were quenched in 10 ml of a 2% aqueous potassium iodide solution. The concentrations of sulfonate and bromine were varied but were kept, essentially, in the molar ratio of 4:1 to reduce the possibility of any dibromination. The reactions were carried out at constant acidity and ionic strength, which were adjusted by means of perchloric acid and sodium perchlorate, respectively. The rate constant for total bromination, k_{obs}, was evaluated by a least-square plot of $\log_{10}(A_0 - B_0 + B)/B$ versus t. (For definition of symbols, see ref. 2.) For the equilibrium

$$Br_2 + Br^- \underset{}{\overset{K}{\rightleftharpoons}} Br_3^-$$

the constant K at 0 °C, equal to 21.09 (l mole^{-1}), has been used in the present work. This value was obtained by extrapolating the values recently determined by Schaife and Tyrrel (6) at 5, 25, and 35 °C.

Resolution of Rate Constant for Total Bromination (k_{obs}) into Bromodesulfonation (k_{obs}^S) and Bromodeprotonation (k_{obs}^H) Rate Constants

In Cannell's study and also in the present work, the observed second-order rate constants, k_{obs}, were independent of the molar ratio of sulfonate to bromine. In addition, it was found in the present work that, at a given Br^- concentration, the ratio of the yield of sulfate to the total amount of bromine consumed was the same irrespective of the ratio of the two reactants or the extent of reaction. This established that the two competing reactions, bromodesulfonation and bromodeprotonation, are of the same kinetic order, namely, first order with respect to sulfonate and first order with respect to bromine. The resolution of k_{obs} into individual rate constants for bromodesulfonation, k_{obs}^S, and bromodeprotonation, k_{obs}^H, can therefore be achieved from a knowledge of the yield of sulfate and the amount of bromine consumed.

For determining the yield of sulfate, extensive preliminary experiments were done to establish that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sulfate formed in the reaction could be recovered quantitatively and estimated gravimetrically as barium sulfate with a good degree of precision and without significant interference by foreign ions. For the sulfate yield results to be kinetically meaningful it was essential that only one molecule of bromine be consumed per molecule of sulfonate, or, in other words, that there be no dibromination. To avoid any possibility of the latter the molar ratio of sulfonate to bromine was always kept at 4:1 and the reaction was allowed to proceed only until about 12% of the sulfonate was consumed. The acidity and ionic strengths were the same as in kinetic experiments. However, to obtain sufficient barium sulfate (~70 mg) for gravimetric estimation and for conversion into sulfur dioxide for isotopic analysis, the concentrations of sulfonate and bromine were changed with changing Br^- concentration, since the extent of bromodesulfonation is strongly dependent upon the concentration of this ion.

In these partial brominations, since one knows the total amount of bromine consumed (as found by the difference between the initial concentration and the concentration when the reaction was stopped) and the correspondinging yield of sulfate formed (as found gravimetrically), the percentage of bromodesulfonation (as related to the total amount of bromine consumed), x, is given by (moles of sulfate formed/moles of bromine consumed) $\times$ 100, and $(100 - x)$ gives the percentage of bromodeprotonation.

Complete Bromodesulfonations

At room temperature, these were performed as follows. To a known amount of sulfonate solution, bromine solution was added, the concentration of bromine being kept at least 10 times greater than that of sulfonate. The system was allowed to stand for many days, during which period the bromodesulfonation would go to completion. At the end of this period, the excess bromine was first removed and the organic product was extracted with carbon tetrachloride. The organic extract was washed several times with water and the washings combined with the aqueous solution. From the resulting solution the sulfate was obtained gravimetrically as barium sulfate. The complete bromodesulfonation results served as a criterion of purity for the sulfonate; also, the barium sulfate samples obtained in these reactions were needed for determining the sulfur isotopic ratio in the reactant.

To carry out the complete bromodesulfonation of potassium 1-methylnaphthalene-4-sulfonate under drastic conditions, a known amount of sulfonate solution and excess bromine were put into a pyrex tube, which was then sealed. After this tube had been kept at 210 °C in a furnace for 8 days the products were isolated as described before.

Evaluation of Kinetic Sulfur Isotope Effect

The barium sulfate samples obtained in the partial and complete bromodesulfonations were converted into sulfur dioxide for mass spectrometric analysis.

The conversion of the sulfur of barium sulfate into sulfur dioxide involved the following steps. The barium sulfate samples were first reduced to hydrogen sulfide by using a mixture of hydrochloric, hypophosphorus, and hydriodic acids; the hydrogen sulfide was then precipitated as cadmium sulfide. The latter was converted into silver sulfide, which was then burned to sulfur dioxide by a high-vacuum technique (7). These procedures have been tested with standard barium sulfate samples and have been found to involve no significant isotopic fractionation.

The relative abundances of the sulfur isotopes were measured on a 6 inch, 90°, simultaneous collection mass spectrometer similar to that described by Wanless and Thode (8). This was a high-precision instrument capable of measuring changes in isotopic ratios with a precision of $\pm 0.02\%$. The $^{32}S/^{34}S$ ratios were obtained from the mass 64/mass 66 ion-current ratios after a suitable correction had been applied for the contribution to mass 66 of the molecular species $^{32}S^{16}O^{18}O$ (9).

The kinetic isotope effect was calculated by the expression shown in eq. [5], which had been derived by Stevens and Attree (10) for a reaction in which there is no complication of competing processes.

$$\frac{k^{32}}{k^{34}} = \frac{\ln\ (1 - f)}{\ln\ (1 - rf)} \qquad [5]$$

In this equation $r = (^{32}S/^{34}S)$ reactant/$(^{32}S/^{34}S)$ product) and f is the mole fraction of the reactant which has undergone reaction. Because of the competing bromodeprotonation, an estimate of f is given by $f'(1 - p)/(1 - f'p)$, where $f' = x/a$, the mole fraction of reactant which has undergone bromination, and p is the fraction of the total reaction which is the bromodeprotonation process.

RESULTS

Bromodesulfonation of Sodium p-Methoxybenzenesulfonate

The results of a series of kinetic experiments and sulfate yield determinations for the bromination of sodium *p*-methoxybenzenesulfonate, carried out at Br^- concentrations ranging from 0 to 0.5 M under conditions of constant ionic strength and acidity, are given in Table I. It can be seen from this table that the amount of bromodeprotonation increases as the Br^- concentration is increased. A plot of $\{k_{obs}(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ over a

mechanism A, the slope of the straight line is k_2/k_1k_3 and its intercept at $[Br^-] = 0$ is $1/k_1$. From these two quantities the ratio k_2/k_3 may be calculated and is found to have the value 66. This is to be compared with the value 22 obtained by Cannell from a plot of $\{k_{obs}(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ in the range of $[Br^-]$ from 0 to 0.15 M, on the assumption that bromodesulfonation is the only reaction. The remaining plot in Fig. 1 (points shown by open triangles) refers to the bromodeprotonation of sodium *p*-methoxybenzenesulfonate and will be discussed in a subsequent paper.

A plot of $k_{obs}{}^S$ versus $\{(1 + K[Br^-])[Br^-]\}^{-1}$, which will be discussed later, for the bromodesulfonation of sodium *p*-methoxybenzenesulfonate is shown in Fig. 2.

The sulfur isotopic ratios ($^{32}S/^{34}S$) of the reactant and of the product produced in various partial reactions are given in Table II. Each of the $^{32}S/^{34}S$ ratios reported in this table is for barium sulfate produced in a separate bromodesulfonation experiment, either complete or partial. The ratios for the product of the complete reactions are averaged and the mean combined with the individual isotopic ratios obtained for the product of the partial reactions to give (($^{32}S/^{34}S$) partial)/(($^{32}S/^{34}S$) complete) values recorded in the same table. These quotients are then substituted into eq. [5], along with the corresponding f values, for the calculation of the kinetic isotope effect, k^{32}/k^{34}, which is recorded in the same table.

Bromodesulfonation of Potassium 1-Methylnaphthalene-4-sulfonate

The kinetic results for the bromination of potassium 1-methylnaphthalene-4-sulfonate are given in Table III, where it can be seen that the competing bromodeprotonation

and giving a 93% yield of barium sulfate and the other performed under drastic conditions in a sealed tube and producing close to the theoretical yield of product. It can be seen from this table that the sulfur isotopic ratios of the barium sulfate produced in the two kinds of "complete" bromodesulfonation are identical (well within experimental error). This shows that the 7% impurity, which it will be recalled is considered to be an unreactive isomer of potassium 1-methylnaphthalene-4-sulfonate, has the same sulfur isotopic abundance as the compound in question.

In Table V are given the sulfur isotopic ratios for the barium sulfate produced in partial reactions carried out in a range of Br^- concentration from 0 to 2 M and at two different ionic strengths. Each of these ratios was divided by the overall mean value obtained for the products of the complete reaction (see Table IV), and the resulting quotients were separately used for the calculation of the isotope effect k^{32}/k^{34} given in the last column of this table.

DISCUSSION

Bromodesulfonation of Sodium p-Methoxybenzenesulfonate

A depression in rate with increasing Br^- concentration, over and above that which can be attributed to Br_3^- formation, found by Cannell for the bromodesulfonation of compounds II and III, and also found from our new kinetic data for the bromodesulfonation of compound IV, can be accommodated fully as well by *another* mechanism (mechanism B) not considered by Cannell. This mechanism is analogous to that proposed (11) for the iodination of phenols and aromatic amines, and involves Br^+ (or H_2OBr^+) as the brominating species.

$$Br_2 + H_2O \overset{K'}{\rightleftharpoons} H_2OBr^+ + Br^-$$

$$Ar{-}SO_3^- + H_2OBr^+ \underset{k_2'}{\overset{k_1'}{\rightleftharpoons}} Ar\begin{matrix}\diagup^{+}Br\\ \diagdown SO_3^-\end{matrix} + H_2O$$

$$Ar\begin{matrix}\diagup^{+}Br\\ \diagdown SO_3^-\end{matrix} \xrightarrow{k_3'} Ar{-}Br + SO_3$$

*f' is the mole fraction of the reactant which has undergone bromination.
†f is the corrected mole fraction of the reactant which has undergone bromodesulfonation.
‡($^{32}S/^{34}S$) complete = 22.209 (see Table IV).
§The limits shown are standard deviations.

The rate equation for this mechanism has the form

$$[6] \qquad k_{obs} = \frac{K'k_1'k_3'}{(k_2' + k_3')(1 + K[Br^-])[Br^-]}.$$

If, instead of the two-step process involving the quinoid intermediate, the brominating species Br^+ (or H_2OBr^+) were to form the product directly in a single step having a rate constant k_4, an equation similar to eq. [6], namely,

$$[7] \qquad k_{obs} = \frac{K'k_4}{(1 + K[Br^-])[Br^-]},$$

would be followed. In either case a plot of k_{obs} versus $\{(1 + K[Br^-])[Br^-]\}^{-1}$ would be expected to be a straight line with a zero intercept. However, examination of eq. [1] shows that, under the circumstance $k_2[Br^-] \gg k_3$, mechanism A, like mechanism B, will also lead to a straight-line plot of k_{obs} versus $\{(1 + K[Br^-])[Br^-]\}^{-1}$. Now when the rate data for compounds II and III were analyzed by Cannell in terms of mechanism A, he obtained a k_2/k_3 ratio such that $k_2[Br^-]$ is large relative to k_3, even at quite low Br^- concentrations. It is therefore not surprising for us to find that Cannell's data for these two compounds give a good linear plot of k_{obs} versus $\{(1 + K[Br^-])[Br^-]\}^{-1}$, and hence do not distinguish between the two mechanisms.

It is tempting, therefore, to see whether our kinetic data for the bromodesulfonation of compound IV would distinguish between the two mechanisms. Inspection of eqs. [6] and [7] shows that mechanism B also predicts a straight-line plot of $\{k_{obs}^S(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$, but, unlike mechanism A, requires a zero intercept.[4] The fact that a small but experimentally real intercept has been observed in the latter plot for the bromodesulfonation of sodium *p*-methoxybenzenesulfonate (Fig. 1) might argue against mechanism B for this compound. It is our opinion, however, that one would not be justified in completely eliminating mechanism B simply on the basis of this very small intercept. The usual way to see whether mechanism B is operative is to test the linearity of k_{obs}^S versus $\{(1 + K[Br^-])[Br^-]\}^{-1}$, as required by the relationships of eqs. [6] and [7]; such a plot for the bromodesulfonation of sodium *p*-methoxybenzenesulfonate is shown in Fig. 2. It can be seen from this figure that, over the range of Br^- concentrations of 0.5 to 0.1 M, the points perfectly fit a straight line. At Br^- concentrations of 0.03 and 0.07 M, deviations from linearity were observed, the deviation being quite considerable for the point corresponding to $[Br^-] = 0.03$ M (it was not convenient to include this point in the plot). These deviations from linearity appear exactly where one would expect them for a reaction by mechanism A with a k_2/k_3 ratio of 66. When $[Br^-]$ is above 0.1 M, $k_2[Br^-]$ is sufficiently large relative to k_3 to cause the kinetic points to fit a straight line within the limits of experimental error. Below 0.1 M, however, the product $k_2[Br^-]$ starts to assume a value comparable with that for k_3 and deviations from linearity become apparent. The kinetic results therefore clearly favor mechanism A over mechanism B, but outright rejection of mechanism B on the basis of the kinetic data alone was not considered justifiable. Strong supporting evidence, however, is desirable, and this has been sought through a kinetic sulfur isotope effect study of the reaction.

An inspection of mechanism B reveals that the sulfur isotope effect should be inde-

[4] *A more vigorously derived kinetic expression for mechanism B, which takes into account the very small amount of titratable bromine which is in the form* H_2OBr^+, *actually does require an intercept for this plot. It can be shown, however, that this intercept is equal to the product of the slope and K', the equilibrium constant for* H_2OBr^+ *formation. Since the slope is ~120 and K' has a value of* 10^{-20} *(12), the intercept required by mechanism B is obviously quite insignificant.*

For personal use only.

pendent of the Br^- concentration, since Br^- is formed in a pre-equilibrium step which has nothing to do with the substitution step. For a two-step process in mechanism B,

$$[8] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = \frac{k_1'^{32}}{k_1'^{34}} \cdot \frac{k_3'^{32}}{k_3'^{34}} \cdot \frac{k_2'^{34} + k_3'^{34}}{k_2'^{32} + k_3'^{32}},$$

and the observed isotope effect will depend on the relative magnitudes of k_3' and k_2'. If $k_3' \gg k_2'$, the effect will be zero (or close to it); if $k_3' \ll k_2'$, the effect will be a normal one. Also, for a one-step process in mechanism B, an isotope effect of appreciable magnitude can be expected since C—S bond rupture is involved in the rate-determining step. On the other hand, for mechanism A, as discussed earlier, the isotope effect can be expected to vary from zero to normal magnitude as the Br^- concentration is increased.

Kinetic sulfur isotope effects have been determined for the bromodesulfonation of sodium *p*-methoxybenzenesulfonate at three different initial Br^- concentrations: 0, 0.03, and 0.5 *M*. In a reaction with no added Br^-, the concentration of this ion will have reached 5×10^{-4} *M* during the 12% reaction (with respect to sulfonate) used in the isotope effect experiments. This means that, if mechanism A is operative, the ratio of the rate of reversion of the intermediate to its rate of conversion into product, $k_2[Br^-]/k_3$, will on the average be only $66 \times 0.00025 = 0.0165$. For all practical purposes then, one can consider that the intermediate proceeds only to product; that is, the formation of the intermediate is rate determining. At $[Br^-] = 0.03$ *M*, rate reverse/rate forward $= 66 \times 0.03 = \sim 2$; that is, of every three intermediates formed, two revert to reactant and one proceeds to product. Finally, at $[Br^-] = 0.5$ *M*, rate reverse/rate forward $= 66 \times 0.5 = 33$; under these conditions the intermediate should be essentially in equilibrium with reactants and a normal isotope effect can be expected.

Inspection of Table II reveals that the kinetic isotope effect does indeed increase with an increase in the concentration of bromide ion. These results completely eliminate mechanism B and provide strong supporting evidence for mechanism A in the bromodesulfonation of sodium *p*-methoxybenzenesulfonate. Thus, at very low Br^- concentrations, the rate-determining step is the formation of the quinoid intermediate in which the C—S bond is still intact. The isotope effect, which is a measure of the rate ratio k_1^{32}/k_1^{34}, is 1.0032. At $[Br^-] = 0.5$ *M*, the rupture of the C—S bond is fully rate determining and a normal isotope effect of 1.0173 is observed. At an intermediate Br^- concentration of 0.03 *M* the rupture of the C—S bond is partially rate determining and the isotope effect is 1.0127.

The magnitude of the isotope effect for the step involving C—S bond rupture, namely k_3^{32}/k_3^{34}, can be evaluated from eq. [3] and the observed isotope effect at the different Br^- concentrations, providing an assumption is made concerning the value of k_2^{32}/k_2^{34}. Since the quinoid intermediate is a high-energy species, it seems reasonable to assume that the transition state for the first step more closely resembles this intermediate than it does the reactant. If this is so, the ratio k_2^{32}/k_2^{34} should be considerably closer to unity than is the ratio k_1^{32}/k_1^{34}, for which the value 1.0032 has been observed. It would seem reasonable, therefore, to assume $k_2^{32} = k_2^{34}$; that is, there is no significant isotope effect for the reverse reaction within the limits of our measurements. With this assumption then, it follows from eq. [3] that

$$[9] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = \frac{k_1^{32}}{k_1^{34}} \cdot \frac{\frac{k_3^{32}}{k_3^{34}} \cdot \frac{k_2^{32}}{k_3^{32}} \cdot [Br^-] + 1}{\frac{k_2^{32}}{k_3^{32}} \cdot [Br^-] + 1}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

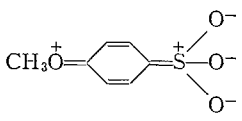
In eq. [9], $k_1^{32}/k_1^{34} = 1.0032$, the isotope effect measured at $[Br^-] = 0$, and $k_2^{32}/k_3^{32} = 66$, a value obtained from the slope and intercept of the plot of $\{k_{obs}{}^S(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ in Fig. 1. Equation [9] reduces to

$$[10] \qquad \left[\frac{k^{32}}{k^{34}}\right]_{obs} = 1.0032\,\frac{(k_3^{32}/k_3^{34})\cdot 66\cdot[Br^-] + 1}{66\cdot[Br^-] + 1}.$$

In this equation if one substitutes the measured isotope effect $(k^{32}/k^{34})_{obs}$ at a given Br^- concentration, the desired ratio, k_3^{32}/k_3^{34}, can be calculated; the latter values at the two different Br^- concentrations are given in Table II. It is significant to note that exactly the same value, within experimental error, is obtained for the k_3^{32}/k_3^{34} ratio at the two different Br^- concentrations, 0.03 and 0.5 *M*. This internal self-consistency of the results, when interpreted in terms of mechanism A, lends further support to this mechanism for the reaction. Furthermore, the value 1.014 for k_3^{32}/k_3^{34} corresponds closely to the theoretical value, 1.016, for a transition state in which there is complete C—S bond rupture.

The evidence obtained in the present work for the operation of mechanism A for the bromodesulfonation of compound IV strongly suggests that this mechanism is being followed also in the same reaction of the more reactive compounds II and III.

There is a small, but certainly real, isotope effect, $k_1^{32}/k_1^{34} = 1.0032$, in the formation of the quinoid intermediate. Since the C—S bond remains intact in this process, one might have expected this effect to be zero. It might therefore be argued that this small effect arises from a slight reversion of the intermediate as a consequence of the bromide ion developed during the course of the reaction. We now intend to show by the method of successive approximations that this is not a primary effect, but rather quite definitely a secondary one.



(*a*) If one assumes $k_1^{32}/k_1^{34} = 1$ (as one would have expected), eq. [10] is used to calculate k_3^{32}/k_3^{34} from the experimental data: $[Br^-] = 0.5$ *M*, $(k^{32}/k^{34})_{obs} = 1.0173$. The value of k_3^{32}/k_3^{34} turns out to be 1.0178.

(*b*) This value of k_3^{32}/k_3^{34} is substituted into eq. [10] to calculate k_1^{32}/k_1^{34} from the experimental data: $[Br^-] = 0.00025$ *M* (average concentration of Br^- developed during the course of the reaction in the partial run in which there is no added Br^-), $(k^{32}/k^{34})_{obs} = 1.0032$. The value of k_1^{32}/k_1^{34} so obtained, which should be somewhat better than the initially assumed value of unity, is 1.0030.

(*c*) Now, by using $k_1^{32}/k_1^{34} = 1.0030$, procedure *a* is repeated and a value of 1.0147 is obtained for k_3^{32}/k_3^{34}.

(*d*) Procedure *b* is again repeated with $k_3^{32}/k_3^{34} = 1.0147$. The value of k_1^{32}/k_1^{34} so obtained is 1.0030, identical with the result from operation *b*.

The fact that through a series of these operations k_1^{32}/k_1^{34} finally assumes a constant value of 1.0030, which is not significantly different from the observed effect, 1.0032, at a bromide ion concentration of 0, clearly shows that this effect is a secondary one associated with the step for the formation of the intermediate. This secondary isotope effect is probably caused by the fact that the sulfonate group in the initial state is capable of conjugated interaction with the benzene ring and that this interaction is destroyed in the formation of the intermediate, thus resulting in some C—S bond weakening.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Evidence in support of such conjugative interaction of the sulfonate group with the aromatic ring has been obtained in studies on the acid strength of naphthylammonium ions (13), $^{-}O_3SC_{10}H_6\overset{+}{N}H_3$, and of substituted benzenesulfonic acids (14). It is to be noted that the very small secondary isotope effects associated with the elements of higher atomic number usually are not detectable. To our knowledge, the only other example reported to date is a secondary ^{14}C effect in the formation of the 2,4-dinitrophenylhydrazone of acetophenone-β-^{14}C (15).

Bromodesulfonation of Potassium 1-Methylnaphthalene-4-sulfonate

Preliminary kinetic studies on the bromination of potassium 1-methylnaphthalene-4-sulfonate revealed that this compound, like compound IV, undergoes competing bromodesulfonation and bromodeprotonation reactions. Again, the latter reaction had been overlooked by Cannell in his kinetic study of the bromination of this compound. Furthermore, there was reason to believe that the salt used by Cannell was quite impure. For these reasons, a careful reinvestigation of the bromination kinetics, including the determination of sulfate yields, was made over a range of bromide ion concentrations from 0 to 0.5 M, and the results are given in Table III. It can be seen from this table that the product $k_{obs}^{S}(1 + K[Br^-])$ is not strictly a constant but shows a decrease of about 33% over this range of Br^- concentration. Similar small decreases in $k_{obs}(1 + K[Br^-])$ have been observed before in certain bromodeprotonation processes (16, 17) and have been attributed to a salt effect resulting from the replacement by sodium bromide of some inert salt used to maintain a constant ionic strength at the different Br^- concentrations. Clearly, this very small depression in rate by Br^- eliminates any form of mechanism with Br^+ (or H_2OBr^+) as the brominating species (see eqs. [6] and [7]), but it is fully consistent with either the one- or two-step mechanism with Br_2 as the brominating agent.

If potassium 1-methylnaphthalene-4-sulfonate does undergo bromodesulfonation by the one-step mechanism, then the small decrease in rate observed must be due entirely to the salt effect. On the other hand, if the reaction is proceeding in two steps through a quinoid intermediate, then the decrease in rate would be due, in part or entirely, to the return of this intermediate to reactant as the Br^- concentration is increased. The fact that a plot of $\{k_{obs}^{S}(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ (Fig. 3) is linear lends support to the two-step mechanism, although the possibility that a salt effect could take a similar form is not excluded. If one interprets this linearity solely in terms of a return of an intermediate to reactant, the slope and intercept of the line in Fig. 3 give a value of 1.1 for k_2/k_3, the ratio of the rate constants for reverse and forward reactions involving this intermediate.

A kinetic sulfur isotope effect study of this reaction was initiated in an attempt to distinguish between the two possibilities. Initial isotope effect experiments were carried out under the same conditions as those used in the sodium p-methoxybenzenesulfonate study. Inspection of Table V reveals that, over the range of Br^- concentration 0 to 0.5 M, the isotope effects are small and show a variation which is barely beyond experimental error. There is, however, a strong suggestion of a small increase in the isotope effect with increasing Br^- concentration, but the change is too small to be meaningful as a mechanistic criterion. These results obviously made it necessary to go to a higher bromide ion concentration. Since, in doing so, the ionic strength of the medium would also change, it was necessary first to demonstrate that a change in ionic strength alone does not significantly influence the magnitude of the isotope effect. That this is indeed the case can be seen from Table V by comparing the results obtained at the two ionic strengths in the absence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

added bromide ion. The difference in the mean k^{32}/k^{34} ratios does not exceed the experimental error.

After this crucial point had been established, a series of isotope effect measurements were made at $[Br^-] = 2\ M$. The mean value so obtained, 1.0076[5] ± 0.0007, is significantly different from the value, 1.0023 ± 0.0008, found at $[Br^-] = 0$ and the same ionic strength. This result amply confirms the trend suggested by the earlier experiments and, in our opinion, clearly establishes the two-step mechanism for the bromodesulfonation of potassium 1-methylnaphthalene-4-sulfonate.

It is of interest to see if the number 1.1 obtained from the plot in Fig. 3 is the true value for the ratio k_2/k_3. For this value of k_2/k_3, at $[Br^-] = 0.5\ M$ one intermediate returns to reactant to two going forward, and the isotope effect should have increased considerably over the value obtained at $[Br^-] = 0$. At $[Br^-] = 2\ M$, the observed isotope effect should have reached nearly a normal value. Clearly, therefore, much of the slope in Fig. 3 is due to the salt effect. It is possible to estimate the true value of the k_2/k_3 ratio from eq. [9]. In this equation $k_1^{32}/k_1^{34} = 1.0023$, while the ratio k_3^{32}/k_3^{34} can, to a first approximation, be considered to be the same as that found for compound IV, namely 1.0144. These ratios, when combined in eq. [9] with the observed isotope effect at $[Br^-] = 2\ M$, gave a value of 0.29 for the k_2/k_3 ratio. That some reliance can be placed on the k_2/k_3 ratio calculated in this way, and on the assumption that $k_3^{32}/k_3^{34} \approx 1.014$, is shown by the agreement between the isotope effects obtained experimentally at the other Br^- concentrations, 0.25 and 0.5 M, and the values calculated by substitution of the values for k_2/k_3, k_1^{32}/k_1^{34}, and k_3^{32}/k_3^{34} in eq. [9]. At $[Br^-] = 0.25\ M$, the experimentally observed isotope effect is 1.0029, and the calculated value is 1.0032; at $[Br^-] = 0.5\ M$, the corresponding values are 1.0037 and 1.0041. It can be inferred, therefore, that nearly 75% of the depression in the quantity $k_{obs}{}^{S}(1 + K[Br^-])$ by bromide ion results from the salt effect.

ACKNOWLEDGMENT

We are grateful to Mr. Jan Monster for the mass spectrometric analysis.

KINETIC HYDROGEN ISOTOPE EFFECTS IN AROMATIC BROMODEPROTONATION[1]

B. T. BALIGA[2] AND A. N. BOURNS
Department of Chemistry, McMaster University, Hamilton, Ontario

Received October 7, 1965

ABSTRACT

The bromodeprotonation of sodium *p*-methoxybenzenesulfonate is an ordinary halogenation reaction in which a hydrogen ortho to the methoxy group is replaced by bromine. The kinetic data for this reaction do not distinguish between a one- and a two-step mechanism with Br_2 as the brominating species. The two-step mechanism was confirmed by the observation of a variation in the kinetic hydrogen isotope effect, k^H/k^D, with changing bromide ion concentration. The observed isotope effects are 1.01, 1.07, 1.18, and 1.31 at bromide ion concentrations 0, 0.5, 1, and 2 *M*, respectively.

The isotope effect study strongly establishes that in this reaction the small depression in rate produced by bromide ion, beyond that due to Br_3^- formation, arises mainly from a salt effect, and only a small amount of this depression is caused by return of the intermediate to reactants.

INTRODUCTION

The displacement of a proton from an aromatic nucleus by a halogen is an important reaction in electrophilic aromatic substitution. In recent years there has been a great deal of interest in the mechanism of halodeprotonations, and a large number of studies have been directed to the problem of establishing the identity of the halogenating species and also to the question of elucidating the detailed pathway of the substitution process itself. Whereas ordinary kinetic studies (1) have frequently provided valuable information on the nature of the halogenating species, they have been of limited value in shedding light on the detailed mechanism of the substitution process itself. Since 1950 a number of kinetic hydrogen isotope effect studies have been made to provide a solution to this latter problem (2). A graded series of isotope effects have been observed with, as yet, no reported effects in chlorination, with effects ranging from zero to an appreciable magnitude in bromination, and with relatively large effects in almost all cases of iodination.

Although a knowledge simply of the magnitude of the isotope effect under a given set of conditions for a reaction provides valuable information about the extent of C—H bond rupture in the highest energy state, it can by no means distinguish between a one-step process (mechanism I)

$$ArH + X_2 \rightleftharpoons \text{transition state} \rightarrow ArX + X^- + H^+$$

and a two-step process (mechanism II)

$$ArH + X_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Ar\overset{+}{\underset{X}{\overset{H}{<}}} + X^-$$

$$Ar\overset{+}{\underset{X}{\overset{H}{<}}} \xrightarrow{k_3} ArX + H^+.$$

One way in which kinetic isotope effects may provide unambiguous support for the two-step mechanism is by the demonstration of a variation in the magnitude of this effect with a change in the concentration of halide ion, X^-. Changes in the concentration of X^- would

be expected to influence the relative rates of return of an intermediate to reactant and of decomposition to product, and hence would affect the extent to which the latter step (in which there is C—H bond rupture) contributes to the overall reaction rate.

Several attempts to achieve a variation in the magnitude of the hydrogen isotope effect by varying the concentration of halide ion have not been decisive. Grimison and Ridd (3) observed in the iodination of glyoxaline by molecular iodine a normal isotope effect ($k^H/k^D = 4.4$) that was unaffected by changes in halide ion concentration, while a similar result has been observed by Berliner (4) in the iodination of anisole with ICl ($k^H/k^D = 3.8$). These results can be interpreted by either a one- or a two-step mechanism with I^+ (or H_2OI^+) as the iodinating species, or by mechanism II in which I_2 or ICl acts as the electrophile. The latter possibility exists because, even at the lowest halide ion concentration used, the rate of reversal of the intermediate could still be faster than the proton loss ($k_2[I^-] \gg k_3$), and hence C—H bond rupture could still be fully rate determining. Finally, Berliner and Schueller (5) have observed in the bromination of diphenyl a small isotope effect ($k^H/k^D = 1.15$) invariant with Br^- concentration, a result which can be interpreted by either mechanism II, with the formation of the intermediate being rate determining (in this case the 15% isotope effect is a secondary one), or by mechanism I through a transition state in which the C—H bond is only slightly weakened.

To date, the positive application of the isotope effect criterion has been reported in only a few cases: (*i*) a variation in hydrogen isotope effect ($k^H/k^D = 6.55$–3.62) with a change in the concentration of base in the coupling reaction of *p*-chlorodiazobenzene with 2-naphthol-6,8-disulfonic acid (6); (*ii*) a variation in carbon isotope effect ($k^{12}/k^{13} = 1.002$–1.045) with changing concentration of Br^- in the bromodecarboxylation of 3,5-dibromo-4-hydroxybenzoic acid (7); (*iii*) a variation in sulfur isotope effect (8) with a change in the concentration of Br^- in the bromodesulfonation of sodium *p*-methoxybenzenesulfonate ($k^{32}/k^{34} = 1.003$–1.017) and potassium 1-methylnaphthalene-4-sulfonate ($k^{32}/k^{34} = 1.002$–1.008); and (*iv*) a variation in hydrogen isotope effect in the iodination of *p*-nitrophenol (9) ($k^H/k^D = 2.3$–5.4) and of aniline (10) ($k^H/k^D = 2.4$–3.6) with a change in the concentration of iodide ion. These results provide unambiguous evidence in support of the two-step mechanism and also establish that the halogenating species that is involved is molecular halogen. Also, Zollinger *et al.* (11–13) have recently demonstrated very strongly by kinetic and nuclear magnetic resonance study the existence of a fairly long-lived intermediate I in the direct bromination of the disodium salt of 2-naphthol-6,8-disulfonic acid. This

I

intermediate is formed rapidly from reactants, builds up to measurable proportions, and then decomposes by a slow unimolecular step which is base catalyzed. In accordance with this mechanism the hydrogen isotope effect ($k^H/k^D = 1.48$–2.34) increased with the ratio of the concentration of reactants.

The kinetic data on the bromodeprotonation of sodium *p*-methoxybenzenesulfonate (temperature 0 °C; ionic strength 0.50 *M*) are given in Table I, where it can be seen that the product $k_{obs}{}^H(1 + K[Br^-])$ is not strictly a constant but diminishes by a considerable amount (~37%) over a range of Br^- concentration of 0 to 0.5 *M*. A similar decrease in rate has been observed in the bromination of substituted anisoles (14) and of 2,6-dibromo-

phenol (15). Although this small decrease in rate eliminates any form of mechanism involving Br^+ (or H_2OBr^+) as the brominating species (see eqs. [6] and [7] of ref. 8), it can be accommodated readily by either mechanism I or mechanism II with Br_2 as the brominating agent.

The question which now arises is whether the *decrease* in $k_{obs}^H(1 + K[Br^-])$ is purely a salt effect resulting from the replacement of sodium perchlorate by sodium bromide as the Br^- concentration is increased (at constant ionic strength), or whether it is due, at least in part, to the return of a reaction intermediate to reactant. The fact that a plot of $\{k_{obs}^H(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ is linear (see Fig. 1[3] of ref. 8) is certainly in accordance with mechanism II, in which the depression of rate with increasing Br^- concentration results from the return of the intermediate. The answer to this question may be provided through a study of the kinetic hydrogen isotope effect at different Br^- concentrations. If the depression in rate is due entirely to a salt effect, the isotope effect should not vary with Br^- concentration. This result cannot distinguish between mechanism I and mechanism II, in which the rate of decomposition of the intermediate is fast relative to its return to reactant at all experimentally realizable bromide ion concentrations, i.e. $k_2[Br^-] \ll k_3$. If, however, any significant part of the depression in $k_{obs}^H(1 + K[Br^-])$ is due to the return of an intermediate to reactant (mechanism II), then this should manifest itself in an increase in k^H/k^D with increasing concentration of Br^-. This observation would provide the strongest possible evidence for the two-step mechanism. In view of this, the kinetic hydrogen isotope effect (k^H/k^D) as a function of Br^- concentration was measured for the bromodeprotonation of sodium *p*-methoxybenzenesulfonate.

EXPERIMENTAL

Reagents

Deuterium oxide that was claimed to be 99.4% pure came from Oak Ridge National Laboratory, Tennessee. Deuteriosulfuric acid was prepared by distilling sulfur trioxide into deuterium oxide and later adjusting the freezing point to 14.21 °C (the freezing point of pure deuteriosulfuric acid) with deuterium oxide. Acetic anhydride (Fisher certified reagent grade) was fractionally distilled through a long column, and the middle fraction, boiling at 139.5–140.5 °C, was collected. This procedure was carried out to ensure that the substance was free of moisture and acetic acid. All other chemicals that were used were the same as before (8).

Sodium p-Methoxybenzenesulfonate-O,O′-d_2

Several attempts were made to prepare this compound by direct exchange between sodium *p*-methoxybenzenesulfonate and deuteriosulfuric acid. The results were unsuccessful and it was concluded that the sulfonic acid group has a pronounced deactivating effect in the exchange of hydrogen atoms on the benzene ring. A similar conclusion was reached by Ingold *et al.* (16) after their unsuccessful attempts to deuterate benzenesulfonic acid by direct exchange with deuteriosulfuric acid. An alternative method is to prepare

[3]*The deviation from linearity of the point at* $[Br^-] = 0$ *in this plot is undoubtedly due to the large experimental error in the value used for the percentage of bromodeprotonation. At* $[Br^-] = 0$, *the sulfate yield is* $88 \pm 1\%$; *hence, bromodeprotonation is* $12 \pm 1\%$.

2,4,6-trideuterioanisole first and then sulfonate it under conditions such that there would be no exchange in the ortho positions. 2,4,6-Trideuterioanisole can be prepared in two ways: either by methylation of 2,4,6-trideuteriophenol or by the deuteration of anisole itself. For economic and practical reasons, the method adopted by Brown *et al.* (17), involving direct exchange between anisole and deuterioacetic acid (CH_3COOD) with sulfuric acid as catalyst, was found to be most suitable. This method has a distinct advantage over the direct exchange of anisole with deuteriosulfuric acid, in the following respects: the deuterium source (D_2O) needed for the operations is much less; the yield of deuterioanisole is greater; and the exchange is exclusively in the 2,4,6-positions of anisole, as desired.

The deuterioacetic acid that was required was prepared by treating acetic anhydride (3.45 moles) with deuterium oxide (3.45 moles). The mixture was heated under reflux for 10 h, every precaution being taken to exclude moisture. To the resulting deuterioacetic acid was added deuteriosulfuric acid (4 ml) as catalyst.

Anisole (25 g; 0.23 mole) was treated with deuterioacetic acid (2.76 moles) in a 500 ml round-bottomed flask whose upper neck was constricted for vacuum sealing. The system was frozen by means of liquid nitrogen and the flask was evacuated. With the stopcock closed, the contents were allowed to thaw and were then frozen again by liquid nitrogen. The system was again evacuated and the flask was sealed off. The flask, enclosed in a copper wire net, was immersed in an oil bath at 90 ± 0.1 °C for 48 h. At the end of this period the flask was removed and well cooled. It was then opened and its contents were carefully poured onto chipped ice. In the meantime, 320 ml of 9 *M* sodium hydroxide solution was cooled in ice. The solution in chipped ice was then slowly poured into the alkali solution with constant stirring, the system being kept well cooled. When the entire solution was added the final pH was about 8.

The separated anisole was extracted with ether in many portions, and the combined extracts were repeatedly washed with water until the washings were neutral to litmus. The ether extract was then dried thoroughly with anhydrous sodium sulfate and the ether was finally removed by vacuum distillation. The recovered anisole was further subjected to two similar exchanges, 2.07 moles of deuterioacetic acid being used each time. The alkali used for neutralization after these exchanges was 9 *M* sodium hydroxide (240 ml). In each of the three exchanges there was approximately 25–30% loss of anisole, the major loss being almost certainly due to its destruction on prolonged heating with the acid. The anisole that was finally obtained was distilled over metallic sodium, and the distillate boiling at 153–153.5 °C was collected. The final yield was 9 g, which is about 36% of the starting material.

A nuclear magnetic resonance spectrum of the deuterioanisole in carbon tetrachloride (the solution was ~25% by weight) is shown in Fig. 1, and that of ordinary anisole obtained under similar conditions in Fig. 2.

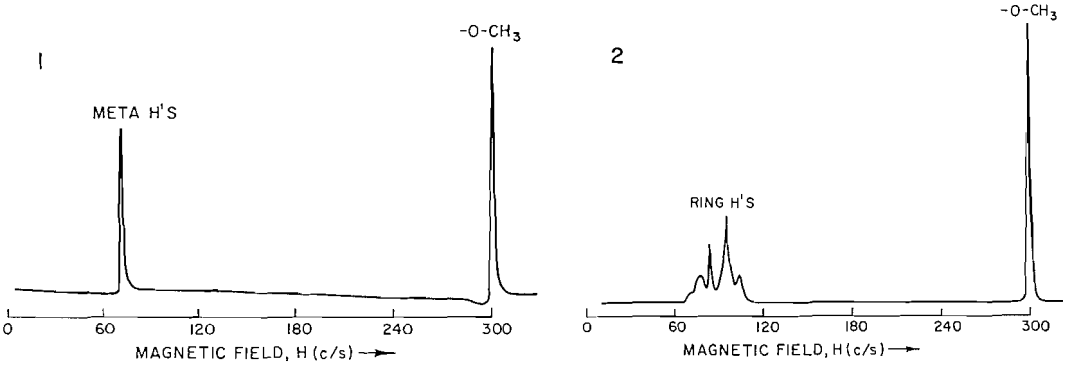

FIG. 1. Proton nuclear magnetic resonance spectrum of 2,4,6-trideuterioanisole at 60 Mc/s in carbon tetrachloride.

FIG. 2. Proton nuclear magnetic resonance spectrum of anisole at 60 Mc/s in carbon tetrachloride.

It can be seen that the multiple spectrum of the five hydrogens of the benzene ring in ordinary anisole is completely replaced by a single sharp peak (of 3,5-meta protons) in the deuterioanisole. The latter peak has two-thirds the area of that of the methyl protons, showing that the anisole is essentially completely deuterated in the 2,4,6-positions.

2,4,6-Trideuterioanisole (9 g; 0.083 mole) was sulfonated with chlorosulfonic acid (9.3 g; 0.08 mole) in 30 ml of carbon tetrachloride as solvent by the procedure described previously (8). The sulfonic acid was filtered and freed from any unreacted anisole by washing it with carbon tetrachloride. The solid acid was then carefully added to an ice-cold saturated solution of sodium carbonate, with constant stirring, such that when all the sulfonic acid was added the pH of the solution was about 7 to 8. The solution was then vacuum distilled at 50 °C to remove water. The dry solid that was left behind was then extracted with 80% ethanol in three portions of 100 ml, 50 ml, and 50 ml. The combined ethanol extracts were vacuum distilled, and the solid that was obtained was found to be almost free from inorganic impurities. It was then subsequently recrystallized twice from aqueous ethanol, and dried thoroughly at 110 °C before use.

Figure 3 shows the nuclear magnetic resonance spectrum of the deuterated sulfonate in deuterium oxide (the solution was 5% by weight), and Fig. 4 the spectrum of the unlabelled sulfonate obtained under similar

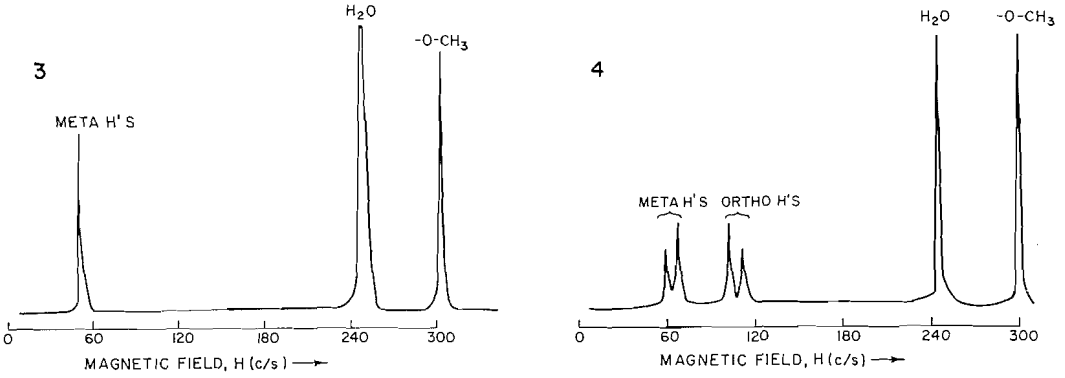

FIG. 3. Proton nuclear magnetic resonance spectrum of sodium *p*-methoxybenzenesulfonate-*O,O'*-d_2 at 60 Mc/s in D_2O.
FIG. 4. Proton nuclear magnetic resonance spectrum of sodium *p*-methoxybenzenesulfonate at 60 Mc/s in D_2O.

conditions. The spectrum of the unlabelled sulfonate consists of two doublets of the ortho and meta protons of the benzene ring. In the deuterated sulfonate the ortho doublet has completely disappeared and the meta doublet has coalesced into a single sharp peak. The latter peak has two-thirds the area of that of the methyl protons, showing that the sulfonate is essentially completely deuterated in the 2,6-positions.

Kinetics of Bromination

The experimental techniques used to measure the rates of bromination for the labelled and unlabelled sulfonates were the same as described previously (8). For the evaluation of bromodedeuteration rates in the bromination of the labelled sulfonate, the latter, being short in quantity, was not used for estimating the yield of sulfate. However, the desired ratio, k^H/k^D, can be obtained as follows. If $(k_{obs})_H$ and $(k_{obs})_D$ are the rate constants for the total bromination of unlabelled and labelled sulfonates, respectively, then

$$[1] \qquad \frac{(k_{obs})_H}{(k_{obs})_D} = \frac{k^S + k^H}{k^S + k^D} = \frac{k^S/k^H + 1}{k^S/k^H + k^D/k^H}$$

or

$$[2] \qquad \frac{k^H}{k^D} = \frac{\dfrac{(k_{obs})_H}{(k_{obs})_D}}{k^S/k^H\left[1 - \dfrac{(k_{obs})_H}{(k_{obs})_D}\right] + 1},$$

where k^S, k^H, and k^D are the rate constants for bromodesulfonation, bromodeprotonation, and bromodedeuteration, respectively. In deriving this equation the assumption is made that the rate constant, k^S, for bromodesulfonation is unaffected by deuterium substitution. Since k^S/k^H is known from the sulfate yield data for the unlabelled compound, the isotope effect can readily be evaluated.

RESULTS AND DISCUSSION

The kinetic isotope effects, k^H/k^D, for the bromodeprotonation of sodium *p*-methoxybenzenesulfonate over a range of Br^- concentration of 0 to 2 *M* are given in Table II, where it can be seen that there is a definite increase in the isotope effect with increasing Br^- concentration. Mechanism II is thus established. Now, if the depression in $k_{obs}{}^H(1 + K[Br^-])$ were due entirely to a return of the intermediate to reactant, then the slope of the linear plot of $\{k_{obs}{}^H(1 + K[Br^-])\}^{-1}$ versus $[Br^-]$ (this plot is shown in our preceding paper; see Fig. 1 of ref. 8) for the bromodeprotonation of sodium *p*-methoxybenzenesulfonate is k_2/k_1k_3 and the intercept is $1/k_1$. From these a value of 1.2 is calculated for the ratio k_2/k_3. That this value is much too high is evident from the small value of the

†$(k^S/k)_H$ = percentage of bromodesulfonation/percentage of bromodeprotonation for the undeuterated sulfonate.
‡Estimated maximum overall error based on variation in the $(k^S/k^H)_H$ and rate constant values.
§The sulfate yield at [Br^-] = 2 M was estimated to be 4%. An accurate experimental determination was not possible at this concentration of salt.

isotope effect (see Table II) and its relative insensitivity to changes in the concentration of bromide ion. Thus, if this ratio were correct, then at $[Br^-] = 2\ M$, for every seven molecules of the intermediate formed, five would return to reactant and only two would proceed to product. This is approaching an equilibrium condition between reactant and intermediate and would be expected to give rise to an isotope effect, k^H/k^D, of several fold.

An estimate of the true k_2/k_3 ratio, and with it the quantity k_3^H/k_3^D, the isotope effect for the C—H bond rupture step, can be obtained by a trial and error substitution into eq. [3][4] to give the best fit to the experimental values of k^H/k^D at the different concentrations of Br^-.

$$[3] \qquad \frac{k^H}{k^D} = \frac{k_1^H}{k_1^D} \cdot \frac{\frac{k_3^H}{k_3^D} \cdot \frac{k_2^H}{k_3^H} \cdot [Br^-] + 1}{\frac{k_2^H}{k_3^H} \cdot [Br^-] + 1}$$

In deriving this equation the reasonable assumption is made that the isotope effect for the return of the intermediate to reactants, k_2^H/k_2^D, is unity. The isotope effect at $[Br^-] = 0$, k_1^H/k_1^D, is, as seen from Table II, also unity. This procedure leads to $k_2/k_3 = 0.027$ and $k_3^H/k_3^D = 7.0$. The fit to the experimental data obtained by substitution of these values into eq. [3] can be seen by comparing the last two columns in Table II.[5]

The value obtained for k_2/k_3 (0.027) from isotope effect results is to be compared with the value (1.2) obtained on the assumption that the depression in $k_{obs}^H(1 + K[Br^-])$ with $[Br^-]$ (Fig. 1 of ref. 8) is due entirely to an increasing return of the intermediate to reactants as the Br^- concentration is increased. Clearly, therefore, almost all this depression in rate is the result of the salt effect. Indeed, it was fortunate that there was sufficient return of the intermediate to give a fruitful result in the application of the isotope effect test for the two-step mechanism. To our knowledge, the present work constitutes the first reported study of *variation* in kinetic hydrogen isotope effect during bromodeprotonation by variation of bromide ion concentration.

It is of interest to note that the isotope effect for the second step, k_3^H/k_3^D, is 7.0, which is about the value to be expected for C—H bond rupture in a reaction at 0 °C. Finally, it is most important to note that the ratio k_1^H/k_1^D, which is the ratio of the rates of formation of the intermediate from the two isotopic sulfonates, is unity within a precision of about ±0.02. The absence of a significant secondary isotope effect in this reaction is to be compared with other results, shown in Table III, where secondary effects of appreciable magnitude have been observed.

TABLE III

Reaction	Isotope effect	Reference
Bromination of benzene	$k^H/k^D = 0.97$	18

[4]*The corresponding equation for the sulfur isotope effect is given in our preceding paper (see eq. [9] of ref. 8).*

[5]*It is recognized that the k_2/k_3 ratio will not be entirely independent of ionic strength. The fact, however, that the isotope effect at two ionic strengths for $[Br^-] = 0.5\ M$ is the same within the limits of measurement indicates that the k_2/k_3 ratio is rather insensitive to changes in ionic strength.*

For personal use only.

It is suggested that the similar rate of formation of the intermediate in the bromodeprotonation of undeuterated and deuterated sodium *p*-methoxybenzenesulfonate is a consequence of a fortuitous cancellation in the transition state of the effect of hyperconjugation and of the rehybridization of the carbon orbitals from sp^2 to sp^3 (2, 23).

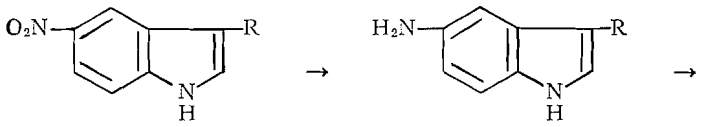
THE SYNTHESIS OF 5-DIMETHYLAMINOINDOLE AND DERIVATIVES[1]

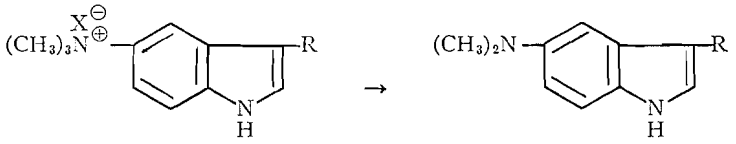
JOSEPH I. DEGRAW
Life Sciences Research, Stanford Research Institute, Menlo Park, California



Received August 17, 1965

ABSTRACT

The preparation of 5-dimethylaminoindole is described. This compound underwent the usual reactions typical of 3-unsubstituted indoles, and various 3-substituted derivatives were prepared. Syntheses for 5-dimethylaminotryptophan, 5-dimethylaminotryptamine, 5-dimethylamino-N,N-dimethyltryptamine, and 5-dimethylamino-α-methyltryptamine are reported.



The preparation of some 2-methyl-5-dimethylaminoindoles bearing a substituent at the 3-position was reported by Shaw (1) in 1954. This appears to be the only work done in this area, and the simplest member of this class of indoles, 5-dimethylaminoindole (IV*a*), has not been described. A synthesis of IV*a* starting from 5-nitroindole (I*a*) has been achieved by employing Shaw's general method. Several reactions pertinent to 3-unsubstituted indoles could be carried out on this compound, and various substituents were introduced at the 3-position.

The preparation of 5-aminoindole (II*a*) from 5-nitroindole (I*a*) has previously been accomplished by catalytic hydrogenation (2), but the extreme sensitivity of II*a* to air oxidation presents a problem in the work-up and purification. A more convenient reduction of I*a* was achieved with hydrazine and palladium in boiling ethanol to give a high yield of II*a*, which, when used immediately, required no further purification. The aminoindole (II*a*) was then treated with excess dimethyl sulfate, and the quaternized base was isolated as its picrate salt (III*a*). Stirring the picrate with Dowex 2 (chloride) resin readily converted it into the chloride (III*b*). Treatment of III*b* with sodium propoxide in boiling *n*-propanol effected demethylation to yield 5-dimethylaminoindole (IV*a*) in an overall yield of 53% from 5-nitroindole (I*a*).

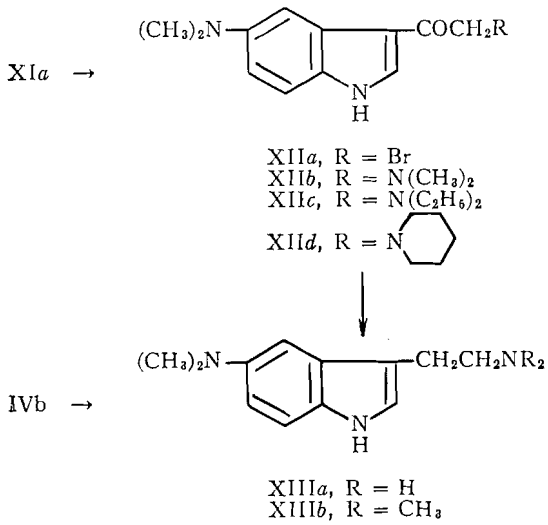
When IV*a* was treated with aqueous formaldehyde and secondary amines under the usual Mannich conditions, the 3-dialkylaminomethyl compounds (V*a*–V*c*) were obtained. Reaction of the gramine V*a* with diethyl formamidomalonate followed by acid hydrolysis and decarboxylation of the resulting amido diester (VI) gave 5-dimethylaminotryptophan (VII) as the hydrochloride salt. The biological properties of VII may be of interest; however, the related 5-aminotryptophan (3) did not seem to possess significant physiological activity (4).

Formylation of IV*a* with the phosphoryl chloride – dimethylformamide reagent according to the general procedure of Smith (5) gave the aldehyde (VIII) in a 51% yield. The aldehyde could not be condensed with nitromethane either by catalysis with ammonium acetate (6) or by water separation methods. However, VIII reacted quite readily with nitroethane and ammonium acetate to yield the nitrone (IX). Reduction of IX with lithium aluminium hydride produced 5-dimethylamino-α-methyltryptamine (X), which was isolated as its bis picrate salt.



If IV*a* was allowed to react with acetyl chloride or benzoyl chloride in the presence of stannic chloride (7, 8), the 3-position was readily acylated to yield the methyl ketone (XI*a*) or the phenyl ketone (XI*b*). Reduction of the ketones with lithium aluminium hydride proceeded very smoothly, and 5-dimethylamino-3-ethylindole (XI*c*) and 5-dimethylamino-3-benzylindole (XI*d*) were obtained. When 5-dimethylaminoindole was stirred with trifluoroacetic anhydride for a few hours, the 3-trifluoromethylketone (XI*e*) was obtained. This ketone was reduced to the corresponding alcohol (XI*f*) with sodium borohydride.

XI*a*, R = $COCH_3$
XI*b*, R = COC_6H_5
XI*c*, R = C_2H_5
XI*d*, R = $CH_2C_6H_5$
XI*e*, R = $COCF_3$
XI*f*, R = $CHOHCF_3$

The methyl ketone was treated with bromine in warm methanol (9) to give the bromoketone (XII*a*) in a poor yield. Displacement of the bromine atom with secondary amines in hot isopropanol generated the 5-dimethylamino-α-alkylaminomethylketones (XII*b*–XII*d*). The α-dimethylamino ketone (XII*b*) was reduced with lithium aluminium hydride to yield 5-dimethylamino-N,N-dimethyltryptamine (XIII*b*), characterized as its picrate salt.

A better method for the synthesis of 5-dimethylaminotryptamines was to hydrogenate 5-dimethylamino-3-indoleacetonitrile (IV*b*) in the presence of an excess of an appropriate amine. 5-Dimethylaminotryptamine (XIII*a*) and its N,N-dimethyl derivative (XIII*b*) were readily prepared in this manner. The nitrile (IV*b*) was prepared from 5-nitro-3-indoleacetonitrile (2*a*, 10) (I*b*) by the sequence I*b* → IV*b*.

EXPERIMENTAL

5-Aminoindole (IIa)

To a mixture of 25.0 g of 5-nitroindole (I), 1.2 g of 10% palladium on carbon, and 200 ml of absolute ethanol was slowly added 25 ml of 98–100% hydrazine. After the resulting exothermic reaction had subsided, the mixture was boiled under reflux for 2 h. The catalyst was removed by filtration and the filtrate was evaporated to leave a yellow solid residue. The crystals were shaken with 200 ml of water and collected, and the cake was dried *in vacuo* to leave 16.5 g (81%) of 5-aminoindole. In this work the aqueous wash was decanted and the damp residue used immediately in the next step to minimize exposure to the air. Recrystallization of a portion from benzene gave a sample, m.p. 131–134° (lit. (2*a*) m.p. 132–133°).

5-Indolyltrimethylammonium Picrate (IIIa)

To a mixture of 2 g (15.5 mmoles) of 5-aminoindole in 32 ml of water containing 5.7 g (68 mmoles) of sodium bicarbonate was added 6.20 ml (65.5 mmoles) of dimethyl sulfate over 12 min with stirring. The resulting dark solution was stirred another 10 min, warmed to 65°, and poured into a warm solution of 3.60 g (15.7 mmoles) of picric acid in 240 ml of water. The yellow, crystalline precipitate was allowed to stand for 2 h. It was collected, washed thoroughly with water and ether, and dried to leave 5.2 g (85%) of the picrate. Recrystallization from 75% ethanol yielded 4.3 g (70%), m.p. 171–173°. An analytical sample, m.p. 172–174°, was obtained by recrystallization from absolute ethanol.

Anal. Calcd. for $C_{17}H_{17}N_5O_7$: C, 50.6; H, 4.25; N, 17.4. Found: C, 50.8; H, 4.58; N, 17.8.

5-Indolyltrimethylammonium Chloride (IIIb)

A mixture of 300 g of Dowex 2 (chloride) resin, 46.0 g of the picrate (III*a*), and 1 200 ml of 83% methanol was stirred for 17 h at room temperature. The resin was removed by filtration and washed with 100 ml of methanol. The filtrate was evaporated *in vacuo* to leave a dark sirup, which was dissolved in 120 ml of hot isopropanol and diluted with 800 ml of acetone. The dark gum that precipitated was removed by decantation and the supernatant was diluted with another 700 ml of acetone. The solution was chilled for 3 days to yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

beige crystals, which were collected, washed with acetone, and dried to leave 13.5 g (57%) of product, m.p. 200–201°. An analytical sample, previously obtained in the same manner from another run, had m.p. 188–191°.

Anal. Calcd. for $C_{11}H_{15}ClN_2$: C, 62.7; H, 7.17; N, 13.3. Found: C, 62.8; H, 7.35; N, 13.0.

5-Dimethylaminoindole (IVa)

To a solution of 1.54 g (0.067 g-atom) of sodium in 270 ml of *n*-propanol was added 13.0 g (62 mmoles) of 5-indolyltrimethylammonium chloride, and the mixture was stirred at reflux for 17 h. It was evaporated to dryness *in vacuo* and the residue partitioned between 100 ml of water and 100 ml of ether. The aqueous portion was extracted with another 50 ml of ether, followed by washing of the combined ether extracts with 50 ml of water. The ether solution was dried over magnesium sulfate and evaported *in vacuo* to leave 8.2 g of a dark sirup. The sirup was distilled at reduced pressure; a total of 7.5 g (76%) of IV*a* as a clear liquid was collected at b.p. 135–140° and 0.25 mm. The liquid solidified to form white crystals, m.p. 45–47°. A sample that was sublimed for analysis had m.p. 49–50°; λ_{max}^{EtOH} 238 mμ (ε 22 900).

Anal. Calcd. for $C_{10}H_{12}N_2$: C, 75.0; H, 7.56; N, 17.5. Found: C, 75.1; H, 7.47; N, 17.4.

An optimum yield of 53% from 5-nitroindole was realized by using the crude intermediates (no purification whatever) directly in the following steps. The final distillation of IV*a* was sufficient for its purification.

3-Cyanomethylindole-5-trimethylammonium Picrate (IIIc)

To a mixture of 1.17 g (5.8 mmoles) of 5-nitro-3-indoleacetonitrile (10), 50 mg of 5% palladium on carbon, and 10 ml of absolute ethanol was added 0.90 ml (28 mmoles) of 100% hydrazine. When the resulting reaction had subsided, the mixture was boiled under reflux for 1.5 h. The catalyst was removed by filtration and the solvent was evaporated *in vacuo* to leave an amber sirup, whose infrared spectrum was in agreement with that of the aminonitrile (II*b*). The crude material was mixed with 2 ml of ethanol, 12 ml of water, and 2.20 g (26 mmoles) of sodium bicarbonate. Then, with stirring, was added 2.40 ml (25 mmoles) of dimethyl sulfate over 5 min. The mixture was stirred for 15 min and the resulting solution was heated at 65° for 5 min. A warm solution of 1.5 g of picric acid in 90 ml of water was added to give a yellow, crystalline precipitate. The picrate was collected, thoroughly washed with water, and dried to leave 1.90 g (73%), m.p. 181–206°. The crude picrate was stirred with 30 ml of hot methanol and chilled for 2 days to yield 1.60 g, m.p. 212–224°. An analytical sample, m.p. 221–224°, was obtained by recrystallization from methanol.

Anal. Calcd. for $C_{19}H_{18}N_6O_7$: C, 51.6; H, 4.10; N, 19.0. Found: C, 51.8; H, 3.97; N, 19.0.

3-Cyanomethylindole-5-trimethylammonium Chloride (IIId)

A mixture of 1.60 g of the picrate (III*c*), 10 g of Dowex 2 (chloride) resin, and 50 ml of 90% methanol was stirred for 3 h. The resin was removed by filtration and washed with a little methanol, and the filtrate was evaporated *in vacuo* to leave 0.90 g (90%) of III*d* as dark crystals. A recrystallization from 10 ml of ethanol yielded 0.68 g of tan crystals, m.p. 221–223°. Another recrystallization from ethanol yielded an analytical sample of off-white crystals, m.p. 220–221°.

Anal. Calcd. for $C_{13}H_{16}ClN_3$: C, 62.5; H, 6.45; N, 16.8. Found: C, 62.1; H, 6.32; N, 17.0.

5-Dimethylamino-3-indoleacetonitrile (IVb)

To a solution of 62 mg (2.7 mg-atoms) of sodium in 12 ml of *n*-propanol was added 600 mg (2.4 mmoles) of the methochloride (III*d*), and the mixture was boiled under reflux for 16 h. The solvent was removed *in vacuo* and the dark residue was partitioned between 20 ml of water and 20 ml of ether. The dark aqueous portion was extracted with another 20 ml of ether and the combined ether extracts were washed with 10 ml of water. The ether was dried over magnesium sulfate and evaporated to leave 340 mg of tan crystals, which were recrystallized from benzene (4 ml) to give 210 mg, m.p. 121–122°; λ_{max}^{Nujol} 3.20 μ (NH), 4.48 μ (C≡N).

Anal. Calcd. for $C_{12}H_{13}N_3$: C, 72.3; H, 6.57; N, 21.1. Found: C, 72.5; H, 6.49; N, 21.1.

3-Dimethylaminomethyl-5-dimethylaminoindole (Va)

A solution of 0.50 g (3.1 mmoles) of 5-dimethylaminoindole, 0.60 ml (3.3 mmoles) of 25% aqueous dimethylamine, 0.28 ml (3.5 mmoles) of 37% formaldehyde, and 2 ml of acetic acid was heated at 50° for 2 h. The solution was chilled and adjusted to pH 10–11 with 10% sodium hydroxide to give a white precipitate, which was collected, washed with water, and dried to leave 0.37 g. Recrystallization from 4 ml of cyclohexane yielded 0.20 g (29%) of V*a* as white crystals, m.p. 110–111°.

Anal. Calcd. for $C_{13}H_{19}N_3$: C, 71.9; H, 8.83; N, 19.4. Found: C, 72.0; H, 8.68; N, 19.2.

The bis methiodide, m.p. 220–225° (decomp.), was prepared in an 80% yield by treatment of V*a* with an excess of methyl iodide in alcohol.

Anal. Calcd. for $C_{15}H_{25}N_3I_2$: I, 50.6. Found: I, 50.0.

3-Piperidinomethyl-5-dimethylaminoindole (Vb)

This compound, m.p. 112–115°, was prepared in a 59% yield by a procedure analogous to that used for V*a*.

Anal. Calcd. for $C_{16}H_{23}N_3$: C, 74.7; H, 9.01; N, 16.3. Found: C, 75.0; H, 8.84; N, 16.1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3-Morpholinomethyl-5-dimethylaminoindole (Vc)

This compound, m.p. 82–85°, was prepared in a 15% yield by a procedure analogous to that used for V*a*.

Anal. Calcd. for $C_{15}H_{21}N_3O$: C, 69.5; H, 8.16; N, 16.2. Found: C, 69.7; H, 8.21; N, 16.1.

Diethyl 5-Dimethylamino-3-indolylmethylformamidomalonate (VI)

A mixture of 500 mg (2.3 mmoles) of 5-dimethylaminogramine, 470 mg (2.3 mmoles) of diethyl formamidomalonate, 60 mg (1.5 mmoles) of powdered sodium hydroxide, and 20 ml of toluene was stirred under reflux for 15 h in a nitrogen atmosphere. It was cooled to 70–80° and filtered, followed by evaporation of the filtrate *in vacuo* to a volume of 10 ml. The solution was chilled for 1 h, and the resulting white crystals were collected, washed with 3 ml of toluene, and dried to leave 580 mg of the amido diester (VI), m.p. 171–176°. Recrystallization from 10 ml of ethanol gave 420 mg (49%) of white crystals, m.p. 177–179°; λ_{max}^{Nujol} 3.05 μ, 3.15 μ (NH); 5.72 μ (ester C=O); 5.99 μ (amide C=O).

Anal. Calcd. for $C_{19}H_{25}N_3O_5$: C, 60.8; H, 6.72; N, 11.2. Found: C, 60.8; H, 6.91; N, 11.1.

5-Dimethylamino-dl-tryptophan (VII)

A solution of 350 mg of the formamidomalonate (VI) in 8 ml of 3 *N* hydrochloric acid was boiled under reflux for 1.5 h. The solution was evaporated to dryness *in vacuo* to give a sirup that was crystallized when mixed with 10 ml of acetone. The crystals were collected, washed with acetone, and dried to leave 160 mg (54%) of the amino acid hydrochloride, m.p. 208–212°; λ_{max}^{pH13} 232 mμ (ϵ 26 100). A thin-layer chromatoplate (cellulose, 1.5 *N* ammonia) showed a single ultraviolet-absorbing spot, R_f 0.8.

Anal. Calcd. for $C_{13}H_{17}N_3O_2 \cdot 2HCl \cdot H_2O$: C, 46.2; H, 6.27; N, 12.4; Cl, 21.0. Found: C, 46.2; H, 6.00; N, 11.9; Cl, 19.6.

The material was quite hygroscopic. A portion was dissolved in hot isopropanol and precipitated out with acetone to yield white crystals, m.p. 220–222°. A chromatoplate (cellulose, *n*-butanol – acetic acid – water (4:1:5)) showed a single spot, R_f 0.5, as detected by iodine vapor.

Anal. Calcd. for $C_{13}H_{17}N_3O_2 \cdot 1.5HCl \cdot H_2O$: C, 48.9; H, 6.32; N, 13.1; Cl, 16.7. Found: C, 49.0; H, 6.53; N, 12.9; Cl, 16.7.

3-Formyl-5-dimethylaminoindole (VIII)

To 1.0 ml of dimethylformamide at 5° was added 0.3 ml (3.4 mmoles) of phosphoryl chloride, the temperature being kept at 10–15°. A solution of 0.50 g (3.1 mmoles) of 5-dimethylaminoindole in 0.60 ml of dimethylformamide was added over 5 min, the temperature being maintained at 20–25°. The mixture was kept for 2 h at room temperature and diluted with 15 ml of ice water, with stirring, to give a yellow solution. The pH was adjusted to 10–11 with 10% sodium hydroxide to give a yellow, crystalline precipitate. The mixture was warmed on the steam bath for about 5 min, with the addition of small amounts of alkali to maintain the pH at 10–11. The precipitate was stirred for 20 min and was filtered. The yellow cake was thoroughly washed with water and dried to give 0.49 g of the aldehyde, m.p. 195–198°. A recrystallization from 12 ml of ethanol yielded 0.3 g (51%) of yellow crystals, m.p. 214.5–217.0°; λ_{max}^{Nujol} 3.15 μ (NH), 6.10 μ (aldehyde C=O); λ_{max}^{EtOH} 240 mμ (ϵ 19 300), 282 mμ (ϵ 11 500).

Anal. Calcd. for $C_{11}H_{12}N_2O$: C, 70.2; H, 6.43; N, 14.9. Found: C, 70.1; H, 6.47; N, 15.1.

1-(5-Dimethylamino-3-indolyl)-2-nitro-1-propene (IX)

A solution of 300 mg of 5-dimethylamino-3-formylindole and 120 mg of ammonium acetate in 5 ml of nitroethane was heated on the steam bath for 1.5 h in an open flask. The dark red solution was evaporated *in vacuo* and the residual sirup was stirred with 10 ml of water, thereby causing crystallization. The red-black crystals were collected, washed with water and ether, and dried to leave 290 mg of product. A recrystallization from 5 ml of ethanol yielded 145 mg, m.p. 168–170°; λ_{max}^{Nujol} 3.1 μ (NH), 6.18 μ (C=C), 7.9 μ (NO_2); λ_{max}^{EtOH} 238 mμ (ϵ 25 400), 415 mμ (ϵ 13 300).

Anal. Calcd. for $C_{13}H_{15}N_3O_2$: C, 63.7; H, 6.16; N, 17.1. Found: C, 63.9; H, 6.44; N, 17.2.

5-Dimethylamino-α-methyltryptamine Picrate (X)

The nitrone (IX) (1.23 g) was reduced with 1.9 g of lithium aluminium hydride in 30 ml of tetrahydrofuran by boiling the solution under reflux for 15 h. The excess hydride was cautiously decomposed at 0–5° by the addition of ethanol, followed by water. The solvent was removed *in vacuo* and the residue was suspended in 100 ml of ether. Water was added until the solid material became pasty, but mobile. The mixture was shaken thoroughly and the ether layer was decanted. Another 20 ml ether extraction was similarly conducted. The ether extract was dried over magnesium sulfate and evaporated *in vacuo* to leave 0.92 g of an amber sirup. The infrared spectrum showed loss of the nitro band at 7.9 μ. The sirup was dissolved in 10 ml of ethanol and added to 2.7 g of picric acid in 150 ml of warm water. The yellow, crystalline picrate was collected and recrystallized from 15 ml of acetone–ethanol (3:2) to give 1.1 g, m.p. 203–206°. A 200 mg portion was further recrystallized from 3 ml of acetone to yield 121 mg, m.p. 215.5–216.5°.

Anal. Calcd. for $C_{25}H_{25}N_9O_{14}$: C, 44.9; H, 3.73; N, 18.7. Found: C, 44.7; H, 3.82; N, 19.1.

3-Acetyl-5-dimethylaminoindole (XIa)

To an ice-cold, stirred solution of 0.50 g (3.1 mmoles) of 5-dimethylaminoindole (IV*a*) in 8 ml of benzene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was slowly added 0.32 ml (4.5 mmoles) of acetyl chloride. Then 0.93 ml (8.0 mmoles) of anhydrous stannic chloride in 2 ml of benzene was added over 10 min to precipitate an orange complex. The mixture was stirred for 1.75 h at room temperature and then poured into 25 ml of ice water. The benzene layer was removed and the aqueous portion was made strongly alkaline with 10% sodium hydroxide. The mixture was extracted with three 15 ml portions of ethyl acetate, which were combined, washed with 10 ml of water, and dried over magnesium sulfate. The solvent was evaporated to leave 0.53 g of a pale yellow, crystalline residue. The residue was treated with 15 ml of ether and the solid collected to give 0.37 g (59%) of XI*a* as yellow crystals, m.p. 223–231°. A recrystallization from ethyl acetate yielded an analytical sample, m.p. 227–230°; λ_{max}^{EtOH} 240 mμ (ϵ 20 900), 282 mμ (ϵ 9 900).

Anal. Calcd. for $C_{12}H_{14}N_2O$: C, 71.3; H, 6.98; N, 13.8. Found: C, 70.9; H, 6.87; N, 14.1.

3-Benzoyl-5-dimethylaminoindole (XIb)

To a well-stirred, ice-cold solution of 1.00 g (6.2 mmoles) of 5-dimethylaminoindole in 15 ml of benzene was slowly added 1.04 ml (9.0 mmoles) of benzoyl chloride. Then, at 0–5°, 1.86 ml (16 mmoles) of stannic chloride in 6 ml of benzene was added over 10 min. Stirring was continued for 1.5 h at room temperature and the mixture was poured into 100 ml of ice water. After the mixture was warmed on the steam bath to obtain complete solution, 10% sodium hydroxide was added until a pH of about 12 was reached. The resulting yellow precipitate was extracted with three 25 ml portions of *n*-butanol, dried over magnesium sulfate, and evaporated to dryness *in vacuo*. The residue was recrystallized from 25 ml of ethanol to yield 1.10 g (67%) of XI*b*, m.p. 213–214°.

Anal. Calcd. for $C_{17}H_{16}N_2O$: C, 77.3; H, 6.10; N, 10.6. Found: C, 76.9; H, 6.38; N, 10.4.

3-Ethyl-5-dimethylaminoindole Picrate (XIc)

5-Dimethylamino-3-acetylindole (XI*a*, 1.27 g) was reduced with 0.50 g of lithium aluminium hydride in 20 ml of tetrahydrofuran by boiling the mixture under reflux for 2.5 h. The excess hydride was destroyed with a little ethanol and water. The solvent was evaporated, the residue was diluted with 25 ml of ether, and enough water was added to create a pasty aqueous phase. The mixture was shaken and the ether decanted. Another extraction with 25 ml of ether was performed, and the ether was dried over magnesium sulfate and evaporated to leave 1.04 g of sirup. The sirup, in 10 ml of ethanol, was added to 1.6 g of picric acid in 120 ml of hot water to yield 2.1 g of the yellow, crystalline picrate. A recrystallization from 200 ml of 90% ethanol gave 1.15 g of yellow crystals, m.p. 197–198°. An analytical sample, m.p. 200–202°, was obtained by a similar recrystallization of material from another run.

Anal. Calcd. for $C_{18}H_{19}N_5O_7$: C, 51.8; H, 4.59; N, 16.8. Found: C, 52.1; H, 4.83; N, 17.0.

3-Benzyl-5-dimethylaminoindole (XId)

The phenyl ketone (XI*b*, 3.30 g) was reduced with lithium aluminium hydride (1.00 g) as described above to yield 3.05 g (99%) of XI*d* as the crystalline free base. A recrystallization from 40 ml of cyclohexane, with carbon treatment, yielded 1.60 g (52%) of white crystals, m.p. 63–64°.

Anal. Calcd. for $C_{17}H_{18}N_2$: C, 81.6; H, 7.25; N, 11.2. Found: C, 81.2; H, 7.19; N, 11.2.

3-Trifluoroacetyl-5-dimethylaminoindole (XIe)

A suspension of 0.5 g of 5-dimethylaminoindole in 5 ml of trifluoroacetic anhydride was stirred at room temperature for 5 h. The mixture was evaporated *in vacuo* and the residue was stirred with 20 ml of a saturated sodium bicarbonate solution for 1 h. The yellow crystals were collected, washed with water, and dried to leave 0.73 g of the trifluoroketone. Recrystallization from 8 ml of ethyl acetate gave 0.35 g of orange crystals, m.p. 234–238°, and a second crop of 0.14 g; λ_{max}^{Nujol} 3.1 μ (NH), 6.1 μ (C=O), 8.5 μ, 8.8 μ (CF_3); λ_{max}^{EtOH} 240 mμ (ϵ 18 200), 300 mμ (ϵ 10 000).

Anal. Calcd. for $C_{12}H_{11}F_3N_2O$: C, 56.4; H, 4.33; N, 10.9. Found: C, 56.4; H, 4.25; N, 11.3.

2,2,2-Trifluoro-1-(5-dimethylamino-3-indolyl)ethanol (XIf)

To a stirred suspension of 0.42 g of 5-dimethylamino-3-trifluoroacetylindole (XI*e*) in 6 ml of ethanol was slowly added 0.40 g of sodium borohydride. The mixture was stirred for 40 min and evaporated to dryness *in vacuo*. The residue was stirred with 25 ml of water for 30 min and filtered. The cake was washed with water and dried to leave 0.43 g (100%) of the product (XI*f*), m.p. 189–191°; λ_{max}^{Nujol} 3.05 μ (OH, NH), 8.65 μ, 8.95 μ (CF_3), *no* ketone at 6.1 μ. An analytical sample that was obtained by recrystallization from benzene of material from another run had m.p. 187–190°.

Anal. Calcd. for $C_{12}H_{13}F_3N_2O$: C, 55.8; H, 5.08; N, 10.9. Found: C, 55.9; H, 5.18; N, 10.8.

3-Bromcacetyl-5-dimethylamincindole (XIIa)

To an ice-cold, stirred suspension of 10.0 g of 5-dimethylamino-3-acetylindole in 200 ml of methanol was slowly added 3.5 ml of bromine in 50 ml of methanol over 15 min. The resulting dark solution was boiled under reflux for 2 h and evaporated to dryness *in vacuo*. The residue was dissolved in 300 ml of water and the solution was taken to pH 7–8 with saturated sodium bicarbonate. The brown precipitate was collected, washed with water, and dried to leave 11.3 g. It was extracted with four 100 ml portions of boiling ethyl acetate, and the solution was chilled for 15 h to yield 1.9 g of product that was suitable for further use.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The infrared spectrum was similar to that of the starting methyl ketone except for a probable C—Br band at 15.0 μ.

3-Dimethylaminoacetyl-5-dimethylaminoindole (XIIb)

A mixture of 1.4 g of the bromoketone (XII*a*), 1.5 ml of anhydrous dimethylamine, and 30 ml of isopropanol was boiled under reflux for 1.5 h. The solvent was evaporated and the residue dissolved in 20 ml of water. The pH was adjusted to 7–8 and a small amount of brown precipitate was removed. The solution was taken to pH 11–12 to precipitate the crystalline product, which was collected, washed with water, and dried to leave 0.97 g, m.p. 196–220°. A recrystallization from isopropanol gave 0.66 g (54%), m.p. 208–213°. An analytical sample, similarly prepared, had m.p. 217–220°.

Anal. Calcd. for $C_{14}H_{19}N_3O$: C, 68.5; H, 7.81; N, 17.1. Found: C, 68.4; H, 7.89; N, 17.0.

3-Diethylaminoacetyl-5-dimethylaminoindole (XIIc)

The bromoketone (280 mg) was allowed to react with diethylamine (1.0 ml) in the same manner as above, to yield 100 mg of XII*c* as white crystals, m.p. 167.5–170°, after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{16}H_{23}N_3O$: C, 70.3; H, 8.48; N, 15.4. Found: C, 69.7; H, 8.26; N, 15.2.

3-Piperidinoacetyl-5-dimethylaminoindole (XIId)

The bromoketone (200 mg) was allowed to react with piperidine (0.4 ml) in the same manner as above, to yield 125 mg of XII*d* as white crystals, m.p. 203–206°, after recrystallization from isopropanol.

Anal. Calcd. for $C_{17}H_{23}N_3O$: C, 71.5; H, 8.12; N, 14.7. Found: C, 70.9; H, 7.93; N, 14.6.

3-(2-Dimethylaminoethyl)-5-dimethylaminoindole Dipicrate (XIIIb)

Method A

The α-dimethylaminoketone (XII*b*, 200 mg) was reduced with lithium aluminium hydride (150 mg) in hot tetrahydrofuran. The excess hydride was destroyed with alcohol and water, and the solvent removed *in vacuo*. The residue was partitioned between water and ether, and the ether was dried over magnesium sulfate. Evaporation of the ether left 120 mg of partially crystalline residue. The bis picrate, m.p. 190–194°, was prepared from aqueous–alcoholic picric acid and recrystallized from 50% 2-methoxyethanol. A second recrystallization from acetone gave yellow crystals, m.p. 193.5–196°.

Anal. Calcd. for $C_{26}H_{27}N_9O_{14}$: C, 45.3; H, 3.95; N, 18.3. Found: C, 45.3; H, 4.10; N, 18.7.

Method B

A mixture of 420 mg of 5-dimethylamino-3-indoleacetonitrile (IV*b*), ½ teaspoonful of W-2 Raney nickel, 15 ml of methanol, and 5 ml of anhydrous dimethylamine was shaken under 3 atmospheres of hydrogen for 18 h. The catalyst was removed and the solvent was evaporated *in vacuo* to leave 426 mg of an amber sirup, whose infrared spectrum was nearly similar to that of the material prepared by method A. The bis picrate (1.13 g) was prepared as above and treated with 25 ml of warm acetone to yield 0.63 g, m.p. 190–193°, and a second crop of 0.16 g, m.p. 189–193°.

5-Dimethylaminotryptamine Dipicrate (XIIIa)

The nitrile (IV*b*, 420 mg) was hydrogenated in the presence of Raney nickel and 25 ml of methanolic ammonia as described above. The bis picrate was similarly prepared to yield 1.06 g (76%) of yellow crystals, m.p. 210–215°. A treatment with hot acetone (12 ml) gave 0.88 g, m.p. 214–217°.

Anal. Calcd. for $C_{24}H_{23}N_9O_{14}$: C, 43.6; H, 3.51; N, 19.1. Found: C, 43.9; H, 3.58; N, 19.1.

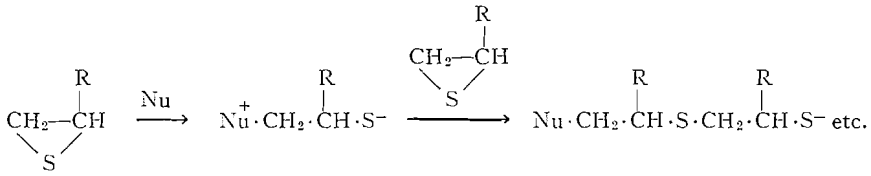
THE CHEMISTRY OF EPISULFIDES

I. THE REACTIVITIES OF PROPYLENE SULFIDE AND PROPYLENE OXIDE TOWARDS ANILINE

NEIL S. ISAACS
Department of Chemistry, University of Victoria, Victoria, British Columbia



Received September 7, 1965

ABSTRACT

The rates of reaction of propylene sulfide and propylene oxide with aniline have been measured at three temperatures between 30° and 50°. The episulfide is found to be the less reactive and has the higher activation energy. The results are interpreted as indicating a considerable degree of ring opening in the transition state, with the strain energy of the ring providing a considerable portion of the activation energy.

Although the ring-opening reactions of 1,2-epoxides have been examined thoroughly and well documented (1, 2) with regard to both the products formed and rate measurements, their sulfur analogues have received scant attention. No kinetic or mechanistic investigations have yet been reported, despite the fact that such work might be expected to yield information concerning the importance of such factors as ring strain and electronic effects in both heterocyclic systems. It was for these reasons that we undertook initially a comparison of the reactivities of a typical episulfide, propylene sulfide, with its analogue, propylene oxide.

Ring opening of episulfides, unlike epoxides, is frequently complicated by polymerization (3, 4), since the initial thiolate ion is strongly nucleophilic.

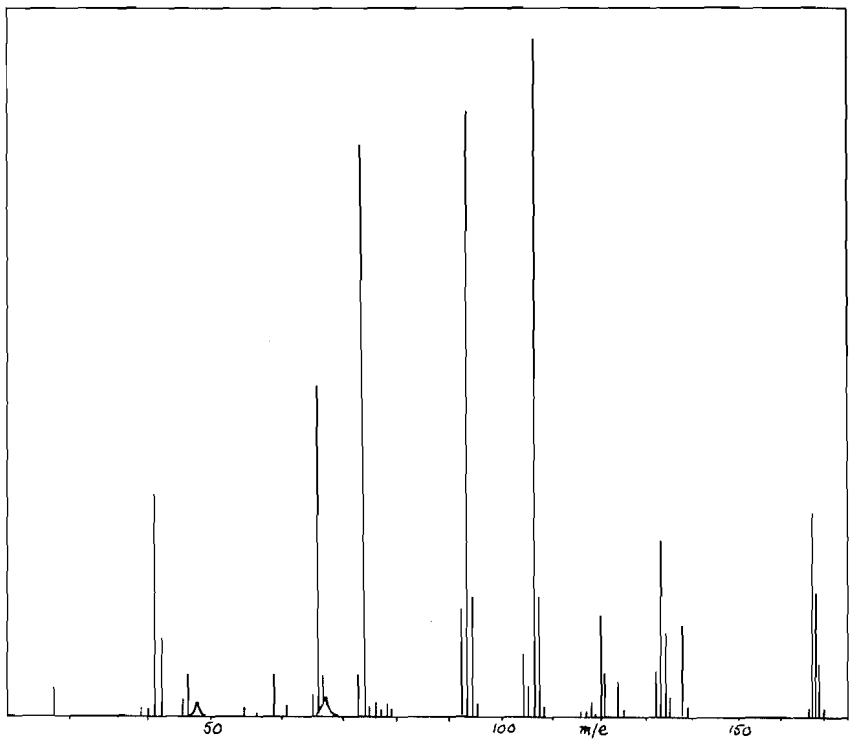
Thus, hydroxide and alkoxide ions, carbanions, and primary and secondary aliphatic amines give rise to polymers which may account for anything from 10 to 90% of the products. These reactions are clearly unsuited to kinetic studies, and our attention was turned to weaker bases. Aniline was found to react smoothly, albeit slowly, with propylene sulfide in ethanol to give the β-anilinothiol in quantitative yield. The analogous product was obtained from the reaction of aniline with propylene oxide. Other reagents which were found to give no polymer were acetic acid and acetyl chloride. Results with these acidic reagents will be published elsewhere.

Products of the Reactions

Propylene Sulfide and Aniline

An unsymmetrically substituted episulfide was chosen to compare the reactivities at either carbon atom of the ring. Thus the products might be either I or II (Z = S), or a mixture of the two. It is necessary to establish that the directions of ring opening of the episulfide and epoxide are similar. The failure to meet this criterion might indicate mechanistic differences between the reactions and thus render comparisons dubious. Propylene oxide in basic solution is usually attacked at the primary carbon atom (1), but

there is at least one reference in the literature (5) to attack by a base on the secondary carbon atom in propylene sulfide. Since chemical tests cannot distinguish between a primary and a secondary thiol, attempts were made to determine the identity of the product by spectroscopic means. Attempted nuclear magnetic resonance measurements in a variety of solvents revealed that the thiol proton resonated very close to the complex methylene absorption and that the splitting pattern could not be differentiated unambiguously even after deuteration. The best structural evidence was given by the mass spectrum (Fig. 1), which confirmed the molecular weight of 167 and indicated an entirely reasonable



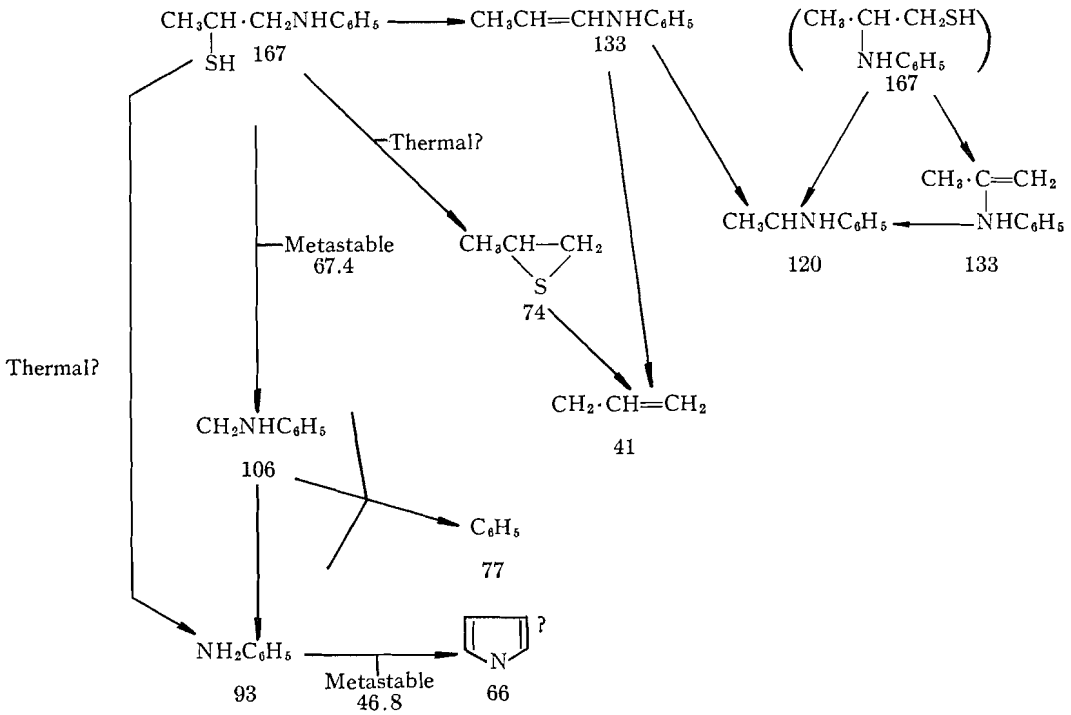


FIG. 1. Mass spectrum (20 V) of the propylene sulfide – aniline product.

degradation based on the secondary thiol (I, Z = S) (Reaction Scheme 1). In particular, the base peak at $m/e = 106$ corresponds to a loss of C_2H_5S, which readily results from the fission of the bond between the original ring carbon atoms of I (with the nitrogen-containing fragment retaining the charge) but which cannot be obtained from structure II (Z = S) without a minimum of two prior rearrangements. The much weaker peak at $m/e = 120$, corresponding to a loss of CH_3S from the molecular ion, could be due to a certain amount of the primary thiol, but could also be explained by successive losses of H_2S (giving rise to the peak at $m/e = 133$) and CH from I. Furthermore, the origin of the base peak by direct fission of the parent molecular ion is confirmed by the presence of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

strong metastable peak at $106^2/167 = 67.3$; no such transition is observed for $120^2/167 = 86.2$.

REACTION SCHEME 1.

Propylene Oxide and Aniline

Considerable evidence has been accumulated which points to the invariably greater susceptibility to attack by amines of the primary carbon of a monosubstituted ethylene oxide (1). The product of the reaction between aniline and propylene oxide has been studied by Petrov (10) and assigned the structure I (Z = O) on the grounds that it cyclized under the action of benzaldehyde to the known 2,3-diphenyl-5-methyloxazolidine. Confirmation of this is provided by the mass spectrum (Fig. 2, Reaction Scheme 2), which is analogous to that of the propylene sulfide product. From the molecular ion at $m/e = 151$ is derived the same base peak at $m/e = 106$ corresponding to a loss of $CH_3CH{\cdot}OH$, the direct transition being established by a metastable peak at $106^2/151 = 74.3$. Again, a weak peak at $m/e = 120$ may be explained as derived from II (Z = O) by scission of CH_2OH or by successive losses of water (leading to $m/e = 133$) and CH from I (Z = O). Precedents for this type of fission with rearrangement are known (6). The reason for the appearance of a peak of mass 79 (pyridine?) although the aniline moiety in the previous spectrum produced a fragment at mass 66 (pyrrole?) is not understood, but this result may indicate a slight change in the conditions under which the spectra were run. Accordingly, we regard the products derived from both propylene sulfide and propylene oxide as being entirely analogous and resulting from attack of the aniline on the primary carbon in either case, with the possibility of the presence of a small amount of the product of secondary attack.

Kinetic Methods

Sufficient pure aniline and either propylene sulfide or propylene oxide were weighed out, separately dissolved in 99.8% ethanol, and brought to the required temperature. The solutions were mixed at $t = 0$ and the mixture was quickly made up to a calibrated volume with ethanol. The initial concentrations were approximately 0.1 M in episulfide or epoxide and 0.15 M in aniline.

Aliquots of 1.0 ml volume were withdrawn at appropriate intervals and analyzed spectrophotometrically. Each aliquot was placed in a 50 ml graduated flask with a little 98% ethanol. The following reagents were added successively over a period of 3–4 min, to convert the aniline into phenylazo-β-naphthol: 2 ml 5% sodium nitrite solution, 5 ml 1.0 N hydrochloric acid, 5 ml 5% β-naphthol solution in ethanol, and 5 moles 2.0 N sodium hydroxide. The flask was then filled to the mark with ethanol. After dilution of 1.0 ml of the resulting deep red solution to 50 ml with ethanol containing 2 ml 2 N sodium hydroxide, the absorbance at 510 mμ was recorded spectrophotometrically with a 10 mm path length. The analytical method was calibrated against standard solutions of aniline in ethanol and with solutions of pure phenylazo-β-naphthol in ethanol, and was shown to be reproducible and accurate to 1.5%. The presence of the reaction product in the analytical solution contributed negligibly to the production of the color, and the very slight brown color inevitably accompanying the β-naphthol was compensated for by subtracting a blank determination carried out with each run. Duplicate kinetic runs were carried out in baths thermostatted to ±0.1° or better and at three or four different temperatures.

Kinetic Results

Good second-order rate plots were obtained as far as the reactions were followed, which, except for the slowest, was to 75% completion. Bimolecular rate constants are shown in Table I and activation parameters in Table II and Fig. 3. The reproducibility of the rate constants, measured as the ratio of the mean deviation of values obtained from individual points on the rate plot to the mean value obtained from the slope, was of the order of 2–3%.

TABLE I

Specific rate constants for reactions with aniline

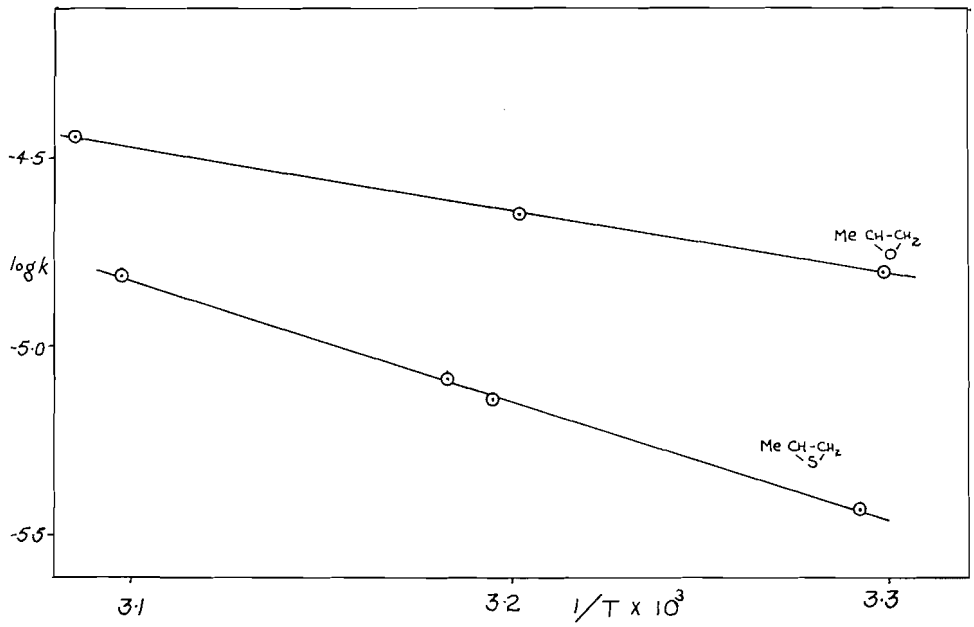

FIG. 3.

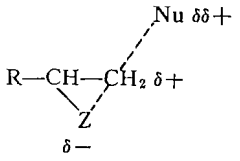
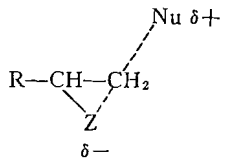


DISCUSSION

The results demonstrate the notably lower reactivity of the episulfide to nucleophilic attack as compared with the epoxide. The difference, a factor of from two to six over the temperature range studied, is remarkably small if one considers the profound structural change involved. However, the reaction rates of epoxides have been noted previously (7, 8) as being influenced very little by the electronic effects of substituents on the ring. The low value for the activation energy for propylene oxide is also striking and indicates convergence of the rates at around 85°. Parker and Isaacs (1) have discussed the ring-opening reactions of epoxides in terms of a gradation of mechanisms ranging from a 'S_N1-like' transition state (III), in which much polar character (though no free carbonium ion) is present, to a 'S_N2-like' transition state (IV), in which bond making and fission are smoothly concerted (though the incoming and leaving groups are not collinear with the carbon atom). The episulfides may similarly be considered.



The attack of aniline should take place more readily on a primary carbon atom than on a secondary carbon atom for steric reasons, and would be expected to attack propylene oxide more readily than propylene sulfide by virtue of the greater polarization of the C—O bond as compared with that of the C—S bond. The latter, however, is probably the more easily broken (the energies for homolysis are of the order of 75 and 55 kcal $mole^{-1}$, respectively (9)). The balance of these effects will determine the reactivities of the compounds and the detailed reaction paths which they follow, each tending towards a minimum of activation energy. Thus we might expect to find in the transition state for propylene sulfide a smaller degree of bond making between aniline and carbon and a greater degree of bond breaking between carbon and the heteroatom than in the case of propylene oxide. In other words, the transition state for episulfide should be a looser structure than that for epoxide, though both are more akin to IV than to III. The greater radius of the sulfur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

atom than of the oxygen atom would also contribute towards a lesser degree of solvation around the developing anionic site in the episulfide. That this is so is demonstrated by the less negative entropy of activation shown by propylene sulfide. Solvation effects are undoubtedly most important. Reactions between amines and epoxides may become very sluggish or immeasurably slow in nonpolar aprotic media (13).

III (Z = S, O)

IV (Z = S, O)

When the values obtained for the enthalpies of activation are discussed, a further factor must be considered, namely, the release of the potential energy of bond-angle deformations in the three-membered rings. This strain energy will tend to reinforce the activation process as the reaction proceeds, and to reduce the energy which has to be drawn from kinetic sources to reach the transition state. The ring-strain energies of ethylene oxide and ethylene sulfide have been estimated (11) by hydrogenation methods as 14 and 9 kcal mole^{-1}, respectively; these values should not be substantially different for propylene oxide and propylene sulfide. The difference between them, namely, 5 kcal mole^{-1}, should be the difference between the activation energies for the two reactions, other effects being equal. The difference found, 7.5 kcal mole^{-1}, is in the predicted direction and is larger by 2.5 kcal than the value suggested by ring-strain considerations alone. This may be accounted for by the factors discussed above, of which, in both reactions, bond formation is more pronounced than bond breaking in the transition state, and this to a greater extent with propylene oxide than with propylene sulfide.

EXPERIMENTAL

Mass spectra were recorded on a Hitachi Perkin–Elmer mass spectrometer with a 20 V electron beam and sample pressures of 1–2 × 10^{-7} Torr.

Visible spectrophotometry was carried out in a Beckman DB machine.

Propylene sulfide was prepared from propylene oxide in 40–60% yield by the method of Bordwell and Anderson (12) and was purified by careful fractionation through a fractionating column having 20 theoretical plates, the middle fraction being collected, b.p. 73.5 °C.

Propylene oxide, Eastman reagent grade, was purified by fractional distillation, b.p. 35 °C.

Aniline was purified by regeneration from the recrystallized hydrochloride followed by distillation through a short Vigreux column, the middle fraction being collected, b.p. 185°. This was stored under nitrogen and in the absence of light, under which conditions it remained colorless.

The Reaction between Propylene Sulfide and Aniline

Propylene sulfide was dissolved in four times its weight of 98% ethanol, and a 1.5-fold *M* excess of aniline added. The mixture was allowed to stand in a water bath at 50° for 3 days, after which the solvent and unreacted episulfide were removed at the pump; then the residue was distilled at 1 mm pressure, 1-anilinopropan-2-thiol being collected (after the excess aniline had passed over) as a colorless, unpleasant-smelling liquid, b.p. 86° at 1 mm, n_D^{25} 1.5829.

Anal. Found: C, 64.69; H, 7.68; mol. wt. (by mass spectrum) 167. $C_9H_{13}NS$ requires C, 64.70; H, 7.78; mol. wt. 167.

A negligible quantity of involatile material remained in the distillation flask. 1-Anilinopropan-2-ol was prepared according to Petrov (10). When the reaction between propylene oxide and aniline was allowed to go to completion, an undistillable material was isolated after the 1-anilinopropan-2-ol had been removed, presumably N,N-bis(2-hydroxypropyl) aniline, amounting to some 10% of the products. The formation of this compound was negligible at 50–70% reaction when an excess of aniline was used.

ÉTUDES SUR LES PHÉNYL-5 CYCLOHEXANEDIOLS-1,3 ISOMÈRES

JEAN-CLAUDE RICHER ET NGUYEN-THI-THANH-HOA[1]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 23 août 1965

RÉSUMÉ

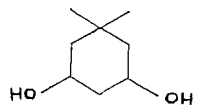
Les trois phényl-5 cyclohexanediols-1,3 isomères ont été préparés et caractérisés. Les configurations de ces produits ont été attribuées grâce à leurs spectres infra-rouges et de résonance magnétique nucléaire. Les vitesses d'oxydation chromique de ces diols ont aussi été déterminées; il a été observé une fois de plus que ces vitesses relatives sont dans l'ordre prévu par l'encombrement stérique auquel est soumis chacun des groupes hydroxyles.

INTRODUCTION

Dans un travail précédent (1), les configurations des diméthyl-5,5 cyclohexanediols-1,3 (I et II) ont été assignées grâce à leurs vitesses relatives d'oxydation chromique. Cette preuve de configuration a récemment été attaquée par Finegold et Kwart (2), qui l'ont qualifiée de douteuse. Depuis, cette méthode a été confirmée pour la détermination des configurations de monoalcools (3, 4) alors que Durocher (5) et Durocher et Favre (6) l'ont appliquée avec succès dans le cas de diols bicycliques. Nous voulons rapporter dans le présent travail quelques observations ayant trait aux phényl-5 cyclohexanediols-1,3 (III–V); à cause de la présence du groupe phényle (7), nous considérons ces diols comme conformationnellement fixés.

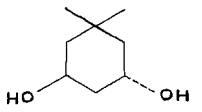
RÉSULTATS

Les diols recherchés ont tous été obtenus à partir de la phényl-5 cyclohexanedione-1,3 (VI), préparée d'après les indications de Vorländer (8). D'une part, l'hydrogénation catalytique de cette cétone en présence de nickel de Raney, à pression atmosphérique et à la température de la pièce (9), conduit au phényl-5 cyclohexanediol-1,3 *cis* (diaxial III), p.f. 135–136°, dont le spectre infra-rouge en solution diluée montre une bande caractéristique due aux ponts hydrogènes intramoléculaires (10); les autres caractéristiques du composé sont résumées dans le Tableau I. D'autre part, la réduction de la dicétone VI par le sodium et l'éthanol d'après les indications de Crossley et Renouf (11) fournit en prépondérance le phényl-5 cyclohexanediol-1,3 *cis* (diéquatorial IV), p.f. 160–161°; une faible quantité du phényl-5 cyclohexanediol-1,3 *trans* (V), p.f. 132.5–133.5° (abaissé par mélange avec le *cis* diaxial), est formée aux côtés du diol IV. Les propriétés caractéristiques de ces produits sont résumées au Tableau I.



Afin de prouver d'une façon non-ambigüe la configuration du diol *trans* V, la synthèse proposée par Tamm (12) et Mühle et Tamm (13) et représentée dans le Schéma Réactionnel 1 a été réalisée en suivant fidèlement la procédure expérimentale décrite par Durocher et Favre (6). Cette synthèse conduit à un diol, p.f. 132.5–133.5, qui est en tous points identique au phényl-5 cyclohexanediol-1,3 *trans* (V) décrit plus haut et que Crossley et Renouf (11) appelaient "*cis* modification".

DISCUSSION



Les configurations proposées pour les diols sont cohérentes avec leurs modes de formation. En effet il est maintenant bien établi, d'une part, que la réduction des dicétones

[1]*Extrait du mémoire présenté par Mlle. Nguyen-Thi en vue de l'obtention du grade de Maître ès Sciences, Faculté des Sciences, Université de Montréal, mars 1965.*

par le sodium et l'alcool conduit principalement aux glycols diéquatoriaux (1, 5, 6, 9, 14, 15); d'autre part, la synthèse du produit *trans* V d'après la méthode de Tamm (12, 13) reprise par Durocher et Favre (6) et Durocher (5) est non-ambigüe. Quant à l'hydrogénation catalytique des dicétones maintenues dans une conformation rigide comme dans

TABLEAU I

	cis diaxial III	*cis* diéquatorial IV	*trans* V
Point de fusion (°C)	135–136	160–161 (litt. (11) 160)	132.5–133.5 (litt. (11) 134)

le cas présent, les résultats obtenus jusqu'à maintenant (5, 6, 9) indiquent que les diols diaxiaux sont formés en prépondérance. De plus le pont hydrogène intramoléculaire observé dans le spectre infra-rouge du produit III ne peut être expliqué que par une configuration diaxiale des deux groupes hydroxyles (10). Le fait que le spectre de résonance magnétique nucléaire du produit V, p.f. 132.5–133.5°, montre deux bandes, à 3.66 et 4.33 p.p.m., dues à des hydrogènes carbinoliques indique que ce composé est non symétrique et supporte la configuration *trans* attribuée à ce produit.

SCHÉMA RÉACTIONNEL 1.

Les vitesses relatives d'oxydation chromique (1:3.24:4.75) sont dans l'ordre prévu grâce à l'empêchement stérique auquel sont soumis les groupes hydroxyles (diéquatoriaux, axial–équatorial, diaxiaux), et confirment les configurations attribuées. Les résultats obtenus dans le présent travail montrent une fois de plus l'utilité des oxydations chromiques pour la détermination des configurations relatives des alcools et des diols secondaires cycliques; il semble donc que les objections soulevées par Finegold et Kwart (2) au sujet de cette méthode ne sont pas justifiées.

L'ordre de grandeur de la différence entre la fréquence d'absorption de l'hydroxyle libre et celle de l'hydroxyle lié intramoléculairement dans le spectre infra-rouge du diol diaxial III, $\Delta\nu$ de 73.7 cm^{-1}, est le même que celui observé par Kuhn (10) pour le cyclohexanediol-1,3, $\Delta\nu$ de 75 cm^{-1}, et par Durocher (5) pour les diols VII, $\Delta\nu$ de 79.5 cm^{-1}, et VIII, $\Delta\nu$ de 76.6 cm^{-1}. On peut donc admettre qu'une valeur de $\Delta\nu$ d'environ 75 cm^{-1} correspond à la valeur que l'on devrait observer pour un pont hydrogène intramoléculaire dans les cyclohexanediols-1,3 diaxiaux "standards". Il a déjà été noté (5, 6, 13) que des déviations majeurs de cette valeur indiquent une déformation de la molécule.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés à l'aide d'un appareil "hot stage apparatus" de la Compagnie Reichert (Autriche). Les spectres infra-rouge de routine ont été déterminés à l'aide d'un spectrophotomètre Beckman, modèle IR-8, à double faisceaux. La position précise des bandes OH a été mesurée à l'aide d'un appareil, modèle 112, de la compagnie Perkin–Elmer avec optique de fluorure de lithium et calibré immédiatement avant et après les spectres grâce aux données de l'I.U.P.A.C. pour la vapeur d'eau; ces mesures, précises à ± 0.5 cm^{-1}, ont été effectuées dans une cellule de 30.9 mm et sur des solutions de produits dans CCl_4. Les spectres de résonance magnétique nucléaire ont été pris avec un appareil, modèle A 60, de la Compagnie Varian pour des solutions dans l'acétone deutériée et utilisant le tétraméthylsilane comme référence interne; les déplacements chimiques (δ) sont exprimés en parties par million (p.p.m.). Des analyses élémentaires satisfaisantes ont été obtenues pour les produits nouveaux par Claude Daesslé, Organic Microanalysis, Montréal. Les vitesses d'oxydation chromique ont été mesurées d'après la méthode décrite récemment (4); les conditions expérimentales sont: température de 25 °C, acide acétique aqueux à 90%.

REMERCIEMENTS

Les auteurs remercient le Conseil National de Recherches du Canada pour l'aide financière accordée sous forme d'octroi de recherches (A 1295); le Bureau de l'Aide Extérieure du Canada (Plan Colombo) pour l'aide financière accordée sous forme de bourses d'études; la Compagnie Bristol Laboratories pour l'aide financière apportée sous forme d'octroi de recherches; le Dr. Aldée Cabana, Université de Sherbrooke, pour la détermination des spectres infra-rouges des diols; et le Dr. Claude Gilardeau pour la mesure des vitesses d'oxydation chromique.

NOTES

RADIATION-INDUCED BROMINATION OF 2,3-DIMETHYLBUTANE

OWEN H. WHEELER AND HILDA BATLLE DE PABON

Although the vapor-phase photochemical bromination (at 100°) of 2,3-dimethylbutane leads to a variety of products (1), the photochemical bromination of the liquid hydrocarbon at room temperature is reported (2, 3) to give largely 2,3-dibromo-2,3-dimethylbutane. The γ-induced (cobalt-60) bromination has now been studied and compared with photochemical bromination.

EXPERIMENTAL

γ-Induced Bromination

2,3-Dimethylbutane (10 ml) (Aldrich Chemical Co., 99% pure by gas chromatography) distilled from sodium was placed in a glass vessel from which the air had been displaced by helium, and bromine (0.5 ml) that had been distilled from phosphorus pentoxide was added. The vessel was fitted with a stopper and tube to allow the escape of hydrogen bromide, and irradiated in the gamma pool (4) for 16 h to a total corrected absorbed dose of 1.72 Mrads. After irradiation the dissolved hydrogen bromide was removed by passing nitrogen through the solution. The hydrolyzable organic bromide was determined by adding an aliquot (4.0 ml) of the irradiated solution to 50% aqueous ethanol (100 ml) at room temperature, and by titrating portions at intervals with 0.01 *N* sodium hydroxide. A total of 4.20 meq of bromide was liberated after 100 h (see Fig. 1*a*). The total organic bromide was determined by heating under reflux another aliquot (4.0 ml) with a solution of sodium in ethylene diglycol (0.25 *N*) for 15 h. Titration with hydrochloric acid showed the liberation of 5.41 meq of bromide.

The irradiation was repeated with the hydrocarbon (50 ml) and bromine (2.5 ml) to a corrected absorbed dose of 2.54 Mrads during 22 h. Solid (1.0 g), m.p. 150–160°, was precipitated in the vessel. The supernatant solution was distilled in a spinning-band column, giving a distillate of 2,3-dimethylbutane (infrared) and a solid residue (5.2 g), m.p. 155–160°. The solid fractions were purified by sublimation to give 2,3-dibromo-2,3-dimethylbutane, m.p. 159–160° (decomp.) (lit. (5) m.p. 160–164°). The nuclear magnetic resonance spectrum in deuteriochloroform showed a single sharp peak at δ 2.03, against tetramethylsilane as an internal standard. The dibromide was soluble in 2,3-dimethylbutane (0.15 g/ml at 26°).

The initial radiolytic yield (G-value = 2 760 $\pm$ 130) was determined by irradiating samples of a solution of bromine (5%) in 2,3-dimethylbutane for periods of 5–80 min in a helium atmosphere. This value remained constant for absorbed doses of 25 000 – 150 000 rads and bromine concentrations of 0.9–2.0 meq/ml. The unreacted bromine was determined by adding potassium iodide (1 g) in water (5 ml) and titrating the solution with 0.1 *N* sodium thiosulfate. The absorbed dose from the source was determined by the Fricke dosimeter with the same cells as used in the irradiations, a correction being made for the relative electron densities of the Fricke solution and the solution of 2,3-dimethylbutane.

2,3-Dimethylbutane was not detectably affected (boiling point and gas chromatography) on irradiation to 2.5 Mrads in an inert atmosphere.

Photochemical Bromination

Distilled 2,3-dimethylbutane (50 g) was contained in a flask immersed in a water bath maintained at 30° and illuminated by a 500 W tungsten lamp, placed 4 inches below the flask. Distilled bromine (8 g) was led in with a current of helium below the surface of the hydrocarbon, with mechanical stirring. After addition of the bromine the gas flow was maintained to remove the hydrogen bromide. A solid (16.4 g), m.p. 150–160°, was deposited in the flask.

A portion (25 ml) of the solution was solvolyzed in 50% aqueous ethanol (250 ml) at room temperature, and aliquots (10 ml) were titrated with 0.1 *N* sodium hydroxide (see Fig. 1*b*).

Another portion (10 ml) was hydrolyzed by heating it under reflux for 6 h with a 0.25 *N* solution of sodium in diethylene glycol (50 ml), and aliquots (10 ml) were titrated with 0.013 *N* hydrochloric acid, thereby showing 1.57 meq of bromine/ml.

A solution of bromine (0.1 *N*) in the hydrocarbon, maintained in the dark, showed no detectable decrease in concentration in 6 h and a decrease of 0.2% in 24 h.

DISCUSSION

In their study of the photochemical bromination of 2,3-dimethylbutane, Russell and Brown (3) determined the total organic bromide by hydrolyzing the solution with base, and the tertiary bromide by solvolyzing an aliquot in aqueous ethanol. They noticed that the liberation of bromide ion during the solvolysis increased with time, and they assumed that the true value of the amount of tertiary bromide could be obtained by extrapolation to zero time. The solution obtained in this work on the γ-induced bromination of 2,3-dimethylbutane showed a steady increase for periods up to more than 1 day (Fig. 1*a*).

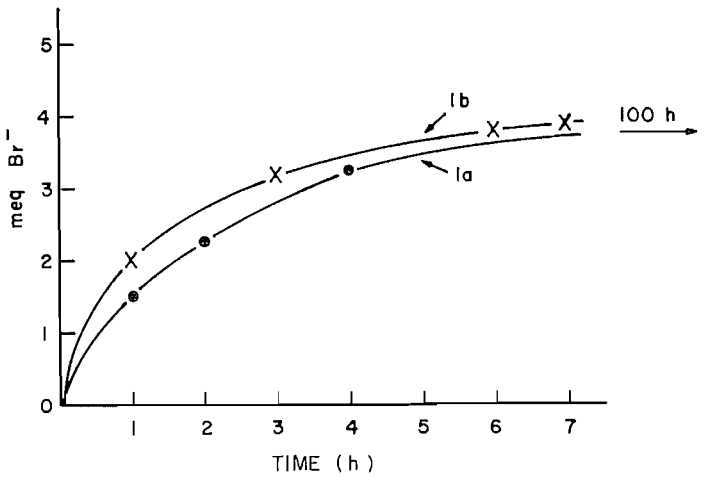

FIG. 1. Solvolysis of bromide solutions.

Distillation of the brominated solution left solid 2,3-dibromo-2,3-dimethylbutane (identified by its melting point and nuclear magnetic resonance spectrum) as the only product. No fraction corresponding to a liquid monobromide was detected. 2,3-Dibromo-2,3-dimethylbutane itself showed the same abnormal behavior on solvolysis, and the bromide analyses of the irradiated solution can be accounted for on the basis of the solubility of the solid dibromide in 2,3-dimethylbutane. The reported rate constant of solvolysis of this dibromide (6), based on only three experimental points, must be treated with reservation.

The photochemical (visible) bromination of 2,3-dimethylbutane also produced exclusively 2,3-dibromo-2,3-dimethylbutane, and the solution of the brominated hydrocarbon showed the same behavior on solvolysis (Fig. 1*b*).

The high G-value (2 760 $\pm$ 130) (molecules reacted per 100 eV) indicates that the reaction proceeds by an initial chain mechanism. (Russell and Brown (3) have suggested that the dibromide is formed from the monobromide in a rapid ionic mechanism.) The chlorination of hydrocarbons gives higher G-values (7). However, the γ-induced and photochemical chlorinations of benzene (8), toluene (9, 10), and *n*-butyric acid (8) give the same products. The photochemical and radiation-induced halogenations of organic compounds seem to produce the same products and probably proceed by similar mechanisms.

ORGANIC SULFUR MECHANISMS
III. A BRIEF INVESTIGATION INTO THE REACTION OF BENZONITRILE OXIDE WITH SULFENES[1]

J. F. KING AND T. DURST

As part of our scrutiny of the chemistry of sulfenes (1, 2 and references therein), we were led to consider whether these species were capable of 1,3-dipolar cycloaddition reactions. 1,2-Cycloadditions leading to products with four-membered rings appear to be well established (3–6); however, although certain reactions of sulfenes may be rationalized in terms of 1,3-dipolar additions, no such processes have actually been authenticated.[2] As the question seemed to have bearing on our study of the mechanism of the coupling of phenylsulfene to form *trans*-stilbene and *cis*-diphenylethylene sulfone (8–10), we sought some information on the point.

We chose to look at the reaction of sulfenes with a nitrile oxide, chiefly because such a species would appear to be able to react both as a dipolar reagent and as a dipolarophile,[3] and would therefore be potentially capable of detecting either type of reactivity in sulfenes. Of the various known nitrile oxides, benzonitrile oxide is comparatively readily accessible. Thus, when an ethereal solution of α-chlorobenzaldoxime (benzoyl chloride oxime) is treated with triethylamine, triethylammonium chloride forms a precipitate immediately, and the nitrile oxide remains in solution along with any excess triethylamine. Since triethylamine is known (1, 2) to react with phenylmethanesulfonyl chloride to give phenylsulfene, the nitrile oxide – triethylamine solution was added directly to a solution of the sulfonyl chloride, in the expectation of observing the reaction of the sulfene and the nitrile oxide. The crystalline product which was obtained (and which could also be

prepared simply by mixing the three reagents and allowing the mixture to stand for 5 min) was not, however, any normal product of a dipolar cycloaddition.

Analysis indicated the empirical formula $C_{14}H_{12}NSO_3Cl$, implying a formal derivation from 1 molecule each of phenylsulfene, benzonitrile oxide, and hydrogen chloride. The nuclear magnetic resonance spectrum showed only a singlet at 4.67 p.p.m. (relative area 1) and aromatic protons from 7.4 to 8.1 p.p.m. (relative area 5). The chemical shift of the nonaromatic proton(s) is well within the range (4.1 to 5.0 p.p.m.) which we (10) have found for the benzylic hydrogens in about a dozen structurally varied compounds containing the $PhCH_2SO_2$ group; the value observed for these protons in benzophenone oxime phenylmethanesulfonate (4.68 p.p.m.) is effectively identical with that found for the compound from the nitrile oxide reaction. The compound shows absorption in the ultraviolet region (λ_{max} 252 mμ, ϵ 10 000) very similar to that of acetophenone oxime and the benzaldoximes (12), which have maxima near 250 mμ with extinction coefficients slightly over 10 000. Three very strong bands are found in the infrared spectrum at 1 386, 1 178, and 816 cm^{-1}. The positions of the two higher frequency bands are in good agreement with those expected for a sulfonic ester, but are distinctly higher than the corresponding bands in sulfones or sulfonamides (13). A strong band around 800 cm^{-1} has been noticed by Freeman and Hambly (14) in the spectra of a number of sulfonic esters, and has been tentatively assigned to the S—OR stretching mode.

The most straightforward assembling of these data leads to structure I*a* for the compound, i.e. the material is simply the phenylmethanesulfonyl ester of α-chlorobenzaldoxime.

$$PhC{\equiv}\overset{+}{N}{-}\overset{-}{O} + RCH_2SO_2Cl \xrightarrow{Et_3N} Ph{-}\overset{Cl}{\overset{|}{C}}{=}N{-}OSO_2CH_2R$$

I*a* R = Ph
I*b* R = H

A structure in which the $PhCH_2SO_2$ group and the chlorine are interchanged is not excluded, but would require a more complex mode of formation, and would therefore seem less likely in the absence of any evidence favoring it.

Though no attempt has been made to explore the full scope of the reaction, its generality is suggested by the fact that a very similar compound is formed when methanesulfonyl chloride replaces phenylmethanesulfonyl chloride in the reaction. By analogy, structure I*b* is assigned to the material.

There appear to be two simple routes by which these materials might be formed from a sulfene in the reactions: (*i*) attack of the sulfene on α-chlorobenzaldoxime, which may be present or re-formed (in small quantity) in the medium, or (*ii*) reaction of the sulfene with the nitrile oxide to form a cationic intermediate ($PhC{\equiv}\overset{+}{N}{-}OSO_2CH_2Ph$) which subsequently picks up a chloride anion. The apparent completeness of the conversion of α-chlorobenzaldoxime into benzonitrile oxide with base suggests that route *ii* is perhaps more probable than route *i*, but clearly distinguishing evidence is lacking.

To the original aim of this study, these observations contribute only the conclusion that benzonitrile oxide and sulfenes do not yield the products of a dipolar addition under the conditions tried. Whether these species would undergo dipolar addition in the absence of triethylammonium chloride remains uncertain, though it seems likely that the reaction would not be extremely rapid; at present, however, it is not particularly easy to obtain direct evidence on the point. The products of these reactions represent an appar-

For personal use only.

ently hitherto unknown type of oxime (or hydroxamic acid) derivative. Their significance in the chemistry of sulfenes remains unestablished, but they promise interesting chemistry in their own right.

EXPERIMENTAL

Melting points were determined on a Kofler block and are uncorrected. Infrared spectra were obtained with Beckman IR-5 or IR-7 spectrophotometers equipped with sodium chloride optics, or a Beckman IR-5A instrument equipped with cesium bromide optics. The silica gel referred to is British Drug Houses "suitable for chromatography" grade.

Reaction of Benzonitrile Oxide, Phenylmethanesulfonyl Chloride, and Triethylamine

α-Chlorobenzaldoxime (15) (1.8 g, 12 mmoles) and phenylmethanesulfonyl chloride (Eastman Kodak white label, sold under the alternative name α-toluenesulfonyl chloride) (3.0 g, 16 mmoles) were dissolved in methylene chloride (30 ml) and treated quickly with excess triethylamine. The solution was allowed to stand at room temperature for 5 min, then poured into water, and extracted with ether. The material remaining after evaporation of the ether was chromatographed on silica gel. Elution with benzene gave a material (2.24 g, 7.3 mmoles, 60%) which was crystallized from methylene chloride – pentane as heavy colorless crystals, m.p. 104–105°.

Anal. Calcd. for $C_{14}H_{12}NSO_3Cl$: C, 54.29; H, 3.88; N, 4.52; S, 10.35; Cl, 11.42. Found: C, 54.22; H, 4.07; N, 4.57; S, 10.54; Cl, 11.59.

The ultraviolet spectrum showed a single maximum at 252 mμ (ε 10 000). Infrared spectrum (0.4 *M* in CH_2Cl_2; IR-7 above 800 cm^{-1}, IR-5A below 800 cm^{-1}): 3 070 (w), 1 593 (m), 1 566 (m), 1 496 (m), 1 457 (w), 1 448 (m), 1 386 (vs), 1 206 (s), 1 178 (vs), 1 143 (w), 1 075 (w), 1 030 (w), 1 001 (w), 978 (m), 899 (s), 874 (s), 816 (vs), 637 (m), 622 (w), 603 (m), 585 (w), 543 (s), 492 (m). The nuclear magnetic resonance spectrum showed complex absorption in the region 7.4 to 8.1 p.p.m. and a singlet at 4.67 p.p.m. (relative areas 5:1).

In a separate experiment α-chlorobenzaldoxime was treated with excess triethylamine in ether solution. The triethylammonium chloride was filtered off and the filtrate added to an ethereal solution of phenylmethanesulfonyl chloride; work-up as above gave the same product.

Reaction of Benzonitrile Oxide, Methanesulfonyl Chloride, and Triethylamine

α-Chlorobenzaldoxime (450 mg, 2.9 mmoles) was dissolved in anhydrous ether (20 ml) and treated with triethylamine (1 ml, 7.2 mmoles). The triethylammonium chloride which precipitated was filtered off. Methanesulfonyl chloride (350 mg, 3.1 mmoles) in ether (5 ml) was added to the filtrate and the solution was allowed to stand at room temperature for a day. The mixture was then poured into water and extracted with ether. Chromatography of the ether extract on silica gel gave, on elution with 1:1 low-boiling petroleum ether – benzene, a white solid (255 mg, 1.1 mmoles, 37%) which, after recrystallization from methylene chloride – pentane, melted at 110–112°.

Anal. Calcd. for $C_8H_8NSO_3Cl$: C, 41.11; H, 3.45; N, 6.03; S, 13.72; Cl, 15.15. Found: C, 41.05; H, 3.54; N, 6.10; S, 13.69; Cl, 15.06.

The nuclear magnetic resonance spectrum showed complex absorption from 8.0 to 7.3 p.p.m. and a singlet at 3.25 p.p.m. (relative areas 5:3). The principal bands in the infrared spectrum ($CHCl_3$, IR-5) between 1 700 and 800 cm^{-1} are: 1 385 (s), 1 265 (s), 1 188 (s), 969 (m), 897 (s), 819 (s).

THE SEPARATION OF ALDOPENTOSE AND ALDOHEXOSE DIETHYL DITHIOACETAL DERIVATIVES BY GAS–LIQUID PARTITION CHROMATOGRAPHY

D. T. WILLIAMS AND J. K. N. JONES

INTRODUCTION

Numerous workers have separated and identified the aldopentoses and aldohexoses by gas–liquid partition chromatography (g.l.p.c.) of certain of their derivatives. The derivatives normally used have been the fully acetylated methyl glycosides, aldose acetates, and alditol acetates (1–5). More recently trimethylsilyl derivatives have been employed instead of the acetylated derivatives (6–8). Except for the alditol acetates, the presence of anomeric isomers invariably causes problems in interpretation when a mixture of sugars is being analyzed. The use of alditol derivatives avoids this confusion but, since the same alditol can arise from two different aldoses, an unambiguous assignment of the parent aldose cannot always be made. Bentley *et al.* (8) investigated the g.l.p.c. of the trimethylsilyl derivatives of aldose oximes, acetals, and thioacetals, but they reported unsatisfactory separations of these compounds. During our work on the oxidation of aldose thioacetals by *A. suboxydans* we have found that fully acetylated aldose diethyl dithioacetals can be separated satisfactorily by g.l.p.c. (Table I). The advantage of thioacetal derivatives is that each aldose gives a single product which has only one peak on g.l.p.c. but which still retains the complete individuality of the parent aldose. A second set of derivatives with these advantages is the fully acetylated 1-deoxyalditols (Table II), which can easily be obtained by boiling the corresponding thioacetal derivatives, shown below, under reflux with freshly prepared Raney nickel. From the relative

retention times of these pairs of derivatives an unambiguous assignment of the parent aldose dithioacetal acetate can be made.

It should be emphasized, however, that this technique is not suitable for the quantitative analysis of sugar mixtures because of the variation in yields of diethyl dithioacetal derivatives and because of the formation of other faster moving products formed during the desulfurization step. De-*O*-acetylation, which might conceivably occur because of the

THE SEPARATION OF ALDOPENTOSE AND ALDOHEXOSE DIETHYL DITHIOACETAL DERIVATIVES BY GAS–LIQUID PARTITION CHROMATOGRAPHY

D. T. WILLIAMS AND J. K. N. JONES

INTRODUCTION

Numerous workers have separated and identified the aldopentoses and aldohexoses by gas–liquid partition chromatography (g.l.p.c.) of certain of their derivatives. The derivatives normally used have been the fully acetylated methyl glycosides, aldose acetates, and alditol acetates (1–5). More recently trimethylsilyl derivatives have been employed instead of the acetylated derivatives (6–8). Except for the alditol acetates, the presence of anomeric isomers invariably causes problems in interpretation when a mixture of sugars is being analyzed. The use of alditol derivatives avoids this confusion but, since the same alditol can arise from two different aldoses, an unambiguous assignment of the parent aldose cannot always be made. Bentley *et al.* (8) investigated the g.l.p.c. of the trimethylsilyl derivatives of aldose oximes, acetals, and thioacetals, but they reported unsatisfactory separations of these compounds. During our work on the oxidation of aldose thioacetals by *A. suboxydans* we have found that fully acetylated aldose diethyl dithioacetals can be separated satisfactorily by g.l.p.c. (Table I). The advantage of thioacetal derivatives is that each aldose gives a single product which has only one peak on g.l.p.c. but which still retains the complete individuality of the parent aldose. A second set of derivatives with these advantages is the fully acetylated 1-deoxyalditols (Table II), which can easily be obtained by boiling the corresponding thioacetal derivatives, shown below, under reflux with freshly prepared Raney nickel. From the relative

retention times of these pairs of derivatives an unambiguous assignment of the parent aldose dithioacetal acetate can be made.

It should be emphasized, however, that this technique is not suitable for the quantitative analysis of sugar mixtures because of the variation in yields of diethyl dithioacetal derivatives and because of the formation of other faster moving products formed during the desulfurization step. De-*O*-acetylation, which might conceivably occur because of the

possible presence of base in the Raney nickel catalyst, was not observed. However, any ambiguity which might be caused as a result of this possibility may be obviated if the mixture is reacetylated after reduction and before analysis.

DISCUSSION AND RESULTS

The best separations were generally obtained with LAC-4R-886 polyester grease on Chromosorb W, although in the case of the aldopentose diethyl dithioacetal tetraacetates 20% Apiezon M grease on Chromosorb W was found to be the most suitable column packing. With this second packing (column III) the aldopentose diethyl dithioacetal tetraacetates were easily identified both as individual standards and when run as mixtures. However, with a column packing of 5% LAC polyester grease (column I), a mixture of D-lyxose and D-arabinose diethyl dithioacetal tetraacetates gave only one peak, with a retention time intermediate between that of the two individual standards. Furthermore, the order of elution of the aldopentose thioacetals varied with the nature of the liquid phase (Table I); therefore, no attempt was made to correlate the structures of the thioacetals with their relative retention times.

TABLE I

Retention times of acetylated diethyl dithioacetals (in min and relative to that of D-ribose diethyl dithioacetal tetraacetate) (flow rate, 92 ml argon/min; temperature, 198°)

Diethyl dithioacetal acetates of:	Column packing: I		III	
	Min	Relative	Min	Relative
D-Ribose	12.2	1.00	26.7	1.00
D-Arabinose	13.5	1.11	29.0	1.08
D-Lyxose	14.0	1.15	30.4	1.14
D-Xylose	14.8	1.21	27.8	1.04
D-Allose	28.3	2.32		
D-Mannose	33.0	2.70		
D-Altrose	33.5	2.75		
D-Talose	33.7	2.76		
D-Glucose	35.3	2.89		
D-Galactose	40.0	3.28		
L-Gulose	40.8	3.34		
L-Idose	44.5	3.65		

The separation of the aldohexose dithioacetal pentaacetates was not as simple, since D-altrose and D-talose diethyl dithioacetal pentaacetates and D-galactose and L-gulose diethyl dithioacetal pentaacetates were not distinguishable from each other (Table I). However, examination of the acetylated 1-deoxyalditols (Table II) by g.l.p.c. on a column of 15% LAC polyester grease (column II) showed that all of these compounds were separable, except for 1-deoxy-D-glucitol and 1-deoxy-L-gulitol pentaacetates. A combination of the results from Tables I and II, therefore, gives an unambiguous identification of each aldose.

EXPERIMENTAL

Preparation of Aldose Diethyl Dithioacetals

The aldose (1 g) was dissolved in concentrated hydrochloric acid (1 ml), cooled to 0°, and then shaken with ethanethiol (1 ml) for 20–30 min. The reaction mixture was then poured into excess alkaline solution and the aqueous solution continuously extracted with chloroform for 3–4 h. The chloroform extract was

TABLE II

Retention times of acetylated 1-deoxyalditols (in min and relative to that of 1-deoxy-D-ribitol tetraacetate) (flow rate, 75 ml argon/min; temperature, 198°)

1-Deoxyalditol acetates of:	Column packing II	
	Min	Relative
D-Ribitol	5.9	1.00
D-Arabinitol	6.3	1.07
D-Lyxitol	6.75	1.14
D-Xylitol	8.7	1.47
D-Allitol	16.3	2.77
D-Mannitol	17.6	2.99
D-Altritol	18.1	3.07
D-Talitol	18.5	3.14
D-Galactitol	20.2	3.42
D-Glucitol	23.6	4.00
L-Gulitol	23.7	4.02
L-Iditol	28.7	4.88

dried (Na_2SO_4), filtered, and concentrated to a syrup which usually crystallized in seconds. Recrystallization from ethanol yielded the aldose diethyl dithioacetal.

The following thioacetals were prepared in this manner: D-arabinose, D-ribose, D-xylose, D-lyxose, D-glucose, D-galactose, D-mannose, D-altrose, D-talose, and D-allose.

Mixtures of D-mannose and L-gulose diethyl dithioacetals and D-glucose and L-idose diethyl dithioacetals were prepared by reduction, with $NaBH_4$, of D-*lyxo*-hexo-5-ulose-1,1-diethyl dithioacetal and D-*xylo*-hexo-5-ulose-1,1-diethyl dithioacetal respectively (9).

Aldose Diethyl Dithioacetal Pentaacetates

The aldose diethyl dithioacetal (0.5 g) was dissolved in dry pyridine (3 ml), and acetic anhydride (4 ml) was added. After the reaction mixture was allowed to stand at room temperature for 18 h, it was worked up in the usual manner to give the aldose diethyl dithioacetal acetates.

1-Deoxyalditol Pentaacetates

The aldose diethyl dithioacetal pentaacetate was boiled under reflux in ethanol for 16 h with approximately four times its weight of freshly prepared Raney nickel (10). The Raney nickel was filtered off and washed well with methanol. The filtrate and washings were then concentrated to a syrup, which consisted mainly of the 1-deoxyalditol acetate. Some other degradation products were also present, but these ran at a much faster rate on g.l.p.c. and did not interfere in any way. 1-Deoxy-D-galactitol and 1-deoxy-1-mannitol were also prepared by sodium borohydride reduction of L-fucose and L-rhamnose respectively. Acetylation with acetic anhydride and pyridine then gave the corresponding acetates.

Gas–Liquid Partition Chromatographic Separations

The recorded separations were made on a Pye argon chromatograph which was fitted with an ionization detector (80 μcuries radium D) and which employed straight glass columns (117 × 0.5 cm inside diameter) packed with the appropriate support and enclosed at each end by small glass wool plugs. The samples (5–20 μl) in dry chloroform were placed on top of the column by a micropipette, and development was carried out with dry argon as the carrier gas.

Column packing I consisted of 5% LAC-4R-886 polyester grease (Chromatographic Specialities, Brockville) on nonacid-washed Chromosorb W, 80–100 mesh. *Column packing II* consisted of 15% LAC-4R-886 polyester grease on nonacid-washed Chromosorb W, 80–100 mesh. *Column packing III* consisted of 20% Apiezon M grease (Fisher Scientific Co.) on nonacid-washed Chromosorb W, 100–120 mesh.

The dried column packings were run into the glass columns under gravity, with gentle tapping to ensure even packing.

ACKNOWLEDGMENTS

We thank the National Research Council for financial assistance (N.R.C. T-19) and for the award of a scholarship to one of us (D. T. W.). We also thank Dr. M. B. Perry and Mr. B. T. Lawton for generous gifts of D-talose and D-allose respectively.

CONCERNING THE REACTION BETWEEN MALEIC ANHYDRIDE AND INDENE

NEIL S. ISAACS

The singular 1,3-addition of maleic anhydride (MA) to indene (1, 2) involving a concomitant hydrogen shift has recently been the subject of a study by Berson and co-workers (3, 4), who have distinguished between a mechanism proposed originally by Alder, in which prior isomerization to isoindene (II) occurs (Reaction Scheme 1A), and one that was postulated by themselves from analogy with a rearrangement in the bicyclo-(3,2,0)-heptene series and which involved 1,2-addition and rearrangement (Reaction Scheme 1B).

REACTION SCHEME 1.

In Reaction Scheme 1A, C-2 of the indene molecule becomes the methylene bridge of the adduct (III), whereas in Reaction Scheme 1B the latter is formed from C-1 with skeletal rearrangement but no hydrogen transfer. When he worked with partially deuterated indene (mostly on C-1 and C-3), Berson concluded that Reaction Scheme 1B

CONCERNING THE REACTION BETWEEN MALEIC ANHYDRIDE AND INDENE

NEIL S. ISAACS

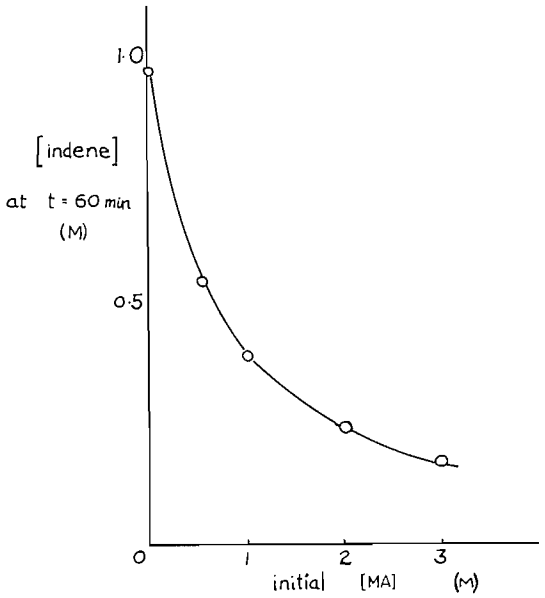
The singular 1,3-addition of maleic anhydride (MA) to indene (1, 2) involving a concomitant hydrogen shift has recently been the subject of a study by Berson and co-workers (3, 4), who have distinguished between a mechanism proposed originally by Alder, in which prior isomerization to isoindene (II) occurs (Reaction Scheme 1A), and one that was postulated by themselves from analogy with a rearrangement in the bicyclo-(3,2,0)-heptene series and which involved 1,2-addition and rearrangement (Reaction Scheme 1B).

REACTION SCHEME 1.

In Reaction Scheme 1A, C-2 of the indene molecule becomes the methylene bridge of the adduct (III), whereas in Reaction Scheme 1B the latter is formed from C-1 with skeletal rearrangement but no hydrogen transfer. When he worked with partially deuterated indene (mostly on C-1 and C-3), Berson concluded that Reaction Scheme 1B

is untenable; we have confirmed this in work with indene-2-*d*, the adduct of which essentially retains all the deuterium on the methylene bridge.

In addition we have found that the rate, measured by the disappearance of indene, appears to depend upon the concentration of maleic anhydride (Fig. 1).



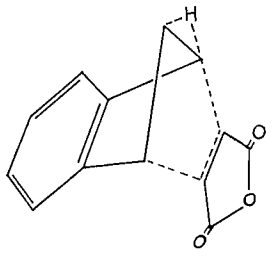


FIG. 1.

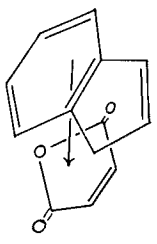

According to Reaction Scheme 1A, the slow step of the reaction is the isomerization of indene, which should be independent of maleic anhydride concentration. If a molecule of maleic anhydride is implicated in the rate-determining step, three possibilities may be considered. Firstly, the isomerization of indene to isoindene may be appreciably reversible, i.e. $k_{-1} \approx k_2$, although Roth's (5) recent study of the thermal isomerization of indene

$$\text{I} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{II} \underset{k_2}{\overset{\text{MA}}{\rightleftharpoons}} \text{III}$$

does not support this. Secondly, a hitherto unconsidered mechanism, albeit one without exact precedent in Diels–Alder type additions, would involve a bimolecular reaction leading directly to 1,3-addition in concert with the hydrogen shift. This could occur through operation of the 'maximum overlapping' principle, thereby leading to the *endo* adduct via an essentially planar transition state (IV). A third way in which the maleic

IV

V

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

anhydride concentration might affect the rate is by charge-transfer complexing (6, 7), thereby leading to a lowering of the activation energy for the isomerization to isoindene and to stabilization of the isoindene intermediate. The maleic anhydride is then, incidentally, in a very favorable environment (V) to react with the diene. Isomerization induced by maleic anhydride before addition has been suggested to account for adducts formed with non-conjugated dienes such as limonene (8), although such reactions may involve hydrogen transfer to maleic anhydride (9). That charge transfer occurs between indene and maleic anhydride is evident from the yellow color (λ_{max} = 630 mμ) produced on admixture of the two compounds (cf. indene (λ_{max} = 245 mμ) and maleic anhydride (end absorption <240 mμ)).

The latter mechanism, perhaps, seems to be the most attractive at present, but further work with substituted indenes might permit a distinction to be made.

EXPERIMENTAL

Nuclear magnetic resonance and infrared spectra were recorded on Varian A60 and Beckman IR-4 spectrometers respectively. Integration measurements are the average of two or three recordings and are consistent to approximately 0.05 proton unit.

Preparation of Indene-2-d

Indan-2-ol-2-d

To indan-2-one (3.28 g, 24.3 mmoles), prepared by the method of Pfeiffer and Hesse (10) in dry ether (25 ml), was added a slurry of lithium aluminium deuteride (0.34 g, 8.1 mmoles). The mixture was stirred for 2 h and boiled under reflux for 1 h, after which water was added, the ethereal solution separated and dried with $MgSO_4$, and the solvent removed to give indan-2-ol-2-*d*.

Without further purification the deuterated indanol was added to acetic anhydride (5.01 ml) and the mixture warmed on a steam bath for 20 min. The acetic anhydride and acetic acid were removed by distillation, and indan-2-yl acetate-2-*d* was distilled at 75° and 3 mm; yield, 4.15 g (95%). Both the alcohol and the ester showed an absorption peak at 2 150 cm^{-1}.

Indene-2-d

The indanyl acetate-2-*d*, dissolved in an equal volume of benzene, was dropped, in a slow nitrogen stream, through a 6 inch tube that was packed with silica chips and which was surrounded by a furnace to maintain the center of the tube at 490 ± 10°. The rate of addition was adjusted to 4–6 drops per min, and the emerging vapors were condensed, washed with sodium bicarbonate solution, and dried with $MgSO_4$. Distillation yielded indene-2-*d*; b.p. 63° at 12 mm; yield, 1.52 g (55%). The deuterium content was estimated as better than 0.95 atom of deuterium per molecule by its proton resonance, in which the peak at 3.6 μ in the indene spectrum is assigned to H-2 and that at 3.3 μ to H-3.

Reaction between Indene-2-d and Maleic Anhydride

Indene-2-*d* (1.0 g), freshly sublimed maleic anhydride (0.6 g), and hydroquinone (2 mg) were dissolved in benzene (1 ml) and sealed under vacuum into a length of 3 mm bore glass tubing. The tube was heated at 210° for 2.5 h. When the solution was allowed to cool, the product crystallized. Recrystallization from ethyl acetate yielded the adduct III, m.p. 188° (lit. m.p. 187–188 (1)).

The nuclear magnetic resonance spectrum of this product in $CDCl_3$ (internal tetramethylsilane) showed 1.1 protons on the methylene bridge at approximately 8 μ, indicating that this is derived from C-2 of indene. The slight loss of deuterium is due to 'scrambling' of hydrogen around the five-membered ring, as studied by Roth (5); this was examined by us in a separate experiment in which partially deuterated indene-1,1,3-*d* was heated under the same conditions but in the absence of maleic anhydride. The results are summarized in Table I.

TABLE I

Thermal stability of indene-2-*d* (protons per molecule)

	Before heating	After heating
Aromatic	4.0	4.0
C-1	0.28	0.37
C-2	0.99	0.78
C-3	0.14	0.15

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Kinetic Experiments

Indene was purified by repeated fractional distillation of reagent-grade indene (Eastman), and maleic anhydride by sublimation *in vacuo*.

Samples (1.00 ml) of a benzene solution of indene (1.0 *M*) containing a trace of hydroquinone and maleic anhydride in concentrations up to 3 *M* were heated for 1 h in sealed tubes at 184°. The samples were cooled, separately diluted to 10 ml with acetone, and analyzed for indene by gas chromatography with a silicone column at 180° and helium as the carrier gas. The results are shown in Fig. 1.

ACKNOWLEDGMENTS

We express our thanks to Professor R. C. Cookson, who suggested the problem and, together with Dr. L. D. Hall, made the nuclear magnetic resonance measurements; and to the Department of Scientific and Industrial Research for a fellowship, during which much of this work was carried on.

SELENIUM ISOTOPE EFFECTS IN THE REDUCTION OF SODIUM SELENITE AND OF SODIUM SELENATE

C. E. REES[1] AND H. G. THODE

Chemistry Department, McMaster University, Hamilton, Ontario

Received August 17, 1965

ABSTRACT

Selenium isotope effects in the reduction of sodium selenite and of sodium selenate have been studied. Rate constant ratios for the ^{76}Se and ^{82}Se species have been determined for the reactions $Se^{iv} \rightarrow Se^{0}$ (1.017), $Se^{vi} \rightarrow Se^{iv}$ (1.018), and $Se^{0} \rightarrow Se^{iv}$ (1.010) at room temperature. Theoretical predictions of the first two ratios, from the use of models in which the rate-controlling steps are assumed to be Se—O bond cleavages in SeO_3^{2-} and SeO_4^{2-}, respectively, lead to predictions in good agreement with experiment.

INTRODUCTION

Krouse and Thode (1) have shown that the isotopes of selenium are fractionated in nature and that, in general, the observed fractionations are similar to but smaller than those observed for sulfur. This paper presents the results of experiments on the fractionation of selenium isotopes during chemical reactions involving the reduction of selenite and selenate to selenium. Such a study is of interest in the interpretation of naturally observed fractionations, and provides results that may be compared with theoretical calculations based on statistical–mechanical methods.

Rate constants for isotopic reactions involving ^{76}Se and ^{82}Se have been compared by measuring the differences in the ^{82}Se:^{76}Se ratios between reactants and reaction products for fractional reductions. Changes in isotope abundance ratios are measured as

$$\delta \text{ (p.p.t.)} = \frac{(^{82}Se/^{76}Se)_x - (^{82}Se/^{76}Se)_{\text{standard}}}{(^{82}Se/^{76}Se)_{\text{standard}}} \times 1000,$$

where p.p.t = parts per thousand. This quantity may be related to ratios of rate constants and is also experimentally measurable with a double collection mass spectrometer. The spectrometer used in this work has previously been described (1).

THEORETICAL

For the competing isotopic reactions

$$A_1 + B + \text{----} \xrightarrow{k_1} P_1 + \text{----}$$
$$A_2 + B + \text{----} \xrightarrow{k_2} P_2 + \text{----}$$

[1]*Present Address: Department of Chemistry, University of California at San Diego, La Jolla, California, U.S.A.*

the isotope effect observed after partial reaction may be related to the ratio of rate constants. For small ($\sim 5\%$) fractions of reaction, the isotope effect, if we compare reaction products with the starting material, is given by:

$$-\delta = k_1/k_2 - 1.$$

More generally, if D is the depletion of the heavy isotope, defined as $[A_2]/[A_{20}]$, the fraction of the heavy isotope which has not yet reacted, and if δ is defined as the isotope effect for products compared with the starting material and δ' as that for substrate compared with starting material, then:

[1] $$-\delta = \frac{D - D^{k_1/k_2}}{1 - D^{k_1/k_2}}$$

[2] $$\delta' = \frac{D}{D^{k_1/k_2}} - 1.$$

The theory of isotope fractionation during chemical reactions is considered in terms of the theory of absolute rates and was first formulated by Bigeleisen (2). For the competing reactions above the ratio of rate constants is given by:

$$k_1/k_2 = ((Q_2/Q_1)/(Q_2^{\ddagger}/Q_1^{\ddagger}))(\upsilon_{1i}^{\ddagger}/\upsilon_{2i}^{\ddagger}).$$

This expression omits the transmission coefficient and Wigner tunnelling correction of absolute rate theory, the assumption being that for heavy elements these terms will remain invariant under isotopic substitution. The terms Q_2/Q_1 and $Q_2^{\ddagger}/Q_1^{\ddagger}$ are ratios of partition functions for the reactants and activated complexes respectively and each may be evaluated as

$$\prod_i^N \frac{u_{2_i}}{u_{1_i}} \frac{e^{-u_{2i}/2}}{e^{-u_{1i}/2}} \frac{1 - e^{-u_{1i}}}{1 - e^{-u_{2i}}},$$

where $u_i = h\upsilon_i/kT$ and υ_i is the i^{th} fundamental vibrational frequency of the molecule. If n is the number of atoms in the molecule, then for the reactants, N is $(3n - 6)$, and for the activated complexes it is $(3n - 7)$, since in an activated complex one of the vibrational degrees of freedom is non-genuine, corresponding to the cleavage of a bond, and is equivalent to a translation along the reaction coordinate.

According to Slater (3), the term $\upsilon_{1L}^{\ddagger}/\upsilon_{2L}^{\ddagger}$, the ratio of the two frequencies which become imaginary in the activated complex, may be evaluated in terms of the reduced masses of the activated complexes as they traverse the critical region of the reaction coordinate, so that:

$$\upsilon_{1L}^{\ddagger}/\upsilon_{2L}^{\ddagger} = (\mu_2^{\ddagger}/\mu_1^{\ddagger})^{1/2}.$$

The theoretical prediction of a ratio of rate constants requires precise knowledge of the form of the activated complex. Such information is not available and it is necessary to consider models in which the nature of the activated complex is assumed to be known. The merits of such models are gauged by their appropriateness to the physical conditions and the degree of agreement between predictions based on them and the observed isotope effects.

Three cases, which give for a particular form of model an estimate of k_1/k_2 and the extreme upper and lower values of k_1/k_2 which may arise from this model, will be considered.

I. The case where the activated complex is identical to the starting material, with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

exception that the frequency associated with the breaking bond is missing. Then

$$(Q_2/Q_1)/(Q_2^{\pm}/Q_1^{\pm}) = Q(\upsilon_{2L})/Q(\upsilon_{1L})$$

where this ratio is the same as the partition function ratio for diatomic isotopic molecules with frequencies υ_{2L} and υ_{1L}. The mass ratio is evaluated by considering the effective mass to be the reduced mass of the activated complex across the bond which breaks. Either mass or atom fragments may be used in this evaluation.

II. The case where the partition function ratio term is very close to unity. This gives a lower limit, and is also the high temperature limit of the ratio of rate constants. Then

$$k_1/k_2 = (\mu_2^{\pm}/\mu_1^{\pm})^{1/2}.$$

III. The case where the activated complex has some structure which is, strictly speaking, unknown, but for which the value of the partition function ratio lies between that for the starting material (with the omission of a frequency term) and unity. The extreme value of unity may be approached if in the transition state there is complexing of the reacting molecule with other material, so that a complicated structure is formed in which not many of the vibrational frequencies are sensitive to isotopic substitution. Then

$$k_1/k_2 = (Q_2/Q_1) \cdot (\mu_2^{\pm}/\mu_1^{\pm})^{1/2}.$$

This approach gives an upper limit for the value of k_1/k_2.

Calculations

To predict the isotope effects in the reductions of selenite and selenate, it is necessary to determine the fundamental vibrational frequencies of the species $^{76}SeO_3^{2-}$, $^{82}SeO_3^{2-}$, $^{76}SeO_4^{2-}$, and $^{82}SeO_4^{2-}$.

The fundamental frequencies for SeO_3^{2-} in Table I are the means of the values reported by Rocchiccioli (4) and Walrafen (5). These have been taken to be the frequencies appropriate to the most abundant species $^{80}SeO_3^{2-}$. The selenite ion has a pyramidal XY_3 structure and a force constant analysis must take into account the apex angle of the pyramid. Wells and Bailey (6) determined the structure of the SeO_3 groups in crystals of selenious acid and their mean apex angle of 100.6° has been used.

TABLE I

Vibrational frequency assignments

Molecule	υ_1	υ_2	υ_3	υ_4
$^{80}SeO_3^{2-}$	805 (1)*	433 (1)	735 (2)	376 (2)
$^{76}SeO_3^{2-}$	808 (1)	435 (1)	739 (2)	377 (2)
$^{82}SeO_3^{2-}$	804 (1)	431 (1)	733 (2)	376 (2)
$^{80}SeO_4^{2-}$	835 (1)	341 (2)	875 (3)	421 (3)
$^{76}SeO_4^{2-}$	835 (1)	341 (2)	882 (3)	423 (3)
$^{82}SeO_4^{2-}$	835 (1)	341 (2)	872 (3)	420 (3)

*Frequencies quoted in cm^{-1}; figures in parentheses indicate degeneracy.

The force constant analysis has been carried out by the *F–G* matrix method, the *F* and *G* matrix elements used being those given by Nakamoto (7). The following set of force constants was determined:

$$Fr = 4.497 \times 10^5 \text{ dyn cm}^{-1}$$
$$F\alpha = 0.629 \times 10^5 \text{ dyn cm}^{-1}$$
$$Frr = 0.420 \times 10^5 \text{ dyn cm}^{-1}$$
$$F\alpha\alpha = 0.092 \times 10^5 \text{ dyn cm}^{-1}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These have been used to determine the frequencies for $^{76}SeO_3^{2-}$ and $^{82}SeO_3^{2-}$ quoted in Table I.

The fundamental frequencies for $^{80}SeO_4^{2-}$ listed in Table I are the means of values reported by Heath and Linnett (8), Pistorius (9), and Walrafen (10). SeO_4^{2-} has T_d symmetry. The force constants were calculated by the *F–G* matrix method, the matrix elements used being those given by Pistorius (9).

From the method of Pistorius, *Frr* is assumed to be 0.347, and, using the frequency data for $^{80}SeO_4^{2-}$, the following set of force constants was determined:

$$\begin{aligned} Fr &= 5.529 \times 10^5 \text{ dyn cm}^{-1} \\ Fr\alpha - Fr\alpha' &= -0.195 \times 10^5 \text{ dyn cm}^{-1} \\ F\alpha - F\alpha\alpha' &= 0.660 \times 10^5 \text{ dyn cm}^{-1} \\ F\alpha\alpha - F\alpha\alpha' &= 0.148 \times 10^5 \text{ dyn cm}^{-1}. \end{aligned}$$

These have been used to determine the frequencies for $^{76}SeO_4^{2-}$ and $^{82}SeO_4^{2-}$ listed in Table I.

Table II shows calculated ratios of partition functions for the molecules SeO_3^{2-} and

TABLE II

Partition function ratios for selenite and selenate

T, °C	$Q(^{82}SeO_3^{2-})/Q(^{76}SeO_3^{2-})$	$Q(^{82}SeO_4^{2-})/Q(^{76}SeO_4^{2-})$
0	1.029 (1.008)*	1.054 (1.015)
25	1.025 (1.007)	1.047 (1.013)
50	1.021 (1.006)	1.041 (1.012)

*The figures in parentheses represent the contributions of individual frequencies, as discussed in the text.

SeO_4^{2-}. Also shown are the contributions to these ratios of (i) for SeO_3^{2-}, one component of the doubly degenerate *E*-type asymmetric stretching vibration ν_3 and of (ii) for SeO_4^{2-}, one component of the triply degenerate F_2-type vibration ν_3.

EXPERIMENTAL

The mass spectrometer and the method for preparing SeF_6 samples for isotopic analysis of selenium have been described by Krouse and Thode (1).

The Reduction of Sodium Selenite

Reductions were performed with ascorbic acid ($C_6H_8O_6$), which gives quantitative reductions quickly at room temperature over a wide range of pH's. For fractional reductions, the percentage reaction can be easily and predictably controlled by the quantity of $C_6H_8O_6$ used. The stoichiometry of the reaction is:

$$SeO_3^{2-} + 2H^+ = H_2SeO_3$$
$$H_2SeO_3 + 2C_6H_8O_6 = Se^0 + 2C_6H_8O_6 + 3H_2O.$$

Two sets of reductions were performed; one, at 24 °C, varying the % reduction, and the other, a set of 20% reductions at 3 °C and 40 °C. In all reductions the procedure was to add the quantity of $C_6H_8O_6$ required to give the correct percentage reduction to a solution of Na_2SeO_3, the solution then being maintained at the required temperature until the precipitated selenium could be filtered and weighed.

The Reduction of Sodium Selenate

It has been reported (11, 12) that selenate is reduced to selenite in strong HCl solutions. However, from the oxidation potentials compiled by Latimer (13), the reaction may be written:

$$SeO_4^{2-} + 4H^+ + 2Cl^- = H_2SeO_3 + H_2O + Cl_2 - 0.21.$$

Thus, in 1 *M* solutions, the components on the left are favored. It has been suggested (14) that in fact the reduction of Se^{vi} to Se^{iv} proceeds as:

$$SeO_4^{2-} + 8Cl^- + 8H^+ \rightarrow SeCl_6^{2-} + Cl_2 + 4H_2O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

If Se^{iv} formed by the above reaction is reduced to Se^0 by the action of $C_6H_8O_6$, then there is the possibility of the reaction

$$2Se^{vi} + Se^0 \rightarrow 3Se^{iv}$$

or, from Latimer:

$$2SeO_4^{2-} + Se^0 + H_2O + 4H^+ = 3H_2SeO_3 + 0.41.$$

In practice this reaction only occurs if the Se^0 is present in the red active form.

Three experiments were performed, at 22 °C in each case, with HCl to reduce Se^{vi} to Se^{iv} and $C_6H_8O_6$ to reduce Se^{iv} to Se^0. In each of these 10 ml of 0.5 *M* Na_2SeO_4 together with 50 ml H_2O and 120 ml concentrated HCl was used.

1. $C_6H_8O_6$ (881 mg, 2.5 meq) was added to the solution. After the formation of red Se^0, 300 ml H_2O was added to quench the oxidation of Se^0.
2. The solution was allowed to stand overnight before the addition of 2.5 meq $C_6H_8O_6$. Red Se^0 was formed, some of which was lost by the oxidation reaction described above.
3. $C_6H_8O_6$ (2.5 meq) was added to the solution. Red Se^0 was formed and after 1 h had virtually disappeared by re-oxidation. A further 2.5 meq $C_6H_8O_6$ was added, more red Se^0 being formed. In each of these experiments, the red Se^0 was allowed to nucleate and was recovered by filtration for weighing and isotopic analysis.

RESULTS AND DISCUSSION

The Reduction of Sodium Selenite

Table III shows the results of the reduction experiments. Column 4 shows the isotope effects, comparing product selenium with the starting material, and column 5 gives the ratio of rate constants for the reactions:

$$^{76}Se^{iv} \xrightarrow{k_1} Se^0$$
$$^{82}Se^{iv} \xrightarrow{k_2} Se^0.$$

The ratios of rate constants are derived from the experimental isotope effects by eq. [1]. The isotope effects involved are appreciable, indicating that a bond involving selenium is broken in the rate-determining step for the reduction. The value for k_1/k_2 at 3 °C is in good agreement with the experimental value reported by Krouse and Thode (1).

TABLE III

Selenium isotope effects in the reduction of sodium selenite

Experiment	T, °C	% reduction	δ, p.p.t.*	k_1/k_2
1	24±1	10	−18.4±1	1.020±0.001
2	24±1	20	−16.9±1	1.019±0.001
3	3±1	20	−14.6±1	1.017±0.001
4	40±1	20	−14.2±0.7	1.016±0.0007

$$*\delta(\text{p.p.t.}) = \frac{(^{82}Se/^{76}Se)_x - (^{82}Se/^{76}Se)_{standard}}{(^{82}Se/^{76}Se)_{standard}} \times 1000.$$

Theoretical predictions of k_1/k_2 may be made from the three arguments discussed above and by supposing the rate-controlling step in the reduction to be the cleavage of an Se—O bond.

In case I (see theoretical section), the activated complex is the same as the starting material with the exception that one vibrational mode has taken on a non-genuine character. This mode is most probably one component of the doubly degenerate *E*-type asymmetric stretching vibration ν_3 ($\sim$730 cm^{-1}). The ratio of partition function terms will be (from Table II): 1.008, 1.007, and 1.006 at 0, 25, and 50 °C, respectively.

The mass term may be evaluated from either atomic masses or mass fragments for the reduced mass of the species O_2Se---O, yielding the values 1.006 and 1.004, respectively. The values for k_1/k_2 are shown in columns 4 and 5 of Table IV.

For personal use only.

TABLE IV

Summary of calculated ratios of rate constants for the reduction of Se^{iv}

T of model, °C	k_1/k_2					
	II (low)		I (intermediate)		III (high)	
	Mass	Atom	Mass	Atom	Mass	Atom
0	1.004	1.006	1.012	1.014	1.033	1.035
25	1.004	1.006	1.011	1.013	1.029	1.031
50	1.004	1.006	1.010	1.012	1.025	1.027

In case II, the lower limit for k_1/k_2 is simply the mass term, 1.006 or 1.004 for atom or mass fragments. These values are shown in columns 2 and 3 of Table IV.

For case III, the upper limit for k_1/k_2 is given by

$$k_1/k_2 = Q(^{82}SeO_3^{2-})/Q(^{76}SeO_3^{2-}) \cdot (\mu_2^{\ddagger}/\mu_1^{\ddagger})^{1/2}$$

for which the values of k_1/k_2 are shown in columns 6 and 7 of Table IV. All three arguments predict a regular decrease in the value of k_1/k_2 with increase of temperature. Thus, while argument I yields predicted values of the right magnitude, the experimental temperature dependence is difficult to account for on the basis of this simple model. It is not possible to give any preference to either the atom or mass fragment estimates of the mass terms.

TABLE V

Experimentally observed isotope effects in the reduction of Se^{iv}

Experiment	Se recovery		δ, p.p.t.
	mg	%	
1	122	32.5	-14.0 ± 1.0
2	72	18.0	-10.4 ± 1.0
3	233	59.2	-8.3 ± 1.0

$$\delta(\text{p.p.t.}) = \frac{(^{82}Se/^{76}Se)_x - (^{82}Se/^{76}Se)_{standard}}{(^{82}Se/^{76}Se)_{standard}} \times 1000.$$

It is possible that at low temperatures some factor such as solvent effects is causing the value of k_1/k_2 to be depressed, but, because of the errors involved in the experimental results, it is not possible to rule out the possibility that this temperature dependence is spurious.

The Reduction of Sodium Selenate

Table V shows the yields of selenium from the experiments described above, together with the isotope effects in product selenium, measured relative to the starting material.

Three reactions are involved in the above experiments, viz

[3] $Se^{vi} \rightarrow Se^{iv}$

[4] $Se^{iv} \rightarrow Se^{0}$

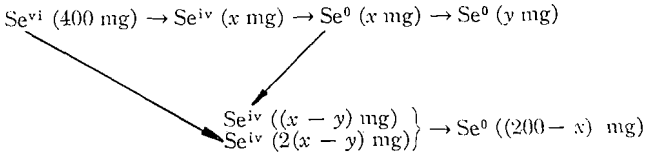
[5] $Se^{0} \rightarrow Se^{iv}$

and from the experimental results it is possible to estimate k_{76}/k_{82} for each of them. Let us consider the experiments in turn.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Experiment 1

With 5 meq Se^{vi} in HCl solution, 2.5 meq $C_6H_8O_6$ was added, and, after the formation of Se^0, the acidity of the solution was reduced to prevent re-oxidation. The reaction may be written as:



$$Se^{vi} \xrightarrow{32.5\%} Se^{iv} \xrightarrow{100\%} Se^0.$$

There is no isotope effect in the second step. The observed isotope effect is −14 p.p.t. for a 33% reduction, which from eq. [1] gives a value of 1.018 for k_1/k_2 in the reduction of Se^{vi} to Se^{iv}.

Experiment 2

Se^{vi} (5 meq) in HCl solution was allowed to stand for 24 h before 2.5 meq $C_6H_8O_6$ was added. No attempt was made to prevent oxidation of Se^0 and 72 mg of Se^0 was recovered.

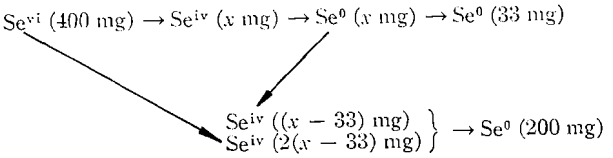
The proposed reaction scheme is shown below.

Here, x mg Se^{vi} is reduced to Se^{iv} and 100% of the Se^{iv} is reduced to Se^0. Of the x mg Se^0, y mg remains unoxidized while $(x - y)$ mg is oxidized to Se^{iv}. In this oxidation, twice this quantity, the total remaining, of Se^{vi} is reduced to Se^{iv}. So $3(x - y)$ mg Se^{iv} are produced. There was sufficient $C_6H_8O_6$ added to reduce 200 mg Se^{iv} and x mg was reduced, so that a further $(200 - x)$ mg are reduced to Se^0 giving a total of $(200 - x) + y$ mg (72 mg experimentally).

From the above considerations:

$$(200 - x) + y = 72$$
$$2(x - y) = 400 - x.$$

So that:



$$x = 144 \text{ mg}; \; y = 16 \text{ mg}.$$

If, in the oxidation of Se^0, one assumes the substrate to be at $+\Delta$ p.p.t. with respect to the original Se^0, so that the 128 mg Se^{iv} formed from the Se^0 is at $-(16/128)\Delta$ p.p.t., and, if k_1/k_2 for reactions [3] and [4] is taken as 1.018 and 1.015, respectively, then, with the observed Δ value of the final product Se^0 (−10.4 p.p.t.), it is possible to work through the reactions, using eqs. [1] and [2] to derive $\Delta = 17$ p.p.t. and k_1/k_2 for reaction [5] = 1.007.

Experiment 3

With 400 mg Se^{vi} in HCl solution, 2.5 meq $C_6H_8O_6$ was added, and red Se^0 formed, some of which was re-oxidized. A further addition of 2.5 meq $C_6H_8O_6$ was made, more red Se^0 being formed to give a total yield of 233 mg.

The proposed reaction scheme is shown below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Here x mg Se^{VI} was reduced to Se^{IV} and to Se^0. Oxidation of Se^0 to Se^{IV} was accompanied by the reduction of all the remaining Se^{VI} to Se^{IV}. When the second addition of $C_6H_8O_6$ was made, only Se^{IV} and Se^0 remained, and this $C_6H_8O_6$ was sufficient to reduce 200 mg Se^{IV} to Se^0, there being no further oxidation.

This being the case, the amount of Se^0 not oxidized by the presence of Se^{VI} must have been 33 mg. From these considerations

$$2(x - 33) + x = 400$$

so that:

$$x = 155 \text{ mg.}$$

Using k_1/k_2 values for the reactions [3], [4], and [5] of 1.018, 1.015, and 1.007, respectively, and working through the various reactions, using eqs. [1] and [2], leads to a predicted value of -6.9 p.p.t. for the recovered Se^0, compared with the experimental value of -8.3 p.p.t.

Reinterpretation of the results of experiments 2 and 3 with adjustment of the value of k_1/k_2 for reaction [4] leads to an optimum set of values in which k_1/k_2 for reactions [3], [4], [5] is 1.018, 1.017, and 1.010, respectively, these values giving a δ-value of -9.1 p.p.t. for the recovered Se^0 in experiment 3, compared with the experimental value of -8.3 p.p.t.

Theoretical predictions of k_1/k_2 for reaction [3], the reduction of Se^{VI} to Se^{IV}, may be made from the three arguments discussed above and by supposing the rate-controlling step in the reduction to be the cleavage of a Se—O bond.

TABLE VI

Summary of the calculated ratios of rate constants for the reduction of Se^{VI} to Se^{IV} at 25 °C

	k_1/k_2 for model:		
	II (low)	I (intermediate)	III (high)
Mass fragments	1.002	1.015	1.049
Atom fragments	1.006	1.019	1.053

In case I (see theoretical section), the activated complex is the same as the starting material with the exception that one vibrational mode has taken on a non-genuine character. This mode is most probably one component of the triply degenerate F_2-type vibration $\nu_3(\sim 880 \text{ cm}^{-1})$. The partition function term will be (from Table II) 1.013 at 25 °C. The mass term may be evaluated from either atomic masses or mass fragments for the reduced mass of species O_3Se---O, yielding the values 1.006 and 1.002, respectively. The values for k_1/k_2 are shown in column 2 of Table VI.

In case II, the lower limit for k_1/k_2 is simply the mass term, 1.006 or 1.002 for atom or mass fragments. These values are shown in column 1 of Table VI.

In case III, the upper limit for k_1/k_2 is given by

$$k_1/k_2 = Q(^{82}SeO_4^{2-})/Q(^{76}SeO_4^{2-}) \cdot (\mu_2^{\ddagger}/\mu_1^{\ddagger})^{1/2}$$

for which the values of k_1/k_2 are shown in column 3 of Table VI.

Comparison of the figures in Table VI with the experimental results shows that the intermediate case, argument I, gives good agreement with experiment, but that it is not possible to give preference to either the atom or mass fragment estimates of the mass term.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The theoretical prediction of k_1/k_2 for reaction [5], the oxidation of Se^0 to Se^{IV}, requires that the partition function ratio for the reactant material, elemental selenium, be known. The elemental selenium will most likely be in the form of open-ended selenium chains, and partition function ratio data for these are not available. All that may be said concerning such a prediction is: If the activated complex is simply selenium or a diatomic molecule containing selenium, so that Q_2/Q_1 is unity and the mass term is either unity or greater than unity, then the predicted ratio k_1/k_2 will be greater than unity, as is observed experimentally.

CONCLUSIONS

The experiments on the reduction of sodium selenite show that the rate constant for the ^{76}Se species is about 1.017 times that for the ^{82}Se species. Theoretical prediction of this ratio, from a simple model where the rate-determining step is the breaking of a Se—O bond in SeO_3^{2-}, leads to good agreement with experiment for the magnitude of the isotope effect. It is not possible to explain the temperature dependence of k_1/k_2 on the basis of this model.

From the experiments on the reduction of sodium selenate, estimates can be made of the ratios k_{76}/k_{82} for the reduction of Se^{VI} to Se^{IV} and the oxidation of Se^0 to Se^{IV}, values of 1.018 and 1.010 being determined. Theoretical prediction of the former ratio, assuming the rate-determining step to be the cleavage of a Se—O bond in SeO_4^{2-}, gives good agreement with experiment.

SECOND VIRIAL COEFFICIENTS AND INTERMOLECULAR FORCES FOR THE AMMONIA–ACETYLENE SYSTEM

H. Y. Cheh, J. P. O'Connell, and J. M. Prausnitz
Department of Chemical Engineering, University of California, Berkeley, California

Received September 8, 1965

ABSTRACT

Volumetric data for gaseous ammonia–acetylene mixtures have been analyzed to obtain second virial coefficients as a function of temperature and composition. From the pure-component virial coefficients of ammonia and acetylene, Kihara-potential parameters were obtained and these were used to calculate the physical contributions to the second cross virial coefficients, B_{12}. The difference between the experimental B_{12} and that calculated from the physical contribution is attributed to chemical interaction, or complex formation, between the two molecules. Chemical equilibrium constants have been calculated, and ΔH^0 and ΔS^0 for complex formation were found to be $-(2\,210)$ cal/mole and -16.6 cal/mole °K respectively. These results indicate very weak hydrogen bond formation between the nitrogen atom in the ammonia and the hydrogen atom in acetylene.

1. INTRODUCTION

The study of chemical association and solvation in the gaseous phase by analysis of second virial coefficient data has been well established by various workers, notably by Lambert (1). Recent volumetric data for the ammonia–acetylene system reported by Khodeeva (2) have provided us with an opportunity to study the intermolecular forces between these two molecules.

2. CALCULATION OF SECOND VIRIAL COEFFICIENTS

2.1. Ammonia

Very precise measurements for the volumetric properties of ammonia have been reported by Meyers and Jessup (3), Beattie and Lawrence (4), and Kasarnowsky (5). Data covering the temperature range 298.2 to 598.2 °K and the pressure range 1 to 250 atm were used in the evaluation of the second virial coefficients of ammonia. The data reduction method used was similar to that of David and Hamann (6). The results are summarized in Table I and in Fig. 1.

423.2	−99

2.2. Acetylene

Volumetric data of acetylene at various temperatures and pressures were measured by Hölemann and Hasselmann (7), by Teranishi (8), and also by Schäfer (9). The substantial disagreement between their results has been discussed by Weber (10). We also found the data to be inadequate for evaluating the second virial coefficients. Therefore second virial coefficients were calculated with the equation of Pitzer and Curl (11) based on a three-parameter theorem of corresponding states. Pitzer and Curl's equation utilizes the critical

For personal use only.

pressure, the critical temperature, and an acentric factor which is determined from the experimental vapor pressure curve. These properties of acetylene and the calculated second virial coefficients are given in Table II and in Fig. 1. We estimate the uncertainty in the second virial coefficients to be about ±5 cc/mole at the lower temperatures and ±2 cc/mole at higher temperatures.

2.3. Ammonia–Acetylene

Recently, Khodeeva (2) published measurements for the volumetric properties of the ammonia–acetylene system over the range 323.2 to 423.2 °K and 10 to 90 atm. Second virial coefficients for the mixture were calculated by the same method as that used for ammonia. The results are shown in Fig. 2.

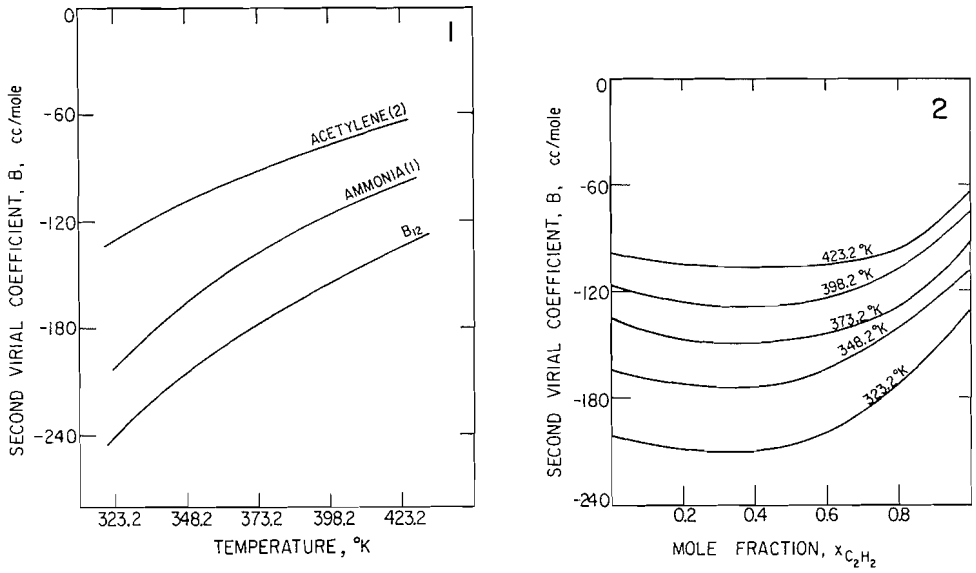

FIG. 1. Second virial coefficients for ammonia, acetylene, and ammonia–acetylene.
FIG. 2. Second virial coefficients for the ammonia–acetylene system.

The second virial coefficient B of a binary system is related to the second virial coefficients of the pure components and to the second cross virial coefficient B_{12} by

$$B = x_1^2 B_{11} + 2x_1 x_2 B_{12} + x_2^2 B_{22} \quad [1]$$

where x is the mole fraction and where the subscripts 1 and 2 stand for components 1 (ammonia) and 2 (acetylene).

3. PHYSICAL INTERACTIONS AND SECOND VIRIAL COEFFICIENTS

3.1. Various Physical Interactions

Physical interactions among molecules possessing dipole and quadrupole moments include in the general case interactions resulting from dispersion, dipole–dipole, dipole–induced dipole, dipole–quadrupole, quadrupole–quadrupole, and off-center dipole forces. For the dispersion and dipole–dipole interactions tables of reduced second virial coefficients for the spherical-core potential have been calculated by O'Connell and Prausnitz (12). For other interactions, the following equations may be applied*

$$[2]\quad B_{\text{ind}} = -\frac{2}{3}\pi N\delta^3 \frac{\alpha\mu^2}{8\delta^6 U_0 y^2}\left[H_6(y) + \frac{\mu^4 y^4}{40\delta^6 U_0^2} H_{12}(y) + \frac{29\mu^8 y^8}{(134\,400)\delta^{12} U_0^4} H_{18}(y) + \dots\right]$$

$$[3]\quad B_{\text{dip–quad}} = -\frac{2}{3}\pi N\delta^3 \frac{\mu^2\theta^2}{64\delta^8 U_0^2}\left[H_8(y) - \frac{\mu^2 y^2}{5\delta^3 U_0} H_{11}(y) - \frac{6\theta^2 y^2}{35\delta^5 U_0} H_{13}(y) + \dots\right]$$

$$[4]\quad B_{\text{quad–quad}} = -\frac{2}{3}\pi N\delta^3 \frac{7\theta^4}{320\delta^{10} U_0^5}\left[H_{10}(y) - \frac{18\theta^2 y^2}{343\delta^5 U_0} H_{15}(y) + \dots\right]$$

$$[5]\quad B_{\text{off-center dip}} = -\frac{2}{3}\pi N\delta^3 \frac{\gamma^{*2}\mu^2}{2\delta^3 U_0}\left[H_8(y) - \frac{\mu^2 y^2 H_{11}(y)}{5\delta^3 U_0} + \dots\right]$$

where

$$y^2 = 4U_0/kT, \quad \gamma^* = 2a/\delta, \quad a^* = 2a/(\delta - 2a),$$

$$H_n(y) = y^{(4.5-(n/6))} \sum_{m=0}^{\infty} \Gamma\left(\frac{6m + n - 3}{12}\right)\frac{y^m}{m!},$$

U_0 = minimum potential energy,
a = radius of the spherical core of the molecule,
δ = distance between molecular centers when the potential energy is zero,
α = polarizability,
μ = dipole moment, and
θ = quadrupole moment.

In general, dispersion and dipole–dipole contributions are by far the most significant. However, the others are not negligible.

**To correct misprints in ref. 12, the exponent of δ in the factor outside the bracket should be changed from 3 to 6 in eq. [14] and from 5 to 8 in eq. [15].*

3.2. Evaluation of Intermolecular Parameters

3.2.a. Ammonia

Ammonia is a tetrahedral molecule with a dipole moment of 1.47 D (debye) (13) and a quadrupole moment of 1.0×10^{-26} electrostatic unit cm^2 (e.s.u. cm^2) (14). Hence all the additional interactions described by eqs. [2] to [5] are significant. The best Kihara parameters were obtained by a fit of the second virial coefficients by a nonlinear, least squares technique on an IBM 7094 computer to all the interaction equations simultaneously. The best values for the parameters and the root mean square (r.m.s.) deviation for the second virial coefficients from 298.2 to 598.2 °K are

$$U_0/k = 145\ ^\circ\text{K},\ \delta = 2.63\ \text{Å},\ 2a = 0.125\ \text{Å},\ \text{and r.m.s. deviation} = 1.36\ \text{cc/mole}.$$

3.2.b. Acetylene

Acetylene is a linear molecule with no dipole moment but a quadrupole moment of 3.0×10^{-26} e.s.u. cm^2 (14). Here only the dispersion and quadrupole–quadrupole interactions are important. The second virial coefficients were fitted to obtain a set of Kihara-potential parameters. These parameters were then used to calculate $B_{\text{quad–quad}}$ by eq. [4]. The difference between the overall second virial coefficients and $B_{\text{quad–quad}}$ thus obtained was then used to provide a new estimate of B_{disp} in order to obtain a better set of potential parameters. These parameters in turn gave a better approximation for $B_{\text{quad–quad}}$. This iterative process was continued until there was no change in the parameters by two successive approximations. The best values for the parameters and the r.m.s. deviation for the second virial coefficients from 273.2 to 533.2 °K are

$$U_0/k = 412\ ^\circ\text{K},\ \delta = 4.11\ \text{Å},\ 2a = 1.54\ \text{Å},\ \text{and r.m.s. deviation} = 0.10\ \text{cc/mole}.$$

3.3. Calculation of Second Cross Virial Coefficients $B_{12\ phys}$ resulting from Physical Interactions

The commonly recommended semiempirical mixing rules were used to obtain the Kihara-potential parameters for the mixtures:

[6] $$U_{0_{12}}/k = (U_{0_1}U_{0_2})^{1/2}/k = 245.2\ ^\circ\text{K}$$

[7] $$\delta_{12} = \tfrac{1}{2}(\delta_1 + \delta_2) = 3.367\ \text{Å}$$

[8] $$a_{12} = \tfrac{1}{2}(a_1 + a_2) = 0.416\ \text{Å}.$$

To calculate $B_{12\ \text{phys}}$, the parameters of eqs. [2] to [4] are as follows:

$$\mu = \mu_1,\ \alpha = \alpha_2,\ \theta = \theta_2$$

[9] (or $\theta = \sqrt{(\theta_1\theta_2)}$ for the quadrupole–quadrupole interaction).

The various contributions to $B_{12\ \text{phys}}$ were then found from the function $H_n(y)$ tabulated by Buckingham and Pople (15). The results are summarized in Table IV and Fig. 3.

TABLE IV

Various physical B_{12} for the ammonia–acetylene system

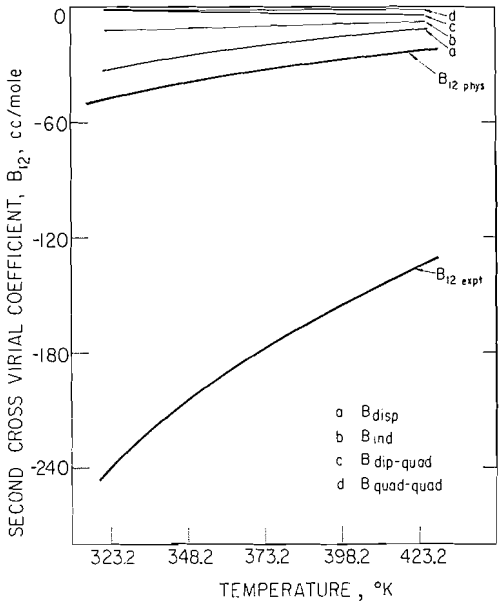

FIG. 3. Physical contributions to the cross coefficient B_{12}.

4. CHEMICAL SOLVATION BETWEEN AMMONIA AND ACETYLENE

Figure 3 clearly shows that the virial coefficients resulting from physical interactions between ammonia and acetylene account for only about 20% of the experimental B_{12}. This discrepancy is due to the chemical association between ammonia and acetylene which probably is a result of hydrogen bonding.

We postulate the following chemical equilibrium:

[10] $$C_2H_2 + NH_3 \rightleftharpoons C_2H_2{-}NH_3.$$

The stoichiometric coefficients are unity in eq. [10] since second virial coefficients represent only two-body interactions. Lambert *et al.* (16) derived the relationship between second virial coefficients and equilibrium constants for a bimolecular reaction provided that the degree of complex formation was small. This method has been applied to various mixtures by Lambert and associates (16, 17) and also by Prausnitz and Carter (18).

For the bimolecular chemical equilibrium,

[11] $$A + B \rightleftharpoons AB$$

the equilibrium constant K_p is defined as

[12] $$K_p = p_{AB}/p_A p_B$$

where p_{AB}, p_A, and p_B are the partial pressures of AB, A, and B respectively.

Lambert *et al.* (16) showed that

[13] $$-RTK_p = B_{12\ chem} = B_{12\ expt} - B_{12\ phys}.$$

The term $B_{12\ phys}$ can be considered to be a result of dispersion and electrostatic forces in instantaneous molecular collisions whereas the term $B_{12\ chem}$ results from the formation of weak chemical bonds. This division is necessarily somewhat arbitrary. The thermodynamic equilibrium constant K is defined by

[14] $$-RT \ln K = \Delta G^0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where ΔG^0 is the standard Gibbs free energy change, and where

[15] $$K = K_p K_\varphi$$

and

[16] $$K_\varphi = \varphi_{AB}/\varphi_A\varphi_B \ (\varphi = \text{fugacity coefficient}).$$

To obtain K from K_p data, it is necessary to extrapolate K_p to its value at zero pressure where $K_\varphi = 1$. Equation [13] then gives the relationship between $B_{12\ \text{chem}}$ and K. Since $B_{12\ \text{expt}}$ and $B_{12\ \text{phys}}$ were both evaluated by extrapolation to zero pressure, the above conditions are automatically satisfied.

The enthalpy and entropy of complex formation are given by the slope and intercept of a plot of ln K versus the reciprocal of the absolute temperature:

[17] $$-\ln K = (\Delta H^0/RT) - (\Delta S^0/R).$$

Table V shows our result for K at various temperatures. The heat and entropy are

$$\Delta H^0 = -(2\,210) \text{ cal/mole} \pm 300 \text{ cal/mole and}$$
$$\Delta S^0 = -16.6 \text{ cal/mole °K} \pm 0.9 \text{ cal/mole °K}.$$

The uncertainties in the enthalpy and entropy of reaction are due mainly to experimental error.

TABLE V

$B_{12\ \text{chem}}$ and equilibrium constants

Temp., °K	$B_{12\ \text{chem}}$, cc/mole	K_p, atm^{-1}
323.2	−193	0.00729
348.2	−165	0.00579
373.2	−145	0.00473
398.2	−128	0.00392
423.2	−112	0.00322

The enthalpy of complex formation is roughly one-half that for typical hydrogen bond formation (19). The enthalpies of the pure components in the ideal gas state at 373.2 °K calculated on the basis of structural parameters (20) are

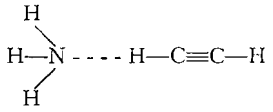
$$H_{NH_3}{}^0 = 3\,060 \text{ cal/mole and } H_{C_2H_2}{}^0 = 3\,230 \text{ cal/mole}.$$

The enthalpy of the complex is then estimated from the heat of complex formation to be 4 080 cal/mole. If one follows Rowlinson's (21) suggestion and assumes that the complex behaves as an ideal diatomic gas (no vibration of the newly formed bond), the enthalpy would be $(7/2)RT$ which is only 2 600 cal/mole. The extra enthalpy of 1 480 cal/mole for the complex may be accounted for by consideration of the vibrational degrees of freedom. For instance, the introduction of two normal modes of very low vibrational frequencies produces an enthalpy of this magnitude.

Similarly, the entropies of ammonia and acetylene as ideal gases, calculated at 373.2 °K and 1 atm, are

[18]
$$\begin{cases} S^0 = S_{trans}{}^0 + S_{rot}{}^0 + S_{vib}{}^0 \\ S_{NH_3}{}^0 = (38.55 + 9.14 + 0.30) \text{ cal/mole °K} = 47.99 \text{ cal/mole °K} \\ S_{C_2H_2}{}^0 = (36.83 + 11.31 + 2.34) \text{ cal/mole °K} = 50.48 \text{ cal/mole °K} \end{cases}$$

Hence the entropy of the complex is 81.9 cal/mole °K.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Shepp and Bauer (22) considered the change in entropy in gaseous, bimolecular association as being the sum of two terms

$$\Delta S^0 = \Delta S^0_{\text{trans+rot}} + \Delta S_{\text{vlb}}{}^0 \quad [19]$$

where $\Delta S^0_{\text{trans+rot}}$ is the change for rigid-body molecules and $\Delta S_{\text{vlb}}{}^0$ includes the difference in the entropy contributions from the nonrigid degrees of freedom, vibration and restricted rotation. They found that $\Delta S_{\text{vlb}}{}^0$ is always positive for the association process. The magnitude of $\Delta S_{\text{vlb}}{}^0$ is determined primarily by the strength of the new bond. For a weak bond, the frequencies are low and $\Delta S_{\text{vlb}}{}^0$ is large.

If one again considers the ammonia–acetylene complex as a diatomic gas held loosely by a hydrogen bond:

the translational and rotational entropy can be written as

$$S_{\text{trans}}{}^0 = R\left[\ln \frac{[2\pi(m_{NH_3} + m_{C_2H_2})kT]^{3/2}}{h^3}\frac{kT}{p}\right] + \frac{5}{2}R \quad [20]$$

$$S_{\text{rot}}{}^0 = R\left[\ln\left(\frac{8\pi^2 IkT}{\sigma h^2}\right) + 1\right] \quad [21]$$

where m_{NH_3} and $m_{C_2H_2}$ are the mass of the ammonia and acetylene molecules respectively, I is the moment of inertia of the complex, and σ is the symmetry factor of the complex. At 373.2 °K and 1 atm, $S_{\text{trans}}{}^0$ for the complex is 38.3 cal/mole °K. $S_{\text{rot}}{}^0$ depends on the N - - - H bond length and has values varying from 14.0 to 14.9 cal/mole °K if the distance between the two "big atoms" varies from 2 Å to 3.5 Å. Thus $S_{\text{rot}}{}^0$ is not very sensitive to the bond length. If we take $S_{\text{rot}}{}^0$ to be 14.5 cal/mole °K, $S^0_{\text{trans+rot}}$ is 52.8 cal/mole °K. Under these conditions $\Delta S_{\text{vlb}}{}^0$ is given as

$$\begin{aligned}\Delta S_{\text{vlb}}{}^0 &= \Delta S_{\text{total}}{}^0 - \Delta S^0_{\text{trans+rot}} \\ &= -16.6 - (52.8 - 48.1 - 47.7) \text{ cal/mole °K} \\ &= +26.4 \text{ cal/mole °K.}\end{aligned}$$

The magnitude of our value indicates that the N - - - H bond is a very weak one; this is in agreement with the conclusion reached from the enthalpy calculations. The $\Delta S_{\text{vlb}}{}^0$ value appears rather high when compared to most of the cases reported by Shepp and Bauer (22), and also by Slutsky and Bauer (23). But the equilibrium constants for the ammonia–acetylene system are also much lower and therefore a much weaker bond should be expected.

5. CONCLUSION

Evidence for chemical solvation between ammonia and acetylene in the gaseous phase has been obtained by analysis of the second virial coefficients for the ammonia–acetylene system. The chemical interaction contributes approximately 80% of the second cross virial coefficients. A molecular analysis of the heat and entropy changes resulting from chemical forces suggests that there is weak hydrogen bonding between ammonia and acetylene.

The authors are grateful to the Computer Center, University of California, Berkeley, for the use of their facilities.

ION PAIR EFFECTS IN THE REACTION BETWEEN POTASSIUM FERROCYANIDE AND POTASSIUM PERSULFATE

R. W. CHLEBEK AND M. W. LISTER
Department of Chemistry, University of Toronto, Toronto, Ontario

Received August 3, 1965

ABSTRACT

The rate of the reaction between potassium ferrocyanide and potassium persulfate has been measured over a range of conditions. The rate is dependent on the potassium ion concentration, and it is shown that this is explained if it is assumed that $KFe(CN)_6^{3-}$ and $KS_2O_8^-$ are the reacting species. The equilibrium constants governing the formation of these ion pairs were measured with a cation-sensitive glass electrode. Similar constants for the products $KFe(CN_6)^{2-}$ and KSO_4^-, and also for KNO_3, were measured. From these equilibrium constants, the true rate constants of the reaction can be obtained, and it is shown that these vary with ionic strength in the manner predicted by Brönsted's equation.

The reaction

$$2K_4Fe(CN)_6 + K_2S_2O_8 \rightarrow 2K_3Fe(CN)_6 + 2K_2SO_4$$

in aqueous solution was examined some time ago by Holluta and Herman (1). They found it to be a second-order reaction, but with rate constants that increased strikingly with the concentration of potassium ions. This might be attributed to an increase in ionic strength, and Brönsted's treatment (2) of the effect of ionic strength on reaction rate would, of course, predict such an increase, since the reacting ions are of the same sign. However, Holluta and Herman's results seem to correlate the rate constants with the potassium ion concentration rather than with the ionic strength; this is the sort of correlation that has been emphasized by Olson and Simonson (3) for other reactions. A possible explanation is that ion pairs such as $KFe(CN)_6^{3-}$ are the real reacting species, and this sort of explanation has been suggested in other cases (4). The object of the present work was, firstly, to investigate the extent of ion pair formation for the reagents and products in this reaction. This was done by measurements with a cation-sensitive glass electrode. Secondly, this information was used to find the nature of the actual reacting species, and hence the true rate constants of the reaction. Finally, the dependence of these rate constants on ionic strength was examined and compared with the predictions of Brönsted's equation.

EXPERIMENTAL

Chemicals

Potassium chloride.—Mallinckrodt analytical reagent was dried at 110 °C and stock solutions were made up by weight.

Tetramethylammonium chloride.—The salt, stated to be more than 99% pure, supplied by Matheson, Coleman and Bell Co. was used. Stock solutions were standardized by silver nitrate titration.

Tetramethylammonium hydroxide.—The 10% solution supplied by Eastman Organic Chemicals was diluted and standardized with potassium hydrogen phthalate.

Potassium nitrate.—The British Drug Houses AnalaR reagent was used after drying at 110 °C.

Potassium sulfate.—The Merck analytical reagent was used after grinding and drying at 110 °C.

Potassium persulfate.—The Fisher certified reagent was used. After drying, the salt was analyzed by adding excess ferrous ammonium sulfate to a solution of the salt, and titrating the excess with ceric ammonium sulfate. The salt was 100% pure within the error of the titration. Solutions were always used the same day that they were made up.

Potassium ferricyanide.—The Baker and Adamson reagent salt was used. Solutions were made up by weight, and standardized with iodometric titration.

Potassium ferrocyanide.—The Fisher certified reagent was used. The purity was checked by titration with ceric ammonium sulfate and found to be 100% within the experimental error. Solutions were always used the same day that they were made up.

RESULTS

Equilibrium Measurements

The concentrations of potassium ions in various solutions were measured with a Beckmann 39137 cation electrode. A saturated calomel electrode with a frit junction was used as a reference electrode, and the voltages were read on a Beckmann 101900 research pH meter. The voltages could be read to 0.05 mV. The apparatus was first calibrated by solutions of potassium chloride, containing 0.001 M tetramethylammonium hydroxide and adjusted to a fixed ionic strength by tetramethylammonium chloride. The tetramethylammonium hydroxide was added to keep the hydrogen ion concentration low, since the glass electrode is sensitive to hydrogen ions. Calibrations were made at different temperatures, which were controlled to within ±0.1 °C by a water thermostat.

It was expected that the variation of the measured voltage with concentration would follow the Nernst equation, in effect

$$dE/d \log [K^+] = 0.1984T,$$

where E is the voltage in mV and T is the absolute temperature. In fact, slightly different values for the slope of E against log [K^+] were obtained, and instead of 0.1984 the following values were found.

t (°C)	20	25	30	40	Mean
Slope	0.1923	0.1937	0.1912	0.1919	0.1923

These are for a range of [K^+] from 0.1 to 0.01 M, and are all at an ionic strength of 0.1. This deviation cannot be caused by formation of ion pairs of KCl, since this would have increased the slope; potassium chloride was chosen as the calibrating compound since earlier work (e.g. ref. 4, p. 169) had shown that ion pair formation was very slight. Probably the electrode responds slightly to tetramethylammonium ions. In practice, for the determination of equilibrium constants, the electrode was placed alternately in a calibrating solution of potassium chloride and in the salt solution whose equilibrium constant was being measured. Both solutions contained 0.001 M tetramethylammonium hydroxide and tetramethylammonium chloride to bring them to the same ionic strength (usually 0.1). It was assumed that the experimental values for $dE/d \log [K^+]$ held for this comparison.

Results for the various compounds investigated are given in Table I. The constants so obtained can be claimed to be only moderately accurate, as an error of 0.1 mV in δE (the difference between the voltage observed with the salt solution and with the calibrating solution) would cause a considerable change in K. For instance, for the second solution of potassium nitrate, a change of 0.1 mV in δE would increase K from 0.382 to 0.438. Table II summarizes the thermodynamic data calculated from the data in Table I. The equilibrium constants were measured at an ionic strength of 0.1. These can be converted to zero ionic strength, if single ion activity coefficients are assumed to be of the usual form,

$$[1] \qquad -\log f = Az^2\left(\frac{\sqrt{\mu}}{1 + Ba\sqrt{\mu}} - C\mu\right).$$

Kielland (5) has found that values of $a = 4$ Å for the $S_2O_8^{2-}$ ion and $a = 5$ Å for the $Fe(CN)_6^{4-}$ ion fit the activity coefficient data for salts of these ions. For potassium ions $a = 3$ Å is a commonly used value. The results in Table II were calculated using these values, 3.5 Å for sulfate and nitrate ions, and values for the ion pairs equal to that for the anion they contain. The values for K^0 in Table II may be compared with results in the literature obtained by other methods of measurement, mostly by conductivity. These are: KNO_3, 0.72 to 0.78 at 18 °C (6, 7) and 0.55 (7) to 0.63 at 25 °C (8); K_2SO_4, 6.6 at 18 °C and 9.1 at 25 °C (9); $K_3Fe(CN)_6$, 20 at 18 °C and 25 at 25 °C (10, 11); $K_4Fe(CN)_6$, 200 at 25 °C (12, 13). Considering the different methods of measurement, and the adjustment to zero ionic strength, these values are in reasonable agreement with the present ones.

Two other comments may be made on Table II. Firstly, ΔH^0 plotted against ΔS^0 gives an approximately straight line with slope about 220 °K. Secondly, ΔS^0 becomes larger as the charge on the ion increases. This would be expected if it arises from polarization of the

solvent (the "Born charging effect") which has been applied by Laidler in treating the entropy of hydrated monatomic ions (14). His equation for these ions was (S^0 in cal/deg mole)

$$S^0 = \tfrac{3}{2}R \ln M + 10.2 - 11.6z^2/r,$$

where M is the atomic weight, z the charge, and r the radius of the ion. The last term is the one arising from polarization and, though many other effects must be involved in determining the entropy of these ions, it is worth noting that qualitatively the order for ΔS^0 is that predicted from considerations of polarization.

Kinetic Measurements

The reaction between potassium ferrocyanide and potassium persulfate was followed by taking samples from the reacting mixture and measuring the optical absorbance at 420 mμ with a Beckmann DU spectrophotometer. At this wavelength, the extinction coefficient is 1 025 cm^{-1} (g mole/l)$^{-1}$ for potassium ferricyanide, ~0.85 for potassium ferrocyanide, and negligibly small for all other substances present. Previous work (15) on the spontaneous decomposition of potassium persulfate showed that, under the conditions used, less than 1% of its total disappearance was due to spontaneous decomposition. This observation was confirmed in the present work by iodometric titration of the reaction mixtures at the beginning and end of a run. The titre, which measures both ferricyanide and persulfate, did not decrease detectably during the reaction.

The reaction is first order in both reagents. Rate constants, calculated on this assumption, did not drift during the runs, which were frequently continued until the reaction was 80% complete. Table III gives such constants defined by

$$-\frac{d[K_2S_2O_8]}{dt} = -\frac{1}{2}\frac{d[K_4Fe(CN)_6]}{dt} = k_{app}[K_4Fe(CN)_6].[K_2S_2O_8].$$

No assumption is made at present about whether free ions or ion pairs are the actual reacting species; hence these are apparent rate constants (indicated by k_{app} throughout). Table III gives the initial reagent concentrations and also the concentration of potassium nitrate, which was added to control the ionic strength. In addition, all reaction mixtures were 0.001 M in potassium hydroxide to prevent formation of hydrolyzed species, particularly $HFe(CN)_6^{3-}$.

DISCUSSION

The results in Table III show the dependence on potassium ion concentration previously noted by Holluta and Herman (1). This is not simply a matter of ionic strength. For instance, runs 1, 3, and 4 all have an apparent ionic strength of almost exactly 0.10; but in run 4 k_{app} is 0.56 with total $[K^+] = 0.043$, in run 1 k_{app} is 0.88 with total $[K^+] = 0.058$, and in run 3 k_{app} is 1.48 with total $[K^+] = 0.089$ *M*. Runs 33, 34, and 35 form a similar series. The most plausible theory of this behavior is to suppose that one or both of the reacting species are ion pairs. The various possible combinations were examined, and the choice made on the basis of whether (i) the rate constants fell on a smooth curve when plotted against ionic strength, and (ii) whether the effect of ionic strength followed the predictions of Brönsted's theory. The details of these calculations were as follows.

Calculation of Ionic Strength

This was calculated for each run, with allowance for the effect of ion pairing. As it inevitably changes a little during each run, the calculation was made for a time halfway through each run. The procedure consisted of first calculating the ionic strength as if no ion pairing has occurred. Activity coefficients for this ionic strength were then calculated for all the species present, using the extended Debye–Hückel equation (i.e. eq. [1] above).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

From these, and from values of the equilibrium constants at 0.1 ionic strength, the equilibrium constants at the first approximation to the ionic strength of the run were calculated. From these constants, the concentrations of all the species present were calculated, and hence a second approximation to the ionic strength was obtained. This cycle was repeated, giving new constants, hence new concentrations, and a new value for the ionic strength, until repetition gave no appreciable change in ionic strength. These values were then used in connection with the calculations on rate constants described below.

Calculation of Rate Constants

It was first assumed that some particular pair of ions were the main reacting species, and the appropriate rate constants were designated as follows.

Reacting Species	Constant
$Fe(CN)_6^{4-} + S_2O_8^{2-}$	k_1
$KFe(CN)_6^{3-} + S_2O_8^{2-}$	k_2
$Fe(CN)_6^{4-} + KS_2O_8^{-}$	k_3
$KFe(CN)_6^{3-} + KS_2O_8^{-}$	k_4

If the equilibrium constants are

$$K_1 = \frac{[KFe(CN)_6^{3-}]}{[K^+][Fe(CN)_6^{4-}]}$$

and

$$K_2 = \frac{[KS_2O_8^{-}]}{[K^+][S_2O_8^{2-}]},$$

then

$$k_1 = k_{app}(1 + K_1x)(1 + K_2x)$$

where x is the free potassium ion concentration, which was obtained during the calculation of ionic strength. It varied little during a run, and was assumed constant. Hence k_1 can be calculated from this equation. Similarly,

$$k_2 = k_{app}(1 + K_1x)(1 + K_2x)/K_1x$$
$$k_3 = k_{app}(1 + K_1x)(1 + K_2x)/K_2x$$
$$k_4 = k_{app}(1 + K_1x)(1 + K_2x)/K_1K_2x^2.$$

Each of these equations assumes that only one mechanism for the reaction is important. Rate constants k_1, k_2, k_3, and k_4 were calculated, and their variation with ionic strength was investigated. Brönsted's equation is

$$\log k = \log k^0 + 2Az_a.z_bF(\mu),$$

where k is the rate constant at some ionic strength μ, k^0 is the constant at zero ionic strength, A is the Debye–Hückel constant, z_a and z_b are the charges on the reacting species, and $F(\mu)$ is the function of the ionic strength in the Debye–Hückel equation (eq. [1] above). The constants in the Debye–Hückel equation are assumed to be the same both for the reacting species and for the activated complex, an assumption which can be avoided at the cost of making the equation somewhat more complicated.

Accordingly $\log k_1$, $\log k_2$, etc. were plotted against $F(\mu)$, taking a with an average value of 4.5 Å. The results are shown in Figs. 1 and 2, for 25 and 40 °C respectively. Two

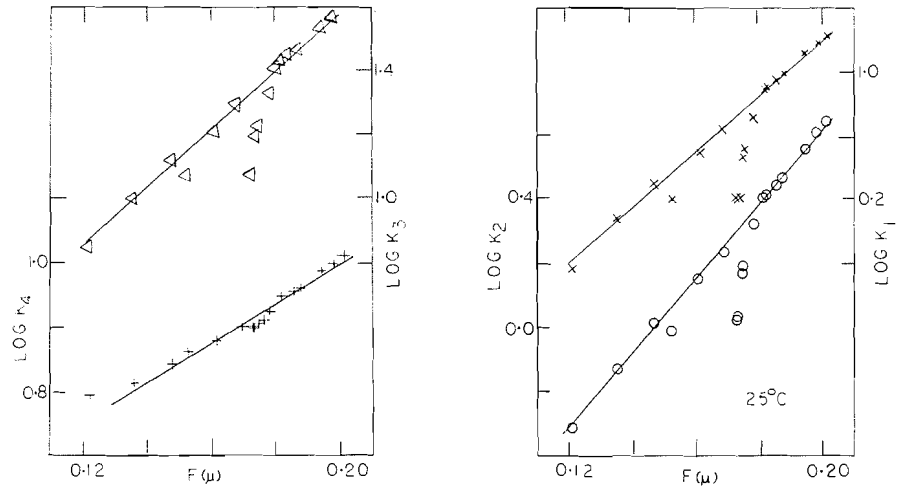

FIG. 1. Logarithms of various rate constants at 25 °C plotted against the Debye–Hückel function of the ionic strength: ×, log K_1; ○, log K_2; △, log K_3; +, log K_4.

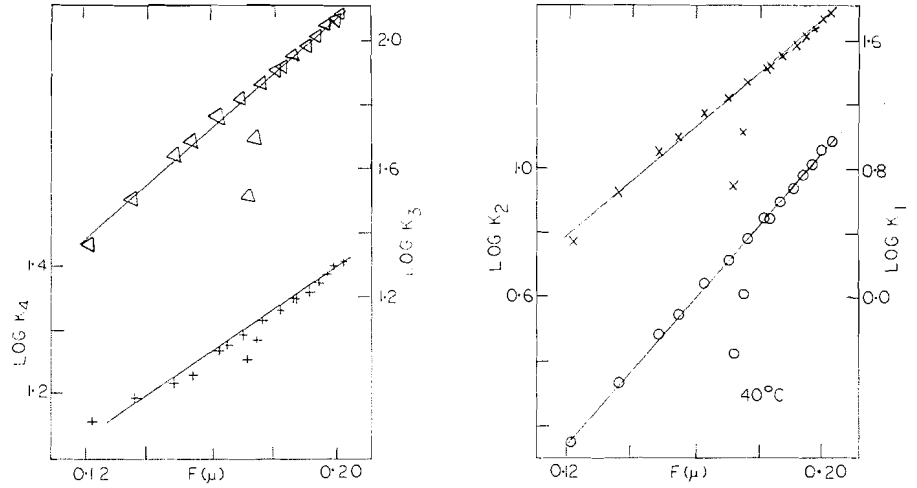

FIG. 2. Logarithms of various rate constants at 40 °C plotted against the Debye–Hückel function of the ionic strength: ×, log K_1; ○, log K_2; △, log K_3; +, log K_4.

things are apparent from these diagrams. (i) The runs with amounts of $K_4Fe(CN)_6$ other than the usual amount of 10^{-3} M fall off the general line (runs 1, 2, 4, 5, 7, 33, 34) but do so to a much smaller extent for log k_4. This is evidence that the reacting species are $KFe(CN)_6^{3-}$ and $KS_2O_8^-$. (ii) Lines can be drawn for all types of k through the points for runs in which the initial ferrocyanide concentration was 0.001 M. The slopes of these lines can be compared with the predictions of the Brönsted equation. This is perhaps most easily seen by comparing the values of $z_a z_b$ calculated from the slope with the actual values. This is done in Table IV, and it is seen that the values only agree for k_4. This also supports the view that the reacting species are $KFe(CN)_6^{3-}$ and $KS_2O_8^-$. To some extent this agreement is fortuitous since it depends on the exact values of the parameters chosen for the Debye–Hückel equations. Fairly large alterations of these parameters could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

change the slope by about 20%, but could not possibly give agreement for any other reacting species in Table IV.

TABLE IV

Comparison of experimental values of $z_a z_b$ with values calculated from the slope of the lines in Figs. 1–2

Reacting species	Rate constant	t (°C)	$z_a z_b$	$z_a z_b$ calcd. from slope
$Fe(CN)_6^{4-} + S_2O_8^{2-}$	k_1	25	8	17.3
		40	8	16.8
$KFe(CN)_6^{3-} + S_2O_8^{2-}$	k_2	25	6	11.9
		40	6	11.1
$Fe(CN)_6^{4-} + KS_2O_8^{-}$	k_3	25	4	9.2
		40	4	8.5
$KFe(CN)_6^{3-} + KS_2O_8^{-}$	k_4	25	3	3.11
		40	3	2.94

These calculations assume only one mechanism is operative. At very low $[K^+]$, others must doubtless become important, but there is no sign of this under the conditions used above. It may be noted that if Holluta and Herman's (1) data are compared with ours, the rate constants appear to be considerably larger. The chief difference in their conditions was that they added no potassium hydroxide. Presumably $HFe(CN)_6^{3-}$, or even $KHFe(CN)_6^{2-}$, is contributing to the reaction.

The lines through the plots of log k_4 against $F(\mu)$, k_4 in units of (g mole/l)$^{-1}$ min^{-1}, give for 25 °C

$$\log k_4 = 0.376 + 3.17F(\mu),$$

and for 40 °C

$$\log k_4 = 0.693 + 3.33F(\mu).$$

This makes the activation energy at zero ionic strength, $\Delta H^{\ddagger}$, equal to 9.0 kcal/g mole. If, as usual, we write

$$k_4 = \frac{kT}{h} e^{\Delta S^{\ddagger}/R} . e^{-\Delta H^{\ddagger}/RT},$$

the entropy of activations, $\Delta S^{\ddagger}$, is found to be −34.7 cal/deg mole. This is rather strongly negative, but Laidler (16) deduces that for ionic reactions like the present one a value of $-10 z_a z_b$ might be expected. This would lead one to expect a value of −30 cal/deg mole in the present reaction, so the observed value is quite plausible. Similar calculations for $\Delta S^{\ddagger}$ at zero ionic strength give: for K_1, $\Delta S^{\ddagger} = 4.7$ cal/deg mole with $z_a z_b = 8$; for K_2, $\Delta S^{\ddagger} = 6.9$ cal/deg mole with $z_a z_b = 6$; and for K_3, $\Delta S^{\ddagger} = -7.8$ cal/deg mole with $z_a z_b = 4$. These results help to confirm the mechanism for the reaction suggested above. The conclusion is not altered if the calculations are made for $F(\mu) = 0.20$.

VISIBLE AND ULTRAVIOLET ABSORPTION SPECTRA OF RHODIUM(III) IN FUSED ALKALI CHLORIDES AND NITRATES

FREDRICK B. OGILVIE[1] AND OWEN G. HOLMES[2]
University of Saskatchewan, Regina, Saskatchewan

Received October 5, 1965

ABSTRACT

The spectrum of $RhCl_3$ in fused LiCl–KCl at 440 °C is sufficiently different from that of $RhCl_6^{3-}$ to suggest the existence of some other species such as dimeric or polymeric bridge-complexes, or, less likely, tetrahedral $RhCl_4^-$. The spectra of $RhCl_3$ and $K_3Rh(NO_2)_6$ in fused $NaNO_3$–KNO_3 at 300 °C indicate the occurrence of nitro coordination in both systems, probably completely in the latter case, but in competition with chloro coordination in the former. Addition of KCl to a solution of $RhCl_3$ in $NaNO_3$–KNO_3 causes spectral changes which suggest that $RhCl_6^{3-}$ is the principal rhodium species present.

INTRODUCTION

The rather complicated chemistry of rhodium(III) in aqueous solutions has recently been the subject of extensive and careful study. On the basis of crystal field theory, Jorgensen (1) was able to interpret the spectra, as measured by himself and by earlier workers, of a variety of rhodium complexes. Kristjanson and Lederer (2) applied chromatographic methods to the separation of the species present in hydrochloric acid solutions of rhodium(III). By ion-exchange techniques, Wolsey, Reynolds, and Kleinberg (3) isolated and characterized a number of chloro–aquo complexes from the rhodium(III)–chloride system in acid solution. Schmidtke (4) has reported the spectra and their theoretical interpretation for a number of species of the type RhA_6.

In this work, rhodium(III) has been dissolved in fused eutectic mixtures of $NaNO_3$ and KNO_3 and of LiCl and KCl, and in NaNO–KNO_3 with added Cl^- and NO_2^-. The visible and ultraviolet spectra of these solutions have been measured and have been compared to aqueous spectra in attempts to determine the rhodium-containing species present.

EXPERIMENTAL

Anhydrous $RhCl_3$ from Alfa Inorganics, Inc., $RhCl_3 . xH_2O$ from Fisher Scientific Co. Ltd., and $K_3Rh(NO_2)_6$ from Engelhard Industries, Inc., were the sources of rhodium for these experiments.

Rhodium was determined by the procedure given by Brito (5). In this method rhodium(III) is reduced by magnesium metal and then the resulting Rh is dried in a stream of H_2 and weighed as the metal.

A stock of $NaNO_3$–KNO_3 eutectic, 45.5 mole % $NaNO_3$, was prepared by fusing the ingredients. The mixture was then cooled, crushed, and stored over silica gel.

Hygroscopic LiCl–KCl, 41.2 mole % KCl, was prepared by a modification of the method of Boston and Smith (6). The mixture of salts for a given experiment was heated under a stream of dry HCl gas to remove traces of water and then under N_2 to remove residual HCl. The molten eutectic was transferred directly to an evacuated optical cell which was then sealed.

Spectral measurements on the fused salt solutions were made with a Beckman DU spectrophotometer, modified by interposing a small furnace assembly between the light source and the monochromator. For spectral study, specimens and blanks were placed in a furnace which was equipped with a light transmission path and a positioning device for 1 cm glass or quartz optical cells.

In each experiment, a sample of the corresponding solvent was used as a blank. Strong ultraviolet absorption by nitrate ion limited measurements to energies of less than 30 000 cm^{-1}.

Combined uncertainties in the determination of rhodium, spectrophotometer response, positioning reproducibility in the light path, and density of the $NaNO_3$–KNO_3 solvent lead to estimated uncertainties of less than 5% in the values for molar absorptivity.

[1]*Present address: Iowa State University, Ames, Iowa.*
[2]*Present address: Lethbridge College, Lethbridge, Alberta.*

Spectra for the $NaNO_3$–KNO_3 solutions were measured at 300 ± 5 °C and for the LiCl–KCl solutions at 440 ± 5 °C.

RESULTS

(a) $RhCl_3$ in LiCl–KCl

At 440 °C anhydrous $RhCl_3$ readily dissolved in fused LiCl–KCl to yield a rose-colored solution whose spectrum is shown in Fig. 1. Also in Fig. 1 is the spectrum obtained for a solution of $RhCl_3 . xH_2O$ refluxed for 4 h in 6 *M* HCl.

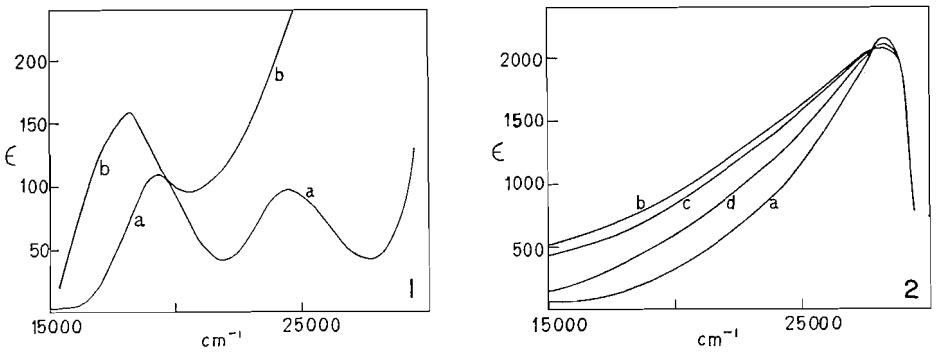

FIG. 1. Absorption spectra of $RhCl_3$: (*a*) 5.5 × 10^{-3} *M* $RhCl_3$ in 6 *M* HCl; (*b*) 1.4 × 10^{-3} *M* $RhCl_3$ in LiCl–KCl.

FIG. 2. Absorption spectra in $NaNO_3$–KNO_3: (*a*) 2 × 10^{-4} *M* $K_3Rh(NO_2)_6$; (*b*) $RhCl_3$, approximately 5 × 10^{-4} *M*; (*c*) $RhCl_3$, mole ratio Rh^{3+}:NO_2^- = 1:3; (*d*) $RhCl_3$, mole ratio Rh^{3+}:NO_2^- = 1:50.

(b) $RhCl_3$ and $K_3Rh(NO_2)_6$ in $NaNO_3$–KNO_3

At 300 °C anhydrous $RhCl_3$ dissolved in $NaNO_3$–KNO_3 over a period of several hours to produce a yellow solution whose spectrum is shown in Fig. 2. Maintenance of the solution at this temperature for 48 h led eventually to the deposition of a black precipitate. An increase in temperature to 350 °C accelerated this deposition, whereas addition of Na_2O_2 to the yellow solution caused immediate precipitation. After isolation and fusion with potassium pyrosulfate, analysis of the black residue showed 80.6% Rh; the theoretical value for Rh_2O_3 is 81.1% Rh.

Addition of $NaNO_2$ to the $NaNO_3$–KNO_3 solvent markedly increased the rate of solution of $RhCl_3$, but did not appreciably alter the rate of formation of the black precipitate. The variation of the spectrum of $RhCl_3$ in $NaNO_3$–KNO_3 with concentration of $NaNO_2$ is illustrated in Fig. 2. Also shown is the spectrum of the yellow solution formed by dissolution of $K_3Rh(NO_2)_6$ in $NaNO_3$–KNO_3.

Fig. 3 shows the spectrum, which varies as the solution ages, of aqueous $K_3Rh(NO_2)_6$.

(c) $RhCl_3$ in $NaNO_3$–KNO_3 with Added KCl

The dependence of the spectrum of $RhCl_3$ in fused $NaNO_3$–KNO_3 upon the concentration of added KCl is shown in Fig. 4. A change in color from yellow to rose accompanied the change in spectrum.

DISCUSSION

There is general agreement that the principal rhodium species in an aged solution of $RhCl_3$ in strong HCl is hexachlororhodate(III) ion. Kristjanson and Lederer (2) have estimated that in 6 *M* HCl, 95 ± 5% of the rhodium is in that form. Wolsey *et al.* (3) have found that even at 2 *M* HCl an equilibrium mixture of chloro-aquo complexes consists largely of $RhCl_6^{3-}$. Fig. 1*a* is therefore presented as that of $RhCl_6^{3-}$, there being

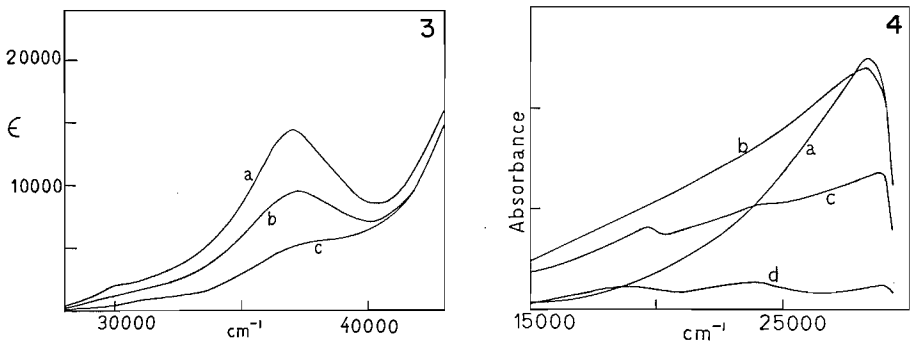

FIG. 3. Absorption spectra of 6×10^{-5} *M* $K_3Rh(NO_2)_6$ in water: (*a*) freshly prepared solution; (*b*) after 24 h at room temperature; (*c*) after 120 h at room temperature.

FIG. 4. Absorption spectra of rhodium(III) in $NaNO_3$–KNO_3: (*a*) 2×10^{-4} *M* $K_3Rh(NO_2)_6$; (*b*) $RhCl_3$, approximately 10^{-3} *M*; (*c*) $RhCl_3$, mole ratio $RhCl_3$:KCl = 1:260; (*d*) $RhCl_3$, mole ratio $RhCl_3$:KCl = 1:600.

two bands with maxima at 19 300 cm^{-1} (ϵ = 109) and 24 400 cm^{-1} (ϵ = 98). Also strong charge transfer absorption is observed at higher energies, beginning around 29 000 cm^{-1}. This spectrum is in good agreement with those reported by several authors, including Wolsey *et al.* (3) who obtained bands at 19 300 cm^{-1} (ϵ = 111.5) and 24 000 cm^{-1} (ϵ = 93.8).

A number of authors, see for example Jorgensen (1), have attributed the bands of $RhCl_6^{3-}$ to transitions from the ground state $^1\Gamma_1$ of the configuration γ_5^6 to states $^1\Gamma_4$ and $^1\Gamma_5$ of the configuration $\gamma_5^5\gamma_3$. Jorgensen also presented evidence for the weaker transitions to states $^3\Gamma_4$ and $^3\Gamma_5$ of the latter configuration.

In fused LiCl–KCl at 440 °C a single peak is observed at 18 200 cm^{-1} (ϵ = 160), along with intense absorption beginning at about 26 000 cm^{-1}. If this spectrum is due to $RhCl_6^{3-}$ in the melt, as might be expected, the lower energy band is shifted 1 100 cm^{-1} to lower energy relative to the aqueous system, with the higher energy band shifted to higher energy where it is obscured by the charge transfer absorption.

It may be that the species in the melt is other than $RhCl_6^{3-}$. Gruen and McBeth (7) have reviewed the coordination chemistry of the 3d transition metal ions in fused salts, pointing out several instances of tetrahedral chloro-complexes at the elevated temperatures. However, they generalized that tripositive 3d ions tend to six- rather than four-coordinate chloro-complexes, a tendency that one would expect to be more pronounced for the larger 4d ion Rh^{3+}.

A more likely possibility is that dimeric or polymeric chloro-bridged complexes exist in the melt. Kristjanson and Lederer (2) proposed that when a solution of $RhCl_6^{3-}$ in HCl was evaporated, and the residue redissolved in HCl, highly charged chloro-bridged ions were obtained, since they found some of the rhodium to be more strongly bound to ion-exchange columns than $RhCl_6^{3-}$. This solution displayed a spectrum with a band maximum at 18 900 cm^{-1} and strong absorption beyond 25 000 cm^{-1}. Upon aging, the solution reverted to the equilibrium with a high proportion of $RhCl_6^{3-}$.

In the range accessible with $NaNO_3$–KNO_3 as solvent, the spectrum of $RhCl_3$ is characterized by one rather strong band with a maximum at 28 200 cm^{-1} and ϵ = 2 100, the band being asymmetric with a long tail of absorption on the low energy side. The addition of NO_2^- to the melt reduces the low energy absorption until the spectrum approaches that of $K_3Rh(NO_2)_6$ in $NaNO_3$–KNO_3.

These results point to nitro-coordination in all of the nitrate solutions studied. The slow rate of solution of $RhCl_3$ in $NaNO_3$–KNO_3 correlates with the slow production of traces of NO_2^- which occurs in that system. The effect of added NO_2^- suggests a gradual shift from chloro- to nitro-coordination. The stability of the spectrum of $K_3Rh(NO_2)_6$ suggests preservation of $Rh(NO_2)_6^{3-}$ in the melt. Since the least absorption in the low energy range is observed for the chloride-free solution of $K_3Rh(NO_2)_6$, that absorption may be caused by the presence of mixed chloro–nitro-complexes in all of the other solutions.

Aqueous $Rh(NO_2)_6^{3-}$, which can be followed well into the ultraviolet, gives a spectrum with a band at 37 000 cm^{-1} (ϵ = 14 400), a shoulder at 30 000 cm^{-1} (ϵ = 2 000), and strong absorption beyond 45 000 cm^{-1}. Schmidtke (4) reported a more complete spectrum with bands at 37 000 cm^{-1} (ϵ = 16 500) and 50 000 cm^{-1} (ϵ = 54 000), both of which he attributed to the nitrite ion, and a ligand-field absorption (shoulder) at 29 800 cm^{-1} (ϵ = 2 380). The spectrum (and pH) of freshly prepared aqueous $Rh(NO_2)_6^{3-}$ changed markedly with time because of hydrolysis. The shoulder at around 30 000 cm^{-1} roughly corresponds to the well-defined band at 28 200 cm^{-1} for the $NaNO_3$–KNO_3 solutions.

A progressive increase in chloride concentration in $NaNO_3$–KNO_3 solution of $RhCl_3$ transforms the spectrum. At high chloride concentration the strong band attributed to $Rh(NO_2)_6^{3-}$ has become a small residual peak, while two new bands have resolved at 18 800 cm^{-1} and 24 000 cm^{-1}. The correspondence between these values and those for $RhCl_6^{3-}$ indicates the presence of $RhCl_6^{3-}$ in the chloride-containing melt. This in turn weighs against the existence of $RhCl_6^{3-}$ as the principal species in LiCl–KCl, one of the possibilities considered earlier in this discussion.

THE THERMODYNAMIC PROPERTIES OF HYDROGEN SELENIDE

J. R. RAWLING AND J. M. TOGURI
Chemistry Department, Noranda Research Centre, Pointe Claire, Quebec

Received August 31, 1965

ABSTRACT

Hydrogen selenide may be generated by the reaction of hydrogen gas with liquid selenium according to the reaction

$$H_{2(g)} + Se_{(l)} \rightleftharpoons H_2Se_{(g)}$$

where $$K = P_{H_2Se}/P_{H_2}a_{Se}.$$

The equilibrium constant K of this reaction was measured by passing hydrogen over liquid selenium at controlled rates of flow over the temperature range 525–625 °C. The equilibrium ratio of hydrogen to hydrogen selenide was determined by gas analysis. Over the temperature range 525–625 °C, the equilibrium constant can be expressed by the equation

$$\log K = 13.07 + 2.97 \times 10^{-4}T - 3.69 \log T - 2\,209T^{-1} - 4.81 \times 10^{3}T^{-2}.$$

This expression leads to $\Delta H_{298}^\circ = 9\,174 \pm 107$ cal mole^{-1}, $\Delta F_{298}^\circ = 5\,132$ cal mole^{-1}, and $\Delta S_{298}^\circ = 13.56$ e.u. (entropy units) for the respective heat, free energy, and entropy of formation of hydrogen selenide from hydrogen and crystalline selenium.

INTRODUCTION

One of the methods for the determination of the chemical potential of selenium in metal selenide systems is by equilibrating the metal in question with a mixture of hydrogen selenide and hydrogen according to the equilibrium,

[1] $$H_2Se_{(g)} + Me = MeSe + H_{2(g)}.$$

To carry out such a study the thermochemistry of hydrogen selenide must be well established. However, investigations (1, 2) on the equilibrium among hydrogen, selenium, and hydrogen selenide according to eq. [2]

[2] $$H_{2(g)} + Se_{(l)} = H_2Se_{(g)}$$

do not agree with the published thermochemical data (3, 4, 5). Furthermore, the only investigation of the reaction between hydrogen and selenium at temperatures above 500 °C (1) indicates a maximum in the equilibrium constant at 575 °C which cannot be explained by any known structural transformation. Consequently, the object of this investigation was to establish reliable values of the equilibrium constant of reaction [2] before a systematic study of the selenium potential in various alloy systems was undertaken.

EXPERIMENTAL

The well-known transpiration method was adopted to measure the equilibrium between liquid selenium, hydrogen, and hydrogen selenide. The procedure involved the bubbling of hydrogen or mixtures of hydrogen and hydrogen selenide through liquid selenium at constant velocity and temperature. The gas mixture leaving the furnace was then analyzed for hydrogen and hydrogen selenide. The important requirement in this method is to ensure the saturation of the equilibrating gases.

The apparatus is shown in Fig. 1. It consisted of a gas purification system, two equilibrating furnaces, and a gas-scrubbing system.

Hydrogen was passed through a Deoxo purifier to remove residual oxygen and then through an Anhydrone column to remove moisture. Argon utilized for flushing the system passed through an Anhydrone drying column and then through a furnace containing titanium turnings at 850 °C to remove oxygen and hydrogen. The required gases were then admitted to the furnace through calibrated flowmeters.

The selenium was contained in a Vycor crucible placed in a Kanthal resistance furnace. With this furnace a uniform temperature zone was readily obtained to within ±1.5 °C along the middle 8 cm of the furnace

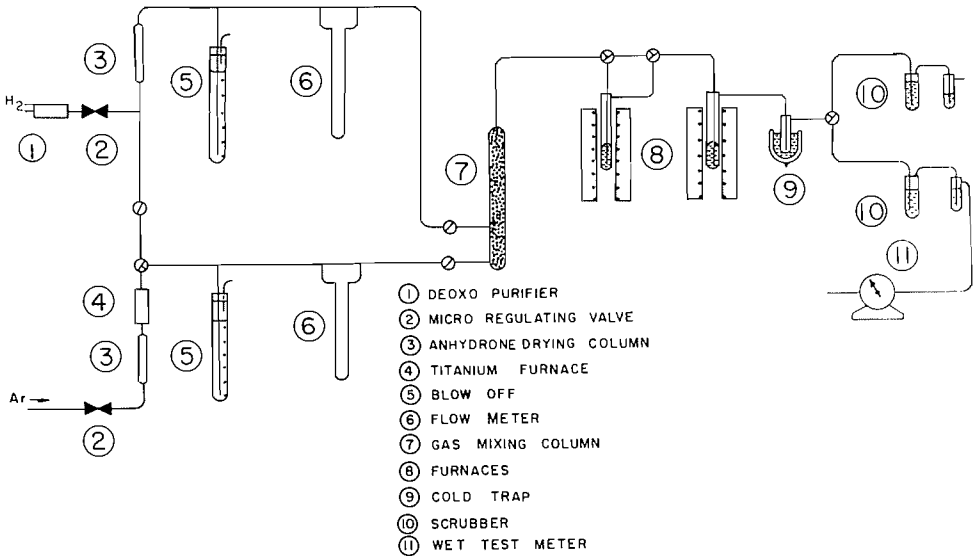

FIG. 1. Diagram of apparatus.

for temperatures of 400–700 °C. The furnace temperature was measured with a calibrated chromel–alumel thermocouple placed directly below the base of the crucible situated in the constant temperature zone.

A Vycor gas inlet tube penetrated to within 2 mm of the bottom of the crucible so that gas entering the crucible bubbled through a column of liquid selenium approximately 3.5 cm deep. Two such furnaces were used when a mixture of hydrogen and hydrogen selenide was required, the first furnace acting as a hydrogen selenide generator which supplied a gas mixture of known composition to the second.

The gases leaving the furnace passed through a cold trap which condensed any selenium vapor present. The cold trap was maintained at approximately −20 °C with an ice – ammonium chloride mixture. On leaving the cold trap the gas mixture passed through a solution containing 50 g/l (grams per liter) of reagent grade sodium hydroxide and 7 g/l of reagent grade potassium bromate. Hydrogen selenide was decomposed in this solution according to the reaction

$$[3] \qquad H_2Se + 2NaOH + 3(O) = Na_2SeO_3 + 2H_2O.$$

The effectiveness of this decomposition was ensured by passing the scrubbed gas through a solution containing 10 g.p.l. of copper sulfate. If decomposition was incomplete a black precipitate of copper selenide was formed. Finally the gas was passed through a wet-test meter to determine the volume of the residual hydrogen. The second scrubber system shown in Fig. 1 was employed as a bypass.

The experimental procedure adopted was to place 40 g of selenium in each furnace. As the furnaces were brought to the required temperature, argon was admitted to the system at a flow rate of approximately 100 ml/min. This gas was replaced with hydrogen when the required temperature was obtained. The hydrogen flow was continued until the solution in the bypass scrubber had turned to a deep brownish red indicating the deposition of selenium. The gas stream was then switched through the main scrubber and the flow rate adjusted to the desired value.

After the required amount of hydrogen, approximately 1 to 3 l, had passed through the apparatus the flow was stopped and the flask containing the scrubber solution removed. A flask of fresh scrubber solution was then put into place and the system purged with hydrogen for a few minutes using the bypass scrubber. The gas stream was then switched through the fresh scrubber and wet-test meter and the procedure repeated at a different flow rate. Approximately eight such experiments were carried out with a charge of 40 g of selenium.

The scrubber solutions obtained from each run were acidified with 80% excess of concentrated hydrochloric acid. The solutions were then heated to 80 °C and the selenium reduced to the elemental form with sulfur dioxide. The selenium thus precipitated was filtered, dried, and weighed.

The molar flow rates of hydrogen and hydrogen selenide leaving the furnace were calculated from the volume of hydrogen passing through the wet-test meter in a given time and from the weight of selenium absorbed in the scrubber system during the same period.

RESULTS AND DISCUSSION

The equilibrium constant for reaction [2] is given by

$$K = P_{H_2Se}/P_{H_2}, \quad [4]$$

since pure liquid selenium is present at unit activity.

In the present experiments

$$P_{H_2} = (n_{H_2}/V)RT = (m_{H_2}/M_{H_2})(RT/V) \quad [5]$$

and

$$P_{H_2Se} = (n_{H_2Se}/V)RT = (m_{H_2Se}/M_{H_2Se})(RT/V) \quad [6]$$

thus

$$K = P_{H_2Se}/P_{H_2} = n_{H_2Se}/n_{H_2} = (m_{H_2Se}/m_{H_2})(M_{H_2}/M_{H_2Se}), \quad [7]$$

where the symbols used have their usual meanings. Consequently, the results lead to a direct measurement of K. However, experiments of this kind are liable to two sources of error because of kinetic factors. Firstly, if the gas is passed through the crucible too rapidly, it will not have time to reach equilibrium with the liquid phase. Secondly, since the molecular weights of the two gaseous components are very different, a strong thermal diffusive effect is to be expected, causing the H_2Se molecules to migrate preferentially to the cold part of the system, and this effect is likely to become pronounced at slow gas flow rates. For true equilibrium conditions the ratio P_{H_2Se}/P_{H_2} will be independent of gas flow rate; therefore experiments were carried out over a range of flow rates in order to establish this condition.

If the ratio of P_{H_2Se}/P_{H_2} in equilibrium with selenium is independent of flow rate, the ratio of the molar flow rates of hydrogen and hydrogen selenide is also independent of flow rate. Under these conditions a plot of molar flow rate of hydrogen selenide n_{H_2Se} against molar flow rate of hydrogen n_{H_2} should yield a straight line passing through the origin. Any errors resulting from nonequilibrium or diffusion effects will cause deviations from this linear relationship. The equilibrium ratio P_{H_2Se}/P_{H_2} is given by the slope of this line since rearrangement of eq. [7] and division by time, t, leads to

$$n_{H_2Se}/t = K(n_{H_2}/t) + f(F) \quad [8]$$

where $f(F)$ represents any deviation from equilibrium conditions, such deviations being some function of the gas flow rate F. If equilibrium is achieved $f(F) \rightarrow 0$.

Fig. 2 shows a typical plot of the molar flow rate of hydrogen selenide against the molar flow rate of hydrogen at 600 °C. The flow rate of hydrogen was varied from 40 to 120 ml/min. Over this region the ratio of the mass flow of hydrogen selenide and hydrogen was found to be independent of the flow rate.

Measurements of the equilibrium constant were carried out over the temperature range 525 to 625 °C. Equilibrium was approached either by the decomposition of H_2Se or by its formation by controlling the H_2Se/H_2 input ratio to the second equilibration furnace. The results are shown in Fig. 3 and tabulated in Table I. The direction of the approach to equilibrium is indicated for each point shown on the figure. At temperatures below 525 °C the reaction proceeded too slowly for the attainment of equilibrium.

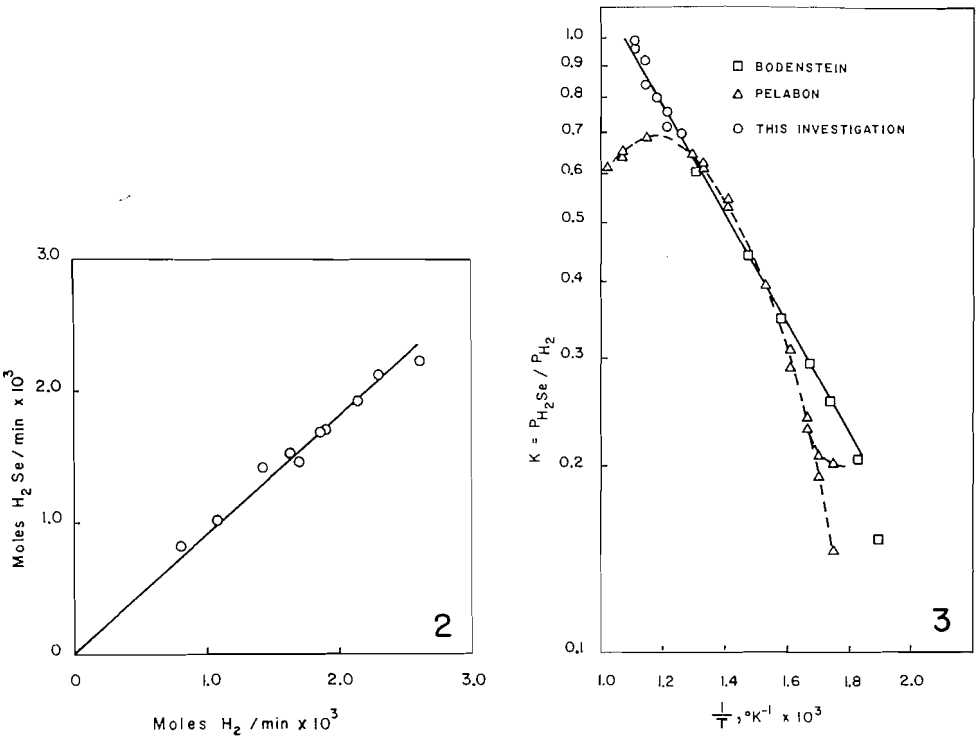

FIG. 2. Relation between molar flow rates of hydrogen selenide and hydrogen leaving the furnace at 600 °C.

FIG. 3. The effect of temperature on the equilibrium constant K for the reaction $H_{2(g)} + Se_{(l)} = H_2Se_{(g)}$.

Pelabon (1) has studied the same reaction over the temperature range 250 to 705 °C, whereas Bodenstein (2) measured this equilibrium over the temperature range 254 to 493 °C. Their results are also summarized in Fig. 3 together with the results of the present study. At temperatures below 300 °C, their results are in poor agreement possibly because of kinetic effects. Above 500 °C, Pelabon's results indicate that K passes through a maximum value of approximately 0.7 at 575 °C. Since there is no known structural

TABLE I

Equilibrium constant for the reaction $H_{2(g)} + Se_{(l)} = H_2Se_{(g)}$ $(K = P_{H_2Se}/P_{H_2})$

Temp. (°C)	Ratio H_2Se/H_2 entering furnace	Equilibrium constant K
525	0.70	0.70
550	0.62	0.72
		0.76
575	0.70	0.80
600	Pure H_2	0.84
	1.04	0.91
625	Pure H_2	0.99
	1.04	0.97

transformation in the system at this temperature, this phenomenon cannot be interpreted as one involving a state of equilibrium. On the other hand our results approximately fall on the extension of a straight line drawn through Bodenstein's data.

A Σ plot has been carried out with the specific heat data of Kelley (6) to permit the calculation of a free energy equation for reaction [2]. From a least square analysis of the Σ function, the following relationships were obtained.

$$\Delta F_T^0 = 10\,107 - 59.80T + 16.88T \log T - 1.36 \times 10^{-3}T^2 + 0.22 \times 10^5 T^{-1}$$
$$\Delta H_T^0 = 10\,107 - 7.33T + 1.36 \times 10^{-3}T^2 + 0.43 \times 10^5 T^{-1}$$
$$\log K = 13.07 + 2.97 \times 10^{-4}T - 3.69 \log T - 2\,209T^{-1} - 4.81 \times 10^3 T^{-2}.$$

For the reaction

[9] $$H_{2(g)} + Se_{(s)} = H_2Se_{(g)}$$

and with Kelley's (6) recommended value of the heat of fusion of selenium of 1 300 cal mole^{-1} at 490 °K, the following thermodynamic relationships were obtained.

$$\Delta F_T^0 = 9\,964 - 30.05T + 5.14T \log T + 3.04 \times 10^{-3}T^2 + 0.22 \times 10^5 T^{-1}$$
$$\Delta H_T^0 = 9\,964 - 2.23T - 3.04 \times 10^{-3}T^2 + 0.43 \times 10^5 T^{-1}$$
$$\log K = 6.57 - 6.64 \times 10^{-4}T - 1.12 \log T - 2\,178T^{-1} - 4.81 \times 10^3 T^{-2}.$$

This leads to $\Delta H_{298}^0 = +9\,174 \pm 107$ cal mole^{-1}, $\Delta F_{298}^0 = 5\,132$ cal mole^{-1}, and $\Delta S_{298}^0 = 13.56 \pm 0.36$ e.u. for the formation of hydrogen selenide from hydrogen and crystalline selenium. Values of the heat of formation summarized by Lumbroso (3) vary from 16.02 to 20.5 kcal mole^{-1} at 298 °K. More recently a value of 18.16 kcal mole^{-1} was obtained by Kapustinskii and Kankovskii (5) from measurements of the heat of combustion of H_2Se, whereas Gunn (7) estimates a value of 8 kcal mole^{-1} from the heat of explosion of H_2Te–H_2Se gas mixtures. This latter value is in close agreement with the value of 9 174 cal mole^{-1} obtained in this study.

The entropy change for the formation of hydrogen selenide from hydrogen and crystalline selenium at 298 °K of 13.56 ± 0.36 e.u. is in reasonable agreement with the calculated value of 10.95 e.u. from the tabulated data of Kelley (8), particularly if one takes into account the uncertainty of the existing literature data which is accumulated in the type of calculation given above.

CONCLUSIONS

The equilibrium constant for the reaction $H_{2(g)} + Se_{(l)} = H_2Se_{(g)}$ has been determined over the temperature range 525 to 625 °C and can be expressed by the relationship

$$\log K = 13.07 + 2.97 \times 10^{-4}T - 3.69 \log T - 2\,209T^{-1} - 4.81 \times 10^3 T^{-2}.$$

This equation leads to $\Delta H_{298}^0 = 9\,174 \pm 0.1$ cal mole^{-1}, $\Delta F_{298}^0 = 5\,132$ cal mole^{-1}, and $\Delta S_{298}^0 = 13.56$ e.u. for the respective heat, free energy, and entropy of formation of hydrogen selenide from hydrogen and crystalline selenium.

No anomaly in the equilibrium constant was observed as reported by Pelabon (1).

ACKNOWLEDGMENTS

The authors wish to express their thanks to Miss E. Schaffer for her assistance in carrying out the experiments and to Drs. P. H. Jennings and W. C. Cooper for their helpful discussion. They are grateful to Canadian Copper Refiners Ltd. for providing the financial support for this work.

THE Hg $6(^3P_1)$ PHOTOSENSITIZATION OF SPIROPENTANE

G. R. De Maré, L. G. Walker, O. P. Strausz, and H. E. Gunning
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received October 13, 1965

ABSTRACT

The triplet mercury photosensitization of spiropentane affords ethylene, allene, and methylenecyclobutane as major reaction products. This indicates an olefinic-type interaction with the quaternary C—C σ-bond of spiropentane, the cleavage of which results in a triplet state diradical. The initially formed diradical may undergo isomerization through ring cleavage or deactivation by collision. The open chain diradical then either decomposes unimolecularly into $C_2H_4 + C_3H_4$ or on collisional relaxation isomerizes to methylenecyclobutane.

The paraffinic-type interaction between Hg* and spiropentane which would lead to C—H bond scission appears to have minor significance.

INTRODUCTION

Our interest in the mercury photosensitization of spiropentane arose from our current investigations on the analogous reactions of cyclopropane. This topic has recently been reviewed (1); therefore only a very brief outline will be given here.

Cyclopropane, in most of its reactions, exhibits an intermediate behavior between olefins and paraffins. In its interaction with Hg* atoms the final reaction products can equally well be accounted for by an olefinic- or paraffinic-type reaction (2, 3). The olefinic interaction would imply quenching into the C—C σ-bond with the formation of a vibrationally excited triplet trimethylene which then may partly decompose into allyl + H. Alternately paraffinic interaction through C—H bond cleavage could lead to the formation of vibrationally excited cyclopropyl radicals which may subsequently isomerize to allyl either unimolecularly or on combination with other radicals.

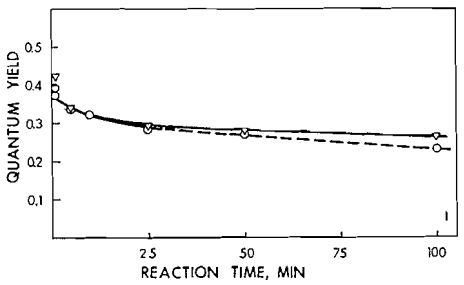
This study was undertaken in the hope that with a more complex cyclopropane derivative such as spiropentane some of the complications mentioned above could be circumvented and a clear distinction made between the two possibilities.

EXPERIMENTAL

The reaction system and the method used to determine the fractional absorption of the resonance radiation have been described in a previous paper (4).

The light intensity, measured by propane actinometry at 730 Torr propane pressure, was 1.42×10^{15} quanta/s.

Spiropentane was prepared by the method of Applequist *et al.* (5) and purified extensively. A neat sample gave a single resonance on an A60 nuclear magnetic resonance instrument at maximum intensity, verifying the excellent purity. Nitric oxide (Matheson C.P.) was purified as previously described. Propylene (Phillips research grade) and propylene-1,1-d_2 (Merck) were degassed at −196° and distilled from −130°.



Ethylene and allene were identified by their mass spectra and relative gas chromatographic retention times. They were determined quantitatively on a 16 ft column of 30% tricresyl phosphate on 30/60 mesh firebrick at 75°. Methylenecyclobutane was identified by its relative gas chromatographic retention time and mass and nuclear magnetic resonance spectra and was determined quantitatively on a dimethylsulfolane column.

RESULTS AND DISCUSSION

The major products of the reaction were ethylene, allene, and methylenecyclobutane. Minor products were hydrogen ($\Phi \simeq 0.04$ at 50 Torr), two isomers of the substrate, and at longer exposure times, a product of mass 70, and a C_{10} compound.

The yields of ethylene and allene were examined as a function of exposure time at a substrate pressure of 53.0 ± 1.5 Torr (see Fig. 1) and as a function of substrate pressure

(see Fig. 2). The yield of methylenecyclobutane as a function of substrate pressure was measured in separate experiments and is also shown in Fig. 2, along with the sum of the yield of ethylene and methylenecyclobutane.

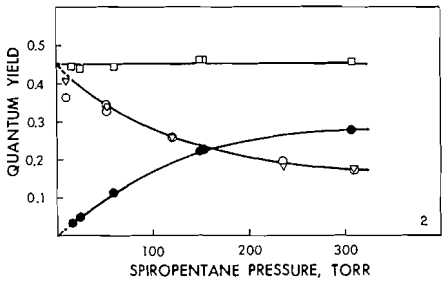


FIG. 1. Quantum yield of ethylene ▽ and allene ○ as a function of reaction time.
FIG. 2. Dependence of the product yields on spiropentane pressure: ethylene ▽, allene ○, methylenecyclobutane ●, and (ethylene + methylenecyclobutane) □.

The effect of added olefin and nitric oxide on the reaction was checked and it was found that besides their function as an inert gas they have no effect on the major reaction products.

The following mechanism is proposed to explain the results.

[1] $$Hg\ 6(^3P_1) + \text{spiropentane} \xrightarrow{\alpha} Hg\ 6(^1S_0) + \text{allene}$$

[2] $$\xrightarrow{\beta} Hg\ 6(^1S_0) + \text{methylenecyclobutyl radical} + H$$

[3] $$\text{methylenecyclobutyl radical} \rightarrow \text{vinylcyclopropyl radical}$$

[4] $$\text{vinylcyclopropyl radical} \rightarrow C_2H_4 + C_3H_4$$

[5] $$\text{vinylcyclopropyl radical} \xrightarrow{M} \text{methylenecyclobutane}$$

[6] $$\text{methylenecyclobutyl radical} \xrightarrow{M} \text{methylenecyclobutane}$$

[7] $$H + \text{methylenecyclobutane} \rightarrow \text{methylenecyclobutyl radical} + H_2$$

[8] $$2\ \text{methylenecyclobutyl radical} \rightarrow \text{dimer}$$

Steady-state treatment gives the following relation for the ratio of product yields:

[I] $$R(\text{methylenecyclobutane})/R(\text{ethylene}) = (k_5/k_4)[M].$$

A plot of the left-hand side of [I] vs. substrate pressure is shown in Fig. 3. A satisfactory straight line is obtained. From the slope then $k_5/k_4 = 5.5_5 \times 10^{-3}$ mm Hg^{-1}. If k_5 is set

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

equal to 1×10^{-10} cc/molecule s (ca. the collision frequency) then $k_4 = 5.8 \times 10^8$ s^{-1} and τ_4, the lifetime of the 1,4-diradical, 2-methylenebutane in this system, is equal to 1.7×10^{-9} s. Also

$$[II] \qquad 1/\Phi(C_2H_4) = 1/\Phi(C_3H_4) = (k_4 + k_5[M])(k_3 + k_6[M])/\Phi(1)k_3k_4$$

where $\Phi(1)$ is the quantum yield of step [1]. Equation [II] reduces to

$$1/\Phi(C_2H_4) = 1/\Phi(C_3H_4) = 1/\Phi(1)$$

at zero pressure. Plots of $1/\Phi(C_2H_4)$ and $1/\Phi(C_3H_4)$ vs. substrate pressure are shown in Fig. 4. Both lines extrapolate to 2.28 at zero pressure giving $\Phi(1) = 0.44$, which agrees well with the experimental value of 0.45 obtained from the sum of molecular split and methylenecyclobutane formation (cf. Fig. 2), and which is unaffected by pressure over the range studied. The actual value of $\Phi(1)$, owing to its exposure time dependence (cf. Fig. 1), is somewhat uncertain and is probably about 10–15% higher than given above, that is, ca. 0.50.

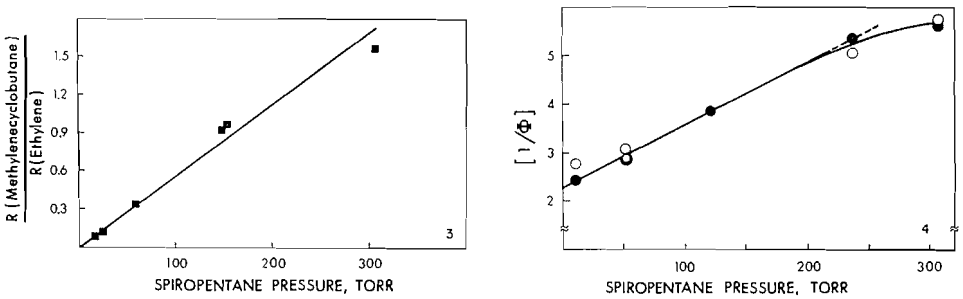

FIG. 3. Plot of R(methylenecyclobutane)/R(ethylene) vs. spiropentane pressure.
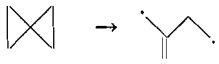
FIG. 4. Plot of $1/\Phi(C_2H_4)$ ● and $1/\Phi(C_3H_4)$ ○ vs. spiropentane pressure.

If now it is assumed that $k_5 = k_6 = 10^{-10}$ cc/molecule then from [II] a value of ca. 10^{-10} s is obtained for the lifetime of the  diradical, and therefore collisional stabilization should not be important for this species over the pressure range studied.



The quantum yield of step [2] is ca. 0.04 as determined from the yield of the H_2 product. Step [7] is probably more rapid with spiropentane than with cyclopropane but self-scavenging of H atoms by C_2H_4 and C_3H_4 still may be significant. In the cyclopropane reaction the main mode of H-atom disappearance is self-scavenging followed by polymerization, and H_2 actually is a very minor product (2, 3). The estimation of $\Phi(2)$ from the H_2 yield alone in the present system is quite uncertain since self-scavenging may also lead to polymer formation. However, in contrast to the cyclopropane case polymer formation could not be observed in the spiropentane system, consequently polymerization via self-scavenging cannot be important.

The two unidentified isomers of spiropentane formed in very small yields (Φ(combined) < 0.05) could have been either vinylcyclopropane, cyclopentene, or a pentadiene. Both of the major reactions, the molecular decomposition into ethylene and allene, [4], and the isomerization to methylenecyclobutane, [5], require no hydrogen migration in contrast to other possible but apparently less probable reactions.

The thermal reaction of spiropentane in the temperature interval of 360 and 410 °C has also been reported (6) to yield the same kind of products, $C_2H_4 + C_3H_4$ and methylenecyclobutane, as the photosensitization. The isomerization is truly unimolecular with an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

activation energy of 57.6 kcal/mole and a pre-exponential factor of $10^{15.86}$. This large value of the pre-exponential factor indicates a very loose transition state in comparison with the highly strained spiropentane structure (strain energy = 63 kcal/mole (7)). The decomposition reaction has been found to be slower than the isomerization and to have a higher activation energy. Whether the thermolysis proceeds via the same reaction paths, that is, triplet potential surfaces, as the mercury sensitization cannot be decided, but the salient features of the reaction are in accord with such a mechanism (7, 8). If this is the case, the activation energy of the isomerization, 57.6 kcal/mole, may be assigned to the formation of 1,4-diradical, 2-methylenebutane

and for this reason the 1,4-diradical, 2-methylenebutane, formed in [3] should have ca. 55 kcal/mole excess vibrational energy.*

Finally it may be concluded that at least ca. 55% of the primary quenching act with spiropentane leads to an olefinic-type energy transfer by the promotion of a $\sigma \rightarrow \sigma^*$ transition in the ring C—C bond which results in a triplet state diradical formation. This unique reactivity of the cyclopropyl ring indicates that, unlike the higher cyclic alkane and non-cyclic alkanes, the cyclopropanes have C—C sigma electrons which are more readily available to electrophilic reagents than the C—H electrons. This behavior is in line with the well-established olefinic character of cyclopropanes (12).

It would also follow that the bond dissociation energy D(C—CH_2) in spiropentane should be less than 57 kcal/mole, with an amount corresponding to the activation energy of the isomerization reaction

which may have a value of about 5–10 kcal/mole. This estimate is based on the following reported values for E_a,

= 35 kcal/mole (9),

= 18 kcal/mole (10),

and also on the observation that cyclopropyl radicals are quite stable at room temperature and readily undergo H-atom abstraction reactions (11).

THE RANGES OF INTERACTIONS IN THE RADIOLYSIS OF SOLID HYDROCARBON MIXTURES[1]

P. J. DYNE AND J. DENHARTOG
Research Chemistry Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received September 22, 1965

ABSTRACT

We describe a novel technique for measuring the ranges of interaction in the radiolysis of hydrocarbon mixtures, e.g. the distance between donor and acceptor molecules in an energy transfer process. Thin layers, 20 to 1 000 Å thick, of solid *c*-C_6D_{12} sandwiched between other materials which activate or deactivate the hydrocarbon, are irradiated. The yields of D_2 and HD are measured as a function of the layer thickness. These yields change rapidly when the layer thickness is comparable with the range of the interaction.

We find: (*a*) the activation of *c*-C_6D_{12} by *n*-C_6H_{14} has a very short range consistent with an ion–molecule reaction between nearest neighbor molecules; (*b*) the deactivation by CCl_4 or benzene has a longer range (180 Å or more) consistent with the average separation of positive ions and electrons in an irradiated hydrocarbon; (*c*) the intermediates in the bimolecular reaction giving HD in layers of C_6D_{12} and C_6H_{12} have a short range (< 100 Å) and cannot be thermal hydrogen atoms.

1. INTRODUCTION

It is now generally believed that charge separation plays an important role in the radiolysis of hydrocarbons. After ionization, electrons move a large distance away from the positive ions so that the time for recombination is long enough for both electrons and positive ions to react with other molecules. We (1), in common with many others (e.g. refs. 2–4), have argued that the inhibiting effects on the radiolysis of hydrocarbons of some additives (e.g. CCl_4) are due to electron capture; other effects of activation and deactivation in mixtures of hydrocarbons are due to charge exchange between a positive ion and a molecule of another hydrocarbon.

In this paper we describe experiments on the radiolysis of hydrocarbon mixtures in which the ranges of the interactions are measured. These may, in some cases, be the average distance between positive ions and electrons when electron capture occurs or, in others, it may be the distance between a positive ion and a molecule when charge transfer takes place.

We irradiate mixtures in which the components are separated into layers. Layers of a hydrocarbon are sandwiched between layers of another material which either activates or deactivates the decomposition of the hydrocarbon. If the layer of hydrocarbon has a thickness T and the range of the interaction with the adjacent layers is R then, when $T \gg R$, the decomposition of the hydrocarbon layer will be unaffected by its environment. If, however, $T \ll R$ the sample will approach the behavior of a homogeneous mixture; activation or deactivation of the hydrocarbon will be observed. Samples with layer thicknesses in the range 20 to 1 000 Å have been prepared. The anticipated changes in yield with thickness were observed and these are used to estimate the ranges of the interaction involved.

We shall interpret these ranges in terms of a mechanism recently suggested by us for the radiolysis of aliphatic hydrocarbons (1). The initial radiation act produces ions and excited molecules. (For this example, we choose deuterated cyclohexane, C_6D_{12}, since it was used in all the experiments described in this paper.)

[1]*Issued as AECL No. 2260.*

[1] $$C_6D_{12} \xrightarrow[[1b]]{[1a]} \begin{cases} C_6D_{12}^+ + e \\ C_6D_{12}^* \end{cases}$$

In the pure hydrocarbon, electron capture by the positive ion also produces the excited species $C_6D_{12}^*$.

[2] $$C_6D_{12}^+ + e \rightarrow C_6D_{12}^*$$

$C_6D_{12}^*$ can then decompose by two routes: forming D_2 by molecular detachment

[3] $$C_6D_{12}^* \begin{cases} \nearrow D_2 + \cdots \\ \searrow X_D + \cdots \end{cases}$$

or producing X_D which subsequently reacts in a bimolecular process as described in Section 4. If C_6D_{12} is present in a mixture with a hydrocarbon with a higher ionization potential (e.g. C_6H_{14}), charge exchange can occur.

[4] $$C_6D_{12} + C_6H_{14}^+ \rightarrow C_6D_{12}^+ + C_6H_{14}$$

Electron capture by the $C_6D_{12}^+$ ion gives an increased yield of C_6D_{12} and hence of D_2 and HD. An electron scavenger such as CCl_4 captures electrons,

[5] $$CCl_4 + e \rightarrow CCl_4^-,$$

and leads, on the reaction of CCl_4^- with $C_6H_{12}^+$, to decompositions other than reactions [2] and [3].

2. EXPERIMENTAL TECHNIQUES

A prerequisite of these 'layer' experiments is an analytical technique which can measure, with high precision, products formed from the layer whose thickness is being varied. Isotopic labelling of the thin layers provides an ideal method. In all these experiments deuterocyclohexane is the component in these layers which are sandwiched between very much thicker layers of a material whose interaction with C_6D_{12} is being studied. We call these the thin or indicator layer, and the thick or blanket layer respectively. For accuracy in analysis the sample must be about 1 g in weight and contain $\sim 1\%$ of C_6D_{12}. For a reasonably sized condensing surface (30 cm²), samples with layer thicknesses in the range of interest, 50–500 Å, must be made up of several hundred layers of deuterated hydrocarbons and blanket material. Automated sample preparation is essential.

The final form of the irradiation cell is shown in Fig. 1. Vapors are condensed onto a copper disc 5.5 cm in diameter which forms the bottom of a liquid nitrogen reservoir. The inner glass tube ensures that vapors condense wholly on the flat portion of the disc. The serrated metal baffle just above the valve disperses the stream of vapor so that it is evenly deposited. During deposition of a sample the cell is continuously evacuated through a lead of 1/4 in. copper tubing. When deposition is complete this tube is crimped and cut with a Kane cold-welding tool to make a vacuum tight seal. The cell is connected to the deposition apparatus (or, after irradiation, to a gas analysis line) through a Hoke metal bellows valve and an Edwards vacuum union. This valve is closed while the cell is being irradiated.

The deposition apparatus for metering out vapors is shown schematically in Fig. 2. Blanket material from ballast volume (1) and deuterated cyclohexane from ballast volume (2) are admitted alternately to the cell through ~ 2 ml metering volumes between valves V_1 and V_2 and between V_3 and V_4. These valves are magnetically operated (Edwards type D-11207).

The valves were opened and closed in a sequence which was actuated by a stepping switch. A microswitch provided the impulses which advanced the stepping switch and this microswitch was, in turn, closed and opened by studs on the circumference of a slowly rotating wheel. The spacing of the studs and the speed of rotation of the wheel controlled the time for each step and the time for a complete cycle.

We were particularly concerned about the possibility of inadvertent mixing of the two components during deposition, and so made liberal allowances for the time taken to complete deposition. Half a minute was allowed for deposition with either V_2 and V_3 open. A further half minute was taken with V_2 or V_3 closed before the next layer was deposited. The time for a complete cycle, deposition of a pair of layers, was 2 min. When our techniques were developed we chose to make samples with 310 layers of each component. The total amount of C_6D_{12} in the sample is, therefore, proportional to the thickness of the layers.

With this arrangement of valves most of the layer is deposited in perhaps a tenth of a second or less. We were concerned that, for the thick layers, this deposition rate could be so high that the latent heat of condensation could produce transient local melting and hence some mixing of the layers. To minimize this,

For personal use only.

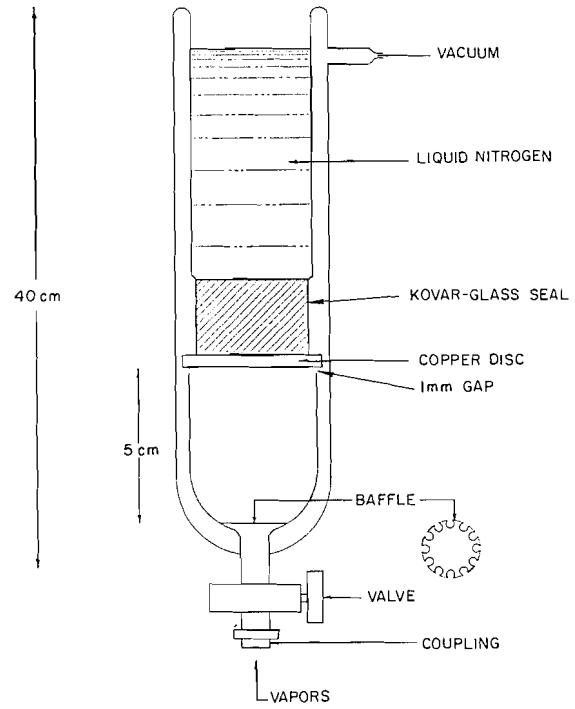

FIG. 1. Cell used for preparing and irradiating multilayered samples.

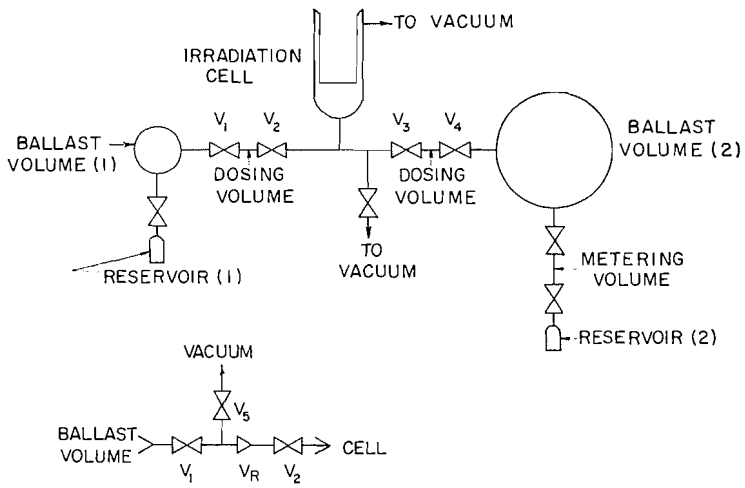

FIG. 2. Vacuum line for deposition of multilayered samples.

another arrangement, shown in the insert, was used for metering the blanket material. Vapor from the reservoir was bled continuously through a needle valve V_R whose setting was chosen so that the correct amount of vapor passed through it in 30 s. The cycle of operation was arranged so that deposition occurred with V_1 and V_2 open and V_5 closed. At the end of the deposition V_1 and V_2 were closed and the dead space between V_1 and V_R evacuated through V_5. The deposition rate with this arrangement is $\sim 10^{-7}$ mole/cm^2 s. This is two orders of magnitude slower than the rates used for trapping free radicals from gases which have been passed through an electric discharge (5). If local melting occurred in these experiments, free radicals could diffuse and recombine. As can be seen (Figs. 5 and 6), this modification produced no change in the experimental results. We are confident that the layers are truly segregated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The amounts deposited in one layer of each component were set by the pressure in the ballast volumes. For the blanket layer, which is normally deposited in a constant thickness, whatever the thickness of the thin layer might be, this pressure was set by the vapor pressure of the liquid at the temperature of the thermostat bath in which the liquid reservoir (1) was placed. For the thin layers the pressure in the ballast volume was varied by adding aliquots from the intermediate metering volume. This metering volume was 50 ml and was filled at the vapor pressure of liquid C_6D_{12}. The ballast volume was ~ 20 l.

Separate vacuum systems, not shown in the figure, were used for evacuating both ballast volumes and the irradiation cell before sample preparation was started. The organic liquids were degassed by conventional freeze–thaw techniques.

After the sample was prepared it was irradiated with Co-60 gamma rays at liquid nitrogen temperature to doses of 1.4×10^{19} eV/ml C_6H_{12} at dose rates of 7.7×10^{17} eV/ml C_6H_{12} per minute. These doses are high because the sample is necessarily small. Because of the geometry of the cell, dosimetry was done by irradiating a thin layer of *n*-hexane on a disc and taking $G(H_2) = 4.3$ (as determined in this laboratory) for this solid material.

After irradiation the sample was melted and the radiolytic gas pumped to a conventional gas analysis line. After the volume of gas was measured, the isotopic composition was determined by mass spectrometry. For samples with blanket materials such as CCl_4 which have zero hydrogen yield, a quantity of H_2 was added to the gas extracted from the sample so that the radiolytic gas could be more conveniently handled. The amount of D_2 was obtained from the mass spectrometric analysis. The liquid mixture of blanket and indicator material in the irradiation cell was weighed and analyzed either by gas chromatography or by mass spectrometry to determine the weight of C_6D_{12} in the sample. From this and the number of layers the layer thickness was calculated. The thickness derived in this way was generally within 10% of that predicted from the pressures and volumes in the deposition apparatus.

3. THE VALIDITY AND PRECISION OF THE TECHNIQUE

As will be seen, we claim to be able to make reproducible layers of hydrocarbons as thin as 20 Å, which is of the order of four molecular layers. In this section we outline the reasons for our confidence in the technique.

The deposition of the thin C_6D_{12} layer could be imperfect in two different ways. There could be considerable mixing in the interfacial regions which would lead to the observation of excitation transfer at erroneously large distances. The observed range would then be a maximum value. Alternatively, the layers could be unevenly deposited. If this occurred to any significant extent it would be observed visually as the layers built up. All our samples have a uniform appearance. When very thin they are transparent and show interference colors; as they grow thicker they become uniformly translucent to opaque.

We regard adventitious mixing as the most likely source of error. If it occurred to a constant extent then we would observe the same long range for all systems. However, this is not the case; the observed ranges vary over a factor of about five. One can then argue that mixing, if it occurs, can only be significant for the system with the smallest range (30 Å) and must be relatively insignificant for all systems giving ranges greater than 30 Å.

The most convincing argument for the validity of these experiments is their reproducibility. In Fig. 4 we present the results we obtained for C_6D_{12} layers sandwiched between layers of $C_6H_{14} + 4\%$ C_6H_6. In this figure, and in all subsequent figures, yields per 100 eV absorbed in the C_6D_{12} are plotted against the thickness of the C_6D_{12} layer. By convention we plot the yields obtained in homogeneous mixtures at $T = 0$.

The cluster of experimental points in the thickness range 90–130 Å should be noted. These results also show the variation of the HD and D_2 yields which is observed when the thick layer consists of an undeuterated hydrocarbon. In thick C_6D_{12} layers D_2 is produced both by molecular detachment,

$$C_6D_{12} \xrightarrow{\sim\sim\sim} C_6D_{10} + D_2,$$

and by a second order process which we can write

$$C_6D_{12} \xrightarrow{\sim\sim\sim} X_D + \cdots$$
$$X_D + C_6D_{12} \rightarrow D_2 + \cdots.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

As the C_6D_{12} layer decreases in thickness an increasing fraction of the intermediate X_D may escape from the layer and react to give HD.

$$X_D + RH \rightarrow HD + \cdots$$

In the homogeneous sample the D_2 yields have fallen to a finite value, the yield of the molecular detachment process in that solid matrix; at the same time the HD yield increases.

4. THE RELATIONS BETWEEN LAYER THICKNESS, RANGE, AND YIELD

First we shall discuss the case where the interaction between the two layers is due to a mobile intermediate with a range or diffusion length large compared to molecular dimensions. The matter in the layers can be regarded as continuous. This mobile species could be an electron, a hydrogen atom, a photon, or an exciton. Let the number of the intermediates formed during radiolysis be N per unit volume of material randomly distributed in the indicator layer and let the number which escape from a unit area of the indicator material into the blanket be N_e. We can then define an arbitrary average escape distance, t, to be such that

$$N_e = Nt. \tag{6}$$

Suppose the indicator layer has a thickness $T \gg t$. If it is remembered that the indicator layer has two sides, then the fraction of intermediates which escape is $2t/T$ and the fraction which is trapped in the layer is $1 - (2t/T)$. Intermediates which escape from the thin layer give product yields characteristic of a homogeneous mixture; intermediates which are trapped in the layer give yields characteristic of the segregated mixture. At a thickness T_h (= half-value thickness), when the yield from the layer is midway between the two extremes of homogeneous and segregated samples, we have

$$2t/T_h = 1 - (2t/T_h) \text{ or}$$

$$t = T_h/4. \tag{7}$$

We now have to find the relation between the escape distance t, which is measured experimentally through eq. [7], and the range of the mobile intermediate. Let the mobile intermediate have a range R and let us consider those which are formed at a distance D below the surface (Fig. 3) of the indicator layer. The fraction of these intermediates which escape through the surface is equal to the area of the cap divided by the total surface area of the sphere. That is, the fraction escaping equals

$$2\pi R(R - D)/4\pi R^2 = \tfrac{1}{2}(1 - (D/R)). \tag{8}$$

If N intermediates are formed per unit volume then dN_e, the fraction which escapes from an increment dD, is

$$dN_e = (N/2)(1 - D/R)\, dD \tag{9}$$

whence

$$N_e = \frac{N}{2}\int_0^R \left(1 - \frac{D}{R}\right) dD = \frac{NR}{4}.$$

It follows, therefore, from eqs. [6], [7], and [9] that $t = R/4$ and

$$R = T_h. \tag{10}$$

It is, however, unlikely that the mobile species would have a unique range. It is almost certain to have some dispersion so that values of R obtained from eq. [10] represent some averaged value of the range.

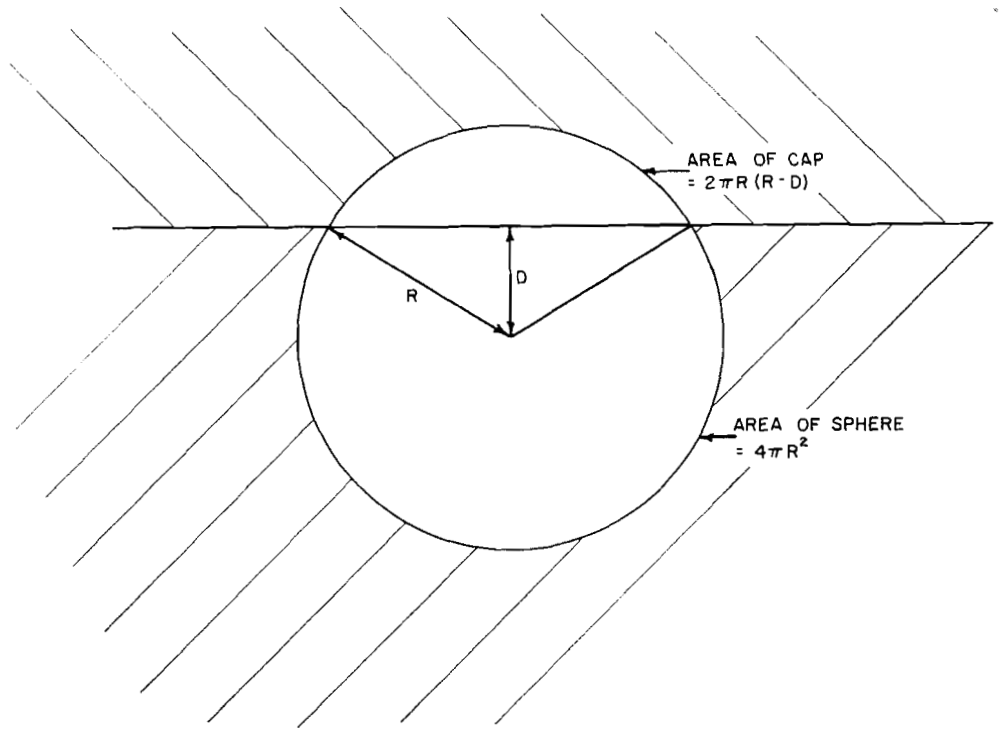

FIG. 3. Geometry of the escape of a particle from a layer.

The probability of an escape from a layer has been treated in detail by Case, de Hoffman, and Placzek (6) for a mobile species which is attenuated exponentially. Values of the escape probability are tabulated as a function of the ratio of the layer thickness to the mean free path λ of the diffusing species. The mean free path λ is the distance in which the species is attenuated by 1/e. For an escape probability of 0.5, equivalent to our condition defining T_h, $\lambda = 1.56T_h$. Values of R obtained from eq. [10] would, therefore, be approximately two thirds of the mean free path.

The tabulation in this reference also allows one to plot the shape of the yield curve as a function of the layer thickness. This plot appears in Fig. 6 which shows our results for the D_2 yield from layers of C_6D_{12} sandwiched between CCl_4 layers. Since the curve is fitted to the data at three points (T = 0, 180 Å, and "∞"), this is not a particularly sensitive test although the agreement is satisfactory. However, for most of our purposes, eq. [10] is an adequate approximation. We will use the symbol $\bar{R}$ to remind us that this range is probably arbitrarily averaged.

The above analysis is incorrect if the range is very short and comparable with molecular dimensions. Suppose that activation or deactivation is restricted to molecules in the surface layers; only molecules in contact with the molecules in the blanket layer interact. Half the layer, the two molecular layers in contact with the blanket material, interact, and the other half of the layer, consisting of the remaining two molecular layers in the middle, are unaffected. Hence T_h = 4 molecular diameters.

Our main interest is in distinguishing between mechanisms of excitation transfer through measurements of $\bar{R}$. We can first distinguish between interactions occurring

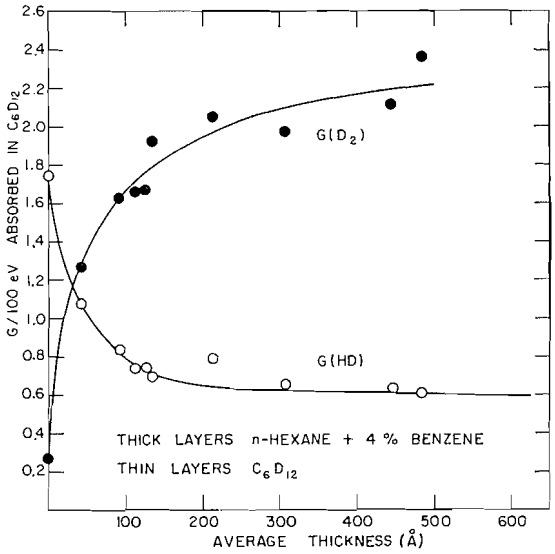

FIG. 4. Yields from the $(C_6D_{12})/(C_6H_{14} + 4\%\ C_6H_6)$ system.

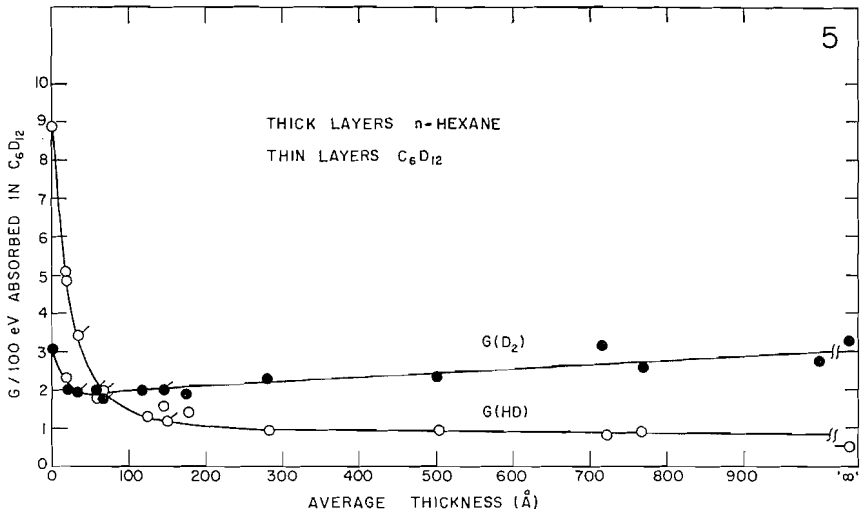
between molecules in contact and interactions in which the diffusing species moves, on the average, several molecular diameters before reacting. For the hydrocarbon systems studied here, nearest neighbor interactions are indicated when $\bar{R} \leq 40$ Å, corresponding to molecular diameters of ≤ 10 Å. Interactions involving diffusing species are indicated by significantly larger values of $\bar{R}$ of 100 Å or more. Intermediate values of $\bar{R}$ = 40–80 Å are difficult to interpret. Suppose that the intermediate is a hot hydrogen atom which reacts efficiently within two molecular diameters. The apparent range will be larger than the 40 Å figure for nearest neighbor interactions and could be, say, 60 Å (as given by eq. [10]). The true range of the hot hydrogen atom is, however, shorter than this since the situation resembles nearest neighbor interactions more closely than it does the diffusion of a reactive intermediate through a continuum.

Values of $\bar{R}$ may be determined from measurements of HD or D_2 and we shall call these $\bar{R}_{HD}$ and $\bar{R}_{D_2}$ respectively. We shall refer to the system of a thin layer of material "X" placed between thick materials of "Y" as the (X)/(Y) system. Samples of thin layers of C_6D_{12} sandwiched between CCl_4 are described by $(C_6D_{12})/(CCl_4)$.

The scatter of the experimental points in these and other experiments suggests that the yield at the half-value is known to about ± 0.1 G units. The effect of this uncertainty on the value of $\bar{R}$ depends, of course, on the slope of the curve of yield vs. layer thickness. An accuracy of ± 10 Å in $\bar{R}$ is consistent with most of our data. These limits are perhaps somewhat reduced if $\bar{R}$ is small and the yield is changing rapidly with layer thickness.



5. THE PRODUCTION OF H_2 AT 77 °K

It is essential for these layer experiments that the reaction chosen for study shall occur at a low temperature, when the layered structure is intact, and not after melting, when the layered structure has been destroyed.

For hydrocarbon samples about one quarter of all the radiolytic hydrogen can be pumped away from the sample before it is melted. If the sample contains a small amount of deuterocyclohexane distributed homogeneously, then the initial fraction contains both

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

HD and D_2 in percentage amounts comparable to that of the second fraction obtained on melting the sample.* Both molecular detachment processes giving D_2 and bimolecular processes giving HD are, therefore, taking place at 77 °K. The addition of benzene to these homogeneous mixtures again shows no large discrimination in D_2 and HD production between the two fractions.

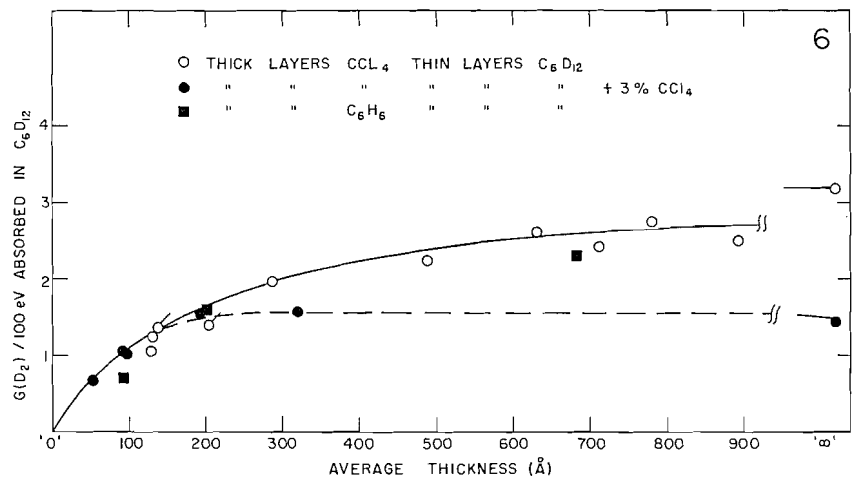


FIG. 5. Yields from the $(C_6D_{12})/(C_6H_{14})$ system. The flagged points were obtained from the slower deposition rates.

FIG. 6. Yields from the $(C_6D_{12})/(CCl_4)$, $(C_6D_{12})/(C_6H_6)$, and $(C_6D_{12} + 3\%\ CCl_4)/(CCl_4)$ systems. The full curve is calculated from the table of ref. 5 fitted to $\bar{R}_{D_2} = 180$ Å. The flagged points were obtained from the slower deposition rates.

In layered samples a similar behavior is observed in that about one fifth of the gas escapes before melting. However, the first fraction contains a much higher percentage of HD and D_2 than the second. For layers ~ 100 Å thick more than 70% of all the HD and D_2 appears in the first fraction. There is thus no question that all the HD and D_2 may be

*For example: In a matrix containing 5.72 mole % C_6D_{12} in n-C_6H_{14} the first fraction (17% of the total) contained 12.1% HD and 5.9% D_2, the second fraction contained 9.9% HD and 4.0% D_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

formed at liquid nitrogen temperature. We attribute the fractionation to physical processes which permit the preferential escape of D_2 and HD from the thin layers. These multilayered samples cannot be ideally uniform and there are likely to be channels and interstices in the vicinity of the layer boundaries.

Further relevant observations were made on the isotopic composition of hydrogen evolved from samples having only one layer of C_6D_{12}. The isotopic composition of the first fraction was independent of the position of the C_6D_{12} layer: whether on top of the light hydrocarbon and thus exposed to the vacuum in the irradiation cell, or underneath a thickness of ~ 1 mm of light hydrocarbon. This supports the suggestion that part of the radiolytic hydrogen can escape from a bulk sample of hydrocarbon.

6. EXPERIMENTAL RESULTS

(a) Thick Layers of n-Hexane

In this system (Fig. 5) there is a strong activation of the C_6D_{12} at very small thicknesses, which is shown most clearly by the increase in the HD yield. The D_2 yield also shows this effect in a somewhat disguised form. From 1 000 Å to 60 Å the D_2 yield decreases because of the effect outlined in Section 4, that of X_D reacting with C_6H_{14} instead of C_6D_{12}. Below 60 Å this process is swamped by the short range processes activating C_6D_{12}. The magnitude of the activation is shown by the D_2 yield, which, in homogeneous mixtures of C_6D_{12} with C_6H_{14} is 3.2 as compared with a value of 0.5 found in homogeneous C_6D_{12}–C_6H_{12} mixtures. (Both values obtained in our laboratory.) The value of $\bar{R}_{D_2}$ is somewhat indeterminate. For the HD yield $\bar{R}_{HD} = 25$ Å. This indicates that the interaction occurs between molecules in contact.

(b) Thick Layers of Carbon Tetrachloride and Benzene

Results for samples with either CCl_4 or C_6H_6 are shown in Fig. 6. The range of the deactivation is identical for both materials. The two flagged points for CCl_4 were obtained in experiments in which the CCl_4 layer was deposited slowly through a small leak and not in one puff. As mentioned in Section 2 this is a reduction of two orders of magnitude in the deposition rate and the yields are unchanged. The long range implied by the results here is, therefore, real and is not due to mixing of the layers during deposition.

For both the $(C_6D_{12})/(CCl_4)$ and $(C_6D_{12})/(C_6H_6)$ systems we find $\bar{R}_{D_2} = 180$ Å.

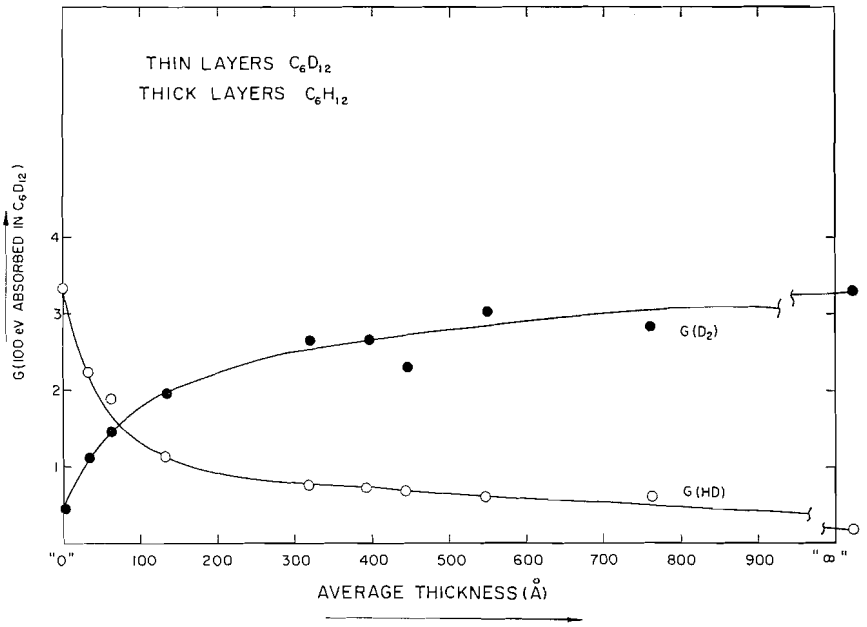
It is well known that the homogeneous addition of carbon tetrachloride (or other additives) to a hydrocarbon reduces the yield in two stages (1, 7); a rapid reduction at low CCl_4 concentrations which terminates at concentrations of about 3% CCl_4, leaving a "residual yield" which is much more weakly reduced by further additions of CCl_4. We accordingly studied the $(C_6D_{12} + 3\%\ CCl_4)/(CCl_4)$ system in which $G(D_2) = 1.5$ in the infinitely thick layers; the yield curve is approximately horizontal until it intersects the curve for the $(C_6D_{12})/(CCl_4)$ system and is then coincident with that curve (Fig. 6). The range of this interaction is, therefore, 60 Å—considerably less than for the $(C_6D_{12})/(CCl_4)$ system. The value of $\bar{R}_{D_2}$ for the $(C_6D_{12})/(CCl_4)$ system is, therefore, the weighted sum of two ranges, 60 Å for the residual part of the yield and a much larger range ~ 340 Å for the part of the yield inhibited by 3% CCl_4 (assuming that the average is obtained by weighting the ranges according to the inhibited and residual yields respectively).

(c) Systems with C_6H_{12} in the Thick Layer

The study of the $(C_6D_{12})/(C_6H_{12})$ system would be expected to give information on the mobility of the species X_H and X_D, the intermediates in the bimolecular reaction giving

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydrogen. As we have already noted $G(D_2)$ will diminish when the C_6D_{12} layer is thin enough for a significant fraction of the X_D formed in the layer to escape and react in the C_6H_{12} layer to give HD. The yield of HD will, further, be increased to a similar extent by the diffusion of X_H from the C_6H_{12} layer into the C_6D_{12} layer. This yield depends on the total surface of C_6D_{12} exposed to the light hydrocarbon. Under our experimental conditions, where the amount of C_6D_{12} is kept constant, the number of layers and hence the surface area is inversely proportional to the layer thickness. If there were no isotope effects ($G(X_H) = G(X_D)$) and the diffusion lengths and reactivity of X_H and X_D were identical, then a reduction in $G(D_2)$ by a certain amount, as the layer thickness decreased, would be matched by an increase in $G(HD)$ of twice that amount. We would also observe $\bar{R}_{D_2} = \bar{R}_{HD}$. Isotope effects might alter the ratio of these changes in $G(D_2)$ and $G(HD)$ from the simple value of 1:2, but $G(HD)$ should always increase in the thinner layers to a greater extent than $G(D_2)$ decreases.



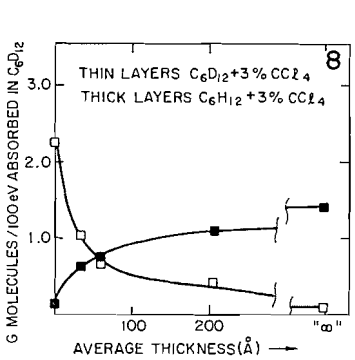


FIG. 7. Yields from the $(C_6D_{12})/(C_6H_{12})$ system.

Experimentally the $(C_6D_{12})/(C_6H_{12})$ system does not follow these predictions. We find $\bar{R}_{D_2} = 110$ Å and $\bar{R}_{HD} = 60$ Å and $G(HD)$ in the homogeneous sample is, at most, equal to $G(D_2)$ in the segregated mixture (Fig. 7). We conclude that there is a process in which C_6H_{12} quenches the decomposition of C_6D_{12} with a range of the order of 100 Å.

Three other systems with C_6H_{12} in the thick layer have been studied: $(C_6D_{12} + 3\%\ CCl_4)/(C_6H_{12} + 3\%\ CCl_4)$, $(C_6D_{12} + 3\%\ CCl_4)/(C_6H_{12})$, and $(C_6D_{12})/(C_6H_{12} + 3\%\ CCl_4)$. For brevity we will refer to the composite layers as $(C_6H_{12} + CCl_4)$ and $(C_6D_{12} + CCl_4)$. These systems were chosen because, on the interpretation we have proposed, electron scavenging is nearly complete at this concentration of CCl_4. The hydrogen from the solid CCl_4 solutions at these concentrations is, we suggest, formed through the decomposition of excited molecules which do not have ionic precursors. The results are shown in Figs. 8, 9, and 10 and in Table I.

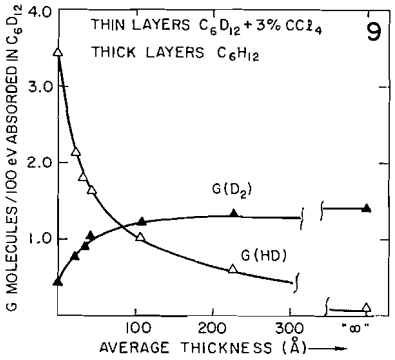

FIG. 8. Yields from the $(C_6D_{12} + 3\%\ CCl_4)/(C_6H_{12} + 3\%\ CCl_4)$ system. (■) $G(D_2)$, (□) G(HD).
FIG. 9. Yields from the $(C_6D_{12} + 3\%\ CCl_4)/(C_6H_{12})$ system.

All the systems with C_6H_{12} in the thick layer show values of $\bar{R}_{HD}$ of 40–60 Å so that interactions do not extend much further than nearest neighbors. It follows that X_H and X_D could be molecular species immobilized in the surface of the layers or mobile species which reacted inside one or, at the most, two molecular diameters.

TABLE I
Observed interaction ranges

Indicator layer	Blanket layer	Fig.	$\bar{R}_{HD}$ (Å)	$\bar{R}_{D_2}$ (Å)
C_6D_{12}	n-C_6H_{14}	5	25	See text
C_6D_{12}	CCl_4	6	—	180
C_6D_{12}	C_6H_6	6	—	180
$C_6D_{12} + 3\%\ CCl_4$	CCl_4	6	—	60
C_6D_{12}	C_6H_{12}	7	60	110
$C_6D_{12} + 3\%\ CCl_4$	$C_6H_{12} + 3\%\ CCl_4$	8	40	60
$C_6D_{12} + 3\%\ CCl_4$	C_6H_{12}	9	40	40
C_6D_{12}	$C_6H_{12} + 3\%\ CCl_4$	10	40	200

By contrast, values of $\bar{R}_{D_2}$ vary from 40 to 200 Å and here we must be observing, in addition, one or more processes inhibiting the decomposition of C_6D_{12} itself (to give D_2 by either a unimolecular or bimolecular route) which are independent of the reactions of X_H or X_D. These have already been noted in the $(C_6D_{12})/(C_6H_{12})$ system.

Systems in which the C_6D_{12} layer contains CCl_4, $(C_6D_{12} + CCl_4)/(C_6H_{12} + CCl_4)$ and $(C_6D_{12} + CCl_4)/(C_6H_{12})$, show a much closer agreement between $\bar{R}_{HD}$ and $\bar{R}_{D_2}$ than is seen in the $(C_6D_{12})/(C_6H_{12})$ system. Further, in both these systems the increase in G(HD), as the layers are made thinner, is approximately twice the decrease in $G(D_2)$. (See Figs. 8 and 9.) These systems approximately follow the predictions for the simple case, outlined above. It appears that addition of CCl_4 to the C_6D_{12} layer has removed or masked the other processes inhibiting the decomposition of C_6D_{12} which we noted in the $(C_6D_{12})/(C_6H_{12})$ system.

The $(C_6D_{12})/(C_6H_{12} + CCl_4)$ system has a large value of $\bar{R}_{D_2}$, 200 Å, which is essentially that observed in the $(C_6D_{12})/(CCl_4)$ system, 180 Å (Fig. 10). This low concentration of CCl_4 in the blanket is, therefore, apparently equivalent to a blanket layer consisting wholly of CCl_4.

7. DISCUSSION

This study is exploratory and we shall, accordingly, take a cautious view of the significance of the data. We regard differences in values of $\bar{R}$ to be significant if they amount to a factor of two; smaller differences will not be discussed in detail as they may or may not be significant.

We have distinguished four processes, in order of increasing range:

1. Activation of C_6D_{12} by n-C_6H_{14}, $\bar{R} \simeq 25$ Å.
2. Reactions of the intermediates X_H and X_D to give HD, $\bar{R} \simeq 40$–60 Å.
3. A deactivation of C_6D_{12} by C_6H_{12}, $\bar{R} \simeq 110$ Å.
4. A deactivation of C_6D_{12} by CCl_4 and C_6H_6, $\bar{R} \simeq 180$–200 Å. If the thin layer contains 3% CCl_4 then the range is shorter, $\bar{R} \simeq 60$ Å.

(a) Activation by n-C_6H_{14}

The value of $\bar{R}_{HD}$ observed in this system, 25 Å, is clearly in the region where the layer is ~ 4 molecular diameters thick. The charge transfer step which we suggest is responsible for the activation

$$C_6H_{14}^+ + C_6D_{12} \rightarrow C_6H_{14} + C_6D_{12}^+$$

can, we conclude, only occur between nearest neighbors.

Referring to the results discussed earlier for the $(C_6D_{12})/(C_6H_{14} + 4\%\ C_6H_6)$ system, we see that the addition of benzene at this low concentration has entirely destroyed the activation process: the sum of $G(D_2) + G(HD)$ in fact shows a net decrease from the thick to the thin layers. According to our proposed mechanism, benzene acts as an electron scavenger

$$C_6H_6 + e \rightarrow C_6H_6^-$$

and reaction of the $C_6H_6^-$ ion with $C_6D_{12}^+$ (or $C_6H_{14}^+$) does not result in decomposition of the positive ions to give hydrogen. In this system this neutralization cannot occur until the sample is melted and the molecules are mobile.

The charge exchange step will occur whether or not benzene is present. Its effect will, however, not be observed if the range of electrons is sufficiently large, since these will then pass into the benzene-containing layer. By hypothesis neutralization of positive ions by negative ions does not yield HD or D_2.

(b) Inhibition by Carbon Tetrachloride and Other Electron Scavengers

According to the arguments of ref. 1, the inhibited part of the yield, which is sharply

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reduced by small additions of electron scavengers such as CCl_4, is identified as the yield of ions (reaction [1*a*]) and the residual yield is the yield of excited molecules [1*b*]. We have inferred that $\bar{R}_{D_2}$ for the $(C_6D_{12})/(CCl_4)$ system, 180 Å, is an average of two components: one with $\bar{R}_{D_2} \simeq 340$ Å which is equivalent to the interaction at low CCl_4 concentrations and the other with $\bar{R}_{D_2} \simeq 60$ Å for the interaction at high concentrations ($> 3\%$). We would accordingly identify the range of 340 Å as the average separation of positive ions and electrons in a matrix of solid C_6D_{12}. Recent studies with organic glasses have shown that G(ions) and $G(e^-)$ are ~ 3 (8) and that these electrons may travel considerable distances in the glass (100 to 1 000 Å) before being recaptured by the positive ion (9). A value for the average positive ion electron separation of 340 Å is, however, admittedly large, and greater than that suggested for liquid hydrocarbons (4).

The large value of $\bar{R}_{D_2}$ in the $(C_6D_{12})/(C_6H_{12} + CCl_4)$ system is relevant to this conclusion. This is also a composite range. On our mechanism the interaction consists of two parts: (i) electron capture in the thick layer inhibiting decomposition of the C_6D_{12} and (ii) escape of the intermediate X_D from the C_6D_{12} layer to give HD instead of D_2 when $t \sim 40$ Å (as will be discussed shortly). Accordingly, the range of the electrons alone must be significantly greater than 200 Å and this would be consistent with the 340 Å value deduced above for electron-positive ion separation.

The interaction in the $(C_6D_{12} + 3\%\ CCl_4)/(CCl_4)$ system for which $\bar{R}_{D_2} \sim 60$ Å could represent the short range part of the spectrum of positive ion electron separation or some other process entirely. If it did represent an interaction with electrons then it would follow that all the hydrogen formed in solid cyclohexane was formed through ionic precursors and none through molecules, a conclusion which would be in conflict with our interpretation of the "residual" yield.

In our opinion the balance of evidence favors the identification of the residual yield with the decomposition of excited molecules which do not have ionic precursors. The interaction of CCl_4 with this excited molecule would then be an energy transfer process. Such a process has also been suggested by Freeman (10) for the interaction in the benzene–cyclohexane system in the concentration range 3–100% C_6H_6. His rate constants for the reaction are small and would be consistent with the short range interactions we observe.

(c) Reactions of the Intermediates X_H and X_D

The small values of $\bar{R}_{HD}$, essentially the interaction distance of the species X_H and X_D, show that they are not thermal hydrogen or deuterium atoms. Firstly, the activation energy for H-atom abstraction by H atoms is sufficiently large (~ 7 kcal) (11) that this reaction could not occur at 77 °K. We have, however, found that the bimolecular process giving HD does occur at low temperatures. Further, Klein and Scheer (12) found that H atoms could diffuse rapidly at 77 °K without reaction through a layer of aliphatic hydrocarbons $\sim 10^4$ Å thick. This would mean that if thermal H atoms were reactive intermediates, $\bar{R}_{HD}$ would be of this order. This would also be true if the H atoms diffused through the sample at 77 °K but only reacted as the sample warmed up, or if they reacted by bimolecular combination. The difference of more than three orders of magnitude between $\bar{R}_{HD}$ values expected for thermal H atoms and those found experimentally is conclusive.

It is possible that X_H and X_D are hot hydrogen and deuterium atoms. Hot hydrogen atoms have often been postulated as reactive intermediates in the radiolysis of hydrocarbons and recent chemical evidence for them has been given by Toma and Hamill (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

We might anticipate that hot hydrogen atoms, if formed, would initially have energies in the range of 1–10 eV. Our results would require then that the major fraction of these atoms would react before moderation in a distance of 40–60 Å. The efficiency of abstraction at one collision must be less than unity but greater than one hundredth.

Abstraction reactions of hot hydrogen and deuterium atoms have been studied by Martin and Willard (13). Photolysis of DBr and HBr produces D and H atoms with energies of about 3 eV. Abstraction from H_2, D_2, CH_4, and CD_4 was studied. The activation energy for abstraction from H_2 and D_2 is 7.5 ±1 kcal (close to that for the higher hydrocarbons we are studying). For D atoms reacting with H_2, Martin and Willard found that 62% reacted while hot and the remainder were moderated. Probabilities of reaction per collision as high as 0.35 were observed. It appears, therefore, that the high total reaction probability required in our systems is reasonable, as is a range corresponding to several molecular diameters. However, as we have already pointed out, the 40–60 Å ranges are in the intermediate region where we cannot properly describe the layers as continuous.

Thermodynamically possible ion–molecule reactions can be written for the production of HD and D_2 in mixtures of light and heavy hydrocarbons (14, 15). As we have argued, these should have small values of $\bar{R}_{HD}$, ~25 Å, as observed in the $(C_6D_{12})/(C_6H_{14})$ system. The somewhat larger values of $\bar{R}_{HD}$ (40–60 Å) observed in systems with C_6H_{12} in the thick layer may be significant evidence against such mechanisms.

(d) Excitation Transfer between C_6H_{12} and C_6D_{12}

Studies of the radiolysis of liquid mixtures of light hydrocarbons and their deuterated counterparts suggest that excitation transfer between the light and heavy molecules may be taking place; the light hydrocarbons being activated and the heavy counterpart being deactivated.

In dilute solutions of C_6D_{12} in C_6H_{12} the yields of D_2 and HD are low and much less than the yields of H_2 and HD from dilute solution of C_6H_{12} in C_6D_{12} (16). These yields are, indeed, so high that C_6H_{12} molecules must be activated by C_6D_{12}. Conversely, then, C_6D_{12} molecules are deactivated by C_6H_{12}. Similar observations have been made for mixtures of C_2D_6 and C_2H_6 (17). H_2 and HD yields in solutions of C_2H_6 in C_2D_6 are so large that activation of C_2H_6 must be occurring. The deactivation of C_6D_{12} by C_6H_{12} shown by the value of $\bar{R}_{D_2}$ in the $(C_6D_{12})/(C_6H_{12})$ system is further evidence for such an interaction.

8. CONCLUSIONS

Our principal conclusions are:

1. The intermediates in the bimolecular reaction which gives HD in mixtures of isotopic hydrocarbons have a short range. They cannot be thermal hydrogen atoms. Plausible arguments for their identification as hot hydrogen atoms can be advanced.

2. No energy transfer processes with extremely long ranges (i.e. ~1 000 Å) have been found. Activation in mixtures of hydrocarbons (e.g. cyclohexane and *n*-hexane) has a very short range corresponding to nearest neighbor interactions, consistent with our identification of these processes as charge transfer.

3. Deactivation by carbon tetrachloride has a long range (200–500 Å) which can be interpreted as the distance separating positive ions and electrons in the ionization process in solids.

4. There is evidence for an energy transfer process between deuterated and undeuterated hydrocarbons.

DIFFUSION IN MULTICOMPONENT AQUEOUS SYSTEMS

J. E. LANE[1] AND J. S. KIRKALDY
Department of Metallurgy and Metallurgical Engineering, McMaster University, Hamilton, Ontario
Received July 20, 1965

ABSTRACT

A vacancy model, originally developed for the description of diffusion in substitutional alloys, is modified for application to aqueous solutions, including those containing ionic species. The results obtained with this model are similar to those of two recently published methods for estimating L-coefficients in dilute multicomponent liquid systems.

Agreement with experimental L-coefficients at relatively high concentrations can be improved for this model by assuming that the jump probability of a diffusing species is inversely proportional to the relative viscosity of the mixture. Good agreement is then found for some systems up to combined solute concentrations of 3 M.

INTRODUCTION

In two recent papers (1, 2), hereinafter referred to as I and II respectively, we have investigated the macroscopic implications of two simple microscopic models of diffusion in multicomponent systems. In I we showed that the form of the concentration dependence of the L-coefficients describing diffusion in multicomponent alloy systems was similar for both an exchange and a vacancy mechanism. In II we adapted the exchange mechanism to describe diffusion in a quasi-crystalline model of a liquid. The calculations based on this approach gave good quantitative agreement with experimental L-coefficients in several dilute ternary liquid systems and gave qualitative agreement in more concentrated solutions. We show in this communication that the vacancy mechanism of diffusion given in I, when suitably modified, gives just as good a description of diffusion in multicomponent liquid systems as the exchange mechanism.

MODEL

As in II, we postulate a quasi-crystalline liquid, with each diffusing entity occupying a lattice site; in addition we postulate that a very small fraction of the sites are vacant. Diffusion occurs by interchange of a diffusing unit (atom, ion, or molecule) with an adjacent vacant site. The lattice sites are all assumed to be equivalent, and hence the partial molar volumes are the same for each diffusing species, and the volume- and number-fixed frames of reference are coincident.

The flux of the i'th component in the lattice-fixed (or Kirkendall) frame of reference of the model was given in I for the vacancy mechanism as,

$$[1] \qquad (J_i)_K = -\frac{\lambda^2}{RT}\hat{C}_i P_i \frac{\partial \mu_i}{\partial x},$$

where λ is the lattice spacing in the direction of the chemical potential gradient, $\hat{C}_i$ is the concentration of the i'th component per unit volume of lattice as determined by averaging normal to the chemical potential gradient, and P_i is the jump probability of the i'th species at the concentration under consideration.

SOLUTIONS CONTAINING NO WEAK ELECTROLYTES

We consider a solution containing solvent, designated as component 0, nonelectrolyte components 1 and 2, and neutral salt components 3 and 4, composed of ions 3^1, 4^1, and 5^1,

[1]*Now at the C.S.I.R.O., Division of Physical Chemistry, Box 4331, G.P.O., Melbourne, Australia.*

the ions of type 5^1 being common to both salts. The ionic fluxes are given by [1] but are also subject to the condition of electrical neutrality, which in this particular case is,

$$[2] \qquad \sum_{k^i=3^i}^{5^i} Z_{k^i}(J_{k^i}) = 0,$$

where Z_{k^i} is the charge on the k^i'th species. In II, a method was given in detail for obtaining salt fluxes from the expressions for the ionic fluxes together with the condition of electrical neutrality. Use of this method and eq. [1] and [2] gives the salt fluxes as,

$$[3] \qquad (J_k)_{\substack{K \\ k,\,l=3,4}} = -\frac{\lambda^2}{RT}\alpha_{kk}\frac{\partial \mu_k}{\partial x} - \frac{\lambda^2}{RT}\alpha_{kl}\frac{\partial \mu_l}{\partial x},$$

where,

$$[4] \qquad \alpha_{kl} = (Z_{5^i})^{-2}\left\{\delta_{kl}\hat{C}_{k^i}P_{k^i} - \prod_{m^i=k,\,l} Z_{m^i}\hat{C}_{m^i}P_{m^i} \Big/ \sum_{m^i=3^i}^{5^i}(Z_{m^i})^2\hat{C}_{m^i}P_{m^i}\right\},$$

and δ_{kl} is the Kröneker delta. The chemical potential gradients in [3] are those of the neutral salts.

A completely general description of diffusion in the lattice-referred coordinate system is given by,

$$[5] \qquad (J_i)_K = -\sum_{j=0}^{4}(L_{ij}')_K\frac{\partial \mu_i}{\partial x},$$

where the $(L_{ij}')_K$ are not unique. For this particular model the $(L_{ij}')_K$ may be summarized as,

$$[6] \qquad (L_{ij}')_K = \frac{\lambda^2}{RT}\delta_{ij}\hat{C}_iP_i,$$

where $\qquad i = 0, 1, 2;\ j = 0, 1, 2, 3, 4 \quad \text{or} \quad i = 0, 1, 2, 3, 4;\ j = 0, 1, 2.$

$$(L_{ij}')_K = \frac{\lambda^2}{RT}\alpha_{ij}, \qquad i, j = 3, 4.$$

THE SYSTEM H_2O–Na_2SO_4–H_2SO_4

This sytem was discussed in detail in II. We designate the water as component 0, the neutral salts as components 1 and 2, and the ionic species Na^+, H^+, SO_4^{2-}, $NaSO_4^-$, HSO_4^- as $1^1, \ldots, 5^1$ respectively. The fluxes of the ions are given by eq. [1], written in terms of the relevant ionic quantities. By a procedure similar to that given in II, the salt fluxes may be written in the form of eq. [5] where the $(L_{ij}')_K$ are given by,

$$[7] \qquad (L_{i0}')_K = (L_{0i})_K = \frac{\lambda^2}{RT}\delta_{0i}\hat{C}_0P_0, \qquad i = 0, 1, 2,$$

$$(L_{kl}')_K = \frac{\lambda^2}{RT}\beta_{kl}, \qquad k, l = 1, 2$$

where

$$\beta_{kl} = \tfrac{1}{4}\left\{(\hat{C}_{k^i}P_{k^i} + \hat{C}_{(k+3)^i}P_{(k+3)^i}) - \prod_{m^i=k^i,\,l^i}(\hat{C}_{m^i}P_{m^i} - \hat{C}_{(m+3)^i}P_{(m+3)^i}) \Big/ \sum_{m=1^i}^{5^i}(Z_{m^i})^2\hat{C}_{m^i}P_{m^i}\right\}.$$

TRANSFORMATION TO THE VOLUME-FIXED FRAME OF REFERENCE

Comparison of the model with experimental systems can be most conveniently made if the L-coefficients are in their unique form pertaining to diffusion in the volume-fixed frame of reference, i.e.

$$[8] \qquad (J_i)_V = -\sum_{i,j\neq 0} (L_{ij})_V \left(\frac{\partial \mu_j}{\partial x} - \frac{\bar{V}_j}{\bar{V}_0}\frac{\partial \mu_0}{\partial x}\right).$$

The $(L_{ij})_V$ are unique and can be obtained from the $(L_{ij}')_K$ of eq. [5] by first transforming the fluxes to the volume-fixed frame of reference of the model, and then using the Gibbs–Duhem equation to replace the dependent forces $\partial\mu_i/\partial x$ by the independent forces

$$\left(\frac{\partial \mu_j}{\partial x} - \frac{\bar{V}_j}{\bar{V}_0}\frac{\partial \mu_0}{\partial x}\right).$$

This procedure was given in detail in I, and for this model,

$$[9] \qquad (L_{ij})_V = (L_{ij}')_K - N_i \sum_{k=0}^{4} \gamma_k (L_{kj}')_K - N_j \sum_{l=0}^{4} \gamma_l (L_{il}')_K + N_i N_j \sum_{k=0}^{4}\sum_{l=0}^{4} \gamma_k \gamma_l (L_{kl}')_K,$$

where γ_i is unity for the solvent and nonelectrolyte solutes, and is given in general by the sum of the moduli of the charges on the constituent ions for each electrolyte solute. The mole fractions N_k are given by (neglecting the vacancy concentration),

$$N_k = \hat{C}_k \Big/ \sum_{l=0}^{4} \hat{C}_l,$$

where for electrolytes the $\bar{C}_i$'s are the concentrations of the neutral salts.

EVALUATION OF THE JUMP PROBABILITIES AT INFINITE DILUTION

The jump probability of the solvent at infinite dilution P_0^0 is given by eq. [56] of I as,

$$[10] \qquad P_0^0 = (D_0^{*,0}) C_0^0 / \hat{C}_0^0 (\lambda^0)^2,$$

the superscript ^{0} indicating the value of a quantity at infinite dilution; $(D_0^{*,0})_V$ is the mutual diffusion coefficient on the molar concentration gradient scale of isotopically labelled solvent molecules in otherwise pure solvent, and C_i is the molar concentration. Equation [10] is approximate because it assumes that solvent molecules with different isotopic composition have the same transport properties. The solvent is water in every system discussed here and we take the value of $(D_0^{*,0})$ at 25 °C to be 2.27×10^{-8} cm^2/s. This value was obtained by Longsworth (3) for mixtures of D_2O–H_2O with a Gouy diffusiometer, and it is in good agreement with the value 2.29×10^{-8} obtained by Andreev (4) with a diaphragm-cell method.

The jump probability of the nonelectrolyte solute components are given by eq. [60] of I as,

$$[11] \qquad P_i^0 = (D_i^0)_V C_0^0 / \hat{C}_0^0 (\lambda^0)^2.$$

The ionic jump probabilities in aqueous solutions are obtained by an analysis similar to that given in II for obtaining the values of the frequency of the ion–water exchange, i.e.

$$[12] \qquad P_{k^i}^0 = (\lambda_{k^i}^0)_{\text{cond}}\, C_0^0 / |Z_{k^i}| F^2 \hat{C}_0^0 (\lambda^0)^2,$$

where $(\lambda_{k^i}^0)_{\text{cond}}$ is the limiting ionic conductance of the k^ith ion, and F is the Faraday.

CALCULATION OF THE $(L_{ii})_V$

In all calculations use is made of the following relations, $\hat{C}_i/\hat{C}_0^0 = C_i/C_0^0$, the value of C_0^0 at 25 °C for water being 55.344 (5), and

$$(\lambda/\lambda^0)^2 = \left\{C_0^0 \Big/ \left(\sum_{i=0}^{2} C_i + \sum_{k^i=3^i}^{5^i} C_{k^i} \right)\right\}^{2/3},$$

except in the H_2O–Na_2SO_4–H_2SO_4 system, where it is given by,

$$(\lambda/\lambda^0)^2 = \left\{C_0^0 \Big/ \left(C_0 + \sum_{k^i=1^i}^{3^i} C_{k^i} + \sum_{k^i=4^i}^{5^i} 2C_{k^i} \right)\right\}^{2/3},$$

obtained by neglecting the vacancy concentration. Here it has been assumed that the ion–pairs $NaSO_4^-$ and HSO_4^- each occupy two lattice sites (the same assumption was made in II).

Two different approximations are made for the P_i at finite concentrations,

[13] $$P_i \approx P_i^0,$$

and

[14] $$P_i \approx P_i^0/\eta_r,$$

where η_r is the relative viscosity.

Ezrokhi (6) has proposed the following empirical relationship for estimating the relative viscosity of mixtures,

[15] $$\log \eta_r(\text{mixture}) = \sum_i \log \eta_r(C_i)$$

where $\eta_r(C_i)$ is the relative viscosity of a binary solution containing the i'th solute at the same molar concentration as it is in the mixture. By eq. [15], Ezrokhi found very good agreement with experimental measurements for the system H_2O–NaCl–KCl.

NOTE: 0 = H_2O; 1 = glycine; 3 = KCl. $D_1^0 \times 10^5 = 1.061$, ref. 11. Conductance data from Robinson and Stokes (10). Relative viscosities estimated by eq. [15] and the binary data of refs. 11 and 12. Experimental L-coefficients from ref. 5.

In Table I are the calculated values of the L-coefficients of the system H_2O–NaCl–KCl at 25 °C using both approximations [13] and [14] with eq. [9], [6], [10], and [12]. The values calculated by the method given in II, and by Wendt (7), are also included, together with the experimental values of Dunlop and Gosting (8) and Dunlop (9). The ionic conductances at infinite dilution were obtained from Robinson and Stokes (10), and the relative viscosities from Ezrokhi (6).

The L-coefficients for the system H_2O–glycine–KCl at 25 °C are given in Table II. The diffusion coefficient of glycine at infinite dilution and 25 °C was obtained from Ellerton *et al.* (11). The relative viscosities were estimated with eq. [15], the experimental data for aqueous glycine solutions (11), and the data of Kaminsky (12). The experimental L-coefficients are those of Woolf *et al.* (5).

The calculations for the system H_2O–Na_2SO_4–H_2SO_4, using approximations [13] and [14] with eq. [9], [7], [10], and [12], are summarized in Table III. The ratios of H^+/HSO_4^- concentrations were calculated by a method given by Baes (13), and with the assumption that the $NaSO_4^-$ concentration was zero, except for the last column of Table III. The relative viscosities were calculated from [15] and the data of Kaminsky (14). The limiting ionic conductance of HSO_4^- at 25 °C is that of Kerker (15) and for the other ionic species those of Robinson and Stokes (10). The experimental L-coefficients are from Wendt (16).

In Table IV, calculations of the L-coefficients are given for the systems H_2O–raffinose–urea, H_2O–raffinose–KCl, H_2O–LiCl–NaCl, and H_2O–LiCl–KCl. These calculations were made by using approximation [14] with eq. [9], [6], [10], [11], and [12], estimating the relative viscosities by means of eq. [15], and using the binary solution data of Dunlop (17), Gosting and Akeley (18), Kaminsky (19, 14, 12) and the limiting ionic conductances given by Robinson and Stokes (10). The calculations of Miller (20) for the same systems are also given. Miller used ternary diffusion data and estimates of the thermodynamic quantities $\partial\mu_i/\partial C_j$ to obtain values of the L-coefficients.

DISCUSSION

The calculations presented here for the exchange and vacancy models of diffusion in multicomponent systems generate very similar macroscopic descriptions. This result is

somewhat analogous to that obtained for substitutional solids in I. Indeed, for infinitely dilute solutions this description may be obtained from purely macroscopic assumptions as shown by Wendt (7). His method for estimating L-coefficients is based on the assumption that the off-diagonal ionic L-coefficients in the solvent-fixed frame of reference are zero and that the mobilities of ionic species in the same frame have the same values as they do at infinite dilution. It is relevant to add that although Wendt proposed his method for electrolyte components only, it can also be used for nonelectrolyte solutes. Since in the limit of infinite dilution the solvent-fixed, volume-fixed, and lattice-fixed frames coincide,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the values of L-coefficients obtained by the various methods tend to coincide so that there is no macroscopic basis on which to choose between them. However, for a kinetic interpretation of the coefficients and extension of the theory to higher concentrations our formulation appears to be mandatory.

In the system H_2O–NaCl–KCl where relative viscosity data is available, and H_2O–glycine–KCl where the relative viscosities can be computed without introducing large errors, the approximation for the P_i from eq. [14] gives better estimates of the L-coefficients than any of the methods based on approximations similar to eq. [13]. For these two systems, the difference between estimated and experimental L-coefficients is within three times the experimental error at all concentrations. The agreement between the estimated values for the system in Table IV and the values given by Miller (20) is also good.

For the system H_2O–Na_2SO_4–H_2SO_4 where the electrolytes are incompletely ionized, approximation [14] still gives better agreement with experiment than approximation [13], but not as good as it does in the other systems considered. There are several reasons for this. The relative viscosities are likely to be in error by as much as 20%, since the relative viscosities of the binary solutions were calculated by methods that are only accurate for concentrations less than a few tenths molar. The estimates of the ratio of the concentrations H^+/HSO_4^-, by the method of Baes (13), is not expected to be accurate at the concentrations used here, and the approximation that the concentration of $NaSO_4^-$ is zero is known to be incorrect (21). There is no value of the limiting ionic conductance of $NaSO_4^-$ available, but on the assumption that it is the same as that of HSO_4^-, values of the L-coefficients at a concentration of 1 M for Na_2SO_4 and H_2SO_4 have been calculated from approximation [14] and the assumption that 10% of the sodium is transported as $NaSO_4^-$. These values are given in the last column of Table III, and are in better agreement with the experimental L-coefficients, the difference being about three times the experimental error.

The introduction of the relative viscosity into the calculations will also improve the accuracy of the other two methods of estimating the L-coefficients. However, there is at present no rigid theoretical justification for this procedure. Indeed, there appears to be no simple connection between viscous flow and the exchange mechanism of diffusion. The use of the relative viscosity with Wendt's (7) method is equivalent to the use of Stoke's law for particles of similar size to the solvent. Glasstone, Laidler, and Eyring (22) have described in detail a vacancy mechanism of viscous flow which also has a term corresponding to the jump probability of a diffusing unit with an adjacent hole. The jump probability in their model varies with viscosity as,

$$P_i = P_i^0(\lambda^0)^3/\eta_r(\lambda)^3,$$

which differs from [14] by the term $(\lambda^0/\lambda)^3$. Inclusion of this term in the calculation of the L-coefficients would lead to poorer agreement with experimental values in every system discussed here.

It is expected that the approximation [14] will fail in high polymer solutions. Stokes and Weeks (23) have reported that values of the limiting equivalent conductances of ions in aqueous solutions of the synthetic sucrose polymer Ficall are of similar magnitude to those in sucrose solutions of similar weight percent solute concentration, although the sucrose solutions are very much less viscous than the Ficall solutions. Osborne and Porter (24) also record that a diffusion-controlled quenching reaction has a rate constant in a high viscosity aqueous gelatin solution not significantly different from the value in pure water.

Estimates of the L-coefficients based on the approximation [14] would seem on the evidence available to be reliable for aqueous solutions of nonelectrolytes (except high polymers) and strong electrolytes of combined solute concentrations of a few molar. By inversion of the analysis of Dunlop and Gosting (8) and Woolf *et al.* (5) and with either experimental or estimated multicomponent thermodynamic data, it then becomes possible to compute the multicomponent diffusion coefficients. Wendt (7) has shown that this procedure yields reliable diffusion coefficients in very dilute solutions using his method of estimating the L-coefficients. Introduction of relative viscosities into the calculations will lead to correspondingly good agreement at higher concentrations, and the estimated diffusion coefficients should be sufficiently accurate for a number of applied problems requiring this information.

It is pertinent to discuss the information, in addition to relative viscosities, necessary for calculating the L-coefficients at finite concentrations. The exchange model requires a knowledge of the quantities C_0^0, C_0, ... , C_{n-1}, $(D_1^0)_V$, ... , $(D_{n-1}^0)_V$ (or limiting ionic conductances of ionic species), and some method of estimating the rate of exchange of the solutes. This latter information can only be obtained experimentally by recourse to multicomponent diffusion data, although, as shown in II, it may be estimated with sufficient accuracy for dilute solutions. The vacancy model requires knowledge of the quantities C_0^0, C_0, ... , C_{n-1}, $(D_0^{*,0})_V$, ... , $(D_{n-1}^0)_V$ (or limiting ionic conductances for ionic species) all of which can be obtained experimentally without the need of multicomponent diffusion data. The method given by Wendt requires less information than the vacancy model, since it does not require C_0^0, C_0, and $(D_0^{*,0})_V$ to estimate the L-coefficients in the solvent-fixed frame of reference. However, an exact transformation to the volume-fixed frame of reference requires a knowledge of the solute partial molar volumes which brings the two methods into equivalence, except for the term $(D_0^{*,0})_V$.

At the concentrations of ternary systems for which precise experimental data are thus far available, it is not possible to use the experimental values of the L-coefficients and their concentration dependence to decide which of the two atomic mechanisms we have investigated gives the better macroscopic description of diffusion in multicomponent liquid systems, although the differences should tend to be significant at the highest concentration of the system H_2O–Na_2SO_4–H_2SO_4. Indeed, it may not be possible to identify the mechanism by a purely macroscopic measurement. It would, nonetheless, be useful to have precise measurements of diffusion coefficients, chemical potential derivatives with concentration, and relative viscosities of ternary solutions in which the solute concentrations approach those of the solvent. In particular, information on ternary systems not containing electrolytes would be most helpful, since the presence of ionic species complicates the analysis of any model. This is particularly evident in the case of a ternary solution containing two electrolytes with a common ion. The relatively large off-diagonal L-coefficients observed in these systems are predominantly the result of the formal coupling of the chemical potentials of the two salts rather than a real coupling of the fluxes.

Since the evidence for a vacancy mechanism of diffusion in substitutional alloys is much better than for aqueous solutions, we believe that the macroscopic implication of the model should at least be as good a description of alloys as it is of aqueous solutions. In particular, the vacancy mechanism was shown in I to be equivalent to the phenomenological description,

$$[16] \qquad (J_i)_K = -(L_{ij}')_K \frac{\partial \mu_j}{\partial x},$$

$$(L_{ij}')_K = 0 \text{ for all } i \neq j.$$

This scheme consisting of a diagonal matrix of phenomenological coefficients is particularly useful in obtaining solutions of the integral equations of multicomponent diffusion (25) when the lattice- (Kirkendall) and volume-fixed frames of reference coincide. The scheme [16] has already been verified experimentally for interstitial components of ternary alloys (26, 27).

THE SOLVENT ISOTOPE EFFECT AND THE PARTIAL MOLAR VOLUME OF IONS[1]

R. E. ROBERTSON, S. E. SUGAMORI, R. TSE,[2] AND C.-Y. WU[3]
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received September 1, 1965

ABSTRACT

The partial molar volume of ions in water furnishes an indication, if not precise information, about the nature of ionic solvation (1–5). Accordingly, it was hoped that differences in this term and particularly the effect of temperatures on the differences in the apparent partial molar volume for a series of ions in light and heavy water would provide a basis for decisions on the nature of solvation of the benzenesulfonic ion. This ion is of considerable interest in the study of solvolysis, but very little is known about the characteristics of solvation.

The present work was initiated as a consequence of a difference in the interpretation of the source of the kinetic solvent isotope effects observed in the solvolysis of halides and sulfonates in light and heavy water. Swain and co-workers (6–8) attached particular emphasis to differences arising from differential solvation of the quasi-ionic transition state, a viewpoint initially shared by ourselves. Subsequently, however, Laughton and Robertson (9), while admitting of the possibility of differences contributing to the kinetic solvent isotope effect k_{D_2O}/k_{H_2O} in the transition state, attributed the major determinant of this ratio to differences in what they referred to as "the stability of the initial state solvation shell" in the respective media. In previous papers evidence supporting this view have been presented (10, 11).

The data presented here marks an attempt to determine the isotope differences in the partial molar volume of two salts of known and different solvation characteristics as a basis of establishing, in a semi-quantitative way, the characteristics of the benzenesulfonic ion. Our choice was governed by the knowledge that the kinetic solvent isotope effect showed that the solvolysis of halides gave about the same values of the k_{D_2O}/k_{H_2O} ratio (0.7–0.8) while the value for the sulfonates was about 0.9; that the fluoride ion is regarded as a "structure builder" and the iodide as a net "structure breaker". The position of the sulfonic ion in this respect was unknown.

EXPERIMENTAL DETAIL

Distilled water passed through an ion exchange column with suitable precautions was the source of H_2O. The D_2O (99.97%) was obtained from Merck, Sharp and Dohme, Montreal, and was redistilled in a scaled down model of the water distillation system of Stuart and Wormwell (12). The efficiency of both systems was controlled by conductivity measurements. Sodium and potassium benzenesulfonate and potassium methanesulfonate were recrystallized at least twice from methanol and then dried under vacuum. Sodium methanesulfonate and butanesulfonate were first dissolved in water and then methanol was added to the saturated solution to initiate crystallization. Sodium methanesulfonate, which was prepared from practical grade methanesulfonic acid, was recrystallized four times by this method. Sodium fluoride and iodide were reagent grade salts and were dried at 110 °C before use. Solutions were made up by weight. All weighings were on a Mettler Semi-Micro Gramatic balance, in a balance room regulated to 22 °C and 55% humidity.

The pycnometer was of the modified Sprengel type described by Robertson (13) and was held in a special rack in a water bath controlled to $\leqslant 0.003$ °C, as determined by a platinum resistance thermometer. A series of pycnometers were used since it was necessary to leave each in the bath at least 20 min to achieve temperature equilibrium before reading the meniscus level, and another 20 min in the balance room after washing with pure acetone and wiping before taking readings.

While our method of determining densities does not appear to be capable of the same accuracy as the hydrostatic balance method (14) or some variant of the dilution method (15–17), the accuracy was about the same as that reported by Jones and Christian using a similar pycnometer (18). At the time the work was initiated, our main concern was with the solvent isotope effect on the partial molar volume and the simpler method seemed desirable. We now hold the view that the simplicity was apparent rather than real.

RESULTS AND DISCUSSION

The apparent partial molar volume for a solute can be determined from the expression

$$[1] \qquad \phi = M_2/d_0 - \frac{1\,000\,(d - d_0)}{d_0\,c},$$

where d and d_0 are densities of solution and solvent at a given temperature, M_2 is the molecular weight of the solute, and c is the concentration in moles/l. The partial molar volume at infinite dilution, $\bar{V}_0$, is obtained by a suitable extrapolation procedure. For ionic solutes, extrapolation usually (19–21) takes the form

$$[2] \qquad \phi = \phi_0 + sc^{1/2}.$$

In the original proposal (19), the coefficient s was empirical and varied with the electrolyte. Redlich has summarized the arguments and evidence in favor of a limiting equation of similar form based on the Debye–Hückel theory where s will have a common value for all electrolytes. As he rightly points out, a failure of the limiting law implies a failure of the Debye–Hückel theory.

However, the validity of eq. [2] has been criticized by several authors. Geffcken and collaborators found that in the range of low concentrations the curve $\phi_t = f(c^{1/2})$ was not linear, but S-shaped (15). Rutskov (22) proposed a modified equation to be used in regions of low concentrations. Stewart (23) further demonstrated that the linear correlation of $\bar{V}_0$ with $c^{1/2}$ is not satisfied by a major part of the data available for strong electrolytes, but the errors in much of the earlier data may exclude this data as valid for use as evidence (21). Bodanszky and Kauzmann (24) observed that the volume change accompanying the ionization of water using a dilatometer is quite different from the value calculated from existing partial molal volume data. It was demonstrated that $d\phi/dc^{1/2}$ was not linearly related to $c^{1/2}$.

A typical set of data for sodium iodide is given in Table I and the corresponding plots of ϕ versus m and $c^{1/2}$ are shown in Fig. 1. Similar sets of data and plots were obtained for each of the salts on which this report is based. It will be noted that the extrapolated value $\bar{V}_0$ for sodium iodide (35.19 ml) is about the same for each plot. The value reported by Owen and Brinkley (25) was 35.10, while that by McInnes and Dayhoff (26) was 35.37 ml as a consequence of much longer extrapolations. Using the Redlich equation we calculated a value of 35.19 ml from their data.

In their recent review of progress in this field during the past 25 years, Redlich and Meyer strongly support the limiting law previously advanced discounting the validity of alternate equations of a similar form on the basis of insufficient accuracy. Current work by Hepler and co-workers (17) shows that data for NaOH and $(CH_3)_4NCl$ approaches the limiting law at low concentrations and, as would be expected, deviates at higher concentrations. While the accuracy of our data is not such as would permit us to contribute to this aspect of the problem, we were unavoidably drawn into it because of our empirical observation that the apparent molar volume of the salts studied by us in the concentration range 0.1–0.01 M showed an unambiguous and consistent linear correlation with concentration rather than some fractional power of c, and d_0 was indistinguishable from d_0^0,

0.008	0.007984	0.089	0.9979630	0.007960	0.0009159	115.061	35.303
0.007	0.006985	0.084	0.9978586	0.006964	0.0008015	115.087	35.277

the density of pure water, within our experimental limits. Correlation with $c^{1/2}$ gave a curved plot which extrapolated to approximately the same $\bar{V}_0$. If we accept the empirical correlation supported by Table II, then

[3] $$d = d_0 + \alpha m$$

and the volume is given by

$$V = \frac{1\,000 + mM}{d_0 + \alpha m},$$

where m is molarity and α an empirical constant.

The apparent molar volume is

$$\phi_2 = \frac{V}{M} - \frac{M}{d_0 + \alpha M} - \frac{(1\,000 + mM)^{\alpha}}{(d_0 + \alpha m)^2}$$

and the partial molar volume of the solute is

[4] $$\bar{V}_0 = \frac{M}{d_0} - \frac{1\,000\,\alpha}{d_0^2}$$

or

$$\bar{V}_0 = \frac{M}{d_0} - \frac{1\,000\,(d-d_0)}{m d_0^2}$$

or

[5] $$\bar{V}_0 = \frac{M}{d_0} - \frac{1\,000\,(d-d_0)}{d_0 c}\left(1 + \frac{\alpha m}{d_0}\right).$$

Since in this investigation $\alpha m/d_0$ is always much smaller than unity, eq. [5] becomes almost identical with eq. [1]; hence we are justified in using eq. [4] to calculate the respective apparent partial molar volumes* presented in Tables II and III. Thus we were able

Because we have used this empirical extrapolation, the apparent partial molar volumes so obtained need not coincide with the limiting values obtained by application of the Redlich–Rosenfeld equation. Were V_0 a fundamental quantity, such as melting point or absolute temperature, this might be disturbing. But when one reflects that even the V_0 based on a Redlich–Rosenfeld extrapolation is a pretty hazy quantity until we have a far better understanding of water and of aqueous solutions of ions, we do not see that the substitution of an extrapolation based on Debye–Hückel considerations offers any particular theoretical advantage and certainly entails practicar disadvantages. Had we chosen to give our values for 0.001 M, or a similar arbitrary concentration, our conclusions would have remained unchanged.

to obtain apparent partial molar volumes from our density data without facing the problem of whether ϕ should be plotted against $c^{1/2}$, c, or some other function of c. The apparent partial molar volumes in the tables are computed from density data using a least squares program with an IBM computer. Our density data show differences of not more than $1 \times 10^{-5} - 2 \times 10^{-5}$ from the computed lines.

Had our experimental techniques been suited to the exploration of densities at low concentrations with high precision, questions relating to the general problem of partial molal volumes in light and heavy water might have been explored. For the purpose of determining the isotope effect on the partial molar volume, the method of extrapolation was not important; hence the simpler form was adopted without prejudice.

The results of our investigation of the apparent partial molar volume for sodium benzenesulfonate, butanesulfonate, and methanesulfonate and for potassium benzenesulfonate and methanesulfonate at 25 °C are given in Table II. In Table III the density

equations and apparent partial molar volumes of NaF, NaI, and $NaC_6H_5SO_3$ in light and heavy water are given for temperatures between 5 and 25 °C.

We have been unable to find a value for the partial molar volume of sodium fluoride. Geffcken (27) gives a value of $\bar{V}_0 = 6.6$ ml for KF but this value was determined on the basis of an extrapolation from rather concentrated solutions (1.79–10.722 moles/l).

If we accept the value of $\bar{V}_0$ of -1.5 and 8.7 ml for Na^+ and K^+ respectively (25), the value of $\bar{V}_0$ for F^- from our work would be -0.31 ml compared to the value -2.1 ml derived from the data of Geffcken. This new value would remove the anomaly noted by Mukerjee (28) for the F^-.

The value of $\bar{V}_0$ for sodium iodide is in good agreement with earlier work (26), considering the difference in concentration range studied and method of extrapolation. Hence we accept the values of $\bar{V}_0$ for the sulfonic salts as being precise to 0.1–0.2 ml. There does not appear to have been a previous determination.

The value of $\bar{V}_0$ for the sulfonic ions will have two components characterized by quite different solute–solvent interaction. That surrounding the hydrocarbon will tend to enhance water–water interaction (29) while that about the SO_3^- group will be dominated by ion–water interaction. The presence of the charged group in close proximity to the neutral group will have some effect on the solvation of the latter (30) as will be apparent in the following. If the partial molal volume of methane is taken as 38.2 ml, ref. 31, and that of butane as 83.3 (allowing 15.8 ml. for CH_2, ref. 31, and 83.2 ml. for benzene, ref. 31,) the corresponding values for SO_3^- are 18.5 ml, 19.4 ml, and 26.4 ml respectively.

These results, while of certain intrinsic interest, were incidental to the basic problem of the relative isotope effect arising from the solvation of the fully charged ions and, more particularly, how these differences change with temperature. The necessary data are given in Table III but the significance of these data is more apparent in the plot of apparent partial molar volumes against temperature, Figs. 2–4.

For each of the three salts, the plot for the partial molar volume in D_2O lies below that in H_2O. This is consistent with the accepted hypothesis that the ion breaks down water structure in varying degrees and hence favors a more close-packed structure. D_2O has more structure than H_2O and since the relative molar volumes of the two solvents differ by only 0.1 ml/mole near 5 °C decreasing to 0.04 ml/mole near 60° (32), the overall effect on the more structured D_2O is greater than on H_2O. As the temperature increases it is apparent that the relative effect of the ions on the structure of H_2O relative to D_2O increases in the case of NaF and Na benzenesulfonate but decreases slightly, if at all, for the NaI. This qualitative observation suggests that the fluoride and the sulfonate have a similar overall effect on contiguous water structure which differs from the corresponding effect of sodium iodide. These are tentative conclusions and will require more precise data in order to be established conclusively.

There have been numerous attempts to correlate the radius and charge of ions with the corresponding thermodynamic properties of aqueous solutions. For our purpose, it is sufficient to assume the qualitative description of a primary solvation layer tightly oriented by ion–dipole interaction surrounded by layers of water, in which ion–dipole interaction competes progressively less successfully with water–water interaction and both with the kinetic energy of the individual water molecules. When allowance is made for varying charge density, size and shape of the ions, and the unique properties of water, the diversity of phenomena associated with ionic solvation can be easily compassed, and for the same reasons less easily defined.

In the lower temperature range where water is most ice-like, $\bar{V}_0$ for many salts first increases with temperature, then decreases (33). Our work is confined to the lower range (5–25 °C), and all $\bar{V}_0$ show an increase with temperature in both H_2O and D_2O. Approximate values of the temperature coefficient of $\bar{V}_0$ in ml/deg are given in Table IV. The

TABLE IV

Approximate values of $d\bar{V}_0/dT$, in the temperature range 5–25 °C, obtained from a least mean square calculation of slopes for Figs. 2–4

	NaF	NaI	Na benzenesulfonate
H_2O	0.198±0.008	0.236±0.013	0.417±0.022
D_2O	0.151±0.009	0.249±0.024	0.259±0.009

value of $d\bar{V}_0/dT$ for sodium iodide is the same as that reported by Eucken (34). One explanation for the increase would be that as the temperature increases there is a decrease in the structure of the water; hence the decrease due to the presence of the ion is reduced and the apparent partial molar volume increases accordingly. This behavior would tend to make the coefficient a function of the size, and there is a slight suggestion of such a trend. But this behavior must be but one of the factors involved, for it would lead to the prediction that $\bar{V}_0^{H_2O} - \bar{V}_0^{D_2O}$ would decrease. Such a trend may occur with NaI only, the tentative value of $d\bar{V}_0/dT$ in that case being greater in D_2O than in H_2O (Table IV). The combination of opposing factors has led some authors to divide ions according to their secondary solvation characteristics in groups designated as "structure breakers" and "structure builders". Whatever detailed significance these terms may have, qualitatively we may conclude that the benzenesulfonic ion appears to be similar to the fluoride, and hence would be considered a strong structure builder.

A question arises as to whether this effect may be attributed to the SO_3^- group or to the phenyl group. If we may judge from the relative constancy with T of the apparent partial molar volume of the methyl halides in water (35), the former must be responsible. This conclusion is consistent with the hypothesis that the solution of the neutral solute in water takes place without evidence of the breaking of water–water bonds (36). The above results provide further evidence that the kinetic solvent isotope effect for the hydrolysis of halides and sulfonates is not the same as that which characterizes the solvation of the product ions. The values of k_{D_2O}/k_{H_2O} for the hydrolysis of fluoride and iodide are very similar, while the value for the sulfonates is about half as large. Here by contrast we find that the fluoride and benzenesulfonate are grouped and the isotope effect for the latter is the largest of the three ions investigated (Na being common throughout). From this observation we may conclude that the factors which determine the kinetic solvent isotope effect are not the same as those determining the solvent isotope effect associated with the solvation of the ions. Davies and Benson (37) reached a similar conclusion from their study of the solvent isotope effect on the enthalpy of solvation of sodium benzenesulfonate in D_2O and H_2O.

KINETICS AND MECHANISM OF COMPLEX FORMATION BETWEEN ETHYLENE AND RUTHENIUM(II) CHLORIDE IN AQUEOUS SOLUTION[1]

ABSTRACT

The formation of a 1:1 π-complex between ethylene and ruthenium(II) in aqueous hydrochloric acid solution is described. The kinetics of the reaction were examined over a range of temperatures and of concentrations of ruthenium(II), ethylene, hydrogen ion, and chloride ion. The results suggest that complex formation proceeds through a stepwise (S_N1) mechanism in which the initial step involves the dissociation of a chlororuthenate(II) complex.

INTRODUCTION

In the course of an investigation of the homogeneous catalytic activation of molecular hydrogen in solution by metal complexes, it was found that chloro complexes of ruthenium(II) were effective catalysts for the hydrogenation of certain olefinic compounds (1). Maleic and fumaric acids were hydrogenated to succinic acid through mechanisms involving 1:1 ruthenium(II)–olefin complexes as catalytic intermediates. Although ethylene itself could not be hydrogenated with this catalyst, aqueous solutions of ruthenium(II) chloride were found to take up ethylene, the extent of the uptake and the accompanying spectral changes being in accord with the formation of a relatively stable 1:1 ruthenium(II)–ethylene complex.

This paper describes a kinetic study of this reaction, apparently the first such study of the formation of a stable metal olefin complex by direct reaction between the metal ion and olefin, uncomplicated by subsequent rearrangement or decomposition of the complex. The fact that the chloro complexes of ruthenium(II) in aqueous solution are not completely characterized imposed certain limitations on the interpretation of the results, but certain features of the mechanism could nevertheless be elucidated.

EXPERIMENTAL

The ruthenium chloride solutions were prepared by dissolving Johnson, Matthey Specpure ammonium aquochlororuthenite[2] in 3 *M* HCl. The spectrum of the resulting solution corresponded to that previously reported for ruthenium(IV) (3, 5). The solution was standardized by reduction with hydrogen to ruthenium(III), using the method of Harrod, Ciccone, and Halpern (2). Ruthenium(II) was generated by the reduction of ruthenium(IV) with an excess of titanium(III) chloride. The spectrum of the blue ruthenium(II) solution agreed with that reported by Jorgensen (6) and by Rechnitz (7).

Ethylene was Matheson Company C.P. grade. Titanium(III) chloride solutions were prepared under a nitrogen atmosphere by dissolving 98.6% $TiCl_3$ (from Stauffer Chemical Co.) in 3 *M* HCl and was stored under nitrogen. The titanium(III) was standardized by titration with ferric ammonium sulfate (8*a*) and by spectrophotometry (9), the two methods yielding consistent results. The chloride ion concentration was determined by the nitrobenzene modification of the Volhard method (8*b*).

Kinetic measurements were made by following the uptake of ethylene at constant pressure using the apparatus and procedure described earlier (10).

RESULTS

Stoichiometry

Blue solutions of ruthenium(II) chloride containing 3 *M* HCl were found to absorb ethylene at conveniently measurable rates in the temperature range 50–65°, the total ethylene uptake corresponding approximately to the number of moles of ruthenium(II) initially present (Fig. 1). The uptake of ethylene was accompanied by disappearance of the blue color of the solution, associated with the absorption band having a maximum at 680 mμ and attributed to $RuCl_4^{2-}$ (6). The final solution was faintly yellow, and its absorption spectrum exhibited a broad shoulder in the region of 360–380 mμ ($\epsilon \sim 200$), on the long wavelength tail of the ultraviolet absorption band.

This complex formation was not readily reversible, the yellow solutions apparently being stable on heating in vacuo. On contact with air the solutions were rapidly oxidized to give the well known spectrum of ruthenium(III) chloride (6). Maleic acid readily displaced the ethylene from the ruthenium(II)–ethylene complex suggesting that the latter is less stable than the ruthenium(II) – maleic acid complex whose formation constant has been determined (1) spectrophotometrically to be $5 \times 10^3\ M^{-1}$ (3 *M* HCl, 20°).

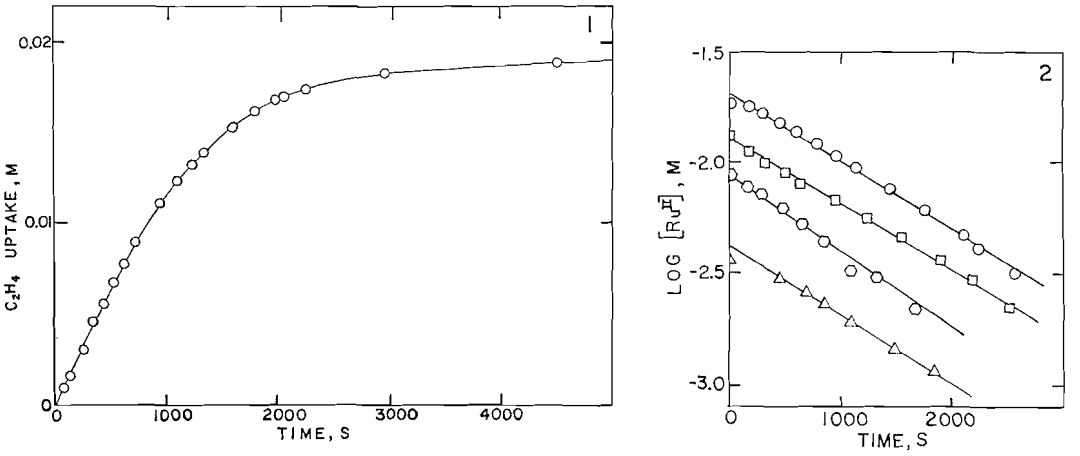

FIG. 1. Uptake of ethylene by a 2.0×10^{-2} *M* Ru^{II} solution at 60° (3.1 *M* HCl; 1.85×10^{-3} *M* C_2H_4).
FIG. 2. First-order rate plots for the uptake of ethylene by solutions of different initial Ru^{II} concentrations (55°; 3.1 *M* HCl; 2.15×10^{-3} *M* C_2H_4).

Kinetics

At constant ethylene and HCl concentrations the uptake of ethylene was found to follow pseudo-first order kinetics, the rate being proportional to the residual concentration of uncomplexed ruthenium(II) (designated as $[Ru^{II}]$), i.e.

$$[1] \qquad -d[Ru^{II}]/dt = k'[Ru^{II}]$$

where the relation

$$[2] \qquad [Ru^{II}] + [Ru^{II}(C_2H_4)] = [Ru^{II}]_{Initial}$$

was used to compute $[Ru^{II}]$ from the observed uptake of ethylene; k' was evaluated from the slopes of first-order plots such as those shown in Fig. 2 (which were generally linear over at least 75% of the reaction) and found to be independent of the initial Ru^{II} concentration when the latter was varied from 3.5×10^{-3} to 1.84×10^{-2} *M*.

Table I summarizes the results of several series of experiments at temperatures ranging from 50° to 65°, in which the ethylene partial pressure was varied to determine the order of the reaction in ethylene. The concentrations of ethylene given in Table I were computed by extrapolating available data (11) for the solubility of ethylene in pure water over the temperature range 0° to 40°, no correction being made for the effect of the ruthenium chloride and hydrochloric acid. The kinetic dependence on the ethylene concentration, revealed by the data in Table I, is complex, corresponding to an apparent order in ethylene of <1; this apparent order decreases with increasing ethylene concentration, the rate tending to approach a limiting value.

Table II summarizes the results of experiments at 55°, made to determine the dependence of the rate on the concentrations of H^+ and Cl^-. The concentration of H^+ was varied from 0.5 to 3.1 *M* while the Cl^- concentration (and ionic strength) was kept constant at 3.4 *M* with LiCl. The Cl^- concentration was varied from 3.1 to 6.4 *M* by addition of LiCl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to solutions containing 3.1 *M* HCl. Unfortunately, no suitable inert anion could be found which could be substituted for Cl^- in order to keep the ionic strength constant in these experiments; ClO_4^- which is commonly used for this purpose is rapidly reduced by Ru(II). The results in Table II reveal a marked inverse dependence of the rate on the concentrations of both H^+ and Cl^-.

In all these experiments the Ti(III) added initially to reduce the Ru(IV) to Ru(II) was in at least tenfold excess over the initial Ru(IV) concentration. Providing this excess was maintained or exceeded, the rate was found to be unaffected by the Ti(III) concentration. The Cl^- concentrations listed in Tables I and II include the contribution from the added titanium(III) chloride.

In the absence of ruthenium(II), solutions containing ruthenium(III) or ruthenium(IV) exhibited no reactivity toward ethylene under the conditions of these experiments.

DISCUSSION

The inverse kinetic dependence of the reaction on the Cl^- concentration along with the observation that the rate tends to approach a limiting value with increasing ethylene concentration, suggest that formation of the $Ru^{II}(C_2H_4)$ complex proceeds through a two-step dissociation (S_N1) mechanism of the type,

$$Ru^{II}Cl_n \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Ru^{II}Cl_{n-1} + Cl^- \qquad [3]$$

$$Ru^{II}Cl_{n-1} + C_2H_4 \overset{k_2}{\rightarrow} Ru^{II}Cl_{n-1}(C_2H_4). \qquad [4]$$

Assuming the steady state approximation for the intermediate $Ru^{II}Cl_{n-1}$ this mechanism yields the rate-law,

$$\frac{-d[Ru^{II}]}{dt} = \frac{k_1k_2[Ru^{II}Cl_n][C_2H_4]}{k_{-1}[Cl^-]+k_2[C_2H_4]}. \qquad [5]$$

At constant $[Cl^-]$ and $[C_2H_4]$, and assuming $[Ru^{II}] \simeq [Ru^{II}Cl_n]$,

$$k' = k_1k_2[C_2H_4]/(k_{-1}[Cl^-] + k_2[C_2H_4]), \qquad [6]$$

whence

$$\frac{1}{k'} = \frac{1}{k_1} + \frac{k_{-1}[Cl^-]}{k_1k_2[C_2H_4]}. \qquad [7]$$

The linear plots of $1/k'$ versus $1/[C_2H_4]$ at constant $[Cl^-]$, shown in Fig. 3, are in accord with this relation and yield the values of k_1 and $(k_{-1}[Cl^-]/k_2)$ listed in Table III. The values of k_1 are fitted by the Arrhenius relation,

$$k_1 = 2.5 \times 10^{12} \exp(-22\,800/RT) \quad s^{-1} \qquad [8]$$

corresponding to $\Delta S_1^{\ddagger} = -4$ e.u.

While the inverse dependence of k' on the Cl^- concentration, revealed by the data in Table II, is qualitatively in accord with the proposed mechanism, these data do not permit the Cl^- dependence predicted by eq. [7] to be tested quantitatively. The circumstances which preclude this are:

(*a*) the very significant variations in ionic strength, and possibly in the solubility of ethylene, which accompany the variations of the Cl^- concentration due to failure to find a suitably inert anion to substitute for Cl^-, and

(*b*) the effect of varying the Cl^- concentration on the distribution of ruthenium(II)–chloro complexes. Spectral evidence (12), including the observation that the absorbance

at 680 mμ due to the blue complex (believed to be $RuCl_4^{2-}$) decreases as the Cl^- concentration is increased from 3 to 6 *M* indicates that the Cl^- variation examined in the kinetic experiments does affect the distribution of ruthenium(II)–chloro complexes in solution. Unfortunately, the equilibria involved have not thus far been elucidated.

The kinetic expressions deduced from the proposed mechanism also fail to account for the observed inverse dependence of k' on the H^+ concentration (Table III). This may reflect hydrolytic equilibria involving chlororuthenate(II) complexes whose reactivity is enhanced through hydrolysis. Some indication of such hydrolytic processes is also provided by recent observations (13) that at lower acidities (0.03 to 0.3 *M* H^+) chlororuthenate (II) complexes are readily oxidized by water to ruthenium (III), whereas this was not observed at the higher acidities (>0.5 *M* H^+) employed in the present investigation.

Because of these complications, the observed rate constant k', and the derived rate constant k_1, must be considered as composite constants which may reflect contributions from more than one ruthenium(II) complex.

The conclusions of the present investigation are consistent with, and derive some support from, those of a recent investigation (12, 14) of the reaction between ruthenium(II) and formic acid in aqueous hydrochloric acid, to yield a ruthenium(II)–carbonyl complex, in accord with

[9] $$Ru^{II} + HCOOH \rightarrow Ru^{II}(CO) + H_2O.$$

For personal use only.

The rate law for this reaction was found to be analogous to that described above for the reaction between ruthenium(II) and ethylene, suggesting that the two reactions proceed through related mechanisms involving a common step, presumably the dissociative step represented by eq. [3].

THE CLEAVAGE OF PHOSPHORUS TO NITROGEN BONDS WITH HYDROGEN FLUORIDE[1]

R. GREENHALGH AND J. R. BLANCHFIELD
Defence Chemical Biological and Radiation Laboratories, Ottawa, Canada
Received October 13, 1965

ABSTRACT

Dialkyl phosphoramidates and alkyl P–alkylphosphonamidates react with hydrogen fluoride breaking the P—N bond to yield the corresponding fluoridates. This cleavage occurred when the nitrogen was unsubstituted, but the yield of product was increased by methyl substitution on the nitrogen. The reaction with diphenyl N,N-dimethylphosphoramidate was not restricted to the P—N bond, since cleavage of the CO—P bonds took place giving, as the ultimate product, hexafluorophosphoric acid. The results obtained indicate that hydrogen fluoride is the most efficient of the hydrogen halides in cleaving P—N bonds.

The introduction of a fluorine atom into an organophosphorus molecule to form a P—F bond can be accomplished by a variety of fluorinating agents. Treatment of diisopropyl phosphorochloridate with sodium fluoride or ammonium fluoride in anhydrous solvents readily converts it into the phosphorofluoridate (1). Similarly, methylphosphonic difluoride can be prepared by bubbling 2 equivalents of hydrogen fluoride into the corresponding dichloride (2). In this latter reaction attempts to isolate the intermediate, methylphosphonic chlorofluoride, were unsuccessful, indicating that the intermediate is more reactive towards hydrogen fluoride than the dichloride (3). In these laboratories it has been found that isopropyl methylphosphonofluoridate can be prepared by the action of hydrogen fluoride on isopropyl N,N,P-trimethylphosphonamidate in anhydrous conditions. This result, however, appears to be at variance with the results reported for phosphoramidates (4), where hydrogen fluoride was the exception among the hydrogen halides in not cleaving the P—N bond. Consequently, it was decided to investigate further the reaction between hydrogen fluoride and phosphoramidates and two limited series of compounds were studied. The first involved varying the substitution on the nitrogen, and consisted of diisopropyl phosphoramidate and its monomethyl and dimethyl derivatives, whereas the second series, where the substitution on the phosphorus was changed, consisted of the dimethyl derivatives of diisopropyl phosphoramidate, diphenyl phosphoramidate, and isopropyl methylphosphonamidate.

The experiments were performed in carbon tetrachloride solution at room temperature. In both series of phosphoramidates it was found that the P—N bond was readily cleaved by hydrogen fluoride. The yields of diisopropyl phosphorofluoridate from diisopropyl phosphoramidate and the mono- and di-methyl derivatives did not vary in any set pattern, but there was sufficient difference in the yields from the substituted amides (79% and 84%) and the unsubstituted amide (61%) to allow speculation on the factors controlling the reaction. The nature of the P—N bond has been discussed by Clark (5). It was suggested that the bond order is enhanced by overlap of the p-orbital of the lone pair of electrons on the nitrogen atom with the d-orbitals of the phosphorus atom resulting in a reduction of the positive charge on the phosphorus and lower susceptibility to nucleophilic attack. Phosphoramidates are, in fact, stable in basic solution, although primary phosphoramidates are known to form salts by abstraction of a proton from the nitrogen (6).

[1]*Issued as DCBRL Report No. 479.*

However, the cleavage of phosphorus to nitrogen bonds under acidic conditions involves prior protonation of the nitrogen atom (5) and $p\pi$–$d\pi$ overlap becomes less important. The greater ease of reaction of the N-substituted derivatives may, therefore, lie in a higher basicity of the nitrogen atoms resulting from the inductive and hyperconjugative effects of the methyl groups, and we propose that the observed results are better explained by increased formation of protonated intermediate than by decrease in bond strength as suggested by Skrowaczewska and Mastalerz (4).

It is also of interest that hydrogen fluoride cleaves primary, secondary, and tertiary phosphoramidates, whereas the other hydrogen halides apparently cleave only the tertiary derivatives (4). This greater reactivity towards the P—N bond may be attributed to the anhydrous nature of the reaction, since it is well known that pure hydrogen fluoride is one of the most acidic media known (*7a*). It is possible, however, that it might also be related to the strength of the phosphorus–halogen bond that is formed in the various reactions. Of these, the P—F bond is by far the strongest (8).

In the other series, the reaction of diphenyl N,N-dimethylphosphoramidate was of special interest because of the reactions which occurred subsequent to P—N bond cleavage. A proton magnetic resonance spectrum of the crude product indicated that the P—N bond had cleaved, since the N-methyl protons appeared as a singlet, whereas if the nitrogen had still been attached to the phosphorus, a doublet would have resulted. However, the only product that was easily isolated was phenol. A fluorine nuclear magnetic resonance (n.m.r.) spectrum was more revealing, showing the presence of two compounds having P—F bonds. The major product showed a doublet, $J = 960$ c.p.s., and the minor product exhibited another doublet, $J = 715$ c.p.s. The coupling constant of 715 c.p.s. is very unusual and is indicative of hexafluorophosphoric acid (9). Although it proved to be impossible to isolate the major product of this reaction, the minor product could be isolated by extending the reaction time and changing the working-up procedure; and it was shown to be, in fact, hexafluorophosphoric acid.

The facts that the major earlier product showed a doublet in the fluorine n.m.r. spectrum and a triplet in the phosphorus n.m.r. spectrum and that the yield of phenol was insufficient for the cleavage of both the phenyl ester bonds led to the postulation that this product was phenyl phosphorodifluoridate. The cleavage of the CO—P bond by hydrogen fluoride was unexpected, since there had been no evidence of the production of isopropanol from the amides of diisopropyl phosphoric acid or any report of the formation of phenol in the conversion of diphenyl N,N-dimethylphosphoramidate to diphenyl phosphorochloridate with hydrogen chloride (10). It is, however, reminiscent of the reaction of hydrogen fluoride with methylphosphonyldichloride (3). Since the P—N bond is cleaved so readily in the case of the other phosphoramidates, it is assumed that this is the bond which breaks first in diphenyl N,N-dimethylphosphoramidate followed by production of 1 molecule of phenol to give the postulated intermediate, phenyl phosphorodifluoridate. The mechanism by which this compound is converted to hexafluorophosphoric acid is unknown, since no other compounds were isolated from the reaction. However, many phosphorus compounds, including phosphorus oxyfluoride, are known to react with hydrogen fluoride to give this acid (*7b*) and it seems probable that this is an intermediate in the formation of hexafluorophosphoric acid from diphenyl N,N-dimethylphosphoramidate.

Summarizing, phosphoramidates and phosphonamidates were found to react with hydrogen fluoride under anhydrous conditions to form fluoridates. The yield of the product appeared to increase with increasing methyl substitution on the nitrogen, a fact attributed to ease of formation of the protonated intermediate. The ability of hydrogen fluoride to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

cleave N-substituted and unsubstituted amidates is in contrast to that of the other hydrogen halides which cleave only the N,N-disubstituted derivatives (4).

EXPERIMENTAL

The infrared spectra were recorded on a Perkin-Elmer 221-G spectrophotometer and the n.m.r. spectra on a Varian V4300C spectrometer operating at 60 mc/s for protons, 24.288 mc/s for ^{31}P and at 56.445 mc/s for ^{19}F. Extreme care was necessary in handling the cleavage products because of their high toxicities.

The amidates were prepared by the action of the appropriate amine on the phosphorochloridate or phosphonochloridate by the methods of McCombie *et al.* (11), and Coe *et al.* (12) respectively. They were characterized by their infrared and proton magnetic resonance spectra and by their melting or boiling points: diisopropyl phosphoramidate, m.p. 55–56° (lit. (13) 56–57°); diisopropyl N-methylphosphoramidate, b.p. 76° at 0.05 mm (lit. (14) 84° at 0.4 mm); diisopropyl N,N-dimethylphosphoramidate, b.p. 61° at 1 mm (lit. (14) 68° at 2 mm); diphenyl N,N-dimethylphosphoramidate, m.p. 30–31° (lit. (15) 30–32°); isopropyl trimethylphosphonamidate, b.p. 75° at 6 mm (lit. (12) 43° at 0.04 mm).

Cleavage of Diisopropyl N-Methylphosphoramidate with Hydrogen Fluoride

Diisopropyl N-methylphosphoramidate (2 g) was dissolved in carbon tetrachloride (10 ml) in a Teflon bottle which was kept at room temperature by cooling in a water bath. The bottle was connected via a trap to a cylinder of anhydrous hydrogen fluoride by a small bore Teflon tube (i.d. 1 mm) and a similar tube was used to lead off the effluent gas. After the system was swept with dry nitrogen gas, a brisk stream of hydrogen fluoride was passed through the solution and within a few minutes an oil separated. The flow of hydrogen fluoride was continued for a total of 17 min. No attempt was made to meter the hydrogen fluoride, whose solubility in carbon tetrachloride is 0.94% at 23°. After the flow of hydrogen fluoride was stopped, the system was again swept with dry nitrogen and then neutralized by adding a solution of triethylamine (2 ml) in chloroform (35 ml). The solution was then washed with 5% sodium bicarbonate solution, dried, and distilled, giving diisopropyl phosphorofluoridate, b.p. 57° at 3 mm (lit. (1) 73° at 16 mm), 1.58 g (yield 84%). The product was identified by means of its infrared and n.m.r. spectra which were identical with those of an authentic sample. Infrared (film): 1 298 cm^{-1}, P=O; 1 180, 1 140, and 1 105 cm^{-1}, $(CH_3)_2CHOP$; 1 013 cm^{-1}, P—OC; and 860 cm^{-1}, P—F. The proton magnetic resonance spectrum in carbon tetrachloride solution showed a doublet centered at $\tau = 8.63$ (isopropyl CH_3) and an octet centered at $\tau = 5.30$ (isopropyl CH) with $J_{P-CH} = J_{CH-CH_3} = 6.2$ c.p.s.

Cleavage of Diisopropyl N,N-Dimethylphosphoramidate with Hydrogen Fluoride

Similar treatment of diisopropyl N,N-dimethylphosphoramidate (2 g) with hydrogen fluoride yielded diisopropyl phosphorofluoridate, 1.38 g (79% yield), which was again identified by its infrared and n.m.r. spectra.

Cleavage of Diisopropyl Phosphoramidate with Hydrogen Fluoride

Prior to reaction, diisopropyl phosphoramidate (2 g) was dissolved in carbon tetrachloride which was then distilled off to remove any traces of water from the starting material. The product isolated after treatment with hydrogen fluoride was identified by spectral methods as diisopropyl phosphorofluoridate, 1.25 g (61% yield).

Cleavage of Isopropyl Trimethylphosphonamidate with Hydrogen Fluoride

Isopropyl trimethylphosphonamidate (2 g) on treatment with hydrogen fluoride as above yielded isopropyl methylphosphonofluoridate, b.p. 46° at 10 mm (lit. (16) 46° at 8 mm), 1.37 g (81% yield). The product was identified by comparison of its infrared and n.m.r. spectra with those of an authentic sample. Infrared (film): 1 315 cm^{-1}, P—CH_3; 1 277 cm^{-1}, P=O; 1 180, 1 142, and 1 105 cm^{-1}, $(CH_3)_2CHOP$; 1 015 cm^{-1}, P—OC; and 838 cm^{-1}, P—F. The proton magnetic resonance spectrum in carbon tetrachloride solution showed a doublet at $\tau = 8.63$ (isopropyl CH_3) with $J_{CH_3-CH} = 6.15$ c.p.s. and a double doublet centered at $\tau = 8.45$ (CH_3P) with $J_{CH_3-F} = 5.5$ c.p.s. and $J_{CH_3-P} = 18.7$ c.p.s.

Reaction of Diphenyl N,N-Dimethylphosphoramidate with Hydrogen Fluoride

With the apparatus described above, hydrogen fluoride was bubbled through a solution of diphenyl N,N-dimethylphosphoramidate (9.8 g) in carbon tetrachloride (25 ml) for 2.5 h and the solution swept with dry nitrogen for a further 1.5 h. Potassium hydroxide solution (2 *N*) (100 ml) was then added and the aqueous layer separated and concentrated to 10 ml. The crystals which precipitated on cooling were recrystallized from water and dried over phoshorus pentoxide to give potassium hexafluorophosphate, 3.67 g (56% yield). The phosphorus and fluoride n.m.r. spectra and an X-ray powder pattern were identical with those obtained from an authentic sample prepared by the method of Woysie (17). The phosphorus n.m.r. spectrum in D_2O solution showed a septet centered at 145.4 p.p.m. upfield from 85% phosphoric acid with $J_{P-F} = 711$ c.p.s., and the fluorine spectrum exhibited a doublet centered at 6.9 p.p.m. downfield from trifluoracetic acid. The X-ray diffraction pattern with a cobalt source, = 1.78890 Å, gave the following lines: 4.5 (s), 3.87 (vs), 2.75 (s), 2.34 (m), 2.24 (m), 1.94 (w), 1.74 (m), 1.59 (m), 1.38 (w), 1.30 (m), 1.23 (w), 1.17 (w), 1.08 (w), and 1.04 (vw).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The aqueous solution remaining after removal of the crystals was saturated with carbon dioxide when an oil separated which was removed by extraction with ether. The ether layer was dried and distilled to give phenol, b.p. 181°, 3.62 g (yield 55%), which later crystallized and had an infrared spectrum identical with that of an authentic sample.

ACKNOWLEDGMENTS

The authors wish to thank Miss P. A. Lutley for determining the n.m.r. spectra, Miss J. A. Rodgers for the infrared spectra, and Mr. L. G. Wilson for the X-ray powder pattern. We are also grateful to Dr. R. M. Heggie and Dr. M. A. Weinberger for helpful discussions.

THE THERMAL DECOMPOSITION OF ETHANE

PART I. INITIATION AND TERMINATION STEPS

M. C. LIN AND M. H. BACK
Chemistry Department, University of Ottawa, Ottawa, Canada

Received August 27, 1965

ABSTRACT

The rates of production of methane and butane in the pyrolysis of ethane have been measured over the temperature range 550–620 °C and at pressures of 40–600 mm. At high pressure the rates of formation of both products were first order in ethane, but below 200 mm the first-order rate coefficients decreased. The ratio of methane to butane was consistent with the interpretation that methane is a measure of the initiation reaction and that the combination and disproportionation of ethyl radicals is the main termination step. The order of the decomposition of the ethyl radical with respect to ethane varied between 0.38 and 0.59. The results are discussed in terms of the mechanism of the overall process.

INTRODUCTION

The initiation and termination steps in the chain decomposition of ethane have been the subject of much controversy. There is general agreement that the rate is first order with respect to ethane and that hydrogen atoms and ethyl radicals are the chain carriers. The mechanisms proposed generally include the following reactions.

[1] $$C_2H_6 \rightarrow 2CH_3$$

[2] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[3] $$C_2H_5 \rightarrow C_2H_4 + H$$

[4] $$H + C_2H_6 \rightarrow H_2 + C_2H_5$$

[5*a*] $$C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$$

[5*b*] $$\rightarrow C_2H_4 + C_2H_6$$

[6] $$H + C_2H_5 \rightarrow C_2H_6$$

[7] $$CH_3 + C_2H_5 \rightarrow C_3H_8$$

Rice and Herzfeld (1) pointed out that termination by reaction [6] would lead to first-order kinetics, as observed. Küchler and Theile (2), however, showed that the rate was increased on addition of inert gases and suggested that the initiation step was a second-order process and that termination occurred by the combination of ethyl radicals. This mechanism also gave first-order kinetics. In an experimental and theoretical examination of the problem, Laidler and Wojciechowski (3) concluded that the Küchler–Theile mechanism was more consistent with the evidence then available. For example, the concentration of ethyl radicals was shown to be much greater than that of hydrogen atoms (4) so that termination by combination of ethyl radicals should predominate. Also, the Küchler–Theile mechanism predicted an activation energy for the decomposition close to that observed, and a change in the order of the decomposition to 3/2 in the regions of temperature and pressure in which this change was found.

More recently, however, several investigations of the initial rate of formation of methane (5–8) have shown that this reaction is first order with respect to ethane, indicating that the initiation step is a first-order process. This fact has been reconciled with the other evidence in various ways. Davis and Williamson (6), whose experiments were done in a flow system at high temperatures (676–775 °C), found that the rate of formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of methane was slightly pressure-dependent. They favored the combination of ethyl radicals as the chain-ending step and suggested that the pressure sensitivity of both the initiation step and the decomposition of the ethyl radical combined to give first-order kinetics, which were, at any rate, only roughly obeyed under their conditions. Quinn (7) made this suggestion more specific by proposing that when the overall rate and the rate of production of methane were exactly first order, the rate constant for decomposition of the ethyl radical should be proportional to the square root of the pressure. Evidence from a previous study of the pyrolysis of *n*-butane (9) supported this view. Gordon (8) found a considerable surface dependence of the rate and suggested that one of the termination reactions was heterogeneous. This probably involved hydrogen atoms, because of their high diffusion coefficient.

The present experiments were undertaken to measure the rate of production of butane and, by a comparison with the rate of production of methane, to establish whether this is the main termination product.

EXPERIMENTAL

Apparatus

The decomposition was studied in a conventional static system. The reaction vessel was a quartz sphere of 511.5 cc with S/V ratio of 0.6 cm^{-1} enclosed in an electrically heated steel cylinder about 2 cm thick. The temperature of the vessel was controlled with a Thermoelectric thermoregulator. When evacuated the temperature could be maintained within 0.2° but because of fluctuations in temperature on admission of reactant, especially at high pressures, the temperature during an experiment was precise only to 0.5°. A reaction vessel packed with silica tubes was used to increase the S/V ratio to 9.4 cm^{-1}, an increase of 15 times that of the unpacked vessel. Both vessels were treated with hot nitric acid followed by several washings with distilled water. Gases to be mixed prior to decomposition were condensed into a large flask on an inner-sealed cold finger. When the finger was warmed rapidly the gases were mixed by convection.

Reagents

Phillips Research Grade ethane was distilled from trap-to-trap several times and finally degassed at −160 °C.

Procedure and Analysis

Before each experiment the system was evacuated to a pressure lower than 10^{-4} mm. At the end of an experiment the products and reactant were removed through a series of traps, which were, in order, a spiral trap, a Le Roy still, a conventional trap, and a final spiral trap, followed by a Toepler pump and gas burette. A mercury diffusion pump between the last two traps aided collection of the non-condensable gases. Initially all traps were cooled with liquid nitrogen. When most of the non-condensable gases had been collected in the gas burette, the first spiral trap was warmed to room temperature and the Le Roy still was warmed to −162 °C. Final traces of occluded non-condensable gases were then collected while most of the ethane distilled into the conventional trap. Butane remained in the Le Roy still and was analyzed by gas chromatography on a 12 ft column of hexanedione on Firebrick maintained at 0 °C. Careful checks of the distillation showed that losses of butane were never more than 10% and could be reliably corrected for. In experiments with carbon dioxide, an additional trap filled with ascarite removed the carbon dioxide before condensation in the Le Roy still.

The mixture of methane and hydrogen collected in the gas burette was analyzed by combustion of hydrogen in a copper oxide furnace maintained at 280 °C. Attempts to separate ethylene from the non-condensable gases by using a trap packed with copper filings maintained at −196 °C resulted in loss of methane, and the packing was finally abandoned. Instead, traces of ethylene were collected in the Toepler pump with the hydrogen and methane, but the gases were admitted to the combustion furnace through a liquid nitrogen trap. The concentration of ethylene in the furnace was then negligible. When combustion of hydrogen was complete the gases were expanded into the large bulb of the Toepler pump, isolated from the combustion furnace, and measured in the gas burette. An amount of ethylene equivalent to the saturated vapor pressure at −196 °C in the Toepler bulb was thus collected in the gas burette, and correction for this amount was made to the final measurement of methane. This correction was not more than 10% of the amount of methane. The yield of hydrogen was obtained by subtracting the yield of methane from the total non-condensable gases.

RESULTS

The yields of hydrogen, methane, and butane were measured as a function of reaction time over the temperature range 550–620 °C and the pressure range 40–600 mm. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

measurements of hydrogen and methane were extended to the range 640–726 °C over a lower pressure range. Initial rates of hydrogen production were obtained by extrapolation of plots of the rate against time. From 400 to 150 mm the order of hydrogen production was 1.0. At higher pressures a slight decrease in order was observed, while at lower pressures the order increased. This continuous change in order of the hydrogen production is shown in Fig. 1, in which the complete temperature range is represented. The first-order rate constant could be represented by the following expression.

$$\log k\ (s^{-1}) = (16.22 \pm 0.11) - \frac{77\,600 \pm 600}{2.303RT}$$

Typical plots of methane yield as a function of time are shown in Fig. 2. The rate of production of methane was constant only in the initial stages of the decomposition and increased at all temperatures as secondary reactions became important. The initial rate was not obtained directly from plots such as Fig. 2, but from an extrapolation to

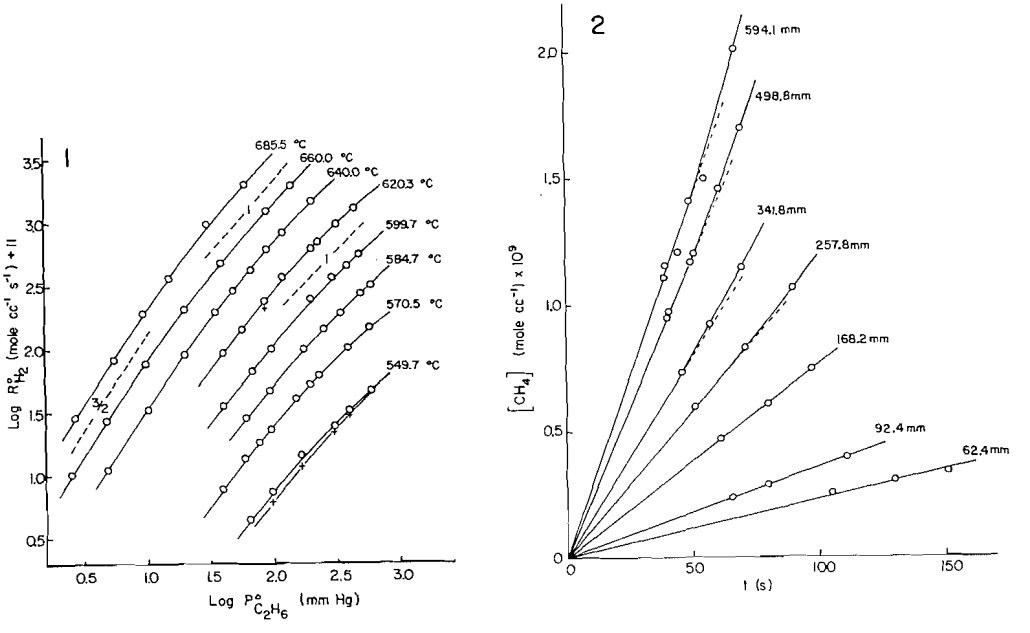

FIG. 1. Log rate of hydrogen production against log ethane pressure: O, for unpacked vessel; +, for packed vessel.
FIG. 2. Yield of methane as a function of time at 584.7 °C.

zero time of the rate as a function of time. This procedure, which is described in Part III (23), was particularly important at high temperatures where secondary reactions occur at very low conversions. The order of the rate of production of methane with respect to ethane was 1.0 above ~200 mm and is illustrated in Fig. 3. The falloff in the first-order rate coefficient is discussed in detail in Part II (23). First-order rate constants were calculated from the equation

$$k_1 = \frac{\frac{1}{2}R^0_{CH_4}}{[C_2H_6]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

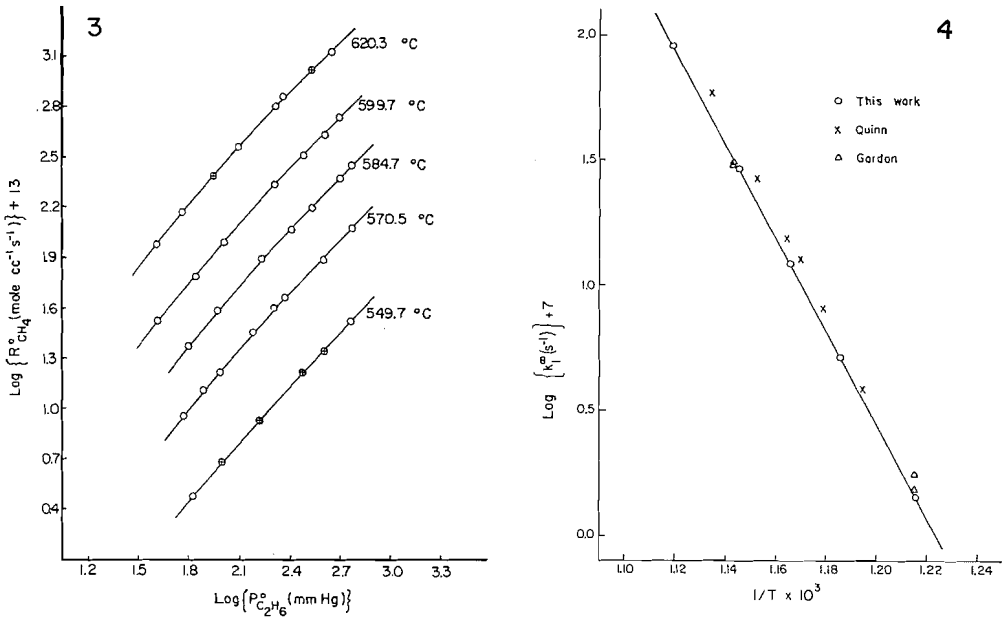

FIG. 3. Log rate of methane production against log ethane pressure: ○, for unpacked vessel; +, for packed vessel.

FIG. 4. Arrhenius plot of first-order rate constant, k_1^{∞}, for rate of methane production: ×, ref. 8; △, ref. 9; ○, present results.

and are listed in Table I. The Arrhenius plot of the first-order constants is shown in Fig. 4 together with the measurements of Quinn (7) and Gordon (8). The following relation was found.

$$\log k_1\ (s^{-1}) = (16.00 \pm 0.066) - \frac{86\,000 \pm 370}{2.303RT}$$

At low temperatures the kinetics of butane production followed a similar pattern to that of methane production, the rate increasing from the initial value at about the same conversion. At 585 °C and above the rate decreased as the reaction time increased. Typical plots of yield as a function of time are shown in Fig. 5. Again, initial yields were obtained by extrapolation of rate vs. time curves. The order of butane production was 1.0 at high pressures but increased as the pressure was lowered. The double logarithmic plot is shown in Fig. 6. The Arrhenius plot of the first-order rate constants gave an activation energy of 89.8 kcal/mole.

The ratio $\frac{1}{2}R^0_{CH_4}/R^0_{C_4H_{10}}$ varied from 1.3 to 1.8 and is included in Table I. If methane is a measure of the initiation step and butane of the termination step and if the ratio of disproportionation to combination for ethyl radicals is 0.15 (10), then the ratio $\frac{1}{2}R^0_{CH_4}/R^0_{C_4H_{10}}$ is 1.15.

If hydrogen is formed only by reactions [3] and [4] and butane only by combination of ethyl radicals then

$$\frac{R^0_{H_2}}{(R^0_{C_4H_{10}})^{1/2}} = \frac{k_3}{k_{5a}^{1/2}}.$$

A plot of log $\{R^0_{H_2}/(R^0_{C_4H_{10}})^{\frac{1}{2}}\}$ against log $[C_2H_6]$ is shown in Fig. 7. If it is assumed that k_{5a} is independent of pressure, the slopes of these curves give the order of reaction

[3] with respect to ethane. This varied from 0.38 at low temperatures and high pressures to 0.59 at high temperatures and low pressures. The activation energy for the decomposition of the ethyl radical, if the combination of ethyl radicals involves no activation energy, is 32.7 ± 1.5 kcal/mole. No trend was observed with pressure.

Rates of hydrogen, methane, and butane production were measured at 585 °C in the presence of various pressures of carbon dioxide. On addition of 100 mm of carbon dioxide to 100 mm of ethane, the rates of methane and butane production were unchanged but the rate of hydrogen production increased by about 20%.

Rates of formation of products measured using the packed reaction vessel are compared with those from the unpacked vessel in Figs. 1, 3, 6, and 7. The rate of methane production was unaffected by the increase in S/V ratio, but the yields of both butane and hydrogen decreased. The effect was greatest at the lower temperatures and pressures, as would be expected for a surface reaction. The order of both butane and hydrogen production increased slightly.

DISCUSSION

The present results largely confirm the mechanism of the decomposition proposed by Davis and Williamson (6) and by Quinn (7). In particular, the measurement of the production of butane supports the combination of ethyl radicals as the main termination step.

We have assumed that the initial decomposition of the ethane molecule occurs by the rupture of the C—C bond to give two methyl radicals. An alternative mode of initiation to give methane and a methylene radical has been suggested (11)

[1a] $$C_2H_6 \rightarrow CH_4 + CH_2$$

but from the present results this appears less likely than reaction [1]. In the subsequent reaction of the methylene radical with ethane, the excited molecule of propane formed would either be stabilized or dissociate into radical fragments, probably $CH_3 + C_2H_5$. By comparison with the reaction of methylene radicals with methane (12), it may be deduced that stabilization would be dependent on pressure in the range of the present experiments. If some of the "hot" propane formed is stabilized, then methane is formed without the production of an ethyl radical and hence without the formation of butane. This would give a high ratio of methane to butane, as actually found, but would show a marked increase with increasing pressure, whereas the observed ratio decreased as the pressure increased. It is very unlikely that formation of propane by reaction of methylene with ethane would be independent of pressure in the range covered by the present experiments. Reaction [1a] must therefore be at most only a minor mode of dissociation of the ethane molecule.

The rate of production of methane is a measure of the rate of reaction [1] only if all methyl radicals react with ethane and none are lost by termination. The most likely termination step involving methyl radicals is reaction [7] and the relative rates of reaction [2] and [7] may be calculated from the following equation.

$$\frac{\text{Rate [7]}}{\text{Rate [2]}} = \frac{k_7(R^0_{C_4H_{10}})^{1/2}}{k_{5a}^{1/2}k_2[C_2H_6]}$$

Inserting the values $k_2 = 10^{11.20}\,e^{-10400/RT}$ (13), $k_{5a} = 2.0 \times 10^{13}$ (14), and $k_7 = 4 \times 10^{13}$ in the units cc mole^{-1} s^{-1}, we obtain for 100 mm ethane $R_7/R_2 = 5.0 \times 10^{-3}$ at 550 °C and 2.8×10^{-2} at 620 °C. The temperature coefficient of k_5 has been ignored in these and later calculations because of the uncertainty involved in the long extrapolation. These ratios are therefore upper limits since an activation energy of 2 kcal/mole causes an increase in k_5 of almost a factor of 10 at 550 °C. In the present experiments it is thus unlikely that methyl radicals are involved in termination, and the first-order production of methane shows that the dissociation of ethane into two methyl radicals is a first-order process above about 200 mm in the temperature range 550–620 °C.

In Fig. 4 the Arrhenius plot of k_1 is compared with two recent measurements in the same temperature range. The absolute values for k_1 agree very well at temperatures in the neighborhood of 570 °C, but some divergence at the higher and lower ranges caused a considerable deviation in the activation energies. We feel that the method of extrapolation which was used in the present experiments at each pressure and temperature to obtain the initial rate of methane production gives rate constants more reliable than those obtained by Quinn, and that his activation energy is consequently too high.

The errors quoted in the present results are the probable errors obtained by a least-squares analysis of the data. The systematic errors are undoubtedly much larger, but because of the difficulty in estimating these quantitatively we have not attempted to state the total error limits. Recent measurements of the Arrhenius parameters of k_1 are summarized in Table II.

TABLE II

Arrhenius parameters of k_1

Reference	Temp. range (°C)	log A (s^{-1})	E (kcal/mole)
(5)	766–836	14.85–15.7	85–89
(6)	675–770	16.29	86.0
(7)	564–608	17.45±0.82	91.7
(8)	475–600	14.5	81.0
Present results	550–620	16.00±0.066	86.0

For a reaction which involves the rupture of one bond and for which the reverse combination of radicals has no activation energy, the activation energy may be related to the bond dissociation energy in the following general way (15).

$$D \leqslant E \leqslant D + RT$$

From the present results and from the values (16) for ΔH_f at 0 °K given in the first column below, one may calculate the values given in the second column.

$\Delta H_f(C_2H_6) = -16.517$ kcal/mole
$\Delta H_f(CH_4) = -15.987$ kcal/mole
$\Delta H_f(H) = 51.620$ kcal/mole

$D(CH_3—CH_3) = 85.0 \pm 0.5$ kcal/mole
$\Delta H_f(CH_3) = 34.2$ kcal/mole
$D(CH_3—H) = 102$ kcal/mole

The observed order with respect to total pressure of the decomposition of the ethyl radical confirms previous suggestions (6, 7) that in this range of temperature and pressure the ethyl radical is roughly halfway into its second-order region. The activation energy for decomposition is in agreement with that found by Purnell and Quinn (9) if an activation energy of 10.4 kcal/mole (17) is taken for the abstraction of hydrogen from butane by the ethyl radical, instead of 15.2 kcal/mole as used by these authors. As expected, the activation energy of 32.7 ± 1.5 kcal/mole is lower than the activation energy of 39.5 kcal/mole (18) for the first-order decomposition. The relation of this decrease to the number of effective oscillators in the ethyl radical is discussed in Part II (23).

In agreement with previous results (7, 8), the rate of methane production was unchanged by increasing the S/V ratio by a factor of about 15. It seems well substantiated that the initiation reaction is the homogeneous dissociation of ethane. The decrease in the rate of hydrogen production, however, would suggest an increased rate constant for the termination process in the packed vessel. This would lower the radical concentration, thus decreasing the overall rate, while the rate of removal of radicals would still equal the rate of initiation. Since butane production was not enhanced, but was in fact decreased, this heterogeneous termination does not yield butane and thus probably does not involve an adsorbed ethyl radical. The adsorbed species must therefore be a hydrogen atom which may become attached to the surface by reaction with an ethyl radical as well as by direct adsorption.

[8] $$H + S \rightleftarrows H—S$$

[9] $$C_2H_5 + S \rightarrow C_2H_4 + H—S$$

Termination may then take place as follows.

[10] $$H + H—S \rightarrow H_2 + S$$

[11] $$C_2H_5 + H—S \rightarrow C_2H_6 + S$$

The surface reaction becomes more predominant at low pressures and its rate is thus probably dependent in some way on the homogeneous concentration of hydrogen atoms.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Although in the present experiments the concentration of hydrogen atoms is always lower than that of ethyl radicals, the rate of reaction [8] may be faster than that of [9] if an appreciable activation energy is required for the latter. This is quite reasonable in view of the strength of the bond broken. Termination may occur by either reaction [10] or [11], since the rate constant of reaction [10] may be much larger than that of reaction [11] and may outweigh the difference in concentration of H atoms and ethyl radicals. Our results therefore favor the occurrence of reaction [8] followed by reactions [10] or [11].

The magnitude of the effect of the surface on the rate was smaller than that observed by Gordon (8). The heterogeneous reaction may be very sensitive to the nature of the surface, which in turn may be a function of the treatment of the vessel prior to the experiments or even of the purity of the quartz of which the vessel is made. For these reasons it may be difficult to obtain quantitative agreement for the surface reaction from one laboratory to another.

The fact that in both vessels the ratio of methane to butane is higher than that expected on the basis of reactions [1] to [5] suggests that a second termination reaction, which does not produce butane, makes a minor contribution. The most probable reaction is reaction [6], but this interpretation is unlikely for two reasons. Calculation of the relative concentrations of hydrogen atoms and ethyl radicals indicates that the concentration of the former is too low to make a significant contribution to the termination, unless the rate constant for reaction [6] is much greater than for reaction [5]. The ratio of hydrogen atoms to ethyl radicals is given by $k_3/k_4[C_2H_6]$, and values for k_3 may be taken from Fig. 7 with $k_{5a} = 2.0 \times 10^{13}$ cc mole^{-1} s^{-1} (14). Using Berlie and Le Roy's measurement of $k_4 = 10^{12.53} e^{-6800/RT}$ cc mole^{-1} s^{-1} (19) at 100 mm ethane $k_3/k_4[C_2H_6] = 7.0 \times 10^{-3}$ at 550 °C and 3.0×10^{-2} at 620 °C. With a recent measurement of $k_4 = 10^{14.12} e^{-9700/RT}$ cc mole^{-1} s^{-1} (20) these ratios are slightly lower. To account for the ratios of methane/butane of 1.7, however, the percentage termination by a reaction other than [5] may be shown to be 33% and for a ratio of 1.4, 20%. Furthermore, even if the calculated values were in error to the extent that at 550 °C reaction [6] could account for about 25% of the termination, the relative temperature coefficients of k_3 and k_4 are such that at 620 °C hydrogen atoms should be the predominant radical and termination should be largely by [6]. The trend, however, in the ratio of methane/butane is in the reverse direction and at 620 °C and high pressures the ratio is exactly as predicted.

Another possible explanation may be that the ratio of disproportionation/combination of 0.15 for ethyl radicals, measured in a temperature region lower than the present experiments, is not the correct ratio under the conditions of these experiments. It seems unlikely, however, that the activation energy difference between the combination and disproportionation reactions would be more than 1 kcal/mole. This was the upper limit suggested by Ivin and Steacie (21). This difference raises the ratio k_{5b}/k_{5a} to 0.27 at 550 °C, which is not sufficient to account for the ratios in Table I.

It seems probable that a heterogeneous termination may contribute to a sufficient extent in the unpacked vessel to account for the ratios of methane/butane. This would necessitate a non-linear extrapolation of the rate of butane production as a function of S/V ratio, the rate rising steeply towards zero S/V ratio to give the required rate of butane production. Such a curve was found by Voevodsky (22) in a study of the decomposition of propane in vessels packed with various amounts of tubing. The heterogeneous reaction would be consistent with the trend of less participation at high temperatures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and high pressures. It is worth noting that this discrepancy between the rates of production of methane and butane affects neither the calculation of k_3 nor the conclusions regarding the order of reaction [3] with respect to ethane, provided only that the yield of butane gives a measure of the concentration of ethyl radicals and that production of hydrogen from possible termination steps is negligible compared to that from reaction [4].

ACKNOWLEDGMENTS

The authors wish to thank Professor K. J. Laidler for many helpful discussions.

The authors also thank the National Research Council for a grant in support of this work and the Ontario Research Foundation for a fellowship awarded to M. C. Lin.

THE CHEMISTRY OF IRIDIUM IN BASIC AQUEOUS SOLUTION

A POLAROGRAPHIC STUDY

GARY VAN LOON AND JOHN A. PAGE

Department of Chemistry, University of Toronto, Toronto, Ontario

Received August 19, 1965

ABSTRACT

The polarographic behavior of iridium(IV) has been studied in basic solutions at 25 °C at an ionic strength maintained with sodium chloride at 0.50 *M*. Between pH 11.3 and 13.0, a reversible, diffusion-controlled, one Faraday per mole reduction wave was obtained. The $E_{1/2}$ was −0.60 V versus a saturated calomel reference electrode at pH 12.0; a shift of −57 mV per pH unit indicated that one hydrogen ion is involved in the reduction. With basic solutions of iridium(III), the corresponding oxidation wave was obtained, but the metal was easily air oxidized. The basic iridium(IV) species gave an absorption peak at 313 mμ. The rate of formation of the basic iridium(III) complex from an acid iridium(III) solution was found to be more rapid than that of the basic iridium(IV) complex from an acid iridium(IV) solution. The reaction of iridium(IV) with ethylenediaminetetracetate was also studied.

INTRODUCTION

There has been some work on the direct polarography of iridium in aqueous solutions, but the only positive results have been obtained with hydrochloric acid solutions (1, 2). Willis (3) was unable to obtain polarographic waves with either iridium(III) or iridium(IV) in the presence of bromide, cyanide, ethylenediamine, pyridine, and thiocyanate electrolytes. Repin (4) was unable to obtain polarographic waves with iridium(III) in chloride, phosphate, tartrate, and tetraethylammonium iodide electrolytes. With solutions of $IrCl_3$ buffered at pH 5 with acetate, Simpson, Evans, and Saroff (5) did obtain a reduction wave with a relatively small diffusion current; this might well be due to the presence of some iridium(IV) in the solution. A precipitate gradually appeared when the solution was left standing. Ezerskaya and Filimonova (6) could not obtain a wave with iridium(III) or indium(IV) in a solution containing ethylenediaminetetracetate at pH 5 to 6. West, Dean, and Breda (7) observed a reduction wave with $E_{1/2}$ of −1.4 V with iridium(IV) in a 0.5 *M* Na_2F_2 electrolyte of pH 5, but the limiting current plateau was very poorly defined.

With a 0.2 *M* HCl electrolyte, Page (1) found that the reduction $Ir^{IV} \rightarrow Ir^{III}$ took place at the dropping mercury electrode (d.m.e.). The $E_{1/2}$ was more positive than the oxidation potential of the mercury, but the limiting current plateau was well defined. Pshenitysn, Ezerskaya, and Ratinova (2) found an $E_{1/2}$ of +0.73 V for this reduction with a rotating platinum microelectrode in an acid 0.1 *M* NaCl electrolyte. They also found that iridium(III) produced an anodic wave with a slightly more positive $E_{1/2}$ under the same conditions, indicating that the $Ir^{IV} + e \rightleftarrows Ir^{III}$ reaction was somewhat irreversible.

This work is a study of the polarographic behavior of iridium in basic solutions. It augments the previous spectrophotometric investigations of iridium by MacNevin and Kriege (8) and Desideri and Pantani (9).

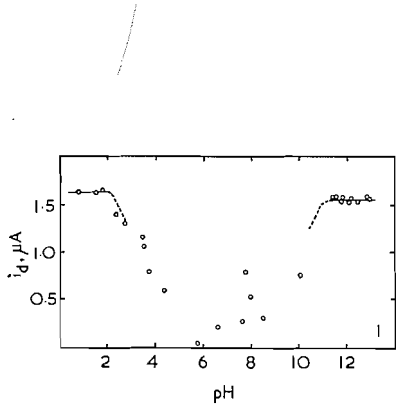
EXPERIMENTAL

All potentials reported, *V*, are in volts relative to the saturated calomel reference electrode.

Polarograms were recorded on a Leeds and Northrup type E electrochemograph with the damping set in the No. 1 position. The cell was of the conventional H-type with a saturated calomel reference electrode, and all polarography was carried out at 25.0 °C. The polarographic currents reported have been corrected for the residual current found on blank polarography. The mercury electrode had a flow rate of 1.850 mg s^{-1} at an effective height, *h*, of 82.7 cm of mercury. Polarographic currents were measured in acid solution at −0.20 V,

at a drop time of 4.21 s and corresponding capillary constant of 1.916 $mg^{2/3}\ s^{-1/2}$. In basic solutions, the polarographic currents were measured at −0.90 V, corresponding to a drop time of 4.20 s and capillary constant of 1.915 $mg^{2/3}\ s^{-1/2}$.

The controlled potential coulometric titrations were carried out with the apparatus and cells previously described (1). A Beckman model G pH meter with a 40495 blue-glass electrode and a saturated calomel reference electrode was used for pH measurements. Corrections were made for the sodium ion present in the solutions. The meter was standardized against a borax solution prepared according to the directions of the National Bureau of Standards from their sample 187a (pH = 9.18 at 25.0 °C). Spectra in the visible and ultraviolet region were recorded with a Bausch and Lomb Spectronic 505 with matched quartz cells of 1 and 10 cm path length. For measurements at a single wavelength (313 mμ) a Beckman DU spectrophotometer was used.



Deaeration of solutions for polarography and coulometry was done with prepurified nitrogen (less than 20 p.p.m. oxygen), but in critical cases the nitrogen was further purified by passage over copper turnings at 500 °C.

All chemicals used were reagent grade. The standard iridium solution was prepared from hydrated sodium hexachloroiridate ($Na_2IrCl_6.6H_2O$) obtained from Englehard Industries Limited (lot A-32). Preliminary experiments showed that the salt contained approximately 5% lead. This was originally detected by a polarographic wave with $E_{1/2}$ of −0.43 V in 0.2 *M* HCl solution and confirmed by spectrographic analysis.

The standard iridium solution was prepared as follows. The salt (4.34 g) was dissolved in 600 ml of aqueous solution containing 4 ml of concentrated hydrochloric acid. The pH of the resulting solution was 1.0. The solution was then passed through a column of Dowex 50W-X8 cation exchange resin according to the procedure prescribed by Marks and Beamish (10) for the separation of base metals from rhodium and iridium. Polarography of the resulting solution showed that the lead had been completely removed. The solution was then diluted to 2 000 ml with water and 13 ml of concentrated hydrochloric acid. This working solution was thus 0.1 *M* in hydrochloric acid. It was standardized according to the method of Page (1) by controlled potential coulometry. The concentration was found to be 0.446 ± 0.006 mg Ir/ml from five such determinations on 5 or 10 mg samples. Chlorination of samples of the solution before electrolysis (1) resulted in the same value, showing that there was no significant amount of iridium(III) in the solution.

RESULTS AND DISCUSSION

The polarographic behavior of iridium(IV) was investigated over a range of pH. Solutions were prepared by dilution of the standard iridium(IV) solution, with the final ionic strength controlled at 0.50 *M* with sodium chloride. The appropriate volume of a standard sodium chloride solution was added before the adjustment of pH by the addition of a sodium hydroxide solution. The final chloride concentration was thus a constant 0.50 *M* up to pH 12, but was lower at the higher pH's where the concentration of free hydroxide was appreciable. The solutions were diluted to final volume, and stabilized at 100 °C for 15 to 30 min before polarography at 25 °C.

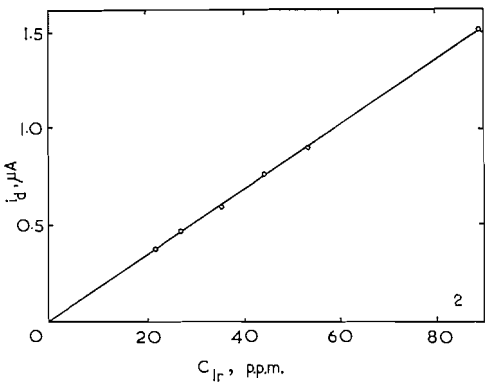


FIG. 1. Diffusion current as a function of pH in stabilized iridium(IV) solutions. μ = 0.50, C_{Ir} = 0.464 m*M*.

FIG. 2. Diffusion current as a function of concentration in stabilized iridium(IV) solutions. μ = 0.50, pH = 11.5 to 12.3.

For personal use only.

The diffusion current, i_d, was a function of pH (Fig. 1). From pH 0 to 2, the previously reported reduction wave with $E_{1/2}$ more positive than the oxidation potential of the mercury was obtained. Above pH 2, the diffusion current of this wave decreased, the wave disappearing completely at pH 6. Above pH 6, a second reduction wave developed, with a diffusion current that was independent of pH above pH 11.3. In the pH range 2 to 11.3, a precipitate was frequently observed in the stabilized solutions, indicating that hydrolysis to an insoluble neutral species had occurred, at least in part. Above pH 11.3, the stabilized solutions were clear.

A linear calibration curve, i_d versus concentration of iridium(IV), was obtained for solutions stabilized in the pH range 11.5 to 12.3 (Fig. 2). A diffusion control of the reduction process was indicated by a proportionality between i_d and the square root of the height of the mercury column of the dropping electrode. The value of $i_d/Ch^{1/2}$ was 1.85 and 1.88 μA mM^{-1} cm$^{-1/2}$ at h 64.8 and 82.7 cm respectively.

The reduction appeared to be a reversible one-electron process. Plots of $E_{d.m.e.}$ versus log $(i/(i_d - i))$ were linear with slopes of 58, 63, 66, 60, and 64 mV at pH's of 11.9, 12.2, 12.4, 12.8, and 13.0 respectively. The half-wave potential was a function of pH, shifting by 57 mV per pH unit in the pH range 11.3 to 13.0; the reduction was more difficult in more basic solutions (Fig. 3).

Since the shift in $E_{1/2}$ is very close to 59 mV per pH unit, it would appear that one hydrogen ion is involved in the one-electron reduction of the iridium(IV). If the iridium (IV) species in the basic solution is $Ir(OH)_6^{2-}$, then the reduction corresponds to:

$$Ir(OH)_6^{2-} + H_2O + e^- \rightarrow Ir(OH)_5(H_2O)^{2-} + OH^-.$$

The one-electron reduction was confirmed by controlled potential electrolyses at a mercury cathode at −0.80 V. The iridium(IV) solutions were prepared and stabilized as in the polarographic experiments, with the final pH in the range 11.5 to 12.5. The reductions proceeded smoothly to low background currents, but the calculated number of electrons was variable, close to but always greater than one (Table I). During the electrolyses, a white precipitate, presumably of iridium(III), formed. This precipitate partially dissolved when the solution was allowed to stand in air subsequent to electrolysis. Coulometry of

‡Solution standardized gravimetrically with 2-mercaptobenzothiazole by Dr. K. S. Chung.

these air-oxidized solutions always gave low results of about 60 to 80% of the initial value, as would be expected if some iridium was present as a nonreactive precipitate.

Polarography was also carried out on iridium(III) solutions prepared by controlled potential electrolysis. Solutions of iridium(IV) in a 0.2 *M* HCl electrolyte were reduced at a mercury cathode at 0 V. When these solutions were made basic with sodium hydroxide in the pH range 11.5 to 12.5, in the absence of oxygen, an anodic wave was obtained on polarography. Subsequent partial air oxidation gave a composite anodic–cathodic wave, while complete air oxidation gave the cathodic wave characteristic of iridium(IV). The $E_{1/2}$'s of the anodic, composite, and cathodic waves were identical, confirming the reversible nature of the polarographic wave.

Although the polarography of iridium in basic solution has not been reported, the spectral characteristics have been investigated. Desideri and Pantani (9) noted an absorption peak at 313 mμ (molar absorptivity, ϵ = 2 880, our value) starting with acid solutions of iridium(IV) or even iridium(III) in the presence of dissolved air. They showed that the iridium(IV) was present in the basic solutions as an $Ir(OH)_6^{2-}$ species. MacNevin and Kriege (8) also produced an absorption peak with iridium(IV) in a basic ethylenediaminetetracetate (EDTA) electrolyte. They postulated that an iridium(IV)–EDTA complex was formed, but since the peak had the same characteristics as that produced in basic solution in the absence of EDTA it may be assumed that the absorbing species is not an EDTA complex.

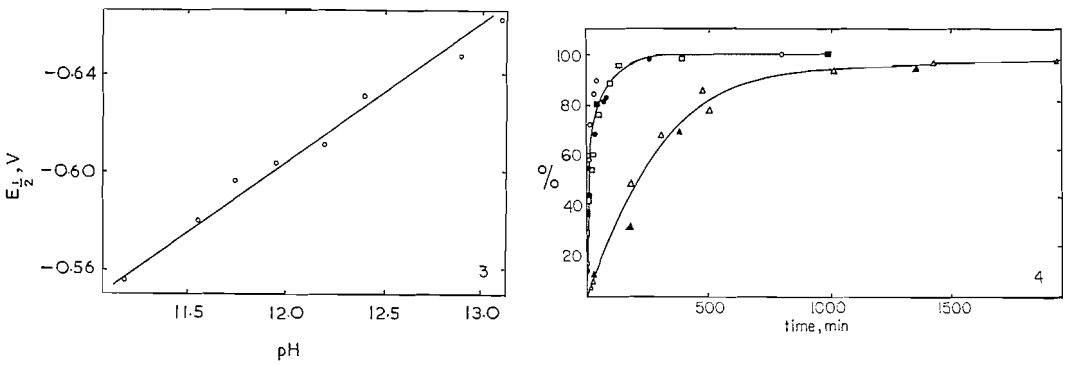

FIG. 3. $E_{1/2}$ as a function of pH in stabilized iridium(IV) solutions. μ = 0.50, C_{Ir} = 0.464 m*M*.
FIG. 4. Development of the polarographic wave in the absence of oxygen: wave height (% of final) as a function of time. μ = 0.50, C_{Ir} = 0.2 m*M*, pH = 11.5 to 12.5. (□, ■) Ir^{III} (anodic wave), (○, ●) Ir^{IV} + ethylenediaminetetracetate (anodic wave), (△, ▲) Ir^{IV} (cathodic wave).

In both of these investigations, chloride ion was present in the basic solutions and may be involved in the absorbing species; however, we have prepared a basic iridium complex with the same absorption characteristics in the absence of chloride ion. Aliquots of the stock iridium(IV) solution were fumed twice with perchloric acid to remove chloride, diluted, and electrolyzed at a mercury cathode at 0 V to give iridium(III). The iridium was then precipitated from the solution with sodium hydroxide and the precipitate was filtered off, washed, and then fused with solid sodium hydroxide in a nickel crucible. The melt when dissolved in water gave the same polarographic and absorption characteristics as previously noted with iridium(IV) in basic solution.

The rate of formation of the active polarographic and absorbing species in the aqueous solutions has been followed at room temperature (Fig. 4).

With the standard iridium(IV) solution as the starting solution, there was a rapid (< 5 min) disappearance of the iridium(IV) chloride spectrum when the solution was made basic. This was followed by a slow development of the new polarographic reduction wave; there was a matching development in absorbance at 313 mμ indicating that the same species is active in both polarography and absorption in the basic solution. On the other hand, with an air-free iridium(III) solution, prepared by controlled potential electrolysis as before, as the starting solution, there was a more rapid growth of the polarographic oxidation wave when the solution was made basic. There was no change in absorbance at 313 mμ. If air was admitted after complete development of the anodic wave, there was a rapid (< 1 min) oxidation of the iridium(III) with a complete development of both the cathodic wave and the absorbance at 313 mμ. These final characteristics could be obtained directly with the solutions of iridium(IV) or iridium(III) in the presence of dissolved air by 15 to 30 min stabilization at 100 °C.

The reactions involved in the presence of EDTA were also studied. On addition of the sodium salt of EDTA to an acid iridium(IV) solution, the characteristic red-brown color changed to pale green over a period of several hours at room temperature. The transformation could be accelerated by heating to 100 °C. The final spectrum closely matched that of iridium(III) prepared by controlled potential electrolysis. The acidic solution gave no characteristic polarographic wave, but the red-brown color of iridium(IV) could be restored by chlorine oxidation.

If an acid 0.2 mM iridium(IV) solution was made 0.001 M in dissolved EDTA, stabilized at 100 °C, and then made air free and basic, a polarographic oxidation wave developed at a rate close to that found when the iridium(III) solution was made basic (Fig. 4). This suggests that there is first a reduction of the iridium(IV) by the EDTA and a subsequent formation of the polarographically active species. The EDTA does not influence the rate of formation of the active species from the iridium(III). The final iridium(III) species was readily air oxidized to give a polarographic reduction wave.

At a given pH, the polarographic wave in a basic solution with added EDTA had the same $E_{1/2}$ as in similar solutions without EDTA.

A second reduction wave appeared in the basic EDTA solutions. It had an $E_{1/2}$ of −1.35 V, corresponding to that of glyoxylate in basic solution. Enns (11) has already found that EDTA can be oxidized by riboflavin in acid solution, and has identified glyoxylic acid as an oxidation product of the EDTA. This second wave does not occur with the EDTA if iridium(III) is used as a starting material in place of iridium(IV).

If air is admitted to the basic solution of iridium(III) and EDTA, there is rapid and complete oxidation of the iridium. Controlled potential coulometry on such solutions gave results consistent with a one-electron reduction process (Table I).

CONCLUSIONS

The polarography of the iridium(IV) in basic solution is suitable for quantitative work and the reversible nature of the one Faraday per mole reduction is in contrast to the irreversible nature of the polarography in other electrolytes. The polarography of iridium (III) was also quantitative, but not of practical use in analysis because of the easy air oxidation of iridium(III) in basic solution.

The controlled potential coulometry consistently gave high results, despite the fact that the reductions proceeded rapidly to a small final background current. The iridium(III) species formed on controlled potential reduction in the basic solution was insoluble, in contrast to that formed on making an acid iridium(III) species basic.

For personal use only.

The polarographic behavior in basic solution matches the spectrophotometric behavior previously reported, although it appears that in the procedure of MacNevin and Kriege (8) the EDTA does not form a complex with iridium. The EDTA does act as a reducing agent for iridium(IV) in acid solution, but not in basic solution.

The formation of the basic iridium(IV) species from an initially acid solution of $IrCl_6^{2-}$ was found to be slow. It is known that $IrCl_6^{2-}$ is kinetically fairly inert (12), and the formation of the basic iridium(IV) species is evidently a two-step process, for while there is a rapid disappearance of the $IrCl_6^{2-}$ spectrum, there is only a slow growth of the polarographically reducible species. The formation of the basic iridium(III) species from an initially acid solution (prepared either by controlled potential or EDTA reduction) is more rapid. This is in agreement with the observations that anionic iridium(III) complexes are labile (12).

ACKNOWLEDGMENTS

The authors are indebted to the National Research Council of Canada for a grant in aid of this research and for scholarship aid (G.V.L.). They are also indebted to the University of Toronto and the Ontario Research Foundation for financial assistance. Thanks are also due to Dr. K. S. Chung for samples of standardized iridium solution.

A SOLVENT-EXTRACTION STUDY OF THE THERMODYNAMICS OF ANILINE AND ITS NITRATE

A. ABOUL-SEOUD AND M. DOHEIM

Chemical Engineering Department, Faculty of Engineering, University of Alexandria, Egypt, U.A.R.

Received September 21, 1965

ABSTRACT

The distribution coefficients of aniline between *n*-heptane and aqueous sodium nitrate solutions were measured at different temperatures. The activity coefficients of aniline in aqueous sodium nitrate solutions were determined. The effect of sodium nitrate on the dissociation of the anilinium ion was studied at different temperatures by a modified distribution method. Attention was directed to the choice of the extracting solvent and of the analytical method. The effect of the presence of undissociated anilinium ions on the distribution coefficients was taken into consideration.

K_0, K_b, ΔH, ΔF, and ΔS for the dissociation of the anilinium ion were evaluated.

INTRODUCTION

During a study of the effect of electrolytes on the rate of diazotization of aniline, it was found necessary to study the dissociation of the anilinium ion in the presence of sodium nitrate solutions of different ionic strengths, and to evaluate thermodynamic quantities such as the activity coefficient of aniline in aqueous sodium nitrate solutions, and the basic dissociation constant of aniline, at different temperatures. These results (1) are to be combined with the results of equilibrium (2) and kinetic measurements involving aniline.

The values were determined by a modified distribution method (3, 5, 7), in which attention was directed to the choice of the extracting solvent and of the analytical method.

EXPERIMENTAL

The distribution method (3, 5, 7) seems to be the most suitable for this and similar studies.

n-Heptane was used as extracting solvent. It is not too volatile, and it does not react with any of the substances involved in this study. Unlike benzene, it is very slightly soluble in water (5.2 mg/100 ml H_2O at 15.5° C (4)), so that there is no need for solubility corrections (5); also, it does not lead to distribution coefficients which are inconveniently high (3, 5).

The aniline in the heptane phase was determined by ultraviolet spectroscopy with a Unicam SP. 500 spectrophotometer. Absorption curves for solutions of aniline in heptane, of different concentrations, showed that 287 mμ is the wavelength of maximum absorption. Consequently, all spectrophotometric measurements of the concentration of aniline in heptane were carried out at this wavelength. The accuracy of this analytical method is estimated to be $\pm 0.01\%$.

Materials

Aniline.—Extra pure quality was used. This was distilled with zinc dust and then redistilled before use; b.p. 184 °C.

Sodium nitrate.—An A.R. product was used.

n-Heptane.—A pure quality was used. This was further purified by distillation; b.p. 98 °C.

Aniline nitrate solution.—Standard solutions of purified aniline in boiled-out distilled water, and of nitric acid prepared from an A.R. product, were mixed together, just before use, in such volumes as to give aniline nitrate solution of the desired concentration.

Procedure

Distribution coefficient measurements.—Twenty milliliters of an aqueous solution, containing a known amount of aniline and the calculated amount of sodium nitrate, were equilibrated at the desired temperature with 20 ml of *n*-heptane. The two phases were then separated by removal of the aqueous layer by suction.

Dissociation constant measurements.—These measurements were carried out in the same way, substituting aniline by aniline nitrate.

All measurements were carried out in duplicate, or in triplicate when necessary.

RESULTS, CALCULATIONS, AND CONCLUSIONS

The Distribution of Aniline between n-Heptane and Aqueous Sodium Nitrate Solutions

In the range of concentrations investigated, the distribution of aniline between *n*-heptane and water was found to be independent of the total concentration of aniline, indicating that no association or compound formation took place in either phase (6). This was determined from the linearity of the plot of the concentration of aniline in heptane (c_H) against its concentration in the aqueous phase (c_A), in distribution experiments at 5, 15, 25, and 35 °C. The results are given in Table I.

TABLE I

The equilibrium concentrations of aniline in the heptane phase (c_H) and in the aqueous phase (c_A), at different temperatures

Temp. (°C)	c_H or c_A	Concentration of aniline (mg/l)			
5	c_H	5.88	15.37	29.50	36.65
5	c_A	12.74	31.19	63.62	75.09
15	c_H	6.65	16.60	32.65	39.65
15	c_A	11.97	29.96	60.47	72.09
25	c_H	7.75	19.15	38.35	46.55
25	c_A	10.87	27.41	54.77	65.19
35	c_H	8.65	21.20	43.85	52.75
35	c_A	9.97	25.36	49.27	58.99

The distribution of aniline between *n*-heptane and aqueous sodium nitrate solutions was studied at 5, 15, 25, and 35 °C. The results are given in Table II.

The values of the distribution coefficients in terms of molalities (m_H/m_A) were calculated, and plotted against the sum of the molalities of the amine and of sodium nitrate in the aqueous phase. The curves thus obtained were extrapolated to zero molality. From the values of m_H/m_A and the corresponding values at zero molality, the values of the activity coefficients of aniline (f_{An}) in aqueous sodium nitrate solutions were determined (7).

The plot of log f_{An} against the sum of the molalities of aniline and of sodium nitrate, in the aqueous phase, was found to be linear up to a salt molality of 2. This is in concordance

with the relationship reported by Harned and Owen (8, p. 398) and the findings of Randall and Failey (9). This plot may be represented by the equation

$$[1] \qquad \log f_{An} = k_m(m_{An} + m_{NaNO_3})$$

where k_m is the salting coefficient (8, p. 398), and m is the molality.

The values of the salting coefficient were found to be 0.07, 0.08, 0.095, and 0.114 at 5, 15, 25, and 35 °C respectively. The value of k_m at 25 °C may be compared with 0.074 for ethyl acetate (10), and with 0.019 for phenyl thiourea (11), at the same temperature.

The fact that k_m is dependent on the nature of the nonelectrolyte is in accord with earlier findings (12).

The plot of $1/f_{An}$ against the molality (8, pp. 58, 403, 404) of sodium nitrate was found to be linear up to a molality of 1. The linearity of this plot indicates that the results conform in a general way to the Debye theory of salt effects (8, pp. 58, 403, 404; 13).

The Dissociation of the Anilinium Ion

The results of the study of the effect of ionic strength and temperature on the dissociation of the anilinium ion are given in Table III, where K_m is the dissociation constant in terms of molalities,

$$[2] \qquad K_m = m_{H^+}m_{Aniline}/m_{Anilinium^+}.$$

In the calculation of K_m, the effect of the presence of undissociated anilinium ions on the distribution coefficients was taken into consideration. Thus, the values of m_H/m_A, corresponding to the values of $m_{NaNO_3} + m_{AnHNO_3}$, in the curves obtained by plotting m_H/m_A against the sum of the molalities of sodium nitrate and of aniline in the aqueous phase, were used for calculating the molality of free aniline in the aqueous phase, in dissociation measurements.

TABLE III

The effect of sodium nitrate on the dissociation of anilinium nitrate

Temp. (°C)	$NaNO_3$ (mole/l)	$NaNO_3$ (m)	m_H/m_A	$m_{An} \times 10^4$	$K_m \times 10^5$ (±0.3%)
	0.0	0.000	0.80	3.0	1.76

	4.0	4.635	2.34	28.7	405.81
	0.0	0.000	1.32	3.8	3.32
	0.5	0.508	1.48	6.0	8.47
35±0.05	1.0	1.034	1.64	8.6	18.39
	2.0	2.135	1.97	11.5	36.73
	4.0	4.635	2.37	25.1	331.94

The thermodynamic dissociation constant (K_0) was obtained for each temperature by plotting pK_m against the sum of the molalities of anilinium and sodium salts, and extrapolating to zero molality.

$$[3] \qquad K_0 = (f_{An}f_{H^+}/f_{AnH^+})\ (m_{An}m_{H^+}/m_{AnH^+}) = (f_{An}f_{H^+}/f_{AnH^+})K_m,$$

where f_{An}, f_{H^+}, and f_{AnH^+} are the activity coefficients of, and m_{An}, m_{H^+}, and m_{AnH^+} are the molalities of, aniline, hydrogen, and anilinium ions, respectively, in the aqueous phase.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

With zero molality as the standard state, therefore, and when by definition $f = 1$, it follows from eq. [3] that at zero molality $K_m = K_0$.

It may be seen from eq. [3] that the value of K_0 is independent of the sodium nitrate concentration. The increase in K_m with sodium nitrate concentration may be attributed to the influence of sodium nitrate on the activity coefficients of aniline, hydrogen, and anilinium ions. From Table II, however, it is seen that the influence on the activity coefficients of aniline is not large. The relatively large increase in K_m with salt concentration is due, therefore, to either a relatively large increase of f_{AnH^+} or decrease of f_{H^+} with sodium nitrate concentration or both. Similar effects of electrolytes on f_{H^+} have already been reported (14). This problem is the subject of further investigation in this laboratory.

Evaluation of K_b, ΔH, ΔF, and ΔS

The plot of log K_0 against $1/T$ was found to be a straight line. From the slope of this line the heat of dissociation of the anilinium ion (ΔH), was calculated to be 5.78 ± 0.02 kcal.

In Table IV, the values of the thermodynamic dissociation constant (K_0), the ionic product of water (K_w), the basic dissociation constant (15) of the anilinium ion (K_b), the heat of dissociation (ΔH), the free energy change (16) (ΔF), and the entropy change (16) (ΔS) are given.

TABLE IV

Evaluation of K_b for aniline and ΔH, ΔF, and ΔS for the dissociation of the anilinium ion, at different temperatures

Temp. (°C)	$K_0 \times 10^5$	$K_w^* \times 10^{14}$	$K_b \times 10^9$	ΔH (kcal)	ΔF (kcal)	ΔS (e.u.)
15	1.76	0.450	0.253	5.78±0.02	6.26±0.02	−1.7±0.01
25	2.43	1.008	0.414	5.78±0.02	6.29±0.02	−1.7±0.01
35	3.32	2.089	0.629	5.78±0.02	6.31±0.02	−1.7±0.01

*From ref. 8, p. 485.

The fact that ΔH is independent of temperature over the range 15–35 °C indicates that in this range the difference of the partial molar heat capacity in the dissociation of the anilinium ion (ΔC_p) equals zero.

The values in Table IV may be compared with Pedersen's (17) values of $\Delta H = 7100$ cal, $\Delta F = 6265$ cal, and $\Delta S = +3.4$ e.u., at 25 °C, and with Everett and Wynne-Jones' (18) values of $\Delta C_p = 0.0$, $\Delta H = 7105$, $\Delta F = 6265$, and $\Delta S = +2.8$, at 25 °C.

NOTES

PARAMAGNETIC CENTERS IN IRRADIATED POTASSIUM SULFATE[1]

V. V. GROMOV[2] AND J. R. MORTON

Recent investigations (1, 2) into the radiolysis of polycrystalline sulfates prompted this examination of the electron spin resonance (e.s.r.) spectra of irradiated potassium sulfate single crystals. By irradiating the samples and studying their spectra at 77 °K and at 300 °K different stages in the radiation damage process were revealed.

The e.s.r. spectra of single crystals of K_2SO_4 irradiated and examined at 77 °K demonstrated the presence of a single paramagnetic species, A, characterized by a highly anisotropic g-tensor. By monitoring the spectrum during warm-up of the sample it could be seen that over 90% of A decomposed to form a second species, B, although the amount of A surviving at 300 °K was sufficient to permit the determination of its g-tensor at this temperature. The radical B was characterized by an almost isotropic g-tensor. The principal values of the g-tensors of the two radicals are given in Table I. Examination of a very large, heavily irradiated crystal revealed ^{33}S hyperfine structure in the spectrum of radical B, the interaction being 275, 270, and 315 Mc/s with H_0 along the a, b, and c crystallographic axes respectively. No ^{33}S hyperfine structure was detected in the spectrum of radical A. However, since a very much smaller crystal had to be used for experiments at 77 °K, the anticipated signal/noise ratio was less than 5:1, and so the absence of ^{33}S signals was not proved unequivocally.

The maximum-slope line widths of the spectra of both radicals were approximately 5 G, and were independent of temperature. The major contributions to the line widths are therefore presumed to be crystal imperfections and unresolved ^{39}K hyperfine structure.

The identification of the two radicals trapped in irradiated K_2SO_4 depended on a comparison of their spectral parameters with those of already well-substantiated species, and it was concluded that A and B were SO_4^- and SO_3^- respectively.

TABLE I

The principal values of the g-tensors of radicals detected in irradiated K_2SO_4 crystals

Radical	Principal g-factors
A (SO_4^-)	2.0486, 2.0082, 2.0037
B (SO_3^-)	2.0033, 2.0033, 2.0023

The g-tensor of radical A has three different principal values (Table I) indicating C_{2v} or lower symmetry. Axially symmetric radicals such as SO_3^- (3), O_2^- (4), or O^- (5) are therefore excluded; even apart from symmetry considerations, their principal g-factors are not similar to those of radical A. The radical SO_2^-, although possessing C_{2v} symmetry, has a maximum g-factor of 2.01 (6) and cannot therefore be identified with radical A. The radical SO_4^- has been observed (7) in both γ-irradiated and ultraviolet-photolyzed alkali–metal persulfates, where it is formed as a result of S–S bond scission. In potassium

[1]*N.R.C. No. 8807.*

[2]*Visiting scientist. Present address: Institute of Physical Chemistry, Soviet Academy of Sciences, Moscow.*

persulfate, for example, SO_4^- has principal g-factors 2.0327, 2.0084, 2.0035; these values are sufficiently similar to those presently reported to suggest the identification of radical A in K_2SO_4 as SO_4^-. The lack of ^{33}S hyperfine interaction for SO_4^-, although not unequivocally established in the present case, is consistent with this identification. Molecular orbital calculations on the perchlorate ion (8), which is isoelectronic with the sulfate ion, suggest that in SO_4^- the unpaired electron would occupy the $1t_1$ orbital, composed entirely of oxygen 2p orbitals. It has also been suggested (7) that as a result of either Jahn–Teller or crystal-field distortion T_d symmetry is lost, the $1t_1$ orbital giving rise to b_1, b_2, and a_2 orbitals under C_{2v} symmetry. With the unpaired electron entering the a_2 orbital, spin–orbit interaction between the ground $^2A_2$ state and a low-lying $^2B_2$ state would account for one principal g-factor being considerably greater than the free spin value 2.0023. None of the principal g-factors would be expected to be lower than 2.0023, however, since recent calculations (9) indicate that no unoccupied orbital is less than 10 eV above the $1t_1$ orbital of SO_4^-.

The radical SO_3^- has been detected as a result of γ-irradiation in several compounds containing the —SO_3 function (3). It is characterized by an almost isotropic g-factor of 2.0036 ± 0.0007 and by a hyperfine interaction in the range 300–400 Mc/s involving the ^{33}S nucleus (spin 3/2) of the 0.74% $^{33}SO_3^-$ radicals present in natural abundance. The unpaired electron occupies an a_1 orbital (symmetry C_{3v}) possessing considerable sulfur 3s character. There can be little doubt that radical B in irradiated K_2SO_4 is SO_3^-. Alternatives such as SO_2^- or SO^-, being π-electron radicals, would not be expected to exhibit a large ^{33}S interaction. In SO_2^-, for example, the isotropic ^{33}S hyperfine interaction is only 41 Mc/s (6).

EXPERIMENTAL

Crystals of K_2SO_4 were grown by slow evaporation of aqueous solution. The unit cell is orthorhombic, having dimensions $a = 5.731$, $b = 10.008$, $c = 7.424$ Å, and contains four molecules of K_2SO_4 (10). The crystal habit was inferred goniometrically and confirmed by X-ray diffraction photographs, being prismatic along [100] and developing {021}. The crystals were irradiated with a Philips X-ray tube type 25623-62, and examined after irradiation with a Varian V-4502 spectrometer previously described (11). To determine the g-tensors of the radicals the K_2SO_4 crystals were mounted on a two-circle goniometer (12) and rotated about each of the orthorhombic axes in turn, spectra being taken every 10°. From these data the principal values of the g-tensors were determined in the usual way (13).

ACKNOWLEDGMENT

The authors are grateful to Dr. L. D. Calvert for determining the unit-cell dimensions and directions of the crystals.

PHOTOLYSIS OF MIXES OF PERFLUOROACETONE AND PERFLUORODIETHYL KETONE REACTIONS OF CF_3 AND C_2F_5 RADICALS

ALVIN S. GORDON

It has been reported that alkyl radicals easily displace a perfluoroalkyl radical from a perfluoroketone (1–3). In the work reported here, the evidence indicates that a perfluoroalkyl radical does not displace a perfluoroalkyl radical from a perfluoroketone even at 300 °C.

The combination reactions of perfluoroethyl and perfluoromethyl radicals result in a ratio for the rate of formation of the various radical–radical addition products,

$$[1] \qquad \frac{k_{CF_3,C_2F_5}}{k_{CF_3,CF_3}^{1/2}\, k_{C_2F_5,C_2F_5}^{1/2}} = \frac{R_{C_3F_8}}{R_{C_2F_6}^{1/2}\, R_{C_4F_{10}}^{1/2}} = 2.08 \pm 0.04 .$$

This ratio is independent of temperature. The k's are the rate constants for the subscripted radical–radical combinations, and the R's are the rate of formation of the subscripted compound. The results are in good agreement with the previously published value of 1.77 ± 0.10 for perfluoromethyl and perfluoro n-propyl radical combinations (4).

It has been shown previously that F atoms are not abstracted by disproportionation of perfluoro radicals or by abstraction from perfluoroketones at temperatures as high as 200° (4, 5). The present work adds further evidence and extends the temperature to 300°, since no CF_4 is found in the products.

Two mixes of perfluoroacetone and perfluorodiethyl ketone were employed, 1:1 and 3:1. As may be noted in Table I, the composition had no effect on the ratio in eq. [1], consonant with a radical–radical combination mechanism. The reactants were photolyzed in a quartz cell with the radiation from a medium pressure mercury lamp; products were analyzed by gas chromatography, with a 1% squalane on pelletex column, temperature programmed from −196 °C to 100 °C. All the peaks were trapped and identified by mass spectrometry. The peak areas were converted to micromoles by instrument calibration factors obtained with pure materials.

TABLE I

Combination of ratios of CF_3 and C_2F_5 radicals from photolysis of perfluoroacetone and perfluoropentanone-3

Temp. (°C)	Pressure of mix (cm)	$\frac{C_3F_8}{(C_2F_6)^{1/2}(C_4F_{10})^{1/2}}$
Perfluoropentanone-3/perfluoroacetone = 1		
151.0	8.1	2.1
150.5	3.7	2.1
201.0	10.1	2.0
201.0	10.1	2.1
251.0	10.0	2.1
300.0	10.0	2.1
Perfluoropentanone-3/perfluoroacetone = 3		
100.0	10.0	2.0
151.0	10.0	2.1

Since the possibility existed that perfluoromethylethyl ketone would appear on the chromatogram at the same place as perfluorobutane, the products of the reaction at the highest temperature were resolved by a silene column which retains ketones. The mass spectral pattern of the perfluorobutane from the silene column proved to be identical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with that from the pelletex column, showing that no perfluoromethylethyl ketone was produced, and that the displacement reactions

[2] $$\dot{C}F_3 + C_2F_5COC_2F_5 \rightarrow CF_3COC_2F_5 + \dot{C}_2F_5$$

and

[3] $$\dot{C}_2F_5 + CF_3COCF_3 \rightarrow CF_3COC_2F_5 + \dot{C}F_3$$

do not occur. Since the heat of reaction in reactions [2] and [3] is about zero, the high activation barrier against the reaction probably results from the electropositive character of both the carbon atom of the attacking radical and that of the attacked carbon atom of the carbonyl group, because of the influence of the F and O atoms. By a similar argument, Gordon (6) has proposed that the electropositive $\dot{C}F_3$ radicals attack the electronegative oxygen atom rather than the carbon atom of the carbonyl group in perfluoroacetone; the present work substantiates the hypothesis.

In combination reactions of unlike radicals, ratio [1] would be temperature independent even if the same barrier existed for the three reactions. A small barrier for such reactions (not over 1.5 kcal/mole) has been suggested for such combinations (7, 8) but very recent work on cross combination of CH_3 and CF_3 (9, 10) indicates no temperature dependence. The results indicate that CF_3 combination has no barrier, since CH_3 combination has no activation barrier.

The results in Table I show that the cross combination ratio for CF_3 and C_2F_5 is very close to 2. The ratio is calculated to be 2.0 on the basis of collisions of CF_3 and C_2F_5 assuming equal diameters, and 2.3 assuming the diameter of C_2F_5 is twice that of CF_3. A realistic choice would be between these extreme values. Since the calculations show that the relative diameters will have little effect on the calculated ratio, any large deviations from a value of 2 must be due to the reaction probabilities. A comparison of the values of ratio [1] obtained in this work with the analogous value from the work of Pritchard, Miller, and Dacey (4) on perfluoromethyl and perfluoro *n*-propyl combination reactions suggests that the probability of reaction on collision is equal for all these radicals. There is an indication that the analogous alkyl radicals also have equal probability for reaction, although the data have considerable error (11). The alkyl radical data also are not corrected for disproportionation reactions; for methyl, ethyl, and *n*-propyl radicals, the correction is quite small (12).

I wish to thank G. O. Pritchard for fruitful discussions.

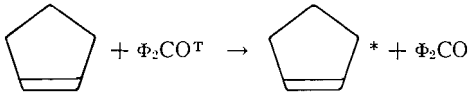
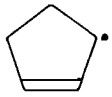
BENZOPHENONE-SENSITIZED PHOTOLYSIS OF CYCLOPENTENE. PREPARATION OF *meso*- AND DL-3,3′-BICYCLOPENTENYL

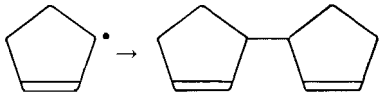
K. S. SIDHU, O. P. STRAUSZ, AND H. E. GUNNING



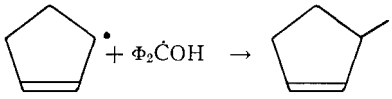
Triplet state energy transfer from benzophenone to simple monoolefins is an inefficient process (1) because the triplet state energy of simple monoolefins lies above the triplet level of benzophenone. No such restriction exists, however, on the photoreduction of benzophenone. Cyclohexene, for example, while being a poor quencher, readily brings about the photoreduction of benzophenone (2). The reactivity of the lowest-lying (n, π^*) state of benzophenone in its photoreduction reactions has been shown to be very selective and sensitive toward electron availability (3). The reactivity, in general, parallels that of *t*-butyl hypochlorite, which reacts with the allylic hydrogen in cyclohexene and cyclopentene 25 and 30 times faster, respectively, than with the hydrogen of the corresponding cycloalkanes (4).



In this note we describe an example of the use of this selective reactivity of triplet state benzophenone for preparative purposes. When we photolyzed solutions of benzophenone in cyclopentene we found 3,3′-bicyclopentenyl ($C_{10}H_{14}$) as the only hydrocarbon product, formed in good yields. The results of some representative runs in which quantum yield values for benzophenone disappearance and benzopinacol and 3,3′-bicyclopentenyl formation were measured are summarized in Table I.



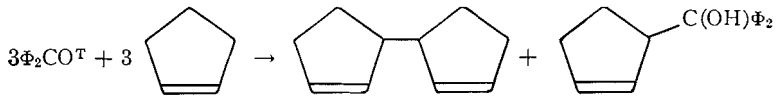
The results can be accounted for by the following scheme,



[1] $\Phi_2CO + h\nu \rightarrow \Phi_2CO^S$

[2] $\Phi_2CO^S \rightarrow \Phi_2CO^T$

[3]  $+ \Phi_2CO$



[3a]  $+ \Phi_2\dot{C}OH$

[4]  (isomers I and II)

[5]  $+ \Phi_2\dot{C}OH \rightarrow$ $C(OH)\Phi_2$ (III)

[6] $2\Phi_2\dot{C}OH \rightarrow (\Phi_2C(OH))_2$ (IV)

where Φ_2CO^S and Φ_2CO^T are excited singlet and triplet states of benzophenone. C_5H_8* is electronically or vibrationally excited cyclopentene. The overall reaction is

$3\Phi_2CO^T + 3$ → I and II + III + $(\Phi_2C(OH))_2$ IV

III has not been definitely identified; however, the petroleum ether soluble fraction of the solid products shows an infrared spectrum which is compatible with this structure. Moreover, similar cross-recombination has been observed in the benzophenone-photosensitized oxidation of toluene and cumene (5). Within the uncertainty in benzopinacol determinations, the results of Table I are in agreement with the above mechanism.

TABLE I

Quantum yield determination results*

Einsteins absorbed $\times 10^3$	Quantum yields (moles einstein^{-1})		
	$-\Phi_2CO$	$C_{10}H_{14}$	$(\Phi_2C(OH))_2$
2.88	0.48	0.15	0.14
4.20	0.49	0.14	0.10
6.02	0.47	0.13	0.12
Average	0.48	0.14	0.12

*With 0.1 *M* solutions of benzophenone in cyclopentene (cf. Experimental).

TABLE II

Values of τ for the different protons of the two 3,3′-bicyclopentenyl isomers

Protons	τ	
	Isomer I	Isomer II
Olefinic	4.38*	4.35*
Tertiary	7.35	7.39
$>CH_2$ (α to π bond)	7.73	7.70
$>CH_2$ (β to π bond)	(i) 8.04	8.06
	(ii) 8.48	8.48

*The corresponding internal olefinic protons absorb near $\tau = 4.38$ in 3- and 4-vinylcyclopentene.

From the quantum yield data the ratio of rate constants of deactivation to abstraction, k_3/k_{3a}, is equal to 1.1.*

No dicyclopentadiene, cyclopentyl cyclopentene, or polymer formation was observed. Therefore, thermalized cyclopentenyl radicals do not disproportionate or add to cyclopentene. It may be noted that no cyclopentadiene was observed in the mercury-photosensitized decomposition of cyclopentene (6). Cyclohexene does not give any oxetane in a similar reaction (2) and a specific search for oxetane in the present case failed to reveal its presence. Since no $C_{10}H_{14}$ product other than 3,3′-bicyclopentenyl was detected, the attack of benzophenone is exclusively on the allylic hydrogen.

On the gas chromatographic column the $C_{10}H_{14}$ product resolved into two fractions with relative retention times of 46 (I) and 53 (II) with respect to cyclopentene. (Column: 19 ft 30% β,β'-oxidipropionitrile on fire brick, at 63 °C, with He-carrier flow 110 ml/min.) Authentic samples (cf. Experimental) gave retention times identical with them. The two peaks were symmetrical and equal in area. They were separately collected and analyzed.

**This figure should be viewed from the standpoint that energy transfer reactions may proceed with near-collision efficiency, whereas abstraction reactions have low frequency factors and considerable activation energies.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Their infrared and mass spectra were identical with each other and with those obtained on synthetic samples. Their nuclear magnetic resonance (n.m.r.) spectra were also identical with the n.m.r. spectra of synthetic materials, but a small difference appeared between I and II. The values of the complex multiplet resonances for the two isomers are listed in Table II. The important difference is in the fine splitting of olefinic protons (shown in Fig. 1). Among the various optical isomers of 3,3′-bicyclopentenyl which have not yet been reported in the literature, the meso structure, in equilibrium position, has the two double bonds closer than the optically active forms. The meso isomer may therefore be expected to show the observed greater splitting (cf. Fig. 1(*a*).) due to proximity effects. This view is supported by the n.m.r. spectrum of 3-cyclopentenylcyclopentane. The two olefinic protons of this molecule appear at a τ value of 4.38 and have almost identical structure to the olefinic protons of II. Thus I and II are most likely the meso- and DL-stereoisomers of 3,3′-bicyclopentenyl, respectively.

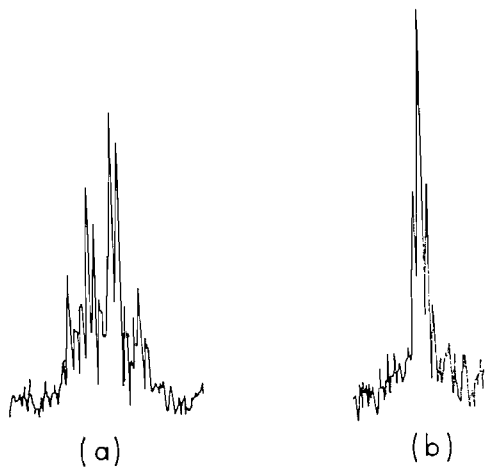


FIG. 1. Nuclear magnetic resonance spectra of the olefinic protons of (*a*) *meso*- and (*b*) DL-3,3′-bicyclopentenyl. HR-100.

Finally a series of experiments for the determination of the effect of conversion of the reaction on the 3,3′-bicyclopentene yield were carried out. Solutions (2.1 *M*) of benzophenone in cyclopentene were irradiated in pyrex vessels with unfiltered radiation from a Hanovia medium-pressure mercury lamp for various durations. The reaction mixtures were separated by distillation (unreacted cyclopentene b.p. 42° at 710 mm, and 3,3′-bicyclopentenyl b.p. 70° at 18 mm). No complications due to secondary reactions were observed up to 12% conversion and the yield for $C_{10}H_{14}$ was 85% based on the benzophenone consumption and the suggested mechanism.

In summary, the photochemical route described in this note offers a convenient single step synthesis from simple starting materials for the preparation of 3,3′-bicyclopentyls. Furthermore, these results confirm the observations of Walling and Thaler (4) on the reactivity of allylic hydrogen in cyclopentene.

EXPERIMENTAL

Solutions (0.1 *M*) of benzophenone (Fisher reagent grade) in freshly distilled cyclopentene (Phillips research grade) were degassed by repeated freezing and thawing. The irradiations were carried out in a cylindrical pyrex cell with a high pressure mercury lamp. The filter system consisted of $CuSO_4.5H_2O$ solution (400 g/l) and a Corning filter 7-51(5970). The passing band observed on a Cary spectrophotometer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

had a maximum at 3 725 Å and was 500 Å wide at half-height. A solution of 0.1186 *M* uranyl oxalate and 0.1210 *M* oxalic acid was used as the actinometer, and a CBS Laboratories type CL-1010 phototube was used to monitor the light intensities.

After irradiation, samples of the reaction mixture were injected into a gas–liquid chromatograph (g.l.c.) column with a microliter syringe and $C_{10}H_{14}$ determined. Benzophenone disappearance was measured by the standard spectrophotometric technique (7). The absorbencies were measured on a Cary spectrophotometer model 14M. For benzopinacol determination an aliquot of the reaction mixture was placed in a tube and the volatile part slowly pumped off. The residue was mixed with petroleum ether (b.p. 60–70°) and allowed to stand overnight. The residual crystalline solid was filtered, dried, and weighed. It was identified by its decomposition point (184°) and infrared spectrum.

Two methods were used to prepare the authentic samples of 3,3′-bicyclopentenyl. (*a*) A good yield for 3,3′-bicyclohexenyl has been reported in the reaction of *t*-butoxy radicals with cyclohexene. Accordingly, a mixture of di-*t*-butyl peroxide and cyclopentene in molar ratio 1:6 was degassed and sealed in a Carius tube and heated to 130° for 40 h. The reaction mixture was then distilled to give the desired fraction (b.p. 70° ± 2° at 18 mm). The yield was poor. (*b*) 3-Chlorocyclopentene was prepared by passing dry HCl through cyclopentadiene. The final product was obtained via Grignard reaction.

The infrared and n.m.r. spectra were obtained in CCl_4 solvent. Tetramethylsilane was the internal standard in the n.m.r. analyses.

REACTIONS OF HYDRAZINE WITH ALKOXIDES

M. S. Bains

It has been reported (1, 2) that coordination complexes of titanium and zirconium alkoxides with hydrazine undergo further chemical reactions when they stand in solution and under vacuum with or without being heated. The reactions of boron and aluminium halides with hydrazine are noteworthy (3). Some of the results of further work on similar reactions of hydrazine with boron alkoxides and boric acid are briefly reported here.

Boron ethoxide and boron isopropoxide do not react with simple amines to give addition complexes of the type $B(OR)_3NR'_3$ where R′ = H or alkyl. In attempts to isolate complexes of boron alkoxides, compounds of hydrazine with boron methoxide and boron mixed methoxide were obtained (4) either when the base reacted with pure boron methoxide, or when boron ethoxide or boron isopropoxide was mixed with it in a large excess of methanol. In addition to these adducts the products $[B(OMe)_{2.5}]_2N_2H_3$, $[B(OPr^i)_{0.75}(OMe)_2]N_2H_{3.75}$, and $[B(OMe)_{2.3}]N_2H_{3.3}$ were isolated from the reaction of boron ethoxide or boron isopropoxide with the base in the presence of excess methanol (5). It appeared that stable adducts are obtained after the ethoxide and isopropoxide groups are replaced by methoxide groups, and subsequently elimination reactions that give these products take place. However, it has now been observed that when pure boron ethoxide or pure boron isopropoxide is mixed with anhydrous hydrazine no simple addition complex can be isolated; replacement of alkoxide groups by hydrazido groups has been observed. The analytical results of a few typical experiments are shown in Table I.

had a maximum at 3 725 Å and was 500 Å wide at half-height. A solution of 0.1186 *M* uranyl oxalate and 0.1210 *M* oxalic acid was used as the actinometer, and a CBS Laboratories type CL-1010 phototube was used to monitor the light intensities.

After irradiation, samples of the reaction mixture were injected into a gas–liquid chromatograph (g.l.c.) column with a microliter syringe and $C_{10}H_{14}$ determined. Benzophenone disappearance was measured by the standard spectrophotometric technique (7). The absorbencies were measured on a Cary spectrophotometer model 14M. For benzopinacol determination an aliquot of the reaction mixture was placed in a tube and the volatile part slowly pumped off. The residue was mixed with petroleum ether (b.p. 60–70°) and allowed to stand overnight. The residual crystalline solid was filtered, dried, and weighed. It was identified by its decomposition point (184°) and infrared spectrum.

Two methods were used to prepare the authentic samples of 3,3′-bicyclopentenyl. (*a*) A good yield for 3,3′-bicyclohexenyl has been reported in the reaction of *t*-butoxy radicals with cyclohexene. Accordingly, a mixture of di-*t*-butyl peroxide and cyclopentene in molar ratio 1:6 was degassed and sealed in a Carius tube and heated to 130° for 40 h. The reaction mixture was then distilled to give the desired fraction (b.p. 70° ± 2° at 18 mm). The yield was poor. (*b*) 3-Chlorocyclopentene was prepared by passing dry HCl through cyclopentadiene. The final product was obtained via Grignard reaction.

The infrared and n.m.r. spectra were obtained in CCl_4 solvent. Tetramethylsilane was the internal standard in the n.m.r. analyses.

REACTIONS OF HYDRAZINE WITH ALKOXIDES

M. S. Bains

It has been reported (1, 2) that coordination complexes of titanium and zirconium alkoxides with hydrazine undergo further chemical reactions when they stand in solution and under vacuum with or without being heated. The reactions of boron and aluminium halides with hydrazine are noteworthy (3). Some of the results of further work on similar reactions of hydrazine with boron alkoxides and boric acid are briefly reported here.

Boron ethoxide and boron isopropoxide do not react with simple amines to give addition complexes of the type $B(OR)_3NR'_3$ where R′ = H or alkyl. In attempts to isolate complexes of boron alkoxides, compounds of hydrazine with boron methoxide and boron mixed methoxide were obtained (4) either when the base reacted with pure boron methoxide, or when boron ethoxide or boron isopropoxide was mixed with it in a large excess of methanol. In addition to these adducts the products $[B(OMe)_{2.5}]_2N_2H_3$, $[B(OPr^i)_{0.75}(OMe)_2]N_2H_{3.75}$, and $[B(OMe)_{2.3}]N_2H_{3.3}$ were isolated from the reaction of boron ethoxide or boron isopropoxide with the base in the presence of excess methanol (5). It appeared that stable adducts are obtained after the ethoxide and isopropoxide groups are replaced by methoxide groups, and subsequently elimination reactions that give these products take place. However, it has now been observed that when pure boron ethoxide or pure boron isopropoxide is mixed with anhydrous hydrazine no simple addition complex can be isolated; replacement of alkoxide groups by hydrazido groups has been observed. The analytical results of a few typical experiments are shown in Table I.

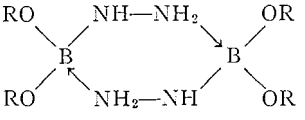
TABLE I

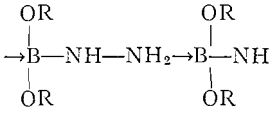
Reactions of boron alkoxides and of boric acid with hydrazine

Expt. No.	Reactants: Boron ethoxide, g	Reactants: Boron isopropoxide, g	Reactants: Boric acid, g	Reactants: Hydrazine, g	Product: Boron Found	Product: Boron Calcd.	Product: Hydrazine Found	Product: Hydrazine Calcd.	Empirical formula
1	3.9			2.0	8.39	8.19	24.05	24.24	$B(OEt)_2N_2H_3$
2	3.3			1.4	8.36	8.19	24.07	24.24	$B(OEt)_2N_2H_3$
3	2.1			2.1	9.68	9.54	28.40	28.17	$B(OEt)_{1.6}N_2H_{2.6}$
4		3.3		2.6	8.60	8.32	24.29	24.61	$B(OPr^i)_{1.5}N_2H_{2.5}$
5		5.9		1.7	10.90	10.82	32.26	32.00	$B(OPr^i)N_2H_2$
6		2.8		1.3	10.70	10.82	32.44	32.00	$B(OPr^i)N_2H_2$
7			10.0	6.0	14.51	14.48	40.00	40.10	$B(OH)_2N_2H_3$
8			4.0	2.5	26.20	26.19	38.10	38.19	$B_2(OH)_2N_2$
9			1.1	1.2	19.05	19.10	55.25	55.50	$B(OH)N_2H_2$



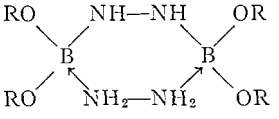
One alkoxide group of boron ethoxide and two alkoxide groups of boron isopropoxide are replaced at room temperature under vacuum (1 mm Hg). It is also significant that the product $B(OEt)_2N_2H_3$ on azeotropic distillation with benzene lost a molecule of hydrazine giving a product $[B(OEt)_2]_2N_2H_2$. This may also signify that the product $B(OEt)_2N_2H_3$ contains a hydrazine of solvolysis according to the formula $[B(OEt)_2]_2N_2H_2.N_2H_4$. Further heating of the product $[B(OEt)_2]_2N_2H_2$ to 200 °C and under vacuum of 0.2 mm Hg resulted in the elimination of a molecule of alcohol per boron atom, the final product having the composition $(BOEt)_2N_2$ with possible B=N double bonds.

Hydrazine also reacts with boric acid, with the elimination of water and the introduction of B—N bonds. The products obtained are given in Table I.



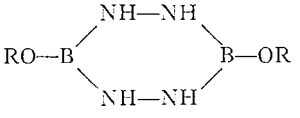
A brief comment on these results may be appropriate. It is well established that the B—N bond is fairly stable and is formed at the expense of B—H, B—X (X = halogen), B—C, and B—O bonds (6). In this context the compounds reported above are quite likely to be formed. These products are not soluble in inert organic solvents, therefore their molecular weights could not be determined; this may mean that the products are polymeric.

The following tentative structures proposed for the products of different general composition as given in the following four categories would emphasize the significance of these results.

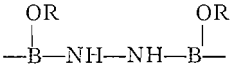


(i) For $B(OR)_2N_2H_3$

(I)

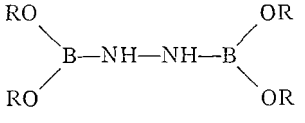


(II)



(III)

(ii) For $B(OR)N_2H_2$



(IV)

(V)

(iii) For $B_2(OR)_4N_2H_2$

(VI)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(iv) For $B_2(OR)_2N_2$

(VII) (VIII)

All these types of products where R may be alkyl or H have been isolated. Due to boron acceptor and nitrogen donor atoms these products may be further polymerized. The formula VIII may, however, not be feasible on grounds of hybridization.

An ethereal solution of anhydrous hydrazine and titanium isopropoxide takes on a violet coloration, the color deepening with time. The reaction

$$4Ti(OPr^i)_4 + N_2H_4 \rightarrow 4Ti(OPr^i)_3 + 4Pr^iOH + N_2$$

accounts for the development of color and may be the result of a trace of titanium(III). However, a mixture of titanium isopropoxide and hydrazine in benzene or toluene turned deep violet when heated under reflux. When the volatile constituents were distilled off under high vacuum a brownish solid was obtained. The titanium content of such products in four experiments was 33–35%, conforming to the formula $(Pr^iO)TiN_2H$. Furthermore, when hydrazine and titanium isopropoxide were heated together and the temperature raised gradually in the absence of any solvent, an explosive reaction took place at about 130 °C bath temperature.

TABLE II

Reaction of zirconium isopropoxide isopropylate with hydrazine

Expt. No.	Volume of ether, ml	Reactants: Zirconium isopropoxide isopropylate, g	Reactants: Hydrazine, g	Product: Zirconium Found	Product: Zirconium Calcd.	Product: Empirical formula
1	150	4.0	1.0	52.5	50.9	$Zr(OPr^i)N_2H$
2	100	7.1	1.0	39.0	38.9	$Zr(OPr^i)_2N_2H_2$

These experiments pointed to the introduction of metal–nitrogen bonds. The following experiment is very instructive in this connection.

Tetrakis(diethylamide)titanium (2 g) was treated with an almost stoichiometric amount of anhydrous hydrazine in ether solution. After the reaction mixture had stood for some time, high vacuum was applied to remove ether and any other volatile materials. After this distillation of ether, when the flask and its contents were still cold, a violent explosion took place. The probable reaction appears to be the following

$$Ti(NEt_2)_4 + N_2H_4 \rightarrow TiN_2 + 4Et_2NH \text{ (explodes)}.$$

For zirconium isopropoxide isopropylate ($Zr(OPr^i)_4Pr^iOH$) and excess hydrazine the results are given in Table II. In the second experiment, since the volume of the solution was less and the concentration of isopropoxide was relatively high, the equilibrium of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the reaction, which is reversible, moved toward the left, and therefore a small number of isopropoxide groups were replaced.

$$Zr(OPr^i)_4Pr^iOH + N_2H_4 \rightleftharpoons Zr(Pr^iO)_{4-n}N_2H_{4-n} + (n+1)Pr^iOH$$

These reactions with titanium and zirconium isopropoxide are remarkable, since amines do not generally displace alkoxide groups whereas alcohols very readily displace amines from dialkylamino derivatives (7). The reactions present an analogy with those between metal chloride and ammonia and metal chloride and hydrazine (8, 9) and they suggest that alkoxide groups are replaced by hydrazine to give products of the general composition $M(OR)_{4-n}N_2H_{4-n}$. Further work to elucidate these reactions and the structure of the products is in progress.

It should be noted that experiments with transition metal alkoxides may result in explosions and therefore caution is necessary. The work with boron compounds is safe, however, and explosions were neither expected nor observed.

HYDROXYL PROTON MAGNETIC RESONANCE IN RELATION TO RING SIZE, SUBSTITUENT GROUPS, AND MUTAROTATION OF CARBOHYDRATES[1]

A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received July 13, 1965

ABSTRACT

Some magnetic resonance properties of hydroxyl protons are described for a variety of sugars and derivatives in dimethyl sulfoxide. Spectral information of this kind is shown to be useful, particularly for differentiating between certain types of interconvertible molecular species. For example, a reducing sugar may be characterized as pyranose or furanose depending upon whether it exhibits a resonance signal that can be ascribed to OH-4 or OH-5, respectively. According to the data obtained, α-D-glucose, α-D-xylose, β-D-arabinose, α-D-lyxose, and α- and β-D-ribose are pyranoses when freshly dissolved, whereas the 2,3-carbonate of D-mannose or D-lyxose is in a furanose form. Selective deuteration and spin decoupling were of primary importance in making some of the spectral assignments.

Although arabinose, ribose, and galactose exist partly as furanoses in mutarotated aqueous solutions, their tendency to adopt the structure of the five-membered ring is much greater in dimethyl sulfoxide. Such variability may be due to an interplay of effects; for example, the furanose forms are relatively stable, but this property is masked in water by preferential solvent stabilization of the pyranose structures.

Depending on the number and kinds of hydroxyl proton signals detected, it is possible to distinguish between cyclic and acyclic forms of certain sugar derivatives, as illustrated with hydrazones and with dialdehydes obtained by oxidative glycol scission. Hydroxyl proton magnetic resonance data are of value also for characterizing partially acetylated sugars.

INTRODUCTION

Hydroxyl protons of alcohols dissolved in dimethyl sulfoxide give magnetic resonance signals that, in contrast to their properties in the more common nuclear magnetic resonance (n.m.r.) solvents, are generally well resolved and permit the detection of spin–spin splitting (1).[2] The anomeric hydroxyl groups of sugars are characterized by resonance at lower field than the other hydroxyl groups (1, 2), and their signals should be of value in assigning configuration and in determining the composition of anomeric mixtures of reducing sugars (2).

The current study utilizes the magnetic resonance characteristics of hydroxyl protons mainly to derive some information about compounds capable of adopting more than one type of structure. Thus attention is centered on reducing sugars that may exist in both pyranose and furanose forms, and on certain carbohydrate derivatives that can be described by cyclic or acyclic formulae. A related application is the use of hydroxyl proton magnetic resonance spectroscopy in the structural elucidation of partially acetylated sugars, compounds that may suffer acyl migration when examined by chemical methods.

[1]*Issued as N.R.C. No. 8791.*

[2]*See, however, a recent communication by J. G. Trayham and G. A. Knesel, J. Am. Chem. Soc. 87, 4220 (1965), and also the Experimental section.*

In addition, some comments are made on the equilibration of reducing sugars in dimethyl sulfoxide as compared with their well-known mutarotation characteristics in water.

Ring Size of Reducing Sugars

It is not always easy to determine the ring size of reducing sugars and derivatives. X-ray crystallography has firmly established that several sugars are pyranoid in the crystalline state (see ref. 3), and there is a great deal of evidence showing that pyranose forms also predominate when these sugars are dissolved (4–6). A particularly facile demonstration of the pyranose structure of α-D-glucose in dimethyl sulfoxide solution is provided by hydroxyl proton resonance data (Fig. 1).[3]

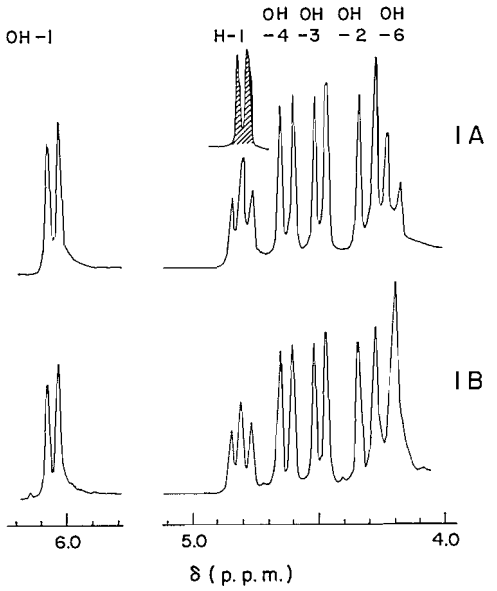

FIG. 1. Partial n.m.r. spectra at 100 Mc.p.s. of (A) α-D-glucose and (B) α-D-glucose-5,6,6′-d_3 in dimethyl sulfoxide solution, showing hydroxyl proton signals (OH) and the anomeric proton signal (H-1). The inset doublet in A represents the only signal (H-1) detected after the addition of deuterium oxide to the solution.

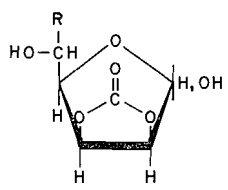
In the region of the spectrum shown, five of the six signals are attributable to hydroxyl protons since they no longer appear after deuterium oxide is introduced. The remaining signal, initially a triplet, collapses to a doublet (inset). Since it is the most strongly deshielded of the protons bonded to carbon, and also since it is coupled with the hydroxyl proton giving a doublet at lowest field, i.e. OH-1 (1, 2), it can be ascribed to H-1 (7). The other three doublets (Fig. 1A) are signals of secondary hydroxyl protons, i.e. OH-2, OH-3, and either OH-4 (pyranose ring) or OH-5 (furanose ring). By using a sample deuterated at position 5, a clear choice between the latter two alternatives is possible. Thus, if one of these three doublets is caused by OH-5 rather than by OH-4, it should be replaced in the spectrum of the deuterated sample by a strongly modified signal, most likely a broad singlet.[4] α-D-Glucose-5,6,6′-d_3 (8) was utilized for this purpose, and as seen in Fig. 1B, the

[3]*The spectrum (Fig. 1A) is the same irrespective of whether the solution is prepared from the crystalline sugar directly or from a syrup obtained by concentrating a fresh aqueous solution of the sugar.*

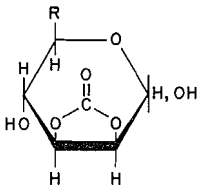
[4]*This effect was cross-checked by comparing the spectrum of 1,2-O-isopropylidene-α-D-glucofuranose in dimethyl sulfoxide with that of the compound deuterated at position 5 (8); the latter gave a singlet in place of one of the doublets exhibited by the undeuterated compound.*



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

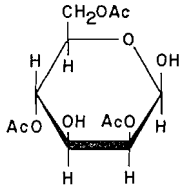
signals for its secondary hydroxyl groups are the same as those shown in Fig. 1A. This shows that the 5 position must be engaged in forming the pyranose ring. In addition, the presence of a broad singlet at 4.20 p.p.m.[5] in Fig. 1B establishes that the high-field triplet in Fig. 1A is caused by the hydroxyl proton of the primary carbinol group.[6]

Assignments in Fig. 1A for signals of the 2, 3, and 4 hydroxyl groups are based on double-resonance experiments (11, 12), frequency-swept spin decoupling being employed and dimethyl sulfoxide-d_6 being used as the solvent. Signals for the protons bonded to carbons 2, 3, and 4 (not shown in Fig. 1), which are not well shifted from each other, were also first located with the aid of the spin-decoupling technique. Each of these protons was then irradiated in turn at the appropriate resonance frequency, causing one or another of the hydroxyl proton doublets to become wholly, or largely, spin decoupled.



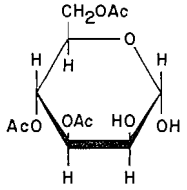
α-D-Xylose exhibits four well-resolved hydroxyl proton doublets that correspond closely both in chemical shift and spacings to hydroxyl protons 1 to 4 of α-D-glucose. Aside from the apparent similarity in molecular architecture between the pentose and hexose, this evidence that the compound has four secondary hydroxyl groups (1) shows clearly that α-D-xylose is a pyranose sugar in dimethyl sulfoxide solution. In this respect, the spectra of α-D-lyxose and β-D-arabinose are also in accord with a pyranose structure for each of these pentoses when first dissolved in dimethyl sulfoxide (however, see below).

An additional problem involving ring size, for which hydroxyl proton magnetic resonance data have proven useful, concerns the preferred size of the sugar ring in some fused-ring derivatives. In an earlier study (13) it was noted that, although D-mannose 2,3-carbonate (I) and related compounds behave chemically as furanose sugars (and certain n.m.r. data support this assignment), the observed coupling between H-3 and H-4 (ca. 3.2 c.p.s.) appears to favor a pyranose (IB) rather than a furanose (IA) structure, if the Karplus curve (7, 14, 15) is closely applicable for compounds of this type. However, the furanose structure has now been confirmed by taking into account hydroxyl proton resonance data.



IA (R=CH_2OH)

IIA (R=H)



IB (R=CH_2OH)

IIB (R=H)

III

IV

The spectrum of I in dimethyl sulfoxide is very similar to that already presented (13) for the compound in deuterium oxide, aside mainly from the added presence of hydroxyl proton signals (two doublets and a triplet). Of particular note is the absence of detectable coupling between H-4 and a hydroxyl group, since H-4 gives virtually the same quartet signal with either solvent, and since this signal is unaffected when deuterium oxide is

[5]*See Experimental section for the basis of the chemical shift values.*

[6]*For a relatively large and diverse group of known compounds examined during this study, the signal ascribable to the proton of a primary hydroxyl group has almost invariably appeared as a triplet. However, n.m.r. spectroscopy has amply confirmed (see ref. 9) that the methylene protons of such groups in sugar molecules usually are magnetically non-equivalent. Since the hydroxyl proton thus constitutes the X part of an ABX system (10), there is the likelihood that a quartet or higher multiplet will be encountered in some instances. Although the presence of a hydroxyl proton triplet or higher multiplet in a spectrum is itself indicative of a primary carbinol group, detection of coupling between that proton and the α-methylene protons is a more rigorous criterion (see below).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

added to the dimethyl sulfoxide solution. Although this clearly indicates that there cannot be a free hydroxyl group at position 4 of I, it is not equally evident that H-5 *is* coupled with a hydroxyl group, because its signal is obscured by those of the 6 protons. However, such coupling was readily demonstrable with the 6-*O*-trityl derivative of I (13) by using the double-resonance technique. In the spectrum of this derivative (Fig. 2) the appearance

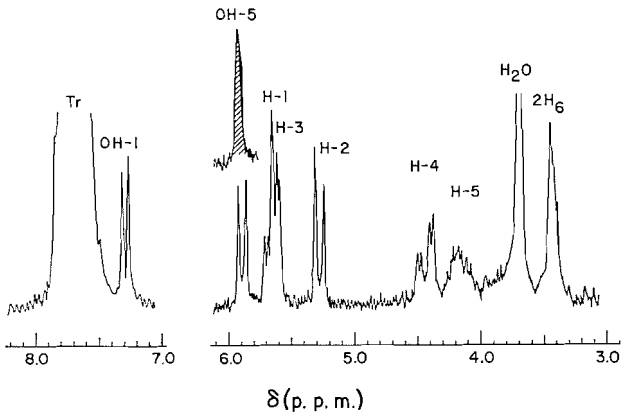


FIG. 2. The n.m.r. spectrum at 100 Mc.p.s. of 6-*O*-trityl-D-mannose 2,3-carbonate in dimethyl sulfoxide-d_6, with tetramethylsilane, contained in a coaxial capillary, as reference. The assignments are based on those reported in ref. 13. The inset signal illustrates the effect on the hydroxyl proton doublet at 5.9 p.p.m. of spin decoupling by irradiation at the resonance frequency of H-5 (Tr = protons of trityl group).

of the H-4 and most other signals is essentially the same as that in the spectrum of I itself, but the H-5 signal is well isolated. By irradiating at the resonance frequency of this proton the doublet at 5.9 p.p.m. is spin decoupled, appearing as a broad singlet (inset). These overall data obviously are not consistent with the pyranose structure (IB), and permit the conclusion that the bicyclic sugar derivative is furanose (IA).

Hydroxyl proton resonance data also help to demonstrate that a related compound, D-lyxose 2,3-carbonate (II) (16), contains a furanose ring. The spectrum of II closely resembles that of I (both in deuterium oxide and dimethyl sulfoxide), again giving an apparent value for $J_{3,4}$ of 3.3 c.p.s. As seen from Fig. 3B and its deuterium-exchanged counterpart (Fig. 3A) the pentose carbonate gives rise to a triplet caused by a hydroxy proton (at 4.9 p.p.m. in Fig. 3B). Furthermore, the C-5 methylene protons show coupling with a hydroxyl group (Fig. 3B) that is removed on addition of deuterium oxide (Fig. 3A). Therefore, the primary carbinol group in II must be free and the sugar can accordingly be ascribed a furanose structure (IIA).

Spectra of Partially Acetylated Derivatives

Hydroxyl protons resonate in dimethyl sulfoxide at lower field than do most protons that are bonded to carbon atoms of sugar molecules. With derivatives containing strongly deshielding substituent groups (e.g. acetyl), both OH and CH signals are found in the same region of the spectrum, but they then can readily be differentiated by "cancelling out" through the addition of deuterium oxide (1). For example, in the spectra of 1,2,3,4- and 1,3,4,6-tetra-*O*-acetyl-α-D-glucose and 1,2,3,6-tetra-*O*-acetyl-β-D-glucose, OH and CH signals are found in close proximity, but, on addition of deuterium oxide, a doublet is removed from each of the latter two spectra and a triplet from that of the 1,2,3,4 derivative. This clearly confirms the presence of a free primary carbinol group in the one instance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

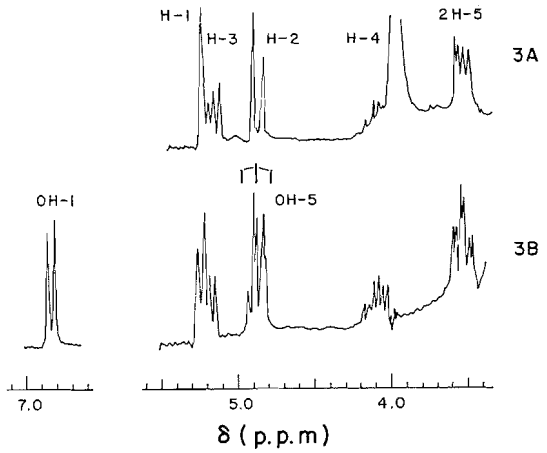

FIG. 3. The n.m.r. spectra at 100 Mc.p.s. of D-lyxose 2,3-carbonate in dimethyl sulfoxide (B) before and (A) after the addition of deuterium oxide to the solution (OH = hydroxyl proton).

and, at least, that the unacetylated hydroxyl group in each of the other two tetraacetates is secondary.[7]

An examination of two tri-*O*-acetyl-D-mannoses illustrates how OH and CH data can supplement each other in defining structure. Earlier, these triacetates were assigned the β-2,4,6 (III) and α-3,4,6 (IV) structures, respectively, mainly on the basis of chemical properties (17). The spectrum of III (Fig. 4B and, after addition of deuterium oxide,

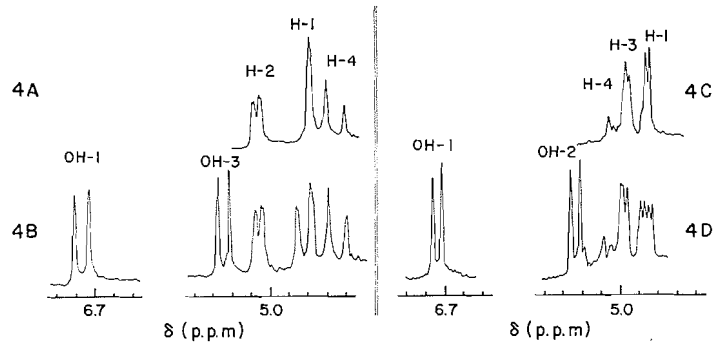

FIG. 4. Partial n.m.r. spectra at 100 Mc.p.s. of 2,4,6-tri-*O*-acetyl-β-D-mannose in dimethyl sulfoxide (B) before and (A) after the addition of deuterium oxide to the solution, and of 3,4,6-tri-*O*-acetyl-α-D-mannose in dimethyl sulfoxide (D) before and (C) after the addition of deuterium oxide (OH = hydroxyl proton).

Fig. 4A) shows the presence of two hydroxyl proton doublets. That at lower field is ascribed to OH-1 because of its location; also, it has the same spacing (7.4 c.p.s.) as the signal at 4.78 p.p.m. (Fig. 4A; 4.82 p.p.m. in Fig. 4B), which, because of its location at relatively low field for a proton bonded to carbon, undoubtedly is that of H-1. Since the anomeric position is free and the primary carbinol group is substituted (only OH doublets are detected), the two CH signals remaining unchanged in going from Fig. 4B to Fig. 4A must be those of protons alpha to secondary acetoxyl groups. The proton exhibiting a

[7]*Such information is rendered particularly accessible by the fact that dimethyl sulfoxide is a very good solvent for compounds of this type.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

quartet at 5.05 p.p.m. shows weak coupling with H-1 and hence is H-2, but since it is not coupled with the doublet at 4.65 p.p.m., the latter can only be on the nonadjacent carbon atom-4 (if one assumes a pyranose ring). This confirms that III is a 2,4,6-triacetate.

Similarly, the spectrum of IV shows that OH-1 in this compound is unsubstituted and that the other free hydroxyl group is secondary. The doublet at 4.99 p.p.m. (spacing of 2.2 c.p.s.) and the broad multiplet that overlaps it must be caused by protons alpha to acetoxyl groups. Since neither is coupled with H-1 (spacing of 1.5 c.p.s.), these signals can be ascribed to H-3 and H-4. A choice between these two follows from the fact that the observed spacing (2.2 c.p.s.) for the doublet is close to that expected for H-3, but far too small for H-4 in the D-*manno* series (7). Hence, these data confirm that IV is the 3,4,6-triacetate. An additional point to be noted in Fig. 4 is that OH-1 splittings are 7.5 and 4.5 c.p.s. for III and IV, respectively. These values are close to those for β-D-mannose (7.9 c.p.s.) and α-D-mannose (4.3 c.p.s.), respectively, in agreement with assignments made on the basis of rotational data (17). In these instances, the corresponding values for H-1 splitting (7) are all much smaller (1.0–1.5 c.p.s.) and hence less satisfactory for configurational assignments. Relative chemical shifts for the OH-1 signals are less reliable for the purpose because of differences in the proximity of each anomeric center to the acetoxyl groups.

Cyclic vs. Acyclic Forms

Hydroxyl proton magnetic resonance spectra may be of value in differentiating between cyclic and acyclic forms of compounds. Hydrazones, for example, may be depicted in either of these forms (18, 19) and, although they may be distinguished chemically (18, 19), the number of hydroxyl proton signals displayed should provide a simple, independent diagnosis. Several hydrazones examined during the current study were found to exist in dimethyl sulfoxide as acyclic compounds. Thus, D-erythrose-2,5-dichlorophenylhydrazone shows two doublets (OH-2 and OH-3) and a triplet (OH-4), and D-fucose-*p*-toluenesulfonylhydrazone shows four doublets (OH-2 to OH-5). The hydroxyl proton signals given by D-mannose-phenylhydrazone are too closely grouped to distinguish individually, but the total integral of these signals (relative to that of the phenyl protons) corresponds to the presence of five free hydroxyl groups. As pointed out in a recent study of acetylated hydrazones (20), the acyclic form of these compounds is characterized by a low-field signal caused by the C-1 formyl proton which, however, is sometimes obscured by resonance signals for the aromatic protons. An additional type of signal clearly observable in the above-mentioned spectra of the unsubstituted hydrazones is that of the NH groups, which was found in the region of 8.5–9.5 p.p.m. Accordingly, these signals no longer were produced after the addition of deuterium oxide.[8]

Dialdehydes formed by oxidative glycol scission of cyclic carbohydrate derivatives are easily hydrated and tend to exist predominantly in forms such as hemialdals, hydrates, or internal hemiacetals (21, 22). The dialdehyde V, produced by cleaving the 2,3-diol group of 4,6-*O*-benzylidene methyl α-D-glucopyranoside and its stereoisomers (21, 23, 24), forms a crystalline dihydrate. Although the latter may be depicted as in VI, its chemical properties are best accounted for by a hemialdal (VII) monohydrate structure (21, 23). The n.m.r. spectrum of the compound in dimethyl sulfoxide (Fig. 5A) clearly favors the latter formulation, since it contains two hydroxyl proton doublets (at 6.74 and 6.80 p.p.m., respectively), whereas the *gem*-diol groups of VI require the presence of four hydroxyl proton doublets.

[8]*However, the* NH *group of* D-*erythrose-2,5-dichlorophenylhydrazone was found to exchange with the deuterium much more slowly than the* NH *group of the other hydrazones.*

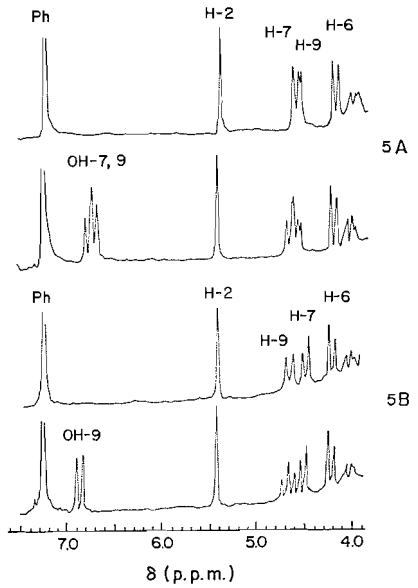

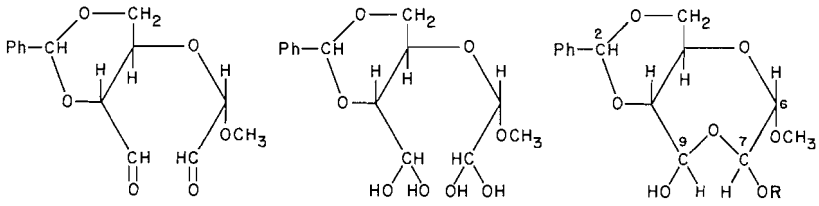

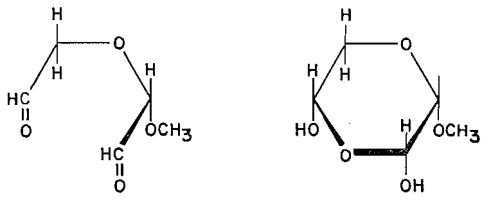

FIG. 5. Partial n.m.r. spectra at 100 Mc.p.s of (A) hemialdal VII and (B) hemialdal ethanolate VIII in dimethyl sulfoxide. The upper portions of A and B show the signals displayed after the addition of deuterium oxide to the two solutions (OH = hydroxyl proton; Ph and H-2 represent the aryl and alkyl protons, respectively, of the benzylidene grouping).

By treating the hemialdal VII with various alcohols crystalline alcoholates are produced (23). These may be depicted as in VIII or, alternatively, by an isomer in which the OR group is at position 9 (22). In accord with this type of structure, the methyl or ethyl derivative, examined in the present study, shows only one hydroxyl doublet (Fig. 5B). By deuterium exchange, the proton alpha to this hydroxyl group (H-9) is accounted for and a doublet at 4.54 p.p.m., not present in Fig. 5A, can be attributed to the proton alpha to the OR group of VIII. This latter proton shows coupling with a proton giving the doublet at 4.25 p.p.m., which is undoubtedly H-6. Hence the dialdehyde methanolate and ethanolate

may, in fact, be represented by VIII, in which the alkoxyl group is at position 7 and the free hydroxyl group at C-9. However, at least one other isomer of each alcoholate is formed in minor proportion, as shown by an examination of the total solvolysis products.

Among other dialdehydes examined are those (IX) derived by oxidative scission of the 2,3,4-triol grouping in methyl pentopyranosides (22, 25). These also are thought to exist as hemialdals (e.g. X) when hydrated, with those derived from a pair of anomers constituting mirror-image forms (22). However, based on the properties of *p*-nitrobenzoate derivatives of the hemialdals, it has been suggested recently that the mirror-image relationship is no longer a tenable concept (26). The current spectral data are nevertheless entirely compatible with the earlier view. Thus the two products obtained by treating methyl α- and β-D-xylopyranosides with 2 molar equivalents of periodic acid (25) give n.m.r. spectra that are indistinguishable. When the freshly prepared, syrupy products are dissolved in dimethyl sulfoxide, signals attributable to hydroxyl protons are detected (Fig. 6A), but they are not well resolved and are broadly dispersed, showing that a mixture

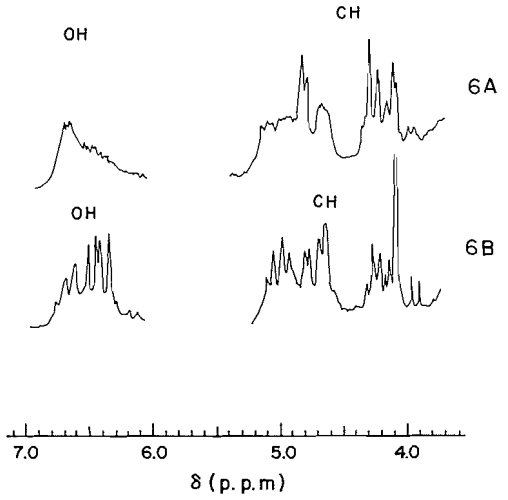

FIG. 6. Partial n.m.r. spectra at 100 Mc.p.s. of the syrupy product obtained by concentrating an aqueous solution of dialdehyde IX prepared from either methyl α- or β-D-xylopyranoside (A) after a few minutes in dimethyl sulfoxide and (B) after 4 days in dimethyl sulfoxide (OH = hydroxyl protons; CH = protons bonded to carbon).

of forms is present. Signals for other protons also display a highly complex pattern. The resolution is considerably improved when the solutions are stored in dimethyl sulfoxide (Fig. 6B) and when, as shown by the changes in the relative intensity of the signals, the composition of the mixture changes markedly. Although the observed changes and the multiplicity of signals make analysis of these spectra difficult, they nevertheless provide a large number of points of reference for comparing the products obtained from the two anomers. On this basis, the oxidation products cannot be differentiated and hence must be regarded as enantiomeric, with each being composed of the same mixture of stereoisomers. To these observations may be added the fact that, when the anomeric D-xylosides are treated in deuterium oxide with 2 molar equivalents of sodium metaperiodate, the spectra of their oxidation products are found to be highly complex but, again, indistinguishable.

Anomeric Composition and Mutarotation

The slow mutarotation of reducing sugars in dimethyl sulfoxide facilitates estimation of mixtures of anomers (2). By the same token, the spectrum of a reducing sugar in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

solvent provides a good criterion of the sample's anomeric purity. In this respect, several crystalline compounds examined during the current study were found to consist of mixtures. Usually one component greatly predominated, but in some instances a substantial proportion of each anomer was detected. For example, 3,4-*O*-isopropylidene-2-*O*-methyl-D-arabinose (27), recently described in an analytically pure, crystalline form (28), shows no detectable mutarotation in water, methanol, or chloroform. According to the spectrum of the compound in dimethyl sulfoxide this anomalous behavior can now be attributed to co-crystallization of both anomers; thus, their ratio in the freshly prepared solution was about the same as that after the sugar had first been dissolved in water. Similarly, samples of D-glucose that had been crystallized from a mixture of methanol and isopropanol were found to contain both anomers, with the β-anomer generally predominant.

Some characteristics of the equilibration of reducing sugars in dimethyl sulfoxide deserve comment. Of particular note is the fact that solutions of D-galactose, D-arabinose, and D-ribose show at least three different hydroxyl proton signals that may be attributed to anomeric protons, whereas D-glucose or D-mannose shows, at most, two such low-field signals. These observations are perhaps not surprising in view of the complex way in which the former sugars mutarotate in water (6), behavior that has been ascribed to the existence of furanose forms together with the anomeric pyranoses in the solutions.

When β-D-arabinose is dissolved in dimethyl sulfoxide each of the hydroxyl groups displays a doublet, consistent with a pyranose structure, as noted above. The anomeric hydroxyl proton resonates at 5.88 p.p.m., but in 24 h a relatively strong overlapping signal is found at 5.94 p.p.m. and a more minor OH-1 resonance at 6.23 p.p.m. In 4 days (Fig. 7A) the latter signal (ascribed to the α-pyranose form) is only slightly more prominent, although it is the major OH-1 signal when the sugar has mutarotated in water (Fig. 7B). The other new signal (ascribed to a furanose form) becomes a main component of the spectrum (Fig. 7A), but represents a trace constituent of the material transferred

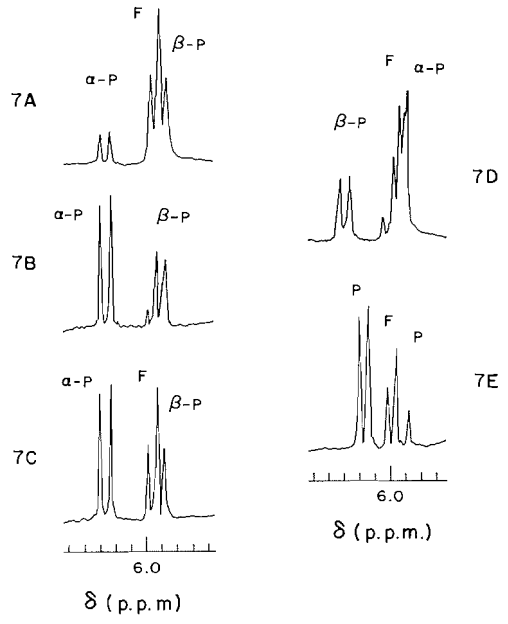

FIG. 7. Partial n.m.r. spectra at 100 Mc.p.s. of (A) D-arabinose, after 4 days in dimethyl sulfoxide; (B) D-arabinose, fresh solution in dimethyl sulfoxide of syrup obtained by concentrating a mutarotated aqueous solution of the sugar; (C) sample B, 2 days later; (D) D-galactose, after 4 days in dimethyl sulfoxide; and (E) D-ribose, after 4 days in dimethyl sulfoxide.

from the aqueous solution (Fig. 7B), although when the latter sample is stored in dimethyl sulfoxide this signal again becomes very prominent (Fig. 7C). The assignments that are made are supported by an examination of the signals for other hydroxyl protons (not shown) which were displayed by solutions of D-arabinose and D-arabinose-5,5′-d_2 and which had the compositions represented by Figs. 7B and 7C. With the undeuterated sample, a signal at 4.52 p.p.m. becomes more complex and intense as the proportion of the presumed furanose form increases. In the spectrum of the deuterated sugar, however, a sharp singlet develops in this region. This shows that the primary carbinol group is liberated as the OH-1 signal at 5.94 p.p.m. becomes more prominent, and hence that the latter is caused by D-arabinofuranose.

Spectral changes closely similar to those for D-arabinose are found with D-galactose (e.g. Fig. 7D; also, the spectrum of the mixture obtained after mutarotation in water strongly resembles that shown in Fig. 7B, except that the pyranose anomeric designations are reversed). Different samples of D-ribose were found to be initially mixtures of two anomers. Although a number of the hydroxyl proton signals overlap in the spectrum of these mixtures, there was no evidence of the presence of a primary carbinol multiplet; therefore, both anomers that were detected are presumed to be pyranoses. Hence, a third OH-1 signal that slowly becomes evident (shown in Fig. 7E) is probably that of D-ribofuranose and, in accord with this likelihood, its appearance is accompanied by that of a triplet at 4.36 p.p.m.

In general, pyranose forms of reducing sugars greatly predominate over furanose forms in aqueous solution. One factor that may contribute substantially to this difference is the relatively satisfactory way in which a pyranose chair can fit into the tridymite structure of water, particularly when the hydroxyl groups are equatorially oriented (30). In addition, if two sugars such as D-glucose and D-galactose are compared, the former is regarded as the *more* stable in a pyranose conformation but the less stable in a furanose conformation (see ref. 29 for a recent discussion of these factors). Therefore, of these two sugars, D-galactose (and similarly D-arabinose) is more likely to exist in a furanose form than is D-glucose. According to the present findings, furanose forms are particularly prominent in dimethyl sulfoxide for those sugars showing complex mutarotation in water. Although dimethyl sulfoxide also is strongly hydrogen bonding, its chain-like structure (31, 32) appears unlikely to favor the stabilization of one form of a sugar over another. Hence, if a particular sugar is "inherently" relatively stable in a furanose form, this fact should become more evident with dimethyl sulfoxide as the solvent than with water.

Other observations appear to be consistent with the possibility of an interplay of effects of this kind. Thus, although hemialdal X appears to prefer one particular conformation in dimethyl sulfoxide, the spectrum of the compound when first transferred from water (Fig. 6A) shows that other forms are dominant initially. Effects such as these suggest that dimethyl sulfoxide, or other solvents, might provide some specific advantage as a medium for comparing the conformational stability of interconvertible forms, by minimizing orienting effects caused by the structure of water itself.

EXPERIMENTAL

Proton magnetic resonance data were recorded with a Varian-100 high-resolution spectrometer. Unless otherwise specified, dimethyl sulfoxide, dried by storage over anhydrous calcium sulfate or by distillation, was used as the solvent. The signal for the methyl protons of the solvent served as a reference signal for the internally stabilized lock system of the spectrometer. For a solution of dimethyl sulfoxide and tetramethylsilane in carbon tetrachloride this signal is 249 c.p.s. downfield from that of the tetramethylsilane protons. Accordingly, all reported chemical shift values are 2.5 p.p.m. (250 c.p.s.) larger than the values actually recorded.

For personal use only.

The concentration of solute was generally 25–50 mg/ml of solvent.

On a few occasions, resonance signals expected for hydroxyl protons were not detected, or the signals were poorly resolved. These effects could usually be attributed to the presence of traces of acid in the sample, particularly with syrupy compounds. In such instances, the dimethyl sulfoxide solution was diluted with water and then treated with a slight excess of ammonia, after which the water and excess of base were removed *in vacuo* at 40 °C.

Materials

Most of the compounds examined in the current study were prepared in this laboratory during the course of other studies, e.g. α-D-glucose-5,6,6′-d_3 (8), D-mannose 2,3-carbonate (13), D-lyxose 2,3-carbonate (16), 2,4,6-tri-*O*-acetyl-β-D-mannose and 3,4,6-tri-*O*-acetyl-α-D-mannose (17), D-erythrose 2,5-dichlorophenylhydrazone (33), and dialdehyde V (22).

Dialdehydes of type X were prepared by oxidizing methyl α- and β-D-xylopyranosides with periodic acid according to ref. 23, except that formic and iodic acids and the excess of the oxidant were removed by use of Dowex-1 (bicarbonate form).

1,2-O-Isopropylidene-β-D-arabinofuranose-5,5′-d_2

1,2-*O*-Isopropylidene-β-D-arabinofuranuronic acid methyl ester (34) (0.15 g) was reduced (35) by slow addition to a solution of sodium borodeuteride (Merck, Sharp and Dohme) (0.10 g) in ice water (3 ml). After 5 h the reaction mixture was treated with Amberlite IR-120 (H^+) and Dowex-1 (bicarbonate form), and concentrated; then residual boric acid was removed as the volatile methyl ester. The product solidified (yield, 0.10 g) and was recrystallized from ethyl acetate – hexane, m.p. 113–116 °C, $[\alpha]_D$ +26° (*c*, 0.9 in water).

Anal. Calcd. for $C_8H_{12}D_2O_5$: C, 50.0. Found: C, 49.8.

In accord with the assigned structure, the n.m.r. spectrum of the compound in deuterium oxide showed the presence of the isopropylidene group (singlets at 1.80 and 1.97 p.p.m.), and signals attributable to protons 1 to 4 at 6.44, 5.10, 4.64, and 4.52 p.p.m. (relative to tetramethylsilane as an external coaxial reference).

D-*Arabinose-5,5′-d_2*

The *O*-isopropylidene derivative (40 mg) was hydrolyzed with 0.1 *N* sulfuric acid (5 ml) on the steam bath for 3 h; the solution was neutralized with Dowex-1 (bicarbonate form), and concentrated to dryness. The n.m.r. spectrum of the syrupy product, freshly dissolved in dimethyl sulfoxide, was virtually indistinguishable from that of the syrup obtained by concentrating a mutarotated aqueous solution of D-arabinose.

ACKNOWLEDGMENTS

The author expresses his gratitude to M. Mazurek, who recorded the n.m.r. spectra, and to Drs. J. C. MacDonald and A. P. Tulloch, who drew the author's attention to the publications listed herein as refs. 1 and 2.

ELECTRON SPIN RESONANCE STUDIES OF PHOTOLYTICALLY GENERATED AROMATIC KETYLS

RAYMOND WILSON[1]
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received August 31, 1965

ABSTRACT

Electron spin resonance observations on the photolytically generated ketyls of benzaldehyde, acetophenone, and benzophenone in protic solvents are reported. Proton coupling constants differ considerably from those reported by other workers for the same ketyls generated by other methods in aprotic solvents.

Molecular orbital calculations of unpaired electron spin densities, in which the effective electronegativities of the oxygen atoms on the ketyls are assumed to be increased by hydrogen bonding in protic solvents, are reported. The calculated changes in spin densities agree qualitatively with the semi-empirical changes calculated by the McConnell relationship.

Observations on the dynamics of solvation of the benzaldehyde ketyl in a mixture of a protic and an aprotic solvent are reported and discussed.

INTRODUCTION

Previous publications (1, 2) have reported electron spin resonance (e.s.r.) studies on the ketyls of benzophenone and fluorenone and on many nitrobenzene radical anions generated by the photolysis of alkaline aqueous ethanolic or methanolic solutions. The mechanism by which these radical anions are formed is suggested by the flash photolysis work of Porter and Wilkinson on benzophenone (3). Benzophenone is excited by ultraviolet radiation (3 300 Å) to the singlet state, which then undergoes a radiationless transition to the triplet state.

[1] $$(C_6H_5)_2CO \xrightarrow{h\nu} (C_6H_5)_2\overset{*}{C}O \text{ (singlet)}$$

[2] $$(C_6H_5)_2\overset{*}{C}O \text{ (singlet)} \rightarrow (C_6H_5)_2\overset{*}{C}O \text{ (triplet)}$$

Benzophenone in the triplet state quite readily abstracts hydrogen atoms from suitable solvents to give the ketyl radical.

[3] $$(C_6H_5)_2\overset{*}{C}O \text{ (triplet)} + RH \rightarrow (C_6H_5)_2\dot{C}OH + \dot{R}$$

A lifetime of 10^{-3} s for this ketyl radical in liquid paraffin (viscosity 30 cP) at room temperatures has been reported (3). In alkaline solutions formation of the familiar blue ketyl radical anion (hereafter referred to as ketyl), which has a lifetime of several seconds, is favored.

[4] $$(C_6H_5)_2\dot{C}OH + OH^- \rightarrow (C_6H_5)_2\dot{C}O^- + H_2O$$

A similar mechanism seems to be followed in the photolytic generation of the nitrobenzene radical anions in alkaline protic solvents (2). This mechanism is also indicated by the detection, by e.s.r. spectroscopy, of the $C_6H_5 \cdot NO_2H$ radical formed by photolyzing a neutral solution of nitrobenzene in tetrahydrofuran (4).

The present report extends previous e.s.r. studies on the photolytically generated ketyls of benzophenone and fluorenone (1) to the far less stable benzaldehyde and

[1]*Postdoctorate Fellow, 1962–1963. Present address: National Physical Laboratory, Teddington, Middlesex, England.*

acetophenone ketyls, which appear to be formed by a similar mechanism. Benzophenone ketyl is included for comparison purposes. Observations on the effects of solvation on the unpaired electron distributions are reported and compared with theoretically estimated values.

EXPERIMENTAL

Reagents

"Eastman grade" benzaldehyde and acetophenone were used without further purification. Freshly prepared absolute ethanolic or acetone-free methanolic solutions, 10^{-2} M in the carbonyl compound and 10^{-1} M in sodium ethoxide or sodium methoxide, respectively, were used.

"Eastman grade" acetonitrile – methanol solutions, 10^{-2} M in the carbonyl compound and 10^{-1} M in sodium methoxide, were freshly prepared for the mixed-solvent experiments.

Ultraviolet Radiation

A 125 W Hanovia quartz alpine sun burner, type S-100, was enclosed in an aluminium tube designed to direct the radiation onto the sample solution within the Varian electron paramagnetic resonance spectrometer multipurpose cavity. The ultraviolet lamp was cooled by a jet of dry air and the aluminium tube was cooled by a water jacket. A water filter, 4 mm wide, between quartz plates was incorporated into the tube to eliminate direct heating of the sample by infrared radiation.

Electron Spin Resonance Observations

The Varian Associates V 4500 electron paramagnetic resonance spectrometer was used. Continuous irradiation of the sample while spectra were being recorded was made possible by utilizing the Varian multipurpose cavity. Reduction of the cavity quality factor by lossy solvents was largely eliminated by the use of Varian flat quartz, aqueous solution sample cells.

The Varian 6 inch magnet system with a pole gap of $2\frac{1}{2}$ inches was used, and the magnetic field was modulated at 100 kc/s.[2]

Spectra were recorded as first derivatives under "standard sweep" conditions, and line spacings were determined by comparison with the known spacings for the nitrobenzene radical anion (2) and the benzophenone ketyl (1). Absolute values of the hyperfine coupling constants are estimated to be better than 2%, while the relative values are better than 1%.

RESULTS

Spectra were observed a few seconds after the ultraviolet irradiations had been begun; maximum intensities were reached after about 20 s. The short inhibition period was probably caused by oxygen or other scavengers that were present as small impurities and which were reacting with the radicals formed initially. Spectra recorded during continuous photolysis of alkaline solutions of benzaldehyde and acetophenone in methanol and ethanol at room temperature (25 °C) are given in Figs. 1–4.

Continuous photolysis caused the spectra to decay almost completely within half an hour. In Figs. 1–4, the asymmetry of line intensity about the center of the spectra is largely caused by this decay.

Accurate line-width measurements were not made. It was necessary to modulate the magnetic field at about 50 mG to obtain a tolerable ratio of signal to noise. The minimum line width that was observed, with low microwave power to avoid saturation and the non-ideal modulation amplitude, was never less than 120 mG.

Careful inspection of the spectra indicated that they could be accounted for by the coupling constants shown in Table I. The calculated "stick" spectra in Figs. 1–4 correspond to these coupling constants. Agreement between experimental and calculated spectra is seen to be good. Assignment of coupling constants to specific protons is not possible from the aforementioned experimental data alone. However, from considerations of molecular orbital calculations described in a later section, the assignations given in Table I are suggested. The absence of a twofold rotation axis through the 1 and 4 positions of the benzaldehyde and acetophenone ketyls should be noted.

[2]*The 100 kc/s oscillator and detector were constructed in the chemistry department by Mr. J. A. Williams.*

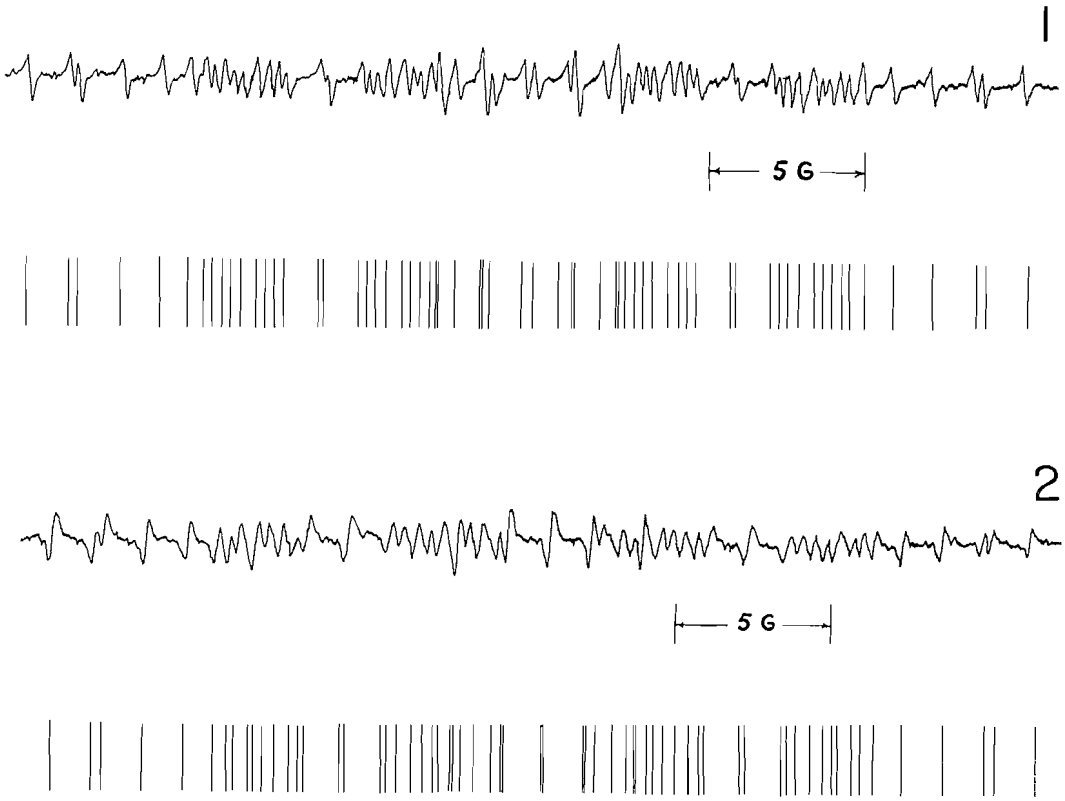

FIG. 1. The observed first-derivative e.s.r. spectrum and the calculated "stick" spectrum of benzaldehyde ketyl in methanol at 25 °C.
FIG. 2. The observed first-derivative e.s.r. spectrum and the calculated "stick" spectrum of benzaldehyde ketyl in ethanol at 25 °C.

The spectra of the benzaldehyde ketyl are slightly but distinctly different in the solvents methanol and ethanol. This is also the case for the acetophenone ketyl. The slight differences in the spectra are paralleled by slight changes in the coupling constants; the changes in the proton coupling constant of the CHO group and the coupling constant of the CH_3 group are the most marked. No differences in the spectrum of the benzophenone ketyl in the solvents methanol and ethanol were detected.

The spectrum resulting from the photolysis of an alkaline solution of benzaldehyde in a mixture of methanol and ethanol is a hybrid and not a superposition of the spectra in the two separate solvents.

The effect of solvent on the benzaldehyde ketyl was investigated further by photolyzing alkaline solutions of benzaldehyde in mixtures of methanol and the aprotic solvent acetonitrile. Increasing the fraction of acetonitrile caused changes of increasing magnitude in all the proton coupling constants, particularly in that of the CHO group, a_7. The experimentally determined points for a_7 versus the fractional volume of methanol in the mixed methanol–acetonitrile solvent are given in Fig. 5. The curve is drawn according to an equation discussed later. Increasing the fraction of acetonitrile caused an apparent decrease in the stability of the ketyl. This resulted in deterioration of the spectra, and it was not possible to obtain a spectrum for 100% acetonitrile.

MOLECULAR ORBITAL CALCULATIONS

The McLachlan modification of the Huckel theory (5), with a value of 1.2 for λ, was used to calculate unpaired electron spin densities. It was assumed that in the solvents used the ketyls were solvated. In particular, the oxygen atoms of the carbonyl groups are most likely to be hydrogen bonded to methanol or ethanol. The proximity of hydrogen atoms to the carbonyl group increases the effective electronegativity of the oxygen atom. This effect can be introduced into molecular orbital calculations by decreasing the value of the oxygen atom Coulomb integral, α_O (6). α_O is given by the familiar relationship $\alpha_O = \alpha + \delta_O\beta$, where α and β are the Coulomb and resonance integrals, respectively, for the benzene molecule. δ_O is a molecular orbital parameter; since β is negative, increasing

δ_O decreases α_O. The resonance integral for the carbonyl group is given by $\beta_{CO} = \gamma_{CO}\beta$. A constant value of 1.6 was used for γ_{CO} irrespective of solvent. Similarly, a value of 0.9 was used for γ_{C-CO}, which gives the resonance integral for the bond between the carbonyl group and the aromatic ring. This is quite reasonable if one considers that the C—CO bond is not typically aromatic and that there is a possibility of oscillation of the aromatic ring about this bond.

Asymmetry was introduced into the calculations on the benzaldehyde and acetophenone ketyls by utilizing the suggestion of Rieger and Fraenkel (7) that the Coulomb integrals of the carbon atoms at the 6 position, that is, the carbon atoms near the oxygen atoms,

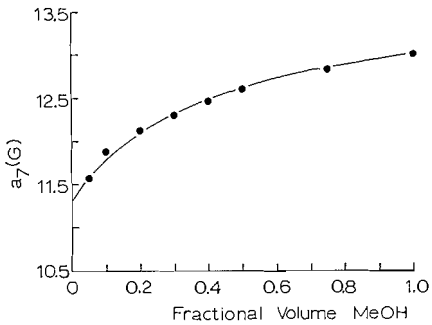

FIG. 5. a_7 versus fractional volume of methanol for the benzaldehyde ketyl in a methanol–acetonitrile mixture.

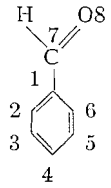
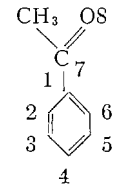
are slightly more positive than those for typically aromatic carbon atoms. This reflects a slight decrease in the electronegativity of these carbon atoms because of the proximity of the oxygen atoms. For the benzaldehyde ketyl, a value of -0.1 was used for δ_6, whereas for the acetophenone ketyl, which the e.s.r. spectra indicate is more symmetrical, a value of -0.05 was used. For the completely symmetrical benzophenone ketyl, the value of δ for all the ortho carbon atoms was set equal to 0.

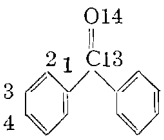
For calculations on the acetophenone ketyl which involves the methyl group, the grouping C—C′—H_3 was considered and the values used for the molecular orbital parameters are $\delta_{H_3} = -0.5$, $\delta_{C'} = -0.1$, $\gamma_{C'-H_3} = 2.5$, and $\gamma_{C-C'} = 0.9$ (8).

In Table II, unpaired spin densities calculated by using various values of δ_O are compared with the semi-empirical values for the ketyls in various solvents. The semi-empirical values for protons attached to the aromatic system were calculated by the McConnell relationship $a_i = Q_H|\rho_i|$, where ρ_i is the unpaired electron spin density at the aromatic carbon atom i adjacent to the proton under consideration. For methyl groups, the relation $a_{Me} = Q_{Me}|\rho|$ was used, where ρ is the spin density on the aromatic carbon atom adjacent to the methyl group. Values of 23.7 G and 27.2 G were used for the constants Q_H and Q_{Me}, since these values have been used extensively with considerable success by Fraenkel and co-workers (6, 7, 9). Semi-empirical values of unpaired spin densities for the electrochemically generated ketyls in N,N-dimethylformamide from publications by Fraenkel and co-workers (7, 9) have been included in Table II for comparison purposes.

Values of unpaired spin density calculated from molecular orbital theory with $\delta_O = 2.9$ and 2.2 are given in columns 1 and 2, and should be compared with the experimental values for the ketyls in the solvents methanol and ethanol. Similarly, the values in column 3 calculated with $\delta_O = 1.5$ should be compared with the experimental values for the solvent N,N-dimethylformamide. A considerable dependence of the unpaired spin density at the carbonyl group carbon atom on the electronegativity of the oxygen atom is expected and in fact observed. Greater effort was therefore made to fit the molecular orbital data with the semi-empirical data at the 7 positions of the benzaldehyde and acetophenone ketyls. The better quantitative agreement at these positions in Table II is therefore not surprising. Quantitative agreement elsewhere is not good but not unreasonable when the limitations of molecular orbital theory are considered. Qualitative trends are indicated quite clearly. For example, increasing the electronegativity of the oxygen atom, that is, increasing δ_O, increases the positive spin density at the ortho positions, and the increase at the carbonyl group carbon atom is particularly marked; the spin densities at the meta positions become more negative and the spin densities at the para positions decrease. All these changes of spin density are paralleled qualitatively in every case by changes with solvent of the semi-empirical spin densities.







DISCUSSION

From the assignation of the proton coupling constants in Table I, it is apparent that the benzaldehyde and acetophenone ketyls do not have a twofold center of symmetry through the 1 and 4 positions as might be expected. It seems that these are examples of hindered rotation of the carbonyl groups about the C—CO bond. The phenomenon was first observed with e.s.r. spectroscopy by Maki and Geske for the *p*-nitrobenzaldehyde radical anion (10) and has since been noted on several other occasions (7, 11), including the electrochemically generated benzaldehyde and acetophenone radical anions in aprotic solvents (9).

†$\delta_O = 2.9$.
‡$\delta_O = 2.2$.
§$\delta_O = 1.5$. Values for acetophenone and benzophenone ketyls are taken from refs. 9 and 7, respectively.
‖Spin densities are calculated from the isotropic coupling constants by using $a_i = 23.7|\rho_i|$ and $a_{Me} = 27.2|\rho_7|$.
¶Spin densities from refs. 7 and 9 are reduced to three figures after the decimal point.

The slight differences in the ortho protons and also in the meta protons arise because rotation is slow compared with the hyperfine frequency difference. In the case of benzaldehyde ketyl in methanol, the CHO group is rotating about the C—CO bond with a frequency $\omega < \gamma|a_2 - a_6| \sim 1.55 \times 10^7$ s^{-1}, where γ is the magnetogyric ratio of the electron.

The acetophenone ketyl also exhibits the hindered rotation phenomenon. In this case, the difference between the ortho coupling constants is less and the undoubted slight difference in the meta protons was not resolved. The expected difference in the meta protons is about 100 mG, which could well have been masked by the line width. Inspection of the three outermost lines in Figs. 3 and 4 does, in fact, show that the observed intensity ratio is less than 1:2:1, which is the ratio expected for two exactly equivalent meta protons.

The benzophenone ketyl appears to have four exactly equivalent meta protons. Apparently, steric hindrance between the ortho protons forces the rings out of a common plane, and it is possible that relatively free, out-of-phase rotation of the phenyl groups about the C—CO bonds occurs.

The coupling constants reported in Table I for ketyls in protic solvents differ considerably from those reported previously for the same ketyls in aprotic solvents such as acetonitrile, dimethylformamide, and 1,2-dimethoxyethane (1, 7, 9, 12). Similar results have been noted for the nitrobenzene radical anion (2, 13) and the semiquinones (6).

Solvation of ketyls via hydrogen bonding to the carbonyl group oxygen atom is certain to occur, and the resultant effect on the unpaired electron spin distributions is quite marked. In the molecular orbital calculations described previously, the effect of hydrogen bonding on the electronegativity of the oxygen atom was considered; it was noted that the calculated changes in unpaired spin density correspond qualitatively with the semi-empirical changes calculated from the isotropic coupling constants. A possible point of significance is the observation that the semi-empirical spin densities, particularly at the 7 position, of the benzaldehyde ketyl in protic solvents agree best with the theoretical values calculated by using a value of 2.9 for δ_O. The acetophenone ketyl data indicate that a value of 2.2 for δ_O gives a better fit. The difference in the values of δ_O reflects a greater electronegativity of the benzaldehyde ketyl oxygen atom, which could be interpreted as resulting from greater solvation. The lesser degree of solvation of the acetophenone ketyl could result from possible steric hindrance by the bulky CH_3 group. Another point is the observation of slightly greater unpaired spin densities at the 7 positions for both benzaldehyde and acetophenone ketyls in methanol than in ethanol. This indicates the slightly greater solvation powers of the smaller methanol molecule, compared with ethanol.

It is difficult to decide what the nature of the solvated ketyl is. The formation of several different species with any one solvent is possible. Each species could give rise to a different e.s.r. spectrum provided the exchange frequency of solvent molecules between the various species is low compared with the hyperfine frequency differences in their e.s.r. spectra. The observation of a single spectrum for each ketyl in the various solvents indicates that either there is a single species, solvated or unsolvated, or the exchange between the various species is fast.

The observation of a single spectrum for the benzaldehyde ketyl in mixed solvents indicates that exchange is fast. Gendell *et al.* (6) have derived a simple expression for the expected value of a coupling constant, a, resulting from the fast exchange of solvent molecules X and Y between singly solvated species RX and RY. In the case of a mixture of acetonitrile, X, and methanol, Y, the expression becomes

$$[5] \qquad a = \frac{a_{RX} - x(a_{RX} + 1.30Ka_{RY})}{1 - x(1 - 1.30K)}.$$

a_{RX} and a_{RY} are the coupling constants for RX and RY respectively. x is the fractional volume of methanol, and the factor of 1.30 arises because of differences in the molecular weights and densities of methanol and acetonitrile. K is the equilibrium constant for the exchange of solvent molecules.

$$[6] \qquad RX + Y \overset{K}{\rightleftharpoons} RY + X$$

In Fig. 5, eq. [5] for a_7 of the benzaldehyde ketyl is plotted for the acetonitrile–methanol mixture, with $K = 2.65$, $a_{RX} = 11.3$ G, and $a_{RY} = 13.01$ G. The agreement with the observed results is better than could be expected when one considers the gross assumptions that were made. Multi-solvation is quite possible and it cannot be assumed that the nature of methanol, which is normally highly associated, remains constant throughout the mixture range.

The value of the equilibrium constant indicates that solvation by methanol is favored over possible solvation by acetonitrile. The e.s.r. spectra also indicate that the benzaldehyde ketyl in acetronitrile is less stable than that in methanol, which implies that solvation by methanol imparts a greater degree of protection to the ketyl. That is, decay of the ketyl by mechanisms such as disproportionation and association or reaction with other molecules is inhibited to a greater extent.

The predicted value of 11.3 G for a_7 in acetonitrile does not compare too well with the value of 8.507 G reported by Steinberger and Fraenkel (9) in the similar solvent, dimethylformamide. This difference could arise from the greater influence of the sodium cation on the unpaired electron distribution compared with the influence of the bulky tetra-*n*-propylammonium cation used by Steinberger and Fraenkel. Cationic field effects have been observed to cause a blue shift of absorption maxima in the ultraviolet spectra of various metal benzophenone ketyls (14 and references therein).[3] Cationic field effects are more likely in acetonitrile than in the strongly solvating protic solvents, which protect the ketyl to a greater extent. They are even more likely in such nonpolar solvents as 1,2-dimethoxyethane. In this case, association between the ketyl and cations such as Na^+ and K^+ occurs (12), thereby resulting in hyperfine interaction with the metal. Hirota (12) has noted that the effect on the unpaired electron distribution in the benzophenone ketyl increases with an increasing ratio of charge to cationic radius. The effect at the 13 position was followed by observing the hyperfine interaction with ^{13}C substituted at that position. The influence at other positions in the aromatic system was observed to be much less and almost negligible at the para positions. One can assume, therefore, that these positions are relatively far from the cation. The observations by Hirota parallel results in this work; protic solvents effect the positions nearest the carbonyl group quite markedly and effect the para positions to a very small degree.

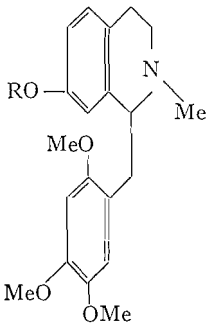
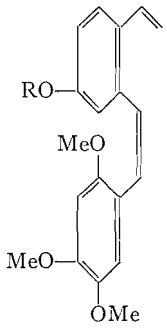
THE ALKALOIDS OF FUMARIACEOUS PLANTS

LV. THE STRUCTURE OF CULARIDINE



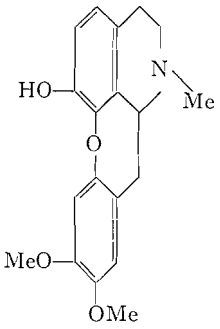
RICHARD H. F. MANSKE
Research Laboratories, Dominion Rubber Co., Ltd., Guelph, Ontario

Received November 19, 1965

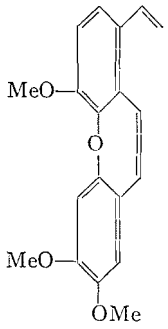


ABSTRACT

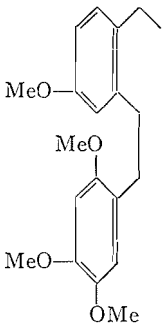
Cularidine, which on O-methylation yields cularine, has one phenolic hydroxyl group. It was O-ethylated with diazoethane, and the resultant O-ethylcularidine was degraded to asaronic and 4-ethoxyphthalic acids via sodium – liquid ammonia fission, O-methylation, double Hofmann degradation, and oxidation. These fragments prove the structure of cularidine to be that shown by III.



The alkaloid cularidine has been isolated from *Dicentra cucullaria* (L.) Bernh. (1) and from *Corydalis claviculata* (L.) DC. (2). It is monophenolic and upon methylation with diazomethane is converted into cularine; therefore, it can have only one of three possible structures. It is evident that the procedure used in determining the structure of cularine (3), when applied to cularidine O-ethyl ether, will give an unambiguous answer. The experimental difficulties, however, are twofold: difficult O-methylation and poor yields on oxidation; hence pilot experiments with cularine were carried out first.



I



II

III

IV

V

The scission of the diphenyl ether bridge with sodium in liquid ammonia is almost quantitative, but the methylation of the resultant phenolic base offered considerable difficulty until the method of Rodionow (4) was used; then moderate yields of the tetramethoxybenzylisoquinoline (I, R = Me) were obtained. The exhaustive methylation of this base also proceeded in moderate yields to give II (R = Me). However, the oxidation of the latter, although it gave the phthalic acid derivative in acceptable yields, gave asaronic (2,4,5-trimethoxybenzoic) acid in very poor yields, presumably because it is attacked rather easily by the oxidizing agent (permanganate). Nevertheless, a very small amount of asaronic acid was obtained not only from the cularine degradation but also from cularidine O-ethyl ether. This observation alone indicates that III is the structure of cularidine; however, it was also possible to isolate 4-ethoxyphthalic acid in better yield from the degradation products, and this fact alone is also sufficient to establish the suggested structure. The ethoxyphthalic anhydride showed the characteristic anhydride infrared peaks at 1 773 and 1 840 cm^{-1} and was characterized as its N-methylimide. A nuclear

magnetic resonance spectrum of the latter clearly showed the signals associated with the O-ethyl group (a quartet at τ 5.92 (2H, J = 7.0 c.p.s.) and a triplet at τ 8.53 (3H, J = 7.0 c.p.s.)) as well as the singlet of the methyl protons (at τ 6.85 shifted to lower field because of the deshielding of the two electronegative carbonyl groups).

An attempt to obtain recognizable degradative fragments from cularine by another route failed at the penultimate stage. When the doubly unsaturated product (IV) of the second stage of the Hofmann degradation was treated with sodium in liquid ammonia, the product was not the phenolic vinylstilbene but a phenolic ethyldibenzyl which, on O-methylation, generated the fully saturated ethyltetramethoxydiphenylethane V, the nuclear magnetic resonance spectrum of which was entirely consistent with this structure.

The help of Dr. Kju Hi Shin in interpreting the nuclear magnetic resonance spectra is gratefully acknowledged.

EXPERIMENTAL

2-Methyl-7,2',4',5'-tetramethoxy-1-benzyltetrahydroisoquinoline (I, R = Me)

The phenolic base obtained by the sodium – liquid ammonia fission of cularine (4 g) was added to phenyltrimethylammonium hydroxide (prepared from 8 g of the corresponding *p*-toluenesulfonate), and the mixture was heated at 110–120° for 1 h. Steam was passed into the reaction mixture to remove the dimethylaniline and then the solution was extracted with ether. The washed ether solution was dried over solid potassium hydroxide and the solvent largely removed. The base (2.5 g) crystallized shortly, and when it was recrystallized from dry ether – hexane it was obtained as stout colorless prisms melting sharply at 98°.*

Anal. Calcd. for $C_{21}H_{27}O_4N$: four OMe, 34.76. Found: OMe, 34.54, 34.38.

Degradation of Cularidine

A solution of cularidine (1.5 g) in ethanol was treated with an ethereal solution of diazoethane, and after 24 h the excess reagent was removed. The base, in ether solution, was washed with water and dried over potassium hydroxide. It was then added to ca. 50 cc liquid ammonia and treated with a dilute solution of sodium in the same solvent until the blue color was permanent for 1 min. After evaporation of the ammonia, the residue was extracted with ether and the residue from the ether extract was heated with an excess of phenytrimethylammonium hydroxide. The non-phenolic base was isolated as described above and converted into the nitrogen-free compound (II, R = Et) by a double Hofmann degradation (3). The resultant product weighed 0.24 g and consisted of a colorless resin. It was dissolved in acetone and treated with a saturated aqueous solution of potassium permanganate until the color was permanent for 30 min. The acetone was boiled off, a little calcium chloride added, and the hot mixture filtered through a layer of Filtercel. The acidified filtrate was exhausted with ether and the residue from the extract sublimed from a distillation tube. There was a small amount of sublimate at 110° and 0.2 mm which melted at 130–141° either alone or in admixture with asaronic acid. This quantity was insufficient for further characterization. A second distillate was obtained at ca. 150° and 0.2 mm; this, when resublimed, melted at 65–70° either alone or in admixture with 4-ethoxyphthalic anhydride. It was treated in methanol with methylamine, the mixture evaporated, and the residue sublimed (140° at 0.2 mm). The crystalline sublimate, when recrystallized from ether–hexane, melted at 108° either alone or in admixture with an authentic specimen of N-methyl 4-ethoxyphthalimide.

4-Ethoxyphthalic Anhydride

This compound has been described by Fritsch (5), but for the present it was prepared by ethylating 4-hydroxyphthalic acid (6) with ethyl sulfate and alkali. From 12 g of diethyl 4-aminophthalate via the hydroxy acid was obtained 5.5 g of twice-sublimed 4-ethoxyphthalic anhydride which, when recrystallized from dry ether, melted at 76°. The *methylimide*, which had been prepared from the anhydride, sublimed *in vacuo*, and recrystallized from dry ether, melted at 109°. The *ethylimide*, similarly prepared and purified, melted at 102°.

Anal. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98. Found: C, 65.39, 65.34; H, 5.66, 6.13.

O-Ethylcularidine

Though the free base could not be obtained in crystalline form, it gave an acid oxalate (m.p. 218°) which was only sparingly soluble in cold methanol. The *picrate*, crystallized from acetone–methanol, melted at 210°. The hydrochloride was obtained as colorless needles melting at 172° when recrystallized twice from hot acetone, in which it is moderately soluble. It appears to be a monohydrate.

Anal. Calcd. for $C_{21}H_{25}O_4N \cdot HCl \cdot H_2O$: C, 61.54; H, 6.84. Found: C, 61.34, 61.99; H, 7.28, 7.27.

When this hydrochloride was recrystallized from methanol a solvated form melting at 195° was obtained. The *methiodide* of the O-ethyl ether melted at 236° and the *methine methiodide* prepared therefrom consisted of fine needles, which were sparingly soluble in methanol and which melted at 205° without darkening.

**All melting points are corrected.*

2-Ethyl-5,2',4',5'-tetramethoxy-1,2-diphenylethane (V)

A solution of compound IV (3) in tetrahydrofuran was added to liquid ammonia in which a small piece of sodium had been dissolved. The blue color was discharged at once. Sodium in small pieces was added until the blue color of the solution remained for 5 min. The ammonia was then evaporated in a current of air, and the residue was treated with an excess of sodium bicarbonate and extracted with ether. The phenolic residue from the washed and dried ether solution did not crystallize. It was methylated with an excess of dimethyl sulfate and caustic soda; the non-phenolic product thus obtained was dried in ether solution with potassium hydroxide. Partial evaporation of the ether and the addition of hexane to the concentrate gave a nearly quantitative yield of the saturated compound (V), m.p. 93°. It was stable to permanganate in acetone solution.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93. Found: C, 72.61, 72.44; H, 7.82, 7.83.

THE CHEMISTRY OF THE AMINOCHROMES

IX. THE REACTIONS OF GLUTATHIONE WITH SOME HALOGENATED AMINOCHROMES[1,2]

Received June 28, 1965

ABSTRACT

7-Iodoadrenochrome reacts with glutathione to give 5,6-dihydroxy-7-iodo-1-methylindole, 5,6-dihydroxy-1-methylindole, 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole, and a trace of a product that is probably 4-*S*-glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole. It reacts with the monosodium salt of glutathione to give mainly 5,6-dihydroxy-7-iodo-1-methylindole and 4-*S*-glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole, with smaller quantities of 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole and 5,6-dihydroxy-1-methylindole. 7-Bromoadrenochrome reacts with glutathione (free acid or monosodium salt) to give mainly 7-bromo-5,6-dihydroxy-1-methylindole and a second product, which is probably 7-bromo-4-*S*-glutathionyl-5,6-dihydroxy-1-methylindole. The main products that are obtained in reactions of this type result from either direct reduction of the aminochrome or 1,4-addition of the thiol to either of the α,β-unsaturated C_5-carbonyl systems in the aminochrome molecule.

INTRODUCTION

It has been shown that the main products of the reaction between adrenochrome and glutathione (GSH)[4] result from the 1,4-addition of the thiol to the C_5-unsaturated carbonyl systems in the aminochrome molecule that involve the C_6—C_7 and C_4—C_9 double bonds. These products are probably 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (I) and 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-1-methylindole respectively (1). It was observed that small quantities of DHMI[5] (II) were formed at the same time (1). A preliminary study by paper chromatography of the products of the reaction between GSH and 7-iodoadrenochrome (III) showed that, in addition to 7-iodo-DHMI (IV), two substances with R_f values[6] of 0.44 and 0.67 were formed (2). In some earlier publications it was reported that the iodine atom occupied the 2-position in iodoaminochromes (cf. ref. 3). It has recently been shown, however, that the halogen atom in halogenated aminochromes and derived products is invariably in the 7-position (4).

This paper reports the results of an extensive examination by spectroscopy and paper chromatography of the products obtained from a number of 7-iodo- and 7-bromoaminochromes when they react with GSH or GSH(Na).

EXPERIMENTAL

Materials

7-Iodoadrenochrome (5), 1-ethyl-7-iodonoradrenochrome (6), 7-iodo-1-isopropylnoradrenochrome (6), 7-iodoadrenochrome methyl ether (6), 5,6-dihydroxy-1-methylindole (7), and 5,6-dihydroxy-7-iodo-1-methylindole (2) were prepared by methods described in the literature (cf. ref. 4). GSH, GSH(Na), and GSSG were obtained from Nutritional Biochemicals Corporation.

[1]*This investigation was supported by grants from the Department of National Health and Welfare (Ottawa) and the Government of Saskatchewan (Department of Public Health).*

[3]*Present address: Atlantic Regional Laboratory, National Research Council, 1411 Oxford Street, Halifax, Nova Scotia.*

[4]*GSH, GSH(Na), and GSSG are used respectively as abbreviations for glutathione (free acid), glutathione (monosodium salt), and oxidized glutathione.*

[5]*DHMI is used as an abbreviation for 5,6-dihydroxy-1-methylindole and the 5,6-dihydroxy-1-methylindole nucleus in its derivatives.*

[6]*All the R_f values reported in this paper were obtained by descending development on Whatman No. 1 paper, with 2% acetic acid in water as the developing solvent.*

Reaction Mixtures

The reaction mixtures were prepared by suspending the 7-iodo- or 7-bromo-aminochrome (10 mg) in a solution of GSH or GSH(Na) (25 mg) in water (1 ml). When the violet color of the solutions had totally disappeared, which usually occurred within several minutes of their preparation, the reaction mixtures were filtered, and samples (30 μl) of the clear filtrates were used directly for chromatographic or spectroscopic investigation.

To investigate the possibility of reactions between 7-iodo- or 7-bromo-adrenochrome and GSSG, an aqueous suspension (1 ml) of the halogenated aminochrome (10 mg) was treated with an excess of GSSG, and the reaction mixture was examined by paper chromatography.

An aqueous suspension of 7-iodo-DHMI (10 mg/ml) was treated with excess GSH and the reaction mixture allowed to stand at room temperature for 2 h. It was then extracted with ether, and the dried (Na_2SO_4) ether extract was examined by paper chromatography.

Paper Chromatography

Descending chromatography was carried out on Whatman No. 1 paper, with acetic acid (2%) in water as the running solvent. In all cases the solvent was allowed to descend ca. 15 inches, which required 2.5–3 h. After they were dried in air at room temperature, the developed chromatograms were examined for fluorescence in ultraviolet light and were then sprayed with one of the following chromogenic reagents:[7] Ehrlich's reagent, cinnamaldehyde, *p*-dimethylaminocinnamaldehyde, diazotized *p*-nitroaniline, Gibb's reagent, or ninhydrin.

In some cases the aqueous solution of the aminochrome reaction products was extracted with peroxide-free ether (4 × 1.0 ml). Samples of both the dried (Na_2SO_4) ether extracts and the aqueous mother liquors (ca. 120–150 μl and 50 μl respectively) were examined chromatographically on paper in the manner described above.

Relatively pure solutions of the individual products were obtained by chromatography on Whatman No. 3MM paper (23 cm × 57 cm) by a procedure previously described (1).

Spectroscopy

Spectra were obtained from suitably diluted solutions of the reaction mixtures or ether extracts, and were recorded on a Beckman DK-2 or a Unicam SP.800 recording spectrophotometer.

RESULTS

The results of a survey by paper chromatography of the products obtained by the action of GSH on five different 7-iodo- and 7-bromo-aminochromes, and of GSH(Na) on 7-iodo- and 7-bromo-adrenochrome are given in Table I. Paper chromatograms of 7-iodoadrenochrome–GSH reaction mixtures usually showed three main spots with R_f values of ca. 0.18, 0.44, and 0.65 after they were sprayed with any one of most of the chromogenic reagents that react positively with indoles and phenols. The developed chromatograms often exhibited a weak pink spot in the 0.8–0.9 R_f zone before spray was applied. As the paper dried, this area slowly developed a yellow-green fluorescence, typical of a 5,6-dihydroxyindoxyl derivative. This suggests that the pink spot was due to free aminochrome (cf. ref. 9) that was produced during the chromatographic procedure from decomposition of one of the materials originally present in the reaction mixture. When the 7-iodoadrenochrome–GSH reaction mixture was exhaustively extracted with peroxide-free ether, and both the ether extracts and aqueous mother liquors were examined separately by paper chromatography, it was observed that one product (R_f 0.18) was totally extracted by the ether and the other (R_f 0.62) was not. At first it appeared that the substance that produced the spot with R_f ca. 0.44 was only partially extracted by the ether. Careful examination of the color reactions and ultraviolet absorption spectra of the products with R_f values of ca. 0.44 on chromatograms of the ether extracts and the mother liquors that had been run individually, however, showed that they were different (see Table I). The product that is not extractable with ether (R_f 0.45) shows color reactions that would be expected of an indole, a catechol, or an α-amino acid (see Table I), and it gives a positive reaction with the ceric sulfate – sodium arsenite reagent (cf. ref. 10), which suggests that it still contains iodine.

[7]*The chromogenic reagents were prepared by common methods described in the literature (cf. ref. 8).*

In the reaction of 7-iodoadrenochrome with GSH(Na), much more of the substance with a R_f of 0.18 (probably 7-iodo-DHMI (IV)) was formed, and only traces of DHMI (II) could be detected in ether extracts of these reaction mixtures. The major product of this reaction was the one that could not be extracted with ether (R_f 0.45), but traces of the product with R_f 0.63 were also present. 7-Iodoadrenochrome–GSH(Na) reaction mixtures were extracted with ether; the mother liquors were kept overnight at room temperature and then examined by paper chromatography. This showed that very little of the product (R_f ca. 0.45) that was not extractable with ether was present, but that a new product with R_f ca. 0.60 was formed. It did not contain iodine and it showed color reactions similar to those of 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (I).

Paper chromatograms of the mixtures obtained from the reaction of 7-bromoadrenochrome with either GSH or GSH(Na) were essentially similar in appearance (see Table I). The overall chromatographic picture in both was more comparable to that obtained in the reaction of 7-iodoadrenochrome with GSH(Na) than with GSH. The main products that were observed had R_f values of ca. 0.22 and 0.48. The former is most probably 7-bromo-DHMI and the latter, which is not extractable with ether, appears to be analogous to the substance (R_f ca. 0.45) not extractable with ether that is one of the major products of the 7-iodoadrenochrome–GSH(Na) reaction.

Paper chromatographic examination of the products obtained from 1-ethyl-7-iodonoradrenochrome, 7-iodo-1-isopropylnoradrenochrome, and 7-iodoadrenochrome methyl ether by the action of GSH in aqueous solution showed that they were basically similar to those obtained from 7-iodoadrenochrome under similar conditions (see Table I). Reaction mixtures of 7-iodoadrenochrome methyl ether and GSH gave a chromatographic pattern that was virtually identical with that obtained from a reaction mixture of 7-iodoadrenochrome and GSH, which indicates that the alkoxy group in the 3-position of the aminochrome ring system has no significant effect on the course of the reaction with GSH (cf. ref. 1).

No reaction that could be detected by paper chromatography occurred in aqueous solution between GSSG and either 7-bromoadrenochrome or 7-iodoadrenochrome, which suggested that the thiol group of GSH (or of GSH(Na)) must have been involved in all the reactions described above. Consequently, none of these reaction products were formed by the interaction of the 7-halogeno substituent of the aminochrome molecule and the primary amino group of the amino acid. Aqueous solutions of 7-bromo-DHMI and of 7-iodo-DHMI were treated individually with GSH, GSH(Na), and GSSG in turn. Paper chromatographic examination of the ether extracts of these reaction mixtures, after they had stood at room temperature for several hours, showed the presence of DHMI, which indicated that dehalogenation of the 7-halogeno-DHMI derivatives had occurred.

The products obtained from 7-iodoadrenochrome by the action of GSH or GSH(Na) in aqueous solution exhibited absorption maxima at 306 mμ and 385 mμ, whereas reaction mixtures obtained from 7-bromoadrenochrome exhibited them at 305 mμ and 380 mμ. The longer wavelength peak was about three times relatively more intense in both cases when the reaction was carried out with GSH(Na) than with GSH. It was not possible in either case, however, to obtain solutions of the substances that absorb in the 380–385 mμ region, by elution of any part of the developed chromatograms.

When freshly prepared reaction mixtures, which are yellow, were diluted with water they became red-pink in color. After they had stood at room temperature for ca. 2 h, however, they showed no significant absorption at 380 mμ and the intensity of the peak at ca. 300 mμ was increased, but the solutions did not become pink after dilution. These

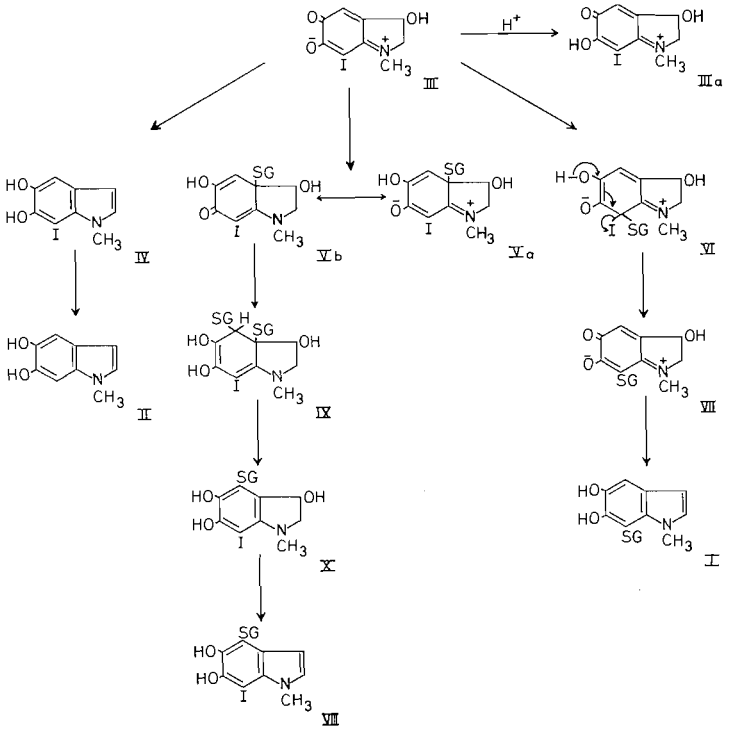
facts indicate that the product (λ_{max} 380 mμ) is relatively unstable and readily decomposes in aqueous solution to give a compound characterized by λ_{max} 300 mμ, and also that the unstable compound is necessary for the regeneration of an aminochrome-type structure.

DISCUSSION



Two of the three main products of the reaction between 7-iodoadrenochrome (III) and GSH or GSH(Na) are extractable with ether, and from the nature of their paper chromatographic and spectroscopic properties (see Table I) they appear to be 7-iodo-DHMI (IV) and DHMI (II). 7-Iodo-DHMI (IV) is a relatively minor product in reactions involving GSH, but much larger amounts of it are formed when GSH(Na) is the reactant. When 7-iodoadrenochrome (III) and GSH react, the main product that is not extractable with ether has a R_f of 0.63. Because of this value, its color reactions, and its absorption maximum it appears to be identical with the main product of the adrenochrome–GSH reaction with the same R_f value, which was previously provisionally identified (1) as 7-*S*-glutathionyl-DHMI (I). The product with a λ_{max} of ca. 380 mμ, that is initially present in the 7-iodoadrenochrome–GSH reaction mixtures, is probably analogous to the substance (R_f ca. 0.80, λ_{max} ca. 350 mμ) in the adrenochrome–GSH reaction mixtures that was tentatively identified as 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-1-methylindole (1). In the present case the product would be 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-7-iodo-6-oxo-1-methylindole (V). The shift of the observed λ_{max} towards longer wavelengths in the spectra of compounds of this type is compatible with iodine substitution in the 7-position of the molecule (cf. ref. 11).

It has been suggested that little of the DHMI that is formed during the course of the adrenochrome–GSH reaction results from the direct reduction of adrenochrome by the thiol (1). The presence of a halogen substituent in the aminochrome nucleus, however, may raise its oxidation potential sufficiently to permit direct reduction by GSH (cf. ref. 12). In this case the initial product would be the corresponding true leuco compound 3,5,6-trihydroxy-7-iodo-1-methylindoline, which would readily give 7-iodo-DHMI (IV) by loss of water from the 2- and 3-positions of the indoline ring system (cf. ref. 11).

The formation of 7-*S*-glutathionyl-DHMI (I) could occur as the result of a 1,4-addition–elimination process. 1,4-Addition of GSH to the α,β-unsaturated C_5-carbonyl system in 7-iodoadrenochrome (III), involving the C_6—C_7 double bond, would give an intermediate compound (VI), which could readily give 7-*S*-glutathionyladrenochrome (VII) by the elimination of hydrogen iodide. Reduction of 7-*S*-glutathionyladrenochrome (VII) would initially give 7-*S*-glutathionylleucoadrenochrome, which would be expected rapidly to undergo intramolecular dehydration (cf. ref. 11) with the formation of 7-*S*-glutathionyl-DHMI (I).

The unstable product showing absorption at ca. 380 mμ (probably 9-*S*-glutathionyl-7-iodo-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-1-methylindole (V*a*)) presumably results from the 1,4-addition of GSH to the α,β-unsaturated C_5-carbonyl system in 7-iodoadrenochrome (III), involving the C_4—C_9 double bond (cf. ref. 1). The formation of the product V*a* probably represents the first stage in the formation of the product (R_f 0.45) that is not extractable with ether. The color reactions and the ultraviolet absorption maximum (see Table I) of this latter substance indicate that it retains the indole nucleus and contains an *o*-diphenol system, an α-amino acid residue, and an iodine atom, which suggests that it is an iodinated DHMI derivative containing a GSH residue. If it is assumed that the iodine atom is retained in the 7-position, the *S*-glutathionyl residue would be in the 4-position of the indole ring system. The final product would therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

REACTION SCHEME 1.

appear to be 4-*S*-glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole (VIII). 7-Iodo substitution in compounds of this type usually results in a lowering of the R_f value in 2% acetic acid and in an increase in the wavelength of the main ultraviolet absorption maximum (e.g. DHMI: λ_{max} 300 mμ, R_f 0.44; 7-iodo-DHMI: λ_{max} 303 mμ and 313 mμ (shoulder), R_f 0.18). Deiodination of VIII occurs readily in aqueous solution at room temperature with the formation of a product, presumably 4-*S*-glutathionyl-DHMI, which has chromatographic properties similar to those of 7-*S*-glutathionyl-DHMI (I).

It has already been pointed out that relatively more deiodinated products are formed in cases when 7-iodoadrenochrome (III) reacts with GSH rather than with GSH(Na). A satisfactory explanation of this is not available at the moment. The course of the reaction may be influenced, however, by the degree of zwitterionic character of the structure of 7-iodoadrenochrome,[8] which would determine the extent of conjugation in the C_5—C_7 α,β-unsaturated C_5-carbonyl system. The formation of the intermediate VI would require a considerable degree of conjugation in this system, which would result from a high degree of dipolarity in the aminochrome molecule. Under the strongly acid conditions of the GSH reaction (pH ca. 3.5), the C_6—C_7 double bond in the zwitterionic form of the 7-iodoaminochrome molecule would be stabilized by the protonation of the polarized C_6-carbonyl group (cf. III*a*), and the addition mechanism III $\rightarrow$ VI (i.e. the route leading to the formation of I) will be favored. The addition product V is probably a resonance hybrid (V*a* $\leftrightarrow$ V*b*). A second molecule of GSH could be added to V*b* by a 1,4-addition to the α,β-unsaturated C_6-carbonyl system, involving the C_4—C_5 double bond, to give the intermediate IX. The elimination of a molecule of GSH (involving the angular GSH

[8]*The properties of the aminochromes are generally better explained by a zwitterionic structure than by a true m-amino-o-quinone structure (cf. ref. 13).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

residue) from IX by a β-elimination mechanism would lead to the formation of the 3,5,6-trihydroxyindoline derivative (X), which would readily give 4-*S*-glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole (VIII) by an internal dehydration mechanism (cf. ref. 11).

There are two different α,β-unsaturated C_5-carbonyl systems in an aminochrome molecule that will accept a thiol by a 1,4-addition mechanism (cf. ref. 1). The degree of conjugation in one of these systems, i.e. that involving the C_4—C_9 double bond, will not be affected materially by the degree of zwitterionic character of the aminochrome molecule. The degree of conjugation in the system involving the C_6—C_7 double bond, however, will be influenced strongly by the degree of dipolarity of the molecule. A high degree of conjugation in the latter system will depend on a large contribution from the zwitterionic form of the molecule. Consequently, addition to the C_5—C_7 α,β-unsaturated carbonyl system will be favored by the relatively acid conditions of the GSH reaction. Under the less acid conditions of the GSH(Na) reaction, however, this route (i.e. III $\rightarrow$ VI) will not be as dominant, which will allow the III $\rightarrow$ V reaction to occur to a relatively greater extent. The addition of a second molecule of GSH to the unsaturated C_6-carbonyl system in V, involving the C_4—C_5 double bond, would be facilitated by a large contribution of the nonpolar form (V*b*) to the overall molecular structure of V, which would be favored by the less acid conditions of the GSH(Na) reaction.

The reactions of 7-bromoadrenochrome with GSH or GSH(Na) are comparable to that of 7-iodoadrenochrome with GSH(Na). Two of the main products obtained from 7-bromoadrenochrome appear to be 7-bromo-DHMI (R_f 0.22, λ_{max} 280 and 301 mμ) and a product that is probably 7-bromo-4-*S*-glutathionyl-DHMI (R_f 0.48, λ_{max} 310 mμ). A third unstable product (λ_{max} ca. 380 mμ), which cannot be detected by paper chromatography, is initially present in these reaction mixtures. It is presumably analogous to the product derived from 7-iodoadrenochrome with a λ_{max} in the same region, and consequently is 7-bromo-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-1-methylindole. As with the 7-iodo compound, there was evidence that more dehalogenation occurred when the reaction was carried out with GSH than with GSH(Na). There was also spectroscopic evidence that there was greater formation (by about a factor of three) of the product with a maximum absorption band at ca. 380 mμ when GSH(Na) was used. The overall amount of dehalogenation observed with both GSH and GSH(Na) was much less in reactions with 7-bromoadrenochrome than in those with the corresponding iodo compound. This phenomenon parallels the order of displacement rates of halides from substituted quinones by sulfite, i.e. I $\gg$ Br $>$ Cl (14). The formation of the products that were obtained in the reaction of 7-bromoadrenochrome with GSH or GSH(Na) may be explained satisfactorily by mechanisms similar to those proposed for the corresponding reactions with 7-iodoadrenochrome.

ACKNOWLEDGMENT

The assistance of Mrs. B. D. Scott with some of the paper chromatographic work is gratefully acknowledged.

THE REACTION OF CHLORAL WITH HALOBENZENES AND WITH 2,4-DICHLOROPHENOL

SYNTHESIS OF HALOGENATED ETHYLBENZENES AND OF α-METHOXYPHENYLACETIC ACIDS

WILKINS REEVE, JOHN P. MUTCHLER, AND CHARLES L. LIOTTA[1]
Chemistry Department, University of Maryland, College Park, Maryland
Received June 24, 1965

ABSTRACT

The Friedel–Crafts reaction of chloral with aromatic compounds to form aryltrichloromethylcarbinols is reviewed. The molar ratio of aluminium chloride to chloral is critical and varies from 0.15 to 2.0 depending on the solvent, steric considerations, and the reactivity of the aromatic ring. The reaction has been used to prepare several new compounds with carbon disulfide or excess aromatic compound as the solvent. From 2,4-dichlorophenol, an *o*-hydroxy-α-trichloromethylbenzyl alcohol is obtained. Both the phenolic and side-chain hydroxy groups of this alcohol are methylated with equal ease by dimethyl sulfate.

It has now been found that changing the solvent from carbon disulfide to methylene chloride results in the hydroxy group of the initial carbinol also being replaced by chlorine. This role of the solvent in controlling the course of the reaction has not been observed previously.

The trichloromethylcarbinols are converted into α-methoxy acids by treatment with methanolic potassium hydroxide. Sodium in liquid ammonia removes the α-methoxy group, as well as the halogens, from 3,5-dichloro-α,2-dimethoxyphenylacetic acid.

Aryltrichloromethylcarbinols may be prepared by a Friedel–Crafts reaction between chloral and aromatic compounds such as benzene, toluene, *p*-xylene, and anisole (1); bromobenzene and chlorobenzene (2); and *o*-dichlorobenzene (3). Naphthalene has been reported to condense in the β-position (4). Other methods of preparing trichloromethylcarbinols have been reviewed (5). Aluminium chloride differs from other acid catalysts in that the reaction can easily be stopped at the carbinol stage. In contrast, the sulfuric acid catalyzed reaction of benzene (6) or chlorobenzene with chloral gives rise exclusively to diaryltrichloroethanes, as in the well-known synthesis of dichlorodiphenyltrichloroethane (DDT).

A general procedure for preparing the aryltrichloromethylcarbinols (Table I) involves mixing 1 equivalent of anhydrous chloral with an excess of the hydrocarbon (which serves as both reactant and solvent) and slowly adding at 0 to 30° sufficient solid aluminium chloride to cause the reaction to occur. The amount of aluminium chloride to be used per mole of chloral is a critical factor, since the use of more than the optimum amount results in the successive formation of diaryltrichloroethanes, diaryldichloroethylenes, tri- and tetra-arylethyl chlorides, and tetraarylethylenes. With large amounts of aluminium chloride, all of the first-formed carbinol is converted into these products. The importance of the amount of aluminium chloride in determining the nature of the reaction products has not been recognized adequately in reviews of the older literature (7).

It is apparent that, for the preparation of the carbinols, the optimum molar ratio of aluminium chloride to chloral is approximately 0.2 when aromatic hydrocarbons are employed as both the reactant and the solvent, and that increased amounts of aluminium chloride are required with the introduction of two chloro groups into the aromatic ring. With carbon disulfide as the solvent, a complex between the aryltrichloromethylcarbinol and the aluminium chloride precipitates. Consequently, an equal molar amount of

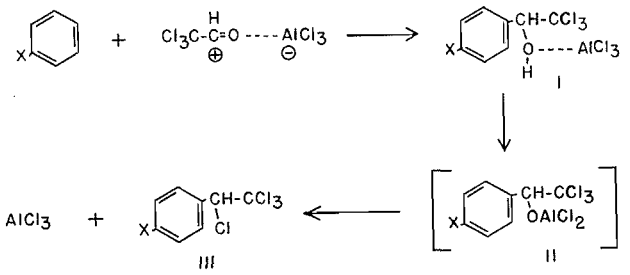
*Reference 1.
†Unpublished work.
‡33% of 1,1,1-trichloro-2,2-bis(*p*-methoxyphenyl)ethane was also obtained.
§Reference 2 reports 42 to 45% yield.
‖When used in excess, 7 to 10 moles is employed.

aluminium chloride was always used with this solvent. With 2,4-dichloroanisole, the reaction could not be induced to occur even under relatively severe conditions at 46°. That this unreactivity was primarily a steric effect caused by the bulky methoxy group was shown by the successful reaction of 2,4-dichlorophenol with chloral.

Methylene Chloride Solvent

With methylene chloride as the solvent (Table II), the reaction products were found to be α-trichloromethylbenzyl chlorides, the carbinol hydroxy group being replaced by chlorine. This was surprising, since the hydroxy group in the aryltrichloromethylcarbinols neither reacts with concentrated hydrochloric acid nor gives a test with the Lucas reagent.

TABLE II



Reaction of chloral with aromatic compounds, methylene chloride being used as solvent*

Aromatic compound	Yield of Ar—CHCl—CCl_3, %
Acetanilide	29†
Fluorobenzene	68
Chlorobenzene	78
Bromobenzene	79
Iodobenzene	66

*0.3 mole of aromatic compound and 0.3 mole anhydrous chloral in 150 ml of methylene chloride were treated at 0° with 0.3 mole aluminium chloride over a 1 h period and allowed to warm to room temperature over a 5 h period.
†Twice the usual amount of aluminium chloride and chloral was used.

The above results strongly suggest that the reactions are proceeding by the mechanism shown in Reaction Scheme 1. The mechanism of formation of complex I closely corresponds to the usually accepted mechanism for the Friedel–Crafts acylation reaction (8). With carbon disulfide as the solvent, the reaction stops at this stage because the complex is insoluble. Further reaction would be difficult in a rigid crystal structure and in the absence of a solvent shell. With methylene chloride as the solvent, the reaction mixture remains

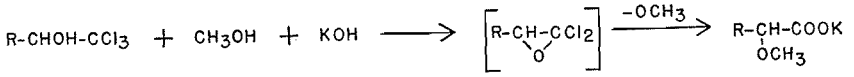
For personal use only.

REACTION SCHEME 1.

homogeneous, and the elimination of hydrogen chloride leads to intermediate II. The conversion of this into tetrachloroethylbenzene (III) is analogous to the conversion of alcohols into alkyl chlorides with retention of configuration by reaction with boron trichloride; the latter reaction is believed to occur by a S_Ni mechanism involving a quasi four atom ring transition state (9). That the reaction in methylene chloride solvent does go through the carbinol complex stage (I) was shown by the fact that phenyltrichloromethylcarbinol reacted with an equal molar amount of aluminium chloride in methylene chloride at 0° to form α-trichloromethylbenzyl chloride in 66% yield.



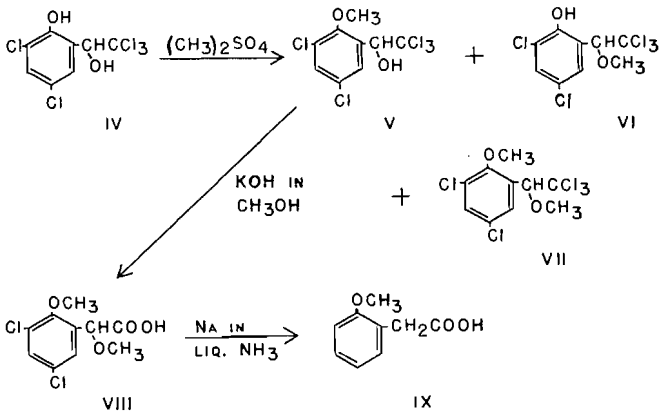
The condensation reaction between benzene itself and chloral to form the tetrachloroethylbenzene fails under the standard conditions employed; only a tar was obtained.

Infrared Data

The spectra of 20 secondary trichloromethylcarbinols prepared in these laboratories have been determined. In addition to the expected absorption bands caused by the hydroxy and aryl groups, two characteristic bands (835 to 815 and 780 to 760 cm^{-1}) are almost always strong. These are associated with the $Cl_3C—CHR—O—$ group.

Reactions of the Carbinols

The most important reaction of the carbinols is their conversion into α-substituted acids, where the nature of the substituent depends on the nucleophile used. Two examples follow in which the aryltrichloromethylcarbinols are converted into α-methoxy acids by treatment with methanolic potassium hydroxide. This conversion is presumed to occur by the mechanism postulated for the reaction of aromatic aldehydes with chloroform, methanol, and base (10) (Reaction Scheme 2).



REACTION SCHEME 2.

3,5-Dichloro-2-hydroxyphenyltrichloromethylcarbinol (IV) was converted into the methoxy carbinol V and then into the dichlorodimethoxy acid VIII. The methylation step was interesting, since the carbinol hydroxy group was almost as reactive as the phenolic hydroxy group and since a mixture composed of more or less equal amounts of the methoxy compounds V, VI, and VII was obtained. The use of excess dimethyl sulfate and base gave only the neutral dimethoxy compound VII. The reaction of the mixture of methoxy compounds with potassium hydroxide in methanol at 65° converted methoxy compound V into the methoxy acid VIII, which could be separated from the other components (Reaction Scheme 3). The dimethoxy compound VII was inert. The position of the side

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chain in the methoxy acid VIII was established by treatment of it with sodium in liquid ammonia. The two chlorines were removed as expected, and most unexpectedly, the side-chain methoxy group was also removed, with the formation of the known 2-methoxyphenylacetic acid.

REACTION SCHEME 3.

3,4-Dichlorophenyltrichloromethylcarbinol was likewise converted by treatment with methanolic potassium hydroxide into the known 3,4-dichloro-α-methoxyphenylacetic acid in 53% of the theoretical yield. The orientation of the chlorine atoms was established by this transformation, and also by preparing the carbinol independently from 3,4-dichlorophenylmagnesium bromide and chloral, and by comparing the crystalline acetate esters.

Physiological Activity in Plants

3,4-Dichloro-α-methoxyphenylacetic acid has been tested as a plant growth regulator on a wide variety of plants. It is qualitatively similar in physiological effects to 2,4-dichlorophenoxyacetic acid but is less active (11). The 3,5-dichloro-α,2-dimethoxyphenylacetic acid was most unusual for a member of this series of compounds, as it exhibited no physiological activity when tested on bean plants.

EXPERIMENTAL

All melting and boiling points are corrected. Analyses were performed by Mrs. Christine Neilson and Dr. Franz Kasler. The infrared spectra were determined on a Beckman IR-5 spectrophotometer, with the liquid, melt, or mull being measured as a film between sodium chloride plates. Mulls were prepared with polychlorotrifluoroethylene[2] for the region 5 000 to 1 310 cm^{-1}, and with Nujol for 1 310 to 650 cm^{-1}.

General Procedure for Preparation of α-Trichloromethylbenzyl Alcohols

3,4-Dichloro-α-trichloromethylbenzyl Alcohol

In a 5 l three-necked flask equipped with a Hershberg stirrer, thermometer, and dropping funnel was placed 2 100 ml of *o*-dichlorobenzene. A solution was prepared consisting of 456 g (3.1 moles) of freshly distilled anhydrous chloral dissolved in 296 ml of *o*-dichlorobenzene. This amounted to 600 ml and was subsequently added to the reaction mixture in 10 equal portions. The *o*-dichlorobenzene in the 5 l flask was cooled to 5° and 60 ml of the chloral solution was added. The first of 10 portions of powdered anhydrous aluminium chloride (40 g each, 0.3 mole) was added, and then 60 ml of the chloral solution was dripped in over a 7 min period. The alternate additions of chloral and aluminium chloride were continued until all had been added. The temperature was kept at 5 to 7° during the first 20% of the reaction. The ice bath was then removed, and during the subsequent additions the temperature slowly rose to, and was maintained at, 20°. After the additions were complete, the dark red reaction mixture was stirred for an additional 10 min at 20°. The reaction mixture was stirred, cooled in an ice bath, and decomposed by the slow addition of 800 ml of 6 *N*

[2]*Series 11–14 light oil from Halocarbon Products Corp., Hackensack, New Jersey.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ice-cold hydrochloric acid followed by 400 ml of water. The temperature was not allowed to exceed 35°. The organic layer was washed with water, and stirred for 0.5 h each time with two portions of 1 500 ml of 5% sodium carbonate solution to remove chloral polymers. The excess *o*-dichlorobenzene was removed by distillation under water pump pressure and the residual 3,4-dichloro-α-trichloromethylbenzyl alcohol was distilled at 160–165° and 3 mm, in agreement with the literature value (3). The yield was 699 g or 76% of theory.

An alternative preparation of 3,4-dichloro-α-trichloromethylbenzyl alcohol was from 3,4-dichlorophenylmagnesium bromide and chloral. The Grignard reagent was prepared by converting acetanilide successively into *p*-bromoacetanilide, 4-bromo-2-chloroacetanilide, 4-bromo-2-chloroaniline, and 3,4-dichlorobromobenzene, and by allowing 108 g (0.80 mole) of the latter to react with 32 g (0.85 mole) of magnesium suspended in 350 ml of ether. Chloral (125 g, 0.85 mole) reacted with the Grignard reagent to form 75 g (32% of theory) of 3,4-dichloro-α-trichloromethylbenzyl alcohol, b.p. 160° at 3 mm.

The 3,4-dichloro-α-trichloromethylbenzyl alcohol from each of the above preparations was purified by conversion into the crystalline acetate, m.p. 83–84° (3), according to Howard's procedure (12). The acetate ester was hydrolyzed by refluxing overnight a solution of 26 g (0.07 mole) of it dissolved in 60 ml of ethanol containing 8 ml (0.1 mole) of concentrated hydrochloric acid and 5 ml of water. The 3,4-dichloro-α-trichloromethylbenzyl alcohol (16 g, 75% of theory) distilled as a clear liquid, b.p. 160° at 3 mm. The infrared spectrum showed absorption bands at 3 530, 3 080, 2 930, 1 590, 1 560, 1 460, 1 365, 1 290, 1 260, 1 190, 1 133, 1 075, 1 030, 1 005, 905, 890, 830, 800, 705, and 692 cm^{-1}.

General Procedure for Preparation of α-Trichloromethylbenzyl Chlorides

1-Chloro-4-(1,2,2,2-tetrachloroethyl)benzene

Chlorobenzene (34 g, 0.3 mole) and chloral (44 g, 0.3 mole) were dissolved in 150 ml of methylene chloride. The stirred solution was cooled to 0° and 40 g (0.3 mole) of anhydrous aluminium chloride was added over a period of 1 h. The reaction mixture was then allowed to warm up to room temperature over about a 5 h period, and was decomposed by adding it to a hydrochloric acid – ice mixture. The methylene chloride solution was washed twice with sodium bicarbonate solution, and with water. On distillation, 65 g (78% yield) of 1-chloro-4-(1,2,2,2-tetrachloroethyl)benzene was obtained, b.p. 158–160° at 15 mm. The infrared spectrum showed absorption bands at 3 040, 2 960, 1 500, 1 455, 1 345, 1 270, 1 230, 1 190, 1 085, 1 035, 1 015, 1 005, 925, 870, 820, 790–778, 760, 740–730, and 697 cm^{-1}.

Anal. Calcd. for $C_8H_5Cl_5$: C, 34.48; H, 1.81; Cl, 63.69. Found: C, 34.75; H, 2.07; Cl, 63.80.

This compound has previously been prepared by the action of phosphorus pentachloride (13) or thionyl chloride (14) on *p*-chlorophenyltrichloromethylcarbinol.

Results similar to those obtained with chlorobenzene were obtained with the compounds listed in Table II. The experimental conditions were identical with those given above, except for acetanilide. The results are summarized in Table III.

TABLE III

Product	Boiling point, °C (mm)	Melting point, °C	Analyses			
			Carbon		Hydrogen	
			Calcd.	Found	Calcd.	Found

With acetanilide, 20 g (0.15 mole) was allowed to react with the 0.3 *M* amounts of chloral and aluminium chloride as in the above procedure, except that the reaction temperature was 4 to 13°. Most of the product was isolated by filtration from the methylene chloride – water mixture after decomposition with the acid. Additional amounts were obtained by evaporating the methylene chloride and adding petroleum ether to a toluene extract of the tarry material. There was obtained a total of 13 g of *4'-(1,2,2,2-tetrachloroethyl)acetanilide*, which was recrystallized from methanol containing a small amount of water. The material has previously been prepared from acetanilide, chloral, and sulfuric acid (15).

1,2-Dichloro-4-(1,2,2,2-tetrachloroethyl)benzene (15 g, 80% of theory; b.p. 140° at 2.5 mm) was prepared by the general procedure of Haller *et al.* (13) from a solution of 17 g (0.06 mole) of 3,4-dichloro-α-trichloromethylbenzyl alcohol in 20 ml of dry benzene and 25 g (0.12 mole) of phosphorus pentachloride. Its infrared spectrum showed absorption bands at 1 475, 1 400, 1 230, 1 195, 1 140, 1 040, 1 015, 920, 885, 835, 825, 805, 760, 705, and 685 cm^{-1}.

α,β,β,3,4-Pentachlorostyrene

To 6.5 g (0.02 mole) of 1,2-dichloro-4-(1,2,2,2-tetrachloroethyl)benzene dissolved in 50 ml of 95% ethanol was added a solution of 1.1 g (0.02 mole) of potassium hydroxide dissolved in 15 ml of ethanol. A white

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

precipitate formed immediately. The reaction mixture was boiled for 1 min and filtered while hot. White crystals (5.1 g, 93% of theory) of the pentachlorostyrene separated out when the filtrate was cooled. After recrystallization from 95% ethanol, the α,β,β,3,4-pentachlorostyrene melted at 48–49°. The infrared spectrum of the melt showed absorption bands at 1 910, 1 770, 1 595, 1 550, 1 470, 1 380, 1 270, 1 225, 1 138, 1 062, 1 035, 998, 992, 952, 908, 880, 812, 802, 723, 717, 695, and 673 cm^{-1}.

Anal. Calcd. for $C_8H_3Cl_5$: C, 34.76; H, 1.09; Cl, 64.14. Found: C, 35.01; H, 1.35; Cl, 63.90.

p-Bromo-α,β,β-trichlorostyrene was likewise prepared in 76% yield from 1-bromo-4-(1,2,2,2-tetrachloroethyl)benzene by treatment with a sevenfold excess of methanolic potassium hydroxide; m.p. 36° from methanol. The infrared spectrum of the mull showed absorption bands of 1 585, 1 490, 1 395, 1 075, 1 015, 980, 880, 830, and 780 cm^{-1}.

Anal. Calcd. for $C_8H_4BrCl_3$: C, 33.55; H, 1.41. Found: C, 33.63; H, 1.70.

3,5-Dichloro-2-hydroxy-α-trichloromethylbenzyl Alcohol (IV)

In a 2 l three-necked flask was placed 250 g (1.53 moles) of 2,4-dichlorophenol dissolved in 650 ml of carbon disulfide. The mixture was cooled to 4° and 240 g (1.63 moles) of freshly distilled anhydrous chloral was added. Powdered anhydrous aluminium chloride (454 g, 3.35 moles) was spooned into the efficiently stirred reaction mixture over a 50 min period. The flask was cooled by an ice bath during the addition. The temperature rose to 15° during the addition of the first few portions of aluminium chloride and then fell slowly. Between additions, the reaction mixture was protected from atmospheric moisture by a calcium chloride drying tube.

After the last of the aluminium chloride had been added, the reaction mixture was warmed to 30° and stirred for another 20 min. It was then cooled to 0° and decomposed by the dropwise addition of 400 ml of cold 6 *N* hydrochloric acid. The temperature was maintained below 20° to prevent the reaction from becoming violent. The solid 3,5-dichloro-2-hydroxy-α-trichloromethylbenzyl alcohol was filtered, washed with dilute hydrochloric acid and with water, and recrystallized from a water–methanol solution. The white crystals (270 g, 60% of theory) melted at 128–129°. The analytical sample was recrystallized from cyclohexane. The infrared spectrum of a Nujol mull showed absorption bands at 3 450, 3 120, 2 950, 1 750, 1 590, 1 470, 1 430, 1 370, 1 330, 1 295, 1 250, 1 215, 1 170, 1 095, 1 070, 1 010, 918, 873, 853, 827, 808, 732, and 675 cm^{-1}.

Anal. Calcd. for $C_8H_5O_2Cl_5$: C, 30.95; H, 1.62; Cl, 57.12. Found: C, 31.02; H, 1.50; Cl, 57.30.

Methylation of 3,5-Dichloro-2-hydroxy-α-trichloromethylbenzyl Alcohol

A well-stirred mixture of 3,5-dichloro-2-hydroxy-α-trichloromethylbenzyl alcohol (IV) (130 g, 0.42 mole) and 170 ml of water was cooled to 0°, and 106 g (0.84 mole) of freshly distilled dimethyl sulfate was added. A solution of 16.8 g (0.42 mole) of sodium hydroxide in 150 ml of water was then dripped in over a 1 h period. After the solution was allowed to stand overnight, the organic layer was extracted with chloroform, washed with an ice-cold 10% sodium hydroxide solution to remove the phenolic components, and then washed with water. On distillation, there was obtained 80 g of a pale yellow oil, b.p. 140° at 3 mm, which was a mixture of approximately equal parts of 3,5-dichloro-2-methoxy-α-trichloromethylbenzyl alcohol (V) and 3,5-dichloro-2-methoxy-α-trichloromethylbenzyl methyl ether (VII), with some of the 3,5-dichloro-2-hydroxy-α-trichloromethylbenzyl methyl ether (VI) still present. The isolation of compound VI is described under the preparation of 3,5-dichloro-α,2-dimethoxyphenylacetic acid.

When the methylation was carried out with 54 g of the starting 3,5-dichloro-2-hydroxy-α-trichloromethylbenzyl alcohol (IV) under the same conditions, except with twice the relative amount of sodium hydroxide and four times as much water, 28 g of crude *3,5-dichloro-2-methoxy-α-trichloromethylbenzyl methyl ether (VII)* separated from the alkaline reaction mixture. On recrystallization from 95% ethanol, 24 g (37% yield) of white crystals, m.p. 79–80°, was obtained. The infrared spectrum of a Nujol mull showed absorption bands at 1 620, 1 425, 1 330, 1 250, 1 230, 1 200, 1 165, 1 120, 1 032, 995, 922, 878, 868, 847, 808, 775, and 724 cm^{-1}.

Anal. Calcd. for $C_{10}H_9O_2Cl_5$: C, 35.46; H, 2.68; OCH_3, 18.34. Found: C, 35.75; H, 3.05; OCH_3, 18.60.

3,5-Dichloro-α,2-dimethoxyphenylacetic Acid (VIII)

Sixty grams of the above mixture of compounds V, VI, and VII from the methylation step was dissolved in 200 ml of methanol, the solution heated to reflux, and a solution of 71 g (0.92 mole) of potassium hydroxide in 170 ml of methanol added. The reaction mixture was stirred and refluxed for 1 h. After the mixture had cooled to room temperature, the potassium chloride was filtered off and washed with small portions of methanol. An equal volume of water was added to the combined filtrates, and the mixture was extracted with chloroform to remove the neutral materials. The aqueous layer was acidified with dilute hydrochloric acid and extracted with chloroform. The chloroform was evaporated and the residual crude acid fraction dissolved in 20 ml of hot carbon tetrachloride. When the solution had cooled in an ice bath, 4 g of white crystalline *3,5-dichloro-2-hydroxy-α-trichloromethylbenzyl methyl ether* (VI) separated and was filtered off. It melted at 150–151°. The infrared spectrum of a mull showed absorption bands at 3 380, 1 595, 1 465, 1 415, 1 325, 1 255, 1 190, 1 150, 1 100, 1 040, 990, 920, 900, 870, 813–795, 750, 730, and 665 cm^{-1}.

Anal. Calcd. for $C_9H_7O_2Cl_5$: C, 33.31; H, 2.17; Cl, 54.63; OCH_3, 9.57. Found: C, 33.38; H, 2.43; Cl, 54.90; OCH_3, 9.55.

The carbon tetrachloride mother liquor was evaporated and 20 ml of water added to the crude residual acid. The mixture was neutralized with 10% sodium hydroxide solution to the phenolphthalein end point, and the solution was evaporated to dryness. The crystals were stirred with acetone, filtered to remove the organic

For personal use only.

impurities, and washed with small portions of acetone until they were white. The resulting 20 g (35% of theory, based on methylated carbinol mixture) of sodium 3,5-dichloro-α,2-dimethoxyphenylacetate was recrystallized from 95% ethanol, and converted into the free acid by acidifying an aqueous solution of the salt. 3,5-Dichloro-α,2-dimethoxyphenylacetic acid (VIII) separated as an oil which solidified after it was stirred for a few minutes. The yield was 14.6 g. It was recrystallized twice from cyclohexane, and then melted at 80–82°. The infrared spectrum of a mull showed absorption bands at 2 940, 1 730, 1 475, 1 420, 1 335, 1 310, 1 250, 1 210, 1 190, 1 110, 1 100, 995, 920, 865, 850, 770, 715, and 670 cm^{-1}.

Anal. Calcd. for $C_{10}H_{10}Cl_2O_4$: C, 45.31; H, 3.80; Cl, 26.75; OCH_3, 23.41. Found: C, 45.40; H, 4.07; Cl, 27.04; OCH_3, 23.72.

Treatment of Acid VIII with Sodium in Liquid Ammonia

In a 400 ml beaker was placed 50 ml of liquid ammonia. Sodium (1 g) and 3,5-dichloro-α,2-dimethoxyphenylacetic acid (0.72 g) were added in small portions with intermittent stirring. The liquid ammonia was allowed to evaporate, and 10 ml of water was added to the residue. The solution was filtered, and the filtrate was acidified with 1 *N* hydrochloric acid and extracted with chloroform. On evaporation of the chloroform, a brown oil remained which solidified when it was allowed to stand. It was recrystallized twice from cyclohexane, and the 0.4 g of *o-methoxyphenylacetic acid* melted at 119–122°, in agreement with the literature value (16). It was identified by analysis and by comparison with an authentic sample prepared from α,2-dimethoxyphenylacetic acid (10) by a similar treatment with sodium in liquid ammonia.

3,4-Dichloro-α-methoxyphenylacetic Acid

In a 5 l three-necked flask equipped with a thermometer, stirrer, and dropping funnel were placed 441 g (1.5 moles) of distilled 3,4-dichloro-α-trichloromethylbenzyl alcohol, as obtained from the Friedel–Crafts reaction without subsequent purification, and 440 ml of methanol. The temperature was brought to 50° by means of a warm water bath, and a solution of 420 g (7.5 moles) of technical flake potassium hydroxide dissolved in 1 680 ml of methanol was added dropwise over a 45 min period. Hot water and ice were available for changing the water bath temperature quickly to maintain the reaction temperature at 50 ± 1°. (The yield drops drastically if the reaction is run at 35 or 65°.) The reaction mixture was stirred for an additional 2 h at 50–55°, after which time heat evolution had stopped; it was allowed to stand overnight.

The precipitated potassium chloride was filtered off and washed with 250 ml of 4:1 methanol–water. An equal volume of water was added to the combined filtrates, and the pH of the alkaline mixture brought to approximately 8 with 6 *N* hydrochloric acid. The solution was poured off from an insoluble neutral oil (about 40 g), and treated with activated carbon to yield a clear, yellow filtrate. It was acidified to a pH of 3.3 with 6 *N* hydrochloric acid, and 400 g of sodium chloride was added. The pH determinations were made with a pH meter on small samples diluted with four volumes of water. After the solution was stirred at room temperature for 2 h, the major crop of the crude sodium acid salt was filtered off. An additional small amount (20 g) was obtained by readjusting the pH to 3.3, seeding the solution, and maintaining the temperature near 0° for several days with occasional stirring. The precipitates were combined, and the impurities were removed by stirring with 300 ml of acetone for 10 min, filtering, and repeating the treatment with 500 ml of water at 0°. After another such washing cycle, the air-dried precipitate of *sodium hydrogen di(3,4-dichloro-α-methoxyphenylacetate)* weighed 195 g (53% of theory). It was converted into the free acid by dissolving it in dilute base and pouring a filtered solution of this into a 100% excess of 6 *N* hydrochloric acid. The acid separated as an oil. It was washed once with water by decantation. It solidified on seeding and stirring and was recrystallized from cyclohexane. The free acid melted at 88–89.5°, in agreement with the literature value (17).

ACKNOWLEDGMENTS

The financial support provided by the Celanese Corporation to C. L. L. is deeply appreciated. The examination of the various compounds for their plant growth regulating properties was carried out by L. L. Danielson or J. W. Mitchell and their co-workers at the U.S. Department of Agriculture Plant Industry Station, Beltsville, Maryland.

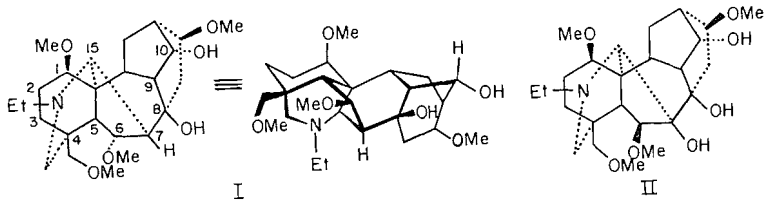
THE CORRELATION OF CHASMANINE WITH BROWNIINE[1]

O. E. EDWARDS, L. FONZES,[2] AND LÉO MARION[3]
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 15, 1965

ABSTRACT



By means of oxidative and reductive fission, respectively, of the 7,15-bridge, the alkaloids browniine and chasmanine were converted into 7,15-seco-7,10-diketones. After epimerization of its C-6 methoxyl the diketone derived from chasmanine was identical with that obtained from browniine. This correlation confirms the structure previously tentatively assigned to chasmanine, and establishes its stereochemistry since browniine and lycoctonine have been interrelated.

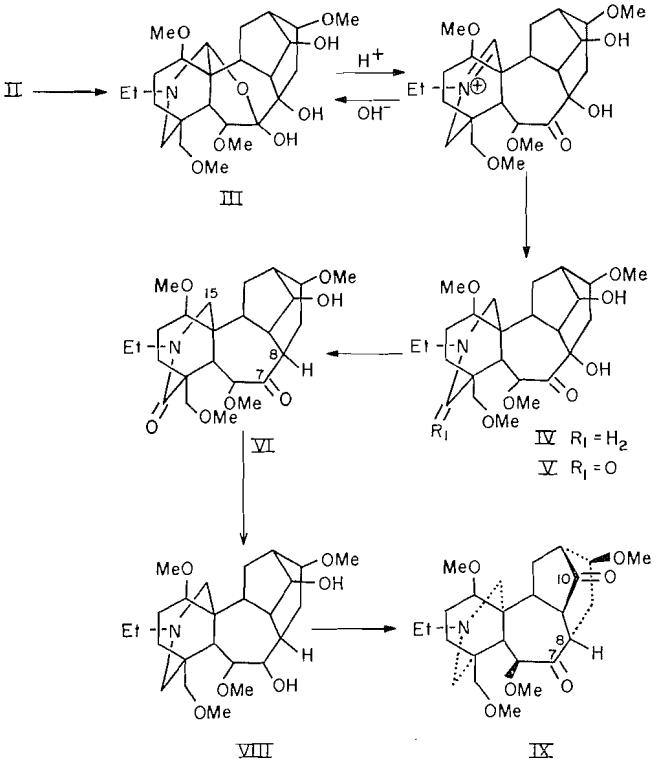
RÉSUMÉ

Au moyen de la fission oxidative et réductive respectivement du pont en 7,15, la browniine et la chasmanine ont été converties en 7,15-seco-7,10 dicétones. Après épimérisation de son groupement méthoxyl en C-6, la dicétone dérivée de la chasmanine est identique à la dicétone obtenue à partir de la browniine. Cette conversion confirme la structure déjà attribuée à la chasmanine, et établie sa stéréochimie puisque la corrélation de la browniine et de la lycoctonine a été préalablement accomplie.

The alkaloid chasmanine, whose empirical formula can be expanded to $C_{19}H_{22}(N{\cdot}C_2H_5)(OH)_2(OCH_3)_4$, was recently discovered among the strong bases of *Aconitum chasmanthum* Stapf (1). Several of its reactions paralleled those of pseudaconitine and bikhaconitine, and on this basis it was tentatively assigned structure I, which accommodated all its reactions (2). No evidence, however, was available concerning the methoxyl assigned to C-1, except by analogy. A notable feature of the postulated structure is the absence of a tertiary hydroxyl on C-11. Neoline (3) is the only other known aconitine-type[4] diterpenoid alkaloid lacking this hydroxyl.

Neoline has not been related to an alkaloid of known structure, and attempts to relate chasmanine to bikhaconine were unsuccessful (2). We now report the conversion of browniine (II), whose structure is known with certainty (4), and chasmanine (I) into a common derivative, thus confirming the structure and proving the stereochemistry of the latter. In this correlation use was made of two unusual reactions of the lycoctonine-type and aconitine-type alkaloids which lead to 7,15-seco derivatives.

I II



The alkaloid browniine, which is closely related to lycoctonine, differs from chasmanine in that it contains a 7-hydroxyl, and its 6-methoxyl is β-oriented; in contrast, this methoxyl in chasmanine is α-oriented. The 6-α-methoxyl of chasmanine is crowded by the substituents on C-4; hence we considered it probable that, if a 7,15-seco-7-ketone could be

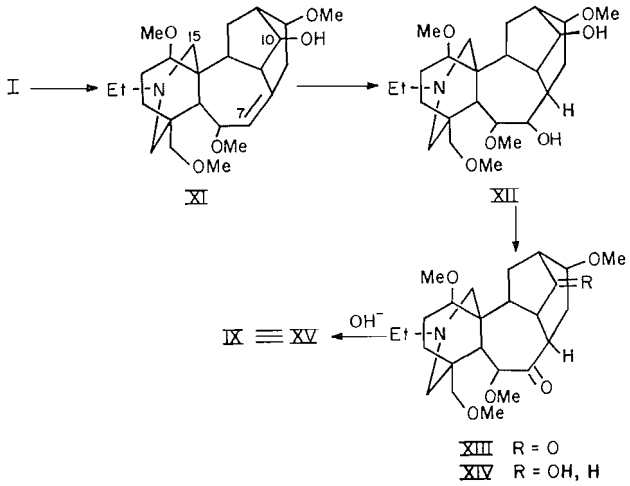
[1]*Issued as N.R.C. No. 8796.*
[2]*National Research Council of Canada Postdoctorate Fellow (1964–1965).*
[3]*Present address: Faculty of Pure and Applied Science, University of Ottawa, Ottawa.*
[4]*We use the term aconitine-type to denote alkaloids with the lycoctonine skeleton but with hydrogen on C-7. Lycoctonine-type alkaloids are those with a hydroxyl on this carbon.*

prepared, this could be epimerized to the 6-β-methoxyl analogue. Correlation could then be made with a 7,15-seco-7-ketone derived from browniine.

When lycoctonine was oxidized with lead tetraacetate (5) it gave rise to a compound originally thought to be a simple carbinolamine, and therefore named hydroxylcoctonine. This compound, which was later shown to contain a carbinolamine masked as a hemiketal (6, 7), produced a ketone (isolycoctonine) when hydrogenated catalytically (7). It was anticipated that browniine would behave in a manner parallel to that of lycoctonine when treated with lead tetraacetate. Indeed, a nearly quantitative yield of hydroxybrowniine[5] (III), m.p. 115–118°, was obtained. The infrared spectrum of this base contained no carbonyl absorption whereas that of its perchlorate showed a strong band at 1 706 cm^{-1}. Hydrogenation of hydroxybrowniine perchlorate produced isobrowniine (IV), which in the infrared showed a carbonyl band at 1 710 cm^{-1}.

Oxidation of IV in acetone with potassium permanganate during 3 min (8) gave a fair yield of oxoisobrowniine (V), which in the infrared showed absorption at 1 710 cm^{-1} (CO) and 1 635 cm^{-1} (lactam CO). That the N-ethyl group was still present was shown by a triplet centered at δ 1.1 in the nuclear magnetic resonance (n.m.r.) spectrum. After one chromatographic purification on a column, the lactam V produced a single spot in thin-layer chromatography, but could not be induced to crystallize.

The reduction of V with a mixture of acetic anhydride, acetic acid, and zinc (9) gave in rather poor yield a mixture of two products, VI (R_f 0.56) and VII (R_f 0.35), accompanied by a small quantity of unchanged starting material. The compound VI, m.p. 152–159°, was identified as the expected 8-deoxyoxoisobrowniine, $C_{25}H_{39}O_7N$, showing in the infrared



[5]*The trivial names used for the analogues in the lycoctonine series have been adopted for the browniine derivatives.*

For personal use only.

absorption bands at 1 697 cm^{-1} (CO) and 1 635 cm^{-1} (lactam CO). Compound VII, m.p. 161–166°, gave analytical figures corresponding to the empirical formula $C_{25}H_{41}O_7N$. Its infrared spectrum contained no ketonic carbonyl absorption, but contained a lactam carbonyl band (1 635 cm^{-1}). That it was 8-deoxy-7-dihydrooxoisobrowniine, the product of the reduction of the ketone carbonyl of 8-deoxyoxoisobrowniine (VI), was proven by its formation from the latter via borohydride reduction.

The total reduction of compounds VI and VII with lithium aluminium hydride gave rise in each case to 8-deoxy-7-dihydroisobrowniine (VIII) which, on oxidation, produced the corresponding diketone, i.e. 10-dehydro-8-deoxyisobrowniine (IX), m.p. 156–158°. The infrared spectrum of IX contained absorption bands at 1 762 cm^{-1} (cyclopentanone) and 1 702 cm^{-1} (six-membered or larger cyclic ketone).

Starting with chasmanine (cf. ref. 2) we obtained the same derivative by a different route (9). Diacetylchasmanine (X), when treated with lithium tri-*t*-butoxyaluminohydride at 140° in diglyme,[6] produced the 7,15-seco olefin XI, m.p. 104–105°, showing in the n.m.r. a badly resolved doublet centered at δ 5.6 (vinyl proton), a triplet centered at δ 0.99 caused by the N-ethyl group (shielded by the double bond), and singlets at δ 3.40 (3H) and δ 3.38 (9H) indicative of four methoxyl groups. Hydration of XI with diborane by Brown's method (10) produced a 7,15-seco-7-hydroxy base XII, $C_{25}H_{43}O_6N$, m.p. 179–181°.

Oxidation of XII with chromic oxide in acetone gave a mixture of two ketones, XIII and XIV, which were separated by column chromatography. The ketone XIII was the expected 7,10-diketone, $C_{25}H_{39}O_6N$ (R_f 0.76). It had infrared absorption at 1 750 cm^{-1} (cyclopentanone) and 1 710 cm^{-1} (carbonyl in a six-membered or larger ring). The ketone XIV was a monoketone with the carbonyl function in a six-membered or larger ring (ν_{max} 1 710 cm^{-1}).

The diketone XIII, when refluxed in a 50:50 ethanol–water solution containing 15% of potassium hydroxide, was epimerized slowly at position 6. The yield of the epimer, however, was low, with degradation products predominating. The epimeric diketone XV thus obtained was in every respect identical with the diketone IX derived from browniine.

This interrelation confirms the structure originally assigned to chasmanine (2) and establishes that, except at C-6, it has the same relative and absolute configuration as

[6]*Trivial name of diethyleneglycol dimethyl ether.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

browniine. It also dispels any slight doubt that the C-6 methoxyl group of browniine has the β-configuration (4). The oxidation studies of Achmatowicz *et al.* (8) were also consistent with this assignment, since browniine gave predominantly the lactam.

It now seems possible to test the structure and configuration proposed for neoline (3) by interrelation with chasmanine through appropriate methyl ethers.

EXPERIMENTAL

For thin-layer chromatography, use was made of glass plates covered with a thickness of 250 μ of Merck's silica gel G which had been reactivated 15 min before utilization by drying in an oven at 120°. The developing solvents consisted of 90:10 dichloromethane–methanol (solvent I), 96:4 dichloromethane–methanol (solvent II), and 99:1 dichloromethane–methanol (solvent III). This last solvent was used in a jar saturated with ammonia vapors. The spots were located by means of modified Dragendorff's reagent, or iodine vapor. Melting points were taken on a Kofler stage and not corrected. Unless otherwise mentioned, the infrared spectra were measured in KBr pellets on a Perkin–Elmer infracord spectrometer, and the n.m.r. spectra were measured in deuteriochloroform solution containing tetramethylsilane as an internal reference, on a Varian A-60 instrument.

Hydroxybrowniine (III)

Browniine perchlorate (580 mg) was dissolved in water and the base liberated by the addition of sodium carbonate. The solution was extracted with dichloromethane, the extract dried over sodium sulfate, and the solvent evaporated under reduced pressure. To the residual base dissolved in glacial acetic acid (10 ml) was added a solution of lead tetraacetate (520 mg) in glacial acetic acid (20 ml). The mixture was allowed to stand at room temperature for 1 h, after which the reaction was stopped by the addition of two drops of glycerol. A concentrated aqueous solution of sodium sulfate was added, and the precipitated lead sulfate was filtered and washed with water. The combined filtrate and washings were evaporated under reduced pressure, the residue was dissolved in water, and the solution was made basic with sodium carbonate and extracted with dichloromethane. The extract was dried over sodium sulfate and the solvent evaporated under reduced pressure. Hydroxybrowniine was left as a colorless oil (485 mg, yield 97%). Thin-layer chromatography showed the presence of very little unchanged browniine. The product was dissolved in benzene and chromatographed on a column of neutral alumina, grade III (20 g). It was eluted with first benzene, then benzene–ether, and finally ether–methanol. The pure hydroxybrowniine was crystallized with difficulty from ether, m.p. 115–118; R_f 0.51 (solvent II). Its n.m.r. spectrum contained a triplet centered at δ 1.08 indicative of a N-ethyl group and singlets at δ 3.30, 3.38, 3.42, and 3.61 caused by four methoxyl groups. The infrared spectrum of the base contained no carbonyl absorption, but that of its amorphous perchlorate showed a carbonyl band at 1 706 cm^{-1}.

Anal. Calcd. for $C_{25}H_{41}O_8N$: C, 62.09; H, 8.55. Found: C, 62.09; H, 8.41.

Isobrowniine (IV)

To platinic oxide (120 mg) suspended in glacial acetic acid (10 ml) and previously hydrogenated was added a solution of hydroxybrowniine (485 mg) in glacial acetic acid (10 ml), and the mixture was shaken at room temperature in an atmosphere of hydrogen. After 10 min the theoretical quantity of hydrogen had been absorbed and the reaction was stopped. The platinum was filtered off and washed with methanol. The combined filtrate and washings were evaporated under reduced pressure and the residue was dissolved in water. After alkalization with sodium carbonate, the solution was extracted with dichloromethane, and the extract was dried with sodium sulfate and evaporated under reduced pressure. Isobrowniine (460 mg) was left as a colorless froth (yield 98%). In thin-layer chromatography a single spot appeared (R_f 0.64, solvent II), but even after chromatography on alumina, the product could not be induced to crystallize. Its infrared spectrum in dichloromethane solution contained a carbonyl absorption band (1 708 cm^{-1}). The n.m.r. spectrum showed a triplet centered at δ 0.95 (N-ethyl) and singlets at δ 3.30, 3.32, 3.35, and 3.40 (four methoxyl groups).

Oxoisobrowniine (V)

A solution of isobrowniine (700 mg) in 80:20 acetone–water (200 ml) was added all at once to a solution of potassium permanganate (500 mg) in 60:40 acetone–water (200 ml). After the solution had been stirred at room temperature for 3 min, the excess permanganate was destroyed by the addition of sodium bisulfite. The mixture was filtered through Celite and the filtrate evaporated to remove the acetone and part of the water. The residual solution, after addition of sulfuric acid (10 ml, 2 *N*), was extracted with dichloromethane. The extract was dried over sodium sulfite and evaporated to dryness under reduced pressure. Oxoisobrowniine was left as a colorless froth (390 mg), which was dissolved in benzene, chromatographed on alumina, and eluted with benzene and benzene–dichloromethane. The colorless oil thus obtained could not be induced to crystallize (R_f 0.93, solvent II). In the infrared taken in dichloromethane solution it showed absorption at 1 710 cm^{-1} (CO) and 1 635 cm^{-1} (lactam CO). Its n.m.r. spectrum contained a triplet centered at δ 1.1 (N-ethyl) and singlets at δ 3.38 (6H), 3.42 (3H), and 3.48 (3H) caused by four methoxyl groups.

8-Deoxyoxoisobrowniine (VI) and 8-Deoxy-7-dihydrooxoisobrowniine (VII)

Oxoisobrowniine (200 mg) was dissolved in acetic anhydride (10 ml) and acetic acid (10 ml). To the refluxing solution, during 1 h, was added zinc powder (14 g) in small portions. Boiling was continued for 30 min after the addition of the zinc, and the cooled mixture was filtered. The filtered zinc was washed thoroughly with benzene. The combined filtrate and washings were evaporated to dryness at 50° under reduced pressure. The white residue that was left was dissolved in water and the solution extracted with dichloromethane. The extract was washed with water, dried over potassium carbonate, and evaporated under reduced pressure. The residue (210 mg) was hydrolyzed by refluxing it for 1 h with 60:40 methanol–water (60 ml) containing 3% potassium hydroxide. The reaction mixture was concentrated at 40° under reduced pressure until the methanol had been removed, and the cooled solution was extracted with dichloromethane. The extract was dried over sodium sulfate and the solvent evaporated under reduced pressure. It left a residual, slightly yellowish oil (175 mg). Thin-layer chromatography revealed that this oil consisted of two products, VI (R_f 0.56) and VII (R_f 0.35), together with a small quantity of unreacted material. The crude product was dissolved in benzene and chromatographed on neutral alumina, grade III (7 g). It was eluted with benzene, dichloromethane, and methanol and the eluant was collected in 25 ml fractions. Elution with benzene gave fraction 1 (20 mg mixture) and fraction 2 (pure VI). Benzene–CH_2Cl_2 (90:10) gave fractions 3–6 (16 mg V and VI). Benzene–CH_2Cl_2 (50:50) gave fractions 7–8 (15 mg V and VI). Together, benzene–CH_2Cl_2 (20:80) and pure dichloromethane gave fractions 9–12 (10 mg V). With CH_2Cl_2 containing 1% methanol, fraction 13 gave 40 mg V and VII and fractions 14–16 gave pure VII (37 mg).

8-Deoxyoxoisobrowniine (VI) (R_f 0.56, solvent II) was crystallized from benzene–hexane, m.p. 152–154°; ν_{max} 1 697 cm^{-1} (CO) and 1 635 cm^{-1} (lactam CO).

Anal. Calcd. for $C_{25}H_{39}O_7N$: C, 64.49; H, 8.44; N, 3.01. Found: C, 64.48; H, 8.55; N, 3.20.

8-Deoxy-7-dihydrooxoisobrowniine (VII) (R_f 0.35, solvent II) was crystallized from benzene–hexane, m.p. 161–166°; ν_{max} 1 635 cm^{-1} (lactam CO).

Anal. Calcd. for $C_{25}H_{41}O_7N$: C, 64.21; H, 8.84. Found: C, 64.39; H, 8.35.

8-Deoxy-7-dihydroisobrowniine (VIII)

To a crude mixture of VI and VII dissolved in dioxane (30 ml) was added lithium aluminium hydride (350 mg) dissolved in ether. The mixture was heated until the ether had evaporated, and then refluxed for 45 min. The excess reagent was destroyed by the cautious addition of methanol. Celite was added to facilitate filtration, followed by water. The mixture was filtered through a Celite bed, the filter cake was washed with methanol, and the combined filtrate and washings were evaporated under reduced pressure. The residue was dissolved in dichloromethane, and the solution was dried over sodium sulfate and evaporated *in vacuo* to leave a colorless froth (360 mg) of crude product containing a quantity of starting material. It was dissolved in hexane and chromatographed on a column of neutral alumina, grade III. The eluate was collected in 20 ml fractions. Twelve fractions were obtained by elution with (*a*) 50:50 benzene–hexane, (*b*) 80:20 benzene–hexane, (*c*) benzene, (*d*) 90:10 benzene–CH_2Cl_2, and (*e*) 80:20 benzene–CH_2Cl_2, which yielded 70 mg of 8-deoxy-7-dihydroisobrowniine (VIII). Further elution yielded 260 mg of a mixture of VIII and starting material. The compound VIII was amorphous and colorless, and could not be induced to crystallize (R_f 0.8, solvent I). Its infrared spectrum contained no carbonyl, but did contain OH absorption bands (3 500, 3 600 cm^{-1}). The n.m.r. spectrum showed a triplet centered at δ 1.04 (N-ethyl) and singlets at δ 3.8 (3H) and 3.30 (9H) caused by four methoxyl groups.

Anal. Calcd. for $C_{25}H_{43}O_6N$: C, 66.19; H, 9.56. Found: C, 66.01; H, 9.59.

10-Dehydro-8-deoxyisobrowniine (IX)

To a solution of the compound VIII (70 mg) in acetone (5 ml) cooled in ice was added an ice-cold solution of chromic oxide (140 mg) in acetone, and the reaction mixture was allowed to stand at room temperature for 15 h. The acetone was evaporated under reduced pressure and the residue dissolved in 2 *N* sulfuric acid (10 ml). Sodium sulfite was added until the green color persisted, and the solution was neutralized with sodium carbonate and extracted with dichloromethane. The extract, after it had been dried over sodium sulfate and evaporated under reduced pressure, left a residual yellowish oil (70 mg). Thin-layer chromatography showed this oil to be a mixture of a small quantity of a weakly polar substance, some unreacted VIII, and several strongly polar products. The crude product was dissolved in hexane and chromatographed on neutral alumina, grade III (3 g). The eluate was collected in 15 ml fractions. Four fractions were obtained by elution with 50:50 hexane–benzene and 20:80 hexane–benzene. Further elution with benzene gave two fractions yielding 12 mg of the desired 10-dehydro-8-deoxyisobrowniine, which was crystallized from ether and recrystallized from ether–hexane, m.p. 156–158°; R_f 0.8 (solvent II); ν_{max} 1 762 cm^{-1} (five-membered cyclic ketone) and 1 702 cm^{-1} (CO in six-membered or larger ring), measured in a KBr pellet on a Perkin–Elmer double-beam, model 21B spectrometer; $[\alpha]_D^{25}$ +12.5° (*c*, 0.48 in absolute ethanol).

Anal. Calcd. for $C_{25}H_{39}O_6N$: C, 66.79; H, 8.75. Found: C, 66.49; H, 8.80.

Reductive Cleavage of Chasmanine (7,15-Seco Olefin XI)

Lithium aluminium hydride (2.5 g) dissolved in ether was added dropwise to anhydrous *t*-butanol (20 ml) maintained at the reflux temperature of ether. After completion of the reaction the precipitated lithium tri-*t*-butoxyaluminohydride was filtered off, washed rapidly and thoroughly with anhydrous ether, and dried

in vacuo. It was dissolved in diglyme (20 ml) which had been previously heated to 100°, and rapidly added to a solution of diacetylchasmanine (X) (3 g) in diglyme (20 ml) previously heated to 140°. The temperature was maintained at 140° for 15 min and the mixture cooled. The excess reagent was destroyed by the cautious addition of methanol. Celite was added to facilitate filtration, followed by water, and the mixture was filtered through Celite. The filter cake was washed thoroughly with methanol, and the combined filtrate and washings were evaporated under the reduced pressure first of a water pump and subsequently of an oil pump. The residue was dissolved in water and the solution extracted with dichloromethane. The extract was washed with several portions of 2 *N* sulfuric acid, and the combined acid washings were made basic with sodium carbonate and extracted with dichloromethane. This last extract was dried over sodium sulfate and evaporated to dryness under reduced pressure. It left the product as a crystalline residue (2 g) which, after crystallization from ether, melted at 104–105°; R_f 0.85 (solvent III); ν_{max} 3 520 cm^{-1} (OH). Its n.m.r. spectrum showed a badly resolved doublet at δ 5.60 indicative of a single olefinic proton, and singlets at δ 3.40 (3H) and 3.38 (9H) caused by four methoxyl groups.

Anal. Calcd. for $C_{25}H_{41}O_5N$: C, 68.93; H, 9.49. Found: C, 69.38; H, 9.45.

7,15-Seco-7-hydroxy Base XII

The seco olefin XI (800 mg) dissolved in tetrahydrofuran (20 ml) was cooled in ice, and to this solution was added a 1 *M* solution (20 ml) of diborane in tetrahydrofuran. After the mixture had been allowed to stand at room temperature for 3 h, 5% aqueous sodium hydroxide (10 ml) was slowly added, followed by 30% hydrogen peroxide. The mixture was then kept on the steam bath for 5 min, and allowed to stand at room temperature until the evolution of gas had ceased. It was then extracted with dichloromethane, and the extract was dried over sodium sulfate and evaporated under reduced pressure. The residual product XII was crystallized twice from ether, m.p. 179–181°; R_f 0.69 (solvent III); ν_{max} 3 450 cm^{-1}. Its n.m.r. spectrum contained a triplet centered at δ 1.00 (N-ethyl) and singlets at δ 3.38 (3H), 3.35 (3H), and 3.33 (6H) caused by four methoxyl groups.

Anal. Calcd. for $C_{25}H_{43}O_6N$: C, 66.19; H, 9.56. Found: C, 66.22; H, 9.73.

The 7,10-Diketone XIII and the 7-Ketone XIV

When compound XII (600 mg) was oxidized exactly as described for the oxidation of 8-deoxy-7-dihydroisobrowniine (VIII), the yield of crude product was 460 mg. In thin-layer chromatography the product showed two main spots. It was dissolved in hexane and chromatographed on a column of neutral alumina, grade III (15 g). The eluant was collected in 25 ml fractions. Elution with 50:50 hexane–benzene, with the 20:80 mixture, with benzene, and with 90:10 benzene–CH_2Cl_2 gave in fractions 3–13 the pure diketone XIII (135 mg). Continued elution with 90:10 benzene–CH_2Cl_2 and the 80:20 mixture gave in fractions 14–16 a mixture of XIII and XIV. Elution with 50:50 and 20:80 benzene–CH_2Cl_2 and with CH_2Cl_2 gave in fractions 17–24 pure compound XIV (61 mg).

Compound XIII was a colorless froth; R_f 0.76 (solvent III); ν_{max} 1 760 cm^{-1} (five-membered cyclic ketone) and 1 700 cm^{-1} (CO in six-membered or larger ring). Its n.m.r. spectrum contained a triplet centered at δ 1.07 (N-ethyl) and singlets at δ 3.37 (3H) and 3.50 (9H) indicative of four methoxyl groups.

Anal. Calcd. for $C_{25}H_{39}O_6N$: C, 66.79; H, 8.75. Found: C, 66.68; H, 8.81.

Compound XIV was crystallized from ether, m.p. 142–146°; R_f 0.59 (solvent III); ν_{max} 1 696 cm^{-1} (CO in six-membered or larger ring).

Anal. Calcd. for $C_{25}H_{41}O_6N$: C, 66.49; H, 9.15. Found: C, 67.08; H, 9.51.

Epimerization of the 7,10-Diketone XIII

Compound XIII (135 mg), dissolved in 50:50 ethanol–water containing potassium hydroxide (6 g), was refluxed and the course of the reaction followed by thin-layer chromatography. After 4 h, XIII had almost entirely disappeared, and a spot with a R_f value identical with that of 10-dehydro-8-deoxyisobrowniine (IX) was observed together with numerous spots of very polar substances. The reaction was then stopped, the ethanol evaporated under reduced pressure, and the remaining aqueous solution extracted with dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated to dryness under reduced pressure. The residue (80 mg) was dissolved in hexane and chromatographed on a column of neutral alumina, grade III (4 g). Elution of the column with 20:80 hexane–benzene yielded the epimerized product XV (15 mg), which was crystallized first from ether and then from ether–hexane, m.p. 158–160°; R_f 0.8 (solvent II); $[\alpha]_D^{25}$ +12.3° (*c*, 0.57 in absolute ethanol). A mixture with compound IX derived from brownine melted at 156–159°; ν_{max} 1 762 cm^{-1} (CO in five-membered ring) and 1 702 cm^{-1} (CO in six-membered or larger ring). The infrared spectrum was taken in a KBr pellet on a Perkin–Elmer double-beam, model 21B spectrometer and was identical with that of compound IX. The X-ray powder pattern was exactly superimposable on that of 10-dehydro-8-deoxyisobrowniine (IX).

REDUCTIVE CLEAVAGE WITH METAL IN LIQUID AMMONIA

I. THE SELECTIVE CLEAVAGE OF THE BENZYLTHIO C—S BOND VERSUS THE BENZYLIDENEDIOXY C—O BOND IN METHYL *S*-BENZYL-4,6-*O*-BENZYLIDENE-2-THIO-α-D-ALTROPYRANOSIDES; THE INFLUENCE OF THE COSOLVENT 1,2-DIMETHOXYETHANE ON THE COURSE OF THE REACTION

U. G. NAYAK[1] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 28, 1965

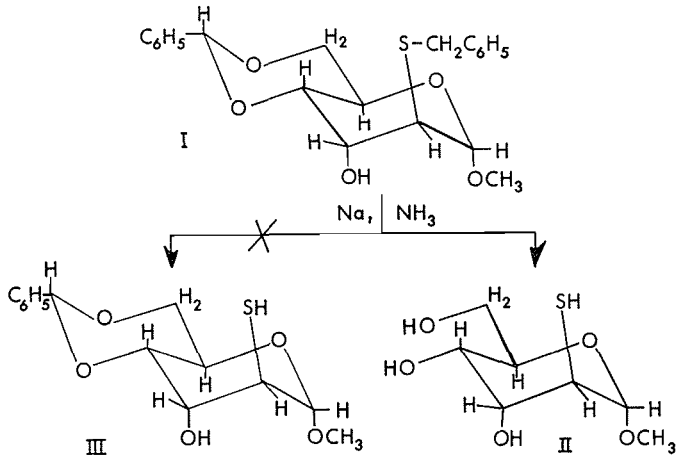
ABSTRACT

The improved solubility of methyl *S*-benzyl-4,6-*O*-benzylidene-2-thio-α-D-altropyranoside (I) in liquid ammonia diluted with 1,2-dimethoxyethane has permitted the selective cleavage by metallic sodium or lithium of the C—S bond to give methyl 4,6-*O*-benzylidene-2-thio-α-D-altropyranoside in 70–75% yield. On the other hand, the slight solubility of I in liquid ammonia alone results only in the completely hydrogenolyzed material, methyl 2-thio-α-D-altropyranoside, along with unchanged I.

Generally, in liquid ammonia alone, reductive cleavage is rapid (15–20 min) and the benzylidene and benzyl groups are converted largely into toluene accompanied by a small amount of bibenzyl. In liquid ammonia – 1,2-dimethoxyethane mixtures the reaction is much slower ($\geqslant$ 1.5 h); under these conditions the benzylidene and benzyl groups are converted to a larger extent into bibenzyl, the rest becoming toluene.

The two strong infrared absorption bands (in Nujol) in the region of 766 to 778 cm^{-1} and 706 to 718 cm^{-1} have been assigned to the phenyl moiety of the benzylidene group, and the one strong band in the region of 702 cm^{-1} to the phenyl moiety of the *S*-benzyl group.

INTRODUCTION



Birch (1, 2) has pointed out that a carbonyl group can be converted into a non-reducible species by acetal or ketal formation, but only if the resulting alkoxy group involved is neither benzylic nor allylic. Groups such as benzyl, benzyloxycarbonyl, and *p*-toluenesulfonyl, which are used to protect amino, hydroxy, or mercapto functions, are readily removed by the reducing action of sodium and liquid ammonia. Several articles have appeared (3–6) which illustrate the use of this technique in the synthesis of carbohydrate derivatives.

A report from this laboratory (3) has described the preparation of some monomercaptomonosaccharides by reductive cleavage of *S*-benzyl-4,6-*O*-benzylidene-2- (or -3-) thioglycopyranosides with sodium and liquid ammonia. At that time some attempts were made, by use of a limited proportion of sodium, to effect a selective cleavage of the *S*-benzyl group with retention of the protecting 4,6-*O*-benzylidene moiety (III, Reaction Scheme 1). However, the only isolable compounds were the unchanged methyl *S*-benzyl-4,6-*O*-benzylidene-2- (or -3-) thioglycoside (I) and the glycoside minus both protecting groups (II, Reaction Scheme 1).

To our knowledge few accounts exist wherein attempts at such selective metal–ammonia hydrogenolysis have been reported. In this connection it is noteworthy that a large excess of Raney nickel removes both the benzylidene and the methylthio groups from methyl 4,6-*O*-benzylidene-*S*-methyl-3-thio-α-D-altropyranoside (7) whereas, with only a fourfold excess of the metal, reductive desulfurization takes place unaccompanied by extensive removal of the benzylidene group (8).

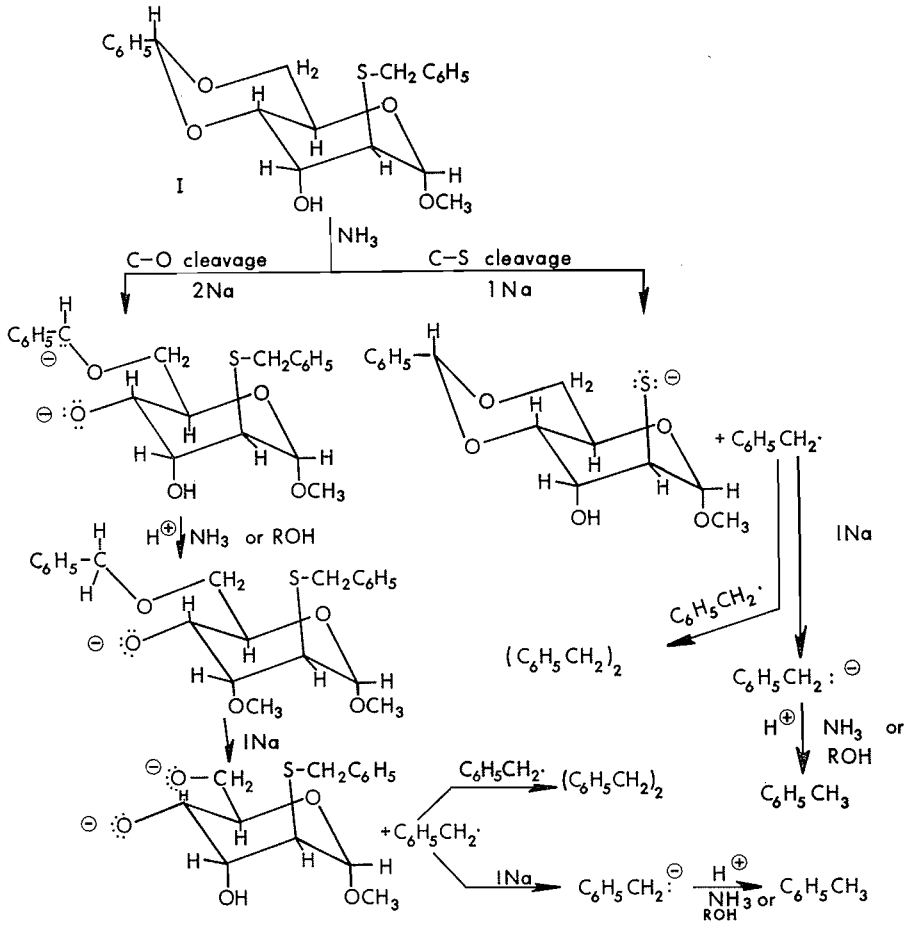
Pinder and Smith (9) found no selective cleavage in the sodium – liquid ammonia reduction of 2-methyl-2-phenyl-1,3-oxathiolane or of 2-methyl-2-phenyl-1,3-dioxolane.

[1] *University of Alberta Postdoctorate Fellow.*

REACTION SCHEME 1.

It has been shown, however, that dialkyl thioethers are readily cleaved by sodium in liquid ammonia whereas the analogous oxygen ethers are practically unaffected (10). Thus one would expect, in a competitive reaction, that a benzylthio group should be hydrogenolyzed in preference to a benzyloxy group. This paper describes the results of attempts at selective cleavage of the benzylthio linkage with sodium and liquid ammonia in the presence of the benzylidene dioxy moiety, examples from the field of carbohydrate chemistry being used as substrates.

RESULTS AND DISCUSSION



Amount of Sodium Required for Cleavage of the C—S and C—O Bonds

Experiments were designed to measure the proportion of sodium required to cleave the C—S and C—O bonds in a molecule such as methyl *S*-benzyl-4,6-*O*-benzylidene-2-thio-α-D-altropyranoside (I). This information was deemed to be necessary in approaching the problem of selective bond cleavage.

The theoretically required amounts of metal are illustrated in Reaction Scheme 2. It is seen that C—S cleavage requires 2 g-atoms of sodium if toluene alone is produced but just 1 g-atom of sodium if bibenzyl is formed exclusively. Whether bibenzyl is made by free-radical coupling as shown in Reaction Scheme 2 or by an anionic process as suggested by Birch (1) is not yet clear, but by either process 1 g-atom of sodium is required for C—S cleavage of 1 mole of compound I to produce the half mole of bibenzyl. For C—O cleavage, 2 g-atoms of sodium are expected to cleave one leg of the acetal (either at C_4—O or C_6—O) to form the *O*-benzyl group, after proton abstraction from the solvent or any alcoholic group present. This is followed by consumption of either 1 or 2 g-atoms of sodium to produce bibenzyl or toluene respectively. Thus, 3 or 4 g-atoms of sodium are required per mole of I depending upon the fate of the benzylidene group (as bibenzyl or toluene).

These predictions were substantiated by the results of experiments which measured the proportion of sodium metal required for the reductive cleavage of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (IV), methyl *S*-benzyl-4,6-O-ethylidene-3-thio-α-D-altropyranoside (V*a*), and methyl *S*-benzyl-4,6-*O*-ethylidene-2-*O*-methyl-3-thio-α-D-altropyranoside (V*b*) (Table I, experiments 1–5). The ethylidene group in compounds V*a* and

REACTION SCHEME 2.

V*b* is unaffected by the metal, and hence permitted estimation of the sodium consumption in the cleavage of the benzyl group from sulfur. In liquid ammonia, the 4,6-*O*-benzylidene group required 4 equivalents of sodium[2] for cleavage, yielding essentially toluene along with a minor amount (3%) of bibenzyl (expt. 1). But in the mixed solvent NH_3–1,2-dimethoxyethane somewhat less than 4 equivalents of sodium were consumed and a larger amount of bibenzyl was formed (16%, expt. 2). Accordingly, as expected, methyl *S*-benzyl-4,6-*O*-benzylidene-2-thio-α-D-altropyranoside (I) in liquid ammonia required 6 equivalents of sodium for complete reduction to methyl 2-thio-α-D-altropyranoside (II) (Table I, expt. 6).

Selective Cleavage of the C—S Rather Than the C—O Bond

When 2 equivalents of sodium was added to 1 equivalent of methyl *S*-benzyl-4,6-*O*-benzylidene-2-thio-α-D-altropyranoside (I) in liquid ammonia, only methyl 2-thio-α-D-altropyranoside (II), bibenzyl, and much unchanged I were obtained. This lack of selective reduction was due to the sparing solubility of I in liquid ammonia.[3] When 1,2-dimethoxy-

[2]*The hydroxyl groups in IV and Va consumed no metal under our conditions.*
[3]*A separate test showed that the bulk of a 100 mg quantity of I failed to dissolve in 500 ml of liquid ammonia*

ethane was added as a cosolvent, to improve the solubility of I in liquid ammonia (4, 11, 13), selective reductive cleavage of the C—S bond did occur (Table I, expt. 7). Optimum results were obtained when the ratio of 1,2-dimethoxyethane to NH_3 was 4 or 5 to 6 (by volume).

Several interesting features became evident when 1,2-dimethoxyethane was used as cosolvent. (*i*) For the quantities of reagents taken (see Table II), the time required for consumption of sodium increased from 15 to 20 min when only ammonia was used, to $1\frac{1}{2}$–$3\frac{1}{2}$ h in the mixed solvent. A larger ratio of 1,2-dimethoxyethane to NH_3 increased the time to several hours. (*ii*) The proportion of bibenzyl increased markedly (>50% of theory) over that (~9%) obtained in just liquid ammonia. The yield of toluene dropped sharply as a consequence. (*iii*) The proportion of sodium metal required for C—S cleavage decreased also. This is in keeping with the requirement of 1 g-atom of metal when bibenzyl is the product of C—S cleavage, and 2 g-atoms when only toluene is obtained (see Reaction Scheme 2). The influence of solvent composition and amount of metal on the proportion of products obtained is shown in Table II. It is noteworthy that the use of lithium instead of sodium, under otherwise identical conditions, gave a larger yield (76%) of the selectively cleaved product III. Table III shows the effects, on the reduction of V*a*, of solvent composition and proportion of metal to substrate, with particular attention to bibenzyl (and therefore toluene) production.

Assignment of Absorption Bands for the Benzylthio and Benzylidene Dioxy Groups

The selective removal of the benzyl group from I has permitted the assignment of infrared absorption bands caused by the two monosubstituted phenyl groups. Strong absorption for monosubstituted phenyl in compound I in Nujol is found at 770 cm^{-1}, 710 cm^{-1}, and 702 cm^{-1}. For methyl 4,6-*O*-benzylidene-2-thio-α-D-altropyranoside (III), absorption (in Nujol) occurred at 766 cm^{-1} and 706 cm^{-1} caused by the benzylidene moiety. The completely reduced substance, methyl 2-thio-α-D-altropyranoside (II), showed none of these three absorption bands. Accordingly, for these altrosides, the 4,6-*O*-benzylidene group absorbs in the region of 766–770 cm^{-1} and 706–710 cm^{-1} (Δcm^{-1} = ~60) whereas the 2-benzylthio group absorbs at 702 cm^{-1}. In agreement with this, methyl 4,6-*O*-benzylidene-2-*O*-methyl-α-D-altropyranoside (14) shows absorption bands at 778 cm^{-1} and 718 cm^{-1} (Δcm^{-1} = 60), methyl 4,6-*O*-benzylidene-2,3-di-*O*-methyl-α-D-altropyranoside (14) exhibits strong absorption at both 766 cm^{-1} and 706 cm^{-1} (Δcm^{-1} = 60), and methyl 4,6-*O*-benzylidene-2-deoxy-α-D-allopyranoside absorbs at 778 cm^{-1} and 718 cm^{-1} (Δcm^{-1} = 60) (Fig. 1).

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were taken with a Perkin–Elmer model 421 instrument. Nuclear magnetic resonance spectra were obtained with a Varian Associates A-60 instrument. Gas–liquid chromatography was accomplished with a Burrell K-2 Kromo-Tog by using a 2.5 m column packed with 25% silicone rubber on Gas Chrom P (60–80 mesh) and a helium flow rate of 100 ml/min.

Syntheses of Compounds

Methyl 4,6-O-Ethylidene-2-O-(p-toluenesulfonyl)-α-D-glucopyranoside

The published procedure (12, 15) was employed, but with the following modifications which improved the isolation and more than tripled the yield. (*a*) The methyl 4,6-*O*-ethylidene-α-D-glucopyranoside (12) was treated with a 15% rather than 48% excess of *p*-toluenesulfonyl chloride. (*b*) The chloroform extract of the reaction mixture was first washed with ice-cold 6 *N* HCl to remove pyridine, and then washed with bicarbonate solution and water. (*c*) The oil left upon removal of the chloroform from the decolorized solution was dissolved in ether. When this was left in a refrigerator overnight a solid was obtained. A hot absolute ethanol solution of this solid, when cooled, gave 11.7% of pure methyl 4,6-*O*-ethylidene-2,3-di-*O*-(*p*-toluenesulfonyl)-α-D-glucopyranoside, m.p. 156° (lit. m.p. 156–157° (12), 154–155° (16)). (*d*) The brownish solid left after removal of solvent from the above alcoholic filtrate, when dissolved in chloroform and diluted with petroleum

§Calculated on the assumption that the metal not used to produce bibenzyl was used to form toluene, thus requiring 2 equivalents of sodium for 1 mole of V*a*. The toluene was not actually isolated or estimated quantitatively.
NOTE: V*a*, methyl *S*-benzyl-4,6-*O*-ethylidene-3-thio-α-D-altropyranoside; VII*a*, methyl 4,6-*O*-ethylidene-3-thio-α-D-altropyranoside.

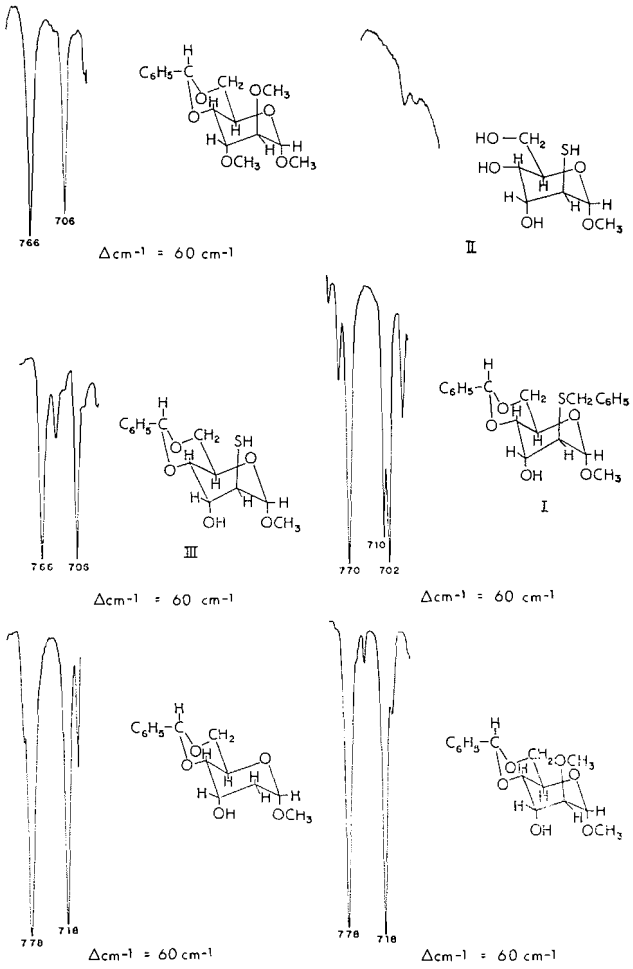

FIG. 1. Infrared absorption in Nujol of a number of altropyranosides in the region of 700 to 780 cm^{-1}.

ether (60–80°) to faint turbidity, gave 42.3% of methyl 4,6-*O*-ethylidene-2-*O*-(*p*-toluenesulfonyl)-α-D-glucopyranoside, m.p. 151° (lit. m.p. 150–151° (12)). (*e*) The mother liquors from the precipitated mono- and di-*p*-toluenesulfonyl compounds, freed from solvent and the residue acetylated (12), gave 11% of methyl 3-*O*-acetyl-4,6-*O*-ethylidene-2-*O*-(*p*-toluenesulfonyl)-α-D-glucopyranoside as long needles, m.p. 171° (lit. m.p. 169–171° (12)).

Methyl 2,3-Anhydro-4,6-O-ethylidene-α-D-mannopyranoside

The following modifications of the published procedure (12) greatly simplified the preparation of pure product. Methyl 4,6-*O*-ethylidene-2-*O*-(*p*-toluenesulfonyl)-α-D-glucopyranoside (or its acetate) was treated with a 25% rather than 100% excess of sodium methoxide in refluxing methanol for 4 h. The cooled mixture (needles separated) was poured into ice water. The water mixture was extracted with chloroform and the extract dried (Na_2SO_4) and freed from solvent. The residual solid was crystallized from methanol to give needles (84%) melting at 100° (lit. m.p. 100–100.5° (12)).

Methyl S-Benzyl-4,6-O-ethylidene-3-thio-α-D-altropyranoside (Va)

Published directions (12) were followed for most of this preparation. However, the isolation and crystallization procedures were modified advantageously. The precipitate obtained when the reaction mixture was poured into ice water was washed with water and petroleum ether as described (12), dissolved in diethyl ether, and dried (Na_2SO_4). The filtered ethereal solution was diluted with an equal volume of petroleum ether (60–80°) and the resulting solution gently refluxed on a water bath. When much of the ether had been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

removed and the boiling point of the solvent had reached 50°, the flask and contents were allowed to cool to room temperature, whereupon V*a* separated as long colorless needles, yield 93%, m.p. 133° (lit. m.p. 132–133° (12)).

*Methyl S-Benzyl-4,6-O-ethylidene-2-O-methyl-3-thio-α-*D*-altropyranoside (Vb)*

To a solution of 16.3 g (0.05 mole) of V*a* in 90 ml of methyl iodide was added 24 g of silver oxide. The mixture, first stirred for 1.5 h at room temperature and then for 1.5 h at reflux, was filtered (cold) and the silver salts were washed with 50 ml of dry ether. The combined methyl iodide and ether solutions were freed from solvent under vacuum. The viscous oily residue showed no absorption for OH in the infrared spectrum. Chromatography on neutral alumina, activity grade I (Alupharm Chemicals, New Orleans, Louisiana), gave, by benzene elution, 11.1 g (65.3%) of an oil which solidified when cooled. Crystallization from cold hexane gave a compound melting at 84–85°; $[\alpha]_D^{24}$ −91° (*c*, 0.5 in chloroform). The infrared spectrum in Nujol showed bands at 710 cm^{-1} (phenyl) but none for OH.

Anal. Calcd. for $C_{17}H_{24}O_5S$: C, 59.97; H, 7.11; S, 9.42. Found: C, 59.84; H, 6.88; S, 9.68.

Ether elution of the column gave 2.5 g (25%) of a compound melting at 98–99° (from methanol). The infrared spectrum in Nujol was identical with that of authentic methyl 2,3-anhydro-4,6-*O*-ethylidene-α-D-mannopyranoside (ref. 12; see also above). No absorption for OH was evident. A mixed melting point was undepressed.

*Methyl S-Benzyl-4,6-O-benzylidene-2-thio-α-*D*-altropyranoside (I)*

This compound was prepared by an improved variation of the literature directions (3). Commercial sodium methoxide (Fisher Scientific Co.) (21.9 g, 0.115 mole) was dissolved in 200 ml of pure, dry methanol. A continuous current of nitrogen was passed through the apparatus, and benzyl mercaptan (67.9 g, 0.58 mole) was then added. When the solution had been stirred for 15 min, 26.4 g (0.1 mole) of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (14, 17) was added and the solution refluxed for 24 h (N_2). When cooled and poured with stirring into 1 l of ice water, the solution gave a precipitate of I. The solid was separated by filtration and dissolved in chloroform; this was combined with chloroform extracts (2 × 250 ml) of the filtrate. After the organic solution had been washed with water, it was dried (Na_2SO_4), separated from the drying agent, and freed from solvent under vacuum in a rotary evaporator. The semisolid residue was triturated with 500 ml of petroleum ether (60–80°), whereupon solidification occurred, yield (crude) 39 g (~100%). Recrystallization from 250 ml of absolute ethanol gave needles (35 g, 90%) melting at 136–137°; $[\alpha]_D^{25}$ +94.7° (*c*, 1 in chloroform) (lit. m.p. 136–137°; $[\alpha]_D^{24}$ +90.6° (*c*, 1.668 in chloroform) (3)). The infrared spectrum in Nujol showed absorption at 3 505 cm^{-1} (OH), 770 cm^{-1} and 710 cm^{-1} (phenyl of the benzylidene group), and 702 cm^{-1} (phenyl of the benzyl group).

Sodium – Liquid Ammonia Reduction

*Methyl 4,6-O-Ethylidene-2-O-methyl-3-thio-α-*D*-altropyranoside (VIIb) from Methyl S-Benzyl-4,6-O-ethylidene-2-O-methyl-3-thio-α-*D*-altropyranoside (Vb) (a Typical Procedure for Estimation of the Consumption of Sodium by Reaction in Liquid Ammonia)*

A dry, 500 ml, three-necked, round-bottomed flask (A) was fitted with a gas inlet tube (C), mercury seal stirrer, and dry ice condenser (B) whose outlet accommodated a tube containing sodium hydroxide pellets as protection against moisture from the atmosphere. The apparatus (A and B) was gently heated with a free flame for 5 min while a current of dry nitrogen was passed through via C to drive out surface moisture. When the system had been cooled (under a constant flow of dry nitrogen) gaseous ammonia from a cylinder of commercial anhydrous liquid ammonia was collected (150 ml) in a dry ice – acetone cooled receiver (D) fitted with a dry ice – acetone condenser (E) whose outlet was protected by a sodium hydroxide pellet tube. Metallic sodium was added to the liquid in D to destroy moisture, and then the ammonia was distilled, by using a cold water bath gradually warmed to 50°, into the dried vessel (A) previously cooled in a dry ice – acetone bath. A few milligrams of metallic sodium were added at intervals to A until the blue color persisted (for about 1 h). To this flask was then added 3.4 g (0.01 mole) of V*b*. A clear solution was obtained. Freshly cut sodium (0.46 g) was weighed in dry toluene, and from this four small pieces of about 100 mg each were added to the reaction mixture in A, one at a time only when the blue color caused by each preceding piece of metal had disappeared. Then the size of each subsequent piece of metal was reduced to ~10 mg and these were added until the blue color persisted for at least 15 min. In all, 440 mg was necessary, over a total reaction time of about 20 min.

The reaction mixture was then decomposed with excess ammonium chloride (5 g) and the ammonia allowed to evaporate in a current of nitrogen. The residue was dissolved in chloroform, and filtered free of solid; then the solvent was removed under vacuum. The remaining solid, when crystallized from cold ether, gave 2.35 g (98%) of VII*b*, m.p. 103–104°, $[\alpha]_D^{24}$ +113.7° (*c*, 1 in chloroform). Absorption in the infrared (Nujol) occurred at 2 600 cm^{-1} (SH) but none between 700 and 800 cm^{-1} for phenyl.

Anal. Calcd. for $C_{10}H_{18}O_5S$: C, 47.98; H, 7.25; S, 12.81. Found: C, 48.13; H, 6.96; S, 12.72.

The residual ethereal filtrate was evaporated and the residue triturated with 20 ml of petroleum ether (60–80°) to dissolve bibenzyl. The petroleum ether extract was freed from solvent to give 80 mg (8.3%) of bibenzyl, m.p. 51° (mixed melting point undepressed).

For personal use only.

Methyl 4,6-O-Ethylidene-3-thio-α-D-altropyranoside (VIIa) from Methyl S-Benzyl-4,6-O-ethylidene-3-thio-α-D-altropyranoside (Va)

Method A: with sodium and liquid ammonia.—The reduction of this compound was carried out by using the apparatus and typical procedure described above. The 3.26 g (0.01 mole) of V*a* required 440 mg (0.02 mole) of sodium over a 15 to 20 min period. The reaction mixture was worked up accordingly to the preceding description to give a solid, after removal of the chloroform solvent, which, when dissolved in ether and diluted with petroleum ether (60–80°) to slight turbidity, gave 2.26 g (95.5%) of VII*a* as needles melting at 106–107°; $[\alpha]_D^{24}$ −123° (*c*, 1 in chloroform).

Anal. Calcd. for $C_9H_{16}O_5S$: C, 45.75; H, 6.83; S, 13.57. Found: C, 45.83; H, 6.91; S, 13.72.

Infrared absorption occurred at 3 465 cm^{-1} (OH) and 2 600 cm^{-1} (SH). There was no absorption for phenyl.

The residual ethereal filtrate, worked up as before, gave 80 mg of bibenzyl.

Method B: with sodium and liquid ammonia and modification to isolate the product toluene.—The preparation of the system and the reduction of the thioether V*a* (3.26 g, 0.01 mole) were carried out exactly as in the typical procedure above, except that the sodium was weighed and cut up in Skellysolve B. The work-up differed as follows. After the decomposition of the reaction mixture with ammonium chloride, the condenser (B) was filled with an ice–salt freezing mixture to retain the toluene but permit vaporization of the ammonia. The stream of nitrogen that was passed through the solution was discontinued, since it might promote loss of toluene by entrainment. The ammonia was allowed to volatilize and escape through B, without the use of a warmed water bath, by allowing the apparatus to remain overnight exposed to room temperature conditions. The residue in A was stirred with dry ether (200 ml) for half an hour and the solution then filtered. Careful fractionation removed the ether (which showed no peak for toluene by gas–liquid chromatography) until the residue was concentrated to about 15 ml. To this residue was added 0.499 g of ethylbenzene as internal standard; the resulting solution was analyzed by gas–liquid chromatography. An authentic mixture of known amounts of toluene and ethylbenzene was used for comparison. A total of 540 mg (58%) of toluene was thus determined. Removal of the ethylbenzene, toluene, and ether by distillation *in vacuo* gave a residue which was washed with water to eliminate the water-soluble VII*a*. The solid remaining (100 mg, 11%) was bibenzyl, m.p. 51°.

Method C: with sodium and liquid ammonia diluted with 1,2-dimethoxyethane.—A quantity of dry ammonia (250 ml) was put into a 1 l, three-necked, round-bottomed flask according to the typical procedure above. To this was added, via a dried dropping funnel, 100 ml of dry 1,2-dimethoxyethane (distilled from potassium metal) followed by a solution of 3.26 g (0.01 mole) of V*a* in 100 ml of dry 1,2-dimethoxyethane. An additional 50 ml of 1,2-dimethoxyethane was used to rinse the funnel, thus giving a 1:1 mixture (by volume) of ammonia and 1,2-dimethoxyethane in the reaction flask. To this solution was added freshly cut sodium (230 mg, 0.01 mole) in four pieces, one at a time, according to the typical procedure. The time required for this sodium to react was 45 min. The mixture was then decomposed with ammonium chloride as usual and the ammonia allowed to escape overnight, without the use of a warmed water bath, by using a constant current of dry nitrogen gas. About 150 ml of chloroform was then added and the mixture stirred for 1 h. This process eliminated the rest of the ammonia (pH paper test). The material was filtered, and chloroform (100 ml) was used to rinse the flask and to wash the collected solid. Removal of the chloroform and 1,2-dimethoxyethane on a rotary evaporator under vacuum left a semisolid. Trituration with water dissolved the mercaptan, and unreacted V*a* and bibenzyl remained as a solid. The mixture was filtered, and the aqueous filtrate concentrated *in vacuo* until the residue solidified. The crude yield was 1.59 g (67.3%). Crystallization from a mixture of ether and petroleum ether (60–80°) gave 1.55 g (66%) of material melting at 106–107°. The infrared spectrum and mixed melting point showed this to be identical with VII*a*.

Anal. Calcd. for $C_9H_{16}O_5S$: C, 45.75; H, 6.83; S, 13.57. Found: C, 46.00; H, 6.87; S, 13.66.

The mixture of unreacted material and bibenzyl left after removal of the aqueous solution was heated in 50 ml of refluxing petroleum ether (60–80°). The cooled mixture was filtered, leaving 1.07 g (32.6%) of solid melting at 132–133° and identical (infrared, mixed melting point) with starting material (V*a*). The petroleum ether filtrate was freed from solvent, leaving 300 mg (32%) of solid bibenzyl melting at 51°.

When the solvent was composed of 250 ml of ammonia and 200 ml of 1,2-dimethoxyethane, and 3.26 (0.01 mole) of V*a* and 0.31 g (0.0134 mole) of sodium were used, an 86% yield of VII*a*, 0.451 g (14%) of unchanged V*a*, and 400 mg (42%) of bibenzyl were obtained.

Table III illustrates the influence of solvent composition and amount of metal on the proportion of products in the ammonia–1,2-dimethoxyethane–sodium reduction of V*a* to VII*a*.

Methyl 4,6-O-Benzylidene-2-thio-α-D-altropyranoside (III) from Methyl S-Benzyl-4,6-O-benzylidene-2-thio-α-D-altropyranoside (I)

Method A: with sodium and liquid ammonia.—Details of the procedure followed those in method A for the reduction of the 3-benzylthioaltroside V*a* described above. The 19.4 g (0.05 mole) of I in 600 ml of ammonia consumed a total of 6.7 g (0.29 mole) of sodium in 200 mg pieces over a period of 15 min. The solution, after decomposition with excess ammonium chloride, was extracted with hot chloroform (4 × 250 ml). The solid left after removal of the chloroform from these extracts was triturated with 100 ml of petroleum ether (60–80°) to remove any bibenzyl, and the residue was dissolved in 50 ml of hot ethanol. When cooled overnight in a refrigerator, the solution yielded II as long colorless needles (8.4 g). A second crop (1.37 g) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtained upon concentration of the mother liquor. The total yield was 9.87 g (94%) of material melting at 146–147° (lit. m.p. 145–146° (3), 145–148° (4)). The infrared spectrum in Nujol showed absorption at 3 415 cm^{-1} (OH) and 2 570 cm^{-1} (SH) but no phenyl absorption.

Method B: with sodium and liquid ammonia and modifications to isolate toluene and bibenzyl.—The procedure used in method B for the reduction of the 3-benzylthioaltroside V*a* was followed here. A total of 1.34 g (0.058 mole) of sodium was required by 3.88 g (0.01 mole) of compound I in 150 ml of ammonia. After decomposition of the reaction mixture with ammonium chloride, 250 ml of dry ether was added to the flask and the ammonia allowed to evaporate through the condenser B cooled by a salt–ice freezing mixture. The residual ethereal mixture was filtered and the solid residue extracted with 200 ml of hot chloroform. Removal of the chloroform from this extract and crystallization of the resulting material from ethanol gave II as colorless needles (1.822 g, 87%), m.p. 146–147°. The ethereal extract was reduced in volume and ethylbenzene added as internal standard according to the details of method B for compound V*a*; 1.02 g (~56%) of toluene and 0.163 g (~9%) of solid bibenzyl, m.p. 51–52°, were obtained.

Method C: with sodium and liquid ammonia diluted with 1,2-dimethoxyethane.—The apparatus and the procedure used for the preparation of the ammonia–1,2-dimethoxyethane solution and subsequent reduction were the same as those in method C described for the reduction of V*a*.

To a mixture of 300 ml of ammonia and 250 ml of 1,2-dimethoxyethane containing 7.76 g (0.02 mole) of I was added 0.69 g (0.03 mole) of sodium cut into seven pieces, each piece being added in accordance with previous directions. The time required for total addition was 2.5 h. The decomposition and solvent elimination also followed cited directions. The solid that was obtained was dissolved in 50 ml of hot ethanol (rather than being triturated with water), and the solution was cooled to room temperature to give 2.3 g of the selectively reduced compound III as needles, m.p. 167–169°. The ethanol was removed from the filtrate with a rotary evaporator under vacuum, and the residue was dissolved in benzene and subjected to chromatography on 100 g of neutral alumina, activity grade II (Alupharm Chemicals, New Orleans, Louisiana). Initial benzene elution gave bibenzyl and unreacted I. With continued elution by benzene the mercaptan III began to appear, as shown by infrared absorption at 2 500 cm^{-1}, whereupon ether replaced benzene as the eluant to hasten the exit of the rest of component III still on the column (1.9 g). The total yield of III was 4.2 g (70.5%). Crystallization of the combined material from ethanol raised the melting point slightly to 168–169°; $[\alpha]_D^{24}$ +80.5° (*c*, 1 in chloroform).

Anal. Calcd. for $C_{14}H_{18}O_5S$: C, 56.37; H, 6.08; S, 10.74. Found: C, 56.23; H, 6.04; S, 10.76.

The infrared spectrum in Nujol showed absorption at 3 483 cm^{-1} (OH), 2 540 cm^{-1} (SH), and 766 cm^{-1} and 706 cm^{-1} (monosubstituted phenyl for the benzylidene group), but none at 702 cm^{-1} (monosubstituted phenyl for benzyl group). The integrated nuclear magnetic resonance spectrum in $CDCl_3$, with tetramethylsilane as reference, agreed with the structure assigned. Signals appeared at τ = 2.35 to 2.75 (multiplet for five phenyl protons), τ = 6.58 (singlet for three methyl protons), and τ = 7.95 and 8.15 (J = 10 c.p.s.) (doublet for SH proton).

The combined benzene eluates, freed from solvent, gave a solid which was heated with 50 ml of refluxing petroleum ether (60–80°). Separation by filtration left 1.61 g (21%) of unreacted I (undepressed melting point and identical infrared spectrum). From the petroleum ether filtrate was obtained, upon solvent removal, 0.87 g (48%) of bibenzyl, m.p. 51°.

Final methanol elution of the column above gave 0.47 g of unidentified oil which showed absorption for SH (2 540 cm^{-1}).

Table II illustrates the effect on product yield of different proportions of mixed solvent and starting materials with compound I as the reducible substance.

Selective Reduction of I with Lithium in Liquid Ammonia – 1,2-Dimethoxyethane

A solution of compound I in ammonia–1,2-dimethoxyethane, with the same quantities of materials as in the preceding experiment for method C, was treated with 0.208 g (0.03 mole) of lithium according to the detailed directions in method C. The solid obtained upon decomposition of the reaction mixture and removal of the 1,2-dimethoxyethane and chloroform used for extraction was heated with benzene to permit separation of the lithium chloride by filtration. The benzene was removed from the filtrate and the solid residue was dissolved in 100 ml of hot ethanol. When cooled, the solution deposited 2.7 g of III as needles, m.p. 168–169°. Chromatography of the residue as described above (method C) gave a further 1.81 g of III. The total yield of the mercaptan was 4.51 g (75.7%). Unreduced starting material amounted to 1.248 g (16%), and bibenzyl to 1.09 g (59%). Here again the same unidentified oil (420 mg) was obtained via the final methanol elution.

Reduction of Methyl 4,6-O-Benzylidene-α-D-glucopyranoside (IV)

Method A: with sodium in liquid ammonia.—Details of the procedure were the same as those in method B for the reduction of I to obtain the products II, toluene, and bibenzyl. Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (11) (5.64 g, 0.02 mole) in 300 ml of ammonia required 1.785 g (0.0776 mole) of sodium over a period of about 15 min. The ethereal extract obtained after removal of the solid by filtration gave, by gas–liquid chromatographic analysis, 1.14 g (62%) of toluene and 0.053 g (~3%) of bibenzyl.

Methanol extraction of the solid obtained after separation of the ether filtrate gave 3.08 g (79%) of methyl α-D-glucopyranoside melting at 164–165° (lit. m.p. 165° (11)).

Method B: with sodium and liquid ammonia containing 1,2-dimethoxyethane.—Details for this experiment

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

followed those in method C for the reduction of I to obtain III. A solution of 5.64 g (0.02 mole) of IV in 300 ml of ammonia diluted with 200 ml of 1,2-dimethoxyethane consumed 1.770 g (0.0756 mole) of sodium over a period of 4 h. After evaporation of the ammonia, however, the residue was extracted with ether to remove bibenzyl.[4] This amounted to 0.30 g (16%). The glycoside that was produced was not isolated in this case and was believed to be only methyl α-D-glucopyranoside. We were concerned in this experiment only with the amount of bibenzyl formed in an ammonia–1,2-dimethoxyethane mixture compared with the amount produced in ammonia alone under otherwise identical conditions.

ACKNOWLEDGMENTS

The financial assistance given by the National Research Council of Canada for part of this work is greatly appreciated. Infrared and nuclear magnetic resonance spectra were made by Mrs. G. Conway of the Department of Chemistry, University of Alberta, Edmonton, Alberta. Elemental analyses were performed by Dr. C. Daessle, Organic Microanalyses, 5757 Decelles Avenue, Montreal, Quebec, and by Dr. F. Pascher, Mikroanalytisches Laboratorium, Buschstrasse, Bonn, Germany.

REACTION OF THIOLS WITH EPOXIDES OF CONJUGATED 1,4-DIKETONES

H. S. WILGUS III, E. FRAUENGLASS, P. P. CHIESA, G. H. NAWN,[1] F. J. EVANS, AND J. W. GATES, JR.

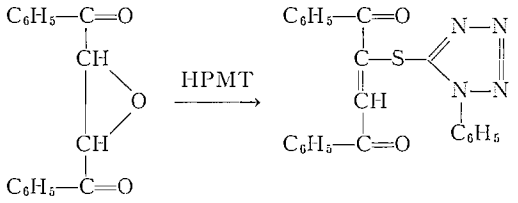
Received July 6, 1965

ABSTRACT



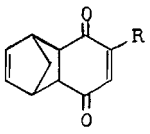
The reaction of thiols with 2,3-epoxides of bicyclo, conjugated 1,4-diketones was found to proceed readily to give the dehydrated thio-substituted enediones or their enolized isomers, depending upon the reaction conditions and the bicyclic bridging of the starting materials. In no case was a mixture of these isomers observed. Enediones generally resulted from these reactions with and without triethylamine catalysis, whereas the use of an equimolar amount of triethylamine generally gave hydroquinones. The ease of rearrangement of enedione to hydroquinone followed the order: 2,3-dimethylbutadiene adduct ≫ reduced cyclopentadiene adduct > cyclopentadiene adduct = 1,3-cyclohexadiene adduct.

Recent reviews on epoxides (1) reveal only one reference to the attack of a sulfhydryl group on an epoxide conjugated to a carbonyl group. In this case (2) hydrogen sulfide in the presence of barium hydroxide reacted with ethyl β,β-dimethylglycidate to give a small amount of ethyl 3-hydroxy-2-mercapto-3-methylbutyrate. The reactions of thiols with 2,3-epoxides of conjugated carbonyl or conjugated 1,4-dicarbonyl compounds have not been reported before. Alder *et al.* (3) have reported the preparation of several epoxides of cyclopentadiene–quinone adducts. The reactions of thiols with these and similar epoxides are reported in this paper.

The thiols that were studied were 1-phenyl-5-mercaptotetrazole (HPMT), 2-mercaptobenzthiazole (HMBT), *p*-toluenethiol (HPTT), 2-quinolinethiol (HQT), methanethiol (HMT), and ethanethiol (HET). Triethylamine (TEA) was often employed, either in catalytic or equimolar amounts. Trimethylamine or sodium salts of some mercaptans were also used.

In all but one case, the diketoepoxides were part of a cyclic system. The exception, *trans*-dibenzoylethylene epoxide (I), reacted with HPMT to produce 1,4-diphenyl-2-(1′-phenyl-5′-tetrazolylthio)-2-buten-1,4-dione (II), as shown in eq. [1]. The structure of II was assigned on the basis of a combustion analysis and an infrared spectrum which shows a conjugated carbonyl doublet at 1 630 and 1 650 cm^{-1}.

[1]



I II

The new diene adducts and epoxides used in this study are described in Tables I and II. Tables III and IV list the products obtained when these epoxides were treated with the various mercaptans. Two possible products of these reactions are the enedione III and the hydroquinone IV (eq. [2]). These structures were assigned on the basis of combustion

analyses and infrared spectra. In several cases, the products were known compounds synthesized in an unambiguous manner. The infrared spectra show conjugated carbonyl bands at 1 650 cm^{-1} for III and O—H bands at 3 325 cm^{-1} for IV.

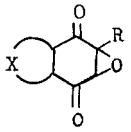
[2] 

III IV

Inspection of Tables III and IV reveals that when no catalyst was used the product was the enedione III. Only one exception was noted: the 2,3-dimethylbutadiene–quinone adduct epoxide (XVII), which gave a substituted hydroquinone. This result is not surprising in view of the ease of rearrangement of the dimethylbutadiene–quinone adducts to the aromatic system (4). Since the enedione from XVII is a known compound, it was prepared by a different synthetic route (5).

The use of a catalytic amount of triethylamine generally gave enediones III. When an equimolar amount of triethylamine was used, the products were naphthohydroquinones. The enediones XXXIV and XXXV are not exceptions to this reaction, since they cannot rearrange to hydroquinones. The use of the sodium salt of the thiol also led to the naphthohydroquinone, as shown by XXIII.

In a previous paper (6) it is shown that the diene–quinone adducts have the *endo-cis* configuration and that the epoxide ring has the *exo* configuration. To determine whether the isolated double bond at the 6,8-position, because of its possible close proximity, had any effect on the reactivity of the epoxide and on the reaction mechanism, several examples of saturated epoxides were prepared. It is clear from the reactions of these epoxides (XLI–L) that the isolated double bond does not affect the reaction course. To verify this type of structure, XLVI was also prepared from the known quinone LIV (7), as shown in eq. [3]. The reduction of the isolated double bond appears to have decreased the strain on the bicyclic ring system, for the enedione XLV readily rearranged after the addition of a trace of mineral acid or after a long reflux period; the corresponding unsaturated enediones of XIX, XXVII, and XXXI required a base for rearrangement (4, 5).



A phenyl or *p*-tolyl substituent did not exhibit any appreciable steric hindrance, as was shown by the reactions of epoxides V, VI, and XIV. When the substituent was isopropyl

LIV XLVI

(VII) or *t*-butyl (VIII), no reaction was observed, even with the sodium mercaptides. In addition, the epoxides of the three isomeric dimethyl quinone – cyclopentadiene adducts were prepared (3). The 2,3-dimethyl epoxide LV did not react. This result is consistent with a S_N2 reaction mechanism.

LV

When nonheterocyclic mercaptans were used in this study, the enedione form could not be isolated and the hydroquinone derivatives were usually not stable; the presence of the latter was indicated by infrared spectra. These reaction products were usually isolated as their stable diacetates. The structure of one of these diacetates (XXIV) was confirmed by an alternate synthesis, as shown in eq. [4]. The conversion of LVI into XXIV was effected by a method of rearrangement used by Meinwald and Wiley (8).

[4] 

LVI

XXIV

EXPERIMENTAL

Unless otherwise specified, all chemicals were Eastman Kodak Company materials. The elemental analyses of all the new compounds reported in this paper were within the accepted tolerances.

1,4-Diphenyl-2-(1'-phenyl-5'-tetrazolylthio)-2-buten-1,4-dione (II)

Chalcone epoxide (9) was allowed to react at room temperature for 2 weeks with an alcoholic solution containing an equimolar amount of HPMT. The solvent was removed and the product was recrystallized from benzene–alcohol to give a 65% yield, m.p. 158–159° (decomp.).

1,4-Diacetoxy-5,8-dihydro-5,8-methano-2-(4'-toluenethio)-1,4-naphthohydroquinone (XXIV)

To a mixture of 1.4 g of 5,8-methano-4*a*,5,8,8*a*-tetrahydro-2-(4'-toluenethio)-1,4-naphthoquinone (LVI) in 25 ml of acetic anhydride was added 0.6 g of triethylamine. Tetrahydrofuran (1 ml) was then added to produce a clear solution. This solution was allowed to stand at room temperature for 3 days and was then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

poured into 300 ml of cold water. Through continued stirring and trituration, the gummy material which separated solidified to give a red-brown solid. This material was collected and recrystallized from alcohol to give 1.4 g (73.7%) of an off-white powder, m.p. 145–147°. This material was identical in all respects with the sample of XXIV prepared as given in Table III.

5,8-Methano-1-(1'-phenyl-5'-tetrazolylthio)-5,6,7,8-tetrahydro-1,4-naphthohydroquinone (XLV)

To 5.0 g of 5,6,7,8-tetrahydro-5,8-methano-1,4-naphthoquinone (5) (LIV) was added 50 ml ethanol, followed by 5.1 g of HPMT. After the mixture had been refluxed for 3 h, the solvent was removed on a rotary evaporator and the residue was dissolved in chloroform. After 2 days, white crystals (2.83 g) were collected, m.p. 174–175° (decomp.). An additional 7.20 g of less-pure product was obtained. An infrared spectrum of this compound was identical with that of the sample prepared by another route, as shown in Table IV.

4'-Toluenethio-p-benzoquinone

To a chilled solution of 18.6 g of *p*-benzoquinone in 100 ml of methanol was added, with stirring, 10.7 g of *p*-toluenethiol in 50 ml of methanol during 30 min. Stirring was continued for 1 h while the reaction mixture warmed to room temperature. At the end of this time, the suspension was poured into 200 ml of ice water and the rust-colored precipitate was collected. The crude product, 19 g, m.p. 100–107°, was crystallized from ethanol to give 16 g of product, m.p. 108–110°.

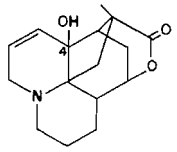
LYCOPODIUM ALKALOIDS

XVII. MASS SPECTRA OF ANNOTINE AND SOME ANNOTINE DERIVATIVES



D. B. MacLean and M. Curcumelli-Rodostamo
Department of Chemistry, McMaster University, Hamilton, Ontario

Received October 13, 1965

ABSTRACT

The mass spectra of annotine and some of its derivatives are recorded and discussed. Fragmentation mechanisms are proposed to account for the formation of the major peaks in the spectra. The composition of the ions has been verified by measurement of the high-resolution spectra of four of the five compounds. The results lend support to the structure previously proposed for this alkaloid.

In a recent publication (1) it was proposed that annotine (2–5) has structure I. This proposal was based upon a number of degradation experiments, upon the examination of annotine and some of its derivatives by infrared and nuclear magnetic resonance spectroscopy, and upon biogenetic considerations. In this communication we report on the mass spectrometric examination of annotine and some of its derivatives.

I

The mass spectra of a representative group of *Lycopodium* alkaloids were reported several years ago (6); they showed that the loss of the bridge carbon atoms was characteristic of all alkaloids examined. Since then mass spectrometric studies have been used as an aid in the elucidation of the structure of several new alkaloids of this family, and in all cases this behavior has again been observed. Among other alkaloids, lycodoline (6, 7), des-N-methyl-hydroxy-α-obscurine (8), and lycofawcine (9), which carry a hydroxyl group at C_4 in the hydrojulolidine system, as has been proposed for annotine, were investigated. In the spectra of the first two of these compounds a large M-17 peak was observed as a result of loss of a hydroxyl radical. The M-17 ion so formed then underwent further fragmentation with loss of the bridge carbon atoms. Lycofawcine and its derivatives do not exhibit a prominent M-17 peak, but the C_4 hydroxyl is eliminated along with the bridge carbon atoms. One might expect that, if annotine has structure I, its fragmentation would follow a pattern similar to that of other alkaloids bearing a C_4—OH group. This expectation was borne out, as the results reported below indicate.

The major peaks in the mass spectrum of annotine, shown in Fig. 1*a*, may be explained by invoking two fragmentation processes. In one process the first step involves loss of the hydroxyl group, giving rise to an ion of mass 258. A metastable peak at *m/e* 242.0 is in accord with this change; the value of m^* calculated for the transformation $275 \rightarrow 258$ is 242.0. The peaks observed at *m/e* 172 and 144 may be considered to arise from the ion of mass 258 as shown in Scheme 1*a*. A metastable peak associated with the change $258 \rightarrow 172$ is observed at *m/e* 115.0 (m^* calcd. = 114.7). The last step, *m/e* $172 \rightarrow 144$, is analogous to the *m/e* $174 \rightarrow 146$ transformation encountered in the fragmentation of dihydrolycopodine and other *Lycopodium* alkaloids (6).

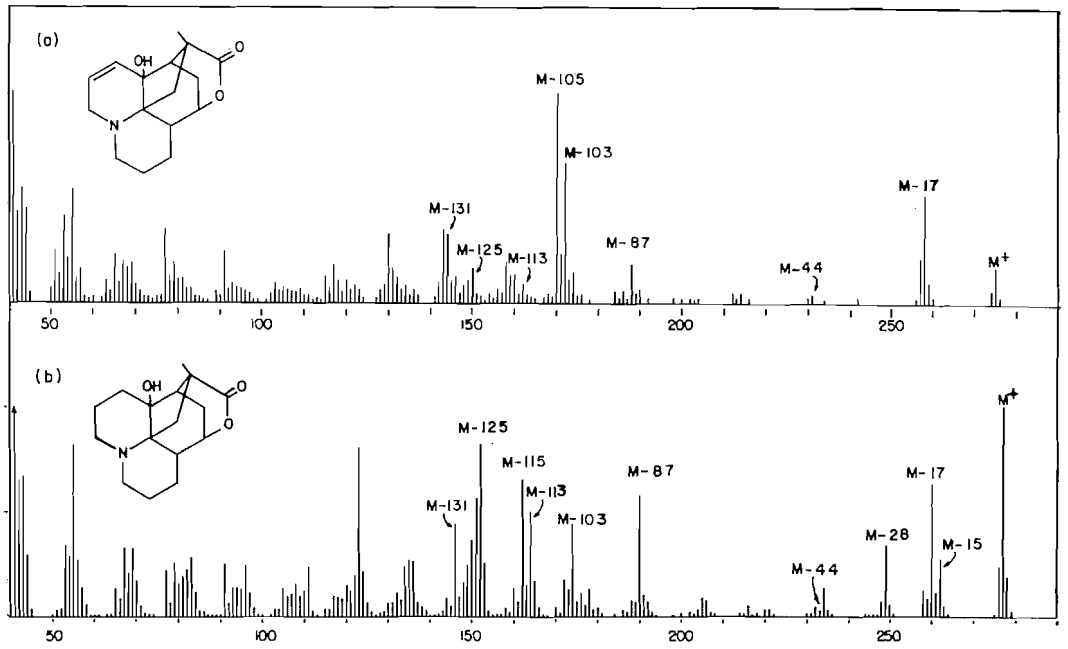

FIG. 1. Mass spectra of (*a*) annotine and (*b*) dihydroannotine.

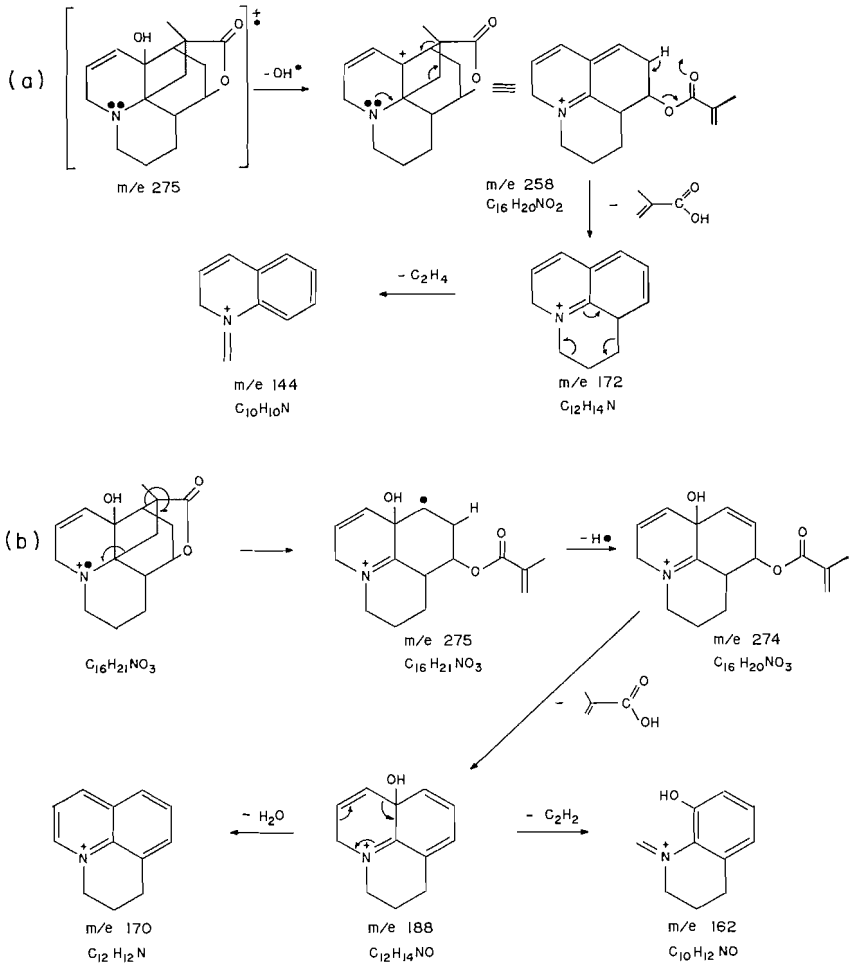
The peaks at *m/e* 274, 188, 170, and 162 may be accounted for in a second fragmentation sequence as outlined in Scheme 1*b*. A metastable peak associated with the change 274 → 188 is observed at *m/e* 129.5 (*m** calcd. = 129.0).



Other peaks in the spectrum of low intensity which merit consideration are those appearing at *m/e* 260 and *m/e* 231 corresponding, respectively, to loss of a methyl group and of carbon dioxide. The presence of the latter peak corroborates the proposal of a lactone function in annotine.

The results of an analysis of the high-resolution spectrum of annotine are recorded in Table I. In every case the composition of the ions is in accord with the mechanism proposed from a study of the low-resolution spectrum. In some cases, however, doublets

TABLE I

Accurate mass measurement of annotine

Measured mass	Error (obs. − calcd.) in milli mass units	Elemental composition	Mass difference from molecular ion

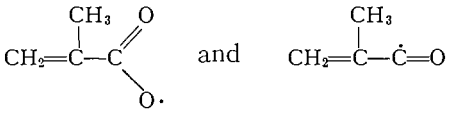
144.0787	−2.6	$C_{10}H_{10}N$	M-131

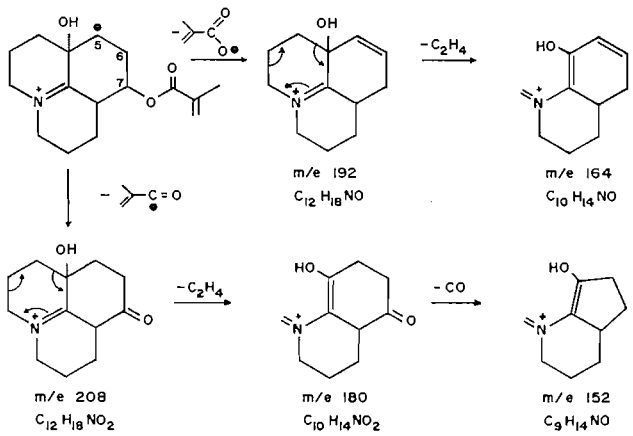
SCHEME 1.

are observed, e.g. at *m/e* 188, 172, and 162, but in each case the major component of the doublet corresponds in composition to the ion proposed in the fragmentation mechanism. In particular it should be noted that the ion of *m/e* 231 corresponds in composition to loss of CO_2 from the molecular ion.



The mass spectrum of dihydroannotine is more complex than that of annotine, but closer examination reveals that both compounds undergo common fragmentation processes upon electron impact. This is shown in Fig. 1*b*, where the peaks are designated by their mass difference from the molecular ion. The fragmentation process discussed in Scheme 1*a* explains the presence of peaks at *m/e* 260, 174, and 146, each appearing 2 mass units above the corresponding peaks in annotine. Metastable peaks are observed at *m/e* 244.5, 116.8, and 123.0 corresponding, respectively, to the transformations 277 $\rightarrow$ 260 (m^* calcd. = 244.0), 260 $\rightarrow$ 174 (m^* calcd. = 116.4), and 174 $\rightarrow$ 146 (m^* calcd. = 122.5).

Scheme 1*b*, when applied to dihydroannotine, gives rise to ions of mass 276, 190, 172, and 162. A metastable peak is present at *m/e* 131.4 (m^* calcd. 276 $\rightarrow$ 190 = 130.8) in accord with the loss of methacrylic acid from the ion of *m/e* 276.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

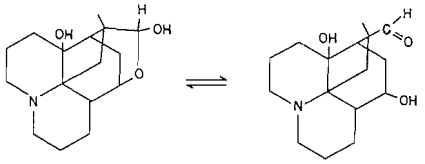
There are differences, however, as well as similarities, in the mass spectra of the two compounds. These differences, to a large extent, reflect the diminished tendency of the molecular ion of dihydroannotine to lose the hydroxyl radical, caused by the fact that such a process does not lead to a resonance-stabilized carbonium ion, as in the case of annotine. The relative difficulty with which the hydroxyl radical is lost from the molecular ion is demonstrated by the intense peak corresponding to the latter. As the molecular ion of dihydroannotine is not consumed to a large extent in the 277 → 260 transformation, other processes, which are insignificant in the fragmentation of annotine, here gain considerable importance. Thus a relatively intense peak is present at *m/e* 262 presumably caused by the loss of a methyl group; it provides evidence, independent from that available earlier, of the presence of this group in the alkaloid. Other peaks prominent in the spectrum of dihydroannotine appear at *m/e* 164, 152, 150, and 123. A possible route to the formation of the first two is outlined in Scheme 2. The peak at *m/e* 150 may be considered to be formed in part by loss of hydrogen from the ion of *m/e* 152. In this mechanism expulsion of the radicals

must be accompanied by hydrogen migration. In the first case hydrogen migration is postulated to occur from C_6 to C_7 and in the second from C_7 to C_5. The formation of a cyclopropane ring between C_5 and C_7 could account equally well for the ion of *m/e* 192. The presence of the strong peak at *m/e* 123 is not easily interpreted on the basis of the low-resolution spectrum alone.

SCHEME 2.



Examination of the high-resolution spectrum of dihydroannotine was carried out, and the results are shown in Table II. The composition of the ions discussed previously has been verified and additional information obtained. Thus the peak at *m/e* 249, formed by the loss of 28 mass units, is a doublet caused by loss of C_2H_4 and of CO from the molecular ion. The peak at *m/e* 123 is actually a quartet and thus not as important in the overall fragmentation as the examination of the low-resolution spectrum alone infers. The peaks at 190, 174, and 162 are O—CH_4 doublets, just as the corresponding ions at *m/e* 188, 172, and 162 are in the case of annotine. Similarly, O—CH_4 doublets are noted for the peaks at *m/e* 164 and 150.

The infrared spectrum of dihydroannotinol (1) shows that the compound in the solid state as well as in solution exists in a hemiacetal form. In the ion source of the mass spectrometer, however, dihydroannotinol is present in the gaseous phase, and may exist in both the hemiacetal and the hydroxy aldehyde forms as shown below. We make use of both isomers in the proposed fragmentation mechanisms.

A study of the mass spectrum of dihydroannotinol (Fig. 2*a*) reveals, as expected, an analogy with the patterns present in the spectra of annotine and dihydroannotine. Here also, we find the two main fragmentation mechanisms advanced previously. The process initiated by the M → M-17 transformation is formulated in Scheme 3*a* for the hydroxy aldehyde form. This mechanism is supported by the presence of metastable peaks at *m/e* 246.5 (*m** calcd. 279 → 262 = 246.0) and 159.0 (*m** calcd. 192 → 174 = 157.7). A metastable peak present at *m/e* 141.0 could be caused by either one of the following transformations: 262 → 192 (*m** calcd. = 140.7) and 192 → 164 (*m** calcd. = 140.1).

The ions of mass 278, 191, 190, 172, and 162 may be accounted for by the fragmentation scheme shown in Scheme 3*b*. The ion–radical of mass 279 may lose methacrylaldehyde and water to form the species of mass 191, or it may be converted into the ion of mass 278 by loss of a hydrogen radical. As shown, both processes may lead to the formation of the ion of mass 190. In Table III are recorded the results of the analysis of the high-resolution spectrum of dihydroannotinol. The composition of the ions postulated according to the proposed fragmentation mechanism have been verified. Some ions appear as

doublets as in the case of annotine and dihydroannotine. The ions of mass 150 and 152 may arise in a manner similar to that postulated for dihydroannotine.

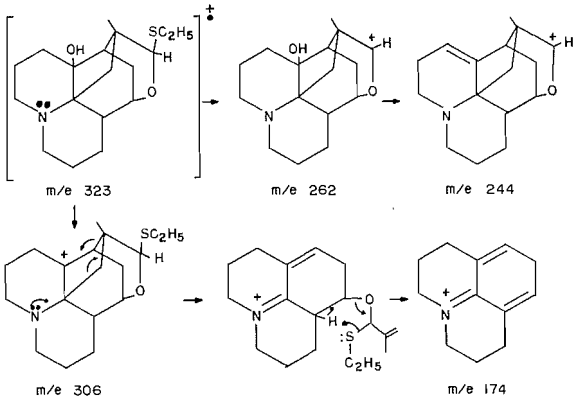

SCHEME 3.

Cleavage of the C—S bond is the dominant feature in the fragmentation of the thioethyl analogue of dihydroannotinol (1) (Fig. 2*b*). The peak at *m/e* 262 is by far the most intense in the spectrum. The peak at *m/e* 244 results from loss of water from the ion of mass 262. Metastable peaks are observed at *m/e* 213.0 (m^* calcd. $323 \rightarrow 262 = 212.5$) and 228.0 ($m^*$ calcd. $262 \rightarrow 244 = 227.2$) in accord with these changes. The peak at *m/e* 294 can be considered to arise by loss of the ethyl group from the molecular ion. Other peaks of low intensity are found at *m/e* 306 and 174; they probably arise by the already familiar process involving loss of the hydroxyl radical followed by expulsion of the bridge. These processes are illustrated in Scheme 4. A metastable peak is observed at 290.5 corresponding to the process $323 \rightarrow 306$ (m^* calcd. = 289.9).

A fourth derivative of annotine, whose spectrum (Fig. 3) is of considerable interest, is phenylannotine, to which we have assigned the structure shown. Instead of a lactone ring it contains a hemiketal function. In the solid state and in solution phenylannotine shows no carbonyl absorption. In the ion source of the mass spectrometer, however, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

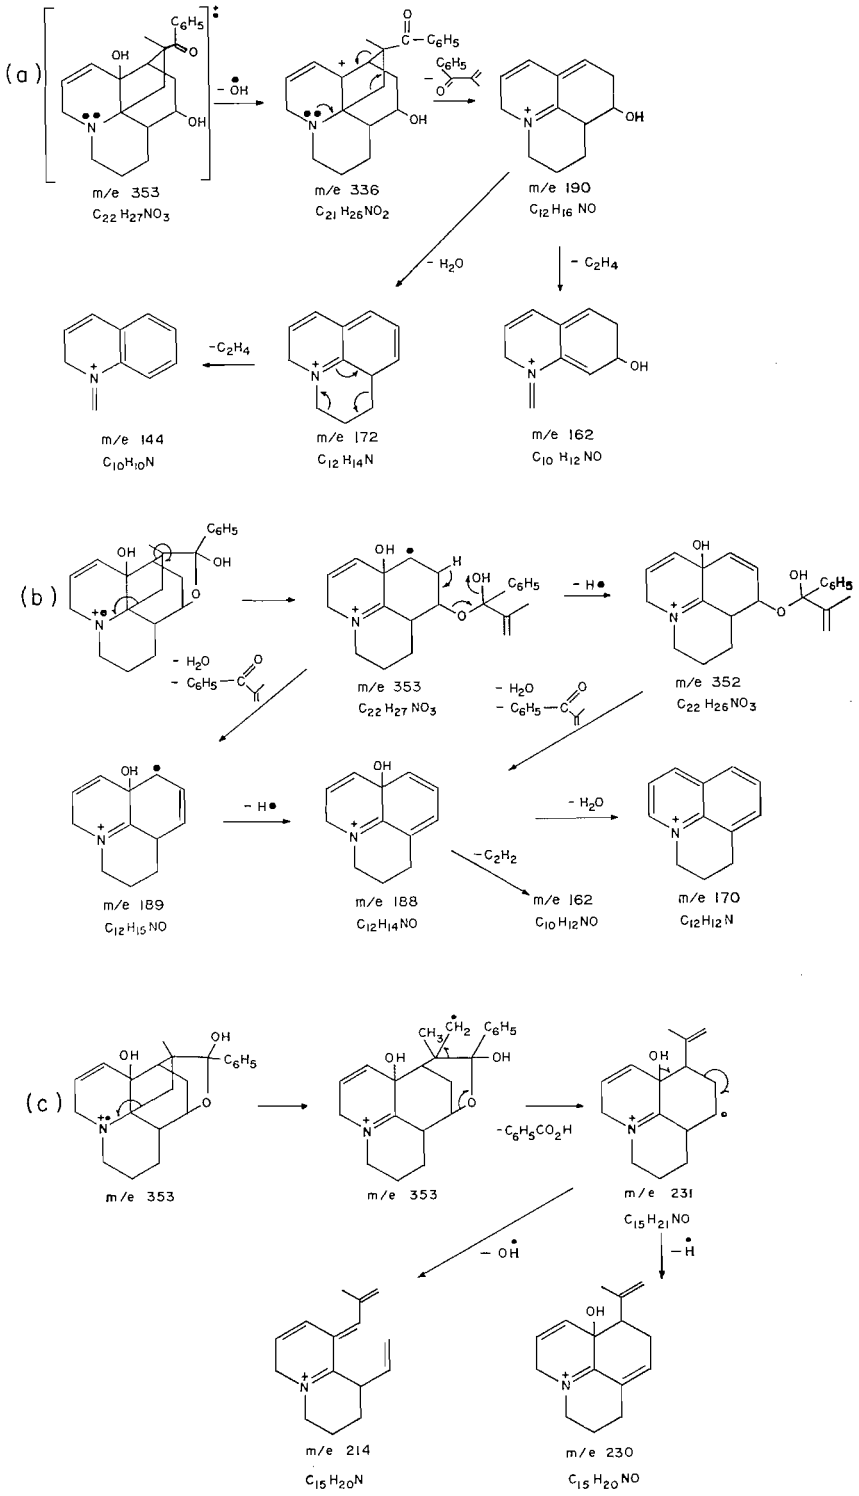
SCHEME 4.

may well exist in the open-chain form as we have proposed for dihydroannitonol, and undergo fragmentation as such. Thus the ions of *m/e* 336, 190, 172, 162, and 144, shown in Scheme 5*a*, are postulated to arise from the open-chain form. The peaks at 352, 189, 188, 170, and 162 may form via Scheme 5*b* from the hemiketal form. The remaining peaks of high intensity which merit consideration are at *m/e* 105, which corresponds to the benzoyl cation, and at *m/e* 231, 230, and 214. The latter three peaks can best be accommodated if one invokes a fragmentation mechanism of the type shown in Scheme 5*c*.

Here again we have corroborated the composition of the ions by examination of the high-resolution spectrum. The data are shown in Table IV and include those ions discussed previously. It is observed that the peaks at *m/e* 188 and 162 are doublets of the

TABLE IV



Accurate mass measurement of phenylannotine

Measured mass	Error (obs. − calcd.) in milli mass units	Elemental composition	Mass difference from molecular ion
354.2036	1.1	$C_{21}H_{27}{}^{13}C_1NO_3$	M+1
353.1973	−1.8	$C_{22}H_{27}NO_3$	M

336.1960	−0.4	$C_{22}H_{26}NO_2$	M-17
231.1596	−2.7	$C_{15}H_{21}NO$	M-122
230.1539	−0.6	$C_{15}H_{20}NO$	M-123
214.1598	0.2	$C_{15}H_{20}N$	M-139
190.1208	−2.4	$C_{12}H_{16}NO$	M-163
189.1135	−1.9	$C_{12}H_{15}NO$	M-164
188.1424	−1.5	$C_{13}H_{18}N$	M-165
188.1068	−0.7	$C_{12}H_{14}NO$	M-165
172.1113	−1.4	$C_{12}H_{14}N$	M-181
170.0966	−0.4	$C_{12}H_{12}N$	M-183
162.1257	−2.6	$C_{11}H_{16}N$	M-191
162.0895	−2.4	$C_{10}H_{12}NO$	M-191
144.0826	1.3	$C_{10}H_{10}N$	M-209

same composition as those in annotine. The loss of benzoic acid from phenylannotine is equivalent to loss of CO_2 in annotine, showing that the molecules fragment in an analogous manner in each system. Modification of the structure, however, as in phenylannotine, makes the formation of the ion of *m/e* 231 a much more favorable mode of fragmentation. The oxygen-free ions at *m/e* 188 and 162 in phenylannotine and in

SCHEME 5.

annotine may owe their origin to further fragmentation of the ions at *m/e* 231, 230, and 214. The oxygen-free ions at *m/e* 190 and 164 in dihydroannotine and dihydroannotinol may form in an analogous manner.

These results lend strong support to the proposal of structure I for annotine, since they provide evidence for the presence of a bridged hydrojulolidine skeleton in the alkaloid. Annotine and its derivatives lose the bridge carbon atoms in one of their major pathways of fragmentation and undergo further fragmentation to ions, appearing at *m/e* 170, 172, and 174, containing a $C_{12}N$ unit but differing in their hydrogen content. This behavior is analogous to that of other *Lycopodium* alkaloids having a bridged hydrojulolidine system (6).

EXPERIMENTAL

Apparatus, Methods, and Materials

The low-resolution spectra were recorded on a CEC21-103C mass spectrometer at an ionizing potential of 70 eV and an ionizing current of 50 μA. Samples were injected directly into the ion source by using a vacuum lock system. Peaks with an intensity $\geqslant 2\%$ of the most intense peak have been plotted. The high-resolution spectra were recorded on a CEC21-110 mass spectrometer. Spectra were measured by the method described by Biemann *et al.* (10).

The compounds used in this investigation were prepared according to methods described in a previous paper in this series (1).

ACKNOWLEDGMENTS

The authors are greatly indebted to Professor K. Biemann, Massachusetts Institute of Technology, in whose laboratory all spectra were recorded. Financial assistance from the National Research Council of Canada is gratefully acknowledged.

THE REACTION OF CARYOPHYLLENE AND DIAZOACETIC ESTER; SOME OBSERVATIONS ON CYCLOPROPANES

E. W. WARNHOFF AND V. DAVE
Department of Chemistry, University of Western Ontario, London, Ontario
Received October 20, 1965

ABSTRACT

The crystalline acid obtained in 1928 from saponification of the caryophyllene – diazoacetic ester reaction product has been found to be a 1:1 mixture of the stereoisomers V and VII. Compound III is an exception to the observation that cyclopropane CH bonds absorb in the 1.55–1.70 μ near-infrared region.

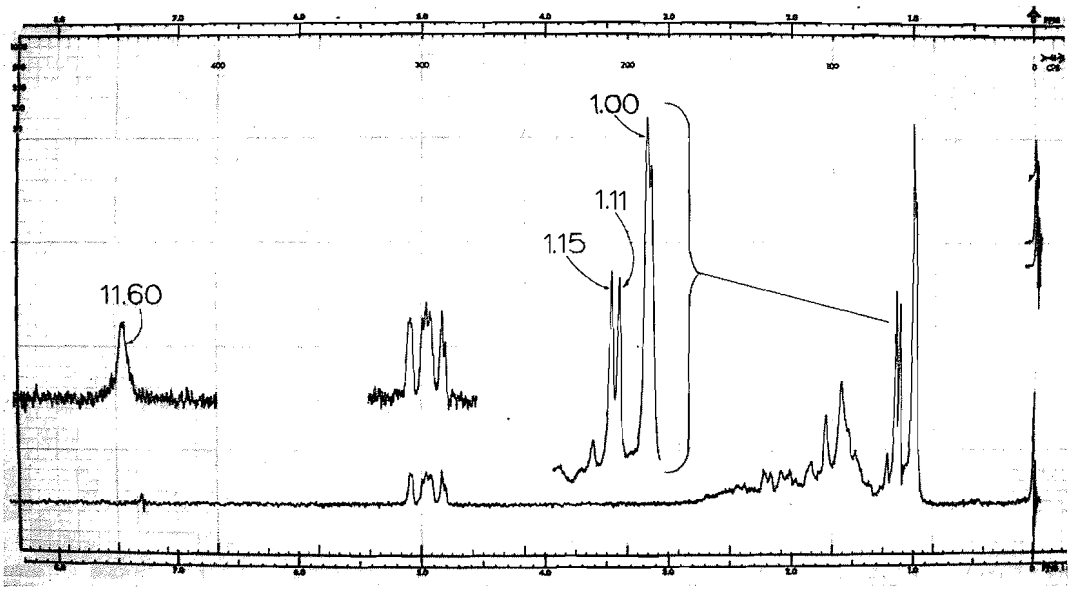
Addition of diazoacetic ester to caryophyllene (I) at 170° in the presence of copper has been reported (1) to yield a 1:1 reaction product whose saponification liberated an acid, $C_{17}H_{26}O_2$, m.p. 165°, $[\alpha]_{5460}$ −40°. The stated failure of this acid to decolorize bromine or to react rapidly with permanganate indicated the absence of double bonds, and, consequently, the presence of *four* rings. This remarkable result was in contrast to the reaction of isocaryophyllene with diazoacetic ester, which produced a normal cyclopropanecarboxylic ester with one double bond remaining (2). If the acid from caryophyllene were indeed saturated, it would require an unusual structure and genesis, and therefore merited reinvestigation.

Repetition of the reaction of diazoacetic ester with caryophyllene followed by saponification of the product gave in 17% yield an acid of constant m.p. 166.5–168°, $[\alpha]_{5460}$ −39.5°, presumably the compound described earlier (1). However, the acid rapidly decolorized both bromine in chloroform and aqueous permanganate solutions.* The presence of an unsymmetrically disubstituted double bond was demonstrated by infrared peaks at 1 650 and 896 cm^{-1} and by absorption (two protons) at δ 4.80–5.13 p.p.m. in the nuclear magnetic resonance (n.m.r.) spectrum (Fig. 1). Being unsaturated, the acid was most likely the normal cyclopropanecarboxylic acid II*a* from the reaction of the more nucleophilic and strained trisubstituted double bond.

In spite of the apparent purity of the acid, two features of the n.m.r. spectrum were not compatible with the acid being a single compound. Instead of the vinyl proton pattern being a pair of broad singlets, it had the appearance (Fig. 1) of two pairs of overlapping singlets, and the methyl group absorption at δ 1.1 p.p.m. was a closely spaced pair of peaks rather than a singlet. Such a spectrum could, however, be displayed by an approximately equimolar mixture of two stereoisomers of II*a*. Although the acid could not be separated into components by thin-layer chromatography or by attempted fractional crystallization from several solvents, its methyl ester was partially resolved into two peaks of about equal area on gas–liquid chromatography. Since saponification of this methyl ester mixture regenerated the original acid, the latter must consist of two isomers; this mixture of stereoisomers was used for the determination of structure and stereochemistry.

On catalytic reduction (Pd/C) the acid absorbed 1.01 mole equivalents of hydrogen. The resulting dihydroacid III (73% yield), which is also an approximately equimolar mixture of stereoisomers notwithstanding its narrow melting range, no longer had C=C

**Eventually, after the present work was completed, it became possible (through the kindness of Dr. D. T. Gibson) to compare the acid with that prepared earlier (1). The two were identical and both gave positive tests with bromine and permanganate solutions (see Experimental).*



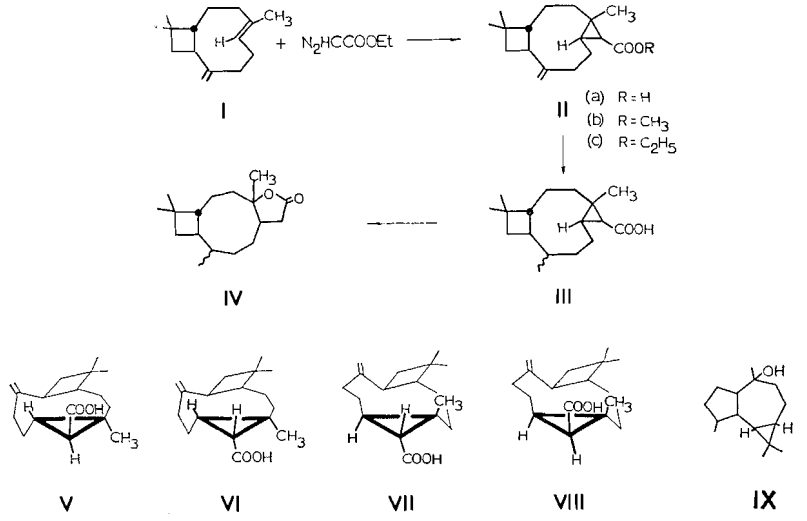


FIG. 1. The n.m.r. spectrum of the crystalline acid from the reaction of caryophyllene and diazoacetic acid.

double bond infrared absorption or vinyl hydrogen n.m.r. absorption, and did not react with bromine in carbon tetrachloride or with permanganate in aqueous acetone. The n.m.r. spectrum of III contained two overlapping doublets at δ 0.82 p.p.m. ($J \sim 6$ c.p.s.) and δ 0.87 p.p.m. ($J \sim 6$ c.p.s.) from the CH_3—CH groups generated, as well as two peaks at δ 1.15 and 1.27 p.p.m. from the quaternary cyclopropane methyl groups of the two stereoisomers.

Physical evidence for the presence of a cyclopropane ring conjugated with the carboxyl group includes the position of the carbonyl infrared peak in the series of compounds (1 700 cm^{-1} in acid II*a*, 1 690 cm^{-1} in dihydroacid III, 1 726 cm^{-1} in ethyl ester II*c*, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1 715 cm^{-1} in methyl ester II*b*), and the ultraviolet end absorption (ϵ_{220} 290, ϵ_{210} 544) of dihydroacid III. On the other hand, while it is not unusual for cyclopropane C—H bonds to absorb at lower field than δ = 0–1 p.p.m. in n.m.r. spectra (3), dihydroacid III did not have any peak in the 1.55–1.70 μ near-infrared region (Fig. 2) attributable to the first overtone of the cyclopropane C—H stretching vibration. Although this spectral correlation has been found to be valid for all cyclopropanes containing at least one methylene group (4), it has been noted that cyclopropanes containing methine groups but no methylene group may not exhibit a recognizable near-infrared absorption peak (4*d*, 4*e*). In agreement, we find that ledol (IX) has no peak between 1.55 and 1.70 μ. Therefore, the interpretation of the absence of peaks in the 1.6 μ spectral region as being indicative of the absence of cyclopropane hydrogen bonds must be treated with reserve.

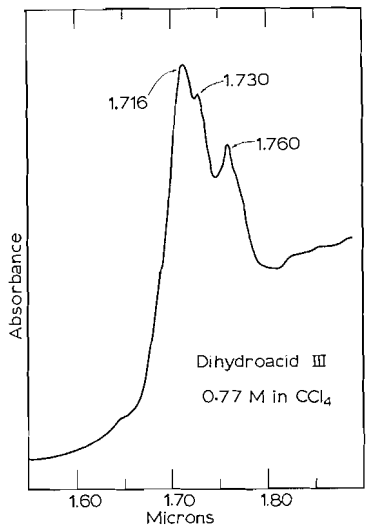

FIG. 2. The near-infrared spectrum of dihydroacid III.

Chemical evidence for the cyclopropane ring was provided by ring opening at room temperature with hydrobromic acid to produce from dihydroacid III the expected (5, 6) saturated γ-lactone IV, $\nu_{C=O}^{CHCl_3}$ 1 760 cm^{-1}. The attachment of the lactone oxygen atom to the carbon atom bearing the methyl group is supported by the singlet (3H) at δ 1.24 p.p.m. in the n.m.r. spectrum. Although both the acid II*a* and the dihydroacid III are known to be mixtures of stereoisomers, the lactone is probably a single pure compound, since the unsaturated acids in equilibrium with the lactone permit the epimerization of both asymmetric centers of the lactone ring, and since on gas–liquid chromatography the lactone gave a single peak.

Assignment of stereochemistry to the two isomers comprising the acid may be made on the following basis. Since the excess caryophyllene recovered from the reaction with diazoacetic ester is identical with the starting material, no isomerization of the *trans* double bond has occurred, and therefore the *trans* arrangement of groups is probably retained in the cyclopropane acid. There is ample precedent for preservation of double bond configuration in the reaction of *cis*- and *trans*-2-butene (7), *cis*- and *trans*-4-octene (8), *cis*-5-decene (9), and *cis*- and *trans*-stilbene (8) with diazoacetic ester under similar conditions. The possible isomers are then limited to two pairs of cyclopropanecarboxylic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acids (V and VI, VII and VIII) formed by addition to the two non-equivalent faces of the *trans* double bond. By analogy with known substituted cyclopropanes, such as the 2-methylcyclopropanecarboxylic acids (10) and the 2-phenylcyclopropanecarboxylic acids (11), each of the acids VI and VIII with the carboxyl and methyl groups *cis* will be appreciably less stable than its epimeric acid V or VII with the *trans* arrangement of these substituents. Of the six possible pairings of the four stereoisomers, V + VI and VII + VIII should be largely epimerizable at the α-position of the acid or its derivative to one of the original components; V + VIII, VI + VII, and VI + VIII should be epimerizable to a mixture containing one or two components not present in the starting material; only V + VII might remain almost unchanged.

When the methyl ester of the acid isomers was refluxed with sodium methoxide in methanol-O-d_1, the recovered ester contained deuterium, thus proving that the α-proton of the ester had been removed, but the composition of the ester was the same as that of the starting material (within experimental error). Therefore, both methyl esters must possess the more stable configuration at the α-carbon atom, and the acid II*a* is most likely a mixture of the *trans* stereoisomers V and VII. Both of these isomers are present in the original diazoacetic ester reaction product, along with two or three other isomers, and were not formed during saponification of the ethyl ester, because hydrolysis of the ethyl ester II*c* with sodium deuteriooxide in dioxane gave acid II*a* containing no deuterium bound to carbon. With no removal of the α-proton occurring during saponification, the stereochemistry of the acid isomers must be the same as that present in the original esters. It is satisfying that these two stereoisomers, which together constituted more than half of the acid mixture, are those expected on the basis of the empirical rule that reaction of diazoacetic esters with double bonds usually occurs to give, as the major cyclopropane product, that isomer in which the carboalkoxy group is subject to the fewest repulsive non-bonded interactions. This generalization is based, *inter alia*, on the examples of *cis*-stilbene (8), *cis*-2-butene (7), *cis*-4-octene (8), cyclohexene (12), styrene (11, 13), 1,3-cyclohexadiene (14), cyclopentadiene (15), and phenanthrene (16). *cis*-5-Decene (9) would appear to be an exception in which the products are formed in nearly equal amounts (57% *cis*, 43% *trans*).

EXPERIMENTAL

General

Melting points were determined on a Reichert microscope hot stage and are corrected.

Optical rotations were measured on a Rudolph model 80 polarimeter with a 1 dm tube, in 95% ethanol solutions unless otherwise specified.

Infrared spectra were carried out on a Beckman IR-5 or IR-7 spectrometer, near-infrared spectra on a Beckman model DK-1 spectrometer with carbon tetrachloride solutions, ultraviolet spectra on a Bausch and Lomb Spectronic 505 spectrometer, and nuclear magnetic resonance spectra on a Varian A-60 spectrometer with deuteriochloroform solutions.

Thin-layer chromatography was performed with Camag Kieselgel DF-5 silica gel. R_f values quoted were taken from one plate developed in petroleum ether – acetic acid (92:8) on which all compounds were present. For detection, plates were sprayed with concentrated sulfuric acid – concentrated nitric acid (1:1) and heated.

Analyses were carried out by Dr. A. Bernhardt and associates, Mülheim, Germany. Combustion deuterium analyses by the falling-drop method were by Josef Nemeth, Urbana, Illinois.

Petroleum ether refers to the fraction boiling at 35–60°.

Methanol-O-d_1 was prepared by deuterium oxide hydrolysis of methyl orthoformate according to a procedure for the preparation of ethanol-O-d_1 (17). The product was estimated to be 98% methanol-O-d_1 from its n.m.r. spectrum.

Caryophyllene was obtained by fractional distillation of saponified clove bud terpenes and had b.p. 120° at 10 mm, $[\alpha]_{21}^{D}$ −9.38° (neat).

Reaction of Caryophyllene and Diazoacetic Ester

To a mixture of 30 g of *trans*-caryophyllene ($[\alpha]_{D}^{21}$ −9.38° (neat)) and 1 g of copper powder (British Drug

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Houses, precipitated) heated to 165–170° was added dropwise a solution of 5.00 g of ethyl diazoacetate (18) in 5.0 g of *trans*-caryophyllene at such a rate that vigorous nitrogen evolution and a temperature around 170° were maintained. When the addition was complete after 20 min, the mixture was maintained at 165–170° for 30 min more. The copper was removed by filtration and the filtrate fractionally distilled through a 1 m Nester and Faust spinning spiral column. There was collected 23 g (66% recovery) of *trans*-caryophyllene, $[\alpha]_D^{21}$ −9.4° (neat), b.p. 121–123° at 10.5 mm. The ethyl ester II*c* distilled at 135–160° and 2 mm; 7.5 g (59% yield based on the diazoester); $[\alpha]_D$ −12.7° (*c*, 2.74); $\nu_{max,\,IR\text{-}7}^{CCl_4}$ 1 726 (C=O), 1 637 (C=C), and 892 cm^{-1} (C=CH$_2$); $\epsilon_{215}^{95\%\ EtOH}$ 3 490.

Anal. Calcd. for $C_{19}H_{30}O_2$ (290.43): C, 78.57; H, 10.41. Found: C, 76.75; H, 9.89.

Gas–liquid chromatography of this product on a 3 m column of 4% SE-30 supported on 100–120 mesh Gas Chrom P at 198° in an all-glass apparatus gave two major peaks of retention times 5.0 and 5.8 min and an overlapping minor peak of retention time 6.4 min.

Unsaturated Acid (IIa)

(*a*) A solution of 5.00 g of the ethyl ester from the previous experiment in 30 ml of 5% ethanolic potassium hydroxide was refluxed for 3 h. The reaction mixture was diluted with water and washed with ether. Acidification of the aqueous layer and extraction with ether yielded 3.90 g of slightly yellow, oily crystals. Several recrystallizations from methanol and ethanol gave 0.80 g (17%) of colorless needles, m.p. 166.5–168°, $[\alpha]_{5460}^{23.5}$ −39.5° (*c*, 1.39), $[\alpha]_D^{23}$ −32.6° (*c*, 2.10), R_f 0.63 (lit. (1): m.p. 165°, $[\alpha]_{5460}$ −40° (alcohol)); $\epsilon_{210}^{95\%\ EtOH}$ 3 524; $\nu_{max,\,IR\text{-}5}^{CHCl_3}$ 1 700 (C=O), 1 650 (C=C), and 896 cm^{-1} (C=CH$_2$). Nuclear magnetic resonance spectrum: δ 0.99 and 1.00 p.p.m. (2s, 6H, *gem*-dimethyl), 1.11 and 1.15 p.p.m. (2s, 3H, CH$_3$—▽), 4.80–5.13 p.p.m. (m, 2H, C=CH$_2$), and 11.60 p.p.m. (s, 1H, COOH).

Anal. Calcd. for $C_{17}H_{26}O_2$ (262.38): C, 77.82; H, 9.99. Found: C, 77.87; H, 9.87; neutral equiv. 260.

Dropwise addition of 5% bromine in carbon tetrachloride solution to the acid dissolved in chloroform gave immediate decolorization. When 2% aqueous potassium permanganate solution was added to the acid dissolved in acetone, the purple color changed within 20 s, but there was no observable change in an acetone blank.

A sample of the acid prepared by Gibson (1) from supa oil caryophyllene and found by him to be identical with the acid from clove bud caryophyllene was compared with the above acid. The melting points (165.5–167°) and infrared and n.m.r. spectra were identical. There was no depression in the melting point of a mixture of the two acids.

(*b*) To a solution of 0.40 g of sodium in a mixture of 4 ml of deuterium oxide (>99%) and 7 ml of dioxane was added 0.47 g of the distilled mixture of ethyl esters from the caryophyllene – diazoacetic ester reaction. The reaction mixture was refluxed for 7 days, diluted with water, and extracted with ether. Acidification of the aqueous layer precipitated 0.45 g (106%) of crystalline acid which, after recrystallization from methanol, had m.p. 164–165.5° (35 mg). The infrared spectrum and R_f were identical with those of II*a*.

Anal. Calcd. for $C_{17}H_{25}DO_2$: D, 3.85 atom % excess. Found: D, 0.00 atom % excess.

Dihydro Acid III

(*a*) A mixture of 40 mg of 5% palladium on carbon catalyst (MCB) and 4 ml of absolute ethanol was equilibrated with hydrogen. Addition of 16.5 mg (0.063 mmole) of unsaturated acid II*a* resulted in the uptake of 1.73 ml (1.01 mole equivalents) of hydrogen at 27° and 738 mm.

(*b*) A mixture of 225 mg of 5% palladium on carbon catalyst and 100 ml of absolute ethanol was equilibrated with hydrogen. Then 1.90 g of the unsaturated acid II*a* was added and the reaction mixture shaken until hydrogen uptake ceased. The solution was evaporated to dryness after the catalyst had been removed by filtration, and the residue was recrystallized twice from methanol to yield 1.40 g (73%) of colorless needles of dihydroacid III, m.p. 152–154°, $[\alpha]_D^{23}$ +23.9° (*c*, 2.06), R_f 0.66, $\epsilon_{210}^{95\%\ EtOH}$ 544, $\nu_{max,\,IR\text{-}7}^{CCl_4}$ 1 690 cm^{-1} (C=O). Nuclear magnetic resonance spectrum: δ 0.82 and 0.87 p.p.m. (2d, $J \sim 6$ c.p.s., 3H, CH$_3$—CH), 0.96 p.p.m. (s, 6H, two unsplit methyls), 1.15 and 1.27 p.p.m. (2s, 3H, CH$_3$—▽), and 11.33 p.p.m. (s, 1H, COOH).

Anal. Calcd. for $C_{17}H_{28}O_2$ (264.39): C, 77.22; H, 10.67. Found: C, 77.23; H, 10.36.

Methyl Ester IIb

To a solution of 350 mg of acid II, m.p. 166.5–168°, in 5 ml of ether was added an ethereal solution of diazomethane at room temperature with stirring. Excess diazomethane was destroyed with a few drops of acetic acid. The ethereal solution was washed with 10% aqueous bicarbonate, water, and saturated sodium chloride solution, and then dried over magnesium sulfate. Evaporation of the ether left 320 mg (89%) of pale yellow oil which was distilled in a tube at 150° and 0.1 mm; $[\alpha]_D^{25}$ −32.8 ± 1.5° (*c*, 1.89); R_f 0.82; $\nu_{max,\,IR\text{-}5}^{CHCl_3}$ 1 715 (C=O), 1 635 (C=C), and 892 cm^{-1} (C=CH$_2$). Nuclear magnetic resonance spectrum: δ 0.98 and 1.00 p.p.m. (2s, 6H, *gem*-dimethyl), 1.09 and 1.12 p.p.m. (2s, 3H, CH$_3$—▽), 3.64 p.p.m. (s, 3H, OMe), and 4.75–5.02 p.p.m. (m, 2H, C=CH$_2$).

Anal. Calcd. for $C_{18}H_{28}O_2$ (276.40): C, 78.21; H, 10.21. Found: C, 77.71; H, 10.03.

Gas–liquid chromatography on a 2 m column of 1% SE-30 supported on 100–120 mesh Gas Chrom P at 147° in an all-glass apparatus gave two partially resolved peaks of approximately equal area and with retention times 9.09 and 9.47 min.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A solution of 320 mg of the methyl ester in 5 ml of 5% ethanolic potassium hydroxide was refluxed for 6 h. The reaction mixture was diluted with water and washed with ether. Acidification of the aqueous layer and extraction with ether gave 296 mg of crystalline acid. One recrystallization from methanol yielded 282 mg (93% recovery) of colorless needles of II*a*, m.p. 166–168°, $[\alpha]_D^{24.5}$ −32.9° (*c*, 2.08), R_f 0.63.

Dihydrolactone IV

Hydrogen bromide gas was slowly passed for 2 h into a solution of 1.40 g of dihydroacid III, m.p. 149–153°, in 20 ml of glacial acetic acid. After the reaction mixture had been kept at room temperature for 34 h more, the acetic acid was evaporated at reduced pressure. The residual brown oil was dissolved in ether and the acids removed by extraction with 10% sodium carbonate solution. Removal of ether from the dried solution left 1.08 g (77%) of yellowish-brown oily crystals. Sublimation at 100–110° and 0.1 mm followed by recrystallization from methanol, ethanol, and finally ethyl acetate gave colorless prisms, m.p. 143.5–145°, $[\alpha]_D^{22.5}$ −19.9° (*c*, 1.75), R_f 0.36, $\epsilon_{215}^{95\%\ EtOH}$ 49, $\nu_{max,\ IR\text{-}5}^{CHCl_3}$ 1 760 cm^{-1} (γ-lactone C=O). Nuclear magnetic resonance spectrum: δ 0.89 p.p.m. (d, $J \sim 7$, 3H, CH_3—CH), 0.97 and 1.00 p.p.m. (2s, 6H, *gem*-dimethyl), and 1.24 p.p.m. (s, 3H, CH_3—C—O).

Anal. Calcd. for $C_{17}H_{28}O_2$ (264.39): C, 77.22; H, 10.67. Found: C, 76.79; H, 10.65.

Gas–liquid chromatography on a 2 m column of 2% SE-33 supported on 80–100 mesh Gas Chrom A at 200° in an all-glass apparatus gave a single symmetrical peak of retention time 0.91 min.

Attempts to open the cyclopropane ring of III by treatment in chloroform solution with anhydrous hydrogen chloride at room temperature and at reflux were unsuccessful; starting material was recovered.

Attempted Epimerization

(*a*) *Deuterium exchange.*—To a solution of 0.5 g of sodium metal dissolved in 10 ml of dry methanol-O-d_1 was added 1.10 g of methyl ester II*b* prepared from pure acid II*a*. The reaction mixture was protected from moisture, refluxed for 24 h, cooled, and diluted with ether. The ethereal solution was washed with 10% aqueous sodium carbonate, water, and saturated aqueous sodium chloride, and then dried over magnesium sulfate. Evaporation of the ether left 0.95 g (86% recovery) of liquid which was distilled at 140–150° and 2 mm, $[\alpha]_D^{23}$ −29.7° ± 1.5° (*c*, 1.93).

Anal. Calcd. for $C_{18}H_{27}DO_2$: D, 3.57 atom % excess. Found: D, 2.63 atom % excess.

The n.m.r. spectrum of the product could not be distinguished in appearance from that of the starting material. Gas–liquid chromatography on a 2 m column of 2% SE-33 supported on 80–100 mesh Gas Chrom A at 140° in an all-glass apparatus gave two partially resolved peaks of retention times 3.50 and 3.68 min, unchanged on 1:1 admixture with untreated methyl ester.

(*b*) To a solution of 1 g of sodium in 20 ml of dry methanol was added 1.20 g of not quite pure methyl ester II*b*, $[\alpha]_D^{26.5}$ −25.0° ± 1° (*c*, 2.29). The solution was refluxed for 2 h, cooled, diluted with water, acidified, and extracted with ether. The organic layer was washed with aqueous sodium bicarbonate, dried, and concentrated to remove the ether. There remained 0.890 g of light tan oil which was distilled at 115° and 0.1 mm, $[\alpha]_D^{24}$ −27.2° ± 2° (*c*, 1.87).

The n.m.r. spectrum of the product could not be distinguished in appearance from that of the starting material. The gas–liquid chromatogram was identical with that of pure methyl ester II*b*, except for the presence of a minor impurity which was also present in the starting material used for this experiment.

ACKNOWLEDGMENTS

We thank Dr. D. T. Gibson for supplying an authentic sample of acid II*a*, and the National Research Council for financial support. The gas–liquid chromatograms were kindly run by Mrs. P. F. Highet, National Institutes of Health, Bethesda, Maryland.

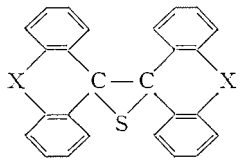
UTILIZATION OF SULFUR

SYNTHESIS OF SYMMETRICAL THIIRANES FROM KETOHYDRAZONES

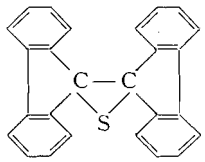
N. LATIF, I. FATHY, N. MISHRIKY, AND B. HAGGAG
National Research Center, Cairo, United Arab Republic

Received July 13, 1965



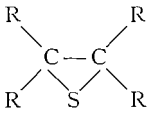
ABSTRACT

Dispiro(xanthene-9,2′-thiirane-3′,9″-xanthene), dispiro(thioxanthene-9,2′-thiirane-3′,9″-thioxanthene), epithiobidiphenyleneethane, epithiotetraphenylethane, epithiotetra-*p*-anisylethane, and epithiotetra-*p*-tolylethane are directly synthesized by the base-catalyzed interaction of the corresponding ketohydrazones, elemental sulfur, and yellow mercuric oxide. The reaction mechanism is discussed. Epithiotetra-*p*-tolylethane is also obtained by the uncatalyzed reaction of sulfur with the corresponding diazoalkane.



The successful use of thiiranes in industry and biology stimulated various authors to investigate the chemistry of this group of compounds in more detail. Thiiranes are usually prepared by the action of diazoalkanes on thioketones (1). Recently, it has been reported that diazoalkanes react with sulfur to give the corresponding thiiranes (2); however, the instability and the inaccessibility of some of the diazo compounds limited the usefulness of this method.

In the present study, the synthesis of symmetrical thiiranes is brought about directly from the readily available and stable ketohydrazones, thus obviating the necessary preparation of the diazoalkanes and thioketones (3). Thus, dispiro(xanthene-9,2′-thiirane-3′,9″-xanthene) (I*a*), dispiro(thioxanthene-9,2′-thiirane-3′,9″-thioxanthene) (I*b*), epithiobidiphenyleneethane (II), epithiotetraphenylethane (III*a*), epithiotetra-*p*-anisylethane (III*b*), and epithiotetra-*p*-tolylethane (III*c*) are produced when the corresponding ketohydrazones are allowed to react with elemental sulfur and yellow mercuric oxide in boiling ether or benzene, and in the presence of ethanolic potassium hydroxide. The corresponding ketazines are also produced in this reaction. In the absence of mercuric oxide and (or) alkali, the episulfides are not obtained. The dimethoxybenzophenone azine, which is produced in the experiment with *p*,*p*′-dimethoxybenzophenone hydrazone, is found to be yellow and melts at 184°, whereas Staudinger and Kupfer (4) reported that the azine is violet and melts at 124°. The structure of the product obtained in the present investigation is supported by analytical data and is rigorously confirmed by the fact that it is synthesized by three established procedures: (*a*) by oxidizing the hydrazone with mercuric oxide in benzene, (*b*) by heating *p*,*p*′-dimethoxydiphenyldiazomethane above its melting point, and (*c*) by fusing the ketone with the hydrazone at 160–170°. It is known that *p*-substituted benzophenone azines are generally high-melting yellow products. The sulfides I*a*, I*b*, II, III*a*, III*b*, and III*c* have been obtained previously by other methods (2, 5). III*c* is now also obtained by the uncatalyzed reaction of sulfur with di-*p*-tolyldiazomethane. The thiiranes are desulfurized by copper bronze or Raney nickel to give the corresponding ethylenes; however, the use of Raney nickel usually gives better yields of the pure ethylenes.



It is believed that the direct production of thiiranes from ketohydrazones may proceed through the intermediate formation of the corresponding diazoalkane VII. The latter gives the corresponding thioketone through its nucleophilic attack on sulfur and the simultaneous splitting off of nitrogen. The thioketone reacts further with another molecule

of the diazo compound to give the cyclic sulfide (cf. Reaction Scheme 1). It has been pointed out (6) that the S—S bonds in sulfur and organic polysulfides are readily broken by nucleophilic reagents. The production of the corresponding diazo compound as an intermediate is evidenced by the fact that its characteristic color is developed during the reaction, and in some experiments it has been isolated from the reaction mixture.

VII

REACTION SCHEME 1.

The alternative mechanism which might suggest itself is that the diazoalkane first splits off nitrogen to give a carbene which then coordinates with sulfur to give the thioketone (2). Production of the carbene as an intermediate is usually accompanied by the formation of the corresponding ethylene as a by-product; however, the ethylenes are not produced in this reaction, except in the case of fluorenone hydrazone, where it is presumably formed through the decomposition of the first-formed sulfide. It is found that II decomposes easily during crystallization from benzene. A polar, rather than a free-radical,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mechanism is also strongly supported by the fact that the reaction is remarkably retarded by benzoyl peroxide, which is a free-radical initiator, and that it is uncatalyzed by sunlight. Addition of an aqueous dimethylamine solution instead of alkali also catalyzes the reaction, but a lower yield is obtained. The presence of heteroatoms having mobile unshared electron pairs, or electron-releasing substituents, which increase the nucleophilic character (basicity) of the diazoalkane carbanion VII, enhances the reaction. Thus, better yields of the sulfides are obtained with xanthone or thioxanthone rather than with fluorenone hydrazone. With substituted benzophenone hydrazones, the best yield is obtained in the case of the dimethoxy derivative.

EXPERIMENTAL

Melting points were not corrected. Microanalyses were performed by A. Bernhardt, Germany, and the Microanalyses Unit, National Research Center, Cairo.

Preparation of Dispiro(xanthene-9,2′-thiirane-3′,9″-xanthene) (Ia)

Freshly prepared ethanolic potassium hydroxide solution (0.5 ml) was added to a suspension of xanthone hydrazone (2 g), yellow mercuric oxide (4 g), and powdered sulfur (0.5 g) in dry ether (30 ml). The mixture was boiled under reflux for 6 h, the green ethereal solution was filtered while hot, the black residue was extracted with boiling acetone, and the acetone extract was concentrated and left to cool. The solid that was obtained (0.52 g) was recrystallized from acetone to give dispiro(xanthene-9,2′-thiirane-3′,9″-xanthene), m.p. 206–207 °C (undepressed when admixed with an authentic sample (2)).

The residue that was left after the acetone extraction was extracted with boiling xylene, the extract was concentrated and left to cool, and the separated crystals were shown to be xanthone azine (VI) (m.p. and mixed m.p. 285°).

When the reaction was repeated with a 20–25% aqueous dimethylamine solution instead of potassium hydroxide, I*a* was produced.

Preparation of Dispiro(thioxanthene-9,2′-thiirane-3′,9″-thioxanthene) (Ib)

Thioxanthone hydrazone was allowed to react with sulfur and mercuric oxide as above. The product that was obtained (0.48 g) was shown to be dispiro(thioxanthene-9,2′-thiirane-3′,9″-thioxanthene) (its infrared spectrum is identical with that of an authentic sample (2)).

Preparation of Epithiobidiphenyleneethane (II)

Fluorenone hydrazone (2 g), yellow mercuric oxide (4 g), and sulfur (0.5 g) were allowed to react in boiling dry benzene (20 ml) for 6 h. The red-brown reaction mixture was filtered while hot and evaporated to dryness, and a few milliliters of acetone was added to the residue. The separated solid (0.17 g) was shown to be epithiobidiphenyleneethane, m.p. 162–163° (undepressed when admixed with an authentic sample (2)). The filtrate was concentrated and cooled, and the separated solid (0.34 g) was shown to be bidiphenyleneethylene (melting point and mixed melting point). The mother liquor was evaporated to dryness, a few milliliters of ether was added to the oily residue, and the solution was cooled. The solid that separated (0.7 g) was shown to be 9-diazofluorene (melting point and mixed melting point).

When the reaction was carried out in dry ether instead of benzene, a small amount of II only was obtained.

Preparation of Epithiotetraphenylethane (IIIa)

The reaction was carried out as above. The violet benzene solution was filtered while hot, concentrated, and left to cool. The separated solid (0.35 g) was shown to be epithiotetraphenylethane (2) (m.p. and mixed m.p. 178°). The mother liquor was evaporated to dryness, a few milliliters of methanol was added, and the solid that was obtained was shown to be diphenyl ketazine (V*a*).

When the reaction was carried out with a dimethylamine solution instead of potassium hydroxide, III*a* was obtained.

When III*a* was heated under reflux with Raney nickel in ethanol, tetraphenylethylene (IV*a*), m.p. 222–224° (undepressed when admixed with an authentic sample), was obtained.

Preparation of p,p′-Dimethoxybenzophenone Azine (Vb)

Method A

p,p′-Dimethoxybenzophenone hydrazone (1 g) and yellow mercuric oxide (2 g) in dry benzene (15 ml) were heated under reflux for 6 h. The violet reaction mixture was filtered while hot, concentrated, and left to cool. The separated solid was crystallized from acetone to give the azine as yellow crystals, m.p. 182–184 °C.

Anal. Calcd. for $C_{30}H_{28}N_2O_4$: C, 74.98; H, 5.87; N, 5.83. Found: C, 74.64; H, 6.10; N, 5.02.

Method B

p,p′-Dimethoxydiphenyldiazomethane (0.2 g) was heated at 150 °C (bath temperature) for 1 h and left to cool. The yellow solid that was obtained was extracted with boiling acetone, and was proved to be the azine (melting point and mixed melting point).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Method C

A mixture of *p,p'*-dimethoxybenzophenone (0.5 g) and the corresponding hydrazone (0.5 g) was heated at 160–170 °C for 3 h. The reaction mixture was left to cool, and the yellow product that was formed was crystallized from acetone and shown to be the azine (melting point and mixed melting point).

Preparation of Epithiotetra-p-anisylethane (IIIb)

A mixture of *p,p'*-dimethoxydiphenyldiazomethane (1 g) and sulfur (0.25 g) in dry ether (25 ml) was heated under reflux for 3 h. The reaction mixture was filtered off, and the residue was extracted with boiling ether. The ether extract was concentrated and cooled, and the separated solid (0.45 g) was crystallized from benzene to give epithiotetra-*p*-anisylethane as colorless crystals, m.p. 220–222°.

Anal. Calcd. for $C_{30}H_{28}O_4S$: C, 74.38; H, 5.78; S, 6.61. Found: C, 74.57; H, 5.91; S, 6.45.

This compound, when heated under reflux with Raney nickel in ethanol, gave tetra-*p*-anisylethylene (IV*b*), m.p. 186–188°.

Anal. Calcd. for $C_{30}H_{28}O_4$: C, 79.62; H, 6.24. Found: C, 80.13; H, 6.14.

Reaction of p,p'-Dimethoxybenzophenone Hydrazone with Sulfur

The hydrazone, sulfur, and mercuric oxide were allowed to react together in dry benzene as usual. The reaction mixture was filtered off, the residue was extracted with boiling benzene, and the benzene solution was concentrated and cooled. The separated solid was extracted with boiling acetone, and the acetone extract was cooled to give *p,p'*-dimethoxybenzophenone azine (melting point and mixed melting point). The acetone-insoluble fraction was crystallized from benzene to give III*b* (0.67 g).

Preparation of Epithiotetra-p-tolylethane (IIIc)

The reaction between di-*p*-tolyldiazomethane (2 g) and sulfur (0.5 g) was carried out as in the case of the dimethoxy analogue. The product (0.37 g) was crystallized from acetone to give epithiotetra-*p*-tolylethane, m.p. 195–196° (5).

Anal. Calcd. for $C_{30}H_{28}S$: C, 85.71; H, 6.66; S, 7.61. Found: C, 85.35; H, 6.81; S, 7.68.

This compound, when heated under reflux with Raney nickel in alcohol, yielded the ethylene (IV*c*) (7), m.p. 150 °C.

Anal. Calcd. for $C_{30}H_{28}$: C, 92.74; H, 7.26. Found: C, 93.10; H, 7.25.

Reaction of p,p'-Dimethylbenzophenone Hydrazone with Sulfur

The reaction was carried out as in the case of the dimethoxy analogue to give III*c*, m.p. 195–196° (0.37 g), and *p,p'*-dimethylbenzophenone azine (V*c*), m.p. 197–198° (Staudinger and Goldstein (8) gave m.p. 190–191°).

Anal. Calcd. for $C_{30}H_{28}N_2$: C, 86.50; H, 6.78; N, 6.73. Found: C, 86.93; H, 6.94; N, 6.96.

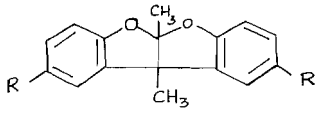
ON THE CONDENSATION OF *p*-CRESOL WITH GLYOXAL



B. S. THYAGARAJAN, K. K. BALASUBRAMANIAN, AND R. BHIMA RAO

Two different methods of synthesis for the formation of coumarano(3,2-*b*)coumarans have long been known in the literature (1–3). One of these is the condensation of phenols with 1,2-dicarbonyl compounds in the presence of sulfuric acid, and the other is the acid-catalyzed cyclodehydration of 2,3-bis-(*o*-hydroxyaryl)-2,3-bis-hydroxybutanes. In both instances, the assumption has tacitly been made that the ultimate products have the benzofuro(3,2-*b*)benzofuran structure (I).

In the course of an attempt to provide synthetic evidence for the products of the acid-catalyzed rearrangement of 1,4-bis-aryloxybut-2-ynes (4), we have recently pointed out the erroneous nature of this assignment and have presented a more rational, alternate representation for two such products (II).

IIa, R = H

IIb, R = CH_3

III

IV

Although the condensation of *p*-cresol with glyoxal is not germane to our main efforts in the rearrangements of the 1,4-bis-aryloxybut-2-ynes, we have reinvestigated the former reaction to verify the validity of a similar structural assignment (III) (5).
