The earlier structural formulation III rested on the evidence that the same product was obtainable by way of the acid-catalyzed dehydration of 1,2-bis-(2-hydroxy-5-methylphenyl)-ethane-1,2-diol (6). Repetition of the published procedure (5) yielded a compound in complete agreement with the earlier description. However, a nuclear magnetic resonance spectrum of the compound (taken in $CDCl_3$ with tetramethylsilane as an internal reference) (Fig. 1) revealed the following characteristics: a singlet at 2.25 p.p.m. caused by the aromatic methyl group integrating for six protons; a signal at 4.8 p.p.m. integrating for one proton; a signal at 4.9 p.p.m. integrating for one proton; and a multiplet centered at 6.95 p.p.m. integrating for six protons.

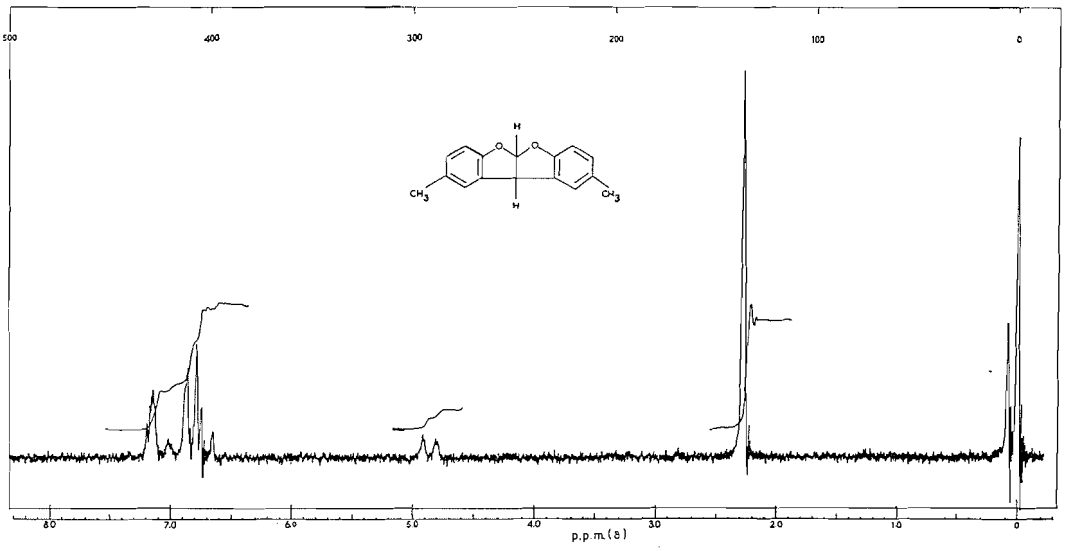

FIG. 1.

The benzofuro(3,2-*b*)benzofuran structure III would be expected to show only a singlet for the benzylic protons, in view of their location on identical environments. On the other hand, the benzofuro(2,3-*b*)benzofuran structure IV would exhibit split absorptions for the bridgehead protons because of the fact that one of them is now benzylic whereas the other is not. The observed nuclear magnetic resonance spectrum leaves no doubt that the product is a benzofuro(2,3-*b*)benzofuran (IV).

Thus, in all the three cyclodehydrations of symmetrical (*o*-hydroxyaryl) glycols as well as the 1,2-dicarbonyl condensations, the products are not the reported coumarano(3,2-*b*)-coumarans but the coumarano(2,3-*b*)coumarans.

ACKNOWLEDGMENTS

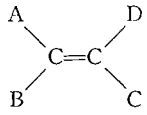
THE PREPARATION AND CHARACTERIZATION OF *cis*- AND *trans*-2-HYDRO-3-CHLORO-HEXAFLUORO-2-BUTENE

DONALD J. BURTON, RICHARD L. JOHNSON, AND RICHARD T. BOGAN

Although the preparation of the 2-hydro-3-chlorohexafluoro-2-butenes has been reported several times in the literature (1–4), no separation or identification of the individual isomers has been reported. In some recent work on the selective reduction of vinylic halogen in polyfluorinated olefins (5), we have carried out the reduction of a mixture of *cis*- and *trans*-2,3-dichlorohexafluoro-2-butene. Gas chromatographic analysis indicated two product peaks (presumed to be the *cis*- and *trans*-2-hydro-3-chlorohexafluoro-2-butenes). Since very few geometrical isomers of highly fluorinated olefins have been reported, and since these isomers are of potential interest in mechanistic studies of polyfluorinated olefins, we undertook the separation and identification of each geometrical isomer.

The isomer mixture was prepared by the monoreduction of the 2,3-dichlorohexafluoro-2-butene mixture with sodium borohydride in diglyme. Each isomer was separated and purified by vapor phase chromatography. Vapor density molecular weight determinations and infrared analysis demonstrated that the two compounds were indeed the isomeric 2-hydro-3-chlorohexafluoro-2-butenes. Assignment of the geometrical configuration of each isomer was made on the basis of the analysis of the ^{19}F nuclear magnetic resonance spectra of the pure isomers. The physical properties and the spectral data for each isomer are tabulated in Tables I and II, respectively.

TABLE I



Physical properties of *cis*- and *trans*-$CF_3CH{=}CClCF_3$

	Boiling point (°C)*	n_D^{20}	Molecular weight†	—C=C—‡
cis-Isomer	41–42	1.3078	195	6.02 μ
trans-Isomer	34.5–35.5	1.3014	195	5.98 μ

*Microboiling point measured at 743 mm.
§Average of two determinations, calcd. mol. wt. 198.
‡Spectra were calibrated versus polystyrene film. Values are consistent with the presence of the —CH=CCl— grouping.

TABLE II

Spectral data for *cis*- and *trans*-$CF_3CH{=}CClCF_3$

	A	B	C	D	J_{AD}*	J_{AC}	J_{AB}	J_{BC}
cis-Isomer	CF_3	H	Cl	CF_3	10.8	—	8.0	—
trans-Isomer	CF_3	H	CF_3	Cl	—	1.0	5.4	1.2

*Spectra were measured at 56.4 Mc.p.s. with CCl_3F as an internal standard; J values are in cycles per second.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The ^{19}F nuclear magnetic resonance spectrum of the *trans*-2-hydro-3-chlorohexafluoro-2-butene consisted of two sets of lines: a line at $\phi^* = +61.2$ which was broken down into two quartets caused by coupling of the CF_3 group (A) with the hydrogen and with the *trans*-CF_3 group (C), and another line at $\phi^* = +70.8$ which consisted of two condensed quartets caused by coupling of the CF_3 group (C) with the *trans*-CF_3 (A) and with the hydrogen.

The spectrum of the *cis*-isomer consisted of two sets of lines: a line at $\phi^* = +57.7$ consisting of a complex pattern (octet) caused by splitting of the CF_3 group (A) by the hydrogen and the other CF_3 group (D), and a second line at $\phi^* = +65.0$ consisting of a quartet caused by splitting of the CF_3 group (D) by the other CF_3 group (A).

The assignment of the *trans*- or *cis*-structure was made on the basis of the magnitude of the coupling constants. The coupling constant between two CF_3 groups (*trans* across the double bond) has been reported to be 1.3–1.5 c.p.s. (6–8). The coupling constant between two CF_3 groups (*cis* across the double bond) has been reported to be 11–13 c.p.s. (6–8). The values of $J(CF_3, CF_3)$ of 1.0 c.p.s. and 10.8 c.p.s. are consistent with these previous assignments.

EXPERIMENTAL

$CF_3CCl{=}CClCF_3 + NaBH_4$

In a four-necked flask were placed 25 ml of dry diglyme (distilled from lithium aluminium hydride) and 23.3 g (100 mmoles) of 2,3-dichlorohexafluoro-2-butene (mixture of the *cis*- and *trans*-isomers). The mixture was cooled to 0 °C, and 99.0 ml of 1.01 *M* sodium borohydride (100 mmoles) in diglyme was added dropwise, the temperature being kept below 5 °C. During the addition of the borohydride solution, 29 mmoles (corrected to s.t.p.) of hydrogen was evolved. After the addition of the borohydride solution was completed, the reaction mixture was stirred at 0 °C for an additional 0.5 h and then cautiously hydrolyzed with water. On hydrolysis, 162 mmoles (corrected to s.t.p.) of hydrogen was evolved. After complete hydrolysis, the reaction mixture was poured into 50 ml of ice water and the organic layer separated.

The pure *cis*- and *trans*-isomers of 2-hydro-3-chlorohexafluoro-2-butene were separated and purified by preparative vapor phase chromatography on a F&M model 720 gas chromatograph having a 10 ft by 0.5 inch (outside diameter) copper column packed with 20% w/w dinonylphthalate supported on 100–120 mesh Gas Chrom P maintained at 40 °C, with the vaporizer at 200 °C and a helium flow rate of 300 ml/min. The retention times were 5.05 min and 9.05 min for the *trans*- and the *cis*-isomers, respectively.

THE ABSOLUTE CONFIGURATION OF THE IBOGA ALKALOIDS

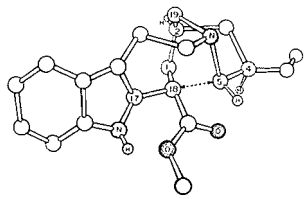
JAMES P. KUTNEY, RICHARD T. BROWN, AND EDWARD PIERS

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The Iboga alkaloids have received considerable attention during recent years; in particular, several groups of workers, including our own, have been interested in the total synthesis of the Iboga skeleton. Indeed we were able to provide a synthetic entry into this series by means of a transannular cyclization process (1), and recently two publications (2, 3) have revealed totally synthetic pathways to the Iboga series. Although the basic structure of this group, initially proposed by the Ciba workers (4), was subsequently confirmed by the X-ray analysis of ibogaine hydrobromide (5), in which the relative configuration was also determined, the absolute configuration of this series was, until recently, an open question. The crucial evidence which allowed a solution to this problem came from our work on cleavamine, in which the structure and absolute configuration were determined by the X-ray method to be as depicted in I (6). A subsequent detailed paper illustrating the three-dimensional structure of cleavamine methiodide has also appeared (7). The isolation of cleavamine from an acid cleavage reaction on catharanthine and the subsequent demonstration that carbomethoxydihydrocleavamine (II) can be cyclized in a stereospecific manner to the alkaloids coronaridine and dihydrocatharanthine (1) provided indisputable evidence for the stereochemical relationship between cleavamine and the Iboga alkaloids. In our most recent paper (8) we discussed our results along with those previously published by other workers, and indicated that structure III represents the absolute configuration of ibogamine, one of the members of the Iboga family. Our purpose in publishing the present note is to emphasize that through a careless error on our part we have drawn the *incorrect* absolute configuration in structure III. We illustrate below that the *correct* absolute configuration for the Iboga family is in fact *antipodal* to the one presented in III.

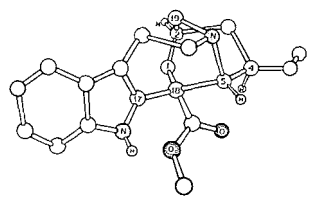
I II III

Since our previous paper (8) has already mentioned all the relevant work in this area, we merely wish to emphasize presently the crucial arguments which invalidate the stereoformula III and which point out that it is in fact impossible to derive III from cleavamine (I) and (or) from carbomethoxydihydrocleavamine (II).



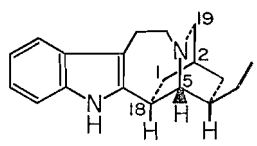
Carbomethoxydihydrocleavamine (II) has the same absolute configuration at C_2 (Iboga alkaloid numbering) as cleavamine (I). Since II, via its iminium salt involving the $C_5{=}\overset{+}{N}$ group, has been cyclized to the Iboga alkaloid system as already mentioned above (1), the absolute configuration at C_2 in the rigid Iboga skeleton must remain the same. It may be argued that an alteration in configuration at C_2 could have taken place in the iminium salt derivative *before* the cyclization process. This argument is made invalid for two reasons. First of all, both cleavamine and carbomethoxydihydrocleavamine are derived from a ring-opening reaction on catharanthine (9, 10). When this result is

taken in conjunction with the above cyclization result, it becomes obvious that either *no* epimerization or *two* epimerizations at C_2 must occur to allow regeneration of the catharanthine system in the cyclization process. Secondly, we have excluded the possibility of epimerization at C_2 in a related series of investigations. We have shown that an iminium salt intermediate with the $C_{19}{=}\overset{+}{N}\!\!\diagup\!\!\diagdown$ group, which is the only intermediate in which epimerization at C_2 could occur, cyclizes to an Aspidosperma skeleton; an X-ray analysis of this product establishes that the absolute configuration at this asymmetric center remains *unchanged* (11).



With the above evidence on hand one immediately notes that, although there are numerous conformations which structures I and II with nonrigid nine-membered rings can attain, there is in fact only *one* conformation of II which allows C_{18} and C_5 to come into reasonable proximity for bond formation. This particular conformation is reproduced in II*a*. It becomes immediately obvious that in II*a* the C_2—C_{19}—N bridge is now α-oriented and that the eventual ring closure between these two centers results in formation of the rigid Iboga system shown in IV, which now represents the complete structure for coronaridine. The absolute configuration in IV is antipodal to that shown above in III. On this basis the complete structure and absolute configuration of ibogamine are now correctly represented by V.

We wish to indicate that the alternate conformation for II, in which the C_2—C_{19}—N bridge is β-oriented, places C_{18} and C_5 far apart and clearly provides an impossible situation for bond formation between these two centers. However, even if such a cyclization were possible, it would in fact provide the Iboga alkaloid with the *wrong* relative configuration, the latter being already available from the X-ray determination of ibogaine hydrobromide (5) as mentioned above.



The absolute configuration of the Iboga family as illustrated above for ibogamine is *opposite* to that originally suggested in the publication from the Ciba group (4). More recently Buchi has also postulated the *opposite* absolute configuration for voacangine based on an incorrect interpretation of our X-ray work on cleavamine (12). For this reason the absolute configuration for the voacangine unit in the dimeric alkaloid voacamine (12) must be altered. Similarly, the absolute configuration of the velbanamine unit in the oncolytic Vinca alkaloids vinblastine and vincristine is now established, since velbanamine can readily be converted into cleavamine. The absolute configuration is antipodal to the stereochemistry presented in a recent communication (10).[1]

IV

V

[1]*After our paper had been submitted for publication, a communication on the X-ray analysis of leurocristine methiodide appeared (13) wherein the absolute configuration for the cleavamine-like unit was shown to be in complete agreement with our previous work. We also acknowledge some recent correspondence with Professor G. Buchi on this point.*

ANODIC OXIDE FILMS ON INDIUM ANTIMONIDE[1]

A. C. HARKNESS
British Columbia Research Council, Vancouver, British Columbia

AND

L. YOUNG
Department of Electrical Engineering, University of British Columbia, Vancouver, British Columbia

Received September 7, 1965

ABSTRACT

The kinetics of formation of anodic oxide films on different crystal faces of single crystal indium antimonide have been investigated by measurements of charge passed, capacitance, and optical properties. Below a transition or breakdown region of voltage no difference in kinetics was found. Above this voltage a marked difference appeared. The transition voltage was found to depend on both the crystal face and the current density at which the film was formed.

INTRODUCTION

Most observations on the growth of high resistance anodic oxide films can be explained in terms of the ionic conduction properties of the oxide film itself (1): that is, the movement of ions through the oxide under the influence of the applied field controls the growth process. The movement of ions across the metal–oxide interface is not an important factor in determining the overall rate.

Dewald (2) anodized different crystal faces of indium antimonide and reported that there were marked differences in the kinetics of film formation on different faces. He reported that the ionic current density and field were not related by the simple equation $i = A \exp BE$ (where i is the current density, E is the field, and A and B are constants); rather there were two such equations, one describing the behavior at low formation rates and the other at high formation rates. At the low rates (0.1 V/s) the field on the (332) face was about 15% lower than the field on the ($\bar{3}32$) face. At higher rates (10 V/s) the fields converged and both faces exhibited the same kinetics.

Venables and Broudy (3) anodized (111) and ($\bar{1}\bar{1}\bar{1}$) faces of indium antimonide at a current density of 2×10^{-4} A/cm^2 which corresponds to Dewald's low rate. Like Dewald they used 0.1 M KOH as the electrolyte. The formation rates on the two surfaces were the same until the voltage had increased to 11 V. At this point the rate of voltage increase on the (111) face decreased sharply, but the film thickness as indicated by the interference colors increased at a greater rate. The ($\bar{1}\bar{1}\bar{1}$) face showed the same behavior at 13 V.

Lavine, Rosenberg, and Gatos (4) have also reported that the rate of anodic oxidation of indium antimonide is faster on (111) surfaces than on ($\bar{1}\bar{1}\bar{1}$) surfaces.

Indium antimonide crystallizes in the zinc blende structure which lacks a center of symmetry and has crystallographic polarity along the ⟨111⟩ axis. The structure may be

[1]*Paper presented at the 48th Chemical Institute of Canada Conference, Montreal, 31 May 1965.*

visualized as composed of tetrahedra of indium atoms interlocked with tetrahedra of antimony atoms in such a manner that each indium atom is at the center of a tetrahedron of antimony atoms and vice versa. If the bonding is considered to be only between nearest neighbors, then each atom is held by four bonds to the other species in the interior of the crystal. In the ⟨111⟩ direction layers of atoms of the same species are alternately singly and triply bound to parallel layers of atoms of the other species. Since surfaces arise by severing single bonds, opposite {111} surfaces are composed of different atom species triply bound to the lattice. Gatos (5) has given a detailed discussion of the bonding and reactivity of group III–IV compounds.

The assignment of the {111} surfaces is quite arbitrary. Dewald defined (111) as that surface showing the faster rate of film formation and others have adopted the same convention. It has since been determined that the (111) face terminates with indium atoms (6).

It would be expected that the free energy of formation of extremely thin oxide films would be different on different crystal faces. However, if the films are thick enough so that surface perturbations become negligible, then the properties of the film and the rate of growth should be independent of crystal face and oxide thickness at constant current density and temperature.

This paper describes experiments on oxide films formed on opposite {111} faces of single crystal indium antimonide. It was hoped that some insight into the previously reported anomalous behavior might be obtained.

EXPERIMENTAL

The indium antimonide was Cominco Grade 35S, a high mobility *n*-type single crystal grown in the ⟨111⟩ direction. Slices were cut parallel to {111} faces with a tungsten wire saw. Specimens were normally prepared by abrasion on metallurgical papers down to 4/0. Those which survived this treatment then had wires soldered to them. Picien wax was applied to stop off one side and the edges. The specimens were chemically polished in a solution containing concentrated nitric acid, concentrated hydrofluoric acid, and glacial acetic acid in the ratio 5:3:3 by volume. The (111) face polishes to a bright finish while the $(\overline{1}\overline{1}\overline{1})$ face is lightly etched and gives a matte finish.

All film forming was done in an electrolyte of 0.1 *M* borax (pH = 9.2) at 25.0°. This electrolyte was chosen to minimize the possible solution of antimony oxide. The cathode was platinized platinum and voltages were measured with respect to the cathode with the solution saturated with hydrogen. The cell was shielded from direct light to avoid the photoeffects reported by Venables and Broudy (3, 7).

Nearly all formation experiments were conducted with a constant current generator with a control apparatus designed and built by Mr. R. Cuthbert in the laboratories of the British Columbia Research Council. This device displays the time required to form through selected voltage intervals and terminates the current on arrival at a preset voltage. During anodization the solution was not stirred, since this resulted in bubbles on the anode. The currents employed were normally too low to cause appreciable heating of the anode.

Specimen areas were determined by photographing the specimen on squared paper and comparing the area covered by the specimen to the area of a square by planimeter measurement or by weighing. An alternative, simpler procedure was to make Xerox copies of the specimens backed by squared paper. No allowance was made for surface roughness.

The series equivalent capacity and resistance of the films were measured with a conventional bridge.

The wavelengths of minimum reflectivity of the interference colors were measured with a Cary Model 14 recording spectrophotometer. Specimens were mounted in a holder so that light was incident at an angle of 11°. A polished (111) surface was used as reference.

The specimens used for ellipsometer determinations were mechanically polished. After abrading on metallurgical papers they were rubbed on a soft cloth soaked with a slurry of fine alumina. This treatment produces bright mirror finishes on both (111) and $(\overline{1}\overline{1}\overline{1})$ faces. Measurements were made with a Gaertner L119 ellipsometer with monochromatic light of 5 461 Å. The method of measurement was the same as that used for oxide films on tantalum (8).

RESULTS AND DISCUSSION

Typical formation curves are illustrated in Fig. 1. Both crystal faces exhibited similar behavior. There is a nearly linear rise in voltage followed by a period where the rate of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rise decreases. During anodization quite bright interference colors are developed through the sequence light gold, deep gold, bronze, pink, purple, blue, green, grey. Second order colors are not well defined and the films break down and evolve gas.

On both surfaces the transition voltage, defined as the voltage where linear growth ceases, increases with increasing current density. Furthermore, the final voltage reached before complete failure is higher with higher current densities.

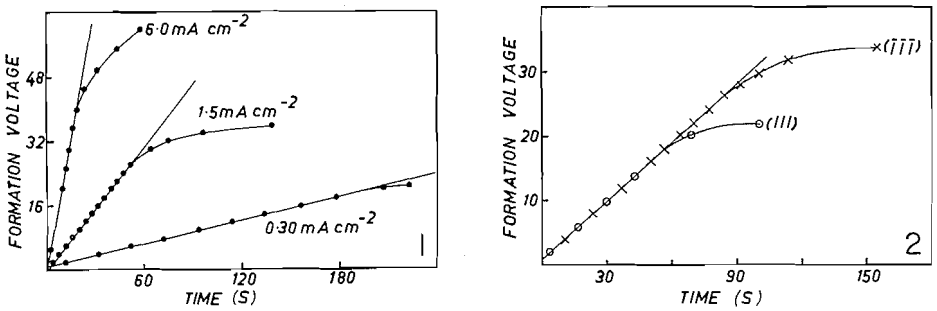

FIG. 1. Formation curves for $(\bar{1}\bar{1}\bar{1})$ surface of InSb. Various current densities.
FIG. 2. Formation curves for (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of InSb. Current density 1.00 mA/cm².

In agreement with Venables and Broudy (3), it was found that the transition voltage was higher for films formed on $(\bar{1}\bar{1}\bar{1})$ surfaces than for those formed on (111) surfaces. Figure 2 shows formation curves for specimens of each surface formed at the same current density. Until the transition voltage for the (111) surface is reached the rates of formation are identical. This behavior was encountered through the range of current densities used. In Fig. 3, transition voltages are plotted against the logarithms of the formation rates for the linear region. The curve for $(\bar{1}\bar{1}\bar{1})$ specimens lies above that for the (111) specimens.

The colors of the films indicate that past the transition voltage their thickness increases rapidly. Thus, for a given current density, the (111) surface will show a faster rate of film growth over a certain voltage range. This of course assumes that no significant change in the optical properties of the film occurs at the transition voltage. The wavelength of minimum reflectivity is a measure of film thickness. A plot of this parameter against formation voltage for {111} specimens formed at similar current densities is given in Fig. 4.

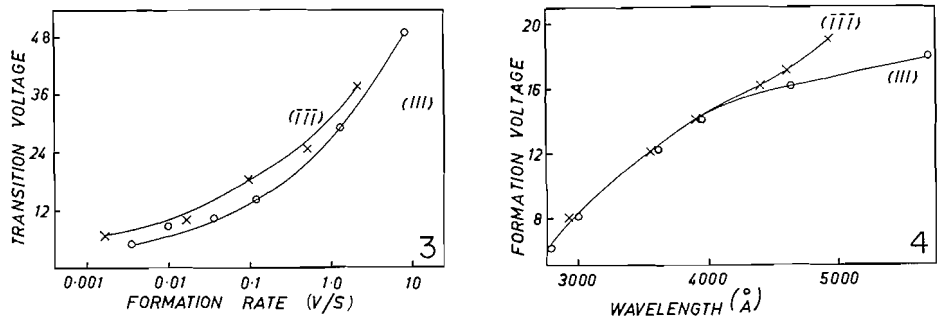

FIG. 3. Variation of transition voltage with formation rate for (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of InSb.
FIG. 4. Wavelength of minimum reflectivity vs. formation voltage for films formed on (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of InSb. Current density 0.3 mA/cm².

To detect differences in the kinetics of film formation, quite accurate estimates of fields are necessary. Measurements of capacity have proved to be particularly effective (1). If the current efficiency is high, measurement of the charge, Q, passed to form through a voltage interval, ΔV, may be combined with a measurement of the increase in reciprocal capacity, $\Delta(1/C)$, to give an estimate of the field which is independent of the specimen area. The quantity $\Delta V/(Q\Delta(1/C))^{1/2}$ is an estimate of the field strength.

Figure 5 shows the field estimate, $\Delta V/(Q\Delta(1/C))^{1/2}$, as a function of the logarithm of the formation rate (below the transition voltage). The scatter is about $\pm 5\%$. This is an order of magnitude worse than can be obtained with tantalum. The results, however, tend to confirm that there is no difference between the {111} faces.

The reflection of polarized light from a surface results in changes in the amplitude and phase of both the p- and s-components. The appropriate equation which relates the ratio of the reflection coefficients to these changes is $R_p/R_s = \tan \psi e^{i\Delta}$. Here, ψ is the relative amplitude change and Δ the relative phase change. These quantities are the experimental parameters. The character of the reflected light is dependent on the wavelength and angle of incidence of the incident light, the optical constants of the substrate (metal), and on the optical constants and thickness of the surface film (oxide).

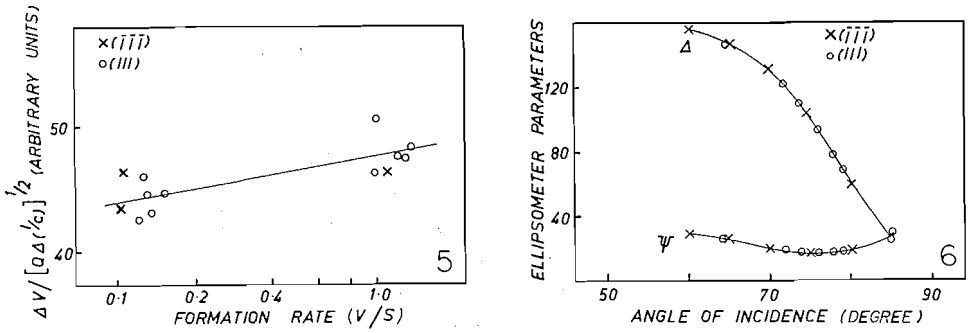

FIG. 5. Field estimates from charge and capacity data vs. formation rate for films formed on (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of InSb below the transition voltage.
FIG. 6. Variation of ellipsometer parameters ψ and Δ with angle of incidence for unanodized (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of InSb.

In principle, the method allows the determination of the optical constants of the film and its thickness provided the optical constants of the bare metal are known. In practice, ultrahigh vacuum techniques would be required to obtain film-free metal in order to measure its optical constants by ellipsometry. For some metals, e.g. tantalum, the optical constants may be obtained by other methods (9). Kumagai and Young (8) have shown that curve-fitting methods (with an IBM 1620 computer) may be used with ellipsometer data to obtain good values of the optical constants of both metal and oxide film. Their procedure was followed in this study.

A plot of the ellipsometer parameters, ψ and Δ, as a function of angle of incidence of 5 461 Å light for unanodized {111} surfaces of indium antimonide is given in Fig. 6. The surfaces had been mechanically polished with alumina. It is seen that there is no apparent difference between the two surfaces.

From data on unanodized metal preliminary estimates of the optical constants of the metal were found to be $n = 3.5$ and $k = 2.1$ for the (111) surface. The corresponding estimates for the $(\bar{1}\bar{1}\bar{1})$ surface were 3.6 and 2.1. These should of course be equal. We are using the convention that the complex index of refraction is written $\bar{n} = n - ik$.

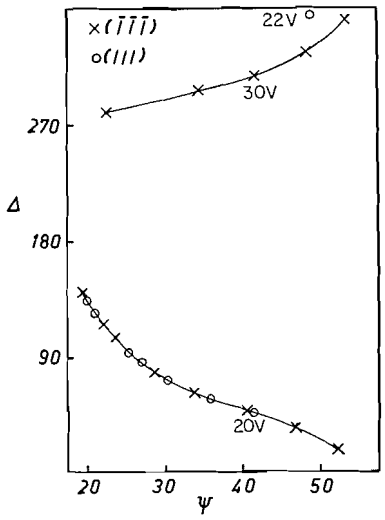

FIG. 7. Ellipsometer curve for films formed on (111) and ($\bar{1}\bar{1}\bar{1}$) surfaces of InSb. Current density 1.00 mA/cm².

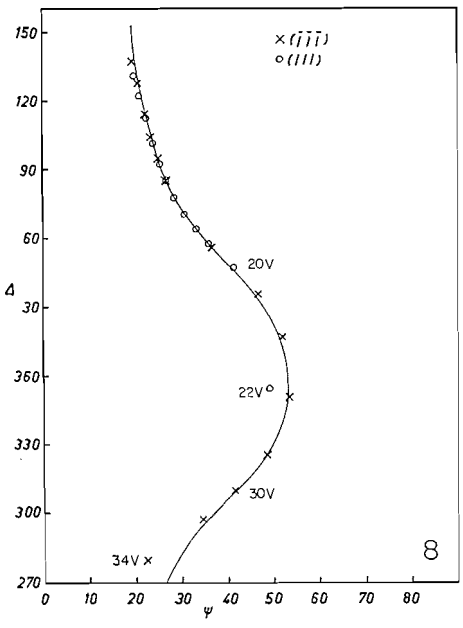
Figure 7 shows Δ vs. ψ plots for films formed on (111) and ($\bar{1}\bar{1}\bar{1}$) surfaces at 1.00 mA/cm². For these specimens the film was formed to a preset voltage and the specimen removed from the cell, rinsed, and dried. After the ellipsometer measurements were made, the film was removed by dissolving in hydrofluoric acid. A new film was formed to a different voltage and the procedure repeated. The formation data for these films are those displayed in Fig. 2.



The significance of Fig. 7 is that, up to the transition voltage of the (111) specimen (18 V), there is complete coincidence of the ellipsometer curves. This indicates that the oxide films formed on both surfaces have identical properties. This, combined with the identical rates of voltage rise, is strong evidence for the same kinetics of formation on both (111) and ($\bar{1}\bar{1}\bar{1}$) surfaces of indium antimonide.

The experimental Δ vs. ψ plot of Fig. 7 was fitted by trial and error curves calculated for various values of the optical constants n_2 and k_2 for the metal and n_1 for the oxide. The oxide was assumed to be non-absorbing, i.e. $k_1 = 0$. Figure 8 shows the calculated curve giving the best fit of the experimental points. The values used in calculating this curve were (for oxide) $n_1 = 2.15$ and (for metal) $n_2 = 4.6$ and $k_2 = 1.6$. Kurdiani (10) reports $n_2 = 4.6$ and $k_2 = 0.5$.

A plot was constructed of Δ and film thickness from the calculated curve. From this plot, thicknesses corresponding to experimental values of Δ for particular formation voltages were read off. This allowed the construction of formation voltage – film thickness plots as shown in Fig. 9. The slopes of these plots yield values of the field across the oxide of 4.6×10^6 V/cm for the (111) surface and 4.3×10^6 V/cm for the ($\bar{1}\bar{1}\bar{1}$) surface (for current density 1 mA/cm²). The difference should be considered as due to experimental variation rather than real field differences.

The evidence indicates that below a transition voltage there is no difference in the formation behavior of anodic films formed on (111) and ($\bar{1}\bar{1}\bar{1}$) surfaces of indium antimonide. Above the transition voltage the ellipsometer data deviate from the calculated curve. This suggests that there has been a change in the optical properties of the films.

ÉTUDE DE LA FORMATION DES COMPLEXES DU PROTACTINIUM AVEC LES ACIDES DI- ET POLY-CARBOXYLIQUES PAR LA MÉTHODE D'ÉCHANGE D'IONS

IOAN GALATEANU

Institut de Physique Atomique Bucarest, Roumanie[1]

Reçu le 28 juin 1965

RÉSUMÉ

On a étudié la formation de complexes du protactinium avec les acides malique, tartrique, trioxyglutarique, oxalique, aconitique, citrique et éthylènediaminetétraacétique, à l'aide de la méthode d'échange d'ions. On en a calculé les constantes d'instabilité. L'ordre de stabilité croissante de ces complexes est le suivant: aconitique, malique, tartrique, oxalique, trioxyglutarique, citrique, éthylènediaminetétraacétique.

ABSTRACT

The formation of the protactinium complexes with malic, tartaric, trioxyglutaric, oxalic, aconitic, citric, and ethylenediaminetetraacetic acids has been studied by the ion-exchange method, and the instability constants have been calculated. The stability of the complexes increases in the following order: aconitic, malic, tartaric, oxalic, trioxyglutaric, citric, ethylenediaminetetraacetic acid.

Dans les travaux scientifiques concernant la chimie du protactinium on trouve des opinions différentes sur la forme du protactinium dans les solutions acides. D'après Elson (1) dans les solutions faiblement acides, le protactinium se trouve sous la forme de complexes hydrolysés: $Pa(OH)_{4.5}^{0.5+}$, $PaO(OH)_{2.5}^{0.5+}$, etc., mais dans les solutions fortement acides, il peut se présenter sous forme ionique Pa^{5+}. Goble, Golden et Maddock (2) ont montré l'existence des complexes du protactinium respectivement $PaOCl_6^{2-}$ et $PaO_2(NO_3)_4^{3-}$ dans les solutions de HCl et HNO_3. En outre, Kraus et Moore (3) pensent qu'il existe un complexe $H_nPaX_5Cl_{n+1}^{1-}$ dans la solution HCl 8 *M*. Starik *et al.* (4) ont étudié le comportement du protactinium dans l'acide nitrique (1–12 *M*) à l'aide de la méthode d'échange d'ions et démontré l'existence des complexes: $Pa(OH)_4^{1+}$, $Pa(OH)_3^{2+}$, $[Pa(OH)_3(NO_3)]^{1+}$, $[Pa(OH)_3(NO_3)_2]^0$, $[Pa(OH)(NO_3)_5]^{1-}$, $[Pa(OH)(NO_3)_7]^{3-}$, etc.

Dans nos travaux antérieurs nous avons étudié le processus de la formation des complexes du protactinium avec les acides lactique (5), α-hydroxy-iso-butyrique et mandélique (6) par la méthode d'échange d'ions. Les résultats obtenus nous montrent que le protactinium, dans les solutions de ces acides (pH = 0.5–1), se trouve sous la forme des complexes du type: $[PaO(OH)_yR_j]^{(5-2-y-j)+}$ où R est le coordinat respectif, mais dans les solutions des mêmes acides à pH plus élevés (pH = 2) prédomine la forme de complexes: $[Pa(OH)_yR_j]^{(5-y-j)+}$ où $y = 1,2,3 \ldots$ et $j = 1$.

Nous avons calculé les valeurs des constantes d'instabilité des complexes du protactinium avec plusieurs acides organiques, à l'aide des méthodes de Froneus (7–10) et de Paramonova (11–15) et nous avons publié ces résultats dans une brève note (16).

Dans la présente communication nous avons décrit le processus de la formation des complexes du protactinium avec les acides malique, tartrique, trioxyglutarique, oxalique, citrique, aconitique et éthylènediaminetétraacétique.

PARTIE EXPÉRIMENTALE

Les solutions de ces acides, préparées avant chaque série d'expériences, avaient des concentrations dans les limites 8×10^{-5} à 7×10^{-1} *M*, et une force ionique $\mu = 0.25$.

[1]*Adresse actuelle: Agence Internationale de l'Énergie Atomique, Vienne I, Kaerntnerring 11, Autriche.*

Tous les réactifs étaient de haute pureté. Le protactinium-233 que nous avons utilisé comme indicateur dans toutes les expériences a été obtenu par la réaction nucléaire:

$$^{232}\mathrm{Th} + \mathrm{n} \rightarrow {}^{233}\mathrm{Th} \xrightarrow{\beta^-} {}^{233}\mathrm{Pa} \xrightarrow{\beta^-} {}^{233}\mathrm{U}.$$

On a effectué la séparation du protactinium-233 à l'aide d'échangeurs d'ions par adsorption (sur anionite Dowex-1, Cl^-) de solutions HCl 10 *M*, puis par élution avec une solution HCl 4 *M* (17). Après séparation, les solutions chlorhydriques du protactinium-233 ont été évaporées à sec et finalement le protactinium a été mis en solution 2 *M* d'acide perchlorique et conservé dans des bouteilles de Teflon. Toutes les expériences, pour la détermination des constantes d'instabilité, ont toujours été effectuées avec des solutions fraîches de protactinium. En ce cas on peut éviter la formation des radiopseudocolloïdes. Des parts aliquotes de solution du protactinium ont été ajoutées aux solutions de chacun des acides, puis mises en contact avec les quantités calculées de cationite (Dowex-50, 400 mesh) et d'anionite (Amberlite IRA-400, 100 mesh). Pour chaque échantillon placé dans un cylindre de Teflon la durée du contact a été de 3 h pour le cationite et 5 h dans le cas de l'anionite, avec agitation dans un thermostat maintenu à la température constante (25 °C). Ensuite on a pris des parts aliquotes de chaque solution et on a mesuré l'activité résiduelle, en déterminant le coefficient de distribution du protactinium-233, à l'aide de la formule:

$$\zeta = I_0 - I/I \cdot v/m \quad \mathrm{l/g}$$

où I_0 est l'activité initiale, I est l'activité après la formation des complexes, v est le volume de la part aliquote et m est la quantité de résine en grammes.

RÉSULTATS

Pour déterminer les constantes d'instabilité, d'après la méthode de Paramonova, il a fallu calculer tout d'abord le rapport $\gamma_+ = G/G^0 . C^0/C$ (l'adsorption relative). Dans cette formule G représente la quantité de protactinium adsorbée sur cationite, en présence du complexant; G^0 est la quantité de protactinium adsorbée sur cationite mais en absence du complexant. La fraction C^0/C en ce cas joue le rôle du facteur de correction où C représente la concentration totale du protactinium en solution (%) en présence du complexant et C^0 est la concentration totale du protactinium (%) dans la solution, en absence du complexant (Tableaux I à III).

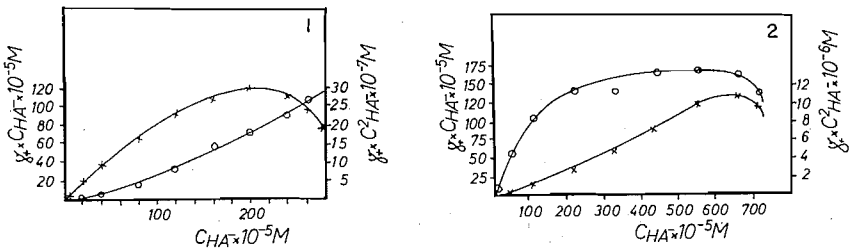

FIG. 1. Formation des complexes du protactinium avec l'acide malique. ×, Pa:HMal$^-$ = 1:1; ○, Pa:HMal$^-$ = 1:2.
FIG. 2. Formation des complexes du protactinium avec l'acide tartrique. ○, Pa:HTart$^-$ = 1:1; ×, Pa:HTart$^-$ = 1:2.

En utilisant le système de coordonées $\gamma_+ . C_{HA^-}$ vs. C_{HA^-} (où C_{HA^-} représente la concentration du coordinat moles/l), nous avons obtenu des courbes (Figs. 1 à 6) qui nous montrent le domaine d'existence du premier complexe, en fonction de la concentration du coordinat. La présence des maximums sur ces courbes indiquent, qualitativement, la formation des complexes du protactinium qui ont le rapport Pa:HA$^-$ = 1:1. A l'aide du système de coordonées log $\gamma_+/1 - \gamma_+$ vs. log C_{HA^-} nous avons aussi déterminé quantitativement le rapport Pa:HA$^-$ pour tous les complexes du protactinium avec les acides mentionnés plus haut. Par exemple pour les acides malique, tartrique et trioxyglutarique de tels graphiques sont montrés dans les Figs. 7 à 9. La pente des droites dans ce système de coordonnées exprime le nombre de molécules du coordinat dans le complexe.

Les constantes d'instabilité ont été calculées en conditions d'équilibre de l'échange ionique, à l'aide des formules adéquates des méthodes de Froneus (7–10) et de Paramonova (11–15) (Tableaux I à III et VI).

Afin de vérifier la présence des complexes avec des charges négatives on a étudié l'adsorption sur l'anionite (Tableau IV). De la même manière on a constaté que le protactinium forme des complexes anioniques avec les acides mentionnés plus haut aussi à concentrations plus petites de l'acide.

Pour déterminer la charge des complexes nous avons employé la méthode de Trofimov et de Stepanova (18) qui permet de calculer la charge moyenne effective (Tableau V). On a observé que la charge des complexes est fonction de la concentration du coordinat et du pH des solutions.

*En ce cas il n'y a pas d'adsorption sur cationite.

DISCUSSIONS

Selon les valeurs du coefficient de distribution ζ (Tableaux I à III) l'adsorption du protactinium sur le cationite de solutions d'acides mentionnés plus haut, est fonction de la concentration du coordinat et du pH. Les courbes des Figs. 1 à 6 montrent que le protactinium avec les acides hydroxy forme des complexes qui ont des rapports $Pa:HA^-$ différents. Par exemple les acides malique et tartrique dans l'intervalle de concentration $10^{-2} - 6.5 \times 10^{-1}$ M forment des complexes ayant le même rapport $Pa:HA^-$ et les constantes d'instabilité respectivement $K_1 = 3.8 \times 10^{-3}$ et $K_1 = 4.6 \times 10^{-3}$ (Tableau I). Par contre les acides trioxyglutarique, oxalique et citrique forment des complexes avec le protactinium qui se comportent de façon différente (Figs. 3 à 5). L'augmentation de la concentration de l'acide trioxyglutarique conduit à la diminution brusque des valeurs du coefficient de distribution sur cationite. Le phénomène est dû à la formation de complexes qui contiennent un nombre différent de molécules d'acide, ayant, comme il a été trouvé, plusieurs charges positives. En même temps la diminution brusque du coefficient de distribution est fortement influencée également par la formation des complexes dimérisés. La dimérisation des complexes du protactinium avec l'acide trioxyglutarique (dans certaines conditions de pH et de concentration du coordinat) est indiquée également par le nombre de molécules du coordinat dans ces complexes et par leur charge moyenne effective (Tableau V et Fig. 9).

Les résultats que nous avons obtenus dans l'étude de la complexation du protactinium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

avec les acides lactique (5), α-hydroxy-iso-butyrique et mandélique (6), montrent que la dimérisation de ces complexes est possible aussi à une concentration constante du protactinium mais en variant le pH et la concentration du coordinat. En ce cas nous pensons qu'une telle dimérisation est due à la formation des liaisons hydrogène intermoléculaires. Analogiquement, pour les acides malique, tartrique, trioxyglutarique et citrique la dimérisation des complexes du protactinium, dans ces conditions de pH et concentration mentionneés plus haut, est due à la formation des liaisons hydrogène intermoléculaires.

TABLEAU VI

Détermination des constantes d'instabilité des complexes du protactinium avec l'EDTA

C_{H_4Y} (mole/l)	$C_{H_3Y^-}$ (mole/l)	pH	ζ (l/g×10³) Sur cationite	Sur anionite	K_1	K_2
8×10^{-5}	8×10^{-7}	2.4	25.3	48.2		
8×10^{-4}	8×10^{-6}	2.6	5.2	3.2		
4×10^{-3}	4×10^{-5}	2.4	4.8	0	6.5×10^{-9}	1.1×10^{-12}
8×10^{-3}	8×10^{-5}	2.4	4.3	0		
12×10^{-3}	12×10^{-5}	2.4	1.3	0		
25×10^{-3}	25×10^{-5}	2.7	1.4	0		

La variation du pH et de la concentration du coordinat conduit également à une variation des valeurs de la charge moyenne effective (Tableau V). L'augmentation du pH renforce le processus d'hydrolyse du protactinium (19, 20) qui favorise la formation des liaisons hydrogène entre les groupes OH du protactinium hydrolysé et le coordinat.

En ce qui concerne la complexation du protactinium avec l'acide oxalique, d'après l'allure de la courbe (Fig. 4) et les valeurs des constantes d'instabilité des oxalates (Tableau II), on a observé une ressemblance avec celles de l'acide trioxyglutarique. Cela conduit à penser que l'acide oxalique se comporte comme un acide hydroxy.

L'augmentation de la concentration des acides citrique, aconitique et éthylènediaminetétracétique conduit à la diminution brusque des valeurs du coefficient de distribution (Tableaux III, IV et VI). Le pH a aussi une influence semblable.

En déterminant le domaine d'existence des complexes du protactinium avec les acides citrique et aconitique, dans l'intervalle de concentrations de 10^{-4} à 10^{-1} M et de pH = 0.65–0.95 (Figs. 5 et 6) on a trouvé que l'acide citrique forme des complexes ayant le rapport $Pa:H_2Cit^- = 1:1$ et 1:2, tandis que l'acide aconitique forme des complexes avec le rapport

TABLEAU VII

Formes possibles des complexes du protactinium avec quelques acides di-carboxyliques, en solution

Acide	Intervalle de concentrations (mole/l)	Valeurs expérimentales			Formes proposées des complexes	
		n_1	n_2	$\bar{z}$	Milieu fortement acide	Milieu faiblement acide
Malique	$10^{-2}-6.5\times10^{-1}$	—	2	4.5+	$[Pa_2O(OH)_{1.5}(HMal)_2]^{4.5+}$	$[Pa_2(OH)_{3.5}(HMal)_2]^{4.5+}$
Tartrique	$10^{-2}-6.5\times10^{-1}$	1	2	3.5+	$[Pa_2O(OH)_{3.5}(HTart)]^{3.5+}$	$[Pa_2(OH)_{5.5}(HTart)]^{3.5+}$
				1.5+	$[Pa_2O(OH)_{4.5}(HTart)_2]^{1.5+}$	$[Pa_2(OH)_{6.5}(HTart)_2]^{1.5+}$
Trioxyglutarique	$5\times10^{-4}-7\times10^{-1}$	1	2.5	4+	$[Pa_2O(OH)_3(HTogl)]^{4+}$	$[Pa_2(OH)_5(HTogl)]^{4+}$
Oxalique	$10^{-4}-7\times10^{-1}$	1	2	4+	$[Pa_2O(OH)_3(HOxal)]^{4+}$	$[Pa_2(OH)_5(HOxal)]^{4+}$
					$[Pa_2O(OH)_2(HOxal)_2]^{4+}$	$[Pa_2(OH)_4(HOxal)_2]^{4+}$

$Pa:H_2Acon^-$ = 1:0.5. L'augmentation de la concentration du coordinat dans les limites ci-dessus citées, conduit dans le cas des citrates, à une diminution de la charge des complexes de $\bar{z} = 8.5+$ à $\bar{z} = 2+$. Pour l'acide aconitique, dans ces conditions, $\bar{z}$ reste presque constant.

En comparant les constantes d'instabilité des citrates et des aconitates de protactinium, on a observé que l'acide aconitique forme des complexes plus instables que les citrates. La diminution de la stabilité des aconitates par rapport aux citrates de protactinium peut être expliquée par le fait que, dans ce cas il n'y a pas comme avec les acides citrique et oxalique, de formation de cycles penta (qui sont plus stables) par l'intermédiaire des groupes hydroxy de l'acide.

En se basant sur les valeurs des coefficients $\bar{z}$ (la charge moyenne effective) et $\bar{n}$ (le nombre des molécules du coordinat dans le complexe respectif) expérimentalement trouvées, nous sommes arrivés à la conclusion que la forme des complexes du protactinium avec les acides hydroxy mentionnés plus haut, dépend du milieu (fortement ou faiblement acide). Les formes les plus adéquates des quelques complexes sont montrées dans le Tableau VII.

Le comportement de l'acide éthylènediaminetétracétique (EDTA) (sel disodique), lors de la formation de complexes, est complètement différent de celui des acides mono-, di- et tri-carboxyliques, que nous avons étudiés. La diminution rapide des valeurs du coefficient de distribution en fonction de la concentration du coordinat nous indique la grande tendance de cet acide à former avec le protactinium des complexes ayant des charges négatives. Par exemple à la concentration très faible du coordinat de 8×10^{-7} M et à pH = 2.4, la formation de complexes est encore appréciable. Dans ces conditions, on trouve environ 50% de l'activité totale du protactinium en solution sur l'anionite et seulement 20% sur le cationite. Ce résultat montre que le protactinium, en dehors des complexes ayant des charges négatives et positives, forme aussi des complexes neutres.

Le rapport $Pa:H_3Y^-$ déterminé à l'aide des graphiques et à la concentration en coordinat de 8×10^{-7} M (pH = 2.4–2.7) a pour valeur 1:1. L'augmentation de la concentration du coordinat conduit aussi à la formation de complexes de type $Pa:H_3Y^-$ = 1:2 et $Pa:H_2Y^{2-}$ = 1:1.

En réalité, le processus de la formation des complexes chelatés du protactinium avec l'EDTA est plus compliqué qu'il n'a été décrit dans cette communication.

THE SYSTEM: ALUMINIUM–INDIUM–SILVER

PART I. THE BINARY AND TERNARY MISCIBILITY GAPS

A. N. CAMPBELL AND R. WAGEMANN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received November 4, 1965

ABSTRACT

The miscibility gap in the binary system: Al–In has been investigated and the critical temperature and composition estimated as 945 °C and 68.8% In, 31.2% Al (by weight).

The liquid–liquid partial miscibility region of the ternary system has also been determined. The lowest temperature at which two liquids can exist in equilibrium before a third (solid) phase appears was found to be approximately 590°. At this temperature, the ternary gap extends to 30.5% Ag, 34.7% Al, and 34.8 In. Isotherms of the ternary gap are given for 50° intervals between 650° and 900°. A true ternary critical point does not exist, i.e. the binary critical temperature is lowered continuously by addition of silver.

INTRODUCTION

In the course of a lengthy investigation of the complicated system named in the title, we have become convinced that the accepted equilibrium diagram for the component binary system: silver–indium, is seriously in error and, indeed, a preliminary experimental investigation has shown that this is so. Since this will delay the completion of the work for some time, we thought it advisable at this stage to give a report on the interesting two-liquid relations.

Valentiner and Puzicha (1) stated that the two metals, indium and aluminium, are largely immiscible in both solid and liquid states. These authors, as well as Raub and Engel (2) give rather inaccurate limits for the liquid gap at the monotectic temperature, which they report as 634°. The latest, most extensive, work is that of Campbell, Buchanan, Kuzmak, and Tuxworth (3), who used a quenching technique and investigated the course of the indium-rich curve between the monotectic and eutectic temperatures. They reported the limits of the gap as 17.5 and 97.2 wt. % indium, at 638.6°: the eutectic contained less than 0.05% aluminium. Campbell and co-workers determined the compositions of conjugate layers up to 800°. In the present work, by raising the temperature to 950°, we have succeeded in closing the gap, and we have deduced the binary critical temperature and composition with reasonable certainty. The addition of silver to the binary system: In–Al increases the mutal solubility and we have completed the determination of the two-liquid surface.

EXPERIMENTAL

Purity of Metals

Silver (Johnson, Matthey) 99.995% Ag.

Indium (Consolidated Mining and Smelting Company of Canada) 99.99% In.

Aluminium (Department of Mines and Technical Surveys, Mines Branch, Ottawa) 99.994% Al, 0.0019% Fe, 0.0018% Si, 0.0018% Cu.

Miscibility Gap (in Binary and Ternary System)

Previous work by Campbell, Buchanan, Kuzmak, and Tuxworth (3) had indicated that the miscibility gap in the system: Al–In might close somewhere between 800° and 900°. In the present investigation the two liquid layers were brought to equilibrium in a furnace at constant temperature and the liquid layers were sampled directly. An investigation of analytical methods, including the flame spectrometer, led us to the conclusion that no really accurate method exists for the chemical determination of indium in the presence of aluminium. The method of analysis adopted was therefore to analyze directly for silver by the Volhard method and, for ternary alloys, determine the composition from density measurements. From calibration graphs of experimentally observed density versus aluminium–indium content for various fixed silver contents, the aluminium–indium ratio could be established as soon as the silver content was known. The relatively large differences in density of the three metals made this method fairly accurate.

A chromel–alumel thermocouple was calibrated in the usual way from the freezing points of pure metals. A Brown recorder permitted an accuracy of reading of 1°; including other sources of error, we estimate the final error of our temperatures to be ±2°. The molten alloys were kept in an argon atmosphere in the Vycor cell shown in Fig. 1.

The cell was evacuated after loading, filled with argon, and connected to a mercury valve to allow for expansion after heating. For isothermal work, a separate chromel–alumel thermocouple, placed in the furnace immediately above the crucible (Fig. 1) was connected to a Wheelco thermostatic control. The furnace temperature was constant to ±1°.

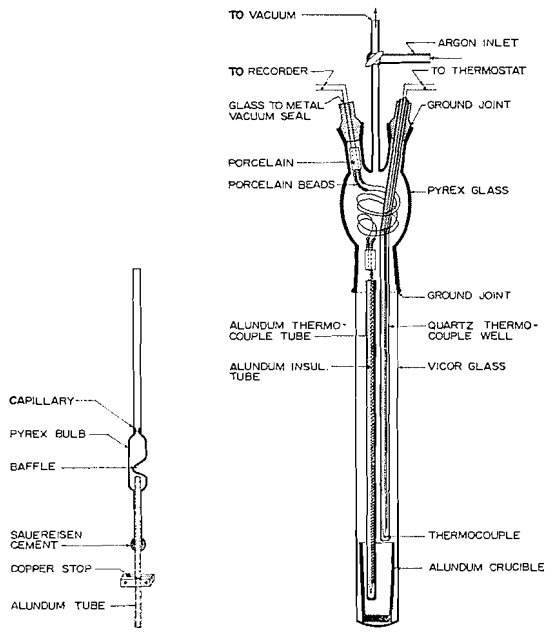

FIG. 1. The alloy pipette and the isothermal and thermal analysis cell.

Preparation of Alloys

Alundum crucibles of 25 ml capacity were used for melting the alloys. For thermal analysis alloys of different composition were obtained from an original alloy by adding increments of one component along a line of constant ratio of concentration of the other two components. Alloys were given a preliminary melting in an induction furnace at 1 000°. In the isothermal work the alloys were equilibrated at the desired temperature, for 14 h. Samples of alloys were withdrawn from the top and bottom layers with the pipette shown in Fig. 1. The depth to which the pipette was lowered was controlled by the copper stop. Immediately after a sample was withdrawn, the pipette was removed from the cell and immersed in cold water, the whole operation requiring less than 30 s. The cracked glass was then removed and the whole sample cut into small pieces for density determination and chemical analysis.

Density Determination

Densities were determined in a 25 ml Weld pycnometer, using redistilled *n*-butyl ether as the inert liquid: some of the alloys react with water. Sixty determinations of density were made in duplicate, for calibration purposes. The results are expressed graphically in Fig. 2. The temperature of all determinations was 25.00 ± 0.02°. We estimate our results to be accurate to 0.002 g/cc corresponding to an error in composition of about ±0.8% In for low concentrations of indium or ±0.02% In for high concentrations of indium. Each curve of Fig. 2 represents a 10% increase in indium content, while the abscissa represents the percentage of silver. It will be observed that the curves have steep slopes indicating that density is very sensitive to composition. To use this set of curves for the analysis of a ternary alloy, determination of the silver content and of the density provides sufficient data (with suitable interpolation) for the determination of indium.

RESULTS

Some 60 isothermal experiments were carried out and the data are available in the thesis of the junior author (R. Wagemann, ref. 4). Figure 3 gives the limits of the ternary isothermal liquid gap at 650°, 700°, 750°, 800°, and 900°.

For personal use only.

The 650° isotherm is separately reproduced in Fig. 4 in order that the slopes of tie lines joining congruent solutions may be evident. The binary liquid gap of the system: aluminium–indium is reproduced in Fig. 5.

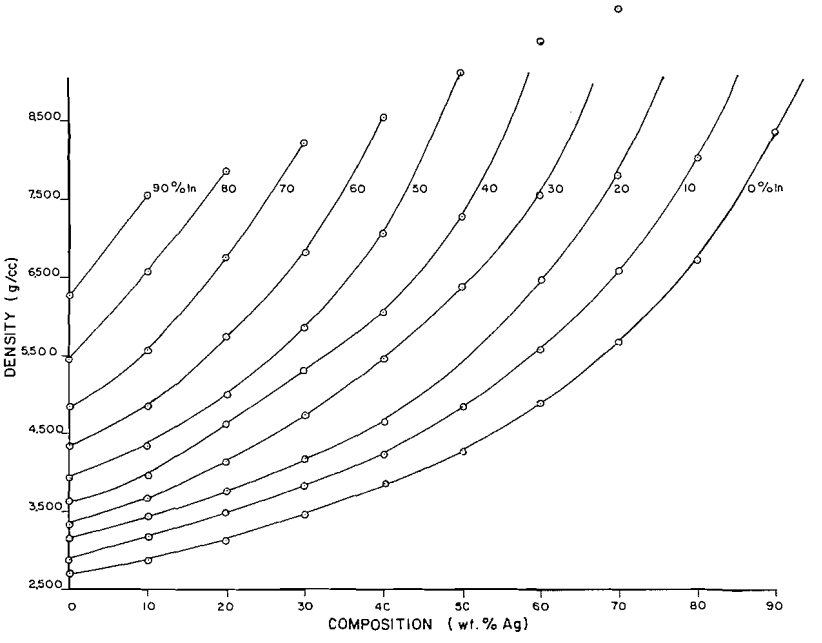

FIG. 2. Density vs. composition for the binary system: Ag–In.

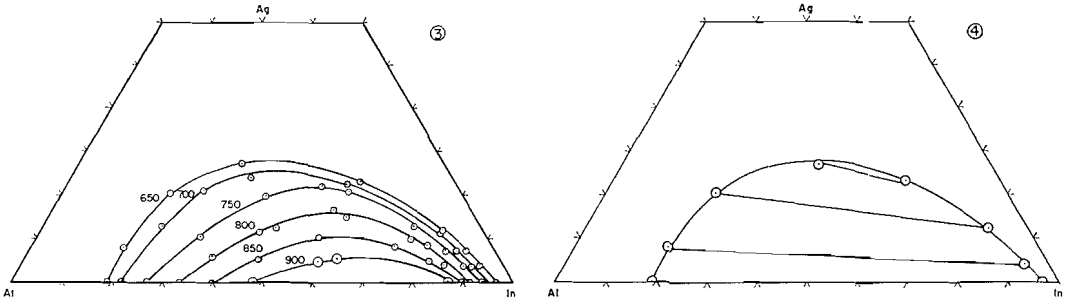

FIG. 3. Isotherms through liquid–liquid immiscibility space at 650, 700, 750, 800, 850, and 900 °C.
FIG. 4. The isotherm at 650 °C for the system: Al–In–Ag showing direction of the tie lines.

The Binary Miscibility Gap

For the binary system: indium–aluminium, an approximate critical temperature of 945° was obtained by the extrapolation of our experimental measurements, which extended to 900° (Fig. 5). The law of the rectilinear diameter is followed rather closely and the extrapolation of this straight line to the critical temperature gave the critical composition as 68.8% In. An alloy of composition 70% In was found to be completely homogeneous at 950°, in the sense that the density was the same throughout.

The Ternary Miscibility Gap

Isotherms through the ternary liquid–liquid space (ternary gap) at 650°, 700°, 750°, 800°, 850°, and 900° are shown in polytherma projection in Fig. 3. A true ternary critical

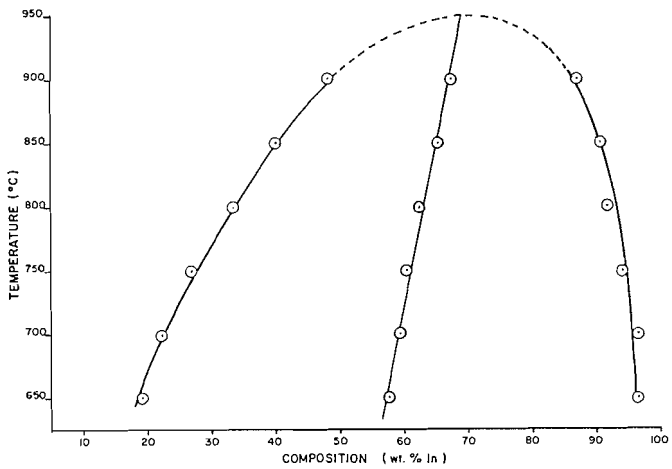

FIG. 5. Liquid–liquid immiscibility in the binary system: Al–In.

temperature does not exist in this system; in other words, the addition of silver to the binary critical mixture of the system: Al–In progressively lowers the temperature of complete miscibility. The lowest temperature at which two liquid layers can coexist, in absence of solid phase, is 590°. The critical composition at 650° is approximately 26 wt. % Ag, 47% In, 27% Al. At 590°, the content of silver has risen to 30%. Attempts by thermal analysis to detect the boundaries of the three-phase region ($L_1 + L_2 + S$), which lies below the ternary miscibility gap, failed, no doubt on account of the smallness of the heat effect.

ACKNOWLEDGMENT

We are indebted to the Consolidated Mining and Smelting Company of Canada, in this as in all our other investigations of indium alloys, for the presentation of a constant supply of pure indium.

Received September 21, 1965

ABSTRACT

The rate coefficients for the acid-catalyzed esterification in methanol at 35.0° of fourteen 3-substituted acrylic acids have been determined. Rate coefficients have also been determined for the alkaline hydrolysis in 70% v/v dioxan–water at 18.8° of 13 methyl esters and the carbonyl-stretching frequencies of the esters have been examined. The effect of *trans*-substitution is assessed by use of the Hammett equation. In the alkaline hydrolysis, the transmission of polar effects is approximately 1.9 that of the meta- and para-substituted benzoates. An analysis of the steric effects in the *cis*-isomers in both reactions shows that the steric effects of the halogeno-substituents in the two reactions differ and an explanation is offered. The application of the Taft–Ingold equation to ortho-substituted benzoates is criticized. The carbonyl-stretching frequencies of the *cis*-halogeno-esters exhibit a shift of $+8$ cm^{-1} compared with the *trans*-isomers; this shift is attributed to an electrostatic effect.

INTRODUCTION

Previous studies, in this series, have been made on the reactivity of 3-substituted acrylic acids (1). The results indicated that there was a similar polar effect from the *cis*- or *trans*-position and that the transmission was about twice that for a similarly substituted *p*-benzoic acid. It was felt that this information equipped us to test thoroughly the Taft separation of polar and steric effects in ester hydrolysis (2), using the 3-substituted acrylic system. Taft's separation of these effects in arylaliphatic and aliphatic systems has received support (3, 4), whereas the related treatment of the ortho-benzoic systems has recently been criticized (5). The latter workers suggest that the separation does not give a true estimate of the polar effect of the ortho-substituent and that the steric effects in alkaline and acidic hydrolysis and esterification are not the same.

In this study, the reactivity of both *cis*- and *trans*-3-substituted acrylic esters and acids have been measured in their alkaline hydrolysis and acid-catalyzed esterification reaction. These results, together with the carbonyl-stretching frequencies of the esters, are reported here.

EXPERIMENTAL

Materials

Methyl acrylate was obtained commercially and was redistilled immediately before use. The preparation and purity of the acids have been described previously (1). The preparation of the other esters was made more difficult because the olefinic bond in a number of the halogeno-substituted acrylic acids is reactive towards diazomethane, which is usually the best methylating agent (cf. ref. 6). Therefore, the methyl esters were prepared by esterification of the acids by methanolic hydrogen chloride. The less stable *cis*-esters could be isomerized by prolonged heating in acid solution. Because of this, these esters were prepared by treatment of the corresponding acids with dry methanolic hydrogen chloride for from 3 to 6 h at 50°. After isolation, the methyl esters were distilled under reduced pressure. Details of the physical properties and, where relevant, the elemental analyses are given in Table I. No evidence of isomer or other impurities was found by gas–liquid chromatography, by nuclear magnetic resonance spectroscopy, or from their saponification equivalents.

Methanol was purified by Lund and Bjerrum's method (9) and had b.p. 64° at 754 mm, d_4^{20} 0.7922 (lit. (10) 64.5°, 0.7914). The water content was found to be less than 0.08% w/w by Karl Fischer titration.

Dioxan was purified by the method of Cavell, Chapman, and Johnson (11) and had b.p 101.5° at 754 mm (lit. (10) 101.3° at 760 mm). Anhydrous toluene-*p*-sulfonic acid (microanalytical reagent grade, Hopkins and Williams Limited) was dried in a vacuum desiccator and had m.p. 105–106° (lit. (10) 106–107°).

Measurements

Acid-Catalyzed Esterification

The method used was similar to that of Smith and Reichardt (12). The acid catalyst used in these studies was, however, toluene-*p*-sulfonic acid. The Goldschmidt eq. [i] (see ref. 12)

$$[i] \qquad k = \frac{(a + r)\ \ln\ [a/(a - x)] - x}{rt[\text{catalyst}]}$$

was used to calculate the rate coefficient k (l mole^{-1} min^{-1}), where a is the initial concentration of the carboxylic acid (approximately 0.05 M) and $(a - x)$ is the concentration at time t. The catalyst concentration was approximately 0.05 or 0.1 M. The constant r was found to be 0.28 at 35.0° which is in agreement with the interpolated value (i.e. 0.28) from earlier work (12). The reaction times were short and no isomerization was detected for less stable *cis*-isomers. There was no trend to faster rates with time, and nuclear magnetic resonance measurements on test samples indicated no detectable (i.e. less than 1%) conversion.

Alkaline Ester Hydrolysis

Rate coefficients were measured as described previously (3). Equal concentrations of ester and alkali (approximately 0.025 or 0.05 M) were used and the reaction studied by the "H" bulb method. The choice of solvent as 70% v/v dioxan–water was dictated by the lack of solubility of the least soluble ester in highly aqueous solution and the occurrence of nucleophilic substitution of the halogen in alkaline methanol–water. The latter reaction appeared to be due to methoxide ion completely. This ion is in equilibrium with the hydroxide ion in these solutions (3, 5). Saponification equivalents indicated no significant (i.e. $< 1\%$) substitution at 18.8° in aqueous dioxan. The solutions were prepared in a manner similar to that previously described (3, 5). The rate coefficient k (l mole^{-1} min^{-1}) was calculated from the second-order expression [ii] when the reactants are present in equal initial concentrations,

$$[ii] \qquad k = x/at(a - x),$$

where a is the initial concentration of the reactants and $(a - x)$ is their concentration at time t.

Since there were no available data for the hydrolysis of methyl benzoates in this medium, rate coefficients were also measured for a series of these esters.

Infrared Spectra

The carbonyl-stretching vibrations of the methyl esters were examined with a Perkin–Elmer Model 221 infrared recording spectrophotometer equipped with sodium chloride prism and cells. The bands were scanned

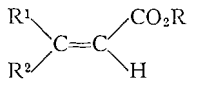
For personal use only.



at 6 cm^{-1} min^{-1} (1 μ in 50 cm of the chart) and a 1 mm cell was used. The solutions were approximately 0.02 *M* in carbon tetrachloride (Hopkin and Williams, Ltd., "Spectrosol" grade) solution. The calibration was checked with a solution of acetone in carbon tetrachloride (band at 1 719 cm^{-1}) and at least two independent measurements were made on each ester. The values of ν_{max} (wave number at the absorption maximum) were measured.

RESULTS AND DISCUSSION

The results are summarized in Tables II and III.

The Effect of Substitution on the Alkaline Hydrolysis Reaction

The effect of the substituents is shown in Table II. The effect of the *trans*-substituents is linearly related to their effect on the ionization reaction (1), as shown in Fig. 1. However, the unsubstituted ester deviates and has an apparently enhanced rate (this is discussed later). It is omitted from the following correlations. Like the ionization reaction, the effect of the *trans*-substituents on the alkaline hydrolysis is well correlated by the Hammett eq. [iii],

[iii] $$\log (k/k_0) = \rho\sigma,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

using either para-σ-values (see ref. 1) or σ^n-values (17). The correlations are shown in Table IV, together with the related benzoate series. The value found for the alkaline ester hydrolysis of the *trans*-isomers, 3.739 or 4.431, is about twice the value, 2.048 or 2.331, found for meta- and para-substituted methyl benzoates under the same conditions. Thus, the reaction constant ratio ϕ is 1.87, in 70% dioxan–water, which agrees well with the ratio of 1.71 and 2.19 found for two other carboxylic acid reactions, in ethanol and water respectively, in our previous studies (1). The dielectric constants of the media are 20.0, 24.3, and 78.5 respectively.

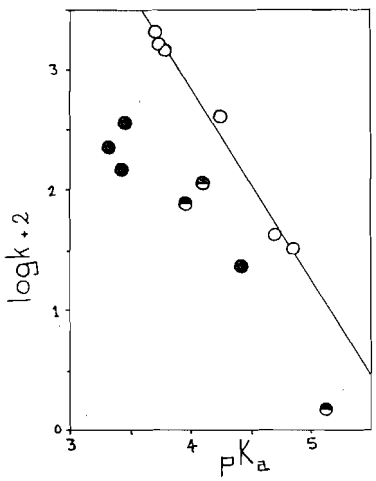

FIG. 1. Relation between the rates of alkaline hydrolysis of the esters and the aqueous pK_a values of the acids (○, *trans*; ●, *cis*; ◓, di-3-substituted).

The reactivity of the *cis*-isomers obviously shows the rate retardation due to a steric influence from the proximate substituents (see Fig. 1). In our previous studies, we found the normal polar effect was almost the same from the *cis*- and *trans*-position. A very reasonable assumption is that this is also true for these ester reactions. The rate decrease of the *cis*- compared with the *trans*-isomers will then be a measure of the "steric" effect of the proximate *cis*-substituent. These values of log (k_c/k_t) are shown in Table V.

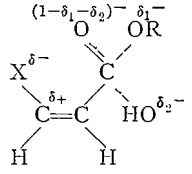
The Effect of Substitution on the Acid-Catalyzed Esterification

The effect of substituents is shown in Table II. These bear a relationship to the ionization of the acids which is similar to that previously seen for the alkaline reaction. An important exception is the marked deviation of the unsubstituted acid, which is excluded from the correlation. This is discussed later. The Hammett reaction constant ρ, for the *trans*-substituents, is −0.360 or −0.437 (see Table IV). The correlation is rather poor. The reaction constant for the *same* para-substituted benzoic acids is −0.226 or −0.291 and the correlation is also poor.[3] The increased transmission of polar effects from the *trans*-position compared with the *para*-substituted benzoic acid is shown and ϕ is given as 1.55. Nevertheless, we can make the same assumption of the equality of the polar effect from the *cis*- and *trans*-position as was made for the alkaline hydrolysis. The "steric" effect of the *cis*-substituent can then be measured by log (k_c/k_t) and these values are shown in Table IV. Our implicit assumption here, as before, that the *trans*-isomers have a negligible steric effect seems very reasonable in view of the occurrence of the polar linear free energy relations and the substituent's "distant" position. The apparently greatly enhanced rate of the unsubstituted acid, however, is difficult to explain.

A consideration of the disubstituted compounds' reactivity confirms our previous indications. Thus, the decreased rate of the 3,3-dimethylacrylic acid in the esterification reaction is only sufficient (log (k_{Me_2}/k_{t-Me}) = −0.69) to account for a very small, favorable polar contribution overcome by a steric effect greater than that present in the *cis*-methyl isomer (log (k_{c-Me}/k_{t-Me}) = −0.37). This increase in steric effect would arise from the increase in internal interactions caused on forming the transition state (3, 21). This rate is impossible to account for by the rate relative to the unsubstituted compound, e.g. log (k_{t-Me}/k_H) = −0.34, log (k_{c-Me}/k_H) = −0.71, and log (k_{Me_2}/k_H) = −1.04, because steric effects are *not* additive, buttressing causing increasing steric effect with increasing substitution (2, 3, 21). The pattern of reactivity of the chloro-crotonic acids verify this. The relative rate (log ($k_{c-Me,t-Cl}/k_{c-Cl,t-Me}$) = −0.30) is identified with the difference in steric effect of the *cis*-substituents (see Table V). The rate coefficient for the unsubstituted acid appears to be enhanced by a factor of $\Delta \log k$ equal to approximately 0.40. An analysis of the rates of the disubstituted esters in the alkaline hydrolysis reaction also indicates that the enhancement of the rate of the unsubstituted ester is a real effect. In this $\Delta \log k$ equals approximately 0.30.

The cause of this effect appears to be obscure. Since it occurs only on the substitution of



[3]*These esterification studies (18) have been correlated by Jaffé using all substituents (19) (ρ = −0.229, r = 0.457, and n = 16) and by Wepster and co-workers (17) using only selected substituents with negligible resonance interactions (ρ = −0.521, r = 0.979, and n = 8). A consideration of the pattern of reactivities of the para-substituents seems to indicate a substituent polar effect* without *its resonance contribution.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the first substituent, a displacement resulting from a resonance effect, such as hyperconjugation (4), appears unlikely and it also appears unlikely to be a ponderal effect (20). However, it was not observed in our earlier study (1) on these systems.

Steric Effects

It is immediately obvious from a consideration of Table V that the "steric" effect of the dipolar halogeno-substituents is very much greater in the alkaline ester hydrolysis than in the acid-catalyzed esterification, whereas it is quite comparable for the alkyl group. The steric effect of the proximate substituents in ester reactions is normally ascribed to the "bulk" effect of the substituent causing crowding in the tetrahedral transition state. These interactions have been used very satisfactorily to account for the steric effects in aliphatic systems (21). The steric effects observed in the acid-catalyzed esterification reaction and, for alkyl substituents, in the alkaline ester hydrolysis appear to be of this kind. The steric factors in Table V, column 1, are more absolute measures of the steric effect than the E_s values of Taft (2) (see below). Their order of size is very reasonable (see ref. 2). The extra-"steric" effect observed in the alkaline hydrolysis has been qualitatively discussed as a steric effect on polar-facilitated solvation (5). Although this is a possibility, a simpler explanation can be offered. It is suggested that this effect is due to an electrostatic repulsion between the negative charge (δ^-) on the halogeno-substituent and the negative charge on the reaction site, as below (I). This effect is similar to one recently postulated to explain certain proximity interactions in nucleophilic substitution reactions (S_N2) (22, 23). The present results clearly demonstrate that steric effects for the *cis*-halogeno-substituents are very different from those in the acid-catalyzed reaction.

I

The Taft Separation of Polar and Steric Effects

Taft (2, 24) proposed the following Taft–Ingold eq. [iv] to separate the polar and steric effects in the hydrolysis of esters,

$$[\text{iv}] \qquad (\rho_B - \rho_A)\sigma^* = \log (k/k_0)_B - \log (k/k_0)_A,$$

where σ^* is the polar substituent constant and the subscripts B, A, and 0 refer to the acidic and basic hydrolysis and the unsubstituted compound respectively. The steric substituent constant E_s is defined by eq. [v].

$$[\text{v}] \qquad \log (k/k_0)_A = E_s$$

Ideally the acid and alkaline ester reactions should be otherwise identical, i.e. same alkyl ester, solvent, and temperature. Suitable data is very limited and difficult to obtain. Taft had previously found linear correlations between ester reactions of the same type (25), the slope being always close to unity, and was able to calculate averaged values. An important modification was to employ the acid-catalyzed esterification reaction to replace or reinforce the less available or accessible acid-catalyzed ester hydrolysis data. This appears a reasonable approximation since the reactant and transition states correspond. The reference ester, in the aromatic series, was usually the ortho-methyl benzoate; but alternatively the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ortho-fluoro or unsubstituted benzoate was used (2, 24). The assumptions are that there are independent contributions from polar, resonance, and steric effects; steric and resonance effects are the same in corresponding acidic and alkaline reactions, and the polar effects are much greater in the alkaline than in the acidic reaction. Taft assumed that $\rho_B - \rho_A$ equalled 2.48. Implicit in this separation is the identity of the steric effects in the alkaline and acid ester reactions. The increased interactions inhibiting the formation of the tetrahedral transition state will only be the same if the transition states for the acidic and alkaline ester reactions can be equated. This in fact appears to be a reasonable assumption (2, 3, and 5).

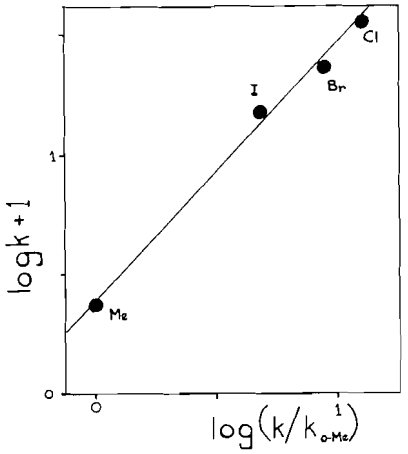


FIG. 2. Relation between the rates of alkaline hydrolysis of the *cis*-esters and Taft's averaged values of log (k/k_{o-Me}) for the alkaline hydrolysis of ortho-substituted benzoates (25).

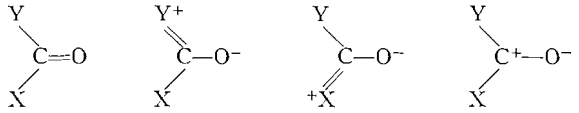
We may now consider the evidence of our model system. The relative rates of the alkaline hydrolysis of the *cis*-isomers are linearly related (slope almost unity) to the corresponding rates of alkaline hydrolysis of methyl ortho-substituted benzoates (25) (see Fig. 2). Likewise the acid-catalyzed esterification rates of reaction are similarly related to the data available for the corresponding ortho-substituted benzoic acids (18). The unsubstituted compound must be excluded. This has been previously discussed. This is an extension of the relation found by Taft (25). It is thus extremely likely that our previous considerations of the steric effects of *cis*-substituents are directly applicable to ortho-substituted benzoates. The conclusions which have previously been reached for the former system are applicable to the latter system.

Thus, the Taft separation of the polar and steric effects involved in the reactions of ortho-substituted benzoates fails on the following counts: (1) the "steric" effects in the acid and alkaline reactions are quite different for a number of strongly dipolar substituents;[4] (2) the factor of $\rho_B - \rho_A$ cannot, in any case, be simply obtained from studies on the meta- and para-substituted benzoic system. The more efficient transmission from the ortho-position would probably require a factor of about 4.10 for the reactions used in this study.

The latter comment derives from our previous studies (1) in identifying the transmission of polar effects from the ortho-benzoic with the *cis*- and thus the *trans*-acrylic system. The

[4]*The ortho-fluoro-substituent (log $(k/k_0) = 0.70$), in alkaline hydrolysis of ethyl benzoates (see ref. 26), appears to have a polar effect alone and have no steric effect. It is presumably due to its small size that it exerts neither of the "steric" effects observed for the other halogens.*



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

transmission from the ortho-position for alkaline hydrolysis would then be 1.9 times that from the para-position. Indirect reasoning by earlier workers (5) gave rise to a similar conclusion, i.e. polar effect of ortho-halogeno-substituents being about three times that of a similar para-substituent.

This criticism is not meant to apply to the separation of polar and steric effects in the aliphatic and arylaliphatic system (2–4). However, it seems possible that the alkyl esters with strongly dipolar substituents may exhibit the extra-"steric" effect found in this study for basic hydrolysis, e.g. see ref. 27.

The Carbonyl-Stretching Vibration

Thompson and co-workers (28) have represented the carbonyl-stretching vibration as being primarily determined by the relative contributions of the canonical structures II–V. As the frequency of the vibration indicates the energy needed to produce a dipolar state, a

II III IV V

reduction in the contribution of structures III, IV, and V will increase the frequency. The smaller steric requirement of the carbonyl oxygen compared to the methoxyl group will cause the proximity of the *cis*-substituent to the carbonyl oxygen when the molecule is coplanar. The direct "bulk" steric effect of these *cis*-substituents appears to be quite small in these esters.

The results in Table II indicate that the strongly dipolar halogeno-substituents result in an increase in the carbonyl-stretching frequency of approximately 8 cm^{-1} when the substituent is *cis*- rather than *trans*-orientated. The methyl substituent has a small effect in the *opposite* direction of 2 cm^{-1}. The effect in the *cis*-halogeno-esters appears to be the same as that previously suggested for related systems (29, 30). The effect of the proximate charge interaction will be to decrease the contribution of the canonical structure V and increase the frequency. This will be especially effective in the solvent used, carbon tetrachloride, which has a low dielectric constant. This effect in a physical property appears to be related to that postulated in the alkaline ester reaction.

HOMOGENEOUS CATALYSIS OF D_2–H_2O EXCHANGE BY RUTHENIUM(III) CHLORIDE: EVIDENCE FOR THE HETEROLYTIC SPLITTING OF HYDROGEN[1]

JACK HALPERN

Received October 29, 1965

ABSTRACT

The prediction, based on earlier studies of the ruthenium(III) chloride catalyzed oxidation of H_2 by iron(III), that in the absence of iron(III) or other oxidants ruthenium(III) chloride should catalyze homogeneously the isotopic exchange between D_2 and H_2O has been confirmed. A kinetic study was made of this exchange reaction in which the dependence of the exchange rate and of the exchange product distribution (HD:H_2 ratio) on the concentrations of ruthenium(III), hydrogen ion, and chloride ion were determined. The results, and in particular the observation that the HD:H_2 ratio of the exchange product increases with the concentrations of H^+ and Cl^-, support the view that the ruthenium(III)-catalyzed oxidation of D_2 by iron(III) and the D_2–H_2O exchange reaction proceed through related mechanisms involving a common rate-determining step in which D_2 is split heterolytically and a deuteridoruthenium(III) complex is formed.

INTRODUCTION

The ruthenium(III) chloride catalyzed oxidation of H_2 by Fe^{III} and Ru^{IV} in aqueous solution, reported by Harrod, Ciccone, and Halpern (1), was interpreted in terms of the mechanism

$$[1] \qquad Ru^{III} + H_2 \overset{k_1}{\rightarrow} Ru^{III}H^- + H^+$$

$$[2] \qquad Ru^{III}H^- + 2Fe^{III} \rightarrow Ru^{III} + 2Fe^{II} + H^+$$

in which the first step, involving the heterolytic splitting of H_2, is rate-determining. In line with this, the kinetics of the oxidation of H_2 were found to be $-d[H_2]/dt = k_1[H_2][Ru^{III}]$. Under the conditions of these measurements (80°, ~1 atm H_2, 3–6 *M* HCl) it was found that there was no appreciable uptake of H_2 by a solution of ruthenium(III) chloride (i.e., no reduction of Ru^{III}) in the absence of an oxidizing agent such as Fe^{III}, which implies that under these conditions reaction [1] must be proceeding reversibly. This should be reflected in isotopic exchange (i.e., formation of HD and (or) H_2) if D_2 is used in place of H_2, a result which has been confirmed by Schindewolf (2). In this paper we describe a more detailed study of this exchange reaction, with particular emphasis on measurement of the HD:H_2 ratio of the exchange product, the results of which provide additional support for the proposed heterolytic splitting mechanism.

EXPERIMENTAL

The preparation and characterization of the aqueous solutions of ruthenium(III) chloride have been described previously (1).

The D_2–H_2O exchange was measured as follows. A bulb of approximately 15 ml volume containing 1–3 ml of an aqueous solution of ruthenium(III) chloride, and immersed in a 80.0° oil bath, was filled to atmospheric pressure with D_2 (obtained from Stuart Oxygen Co.). The bulb was shaken for a given time, and the gas was then sampled and its isotopic composition determined mass spectrometrically using a Consolidated 21-611 mass spectrometer. The H^+ and Cl^- concentrations of the solution were adjusted with HCl and LiCl.

RESULTS

Kinetic plots depicting the ruthenium(III) chloride catalyzed D_2–H_2O exchange are shown in Fig. 1. The rate plots for the formation of both HD and H_2 are seen to be approximately linear over a range corresponding to exchange of some 30% of the D_2 initially present. The overall exchange rate of D_2 in this experiment, $-d[D_2]/dt = d[HD]/dt + d[H_2]/dt = 9.5 \times 10^{-6}$ mole/l s, was about 25% lower than the corresponding rate of oxidation of D_2 by Fe^{III} (1.3×10^{-5} mole/l s) under the same conditions.[2] As will be shown below, this discrepancy is attributable to neglect of multiple exchange processes in computing the exchange rate.

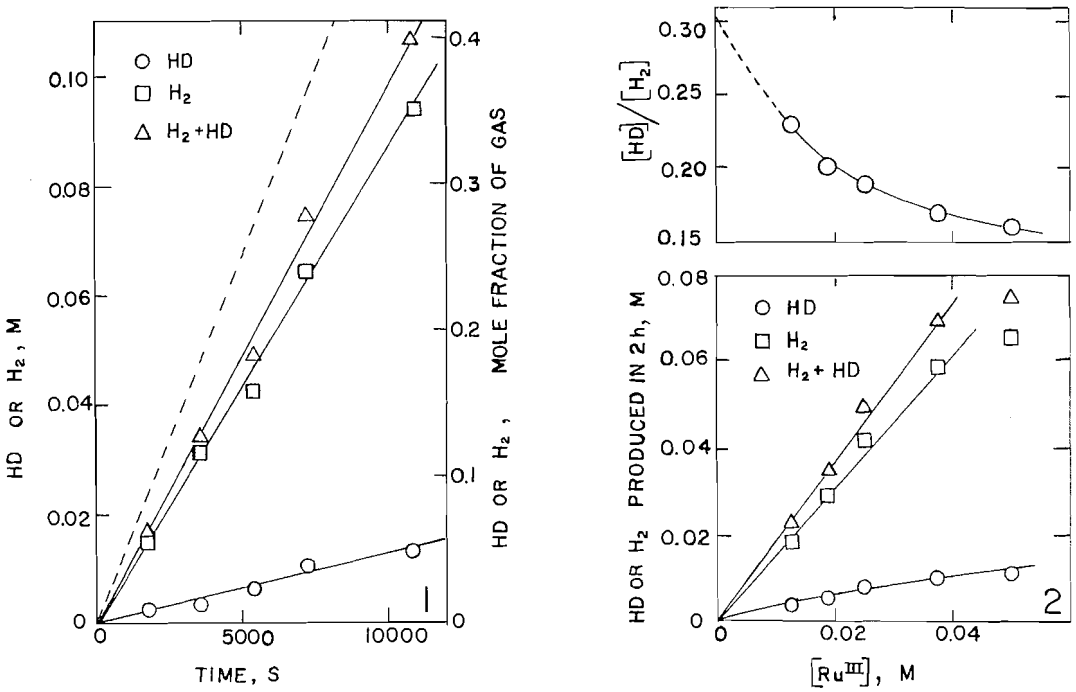

FIG. 1. Rate plots for the exchange of 13 ml D_2 gas (450 mm) with 1 ml H_2O containing 0.05 *M* Ru^{III} and 3.0 *M* HCl at 80°. The broken line corresponds to the rate of oxidation of D_2 by Fe^{III} under the same conditions.

FIG. 2. Dependence of the rate of exchange and the exchange product distribution on the Ru^{III} concentration (13 ml D_2 gas (450 mm) exchanged with 1 ml Ru^{III} solution containing 3 *M* HCl at 80°).

In subsequent experiments the total extent of exchange at the end of a given reaction period (generally 1 h) was used as a measure of the exchange rate. In no case did the extent of exchange (i.e., HD + H_2 produced) during this period exceed 30% of the initial D_2. In view of the linearity of the rate plots over this range (Fig. 1) this method of estimating the exchange rate appears justified.

The dependence of the exchange rate (measured in 3 *M* HCl) on the Ru^{III} concentration is depicted in Fig. 2. The total exchange rate is seen to be approximately first order in Ru^{III}, while the [HD]/[H_2] ratio of the exchange product increases with decreasing [Ru^{III}]. This presumably reflects the contribution to the H_2 yield from a multiple exchange

[2]*The corresponding rate of oxidation of* H_2 *was found to be* 1.46×10^{-5} *mole/l s. The kinetic isotope effect,* $k_1(H_2)/k_1(D_2)$ *is thus* ~*1.12.*

process whereby a dissolved HD molecule, produced by the primary exchange reaction between D_2 and H_2O, undergoes a second exchange reaction with H_2O to produce H_2 before escaping from the solution into the gas phase. The probability of occurrence of such multiple exchanges should decrease with decreasing exchange rate, i.e., with decreasing $[Ru^{III}]$, which would account for the observed inverse dependence of the $[HD]/[H_2]$ ratio on $[Ru^{III}]$. Extrapolation to $[Ru^{III}] = 0$, where such multiple exchange is negligible, gives $[HD]/[H_2] \simeq 0.3$. This value presumably corresponds to the primary product distribution, so that both HD and H_2 are primary products of the exchange reaction.

When corrected for this multiple exchange contribution the total D_2–H_2O exchange rate in Fig. 1 ($\sim 1.3 \times 10^{-5}$ mole/l s) approaches the corresponding rate of oxidation of D_2 by Fe^{III}.

A series of experiments was made to determine the effects of varying the H^+ and Cl^- concentrations on the exchange rate and product distribution. At each of three constant total Cl^- concentrations (3.0, 5.0, and 7.0 *M*) the H^+ concentration was varied by varying the proportions of HCl and LiCl in the solution. In each experiment the isotopic composition of the gas was determined after 1 h. The results are summarized in Table I.

TABLE I

Dependence of exchange rate and product distribution on concentrations of H^+ and Cl^- (based on exchange experiments at 80° between 13.0 ml D_2 (at 450 mm) and 3.0 ml 0.017 *M* Ru^{III})

Total Cl^-, *M*	HCl, *M*	LiCl, *M*	Exchange product after 1 h, (moles/l of solution) $\times 10^5$		
			H_2	HD	HD+H_2
3.0	1.0	2.0	9.3	1.0	10.3
	2.0	1.0	8.5	1.1	9.6
	3.0	0	13.0	2.0	15.0
5.0	1.0	4.0	10.2	2.0	12.2
	2.0	3.0	11.1	2.7	13.8
	3.0	2.0	11.9	3.2	15.1
	4.0	1.0	12.4	3.9	16.3
	5.0	0	12.0	4.2	16.2
7.0	1.0	6.0	6.6	2.1	8.7
	2.0	5.0	7.4	2.5	9.9
	3.0	4.0	8.2	3.5	11.7
	4.0	3.0	7.7	3.6	11.3
	5.0	2.0	7.1	4.1	11.2
	6.0	1.0	8.0	5.1	13.1
	7.0	0	7.9	5.5	13.4

The slight increase in the exchange rate with increasing H^+ concentration is consistent with the trend noted earlier (1) for the Ru^{III}-catalyzed oxidation of H_2 by Fe^{III}. No appreciable trend is apparent in the dependence of the exchange rate at constant $[H^+]$ on the Cl^- concentration. The distribution of the exchange products, however, exhibits a marked dependence, depicted in Fig. 3, on the concentrations of both H^+ and Cl^-. The $[HD]/[H_2]$ ratio is approximately proportional[3] to $[Cl^-]$ at constant $[H^+]$, and also increases linearly with $[H^+]$ at constant $[Cl^-]$.

Addition of Fe^{III} to solutions containing Ru^{III} inhibited the exchange between D_2 and H_2O completely until the Ru^{III}-catalyzed reduction of Fe^{III} to Fe^{II} was complete.

[3]*This observation should be interpreted with caution in view of the variation in ionic strength which accompanies variation of the* Cl^- *concentration.*

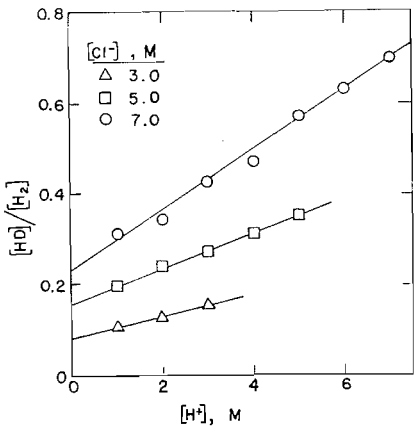

FIG. 3. Dependence of the exchange product distribution on the concentrations of H^+ and Cl^- (based on data in Table I).

DISCUSSION

The similarity of the kinetics of the Ru^{III}-catalyzed D_2–H_2O exchange and oxidation of D_2 by Fe^{III} reinforces the view already advanced that the two reactions proceed through related mechanisms involving a common rate-determining step. The mechanism proposed earlier (eq. [1] and [2]) for the oxidation of $H_2(D_2)$ by Fe^{III} can be extended to accommodate both reactions according to the following scheme (where $Ru^{III}Cl^-$ denotes one of the catalytically active chlororuthenate(III) complexes which are believed (1) to include $RuCl_6^{3-}$, $Ru(H_2O)Cl_5^{2-}$, and $Ru(H_2O)_2Cl_4^-$).

[3] $$Ru^{III}Cl^- + D_2 \xrightarrow{k_1} Ru^{III}D^- + D^+ + Cl^-$$

[4a] $$Ru^{III}D^- \xrightarrow[H^+ + Cl^-]{k_{-1}} Ru^{III}Cl^- + HD$$

[4b] $$Ru^{III}D^- \xrightarrow[+ H_2O]{k_2} Ru^{III}H^- + HDO$$

[5] $$Ru^{III}H^- \xrightarrow[H^+ + Cl^-]{k_{-1}} Ru^{III}Cl^- + H_2$$

[6] $$Ru^{III}D^- + 2Fe^{III} + Cl^- \rightarrow Ru^{III}Cl^- + 2Fe^{II} + D^+$$

This mechanism incorporates the following assumptions and conclusions:

(*a*) The rate-determining step [3] involves the heterolytic splitting of D_2 with formation of a deuteridoruthenium(III) complex. The D^- which is transferred to Ru^{III} displaces a Cl^- from the coordination shell. This implies that D^- occupies one of the normal ligand positions in the coordination shell of the ruthenium ion, in line with what is known about other hydrido complexes of transition metals (3).

(*b*) Isotopic exchange between D_2 and H_2O occurs through the reversal of step [3] (i.e., through steps [4*a*] and [5]). The D^+ which is released in step [3] undergoes complete exchange (conversion to H^+) with H_2O, whereas the $Ru^{III}D^-$ complex exchanges more slowly with H_2O, by what is assumed to be a pH-independent mechanism. According to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this, the total exchange rate $(-d[D_2]/dt)$ is determined by step [3], whereas the distribution of primary exchange products is determined by competition between steps [4*a*] and [4*b*]. This predicts that

$$[7] \qquad \frac{[HD]}{[H_2]} = \frac{k_{-1}[H^+][Cl^-]}{k_2}.$$

Interference from the multiple exchange process referred to earlier makes it difficult to determine the primary $[HD]/[H_2]$ ratio of the exchange product in order to test this prediction rigorously. Nevertheless, it is evident that eq. [7] is at least qualitatively in accord with the observed increase of the $[HD]/[H_2]$ ratios (which are not corrected for multiple exchange) with increasing H^+ and Cl^- concentrations (Fig. 3). The finite intercepts obtained on extrapolating to $[H^+] = 0$ the linear plots of $[HD]/[H_2]$ versus $[H^+]$ (Fig. 3) are, however, not predicted by eq. [7] and may reflect contributions to exchange at low H^+ concentrations from an H^+-independent back reaction (in addition to [4*a*]), e.g.,

$$[8] \qquad Ru^{III}D^- + H_2O + Cl^- \rightarrow Ru^{III}Cl^- + HD + OH^-.$$

(*c*) Oxidation of the intermediate, $Ru^{III}D^-$, by Fe^{III} (reaction [6]) is rapid and competes effectively with the back reactions [4*a*] and [5]. Thus, Fe^{III} inhibits the D_2–H_2O exchange reaction while undergoing reduction to Fe^{II} at the same rate as the Ru^{III}-catalyzed D_2–H_2O exchange in the absence of Fe^{III}.

Despite the difficulties involved in subjecting eq. [7] to a completely satisfactory quantitative test, it appears that, qualitatively at least, the observed dependence of the $[HD]/[H_2]$ ratio on the H^+ and Cl^- concentrations provides strong evidence for a mechanism involving heterolytic splitting of D_2 and the displacement of a Cl^- ligand. In favorable cases, this approach to the study of isotopic exchange patterns can provide evidence of a heterolytic splitting mechanism and can identify the displaced ligand, even without an explicit knowledge of the nature of the catalytic species or of the kinetics. It is of interest that an early suggestion by Rittenberg and Krasna (4) that the hydrogen-activating enzyme, hydrogenase, splits H_2 heterolytically was based on an essentially similar observation, namely that the initial product of the hydrogenase-catalyzed H_2–D_2O exchange is predominantly HD rather than D_2.

EFFECT OF α-METHYLATION ON THE PARAMETERS CHARACTERIZING HYDROLYSIS IN WATER FOR A SERIES OF HALIDES AND SULFONATES[1]

R. L. HEPPOLETTE[2] AND R. E. ROBERTSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received October 15, 1965

ABSTRACT

The aim of this work was to explore the effect of α-methylation on the reactivity and detailed mechanism of hydrolysis. Accordingly, rate data and derived parameters are given for the hydrolysis of a series of halides and sulfonates in water. From the differences in kinetic parameters, an attempt is made to infer further information relating structure and mechanism.

This paper summarizes the results of a study of the effect of α-methylation on the solvolytic displacement of halides and sulfonates in water, thus extending our earlier study on the corresponding methyl compounds (1).

As a medium for solvolysis, water is known to have excellent ionizing properties and to be a fair nucleophile. Its position in these respects, relative to other solvents, is well known (2) and is not altered by our rate studies.

Relative rates, however, provide little evidence on which to base conclusions concerning the detailed mechanism, particularly with respect to solvent reorganization. This point has been repeatedly illustrated in the studies of Tommila (3) and of Winstein and Fainberg (4) and may be attributed to the compensating effect of solvent reorganization on $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Hence it was from the latter terms and particularly from the values of $\Delta C_p^{\ddagger}$ that more detailed information about the reactions was expected. Even though the relation between changes in these parameters and mechanism is not as yet defined, these values should provide both an indication and a guide to the development of an acceptable hypothesis.

The basic aim here was to explore the pattern of values for a series of compounds rather than to investigate the temperature dependence of the rates for a few substrates with highest precision. To achieve this aim certain approximations were accepted, but there is no evidence that these approximations introduce significant differences in the derived parameters (see Experimental section).

EXPERIMENTAL

Halides

The halides were reagent grade samples, purified by distillation to give physical constants in agreement with the literature and passed through alumina for adsorption. These purified samples were protected from light and refrigerated during the kinetic study. The final criteria for kinetic purity was adherence to first order linearity. Because of the low solubility, particularly for the chlorides and iodides, the experimental difficulties here were much greater than for the corresponding sulfonates or even the methyl halides (1) and the experimental errors were correspondingly increased.

Sulfonates

Ethyl *p*-toluenesulfonate was obtained from distillation products and recrystallized several times from the melt; m.p. 32.1 °C. Isopropyl *p*-toluenesulfonate, methanesulfonate, and ethyl methanesulfonate were

[1]*Issued as N.R.C. No. 8831.*
[2]*N.R.C. Fellow 1956-1958.*

synthesized by the method of Morgan and Cretcher (5). All gave satisfactory neutral equivalents. Isopropyl *p*-Me: m.p. 19.8 °C, n_D^{25} 1.5002; ethyl mesylate: n_D^{25} 1.4151, d_4^{21} 1.20492; isopropyl mesylate: n_D^{25} 1.4167, d_4^{25} 1.01521.

Water

Distilled water was passed through an ion exchange column and sufficient backing electrolyte of the common anion added to give a concentration 0.001–0.003 *M*. The solution was evacuated and the halide introduced under vacuum. The sulfonates were added to the water prior to evacuation.

Rate Determinations

Rates were determined by the conductance method described previously (6). Details of temperature control, determination of time, and calculations were identical with the earlier work, save where noted specifically. The rate data reported in this paper were determined at a time when techniques and equipment were evolving. Temperature control was usually ±0.001–0.002 °C though in longer runs ($t_{1/2} > 6$ h) somewhat larger variation may have occurred. Some temperature variation may have arisen in the faster runs which would now be avoided (7). Errors in time may have also been present in the latter, but these should not have been large and should have been random. Temperature determination was by a platinum thermometer and temperature-controlled Mueller bridge.

The approximation (8)

$$\log (1/R_2 - 1/R_1) = k_1 t + c$$

was justified by the low concentrations used, and the small range of concentration involved (0.002–0.005 *M*). This approximation may have introduced a small error in $\Delta C_p^{\neq}$, but this would tend to be the same for all halides and unimportant in comparisons. Empirical calibrations of *R* vs. concentration (9) by dilution techniques do not alter the rates significantly.

RESULTS

Since it was our intention to relate changes in the derived parameters $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta C_p^{\neq}$ to changes in mechanism and in solvent reorganization, there seemed little to be gained in a detailed study of the rates of hydrolysis of the ethyl halides; all evidence suggested these results would be similar to those for the corresponding methyl halides (1). Accordingly, rate determinations on the former, save for ethyl bromide, were made over a limited range only (Table I). With these exceptions, rate determinations covered the range 40–60 °C.

TABLE I

Kinetic data for the hydrolysis of a series of ethyl halides in water

Halide	*T* (°K)	*k* ($s^{-1} \times 10^5$)	*n*

DISCUSSION

Until recently, the question of whether the isopropyl halides and sulfonates hydrolyzed in water by an S_N1 or S_N2 mechanism was uncertain, a position dignified by the label, "borderline case". This uncertainty was supported by the "normal" α-deuterium isotope effect found for the hydrolysis of secondary halides in water, compared to the inverse effect found for primary compounds (12). It is known now that this isotopic difference

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

does not provide a test for detecting nucleophilic interaction (13–15). Similarly the k_{OH^-}/k_{H_2O} ratio is inconclusive as a test for mechanism where the nucleophilic assistance required is small.

Positive evidence of an important difference in solvent reorganization is apparent in the systematic difference in $\Delta C_p^{\ddagger}$ for reactions involving primary and secondary centers compared to those involving displacement from a tertiary carbon (7, 16).

Moreover, recent studies of temperature dependence of the β-deuterium isotope effect in displacement from secondary and from tertiary carbon centers (17) and theoretical calculations of Wolfsberg and Stern (18) may be taken as empirical evidence of differences related to mechanism and hence for the conclusion that solvolytic displacement from primary and secondary carbon centers in water normally involve some degree of nucleophilic interaction while corresponding displacement from a tertiary does not. In the latter case the question of "limiting mechanism" is unimportant.

The probability of attaining the degree of nucleophilic overlap required as a prerequisite for the activation of primary and secondary compounds may be an important factor in evaluating $\Delta S^{\ddagger}$ in particular, and our lack of an a priori method for estimating these differences imposes limitations on the present utility of this parameter.

Effect of α-Methylation on Reactivity

Relative rates provide a direct guide to the effect of structure on reactivity, a matter of practical importance to the synthetic chemist but of less obvious utility in revealing mechanistic details. In Table IV a systematic difference is apparent in the ratio $k_{i\text{-Pr}}/k_{Et}$ between the sulfonates and the halides. This difference can readily be accounted for in terms of the relative requirements of nucleophilic overlap in the two series and the opposing effect of enhanced steric opposition of the α-methyl in those examples where nucleophilic interaction is presumed to be greater.

TABLE IV

A comparison of relative rates of hydrolysis in water at 50 °C

Displaced anion	k_{Me}/k_{Et}	$k_{i\text{-Pr}}/k_{Et}$
Benzenesulfonate	1.03	63.2
Tosylate	1.08	57.8
Methanesulfonate	1.18	50.9
Chloride	1.15	9.5
Bromide	0.99	9.9
Iodide	0.51	17.4

Effect of α-Methylation on $\Delta C_p^{\ddagger}$

While solvent reorganization contributes to changes in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, it is recognized that $\Delta C_p^{\ddagger}$ should be a much better indicator of solvent changes associated with the activation process. The particular utility of the latter parameters in this respect has been presented elsewhere and stems from the nature of aqueous solutions of weakly polar solutes (19–22). In water, such a solute may be regarded as surrounded by a dynamic hydrogen-bonded solvation shell. Insofar as the process of hydrolysis is concerned, the significant characteristics of this shell are (i) halide–water interaction is much smaller than water–water interaction, and (ii) the structure of the solvent shell appears to be more stable than the structure of bulk solvent. This may be attributed to a loss of librational freedom due to the presence of the solute: (iii) the stability of this solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

shell decreases with increasing temperature, and (iv) charge development on the anion, as a consequence of nucleophilic interaction and favorable collisions, will lead to a breakdown of this solvation shell in the immediate neighborhood of the anion.

Since the work required to break down the initial state solvation shell alters with temperature, $\Delta H^{\ddagger}$, which includes this factor, will show a corresponding negative temperature coefficient due to this cause whatever other temperature dependent factors may be involved. For example, the contribution of varying degrees of nucleophilic interaction on $\Delta C_p^{\ddagger}$ is by no means clear but appears to be small. As a working hypothesis (21) we assume that the transition state is reached when, by a suitable combination of activating forces,

[1] anion–water interaction = water–water interaction.

According to this hypothesis, charge development will be the same for S_N2 mechanism whether displacement is from a primary or secondary halide. Accordingly, the contribution to $\Delta C_p^{\ddagger}$ from the breakdown of water structure about the halide will tend to be the same whether displacement is from a primary or secondary carbon. Thus in Table III there is no large unidirectional shift in $\Delta C_p^{\ddagger}$ with α-methylation. Closer inspection of a series of $\Delta C_p^{\ddagger}$ values suggests, however, that the values for S_N2 displacement from a secondary carbon are somewhat more negative than from the corresponding primary center. Such a difference might very well be related to specific initial state differences and seems more prominent for the halides than for the sulfonates. In this connection, the value of $\Delta C_p^{\ddagger}$ for the hydrolysis of isopropyl chloride (−38 cal/deg) would appear to be atypical. Similar positive shifts have been noted where a sparingly soluble reactant has been studied (23).

Effect of α-Methylation on $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$

In an earlier paper (24) a correlation between $\Delta S^{\ddagger}$ and ΔS_{sol} (where ΔS_{sol} is the entropy change for the solvation of the corresponding product halide ion) prompted the conclusion that the quasi-anion was 80–98% solvated at the transition state in the case of the solvolysis of methyl and isopropyl halides in water. By using this approximation, the earlier calculations of the energy of activation, E_A, for the S_N1 solvolytic reactions by Evans (25) and by Franklin (26) were extended to cover the corresponding S_N2 hydrolysis of the above halides in water, and satisfactory agreement was obtained between the observed and calculated activation energies. As we have noted elsewhere (21), such agreement is not conclusive since the calculation involves essentially the difference of large numbers and there must always be some degree of reaction where the difference $(E_A)_{calc}$ will correspond to the observed activation parameter. It is equally clear that this type of calculation is not consistent with the qualitative hypothesis advanced above to define the condition for the transition state, eq. [1].

A comparison of the difference in $\Delta H^{\ddagger}$ resulting from α-methylation (Tables IV and V) shows that these are small compared with the total values (Table III) and compared with the differences in bond strengths and corresponding values for gas phase ionization. (Table 21 of ref. 27). It is possible that such nice cancellation of large differences occurs, but it seems equally feasible that we have in E_A (or $\Delta H^{\ddagger}$) a summation of smaller terms which do not change much with α-methylation. For such a structural change it is reasonable to expect a compensation between enhanced steric hindrance and the reduced requirement for nucleophilic overlap. If these opposing effects are approximately the same, the apparent lack of system in $(\Delta H_{Me}^{\ddagger} - \Delta H_{Et}^{\ddagger})$ and $(\Delta H_{i\text{-}Pr}^{\ddagger} - \Delta H_{Et}^{\ddagger})$ with different displaced groups is not surprising.

TABLE V

Comparison of enthalpy changes with α-methylation at 50 °C

Displaced group	$\Delta H_{Me}^{\neq} - \Delta H_{Et}^{\neq}$ (cal/mole)	$\Delta H_{i\text{-}Pr}^{\neq} - \Delta H_{Et}^{\neq}$ (cal/mole)
Benzenesulfonate	−600	−250
Tosylate	−520	−290
Mesylate	−680	120
Chloride	−290	−560
Bromide	−40	20
Iodide	350	−60

TABLE VI

A comparison of entropy differences resulting from α-methylation

Leaving group	$\Delta S_{Me}^{\neq} - \Delta S_{Et}^{\neq}$ (e.u.)	$\Delta S_{i\text{-}Pr}^{\neq} - \Delta S_{Et}^{\neq}$ (e.u.)
Benzenesulfonate	−1.3	6.4
Tosylate	−1.5	7.4
Mesylate	−1.8	8.3
Chloride	−0.2	3.4
Bromide	−0.7	4.6
Iodide	−0.3	5.5

By contrast, a regularity is apparent in $\delta_R\Delta S^{\neq}$ (Table VI) with different leaving groups and this difference ($\Delta S_{i\text{-}Pr}^{\neq} - \Delta S_{Et}^{\neq}$) would appear to be the main determinant of rate differences. For the halides, there is a fair correlation between $\delta_R\Delta S^{\neq}$ and the polarizability, α, (Fig. 1), an observation probably related to the correlation noted by Edwards (28) and Bunnett (29). The value for the sulfonates was not included because of uncertainty as to an acceptable approximation (29). Since the differences in $\Delta H^{\neq}$ among the sulfonates are about the same as for the halides (Table V), we would expect the sulfonates to occupy the same position relative to the halides in the upper curve where the entropy difference is plotted against polarizability as in the lower plot where the ordinate represents the difference in free energy. In the latter, the relative order of the sulfonates can be understood in terms of relative dispersal of charge on the sulfonic oxygens. Thus the methanesulfonate will be most effective in terms of eq. 1 because of the small polarizability of the methyl group compared to that of phenyl.

This is borne out both by the differences apparent in relative hydrogen bonding ability through this series (30), and the small but significant differences in the kinetic solvent isotope effect for the methanesulfonates and benzenesulfonates (31). In the benzenesulfonic series, while the phenyl group will tend to increase the polarizability, it will do so by dispersing the charge; hence the corresponding $\Delta S^{\neq}$ will be less than for the mesylate, and also less for the benzenesulfonate than for the tosylate, where the *p*-Me group will tend to reduce charge dispersal due to the phenyl group.

Apparently[4] the difference, $\delta_R\Delta S^{\neq}$, is not necessarily related to the degree of overlap required since we find approximately the same value for $\Delta S_{i\text{-}Pr}^{\neq} - \Delta S_{Et}^{\neq}$ for the solvolysis of the benzenesulfonates in water ($\delta_R\Delta S^{\neq}$ = 6.4 cal/mole deg), in methanol ($\delta_R\Delta S^{\neq}$ = 6.8 cal/mole deg), and in ethanol ($\delta_R\Delta S^{\neq}$ = 6.3 cal/mole deg). The corresponding relative rates are 62, 5, and 3.3 (32). The difference in the rate ratio is most easily accounted for

[4]*The assumption is made that a greater degree of nucleophilic interaction would be required where the solvent had poorer ionizing properties.*

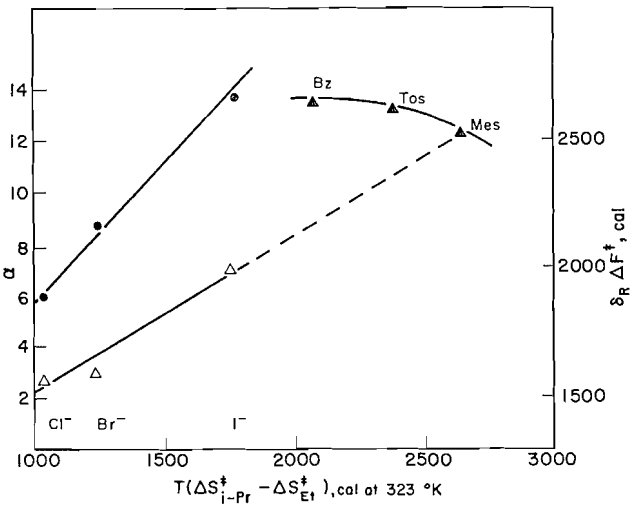

FIG. 1. Effect of α-methylation on the entropy of activation compared to the polarizability, α, and to the free energy difference, $\delta_R \Delta F^{\ddagger}$.

in terms of the effect of increased steric hindrance arising from a corresponding increased requirement for nucleophilic overlap.

The lack of any apparent systematic change in $\Delta H^{\ddagger}$ or $\Delta C_p^{\ddagger}$ with α-methylation stands in contrast to the effect of this change on the entropy, hence the familiar "compensatory effect" is absent (33–35), and this would seem to dispose of solvent reorganization as a root cause in this instance. This may be taken as a further support for our argument that the subtraction of $\Delta S_{Et}^{\ddagger}$ removes solvation differences associated with the anionic moiety in the activation process. Those uncertainties associated with $\Delta S^{\ddagger}$ in the transition state theory are also minimized.

Polarizability has been recognized to be an important factor in determining the rate of nucleophilic displacement (36–38), and is an essential feature of several empirical correlations relating structure and reactivity. Logically, this interaction would seem to require changes in $\Delta H^{\ddagger}$ or possibly in both $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Clearly, such is not the case here, though the reason remains obscure.

THE HYDROLYSIS OF SUBSTITUTED METHYL BENZENESULFONATES IN WATER[1]

R. E. ROBERTSON, A. STEIN,[2] AND S. E. SUGAMORI
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 29, 1965

ABSTRACT

Rate data and derived parameters for the hydrolysis of a series of para-substituted methyl benzenesulfonates are given. The introduction of such substituents has negligible effect on $\Delta C_p^{\neq}$, and the difference in rate is largely reflected in $\delta_X \Delta S^{\neq}$.

In this paper we report rate data for the hydrolysis of a series of substituted methyl benzenesulfonates in water. These, together with similar data already presented (1, 2), reveal certain trends in $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta C_p^{\neq}$ which we hope will be of assistance in developing an understanding of the detailed mechanism of ionogenic reactions in water. The esters were the same as used in a previous investigation (3) redistilled or recrystallized where needed to give acceptable physical constants.

RESULTS AND DISCUSSION

Rates of hydrolysis for a series of temperatures[3] were determined by a conductance method as described in earlier papers (4). Here, as in previous papers, we take advantage of the convenience of using the approximation $\log (1/R_i' - 1/R_i) = \log (c_i' - c_i)$ where R and c are the measured resistance of the solution and the concentration of the product acid at times t and $t - \gamma$ respectively as required by the relation (5)

$$[1] \qquad kt_i - \log_e (c_{2_i} - c_{1_i}) = \log_e (c_\infty - c_0)(1 - e^{-kt}).$$

Where the concentrations of solute were low, a normal consequence of studying halides in water, and where γ was in the range of one or two half-lives, there was no indication of rate dependence on the individual cell constants. Hence, the error introduced through a neglect of the Onsager term was not larger than the random variation due to other causes. We have recently shown that, in the case of *t*-butyl chlriode, this approximation makes a negligible change in the derived parameters and a change in k_i in the order of 0.1%.

For each compound, the temperature dependence of the rate of hydrolysis has been shown to fit the empirical three-constant equation $\log_{10} k = A/T + B \log_{10} T + C$ within experimental error. The corresponding least mean square constants are given in Table I along with the temperature range over which the rates were determined, the number of determinations, and the unbiased standard deviation

$$\sigma = \left(\frac{\sum (\log k_{calc} - \log k_{obs})^2}{n - 1} \right)^{1/2}.$$

In Table I, $n_{T_2}^{T_1}$ refers to the number of individual rates used in the least mean square calculation, where T_1 and T_2 are the upper and lower temperatures defining the experimental range.

*Recalculated.

While it is true that the k_{OH^-}/k_{H_2O} ratio is smaller for the methyl benzenesulfonate than for the halides (6), there is no evidence that excludes the requirement for some degree of nucleophilic interaction in order to achieve the transition state. Whether the degree of nucleophilic interaction alters with para substitution was not explored, but it is worth noting that the relative effect of para substitution shows no unusual increase for attack by EtO^- in ethanol compared to solvolysis in ethanol. The secondary α-deuterium isotope effect for the hydrolysis of Me *p*-NO_2 ester is essentially the same ($k_H/k_D = 0.95$) as that reported for the *p*-Me ester (7). The value of the rate at 40.008 °C for the protonated ester was $3.49_3 \pm 0.007 \times 10^{-4}$ on four determinations, (3.498×10^{-4} calculated, see Table I) and for the deuterated compound $3.67_2 \pm 0.002 \times 10^{-4}$ on three determinations. The inferential value of this ratio as a test for differences in the degree of nucleophilic interaction is seriously weakened by the findings of Leffek (8) and of Wu and Robertson (9) in another system, but it is obvious that if para substitution causes a difference in respect to required overlap, it is not large. The change in the relative effect of para substitution on the rate of solvolysis in various solvents is probably a better indicator, but other factors (e.g. initial state differences) could account for the modest differences apparent in Table II.

In keeping with previous work, we accept the transition state hypotheses with the usual approximation of $d\Delta C_p^{\ddagger}/dT = 0$ and by analogy with true equilibria interpret the constants of the temperature–rate equation as follows.

$$A = -\Delta H_0^{\ddagger}/2.3026R \quad [2]$$

$$B = (\Delta C_p^{\ddagger}/R) + 1 \quad [3]$$

$$C = (\Delta S_0^{\ddagger} + \Delta C_p^{\ddagger})/2.3026R + \log_{10} k/h \quad [4]$$

The corresponding derived parameters are given in Table III.[4] We are well aware that it has been frequently argued that $\Delta F^{\ddagger}$ gives the truest reflection of the effect of a substituent on E_0, or on the potential energy (10), but it is just because substitution alters the rate of reaction through other factors than bond strength, that added useful information may be derived from a comparison of the derived constants $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$.

If the transition state is reached when

anion–water interaction = water–water interaction,

[4]*The errors in these terms have not been specified. We are particularly grateful that Dr. D. N. Glew has recently provided an estimate for the case of isopropyl bromide where $\sigma = 0.0017$ from our calculation. The quantity $\delta\Delta H^{\ddagger}$ was shown to have a value of ~30 cal at 25 °C, 8.3 at 50 °C, and 32.5 at 75 °C. The corresponding error in $\Delta C_p^{\ddagger}$ was about 1.0 cal/mole deg over the entire range.*

TABLE II

Relative rates of solvolysis of substituted methyl benzenesulfonates

Para substituent	Water	MeOH	EtOH
MeO	0.5	—	0.45
Me	0.7	0.65	0.64
H	1	1	1
Br	1.67	2.20	2.2
NO_2	5.9	8.6	9.3

then the observed activation parameters are not reduced to "reasonable levels" (11–13) by solvation of the developing anions, but rather the contribution from this source is just about to begin. This hypothesis which was introduced to account for our solvolytic results for the halides (13) would be expected to hold for the hydrolysis of sulfonates as well. The $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ (Table III) then relate to those processes leading up to the critical conditions given above. The most important factors in the activation process will still be related to (*a*) repulsion energy, (*b*) bond strength/bond stretching, (*c*) reorganization of the solvent. Here, the question is how para substitution will be expected to alter these contributors.

TABLE III

Thermodynamic parameters for the hydrolysis of a series of methyl para-substituted benzenesulfonates in water at 50 °C

Compound	k_1 (s × 10^5)	$\Delta H^{\ddagger}$ (cal/mole)	$\Delta S^{\ddagger}$ (cal/mole deg)	$\Delta C_p^{\ddagger}$ (cal/mole deg)
Me Mes	8.40	20 450	−14.1	−38
Me *p*-MeO	10.71	20 960	−12.0	−39
Me *p*-Me	13.78	20 770	−12.1	−33
Me *p*-H	19.66	20 570	−12.0	−36
Me *p*-Br	54.50	20 570	−11.0	−35
Me *p*-NO_2	100.0	20 370	−9.3	−19
Me *m*-NO_2	89.13	20 600	−9.0	−32

If we take methyl methanesulfonate as an arbitrary reference, then the change to the benzenesulfonate series will probably (*a*) lower the repulsion, (*b*) lower the bond energy, (*c*) disperse the charge.

While the effect of para substitution on the rate is relatively small, it is the modification of electron density under nucleophilic attack which appears to be effective in determining differences in $\Delta F^{\ddagger}$, i.e. a combination of inductive ability and polarizability (14–16), which, it will be noted, appears to influence $\Delta S^{\ddagger}$ more than $\Delta H^{\ddagger}$, the latter save in one example being higher than for the reference compound.

The $\Delta C_p^{\ddagger}$ values for the series, in common with the sulfonates previously studied (2, 10), give values which are some 10–15 cal less negative than the corresponding term where a halide ion is the displaced group. All evidence available suggests that this difference arises from a difference in the degree of interaction between the sulfonic oxygens and the initial state solvation shell. The similarity of the $\Delta C_p^{\ddagger}$ values throughout the series suggests that solvent reorganization is about the same whatever the substituent—with the exception of the *p*-NO_2 derivative.

In spite of the difference in the size of the anion, the similarity in the value of $\Delta C_p^{\ddagger}$ throughout the series (with one exception) may be taken as an indication of uniform

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solvent reorganization in the activation process. In the exceptional case (p-NO_2) there is the added possibility of hydrogen bonding to the oxygens of the NO_2 group which might, in principle, introduce an unusual factor. Against this may be cited the unexceptional value of $\Delta C_p^{\neq}$ for the m-NO_2 homologue; hence we attribute the low value of $\Delta C_p^{\neq}$ for the p-NO_2 compound to some feature associated with low solubility rather than interaction with the initial state solvent shell. Kartha (17) found that the effect of para substitution on hydrogen bonding as shown by Δ cm^{-1} vs. the displacement of the maximum of the OH band of the hydrogen-bonded complex from that of the free p-Cl phenol was in the order:

$$p\text{-}NO_2\ (83.5) < p\text{-Br}\ (97.6) < p\text{-H}\ (111.1);$$

$$p\text{-Me}\ (116.4) < \text{Mesylate}\ (117.9) < p\text{-MeO}\ (121.4).$$

These differences follow the trend to be expected from normal electronic effects of the respective substituents on the unshared electrons of the sulfonic oxygens. Since interaction of this kind in the initial state will tend to make $\Delta C_p^{\neq}$ less negative (this is the same argument used to account for the difference between the halides and the sulfonates) we may assume that initial state differences as a consequence of para substitution or transition state differences due to solvent exclusion are unimportant throughout this series.

ISOTOPE EFFECTS IN MIXTURES OF LIQUID H_2O AND T_2O

MARK SALOMON
School of Chemistry, Rutgers, The State University, New Brunswick, New Jersey
Received August 31, 1965

ABSTRACT

Calculations are presented for the equilibrium tritium isotope effect involving water, hydronium ion, and hydroxide ion. The results are used to predict the kinetic isotope effect in the transfer of protons to a mercury cathode.

INTRODUCTION

The use of tritium for studying the kinetics of proton transfer reactions has some major advantages over the deuterium isotope. This is particularly true for reactions which proceed by small amounts of proton tunneling. The use of deuterium to evaluate proton tunneling contributions may not, in this case, be critical enough unless the kinetics are studied down to very low temperatures. In aqueous solutions one is severely limited to a relatively small temperature range. Hence criteria more diagnostic than the H/D isotope effect is sought. By employing the tritium isotope, which gives larger isotope effects, the experimental confirmation of proton tunneling may indeed be more significant. It is of interest, therefore, to calculate the solvent isotope effects for equilibria involving mixtures of H_2O and T_2O and to apply these calculations to a kinetic mechanism involving a proton transfer.

CALCULATION OF EQUILIBRIUM CONSTANTS

The calculations presented below were performed by the method of Bader (1, 2). This method was used recently by Thornton (3) to calculate the equilibrium properties for water containing the ^{16}O–^{18}O isotopes. This method, applied to hydrogen and tritium, has enabled the following equilibrium constants (for aqueous systems at 25 °C) to be calculated.

$H_2O + H_2TO^+ = HTO + H_3O^+$	$K_1 = 1.051$
$H_2O + T_3O^+ = HTO + HT_2O^+$	$K_2 = 9.474$
$H_2O + T_3O^+ = T_2O + H_2TO^+$	$K_3 = 7.459$
$2T_3O^+ + 3H_2O = 3T_2O + 2H_3O^+$	$L_T = 15.36$
$H_2O + T_2O = 2HTO$	$K_4 = 4.00$

These equilibrium constants were caclulated by first evaluating the partition function ratios, q_T/q_H, for the various isotopic species involved. The rotational partition function is calculated by Bader's method (1, 2) of treating the librations of the solvated H and T species as harmonic oscillators. The librational and vibrational frequencies for H_2O and OH^- were taken from Bader's work (1) and the corresponding frequencies for T_2O were calculated from Herzberg's equations (4). The force constants for H_2O given by Herzberg (4) were used in this calculation. The force constants and vibrational frequencies for H_3O^+ were obtained from Wolfsberg (5). The force constants for H_3O^+ are: $k_s = 4.915$, $k_\phi = 0.5$, $k_w = 0.06$, and $k_{int} = -0.4896$ mdyn Å^{-1}. The subscripts s, ϕ, w, and int refer, respectively, to the O—H stretch, the H—O—H bend, the O—H wag, and the OH . . . . OH interaction. The corresponding vibrational frequencies for T_3O^+ were calculated from Herzberg's equations (6).

The librational frequency shifts for T_2O and T_3O^+ were calculated from the inverse square roots of the average moments of inertia (cf. Bader, ref. 1). The moments of inertia were calculated from the formulae given by Moelwyn-Hughes (7). The bond length and valency angle for H_2O were taken, respectively, as 0.96 Å and 105° (7). The bond length and valency angle for pyramidal H_3O^+ were taken, respectively, as 1.05 Å (8) and 107° (3). The bond length for OH^- is not required. The vibrational and librational frequencies for the various H and T species in aqueous solution at 25 °C are given in Table I.

TABLE I

Frequency assignments for liquid waters at 25 °C

Molecule	Frequency (cm^{-1}) H species	Frequency (cm^{-1}) T species	Mode	Degeneracy
H_2O	3 400	2 003	ν_1	1
	1 645	988	ν_2	1
	3 440	2 183	ν_3	1
	667	408	ν_{lib}	3
H_3O^+	2 600	1 680	ν_1	1
	1 086	738	ν_2	1
	3 171	1 993	ν_3	2
	1 729	1 058	ν_4	2
	643	385	ν_{lib}	3
OH^-	3 615	2 206	ν_1	1
	477	291	ν_{lib}	2

Using the frequencies in Table I, the following partition function ratios were calculated.

$$\frac{q_{T_2O}}{q_{H_2O}} = 4.034 \times 10^4; \qquad \frac{q_{T_3O^+}}{q_{H_3O^+}} = 2.068 \times 10^6; \qquad \frac{q_{OT^-}}{q_{OH^-}} = 286.5$$

By applying the rule of the geometric mean (cf. ref. 2) the following partition function ratios were calculated.

$$\frac{q_{HTO}}{q_{H_2O}} = 402 \qquad \frac{q_{T_2O}}{q_{HTO}} = 100.5$$

$$\frac{q_{H_2TO^+}}{q_{H_3O^+}} = 382.2 \qquad \frac{q_{T_3O^+}}{q_{H_2TO^+}} = 5\,410$$

$$\frac{q_{HT_2O^+}}{q_{H_2TO^+}} = 127.4 \qquad \frac{q_{T_3O^+}}{q_{HT_2O^+}} = 42.47$$

The equilibrium constants, K_1 to K_4 and L_T, were calculated using these partition function ratios.

DISCUSSION

In this section, the above results are applied to the kinetics of electrochemical proton transfer with the primary object of trying to correlate the available experimental data with either a non-tunneling or a tunneling mechanism. Most of the experimental data for proton transfer to a mercury cathode involves the use of the deuterium isotope (9–13). In all cases the H/D isotope effect was observed to be quite small and potential dependent. Low temperature studies for transfer from alcoholic solutions to mercury cathodes indicates that proton tunneling plays a very negligible role in the overall rate of proton transfer (13). Similar conclusions have been reached for the aqueous system where one is considerably limited by the temperature range over which the kinetic isotope effect

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

can be studied (13–15). These conclusions are based upon the experimental findings that in both aqueous and non-aqueous systems (i) the activation energies for H and D transfer are temperature independent and (ii) the ratio of "true" frequencies factors, A_H/A_D, is equal to 1.2. If tunneling were a significant pathway in this reaction then, according to Bell (16), $A_H/A_D \leqslant 0.5$ is an excellent criteria.

The isotopic quantity most often studied in electrochemical kinetics is the separation factor S. In terms of a rate-determining proton transfer from an acid species to a mercury cathode, the tritium separation factor is defined (cf. 15, 17) as

$$S_T = \frac{C_T[H_3O^+]}{C_H[H_2TO^+]} \frac{q_{H_2TO^+}}{q_{H_3O^+}} \frac{q_H^{\ddagger}}{q_T^{\ddagger}},$$

where C_T/C_H is the atomic ratio of tritium to hydrogen in solution and ‡ refers to the activated complex. This relation is valid for the case where the only significant source of tritium is the species H_2TO^+. This condition is easily met by making C_T/C_H very small; e.g. when 10^{-5} mole of T_2O is placed in 1 l of normal acid solution, the concentration ratio $[H_3O^+]/[H_2TO^+] = 2.958 \times 10^6$ as calculated from the equilibrium relations for K_1 and K_4. The species HT_2O^+ is present in a concentration of the order of 10^{-11} M so that it need not be considered as a source of tritium. Inserting these quantities into the above equation with the value for $q_{H_2TO^+}/q_{H_3O^+}$ calculated above, one now has

$$S_T = 204.3 \frac{q_H^{\ddagger}}{q_T^{\ddagger}}. \qquad [1]$$

The partition function ratio for the activated complex, $q_H^{\ddagger}/q_T^{\ddagger}$, can be evaluated by empirical or semiempirical methods and different answers will result depending upon the method used. Hence Bockris *et al.* (17) assumed the rate-determining step to be

$$Hg + H_3O^+ + e \rightarrow HgH + H_2O, \qquad [2]$$

and from thermodynamic cycles an Eyring–Polanyi semiempirical potential energy surface was constructed. The use of the semiempirical method has been questioned even for *qualitative* analysis (18, 19). Also if one considers the mechanism to be that as written above, then one could not in fact use the semiempirical method because it uses a single eigenfunction to represent the state of the electron throughout the course of reaction (20). Hence the use of a single potential energy surface to represent mechanism [2] is a violation of the so-called adiabatic principle (20). The results of this calculation (17) gives an activation of around 2–6 kcal mole^{-1} which becomes *negative* when zero point energies are included. Also, the symmetric stretching frequency of Hg—H—OH_2 was calculated to be 3 000 cm^{-1} and this was attributed to the results obtained from the potential energy surface in which it was found that the O—H bond in the activated complex was *not* stretched from its equilibrium position in H_3O^+. This high frequency gave very small isotope effects which could be increased somewhat by assuming the bending frequencies to approach zero. Even with the assumption that the bending frequencies approach zero, the predicted isotope effect was still too small and a tunneling factor was required to increase it. In a more recent paper, Bockris and Matthews (21) have offered a model of charge transfer which involves stretching of the O—H bond and is therefore contrary to the model used in the quantitative calculations (17).

Conway *et al.* (14, 15, 22) have proposed a different model for slow proton discharge. According to this model the slow step corresponds to the reaction

$$Hg + H_3O^+ \rightleftharpoons X^{\ddagger} \rightarrow HgH^+ + H_2O, \qquad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

and electron transfer proceeds either by tunneling to the fully charged activated state, $X^{\pm}$, or by tunneling to the final state, HgH^{+}. This model of the activated complex was proposed in order to explain the observed results that (i) proton tunneling plays an insignificant role in the overall mechanism [2] for proton discharge and (ii) the potential dependence of S_D could be explained in terms of a non-tunneling mechanism if a fully charged activated complex could be justified.

The reasons leading to conclusion (i) has been discussed above and in more detail elsewhere (12–15, 22). The concept of a charged activated complex results from the successful application (15, 22) of Bader's model of proton transfer (23, 24) to the present electrochemical case. In this model, $q_H^{\pm}/q_D^{\pm}$ is evaluated by using a three center model. The activated complex is formed by electrons from mercury ($6s^2$) and oxygen ($2p^2$) and can be considered to form σ-bonding and σ-antibonding orbitals. According to Bader (23, 24), the antibonding effects will give rise to higher bending force constants when electrons are supplied to either end of the linear M . . . H . . . O complex and therefore result in smaller isotope effects. Since electron supply to the electrode surface is a variable in electrochemical kinetics, one would expect the bending frequency to be a function of electrode potential such that the kinetic isotope effect will decrease as the potential is made more cathodic. Calculation of bending frequencies from first principles then becomes exceedingly difficult and we have therefore chosen this frequency by comparing the activated complex with similar stable structures in which ν_ϕ is known, e.g. as in FHF^- (14, 15, 22). The variation of ν_ϕ has been used to explain the dependence of the H/D isotope effect on electron-donating substituents (23) and has been treated theoretically by the same author (24). We have found (14, 15) that bending frequencies of $\nu_{\phi,H} = 1\,000$ to $1\,200\ cm^{-1}$ could explain the observed decrease in the deuterium separation factor, S_D, from 3.7 at -0.9 V to 2.5 at -1.4 V (the potentials are referred to the reversible hydrogen electrode (12)). The vibrational frequency for the symmetrical stretching mode was calculated from Johnston's empirical method of bond orders (19). This method has been shown to predict activation energies to within ± 2 kcal $mole^{-1}$ for hydrogen transfer reactions and is therefore considered to be superior to the semiempirical method. The symmetrical stretching mode for the electrochemical proton transfer was found (22) to have a frequency $\nu_{s,H} = 1\,503\ cm^{-1}$. This is rather high for this type of vibration (e.g. in FHF^- $\nu_{s,H} = 600\ cm^{-1}$) and is attributed to the calculated result that the $(Hg—H—OH_2)^+$ complex is asymmetric (22).

Bockris *et al.* (17) and Christov (25) agree that, while tunneling is not a significant pathway in proton discharge at Hg cathodes in alcoholic solutions, in aqueous solutions up to 80% of the total rate of discharge is due to proton tunneling. The tritium isotope effect studied experimentally and theoretically has been offered as more dramatic proof for large amounts of proton tunneling in the aqueous system (17). It was found that the experimental S_T values decreased from ~ 9 at -0.9 V to ~ 4 at -1.4 V; also theoretical calculations based on a tunneling mechanism were presented which gave a satisfactory fit to the experimental data.

Values of S_T can be calculated from eq. [1] by evaluating $q_H^{\pm}/q_T^{\pm}$ as follows: first, the activated complex is assumed to be immobile (22); second, we can use the frequencies found for the $(Hg—H—OH_2)^+$ activated complex to calculate the corresponding frequencies for the $(Hg—T—OH_2)^+$ complex. It is found that $\nu_{s,T} = 870\ cm^{-1}$ for the stretch and $\nu_{\phi,T} = 584\ cm^{-1}$ at -0.9 V and $\nu_{\phi,T} = 696\ cm^{-1}$ at -1.4 V for the variable bending frequency. These last two bending frequencies were calculated from the H isotope frequencies which were used to fit the observed S_D versus potential relationship

(15). Hence the values of S_T calculated from eq. [1] are 5.3 and 2.9 for potentials of -0.9 and -1.4 V, respectively. Providing the mechanism proposed by Conway *et al.* (14, 15, 22) is correct, then the values of S_T predicted here should be fairly reliable and the problem is to explain the difference between these results and the experimental values of Bockris *et al.* (17).

There appears to be a serious anomaly in the experimental values in that the temperature coefficient of S_T, i.e. dS_T/dT, is positive; i.e. the isotope effect was observed to *increase* as the temperature was increased. The results for the H/D isotope effect all show a negative value for dS_D/dT when discharge is kinetically rate-determining. One cannot theoretically predict this effect based on a kinetic mechanism when k_H/k_D (the ratio of rate constants) is greater than unity, which it is (10, 13). Yet Bockris *et al.* do in fact predict this phenomena and this becomes even more difficult to comprehend if, as claimed, 80% of the rate proceeds by a tunneling mechanism. The experimental results indicating a positive dS_T/dT value could possibly be explained by slow diffusion of H_2TO^+ since it is present in micromolar quantities in the bulk. Such a process was suggested by Rome and Hiskey (11) to explain their one point where $(dS_D/dT)_i$ was positive. This occurred at the highest current density (i.e. the highest rate of reaction) in isotopically mixed solutions dilute in its D content. In no other case did Rome and Hiskey (11) or Walton and Wolfenden (9) observe this anomolous value for $(dS_D/dT)_i$.* It is quite possible therefore that the experimental S_T values are too high because of a further isotopic separation by slow diffusion. Hence the values of S_T predicted here would be expected to be lower than the experimental values, and the conclusion that proton tunneling is a significant pathway (based on the observed S_T values and the theoretical calculations including tunneling corrections) is not well founded. The values calculated here on the basis of a non-tunneling mechanism indicate low values of S_T and this is, partially at least, borne out by a low experimental value. It might be mentioned that the maximum isotope effect which would occur if there were no difference in zero point energies of the H and T activated complexes is 204 as obtained from eq. [1]. Hence the maximum theoretical S_T value is at least 20 times greater than the experimental value and this in itself is suggestive of a non-tunneling mechanism. Conclusive evidence in support of a non-tunneling mechanism should, however, involve values for the activation energies over a wide temperature range and the frequency factor ratio A_H/A_T. Although this information is not yet available, the present results are considered to be sufficient evidence in favor of the non-tunneling mechanism since they were derived by a simple extension of our previous H/D results as discussed above.

THE ANIONIC POLYMERIZATION OF ALLYL ACRYLATE AND OF ALLYL METHACRYLATE[1,2]

S. Bywater, P. E. Black, and D. M. Wiles
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received October 29, 1965

ABSTRACT

The low temperature polymerization of allyl acrylate in toluene solution has been investigated with *n*-butyllithium and 1,1-diphenyl-*n*-hexyllithium initiators. The latter was also used in a study of the polymerization of allyl methacrylate under the same conditions. The reactions between initiator and monomer were rapid in all cases. More than half of the initiator molecules reacted with monomer acrylic double bonds to start polymer chains, only a few of which grew to a high molecular weight, highly isotactic product. Most of the chains remained as a low molecular weight, precipitant-soluble product. The remaining initiator molecules reacted with the carbonyl groups of the monomers to produce species which could be detected as allyl alcohol, after termination of the reaction with acetic acid. The allyl double bonds were not involved in reactions during polymerization but were presumably responsible for the cross-linking which occurred when the polymers were exposed to air.

INTRODUCTION

Several of the many complex aspects of the anionic polymerization of methyl methacrylate in toluene solution have been shown to be due to the presence of the two unsaturated bonds in this monomer (1, 2). Both the acrylic double bond and the carbonyl group are susceptible to reaction with organometallic compounds (3). The reaction with the carbonyl group leads to kinetic complications (4, 5) and unusual polymer molecular weight distributions (6) when the initiator is *n*-butyllithium (BuLi). Some simplification of the kinetics is obtained by the use of a relatively less reactive initiator, 1,1-diphenyl-*n*-hexyllithium (DPHL), in toluene solution (2). Nevertheless, there is still evidence of reaction between DPHL and methyl methacrylate carbonyl groups at −78 °C.

A recent publication by Donati and Farina (7) deals with the organometallic-initiated polymerization of allyl acrylate (AA) in toluene solution. It is implied that BuLi reacts only with the acrylic double bond of the monomer. If this were so, allyl acrylate would then be preferable to methyl methacrylate for kinetic studies; the results could be more amenable to interpretation and explanation.

This paper is a report in some detail of the polymerization of AA in toluene solution at low temperatures with BuLi and DPHL initiators. The DPHL-initiated polymerization of allyl methacrylate (AMA) under the same conditions is also described. Polymer structures have been investigated in some cases by infrared, X-ray diffraction, and proton magnetic resonance techniques. The electronic spectra of living poly(allyl methacrylate) (PAMA) initiated by DPHL have been measured in toluene and tetrahydrofuran (THF) solutions.

EXPERIMENTAL

The sources of the initiators, BuLi and DPHL, and the handling and measurement of them has been described elsewhere (2). The monomers were obtained from the Borden Chemical Company and were purified as follows. After fractional distillation in a dry nitrogen environment at reduced pressure, the monomers were degassed on a vacuum line, stirred over calcium hydride, stirred in contact with a sodium mirror at −30 °C for 30 min, stirred on fresh calcium hydride again, and finally stored in a connected bulb at 0 °C in the dark. The desired quantity was distilled into a calibrated tube and then distilled into and sealed in a pre-weighed break-seal container. A final weighing determined the amount of monomer.

An all-glass polymerization apparatus (4) was used for the kinetic experiments. The toluene solvent, purified as before (4), and all the glass surfaces with which the toluene solutions of initiator came in contact were pre-washed with BuLi. Details of the polymerization procedure have been published previously (2, 4). After polymerization occurred for various times to different degrees of conversion, acetic acid was added to terminate reaction. Triplicate 10 μl samples of each reaction mixture were analyzed for allyl alcohol by gas chromatography with a 2 m column of diglycerol on chromosorb W. The reaction mixture was then poured into a 10-fold excess of petroleum ether (boiling range 30–90 °C). The product was separated into precipitant-soluble and precipitant-insoluble portions. The latter portion from AA polymerizations was washed repeatedly with warm distilled water to remove lithium salts; the petroleum ether insoluble product from AMA polymerizations cross-linked too rapidly in air for the washing to be effective. All products were weighed after final drying in a vacuum desiccator under pumping at room temperature. The product yields were corrected to take into account the weight of diphenylhexyl end groups.

Number-average molecular weights of some of the soluble products were measured with a Mechrolab vapor-pressure osmometer. Viscosity-average molecular weights of a few samples of precipitant-insoluble polymers were determined from the relationship (8) which is quoted for poly(butyl acrylate) in acetone solution at 25 °C. The details of the proton magnetic resonance measurements are described elsewhere (9). Optical densities of some of the polymerizing allyl methacrylate systems were measured in the wavelength range 250–500 mμ with a Bausch and Lomb 505 recording spectrophotometer. The apparatus and techniques were similar to those described previously (10). The polymerization vessel and the quartz cell fastened to it were maintained at the desired temperature in the cell compartment by immersion in cold, absolute ethanol in a large quartz dewar vessel with optical windows.

RESULTS

The same general features found in the organometallic-initiated polymerization of methyl methacrylate have been observed in the polymerizations reported here. There is an initial rapid (< 2 min) consumption of monomer and initiator to form low molecular weight, precipitant-soluble polymer, followed by a slower process which produces high polymer. Much of the initiator is consumed in the first process. Most of the monomer, however, is incorporated in the molecules of high polymer which necessarily have a molecular weight higher than predicted from the [monomer]/[initiator] ratio used. Evidently there is attack of organometallics on the carbonyl groups in the system because lithium alkoxides, which appear in the terminated reaction mixtures as allyl alcohol, are formed.

Allyl Acrylate

The kinetic data for allyl acrylate polymerizations are shown in Fig. 1 as first order plots of monomer consumption. With a constant number of growing chains such plots would be linear. The rapid decrease in slope indicates that the number of active polymer chains decreased with time, with both initiators. This correlates with the visual observation that the yellow color, previously ascribed to the presence of the methacrylate – lithium ion pair (10), faded steadily during polymerization. The decrease in number of active centers proceeds to such an extent at higher [monomer]/[initiator] ratios that complete conversion to polymer could not be obtained in any reasonable time.

When BuLi initiator was used, about 10% of the monomer was converted to precipitant-soluble product ($\bar{M}_n \approx 900$) early in the reaction and there was a gradual increase in weight, as polymerization proceeded, to about $1\frac{1}{2}$ times the initial quantity. With DPHL initiator the weight of soluble product ($\bar{M}_n \approx 600$) was in general much higher initially but remained constant throughout a polymerization. When the initial concentrations of BuLi or DPHL were increased the weight of soluble product was higher, but there was no simple relationship between [initiator] or [monomer]/[initiator] and the weight of soluble product.

Allyl alcohol was detected in terminated reaction mixtures when either initiator was used. With BuLi, about 25% of the initiator was recovered as this product within the first 2 min of reaction. The amount subsequently increased rapidly until at long reaction

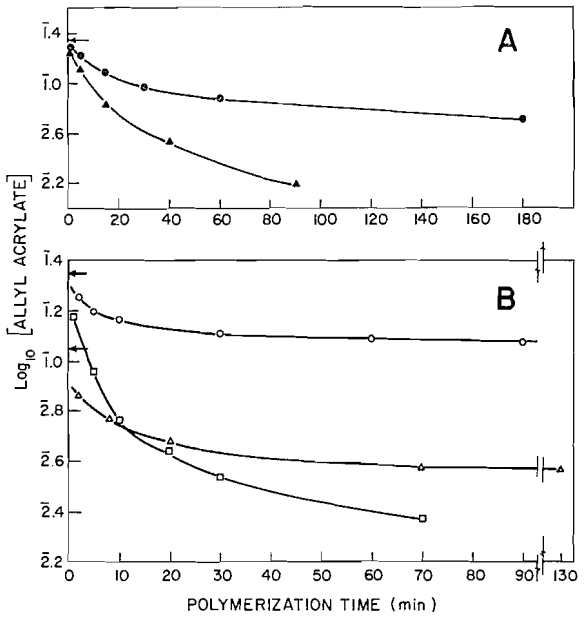

FIG. 1. Allyl acrylate polymerization in toluene at −78 °C. The symbol ← denotes initial monomer concentration. A: [AA] = 0.223 M; (●) [BuLi] = 4.0 mM; (▲) [BuLi] = 8.0 mM. B: (○) [DPHL] = 2.9 mM, [AA] = 0.223 M; (△) [DPHL] = 2.9 mM, [AA] = 0.112 M; (□) [DPHL] = 7.2 mM, [AA] = 0.223 M.

times virtually all the initiator was recovered in this form. The results for DPHL are shown in Fig. 2. About 35% of the initiator is rapidly converted to alkoxides at 2.9 mM initiator; at 7.6 mM an even larger fraction appears rapidly as lithium alkoxide. In all cases subsequent production increases steadily but monomer consumption does not.

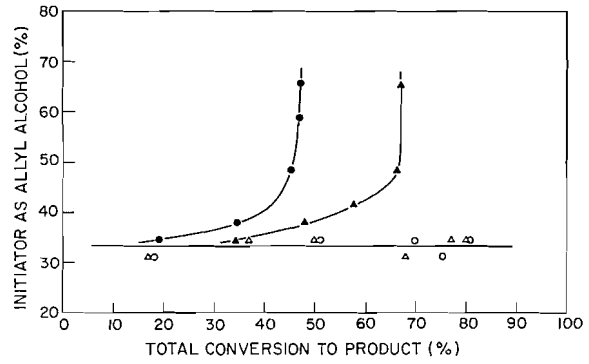

FIG. 2. Allyl alcohol in terminated reaction mixtures. Polymerization temperature = −78 °C. [DPHL] = 2.9 mM. (●) [AA] = 0.223 M; (▲) [AA] = 0.112 M; (○) [AMA] = 0.223 M; (△) [AMA] = 0.112 M.

Infrared analysis of typical poly(allyl acrylate) (PAA) showed that there was no detectable acrylic unsaturation but a great deal of carbonyl and allylic unsaturation. An oriented fibre of one PAA sample gave an X-ray diffraction pattern typical of a highly crystalline material probably having an isotactic polymer backbone (7).

Allyl Methacrylate

From Fig. 3 it can be concluded that the DPHL-initiated polymerization of AMA is less complicated than the polymerizations of AA described above. The consumption of monomer is first order, both internally and externally, at −78 °C and has been shown to be internally first order at −30 °C. This correlates with the visual observation that with this monomer the yellow color present in polymerizing systems faded little or not at all before termination.

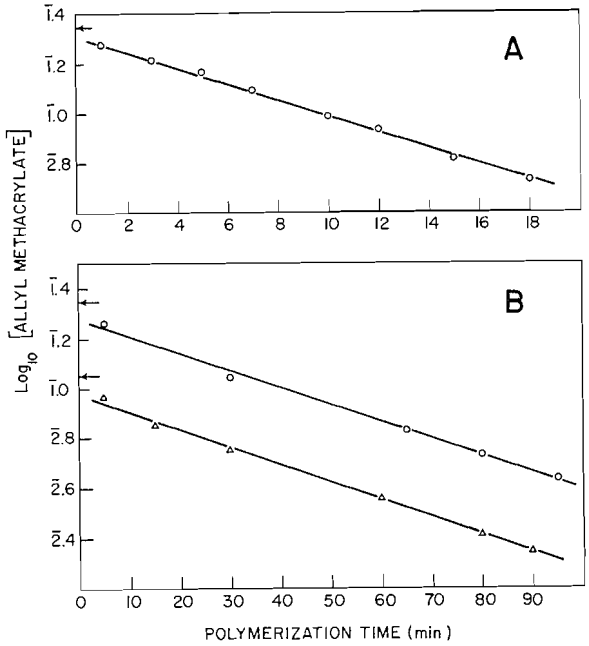

FIG. 3. Allyl methacrylate polymerization in toluene solution. The symbol ← denotes initial monomer concentration. [DPHL] = 2.9 mM. A: polymerization temperature = −30 °C; [AMA] = 0.223 M. B: polymerization temperature = −78 °C; (○) [AMA] = 0.223 M; (△) [AMA] = 0.112 M.

The absorption spectra for living PAMA anion – lithium cation systems in toluene and in THF are shown in Fig. 4. The curves represent the difference, in each of the two solvents, between the absorption at complete conversion and the absorption following termination with absolute ethanol. The spectra are very similar to those observed with the poly(methyl methacrylate) anion (10), as would be expected.

The conversion of monomer to polymer during polymerization in either solvent was accompanied by a decrease in optical density in the region 390–500 mμ and by an increase below 390 mμ. The gross optical density around 300 mμ actually increased by about 30% during polymerization, but this seemed to be largely due to an increase in background absorption in this wavelength region, since the absorption in the killed systems was greater than that of the reactants. The changes in optical density continued while polymer chains were growing and then stopped when monomer had been used up. Since there was no change, in particular no decrease thereafter in the region of absorption of the living polymer – lithium ion pair, it is reasonable to conclude that there was a constant number of living PAMA chains over the period of the experiments reported here. This conclusion is in agreement with the kinetic data shown in Fig. 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The weight of soluble product remains reasonably constant throughout the course of any given polymerization. The weight changes from one system to another, that is, varies with changing monomer concentration in a non-systematic way. The number-average molecular weight was found to be 450 for one system and was assumed to be similar in the other two.

The concentration of allyl alcohol (Fig. 2) was the same (about 33% of the initial [DPHL]) in each terminated reaction mixture for both systems at −78 °C. The value was a bit higher (39%) and also independent of polymerization time in the experiments at −30 °C.

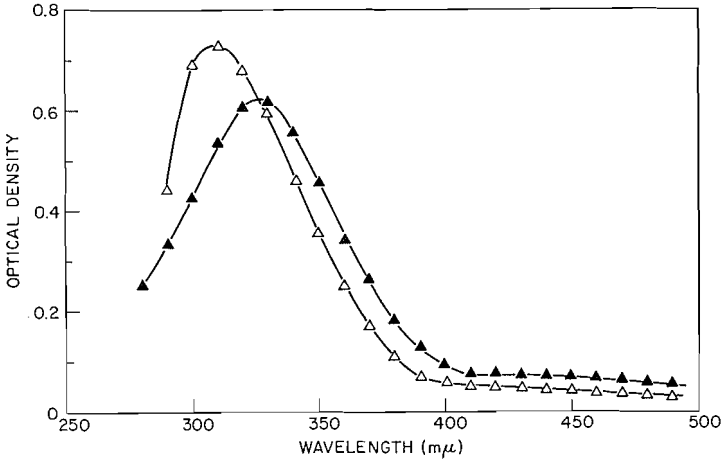

FIG. 4. Electronic absorption spectra of PAMA anions at −30 °C. 1.0 cm cell; [DPHL] = 0.725 mM, [AMA] = 0.112 M. (△) Toluene solvent; (▲) THF solvent.

The PAMA samples cross-linked very rapidly on exposure to air. Perhaps partly because of this it was not possible to crystallize these polymers. The proton magnetic resonance spectrum of samples prepared and recovered in vacuum showed that polymerization had occurred through the acrylic double bond and that polymers prepared in toluene solvent were highly isotactic. The tacticity changed to stereoblock, then to syndiotactic (9) as the polymerization solvent was altered to partly and then entirely tetrahydrofuran. There is much the same effect of reaction medium upon PAMA tacticity as was found (11) for fluorenyllithium-initiated poly(methyl methacrylate).

DISCUSSION

The kinetics of the organolithium-initiated polymerization of AA or of AMA are influenced by the fact that, for each of these monomers, two of the three unsaturated bonds are susceptible to reaction with initiator. There is apparently no appreciable reaction with the allylic double bonds of the monomers. Comparison with the anionic polymerization of methyl methacrylate indicates that the monomer acrylic double bonds are involved in polymer formation and the monomer carbonyl bonds cause complicating side reactions.

A diagram showing the two possible reactions of an organolithium compound with either AA or AMA is given in Fig. 5. Whereas reactions [1] and [2] are believed to be quite rapid it is not known to what extent reaction [3] occurs, before the polymerization is terminated. It is assumed that lithium allyl oxide present in a polymerizing system will be converted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

quantitatively to allyl alcohol by reaction with acetic acid terminating agent. In the discussion to follow, reference to allyl alcohol should be regarded as synonymous with reference to its precursor(s) in an unterminated system in which, of course, there is no allyl alcohol as such.

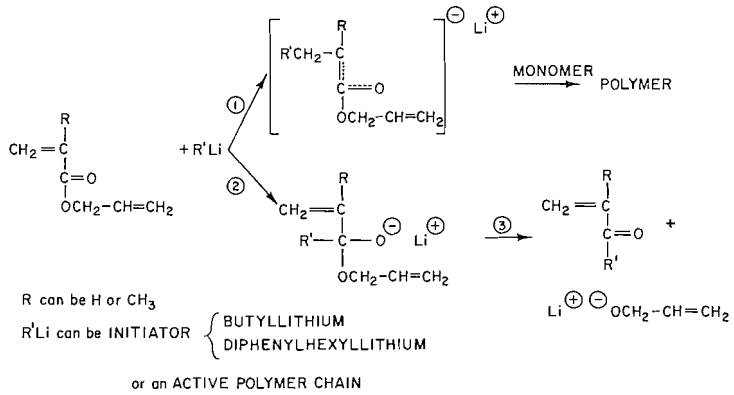

FIG. 5. The reactions of organolithium compounds with either AA or AMA.

Lithium allyl oxide or its precursor must be formed during the early stages of polymerization since allyl alcohol is invariably found in reaction mixtures terminated after short polymerization times. This amount of allyl alcohol probably reflects the extent of reaction between initiator and monomer carbonyl groups. Subsequently any reaction between growing polymer chains and monomer carbonyl groups would only give rise to a small increase, linear with conversion, in allyl alcohol concentration. This presumably occurs in the polymerizations of AA where the kinetic data and yellow color observations indicate a decreasing number of growing chains. It does not seem to occur in the DPHL-initiated polymerizations of AMA at −78° and −30 °C.

The percentage of added initiator which appears as allyl alcohol increases faster than conversion in AA polymerizations (Fig. 2). The increase in concentration of allyl alcohol precursor during chain growth is, in fact, far greater than the maximum concentration of polymer chains growing to high molecular weight. In addition, the concentration of allyl alcohol in reaction mixtures terminated at longer times continues to increase with increasing time before termination, even after polymerization has virtually ceased. There must, therefore, be a third source of allyl alcohol. Figure 6 shows a possible source which is connected with the formation of precipitant-soluble product. The idea of a short-chain, cyclic structure for this product, originally proposed by Glusker *et al.* (11), has since been used to explain some features of the polymerization of methyl methacrylate by DPHL (2). In the latter investigation the evidence indicates that the formation of soluble product is not concomitant with or followed immediately by the formation of lithium alkoxide. The sequence in the AA polymerizations seems to be a rapid formation of polymerization-inactive cyclic complex followed by a much slower irreversible cyclization with the eventual formation of lithium allyl oxide (cf. ref. 2). Although precipitant-soluble product is produced in the polymerizations of AMA also, there is no change in allyl alcohol concentration from low to higher percentage conversions to polymer. Presumably there is no reaction in these systems between growing polymer chains and monomer carbonyl groups nor is there any complete sequence of reactions like the one shown in Fig. 6 to produce allyl alcohol. The substitution of a methyl group (AMA) for the hydrogen

For personal use only.

atom (AA) in the α-position to the acrylic double bond at which polymerization occurs may have the effect of preventing the inactive cyclic complex from undergoing true cyclization, just as it seems to prevent the reaction of a growing polymer chain with a monomer carbonyl group.

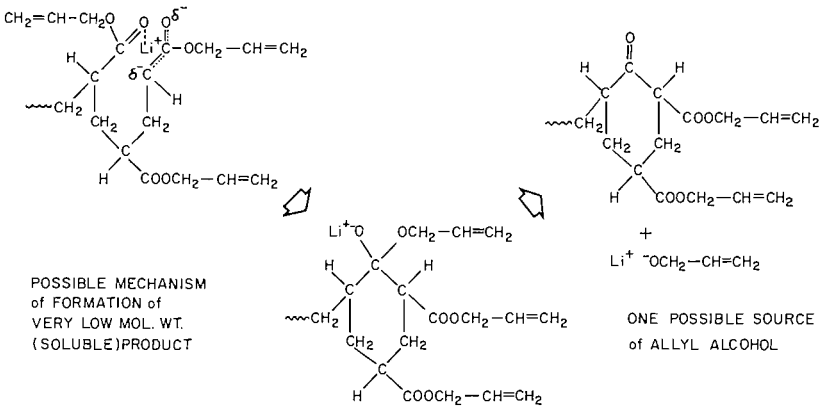

FIG. 6. A possible mechanism of lithium allyl oxide formation during AA chain propagation.

Other differences between AA and AMA (and their polymers) may also be the result of replacing an α-hydrogen with an α-methyl group. PAA has been found to cross-link slowly over a period of days at room temperature on exposure to air. PAMA on the other hand cross-links very rapidly under the same conditions. The polymerization of both monomers was attempted in tetrahydrofuran solution with DPHL initiator at −78 °C. In both cases a large proportion of the initiator led to the formation of precipitant-soluble product, a strong yellow color persisted until terminating agent was added, and allyl alcohol was present in the terminated reaction mixture. However, only with AMA monomer was a high molecular weight, precipitant-insoluble polymer formed.

The differences in crystallizability between highly isotactic PAA and PAMA presumably also arises because of the α-methyl group in each unit of the latter. It is relatively simple to induce sufficient ordering in the PAA such that a crystalline X-ray diffraction pattern is obtained. The same treatment of PAMA samples which have as high as 90% isotacticity does not provide sufficient ordering. There may be some connection between this situation and the observation (12) that butyllithium-initiated poly(methyl methacrylate), which may be highly isotactic if prepared in toluene solution at low temperatures, can not be crystallized by ordinary methods.

It can be assumed that the molar extinction coefficient which has been calculated (10) for poly(methyl methacrylate)-lithium in THF applies to the PAMA–lithium systems as well. This assumption would lead to the conclusion that approximately 1/3 of the DPHL initiator gives rise to growing PAMA chains, but this must be regarded as a rather unreliable estimate. A more accurate estimation of the number of growing chains in the polymerization systems being considered here would involve a calculation of the number of short chains in the precipitant-soluble products. Ordinarily the $\bar{M}_n$ of the material could be used for this purpose (cf. ref. 2), but in this work the values obtained were unacceptable. If both the weight and $\bar{M}_n$ values obtained were taken literally, the soluble material would account for more chains than there were initiator molecules added. The $\bar{M}_n$ values are believed to be too low because the soluble products (tacky, semisolids)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

could not be pumped to constant weight at an elevated temperature as was normally done (4). Such a procedure would have led to a cross-linked material insoluble in benzene, the solvent for $\bar{M}_n$ measurements. The weights of the soluble products are believed to be too high owing to the presence of lithium salts and perhaps a component such as allyl alcohol which was not completely removed by pumping overnight at room temperature. For these reasons the concentrations of growing polymer chains could not be estimated from the soluble-product data, and a complete kinetic investigation was not attempted.

THE PHOTOCHEMICAL DECOMPOSITION OF SODIUM AZIDE

P. W. M. JACOBS[1] AND A. R. TARIQ KUREISHY[2]
Department of Chemistry, Imperial College, London, S.W. 7, England
Received November 1, 1965

ABSTRACT

When sodium azide is irradiated with ultraviolet light the rate of photolysis at first decreases and then becomes constant. Two reaction mechanisms are involved: the first occurs only in salt which has not previously been irradiated, whereas the second requires the presence of metallic sodium. These two reactions are interpreted as the formation and linear growth of nuclei in the dislocation network of the salt and an equation developed from this model gives good agreement with the experimental results. Incorporation of Fe^{3+} ions in NaN_3 leads to a greater number of nucleus-forming sites.

When crystals of the inorganic azides are irradiated with light of wavelength corresponding to a characteristic absorption band of the solid, photochemical decomposition takes place according to the equation

$$2MN_3 + h\nu \rightarrow 2M + 3N_2.$$

The kinetics of the reactions may thus be followed by measuring the pressure of nitrogen evolved as a function of time. A preliminary study of photolysis of sodium azide (1) has shown that the reaction possesses unique features. The characteristic behavior of barium (2), strontium (1), and potassium (1) azides is that the rate of photolysis at first decreases with the time of exposure to ultraviolet light and then subsequently increases again, finally attaining a constant rate. The initial deceleratory process is absent in a second irradiation of the sample. The secondary acceleratory process may be prevented (1, 2) by inserting a water filter between the low-pressure mercury lamp and the reaction vessel, thus showing that the reaction is initiated by light of wavelength $< 2\,000$ Å. The absorption spectra (3) of sodium and potassium azides are, however, very similar and so it does not seem likely that the explanation for the lack of the acceleratory process in sodium azide lies in the energy band structure of the salt.

Because of this apparently anomalous behavior of sodium azide we have investigated its photolysis in greater detail. The analysis of these results has important implications in discussions of the mechanism of the photolytic decomposition of azides generally.

EXPERIMENTAL

The experimental technique has been described in a previous paper (2). Since it has been shown (1) that 'static' and 'dynamic' runs yield essentially the same results, only the 'static' method was used, the kinetics of the reaction being followed by measuring the change in the pressure of nitrogen in a constant volume system with a Pirani gauge. The initial pressure in the system was $< 10^{-6}$ Torr and the outgassing rate about 10^{-5} Torr/h. Details of the method of preparation of the four sodium azide samples used have been given in a paper on their thermal decomposition (4). Preserving the same labels (4), these were:

II: Commercial grade sodium azide (from Hopkin and Williams) twice recrystallized from aqueous solution.

III: Commercial grade sodium azide twice recrystallized from a solution acidified with hydrazoic acid.

V*a*, V*b*: Commercial grade sodium azide recrystallized from solutions containing respectively, 0.06 mole % and 1 mole % ferric chloride.

RESULTS

Effect of Impurities

Plots of the rate of photochemical decomposition of 200 mg samples of sodium azide II, III, V*a*, and V*b* against the total number of nitrogen molecules evolved are shown in Fig. 1. The runs were carried out at room temperature (24 °C) and the light intensity was 1.2×10^{15} quanta $cm^{-2}\,s^{-1}$, calculated on the basis of a 2 537 Å monochromatic source. For II, III, and V*a* the usual (1) deceleratory process is evident, the photolysis rate finally attaining a constant value. For the sodium azide more highly doped with Fe^{3+}, however, the rate at first increases, then becomes constant, and finally decreases slowly (not shown in the figure) in a manner similar to the other preparations. There is evidence for an initial acceleratory process in V*a* also, but this is not so well marked.

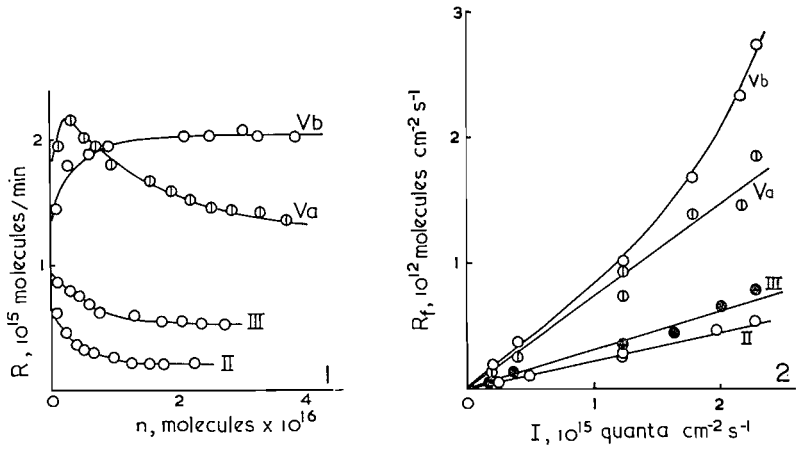

FIG. 1. Rate of photolysis R of 200 mg samples of sodium azide at room temperature and constant intensity as a function of n, the total number of nitrogen molecules evolved in the reaction. The methods used for the preparation of the azide samples are given in the text.
FIG. 2. Variation of the final constant rate of photolysis, R_f, with intensity of radiation.

The intensity dependence of the constant rate, R_f, is shown in Fig. 2. For II, III, and V*a* the plots of R_f against intensity are linear, but again V*b* behaved differently. By measuring the constant rate R_f at ice temperature also, the thermal activation energy E for the photolytic reaction was evaluated. The results were:

Sodium azide	II	III	V*a*	V*b*
E, kcal $mole^{-1}$	4.1	1.1	1.2	0

Kinetics

Plots of log $(R - R_f)$ against t are shown in Fig. 3, where R denotes the rate at time t and R_f is the final constant rate. Within the limits of experimental error, the points for preparations II and III scatter about the same line but those for the Fe^{3+}-doped sample V*a* lie on a different line of lower slope.

Quantitatively reproducible results were obtained when 400 mg samples of III were decomposed at room temperature. (The significance of the mass used is that it must be sufficient for the azide to cover the bottom of the silica reaction cell.) Plots of R against t for two different runs at the same temperature and intensity are shown in Fig. 4*a*. A series of runs at different intensities showed that both the initial and final rates, R_0 and

R_f, are proportional to the first power of the intensity (Fig. 5). The quantum yields for R_0 and R_f calculated from the slopes of these lines are 1.5×10^{-3} and 0.5×10^{-3} molecules of nitrogen per incident quantum, respectively.

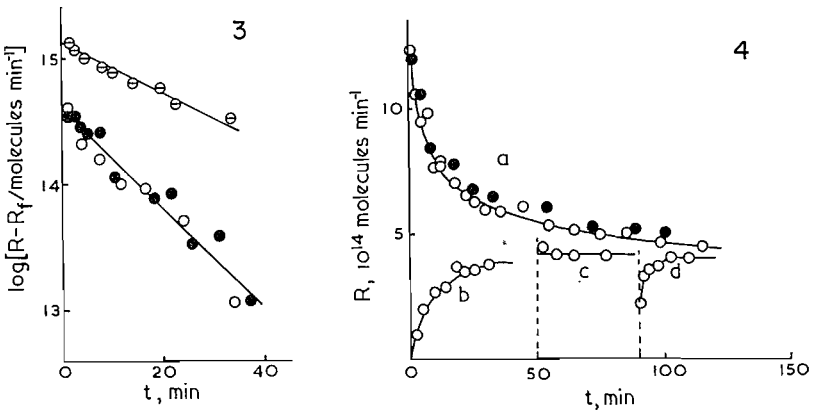

FIG. 3. Plots of log $(R - R_f)$ against time. (○) NaN_3 II; (●)III; (⊖) V*a*.
FIG. 4. Rate of photolysis of 400 mg samples of NaN_3 III at room temperature and constant intensity: (*a*) first run, showing reproducibility of the kinetics; (*b*) after 17 h exposure to gaseous products from first run; (*c*) after 2 h pumping in the dark; (*d*) after 1 h exposure to nitrogen.

Effect of Nitrogen

A sample of sodium azide was photolyzed until the rate of decomposition became constant (Fig. 4*a*). The decomposed sample was then left in contact with nitrogen for about 17 h in the dark. The variation of the rate of photolysis with time on resuming irradiation of the sample is shown in Fig. 4*b*. The rate starts at zero and rises to a constant value which is slightly lower than the previous constant rate. The lamp was then switched off and the sample left open to the pumps for 2 h. On re-irradiation photolysis commences at a rate which is slightly higher than the previous value (Fig. 4*c*) and it remains constant at this value. Fig. 4*d* shows that if the sample is left in contact with nitrogen for only 1 h the initial rate of photolysis is lower than the previous constant rate, but not zero, and that it rises more rapidly to the constant value.

DISCUSSION

Mechanisms

Previously (1, 2) we have associated distinct reaction mechanisms with the deceleratory and acceleratory reactions found in potassium, barium, and strontium azides. The primary deceleratory reaction occurs only in azides which have not been irradiated previously, whereas the acceleratory reaction is dependent on the presence of metal produced by the primary reaction. Since sodium azide does not show the acceleratory reaction, the question arises as to whether there are one or two mechanisms for the decomposition of the sodium salt. The results for successive irradiations of the same specimen (Fig. 4) show clearly that there are in fact two mechanisms and that the second of these, which is responsible for the constant-rate process, requires the presence of sodium metal. As in other azides the deceleratory reaction occurs only in the first run on a new sample. Successive runs either show a constant rate (Fig. 4*c*) or an accelerating reaction leading to a constant rate (Fig. 4*b*, *d*), depending on whether or not the sample has been exposed to nitrogen between irradiations. When the photolyzed azide is exposed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to nitrogen the gas evidently diffuses into the partly decomposed crystal and reacts with the metallic product. The extent of reaction is not determined by these experiments but it probably amounts only to chemisorption or surface nitridation, since macroscopic nitride formation requires much higher temperatures (4). This surface reaction is sufficient to prevent the catalysis of the photolysis by sodium metal until the metal has been reformed.

Absorption spectra (3) show that the primary process (1) is the production of excited azide ions N_3^{-*}. If these are adjacent to special sites S they may become trapped yielding the temporary species N_3eS, the electron e being shared between the trap S and the positive hole, N_3. Formation of a second excited azide ion then leads to decomposition, the whole process being represented by the equations

$$[1] \qquad N_3^- \overset{h\nu}{\rightleftarrows} N_3^{-*}$$

$$[2] \qquad N_3^{-*} + S \rightleftarrows N_3eS$$

$$[3] \qquad N_3^{-*} + N_3eS \rightarrow 3N_2 + \ominus e \ominus + S^-.$$

A combination of absorption spectra and electron spin resonance measurements (5) has shown that the F_2^+ center is the major product at low temperatures although F centers are also formed. At room temperature the F_2^+ center is unstable and forms a Na atom and two anion vacancies.

$$[4] \qquad Na^+ + \ominus e \ominus \rightarrow Na + 2\ominus$$

Whether or not the site S can hold an extra electron permanently depends on its nature. An impurity ion (e.g. Fe^{3+}) could be reduced but other sites (dislocation jogs) may prefer to shed it to form a second Na atom.

$$[5] \qquad S^- + Na^+ \rightarrow Na + S'$$

Nevertheless the site S′ will not be the same as before the reaction (S), since it is now associated with two sodium atoms and two anion vacancies. Repetition of this process r times leads to the *formation* of a stable nucleus of sodium. It is unknown as yet what value should be given to r; provisionally we assume that r is unity, that is, a single cycle of reactions [1] to [5] prevents the further functioning of the site S. The rate of nucleus formation is clearly a deceleratory process, since potential nucleus-forming sites S are being steadily consumed during the reaction.

The subsequent constant-rate reaction in the photolysis of sodium azide is due to the growth of these nuclei. After ultraviolet irradiation of sodium azide at room temperature, a broad absorption band (6) peaking at 3.60 eV is formed. This band is associated with the photoemission of electrons from sodium specks, which are probably filamentary in shape, the result of linear growth of the nuclei produced by the first process. Suppose a nucleus contains initially n atoms (where $n \sim 2r$). Then electrons may tunnel from excited azide ions to be trapped by nuclei which have become ionized by the light.

$$[6] \qquad Na_n \overset{h\nu}{\rightleftarrows} Na_n^+ + e$$

$$[7] \qquad N_3^{-*} + Na_n^+ \rightarrow Na_n + N_3.$$

Either by a repetition of [6] and [7], or by the reaction of an excited azide ion and a positive hole,

$$[8] \qquad N_3^{-*} + N_3 \rightarrow 3N_2 + 2\ominus + e,$$

there are formed three molecules of nitrogen, two electrons, and two anion vacancies.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The electrons produced in reactions [6] and [8] are trapped by anion vacancy pairs forming (transient) F_2^+ centers which then react with Na^+ (eq. [4]) to form Na atoms, the net result being:

[9] $$Na_n + 2e + 2Na^+ \rightarrow Na_{n+2}.$$

Repetition of the cycle leads to *growth* of the nucleus.

Kinetics

A steady state analysis is only possible when all the original centers (S) have been converted to growth nuclei. Once this has happened there are a constant number (n_0) of nuclei, equal to the number of original sites S, and the rate of photolysis is given by

[10] $$d(N_2)/dt = p_6 n_0 I = k_2 n_0,$$

if reaction [7] is preferred to reaction [−6]. p_6 is the rate constant for the forward step in [6] and k_2 is a new constant equal to $p_6 I$. Equation [10] predicts a linear dependence of the final constant rate, R_f, on intensity, as found experimentally (Figs. 2, 5). The converse assumption, reaction [−6] more important than reaction [7], does not lead to a rate linearly dependent on intensity (7).

To analyze the initial process, let r_j denote the rate of the elementary step j; then the rates of the forward and reverse steps of reactions [1]–[3] can be placed in order intuitively as $r_1 > r_{-1} \gg r_2 \gg r_{-2}, r_3$, if we accord a long lifetime to the excited state N_3eS. If this is correct, it follows that the rate of consumption of sites is

[11] $$-dn/dt = (p_3 p_1 I/p_{-1})[N_3^-]n_S = k_1 n_S,$$

where p is the rate constant for the jth step and k_1 is a constant at constant I because the consumption of N_3^- available is negligibly small. Equation [11] predicts that the initial rate $R_0(n_s = n_0)$ is proportional to I (Fig. 5) and that there will be a unimolecular decay in the number of sites at which this reaction can occur.

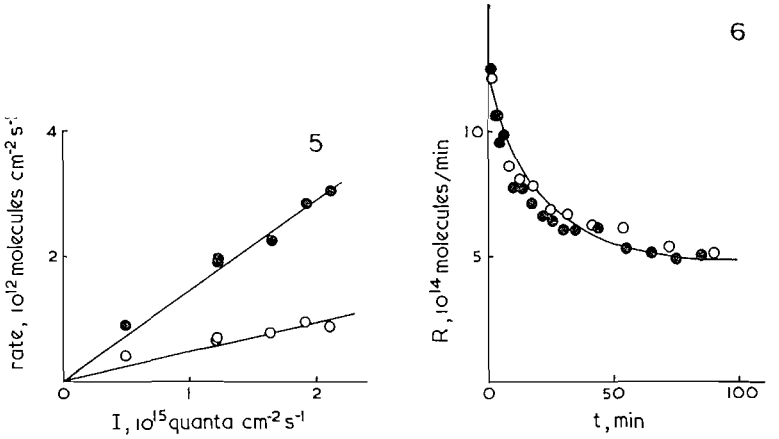

FIG. 5. Intensity dependence of the initial (●) and final (○) rates of photolysis of sodium azide.
FIG. 6. Rate of photolysis of NaN_3 as a function of time, showing the fit of eq. [15].

The kinetics of the photolysis of sodium azide may now be analyzed in terms of the nucleation and growth processes. There are n_0 potential nucleus-forming sites which are being transformed into growth nuclei at a rate given by the unimolecular decay law, the rate constant for this process being k_1. Since nuclei are postulated to grow linearly at a constant rate, a nucleus formed at time y will have attained a size $k_2(t - y)$ at time t.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

There will be $n_0k_1 \exp(-k_1y)$ such nuclei. If n denotes the total number of nitrogen molecules produced by reaction in time t and n_1, n_2 are the numbers of molecules produced by the nucleation and growth mechanisms respectively, then

$$[12] \qquad n = n_1 + n_2 = 3n_0(1 - e^{-k_1 t}) + \int_0^t n_0k_1 e^{-k_1 y} k_2(t - y)\, dy.$$

On integration

$$[13] \qquad n = 3n_0(1 - e^{-k_1 t}) + (n_0k_2/k_1)(e^{-k_1 t} + k_1t - 1)$$

and therefore

$$[14] \qquad R = dn/dt = 3n_0k_1 e^{-k_1 t} + n_0k_2(1 - e^{-k_1 t}).$$

When $t = 0$, $R_0 = 3n_0k_1$ and when $t \rightarrow \infty$, $R_f = k_2n_0$. Substituting these values in eq. [14] and rearranging gives

$$[15] \qquad R - R_f = (R_0 - R_f) e^{-k_1 t}.$$

Equation [15] predicts that log $(R - R_f)$ should be a linear function of the time t. The photolysis data are in reasonable accord with this prediction (Fig. 3). From the slopes of such plots, and the values of the initial and final rates, the three constants k_1, k_2, and n_0 may be evaluated.

Figure 3 shows that the nucleation constant k_1 is the same for NaN_3 precipitated from alkaline and acid solutions and that the difference in rates is due primarily to a difference in n_0. Thus OH^- appears to poison some of the potential nucleus-forming sites. For the Fe^{3+}-doped sample, n_0 is higher still (some 4 times larger than for NaN_3 III) but k_1 has half its value for the undoped azides. Thus in NaN_3 containing Fe^{3+}, it is more difficult to nucleate the sites, but the larger number of them means that the overall reaction rate is higher.

TABLE I

Values of the nucleation rate constant k_1, growth rate constant k_2, and number of sites n_0 for 400 mg samples of NaN_3 III

Intensity, 10^{14} quanta cm^{-2} s^{-1}	$k_1 \times 10^4$, s^{-1}	$k_2 \times 10^4$, s^{-1}	$n_0 \times 10^{-16}$
5.0	5.5	7.0	0.6
12.3	7.7	8.3	1.0
12.3	7.7	7.9	0.9
16.6	10.9	11.3	0.8
19.2	10.4	10.3	1.1
22.1	11.6	10.0	1.0

Values of the constants for 400 mg samples of NaN_3 III decomposed at different intensities are given in Table I. The values are significant more for their order of magnitude than for the actual values quoted; nevertheless it may be seen that n_0 is independent of intensity whereas k_1, k_2 increase with increasing intensity (eqs. [10], [11]). The order of magnitude n_0 is $1\text{–}2 \times 10^{18}$ per mole or 1 in 4×10^5. This is a reasonable result for the number of nucleus-forming sites, but unfortunately does not identify them unequivocally. Nevertheless, we favor a model in which nucleation occurs at sites along dislocations whereupon the nuclei grow one-dimensionally, in both directions, along the dislocations. It would be hard to justify one-dimensional growth (an essential feature of the model) ssociated with point defects, for example. There are 6.7×10^{14} ion pairs per cm^2 in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

NaN_3 so that, if the nucleation sites are points on dislocations, this would imply a dislocation density of $10^9/cm^2$. Dislocation counts of $10^5/cm^2$ have been recorded (8) for well-annealed ionic crystals, whereas a density of 10^{12} dislocations $/cm^2$ can occur in cold-worked metals (9). The calculated value, though high, would thus not appear unreasonable for NaN_3 precipitated as a mass of fine crystals. The dislocation model is the basis for eq. [14] and to show how well this equation is capable of representing the data we have calculated R from the values of the constants in Table I. This line is shown, together with data points for two runs, in Fig. 6. The dislocation model is also applicable to the thermal decomposition (4) of NaN_3, though at elevated temperatures the nuclei spread very rapidly along the dislocations and then grow two-dimensionally into the regions of good crystal surrounding the dislocations.

The effect of doping with Fe^{3+} can also be understood in terms of our model. The experimental results show that (i) n_0 increases, (ii) k_1 is reduced, and (iii) there is an initial acceleratory process (Fig. 1). An increase in n_0 is to be expected if Fe^{3+} ions incorporated along the dislocations act as nucleation sites. A change in k_1 the nucleation rate constant is to be expected with change in site, but one cannot say a priori whether nucleation will be easier or more difficult at the Fe^{3+} sites. However, p_1, p_{-1} should not be affected since they involve only the transition probabilities between ground and excited states of the azide ion. A decrease in k_1 thus means a decrease in p_3. This may indicate that the Fe^{3+} ions are complexed.

Equation [11] only applies once the traps are filled and for undoped azide this process (eq. [2]) takes place too rapidly to be distinguished. For the Fe^{3+} -doped samples, however, the initial process is visible because it takes longer to fill the greater number of traps. Thus additionally p_2 might be smaller at Fe^{3+} sites.

ELECTROLYTIC FORMATION OF LIVING POLYMERS FROM STYRENE

B. L. FUNT, D. RICHARDSON, AND S. N. BHADANI
Department of Chemistry, University of Manitoba, Winnipeg, Canada
Received November 16, 1965

ABSTRACT

Electrolysis of solutions of styrene in tetrahydrofuran produced living polymers and the typical colors of the living anions were observed. $NaAl(C_2H_5)_4$ and $NaB(C_6H_5)_4$ were each found suitable as conducting electrolytes.

When naphthalene was added to the solution in the absence of monomer the green sodium naphthalene complex was produced by electrolysis. Upon the addition of styrene monomer the orange living polystyryl anions were formed immediately. These changes were followed spectrophotometrically.

At the anode a terminating species was formed in a corresponding ratio to the living ions generated at the cathode. A mixing of the anode and cathode solutions resulted in a destruction of the living species and decolorization of the solution. The substances responsible were believed to be $Al(C_2H_5)_3$ and $B(C_6H_5)_3$ for the corresponding salts.

Possible mechanisms for the electro-polymerization reaction are proposed and discussed.

It is now generally recognized that the passage of an electrolytic current through a suitable solution of monomer can produce species which will initiate polymerization (1–4). Although the majority of investigations have been confined to free radical polymerizations (1, 2, 5–9), a significant number of reports of anionic polymerization initiated electrolytically have appeared. Most of these studies were performed in polar organic solvents, such as dimethyl formamide (3, 4, 10), which react readily with polymeric anions. The characteristic colors of the 'living' carbanions were never, therefore, observed in such systems, nor did polymerization continue after the cessation of current passage.

The first report of the production of 'living' polymers by an electrolytic method must be attributed to Yamazaki, Nakahama, and Kambara (11), who used tetrahydrofuran as solvent, and lithium aluminium hydride or sodium aluminium tetraethyl as electrolyte, for the polymerization of α-methylstyrene. Passage of an electric current through the solution did not immediately yield polymer, but rather a deep-red solution of the 'living' anion in the cathode compartment of a divided cell. Cooling the cell to -80 °C resulted in almost quantitative yields of high molecular weight polymer ($\sim 10^4$). From a comparison of the calculated with experimental molecular weight the authors concluded that the polymerization propagation mechanism was identical with the living polymerizations described by Szwarc (12). Further, the reduction potentials indicated that the initiation step proceeded by a direct electron addition to the double bond of α-methylstyrene.

In this paper we report investigations of the polymerization of styrene by a living anionic mechanism. It was expected that the charge transferred at the electrode could be correlated with the number of living anions produced in the solution. In the ideal case each electron transferred at the cathode would result in the formation of a living end, the concentration of which can be readily determined by absorption spectrophotometry. This living anion concentration, in turn, determines the kinetics of the reaction and the molecular weight of the product. Thus the estimation and control of the population of living ends could be expected to yield a new insight into the kinetics of the reaction and a refined control over the progress of the polymerization.

Inasmuch as this represents the first full reort of a living anionic polymerization with electrolytic control, a relatively complete description of the experimental technique is included.

EXPERIMENTAL

The complete absence of both oxygen and water is desirable in polymerizations of this type, and in endeavoring to achieve this, all materials were handled in vacuum or under an atmosphere of purified nitrogen.

The nitrogen was purified by passing it through a liquid nitrogen trap, columns of potassium hydroxide, heated copper turnings, a further liquid nitrogen trap, a silica gel column, a magnesium perchlorate column, and glass wool to remove dust.

The solvent tetrahydrofuran (THF) was refluxed over calcium hydride for over 24 h and distilled into a flask containing lumps of sodium. To this was added 10–20 mg of recrystallized naphthalene, and the flask was fitted to the reflux condenser of the vacuum system. With the pressure release open, refluxing was continued until formation of sodium naphthalene complex, characterized by the appearance of a dark green color. Following this the THF solution of sodium naphthalene was thoroughly degassed by alternate freezing and thawing, with pumping to the main vacuum line at 10^{-6} mm Hg. The THF solvent was then distilled under vacuum to a storage bulb coated with a fresh sodium film. When required it was distilled into an evacuated graduated tube.

The styrene, supplied by Matheson, Coleman and Bell, was first carefully fractionated under reduced nitrogen pressure. Finely ground calcium hydride was added and the mixture was stirred magnetically for about 16 h, all the while being attached to the vacuum line. The mixture was degassed by occasionally flashing to the backing pump. Further to this it was flash-distilled past a sodium-coated bulb to a flask containing calcium hydride. On warming, the styrene was quickly distilled into a vessel provided with several break-seals, degassed several times, and sealed from the line. The container was stored at −20 °C in the dark and, when required, styrene was transferred under vacuum via a break-seal to a graduated tube.

Whenever possible, glassware was thoroughly flamed under vacuum before use.

Electrolytes

$NaAl(Et)_4$

The $NaAl(Et)_4$ was prepared according to the following reaction (13).

$$3Na + 4Al(Et)_3 \rightarrow 3Na[Al(Et)_4] + Al\downarrow$$

The apparatus used is shown in Fig. 1. An excess of freshly cut sodium was placed in a 500 ml flask which was then attached by a Teflon joint, A, to the $Al(Et)_3$ container, I. Benzene was pumped off the sodium and the tube to the container was evacuated via B, which was connected to a backing pump. When sufficient alkyl had been added E was closed. From time to time the flask was opened to the pump momentarily at B. Eventually the sodium became coated with aluminium and the reaction almost ceased. To reactivate it the temperature of the flask was raised to >100 °C and further reaction took place in a homogeneous molten phase. At the completion of the reaction the flask and contents were allowed to cool, removed at A with C and D closed, and transferred to the dry-box; the $NaAl(Et)_4$ product was removed by crystallization from freshly distilled benzene. After further recrystallizations the product was pumped on the vacuum line for several hours, yielding white crystals. The storing and all subsequent handling of the electrolyte was performed under a nitrogen atmosphere in the dry-box.

$Na(C_6H_5)_4B$

This was acquired from Fisher (99.7%) and used without further purification as all attempts to recrystallize it from aqueous acetone failed (14).

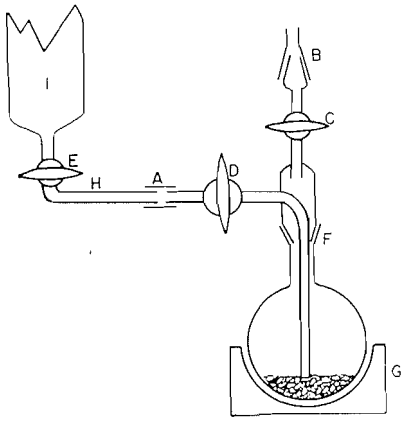

FIG. 1. Apparatus for preparation of $NaAl(Et)_4$: A, Teflon connector; B and F, B-24 joints C and; D Teflon-plug stopcocks; E, metal tap; G, heating mantle; H, copper tubing; I, $Al(Et)_3$ cylinder.

Experimental Procedure

All the early investigations were performed in the cell shown in Fig. 2, hereafter referred to as the single cell, since there is no separation of anode and cathode compartments.

With reference to the figure, A is a glass-enclosed magnetic stirring bar, BB are 1 × 1 in. platinum electrodes, D is a 1.0 cm quartz optical cell joined to the reaction vessel by a Pyrex-to-quartz graded seal, CC are tungsten electrode leads which make a vacuum tight seal with glass and appear to be inert to the reaction components, and E is a glass constriction. The reaction vessel itself is of Pyrex glass. In later experiments it was found necessary to use a divided cell of the type shown in Fig. 3.

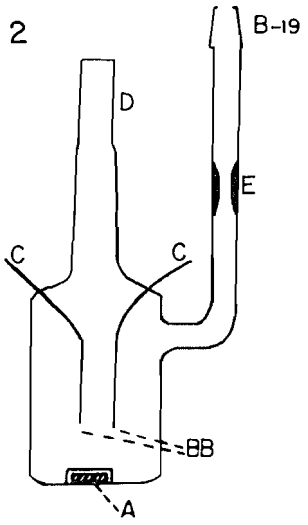

FIG. 2. Single cell.

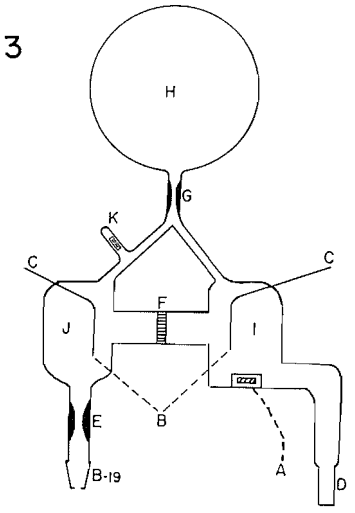

FIG. 3. Divided cell.

This figure bears the same notation as for Fig. 2 with the additions: F is a coarse porosity sintered glass disc, G is a further constriction, H is a 100 ml flask, I is the cathode compartment, J is the anode compartment, and K allows for a break-seal attachment. In addition, provision was made for the insertion of a 9 mm quartz spacer into the optical cell.

The experimental procedure involved charging the vessel with a weighed quantity of electrolyte through the B-19 joint, in the dry box under completely anhydrous conditions. Transfer of the vessel to the vacuum line in the absence of air was facilitated with a joint–stopcock–socket arrangement. The vessel was subsequently pumped on the vacuum line for several hours until the pressure, as recorded on the McLeod gauge, was 10^{-5}–10^{-6} mm Hg. Measured quantities of THF solvent and styrene monomer were distilled in from graduated tubes on other parts of the line and the vessel was sealed off at E. The contents of the flask H or the single cell were thoroughly mixed at room temperature. Inversion of the divided cell filled the anode and cathode compartments, J and I, with solution above the level of the electrodes, and the flask H was sealed and removed. The tube between the two compartments was intended to equalize the vapor pressures. The total volume of the single cell was approximately 50 ml and that of the double cell 100 ml.

After equilibration of the cell to room temperature a current was supplied from a constant direct current supply (0–16 mA at 0–600 V), stirring being maintained by the magnetic stirring bar, A. The progress of the electrolysis was followed optically on a Beckmann DB spectrophotometer, coupled with a pen recorder. The increase in optical density in the 340 mμ region of the spectrum caused by the CH_2—$CH(PH)^-$ Na^+ ion-pair in THF solvent was measured. Any attempt to measure the decrease in concentration of styrene from the characteristic absorption maxima in the 291 mμ region of its spectrum was prevented by a broad background absorption in this region. This may be seen from Fig. 4, which shows the absorption curves of a 0.012 *M* solution of $NaAl(Et)_4$ in THF before and after electrolysis.

RESULTS AND DISCUSSION

Preliminary investigations of the formation of living polystyryl anions were conducted in the cell shown in Fig. 2 with $NaAl(Et)_4$ as electrolyte. The characteristic orange color of the ion was formed at the cathode surface, but the solution became quickly decolorized with stirring. Only at very high viscosities, where diffusion was obviously a limiting factor,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was there any prolonged persistence of the characteristic color. Nevertheless in all these single cell experiments polystyrene was formed at high electrical efficiencies.

To investigate the nature of the polymerization process in greater detail, the divided cell shown in Fig. 3 was constructed. The cathode and anode compartments of this cell were separated by a sintered glass disc. Under these conditions a colored solution was formed in the cathode compartment and the color persisted for long periods of time after the current was switched off. Obviously living polystyryl anions were formed and were not being terminated. In the same cell the anode compartment was colorless and no polymer was recovered from this region. The nature of the species responsible for the destruction of the living ions is still indeterminate. Experiments have shown, however, that the color can be discharged by mixing the anolyte into the cathode compartment or by pouring the living ions into the anolyte solution. As expected the color was also discharged by exposing the solution to the atmosphere. The fact that color persists longer in the solutions which are more viscous and which have been subjected to greater electrolysis suggests that there is no buildup of any quenching impurity and that it is likely that the living ions and the killing species are formed in a 1:1 ratio in the electrolysis.

The divided and single cell experiments were repeated with $Na(C_6H_5)_4B$ with exactly the same results as for $NaAl(Et)_4$. The color formation and destruction follow the same pattern for the two different electrolytes.

Attempts to measure the optical spectrum of the polymer solution in the divided cell were aborted by the difficulties encountered in rendering the solution homogeneous. The polymerization tends to be heterogeneous in nature and the polymer formed at the cathode surface dissolves slowly in the solution.

In addition to direct formation of living polystyryl anions subsidiary experiments were performed in which naphthalene was added to the electrolyte solution. After a period of electrolysis the green color typical of sodium naphthalene was obtained. Its spectrum was considered to be identical with that of the complex formed by conventional methods (15). On the addition of styrene to this solution, the green color changed very rapidly to orange and then quickly decolorized. No polymer was extracted from the mixture. In the presence of styrene, it is of interest to note that on prolonged electrolysis the sodium naphthalene spectrum was again eventually obtained, but no polymer was isolated.

These experiments could suggest that the styrene added was impure and that the impurities prevented the formation of the living polystyryl anions. To check this possibility the styrene was added to conventionally prepared sodium naphthalene and there was an immediate and lasting formation of the characteristic color of the anion. Thus, again, the existence of a species which interfered with the polymerization was confirmed, even though this did not apparently interfere with the formation of sodium naphthalene itself.

When these experiments were repeated using a divided cell, the sodium naphthalene complex was formed in the cathode compartment. Its optical absorption spectrum is shown in Fig. 5, and is considered to be identical with the one obtained by Szwarc (15) using a conventional technique. Addition of styrene to the cathode compartment caused a rapid and lasting conversion to the living polystyryl anions, with their characteristic color (Fig. 6).

A further experiment was performed with $(Bu)_4NBr$ as electrolyte in the presence of naphthalene and, though a green color formed slowly, its absorption spectrum could in no way be reconciled with that in which an alkali metal acted as counterion.

Our information is not sufficiently complete to enable us to formulate a detailed reaction mechanism to explain the polymerization process. However, enough is known to delineate the more likely possibilities.

FIG. 5. Absorption spectrum of solutions of naphthalene and $Na(C_6H_5)_4B$ in THF versus a THF reference: ○, after electrolysis for 14 min at 5.9 mA; ●, before electrolysis. The broken curve represents the differential spectrum.

FIG. 6. Spectrum of living polystyryl anions obtained on the addition of styrene to the cathode solution shown in Fig. 5. The solid curve represents the absorption spectrum, and the broken curve the differential spectrum relative to that of the solution before electrolysis.

If initiation proceeds at the cathode by the transfer of an electron from an electron donor, whether this be the electrode or sodium metal, then the end result for styrene is the same, namely the formation of a primary radical ion $\dot{M}^-$.

Following this step there are two possibilities of further reaction (16).

[i] $$C_6H_5CH{=}CH_2^- + C_6H_5CH{=}CH_2 \rightarrow \cdot CH(C_6H_5){-}CH_2{-}CH_2{-}CH(C_6H_5)^-$$

Thus a dimer is formed upon addition of one monomer molecule. This dimer possesses one "true" radical end and one "true" carbanion end and may grow in further polymerization by mechanisms involving both centers.

[ii] $$2CH(C_6H_5){=}CH_2^- \rightarrow {}^-CH(C_6H_5){-}CH_2{-}CH_2{-}CH(C_6H_5)^-$$

Monomeric radical ions $\dot{M}^-$ may also dimerize and form dimeric dicarbanions which may continue their growth by an anionic mechanism only.

Any initiation process which gives rise to a relatively high concentration of radical ions, e.g. homogeneous initiation by sodium naphthalene, favors mechanism [ii], the formation of dicarbanions. On the other hand, slow heterogeneous initiation by metallic mirrors, particularly if carried out at high monomer concentrations, favors mechanism [i], with the formation of dimeric radical ions.

At the anode the following process has been postulated by Ziegler (13, p. 251).

$$Al(Et)_4^- - e \rightarrow Al(Et)_4 \rightarrow Al(Et)_3 + \cdot Et$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Disproportionation of ethyl radicals to form ethane and ethylene would be expected, but no gas evolution whatsoever is observed in these polymerizations, though this may reflect the solubility of the gases in the solution. It seems likely that the $Al(Et)_3$ or, in the case of $Na(C_6H_5)_4B$, the $B(C_6H_5)_3$ formed represent suitable terminators for the anionic polymerization of styrene.

We are not yet able to distinguish between the two initiation processes, but favor mechanism [ii]. The fact that polymer is formed in good yield and at high electrical efficiency in the single cell might be explained by radical growth of the radical anion formed by mechanism [i], the anion end having been terminated by anode products. This is unlikely, as previous work has shown that both current efficiencies and rates of polymer formation are low in radical polymerization (1, 2). On the other hand, a dianion propagation mechanism could only be possible if the individual polymer chain grew to its final length before termination. Although the living ions may have a short existence, new species are continually being formed at the electrode and a high current efficiency may still be consistent with the mechanism. It is, however, possible that both mechanisms contribute to the overall polymerization process.

In conclusion the experimental findings demonstrate that polystyryl anions are produced via electron transfer processes at the cathode, and their concentration can be controlled by the impressed current. The influence of added naphthalene on the course of the reaction is not clear, but the electrolytic formation of sodium naphthalene complex has been established in this work. Further work on the quantitative aspects of the kinetics of the polymerization is in progress.

ABSTRACT

The infrared spectra (4 000 to 200 cm^{-1}) of some trimethylphenyl-, dimethyldiphenyl-, methyltriphenyl-, triethylphenyl-, and diethyldiphenyl-arsonium salts have been recorded. Vibrational assignments have been made for the quaternary 'onium cations and have been compared with those for related compounds including one alkylarylgermane.

The vibrational spectra of some simple alkylarsonium cations have been recorded and assigned previously (1). The present paper reports an extension of the work to some salts of mixed alkylarylarsonium cations, for which infrared spectral data have been obtained over the range 4 000 to 200 cm^{-1}. Assignments have been made by reference to those for the alkylarsonium compounds (1) and to those made by one of us (2) for dimethylphenylarsine, methyldiphenylarsine, and triphenylarsine. They are consistent with partial assignments previously reported for the methyltriphenylarsonium cation and triphenylarsine (3).

RESULTS AND ASSIGNMENTS

Trimethylphenylarsonium Salts

The infrared spectra of three trimethylphenylarsonium salts are given in Table I together with the assignments. All the bands are attributable to the 'onium cations and show only small variations with the nature of the anion. The assignments are considered first in terms of the alkyl groups and skeleton, and then in terms of the phenyl group and the phenyl–arsenic modes.

The skeleton of the cation has C_{3v} symmetry and the $(CH_3)_3As$ group therefore has infrared active modes as follows: CH_3 asym. stretch $(a_1 + 2e)$; CH_3 sym. stretch $(a_1 + e)$; CH_3 asym. deformations $(a_1 + 2e)$; CH_3 sym. deformations $(a_1 + e)$; CH_3 rock $(a_1 + 2e)$; CH_3—As stretch $(a_1 + e)$; CH_3—As—CH_3 deformations $(a_1 + e)$, and CH_3 torsion (e). While the effect of the phenyl group might be to lift the degeneracies of the e class modes, the spectra do not reveal this for the internal methyl modes. From the results (1) for the tetramethylarsonium ion, the assignments of Table I follow readily. For $(CH_3)_4As^+$, the methyl rocking modes are evidently coincident at about 924 cm^{-1}, whereas in the trimethylphenylarsonium salts they are clearly resolved into at least three bands. Likewise, the CH_3—As—CH_3 deformation modes, not detectable above 200 cm^{-1} in the infrared spectrum of the tetramethylarsonium ion (1), are both seen in $(CH_3)_3(C_6H_5)As^+$, where they are assigned by comparison with trimethylarsine (4). No assignment is made here for the CH_3 torsion.

INTENSITIES: s, strong; m, medium; w, weak; v, very; br, broad.

The phenyl vibrations fall into two groups: firstly those whose positions change little with mass and nature of the substituent, and secondly the 'X-sensitive' modes. (We use the notation of Whiffen (5) for the symmetry and form of the phenyl modes, but with the recommended (6) orientation of axes for C_{2v} symmetry.) The assignments follow from those for dimethylphenylarsine (2) and only a few points require comment. The region 1 250 to 1 340 cm^{-1} is rather confused in several phenyl derivatives, and in the present compounds the methyl symmetric deformations also occur here. These are taken as coincident at 1 268 cm^{-1}. There remain three bands to be allocated to two fundamentals, both in the b_2 class, and the choice made (cf. refs. 2 and 5) leaves the band at 1 310 cm^{-1}, which can be satisfactorily explained as either of two possible transitions to a b_2 level: 275 + 1 027 = 1 302 and 395 + 905 = 1 300. Three out-of-plane C—H deformations, γ(CH), are to be expected near 990(b_1), 960(a_2), and 905(b_1) cm^{-1}, but only what is probably the first of these is observed, in one salt only. The others are probably obscured by the CH_3 rocking absorptions. A fourth γ(CH) mode is expected around 840 cm^{-1}, but in all the spectra this absorption is too intense to be due to this fundamental alone and is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

considered to derive from the third CH_3 rocking mode. The a_1 'X-sensitive' modes q and t are shifted by some 10 cm^{-1} to higher wavenumbers relative to their positions in dimethylphenylarsine (2) and a third such mode (r) is believed to have shifted to at least the same extent and become obscured by the strong band at 690 cm^{-1} (see Discussion). Thus all the fundamentals expected in the recorded region are accounted for; there remains the lowest b_1 mode, the 'X-sensitive' mode x, which is probably below 200 cm^{-1}.

Dimethyldiphenylarsonium Triiodomercurate(II)

The infrared spectrum of this salt is given in Table II together with the assignment and that (7) of dimethyldiphenylgermane, which is based on the available infrared and Raman spectra (8). The skeleton of the cation has C_{2v} symmetry and the $(CH_3)_2As$ group will therefore have infrared active modes as follows: CH_3 asym. stretch ($a_1 + b_1 + b_2$); CH_3

sym. stretch ($a_1 + b_2$); CH_3 asym. deformations ($a_1 + b_1 + b_2$); CH_3 sym. deformations ($a_1 + b_2$); CH_3 rock ($a_1 + b_1 + b_2$); CH_3—As stretch ($a_1 + b_2$); CH_3—As—CH_3 deformation (a_1); and CH_3 torsion (b_1). Assignments for all of these fundamentals can be made, but for the internal modes the components are not all resolvable. (Examined as a disc in potassium chloride, the spectrum of the compound showed additional splitting of several bands, but the mean positions agreed well with the listed (mull) values.)

On the basis of C_{2v} symmetry for the skeleton of the cation, the phenyl '*X*-sensitive' modes *q*, *r*, and *t* are expected to show splitting into a_1 and b_2 components, as observed in methyldiphenylarsine (2). While the doublet attributed to mode *q* may be due to a crystal field effect, that of mode *t* is to be compared with the 298/310 cm^{-1} doublet in the arsine. In $(CH_3)_2(C_6H_5)_2As^+$, *r* is again obscured by the very strong band at 690 cm^{-1}, though it may contribute to the shoulder at 680 cm^{-1}. The strength of the 840 cm^{-1} band is considered too great to be solely due to the γ(CH) (a_2) mode expected here and is believed to derive from the third methyl rocking vibration.

Methyltriphenylarsonium Compounds

The infrared spectra and assignments for the iodide and the tetraiodomercurate are given in Table III. The former, examined both as mulls and discs, shows very considerable splitting of the bands which suggests a different site symmetry for the cation in this salt from that in the tetraiodomercurate. Assignments of the modes of the single methyl group and of the CH_3—As stretching frequency are straightforward. The C_{3v} symmetry of the skeleton of the cation may result in splitting of the phenyl–arsenic modes into a_1 and *e* components, but this is observed only for the lowest mode (*t*) involving stretching of the C_6H_5—As bond.

Ethylphenylarsonium Compounds

The infrared spectra of triethylphenylarsonium and diethyldiphenylarsonium triiodomercurates are listed in Table IV, together with assignments made, so far as the ethyl group is concerned, with reference to these for $(C_2H_5)_4As^+$ and $(C_2H_5)_3(CH_3)As^+$ (1). Some overlapping of the ethyl frequencies with those of the phenyl group is found, but all the expected fundamentals can be assigned if the band intensities are considered. Thus, the band at 1 000 cm^{-1} is much stronger than in the corresponding methylphenylarsonium compounds owing to a coincidence of the C—C stretching of the ethyl group with the relatively weakly absorbing a_1 phenyl ring mode. Again, the shifted position of the methyl rocking modes compared with the methylphenyl compounds reveals the three γ(CH) modes near 973, 923, and 846 cm^{-1}, and the weakness of the last confirms that in the methyl compounds the intensity of the 840 cm^{-1} band derives from a methyl rocking mode. The strong γ(CH) band near 740 cm^{-1} has, in the ethyl compounds, shoulders attributable to the adjacent strong methylene rocking mode, observed at 738 cm^{-1} in the triethylmethylarsonium ion (1). Additional bands, observed at 345 and 324 cm^{-1} in the triethylphenylarsonium compound compared with $(CH_3)_3(C_6H_5)As^+$, are clearly due to the C—C—As deformation. Similarly, bands of the diethyl compound at 357 and 338 cm^{-1} are due to C—C—As deformation, whereas the band at 328 cm^{-1} may either be due to this mode, or to the second of the two possible components of vibration *t*. However, *q* is not split, whereas in $(CH_3)_2(C_6H_5)_2As^+$ both *q* and *t* show splitting.

DISCUSSION

The results of the present work enable a number of comparisons to be made among the frequencies of certain vibrations in these and related compounds. The relevant values are assembled in Table V, and the alkyl groups and skeleton are considered first.

It was shown previously (1) that the carbon–arsenic stretching frequencies are shifted to higher wavenumbers from $(CH_3)_3As$ to $(CH_3)_4As^+$. For purposes of comparison it is convenient to use the average value of the ν(C—As) frequencies weighted according to the degeneracies. For $(CH_3)_3As$ (4) and $(CH_3)_4As^+$ (1), this is 580 and 635 cm^{-1}, respectively. Replacement of successive methyl groups in $(CH_3)_4As^+$ by phenyl groups causes the value

to drop only to 632, 627, and 625 cm^{-1}, and implies very little change in the strength of the methyl–arsenic bond. Conversion of $(CH_3)_2(C_6H_5)As$ and $(CH_3)(C_6H_5)_2As$ to $(CH_3)_3(C_6H_5)As^+$ and $(CH_3)_2(C_6H_5)_2As^+$, respectively, increases the methyl–arsenic stretching frequency by at least 53 cm^{-1}. The changes in the methyl rocking frequencies follow the same trend, as do the much smaller changes in the methyl symmetric deformations. In the alkyl compounds (1) the increase in the ν(C—As) frequency on 'onium ion formation was found to be accompanied by a small but significant increase in the carbon–hydrogen stretching frequencies. The same effect is observed here in the mixed methylphenyl compounds, so that evidently 'onium ion formation again results in both stronger C—As and C—H bonding. Comparison of the frequencies of the dimethyldiphenylarsonium cation with those of the isoelectronic germane (Table II) shows that methyl–metal

§See text.

stretching, methyl rocking, methyl symmetric deformation, and carbon–hydrogen (of methyl) stretching frequencies are all higher in the cation than in the germane, as was found (1) for the corresponding tetramethyl compounds.

Stretching of the phenyl–arsenic bond makes contributions to all the a_1 'X-sensitive modes q, r, and t. Accordingly the shift of these vibrations to higher wavenumbers on 'onium ion formation is in accord with stronger phenyl–arsenic bonding in the cations than in the corresponding tertiary arsines. Both r and t are at higher frequencies in $(CH_3)_2(C_6H_5)_2As^+$ than in $(CH_3)_2(C_6H_5)_2Ge$. The findings and conclusions for the alkylarsonium salts (1) can therefore be extended to the mixed alkylaryl compounds, and the behavior of the phenyl–arsenic bond on 'onium ion formation parallels that of the methyl–arsenic bond.

Finally, it is to be noted that all the present compounds show strong absorption near 1 440 cm^{-1}, assigned to a b_2 ν(CC) mode. Similar intense absorption is generally found in the spectra of other phenyl–metal compounds (9 and references therein; 10 and references therein) and is not specific for a particular phenyl–metal link.

EXPERIMENTAL

The preparation of the majority of the compounds has been reported (11, 12).

Trimethylphenylarsonium iodide was obtained from the reaction of dimethylphenylarsine with methyl iodide and had m.p. 257° (lit. (13) m.p. 250°).

Anal. Calcd. for $C_9H_{14}AsI$: C, 33.4; H, 4.3. Found: C, 33.6; H, 4.6.

Bis(trimethylphenylarsonium) tetraiodomercurate (II) was obtained from the above iodide and mercuric iodide (14) and had m.p. 194–195° (lit. (14) m.p. 192°).

Anal. Calcd. for $C_{18}H_{28}As_2HgI_4$: C, 19.6; H, 2.5; Hg, 18.2. Found: C, 19.85; H, 2.6; Hg, 17.5.

Microanalyses were by Dr. A. Bernhardt.

Infrared spectra of the compounds as Nujol and hexachlorobutadiene mulls were obtained as described previously (1).

ACKNOWLEDGMENT

PREPARATION AND CHARACTERIZATION OF SULFONATED POLYSTYRENE LATEXES

F. S. CHAN AND D. A. I. GORING

Physical Chemistry Division, Pulp and Paper Research Institute of Canada, and Department of Chemistry, McGill University, Montreal, Quebec

Received October 26, 1965

ABSTRACT

The purpose of the work was the preparation of aqueous suspensions of model spherical particles stabilized by ionizable groups covalently bound to the surface. Starting material was a 80/20 styrene/divinylbenzene latex. The latex had an average particle diameter of 500 Å as determined in the electron microscope. The copolymer was sulfonated in dichloroethane with a 3/1 SO_3/triethylphosphate complex in a concurrent-flow fast-reaction apparatus and was purified by dialysis and ion exchange.

Three main fractions with neutralization equivalents, N_e of 0.9, 1.8, and 2.7 meq g^{-1} were prepared. Elemental analysis revealed that the varying N_e in these fractions resulted from the absorption of Ca^{2+} and Mg^{2+} ions which were tightly bound to the inner-lying sulfonic groups of the particles. Treatment with strong acid followed by ion exchange eliminated the bivalent ions and increased N_e, but the titration pattern was markedly changed after such treatment. Sulfonation caused both the partial specific volume and the refractive index increment to decrease. Electron micrographs showed that the latex particles were only slightly polydisperse and that there was little change in size and shape after sulfonation. Light-scattering measurements established the absence of aggregates in the sulfonated latex. Particle sizes, determined from the intrinsic viscosities, indicated some swelling of the particles in 1 *M* aqueous NaCl. The extent to which the sulfonated latex satisfies the criteria required of a model colloid to be used for a study of electroviscous behavior is discussed.

INTRODUCTION

The electroviscous behavior of polyelectrolytes is of fundamental importance in processes involving the interaction of colloidal materials and water. For experimental study, it would be useful to have a system of charged particles in which parameters such as size, shape, and potential are accurately known for all conditions of concentration and ionic strength of the aqueous medium. Results obtained would permit easier and more precise interpretation. The purpose of the present work is to prepare and characterize such a colloidal polyelectrolyte. Subsequent reports will deal with the investigation of the primary and secondary electroviscous effects by using this model system.

Certain desired features for the model particles are listed below.

Criterion No. I. Spheres of uniform size.
II. Macromolecular dimensions (200 – 2 000 Å in diameter).
III. Density near to that of water.
IV. Permanently stabilized in aqueous solutions by having strongly ionizable groups attached by covalent bonds to their surface.
V. Constant in size and shape over a wide range of ionic strengths.

The criterion of spherical shape is adopted because hydrodynamic theories are most complete for spheres. In addition, spherical particles are conveniently prepared. Despite their wide use, inorganic sols (1) usually violate criterion I by their irregular shape and polydispersity. Criterion II is necessary because of the much diminished electroviscous effect of the double layer with larger particles. Goldfarb *et al.* (2) recently prepared surface-charged spheres by emulsifying a mixture of molten paraffin and a long-chain surface-active compound. When the mixture was poured into cold water and fractionated by sieving and sedimentation, surface-charged paraffin particles with diameters of 3 and 10 μ were obtained. This particle size is much larger than the present requirement. Our attempts to use such paraffin sols have been unsuccessful because of a low yield in the

size range specified above. Schenkel and Kitchener (3) have described a "model suspension" consisting of spherical particles of cross-linked polystyrene which were sulfonated near the surface by a complex of SO_3/dioxane dissolved in dry dibutyl phthalate. However, the large particle size (10 μ) and the instability of the suspension would make this system unsuitable for the study of electroviscous effects.

The criterion of approximately aqueous density is needed to avoid settling due to the effect of gravity. In this respect, heavy metal sols (4), though spherical and monodispersed, may be unsatisfactory. Criterion IV establishes the condition that the number of charges attached to the particle is always well defined. A strongly ionizable group is preferred because weak acids are susceptible to hydrolysis and conversion of the salt into the corresponding undissociated acids (5, 6). Charged particles for hydrodynamic studies have been prepared by absorption of surface-active agents on latexes (7, 8) or emulsions (9, 10). But the tendency of the soap or stabilizer to desorb at low ionic strength (11) reduces the number of charges on the particle and renders the suspension unstable.

Exact knowledge of the size and shape of the particle is of primary importance in the interpretation of electroviscous effects. Hence the requirement of constant dimensions is listed as criterion V. A considerable variety of theory and experiment can be found in the literature dealing with the solution properties of polyelectrolytes. Such macromolecules are capable of large molecular expansion, and their configuration in solution may lie anywhere between that of a Gaussian coil and a rigid rod (12). The exact assignment of size and shape to the polyion is difficult. Therefore, linear polyelectrolytes cannot be regarded as being suitable models for a study of the primary and secondary electroviscous effects. The use of detergent micelles is also unsatisfactory because of the fluid interior and the possible decrease in size at low ionic strengths (13).

In the present investigation, the approach of Schenkel and Kitchener (3) was followed for the preparation of sulfonated latex particles of about 500 Å in diameter. The use of synthetic latexes has the advantage of yielding spheres of narrow particle-size distribution. The particle would be permanently stabilized by the sulfonic groups and, if heavily cross-linked, would retain its size and shape under all conditions of ionic strength. Also, the density of the dispersed phase would be similar to that of water. The drawback of this method appears to be the problem of avoiding coagulation and of limiting sulfonation to the surface of the particle. An attempt has been made to overcome these difficulties by use of a simple concurrent-flow fast-reaction apparatus, which allows reduction of the reaction time to less than 10^{-1} s. Also, sulfonation was carried out in an organic medium by the method of Turbak (14) to avoid coagulation of the latex by sulfone formation. This method is described in the first part of the paper. The second part of the paper deals with the characterization of the sulfonated latex particles with respect to their size, their shape, and the number of charges introduced. The methods used include potentiometric titration, elemental analysis, light scattering, electron microscopy, and viscometry. Finally certain anomalous properties of the sulfonated latex particles are described and the extent to which they satisfy the listed requirements is discussed.

PREPARATION

Starting Material

The starting material was a highly cross-linked styrene/divinylbenzene (80/20) latex kindly made for us by the Polymer Corporation, Sarnia, Canada,* with the characteristics given in Table I. The three lots

We are especially indebted to Drs. L. Brietman and W. G. Forbes for the gift of the samples without which the investigation would have been much more difficult. The electron micrographs and particle-size determinations described later in the paper were also made for us by Polymer Corporation.

For personal use only.

shown in Table I were thoroughly mixed in equal proportions and filtered through Whatman papers to remove the aggregated particles. The filtrate was freeze-dried and stored over magnesium perchlorate before sulfonation.

TABLE I

Characteristics of the styrene/divinylbenzene latexes

Code No.	% conversion	% stripped solids	Particle size (Å)
LB/7-1	74.5	27.8	486
LB/7-2	72.1	27.3	468
LB/7-3	73.1	29.9	495

Sulfonating Agent

Initial attempts were made to sulfonate the latex particles by use of concentrated sulfuric acid and chlorosulfonic acid. These reagents produced dark-brown agglomerates because of charring and the probable formation of sulfones which gave rise to cross-linking between particles. These difficuties were obviated by using the SO_3/phosphate complex system discovered by Turbak (14).

Reaction Apparatus

A fast reaction apparatus was constructed and used in the sulfonation of the latex particles. A schematic diagram of the apparatus is shown in Fig. 1. The reactants are mixed in a flat cylindrical chamber machined on the surface of a stainless-steel plate and covered with a Teflon block. The mixing chamber (diameter = 0.5 cm, thickness = 0.1 cm) is fed by four jets which deliver reactants tangentially thus imparting a rotary motion to the fluid in the chamber and down the reaction tube (length = 14 cm, inside diameter = 0.2 cm). The reaction is stopped by flow into a bath of vigorosly stirred quenching solution. The driving force is supplied by a cylinder of compressed nitrogen fitted with a precision automatic regulator to give a constant pressure of 5 p.s.i. Under such conditions, the total resident time of the reaction mixture in the mixing chamber and the reaction tube was approximately 10^{-1} s.

The reagent was prepared by adding freshly distilled liquid SO_3 (Sulfan B) dropwise to an agitated solution of triethyl phosphate in dichloroethane at room temperature. Before use, the dichloroethane was distilled over P_2O_5. The molar ratio of SO_3/phosphate was 3/1, and the percentage of the complex in dichloroethane was 2–4%. All glassware was thoroughly dried and the complex reagent was used within a few hours after

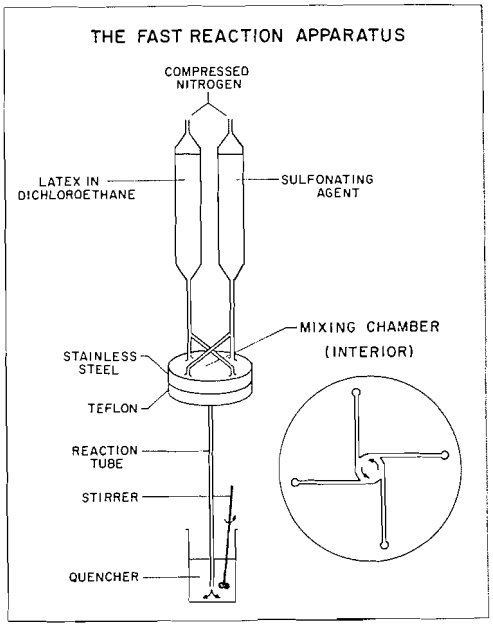

FIG. 1. Schematic diagram of the fast-reaction apparatus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

preparation to prevent deterioration due to the absorption of moisture from the atmosphere. Just before reaction, distilled dichloroethane was added to the freeze-dried latex particles to make up a solution of 0.5% by weight. Ultrasonic waves from an M.S.E. 60 W disintegrator operated at 20 kilocycles/s were passed through the solution for about 2 min to obtain a homogeneous dispersion. Electron micrographs of the ultrasonically treated latex showed that the particles were not damaged by this treatment.

Several types of quencher were tried. Some stopped the reaction by decomposition of the complex (water), others by formation of sulfonates (methanol, thiopene) or of non-reactive complexes (triethyl phosphate). The difference in their effectiveness seemed to be small. For all subsequent sulfonations, an aqueous solution containing enough NaOH for the neutralization of the reaction mixture was used as the quencher. The conversion of the sulfonic groups to the sodium form stopped the reaction and the resulting neutrality of the solution facilitated the purification process.

Purification

After the reaction was quenched, the sulfonated latex particles were found in the upper aqueous phase. The lower dichloroethane layer was removed in a separating funnel. Any remaining dichloroethane was evaporated off at 45 °C in a rotary evaporator. The aqueous suspension was then dialyzed in cellophane bags to remove excess inorganic ions and traces of low molecular weight impurities. To conserve distilled water, tap water was used in the initial stage of the dialysis. Finally, the solution was dialyzed for 4–6 d with 12 changes of distilled water, and then neutralized to pH 8 with carbonate-free sodium hydroxide. The product was a milky-white stable suspension of sulfonated latex particles which, when oven-dried at 110 °C, formed a feathery, translucent film. Freeze-drying produced white, fluffy, very fine powders. Both types of solid product could be redispersed instantaneously on addition of water to form a homogeneous, stable suspension having the same appearance as the sulfonated latex before drying.

Main Fractions

Considerable trial and error were applied to the fast-reaction method. Changes in the concentrations of the reactants and the flow rate were studied in an attempt to control the neutralization equivalent, N_e, of the sulfonated product. But in spite of great care in the preparation of the reagents, N_e varied unpredictably from batch to batch. It was then decided that the reaction was particularly sensitive to some unknown variable. Accordingly, 40 batches of the sulfonated latex particles were prepared. Each batch weighed about 2 g. The neutralization equivalent was determined (see "Characterization") for each batch, and was found to vary from 0.5 to 3.0 meq/g of solid. Based on their N_e values, the small batches were combined into three main fractions of about 25 g each, designated F1, F2, and F3. The maximum variation of N_e in each main fraction was ± 0.25 meq g^{-1}. An additional fraction, F4, was also prepared by simple mixing of the reagents without using the fast-reaction apparatus. In this case, the reaction time was increased to 2 h and the sulfonated latex had a slightly yellowish color. The main fractions were stored in aqueous suspensions in polyethylene bottles at -10 °C to avoid the growth of bacteria.

CHARACTERIZATION

Potentiometric Titration and Elemental Analysis

The sulfonated latex particles (hereafter designated as s.l.p.) were converted to the hydrogen form by a number of passes through a mixed-bed ion-exchange column (Rexyn 1-300, H–OH). The solution was titrated with carbonate-free 0.01 N NaOH by means of a Beckman model G pH meter with glass and calomel electrodes under an atmosphere of nitrogen, and pH readings were taken 2 min after each addition of titrant. Curve A in Fig. 2 is an example of the titration curves obtained. The shape of the curve is similar to that observed in the titration of strong mineral acids with NaOH. The neutralization equivalent was calculated from the amount of NaOH added at the equivalent point (pH = 8), and the weight of the solid was determined by evaporation of the solution to constant weight. Three or four determinations were made for each fraction and the mean values (average deviation from the mean = ± 0.05 meq g^{-1}) are given in the second column of Table II.

The sulfur contents determined in a Leco apparatus are given in the third column of Table II. Fraction F4 contains the highest percentage of sulfur, but the sulfur content is roughly the same for the other fractions which were sulfonated in the fast-reaction apparatus. All the sulfur contents are higher than the potentiometrically determined values of N_e. To check the efficiency of the ion-exchange column in converting the sodium sulfonate groups to the acidic form before titration, the sodium content of each fraction

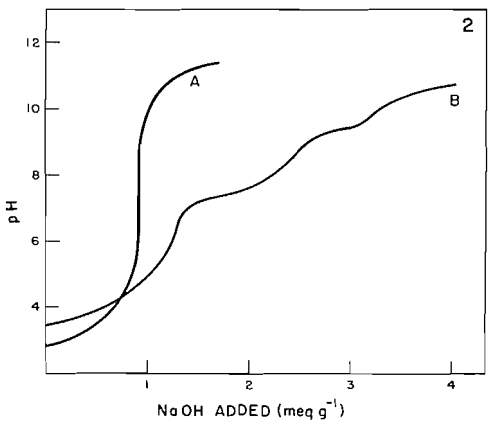
TABLE II
Analytical results (meq/g solid)

Fraction	N_e	Sulfur	Na (in neutralized latex)	Ca	Mg
Non-sulfonated	—	0	0.1	0.01	—
F1	0.9	2.6	0.9	2.2	0.6
F2	1.8	3.0	2.0	1.4	0.4
F3	2.7	2.8	2.7	0.8	0.3
F4	2.0	4.0	2.1	1.7	0.5

after passage through the column was determined in a Beckman DU flame spectrophotometer at $\lambda = 589$ mμ. No trace of sodium was detected in any of the fractions. Using the same method the sodium content of the neutralized s.l.p. was determined. As shown in the fourth column of Table II there is good agreement between the sodium content and N_e for all fractions.

The question then arises why the sulfur content should be higher than the neutralization equivalent of the sulfonic groups. Examination of the emission spectrum of the s.l.p. in the acid form revealed the presence of calcium ($\lambda = 554$ and 622 mμ) and magnesium ($\lambda = 370$ mμ); approximate amounts are given in the last two columns of Table II. The calcium and magnesium contents decreased from F1 to F3 in contrast with the trend of increasing N_e values.



Absorption of Bivalent Ions

The latex did not contain calcium or magnesium before sulfonation (Table II). The source of these bivalent ions was traced back to the tap water which was used in the initial stage of dialysis to remove the excess inorganic ions in the reaction mixture. The fact that the bivalent ions were not removed by later dialysis against distilled water and passage through the ion-exchange column was unexpected. To confirm this point, solutions of a fraction which contained no bivalent ion were dialyzed against $1.4 \times 10^{-4} M$ $Ca(NO_3)_2$ for different intervals of time. Values of N_e for the dialyzed s.l.p. were determined as previously after several passages through an ion-exchange column. The amount of Ca^{2+} ion immobilized in the s.l.p. was likewise determined by flame photometry. As shown in Fig. 3, the neutralization equivalent decreases to 0.4 meq g^{-1} after prolonged treatment with dilute calcium nitrate. In the opposite sense, the amount of bound calcium increases until it reaches a value about the same as N_e before dialysis. These results leave little doubt that the absorption of various amounts of bivalent ions led to the different values of N_e shown in Table II.

Attempts to remove the absorbed bivalent ions were first made by repeated passage through ion-exchange columns. Between each passage, the solution was shaken for at least 24 h in the hope that the absorbed ions would diffuse out by osmotic forces. But the method failed either to increase the neutralization equivalent or to reduce the calcium content of the s.l.p. Similarly, repeated electrodialysis against distilled water (15) did not remove the bound Ca^{2+} ions. These experiments illustrated how strongly the bivalent ions were held by the s.l.p.

When the s.l.p. was treated with an excess of 0.5 M HCl which was subsequently removed by ion exchange, the emission spectrum of the acid-treated s.l.p. showed almost complete absence of calcium and magnesium. Titration curves of the s.l.p. after acid treatment were flatter and exhibited more than one inflection point. An example is

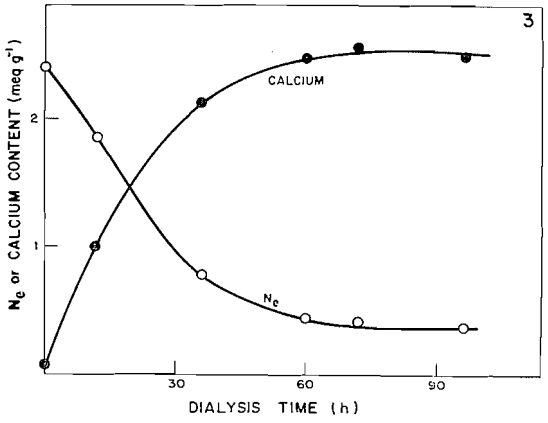

FIG. 2. Potentiometric titration curves: A, fraction F1; B, fraction F1 after acid treatment.
FIG. 3. Variation of N_e and calcium content of the s.l.p. with time of dialysis against aqueous calcium nitrate solution.

curve B in Fig. 2. If the equivalent point is taken at pH = 8, the exchange capacity increased to a value corresponding to the sulfur content of the s.l.p. When the acid-treated s.l.p. was dialyzed against dilute $Ca(NO_3)_2$, the titration curve approached the shape of curve A in Fig. 2.

The shape of the titration curve for the acid-treated material is similar to that obtained in titrating a mixture of weak and strong acids. In the present instance, however, the phenomenon is probably related to the structural properties of the s.l.p. rather than to the titration behavior of the $—SO_3^-$ functional group. Steric hindrance offered by the compact polymer network to the exchange of Na^+ ions with the protons of the inner layers of sulfonate groups seems a reasonable postulate. A similar type of titration curve has been observed for some compact globular proteins (16, 17).

Partial Specific Volume

The partial specific volume, $\bar{v}$, was determined with 5 ml Lipkin pycnometers (18) by the method of Svedberg and Pedersen (19). Measurements were made at 25 °C in distilled water with concentrations varying from 1% to 5% of solid. Values of $\bar{v}$ were constant over this range of concentrations. Partial specific volumes are listed in Table III. Pugh and Heller (20) have reported 0.9461 $cm^3\ g^{-1}$ for the specific volume of polystyrene latex particles which agrees well with $\bar{v}$ for the non-sulfonated latex in Table III. It can be seen, however, that $\bar{v}$ decreased markedly after sulfonation. This is caused by the acquisition of the relatively heavy cation and sulfonate groups by the particle. Butler *et al.* (21) have reported 0.697 ± 0.013 ml g^{-1} for the partial specific volume of sodium styrene sulfonate, which is comparable with the $\bar{v}$ values for F1 → F3 in Table III.

Refractive Index Increment

Refractive index differences were measured with a Brice–Phoenix differential refractometer (22, 23) at λ = 5 461 Å and 25 °C. The increments, dn/dc, obtained are given in Table III. The value for the non-sulfonated latex agrees well with 0.257 ± 0.005 ml g^{-1} found by Dandliker (24) for polystyrene latex particles at λ = 4 358 Å. Orofino and Flory (25) have reported an increment of 0.197 ml g^{-1} for polystyrene–*p*-sulfonic acid, which is in reasonable accord with dn/dc for the s.l.p. Thus, like the partial specific volume, the refractive index increment also decreased after sulfonation.

TABLE III

Partial specific volumes, refractive index increments, light scattering dissymmetries, and molecular weights of the neutralized latex

Fraction	$\bar{v}$ (ml g^{-1})	dn/dc (ml g^{-1})	$[z]_{c=0}$	$\bar{M}_w \times 10^6$ By light scattering	$\bar{M}_w \times 10^6$ Calculated
Non-sulfonated	0.9467	0.256	1.16	35	—
F1	0.7023	0.212	1.39	52	48
F2	0.6925	0.207	1.45	53	50
F3	0.6947	0.205	1.41	49	49
F4	0.5920	0.195	1.50	73	59

Light Scattering

Light scattering measurements were made at a wavelength of 5 461 Å with a Brice–Phoenix (26) photometer by methods described in several previous publications (22, 23, 27). The solvent was 0.05 M NaCl for F1 and F2 and 0.1 M NaCl for F3 and F4. Distilled water was used for the non-sulfonated latex since addition of a slight amount of salt caused rapid coagulation. All the solutions were filtered through 0.2 μ Millipore filters. Concentrations were between 0.005 and 0.05 g dl^{-1} and were determined by evaporation of aliquots and volumetric dilution with the solvent. Scattered intensities were measured at 0°, 45°, 90°, and 135° to the direction of the incident beam. The data were plotted by the usual methods. The weight-average molecular weight $\bar{M}_w$ was computed from an extrapolation of the turbidity function to zero concentration and was corrected for dissymmetry by means of the factors available in the literature (28). Values of the dissymmetry at zero concentration, $Z_{c=0}$, and of $\bar{M}_w$ are given in Table III. Also listed in Table III are molecular weights for the s.l.p. derived by adding to the weight of the original latex particle the sulfonate and cation content shown in Table II. The agreement for F1, F2, and F3 is excellent indicating that no aggregation occurred on sulfonation. The discrepancy in the case of F4 will be discussed later.

Electron Microscopy

Electron micrographs of the latex particles before and after sulfonation are shown in Figs. 4 and 5. The number-average diameter, D_n, weight-average diameter, D_w, and z-average diameter, D_z, of the particles together with the polydispersities, P, for different fractions are given in Table IV. Measurements were made of the diameters of 1 000 particles in each fraction, and average dimensions were calculated from the relation

$$[1a] \qquad D_n = \frac{\sum n_i D_i}{\sum n_i}$$

$$[1b] \qquad D_w = \frac{\sum n_i D_i^4}{\sum n_i D_i^3}$$

$$[1c] \qquad D_z = \frac{\sum n_i D_i^5}{\sum n_i D_i^4}$$

$$[1d] \qquad P = \frac{D_w}{D_n}$$

where n_i is the number of particles having diameter equal to D_i. The results demonstrate that the latex particles are fairly monodisperse spheres whose size and shape does not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

seem to have altered by sulfonation. The lower particle size and higher polydispersity for F4 is probably due to slight fragmentation as a result of a longer sulfonation time.

TABLE IV

Particle dimensions from electron microscopy and viscosity

Fraction	D_n (Å)	D_w (Å)	D_z (Å)	P	$[\eta]_{1M}$ (dl g^{-1})	$D_{[\eta]}$ (Å)
Non-sulfonated	480	580	600	1.20	0.040	560
F1	510	590	610	1.16	0.068	760
F2	500	580	600	1.16	0.080	810
F3	490	600	620	1.21	0.074	770
F4	420	560	590	1.32	0.072	880

Viscometry

The intrinsic viscosity, $[\eta]$, was measured in Ubbelohde-type viscometers (29) at 25 ± 0.002 °C. To eliminate the electroviscous effect, measurements were made in 1 M NaCl solution for the sulfonated fractions. The diameter, $D_{[\eta]}$, of the equivalent Einstein sphere was computed from

$$[2] \qquad D_{[\eta]} = 2\left(\frac{30\bar{M}_w[\eta]_{1M}}{\pi N}\right)^{1/3}.$$

Values of $[\eta]_{1M}$ and $D_{[\eta]}$ are given in Table IV.

DISCUSSION

Let us review the degree to which the s.l.p. fractions meet the listed criteria. The electron micrographs shown in Figs. 4 and 5 indicate that the latex particles are spherical and that sulfonation has produced no visible change in their shape and general appearance. With the exception of F4, the average polydispersity is 1.18 (Table IV), which is sufficiently low for the latex particles to be considered monodisperse. Figures 4 and 5 show some agglomeration of the particles. The agreement of $\bar{M}_w$ from light scattering with the $\bar{M}_w$ computed by adding the sulfonate and cation weight to the particle (Table III) for fractions F1, F2, and F3 suggests that the aggregation is an artifact produced by the drying process in the preparation of specimens for electron microscopy. The absence of aggregates in polystyrene latexes has previously been reported by Dandliker (24) and more recently by Kratohvil and Smart (30). Thus the first two criteria are satisfactorily met by fractions F1, F2, and F3.

Fraction F4 is an exception to the above consistent picture. This fraction was in contact with the sulfonating agent for a longer period of time than F1, F2, and F3. The smaller particle size and higher polydispersity by electron microscopy (Table IV) is an indication of chemically-induced fragmentation of the latex and leaching out of degraded products. Furthermore, $\bar{M}_w$ (from light scattering) for F4 is 25% higher than $\bar{M}_w$ (calculated) (Table III), which suggests that the longer reaction time caused aggregation by interparticle cross-linking. Hence, in this respect, the fast-reaction technique yielded a sulfonated latex which was superior to the product obtained by conventional mixing of the reactants.

From Table III, the density of the s.l.p. is about 1.4 g ml^{-1}. This is slightly lower than that of polysaccharides or proteins (~1.5 g ml^{-1}) and considerably less than for many inorganic sols such as AgI (5.67 g ml^{-1}), with which many interesting hydrodynamic studies have been made (31, 32). Thus the s.l.p. can be regarded as having approximately the density of water in accordance with criterion III.

$[\eta]$ value of 1.4×10^3 dl g^{-1} in 0.5 M NaCl, from which $D_{[\eta]}$ would be 2×10^4 Å. This is approximately 30 times greater than the diameter of the corresponding dry sphere. In contrast, $D_{[\eta]}$ exceeds D_z for the s.l.p. by a factor of only 1.3. Hence, it is likely that the imbibed water stretched the highly cross-linked network to the fullest extent at 1 M and that further swelling at lower ionic strength was eliminated by the large contractile energy of the network. A test of the correctness of the above speculation will be described in a later report dealing with the primary electroviscous effect.

Concluding Remarks

These experiments have indicated the feasibility of preparing permanently stabilized suspensions of charged spheres by direct sulfonation of a cross-linked styrene/divinylbenzene latex in the macromolecular range of particle size. The inactivation of some of the $—SO_3^-$ groups in the interior of the particles by the absorption and immobilization of bivalent ions was unexpected, but it opened up the possibility of producing particles of low surface charge for hydrodynamic studies. Undoubtedly, a superior method would be to limit sulfonation to the surface as originally planned, perhaps by repeated sulfonation at very fast flow rates or by a rapid reaction in a non-swelling or gaseous medium.

In the succeeding investigation of electroviscous effects, it was decided to use materials already prepared rather than to embark on the uncertainties of a new preparation technique. Among the fractions in Table II, F1 contained the lowest number of ionizable groups and was closest to the requirements of our model polyelectrolyte. Therefore, it was chosen for subsequent use.

In addition to the primary interest of measuring the various electroviscous effects of charged spheres, the sulfonated latex particles may be used for other definitive investigations of colloidal behavior. Examples are the influence of charge on the concentration dependence of the sedimentation coefficient, or the effect of the double layer in light scattering. For such purposes, it would be useful to prepare fractions covering a range of particle size. Lastly, the possibility of using the sulfonated latex particles in the physiological characterization of diffusion paths in living organisms should be mentioned. Here the permanent absorption of bivalent ion might be an asset, since radioactive ions could be chosen and thus permit use of the extremely sensitive tracer technique in following the movement of the particle in vivo.

THE RADIOLYSIS OF ALKALINE AQUEOUS SOLUTIONS CONTAINING HYDROGEN AND OXYGEN[1]

W. A. ARMSTRONG

Defence Chemical Biological and Radiation Laboratories, Department of National Defence, Ottawa, Canada

Received October 13, 1965

ABSTRACT

The initial yields of H_2O_2 in aerated water, $G(H_2O_2)^{O_2}$, and in water containing H_2 and O_2, $G(H_2O_2)^{H_2,O_2}$, have been measured for alkaline solutions irradiated with ^{60}Co γ-rays. $G(H_2O_2)^{O_2}$ decreases with increasing pH from a value of 1.22 in neutral solution to 0.63 in solutions of pH 13.92 and the relationship

$$G(H_2O_2)^{O_2} = G_{H_2O_2} - \tfrac{1}{2}G_{OH} + \tfrac{1}{2}G_{red}$$

is valid over the pH range 7 to 14.

$G(H_2O_2)^{H_2,O_2}$ decreases from 3.30 in neutral solution to a minimum of 2.00 at pH 11.35 and then increases to 2.65 at pH 13.92. The equation

$$G(H_2O_2)^{H_2,O_2} = G_{H_2O_2} + \tfrac{1}{2}G_{OH} + \tfrac{1}{2}G_{red},$$

which is applicable for neutral solutions, is not valid for basic solutions.

A reaction mechanism in accordance with the observed results and the literature values of the rate constants of likely radical reactions has been developed. It is assumed that in the alkaline solutions investigated OH radicals react with OH^- ions to form O^- radicals which react preferentially with O_2 to form O_3^- radicals which then react either with H_2 or H_2O_2. The increase in $G(H_2O_2)^{H_2,O_2}$ at pH > 12 is attributed to a difference in the rate of reaction of O_3^- with H_2O_2 and HO_2^-, $k(O_3^- + H_2O_2)/k(O_3^- + HO_2^-) = 2.45$.

INTRODUCTION

Studies of the hydrogen–oxygen–water system have produced valuable information about the yields of the primary products of the radiolysis of neutral water (1–3). Therefore, it was decided to attempt similar studies in the higher pH range where reported primary yields are not in agreement (3).

EXPERIMENTAL

Solutions were prepared with specially purified water (4) and reagent grade KOH and $Ba(OH)_2$. Solutions of pH 12 or greater were made 5×10^{-3} *M* in $Ba(OH)_2$ to remove carbonate ions while those of lower pH were prepared with either KOH or $Ba(OH)_2$. Certified 99.93% H_2 and O_2 gases, after being monitored with flowrators, were passed through activated charcoal, mixed, bubbled through a gas washer containing water at the same pH as the solution to be irradiated, and passed through a trap cooled with a dry ice – acetone mixture. The gas mixture was then bubbled for 30 min through the desired solution which was in a quartz flask equipped with a sidearm vent. After bubbling, the solution was poured through the sidearm to fill clean quartz tubes (4) which had been swept out with the gas mixture. Clamped wet ball-and-socket joints were used throughout the apparatus.

Samples were irradiated with ^{60}Co γ-radiation at a dose of 200 rads/min to doses of 2 000 to 8 000 rads. The dosimetry has been described elsewhere (4).

Initial dissolved H_2 and O_2 concentrations were calculated from the partial pressure of each gas at the measured barometric pressure and solution temperature (5).

Hydrogen peroxide was determined by the Ghormley method (4, 6). To verify the accuracy of the method with solutions of pH > 12, H_2O_2 solutions of known concentration were brought to the desired pH and analyzed. No effect due to high pH could be detected with H_2O_2 solutions which had been neutralized with potassium acid phthalate immediately before analysis.

RESULTS AND DISCUSSION

Typical $[H_2O_2]$ vs. dose plots are given for aerated water in Fig. 1 and for solutions of H_2 and O_2 in Fig. 2. The yield of H_2O_2 increases linearly with dose up to about 6 000 rads. The small intercept on the H_2O_2 axis in some of the plots is probably due to impurities.

The effects of increasing pH on the initial yield of H_2O_2 in irradiated aerated water, $G(H_2O_2)^{O_2}$, and solutions of H_2 and O_2, $G(H_2O_2)^{H_2,O_2}$, are listed in Table I. These G-values were determined from the slopes of $[H_2O_2]$ vs. dose plots. The yield of H_2O_2 in aerated solutions decreases as the pH increases from neutrality to $\sim$ pH 11, remains constant from pH 11 to 13, and then drops sharply at pH $>$ 13. With solutions containing both H_2 and O_2, the yield of H_2O_2 decreases rapidly as the pH increases from neutrality to $\sim$ pH 11, then increases rapidly at pH $>$ 12. It should be noted that $G(H_2O_2)^{H_2,O_2}$ is dependent on the ratio $[H_2]/[O_2]$ only for solutions of pH 10.62 and 11.35.

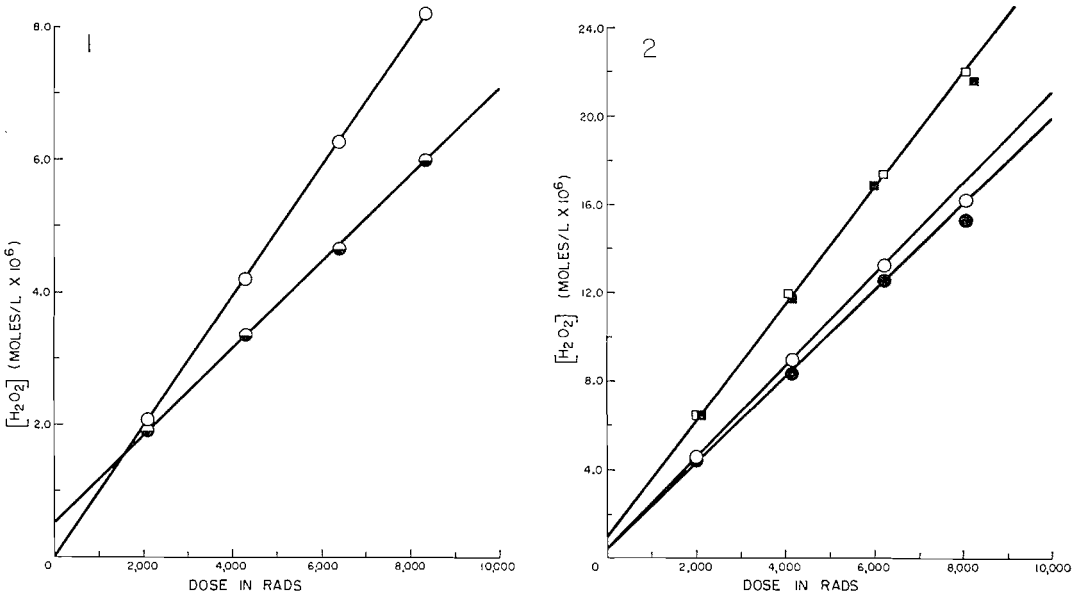

FIG. 1. H_2O_2 yields in aerated water: (○) 5×10^{-4} M KOH, pH 10.62; (◒) 0.5 M KOH – 5×10^{-3} M $Ba(OH)_2$, pH 13.55.

FIG. 2. H_2O_2 yields in water containing H_2 and O_2: (○) 5×10^{-4} M KOH, pH 10.62; (□) 0.1 M KOH – 5×10^{-3} M $Ba(OH)_2$, pH 12.85. (Open symbols $[H_2]/[O_2] = 1.20$, closed symbols $[H_2]/[O_2] = 0.60$.)

Allen (3) has shown that the yield of oxidizing radicals, G_{OH}, may be determined by comparing the initial yields of hydrogen peroxide in neutral water containing both dissolved oxygen and hydrogen and in water containing only oxygen (aerated water).

[A] $$G(H_2O_2)^{H_2,O_2} = G_{H_2O_2} + \tfrac{1}{2}G_{OH} + \tfrac{1}{2}G_{red}$$

[B] $$G(H_2O_2)^{O_2} = G_{H_2O_2} - \tfrac{1}{2}G_{OH} + \tfrac{1}{2}G_{red}$$

[C] $$G_{OH} = G(H_2O_2)^{H_2,O_2} - G(H_2O_2)^{O_2}$$
$$= 2.2 \text{ for neutral water.}$$

Where $G_{H_2O_2}$ is the "molecular" yield of H_2O_2, and G_{red} is the sum of the yield of hydrated electrons, $G_{e_{aq}^-}$, and the yield of H atoms, G_H.

During the course of the present investigation, Hayon (7) published the results of his studies on the radiolysis of alkaline aqueous solutions of nitrate + formate ions, ferricyanide + formate + O_2, and ferricyanide + ethanol + O_2 in the pH range 6 to 14. From these data he determined the yields of radicals and molecular products for the radiolysis of water at many pH values. We have used some of these values and expressions

*$G(H_2O_2)^{O_2} = G_{H_2O_2} + \frac{1}{2}G_{red} - \frac{1}{2}G_{OH}$, calculated with Hayon's values (7) for $G_{H_2O_2}$, G_{red}, and G_{OH}.
†$G(H_2O_2)^{H_2,O_2} = G_{H_2O_2} + \frac{1}{2}G_{red} + \frac{1}{2}G_{OH}$, calculated with Hayon's values (7) for $G_{H_2O_2}$, G_{red}, and G_{OH}.

[B] and [A] to determine the calculated values of $G(H_2O_2)^{O_2}$ and $G(H_2O_2)^{H_2,O_2}$ listed in Table I. The measured and calculated values of $G(H_2O_2)^{O_2}$ are in good agreement, whereas those of $G(H_2O_2)^{H_2,O_2}$ are not in agreement. These results infer that each of the oxidizing radicals present in irradiated alkaline aerated water reacts in such a way as to ultimately destroy $\frac{1}{2}$ molecule of H_2O_2, whereas in solutions of H_2 and O_2 the fraction of the oxidizing radicals which reacts with H_2 to ultimately form $\frac{1}{2}$ molecule of H_2O_2 decreases from unity at neutral pH to a minimum at about pH 12 then increases at pH > 12 but does not return to unity. This abrupt change at pH $\sim$ 12 may be related to a difference in the reactivity of the dissociated and undissociated forms of H_2O_2 since the pK value for the dissociation of H_2O_2 is 11.75 (8).

A reaction mechanism in accordance with these observed results may be developed from a consideration of the following reactions and their respective rate constants.

$$H_2O \longrightarrow\!\!\!\!\!\sim\!\!\!\!\!\sim\!\!\!\!\!\sim

[12] $O_3^- + H_2O_2 \rightarrow O_2^- + O_2 + H_2O$

[12a] $O_3^- + HO_2^- \rightarrow O_2^- + O_2 + OH^-$

[13] $O_3^- + H_2 \rightarrow O_2 + OH^- + H$ or $O_2^- + H_2O$

[14] $O_2^- + O_2^- + 2H_2O \rightarrow H_2O_2 + 2OH^-$ $\quad k_{14} = 1.7 \times 10^7$ (14)

Many of the above reactions are accepted in the mechanism for the radiolysis of neutral water. However, reactions [4] and [8] to [13] can occur only in basic solutions. Reaction [4] has been demonstrated by Matheson and Rabani (12), and Adams, Boag, and Michael (15) have presented evidence for [8]. The rate constant for reaction [10] has been determined from the optical absorption of the O_3^- (13) species but very little is known about its reactivity. The only demonstrated reaction is the oxidation of ferrocyanide (15).

In aerated solutions for initial yields, reactions [1] and [3] will predominate over [2] and [5] and each reducing radical will result in the formation of $\frac{1}{2}$ molecule of H_2O_2 either via [1] and [14], [3] and [14], or [4], [1], and [14]. Reactions [6], [9], and [13] will be negligible and each oxidizing radical will result in the destruction of $\frac{1}{2}$ molecule of H_2O_2 either directly by [7] or through [8] followed by either [11] or [10] and [12]. Hence

$$G(H_2O_2)^{O_2} = G_{H_2O_2} + \tfrac{1}{2}G_{red} - \tfrac{1}{2}G_{OH}.$$

In solutions containing both H_2 and O_2, each reducing radical will again react to ultimately form $\frac{1}{2}$ molecule of H_2O_2. For initial yields, reactions [7] and [11] will be negligible and H_2 and OH^- will compete for OH radicals in reactions [6] and [8]. There will also be a competition between H_2 and O_2 for O^- radicals in reactions [9] and [10] and between H_2O_2 and H_2 for O_3^- radicals in [12] and [13]. Assuming this reaction scheme

$$G(H_2O_2)^{H_2,O_2} = G_{H_2O_2} + \tfrac{1}{2}G_{red} + \tfrac{1}{2}G_{OH} - \frac{G_{OH}}{(1 + (k_6[H_2]/k_8[OH^-]))(1 + (k_9[H_2]/k_{10}[O_2]))(1 + (k_{13}[H_2]/k_{12}[H_2O_2]))}$$

$$[D] \quad \Delta G(H_2O_2) = G(H_2O_2)^{H_2,O_2} - G(H_2O_2)^{O_2} = G_{OH}\left(1 - \frac{G_{OH}}{(1 + (k_6[H_2]/k_8[OH^-]))(1 + (k_9[H_2]/k_{10}[O_2]))(1 + (k_{13}[H_2]/k_{12}[H_2O_2]))}\right).$$

At neutral pH, $k_6[H_2]/k_8[OH^-]$ is very large and the expression reduces to $\Delta G(H_2O_2) = G_{OH}$.

At pH > 12, $k_6[H_2]/k_8[OH^-]$ is negligibly small and as the pK value for the dissociation of H_2O_2 is 11.75 (8), reaction [12a] replaces [12]. Substitution in [D] of the appropriate values from Table I for solutions of pH 12.85 along with the literature values for the rate constants k_9 and k_{10} and Hayon's value (7) of $G_{OH} = 2.72$ at pH 12.90 gives $k_{13}[H_2]/k_{12a}[H_2O_2] = 1.52$. A similar calculation with literature values for k_6, k_8, k_9, and k_{10}, experimental results at pH 10.60, and Hayon's $G_{OH} = 2.27$ at this pH gives $k_{13}[H_2]/k_{12}[H_2O_2] = 0.62$. Thus $k_{12}/k_{12a} = 2.45$.

During an investigation of transient species in irradiated alkaline oxygenated solutions, Dorfman (14) observed a dependence on pH of the half-life of the transient absorption at 430 mμ due to O_3^-. The half-life increased from 0.4 ms at pH 11 to 2 ms at pH 13. On the assumption that the O_3^- disappeared by reaction with hydrogen peroxide, this observation supports our contention that the rate of reaction of O_3^- with H_2O_2 is greater than that with HO_2^- ($k_{12} > k_{12a}$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In the final column of Table I, the values of $\Delta G(H_2O_2)$ calculated with expression [D] using the G_{OH} figures of Hayon and $k_{13}[H_2]/k_{12}[H_2O_2] = 0.62$ for solutions of pH < 12 and $k_{13}[H_2]/k_{12a}[H_2O_2] = 1.52$ for solutions of pH > 12 are compared with the measured values. Differences between the two throughout the entire alkaline pH range are never greater than 10% except at pH 12.10 where the experimental value lies between the two calculated values of 0.99, assuming $k_{13}[H_2]/k_{12}[H_2O_2] = 0.62$, and 1.50, assuming $k_{13}[H_2]/k_{12a}[H_2O_2] = 1.52$. Since the experimental error in measuring $G(H_2O_2)^{H_2,O_2}$ or $G(H_2O_2)^{O_2}$ at a given pH is about $\pm 5\%$, the proposed mechanism fits the data reasonably well.

One reaction that might be questioned is

$$O_3^- + H_2 \rightarrow O_2 + OH^- + H.$$

If this does not occur, only O^- can react with H_2 at pH > 12 and the high yield of $G(H_2O_2)^{H_2,O_2}$ will require k_9/k_{10} to be approximately 2 instead of the value 0.0308 derived from rate constants appearing in the literature. Also $G(H_2O_2)^{H_2,O_2}$ will be more dependent on $[H_2]/[O_2]$ than is indicated by the experimental results. In most alkaline systems the formation of O_3^- can be suppressed by employing a solute concentration much greater than the oxygen concentration. The low solubility of hydrogen prevented this in the present investigation.

The observed effects of increasing pH on $G(H_2O_2)^{H_2,O_2}$ may also be explained by postulating the presence in irradiated H_2O of an additional oxidizing species, X, different from OH. This proposed radical, first suggested by Allen (3), would have to react much less readily with H_2 than with H_2O_2. If such a species were present, reaction [13] could be replaced by

$$X + H_2 \rightarrow H + HX$$

and all O_3^- radicals could be assumed to react with H_2O_2 or its precursors. The increase in $G(H_2O_2)^{H_2,O_2}$ at pH > 12 might then be explained by assuming $k_{X+H_2O_2} > k_{X+HO_2^-}$.

Since there is no direct evidence for the presence of radical X in irradiated water, we prefer to base the mechanism on reactions of known species.

ACKNOWLEDGMENT

The author wishes to thank Mr. W. G. Humphreys for valuable technical assistance and Drs. P. J. Dyne and A. W. Boyd for helpful discussions.

INFRARED SPECTRA OF GeH_2Br_2 AND GeD_2Br_2

ALEXANDER L. BEACH AND JAMES E. GRIFFITHS

Earlier studies of the infrared spectra of GeH_2F_2, GeH_2Cl_2, and GeH_2Br_2 (1, 2) satisfactorily located all of the fundamental frequencies except $\nu_4(a_1)$, the symmetric GeX_2 bending mode. With the availability of samples of GeH_2Br_2 and GeD_2Br_2, synthesized for another purpose, it was convenient to observe their infrared spectra as a check on previous work and to locate ν_4 with certainty. In $(CH_3)_2GeBr_2$ and $(CD_3)_2GeBr_2$ the fundamentals analogous to ν_4 occur at 99 and 98 cm^{-1} respectively (3).

Dibromogermane-d_2 was prepared by the reaction of GeD_4 with bromine in a glass vacuum system (4). Increased yields of the dibromide at the expense of the monobromide were obtained by the addition of larger quantities of bromine to the reaction tube than is usual when high yields of GeD_3Br are desired. Purification of the dibromide was effected by fractional vaporization and condensation in the usual way (4). The corresponding hydrogen compound was made similarly. Spectra of GeD_2Br_2 and GeH_2Br_2 were recorded with Beckman IR-11 and IR-12 spectrophotometers (33 to 4 000 cm^{-1}) and liquid and gas phase samples were confined in cells fitted with KBr or high density polyethylene windows.

The instrument was calibrated to ± 0.2 cm^{-1} throughout with the spectra of HCl, DCl, HBr, DBr, CH_4, NH_3, CO_2, CO, and H_2O. Frequencies reported are as accurate as this except when bands are naturally broad and the determination of the band center becomes less definite. In such cases the band centers are probably accurate to ± 1 cm^{-1}.

TABLE I

Fundamental frequencies (cm^{-1}) of GeH_2Br_2 and GeD_2Br_2

No.	Species	Description	GeH_2Br_2	GeD_2Br_2
1	a_1	$GeH_2(D_2)$ stretch	2 121.5	1 521.9
2	a_1	$GeH_2(D_2)$ bend	847.8	607.1
3	a_1	$GeBr_2$ stretch	298.3	297.2
4	a_1	$GeBr_2$ bend	104*	104*
5	a_2	Torsion	—	—
6	b_1	$GeH_2(D_2)$ stretch	2 138.3	1 543.0
7	b_1	$GeH_2(D_2)$ rock	491.8	362.6
8	b_2	$GeH_2(D_2)$ wag	756.8	543.1
9	b_2	$GeBr_2$ stretch	324.3	320.0

*Liquid state values.

Arguments favoring particular assignments in terms of a C_{2v} structure have been given previously (1, 2) and need not be repeated here. The results are summarized in Table I where frequency shifts clearly identify fundamentals associated with hydrogen or deuterium motions and the absence of significant changes in frequency confirm assignments of the $GeBr_2$ modes. The value for ν_4 is for the liquid. Product rule ratios, based upon reasonable structural parameters r(Ge—H) = 1.52 Å, r(Ge—Br) = 2.30 Å and

tetrahedral angles (5, and references therein), for $a_1 = 0.51$ (calcd. 0.50), $b_1 = 0.52$ (calcd. 0.51), and $b_2 = 0.71$ (calcd. 0.71) species agree satisfactorily with the calculated values.

In one sample sufficient $GeDBr_3$ was present to allow the measurement of the two Ge—Br_3 stretching fundamentals. These occur at $\nu_2(a_1) = 292.6$ and $\nu_5(e) = 316.4$ cm^{-1}.

DIMETHYLBERYLLIUM BIS(TRIMETHYLAMINE) AND DIMETHYLBERYLLIUM TETRAMETHYL-*o*-PHENYLENEDIAMINE

N. A. Bell and G. E. Coates

The ready formation of complexes in which one molecule of dimethylberyllium is coordinated to two molecules of pyridine or one of tetramethylethylenediamine (1), and the recent description (2) of the addition of a second molecule of trimethylamine at low temperature to the diethylberyllium–trimethylamine complex ($Et_2Be.NMe_3$) (3), prompted us to reexamine the reported nonexistence of dimethylberyllium bis(trimethylamine) (4).

Addition of successive quantities of trimethylamine to the solid 1:1 complex, $Me_2Be.NMe_3$, at 0° resulted in very slow reactions and the attainment of equilibrium required many hours. When an excess of trimethylamine was condensed on the 1:1 complex, and the excess removed in successive amounts, then equilibration occurred in 15–20 min. At 0° the pressure of amine fell until the composition of the condensed crystalline phase corresponded to a Be:N ratio of 1:2.03. Further removal of amine resulted in a steady amine pressure of 22.7 mm until the Be:N ratio became nearly 1:1. There was no evidence for a complex of composition $(Me_2Be)_2(NMe_3)_3$ described earlier (4). The results now reported are entirely consistent with the presence of two solid complexes, $Me_2Be.NMe_3$ and $Me_2Be(NMe_3)_2$. By repeating the above procedure at −9° and −4.5°, the dissociation pressure of the bis(trimethylamine) adduct was measured as 9.7 and 16.0 mm respectively. Dimethylberyllium bis(trimethylamine) melts sharply at 20° under 1 atm pressure of trimethylamine.

We also find that dimethylberyllium forms a complex, sufficiently stable to be purified by vacuum sublimation, with the chelating aromatic amine N,N,N′,N′-tetramethyl-*o*-phenylenediamine.

EXPERIMENTAL

Dimethylberyllium mono(trimethylamine) was prepared as described earlier (4), and after a tensimetric experiment the amount of beryllium complex was determined by hydrolysis and gas-volumetric measurement of methane by vacuum-line methods.

tetrahedral angles (5, and references therein), for $a_1 = 0.51$ (calcd. 0.50), $b_1 = 0.52$ (calcd. 0.51), and $b_2 = 0.71$ (calcd. 0.71) species agree satisfactorily with the calculated values.

In one sample sufficient $GeDBr_3$ was present to allow the measurement of the two Ge—Br_3 stretching fundamentals. These occur at $\nu_2(a_1) = 292.6$ and $\nu_5(e) = 316.4$ cm^{-1}.

Dimethylberyllium mono(trimethylamine) was prepared as described earlier (4), and after a tensimetric experiment the amount of beryllium complex was determined by hydrolysis and gas-volumetric measurement of methane by vacuum-line methods.

The Dimethylberyllium N,N,N',N'-Tetramethyl-o-phenylenediamine Complex

The diamine (2.0 g, 0.012 mole) was added to 10 cc of a 0.929 *M* solution of dimethylberyllium (0.0093 mole) in diethyl ether, resulting in a perceptibly exothermic reaction. Solvent was removed by evaporation and colorless crystals appeared when the solution had become concentrated. The complex was separated by removal of all the solvent under reduced pressure, and was purified by sublimation at 80–90° and 10^{-2} mm (m.p. 103–104° in a sealed tube). Hydrolysis of a sample followed by measurement of evolved methane and determination of beryllium gave results in agreement with the formula $C_{12}H_{22}BeN_2$.

Anal. Calcd.: Be, 4.42; hydrolyzable methyl, 14.8. Found: Be, 4.52, 4.29; hydrolyzable methyl, 14.6.

The molecular weight, determined cryoscopically in 0.42, 0.65, and 0.92 wt. % benzene solution, was 206, 211, and 215 respectively, corresponding to degrees of association of 1.01, 1.03, and 1.05.

THE REACTION OF HEXAFLUOROACETONE WITH SILANOLS

A. F. Janzen and C. J. Willis

We have recently shown (1) that hexafluoroacetone will react readily with a variety of compounds containing Si—H bonds, the products being hexafluoroisopropoxysilanes containing the grouping Si—O—$CH(CF_3)_2$. These reactions proceed under radical conditions, and also, in the case of trimethylsilane, ionic conditions. It has also been reported (2) that similar addition of hexafluoroacetone occurs across Ge—H and Sn—H bonds.

We now find that a ready reaction occurs between hexafluoroacetone and silanols, e.g. with trimethylsilanol at 20°:

$$(CH_3)_3SiOH + (CF_3)_2CO \rightarrow (CH_3)_3SiOC(CF_3)_2OH.$$

The product, 2-trimethylsiloxy-hexafluoroisopropanol, is readily purified by distillation (b.p. 106° at 740 mm) and may be kept in a sealed tube at 20° with no sign of decomposition. This behavior may be contrasted with that of the corresponding products from the reaction of hexafluoroacetone with other hydroxylic compounds. With water, the adduct is the "hydrate", i.e. hexafluoropropane-2,2-diol (3). This is a hygroscopic solid, m.p. 44°, which even at 20° shows a slight equilibrium dissociation to give hexafluoroacetone. With alcohols, hexafluoroacetone reacts reversibly to give unstable hemiketals (4), which are difficult to purify and readily dissociate:

$$(CF_3)_2CO + ROH \rightleftharpoons (CF_3)_2C\begin{matrix}\diagup OH \\ \diagdown OR\end{matrix}$$

where R = CH_3 or C_2H_5.

THE REACTION OF HEXAFLUOROACETONE WITH SILANOLS

A. F. Janzen and C. J. Willis

We have recently shown (1) that hexafluoroacetone will react readily with a variety of compounds containing Si—H bonds, the products being hexafluoroisopropoxysilanes containing the grouping Si—O—$CH(CF_3)_2$. These reactions proceed under radical conditions, and also, in the case of trimethylsilane, ionic conditions. It has also been reported (2) that similar addition of hexafluoroacetone occurs across Ge—H and Sn—H bonds.

We now find that a ready reaction occurs between hexafluoroacetone and silanols, e.g. with trimethylsilanol at 20°:

$$(CH_3)_3SiOH + (CF_3)_2CO \rightarrow (CH_3)_3SiOC(CF_3)_2OH.$$

The product, 2-trimethylsiloxy-hexafluoroisopropanol, is readily purified by distillation (b.p. 106° at 740 mm) and may be kept in a sealed tube at 20° with no sign of decomposition. This behavior may be contrasted with that of the corresponding products from the reaction of hexafluoroacetone with other hydroxylic compounds. With water, the adduct is the "hydrate", i.e. hexafluoropropane-2,2-diol (3). This is a hygroscopic solid, m.p. 44°, which even at 20° shows a slight equilibrium dissociation to give hexafluoroacetone. With alcohols, hexafluoroacetone reacts reversibly to give unstable hemiketals (4), which are difficult to purify and readily dissociate:

$$(CF_3)_2CO + ROH \rightleftharpoons (CF_3)_2C\begin{matrix}\diagup OH \\ \diagdown OR\end{matrix}$$

where R = CH_3 or C_2H_5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The trimethylsilanol adduct, by contrast, shows no sign of dissociation, and infrared spectroscopic examination (vapor phase at 20°) shows no hexafluoroacetone to be present. Since p_π–d_π back bonding from oxygen to silicon is a well-recognized factor in the stabilization of siloxy compounds (5), it may be suggested that such an effect enhances the stability of the trimethylsilanol adduct over similar carbon compounds.

It was of interest to extend this reaction to silanediols, since a similar addition of two molecules of hexafluoroacetone should produce a bifunctional adduct, $R_2Si[OC(CF_3)_2OH]_2$, which might condense to give linear or cyclic compounds with the interesting chain structure $[—SiR_2—O—C(CF_3)_2—O—]_n$, given similar stability by p_π–d_π bonding.

Such systems appear to have received little study in the organosilicon field. Henglein and co-workers (6) have prepared compounds of structure $C_2H_5OSi(CH_3)_2[OCH_2OSi(CH_3)_2]_nOC_2H_5$, where n = 1–5, and report that they show fair stability to water and alkali. In later papers (7), they describe the preparation of compounds containing the grouping Si—O—CH(CCl_3)—O—Si and claim that the —CCl_3 group exerts a stabilizing influence on the Si—O—C bond.

We now find that hexafluoroacetone will react readily with diphenylsilanediol in a donor solvent, such as ether or glyme, at 20°. The molar combining ratio is slightly above the 2:1 ratio which would be in accordance with the formation of the product $(C_6H_5)_2Si[OC(CF_3)_2OH]_2$. Removal of the solvent cannot be completed, however, without the decomposition of the product to evolve hexafluoroacetone and deposit of a mixture of the cyclic compounds $[(C_6H_5)_2SiO]_3$ and $[(C_6H_5)_2SiO]_4$.

It is apparent, then, that, in spite of the added stability expected from the π-bonding described above, the system Si—O—$C(CF_3)_2$—O—Si is unstable with respect to hexafluoroacetone and the silyl oxide. Consistent with this, we have failed to prepare, by several routes, the compound $(CH_3)_3SiOC(CF_3)_2OSi(CH_3)_3$, the inevitable products being hexafluoroacetone and hexamethyldisiloxane. This instability may be ascribed to the formation of an intermediate involving coordination from an oxygen atom to a more distant, rather than adjacent, silicon atom, i.e.

$$\begin{array}{c}(CF_3)_2C—O\\ \quad\quad|\quad\quad|\\ —R_2Si—O\quad SiR_2—\end{array} \rightarrow \begin{array}{c}(CF_3)_2C—O\\ \quad\quad|\quad\quad|\\ —R_2Si—O\rightarrow SiR_2—\end{array} \rightarrow \begin{array}{c}(CF_3)_2C{=}O\\ \\ —R_2Si—O—SiR_2—\end{array}$$

EXPERIMENTAL

General techniques have been described previously (1).

Reaction of Hexafluoroacetone with Trimethylsilanol

Hexafluoroacetone (6.86 g, 41.3 mmole) was condensed onto trimethylsilanol (1.90 g, 21.1 mmole, prepared by the method of Sommer *et al.* (8)) in an evacuated reaction tube (100 ml). On sealing the tube and warming to 20° immediate reaction was apparent. Fractionation after 5 h at 20° gave unreacted hexafluoroacetone (3.69 g, 22.2 mmole) and 2-trimethylsiloxy-hexafluoroisopropanol (3.6 g, 14.1 mmole, b.p. 105–106° at 740 mm).

Anal. Calcd. for $C_6H_{10}F_6O_2Si$: C, 28.1; H, 3.93; F, 44.5. Found: C, 27.5; H, 4.4; F, 44.3.

Infrared spectroscopic examination (gas phase) showed absorptions at 3 600 cm^{-1} (O—H), 2 960 cm^{-1} (C—H), and strong absorption centered on 1 250 cm^{-1} (C—F). The proton nuclear magnetic resonance spectrum showed a broad singlet at 3.59 p.p.m. and a sharp singlet at 0.18 p.p.m. (at 60 Mc/s to low field of tetramethylsilane). The former is assigned to the hydroxylic proton, the broadening being due to coupling with the fluorine atoms to give an unresolved septet, and the latter peak is assigned to the methyl protons. Integrated peak areas support these assignments.

The compound showed no sign of change after it was stored in a sealed tube for 3 months.

Reaction of Hexafluoroacetone with Diphenylsilanediol

No reaction was found when the two substances were kept together at 20° for 24 h.

When hexafluoroacetone (1.45 g, 8.75 mmole) was condensed onto diphenysilanediol (0.32 g, 1.5 mmole) in glyme (3.3 g) in a reaction tube (100 ml), a reaction was apparent on warming to 20°. After it was kept at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

20° for 20 h, excess hexafluoroacetone and the bulk of the glyme were removed, leaving a viscous liquid. The amount of hexafluoroacetone recovered (0.86 g, 5.15 mmole) showed that the molar reacting ratio, $(CF_3)_2CO$ to $(C_6H_5)_2Si(OH)_2$, was 2.3:1.

Infrared spectroscopic examination of the viscous liquid showed that it still contained glyme, with O—H and C—F absorptions also present. The remaining solvent was not removable under vacuum at 20°. On heating to 80°, rapid evolution of hexafluoroacetone occurred and a white residue remained. After recrystallization from acetone, the residue had m.p. 160° and an infrared spectrum consistent with a mixture of $[(C_6H_5)_2SiO]_3$ and $[(C_6H_5)_2SiO]_4$. It has been reported (9) that these two compounds give a eutectic with m.p. 164–165°.

When ether was used as a solvent instead of glyme, the reaction followed a similar course, with the viscous liquid decomposing to give hexafluoroacetone even at 20°.

LA SOLUBILITÉ DANS LES MÉLANGES ÉTHER ÉTHYLIQUE – ACIDES INORGANIQUES DE CERTAINS SELS DE FER, COBALT ET MANGANÈSE

R. A. A. MUZZARELLI

INTRODUCTION

Les connaissances actuelles sur la solubilité des sels inorganiques dans l'éther éthylique sont très limitées. Il est pourtant bien connu que certains composés inorganiques y sont solubles, en particulier $LiAlH_4$, et y sont légèrement dissociés, bien que les sels minéraux soient beaucoup moins dissociés que les organo-magnésiens, par exemple.

Le chlorure ferrique dans ses différents états d'hydratation est très soluble dans l'éther éthylique et il a été étudié (1). Encore quelques chlorures comme $TiCl_4$, $SnCl_4$ et $SiCl_4$ ont été l'objet d'études (2) et aussi on a noté que dans l'éther éthylique peuvent exister des complexes tels que $HFeCl_4$, $HSbCl_6$, H_2SnCl_6, qui sont des acides forts.

Mais les sels les plus intéressants du point de vue de la technologie moderne, capables de se dissoudre dans l'éther, sont les nitrates de thorium et d'uranyle. Ces nitrates représentent les sels qu'on obtient quand on veut mettre en solution le thorium ou l'uranium métalliques: les deux passent en solution facilement par réaction avec HNO_3 sous reflux.

20° for 20 h, excess hexafluoroacetone and the bulk of the glyme were removed, leaving a viscous liquid. The amount of hexafluoroacetone recovered (0.86 g, 5.15 mmole) showed that the molar reacting ratio, $(CF_3)_2CO$ to $(C_6H_5)_2Si(OH)_2$, was 2.3:1.

Infrared spectroscopic examination of the viscous liquid showed that it still contained glyme, with O—H and C—F absorptions also present. The remaining solvent was not removable under vacuum at 20°. On heating to 80°, rapid evolution of hexafluoroacetone occurred and a white residue remained. After recrystallization from acetone, the residue had m.p. 160° and an infrared spectrum consistent with a mixture of $[(C_6H_5)_2SiO]_3$ and $[(C_6H_5)_2SiO]_4$. It has been reported (9) that these two compounds give a eutectic with m.p. 164–165°.

When ether was used as a solvent instead of glyme, the reaction followed a similar course, with the viscous liquid decomposing to give hexafluoroacetone even at 20°.

LA SOLUBILITÉ DANS LES MÉLANGES ÉTHER ÉTHYLIQUE – ACIDES INORGANIQUES DE CERTAINS SELS DE FER, COBALT ET MANGANÈSE

R. A. A. MUZZARELLI

INTRODUCTION

Les connaissances actuelles sur la solubilité des sels inorganiques dans l'éther éthylique sont très limitées. Il est pourtant bien connu que certains composés inorganiques y sont solubles, en particulier $LiAlH_4$, et y sont légèrement dissociés, bien que les sels minéraux soient beaucoup moins dissociés que les organo-magnésiens, par exemple.

Le chlorure ferrique dans ses différents états d'hydratation est très soluble dans l'éther éthylique et il a été étudié (1). Encore quelques chlorures comme $TiCl_4$, $SnCl_4$ et $SiCl_4$ ont été l'objet d'études (2) et aussi on a noté que dans l'éther éthylique peuvent exister des complexes tels que $HFeCl_4$, $HSbCl_6$, H_2SnCl_6, qui sont des acides forts.

Mais les sels les plus intéressants du point de vue de la technologie moderne, capables de se dissoudre dans l'éther, sont les nitrates de thorium et d'uranyle. Ces nitrates représentent les sels qu'on obtient quand on veut mettre en solution le thorium ou l'uranium métalliques: les deux passent en solution facilement par réaction avec HNO_3 sous reflux.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Il faut rappeler que l'éther éthylique a été un des cinq solvants considérés pour le projet d'extraction "Butex", et qu'il a été écarté car il ne donnait pas une satisfaisante séparation de l'uranium de ses impuretés (3). Or, il semble que cette même propriété de l'éther, de pouvoir dissoudre les sels de nombreux métaux, peut être mise à profit. Par exemple, une solution de 50 g de nitrate d'uranyle dans 95 cc d'éther éthylique a été soumise à chromatographie sur colonne de cellulose (4, 5), et il a été possible de séparer l'uranium des traces des lanthanides et de 15 autres métaux, tous retenus sur la cellulose.

Ces solutions de nitrate d'uranyle dans l'éther sont convenables pour la chromatographie sur cellulose, car la poudre de cellulose ne se gonfle pas en contact avec l'éther, à différence de ce qu'elle fait avec les solutions aqueuses; il est aussi très facile de récupérer le sel d'uranium. Le fait que le nitrate d'uranyle, à différence des autres nitrates, ne soit pas retenu sur la cellulose est expliqué par l'hypothèse que il est capable de se complexer à $UO_2(NO_3)_4^{2-}$ (6).

Les études citées offrent les perspectives suivantes:

(*a*) Les métaux contenus dans l'uranium comme impuretés doivent posséder eux aussi une bien que limitée solubilité dans l'éther. Il serait intéressant d'établir quelles sont ces limites de solubilité, soit pour prévoir s'il est possible de purifier par la méthode chromatographique un échantillon d'uranium à haute téneur d'impuretés, soit pour expliquer pourquoi les différents métaux forment dans la colonne des bandes à niveaux différents (5).

(*b*) Les connaissances en fait de solubilité pourraient orienter pour le choix des conditions favorables à la séparation des traces métalliques d'entre elles-mêmes par chromatographie de précipitation sur couche mince ou sur papier.

Les sels considérés dans cette étude ont été choisis à titre d'exemple. On a tenu compte de l'intérêt qu'on a, à l'heure actuelle, à purifier des mélanges de fluorures (7, 8), spécialement provenant des réacteurs nucléaires à sels fondus. La possibilité de mettre en solution les fluorures dans l'éther serait mise à profit dans les projets de chromatographie.

PARTIE EXPÉRIMENTALE

Ont été utilisés les solvants et les produits de degré analytique.

Solvants.—Les solvants étaient: acide nitrique fumant 98% (Canlab); fluorure d'hydrogène gazeux 100% (Matheson) et éther éthylique anhydre (Fisher).

Sels.—Les sels étaient: nitrate cobalteux hexahydrate; chlorure cobalteux hexahydrate; fluorure cobalteux anhydre; nitrate ferrique ennéahydrate; chlorure ferrique hexahydrate; fluorure ferrique anhydre; chlorure manganeux tetrahydrate et fluorure manganeux anhydre.

Solutions de ^{60}Co, ^{59}Fe et ^{54}Mn

Le cobalt-60, et le fer-59, ont été fournis par Atomic Energy of Canada Ltd., sous forme de fils métalliques, et chacun a été mis en solution dans la quantité indispensable de HNO_3 5 *N*, et porté à volume avec HNO_3 concentré.

Le manganèse-54 a été fourni par l'Oak Ridge National Laboratory, sous forme de solution de $MnCl_2$ en HCl 5 *N*. Cette solution a été diluée 1:10 avec HNO_3 concentré.

Préparation des solutions

Le fluorure d'hydrogène gazeux a été condensé, et mesuré avec des pipettes en polypropylène. Généralement la quantité prévue de fluorure d'hydrogène ou d'acide nitrique a été diluée à 50 cc avec l'éther éthylique, et un poids de sel, variant entre 1 g et 0.5 g, a été ajouté. Quelques microlitres de solution de métal radioactif ont été introduits dans la solution. Les solutions ont été tenues en agitation pendant 18 h, en thermostat à 29 °C. La phase solide a été toujours présente.

Vingt centimètres cubes de solution, après centrifugation, ont été prélevés et leur activité gamma a été enregistrée immédiatement. Les récipients en polypropylène ont été largement employés à toutes les étapes.

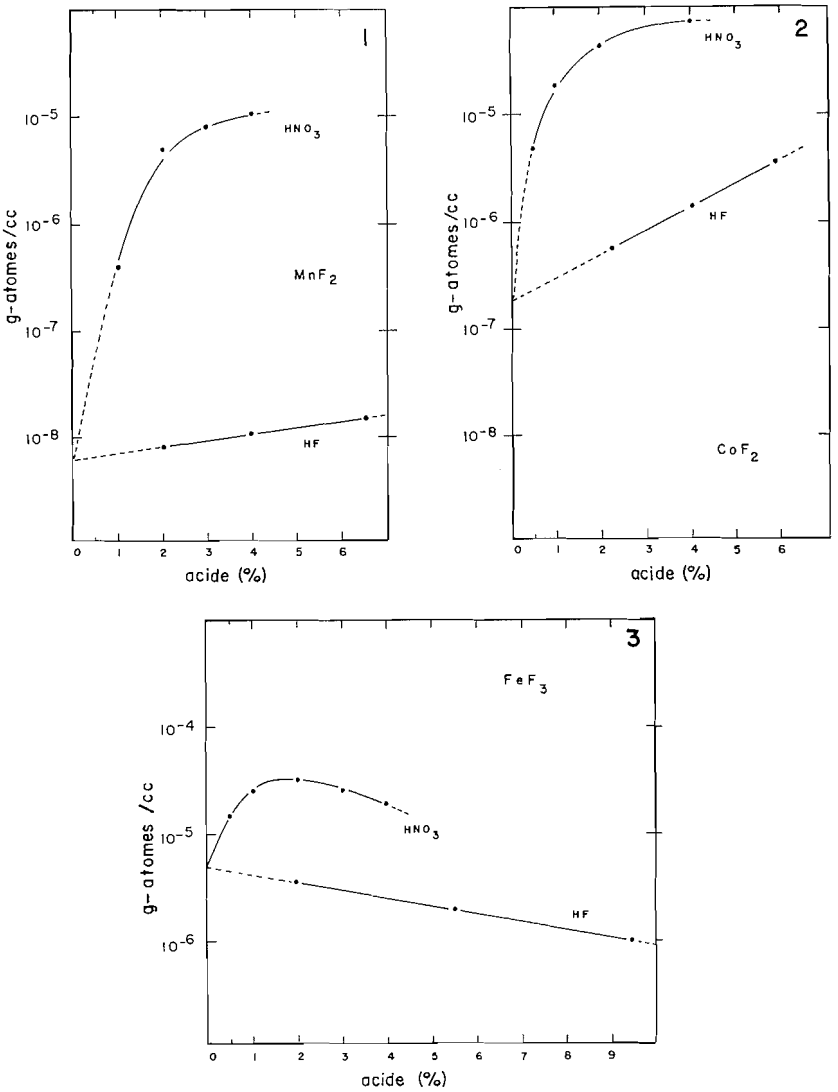
Mesures de radioactivité

Les bouteilles en polypropylène contenant la solution à mesurer ont été déposées sur un cristal de NaI, couplé électroniquement au spectromètre de rayonnements gamma à 128 canaux.

Les hauteurs des pics de 1.173 MeV, 0.835 MeV et 1.097 MeV respectivement pour ^{60}Co, ^{54}Mn et ^{59}Fe ont été mesurées et comparées avec celles des solutions étalons. Le rapport entre la quantité du sel utilisé et la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

radioactivité qui la représente est le même pour la quantité inconnue de sel en solution et la radioactivité mesurée.



Evidemment, pour que le composé radioactif ajouté représentât tout le sel, ou en d'autres mots, pour que le sel utilisé fût homogènement radioactif, il a été nécessaire de permettre que les échanges isotopiques prissent place.

La précision des mesures, incluant toutes les erreurs expérimentales (principalement dues à la volatilité de l'éther), est environ de ±8%.

DISCUSSION DES RÉSULTATS

Solubilités dans l'éther éthylique

La mesure de la solubilité en éther éthylique saturé de sel a été obtenue pour chaque sel par extrapolation des deux courbes correspondantes aux solubilités dans les deux mélanges éther–HNO_3 et éther–HF (Figs. 1 à 7).

FIGS. 1–3. Les solubilités des fluorures de manganèse, de cobalt et de fer dans l'éther éthylique pur, l'éther–HNO_3 et l'éther–HF, à 29 °C. (Logarithme de g-atomes de métal, par cc.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Puisque cette technique radiosotopique comporte l'introduction d'une quantité de sel radioactif dissous en HNO_3, il est clair que la mesure dans l'éther pur est impossible; l'extrapolation des deux courbes, d'ailleurs, donne une mesure assez précise et indique l'accord des résultats obtenus par deux voies différentes. L'extrapolation est aussi légitime, car la plupart des courbes sont des droites ou des branches de paraboles.

Les Figs. 1 et 7 montrent que les halogénures de manganèse sont moins solubles dans l'éther pur, que ceux des autres métaux. En général, on peut voir que les sels étudiés sont solubles dans l'éther, à un niveau suffisant pour permettre l'analyse et la chromatographie des traces des métaux en solution dans l'éther.

Solubilités dans les mélanges éther–HNO_3 et éther–HF

Les courbes qui illustrent les concentrations de métal dans la solution éther–HF, au varier du pourcent de HF, sont essentiellement des droites, avec l'exception remarquable

FIGS. 4–7. Les solubilités des nitrates et des chlorures de manganèse, de cobalt et de fer dans l'éther éthylique pur, l'éther–HNO_3 et l'éther–HF, à 29 °C. (Logarithme de g-atomes de métal, par cc.)

de la courbe du $Fe(NO_3)_3.9H_2O$ qui présente un point d'inflection. Il n'est pas possible de donner une explication de ce phénomène, mais les fluorures complexes qui se forment en solution aqueuse (9) se forment aussi dans l'éther (Figs. 1-3); et dans le cas illustré en Fig. 5, il se forme probablement un complexe particulièrement soluble.

Les courbes relatives aux mélanges éther–HNO_3 indiquent que les sels étudiés y sont beaucoup plus solubles que dans le mélange éther–HF, spécialement dans le cas du MnF_2 (Fig. 1). Généralement, à l'augmenter du pourcent de HNO_3, ces courbes montrent une nette et progressive augmentation de la concentration du métal.

Le mélange éther–HNO_3 est de mineure importance pour des teneurs en HNO_3 supérieures à 4%, étant donné qu'il devient un mélange explosif, du fait que des peroxides se forment. Mais aux faibles teneurs en HNO_3, ce mélange est de grand intérêt. D'autre part, en chromatographie sur cellulose, l'effet de l'acide nitrique sur la retention du cobalt de la part de plusieures celluloses a été trouvé négligeable (10).

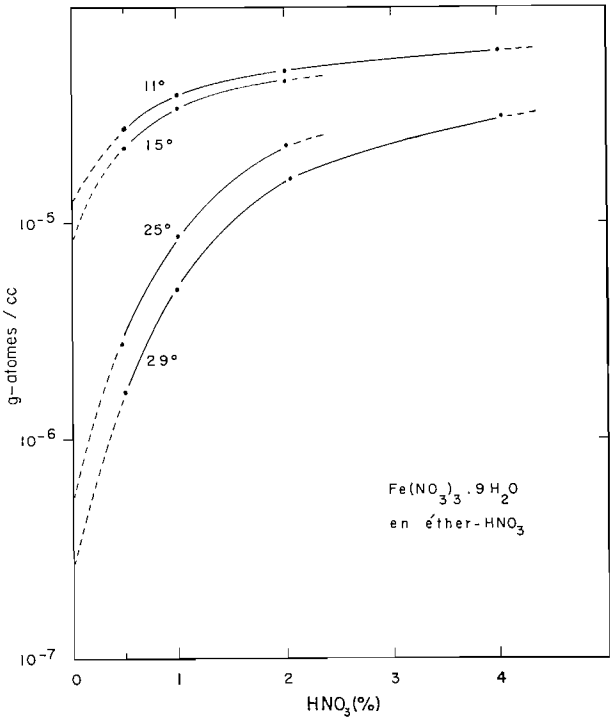

FIG. 8. La solubilité du nitrate ferrique ennéahydrate en éther éthylique pur et en éther–HNO_3, en fonction de la température. (Logarithme de g-atomes de métal, par cc.)

Variation de la solubilité en fonction de la température

La température a certainement un effet important sur la solubilité des sels dans l'éther.

Le nitrate ferrique ennéahydrate a été étudié en éther–HNO_3, et les résultats sont illustrés en Fig. 8.

CONCLUSIONS

Sur la base de ces résultats, il a été possible de séparer par chromatographie descendante les traces de chlorures de cobalt et manganèse d'avec microgrammes de chlorure ferrique (11).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

En outre, si un échantillon d'uranium doit être analysé pour déterminer les traces de fer, de manganèse et de cobalt, et s'il est dissous en HNO_3, le nitrate d'uranyle cristallisé peut être facilement dissous dans l'éther–HNO_3, 2%. Compte tenu des résultats de cette étude, on pourra être sûrs que les traces des trois métaux passeront complètement en solution dans l'éther, pour une successive séparation chromatographique.

THE NUMERICAL ANALYSIS OF ELECTRON SPIN RESONANCE SPECTRA WITH HYPERFINE STRUCTURE[1]

R. Newton, K. F. Schulz, and R. M. Elofson

Numerical techniques have been devised that provide for the complete analysis of an electron spin resonance spectrum with any amount of hyperfine structure, provided the source material contains not more than two radicals.[2] These techniques depend primarily on the condition that each separate splitting constant has a symmetric effect on the spectrum, and their successful application depends equally on the accuracy with which this symmetry is recorded.

In the simplest case, a recorded spectrum of a single radical may be defined mathematically as $S(x)$, x being the magnetic intensity measured relative to the center of the spectrum. If the spectrum is known to have a splitting constant of value s and a corresponding spin of one half, then the definition of this splitting constant requires that the spectrum $S'(x)$, which is defined as the spectrum $S(x)$ with s removed, be related to $S(x)$ by:

$$[1] \qquad S(x) = S'(x + s) + S'(x - s).$$

THE NUMERICAL ANALYSIS OF ELECTRON SPIN RESONANCE SPECTRA WITH HYPERFINE STRUCTURE[1]

R. Newton, K. F. Schulz, and R. M. Elofson

Numerical techniques have been devised that provide for the complete analysis of an electron spin resonance spectrum with any amount of hyperfine structure, provided the source material contains not more than two radicals.[2] These techniques depend primarily on the condition that each separate splitting constant has a symmetric effect on the spectrum, and their successful application depends equally on the accuracy with which this symmetry is recorded.

In the simplest case, a recorded spectrum of a single radical may be defined mathematically as $S(x)$, x being the magnetic intensity measured relative to the center of the spectrum. If the spectrum is known to have a splitting constant of value s and a corresponding spin of one half, then the definition of this splitting constant requires that the spectrum $S'(x)$, which is defined as the spectrum $S(x)$ with s removed, be related to $S(x)$ by:

$$[1] \qquad S(x) = S'(x + s) + S'(x - s).$$

[1]*Contribution No. 319, Research Council of Alberta, Edmonton, Alberta.*
[2]*A detailed account has been placed in the Depository of Unpublished Data. Photocopies may be obtained upon request to Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada.*

By replacing x in this equation with $x + 2s$, $x + 4s$, etc. the following series of equations result:

$$[2] \qquad \begin{aligned} S(x + 2s) &= S'(x + 3s) + S'(x + s) \\ S(x + 4s) &= S'(x + 5s) + S'(x + 3s) \\ &\text{etc.} \end{aligned}$$

By alternately adding and subtracting these equations, all the terms on the right hand side disappear in the limit, except for the first.

$$[3] \qquad \text{i.e. } S(x) - S(x + 2s) + S(x + 4s) - \text{etc.} = S'(x - s)$$

By putting $x = s$ on the left of eq. [3] a function $F(s)$ is defined which is a valid function of s, regardless of whether s is an actual splitting constant of $S(x)$ or not.

$$[4] \qquad F(s) = S(s) - S(3s) + S(5s) - \text{etc.}$$

However, if s does take the value of one of the splitting constants then

$$[5] \qquad F(s) = S'(0) = 0$$

since $x = 0$ is the center of a validly defined spectrum $S'(x)$. This eq. [5] represents a necessary condition for a value of s to be valid as a splitting constant of $S(x)$.

The basic approach used above has been elaborated for all the conditions which might be encountered in an electron spin resonance spectrum. In addition, a suitable curve-fitting technique has been detailed that allows an analysis of the line shape function and a more accurate determination of the splitting constants, when they are known approximately.

These techniques have been applied to a series of methyl-anthrasemiquinone spectra (1) and the results are discussed relative to the analysis.

of an e.p.r. spectrometer by the reduction of hydrogen peroxide with titanous ions in acidified aqueous solution. When an organic substrate is included in the reactant streams, it is attacked by the hydroxyl radicals to give products which can be detected by e.p.r. spectroscopy. 2,2,2-Trifluoroethanol, CF_3CH_2OH, was employed as the substrate and yielded a well-resolved e.p.r. spectral absorption of the form expected for the $CF_3\dot{C}HOH$ radical, i.e. a doublet of quartets resulting from coupling with the single CH proton and three equivalent CF_3–fluorine nuclei, respectively. In addition, each line of the quartets was split further into a narrow doublet. This narrow splitting is attributed to hyperfine interaction with the OH proton, a form of interaction which has been reported before for only a few organic radicals (4, 5). This spectrum is compared with that of the $CH_3\dot{C}HOH$ radical formed from ethanol under similar reaction conditions.

EXPERIMENTAL

The technique was essentially as before (2). The reactant streams were of line-distilled water 0.1 *M* in sulfuric acid (Baker and Adamson, chemically pure) and, respectively, 0.04 and 0.01 *M* in hydrogen peroxide (Becco, 98% w/w) and titanous chloride (Fisher, 20% w/w solution). The total flow rate was 5 ml s^{-1}, this being divided equally between the two streams. The reaction temperature was 27 ± 1 °C. Fresh samples of 2,2,2-trifluoroethanol (Halocarbon Products Co.) and ethanol (U.S. Industrial Chemical Co.) were used as substrates without further purification, since no impurities, except water, were detected by vapor-phase chromatography. The substrate was included in both reactant streams at the same concentration. When 2,2,2-trifluoroethanol was employed this concentration was 1 *M*, the value necessary for complete quenching of the absorption attributed to the hydroxyl radical. In the case of ethanol, a concentration of 0.1 *M* was easily enough for the signal of the hydroxyl radical to be suppressed. However, the concentration was varied over the range 0.1–1 *M*, no change being noticed in the results that were obtained. As before (2), spectra were recorded in the first-derivative form and all hyperfine coupling constants were measured against peroxylamine disulfonate as reference standard.

RESULTS AND DISCUSSION

A typical spectrum for 2,2,2-trifluoroethanol as substrate is shown in Fig. 1. The spectral structure is composed of 16 narrow lines, and is ascribed to the $CF_3\dot{C}HOH$ radical formed

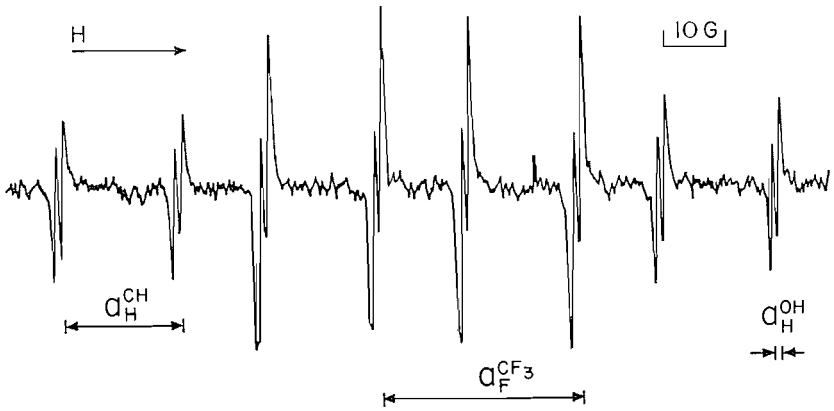

FIG. 1. First-derivative e.p.r. spectrum for the reaction of hydroxyl radicals with 2,2,2-trifluoroethanol (chart speed, 1 in. min^{-1}; time of scan, 10 min).

by the abstraction of a secondary hydrogen atom. These lines display the expected doublet (1:1) of quartets (1:3:3:1) arising from coupling with one CH proton and three CF_3–fluorine nuclei, respectively. However, each quartet is split further into a closely spaced doublet (1:1) which is attributed to coupling with the OH proton. This coupling

For personal use only.

is reasonably interpreted by a resonance-stabilization mechanism similar to that proposed (3) to operate in the $\cdot CH_2OH$ radical, as shown in eq. [1].

[1] $$CF_3\dot{C}H\ddot{O}H \leftrightarrow CF_3\ddot{\dot{C}}H\dot{\ddot{O}}H$$

Support for this view is provided by the fact that a coupling with the OH proton of a similar size has been noticed for $\cdot CH_2OH$ (6–8) and for a number of related radicals where resonance stabilization of the above sort might be expected, e.g. $\cdot CH(COOH)OH$ (6, 9) and $\cdot CH(CN)OH$ (10). In the case of $CH_3\dot{C}HOH$, coupling with the OH proton has not definitely been reported so far (3, 8). This is perhaps not surprising in view of the probable electron-releasing character (11) of the CH_3 group with respect to radical stabilization by the resonance mechanism. Neverthless, for comparison purposes, ethanol was examined as substrate over a range of concentration, particular attention being directed to the detection of the possible presence of coupling with the OH proton in the $CH_3\dot{C}HOH$ radical. The spectral absorption that was produced was essentially as previously observed (3, 8), a doublet (1:1) of quartets (1:3:3:1) with no resolved doublet splitting arising from the OH proton. Table I summarizes all the spectral results that were obtained.

TABLE I

Hyperfine coupling constants for radicals formed by hydroxyl radical attack on 2,2,2-trifluoroethanol and ethanol*

Radical	Isotropic hyperfine coupling constants, G			
	a_H^{CH}	$a_H^{CH_3}$	$a_F^{CF_3}$	a_H^{OH}
$CF_3\dot{C}HOH$	18.1±0.4	—	31.8±0.6	1.17±0.28
$CH_3\dot{C}HOH$†	15.0±0.2	22.5±0.3	—	—‡

*Each coupling constant given is the arithmetical mean of all measurements of that coupling constant taken from several field scans. The cited precision index is the maximum absolute deviation from the arithmetic mean.

†In addition, there was a weak background absorption. Subsequent work has shown (8, 10) that this weak absorption can be made of comparable intensity to the signal from $CH_3\dot{C}HOH$ by decreasing the initial value of the ratio $[TiCl_3]/[H_2O_2]$ in the mixed streams while keeping the other reaction conditions unchanged; consequently, it is possible to identify this absorption as a triplet (1:2:1) of triplets (1:2:1) consistent with the radical $\cdot CH_2CH_2OH$.

‡Less than 0.3–0.4 G, the estimated resolution limit of the instrument.

The temperature dependence of the spectral data obtained with 2,2,2-trifluoroethanol was not investigated. The results from such a study might have some bearing on the possible contribution of hydrogen bonding between the OH proton and the CF_3 group similar to that now established to occur (12–16) in 2,2,2-trifluoroethanol itself. However, the occurrence of this kind of intramolecular hydrogen bonding in the $CF_3\dot{C}HOH$ radical would appear to be sterically less favored than in the CF_3CH_2OH molecule. This is because of the trigonal bond hybridization at the unsaturated carbon atom in the former compared with the tetrahedral bond hybridization at the 1-carbon atom in the latter.

Of particular concern is the result for the CF_3–fluorine coupling constant, $a_F^{CF_3}$, for which no directly comparable data appear to have been published before. Perhaps the most nearly comparable investigation reported so far is the single-crystal study of the radical $^-O_2C—CF_2—\dot{C}F—CO_2^-$ trapped in irradiated sodium perfluorosuccinate (17). For this radical the two CF_2–fluorine nuclei gave roughly equivalent coupling tensors, the isotropic components being equal to 34.6 and 40.3 G. These data are not greatly different from the value of 31.8 G for $a_F^{CF_3}$ in $CF_3\dot{C}HOH$ reported in Table I. Another pertinent investigation concerns perfluoroalkyl polymeric radicals of functional structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$-CF_2-\dot{C}F-CF_2-$ trapped in irradiated, randomly oriented polytetrafluoroethylene (18).[3] For these radicals the observed value of $a_F^{CF_2}$ was 33 G (18), in reasonable agreement with the result of this present research. This agreement provides support for the claim by Rexroad and Gordy (18) that the CF_2–fluorine coupling for perfluoroalkyl polymeric radicals of the type they investigated appears to be predominantly isotropic in character. However, it should be emphasized that anisotropy is generally difficult to evaluate in randomly oriented samples such as those studied by Rexroad and Gordy. The fact that $a_F^{CF_3}$ ($CF_3\dot{C}HOH$) is so much larger than $a_H^{CH_3}$ ($CH_3\dot{C}HOH$) appears to be consistent with the powerful inductive effect ($-I$) of the CF_3 group relative to the $+I$ effect of the CH_3 group (11). Furthermore, it is in general agreement with the possibility of differences in the spin-delocalization mechanism operating in fluorocarbon radicals compared with that in hydrocarbon radicals (17, 20–22); for example, in the $CF_3\dot{C}HOH$ radical there is the likelihood of fluorine (2s) orbital mixing with the unsaturated-carbon (2p) orbital, whereas in the $CH_3\dot{C}HOH$ radical methyl-proton coupling is thought to arise via a hyperconjugative mechanism involving hydrogen (1s) orbitals and the unsaturated-carbon (2p) orbital.

That a a_H^{CH} is larger for $CF_3\dot{C}HOH$ than for $CH_3\dot{C}HOH$ is worth noting and may be another consequence of the factors discussed above in relation to the difference between $a_F^{CF_3}$ ($CF_3\dot{C}HOH$) and $a_H^{CH_3}$ ($CH_3\dot{C}HOH$). It might be mentioned that a part of the difference is presumably accountable on the basis of the expected (23) difference in excess charge density on the unsaturated carbon atom in the two radicals that were compared. Detailed consideration of these possibilities is hampered by the scarcity of e.p.r. data on comparable systems. Recently, Fischer (24) has developed a first-order treatment of substituent effects on the size of α-proton coupling constants in substituted simple alkyl radicals. For a similar reason, this approach is not readily extended to the $CF_3\dot{C}HOH$ radical at present. Moreover, it is likely that Fischer's approach would not be directly applicable here, inasmuch as both the CF_3 and OH groups are strongly inductive (11). Clearly, it would be interesting to have experimental data for other fluorinated aliphatic radicals.

The minimum concentrations of substrate needed to quench the signal of the hydroxyl radical under otherwise essentially identical reaction conditions are 1 and <0.1 M for 2,2,2-trifluoroethanol and ethanol, respectively. These results are somewhat preliminary, for the effect of changes in reaction conditions was not studied (8, 10). Nevertheless, the following qualitative comment may be made. The apparent difference in reactivity toward hydrogen atom abstraction at the 1 position is in line with the greater electron-withdrawing power of the CF_3 group compared with that of the CH_3 group (11) and the expected electrophilicity of hydroxyl radicals in reactions of this sort (6, 8, 10).

NOTE ADDED IN PROOF: After this present work was submitted for publication a pertinent paper (25) became available. This claims that the OH-proton splitting in the e.p.r. spectrum of the $\cdot CH_2OH$ radical under conditions similar to those employed in this present work is pH dependent as a consequence of OH-proton exchange. Similar spectral results for the $\cdot CH_2OH$ radical have recently been observed (10) in these laboratories as part of an already started investigation (8) which includes simple unsubstituted aliphatic alcohols; it might be noted that quantitative study of this phenomenon is complicated by the possibility of spectral-line broadening brought about by the presence of titanous ion.

[3]*It is relevant to add that results of size similar to those of Rexroad and Gordy (18) have been reported for irradiated samples of randomly oriented (19) and oriented (20) polytetrafluoroethylene.*

Consequently, the present work is being extended to cover a wider range of reaction conditions. It is hoped to report the resultant findings together with those arising from a current investigation of other fluorinated aliphatic substrates.

ABSTRACT

Infrared, ultraviolet, and nuclear magnetic resonance spectra of the following compounds are reported: 2-indanone (I), *trans*- and *cis*-hexahydro-2-indanone (V and XI), 1-chloro-2-indanone-1,3,3-d_3 (III), 1-bromo-2-indanone-1,3,3-d_3 (IV), 1-chloro-*trans*-hexahydro-2-indanone (VII), 1-bromo-*trans*-hexahydro-2-indanone (VIII), some deuterated forms of these compounds, 2-chlorocyclohexanone-2,6,6-d_3, and 2-bromocyclohexanone-2,6,6-d_3.

2-Indanone and *trans*-hexahydro-2-indanone each display two peaks in the carbonyl infrared region with intensity ratios of approximately 40:1. The origin of these doublets is discussed.

Nuclear magnetic resonance spectra were determined to indicate the presence or absence of ring mobility, and spin–spin coupling data were used to support some of the conclusions deduced from the infrared data for some of the compounds.

INTRODUCTION

It has previously been reported (see ref. 1 and references cited there) that film, solution, and KBr pellet infrared spectra of the 2-indanone ring system consistently gave a carbonyl doublet, whereas only one carbonyl frequency is reported for the 1-halo-2-indanones (2). To determine the origin of this doublet, we have re-investigated these spectra and prepared some appropriate α-substituted indanones. In addition, the ultraviolet and nuclear magnetic resonance (n.m.r.) spectra of these compounds are reported.

EXPERIMENTAL

Most of the infrared spectra were determined in replicate on a Perkin–Elmer model 21 spectrophotometer calibrated against atmospheric water vapor peaks at 1 784.95, 1 772.6, 1 768.17, and 1 756.82 cm^{-1} (25°), with a calcium fluoride prism at a computed spectral slit width (S') of 1.75 cm^{-1} in the carbonyl band region (3). The precision of the carbonyl band positions is estimated to range between 0.5 and 0.1 cm^{-1} depending on the symmetry of the peaks that are measured. The frequency accuracy of the ν^{I} values is believed to be better than ± 1 cm^{-1}, but the lower frequency ν^{II} peaks may be accurate to only ± 2 cm^{-1}

because of overlapping with the stronger, higher frequency peaks. The integrated absorption intensities (mole^{-1} l cm^{-2} $\times$ 10^{-4}) were calculated from the equation (4)

$$A = \frac{2.303}{2cl} \pi \log_{10} (T_0/T)_{max} \times \Delta\nu_{\frac{1}{2}}^{a}.$$

The accuracy of the A values is estimated to be $\pm 5\%$. Solute concentrations were about 0.015 ± 0.002 mole/l. Base lines were determined by Wright's method (5). The cell thickness (0.548 mm) was determined from interference fringes. A Perkin–Elmer heated cell assembly (sodium chloride windows; Bodenseewerk, Germany) was used to obtain spectra of liquids at elevated temperatures.

Ultraviolet absorption spectra were determined by standard methods in 1 cm cells with a Cary model 15 spectrophotometer. The accuracy of the λ_{max} values is estimated to be ± 1 mμ, and the precision of the molar absorptivities $\pm 5\%$ or better. Most molar absorptivity values were reproducible to within $\pm 2\%$.

Nuclear magnetic resonance spectra were obtained in carbon tetrachloride solutions on a Varian A 60 model with tetramethylsilane as an internal standard. A microcell (Varian) was used for compounds which were available only in small amounts.

All solvents that were used were commercially available, spectroanalyzed solvents, redistilled when necessary. Chloroform was freed from its preservative by shaking it with concentrated sulfuric acid. After separation and filtration through soda lime and anhydrous sodium sulfate, the chloroform was distilled; a center fraction was used.

Some of the compounds were prepared and purified by standard methods, as described in the literature, or were commercially available. The remaining compounds were prepared as follows (melting and boiling points are corrected; elemental analyses by Schwarzkopf Microanalytical Laboratory, 56-19 37th Avenue, Woodside 77, New York; deuterium analyses by Mr. J. Nemeth, Department of Chemistry, University of Illinois, Urbana, Illinois).

2-Indanone-1,1,3,3-d_4 (II) was prepared by refluxing 2-indanone (I; 6.6 g) eight times for 4 h with 10 ml portions of D_2O (99.5%, Isomet Corp.). No basic catalyst was used since its presence was found to accelerate self-condensation. The product was purified by steam distillation (with D_2O), chromatographed from a 10 cm column of silica (Mallinckrodt, 100 mesh) with redistilled pentane (Eastman) containing 5% reagent grade anhydrous ether (Fisher), and finally crystallized from pentane to yield *2-indanone-1,1,3,3-d_4* (II; 2.2 g), m.p. 57.0–57.5 °C.

Anal. Calcd. for $C_9D_4H_4O$: D, 50.00 atom % excess D. Found: D, 49.05 atom %.

trans-Hexahydro-2-indanone-1,1,3,3-d_4 (VI) was prepared by refluxing *trans*-hexahydro-2-indanone (V; prepared by Hückel's method (6)) four times for 4 h with 10 ml portions of D_2O, each containing 15 mg of sodium carbonate. After extraction with peroxide-free anhydrous ether, the product was dried (Na_2SO_4), evaporated in vacuum to 2 ml, and chromatographed on a 19 mm (inside diameter) column of specially prepared silicic acid. (Mallinckrodt 100 mesh silicic acid (300 g) was washed five times with distilled water (3 l), the water being decanted after ca. 5 min settling. After filtration, this silicic acid was further washed with 95% ethanol and absolute ethanol and then heated for 2 days at 120 °C. To this was then added 3% D_2O, and the mixture was shaken for 24 h.) Elution with pentane containing 3% anhydrous ether and solvent removal gave *trans-hexahydro-2-indanone-1,1,3,3-d_4*, n_D^{25} 1.4741. The infrared spectrum showed complete α-deuteration in a freshly prepared sample (see Discussion).

1-Chloro-*trans*-hexahydro-2-indanone (VII) was prepared by direct chlorination at 0 °C of *trans*-hexahydro-2-indanone (V; 500 mg) in the presence of a small amount of water (3 ml) until a slight excess of the theoretical amount of chlorine that was necessary (257 mg) had been added. After extraction with peroxide-free ether, the products were dried (Na_2SO_4), reduced in volume, and chromatographed as previously described, but protected from light and heat as much as possible. Re-chromatography gave *1-chloro-trans-hexahydro-2-indanone* (VII; 25 mg), n_D^{25} 1.4998.

Anal. Calcd. for $C_9H_{13}OCl$: C, 62.6; H, 7.6; Cl, 20.5. Found: C, 62.6; H, 7.45; Cl, 20.7.

1-Bromo-*trans*-hexahydro-2-indanone (VIII) was prepared by direct bromination (bromine; 578 mg dissolved in methylene chloride; 10 ml) of *trans*-hexahydro-2-indanone (V; 500 mg) dissolved in methylene chloride (15 ml). Sunlight was usually necessary to initiate and to accelerate the reaction, and sometimes more concentrated solutions had to be used. After solvent removal under vacuum, the products were worked up as described for the chloro compound, but in addition all processes were carried out in an atmosphere of nitrogen. *1-Bromo-trans-hexahydro-2-indanone* (VIII) thus obtained had $n_D^{25.2}$ 1.5289.

Anal. Calcd. for $C_9H_{13}OBr$: C, 49.8; H, 6.0. Found: C, 49.0; H, 5.8.

1-Chloro-*trans*-hexahydro-2-indanone-1,3,3-d_3 (IX) was prepared by direct chlorination of *trans*-hexahydro-2-indanone-1,1,3,3-d_4 (VI; 447.5 mg) as described for the preparation of 1-chloro-*trans*-hexahydro-2-indanone (VII), except that D_2O was used instead of H_2O in all instances. *1-Chloro-trans-hexahydro-2-indanone-1,3,3-d_3* (IX; 35 mg) thus obtained had $n_D^{24.4}$ 1.5002.

Anal. Calcd. for $C_9H_{10}D_3OCl$: C, 61.5; H (+ D), 7.65; Cl, 20.2; D, 23.1 atom % excess D. Found: C, 61.7; H (+ D), 7.9; Cl, 20.1; D, 18.5 atom %.

1-Bromo-*trans*-hexahydro-2-indanone-1,3,3-d_3 (X) was prepared by bromination of *trans*-hexahydro-2-indanone-1,1,3,3-d_4 (VI; 391.8 mg) as described for the preparation of 1-bromo-*trans*-hexahydro-2-indanone

(VIII), except that D_2O was used instead of H_2O in all instances and that fluorotrichloromethane (Freon 11) was used as the solvent. *1-Bromo-trans-hexahydro-2-indanone-1,3,3-d_3* (X) was obtained in poor yield (9 mg) and, not consistently so, as a light yellow-brown liquid.

Anal. Calcd. for $C_9H_{10}D_3OBr$: C, 49.1; H (+ D), 6.1. Found: C, 47.5; H (+ D), 5.9.

Irradiation with a mercury lamp resulted almost exclusively in the dibromo compound.

1-Chloro-*cis*-hexahydro-2-indanone (XII) was prepared from *cis*-hexahydro-2-indanone (XI; prepared as described in ref. 6) as in the preparation of the corresponding *trans* isomer. It showed n_D^{25} 1.5068, but the elemental analysis indicated that, even after three chromatographs, the product still contained some dichloro impurity.

Anal. Calcd. for $C_9H_{13}OCl$: C, 62.6; H, 7.6; Cl, 20.5. Found: C, 61.5; H, 7.3; Cl, 23.2.

1-Bromo-cis-hexahydro-2-indanone (XIII) was prepared in the same way as the *trans* isomer (VIII) and had n_D^{24} 1.5283. The elemental analysis indicated the presence of some dibromo compound as an impurity.

Anal. Calcd. for $C_9H_{13}OBr$: C, 49.8; H, 6.0; Br, 36.8. Found: C, 49.3; H, 5.8; Br, 38.2.

2-Chlorocyclohexane-2,6,6-d_3 was prepared from cyclohexanone-2,2,6,6-d_4 (489.4 mg) by chlorination (343.5 mg chlorine) as in the preparation of 1-chloro-*trans*-hexahydro-2-indanone-1,3,3-d_3 (IX). *2-Chlorocyclohexanone-2,6,6-d_3* (123.2 mg) thus obtained had $n_D^{23.5}$ 1.4827.

Anal. Calcd. for $C_6H_6D_3OCl$: C, 53.1; H (+ D), 6.9; Cl, 26.1; D, 33.3 atom % excess D. Found: C, 53.3; H (+ D), 7.1; Cl, 26.1; D, 31.5 atom %.

2-Bromocyclohexanone-2,6,6-d_3 was prepared from cyclohexanone-2,2,6,6-d_4 (748 mg) by sunlight-catalyzed bromination (1.17 g bromine) as in the preparation of 1-bromo-*trans*-hexahydro-2-indanone (VIII). Purification and redistillation yielded *2-bromocyclohexanone-2,6,6-d_3* (149.7 mg), $n_D^{22.5}$ 1.5107.

Anal. Calcd. for $C_6H_6D_3OBr$: C, 40.0; H (+ D), 5.2; Br, 44.4; D, 33.3 atom % excess D. Found: C, 40.2; H (+ D), 5.3; Br, 44.1; D, 29.6 atom %.

1-Chloro-2-indanone-1,3,3-d_3 (III) was prepared from 2-indanone-1,1,3,3-d_4 (II; 509.9 mg) by chlorination (150 mg chlorine) as in the preparation of 1-chloro-*trans*-hexahydro-2-indanone-1,3,3-d_3 (IX). After crystallization from pentane, *1-chloro-2-indanone-1,3,3-d_3* (III; 174.1 mg) had m.p. 71–71.5° (Brutcher *et al.* (7) report m.p. 71–71.5° for the non-deuterated analogue).

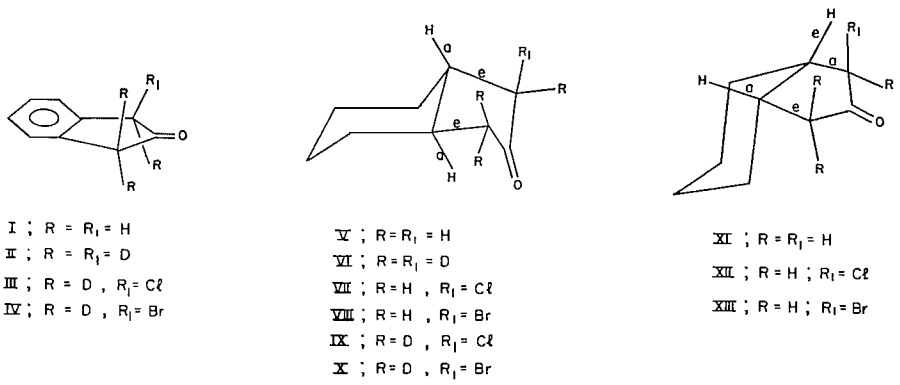
Anal. Calcd. for $C_9H_4D_3OCl$: C, 63.7; H (+ D), 4.36; Cl, 20.9; D, 42.9 atom % excess D. Found: C, 63.9; H (+ D), 4.5; Cl, 21.1; D, 42.9 atom %.

1-Bromo-2-indanone-1,3,3-d_3 (IV) was prepared by direct bromination (bromine; 471.8 mg dissolved in methylene chloride; 10 ml) of 2-indanone-1,1,3,3-d_4 (II; 401.9 mg) dissolved in methylene chloride (10 ml). After solvent removal under vacuum, the products were worked up as for compound II. *1-Bromo-2-indanone-1,3,3-d_3* (IV; 424.7 mg) was crystallized from 5% ether in pentane and had m.p. 90–91° (Brutcher *et al.* (7) report m.p. 91° for the non-deuterated analogue).

Anal. Calcd. for $C_9H_4D_3OBr$: C, 50.5; H (+ D), 3.45; Br, 37.3; D, 42.9 atom % excess D. Found: C, 50.2; H (+ D), 3.3; Br, 37.2; D, 41.0 atom %.

DISCUSSION

Infrared Spectra



The relevant spectral data are listed in Table I. 2-Indanone-1,1,3,3-d_4 (II) and 2-indanone (I) are presumably planar or near-planar molecules (see also discussion of n.m.r. spectra). The frequency displacements of the main carbonyl bands in carbon tetrachloride solution observed on halogen substitution for compounds III and IV relative to these bands in compound II (20 and 9.9 cm^{-1}; see Table I) are similar to the displacements observed on halogen substitution of the non-deuterated analogues (19 and 13 cm^{-1}; see Table II) and in other related molecules (7). The halogen-substituted indanones III and IV may be slightly non-planar (see discussion of n.m.r. spectra), but there is no reason to suppose that the planarity of the indanone system is appreciably disturbed.

A small spectral displacement is observed between the main carbonyl bands of compounds I and II (0.5 cm^{-1}), if the bands are measured under identical conditions; similar small displacements may occur between compounds III and IV and their respective non-deuterated analogues. Inspection of the actual traces (Fig. 1) also shows that for 2-indanone (I) and compound V subsidiary bands occur at 1 728.8 cm^{-1} and 1 706.1 cm^{-1}, respectively, which are less intense and displaced in the deuterated compounds II and VI.

A number of possible explanations can account for the appearance of two carbonyl bands. Before these are discussed, however, a number of possibilities may be ruled out.

First, the absence of any concentration dependence within the concentration range 0.25

to 0.025 mole/l for compounds I and V (see Table I) eliminated intermolecular association complexes. The absence of such interactions is also indicated by the absence of a subsidiary band in the *cis* isomer (XI).

Next, enolization is unlikely as an explanation since no OH absorption could be detected in the infrared spectra, even at elevated temperatures. Figure 2 shows the overtone bands at 2.859 μ (3 498 cm^{-1}) and 2.878 μ (3 475 cm^{-1}) for compounds I and V, respectively, which are identified as such since these bands also occur in the deuterated analogues at 2.863 μ (3 493 cm^{-1}) for compound II and at 2.885 μ (3 466 cm^{-1}) for compound VI (see Fig. 2). Moreover, the n.m.r. spectra of compounds I, V, and XI show no hydroxyl protons (see Figs. 4*d*, 4*i*, and 4*l*).

Conformational isomerism also seems unlikely, since in such an equilibrium, when the

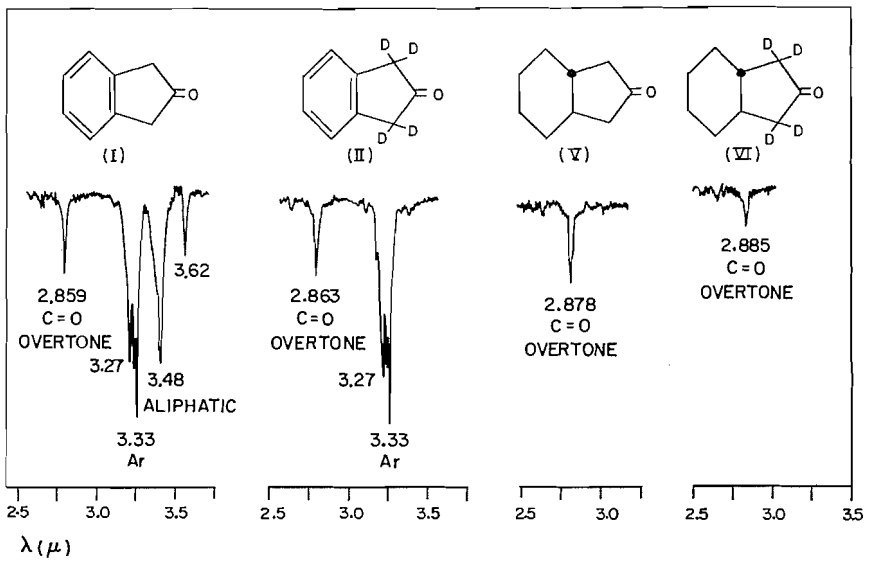

FIG. 2. Infrared spectra of compounds I, II, V, and VI (carbon tetrachloride solution) in the 2.5–3.5 μ region.

temperature is raised, the less-favored isomer would be expected to equilibrate with the more stable form. Figure 3 shows no such equilibrium for compounds I and V.

"Hot bands" also probably do not account for the subsidiary bands in compounds I and V, because such an explanation cannot readily account either for the changes observed in the deuterated analogues or for the observed spectral changes when the solvent is altered (see Table I). Moreover, hot transitions would be expected to be temperature dependent, and no such dependence is observed (see Fig. 3).

Finally, the presence of impurities, particularly water vapor, was looked for as a possible explanation of the subsidiary band, but careful repurification did not affect the observed spectra.

On the other hand, weak Fermi coupling is a possible explanation for the subsidiary bands observed in compounds I and V; such weak coupling between overtones and (or) combination bands on the one hand, and the strong carbonyl fundamental band on the other hand, may account partly for the small displacements observed in the main carbonyl bands of compounds II, III, IV, and VI and their non-deuterated analogues. The hypothesis of Fermi coupling similarly may also account, at least partly, for the decreased intensity of the subsidiary band in compound II and in compounds where the α-hydrogen atoms have been replaced by deuterium (see Fig. 1). If this explanation is correct, Fermi coupling seems to be more effective in compound V than in 2-indanone (I). This can be rationalized on the basis that the cyclopentanone ring in *trans*-hexahydro-2-indanone (V), unlike this ring in 2-indanone (I), is not planar (see discussion of n.m.r. spectra and refs. 7 and 8 and references cited there); possibly the molecule is then in a more favorable conformation for Fermi coupling to occur. No pronounced doublet formation could be detected in the *cis* isomer (see Fig. 1), which, however, may exist in a different conformation.

Moreover, some of the solvent changes (see Table I) are similar to those occurring in cyclopentanone (9) and ethylene carbonate (10), where Fermi resonance has been suggested as an explanation of the observed doublet.

However, there are difficulties with this explanation, based on Fermi coupling. First, the

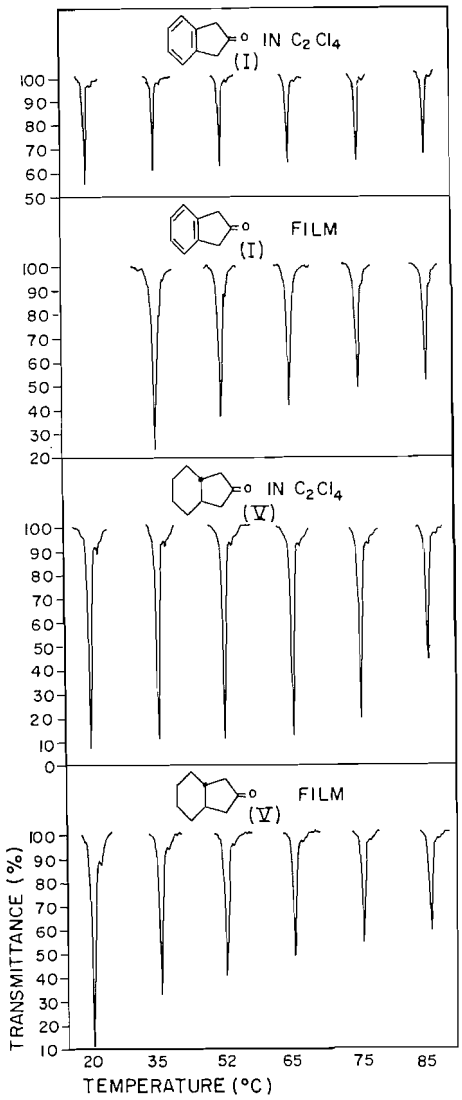

FIG. 3. Effect of temperature on the C=O stretching absorption in film and *sym*-tetrachloroethylene solutions of 2-indanone (I) and *trans*-hexahydro-2-indanone (V).

main carbonyl bands in compounds I and V are only weakly sensitive to isotopic substitution; hence, it is unlikely that one of the excitations corresponds to a combination band or overtone involving predominantly α-hydrogen motions. Also, there are no plausible bands in the infrared spectrum, overtones or combination bands of which could readily account for the Fermi coupling.

Next, it may be noted that the observed weak band could represent a weak fundamental vibration of the complex molecule. Such a vibration may be forbidden in a molecule in which the local symmetry (carbonyl and α-carbonyl region) is relatively high, as in the *cis* isomer (IX), where no subsidiary band is observed. If this is so, the various changes of position and intensity with substitution may predominantly reflect mass changes.

TABLE I

*These bands were found to be concentration independent (by using different path lengths) within the concentration range 0.25 to 0.025 mole/l.

Also, it is possible that the weak transition corresponds to a combination band which for symmetry reasons, or because of the absence of anharmonic mixing with the carbonyl fundamental vibration, is behaving independently with respect to substitution. That is, no Fermi coupling need be involved for at least some of the molecules studied.

Further, it is possible that in the aromatic systems the symmetry tends to inhibit Fermi coupling but that in some of the *trans*-hexahydro molecules it allows more Fermi coupling. Then, if the local symmetry (carbonyl and α-carbonyl region) is greater in the *cis* molecule, as seems likely, this could account for the absence of the subsidiary band in the *cis* molecules. In any case, Fermi coupling applies only to the interaction between a fundamental vibration and an overtone or combination tone, and carbonyl stretching modes not only involve stretching of the C=O bond but also motions of the adjacent C—C and C—H bonds and bond angles. Hence, it is probable that changing the adjacent masses changes significantly the form of the mode and thus its frequency. Any Fermi coupling may therefore only be a secondary interaction superimposed on this more fundamental effect. For example, the displacement in the carbonyl band for compound VIII on deuteration (-9.4 cm^{-1}; see Table I) may be caused by the non-equivalence of the α-positions on bromo substitution. Whatever their precise origin, these perturbations are unfortunate, since therefore the displacements observed on 1-chloro or 1-bromo substitution, *in the*

absence of the above-mentioned effects, cannot readily be determined. It is these displacements which are used to provide information concerning the conformation of the halogen-substituted compound. The uncorrected displacements obtained for these and some reference compounds on chloro and bromo substitution are listed in Table II.

Ultraviolet Spectra

The data (Table III) show that, in some of the compounds investigated, slight spectral variations are observed in the $n \rightarrow \pi^*$ carbonyl band transitions on deuteration of the neighboring carbon atom. This is not inconsistent with the infrared data, which have indicated that the carbonyl stretching mode in the ground state is affected by α-substitution; hence the excited-state carbonyl stretching mode may also be affected by such substitution. However, the ultraviolet data must be interpreted cautiously since most of the compounds studied exhibit, like cyclopentanone, a number of peaks in the region studied; hence the location of the maximal absorption cannot readily be determined. Only the main maxima are recorded in Table III. For compounds I to IV, the low-intensity $n \rightarrow \pi^*$ electronic transition could not be measured, because of the large benzenoid absorption.

Nuclear Magnetic Resonance Spectra

The n.m.r. spectrum of cyclohexanone exhibits two peaks, one caused by four α-carbonyl hydrogens and the other by the six remaining hydrogens (12). Cyclohexanone-2,2,6,6-d_4, on the other hand, exhibits only one peak with no spin–spin splitting (see

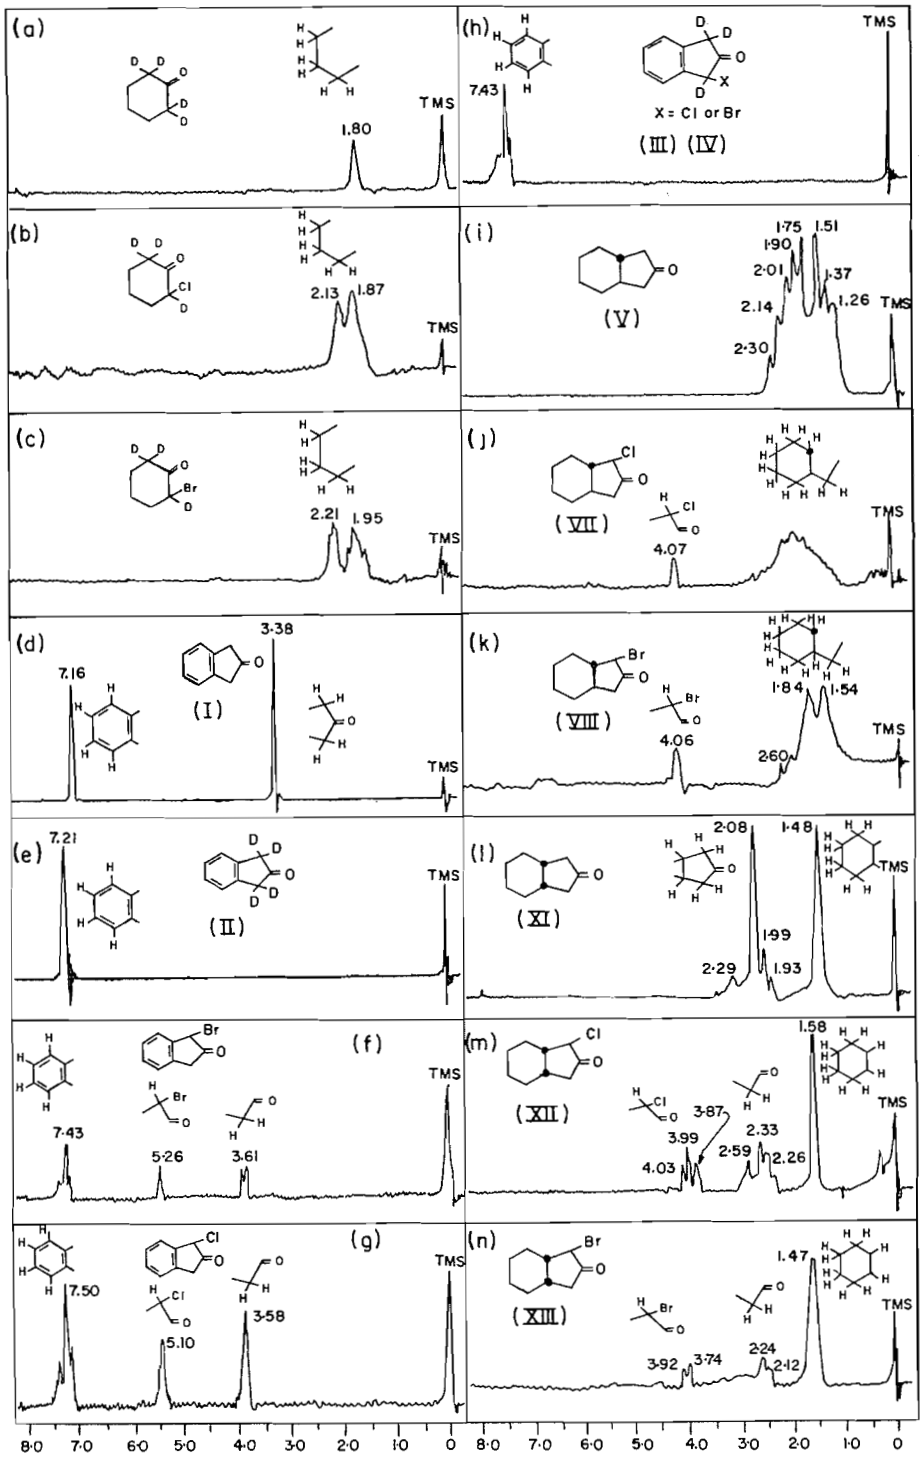

FIG. 4. Nuclear magnetic resonance spectra in carbon tetrachloride solution of (*a*) cyclohexanone-2,2,6,6-d_4, (*b*) 2-chlorocyclohexanone-2,6,6-d_3, (*c*) 2-bromocyclohexanone-2,6,6-d_3, (*d*) I, (*e*) II, (*f*) 1-bromo-2-indanone, (*g*) 1-chloro-2-indanone, (*h*) III and IV, (*i*) V, (*j*) VII, (*k*) VIII, (*l*) XI, (*m*) XII, and (*n*) XIII (TMS = tetramethylsilane).

Fig. 4*a*). This shows that the ring is mobile. Likewise, the n.m.r. spectrum of 2-chlorocyclohexanone (12) gives no indication of ring rigidity. The n.m.r. spectra of the chlorinated and brominated trideuterio analogues (see Figs. 4*b* and 4*c*) show two distinct peaks, one caused by the two hydrogens vicinal to the halogen and the other by the remaining four hydrogens on the ring. All these data confirm the mobility of the cyclohexanone ring.

The n.m.r. spectrum of compound I does not show any splitting (Fig. 4*d*), and that of its deuterated analogue (II; see Fig. 4*e*) shows only one sharp peak. 1-Bromo-2-indanone (see Fig. 4*f*) and 1-chloro-2-indanone (see Fig. 4*g*) yield three peaks in the ratio 4:2:1. Both spectra show a small amount of fine structure in the peak caused by the aromatic hydrogen atom; similar effects are observed in the deuterated analogues (III and IV; see Fig. 4*h*). This splitting is ascribed to the inductive effect of the halogen atom. The spectrum of 1-bromo-2-indanone shows a doublet for the geminal hydrogens (see Fig. 4*f*), thus suggesting that these hydrogens are not identical, one being slightly axial and the other slightly equatorial, presumably because of the steric effect of the larger bromine atom and its more axial character.

The spectra of *trans*-hexahydro-2-indanone (V) and its halogenated analogues (VII and VIII) suggest a rigid system with considerable spin coupling (see Figs. 4*i*, 4*j*, and 4*k*). The spectrum of the corresponding hydrocarbon also indicates a rigid system (13). Moreover, 1-chloro-*trans*-hexahydro-2-indanone (VII) gives a single peak (see Fig. 4*j*) at 4.07 p.p.m. with a band width of about 8 c.p.s. This relatively large band width suggests a limited amount of splitting between the angular hydrogen and the hydrogen geminal to the chlorine atom. Such a splitting is consistent if the angle between the two hydrogen atoms is about 85° (see Karplus' corrected equation (14)), but splitting probably also occurs across the carbonyl group with the methylene protons. 1-Bromo-*trans*-hexahydro-2-indanone (VIII) shows a similar peak with a band width of about 16 c.p.s. (Fig. 4*k*); this splitting is consistent with an angle, as defined above, of about 40°. The chloro and bromo derivatives (IX and X) of the appropriate deuterated compound (VI), as anticipated, give n.m.r. spectra identical with that of the parent compound (VI). The spectrum of *cis*-hexahydro-2-indanone (XI; see Fig. 4*l*) indicates a mobile molecule, as do the spectra of the corresponding halogen derivatives (XII and XIII; see Figs. 4*m* and 4*n*). *cis*-Hydrindane has been shown to have a low energy barrier to rotation (13).

1-Chloro-*cis*-hexahydro-2-indanone (XII) exhibits four peaks for the hydrogen geminal to chlorine (see Fig. 4*m*), which can be explained by assuming two non-equivalent α-positions, located in a molecule which itself can assume two conformational isomers. 1-Bromo-*cis*-hexahydro-2-indanone shows two peaks, with a possibility of further unresolved spin–spin splitting for the hydrogen geminal to bromine. This can be explained by assuming that, for this compound in both isomers, the conformation containing the bromine atom in the axial position is preferred.

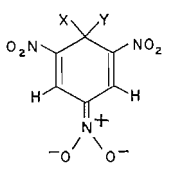
HYDROGEN EXCHANGE IN *s*-TRINITROBENZENE

E. BUNCEL AND E. A. SYMONS
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 15, 1965

ABSTRACT

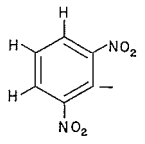
Hydrogen exchange in *s*-trinitrobenzene has been observed in the medium 90% dimethylformamide – 10% deuterium oxide containing sodium deuteriooxide (0.01 *M*). The proton transfer process between *s*-trinitrobenzene and base is therefore established. The factors which may contribute to the importance of the proton transfer process relative to the formation of Meisenheimer-type complexes are considered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



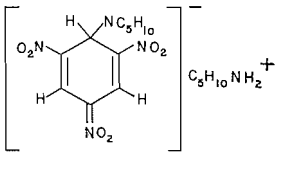
A particularly challenging problem is presented by the nature of the colored solutions formed in the interaction of aromatic polynitro compounds with bases. The following types of interaction have been proposed: attachment of the base to aromatic carbon with formation of an adduct having a pentadienyl structure (e.g. I) (1–7); formation of charge transfer complexes caused by partial overlap of electronic charge to the nitro compound (8–12); formation of anions such as II resulting from abstraction of nuclear hydrogen from the nitro compound (13–15).[1]

The pentadienyl anion structure (I, X = OR, Y = OR′) has now been well established through studies of visible (2), infrared (5), and most particularly nuclear magnetic resonance (17) spectroscopy; its role as the intermediate in nucleophilic aromatic substitution processes is understood (18). Theoretical aspects of the charge transfer process have been discussed (19 and references therein). In contrast, there is considerable uncertainty about the circumstances under which proton transfer processes are possible and about the role of the resulting anions in the overall scheme.

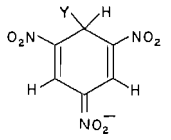


The formation of II, at least in a small concentration, from *m*-dinitrobenzene was demonstrated (15) by the observation of hydrogen exchange with a medium of dimethylformamide – deuterium oxide containing sodium deuteriooxide (0.005 *M*). It was suggested (15) that this anion may be responsible for the deep color of the solution, but this was not supported by other work (20). Even more uncertain was the situation with regards to the formation of the anion from *s*-trinitrobenzene. Thus Kharasch *et al.* (21) reported that treatment of *s*-trinitrobenzene with 0.02 *M* sodium hydroxide in ethanol – deuterium oxide resulted in the dilution of the deuterium of the medium, equivalent to the exchange of over 2 g-atoms of hydrogen from the trinitrobenzene. However, Ketelaar *et al.* (22) detected no deuterium enrichment in the *s*-trinitrobenzene recovered from 8 *M* sodium hydroxide in D_2O, and Miller and Wynne-Jones (8) observed no exchange after treatment with pyridine–D_2O. Recently an alternative explanation has been offered (6) to account for the observations of Kharasch *et al.*

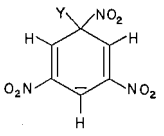
Opinions based on measurements of conductivity and cryoscopy are likewise not unanimous. From both types of measurement Baliah and Ramakrishnan (14) concluded that in ethanolamine solutions *s*-trinitrobenzene does ionize by a proton transfer mechanism. A similar explanation was given by Lewis and Seaborg (13) for the conductivity of *s*-trinitrobenzene in pyridine. On the other hand, from conductivity and spectroscopic data Briegleb *et al.* (23) concluded that the ionic species formed from *s*-trinitrobenzene and piperidine in acetonitrile solution was the Meisenheimer-type adduct III.



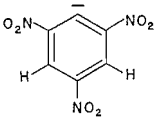
[1] *Under certain conditions the formation of radical anions has also been reported (16).*



I



II



III

IV

V

VI

In view of this apparently conflicting evidence and in light of our previous findings (24) of an aromatic hydrogen exchange under mild conditions (CH_3ONa–CH_3OD), it was decided to re-investigate hydrogen exchange in the polynitrobenzenes.

RESULTS AND DISCUSSION

In the present study the exchange of hydrogen was investigated by two methods: measurement of the dilution of the deuterium of the medium during reaction by hydrogen by means of infrared spectroscopy, and estimation of the deuterium content in the recovered *s*-trinitrobenzene by spectral means and by analysis. We now report that *s*-trinitrobenzene does in fact undergo extensive hydrogen exchange in a medium of dimethylformamide–D_2O containing NaOD.[2]

The addition of NaOD in D_2O to a solution of *s*-trinitrobenzene in dimethylformamide gave a solution (0.01 *M* NaOD in 90% dimethylformamide – 10% D_2O) which was ruby red in color. The entry of hydrogen into the medium was first followed at room temperature; during 24 h there was only a small development of OH (measured at 3 450 cm^{-1}), indicating that exchange had occurred to about 15%. The temperature was then raised to 100 °C; in 30 min the OH peak increased to about 95% of its theoretical value. There was no significant increase in the OH peak during the next hour. The reaction was then stopped and the trinitrobenzene recovered. It was identified by its melting point, elemental analysis, and ultraviolet and visible spectra. In the infrared spectrum a band at 2 310 cm^{-1} showed the presence of C—D. The nuclear magnetic resonance spectrum showed a barely detectable signal corresponding in position to the hydrogens of *s*-trinitrobenzene. Deuterium analysis corresponded to 93.8% deuteration (the theoretical value for complete equilibration, if one ignored any possible isotope effects, was 96.9% deuteration). Hence it can be concluded that practically complete exchange of hydrogen in the *s*-trinitrobenzene had occurred.

s-Trinitrobenzene can be considered to be in equilibrium with anions IV, V, and VI as a result of the interaction with base Y^- (charge transfer complexes being disregarded). Of the two pentadienyl-type anions the Meisenheimer-type anion IV will be present in far greater concentration, even though V must be the reactive intermediate (6) in the formation 1-Y-3,5-dinitrobenzene, which is the main product of substitution (6). However,

[2]*Hydrogen exchange in s-trinitrobenzene has also been observed recently by Crampton and Gold: cited in ref. 25 as "unpublished observations" and in a personal communication from Professor Gold.*

only anion VI, formed by proton abstraction, leads to hydrogen exchange. In terms of the terminology recently advanced by Parker (26) and by Bunnett (27), the nucleophile Y^- takes part in competing processes resulting from its "carbon basicity" (equilibrium formation of IV and V) and its "hydrogen basicity" (equilibrium formation of VI). Any factor which will displace the balance between these equilibria will have an effect on the relative importance of hydrogen exchange in the overall scheme. An important example of such a factor is solvation of the nucleophile Y^-.[3] Parker (26) has shown that the nucleophilic reactivity, in rate processes, and the basicity, in equilibria, towards carbon of a number of nucleophiles are greatly enhanced by a change from a hydroxylic medium to a dipolar aprotic one (e.g. dimethylformamide), and that even relative orders of efficacy of the nucleophiles may be reversed in the two types of media. Cram *et al.* (32) observed that the nucleophilic reactivity of alkoxide ion in proton abstraction from carbon increased by as much as 10^9 when the solvent was changed from alcohol to dimethyl sulfoxide. Similarly it has recently been shown that deuteriooxide ion can bring about hydrogen exchange of dimethyl sulfoxide in its aqueous solutions (33). The observation of hydrogen exchange with *s*-trinitrobenzene in 90% dimethylformamide – 10% D_2O medium containing NaOD is in accord with the above discussion. It is hoped that a combination of rate and equilibrium studies will allow a dissection of the various possible processes.

The apparently conflicting evidence in the literature on the importance of the proton transfer process is, at least in part, explainable. The reaction medium and temperature were sufficiently diverse in the various studies to allow a shift in emphasis in the equilibria referred to above, in favor of or against the proton transfer process. The respective conclusions are thus not necessarily incompatible with one another. A systematic study is called for.

EXPERIMENTAL

Materials

s-Trinitrobenzene (Eastman) was recrystallized from ethanol, m.p. 122.0–122.5°.[4] Dimethylformamide was dried over molecular sieves and distilled under reduced pressure. NaOD solution was prepared by dissolving freshly cut sodium in 99.5% D_2O (Diaprep Inc.), and was standardized by titration with acid.

Methods

The infrared method for OH analysis in the aqueous dimethylformamide solutions was based on the measurement of absorbance at 3 450 – 3 500 cm^{-1} caused by OH stretching. Spectra were taken on a Perkin–Elmer model 21 instrument, usually over the region 3 700 – 2 300 cm^{-1}, cells with calcium fluoride or "irtran" (Connecticut Instrument Co.) windows, and a hypodermic syringe (for transfer of the solutions) being used. A calibration curve was first prepared with solutions of known H_2O and D_2O content; these solutions always contained 90% of dimethylformamide by volume. The calibration curve (absorbance versus hydrogen concentration) was almost linear up to a concentration of 1.0 g-atom hydrogen/l. The reproducibility of a measurement of hydrogen concentration was between 2 and 5%.

Hydrogen Exchange

In one experiment a solution was prepared containing 1.065 g *s*-trinitrobenzene in 50 ml of 0.01 *M* NaOD in 10% D_2O – 90% dimethylformamide. The red solution was sampled for OH analysis, first at room temperature (26°) and then while immersed in a constant temperature bath at 100°. To stop the reaction, the solution was added to dilute sulfuric acid (1 ml of 1 *N*) on ice; the red color was immediately discharged. The precipitated solid was recrystallized twice from ethanol to give pale yellow crystals (0.608 g), m.p. 122°, mixed m.p. with *s*-trinitrobenzene (after evaporation to dryness of a mixture of the two materials) 122°. This recrystallized material was used in the identification tests described below. An additional 0.132 g material (m.p. 119–121°) was recovered by ether extraction of the acidified reaction mixture.

Comparison of the infrared spectra in chloroform solution of the trinitrobenzene used in the exchange reaction (A) and of the recovered material (B) showed the following characteristics. Both A and B had bands at 924, 1 345, 1 545, and 1 620 cm^{-1}. B had new bands at 2 315 (C—D stretching), 1 385, and 1 400 cm^{-1} (doublet). Bands present in A but absent in B were those at 3 080 (C—H stretching) and 1 076 cm^{-1} (C—H in-plane vibration (15)).

[3]*Other factors which influence nucleophilicity and basicity have been considered by several authors (27–31).*
[4]*All melting points are uncorrected.*

The ultraviolet and visible spectra of A and B were identical, both qualitatively and quantitatively: in 96% ethanol, $\lambda_{max} = 225$ mμ, log $\epsilon_{225} = 4.41$ (lit. (34) values for *s*-trinitrobenzene in 96% ethanol are $\lambda_{max} = 225$ mμ, log $\epsilon_{225} = 4.41$).

The nuclear magnetic resonance spectrum (in deuteriochloroform with tetramethylsilane as external standard) of A showed a sharp singlet at $\tau = 0.59$. The spectrum of B had only a barely detectable signal at $\tau = 0.59$.

Carbon, hydrogen, and nitrogen analytical data for A and B were obtained consecutively.

Anal. Calcd. for A: C, 33.80; H, 1.42; N, 19.71. Found for A: C, 33.73, 33.82; H, 1.47, 1.50; N, 19.72. Found for B: C, 33.52, 33.27; H, 1.74, 1.60; N, 19.36.

Deuteration of A will cause the carbon and nitrogen analytical data to decrease slightly and the hydrogen value to increase slightly, in the region of the observed results for B.

Deuterium analysis was done by combustion and analysis by the falling-drop method (performed by J. Nemeth, Urbana, Illinois) of the water that was formed. To optimize the sensitivity of the analytical method, the sample submitted for analysis was a 50:50 mixture of A and B; this mixture had a deuterium content of 46.9%. The deuterium content of B was hence 93.8%.

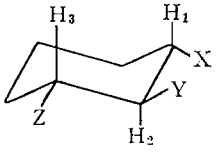
CYCLOHEXANE COMPOUNDS

VI. NUCLEAR MAGNETIC RESONANCE SPECTRA OF SOME DERIVATIVES OF THE STEREOISOMERIC 3-BROMO-1,2-CYCLOHEXANEDIOLS AND THE 2-BROMO-1,3-CYCLOHEXANEDIOLS[1]



R. A. B. BANNARD

ABSTRACT

First-order analysis of the 60 Mc.p.s. proton magnetic resonance spectra of 1α-methoxy-2β-acetoxy-3α-bromocyclohexane, 1α-methoxy-2α-acetoxy-3β-bromocyclohexane, 1α-methoxy-2β-bromo-3α-acetoxycyclohexane, 1α-methoxy-2α-bromo-3β-acetoxycyclohexane, and the corresponding diol diacetates confirmed the stereochemical interrelationships of substituents which were assigned previously on chemical grounds, and demonstrated that the compounds exist in chair conformations. The chemical shifts of the methoxy methyl and acetoxy methyl protons did not provide reliable criteria for the assignment of conformations to these substituents in this series. The coupling constants of the methine protons followed, in general, the pattern predicted by the Karplus equation, and the smaller $J_{2,3}$ values observed in the *cis,trans* compounds relative to those in the *trans,trans* compounds are interpreted mainly on the basis of conformational equilibration, upon which is superimposed a small dihedral angular distortion or a remote substituent orientational effect.

Analysis of the multiplet patterns and chemical shifts of the methine protons in the nuclear magnetic resonance spectra of the stereoisomeric 1-methoxy-2-acetoxy-3-acetylaminocyclohexanes I*a* and II*a*, their ethoxy analogues (I*c* and II*c*), and certain of their derivatives (I*b*–I*e* and II*b*–II*e*) (1) permitted unambiguous assignment of both gross structure and conformation to these compounds. This work also indicated that the chemical

shifts of axially (6.59–6.62 τ) and equatorially (6.63–6.66 τ) oriented methoxy methyl protons are not sufficiently well separated to serve as criteria for the assignment of conformations to these substituents in these particular compounds (however, cf. ref. 3), whereas the chemical shifts of equatorially oriented acetoxy (7.90–7.99 τ) and acetamido (8.00–8.09 τ) methyl proton resonances appeared of possible utility in this series as well as

[1]*Issued as D.C.B.R.L. Report No. 483.*

in acetylated pyranose carbohydrates (4–8). In view of the potential usefulness of such correlations for conformational assignment in alicyclic molecules which contain these substituents in environments in which analysis of the methine proton resonances is complicated or prevented by the presence of numerous adjacent protons, it was considered desirable to extend the study to other cyclohexane derivatives of known structure. In this connection the nuclear magnetic resonance spectra of the stereoisomeric 1-methoxy-2(3)-hydroxy-3(2)-bromocyclohexanes (I*g*, I*h*, and II*g*, II*h*) (9, 10), their acetyl derivatives (I*j*, I*l*, and II*j*, II*l*), and the diacetates of the corresponding bromodiols (I*k*, I*m*, and II*k*, II*m*) were measured.

The spectra of the bromohydrins (I*g*, I*h*, and II*g*, II*h*) did not prove to be amenable to analysis because of overlap in the multiplet patterns of the methine protons. This situation was not improved when the compounds were acidified with trifluoroacetic acid to eliminate coupling between the hydroxylic proton and that attached to C_2. The only readily assignable resonances in these spectra were those caused by the methoxy methyl protons, which are given in Table I. On the other hand, in the spectra of the methoxybromoacetates (I*j*, I*l*, and II*j*, II*l*) and bromodiol diacetates (I*k*, I*m*, and II*k*, II*m*), the methine proton resonances were, in general, sufficiently chemically shifted from one another and from those of the methylene protons (7.4–9.2 τ) to permit first-order analysis of the spectra in the same manner as described previously (1). The chemical shifts and coupling constants thus obtained are shown in Tables I and II, respectively. That the measured splittings correspond closely to the true coupling constants was confirmed by measuring the spectra of compounds I*k*, I*l*, and I*m* (which had the largest J/δ ratios) at 100 Mc.p.s. (11, p. 139). The coupling constants thus found agreed within 0.2 c.p.s. with those recorded in Table II.

The magnitudes of the coupling constants ($J_{1,2}$ and $J_{2,3}$) together with the multiplet patterns (triplet or quartet) and signal widths of the H_2 resonances (8, 12) confirmed that the structures of the methoxybromoacetates and bromodiol diacetates, which were assigned previously (9, 10) on chemical grounds, are indeed correct and that the conformations of the substituents are mainly as shown in formulae I and II.

It is evident from Table I that the chemical shifts of the acetoxy and methoxy methyl protons do not provide reliable criteria for the assignment of conformation to these substituents in 1,2,3-trisubstituted cyclohexanes, because of overlap in the ranges of values observed for these groups in the axial (acetoxy, 7.88–7.94 τ; methoxy, 6.61–6.65 τ) and equatorial (acetoxy, 7.87–8.04 τ; methoxy, 6.55–6.66 τ) orientations.

In the 3-bromo series (I*j*, I*k*, and II*j*, II*k*), equatorial H_1 is shifted downfield 0.5–0.6 p.p.m. from axial H_1. The change in orientation of H_1 from axial to equatorial also causes a paramagnetic shift of 0.4–0.5 p.p.m. in the resonance of axial H_3, whereas axial H_2 is either unaffected or slightly shielded (0.1 p.p.m.). The 1-alkoxy-2-acetoxy-3-acetylaminocyclohexanes (I*a* and II*a*) exhibit parallel but slightly smaller shifts in the resonances of the methine protons, and it thus appears likely that the downfield shift in axial H_3 which accompanies the change in orientation of H_1 from axial to equatorial in these derivatives may owe its origin principally to the interaction of the axial anisotropic methoxyl or acetoxyl group at C_1 with axial H_3. A similar effect has recently been observed in acetylated methyl glycopyranosides of some aminohexoses (13). In the 2-bromo series (I*l*, I*m*, and II*l*, II*m*), equatorial H_1 is deshielded with respect to axial H_1 to a smaller extent (0.1–0.3 p.p.m.) than in the 3-bromo series, and the concomitant downfield shift in axial H_3 is likewise reduced. However, the shift in the resonance of axial H_2 which accompanies the change in orientation of H_1 from axial to equatorial is opposite in direction to and larger in magnitude than that observed in the 3-bromo series. Thus the chemical shifts of methine protons in these compounds depend upon the nature and orientation of adjacent and

remote substituents as well as upon the conformation of the proton and the substituent attached to the same carbon atom. The anisotropic effects of all possible conformations of the substituents cannot be estimated; it is therefore not surprising that it is not possible to define narrow chemical shift ranges which are highly characteristic of the orientation of the methine proton concerned and of the functional group which is bonded to the same carbon atom.

The magnitudes of the coupling constants ($J_{1,2}$ and $J_{2,3}$) shown in Table II fall within the general ranges of values observed for $J_{a,e}$ (2–7 c.p.s.) and $J_{a,a}$ (5–13.4 c.p.s.) in six membered ring compounds in the chair form (14 and references therein). The dihedral angles between protons on adjacent carbon atoms for the chair, boat, and skew-boat forms of *trans,trans*- and *cis,trans*-1,2,3-trisubstituted cyclohexanes were obtained from measurements on Drieding models. Coupling constants corresponding to these angles were calculated by using the original Karplus parameters (15), and also by using a modification in which the entire curve was displaced upward by 1.1 c.p.s. (see below) at $J_{0°}$ and $J_{180°}$. Comparison of the observed couplings with the calculated values made it quite clear that the former are best rationalized on the grounds that the compounds are in the chair form principally in the conformations indicated in structures I and II.

Because of the rather wide range of $J_{a,a}$ values (7.3–10.3 c.p.s.) in the 1-methoxy-2(3)-acetoxy-3(2)-bromocyclohexanes as opposed to the narrow range for $J_{e,a}$ (2.8–3.0 c.p.s.), it was not clear how the Karplus parameters (15) should be modified, if at all, for the calculation of possible angular deformations in this series. However, a small upward displacement of the entire curve (cf. ref. 16) appeared to offer a reasonable approach. Compound I*j* has the largest $J_{2,3}$, and if it is assumed that $J_{180°} = 10.3$ c.p.s., displacement of the Karplus curve by an amount sufficient to give this magnitude of coupling constant at 180° (1.1 c.p.s.) would make $J_{60°} = 2.9$ c.p.s., which is in good agreement with the observed small couplings.

The observed variations in $J_{2,3}$ could owe their origin to the existence of an equilibrium between chair conformers, to distortion of dihedral angles between axially oriented protons, to electronegativity effects of substituents (17), or to differences in the orientation of remote functional groups (1; 11, p. 49). The earlier studies on the 1-alkoxy-2-acetoxy-3-acetylaminocyclohexanes (1, 2) made it seem unlikely that conformational equilibration is a major factor contributing toward the variations in $J_{a,a}$ in that series, but the same situation does not apply to the 1-methoxy-2(3)-bromo-3(2)-acetoxycyclohexanes. An exact determination of the extent of conformational equilibration in these compounds would be a major research project and is beyond the scope of this study. However, the equilibrium constants can roughly be estimated by making use of the conformational free-energy differences for the methoxyl group, acetoxyl group, and bromine (18). The values obtained, together with their predicted effects on $J_{2,3}$, are given in Table II, from which it is clearly apparent that all the experimentally observed values for $J_{2,3}$ in the *trans,trans*-bromocyclohexanediol derivatives (I*j*–I*m*) agree with the calculated couplings within experimental error (±0.3 c.p.s.). In the *cis,trans* analogues (II*j*–II*m*), however, there remains a significant difference between the observed and calculated couplings (except for II*m*), and it must be concluded that conformational equilibration is not the only one of the above-mentioned factors responsible for the changes in $J_{2,3}$. Since the same three (or two) substituents are always involved, electronegativity effects can probably be discounted. The residual discrepancies could be caused by small dihedral angular distortions of the protons caused by crowding of the *cis*-oriented substituents at C_1 and (or) by the change in orientation of the substituent at C_1 relative to those at C_2 and C_3. Evidence supporting the viewpoint that sizes of coupling constants can significantly be affected by changes in the

orientation of remote substituents has recently been presented (14, 19). The constancy of the small couplings in relation to the variability of the large couplings (Table II) would seem to be inconsistent with an interpretation based solely upon the dihedral angular distortion factor. However, there is insufficient evidence at present to differentiate between which of these factors is mainly responsible for the discrepancies observed.

The large 2,3 couplings in the acetylamino analogues (I*a*–I*f* and II*a*–II*f*) which were referred to earlier (1) present a picture quite different from those of the bromocyclohexanediol derivatives (I*j*–I*m* and II*j*–II*m*). The changes in the sizes of the coupling constants are in different directions in the two series as the orientation of the substituent at C_1 is changed in relation to those at C_2 and C_3 (Table II). Conformational equilibration and dihedral angular distortion were discounted as possible causes for the changes observed in the acetylamino series, and it was suggested that a remote substituent orientational effect is implicated (1) since electronegativity effects can also probably be discounted for isomeric pairs. The large divergences in $J_{2,3}$ for analogues of similar gross stereochemistry in the two series, e.g. I*a* and I*j*, II*a* and II*j*, undoubtedly owe their origin to a complex interplay of the four factors mentioned earlier, the complete analysis of which is beyond the scope of this work. It is sufficient to say that, although the relative electronegativities of substituents would be anticipated to play an important role in interpreting the observed divergences, the application of simple electronegativity considerations similar to those used by Williamson (17) in the more rigid hexachlorobicyclo[2.2.1]heptenes does not provide even an approximate rationalization.

EXPERIMENTAL

The proton magnetic resonance spectra were measured on a Varian V-4300C spectrometer operating at 60 Mc.p.s., a Varian V-3521 integrator being used for base-line stabilization. All solutions were 25% w/v in chloroform and were calibrated with reference to internal tetramethylsilane by the usual side-band technique. The preparation of all the compounds used herein was described previously (1, 2, 9, 10, 20, 21).

ACKNOWLEDGMENTS

The author is indebted to Dr. M. A. Weinberger and Miss P. Lutley for recording all the 60 Mc.p.s. spectra; to Dr. S. Brownstein for recording the 100 Mc.p.s. spectra of compounds I*j*, I*k*, and I*l*; and to Dr. R. R. Fraser for several helpful discussions.

MASS SPECTRA OF OXYGENATED QUINOLINES

D. M. CLUGSTON AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received November 18, 1965

ABSTRACT

The mass spectra of the monohydroxyquinolines, the monomethoxyquinolines, N-methyl-2-quinolone, and N-methyl-4-quinolone have been recorded. The isomeric hydroxy compounds vary somewhat in the stability of the molecular ion, but all show the same fragmentation mechanism. Two general fragmentation patterns are discernible in the spectrum of each of the monomethoxyquinolines, but there is considerable variation among the isomers in the extent to which the two patterns occur. In addition, 8-methoxyquinoline undergoes a peculiar fragmentation wherein all three methyl hydrogens are lost. The 3-methoxy compound is unusual in that loss of 43 mass units from the molecular ion occurs in one step. Deuterium- and ^{13}C-labelling experiments have proved to be useful in interpreting the fragmentation pathways. The spectra of the two N-methylquinolones prove that O to N methyl rearrangement does not occur to any significant extent upon electron impact.

In a recent paper we reported on the behavior of some furoquinoline alkaloids upon electron impact (1). Except for quinoline (2) and some alkylquinolines (2, 3), no other systematic study of fragmentation in a quinoline system has been reported. It seemed appropriate, therefore, to examine the mass spectra of some simple oxygenated quinolines without the complicating effect of the furan ring present in the furoquinoline alkaloids. In this investigation, therefore, we report on the fragmentation of the seven monomethoxyquinolines, the seven monohydroxyquinolines, and the two isomeric N-methylquinolones.

Although the spectra of substituted quinolines have not been discussed, the spectra of other substituted aromatic systems have been examined in detail. The spectra of some methoxy derivatives of benzene (2, p. 174ff; 4) and naphthalene (5) have been reported, as have the spectra of phenols (6). In these compounds as well as in aromatic systems containing other substituents (2, p. 186ff; 4; 7), marked differences in the fragmentation of isomers have been noted. The mass spectra of several nitrogen-containing heterocyclic aromatic systems have been examined, and in many of them the loss of hydrogen cyanide has been found to be a major fragmentation pathway (2, p. 251ff). In 2- and 4-pyridone the spectra exhibit intense peaks for the loss of carbon monoxide (8). One might expect, therefore, that the quinoline derivatives discussed below would undergo fragmentation by pathways similar to those cited above. Our results show that this is so and that the expected differences among the various isomers are found.

The spectra of the monomethoxyquinolines are recorded in Fig. 1. It will be noted that there is considerable variation among the isomers, but that they can be divided into two main groups. The first group is made up of the 2- and 8-isomers while the second group comprises the rest. The major peaks found in each spectrum can be accounted for by two fragmentation schemes, both of which involve the methoxyl group in the initial fragmentation. Scheme 1 depicts the mechanism proposed for the formation of the ions appearing at M-1 (*m/e* 158), M-29 (*m/e* 130), M-30 (*m/e* 129), M-57 (*m/e* 102), and M-83 (*m/e* 76), and Scheme 2 outlines the mechanism by which the ions appearing at M-15 (*m/e* 144), M-43 (*m/e* 116), M-70 (*m/e* 89), and M-96 (*m/e* 63) are believed to arise. Both schemes are shown for 7-methoxyquinoline since the spectrum of this compound contains all the pertinent peaks, as well as metastable peaks supporting all the proposed fragmentations. Table I lists the metastable peaks which are observed for the various transformations for each of the seven isomers.

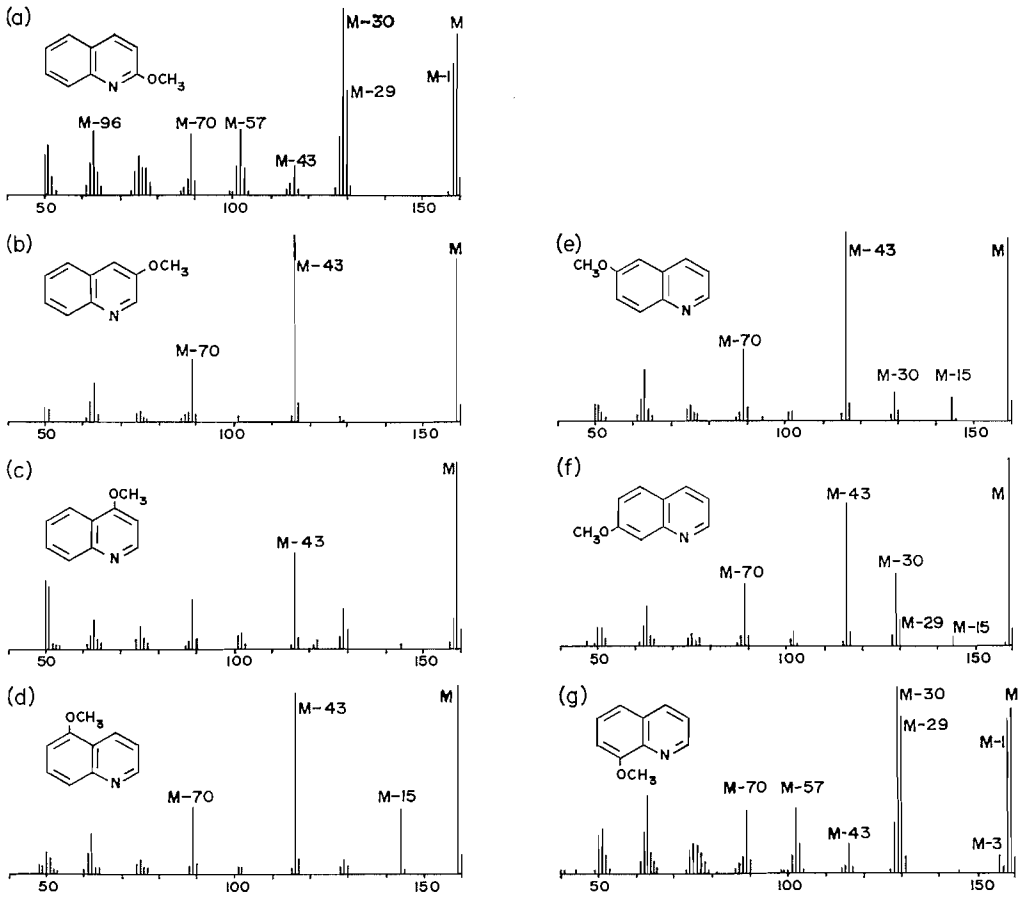

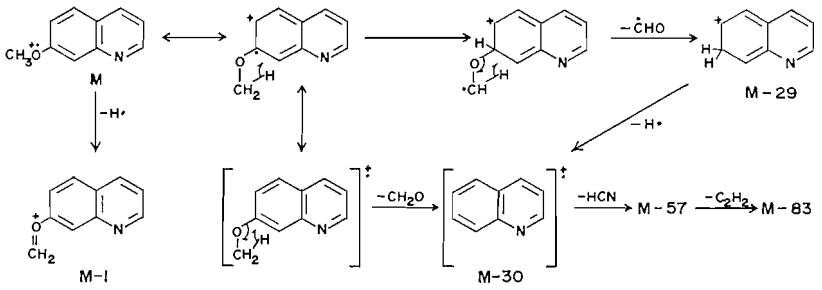

FIG. 1. Mass spectra of (*a*) 2-methoxyquinoline, (*b*) 3-methoxyquinoline, (*c*) 4-methoxyquinoline, (*d*) 5-methoxyquinoline, (*e*) 6-methoxyquinoline, (*f*) 7-methoxyquinoline, and (*g*) 8-methoxyquinoline.

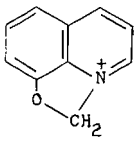
TABLE I

Metastable peaks in the spectra of the methoxyquinolines

Transformation	Calcd.	Observed in the spectra of:
M → M-1 159 → 158	157.0	2-, 4-, 5-, 7-, 8-
M → M-15 159 → 144	130.4	3-, 5-, 7-
M → M-29 159 → 130	106.3	2-, 4-, 7-, 8-
M → M-30 159 → 129	104.7	4-, 5-, 6-, 7-
M-15 → M-43 144 → 116	93.4	4-, 5-, 6-, 7-
M-30 → M-57 129 → 102	80.7	2-, 4-, 7-, 8-
M-43 → M-70 116 → 89	68.3	2-, 3-, 4-, 5-, 6-, 7-, 8-
M-70 → M-96 89 → 63	44.6	2-, 3-, 4-, 5-, 6-, 7-, 8-



The spectra of 2- and 8-methoxyquinoline are similar in that the major fragment ions in each case are those which arise by the transformations depicted in Scheme 1. Both show intense peaks for the molecular ion, as expected for aromatic compounds, and at M-1,

SCHEME 1.

M-29, and M-30. That the methoxyl group is involved in the formation of all the major fragment ions is verified by examination of the mass spectra of the OCD_3 analogues of 2- and 8-methoxyquinoline. The spectra of the deuterated compounds are recorded in Figs. 2*a* and 2*c*. It is seen that the M-1, M-29, and M-30 peaks of the undeuterated compounds are found at M-2, M-30, and M-32, respectively, in the spectra of the deuterated compounds. Therefore, the M-1 peak arises by loss of one of the methyl hydrogens, and the M-29 and M-30 fragments arise by loss of CHO· and CH_2O, respectively, from the methoxyl group. The mechanism shown in Scheme 1 for loss of CHO· and CH_2O is that originally proposed by Barnes and Occolowitz (4) for the fragmentation of 1,3-dimethoxybenzene.

In a previous paper on the mass spectra of furoquinoline alkaloids (1) we noted that the furoquinolines containing an 8-methoxy substituent in the quinoline ring gave rise to an intense peak at M-1 in their mass spectra. We suggested that a hydrogen was lost from the methoxyl group and that the positive charge on the methyl carbon was stabilized by the unshared pair of electrons on the nearby nitrogen atom as shown below. A similar structure for the ion derived by loss of a hydrogen atom from the methyl group of the molecular ion of 2-methoxyquinoline may be written. The fact that, of all the methoxyquinolines examined, only the 2- and 8-isomers exhibit an intense M-1 peak in their spectra indicates that stabilization by neighboring nitrogen may indeed be involved.

We also suggested in our paper on the furoquinoline alkaloids that those alkaloids containing an 8-methoxyl substituent might undergo methyl migration from oxygen to nitrogen followed by elimination of CO or CHO·. The lack of any significant M-28 peak in the mass spectrum of 8-methoxyquinoline casts doubt on such a rearrangement, and the deuterium-labelling experiments discussed above all but eliminate such a possibility. An examination of the spectrum of 8-methoxyquinoline labelled in the methoxyl carbon with ^{13}C disproves completely any possibility of methyl migration before fragmentation. The spectrum of the ^{13}C-labelled compound is shown in Fig. 2*d*. It is evident that the peaks at *m/e* 129 (M-CH_2O) and *m/e* 130 (M-CHO·) are not shifted in the labelled compound, occurring in the same position as in the unlabelled analogue. The methoxyl carbon atom, therefore, is lost when these fragment ions are formed.

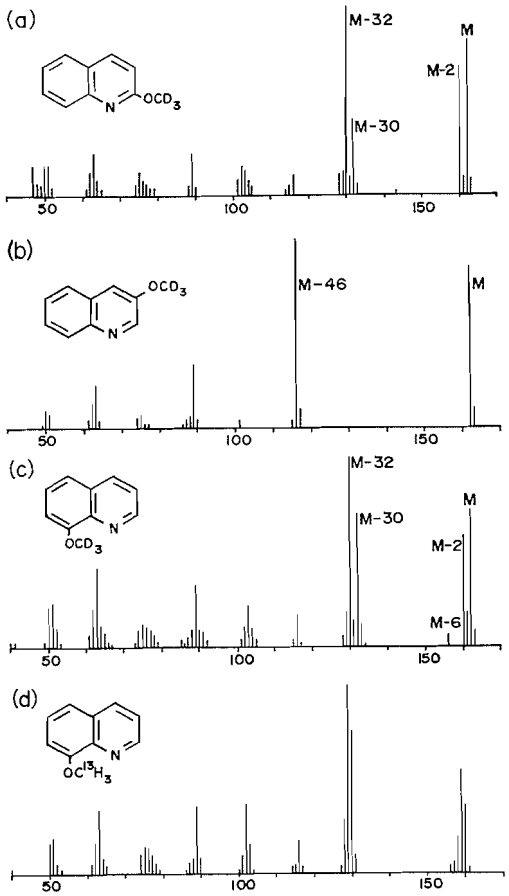

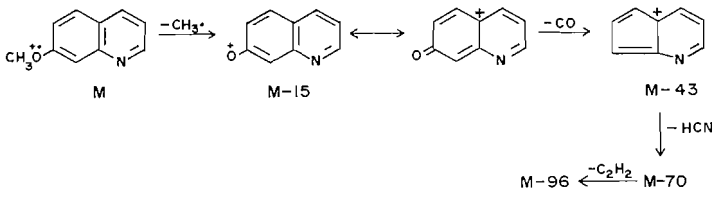

FIG. 2. Mass spectra of (*a*) 2-methoxy-d_3-quinoline, (*b*) 3-methoxy-d_3-quinoline, (*c*) 8-methoxy-d_3-quinoline, and (*d*) 8-methoxy-^{13}C-quinoline.

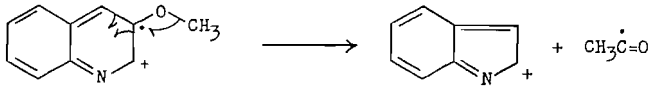
The presence of a peak at M-3 in the mass spectrum of 8-methoxyquinoline enables one to differentiate it from all the other methoxyquinolines examined. The fact that a similar fragmentation giving rise to a M-6 peak occurs in the deuterium-labelled analogue (Fig. 2*c*) indicates that all three methyl hydrogens, and only the methyl hydrogens, are lost to form the M-3 fragment ion from 8-methoxyquinoline. The M-3 ion apparently arises by loss of H_2 from the M-1 ion (m^* calcd. for $158 \rightarrow 156 = 154.0$; m^* obs. = 154.3), or in the case of the deuterated compound the M-6 ion arises by loss of D_2 from the M-2 ion (m^* calcd. for $160 \rightarrow 156 = 152.1$; m^* obs. = 152.5). A M-3 peak is apparently characteristic of quinolines carrying an 8-methoxyl substituent, although it is usually of much lower intensity than in the case of 8-methoxyquinoline itself. Thus, we have observed a M-3 peak in the mass spectra of 8-methoxyquinaldine and of three furoquinoline alkaloids containing an 8-methoxy substituent, skimmianine, maculosidine, and flindersiamine (1). In every case we have also observed a metastable peak corresponding to loss of H_2 from the M-1 fragment ion.

Both 2- and 8-methoxyquinoline exhibit peaks at *m/e* 116 (M-43) in their mass spectra, but of low intensity. This fragment is apparently formed in each case by the mechanism

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

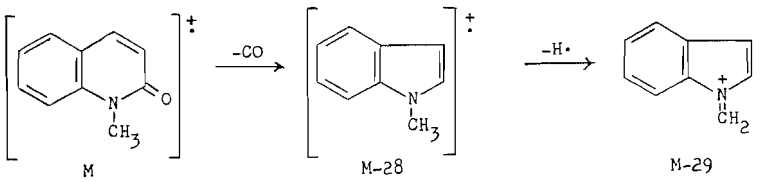


outlined in Scheme 2, even though the intensity of the M-15 peaks is too low to plot. The possibility that the ion of M-43 may arise by a concerted loss of 43 mass units cannot be excluded (see below).

SCHEME 2.

The most intense fragment ion peak in the mass spectra of 3-, 4-, 5-, 6-, and 7-methoxyquinolines is found at *m/e* 116 (M-43). A peak is also observed at *m/e* 144 (M-15) in every case except that of the 3-methoxy compound. Thus, the fragmentation pattern outlined in Scheme 2 would appear to be dominant in the cases of the 4-, 5-, 6-, and 7-methoxy compounds. Fragmentation according to Scheme 1 is discernible in all the isomers, but it is only in the 7-methoxy compound that it is apparent to any appreciable degree. Metastable peaks in the spectra of the 4-, 5-, 6-, and 7-isomers corroborate the major fragmentation processes (Table 1) as proposed in Schemes 1 and 2.

Apparently 3-methoxyquinoline is unique in that the loss of 43 mass units occurs in a concerted fashion. The peak at M-15 is of very low intensity whereas that at M-43 is the base peak of the spectrum. A metastable peak at *m/e* 85.0 corresponds to the transformation M → M-43 (*m** calcd. for 159 → 116 = 84.6). A possible mechanism for such a fragmentation is shown below. Confirmation of the fact that the methoxyl methyl group is



lost in this fragmentation is obtained by an examination of the spectrum of the deuterium-labelled analogue (Fig. 2*b*). The base peak is again at *m/e* 116, corresponding to the loss of 46 mass units from the molecular ion, and a metastable peak at *m/e* 83.4 corresponds to the fragmentation 162 → 116 (*m** calcd. = 83.1). To our knowledge, this is the first report of the loss of 43 mass units in a concerted step involving a methoxyl substituent.

We considered it possible that the 2- and 4-methoxyquinolines might undergo electron impact induced rearrangement of the methyl group from oxygen to nitrogen with subsequent fragmentation of the N-methylquinolone that was formed. It is known that such a rearrangement is induced thermally (9, 10). Accordingly, we prepared and recorded the mass spectra of N-methyl-2-quinolone and N-methyl-4-quinolone. The spectra, shown in Fig. 3, are distinctly different from the isomeric O-methyl compounds in that they contain only very small M-1 peaks and in that the major fragment in each case is formed by the loss of 28 mass units (CO) from the molecular ion. Metastable peaks in both spectra indicate that the fragmentation occurs in the sequence M → M-28 → M-29, as shown below for N-methyl-2-quinolone.

In the mass spectra of all of the monohydroxyquinolines the peak corresponding to the molecular ion (*m/e* 145) is the strongest in the spectrum. The spectra of the hydroxyquinolines may be divided, however, into two distinct groups on the basis of the intensities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the peaks of the fragment ions. The two groups are represented in Fig. 4 by the spectra of 2- and 3-hydroxyquinoline. The first group, composed of the 2-, 4-, and 8-hydroxy compounds, exhibits relatively strong peaks for the fragment ions corresponding to the loss of 28 mass units (CO) followed by the loss of 27 mass units (HCN) and then 1 mass unit (H·) from the molecular ion. The second group, composed of the 3-, 5-, 6-, and 7-hydroxy compounds, exhibits the same fragment peaks, but at greatly reduced intensities. Facile loss of CO from the molecular ions of 2- and 4-hydroxyquinolines may

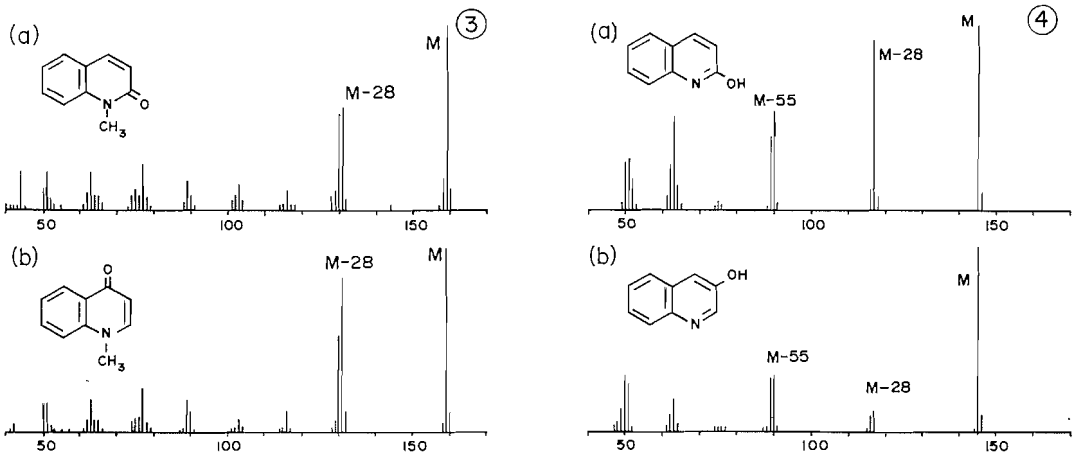


FIG. 3. Mass spectra of (*a*) N-methyl-2-quinolone and (*b*) N-methyl-4-quinolone.
FIG. 4. Mass spectra of (*a*) 2-hydroxyquinoline and (*b*) 3-hydroxyquinoline.

be explained on the basis of participation of the tautomeric quinolone structures shown below. In the case of 8-hydroxyquinoline, however, no such structure is permitted, and it is more difficult to rationalize the loss of carbon monoxide. It may be that the nearby nitrogen accepts the hydrogen of the 8-hydroxyl function, thereby allowing for the facile loss of CO.

EXPERIMENTAL

Apparatus, Methods, and Materials

Mass spectra were determined on a Hitachi Perkin–Elmer RMU-6A mass spectrometer at an ionizing potential of 80 eV and an ionizing current of 50 μA. Samples were introduced through an all-glass inlet system maintained at 200°. Spectra are plotted in terms of relative abundance, with the most intense peak (base peak) being taken as 100%. Only peaks equal to or greater than 2% of the base peak are recorded.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

All samples were purified by vapor phase chromatography on a 6 ft column of 3% SE-30 silicone gum rubber on Chromosorb P. The column temperature was maintained at 150° or 200° depending on the volatility of the material. 6-Methoxyquinoline and 2-, 4-, and 8-hydroxyquinoline were obtained commercially; CD_3OH (99 atom % D), CD_3I (99 atom % D), and $^{13}CH_3I$ (53 atom % ^{13}C) were obtained from Merck, Sharp and Dohme of Canada Ltd.

2-Methoxyquinoline and 4-Methoxyquinoline

The hydroxyquinoline was converted into the chloroquinoline by treatment with phosphorus oxychloride (11). The chloro compound was heated under reflux with an excess of sodium methoxide in methanol for 3 h (11). The methanol was removed, water added, and the mixture extracted with chloroform. The chloroform extract was dried and evaporated to dryness, and the residue was purified by vapor phase chromatography.

2-Methoxyquinoline-d_3 and 4-Methoxyquinoline-d_3

The procedure used was identical with that above, except that sodium methoxide-d_3 and CD_3OH were used.

3-Hydroxyquinoline and 3-Methoxyquinoline

The diazonium chloride obtained from 3-aminoquinoline by the method of Abramovitch (12) was slowly added to boiling water. The resulting solution was cooled, excess $NaHCO_3$ added, and the hydroxyquinoline filtered off. The product was recrystallized from ethanol–water. Conversion into 3-methoxyquinoline was accomplished with diazomethane in ether.

5-Hydroxyquinoline

5-Nitroquinoline was converted into 5-hydroxyquinoline by the method of Kochanska and Brobanski (13).

5-Methoxyquinoline

5-Methoxyquinoline was prepared by the method of Bradford *et al.* (14).

6-Hydroxyquinoline

6-Methoxyquinoline was heated under reflux with 47% HI for 5 h. The acidic solution was neutralized and the 6-hydroxyquinoline recovered by extraction with chloroform. A sample for mass spectrometry was purified by vapor phase chromatography.

7-Methoxyquinoline

m-Anisidine (6 g), nitrobenzene (6 g), glycerol (45 g), and powdered $FeSO_4$ (4 g) were mixed together and stirred, and concentrated H_2SO_4 (35 g) was added slowly. The mixture was brought to a boil, allowed to stand for 0.5 h, and then heated under reflux for 4 h. Nitrobenzene was removed by steam distillation and primary amine destroyed by adding excess $NaNO_2$ and boiling the reaction mixture. The resulting solution was made basic with KOH and steam-distilled until the distillate was clear. The distillate was extracted with chloroform, and the oil (7 g) obtained from the $CHCl_3$ extract was distilled at 12 mm. A fraction collected up to 140° was discarded and a second fraction collected from 140–145° was further purified by vapor phase chromatography.

7-Hydroxyquinoline

This compound was prepared in the same manner as 6-hydroxyquinoline.

8-Methoxyquinoline

8-Hydroxyquinoline was treated with excess methyl iodide in the presence of sodium hydroxide in a solution of methanol–water. The solution was heated in a sealed tube at 100° for 0.5 h. The reaction mixture was poured into H_2O and extracted with chloroform. The dried chloroform solution was evaporated to dryness and the residue purified by vapor phase chromatography.

8-Methoxyquinoline-d_3

The procedure used was that described above, except that CD_3I was used instead of CH_3I.

8-Methoxyquinoline-^{13}C

The procedure used was that described for 8-methoxyquinoline, except that $^{13}CH_3I$ was used instead of CH_3I.

N-Methyl-2-quinolone and N-Methyl-4-quinolone

The hydroxyquinoline, aqueous sodium hydroxide, methyl iodide, and sufficient methanol to give a homogeneous solution were heated under reflux for 2 h (15, 16). The N-methylquinolones were isolated and purified by conventional procedures.

ACKNOWLEDGMENTS

We thank Dr. A. Corsini of this university for a sample of 8-methoxyquinaldine and Mr. John Wells of these laboratories for technical assistance in the preparation of the

MASS SPECTRA AND REACTION MECHANISM STUDIES

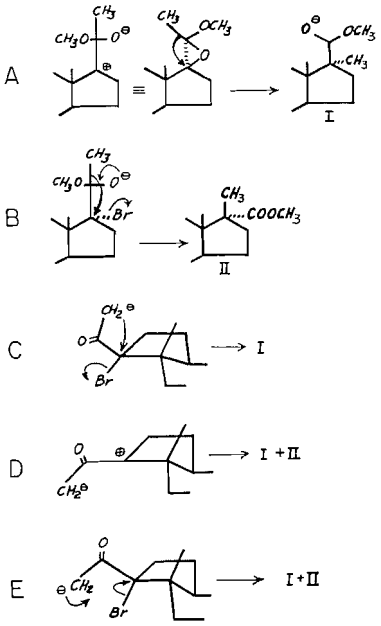
THE FAVORSKY–MARKER REARRANGEMENT OF 17α-BROMOPREGNENOLONES IN DEUTERATED METHANOL[1]

R. DEGHENGHI, G. SCHILLING, AND G. PAPINEAU-COUTURE
Ayerst Research Laboratories, Montreal, Quebec
Received October 13, 1965

ABSTRACT

An examination of the mass spectra of the products isolated from a Favorsky rearrangement of 17α-bromopregnenolone acetate (Marker's conditions) in deuterated solvents offers a clue to the reaction mechanism. The stereochemical implications and the mass fragmentation pattern of the products examined are discussed.

The reaction of α-halo ketones in alkaline media, known as the Favorsky rearrangement, has received considerable attention recently (1–7, 29, 30). The proposed mechanisms have been numerous, and it is now obvious that, more than questioning their multiplicity, one has to limit their validity to the appropriate substrate and conditions of the reaction under study.



In 1942, Marker (8) reported the alkaline rearrangement of 17-bromo-20-ketopregnanes in aqueous methanolic potassium bicarbonate. The methyl ester of a 17-methyletianic acid was the principal product of the reaction. The stereochemistry of this type of compounds was later established by Plattner and co-workers (9), on the basis of the biological activities of the derived epimeric 17-methylprogesterones, and, more rigorously, by Wendler (10), who also established the configuration of the starting 17-bromo-20-ketones.

The mechanism of the Favorsky–Marker rearrangement of this type of compounds is particularly interesting in that a substantial stereospecificity with *retention of configuration* is achieved. Our careful study of the products of the alkaline rearrangement of 17α-bromopregnenolone (*vide infra*) shows that, of the two epimeric esters (or acids) formed, the 17α-methyl epimer (retention) is present to the extent of 85–90%. Both the (Tchoubar) (12) semibenzilic mechanism (11) (B) and the (Loftfield) synchronous (12) cyclopropanone intermediate (C) therefore have to be excluded for the formation of the major product, thereby leaving the original (Favorsky) epoxyether mechanism (13) (A), the zwitterionic non-synchronous (Aston–Dewar) cyclopropanone formation (14) (D), and the bromine transfer (31) from C-17 to C-21 proposed by Wendler (10) (E).[2]

The epoxyether mechanism, which was favored in the quasi-Favorsky rearrangement (15), found early supporters (16, 17) in the open-chain or monocyclic series. It is analogous to the quantitative formation of epoxynitrile from the reaction of 17-bromo-20-ketopregnanes and KCN in aqueous alcohol (18), and is the most plausible mechanism for the formation of D-homo ketolic steroids when 17-bromo-20-ketopregnanes react with aqueous NaOH in acetone (19). However, the failure of epoxyethers in general to yield Favorsky-type products (1) does not favor, although it does not rigorously exclude, this mechanism.

[1]*Presented in part at the meetings of the "Association Canadienne Française pour l'Avancement des Sciences", Ottawa, November 1961, and Quebec, November 1963, and at the 47th Canadian Chemical Conference, Kingston, Ontario, June 1964.*

[2]*We thank a referee for pointing out an earlier reference to this mechanism (31).*

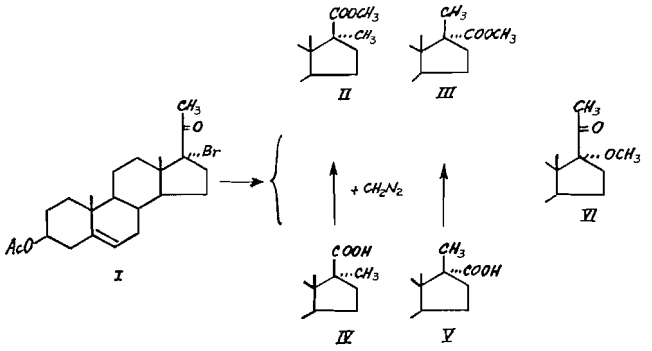
The Aston–Dewar and Wendler non-synchronous mechanisms both postulate a cyclopropane intermediate preceded by a zwitterionic "no-bond" species (D), or by a bromoenolate resulting from an allylic shift of the bromine from C-17 to C-21 (3).

Evidence for a delocalized intermediate in monocyclic systems has recently (3) been claimed, and the allylic shift of Wendler is analogous to the "internal return" of Winstein (20) (shift from a tertiary to a primary allylic halide).

In a recent review (21) Engel, because of discrepancies in the epimer ratio after the rearrangement of 21- versus 17-halogenated 20-ketopregnanes, did not favor Wendler's suggestion.[3] Wendler's bromoenolate is also rather improbable because of the absence of solvolysis products derived from it (*vide infra*).

The influence of the solvent on the stereochemical outcome of the Favorsky rearrangement has been analyzed thoroughly by House (22, 29) and by Tchoubar (5). Their modified versions of the detailed Loftfield mechanism overcome the stereochemical objections to that mechanism.

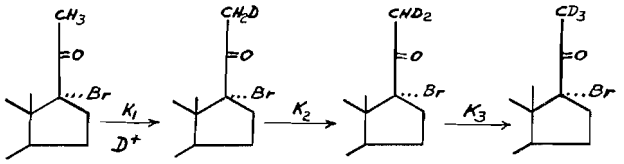
A reexamination of the Favorsky–Marker rearrangement in methanolic aqueous potassium bicarbonate solution of pure[4] 17α-bromopregnenolone acetate (I) followed by reacetylation revealed the presence of five products: two epimeric esters II and III, two epimeric acids IV and V, and 17α-methoxypregnenolone acetate (VI).



The acid fraction (IV + V) amounted to 4% of the total, and the neutral fraction had the following composition (by vapor phase chromatography): II, 90%; III, 5%; VI, <1% of the total. When the same reaction was run in the presence of K_2CO_3 instead of $KHCO_3$,[5] a slight change in the ratio of the epimers was observed, namely, II, 80%;

[3]*On closer analysis, this argument alone fails to be convincing if one considers that the rearrangement of a 21-halo-20-ketopregnane involves the abstraction of a 17-proton, and that Wendler's enolate derived from a 17-halo-20-ketone owes its negative charge to an allylic displacement through possibly a four-membered intermediate. The different origin of the two species, particularly in a polar solvent like methanol, may well account for differences in the reaction products.*

[4]*Recrystallized from methanol to a constant melting point and rotation, and to absolute homogeneity as judged by thin-layer chromatography and nuclear magnetic resonance spectra.*



[5]*To avoid proton species in the deurated experiment (vide infra).*

III, 12%; VI, 2%; IV, 5.5%; V, 0.5%. The reaction was then run in the presence of K_2CO_3 and deuterated solvents (CH_3OD, D_2O), and the products isolated as usual. The infrared spectra of the products revealed incorporation of deuterium, which conceivably could have been introduced by one or both of the following routes:

A. Before Favorsky rearrangement, by enolization and exchange with the medium.

B. By opening of a cyclopropane intermediate.

An examination of the products for the D_1, D_2, or D_3 species as well as for the non-deuterated material suggested itself for the following reasons: (*a*) The presence of any non-deuterated material should favor the epoxyether mechanism or (for the epimers III and V) the semibenzilic mechanism, indicating also that the exchange rates K_1, K_2, and K_3 are negligible. (*b*) The presence of polydeuterated (D_2, D_3) species is of course inconclusive, since the incorporation of deuterium could have occurred before any rearrangement (K_1, K_2, and K_3 not negligible). (*c*) The presence of only the monodeuterated species in both epimers, although not rigorously excluding the non-cyclopropanonic mechanisms, strongly favors a cyclopropanone fission (route *B*), indicating also that exchange before rearrangement is negligible.

An examination of the nuclear magnetic resonance spectra of the products was not revealing, since the band attributed to the 17-methyl group, reduced to approximately two-thirds of the original intensity, could have been attributed to the presence of some non-deuterated species together with a multideuterated (CHD_2 or CD_3) group, to the presence of a pure monodeuterated (CHD_2 or CD_3) group, or to the presence of a pure monodeuterated (CH_2D) substituent.[6]

[6]*We thank Dr. G. Just, Montreal, for suggesting this point to us.*

An examination of the mass spectra of the epimeric pairs (Figs. 1–4) provided the unequivocal answer: both deuterated epimers contain essentially one deuterium atom, and non-deuterated or polydeuterated species are absent.

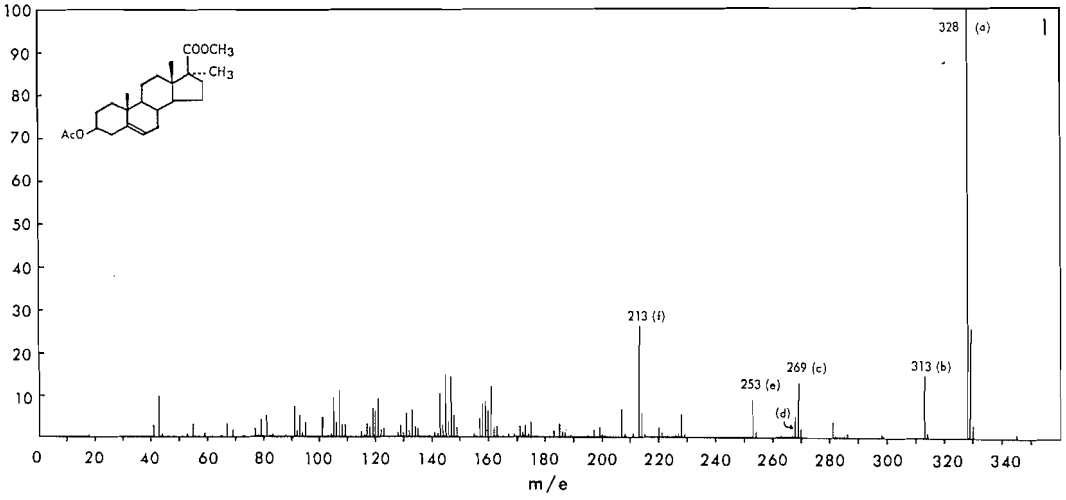

FIG. 1.

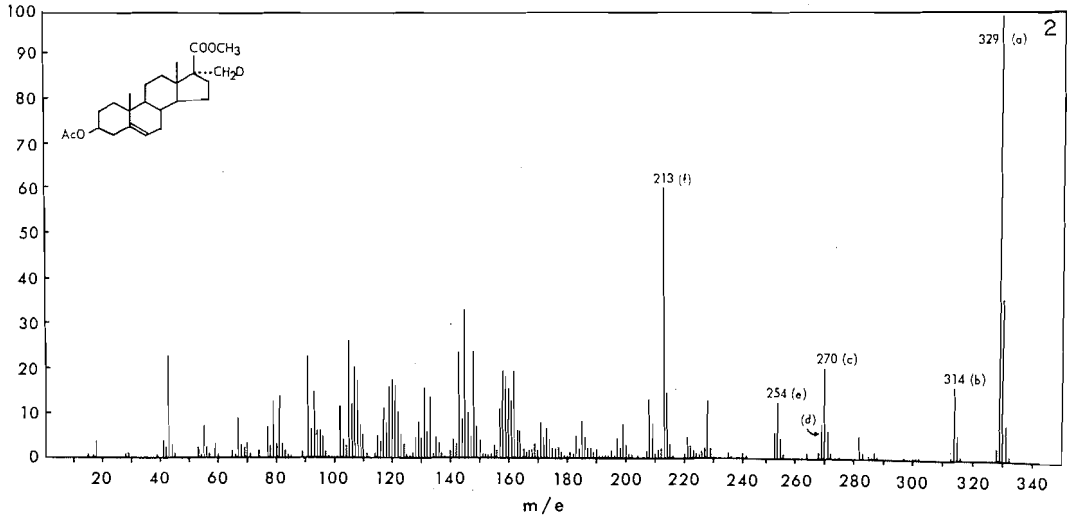

FIG. 2.

It seems reasonable to conclude, therefore, that *the deuterium is incorporated during an intermediate cyclopropanone fission and that the rate of deuterium exchange before rearrangement is negligible.* This finding militates strongly against the epoxyether or the semibenzilic rearrangements, the products of which would have contained all possible combinations of non- and poly-deuterated species.

The interesting solvolysis by-product, 17α-methoxypregnenolone acetate (23) (VI), was unequivocally characterized by comparison with an authentic sample prepared by methylation of 17α-hydroxypregnenolone acetate.

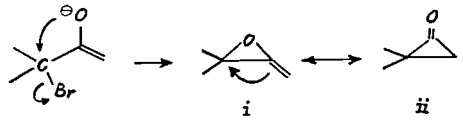
DISCUSSION



The Favorsky–Marker rearrangement of 17-bromo-20-ketopregnanes results in products with predominant retention of configuration. Careful analysis of the reaction mixture revealed the presence of only one solvolysis product, a 17α-methoxy-20-ketopregnane derivative. The incorporation of deuterium was homogeneous in both epimeric Favorsky products and D_1 was by far the predominant, if not the only, species.

These experimental facts can best be accommodated by a mechanism involving a common intermediate with a lifetime sufficient to give the solvolysis product VI before collapsing to the cyclic structures responsible for the epimeric esters II and III. The fact that no appreciable incorporation of deuterium occurs before rearrangement, as evidenced by the absence of D_2 or D_3 species, seems to indicate that the cyclopropanone formation goes faster than the ketonization of the enolate.

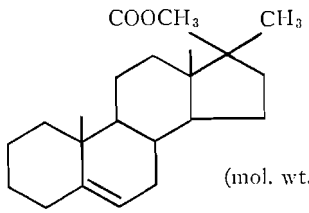
We can speculate about a stepwise mechanism for the Favorsky–Marker rearrangement for 17α-bromo-20-ketopregnanes as follows: step 1, enolate ion formation favored by the polarity of the solvent medium; step 2, oxygen–bromine dipole repulsion, bringing the oxygen to the beta side of the molecule; and step 3, loss of the halide to provide a delocalized intermediate which then collapses stereospecifically to a cyclopropanone (carbonyl on the beta side) or, alternatively, loss of halide assisted by a S_N2-type displacement to give structure *i*, which is a valency tautomer (30) of structure *ii* with the predominant stereochemistry.

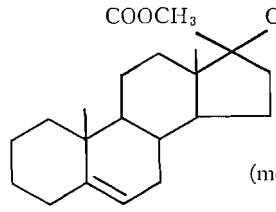
Step 1 would be peculiar to Marker's conditions (methanol – aqueous alkali) whereas step 2 would be favored particularly by the stereochemistry of the steroidal side chain (24). A clockwise rotation of about 90° along the $C_{20} \rightarrow C_{17}$ axis of the solvated enolate is required to alleviate dipole interaction, thereby bringing the negatively charged oxygen to the beta side.

Unassisted loss of bromine or concerted bromine displacement (step 3) by the negative oxygen should then provide a "no-bond" zwitterion or the valency tautomer *i*, respectively, *with the oxygen always on the beta side* of the molecule. Both species can react with the solvent to provide the solvolysis product 17α-methoxypregnenolone, or collapse to the sterically predominant cyclopropane structure *ii*.



We believe that the 18-methyl and the 12-methylene groups responsible for the preferred rotational configuration (24) of the halogenated side chain are indirectly governing the stereochemistry of the Favorsky–Marker rearrangement, more than affecting the chemistry of the transition state.[7]

Mass Spectra of the Favorsky Products



Significant peaks in the deuterated and non-deuterated pair of epimers are tabulated in Table I.

TABLE I

Mass spectra of the Favorsky products

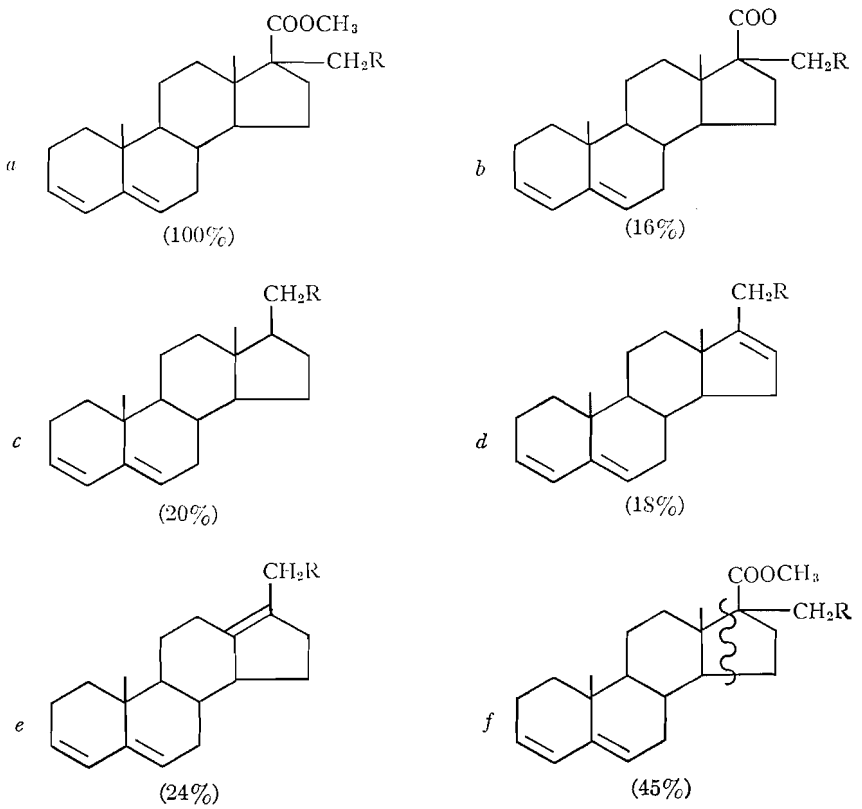
(mol. wt. 388)

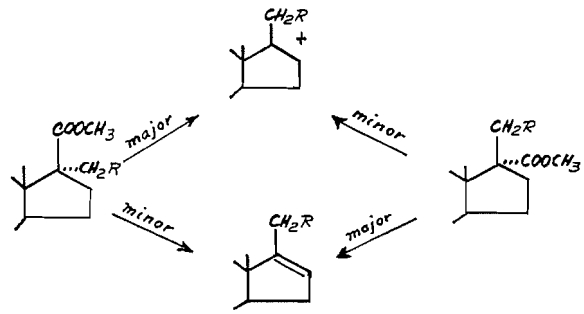
(mol. wt. 389)

Peak	*m/e*		*m/e*	
a	328	M′ (M-60)	329	M′ (M-60)
b	313	M′-15	314	M′-15
c	269	M′-59	270	M′-59
d	268	M′-60	269	M′-60
e	253	M′-75	254	M′-75
f	213	M′-115	213	M′-116

[7]*The noted (21) influence of a carbonyl group in position 11, in view of Woodward's analysis of the geometry of cyclic ketones (25), can hardly be explained only by a minimal steric distortion of the 18-methyl group. It is known that a bulky 12α-acetoxy group does not interfere with the steric retention of the Favorsky–Marker rearrangement (21). An influence of the 11-carbonyl on the reactivity of a 17,20-epoxynitrile system has been noted (18), but could not be accounted for on steric grounds. See also ref. 26 for other influences of the 11-keto group on reactions involving the side chain.*

The molecular ion is not present in the spectra. The base peaks (100%) are attributable to M-60 (loss of acetic acid) (27) (peaks *a*). Peaks *b* (M′-15) are attributable to a further loss of CH_3 from the ester group, peaks *c* (M′-59) to loss of the carbomethoxy group ($COOCH_3$), peaks *d* (M′-60) to loss of $COOCH_3$ + H, peaks *e* (M′-75) to loss of $COOCH_3$ + CH_4, and peaks *f* (M′-113 and M′-114) to loss of ring D ($C_6H_{11}O_2$ and $C_6H_{10}DO_2$).





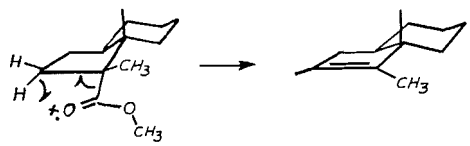


FIG. 5. The probable structure of fragments (R = H, D). The percentages in parentheses indicate the relative percentage intensity of the peaks.

The fragmentation pattern of the epimeric pairs (A and B) was remarkably similar, the only difference being in the relative intensity of peaks *c* and *d* (see spectra). These peaks (*m/e* 269 and 268 when R = H, *m/e* 270 and 269 when R = D) correspond to loss of a carbomethoxy ($COOCH_3$) and of a carbomethoxy plus hydrogen group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This fact can be accounted for by invoking a cyclic mechanism for the elimination of a carbomethoxy plus hydrogen group favored by coplanarity of the two leaving groups. The more freely rotating 17α-carbomethoxy group can better satisfy a coplanar accommodation of the carboxyl with a 16-hydrogen, thus facilitating the concerted expulsion.

EXPERIMENTAL

Melting points are corrected. Rotations were determined at 10% concentration.

Favorsky–Marker Rearrangement in Deuterated Solvents

A quantity of 17-bromo-pregn-5-en-3β-ol-20-one 3-acetate (28) (5.0 g), which was purified by repeated crystallization from methylene dichloride – methanol to m.p. 149° and which was chromatographically homogeneous, was suspended in 20 ml CH_3OD and 5 ml D_2O (both >99.5% pure). To this was added 5 g of K_2CO_3, and the mixture was stirred and refluxed during 4 h with the exclusion of moisture. The cooled and clear solution was extracted twice with ether, and the organic phase was washed with water to neutrality, dried over $MgSO_4$, and evaporated to give 3.563 g of a neutral residue, which was dissolved in 25 ml dry pyridine and acetylated with 5 ml acetic anhydride for 1 h at 90°. The usual work-up gave a neutral crystalline *residue (A)* (4.149 g). The alkaline aqueous layer from the Favorsky rearrangement was acidified with 100 ml 1 *N* H_2SO_4 and extracted 4 times with CH_2Cl_2. The organic phase was washed once with water, dried over $MgSO_4$, and evaporated to give 0.467 g of acidic *residue (B)*.

The neutral residue A was resolved on thin-layer chromatography (system: 10% diisopropyl ether in CCl_4) into three spots, corresponding to the 17-isomeric etienic esters II and III and the solvolyis product 17α-methoxy-pregn-5-en-20-one-3β-ol acetate (VI). Gas–liquid chromatographic analysis (6 ft column, 2.2 mm inside diameter, packed with 5% DC 710-phenylmethylpolysiloxane on Gas Chrom P silanized (80–100 mesh), temperature 270 °C, helium 40 p.s.i.) revealed 86.5% of isomer II (17α-deuteriomethyl-17β-carbomethoxyandrost-5-en-3β-ol acetate), 11.3% of isomer III (17β-deuteriomethyl-17α-carbomethoxy-androst-5-en-3β-ol acetate), and 2.2% of 17α-methoxypregnenolone acetate (VI) (*vide infra*). This mixture was recrystallized twice from methanol to give 1.506 g of crystals, m.p. 163–166°, consisting of essentially pure isomer II. Further recrystallization from methanol yielded the analytically pure product, m.p. 166–169°, $[\alpha]_D^{23}$ −61.5° ($CHCl_3$). The infrared spectrum contained a weak deuterium band at 2 190 cm^{-1}, and the fingerprint region was different from that of the corresponding non-deuterated compound (9). The nuclear magnetic resonance spectrum showed a decreased intensity of the peak at 8.81 τ (17-methyl) to about two-thirds of the intensity of the peak in the non-deuterated product. The mass spectrum is shown in Fig. 2.

Anal. Calcd. for $C_{24}H_{35}O_6D$: C, 74.00; H, 9.57. Found: C, 73.75; H, 9.34.

The mother liquors of the first crystallization were recrystallized to give a crystalline (m.p. 135–140°) mixture (0.678 g) of II (90%) and III (10%); the filtrate (0.892 g), which was shown by gas–liquid chromatographic analysis to contain 67.5% of the isomer III, was separated on preparative thin-layer chromatography (system: 10% diisopropyl ether in CCl_4) to give pure isomer III, 0.150 g, m.p. 153.5° from *n*-heptane, $[\alpha]_D^{23}$ −70.6° ($CHCl_3$). The nuclear magnetic resonance spectrum showed that the 17-methyl peak at 8.85 τ had decreased to about two-thirds of the intensity of the peak in the non-deuterated product (9). The mass spectrum is shown in Fig. 4.

Anal. Calcd. for $C_{24}H_{35}O_4D$: C, 74.00; H, 9.57. Found: C, 74.08; H, 9.55.

The acidic residue B (0.467 g) was methylated with excess diazomethane in ether at room temperature and acetylated as described above to give a mixture consisting of 17α-deuteriomethyl-17β-carbomethoxy-androst-5-en-3β-ol acetate (II, 92%), the 17β-deuteriomethyl isomer (III, 6.9%), and 17α-methoxypregnenolone acetate (VI, 1.1%), as shown by gas–liquid chromatography. The solvolysis product VI (17α-methoxy-pregn-5-en-20-one-3β-ol acetate) was isolated by preparative thin-layer chromatography and recrystallized from *n*-heptane to m.p. 179–181 °C; $[\alpha]_D^{23}$ −10.4° ($CHCl_3$). The nuclear magnetic resonance spectrum showed a methoxy peak at 3.12 p.p.m., and the product was identical with authentic 17α-methoxypregnenolone acetate prepared according to the procedure of Hoffmann (23).

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.19; H, 9.34. Found: C, 73.94; H, 9.15.

SYNTHESIS OF POSSIBLE ACTINOMYCIN D PRECURSORS[1]

JOHN P. MARSH, JR. AND LEON GOODMAN
Life Sciences Research, Stanford Research Institute, Menlo Park, California
Received November 1, 1965

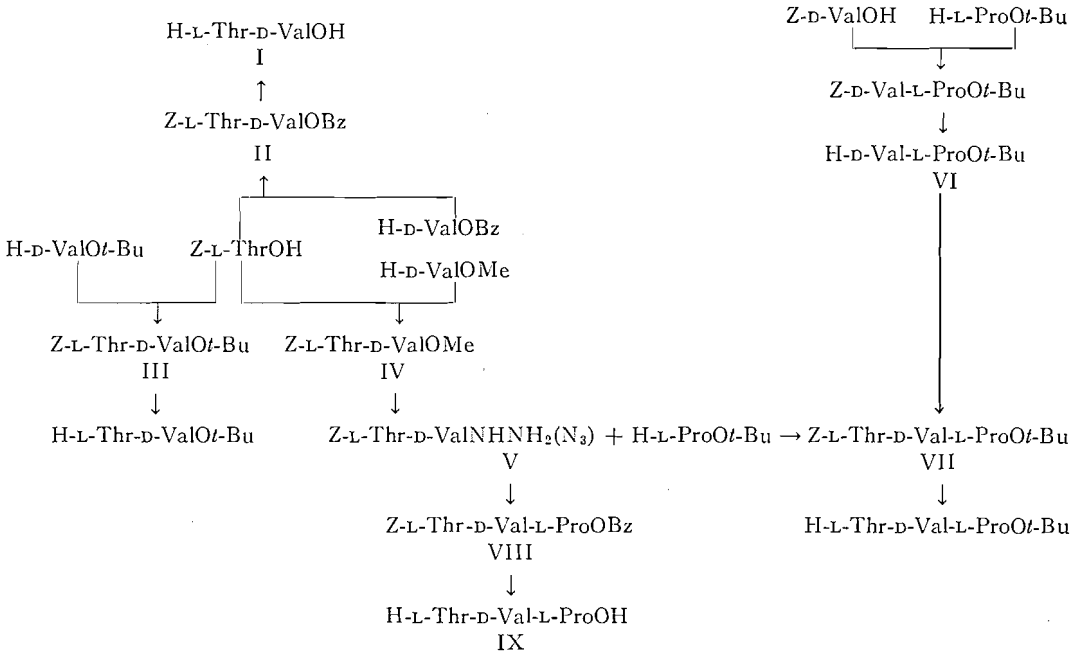
ABSTRACT

The preparation of a number of polypeptides whose sequences are found in the actinomycin D molecule is described. The 4-methyl-3-hydroxyanthranoyl derivatives of these peptides were also prepared as possible substrates for an enzyme that forms the phenoxazinone system of the antibiotic.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

An enzyme that has been named phenoxazinone synthetase (1) catalyzes the oxidative condensation of 2 moles of 4-methyl-3-hydroxyanthranilic acid to 1 mole of actinocin, the chromophoric unit of the actinomycins;[2] this enzyme is believed to play an important role in actinomycin biosynthesis. In order to try to elucidate the steps in the biosynthesis of this family of antibiotics, a group of polypeptides whose sequences appear in actinomycin D has been attached to the 4-methyl-3-hydroxyanthranoyl unit for study as possible substrates for the oxidative enzyme;[3] the preparation of these compounds is the subject of this manuscript.

Because we were interested in obtaining both the free polypeptides and the anthranoyl peptides, a stepwise addition of a N-carbobenzyloxyamino acid to a *t*-butyl aminoester was generally employed to give a blocked peptide that could serve as a common intermediate. Catalytic hydrogenation of the blocked peptide prepared in this way yielded an aminoester suitable for coupling with 3-(benzyloxy)-2-nitro-*p*-toluic acid (XXVIII) (3) to prepare the anthranoyl peptides, whereas a two-step process of hydrogenation and cleavage of the tertiary ester with trifluoroacetic acid yielded the free peptide, usually as a trifluoroacetic acid salt.



The phosphoryl chloride coupling method (4, p. 1006), because of its convenience, was used mostly in preparing the peptides (see Reaction Schemes 1 and 2). The blocked tripeptide (VII) was also prepared by the azide method (4, p. 1949), which is known to proceed without racemization, and by the carbodiimide technique (4, p. 1016); the products from the three preparations had identical optical rotations. The blocked pentapeptide (XXIV) was more conveniently prepared by coupling of the azide derived from V with the tripeptide ester (XXI); the alternative preparation of XXIV by the stepwise route using phosphoryl chloride couplings, however, gave an essentially identical product.

Hydrogenolysis of the blocked dipeptide (XI) proceeded normally, but the product, L-ProSarO*t*-Bu, cyclized to the diketopiperazine (XXVII) very readily at room temperature; special reaction conditions were required to obtain useful yields of the blocked tripeptide (XII). Ordinarily the *t*-butyl esters of dipeptides are quite stable to diketopiperazine cyclization and are thus advantageous in synthetic work. For example, Anderson (5) noted that *t*-butyl glycylphenylalaninate showed no evidence of diketopiperazine when held at room temperature for 23 days. The present work shows that, at least in

[1]*This work was carried out under the auspices of the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health, U.S. Public Health Service, contract No. PH 43-64-500. The opinions expressed are those of the authors and not necessarily those of the Cancer Chemotherapy National Service Center.*

[2]*For pertinent reviews see ref. 2.*

[3]*The enzymatic studies will be reported separately by Dr. Katz and his co-workers.*

REACTION SCHEME 1.

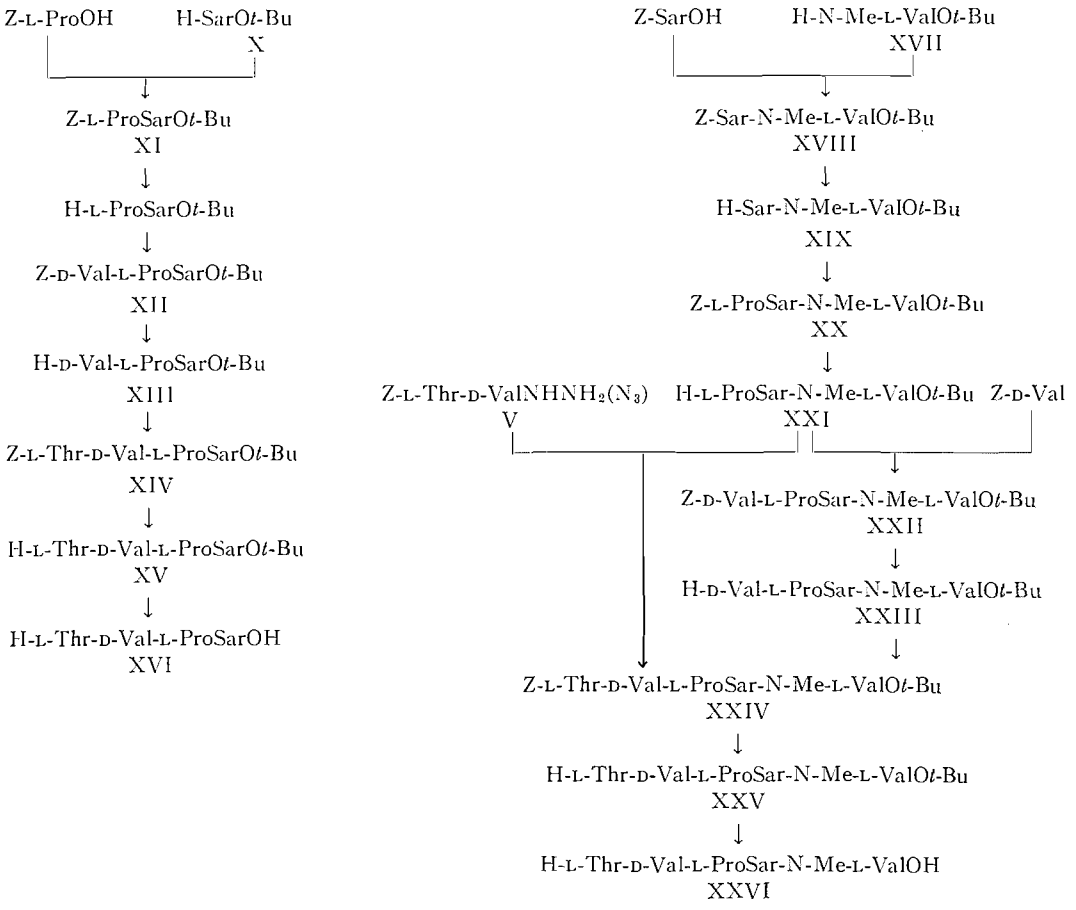
certain cases, *t*-butyl esters of dipeptides are not stable to intramolecular cyclization. The ease of cyclization of L-ProSarO*t*-Bu may be attributable to the presence of the proline moiety; recently, the enhanced tendency of proline dipeptides to undergo intramolecular cyclization has been noted in some mass spectral work (6). However, in our own work SarSarO*t*-Bu also cyclizes readily, and the presence of the sarcosine moiety in the dipeptide ester derived from XI may be the dominant factor.

The nuclear magnetic resonance (n.m.r.) spectra of all the peptides containing sarcosine and N-methyl-L-valine showed the double resonances for the N-methyl protons that result from amide *cis–trans* isomerism.

To prepare the anthranoyl peptides (XXXI) the respective *t*-butyl peptide esters were coupled with the acid (XXVIII) (3) by the phosphoryl chloride method (4, p. 1006) to form XXIX (Reaction Scheme 3). Reaction of XXIX with trifluoroacetic acid cleaved both the ester group and the aromatic O-benzyl group (7) to give XXX. Catalytic hydrogenation of XXX yielded the anthranoyl peptides that were stable in the form of their hydrochlorides (XXXI).

EXPERIMENTAL[4]

t-Butyl N-(Carbobenzoxy)-L-threonyl-D-valyl-L-prolinate (VII)



Phosphoryl Chloride Method

A solution of 1.319 g (4.76 mmoles) of *t*-butyl D-valyl-L-prolinate (VI) and 1.206 g (4.76 mmoles) of N-(carbobenzoxy)-L-threonine in 32 ml of dry, freshly distilled tetrahydrofuran was prepared and cooled

[4]*Boiling points and melting points are uncorrected; the latter were obtained with the Thomas–Hoover apparatus. Paper chromatography was run by the descending technique on Whatman No. 1 paper with the solvent system n-butanol – acetic acid – water (5:2:3); ninhydrin was used for detection. Magnesium sulfate was used to dry organic solutions unless otherwise noted. The n.m.r. spectra were run in deuteriochloroform on the Varian A-60 spectrometer with tetramethylsilane as the internal standard unless otherwise noted. Thin-layer chromatography was carried out on Brinkman silica gel HF, 0.25 mm thick. Detection was accomplished by ultraviolet and by 20% H_2SO_4 (v/v) spray. Silicic acid used for chromatography was a reagent grade, 90–200 mesh material. Optical rotations were run in chloroform at the D line unless otherwise noted. Gas chromatography was run in a 5 ft × $\frac{3}{8}$ inch phenyldiethanolamine succinate column, helium being used as a carrier gas.*

aqueous sodium bicarbonate, and water; then the filtrate was dried and evaporated. The residue, which contained some solid, was dissolved in 25 ml of cyclohexane, filtered through Celite, and evaporated *in vacuo* to give 2.26 g of an oil that showed several spots on t.l.c. The oil was chromatographed on 76 g of silicic acid to yield, by elution with chloroform and ethyl acetate – chloroform (1:9), 1.819 g (67%) of an oil that showed a single spot on t.l.c. and had $[\alpha]^{25}$ $-33.1 \pm 0.9°$ (*c*, 1.91).

Azide Method

To a stirred solution at 0° of 4.20 g (11.5 mmoles) of N-(carbobenzoxy)-L-threonyl-D-valyl hydrazide (V) in a mixture of 42 ml of glacial acetic acid and 28 ml of 2 *N* hydrochloric acid was added 0.79 g (11.5 mmoles) of sodium nitrite dissolved in 4 ml of cold water. The mixture was diluted with 3 volumes of ice water and was extracted with 40 ml of cold ethyl acetate. The organic layer was washed with two 20 ml portions of ice water and two 20 ml portions of cold saturated aqueous sodium bicarbonate, dried over sodium sulfate, and decanted into a solution of 2.07 g (12.1 mmoles) of *t*-butyl L-prolinate in 10 ml of cold ethyl acetate. All operations were carried out rapidly in a cold room maintained at 4°. The mixture was stirred at 4° for 48 h; washed successively with 25 ml portions of water, saturated aqueous sodium bicarbonate, water, 2 *N* hydrochloric acid, and water; dried; and evaporated *in vacuo* to leave 4.44 g of a glass. This residue showed several spots on t.l.c. A portion of it, 3.218 g, was chromatographed on 76 g of silicic acid and the material that was eluted with ethyl acetate – chloroform (1:9) (1.971 g (45% from V)) had $[\alpha]^{23}$ $-33.1 \pm 1.0°$ (*c*, 1.94) and showed a single spot on t.l.c.

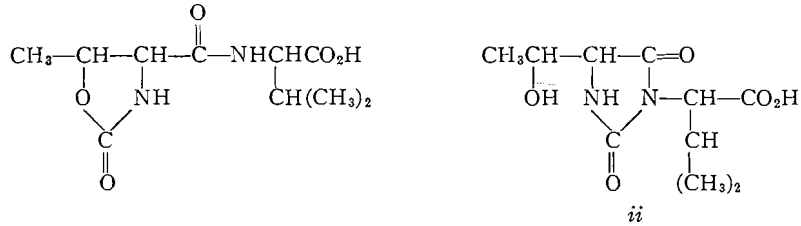
Anal. Calcd. for $C_{26}H_{39}N_3O_7$: C, 61.8; H, 7.77; N, 8.31. Found: C, 61.0; H, 7.51; N, 7.94.

Benzyl N-(carbobenzoxy)-L-threonyl-D-valinate (II) was prepared by the carbodiimide route to give an 80% yield of II, m.p. 90.1–90.6° (from methanol–water), that had $[\alpha]^{24}$ $-19.3 \pm 0.4°$ (*c*, 4.63).

Anal. Calcd. for $C_{24}H_{30}N_2O_6$: C, 65.2; H, 6.83; N, 6.33. Found: C, 65.1; H, 6.81; N, 6.53.

L-*Threonyl-D-valine (I)* was prepared by catalytic hydrogenolysis of II in 80% aqueous acetic acid over 5% palladium on carbon to give a 56% yield of I, m.p. 238.2–239.5° (from water–ethanol), that had $[\alpha]^{22}$ $+47.1 \pm 1.0°$ (*c*, 2.20 in water). On paper chromatography the compound showed a single spot with R_f 0.62.

Anal. Calcd. for $C_9H_{18}N_2O_4$: C, 49.5; H, 8.31; N, 12.8. Found: C, 49.6; H, 8.19; N, 12.6.



Methyl N-(carbobenzoxy)-L-threonyl-D-valinate (IV) was prepared by the carbodiimide route to give a 45% yield of IV, m.p. 121–122.5° (from benzene – petroleum ether (30–60°)), that had $[\alpha]^{22}$ $-33.7 \pm 0.5°$ (*c*, 4.97).

Anal. Calcd. for $C_{18}H_{26}N_2O_6$: C, 59.0; H, 7.16; N, 7.84. Found: C, 59.3; H, 7.23; N, 7.84.

N-(Carbobenzoxy)-L-threonyl-D-valine hydrazide (V) was prepared conventionally in 60% yield from IV[5] and had m.p. 244.8–246.5° (decomp.) (from absolute ethanol).

Anal. Calcd. for $C_{17}H_{26}N_4O_5$: C, 55.7; H, 7.16; N, 15.3. Found: C, 55.2; H, 7.22; N, 15.0.

[5]*An attempt to saponify IV with dilute base in aqueous dioxane gave a low yield of a solid, m.p. 225–228° (decomp.), whose elemental analysis and spectral data are compatible with the cyclic urethan i. As a referee has pointed out, these data do not eliminate the isomeric hydantoin ii as a possible structure.*

For personal use only.

*t-Butyl N-(carbobenzoxy)-*L*-threonyl-*D*-valinate (III)* was prepared by the carbodiimide method to give a 68% yield of solid, m.p. 112.8–115.0° (from cyclohexane–hexane), that had $[\alpha]^{24}$ −27.1 ± 0.5° (*c*, 5.07).

Anal. Calcd. for $C_{21}H_{32}N_2O_6$: C, 61.8; H, 7.90; N, 6.86. Found: C, 61.8; H, 7.87; N, 6.95.

t-Butyl D*-valyl-*L*-prolinate (VI)* was prepared by catalytic hydrogenation over 5% palladium on carbon in 95% ethanol of crude *t*-butyl N-(carbobenzoxy)-D-valyl-L-prolinate that had been prepared as an oil in 77% yield by the phosphoryl chloride method. The dipeptide ester (VI) was an oil with $[\alpha]^{23}$ −107 ± 2° (*c*, 1.56).

Anal. Calcd. for $C_{13}H_{26}N_2O_3$: C, 60.7; H, 9.79; N, 10.9. Found: C, 60.1; H, 9.67; N, 10.6.

*Benzyl N-(carbobenzoxy)-*L*-threonyl-*D*-valyl-*L*-prolinate (VIII)* was prepared from V in 68% yield by the azide method to give an oil that was purified by silicic acid chromatography and which had $[\alpha]^{23}$ −37.4 ± 1.7° (*c*, 1.12).

Anal. Calcd. for $C_{29}H_{37}N_3O_7$: C, 64.5; H, 6.91; N, 7.79. Found: C, 63.4; H, 7.00; N, 7.60.

L*-Threonyl-*D*-valyl-*L*-proline (IX)* was prepared by catalytic hydrogenolysis of VIII in 80% aqueous acetic acid over 5% palladium on charcoal. The tripeptide (IX) had m.p. 180.0–181.5° (decomp.) (from water–ethanol) and $[\alpha]^{25}$ −2.8 ± 0.7° (*c*, 1.48 in water). On paper chromatography the compound showed a single spot with R_f 0.64.

Anal. Calcd. for $C_{14}H_{25}N_3O_5 \cdot 0.8H_2O$: C, 51.0; H, 8.13; N, 12.7. Found: C, 50.9; H, 8.01; N, 13.0.

t-Butyl sarcosinate (X) was prepared by catalytic hydrogenolysis of crude *t*-butyl N-(carbobenzoxy)-sarcosinate (prepared from N-(carbobenzoxy)-sarcosine by Anderson's (5) procedure) in 95% ethanol over 5% palladium on carbon. The hydrogenolysis product was purified by distillation to give material that had b.p. 76.5–78° at 40 mm and which showed a single peak on vapor phase chromatography with a retention time of 1.80 min, a column temperature of 130° and a flow rate of 51 ml/min being used. The analytical sample had n_D^{23} 1.4148.

Anal. Calcd. for $C_7H_{15}NO_2$: C, 57.9; H, 10.4; N, 9.65. Found: C, 57.7; H, 10.4; N, 9.42.

*t-Butyl N-(carbobenzoxy)-*L*-prolylsarcosinate (XI)* was prepared in 85% yield by the phosphoryl chloride procedure to give the blocked dipeptide as an oil that showed a trace impurity on t.l.c. and had $[\alpha]^{22.5}$ −52.1 ± 0.9° (*c*, 2.85 in ethanol).

Anal. Calcd. for $C_{20}H_{28}N_2O_6$: C, 63.8; H, 7.49; N, 7.44. Found: C, 63.8; H, 7.47; N, 7.39.

2,5-Dioxo-1-methyl-3,4-trimethylenepiperazine (XXVII)

The blocked dipeptide (XI, 2.92 g) was dissolved in 30 ml of 95% ethanol and was hydrogenated conventionally with 5% palladium on carbon. After evaporation there was an oil (1.80 g) whose n.m.r. spectrum indicated loss of the *t*-butyl group by the reduced integrated intensity of the *t*-butyl protons relative to the rest of the molecule. Distillation (short path) of the material gave 0.68 g (bath temperature 125° at 0.008 mm) of a semisolid which was crystallized from ethyl acetate – cyclohexane to give the hygroscopic product, m.p. 46.2–47.5°, $[\alpha]^{22}$ −131.8 ± 2.9° (*c*, 0.613 in ethanol).

Anal. Calcd. for $C_8H_{12}N_2O_2$: C, 57.1; H, 7.20; N, 16.7. Found: C, 56.7; H, 7.20; N, 16.3.

*t-Butyl N-(carbobenzoxy)-*D*-valyl-*L*-prolylsarcosinate (XII)* was prepared in 71% yield by the phosphoryl chloride method from *t*-butyl L-prolylsarcosinate to give XII as an oil that showed two trace contaminants on t.l.c. The *t*-butyl dipeptide used in the condensation was prepared from XI by hydrogenation at 0°, rapid removal of the solvent at −10 to 0° in a high vacuum, and immediate use of the crude product in the coupling.

Anal. Calcd. for $C_{25}H_{37}N_3O_6$: C, 63.1; H, 7.84; N, 8.83. Found: C, 63.0; H, 7.91; N, 8.81.

t-Butyl D*-valyl-*L*-prolylsarcosinate (XIII)* was obtained in 93% yield as a solid with no definite melting point, by conventional hydrogenolysis in 95% ethanol. It had $[\alpha]^{23}$ −103 ± 1.3° (*c*, 1.55 in ethanol).

Anal. Calcd. for $C_{17}H_{31}N_3O_4$: C, 59.8; H, 9.16; N, 12.3. Found: C, 59.3; H, 9.11; N, 12.3.

*t-Butyl N-(carbobenzoxy)-*L*-threonyl-*D*-valyl-*L*-prolylsarcosinate (XIV)* was prepared in 67% yield by the phosphoryl chloride method to give the blocked tetrapeptide as a foam that showed a single spot on t.l.c. and had $[\alpha]^{23}$ −37.8 ± 1.4° (*c*, 0.923 in ethanol).

Anal. Calcd. for $C_{29}H_{44}N_4O_8$: C, 60.4; H, 7.69; N, 9.72. Found: C, 59.9; H, 7.80; N, 9.79.

t-Butyl L*-threonyl-*D*-valyl-*L*-prolylsarcosinate (XV)* was obtained in 92% yield as a white solid with no definite melting point, by conventional catalytic hydrogenolysis of XIV. It had $[\alpha]^{23}$ −28.1 ± 5.0° (*c*, 0.354 in ethanol).

Anal. Calcd. for $C_{21}H_{38}N_4O_6 \cdot H_2O$: C, 54.8; H, 8.75; N, 12.2. Found: C, 54.5; H, 8.40; N, 11.8.

L*-Threonyl-*D*-valyl-*L*-prolylsarcosine (XVI) Trifluoroacetate*

The tetrapeptide ester (XV, 0.700 g) was dissolved in 15 ml of trifluoroacetic acid, and the solution was allowed to stand at room temperature for 45 min and then was evaporated *in vacuo*. The residue was treated with 20 ml of benzene, the mixture evaporated *in vacuo*, and the treatment repeated. The residue was then dissolved in 10 ml of absolute ethanol, the solution filtered, and the filtrate treated with excess dry ether to precipitate the peptide salt. After a second ethanol–ether precipitation the product was isolated by centrifugation to yield 0.415 g (55%) of the salt, m.p. 147–160° (decomp.), $[\alpha]^{23}$ +9.1 ± 1.5° (*c*, 0.667 in ethanol). On paper chromatography the compound showed a single spot with R_f 0.67.

Anal. Calcd. for $C_{17}H_{30}N_4O_6 \cdot CF_3CO_2H$: C, 45.6; H, 6.25; F, 11.4; N, 11.2. Found: C, 45.6; H, 6.65; F, 11.7; N, 11.7.

Amino acid analysis of the tetrapeptide showed a molar ratio for Thr:Val:Pro:Sar of 1.06:1.04:1.01:0.77.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

*t-Butyl N-Methyl-*L*-valinate (XVII)*

Liquid isobutylene (25 ml) was added to a solution of 2.9 g of N-methyl-L-valine (8) in 25 ml of dry dioxane containing 2.4 ml of concentrated sulfuric acid. The mixture, in a heavy-walled, tightly stoppered bottle, was stirred vigorously for 18 h at room temperature; then the excess isobutylene was vented and the residue was poured into an ice-cold mixture of 100 ml of water and 200 ml of ether. The water layer was separated, adjusted to pH 10 with 1 *N* sodium hydroxide, and extracted with three 25 ml portions of ether. The ether extract was dried and the ether removed by distillation through a short Vigreux column. Finally some dioxane was removed by application of an aspirator vacuum at room temperature. The residual liquid (3.0 g) was distilled through a spinning-band column to give 1.87 g (77%) of distillate collected in two fractions, b.p. 64–76° at 16 mm and 70–73° at 12 mm. The second fraction was used for analysis and had $[\alpha]^{20}$ +4.7 ± 0.9° (*c*, 0.95). Vapor phase chromatography showed a single peak with a retention time of 1.55 min, a column temperature of 139° and a flow rate of 143 ml/min being used.

Anal. Calcd. for $C_{10}H_{21}NO_2$: C, 64.1; H, 11.3; N, 7.48. Found: C, 63.8; H, 11.5; N, 7.36.

On a larger scale the removal of the dioxane was troublesome and caused difficulty in the isolation of XVII. The conversion of N-benzyl-N-methyl-L-valine (8) into the *t*-butyl ester, isolated as a crystalline hydrochloride, was simpler, but no practical system for debenzylation of the ester could be found.

*t-Butyl N-(carbobenzoxy)sarcosyl-N-methyl-*L*-valinate (XVIII)* was prepared in 71% yield by the phosphoryl chloride method to give the product as an oil that showed several trace spots on t.l.c. and had $[\alpha]^{23}$ −78.0 ± 0.9° (*c*, 1.08 in ethanol). The integration of the n.m.r. spectrum of the product showed the proper ratios for structure XVIII.

Anal. Calcd. for $C_{21}H_{32}N_2O_5$: C, 64.3; H, 8.22; N, 7.14. Found: C, 63.9; H, 7.95; N, 7.41.

*t-Butyl sarcosyl-N-methyl-*L*-valinate (XIX)* was prepared by conventional hydrogenolysis of XVIII to give a 65% yield of an oil that had $[\alpha]^{22}$ −68.1 ± 3.2° (*c*, 1.71 in ethanol) and which showed no signs of cyclization at room temperature.

Anal. Calcd. for $C_{13}H_{26}N_2O_3$: C, 60.4; H, 10.1; N, 10.9. Found: C, 60.4; H, 10.2; N, 11.0.

*t-Butyl N-(carbobenzoxy)-*L*-prolylsarcosyl-N-methyl-*L*-valinate (XX)* was prepared by the phosphoryl chloride method to give a 75% yield of an oil that was purified by silicic acid chromatography. The fraction eluted with chloroform represented a 44% yield and had $[\alpha]^{21}$ −102.8 ± 2.0° (*c*, 0.864 in ethanol).

Anal. Calcd. for $C_{26}H_{39}N_3O_6$: C, 63.8; H, 8.03; N, 8.58. Found: C, 63.7; H, 8.05; N, 8.79.

t-Butyl L*-prolylsarcosyl-N-methyl-*L*-valinate (XXI)* was prepared conventionally from XX to give 95% of an oil that had $[\alpha]^{23}$ −141.2 ± 0.6° (*c*, 0.91 in ethanol).

Anal. Calcd. for $C_{18}H_{33}N_3O_4$: C, 60.8; H, 9.36; N, 11.8. Found: C, 60.7; H, 9.21; N, 11.9.

*t-Butyl N-(carbobenzoxy)-*D*-valyl-*L*-prolylsarcosyl-N-methyl-*L*-valinate (XXII)* was prepared by the phosphoryl chloride procedure to give, after silicic acid chromatography, a 63% yield of an oil that had $[\alpha]^{21}$ −75.3 ± 2.0° (*c*, 1.00 in ethanol).

Anal. Calcd. for $C_{31}H_{48}N_4O_7$: C, 63.2; H, 8.22; N, 9.53. Found: C, 63.0; H, 8.71; N, 9.43.

t-Butyl D*-valyl-*L*-prolylsarcosyl-N-methyl-*L*-valinate (XXIII)* was prepared from XXII to give a 97% yield of a gum that had $[\alpha]^{25}$ −125.2 ± 2.4° (*c*, 1.15 in methanol).

Anal. Calcd. for $C_{23}H_{42}N_4O_5$: C, 60.8; H, 9.31; N, 12.3. Found: C, 60.9; H, 9.09; N, 12.4.

*t-Butyl N-(carbobenzoxy)-*L*-threonyl-*D*-valyl-*L*-prolylsarcosyl-N-methyl-*L*-valinate (XXIV)* was prepared both by the phosphoryl chloride procedure from XXIII and by the azide coupling of XXI and the azide derived from V. The phosphoryl chloride procedure provided, after chromatography on activated Florosil, 57% of a gum that gave a single spot on t.l.c. and had $[\alpha]^{21}$ −78.3 ± 1.0° (*c*, 0.548 in ethanol).

Anal. Calcd. for $C_{35}H_{55}N_5O_9$: C, 60.9; H, 8.04; N, 10.2. Found: C, 60.5; H, 8.16; N, 9.78.

The product from the azide coupling reaction was obtained in 60% yield after chromatography on Florosil and showed t.l.c. behavior identical with that of the phosphoryl chloride product; it had $[\alpha]^{21}$ −74.4 ± 1.7° (*c*, 1.10 in ethanol).

t-Butyl L*-threonyl-*D*-valyl-*L*-prolylsarcosyl-N-methyl-*L*-valinate (XXV)* was prepared from XXIV to give 92% of a foam that had $[\alpha]^{21}$ −75.4 ± 1.8° (*c*, 0.966 in ethanol).

Anal. Calcd. for $C_{27}H_{49}N_5O_7$: C, 58.4; H, 8.89; N, 12.6. Found: C, 57.8; H, 8.72; N, 12.3.

L*-Threonyl-*D*-valyl-*L*-prolylsarcosyl-N-methyl-*L*-valine (XXVI) trifluoroacetate* was prepared from XXV by the procedure described for XVI to give an 81% yield of a white foam that had $[\alpha]^{22}$ −42.4 ± 1.6° (*c*, 1.05 in ethanol). On paper chromatography the compound showed a single spot with R_f 0.69.

Anal. Calcd. for $C_{23}H_{41}N_5O_7 \cdot CF_3CO_2H$: C, 48.9; H, 6.90; F, 9.29; N, 11.4. Found: C, 48.7; H, 7.05; F, 9.66; N, 11.9.

*t-Butyl N-[3-(benzyloxy)-2-nitro-p-toluoyl]-*L*-threonyl-*D*-valinate (XXIXa)* was prepared by the phosphoryl chloride coupling of XXVIII and *t*-butyl L-threonyl-D-valinate to give a 60% yield of a crystalline solid having an undefined melting point after crystallization from cyclohexane.

Anal. Calcd. for $C_{28}H_{37}N_3O_8$: C, 61.9; H, 6.86; N, 7.73. Found: C, 61.8; H, 6.75; N, 7.53.

*N-(2-Nitro-3,4-cresotoyl)-*L*-threonyl-*D*-valine (XXXa)*

A solution of 3.578 g of XXIX*a* in 25 ml of trifluoroacetic acid was allowed to stand at room temperature for 1.5 h, and then was evaporated *in vacuo*. The residue was freed of acid by the successive addition and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evaporation of three 25 ml portions of benzene. The residue was partitioned between 25 ml each of chloroform and saturated aqueous sodium bicarbonate. The aqueous extract was acidified to pH 1 with 3 *N* hydrochloric acid and was extracted with 25 ml of chloroform. The organic extract was dried and evaporated *in vacuo* to leave 2.59 g of a yellow solid. Recrystallization from benzene yielded three crops of crystalline solid, 1.63 g (62%). A sample that was recrystallized for analysis had m.p. 101.2–104.0°.

Anal. Calcd. for $C_{17}H_{23}N_3O_8$: C, 51.4; H, 5.83; N, 10.6. Found: C, 51.6; H, 6.31; N, 10.3.

N-(2-Amino-3,4-cresotoyl)-L-*threonyl*-D-*valine Hydrochloride (XXXIa)*

A stirred mixture of 1.467 g of XXX*a*, 25 ml of absolute ethanol that contained 5 drops of glacial acetic acid, and 350 mg of 5% palladium on carbon was maintained under a hydrogen atmosphere for 18 h, during which time 343 ml (corrected for catalyst absorption) of hydrogen was absorbed. The mixture was filtered through Celite and the filtrate was treated with 10 ml of hydrogen chloride saturated ether. Dry hydrogen chloride was bubbled through the chilled solution for about 15 min, and then the solution was evaporated *in vacuo*. The residue was dissolved in the minimum amount of absolute ethanol, and the product was precipitated with excess dry ether. The precipitate (1.135 g (76%)) was collected by centrifugation to give a solid that showed no definite melting behavior and had $[\alpha]^{23}$ +13.8 ± 0.4° (*c*, 3.82 in 1 *N* hydrochloric acid), λ_{max}^{pH1} 221 mμ (ε 27 400) and 285 mμ (ε 6 450).

Anal. Calcd. for $C_{17}H_{26}ClN_3O_6$: C, 50.6; H, 6.49; Cl, 8.78; N, 10.4. Found: C, 50.8; H, 6.65; Cl, 8.66; N, 10.4.

t-Butyl N-[3-(benzyloxy)-2-nitro-p-toluoyl]-L-*threonyl*-D-*valyl*-L-*prolinate (XXIXb)* was a foam that was chromatographed on silicic acid to give a low yield of an amorphous material that gave a single spot on t.l.c. and whose n.m.r. spectrum was in good agreement with that of the postulated structure.

N-(2-Nitro-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*proline (XXXb)* was prepared from crude XXIX*b* with trifluoroacetic acid to give a 61% yield of solid after crystallization from ethyl acetate – cyclohexane. The material did not have a definite melting point; it had $[\alpha]^{26}$ −19.6 ± 0.8° (*c*, 1.87 in ethanol).

Anal. Calcd. for $C_{22}H_{30}N_4O_9$: C, 53.4; H, 6.14; N, 11.33. Found: C, 53.5; H, 6.73; N, 11.2.

Crystallization of the compound from carbon tetrachloride gave a solvate.

Anal. Calcd. for $C_{22}H_{30}N_4O_9 \cdot 0.4CCl_4$: C, 48.4; H, 5.44; Cl, 10.2; N, 10.1. Found: C, 48.6; H, 5.77; Cl, 9.90; N, 10.2.

N-(2-Amino-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*proline hydrochloride (XXXIb)* was an amorphous powder that was prepared in 66% yield from XXX*b* and which had $[\alpha]^{23}$ −16.9 ± 0.6° (*c*, 2.28 in 1 *N* hydrochloric acid).

Anal. Calcd. for $C_{22}H_{33}ClN_4O_7$: C, 52.8; H, 6.64; Cl, 7.08; N, 11.2. Found: C, 52.6; H, 6.77; Cl, 6.68; N, 10.6.

t-Butyl N-[3-(benzyloxy)-2-nitro-p-toluoyl]-L-*threonyl*-D-*valyl*-L-*prolylsarcosinate (XXIXc)* was obtained as a chromatographically homogeneous foam in 35% yield after chromatography on Florosil. It had $[\alpha]^{23}$ −20.9 ± 1.2° (*c*, 0.94 in ethanol).

Anal. Calcd. for $C_{36}H_{49}N_5O_{10}$: C, 60.8; H, 6.94; N, 9.84. Found: C, 60.9; H, 6.90; N, 9.17.

N-(2-Nitro-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*prolylsarcosine (XXXc)* was obtained from XXIX*c* as an amorphous solid after the usual trifluoroacetic acid treatment and a final precipitation from ethyl acetate with hexane. The material gave poor analytical results.

N-(2-Amino-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*prolylsarcosine hydrochloride (XXXIc)* was obtained as an ethanol solvate from hydrogenation of XXX*c*. It had $[\alpha]^{24}$ −30.3 ± 1.2° (*c*, 0.99 in 1 *N* hydrochloric acid) and λ_{max}^{pH1} 216 mμ (ε 31 200), 222 mμ (shoulder, ε 28 900), and 330 mμ (ε 2 205).

Anal. Calcd. for $C_{25}H_{38}ClN_5O_8 \cdot C_2H_5OH$: C, 52.4; H, 7.17; Cl, 5.74; N, 11.3. Found: C, 52.1; H, 6.85; Cl, 5.71; N, 11.3.

The presence of ethanol was confirmed by mass spectrometry.

t-Butyl N-[3-(benzyloxy)-2-nitro-p-toluoyl]-L-*threonyl*-D-*valyl*-L-*prolylsarcosyl-N-methyl*-L-*valinate (XXIXd)* was obtained in 58% yield as a chromatographically homogeneous foam after chromatography on activated Florosil.

Anal. Calcd. for $C_{42}H_{60}N_6O_{11}$: C, 61.1; H, 7.33; N, 10.2. Found: C, 61.0; H, 7.65; N, 9.45.

N-(2-Nitro-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*prolylsarcosyl-N-methyl*-L-*valine (XXXd)* was obtained in 85% yield from XXIX*d* as a yellow powder that showed a single spot on t.l.c.

Anal. Calcd. for $C_{31}H_{46}N_6O_{11}$: C, 54.9; H, 6.84; N, 12.4. Found: C, 55.3; H, 7.00; N, 12.3.

N-(2-Amino-3,4-cresotoyl)-L-*threonyl*-D-*valyl*-L-*prolylsarcosyl-N-methyl*-L-*valine hydrochloride (XXXId)* was obtained conventionally in 76% yield as an amorphous powder that had $[\alpha]^{22}$ −84.0 ± 2.1° (*c*, 0.61 in ethanol).

Anal. Calcd. for $C_{31}H_{49}ClN_6O_9$: C, 54.3; H, 7.21; Cl, 5.17; N, 12.3. Found: C, 54.1; H, 7.31; Cl, 4.86; N, 12.0.

ACKNOWLEDGMENTS

The authors thank Dr. Peter Lim and his staff for the infrared, ultraviolet, and n.m.r. spectra, the optical rotations, and the paper chromatography. They also are indebted to Mr. O. P. Crews and his group for the preparation of certain intermediates.

STEROIDS AND RELATED NATURAL PRODUCTS

XXVIII. STEREOCHEMISTRY OF 3-HYDROXY-4-OXA-5α-CHOLESTANE AND RELATED HEMIACETALS[1,2]

GEORGE R. PETTIT,[3] JOHN C. KNIGHT,[4] AND WILLIAM J. EVERS

Received November 23, 1965

ABSTRACT

Several new 3-hydroxy-4-oxa type steroidal hemiacetals (V and VII) have been prepared by diborane reduction of the corresponding δ-lactones. A detailed proton magnetic resonance study of the hemiacetal (IX*a*) derived from 3-oxo-4-oxa-5α-cholestane (VIII) indicated that diborane reduction led in each case to an epimeric mixture. Treating hemiacetal IX*a* with methanol – hydrochloric acid gave a mixture of acetals IX*b* and IX*c*. Pure specimens of the epimeric acetals were obtained by preparative thin-layer chromatography, and configurational assignments based on proton magnetic resonance studies were provided for each isomer. Allowing lactone VIII (in tetrahydrofuran solution) to react with 1 equivalent of diborane during 4 min resulted in approximately 80% conversion into hemiacetal IX*a*, and provided an illustration of the potential utility of the reduction reaction.

After the discovery (2) that certain steroidal lactones could conveniently be reduced to cyclic hemiacetals with diborane, the reduction reaction was applied (2, 3) to four A-ring steroidal lactones.[5] The first hemiacetal prepared in our laboratory by the diborane route was 3ξ-hydroxy-4-oxa-5α-cholestane (IX*a*), and the isomer (m.p. 197–199°) that was characterized was assumed (2*b*) to represent the 3β-equatorial epimer. Concurrently, Edward and his colleagues (4*c*) performed the same experiment by a lithium aluminium hydride procedure and isolated one isomer (m.p. 188–190°) that was assigned, on the basis of molecular rotation studies, the 3α-axial configuration. Although fractional recrystallization of the hemiacetal failed to reveal the presence of the 3β-isomer, a solution of the hemiacetal in tetrahydrofuran–water was found (4*c*) to represent 45% equatorial isomer and 55% axial epimer. Later, when we began a general study of the lactone → hemiacetal reduction reaction with diborane, the stereochemistry of A-ring steroidal hemiacetals became of increasing importance. Accordingly, a detailed examination of hemiacetal IX*a* was undertaken by proton magnetic resonance (p.m.r.) spectroscopy, and the study was expanded to include related hemiacetals representing the androstane (V) and pregnane (VII*a*) ring systems.

Synthesis of the required hemiacetals was conveniently achieved as follows. First, dehydroepiandrosterone (I) was converted into 3-oxo-androst-4-ene (II) essentially as previously reported (6) and the ketone was oxidized to lactone III*a* with peroxydisulfuric acid (2*b*, 3*a*). For chemical and subsequent biological comparative purposes, lactone III*a* was reduced by boron trifluoride – sodium borohydride to tetrahydropyran III*b* and by lithium aluminium hydride to diol IV. Then lactone III*a* in tetrahydrofuran was readily reduced to hemiacetal V by externally generated (sodium borohydride – boron trifluoride)

[4] *Smith, Kline, and French Postdoctorate Fellow, 1962.*

[5] *Meanwhile, a variety of other steroidal hemiacetals have been prepared from the corresponding lactone by specialized lithium aluminium hydride or sodium borohydride techniques (4). In the same period, several novel approaches to steroidal hemiacetals and (or) acetal derivatives were also reported (5).*

diborane. Next, progesterone was converted (2*b*) into lactone VI*a*. Treating the 20-ketone (VI*a*) with boron trifluoride – ethanedithiol yielded thioketal VI*b*. Raney nickel desulfurization (7) of ethylenethioketal VI*b* gave the required lactone (VI*c*). Diborane (externally generated) reduction of lactones VI*b* and VI*c* provided the corresponding hemiacetal derivatives (VII*a* and VII*b*). At this point, the reduction reaction appeared to be of a general nature, and the necessary experimental conditions were more carefully defined, lactone VIII being used as a model substrate. Eventually, a 4 min reaction period at room temperature and with equivalent quantities of standard diborane in tetrahydrofuran[6] was found to convert lactone VIII in good yield (approximately 80%) into hemiacetal IX*a*. The remaining product, as evidenced by thin-layer chromatography, was the corresponding diol resulting from further reduction. In general, a 30 min reaction period was found to be satisfactory.

A chromatographically pure specimen of hemiacetal IX*a*, m.p. 185–190°, in deuteriochloroform was found by p.m.r. spectral comparison (Fig. 1) with specimens of 3β-hydroxy-5α-cholestane (8) and 3α-hydroxy-5α-cholestane (9) to represent a mixture of 3β- and 3α-epimers in approximately equal amounts. In the 5α-steroid series an axial C-3 proton generally exhibits a broad response upfield from the more well defined signal usually exhibited by an equatorial C-3 proton (10). The p.m.r. spectra of the 3-hydroxy-5α-cholestanes (Fig. 1) were in agreement with these observations. The 3β-hydroxy epimer of hemiacetal IX*a* displayed a broad 3α-proton signal at 4.58 δ and a broad 5α-proton signal centered at 3.07 δ. Corresponding signals at 5.08 (3β-proton) and 3.6–3.8 (5α-proton) δ of the composite spectrum were attributed to the 3α-hydroxy isomer (IX*a*).

[6]*Recently 1M borane in tetrahydrofuran has become commercially available (metal hydride division of Ventron Corporation) and is now being routinely employed (e.g. for preparation of hemiacetals) in our laboratory.*

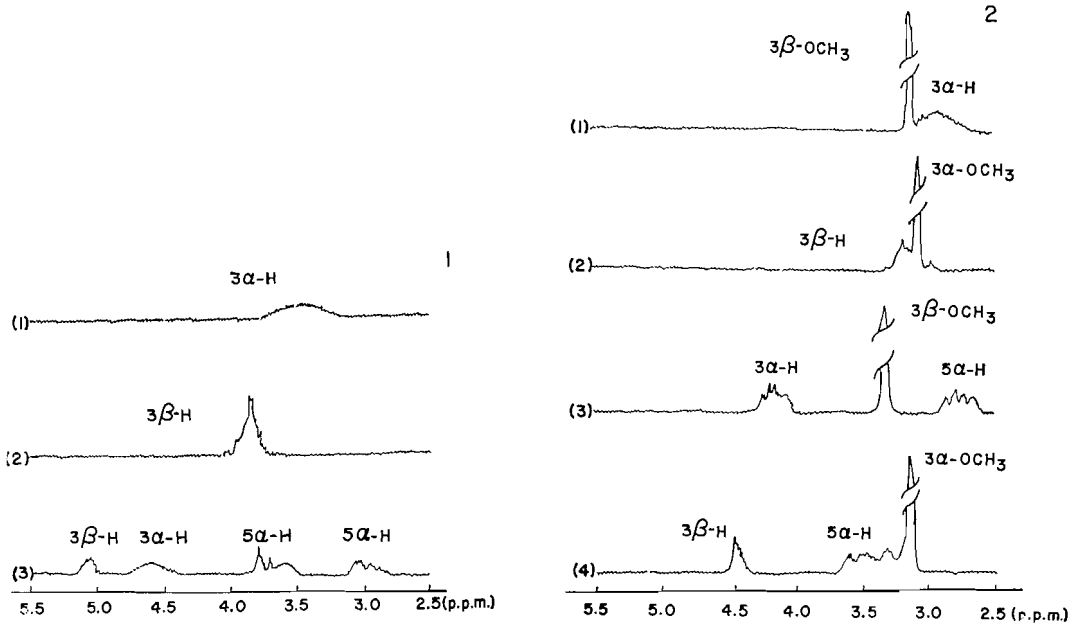

FIG. 1. The p.m.r. spectra of 3β-hydroxy-5α-cholestane (1), 3α-hydroxy-5α-cholestane (2), and the epimeric 3α- and 3β-hydroxy-4-oxa-5α-cholestanes (3) in deuteriochloroform. Resonance frequencies are recorded downfield from tetramethylsilane at 0.0 δ.

FIG. 2. The p.m.r. spectra of 3β-methoxy-5α-cholestane (1), 3α-methoxy-5α-cholestane (2), 3β-methoxy-4-oxa-5α-cholestane (3), and 3α-methoxy-4-oxa-5α-cholestane (4) in benzene recorded as noted in Fig. 1.

Analogous p.m.r. evidence was compiled and used to assign configurations to the epimeric methylacetals (IX*b* and IX*c*) derived from hemiacetal IX*a*.[7] Preparative thin-layer chromatography was used to separate the epimeric mixture of methylacetals obtained by treating hemiacetal IX*a* with methanol containing a drop of hydrochloric acid. By this method, pure specimens of the axial (IX*b*, m.p. 101–102°) and equatorial (IX*c*, m.p. 79–80°) epimers were obtained. A comparison (Fig. 2) of the p.m.r. spectra of both epimers in benzene solution with the p.m.r. spectra of 3α-methoxy- (13) and 3β-methoxy-5α-cholestane confirmed the structures previously assigned by Edward and collaborators.[7,8] Interestingly, the 5α-proton of the axial hydroxyl (IX*a*) and methoxy (IX*b*) isomers gave a p.m.r. signal displaced downfield by 0.6–0.7 δ from that of the C-3 equatorial isomers.[9]

A survey of hemiacetals V and VII indicated that each represented (in deuteriochloroform solution) a nearly equal mixture of epimers. Thus, the anomeric effect in 3-hydroxy-4-oxa steroids, in solution, is as important as conformational factors, and in the case of 3-methoxy-4-oxa-5α-steroids becomes of major importance. These conclusions reached on the basis of p.m.r. data support and confirm the earlier conclusions of Edward and his colleagues (4*c*, 11) regarding the stereochemistry of 3-hydroxy-4-oxa-5α-cholestane (IX*a*).

[7]*The isomeric acetals corresponding to structures IXb and IXc were prepared (2b, 4c, 11) in conjunction with earlier studies of hemiacetal IXa. The isomer, m.p. 98–99.5°, obtained from hemiacetal IXa and methanol – hydrogen chloride was shown (4c), on the basis of careful mutarotation determinations, to represent a 3α-methoxy configuration. Similarly, the β-anomer (m.p. 74–76°) obtained (11) by acid-catalyzed isomerization of the 3α-methoxy epimer was assigned structure IXc. Before these reports Fieser and his colleagues isolated a sample of the acetal melting at 89–92° (12).*

[8]*Edward and Puskas (11) also noted that acid-catalyzed isomerization of the 3-methoxy anomers favored formation of the 3α-methoxy isomer in the approximate ratio 7:3. A p.m.r. spectrum of the crude methylation product in benzene solution, prepared as described in the Experimental section, clearly verified the 3α-methoxy epimer as the major product.*

[9]*An example of 1,3-diaxial deshielding in the reverse direction, that is, of a C-3 proton by a bromine substituent at C-5, has been recorded (14).*

EXPERIMENTAL

The diethyl ether, diglyme (diethylene glycol dimethyl ether), and tetrahydrofuran were redistilled from sodium or lithium aluminium hydride and stored over sodium wire. Final purification of diglyme by distillation from lithium aluminium hydride in one case (observed by Dr. A. K. Das Gupta) resulted in an explosion. The same observation has recently been reported by Watson (15). In view of these experiences, distillation of diglyme from lithium aluminium hydride is not now recommended. All other solvents and boron trifluoride etherate were also redistilled. The sodium borohydride was used as supplied by Metal Hydrides, Inc. Each reduction reaction was conducted in a nitrogen atmosphere. Solvent extracts of aqueous solutions were dried over magnesium sulfate. Activated alumina refers to Merck "suitable for chromatography". Thin-layer chromatography plates were prepared with silica gel G (E. Merck, AG, Darmstadt) and developed with concentrated sulfuric acid.

A Kofler melting point apparatus was employed for melting point determinations (corrected). Optical rotation (chloroform solution) and elemental composition values were determined, respectively, in the laboratories of Dr. P. Demoen, Janssen Pharmaceutica, Beerse, Belgium, and Dr. A. Bernhardt, Mülheim, Germany. The infrared (potassium bromide) and p.m.r. spectra were recorded by Dr. R. A. Hill (University of Maine).

3-Oxo-4-oxa-5α-androstane (IIIa)

After chromatography on activated alumina in 1:1 petroleum ether – benzene, 3-oxo-androst-4-ene (II) (10 g (6)) was obtained as colorless needles, m.p. 106–108°. Oxidation to lactone III*a* was accomplished as previously described for 19-nortestosterone acetate (3*a*) with a reagent prepared from sulfuric acid (28 g), potassium persulfate (26 g), and glacial acetic acid (500 ml). The crude lactone (III*a*) was crystallized from petroleum ether – acetone as tacky yellow prisms (4.4 g). A solution of the product in 1:1 petroleum ether – benzene was percolated through a column of neutral alumina (Merck, Darmstadt) and, after removal of solvent, the filtrate residue was crystallized from petroleum ether – acetone as colorless needles (1.9 g), m.p. 115–116°. Repeated recrystallization from the same solvent mixture did not alter the melting point, and an analytical specimen exhibited $[\alpha]_D^{22}$ +77.3° (*c*, 1.25) and ν_{max} 1 735 cm^{-1}.

Anal. Calcd. for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21. Found: C, 78.61; H, 10.27.

3,5β-Dihydroxy-3,5-seco-A-nor-5α-androstane (IV)

A solution of lactone III*a* (0.5 g) in tetrahydrofuran (20 ml) was reduced with lithium aluminium hydride (0.5 g in 30 ml of tetrahydrofuran) by the technique employed with 3-oxo-17β-hydroxy-4-oxa-5α-androstane (see ref. 3*a*). The diol (IV) was recrystallized from chloroform–methanol as needles weighing 0.45 g and melting at 189–190°. Several recrystallizations from the same solvent mixture provided an analytical sample (unchanged melting point); $[\alpha]_D^{22}$ 0.0° (*c*, 1.31);[10] ν_{max} 3 300, 1 085, 1 065, 1 040, and 1 025 cm^{-1}.

Anal. Calcd. for $C_{18}H_{32}O_2$: C, 77.09; H, 11.50; active H, 0.72. Found: C, 76.99; H, 11.26; active H, 0.62.

3ξ-Hydroxy-4-oxa-5α-androstane (V)

A solution of lactone III*a* (0.60 g) in tetrahydrofuran (20 ml) was treated with diborane generated from sodium borohydride (0.7 g) and boron trifluoride etherate (2.0 g) in diglyme (35 ml) as noted in earlier experiments (2, 3*a*). A solution of the solid product in 3:1 benzene–chloroform was chromatographed on neutral alumina. Elution with 60 ml of the same solvent mixture led to the recovery of lactone III*a* (0.05 g). Continued elution provided the epimeric hemiacetals (V). Three recrystallizations from chloroform – petroleum ether gave needles (0.40 g) melting at 188–192° (sintering from 178°). A thin-layer chromatogram of the hemiacetal mixture on Kieselguhr G (with chloroform or 19:1 chloroform–methanol as mobile phase) indicated that the analytical specimen represented only hemiacetal V: the epimeric mixture displayed $[\alpha]_D^{22}$ +56.4° (*c*, 1.17); ν_{max} 3 300, 1 115, 1 082, 1 042, and 1 030 cm^{-1}; p.m.r. (deuteriochloroform solution) response at 0.7, 0.95, 1–2 (broad), 3.1, 3.2, 4.75 (broad), and 5.2 δ.

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86; active H, 0.36. Found: C, 77.92, 77.81; H, 11.01, 10.89; active H, 0.40.

Further elution of the column with 1:1 chloroform–methanol gave 0.10 g, m.p. 189–190°, of diol IV.[11]

4-Oxa-5α-androstane (IIIb)

Reduction of lactone III*a* (1.0 g) to tetrahydropyran III*b* was accomplished with the sodium borohydride (0.3 g) – boron trifluoride etherate (15 g) reagent in diglyme (30 ml) as previously described (1). A solution of the crude product in petroleum ether was passed through a column of activated alumina. After removal of the solvent *in vacuo* the residue was recrystallized from methanol–water; yield 0.45 g. Four recrystallizations from the same solvent yielded a pure specimen as colorless needles; m.p. 56–57°; $[\alpha]_D^{20}$ +34.7° (*c*, 1.86); ν_{max} 1 085, 1 105 cm^{-1}.

Anal. Calcd. for $C_{18}H_{30}O$: C, 82.38; H, 11.52. Found: C, 82.35, 82.34; H, 11.77, 11.46.

[10] *Methanol as solvent.*

[11] *By mixture melting point determination and infrared spectral comparison, the substance was found to be identical with an authentic sample.*

3-Oxo-4-oxa-5α-pregnane 20-Ethylenethioketal (VIb)

A solution of 3,20-dioxo-4-oxa-5α-pregnane (1.0 g, VI*a* (2*b*)) in boron trifluoride etherate (11 g) – ethanedithiol (3.0 g) was prepared at room temperature. Within a few minutes, the thioketal crystallized from solution as colorless needles. After a total of 1.5 h the mixture was cooled and diluted with methanol; the thioketal (VI*b*) was collected, washed with methanol, and recrystallized from acetone to yield 0.81 g melting at 237–239°; $[\alpha]_D^{23}$ +68.8° (*c*, 1.25); ν_{max} 1 740 cm^{-1}.

Anal. Calcd. for $C_{22}H_{34}O_2S_2$: C, 66.96; H, 8.69; S, 16.26. Found: C, 66.70; H, 8.58; S, 16.54.

3ξ-Hydroxy-4-oxa-5α-pregnane 20-Ethylenethioketal (VIIa)

Conversion of lactone VI*b* (0.45 g) in tetrahydrofuran (20 ml) into the epimeric mixture of hemiacetals corresponding to structure VII*a* was accomplished with diborane generated from sodium borohydride (0.5 g) and boron trifluoride etherate (2.9 g) in diglyme (18 ml) as described for hemiacetal V. The epimeric hemiacetals were recrystallized from chloroform – petroleum ether as colorless needles (0.32 g) melting at 187–188°; $[\alpha]_D^{21}$ 0.0°; ν_{max} 3 350 cm^{-1}.

Anal. Calcd. for $C_{22}H_{36}O_2S_2$: C, 66.60; H, 9.15; S, 16.17. Found: C, 66.28, 66.07; H, 8.89, 9.07; S, 16.36, 16.55.

3-Oxo-4-oxa-5α-pregnane (VIc)

Raney nickel (30 ml, W-4 (7)) was added to a solution of thioketal VI*b* (2.0 g) in ethanol (150 ml), and the mixture was heated at reflux for 4 h. After the solution was filtered, the nickel residue was washed with warm ethanol and the combined filtrate was concentrated to a colorless solid. Recrystallization from ethanol – petroleum ether gave 0.49 g of needles melting at 186–187°. Placing the nickel residues in a Soxlet apparatus and extracting with ethanol gave 0.16 g, and final dissolution of the nickel by-products in hydrochloric acid gave another 0.22 g of crude product. An analytical sample that was recrystallized from methanol – petroleum ether melted at 188–190°; $[\alpha]_D^{23}$ +107.4° (*c*, 0.619); ν_{max} 1 740 cm^{-1}.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59. Found: C, 78.38; H, 10.33.

3ξ-Hydroxy-4-oxa-5α-pregnane (VIIb)

Lactone VI*c* (0.3 g) in tetrahydrofuran (20 ml) was reduced to a mixture of epimeric hemiacetals (VII*b*, 0.2 g) by (see V) diborane prepared from sodium borohydride (0.4 g) and boron trifluoride etherate (2.2 g). Recrystallization from chloroform – petroleum ether yielded colorless crystals melting at 161–163°; $[\alpha]_D^{23}$ 69.3° (*c*, 1.0); ν_{max} 3 350 cm^{-1}.

Anal. Calcd. for $C_{20}H_{34}O_2$ (306): C, 78.38; H, 11.18; O, 10.44; active H, 0.33. Found: C, 78.33, 77.93; H, 11.19, 11.11; O, 10.79; active H, 0.25; mol. wt. (Rast) 271.

3ξ-Hydroxy-4-oxa-5α-cholestane (IXa)

In a typical experiment, 0.38 *M* borane in tetrahydrofuran (30 ml (16)) was added at room temperature to 3-oxo-4-oxa-5α-cholestane (5.1 g, VIII). Before dilution with water (10 ml) and extraction with diethyl ether (60 ml), the solution was allowed to stand for 0.5 h. The combined ethereal extracts were washed with water and dried (potassium carbonate). Removal of solvent *in vacuo* gave a solid residue (5.0 g). A solution of the crude product in tetrahydrofuran–benzene (1:3) was chromatographed on silica gel (250 g). Elution with the same solvent mixture led to 4.2 g of hemiacetal IX*a*, m.p. 183–190°. Recrystallization from either methylene chloride – acetone or tetrahydrofuran–ligroin (b.p. 90–120°) gave a specimen (IX*a*) melting at 185–190°. In both cases, thin-layer chromatograms (7:3 benzene – diethyl ether being used as the mobile phase) and mixture thin-layer chromatograms with an authentic sample (2*b*) indicated the presence of only hemiacetal IX*a* (see Fig. 1). Melting points of 188–190° (4*c*) and 197–199° (2*b*), representing different proportions of the epimeric hemiacetals, have been reported.

When the preceding experiment was repeated with 0.5 g of lactone VIII (and with appropriately adjusted amounts of the other reagents) for a total reaction time of 4 min, essentially the same result was obtained. A thin-layer chromatogram of the crude product suggested the presence of approximately 80% hemiacetal IX*a* accompanied by 3,5β-dihydroxy-3,5-seco-A-nor-5α-cholestane (2*b*). However, conducting the same reaction with one-half the previous quantity of diborane and a 30 min reaction period yielded a mixture (as evidenced by a thin-layer chromatogram) composed of approximately equal amounts of lactone VIII, hemiacetal IX*a*, and the diol resulting from complete reduction.

3α-Methoxy- and 3β-Methoxy-4-oxa-5α-cholestane (IXb and IXc)

A solution composed of the epimeric hemiacetals (0.40 g, IX*a*) prepared above, tetrahydrofuran (7 ml), methanol (15 ml), and 1 drop of concentrated hydrochloric acid was prepared by warming the mixture for approximately 3 min. Next, the solution was cooled and concentrated (*in vacuo*) to a crystalline residue. Six 0.06 g portions of the crude product were applied to each of six preparative silica gel G (1 mm layer) thin-layer chromatography plates. Each plate was developed 3 times with 9:1 hexane – diethyl ether, and the bands were identified by holding the plate in iodine vapor for a few seconds. Two very close bands were observed at approximately the middle of the plate, and each was carefully collected. Elution of the less-polar component with diethyl ether gave 0.19 g of acetal IX*b*, which was rechromatographed on four preparative thin-layer plates. By this means, a 0.16 g sample of 3α-methoxy-4-oxa-5α-cholestane (IX*b*) melting at 98–101.5° was obtained. Recrystallization from acetone raised the melting point to 101–102.5° (melting points of 98–99.5° and 106–107° have been reported (2*b*, 4*c*)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The more polar acetal was eluted from the silica gel in the same manner, and rechromatographed (twice) on two preparative silica gel thin-layer plates to yield 0.06 g of 3β-methoxy-4-oxa-5α-cholestane (IX*c*) melting at 77–80°. Two recrystallizations from acetone and one from methanol–acetone raised the melting point to 79–80° (ref. 11 reports m.p. 78°).

The configuration assigned to each hemiacetal was supported by a p.m.r. study (see Fig. 2).

ACKNOWLEDGMENTS

This investigation was supported in part by Public Health Service research grants Nos. CA-04074-04 to CA-04074-07 and CA-08705-01 from the National Cancer Institute. We are also grateful for financial support provided to W. J. E. (1960–1963) in the form of a NDEA Predoctorate Fellowship, and to Dr. George Slump, The Upjohn Co., for determining the p.m.r. response of hemiacetal V.

ANTINEOPLASTIC AGENTS

XVII. N-(2-BROMOETHYL)-N-(2-CHLOROETHYL)AMINES[1,2]

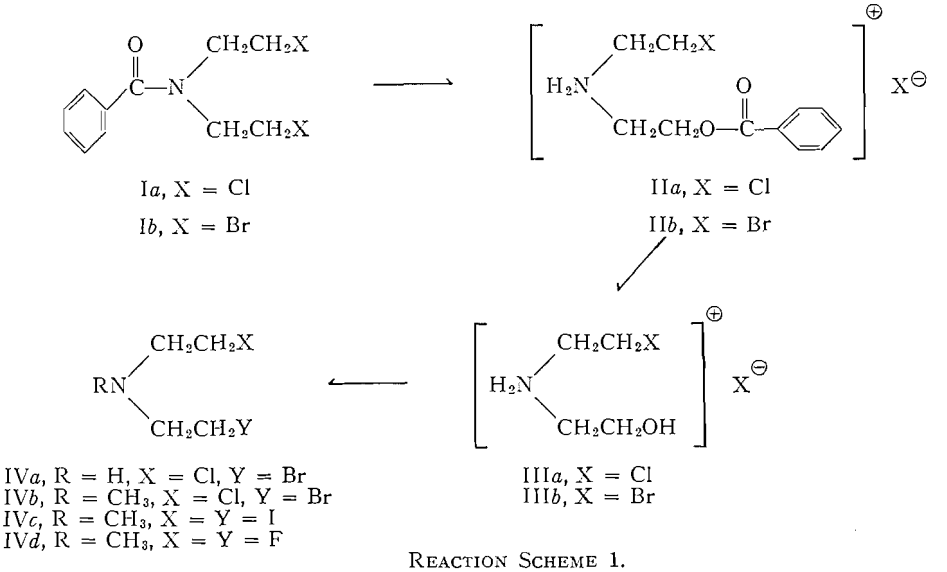
ABSTRACT

A convenient synthesis (I*a* → IV*a*) starting with N-bis(2-chloroethyl)amine has been devised for obtaining N-(2-bromoethyl)-N-(2-chloroethyl)amine. Several N-alkyl (IV*b* and VIII) and N-benzyl (VII) derivatives of the unsymmetrically halogenated amine (IV*a*) were prepared for cancer chemotherapeutic evaluation.

The majority of characterized N-bis(2-haloethyl)amines are those bearing symmetrically substituted chlorine atoms (1). With the exception of derivatives of N-(2-chloroethyl)-N-(2-fluoroethyl)amine (see e.g. ref. 2), only a few examples of unsymmetrically halogenated nitrogen mustards have been described. Of the five remaining analogous possibilities, only derivatives of N-(2-chloroethyl)-N-(2-iodoethyl)amine appear to have been reported (3). For example, Ross has isolated N-(2′-chloroethyl)-N-(2′-iodoethyl)-4-methoxybenzylamine among products obtained by treating the corresponding dichloro derivative with sodium iodide in aqueous acetone (3*a*). Continued interest in utilizing (for the design of nitrogen mustards with more desirable antineoplastic properties) differences in chemical reactivity based on variance of halogen substituents in N-bis(2-haloethyl)amines led us to evaluate N-(2-bromoethyl)-N-(2-chloroethyl)amines. Interesting biological properties discovered recently in the case of several bromine-containing amines (5), combined with the results of our prior study of N-bis(2-bromoethyl)amines (6), suggested that amine IV*a* and several selected derivatives should receive biological evaluation.



Although a number of synthetic methods were initially considered, the general route illustrated in Reaction Scheme 1 appeared to be the most promising from a practical standpoint, and emphasis was placed on this approach. Also, a useful procedure for obtaining amine III would provide, in principle, a method for obtaining the remaining unknown unsymmetrically halogenated nitrogen mustards. A sequence based on N-bis(2-chloroethyl)amine was first investigated. Preparation of amide I*a* and subsequent rearrangement in ethanol to ester II*a* was effected by a routine method previously developed in our laboratory (7). Ester II*a* was subjected to acid hydrolysis and 2-(2′-chloroethylamino)ethyl alcohol hydrochloride (III*a*) was isolated in essentially quantitative yield. Of several procedures explored for the bromination of alcohol III*a*, one based on phosphorus tribromide (providing 78% conversion into amine IV*a* hydrobromide) was found to be most satisfactory whereas another employing thionyl bromide (75% conversion of amine IV*a* hydrobromide) was considered to be less useful. An alternate reaction sequence starting with N-bis(2-bromoethyl)amine was also studied. Here amide I*b* was prepared and converted into ester II*b* as described earlier (6), and the ester was hydrolyzed with hydrobromic acid to yield alcohol III*b*. Although chlorination of alcohol III*b* with thionyl chloride readily gave amine IV*a* hydrochloride in good yield (98%), the overall method

REACTION SCHEME 1.

was less suitable, as N-bis(2-chloroethyl)amine is a more readily available starting material. To compare the antineoplastic activity of N-methylamine IV*b* with that of N-methyl-N-bis(2-chloroethyl)amine, nitrogen mustard IV*a* hydrobromide was methylated by a formaldehyde – formic acid technique (8). Methylation of N-bis(2-fluoroethyl)-amine and N-bis(2-iodoethyl)amine was performed for the same reason.

REACTION SCHEME 2.

For biological studies four derivatives (VII*a*–VII*c*, VIII) of N-(2-bromoethyl)-N-(2-chloroethyl)amine were selected for preparation. Two of these substances, amines VII*b* and VII*c*, were chosen because of promising antitumor activity evidenced by the corresponding dichloro derivatives (7*a*). Synthesis of benzylamines VII*a*–VII*c* and aliphatic amine VIII proceeded as shown in Reaction Scheme 2.[4] The acyl bromide was

VIII

[4]*Previously (7a) a novel halogen exchange reaction provided the key step in a route believed to yield amine VIIb hydrochloride. However, the synthesis of amine VIIa described in the present contribution provides a more uniformly reliable synthetic approach to substances of this type.*

For personal use only.

prepared with oxalyl bromide[5] or phosphorus tribromide. Reaction between the acyl bromide and 2 equivalents of amine IV*a* (in benzene solution) yielded the corresponding amide (VI), which was easily reduced with lithium aluminium hydride. In each case, the amine derivative was characterized as the hydrobromide salt. Structural assignments were confirmed by the results of infrared and proton magnetic resonance (p.m.r.) (e.g. see ref. 4*b*) spectral studies. Presently available results of biological studies[6] allow comparison of the effects of amine VII*a* and its dichloro (7*a*) and dibromo (6) analogues against Walker 256 (subcutaneous) in randomly bred albino rats. The N-(2-bromoethyl)-N-(2-chloroethyl)-amine VII*c* hydrobromide at a dose of 12.5 mg/kg caused 92% inhibition of tumor growth whereas the N-bis(2-chloroethyl)amine (at 4.8 mg/kg) and N-bis(2-bromoethyl)amine (at 12.5 mg/kg) counterparts showed, respectively, complete and 95% inhibition. The dose (in saline solution given intraperitoneally) regimen was begun on the first day of tumor transport and continued for 5 days. Tumor growth was measured on the 10th day.

EXPERIMENTAL

The p.m.r. spectra were obtained in deuterium oxide solution and are reported relative to the peak response of HDO as internal reference. The p.m.r. equipment and general experimental techinques used below are described in introductions to the Experimental sections of refs. 4*b* and 6. All analytical samples were colorless, and infrared spectra were recorded in potassium bromide.

2-(2′-Chloroethylamino)ethyl Benzoate Hydrochloride (IIa)

First, preparation of N-bis(2-chloroethyl)benzamide (I*a*) was achieved by condensing (cf. ref. 7*a*) N-bis(2-chloroethyl)amine (from 100 g of the hydrochloride derivative) with benzoyl chloride (40 g) in benzene (250 ml) solution. After N-bis(2-chloroethyl)amine hydrochloride was collected, the filtrate was concentrated *in vacuo* to a pale yellow oil. A solution of the crude amide in 95% ethanol (300 ml) was heated at reflux for 2 h. Evaporation (*in vacuo*) of solvent yielded ester II*a* as pale yellow crystals weighing 58.6 g (79%). Recrystallization from acetone gave colorless needles melting at 134–135° (ref. 9 reports m.p. 135°).

N-(2-Bromoethyl)-N-(2-chloroethyl)amine (IVa) Hydrobromide

Method A

A solution of 2-(2′-chloroethylamino)ethyl benzoate hydrochloride (II*a*, 50.0 g) in 10% hydrochloric acid (200 ml) was heated at reflux for 3 h. After cooling, the solution was filtered to remove benzoic acid (22.6 g, corresponding to a 98% recovery) and washed with chloroform (2 × 100 ml). The hydrochloric acid solution was concen trated *in vacuo* to a clear viscous oil, which was further dried azeotropically with benzene. The oily sample of *2-(2′-chloroethylamino)ethyl alcohol hydrochloride (IIIa)* was obtained in a quantitative yield and resisted a number of attempts at crystallization. However, the viscous oil proved to be satisfactory for conversion into amine IV*a*.

A sample (18 g) of hydrochloride III*a* was slowly added with rapid stirring to warm (steam bath) phosphorus tribromide (43 ml). Heating at steam bath temperature and stirring were continued for an additional hour while a deep straw colored solid separated. The mixture was washed with benzene (3 × 100 ml); the residual solid was dissolved in water (150 ml), neutralized (with cooling) with 6 *N* sodium hydroxide (60 ml), and extracted with benzene (500 ml). The dry benzene solution was treated with anhydrous hydrogen bromide and diluted with diethyl ether to yield 23.4 g (78%) of colorless crystals melting at 190–194°. Two recrystallizations from methanol – diethyl ether gave needles[7] melting at 198–200°; ν_{max} 2 900, 2 750, 2 400, 1 580, 1 450, 1 430, 1 395, and 1 280 cm^{-1}.

Anal. Calcd. for $C_4H_{10}Br_2ClN$: C, 17.96; H, 3.77; Br, 59.77; Cl, 13.26; N, 5.27. Found: C, 17.85; H, 3.77; Br, 59.96; Cl, 13.14; N, 5.11.

The procedure described directly above for obtaining amine IV*a* hydrobromide gave consistently good results and was used routinely.

Method B

A sample (25 g) of hydrochloride III*a* was suspended in dry benzene (100 ml) and treated with thionyl bromide (63.0 g, freshly prepared as described in ref. 10 during a 45 h reaction period) in benzene (50 ml). The mixture was stirred at reflux for 1 h and at room temperature for an additional hour. During the reaction

[5]*A cursory examination of the reaction between benzoyl chloride and amine IVa indicated that concomitant halogen exchange as previously observed in the case of N-bis(2-bromoethyl)amine (7a) might generally preclude use of the acyl chloride approach.*

[6]*We are indebted to the Cancer Chemotherapy National Service Center, National Institutes of Health, U.S. Public Health Service, for this valuable information.*

[7]*Consult ref. 4b for the p.m.r. spectrum of this substance.*

For personal use only.

period, a color change from golden yellow to reddish brown was noted, and a more dense and darker oily phase appeared. The upper layer was decanted and the residue was diluted with methanol. The methanol solution in turn was diluted with diethyl ether. Cooling the solution led to amine IV*a* hydrobromide as colorless needles weighing 30.9 g (75%), m.p. 197–199°.

N-(2-Bromoethyl)-N-(2-chloroethyl)amine (IVa) Hydrochloride

Method A

A 1.0 g specimen of amine IV*a* hydrobromide (prepared by method B in the preceding experiment) was neutralized with 3 *N* sodium hydroxide. The base was extracted with benzene and the dry organic phase was treated with ethereal hydrogen chloride. The resulting hydrochloride derivative was recrystallized (3 times) from methanol – diethyl ether to yield an analytical sample melting at 195–197°.

Anal. Calcd. for $C_4H_{10}BrCl_2N$: C, 21.55; H, 4.52; Br, 35.85; Cl, 31.80; N, 6.28. Found: C, 21.48; H, 4.34; Br, 36.21; Cl, 32.01; N, 6.01.

Method B

A mixture of 2-(2′-bromoethylamino)ethyl benzoate (II*b*, 23 g, prepared as described in ref. 6) and 10% hydrobromic acid (150 ml) was heated at reflux for 3 h. After cooling, filtration, and washing with chloroform, the hydrobromic acid solution was concentrated *in vacuo* to a pale yellow oil (15.8 g, nearly quantitative conversion into amine III*b*). The oil was suspended in chloroform (130 ml) and treated (dropwise) with thionyl chloride (25 ml) in chloroform (30 ml). The mixture was heated at reflux for 0.5 h. Cooling the solution led to separation of amine IV*a* hydrochloride as yellow crystals, yield 16.9 g (98%), m.p. 185–189°. Three recrystallizations from ethanol – diethyl ether gave pure colorless needles melting at 195–197°. An infrared spectral comparison of the product and that obtained by method A confirmed the mutual identity of both hydrochloride salts.

Anal. Found: C, 21.26; H, 4.40; Br, 36.70; Cl, 31.80; N, 6.30.

N-Methyl-N-(2-bromoethyl)-N-(2-chloroethyl)amine (IVb) Hydrobromide

A mixture of amine IV*a* hydrobromide (3.0 g), 37% formalin (2.5 ml), and 98% formic acid (2 ml) was heated on a steam bath for 2 h. The solution was concentrated (*in vacuo*) to dryness and the residue dissolved in water (20 ml). The solution was neutralized with 6 *N* sodium hydroxide (20 ml) and the aqueous mixture extracted with benzene. Treating the benzene solution with ethereal hydrogen bromide yielded 2.8 g (87%) of amine IV*b* hydrobromide as colorless crystals, m.p. 114–115°. Two recrystallizations from methanol – diethyl ether yielded an analytical sample as needles melting at 122–125°; ν_{max} 2 900, 2 650, 2 575, 2 500, 2 350, 1 470, 1 375, 1 320, 1 285, 1 290, 950, and 760 (broad) cm^{-1}; p.m.r. responses at 3.15 (three methyl protons) and 3.7–4.3 (complex, eight methylene protons, principal signal at 3.91) δ.

Anal. Calcd. for $C_5H_{12}Br_2ClN$: C, 21.34; H, 4.30; Br, 56.79; Cl, 12.60; N, 4.98. Found: C, 21.36; H, 4.60; Br, 56.73; Cl, 12.65; N, 4.85.

N-Methyl-N-bis(2-iodoethyl)amine (IVc) Hydroiodide

Amine IV*c* hydroiodide was prepared from N-bis(2-iodoethyl)amine hydroiodide (4.5 g (6)), 37% formalin (3 ml), and 98% formic acid (2.0 g) as described in the preceding experiment (see IV*b*). The product weighed 4.1 g (88%) and melted at 165–167°. Three recrystallizations from methanol gave an analytical specimen as needles; m.p. 173–175° (11); ν_{max} 2 900, 2 700, 1 460, 1 450, 1 425, 1 365, 1 210, 1 190, 1 060, 1 010, 965, and 930 cm^{-1}.

Anal. Calcd. for $C_5H_{12}I_3N$: C, 12.86; H, 2.59; I, 81.56; N, 3.00. Found: C, 12.74; H, 2.74; I, 81.66; N, 3.13.

N-Methyl-N-bis(2-fluoroethyl)amine (IVd) Hydrobromide

The procedure used for converting N-bis(2-fluoroethyl)amine hydrobromide (2.3 g (4*a*)) into amine IV*d* hydrobromide (m.p. 96–98°, 1.4 g, 57% yield) with 37% formalin (2 ml) and 98% formic acid (1.0 g) was that illustrated in the case of amine IV*b* hydrobromide. Recrystallization (twice) from methanol – diethyl ether gave an analytical sample as needles melting at 102–104°; ν_{max} 2 900, 2 700, 2 650 (doublet with shoulder at 2 500), 1 460, 1 450, 1 435, 1 420, 1 240, 1 195, 1 170, 1 110, 1 090, 1 070, 1 045, 1 035, 1 010, 970, 900, 880, and 860 cm^{-1}.

Anal. Calcd. for $C_4H_{10}BrF_2N$: C, 29.43; H, 5.93; Br, 39.16; N, 6.86. Found: C, 29.64; H, 6.00; Br, 39.15; N, 6.68.

Childs (12) has summarized a route to amine IV*d*, and more recently Nemets and Epshtein (13) reported conversion of bromofluoroethane (with methylamine) into amine IV*d* hydrochloride.

N-(2-Bromoethyl)-N-(2-chloroethyl)benzylamine (VIIa) Hydrobromide

In a typical experiment, amine IV*a* hydrobromide (10.0 g) was dissolved in water (50 ml) – ice (20 g) and treated with 6 *N* sodium hydroxide (20 ml). The mixture was extracted with benzene, and the dry (magnesium sulfate) extract was treated (dropwise during 10 min) with benzoyl bromide (3.5 g, prepared from benzoic acid and phosphorus tribromide). Before the solution was cooled, stirring was continued at room temperature for 2 h. The solution was filtered to remove amine IV*a* hydrobromide (4.5 g, 89% recovery) and the filtrate was slowly added with stirring during 0.5 h to a mixture of lithium aluminium hydride (0.76 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and dry diethyl ether (100 ml). After a total reaction period at room temperature of 1 h, water (approximately 4 ml) was cautiously added to the mixture. The general procedure employed at this point has been described in a prior contribution (6). Next, the solution was filtered, dried, and treated with anhydrous hydrogen bromide. Further dilution with diethyl ether led to the separation of amine VII*a* hydrobromide as colorless crystals, yield 4.3 g (63%), m.p. 165–170°. Two recrystallizations from methanol – diethyl ether gave a pure sample as needles; m.p. 176–179°; ν_{max} 2 900, 2 650, 2 550, 2 350, 1 490, 1 450, 1 430, 1 375, 1 245, 1 210, 1 010, 960, 930, 765, 750, and 700 cm^{-1}; p.m.r. responses at 3.8–4.2 (complex, eight methylene protons, principal signal at 3.92), 4.70 (two benzyl protons), and 7.72 (five aromatic protons) δ.

Anal. Calcd. for $C_{11}H_{16}Br_2ClN$: C, 36.95; H, 4.51; Br, 44.70; Cl, 9.92; N, 3.92. Found: C, 36.85; H, 4.46; Br, 44.97; Cl, 9.76; N, 3.92.

N-(2′-Bromoethyl)-N-(2′-chloroethyl)-3,4-methylenedioxybenzylamine (VIIb) Hydrobromide

The acid bromide prepared from piperonylic acid (2.5 g) and oxalyl bromide (6 g) was allowed to react with the base corresponding to amine IV*a* hydrobromide (10.7 g) as described in the preceding experiment (see VII*a*). The crude amide was reduced by the lithium aluminium hydride (0.6 g) procedure (compare VII*a*), and the resulting amine hydrobromide weighed 5.3 g (88%), m.p. 159–163°. After two recrystallizations from methanol – diethyl ether the analytical sample (needles) melted at 164–165°; ν_{max} 2 900, 2 625, 2 500, 2 350, 1 500, 1 490, 1 445, 1 385, 1 260, 1 245, 1 105, 1 045, 950, 930, 880, 820, 810, 780, and 765 cm^{-1}; p.m.r. responses at 3.4–4.2 (complex, eight methylene protons, principal signal at 3.78), 4.50 (two benzyl protons), 6.08 (two methylenedioxy protons), and 7.08 (three aromatic protons) δ.

Anal. Calcd. for $C_{12}H_{16}Br_2ClNO_2$: C, 35.89; H, 4.02; Br, 39.80; Cl, 8.83; N, 3.49. Found: C, 35.76; H, 4.08; Br, 40.04; Cl, 8.75; N, 3.41.

N-(2′-Bromoethyl)-N-(2′-chloroethyl)-3,5-dimethoxybenzylamine (VIIc) Hydrobromide

A sample of 3,5-dimethoxybenzoyl bromide (3.7 g, prepared as noted in ref. 6) was allowed to react with the amine corresponding to 10.7 g of nitrogen mustard IV*a* hydrobromide. The resulting amide was reduced with lithium aluminium hydride (0.57 g). The hydrobromide derivative of the product weighed 4.8 g (80%) and melted at 160–163°. The general experimental technique and method used for purifying the product was that illustrated in the case of amine VII*a*. The analytical specimen was obtained as needles; m.p. 165–167°; ν_{max} 2 850, 2 800, 2 600, 2 575, 1 595, 1 480, 1 460, 1 430, 1 360, 1 305, 1 215, 1 170, 1 160, 1 070, 1 060, and 845 cm^{-1}; p.m.r. responses at 3.4–4.2 (complex, eight methylene protons and six methoxy protons, principal signals at 3.80–3.90), 4.50 (two benzyl protons), and 6.80 (three aromatic protons) δ.

Anal. Calcd. for $C_{13}H_{20}Br_2ClNO_2$: C, 37.39; H, 4.83; Br, 38.28; Cl, 8.49; N, 3.35. Found: C, 37.41; H, 5.10; Br, 38.60; Cl, 8.35; N, 3.47.

N-(2′-Bromoethyl)-N-(2′-chloroethyl)-4-methoxyphenoxyethylamine (VIII) Hydrobromide

Oxalyl bromide (9 g) containing 4-methoxyphenoxyacetic acid (3.6 g) was heated at reflux for 2 h. After removal (*in vacuo*) of excess oxalyl bromide the acyl bromide was obtained as a light brown oil. Without further purification the acyl bromide was treated with the free amine corresponding to 11.8 g of amine IV*a* hydrobromide. Subsequent reduction and purification of the product was accomplished as described for the isolation of amine VII*a* hydrobromide. The hydrobromide derivative of amine VIII was obtained in 63% yield (5.3 g). A pure specimen melted at 143–145°; ν_{max} 2 900, 2 650, 2 550, 2 350, 1 510, 1 485, 1 465, 1 440, 1 230, 1 020, 830, and 735 cm^{-1}; p.m.r. responses at 3.7–4.2 (complex, ten methylene and three methoxy protons, principal signals at 3.75 and 3.82), 4.22–4.50 (two methylene protons), and 6.90 (four aromatic protons) δ.

THE REACTION OF PHENYLMETHANESULFONYL CHLORIDE WITH TERTIARY AMINES: FORMATION OF GEOMETRICAL ISOMERS ABOUT A CARBON–SULFUR DOUBLE BOND[1]

J. F. KING and T. DURST
Department of Chemistry, University of Western Ontario, London, Ontario
Received November 23, 1965

ABSTRACT

In methylene chloride or ether solution, phenylmethanesulfonyl chloride reacts with triethylamine to give a mixture consisting primarily of *trans*-stilbene and *cis*-diphenylethylene sulfone. In cyclohexane the same reagents yield principally a material which is shown to be a roughly 2:1 mixture of *cis*- and *trans*-oxythiobenzoyl chlorides (I and II, respectively). The latter compounds represent the first examples of geometrical isomerism about a double bond in which one of the atoms of the double bond is outside the first short period of the Periodic Table.

In 1911 Wedekind and Schenk (1) reported that the action of tertiary amines on phenylmethanesulfonyl chloride yielded *trans*-stilbene, and suggested that a species $RR'C{=}SO_2$, for which they coined the name "sulfene", was an intermediate in the reaction. The next 50 years yielded little that contributed directly to anything that could be regarded as a satisfactory description of the mechanism of the reaction in modern terms, although some, rather sporadic, reports on related aspects of the chemistry of sulfenes have appeared (for recent reviews of the latter see refs. 2–4). A few years ago we began a reexamination of the Wedekind reaction, starting with a simple repetition of the early work. We have confirmed Wedekind's report as far as it went, but in addition have encountered other aspects of the reaction which we have found to be of considerable interest. The most notable of these is the isolation of compounds which we will show in this account are the first examples of geometrical isomerism about a carbon–sulfur double bond, indeed about any double bond in which one of the atoms is of a higher atomic number than nitrogen.

In this paper the various products of the reaction of phenylmethanesulfonyl chloride with triethylamine are discussed and their structures (where previously unknown) proved, primarily with the aid of analytical and physical measurements. In a forthcoming paper corroborative evidence derived from *chemical* studies will be presented for the structures of the *cis*- and *trans*-oxythiobenzoyl chlorides. Two preliminary communications describing some of the work in these papers have already appeared (5, 6).

RESULTS AND DISCUSSION

The Reaction in Methylene Chloride and Ether

When the reaction of phenylmethanesulfonyl chloride and triethylamine was carried out in either ether or methylene chloride solution, sulfur dioxide was produced together with *trans*-stilbene and a material which was found to be *cis*-diphenylethylene sulfone, along with a small amount of the mixed *cis*- and *trans*-oxythiobenzoyl chlorides. (The isolation and proof of structure of the latter materials are discussed in a later section, those of the ethylene sulfone in the next paragraph.) The yields varied somewhat with the amount of care taken, but when the reactions were carried out at $-60°$ with appropriate precautions to exclude moisture, the yield of the isolated, crystalline *trans*-stilbene was 48%, that of the sulfone 28%.

cis-Diphenylethylene sulfone was obtained directly by crystallization from the crude reaction mixture as a white solid melting with decomposition at 83–85°. Its structure is implied by (*i*) analysis, which indicates the formula $C_{14}H_{12}SO_2$, (*ii*) its infrared spectrum, which shows strong bands at 1 333 and 1 140 cm^{-1} characteristic of the sulfonyl group, and (*iii*) the nuclear magnetic resonance (n.m.r.) spectrum, which shows only two peaks, a singlet at 4.89 p.p.m. and a slightly broadened band at 7.3 p.p.m. (relative areas 1:5). Heating the compound to its melting point, or refluxing in a low-boiling solvent such as carbon disulfide or methylene chloride, causes loss of sulfur dioxide with concomitant production of *cis*-stilbene. The infrared spectrum of the stilbene thus produced showed it to be almost entirely free of the *trans* isomer. The fact that this reaction is highly stereospecific and is induced under such mild conditions may be reasonably accounted for only on the basis of a cyclic, concerted reaction in which the stereochemical relationship of the substituents is unchanged; in other words, it is highly probable that the phenyl groups are also *cis* in the starting material. Confirmation of this view appeared shortly after these experiments were completed, in the form of a communication by Neureiter and Bordwell (7), who showed that ethylene sulfones lose sulfur dioxide with preservation of the orientation of the substituents.

The Reaction in Cyclohexane and Benzene Solutions

In remarkable contrast to what occurs in either methylene chloride or ether, the reaction of phenylmethanesulfonyl chloride and triethylamine in cyclohexane yields a product which contains only a small amount of *trans*-stilbene, and which consists primarily of triethylammonium phenylmethanesulfonate (as well as triethylammonium chloride) and a reddish-brown oily product. This latter material, which was dubbed "red oil", was found to be a mixture of the geometrical isomers *cis*- and *trans*-oxythiobenzoyl chloride (I and II, respectively). These compounds were most conveniently isolated by silica gel chroma-

I II III

IV V VI

tography of the cyclohexane-soluble portion of the reaction mixture. The *trans* isomer (II), which was eluted first, crystallized from cold pentane to give slightly pink needles melting at 5°. Further elution of the chromatographic column yielded the *cis* isomer (I) as yellowish plates, m.p. 38–39°, in about double the quantity of the *trans* compound (II). The *cis* isomer was also obtained by a short-path distillation of the crude cyclohexane-soluble product, followed by recrystallization. Both compounds can be kept without significant decomposition for a few weeks in a refrigerator at −5°, but at room temperature, especially in the light or in a humid atmosphere, they are much more rapidly decomposed.

For personal use only.

When the reaction of phenylmethanesulfonyl chloride and triethylamine was carried out in benzene solution, a mixture of all of the above products was obtained, viz. *trans*-stilbene, *cis*-diphenylethylene sulfone, *cis*- and *trans*-oxythiobenzoyl chloride, triethylammonium chloride, and triethylammonium phenylmethanesulfonate. These results correspond to the observations of Wedekind and Schenk (1), who, under similar conditions, isolated *trans*-stilbene and triethylammonium chloride, and described the residue as a "rötlich gefärbte Masse", clearly essentially the same material as our "red oil".

Preliminary experiments (8) indicate that phenylmethanesulfonyl bromide also yields, on reaction with triethylamine, a mixture containing the oxythiobenzoyl halides. When phenylmethanesulfonyl fluoride, however, was treated with triethylamine under similar conditions, the sulfonyl fluoride was recovered unchanged. More vigorous conditions gave reaction but no isolated product.

Proof of Structure of the Oxythiobenzoyl Chlorides

Because there is no adequately established precedent for structures I and II, it was felt that more than usual care ought to be exercised in assigning the structures of the compounds isolated from the "red oil". To this end both physical and chemical evidence was adduced, though this account deals primarily with the former. Table I summarizes a

number of physical data, and Figs. 1 and 2 show, respectively, the infrared and ultraviolet spectra of the compounds. Elemental analyses (see Experimental) taken together with the molecular weight (as determined by mass spectrometry and from the freezing point depression of cyclohexane solutions) establish the molecular formula as C_7H_5ClOS. The five hydrogen atoms in each compound are shown to be attached to an aromatic nucleus, from (*a*) the absorption around 7.5 to 8.5 p.p.m. (only) in the proton n.m.r. spectra (Table I), and (*b*) the observation of bands at 685 ± 3 and 755 ± 3 cm^{-1} in the infrared spectra. (The latter infrared band, which is not visible in the spectra of the CCl_4 solutions shown in Fig. 1, was obtained from solutions in CS_2.) This then leads to the partial structure III. Further confirmation of III is given by the hydrolytic reactions of these compounds (8, 9), which gave in each case a mixture of benzoic acid and dibenzoyl disulfide (Ph—CO—S—S—CO—Ph). It can readily be shown that the only full structures, in addition to I and II, which can be derived by completing III without involving electron-deficient species or placing a formal positive charge on either carbon or chlorine are formulae IV, V, and VI.

Examination of the properties of the two materials reveals a number of similarities which strongly suggest that the compounds are stereoisomers rather than merely structural isomers. The ultraviolet and ^{13}C n.m.r. spectra and the molecular refractivities are very similar. In the infrared spectrum of the lower melting isomer the strongest bands are at 1 120, 1 005, and 910 cm^{-1} (in addition to those at 758 and 683 cm^{-1}), and these have intense counterparts in the spectrum of the other isomer at 1 145, 1 025, and 920 cm^{-1}. If one of the isomers had either structure IV, V, or VI, then this would mean that two compounds with quite different functional groups would coincidentally show very similar physical properties. Structures I and II, on the other hand, account very well for the observed similarities.

There are, in addition, specific reasons for excluding structures IV, V, and VI, for each of these is incompatible with at least one physical property of the compounds. Structure IV would require absorption in the infrared spectrum appropriate to a carbonyl group. It is clear from Fig. 1 that there is no such band in either spectrum. On the other hand, structure V would be expected to absorb at longer wavelengths in the ultraviolet-visible region than is observed for either compound. For example, allylic thionbenzoates (e.g. Ph—CS—O—CH_2CH=CH_2) show a band at 420 mμ with an extinction coefficient of 97. Neither of the compounds under discussion shows any absorption maximum in the visible region of the spectrum; the extinction coefficient at 420 mμ is less than 4 for both materials. On the other hand, the spectrum of N-sulfinylaniline (PhN=SO), with bands at 231 mμ (ϵ 6 000) and 314 mμ (ϵ 10 000) (10), is strikingly similar to those of the "red oil" components (Fig. 2), in excellent agreement with the oxythiobenzoyl chloride structures, I and II. Finally, structure VI would be expected to display only the ultraviolet spectrum of a monosubstituted benzene ring superimposed on absorption caused by the individual sulfur and chlorine atoms. Such a structure does not adequately account for the maxima found around 325 mμ. The ^{13}C n.m.r. spectra also clearly rule out structure VI. In addition to the complex bands around 60–70 p.p.m. from carbon disulfide, both compounds show a singlet at 12 p.p.m. corresponding to one carbon atom. This signal is in the region characteristic of carbons constituting double bonds (particularly carbon–oxygen and carbon–sulfur double bonds), but is well below the range appropriate to singly bonded carbon atoms (11–13).

Having thus limited the possible structures of the two compounds to formulae I and II, we proceeded to decide which material corresponded to which structure. If one assumes that the C—Cl and S—O bonds are polarized so that the more electronegative elements Cl and O are partially negatively charged, the *cis* isomer (I) must have the higher dipole moment. On this basis, the *cis* structure (I) is assigned to the higher melting isomer (which also has the higher dipole moment (see Table I)); the lower melting isomer therefore has the *trans* structure (II).

The proposal of an oxythioacyl halide structure (such as I or II) is in itself not new, since it had been made in 1923 by Wedekind and co-workers (14) for the product (VIII)

VII VIII

of a very similar reaction of camphor-10-sulfonyl chloride (VII). What are new in the present study, however, are the isolation of both geometrical isomers and the presentation

of convincing evidence for the oxythioacyl halide structures. Wedekind's work, though admirable when judged with regard to the tools available at that time, gives little basis for excluding structures analogous to IV and V and none at all for the structure analogous to VI. As we have already mentioned in one of the preliminary communications (5), we have prepared Wedekind's "chlorsulfoxyd-campher" and have found its n.m.r. and infrared spectra to be in good agreement with his structure (VIII).

The Stoichiometry and Mechanism of the Reactions

Since the structures of the products have just been derived, it is appropriate to consider, briefly at least, the nature of the actual processes leading to these products. The overall transformation for the principal reaction in methylene chloride solution may be summarized by eq. [1].

[1] $$2PhCH_2SO_2Cl + 2Et_3N \rightarrow \left\{ \begin{array}{c} \begin{array}{cc} H & Ph \\ & C{=}C \\ Ph & H \end{array} \\ \text{or} \\ \begin{array}{ccc} H & SO_2 & H \\ & C{-}C & \\ Ph & & H \end{array} \end{array} \right\} + 2Et_3NH^+Cl^-$$

With the reaction in cyclohexane solution, certain factors make the picture a little more complicated. The major products are low-melting, highly soluble compounds which tend to decompose during isolation, thereby making quantitative recovery difficult. In addition, the reaction does not proceed entirely with formation of the oxythiobenzoyl chlorides, but also with production of a small amount of stilbene (presumably via eq. [1]) together with what appears to be a polymeric material, perhaps a "polysulfene", $(PhCHSO_2)_n$. The yields of the various products, however, are consistent with the major reaction being as shown in eq. [2] accompanied by a polymer-forming process and a limited amount of reaction via eq. [1].

[2] $$2PhCH_2SO_2Cl + 2Et_3N \rightarrow \underset{\displaystyle Cl}{\overset{\displaystyle |}{PhC{=}SO}} + Et_3NH^+Cl^- + Et_3NH^+PhCH_2SO_3^-$$

The above equations merely summarize the stoichiometry of the reactions and indicate neither how these products are actually formed nor how a change in solvent effects such a remarkable change in the course of the reaction. In a preliminary communication (5), we tentatively put forward a scheme in which the first step was the formation of phenylsulfene, as initially proposed by Wedekind. More recent work on the interaction of the same reagents in alcohols and amines (15–17) has demonstrated that sulfenes are intermediates in these reactions. The latter experiments, and others as well, have generally lent support to our tentative description,[2] though one modification seems necessary. In the original proposal we postulated the formation of the ethylene sulfone by the reaction of phenylsulfene with phenylcarbene, the latter being formed from another molecule

[2]*The mechanistic scheme in the communication contains an unfortunate mistake stemming from inadequate checking of the manuscript: the intermediate in the proposed conversion of α-chlorophenylmethanesulfinate anion (structure X in the scheme) into oxythiobenzoyl chloride should be* $\underset{\displaystyle Cl}{\overset{\displaystyle |}{PhCHSOZ}}$, *where* Z = Cl *or* SO_3CH_2Ph.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of phenylsulfene by loss of sulfur dioxide. However, it no longer seems likely that the formation of stilbene and the ethylene sulfone takes place via a carbene, since attempts both by us (8) and others (3, 18, 19) to trap such a species have been fruitless. We have carried out further studies designed to test aspects of our mechanistic proposal, but prefer to leave further discussion of the nature of these reactions to a forthcoming paper describing these experiments.

Geometrical Isomerism about Double Bonds with Sulfur Atoms

As was pointed out earlier, the isolation and characterization of the *cis*- and *trans*-oxythiobenzoyl halides represents the first demonstration of *cis–trans* isomerism about a double bond in which one of the atoms of the double bond is a second (or higher) period element. Previous examples of geometrical isomerism had been restricted to double bonds made up of first-period elements exclusively—notably carbon and nitrogen, though a case of geometrical isomerism involving boron has been suggested (20). To be sure, occasions in which a second-period element might show such geometrical isomerism are severely limited. If one confines the discussion to known functional groups, such isomerism would appear to be restricted to the carbon–sulfur double bond (as in the oxythioacyl compounds in the present study) and the analogous nitrogen–sulfur double bond (as in N-sulfinylamines, R—N=SO). The latter class of compounds has been known for 75 years, though no *cis–trans* isomers have been isolated or even been proved to exist. They have, however, been postulated to account for certain kinetic data (21). In addition, a study of the infrared spectra of some N-sulfinylamines (22) notes the possibility of *cis–trans* isomerism in these compounds, as does also a lecture (23) mentioning an investigation of the microwave spectrum of thionylimide (HN=SO). By analogy with the results of the present study it would seem probable that N-sulfinylamines should be capable of existing as *cis–trans* isomers, perhaps even with a sufficiently high energy barrier to their interconversion to enable their separation and characterization in the traditional manner.

The discovery of geometrical isomerism about a carbon–sulfur double bond is noteworthy both as a stereochemical curiosity and also, rather more significantly, because it provides evidence about the location of the atoms in a C=SO system. This fact, in turn, should be of value in testing any theoretical description of such bonds, or indeed of any double bonds between a first-row element and one from the second period of the Periodic Table.

EXPERIMENTAL

Infrared spectra were obtained on Beckman IR-5 or IR-7 spectrophotometers equipped with sodium chloride optics; if not otherwise specified, all values quoted for infrared frequencies were obtained on the IR-7 instrument. Ultraviolet spectra were determined on a Beckman DK-1 instrument with 1 cm quartz cells. Proton n.m.r. spectra were measured on Varian A-60 or DP-60 instruments with tetramethylsilane as internal standard. The ^{13}C n.m.r. spectra were obtained on the DP-60 instrument at 15.1 mc/s by the rapid-passage dispersion mode technique (11, 12). Refractive indices were measured with a thermostatically controlled Bausch and Lomb refractometer. Melting points were determined on a Kofler hot stage and are uncorrected. Density determinations were carried out with a Fisher–Davidson gravitometer.

Petroleum ether refers to the fraction of boiling range 35–60°. The silica gel used was British Drug Houses "suitable for chromatography" grade. Eastman Kodak "white label" grade phenylmethanesulfonyl chloride (α-toluenesulfonyl chloride) and triethylamine were used without further purification, except when otherwise specified.

Reaction of Phenylmethanesulfonyl Chloride and Triethylamine in Cyclohexane

Phenylmethanesulfonyl chloride (1.91 g, 10.0 mmoles) was dissolved in cyclohexane (150 ml) freshly distilled from calcium hydride. Addition of triethylamine (1.6 ml, 11.4 mmoles) in one portion gave an immediate white precipitate and a yellow color which slowly turned to red. The reaction was allowed to stand at room temperature for 3 h. The cyclohexane solution was decanted off and the solvent evaporated under reduced pressure. The yield of the reddish oil was 462 mg; its infrared spectrum showed it to be almost

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

For personal use only.

entirely a mixture of *cis*- and *trans*-oxythiobenzoyl chlorides. (The isolation of the *cis*- and *trans*-oxythiobenzoyl chlorides from the "red oil" is described below.) The cyclohexane-insoluble material was dissolved in water (100 ml) and extracted with ether. Evaporation of the ether left a yellow oil (189 mg) whose infrared spectrum showed that it consisted of the isomeric oxythiobenzoyl chlorides together with a small amount of what appeared to be dibenzoyl disulfide. The total material extracted by the organic solvents is therefore 651 mg, which (if pure) would correspond to 3.8 mmoles of the oxythiobenzoyl chlorides (or, on the basis of eq. [2], a 76% yield of the crude oxythiobenzoyl chloride mixture).

A 25 ml aliquot of the aqueous layer (one-quarter of the total) was made basic by addition of 10% KOH solution. The liberated triethylamine was extracted with ether and the solution added to a solution of picric acid in ether. The resultant precipitate of triethylammonium picrate was filtered off, dried, and weighed; yield 753 mg (2.3 mmoles), m.p. 167–169°.

Glacial acetic acid (1 ml) was added to a second portion (33 ml) of the original aqueous phase. Aliquots of 15, 10, and 8 ml gave, respectively, titers of 8.84, 5.94, and 4.80 ml with 0.1 *N* $AgNO_3$, corresponding in turn to a total chloride ion content in the original cyclohexane-insoluble portion of the reaction mixture of 5.8, 5.9, and 6.0 mmoles.

Finally, a third portion of the aqueous solution (40 ml) was made basic and extracted with ether. The aqueous layer was evaporated to dryness and the residue treated with phosphorus pentachloride (1 g) in the usual manner (17). The reaction mixture was poured into water and extracted with ether. Evaporation of the ether gave an oil (235 mg, 1.2 mmoles) which was recrystallized from chloroform – petroleum ether, m.p. 90–92°, mixed m.p. with an authentic sample of phenylmethanesulfonyl chloride 90–92°.

In a separate experiment, the original aqueous phase was acidified after the ether extraction. Subsequent continuous extraction with ether for several hours followed by evaporation of the ether yielded a gummy material equal in weight to approximately 10% of the original sulfonyl chloride. The material resisted all attempts at crystallization and appeared to be polymeric. The infrared spectrum showed only a few very broad bands.

Isolation of the cis- and trans-Oxythiobenzoyl Chlorides

Crude "red oil" (285 mg) was placed on a column of silica gel (11 g). Elution with petroleum ether gave *trans*-stilbene (10 mg), identified by comparison of its infrared spectrum with that of an authentic sample. Elution with 3:1 petroleum ether – benzene yielded *trans*-oxythiobenzoyl chloride (60 mg). The *trans*-oxythiobenzoyl chloride was further purified by recrystallization from pentane at dry ice – acetone temperatures to give slightly pink needles, m.p. 5°.

Anal. Calcd. for C_7H_5SOCl: C, 48.70; H, 2.92; S, 18.54; Cl, 20.55. Found: C, 48.88; H, 3.07; S, 18.85; Cl, 20.44.

Finally, on elution with benzene, *cis*-oxythiobenzoyl chloride (150 mg) was obtained. Three recrystallizations from ether – petroleum ether and one from pentane gave slightly yellowish plates, m.p. 38–39°.

Anal. Calcd. for C_7H_5SOCl: C, 48.70; H, 2.92; S, 18.54; Cl, 20.55. Found: C, 48.59; H, 3.02; S, 18.67; Cl, 20.81.

Other physical properties are given in Table I. The infrared and ultraviolet spectra of the isomers are reproduced in Figs. 1 and 2. The quantities of the high-melting (*cis*) and low-melting (*trans*) isomers obtained directly from the chromatogram correspond to, respectively, 0.06 and 0.14 mmole from 1.0 mmole of phenylmethanesulfonyl chloride.

The dipole moments were determined in benzene solution with a Dipolmeter DM 01 instrument. The values were calculated according to the method of Guggenheim (24) from data obtained from solutions at four different concentrations. To ensure that the low-melting (*trans*) isomer was chemically unchanged, the infrared spectrum was determined after the measurements were completed, and was found to be unaltered.

The cryoscopic molecular weight determinations were carried out in cyclohexane solution. The cyclohexane (Fisher spectranalyzed) was purified by stirring it overnight with concentrated H_2SO_4, then for 5 h with 10% H_2SO_4 and $KMnO_4$, followed by drying with Na_2SO_4 and distillation from CaH_2. With the low-melting (*trans*) isomer, 156.6 mg in 29.78 g of cyclohexane lowered the freezing point by 0.644°, corresponding to a molecular weight of 170 (calcd. mol. wt. 172.6). In a repeat run 128.5 mg in 30.30 g gave a depression of 0.509°; mol. wt. 167. With the high-melting (*cis*) isomer, 151.8 mg in 32.50 g of cyclohexane lowered the freezing point by 0.553°; mol. wt. 170. In a repeat determination 223.9 mg in 33.48 g gave a lowering of 0.752°; mol. wt. 178.

Reaction of Phenylmethanesulfonyl Chloride with 2,4,6-Trimethylpyridine in Cyclohexane

Phenylmethanesulfonyl chloride (450 mg) was dissolved in cyclohexane (50 ml) and added over a period of 15 min to a solution of 2,4,6-trimethylpyridine (collidine) in cyclohexane (10 ml). The ultraviolet spectrum of a sample removed immediately after the addition of the sulfonyl chloride showed no 325 mμ peak. The reaction was allowed to stand for 12 h at 50°; the 325 mμ band was then found to be present in the ultraviolet spectrum. Work-up of the reaction mixture yielded a product whose infrared spectrum was virtually identical with that of the crude "red oil".

Reaction of Phenylmethanesulfonyl Chloride with Triethylamine in Methylene Chloride

Phenylmethanesulfonyl chloride (1.65 g) was dissolved in methylene chloride (30 ml) and the solution cooled to −60°. Triethylamine (2 ml) was added slowly during 2 min. The reaction was worked up by

washing the solution with water, drying it, and evaporating the methylene chloride under reduced pressure without heating. The crude yield of solid material was 826 mg. Recrystallization from methylene chloride – pentane yielded *cis*-1,2-diphenylethylene sulfone (259 mg, 27%), m.p. 83–85° (with bubbling).

Anal. Calcd. for $C_{14}H_{12}O_2S$: C, 68.84; H, 4.95; S, 13.10. Found: C, 68.81; H, 5.24; S, 13.28.

Infrared absorption ($CHCl_3$, IR-5) at 1 333 and 1 140 cm^{-1}; n.m.r. absorption ($CDCl_3$) at 4.89 (singlet) and 7.2 p.p.m. (complex phenyl hydrogen absorption), relative areas 1:5. The mother liquor was chromatographed on silica gel. Elution with petroleum ether gave *trans*-stilbene (419 mg, 48%), m.p. 124–126°, mixed m.p. with an authentic sample of *trans*-stilbene 124–126°.

Conversion of cis-1,2-Diphenylethylene Sulfone into Stilbene(s)

cis-1,2-Diphenylethylene sulfone (21.6 mg) was heated in an oil bath at 90° for 15 min. Bubbling was observed as the sulfone melted. The yield of *cis*-stilbene was 16.1 mg (100%). It was identified by comparison of its infrared spectrum with that of an authentic sample, and by conversion into *dl*-stilbene dibromide (in 73% yield) by treatment with bromine in carbon tetrachloride; m.p. of the dibromide 110–113°, mixed m.p. with an authentic sample 110–113°. The sulfone could also be decomposed by refluxing in carbon disulfide or methylene chloride for 1 h. The product was mainly *cis*-stilbene. Chromatography of *cis*-diphenylethylene sulfone on silica gel yielded a mixture containing mostly *cis*-stilbene plus a little *trans*-stilbene. Decomposition by refluxing in methylene chloride and triethylamine, or by dissolving in aniline for 4 h, yielded almost pure *cis*-stilbene, as determined by comparison of its infrared spectrum with that of an authentic sample.

Reaction of Phenylmethanesulfonyl Chloride with Triethylamine in Ether

Phenylmethanesulfonyl chloride (1.20 g) was dissolved in anhydrous ether (35 ml). The solution was cooled to −60° and triethylamine (2.0 ml) was added over a period of about 2 min. On addition of triethylamine a white precipitate was obtained immediately. The solution was allowed to stand at −60° for 10 min and then allowed to warm up to room temperature. The reaction mixture was washed with water, the ether layer was dried, and the solvent was evaporated to yield a white solid (570 mg). Chromatography on grade III neutral alumina (17 g) yielded, on elution with 1:1 benzene – petroleum ether, *trans*-stilbene (349 mg, 62%); its infrared spectrum was identical with that of an authentic specimen. A similar yield of *trans*-stilbene was obtained when the reaction was carried out at room temperature.

Reaction of Phenylmethanesulfonyl Chloride with Triethylamine in Benzene

Triethylamine (500 mg) was added in one portion under a nitrogen atmosphere to a solution of phenylmethanesulfonyl chloride (950 mg) in dry benzene (20 ml). On addition of the triethylamine the solution turned reddish orange, but this color soon faded to yellow. The reaction mixture was allowed to stand at room temperature for 10 min; then it was poured into water and extracted with ether. The ether layer was dried and the solvent evaporated to yield a reddish oil (247 mg) whose infrared spectrum showed the presence of *trans*-stilbene and *cis*- and *trans*-oxythiobenzoyl chlorides. Chromatography on grade III neutral alumina yielded, on elution with petroleum ether, *trans*-stilbene (141 mg, 31%), m.p. 125–126°, mixed m.p. with an authentic sample 125–126°. The infrared spectrum of the sample was identical with that of an authentic specimen of *trans*-stilbene.

Reaction of Phenylmethanesulfonyl Fluoride with Triethylamine

Phenylmethanesulfonyl fluoride was dissolved in ether containing a threefold quantity (on a molar basis) of triethylamine. The reaction was allowed to stand for 2 months, during which time a small amount of white material precipitated. The reaction was worked up by pouring the mixture into water and extracting it with ether. The ether-soluble material was identified as phenylmethanesulfonyl fluoride by comparison of its infrared spectrum with that of the starting material. When phenylmethanesulfonyl fluoride was refluxed with excess triethylamine for 1 h, a product was formed which appeared, from thin-layer chromatography, to consist of at least five products, and was not studied further.

ACKNOWLEDGMENTS

This work was supported by the National Research Council of Canada via scholarships and grants-in-aid. We thank Dr. W. A. Ayer (University of Alberta, Edmonton) for the mass spectra; Dr. J. B. Stothers, Dr. K. S. Dhami, and Dr. R. E. Klinck for the n.m.r. spectra and for help in their interpretation; and Dr. R. K. Chan for aid and advice in determining dipole moments.

THE REACTION OF SOME COMPOUNDS CONTAINING THIOAMIDE GROUPS WITH 2,4,6-TRICHLORO-1,3,5-TRIAZINE

A. Pollak, B. Stanovnik, and M. Tišler
Department of Chemistry, University of Ljubljana, Ljubljana, Yugoslavia

Received November 23, 1965

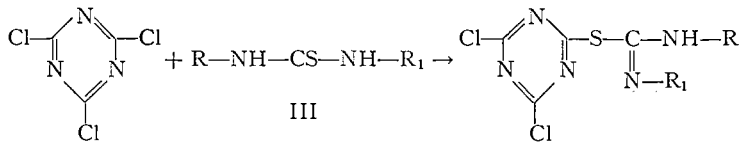
ABSTRACT

The reaction between some compounds containing thioamide groups and cyanuric chloride was investigated. Evidence is presented that the reaction proceeds on the thioamide sulfur and not on the nitrogen as postulated earlier. The reaction with thiourea was used for the preparation of trithiocyanuric acid, as well as for the preparation of 3-chloro-6(1*H*)-pyridazinethione or 3-mercapto-6(1*H*)-pyridazinethione, and presents a new and convenient method for the synthesis of these compounds.

In connection with our investigations of the reactivity of heterocyclic compounds containing thioamide groups as a part of the ring system (1–4), it seemed of interest to investigate the reaction between compounds with thioamide groups and compounds with reactive halogens, particularly cyanuric chloride. An examination of the literature (5) revealed that the reaction of cyanuric chloride (2,4,6-trichloro-1,3,5-triazine) with different thiosemicarbazones was interpreted as proceeding on the N_2-nitrogen of the thiosemicarbazones. N-(4,6-Dichloro-1,3,5-triazinyl-2)-thioureas are also known, but they were prepared in a different manner (6).

A substantial amount of work on alkylations and acylations of different compounds with thioamide groups has been reported (7). Several recent publications have enlarged the earlier reports on the alkylation or acylation of thioureas (8), thioamides (9), thiosemicarbazides and thiosemicarbazones (10, 11), and heterocyclic compounds containing thioamide groups as a part of the ring system (12–15). In all cases the reaction proceeds with the attack on the thioamide sulfur, except in the reaction between 2-thiobenzothiazoline and diethylaminomethylchloride, in which case a N-substituted product was isolated; this is explained by the predisposition of these compounds to undergo unimolecular substitution (12).

Compounds containing thioamide groups were formerly postulated as reacting in their normal form (I) or in their tautomeric iminothiol form (II). This must certainly not be a



I II

condition, as in recent years the dipolar character of the thioamide group has been established (1, 2, 16–22). Thioamides are protonated on the sulfur atom and not on the nitrogen (23, 24), and the evidence, obtained from measurements of bond distances (25), provides additional support for the dipolar character. Furthermore, alkylations of ambident anions have been discussed (26) and evidence has been presented that the reaction course depends on the character of the transition state.

Finally, one must take into account the possibility of the migration of the initially bound alkyl group. So far, only the spontaneous O → S alkyl migration is known in the case of solid thioisobiuret hydrohalides at room temperature (27), and it seems very unlikely that, under the relatively mild reaction conditions used, a migration from the sulfur of the initially bound triazine would occur to give a N-substituted derivative.

Thus, the reaction between cyanuric chloride and compounds with thioamide groups (III) should proceed preferentially in the direction of the formation of isothiuronium salts or their derivatives; the present findings give a satisfactory basis for such an interpretation of the reaction course.

III IV

Regardless of which compound containing a thioamide group was employed for the reaction with cyanuric chloride, all reaction products gave a negative iodine–azide reaction (28), characteristic of the presence of a mercapto or thiocarbonyl group. This test was positive with all starting compounds containing thioamide groups. An assignment of the thiocarbonyl stretching frequency, which was used for the indication that such a reaction does proceed as N-substitution (5), seems to be very delicate, as this frequency is dependent on the structural environment and falls within a wide range, 1 400 – 1 000 cm^{-1} (29, 30).

Further evidence for the alkylation site could be obtained from the hydrolysis of the alkylation products that were obtained, as this is one of the possible methods of introducing a thiol (thione) group in many heterocyclic systems. The method involving the action of aqueous alkali on isothiuronium salts has superseded most of the others used for the laboratory-scale syntheses (31).

Thiourea, which appears to have the required combination of a considerable nucleophilic power and a weak basic strength ($pK_a = -1.19$) (32), reacted readily with cyanuric chloride or with 3,6-dichloropyridazine; the initially formed isothiuronium salts were then hydrolyzed to the corresponding trithiocyanuric acid (2,4,6-trimercapto-1,3,5-triazine), 3-chloro-6(1*H*)-pyridazinethione, or 3-mercapto-6(1*H*)-pyridazinethione. It is well known that the reactivity of the 1,3,5-triazine system is very great and exceeds the reactivity of different 3-substituted pyridazines (33). This was also observed in the case of the above reaction where, regardless of the amount of the thiourea used in the reaction, the trithiocyanuric acid was always obtained, in a smaller yield of course.

Some evidence of the reaction course may also be obtained from the ultraviolet spectra. Only a few publications have dealt with the ultraviolet spectra of 1,3,5-triazines; a useful compilation of some spectral data was presented by Koopman (34). He reported that 2,4-dichloro-6-amino- or substituted amino-1,3,5-triazines possess two absorption bands, one in the 2 250 – 2 440 Å region (high intensity) and the other in the 2 600 – 2 800 Å region (low intensity), whereas the 2,4-dichloro-6-alkylthio- or arylthio-1,3,5-triazines exhibit only one absorption band, that in the 2 600 – 2 670 Å region (high intensity). The ultraviolet spectra of some of our products all show a high-intensity band in the 2 960 – 3 180 Å region; these findings present additional evidence for the proposed S-alkylated products.

EXPERIMENTAL

Melting points were determined on a Kofler heating microscope. Ultraviolet spectra were measured on a Beckman model DU spectrophotometer.

S-(4,6-Dichloro-1,3,5-triazinyl-2)-acetone Thiosemicarbazone (IV, R = H, R_1 = N=C(CH_3)$_2$)

A solution of acetone thiosemicarbazone (2.6 g, 0.02 mole) (35) in acetone (100 ml) was added slowly to a stirred solution of cyanuric chloride (3.7 g, 0.02 mole) in acetone (300 ml). The reaction mixture was stirred at room temperature for 20 min and a saturated aqueous solution of sodium bicarbonate added until the

For personal use only.

pH reached 7. The solvent was evaporated *in vacuo*, the residue treated with cold water (50 ml), and the precipitate collected by filtration and dried. The product was crystallized from a mixture of cyclohexane and ethyl acetate, yield 56%, m.p. >340 °C. The compound gave a negative iodine–azide reaction. Ultraviolet spectrum (in methanol): λ_{max} 3 020 Å, ϵ = 12 850.

Anal. Calcd. for $C_7H_8Cl_2N_6S$: C, 30.11; H, 2.89; N, 30.11; S, 11.48. Found: C, 29.92; H, 3.15; N, 30.32; S, 11.73.

In the same way as described above the following compounds were prepared, and in all cases the iodine–azide reaction was negative.

S-(4,6-Dichloro-1,3,5-triazinyl-2)-acetone 4'-phenylthiosemicarbazone (IV, R = C_6H_5, R_1 = N=CH$(CH_3)_2$) was obtained from acetone 4-phenylthiosemicarbazone (36). The product was crystallized from benzene, yield 47%, m.p. 193 °C. Ultraviolet spectrum (in dioxane): λ_{max} 2 540 and 3 180 Å, ϵ = 10 520 and 23 050.

Anal. Calcd. for $C_{13}H_{12}Cl_2N_6S$: C, 43.94; H, 3.38; N, 23.66; S, 9.02. Found: C, 44.14; H, 3.67; N, 23.55; S, 9.48.

S-(4,6-Dichloro-1,3,5-triazinyl-2)-phenylthiourea (IV, R = C_6H_5, R_1 = H) was obtained from phenylthiourea. The crude product was dissolved in ethyl acetate and poured into water. The precipitate was separated by filtration, washed with water, and air-dried, yield 12%, m.p. 198 °C.

Anal. Calcd. for $C_{10}H_7Cl_2N_5S$: C, 40.01; H, 2.35; N, 23.33; S, 10.67. Found: C, 40.18; H, 2.56; N, 23.64; S, 10.45.

S-(4,6-Dichloro-1,3,5-triazinyl-2)-1'-phenyl-3'-methylthiourea (IV, R = C_6H_5, R_1 = CH_3) was obtained from 1-phenyl-3-methylthiourea (37). The product was purified from ethanol, yield 10%, m.p. 136 °C.

Anal. Calcd. for $C_{11}H_9Cl_2N_5S$: C, 42.04; H, 2.89; N, 22.29. Found: C, 42.30; H, 3.02; N, 22.46.

S-(4,6-Dichloro-1,3,5-triazinyl-2)-n-heptanal thiosemicarbazone (IV, R = H, R_1 = N=CH$(CH_2)_5CH_3$) was prepared according to the procedure of Gingras *et al.* (5), m.p. 179 °C. Ultraviolet spectrum (in methanol): λ_{max} 2 960 Å, ϵ = 19 310.

S-(6-Chloropyridazinyl-3)-acetone Thiosemicarbazone

To a solution of acetone thiosemicarbazone (1.3 g, 0.01 mole) (35) in acetone (50 ml) was added 3,6-dichloropyridazine (1.5 g, 0.01 mole), and the mixture was left overnight at room temperature. The precipitated product was collected and dissolved in water (30 ml), and a saturated solution of sodium bicarbonate added until the pH reached 7. The precipitate was separated by filtration, dried, and crystallized from ethanol with the addition of some N,N-dimethylformamide, yield 18%, m.p. 121 °C.

Anal. Calcd. for $C_8H_{10}ClN_5S$: C, 39.42; H, 4.11; N, 28.75. Found: C, 39.56; H, 3.84; N, 28.98.

S-(6-Chloropyridazinyl-3)-benzaldehyde Thiosemicarbazone

The same reaction as above was applied, and the starting compound was benzaldehyde thiosemicarbazone (35, 37). After neutralization with sodium bicarbonate solution, the solvent was evaporated *in vacuo* and a red oil separated. This oil was separated from the residual liquid and, after it was allowed to stand overnight, crystals separated. The product was washed with ether and crystallized from ethanol with the addition of some N,N-dimethylformamide, yield 29%, m.p. 159 °C. Ultraviolet spectrum (in dioxane): λ_{max} 3 020 Å, ϵ = 20 450.

Anal. Calcd. for $C_{12}H_{11}ClN_5S$: C, 49.23; H, 3.76; N 23.93. Found: C, 49.46; H, 3.79; N, 23.88.

Trithiocyanuric Acid

To a solution of thiourea (6.8 g, 0.09 mole) in acetone (130 ml) was added cyanuric chloride (5.55 g, 0.03 mole), and the mixture was heated under reflux for 2 h on a water bath. The precipitated isothiuronium compound was filtered off and transferred to a solution of sodium hydroxide (6 g in 50 ml of water). The resulting solution was filtered, acidified with concentrated hydrochloric acid until the pH reached 1, filtered, and dried. The product was purified by dissolution in a 5% aqueous solution of sodium bicarbonate (30 ml) and subsequent acidification with concentrated hydrochloric acid to a pH of 1. The product was collected by filtration and dried *in vacuo*, yield 86%, m.p. >300 °C (38, 39).

Anal. Calcd. for $C_3H_3N_3S_3$: S, 54.18. Found: S, 54.01.

The above reaction was also conducted with a different mole ratio of the starting compounds (2:1 and 1:1), but in both cases only trithiocyanuric acid was obtained; however, the yields were correspondingly lower.

3-Chloro-6(1H)-pyridazinethione

To a solution of thiourea (1.52 g, 0.02 mole) in acetone (50 ml) was added 3,6-dichloropyridazine (3.0 g, 0.02 mole), and the reaction mixture was heated under reflux on a water bath for 2 h. The cooled reaction mixture was separated by filtration and the isolated isothiuronium compound was dissolved in an aqueous solution of sodium hydroxide (1 g in 20 ml of water). The solution was acidified with concentrated hydrochloric acid to a pH of 1, and the precipitate was separated and dried. It was purified by dissolution in 5% sodium bicarbonate solution (30 ml), filtration, and acidification with concentrated hydrochloric acid to a pH of 1, yield 80%, m.p. 150 °C (lit. (40) m.p. 130–140 °C). The mixed melting point with an authentic specimen was not depressed.

3-Mercapto-6(1H)-pyridazinethione

By the above procedure, but with double the amount of thiourea, the compound was obtained in 74% yield, m.p. 246 °C (1) (lit. (40) m.p. 230–240 °C). The mixed melting point with an authentic specimen was undepressed.

1,4-DIARYLPHTHALAZINES AND 1,3-DIARYLISOBENZOFURANS

WALTER W. ZAJAC, JR. AND DONALD E. PICHLER[1]

In connection with our studies on polynuclear aromatic compounds it became necessary to synthesize a series of unsymmetrically substituted 1,4-diarylphthalazines and 1,3-diarylisobenzofurans. Unsymmetrically substituted 2-benzoylbenzophenones (I) were the starting compounds for both the phthalazines and the isobenzofurans.

The most general route for the synthesis of the diketones (I) is via the oxidation of the substituted 2-benzylbenzophenones (IV) (1–4). During this investigation the chromium trioxide – acetic acid system (3) was used to effect the oxidation of the substituted 2-benzylbenzophenones (IV; X = 4′-CH_3, 4′-Cl, or 4′-Br) (see Table I). The remaining diketones (I; X = 2′-Cl, 2′-Br, 3′-CF_3, and 4′-F) used in this work had been prepared previously (3–5).

The diketones (I) were smoothly condensed with 85% hydrazine hydrate in acetic acid to the corresponding 1,4-diarylphthalazines (II) (see Table II).

The method of Cava *et al.* (6) employing potassium borohydride for the conversion of 1,2-diaroylbenzenes (I) into 1,3-diarylisobenzofurans (III) was used in this work and

THE OXIDATION OF 1,2;5,6-DI-*O*-ISOPROPYLIDENE-D-GLUCOSE BY DIMETHYL SULFOXIDE – ACETIC ANHYDRIDE

W. Sowa and G. H. S. Thomas

A simple method of selective oxidation with a readily available reagent would be of great value in the field of carbohydrate chemistry. Recently Albright and Goldman reported a general method for the oxidation of alcohols to their corresponding carbonyl derivatives with dimethyl sulfoxide (DMSO) and certain acid anhydrides (1). The procedure, especially useful for the oxidation of sterically hindered hydroxyl groups, was recommended for compounds such as indole alkaloids which are sensitive to nonselective oxidizing agents. The present communication reports the use of DMSO – acetic anhydride for the oxidation of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (I). Although it is possible to convert this compound into 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (II) in 80% yield with ruthenium tetroxide (2), oxidation with more common reagents is difficult (3, 4). By careful control of the conditions, Theander (4) oxidized I with chromium trioxide – pyridine complex in acetic acid and obtained the 3-keto derivative (II) in 6% yield. Theander also found that sodium borohydride reduced II stereospecifically and practically quantitatively to 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose (III), which crystallized with ease. This provided a convenient route to the rare monosaccharide D-allose, as well as evidence for the presence of II.

In the present work, the oxidation of I by DMSO – acetic anhydride was found to be virtually complete after 24 h at room temperature. After removal of the solvents by distillation, the oxidized residue was dissolved in aqueous ethanol and reduced with sodium

THE OXIDATION OF 1,2;5,6-DI-*O*-ISOPROPYLIDENE-D-GLUCOSE BY DIMETHYL SULFOXIDE – ACETIC ANHYDRIDE

W. Sowa and G. H. S. Thomas

A simple method of selective oxidation with a readily available reagent would be of great value in the field of carbohydrate chemistry. Recently Albright and Goldman reported a general method for the oxidation of alcohols to their corresponding carbonyl derivatives with dimethyl sulfoxide (DMSO) and certain acid anhydrides (1). The procedure, especially useful for the oxidation of sterically hindered hydroxyl groups, was recommended for compounds such as indole alkaloids which are sensitive to nonselective oxidizing agents. The present communication reports the use of DMSO – acetic anhydride for the oxidation of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (I). Although it is possible to convert this compound into 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (II) in 80% yield with ruthenium tetroxide (2), oxidation with more common reagents is difficult (3, 4). By careful control of the conditions, Theander (4) oxidized I with chromium trioxide – pyridine complex in acetic acid and obtained the 3-keto derivative (II) in 6% yield. Theander also found that sodium borohydride reduced II stereospecifically and practically quantitatively to 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose (III), which crystallized with ease. This provided a convenient route to the rare monosaccharide D-allose, as well as evidence for the presence of II.

In the present work, the oxidation of I by DMSO – acetic anhydride was found to be virtually complete after 24 h at room temperature. After removal of the solvents by distillation, the oxidized residue was dissolved in aqueous ethanol and reduced with sodium

I II III

borohydride. Extraction of the product with ethyl acetate was followed by chromatography on a column of silicic acid. The D-allose derivative (III) was obtained in 62% yield based on I. The major by-product after oxidation was an unidentified reducing compound with a high R_F* value. A minor by-product was an ester, probably the 3-*O*-acetyl derivative of I.

The good yield of II indicates the usefulness of DMSO – acetic anhydride for the oxidation of hydroxyl groups of carbohydrates which are difficult to oxidize by other means. After the completion of this work, similar results were published by Onodera *et al.* (5), who obtained II in 65% yield by oxidation of I with DMSO containing phosphorus pentoxide.

EXPERIMENTAL

Thin-layer chromatography was carried out on layers (250 μ thick) of silica gel G on glass plates in (*a*) ethyl acetate – light petroleum, b.p. 30–60° (3:1 v/v), or (*b*) benzene–methanol (95:5 v/v). Compounds on the plates were detected by the following spray reagents: (*i*) sulfuric acid (30% v/v), followed by heating in an oven at 100–110°; (*ii*) saturated silver nitrate solution (1 ml) in aqueous acetone (100 ml), followed by a solution of sodium hydroxide (2 g) in aqueous ethanol (100 ml) (6); and (*iii*) ester spray reagent for thin-layer chromatography based on ferric hydroxamate reaction, according to Tate and Bishop (7). Preparative chromatography was carried out on a column of silicic acid (4 × 33 cm) with solvent *a*. Aliquots (15 ml) were collected at 30 min intervals. Evaporations were done under diminished pressure below 40 °C.

1,2;5,6-Di-*O*-isopropylidene-α-D-glucofuranose (I, 2.60 g) was dissolved in a mixture of DMSO (30 ml) and acetic anhydride (20 ml). Thin-layer chromatography of the solution during the course of the reaction showed that only a faint trace of I remained after 24 h at room temperature. The mixture was distilled at 0.05–0.1 mm, bath temperature 35–40°, to yield a syrupy residue (2.96 g) which consisted mainly of 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (II). It had R_I* 1.14 in solvent *a* and R_I 1.33 in solvent *b*; the reported value is R_I 1.04 in ethyl acetate – light petroleum, b.p. 40–60° (3:1 v/v) (3). The major by-product, also a reducing compound (spray *ii*), had R_I 1.34 in solvent *a*. In addition, there was a trace of an ester (spray *iii*) with R_I 1.25 in solvent *a*. A solution of the syrupy mixture in aqueous ethanol (100 ml, 70% v/v) was cooled and treated with sodium borohydride (2.6 g) for 30 min. The reaction mixture was poured into water (150 ml) and extracted with ethyl acetate (8 × 100 ml). Separation of the aqueous and organic layers was promoted by the addition of a small amount of sodium chloride. The combined extracts were dried over anhydrous sodium sulfate and concentrated to a syrup (2.81 g). This was redissolved in ethyl acetate and fractionated by column chromatography. First to be eluted was the reduced by-product (0.70 g), R_I 1.33 in solvent *a*. A mixture (0.05 g) of the reduced by-product and ester then followed. The starting material (I, 0.03 g) was next obtained and was well separated from the product, 1,2;5,6-di-*O*-isopropylidene-α-D-allose (III, 1.60 g, 62% yield based on I), R_I 0.85 in solvent *a* and R_I 1.00 in solvent *b*. I and III crystallized spontaneously when the eluting solvent was evaporated. After recrystallization of crude III (m.p. 72–75°) from benzene – light petroleum (b.p. 30–60°), it had m.p. 77–78° and $[\alpha]_D^{22}$ +36° (*c*, 0.5 in water). The reported values are m.p. 76–77° and $[\alpha]_D^{22}$ +37.7° (*c*, 0.5 in water) (4).

ACKNOWLEDGMENTS

The authors are grateful to Mrs. Claire Isaac for technical assistance. This research was made possible by a grant received by the Ontario Research Foundation from the Province of Ontario through the Department of Economics and Development.

R_F and R_I are the rates of movement of the sugars relative to that of the solvent front and of 1,2;5,6-di-O-isopropylidene-α-D-glucofuranose (I), respectively.

REACTION OF AROYL HALIDES WITH AROMATIC ALDEHYDES AND ACETOPHENONES

ROBERT FILLER AND FREDRIC N. MILLER

Adams and Vollweiler (1) reported in 1918 that aromatic acid chlorides and bromides react slowly at room temperature with aromatic aldehydes to form addition compounds, which were shown to be α'-halo esters (eq. [1]). The structures of the products were

[1] $$\underset{X = Cl, Br}{ArC(=O)-X} + O{=}CHAr' \rightarrow ArC(=O)-O-\underset{X}{CHAr'}$$

established by elemental analyses and by conversion of the halo ester into a diester on reaction with silver benzoate. The addition reaction has attracted little attention since that time, although recently it has been used as a method for obtaining an authentic sample of a diester (2).

In the discussion which follows, we provide infrared spectral evidence for the ester structure, as well as other observations concerning the reaction.

Infrared spectral analysis of the products reveals intense ester carbonyl absorption in the 1 755 – 1 735 cm^{-1} region, the position depending on the nature of the Ar group. The presence of the α'-halo group causes a substantial shift to higher frequencies (Table I).

TABLE I

Esters prepared from aroyl halides and aromatic aldehydes

Reactants	Product	$\nu_{C=O}$ (cm^{-1})*
$C_6H_5COBr + C_6H_5CHO$	$C_6H_5CO_2CHBrC_6H_5$	1 735
$C_6H_5COBr + p\text{-}ClC_6H_4CHO$	$C_6H_5CO_2CHBrC_6H_4Cl\text{-}p$	1 740
$p\text{-}NO_2C_6H_4COCl + C_6H_5CHO$	$p\text{-}NO_2C_6H_4CO_2CHClC_6H_5$	1 745
$C_6F_5COCl + C_6H_5CHO$	$C_6F_5CO_2CHClC_6H_5$	1 755
$C_6F_5COCl + C_6F_5CHO$	No reaction after 3 months, $p\text{-}NO_2C_6H_4CO_2CH_2C_6H_5$†	1 722

*All infrared spectra were measured in $CHCl_3$ except $C_6F_5CO_2CHClC_6H_5$, which was measured in CCl_4.
†Reference compound, prepared from the acid chloride and benzyl alcohol.

Adams and Vollweiler (1) reported that these compounds reacted with water according to eq. [2]. Ammonia and ethanol similarly gave the corresponding amide and ester.

[2] $$ArCO_2CHXAr' + H_2O \rightarrow ArCO_2H + HX + Ar'CHO$$

We found that, immediately after isolation, most of the products exhibited some absorption near 1 695 cm^{-1} caused by the presence of carboxylic acid. There was also some

ROBERT FILLER AND FREDRIC N. MILLER

Adams and Vollweiler (1) reported in 1918 that aromatic acid chlorides and bromides react slowly at room temperature with aromatic aldehydes to form addition compounds, which were shown to be α'-halo esters (eq. [1]). The structures of the products were

[1] $$\underset{X = Cl, Br}{\overset{\overset{O}{\|}}{ArC}—X} + O{=}CHAr' \rightarrow \overset{\overset{O}{\|}}{ArC}—O—\underset{X}{\overset{|}{C}}HAr'$$

established by elemental analyses and by conversion of the halo ester into a diester on reaction with silver benzoate. The addition reaction has attracted little attention since that time, although recently it has been used as a method for obtaining an authentic sample of a diester (2).

In the discussion which follows, we provide infrared spectral evidence for the ester structure, as well as other observations concerning the reaction.

Infrared spectral analysis of the products reveals intense ester carbonyl absorption in the 1 755 – 1 735 cm^{-1} region, the position depending on the nature of the Ar group. The presence of the α'-halo group causes a substantial shift to higher frequencies (Table I).

TABLE I

Esters prepared from aroyl halides and aromatic aldehydes

Reactants	Product	$\nu_{C=O}$ (cm^{-1})*
$C_6H_5COBr + C_6H_5CHO$	$C_6H_5CO_2CHBrC_6H_5$	1 735
$C_6H_5COBr + p\text{-}ClC_6H_4CHO$	$C_6H_5CO_2CHBrC_6H_4Cl\text{-}p$	1 740
$p\text{-}NO_2C_6H_4COCl + C_6H_5CHO$	$p\text{-}NO_2C_6H_4CO_2CHClC_6H_5$	1 745
$C_6F_5COCl + C_6H_5CHO$	$C_6F_5CO_2CHClC_6H_5$	1 755
$C_6F_5COCl + C_6F_5CHO$	No reaction after 3 months, $p\text{-}NO_2C_6H_4CO_2CH_2C_6H_5$†	1 722

*All infrared spectra were measured in $CHCl_3$ except $C_6F_5CO_2CHClC_6H_5$, which was measured in CCl_4.
†Reference compound, prepared from the acid chloride and benzyl alcohol.

Adams and Vollweiler (1) reported that these compounds reacted with water according to eq. [2]. Ammonia and ethanol similarly gave the corresponding amide and ester.

[2] $$ArCO_2CHXAr' + H_2O \rightarrow ArCO_2H + HX + Ar'CHO$$

We found that, immediately after isolation, most of the products exhibited some absorption near 1 695 cm^{-1} caused by the presence of carboxylic acid. There was also some

evidence of the aldehyde. The presence of these hydrolysis products is probably the result of exposure to atmospheric moisture as suggested previously (1). Indeed, on continued exposure, a progressive increase in the intensity of the acid carbonyl band is observed, accompanied by a corresponding diminution in the ester carbonyl frequency. This sensitivity to moisture made it difficult to obtain reliable analytical data for new compounds, except in the cases of a pentafluorophenyl ester (*vide infra*), and two esters derived from substituted acetophenones.

In confirmation of the earlier studies, we observed that esters in which Ar′ = C_6H_5 and Ar contains an electron-withdrawing group, e.g. *p*-$NO_2C_6H_4$ or C_6F_5, form much more slowly and are more stable to hydrolysis, thus indicating that attack of water on the carbonyl carbon is not involved in the rate-determining step. An example of a fairly stable ester is $C_6F_5CO_2CHClC_6H_5$, whose spectrum is shown in Fig. 1.

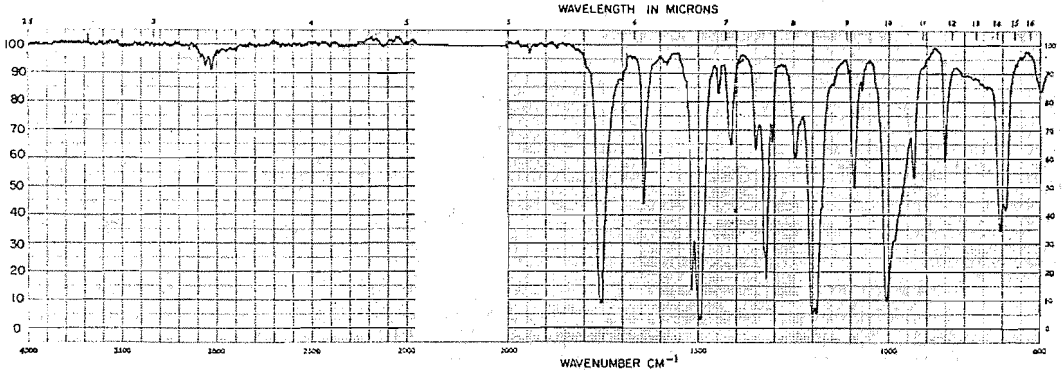

FIG. 1. The infrared spectrum of $C_6F_5CO_2CHClC_6H_5$ (in CCl_4 solvent) prepared from C_6F_5COCl and C_6H_5CHO.

p-Bromoacetophenone and *p*-nitroacetophenone also react slowly (8 days) with *p*-nitrobenzoyl chloride, and the infrared spectra of the products indicate the presence of esters of the type $ArCO_2CCl(CH_3)Ar'$. When the esters are heated, they revert to starting materials. Acetophenone and *p*-methylacetophenone failed to react with *p*-nitrobenzoyl chloride after 4 days.

From Adams' data and our own observation on the attempted reaction of pentafluorobenzaldehyde with pentafluorobenzoyl chloride, it appears that electron-withdrawing groups on the aromatic nucleus of the aldehyde slow down or inhibit the reaction. Although we have insufficient information to support a specific mechanism for the formation of the ester, it is apparent that increased nucleophilic character of the aldehyde oxygen (for attack on the carbonyl carbon of the acid halide) enhances the rate of reaction. Moreover, the observation that acid bromides react much faster than acid chlorides is consonant with the evidence that bromide is the better leaving group. At this stage, both stepwise mechanisms and a four-center transition state are possible.

EXPERIMENTAL

Infrared spectra were obtained on a Beckman IR-8 grating spectrophotometer.

Benzoyl Bromide and Benzaldehyde

Equimolar amounts of the two compounds were mixed in a flask and stoppered tightly. Solidification occurred after 2 days to give a product which fumed in air and decomposed readily. It was not possible to purify this material, in agreement with previous observations (1). The infrared spectrum in $CHCl_3$ showed two peaks in the carbonyl region at 1 695 cm^{-1} (with a shoulder at 1 705 cm^{-1}) and at 1 735 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Benzoyl Bromide and p-Chlorobenzaldehyde

Solidification took place 3 h after equimolar amounts of the two liquids were mixed. The grey-white solid decomposed rapidly with fuming in the air. Again it was not possible to purify the product, and the infrared spectrum showed that it underwent rapid decomposition in solution.

The spectrum in $CHCl_3$ was very similar to that of the product obtained in the previous reaction, with a strong band at 1 740 cm^{-1} attributed to the addition product, another strong band at 1 695 cm^{-1}, and a shoulder at 1 705 cm^{-1}. Also present was a broad band centered at 3 000 cm^{-1} and attributed to the bonded OH of the carboxylic acid.

A spectrum of the solution taken 1 h after the first showed the same features, although the band at 1 740 cm^{-1} had diminished in intensity and the others increased in intensity. The sample was then stored for 20 h and another spectrum taken at that time. This spectrum showed even greater changes, although the 1 740 cm^{-1} band was still fairly intense.

p-Nitrobenzoyl Chloride and Benzaldehyde

An equimolar amount of *p*-nitrobenzoyl chloride was dissolved in benzaldehyde, and the tightly stoppered flask kept at room temperature. Solidification occurred after 5 days, and the solid was recrystallized from Skellysolve B to give white crystals, m.p. 119–120° (lit. (1) m.p. 118–118.5°). The compound appears to be stable in the air, and a sample stored in a bottle for 3 months melted at 119–120°.

The spectrum in $CHCl_3$ showed a band in the carbonyl region at 1 745 cm^{-1} (strong) with shoulders at 1 740 cm^{-1} and 1 735 cm^{-1}. These bands are all assigned to the addition compound.

Pentafluorobenzoyl Chloride and Benzaldehyde

Equimolar amounts of the two compounds were mixed in a tightly stoppered flask and kept at room temperature. After 1 week the solution had turned yellow but no solid had formed. After an additional 2 weeks the mixture had solidified. Crystallization from petroleum ether gave white crystals (later turning pink), m.p. 93–94°. The infrared spectrum in CCl_4 showed strong absorption at 1 755 cm^{-1}, the only absorption in the carbonyl region.

Anal. Calcd. for $C_{14}H_6ClF_5O_2$: F, 28.3. Found: F, 29.5.

Pentafluorobenzoyl Chloride and Pentafluorobenzaldehyde

Equimolar amounts of the two compounds were mixed in a tightly stoppered flask and kept at room temperature. The solution turned light brown after 4 days and progressively darkened for 3 months, but no solid precipitated. After 3 months a small amount of pentane was added and an oil separated, but no product could be isolated.

p-Nitrobenzoyl Chloride and p-Bromoacetophenone

The reaction was conducted by dissolving equimolar amounts of the two compounds (0.1 mole each) in a minimum amount of anhydrous ether and keeping the tightly stoppered flask at room temperature for 8 days. On addition of *n*-pentane, a solid was obtained which was crystallized from Skellysolve B to give white needles, m.p. 49–52°.

Anal. Calcd. for $C_{15}H_{11}NO_4BrCl$: C, 46.84; H, 2.88. Found: C, 46.56; H, 2.96.

The spectrum of a CCl_4 solution showed four peaks in the carbonyl region. When the solution was allowed to stand in the spectrometer, the ester reverted to starting materials; the spectrum showed a strong band at 1 785 cm^{-1} caused by *p*-nitrobenzoyl chloride, a very strong band at 1 760 cm^{-1} and a medium band at 1 725 cm^{-1} caused by the addition compound, and a very strong band at 1 690 cm^{-1} caused by *p*-bromoacetophenone.

p-Nitrobenzoyl Chloride and p-Nitroacetophenone

The reaction was carried out in the same manner as above, and the product was isolated after 8 days as brownish-white needles, m.p. 62–64°. The infrared spectrum showed a strong band at 1 785 cm^{-1} caused by *p*-nitrobenzoyl chloride, a very strong band at 1 760 cm^{-1} and a medium band at 1 728 cm^{-1} caused by the addition compound, and a very strong band at 1 695 cm^{-1} caused by *p*-nitroacetophenone.

Anal. Calcd. for $C_{15}H_{11}N_2O_6Cl$: C, 51.37; H, 3.16. Found: C, 52.44; H, 3.50.

p-Nitrobenzoyl Chloride and Acetophenone (p-Methylacetophenone)

p-Nitrobenzoyl chloride (0.1 mole) was dissolved in 0.1 mole of acetophenone with the aid of a small amount of anhydrous ether. The tightly stoppered flask was kept at room temperature for 4 days and enough *n*-pentane was added to precipitate a solid. This solid was crystallized from Skellysolve B to give an off-white compound, m.p. 73–75°, shown by mixed melting point to be unreacted *p*-nitrobenzoyl chloride. *p*-Methylacetophenone behaved similarly.

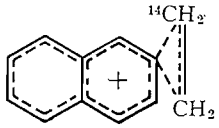
REARRANGEMENT STUDIES WITH ^{14}C
XXVI. SOLVOLYSES OF 2-(β-NAPHTHYL)-1-^{14}C-ETHYL *p*-TOLUENESULFONATE

C. C. LEE AND A. G. FORMAN



In an earlier paper (1), the results obtained from the acetolysis and formolysis of 2-(α-naphthyl)-1-^{14}C-ethyl *p*-toluenesulfonate (α-I-OTs) were reported, and it was concluded that these solvolyses involved the nonclassical ethylene-α-naphthonium ion as an intermediate. This ion was drawn as II*a* by analogy with the suggested representation of the ethylenephenonium ion by Brown *et al.* (2). Recently, Eberson, Winstein, and co-workers (3, 4) have presented very strong evidence, including the direct observation of the nuclear magnetic resonance spectrum, for the bridged ion from the 9-anthrylethyl system. These workers (3, 4) preferred a structure which was regarded as a better representation of positive-charge delocalization and from which, by analogy, the ethylene-α-naphthonium ion would be written as II*b*. In the present work, the acetolysis and formolysis of 2-(β-naphthyl)-1-^{14}C-ethyl *p*-toluenesulfonate (β-I-OTs) were studied, and the results also suggest some involvement of the ethylene-β-naphthonium ion III or its equivalent of a pair of rapidly equilibrating classical ions.

II*a*

II*b*

III

β-I-OTs was prepared from β-chloromethylnaphthalene (5) by a series of reactions analogous to those already described for the preparation of α-I-OTs (1). Acetolysis and formolysis of β-I-OTs were allowed to proceed to 50% completion; the "unreacted" β-I-OTs and the respective products, 2-(β-naphthyl)ethyl acetate and formate (β-I-OAc and β-I-OCHO), were recovered, converted into 2-(β-naphthyl)ethanol (β-I-OH), and degraded to β-naphthoic acid (IV) by procedures previously described for the α-naphthyl series (1). The radioactivity in IV gave the extents of rearrangement of the ^{14}C label from the C-1 to the C-2 positions of the ethyl chain in the various products and in the recovered β-I-OTs. The results are summarized in Table I.

The isotope position rearrangements tabulated in Table I show a trend very similar to those observed in the solvolyses of α-I-OTs (1), but the actual extents of rearrangement are somewhat lower than those obtained in the corresponding reactions with the α-naphthyl series. Thus the rearrangements in the solvolysis products from β-I-OTs are 34% and 43%, respectively, for acetolysis and formolysis, whereas the corresponding rearrangements from acetolysis and formolysis of α-I-OTs are 46% and 50% (1). This difference is not surprising when the well-known greater reactivity of the α-position than the β-position of the naphthalene nucleus towards aromatic substitution, and theoretical considerations (6) are taken into account. It is therefore expected that nonclassical ion II*b* will have somewhat greater stability than nonclassical ion III. Solvolyses of β-I-OTs will thus show a greater S_N2 component than the corresponding reactions with α-I-OTs. Hence, slightly lower extents of ^{14}C rearrangement are observed in the present studies with β-I-OTs. It is of interest to point out that a change in the same direction has also been observed in the isotope position rearrangements accompanying the nitrous acid deamination of the 2-(α-naphthyl)- and 2-(β-naphthyl)-1-^{14}C-ethylamines (5).

TABLE I

Rarrangements in solvolyses of 2-(β-naphthyl)-1-^{14}C-ethyl *p*-toluenesulfonate

Reaction	Compound assayed	Reaction product				Recovered tosylate			
		Activity* (c.p.m./mmole)		% rearrangement		Activity* (c.p.m./mmole)		% rearrangement	
		Run 1	Run 2	Run 1	Run 2	Run 1	Run 2	Run 1	Run 2
Acetolysis	β-$C_{10}H_7CH_2CH_2OH$	906	906			239	184		
	β-$C_{10}H_7COOH$	308	311	34	34	73	58	31	32
Formolysis	β-$C_{10}H_7CH_2CH_2OH$	72	77			68	82		
	β-$C_{10}H_7COOH$	32	33	43	43	0.5	0.6	0.7	0.7

*Measured by a liquid scintillation counter.

The rearrangement found in the β-I-OTs recovered from the acetolysis reaction is about 31% compared with a corresponding rearrangement of about 38% in the sulfonate recovered from the acetolysis of α-I-OTs (1). As in the case with the α-isomer, the rearrangement in the sulfonate recovered from the formolysis of β-I-OTs is almost negligible. As pointed out previously (1), these isotopic rearrangements in the recovered starting material indicate some return from an ionic intermediate, such as III, to covalent bonding. The fact that extensive return takes place in acetic acid whereas the return is almost negligible in formic acid is consistent with well-established concepts regarding the effects of reaction medium on internal return. The ionizing power and nucleophilic character of acetic acid are such that an optimum opportunity is provided for return from ionic to covalent bonding, whereas in the highly ionizing formic acid the return process cannot compete favorably with product formation (7, 8).

EXPERIMENTAL

Preparation of β-I-OTs

The reaction of ^{14}C-carbon dioxide with the Grignard reagent from β-chloromethylnaphthalene gave β-naphthylacetic acid, m.p. 142–143 °C (lit. (9) m.p. 143.1–143.4 °C), which was reduced with lithium aluminium hydride to β-I-OH, m.p. 67–68 °C (lit. (5) m.p. 67–68 °C). The alcohol was then treated with *p*-toluenesulfonyl chloride in pyridine (10) to give β-I-OTs, m.p. 75–76 °C.

Anal. Calcd. for $C_{19}H_{18}O_3S$: C, 69.91; H, 5.56; S, 9.82. Found: C, 70.01; H, 5.60; S, 9.80.

Acetolysis

A solution of 5.712 g (0.0175 mole) of β-I-OTs in 100 ml of anhydrous acetic acid was heated at 110.6 °C for one half-life (1 110 min). The resulting mixture was worked up in the same manner as described for the acetolysis of α-I-OTs (1). Both "unreacted" β-I-OTs and the reaction product, β-I-OAc, were recovered in about 80% yields based on 50% reaction. β-I-OAc was distilled at 148–153 °C and 1 mm.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.66; H, 6.67.

Formolysis

A solution of 2.448 g (0.0075 mole) of β-I-OTs in 250 ml of anhydrous formic acid was heated at 56.5 °C for one half-life (1 300 min), and the resulting mixture was worked up as previously described (1). For the two runs, 0.7 and 0.8 g (57% and 65% based on 50% reaction) of β-I-OTs were recovered, and the yields of β-I-OCHO were 0.37 g and 0.42 g (48% and 54% based on 50% reaction). β-I-OCHO was distilled at 140–146 °C and 1 mm.

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04. Found: C, 78.02; H, 6.01.

Degradation

The recovered β-I-OTs and the reaction products, β-I-OAc and β-I-OCHO, were converted into β-I-OH and then oxidized to β-naphthoic acid (IV) by the same procedures already described for the α-naphthyl series (1). A control degradation showed that these reactions did not cause any isotopic rearrangement.

STEROIDS AND RELATED NATURAL PRODUCTS XXVI. SYNTHESIS OF 3β-ACETOXY-20-OXO-5β-PREGNA-14,16-DIENE[1,2]

GEORGE R. PETTIT[3] AND DAVID M. PIATAK[4]

A pure specimen of 3β-acetoxy-20-oxo-5β-pregna-14,16-diene, obtained by a synthetic procedure which would constitute formal total synthesis, was required as part of another problem. Although a variety of similar D-ring dienes have been prepared (1), none was considered to be suitable; hence we developed the following synthetic route.

The important total synthesis of tigogenin by Sondheimer and colleagues (2) completes, in turn, a total synthetic route (3) to smilagenin (I*a*) and allowed the latter compound to serve as starting material. Smilagenin acetate (I*b*) was degraded to 3β-acetoxy-20-oxo-5β-pregna-16-ene (II) essentially as reported by Wall,[5] and the olefin was treated with N-bromosuccinimide.[6] Dehydrohalogenation of the product by a sodium iodide procedure yielded a mixture of starting material (II) and the required diene (III). Partial purification of diene III was achieved by successive column chromatography on basic alumina and Florisil. Final purification of diene III was realized by a combination of preparative thin-layer chromatography and recrystallization procedures.

Several other methods were used in early attempts to obtain diene III; during this phase ethylenethioketal IV*b* was prepared, and regeneration of the original ketone by a mercuric chloride desulfurization (7) method was studied. In addition, a route to androstane derivative V*b* was developed.

EXPERIMENTAL

All solvents were redistilled, and melting points were determined on a Fisher–Johns apparatus. The new compounds reported are colorless, and the purity of each was determined by thin-layer chromatography on Kieselguhr G (E. Merck, A.G.). Optical rotation measurements (in chloroform) were determined in the laboratory of Drs. Weiler and Strauss, Oxford, England. Ultraviolet (ethanol solution) and infrared spectra were recorded by Dr. R. A. Hill, University of Maine; Dr. A. Bernhardt, Max-Planck Institut, Mülheim, Germany, provided the elemental analyses.

3β-Acetoxy-20-oxo-5β-pregna-14,16-diene (III)

In a typical experiment smilagenin acetate (I*b*, 10. 0 g) was converted into 3β-acetoxy-20-oxo-5β-pregna-16-ene (II, 3.6 g, m.p. 141–143°) essentially[7] as described by Wall and his colleagues (reported (5) m.p. 141–143°). Degradation of smilagenin acetate to ketone II was repeated a number of times, with similar results in each case. A solution of the 20-ketone (II, 2.0 g) and N-bromosuccinimide (1.24 g) in carbon tetrachloride (60 ml) was heated at reflux and irradiated for 12 min with a General Electric sunlamp (250 W). The bromination reaction was repeated a total of seven times and the reaction mixtures were combined. After succinimide was collected, the solvent was removed (*in vacuo*) and the residue dissolved in acetone (230 ml). Sodium iodide (28 g) was added and the mixture was stored at room temperature for 65 h. After dilution with water and diethyl ether, the organic layer was successively washed with 5% sodium hydrogen sulfite, 5% sodium bicarbonate, and water. Removal of solvent provided an oily residue (14.0 g) which was chromatographed, in 4:1 petroleum ether – benzene, on basic alumina (250 g, Merck "suitable for chromatography"). Elution with the same solvent followed by 1:1 petroleum ether – benzene and benzene gave a series of fractions (7.0 g) containing increasing quantities of diene III. A qualitative estimation of monoolefin II content (as evidenced by infrared spectral determination) was determined for each fraction. The fractions eluted by 9:1 to 1:1 benzene–chloroform weighed 6.1 g and represented (based on infrared spectra) principally the diene. The 6.1 g portion was reacetylated (1:1 acetic anhydride – pyridine, room temperature, 24 h), and the product was crystallized from methanol and recrystallized from benzene – petroleum ether to yield needles melting at 131–132°. However, a detectable (by infrared spectral analysis) amount of starting material (II) was still present. The crystalline, but slightly impure, diene was further purified as follows. A 0.50 g portion was dissolved in 20:1 petroleum ether – benzene and carefully chromatographed on Florisil (15.0 g; Floridine Company, Tallahassee, Florida). A 25 mg specimen of the fractions (0.173 g) eluted with 1:1 petroleum ether – benzene was subjected to preparative thin-layer chromatography on Kieselguhr G (1:1 benzene–chloroform being used as the mobile phase). The diene was located with an ultraviolet lamp (dark spot) and eluted with chloroform. The chloroform solution was filtered through a column of neutral alumina (E. Merck, A.G.); removal of solvent led to 12 mg of 3β-acetoxy-20-oxo-5β-pregna-14,16-diene (III) melting at 112–115°. Several recrystallizations from benzene–ligroin (b.p. 80–90°) gave an analytical specimen as needles melting at 118.5–119.5°; λ_{max} 310 mμ (log ε 4.15); the optical rotatory dispersion[8] in methyl alcohol (*c*, 0.015) at room temperature, $[\alpha]_{254}$ −22 000, $[\alpha]_{285}$ −27 800, $[\alpha]_{335}$ +27 800, $[\alpha]_{350}$ +20 000, $[\alpha]_{356}$ +10 000, and $[\alpha]_{440}$ +4 000;[8] $[\alpha]_D^{22}$ +374° (*c*, 1.28); ν_{max}^{KBr} 1 733, 1 638, 1 526, and 1 258 cm^{-1}.

Anal. Found: C, 77.36; H, 9.03. $C_{23}H_{32}O_3$ requires C, 77.49; H, 9.05.

The same procedure was employed to prepare a larger quantity (0.06 g) of pure diene (III).

3β-Acetoxy-pregna-5-ene 20-Ethylenethioketal (IVb)

To a warm (steam bath) solution of 3β-acetoxy-20-oxo-pregna-5-ene (IV*a*, 4.0 g) in glacial acetic acid (50 ml) – ethanedithiol (7 ml) was added boron trifluoride etherate (7 ml). The reaction mixture was slowly cooled, and the crystalline product which separated was collected and washed with methanol to yield 4.6 g (92%) of thioketal IV*b* melting at 209–211°. Recrystallization from chloroform–methanol provided a pure crystalline specimen, m.p. 211.5–212.5°, $[\alpha]_D^{18}$ −27.8° (*c*, 1.32), $\nu_{max}^{CHCl_3}$ 1 722 cm^{-1}.

Anal. Found: C, 68.99; H, 8.65; S, 15.01. $C_{25}H_{38}O_2S_2$ requires C, 69.09; H, 8.81; S, 14.73.

The original ketone was regenerated by application of the following procedure. A mixture of thioketal IV*b* (0.50 g), cadmium carbonate (2.0 g), mercuric chloride (2.0 g), water (3 ml), chloroform (3 ml), and acetone (15 ml) was allowed to stand at room temperature for 22 h. After the solution was filtered through Celite, additional chloroform was added and the mixture washed successively with water, 5% aqueous potassium iodide, and water. Removal of solvent gave 0.40 g (97%) of 3β-acetoxy-20-oxo-pregna-5-ene (IV*a*) melting at 147–150°. Recrystallization from methanol provided a specimen melting at 147–148°. Mixture melting point determination and infrared spectral comparison with an authentic specimen confirmed the product's composition.

3β-Acetoxy-16-acetoxymethylene-17-oxo-5α-androstane (Vb)

A specimen of 3β-hydroxy-16-hydroxymethylene-17-oxo-5α-androstane (V*a*, 92% yield, m.p. 222–225°) was prepared from 3β-acetoxy-17-oxo-5α-androstane (5.0 g) as described by Ruzicka (reported (8) m.p.

[7]*Substitution of chloroform for diethyl ether in the extraction step led to a more easily crystallized product.*

[8]*We thank Dr. Herman Ziffer, National Institutes of Health, U.S. Public Health Service, for providing the optical rotatory dispersion data.*

223.5–225.5°). The formyl compound (V*a*) was acetylated (see III) and the product was recrystallized from methanol to yield 3.7 g (66%, m.p. 148–149.5°) of diacetate V*b*. Recrystallization from the same solvent gave pure crystals melting at 150.5–151.5°; $[\alpha]_D^{23}$ −21.4° (*c*, 1.27); $\nu_{max}^{CHCl_3}$ 1 770, 1 726, and 1 656 cm^{-1}.

Anal. Found: C, 71.48; H, 8.67. $C_{24}H_{34}O_5$ requires C, 71.61; H, 8.51.

THE SYNTHESIS OF SUBSTITUTED BIURETS[1]

H. STOLLAR, R. J. RANZ, AND FRANCIS L. CHUBB

In a previous communication (1) the synthesis and pharmacology of some 1-substituted biurets were described. We now report the synthesis of a new series of mono- and poly-substituted biurets (Table I), some of which were synthesized by a novel method. This method, while being generally applicable to the synthesis of biurets, is particularly suitable for the synthesis of 1,5-disubstituted biurets.

Most of the biurets herein reported were synthesized by the reaction of nitrobiuret with a primary or secondary amine (2), or by the reaction of a 1,1-disubstituted-5-nitrobiuret (Table II) with a primary amine (3). However, there are no reports in the literature of this method having been used for the synthesis of 1,5-disubstituted biurets (4, 5). We found that the reaction of 1-methyl-5-nitrobiuret with phenethylamine gave very low yields of the required 1-methyl-5-phenethylbiuret.

The reaction of allophanic esters with amines has been used to prepare some 1,5-disubstituted biurets, but has been found to be of limited usefulness (4). When we attempted to prepare 1,5-disubstituted biurets by causing methyl-4-phenethylallophanate to react with various amines, we were successful only in the case of methylamine and benzylamine.

Another method which has been used for the synthesis of 1,5-disubstituted biurets is the condensation of an isocyanate with an O-alkyl-N-substituted isourea to yield an isobiuret,

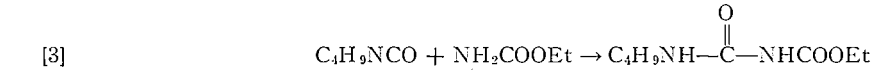
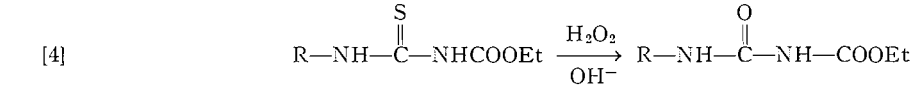
*These rather unstable compounds were used in the next step without further purification or analysis.



which was then hydrolyzed to the biuret (4). This method necessitates the synthesis of both the required isocyanates and isoureas, and the reported yields were low.



Lipschitz (6) has reported biuret to be the only product of the reaction of allophanyl azide with ammonia. We have found that 4-substituted allophanyl azides react smoothly with primary amines to yield 1,5-disubstituted biurets. In general, allophanyl azide or 4-substituted allophanyl azides react with primary or secondary amines to give high yields of the corresponding substituted biurets.

[1] 

Key intermediates required for the preparation of allophanyl azides were the corresponding allophanic esters (Table III). Three different methods of synthesis were investigated. The most convenient and generally applicable synthesis was the base-catalyzed condensation of diethyl carbonate with the appropriate substituted urea (eq. [2]) according to the procedure of a German patent (7). Ethyl 4-*n*-butylcarbamate was synthesized by the reaction of butyl isocyanate with ethyl carbamate (eq. [3]), but this method was not found to be generally applicable. A third method investigated was the oxidative desulfurization of 4-substituted-3-thioallophanic esters. Dixon and Taylor (8) reported that methyl 4,4-diphenyl-3-thioallophanate was resistant to heavy metal desulfurization. We have found that oxidative desulfurization of 4-substituted-3-thioallophanates by hydrogen peroxide (eq. [4]) worked in the case of the 4-*n*-butyl and 4-*n*-propyl derivatives, but we did not investigate the method any further since it was not as convenient as the ethyl carbonate method.

[2] 

[3] 

[4] 

The allophanic esters were then converted into hydrazides (Table IV), which were in

Melting points are uncorrected. Microanalyses were carried out by C. Daessle, 5757 Decelles, Montreal.

4-Substituted Allophanic Esters

The synthesis of ethyl 4-*n*-butylallophanate by the three methods used is given by way of illustration.

Ethyl 4-n-Butylallophanate

Procedure A.—N-Butylurea (7.3 g, 0.046 mole) and diethyl carbonate (5.9 ml, 0.048 mole) were added to a solution of 1.05 g (0.046 mole) sodium in 25 ml of absolute alcohol. After the solution was refluxed for 45 min it was evaporated to near dryness. The residue was dissolved in water and the aqueous solution was acidified with acetic acid, causing an oil to separate which soon solidified. The precipitate was filtered, and when water was added to the filtrate a second crop of product was obtained. The total yield of crude product was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

5.2 g (77%), m.p. 54–60°. Recrystallization from *n*-hexane yielded a product, m.p. 60–61°, whose infrared spectrum was identical with that of the analytical sample.

Procedure B.—A mixture of 89 g (1 mole) of ethyl carbamate, 99 g (1 mole) of *n*-butyl isocyanate, and 5 drops of triethylamine was heated on the steam cone overnight. The cooled solid residue was recrystallized twice from *n*-hexane to yield 103 g (54%) of ethyl 4-*n*-butylallophanate, m.p. 55–61°. Repeated recrystallization from *n*-hexane gave the analytical sample, m.p. 61°; ν_{max}^{Nujol} 3 330, 1 730, and 1 710 cm^{-1}.

Procedure C.—To a mixture of ethyl 4-*n*-butyl-3-thioallophanate (3 g, 0.015 mole) prepared according to the procedure of Elmore and Ogle (9), 5 ml of concentrated ammonia, and 50 ml of alcohol in a three-necked flask was added 7 ml of 30% hydrogen peroxide at such a rate that the temperature was prevented from rising above 30°. After the mixture was stirred for 2 h it was made acidic with hydrochloric acid. When the solution was concentrated and cooled 1.2 g of crude product was obtained. One recrystallization from alcohol yielded 0.95 g (33.5%) of ethyl-4-*n*-butylallophanate, m.p. 57–60°, whose infrared spectrum was identical with that of the analytical sample.

Allophanyl Hydrazides

The 4-substituted allophanyl hydrazides (Table IV) were prepared according to the procedure of Audrieth and Gordon (10). Analytical samples were prepared by careful recrystallization from low-boiling solvents such as methanol–water or methylene chloride – hexane.

Allophanyl Azides

The 4-substituted allophanyl azides (Table V) were prepared according to the procedure of Audrieth and Gordon (10).

Substituted Biurets

1-Benzyl-5-n-propylbiuret (Azide Method)

A mixture of 10.7 g (0.1 mole) of benzylamine and 17.1 g (0.1 mole) of 4-*n*-propylallophanyl azide in 150 ml of benzene was stirred for 30 min at room temperature. The mixture was then heated to reflux on the steam cone. After evaporation of the solvent under reduced pressure the residue was recrystallized from water–alcohol to yield 20.2 g (86%) of 1-benzyl-5-*n*-propylbiuret, m.p. 85–87°.

Nitrobiuret Method

These biurets were prepared by the reaction of amines with nitrobiuret or a 1,1-disubstituted-5-nitrobiuret according to the procedure of Davis and Blanchard (2) as modified by Dunnigan and Close (11).

1-Methyl-5-phenethylbiuret (Allophanic Ester Method)

Methyl 4-phenethylallophanate (5 g, 0.0225 mole) was heated with an excess of anhydrous methylamine at 120–125° for 3 h in a Parr pressure reaction apparatus. After the solution was cooled, the excess amine was evaporated and the residue was recrystallized from methanol–water to yield 3.0 g (60%) of 1-methyl-5-phenethylbiuret, m.p. 105–110°.

Two recrystallizations from methanol–water gave the analytical sample, m.p. 119.5–120.5°.

1,1-Disubstituted-5-nitrobiurets

These derivatives (Table II) were prepared according to the procedure of Davis and Constan (3).

ELECTRICAL PROPERTIES AND STRUCTURES OF SOLID AND LIQUID GeS, SnS, AND PbS[1]

G. HANDFIELD, M. D'AMBOISE, AND M. BOURGON

Department of Chemistry, Université de Montréal, Montreal, Quebec

Received November 2, 1965

ABSTRACT

The electrical conductivity of germanium(II) sulfide in the liquid state has been measured with a capillary-type cell. Both a-c. and d-c. methods were used. The conductivity of liquid GeS increases regularly with temperature from 1.33 Ω^{-1} cm^{-1} at 664 °C to 2.52 Ω^{-1} cm^{-1} at 705 °C. The experimental facts lead to the conclusion that GeS remains a semiconductor in the liquid state with a conduction band situated at 2.5 eV above the valence band.

The energy gaps of GeS, SnS, and PbS in the solid state are compared with those of the corresponding liquids. It is concluded that these sulfides, in the liquid state, have structures very similar to that of the solids. Liquid PbS has a structure somewhat similar to that of metals. In the case of SnS and GeS, heating and melting are accompanied by a gradual loosening of the double layers which constitute the crystals. Accumulated evidence indicates that the molecular character of SnS and GeS is increased on going from the solid to the liquid state.

INTRODUCTION

Work done in recent years (1–3) has established beyond any doubt that semiconduction can be a property of liquids and glasses as well as of solids. This experimental evidence has led to the view that the existence of energy bands is to be considered as a general property of substances in a condensed state, the structure of the bands and the width of the forbidden energy gaps being determined by the short-range order (1, 4, 5). By short-range order is meant the relative disposition around an atom of its nearest neighbors and the nature of the chemical bonds between these atoms.

It should thus be possible to obtain information, qualitative at least, about the structural changes which a solid undergoes on melting by a study of the electrical properties of substances in both the solid and liquid states. That this is the case has been shown by Ioffe and Regel (1) and other workers.

The present paper reports on the electrical properties of germanium(II) sulfide GeS in the liquid state and from this, and other available data, attempts to establish a correlation between the structures of the sulfides of the fourth group elements GeS, SnS, PbS in the solid state and their structures in the liquid state.

EXPERIMENTAL

Preparation of GeS

Three methods of preparation of GeS were investigated: precipitation from aqueous solutions of $GeCl_2$ by H_2S, high temperature reaction between GeO_2 and H_2—H_2S mixtures, and high temperature synthesis from the elements. The first method proved to be tedious and gave a product of doubtful purity. Although good crystals were obtained by the second method, the third method was finally adopted because of its convenience and simplicity. Quantitative yields were also obtained by this method.

[1]*This paper was presented in part at the 48th Annual Conference, Chemical Institute of Canada, Montreal, Quebec, June 1965.*

The germanium was obtained in powder form by hydrogen reduction of high purity GeO_2 (Sylvania Corporation). Sublimed sulfur was used. The elements reacted in Pyrex vials at 375–410 °C under vacuum. Spectrographic analysis of the final product showed traces of silicon as the only contaminant. Repeated vacuum sublimation of the sulfide eliminated this impurity.

Germanium(II) sulfide obtained under the above conditions has a metallic appearance (the powder is black), cleaves very easily to give very thin red crystals, and melts at 665 °C. X-ray powder patterns of the sublimed product were taken (114.8 mm camera, Cu radiation, Ni filter); these were strictly identical with the known X-ray powder pattern of GeS (6). Chemical analyses of the product were performed to determine possible deviations from stoichiometric proportions. This proved to be impossible. The deviations, if any, are within the experimental errors of the analytical methods.

The Conductivity Cell

The cell used for measuring the electrical conductivity was a four-terminal capillary-type cell and is shown in Fig. 1. Because of the high vapor pressure of liquid GeS, a closed cell must be used. It is made entirely of Vycor tubing. Contacts to the melt are made by means of machined high purity (AUC grade National Graphite) graphite plugs fitted into female standard joints. Necessary connections to the graphite are made by means of chromel wires held in the bottom of the wells by copper sleeves. The potential probe wires and the current wires are protected by double-bore insulated sheathing. Since preliminary measurements had shown that the resistance of GeS is rather high and since the resistance of graphite is quite low in comparison, the depth of the wells is not critical. The capillary bore is 1 mm and its length is approximately $1\frac{1}{4}$ in.

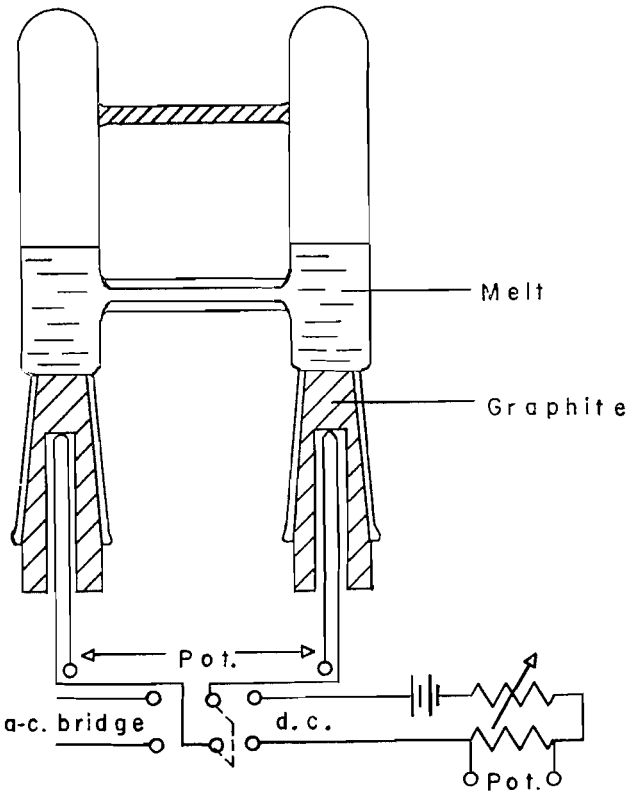

FIG. 1. Cell used for measuring the specific conductivity of GeS in the liquid state.

The cell was enclosed in a steel casing connected to ground and surmounted by steel radiation shields. Temperature measurements were made with uncalibrated chromel–alumel thermocouples suitably protected and located at a distance of 1 in. from the cell. The whole assembly was enclosed in a 4 in. × 1/2 in. × 30 in. gas-tight Rotosil fused silica tubing closed at one end and fitted at the other end with a cooling head. This head allowed passage of the necessary electrical connections and also permitted the introduction of special atmospheres in the furnace tube or the evacuation of the latter. This tube was heated by a Globar furnace

For personal use only.

controlled by a Celectray Indicating Potentiometer Controller. The constant temperature section of the furnace was approximately 8 in. long. The maximum temperature drift in the constant temperature section of the furnace was ±0.5 °C per day. The furnace was mounted on rockers to provide thorough mixing of the sample.

The cells were calibrated at 25 °C by mercury and d-c. methods. The resistance of the graphite proved to be significant; for this reason the graphite plugs were replaced, for calibration purposes, by rubber stoppers through which copper wires were inserted. These calibrations were checked by further calibrations with KCl solutions, H_2SO_4 (30.4%) solutions, and a-c. methods. In the last case, the rubber stoppers were covered with a layer of mercury which in turn was covered with the solution used for calibration. All these measurements agreed extremely well. A typical value of the cell constant is 215 ± 0.5 cm^{-1}.

Resistance Measurements

To detect polarization effects in the cell, both d-c. and a-c. measurements were made. With the d-c. method, potential drops were measured across the potential probes of the cell, and across a precision resistor (Guildline Multiple Standard Resistor type 9200) in series with the cell, with a high precision potentiometer (Honeywell 2781). By this method the lead resistances are eliminated. The a-c. measurements were made by means of an a-c. bridge (10 to 20 000 c.p.s.) provided with an amplifier and an oscillograph as detector. The resistance of the leads was duly accounted for. All measurements were made under a purified helium atmosphere.

RESULTS

The results are shown graphically in Fig. 2, where the natural log of the specific conductivity is plotted against the inverse of the absolute temperature. The following experimental details are pertinent:

(*a*) No polarization effects could be detected; a-c. measurements (400 to 1 000 c.p.s.) and d-c. measurements agreed very well. For this reason, a-c. measurements were discontinued after some time and the reported results are those obtained from d-c. measurements.

(*b*) After each d-c. measurement, the polarity was reversed and the reading repeated to detect possible thermoelectric effects. The maximum difference observed between two such measurements was 0.2 Ω (out of a total of approximately 100 Ω), which gives a negligible error in the value of the specific conductivity.

(*c*) At the start of a run, after the sulfide had melted, it took several days for equilibrium to be attained. No final readings were taken until consecutive measurements, made after repeated mixing of the sample, gave identical results. After the initial equilibration period, the technique of measurement adopted was to increase the temperature to a given value and make repeated measurements until reproducibility of the readings indicated that thermal equilibrium had been established. The temperature was periodically lowered during the measurements and other readings taken to insure that the melt had undergone no change, decomposition or otherwise, during the heating. No such change could be detected and the measurements were quite reproducible.

(*d*) The cells often broke during the measurements; this was caused by the expansion of the graphite plugs. The results reported in this paper are those obtained during a good run where no breakage was experienced. Although a second complete run could not be achieved, sufficient results were obtained to insure that the reported data are reliable. The maximum error in the absolute values of the conductivity is believed to be 1.5%; this error is mainly due to the uncalibrated chromel–alumel thermocouples.

The specific conductivity of liquid GeS as determined in this work follows the exponential law:

$$\sigma = A \exp(-E/RT).$$

The absence of polarization effects in the melt, the exponential dependance of the conductivity on the temperature, and the positive temperature coefficient of conductivity

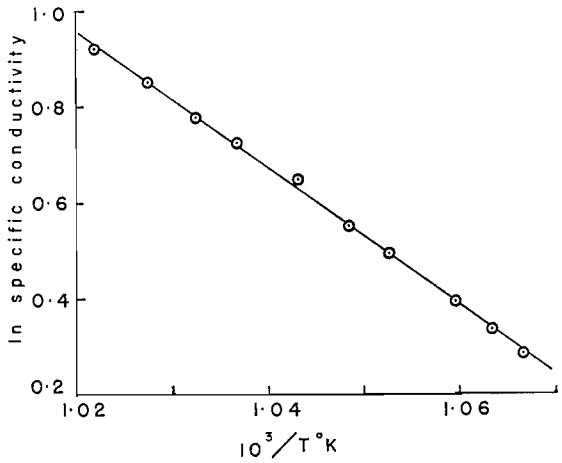

FIG. 2. Specific conductivity of liquid GeS as a function of temperature.

allow the conclusion that GeS remains a semiconductor in the liquid state in the temperature range considered. This is to be expected since other sulfides of the fourth group elements, SnS and PbS, have been reported to be a semiconductor and a metallic conductor respectively in the liquid state.

If a hole-electron equilibrium is assumed in the GeS melt, the above expression takes the form

$$\sigma = A \exp(-E_g/2RT),$$

where the value of E_g, the width of the energy gap for intrinsic conduction, has been calculated from the slope of the curve in Fig. 2 to be 2.47 $\pm$ 0.05 eV.

The only other reported values of the specific conductivity of liquid GeS are those of Velikanov (7) who found 0.02, 0.05, and 0.1 Ω^{-1} cm^{-1} at 600, 700, and 800 °C. The author states, however, that "these values are to be considered as very approximate".

DISCUSSION

The electrical conductivity of liquid SnS has been studied by Bourgon and Boutin (8) and also by Velikanov (7). The former authors reported specific conductivity values of 24 to 33.4 Ω^{-1} cm^{-1} in the temperature range 895–937 °C. From these results the value of the forbidden energy gap is calculated to be 1.7 eV. They also observed the partial dissociation of SnS at approximately 938 °C and for this reason did not extend their measurements beyond this temperature. Velikanov reports specific conductivity values of 19 to 54.6 Ω^{-1} cm^{-1} in the temperature range 885 to 1 138 °C. Examination of his results shows that there is a change in the slope of the (log σ vs. $1/T$) curve at approximately 950 °C which would seem to confirm the dissociation mentioned above. This change of slope corresponds to a decrease in the calculated energy gap from 1.3 to 1.05 eV. This decrease is consistent with a more metallic nature due to an excess of metal in the melt. Since it is believed that the work of Bourgon and Boutin was performed under more rigorous conditions, more weight is given to their value of the energy gap and the latter can be taken to be 1.7 eV in the temperature range close to the melting point.

Velikanov (7) also studied the electrical conductivity of liquid PbS. The data show that the conductivity decreases steadily from a maximum of approximately 110 Ω^{-1} cm^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in the vicinity of the melting point to 97 Ω^{-1} cm^{-1} at 1 200 °C. The negative temperature coefficient of conductivity is interpreted by the author as being indicative of metallic conduction. The value of the conductivity, however, is several orders of magnitude lower than the value typical of metals. It is quite possible therefore that PbS remains a semiconductor in the liquid state, the energy gap being very small, i.e. close to zero.

TABLE I

Energy gaps (eV) of GeS, SnS, and PbS in the solid and liquid states

	E_g(solid)				E_g(liquid)	
	Optical	References	Thermal	References	Thermal	References
GeS	1.8	(9, 11)	1.5	(9, 10)	2.47	This paper
SnS	1.1	(13)	1.2	(12)	1.7	(7, 8)
PbS	0.22	(22)	0.37	(14)	0	(7)

The energy gaps of liquid GeS, SnS, and PbS are compared in Table I with the energy gaps for intrinsic conduction of the corresponding solids. The onset of intrinsic conductivity in these solids takes place at temperatures below 300 °C and, in general, the conductivity has not been studied at temperatures greater than 500 °C except in the case of SnS (12).

Mooser and Pearson (4) have pointed out the trend in the energy gaps of the group V elements As, Sb, and Bi where the atoms are arranged in double layers (Strukturbericht A7) each atom having three nearest neighbors in its own double layer and three next nearest neighbors in the adjacent double layer. As the atomic number increases the distance between the different double layers decreases in such a way that the ratio of the distances between the nearest and next nearest neighbors approaches unity. At the same time the bond angles approach 90°. The limiting case in which the ratio of the bond lengths is 1 and the bond angles are 90° correspond to a NaCl type of structure. Thus, strong interaction between the layers leads to a metallic-type conductivity (Bi is metallic, Sb is either a metal or a semiconductor with a low energy gap), whereas weak interaction increases the molecular character (As is a semiconductor).

A similar situation prevails among the group VI elements Se, Te, and Po. Selenium and tellurium have chain structures (Strukturbericht A8) in which the ratio of the bond length inside the chains to the bond length between the chains increases from Se to Te; this increase is accompanied by a decrease of the energy gaps from 1.6 to 0.34 eV. Polonium is a metal and crystallizes with a coordination number of 6. When selenium melts the resistance increases (1, 15) as the energy gap increases to 2.31 eV. This has been interpreted as corresponding to a loosening of the bonds between the chains, this loosening having the effect of increasing the bond strength inside the chains and thus increasing the energy gap. The fact that selenium easily forms a glass on rapid cooling is consistent with the presence of a chain structure in the melt. Liquid tellurium has a chain structure (1, 16) near the melting point but the chains are destroyed on further heating to give a metallic melt. The process of fusion, in this case, is accompanied by a sudden rise in the conductivity.

The behavior of the solid sulfides GeS, SnS, and PbS is quite similar to that of the above substances. It is to be expected that the structures of these group IV–VI compounds will be related to the structures of the group V elements. This is indeed the case. PbS crystallizes in the NaCl arrangement, whereas GeS and SnS have layer-type structures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

(Strukturbericht B29) reminiscent of the structure of the group V elements. That the interaction between the double layers decreases steadily from PbS to GeS is shown by the fact that GeS cleaves much more easily than SnS or PbS in a direction perpendicular to the layers. This decrease in the interlayer binding is accompanied by an increase in the value of the energy gap (see Table I).

It is interesting to compare the energy gaps of the solid sulfides with those of the corresponding liquids to obtain information on the change of structure which accompanies melting. It may be argued that no such comparison can be made, since the energy gaps of the solids were determined in a temperature range quite lower than the melting point. Solid state transformations in the upper temperature range could lead to significant changes in the values of the energy gaps. This objection is quite valid, but we believe that a correlation can be established between the structures of the solids and those of the corresponding liquids by reasoning along the following lines.

Solid state transformations in the higher temperature region have been reported for GeS, SnS, and the related compound SnSe. Dembovskii *et al.* (17) have shown that SnSe suffers a transformation of the second order, the "λ" point being situated at 540 °C. This transformation is not accompanied by a phase change, but gives rise to an anomalous Hall resistance. In the same manner, Orr and Christensen (18) have detected a minor transformation in SnS at 602 °C, while studying the heat content – temperature curve of this compound. The anomalous Hall effect reported for SnS (13) at high temperature is probably related to this change. Examination of the recently reported phase diagram of the Ge—S system (19) reveals a solid state transformation at 590 °C. In view of the fact that GeS, SnS, and SnSe are isostructural it has been suggested (17, 19) that the observed transformations are all of the second order. No such change, to our knowledge, has been reported for PbS or the related compounds PbSe and PbTe (20).

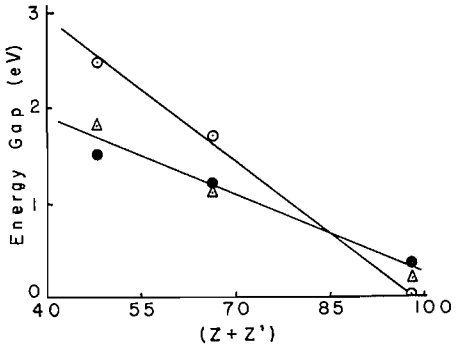

FIG. 3. Energy gap as a function of the sum of the atomic numbers of the elements in GeS, SnS, and PbS. (●) Solid (thermal), (△) solid (optical), (○) liquid.

Examination of the data in Table I reveals clearly that the energy gaps of the liquid sulfides increase regularly in a manner similar to that of the solid sulfides. The close similarity between the two trends is indicated further in Fig. 3 where the values of the energy gaps of the solids and the liquids are plotted as a function of $(Z + Z')$, the sum of the atomic numbers of sulfur and the metal in a given sulfide ($Z = 16$ is merely an additive constant for sulfides, but $Z + Z'$ is used in order to conform to usage). The value $(Z + Z')$ was chosen for comparison since this parameter has been used by some authors

(21) as a measure of the polarity of bonds and appears, together with electronegativity data, in empirical equations used for calculating values of energy gaps of solid semiconductors.

The fact that the liquid sulfides are semiconductors indicates that there must be one, two, or three dimensional continuity in the melts. This fact and the experimental evidence given above indicate that there is no essential difference between the structures of the solid sulfides and those of the corresponding liquids in the temperature range considered. In the case of PbS, all bonds are equivalent and the lower energy gap of the liquid is due to a more "chaotic" type of short-range order. In the case of SnS and GeS the transition to the liquid state is accompanied by a gradual loosening of the double layers. This loosening of the layers may well begin in the solids and is perhaps related to the minor transformations mentioned above. The absence of such transformations in PbS corroborates this view. There is probably some interaction between the layers in liquid SnS, whereas in GeS this interaction is much weaker. This conclusion is based on the high value of the energy gap of liquid GeS and on the following experimental facts.

Goryunova and Kolomiets (3) have examined the problem of vitrification in the sulfur-group compounds of phosphorus, arsenic, antimony, and bismuth. From this work, they concluded that a necessary condition for vitrification is the existence of covalent bonding in the material both in the solid state and also in the liquid state. If these covalent bonds become more metallic this would make vitrification more difficult, and if the process continued too far it would, in the limit, prevent vitrification altogether. It has been observed in our laboratory that GeS can form a reddish glass when quenched from the liquid state. To our knowledge, SnS and PbS have no glass-forming properties.

Examination of the phase diagrams of the Ge—S (19), Sn—S (20), and Pb—S (20) systems reveals that Pb and PbS show complete miscibility in the liquid state, whereas Sn and SnS show light miscibility and Ge and GeS show very light miscibility. This is to be expected if the molecular character of the melt increases from PbS to GeS. It is significant that the related compounds SnTe, PbSe, and PbTe which crystallize in the NaCl structure and give highly conducting melts show complete or high miscibility with the respective metals in the liquid state (20). SnSe on the other hand is isostructural with GeS and SnS and the phase diagram reveals light miscibility of Sn with SnSe (20).

Mention should be made finally of the change in conductivity on melting these sulfides. Accurate information on this point is difficult to obtain experimentally. It was nevertheless observed during the course of this work that there is no sudden change in the value of the conductivity of GeS on freezing the melt. While Bourgon and Boutin (8) reported a slight increase in the value of the conductivity of SnS on melting, Anderson and Morton (12) observed no such change. According to these authors there is no discontinuity in the conductivity on going from the solid to the liquid state. These facts give support to the suggestion that there is very little change on melting.

THE INHIBITED AUTOXIDATION OF STYRENE

PART V. THE KINETICS AND DEUTERIUM ISOTOPE EFFECT FOR INHIBITION BY DIPHENYLAMINE, PHENYL-α-NAPHTHYLAMINE, AND PHENYL-β-NAPHTHYLAMINE[1]

I. T. BROWNLIE[2] AND K. U. INGOLD

Received November 10, 1965

ABSTRACT

The thermal oxidation of styrene inhibited by diphenylamine, phenyl-α-naphthylamine, and phenyl-β-naphthylamine has been examined. It has been shown that the autocatalysis of the diphenylamine- and phenyl-β-naphthylamine-inhibited oxidations is probably due to a reaction between the inhibitor radical and the hydroperoxide formed in the primary step of inhibition. This reaction is too slow to produce significant autocatalysis with phenyl-α-naphthylamine under the present experimental conditions.

The primary inhibition reaction involves abstraction of the amino hydrogen since its replacement by deuterium leads to a fairly large kinetic isotope effect ($k_H/k_D \sim 3$–4).

INTRODUCTION

The previous papers in this series (1) have shown that the kinetics for the inhibition of the autoxidation of styrene by phenols can be described by the following simplified reaction scheme

[1] $$I_2 \rightarrow 2I\cdot$$

[2] $$R\cdot\ (I\cdot) + O_2 \rightarrow RO_2\cdot$$

[3] $$RO_2\cdot + RH \rightarrow ROOR\cdot H$$

[5] $$RO_2\cdot + RO_2\cdot \rightarrow \text{Inactive products}$$

[6] $$RO_2\cdot + AH \rightarrow ROOH + A\cdot$$

[7] $$RO_2\cdot + A\cdot \rightarrow \text{Inactive products}$$

where I_2 represents α,α′-azo-bis-isobutyronitrile (AIBN) which was used to initiate the oxidations, RH represents the styrene, and AH the phenolic inhibitor. The chain-breaking step of inhibition, reaction [6], undoubtedly involves abstraction of the phenolic hydrogen since the overall reaction exhibits a large kinetic isotope effect ($(k_6)_{AH}/(k_6)_{AD} \sim 10$). More complicated kinetics are observed with non-hindered phenols in tetralin and in other hydrocarbons which yield a hydroperoxide rather than a polyperoxide as the main oxidation product (2–4). The complications arise mainly from the reversibility of reaction [6] (2, 4).

[−6] $$A\cdot + ROOH \rightarrow AH + RO_2\cdot$$

In addition, A· may abstract a hydrogen atom from the hydrocarbon (3) and, with certain

[8] $$A\cdot + RH \rightarrow AH + R\cdot$$

phenols, chain termination is apparently due to the coupling of phenoxy radicals (4).

[9] $$A\cdot + A\cdot \rightarrow \text{Inactive products}$$

Although these additional reactions complicate the overall kinetics of inhibition they do not disguise the fact that reaction [6] has a large deuterium isotope effect (4).

The inhibition of autoxidation by phenols can now be said to be fairly well understood, but the situation with regard to inhibition by substituted anilines is still in an extremely confused state. In the liquid phase, most workers have reported that there was no

For personal use only.

deuterium isotope effect for inhibition (5–8) or, at best, only a very small one ~1.0–1.3 (9, 10). In contrast, Shelton and co-workers have shown that in the solid phase (styrene–butadiene polymer (11, 12) and a highly purified *cis*-1,4-polyisoprene (13)) quite significant isotope effects (up to 2.1) are readily observed. Boozer and Hammond, who first reported the absence of an isotope effect, observed that the rate of oxidation of tetralin inhibited by *N*-methylaniline (or phenol) was proportional to $[I_2]^{\frac{1}{2}}/[AH]^{\frac{1}{2}}$ (6). This was attributed to the reversible formation of a complex between AH and a peroxy radical, the complex then reacting with a second peroxy radical to give inactive products. Although a good deal of subsequent work has been interpreted on the basis of this mechanism, the half-order kinetics are in fact much more readily explained by the chain transfer reactions [−6] and [8] (2–4, 14). In this connection, Bickel and Kooyman (15) have shown that both aniline and *N*-methylaniline readily undergo reaction [8] with 9,10-dihydroanthracene at 60°. However, this reaction is much slower or does not occur with *N*-phenyl-α- and -β-naphthylamines and for these two compounds the inhibited rate is proportional to $[I_2]/[AH]$ (15).

Probably the most important development in recent years towards our understanding of the overall inhibition process with amines was the discovery by Thomas and co-workers (16–18, see also ref. 19) that stable diaryl nitric oxide radicals are produced in fairly high concentrations during inhibition with diaryl amines, i.e.,

$$[10] \qquad A\cdot + RO_2\cdot \rightarrow AO\cdot + RO\cdot$$

The nitric oxide radical stops about half as many chains as the parent amine (8). Thomas and Tolman interpreted the results of their very thorough study of the diphenylamine and diphenyl nitric oxide inhibited oxidation of cumene (8) in terms of peroxy radical – inhibitor complex formation (5, 6) since the importance of reaction [−6] was not appreciated at that time. However, later attempts by Thomas to observe such complexes directly in electron spin resonance studies of cumene oxidizing in the presence of pyridine, triphenylamine, and trialkyl amines were unsuccessful (20) and can be interpreted as throwing a very considerable doubt on the existence of peroxy radical – amine complexes.

The kinetics of the inhibition of the oxidation of styrene and tetralin by 2,4,6-tri-*t*-butylaniline has been described in a recent paper from this laboratory (21). In contrast to a similarly hindered phenol this aniline appears to undergo extensive chain transfer with styrene and with tetralin hydroperoxide so that the inhibited rate has a non-integral dependence on the $[I_2]$ and [AH] concentrations. There is a pronounced deuterium isotope effect in both substrates ($k_H/k_D \geqslant 3.0$). Since this aniline is hardly a representative amine inhibitor, we decided to examine diphenylamine (DPA), *N*-phenyl-α-naphthylamine (PAN), and *N*-phenyl-β-naphthylamine (PBN) as typical inhibitors which have been studied extensively by previous workers. Styrene was chosen as the oxidizing substrate so as to prevent or at least reduce reaction [−6]. While this work was in progress, a paper by MacLachlan was published (22) which described the reaction of diphenylamine, *N*-methylaniline, and *N*,*N*′-diphenyl-*p*-phenylenediamine with the peroxy radicals formed during the pulse radiolysis of cyclohexane and ethanol. The rate of reaction was estimated from the rate of formation of a colored product which, in the case of the phenylenediamine, was shown to be the corresponding quinodiimine as would be expected (cf. 23). The colored products from the other two amines were not identified. Although this technique is obviously of great value in providing data on the overall process of inhibition, it is a rather indirect method of studying reaction [6] since the kinetics of color formation may be only indirectly connected with the rate of this reaction. As a case in point, a deuterium isotope effect of about 3.0 was found with the phenylenediamine but none was found with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

diphenylamine. However, the diphenylamine would be expected to form its nitric oxide radical rapidly at the high peroxy radical concentrations produced by pulse radiolysis ($\sim 4 \times 10^{-4}$ *M*) and an isotope effect would not necessarily be observed if the rate of color formation was connected with the subsequent destruction of this radical. The observation of a deuterium isotope effect of about 3.0 with diphenylamine in the present work (see below) provides a much more logical picture of the inhibition process than one in which the isotope effect could vary from 0 to 3 for what is after all a very minor change in the structure of the inhibitor.

EXPERIMENTAL

The apparatus and general experimental technique have been described previously (1). In the present work it was frequently necessary to measure rather small initial oxidation rates. A solution of AIBN in purified *o*-dichlorobenzene was added to a thin-walled glass bucket (maximum capacity 3 ml). This bucket was hung above the reaction vessel which contained the styrene (up to 100 ml) and diphenylamine. The suspension for the bucket could be manipulated through a ground glass joint from outside the reaction vessel system in such a way as to drop the bucket into the styrene after thermal equilibrium was achieved. The bottom of the bucket broke on contact, so that the AIBN was rapidly and thoroughly mixed with the warmed styrene and true initial oxidation rates could be quite readily obtained. In general, the styrene concentration was 7.24 mole/l, i.e., 5:1 styrene:*o*-dichlorobenzene.

The inhibited rates did not normally depend on the oxygen pressure (75–750 mm) and low rates were therefore usually measured at low pressures. However, at AIBN concentrations below about 5×10^{-4} mole/l it was necessary to make allowance for the self-initiation process in which chains are started by a direct reaction of the styrene with oxygen, the rate of this reaction naturally depending on the oxygen pressure (24).

The DPA, PAN, and PBN were recrystallized from benzene–hexane and were further purified to completely colorless materials by zone-refining. This was done to eliminate impurities since these might be more efficient inhibitors which could perhaps affect initial oxidation rates at high inhibitor concentrations.

All the work reported in this paper was done at 65 °C and all oxidation rates have been corrected for nitrogen evolution and oxygen absorption by the initiator.

RESULTS AND DISCUSSION

Autocatalysis

The diphenylamine-inhibited oxidation of styrene has a quite pronounced autocatalysis. A typical oxygen absorption curve is shown in Fig. 1, curve 1 ($[I_2] = 4.33 \times 10^{-3}$ mole/l, $[AH] = 4.33 \times 10^{-3}$ mole/l). This autocatalysis is not due to consumption of the inhibitor

since a completely linear absorption of oxygen is observed for over 12 000 s when 2,6-di-*t*-butyl-4-methylphenol (a compound which gives simple inhibition kinetics in both styrene and tetralin (1, 4)) or phenyl-α-naphthylamine is used under identical conditions.[3] The autocatalysis observed in the phenol-inhibited oxidation of tetralin (2, 4) or cumene (2) has been shown to be due to the hydroperoxide formed in the oxidation, i.e., to reaction [−6]. A similar explanation seemed possible in the present instance since hydroperoxide will be formed both in reaction [6] and in some chain transfer reactions which are involved in the normal propagation sequence (24). If reaction [−6] occurs, the inhibited rate P should be proportional to the square root of the hydroperoxide concentration (2, 4), i.e.,

$$[I] \qquad P = \frac{ek_1k_3[RH][I_2]}{2k_6[AH]}\left\{1 + \left(1 + \frac{4k_6k_{-6}[AH][ROOH]}{ek_1k_7[I_2]}\right)^{1/2}\right\}$$

where e is the efficiency with which the AIBN initiates the oxidation.[4]

In agreement with this equation, the increase in the rate of a DPA-inhibited oxidation is found to be very roughly proportional to the square root of the amount of oxygen absorbed. This autocatalysis is not due to styrene polyperoxide since the addition of 0.2 mole/l of highly purified $[C_8H_8O_2]_n$ had very little effect on the rate of oxidation under the experimental conditions of curve 1, Fig. 1. However, the addition of tetralin hydroperoxide had a very pronounced effect on the rate and, moreover, the rate showed the expected half-order dependence on the hydroperoxide concentration (see Fig. 2). In this figure the rates at the higher hydroperoxide concentrations have been corrected to allow for chain initiation by the hydroperoxide itself (25, 26). At this temperature AIBN is about 55 times more efficient than tetralin hydroperoxide as an initiator.

Further confirmation that the autocatalysis is due to the hydroperoxide which is formed during the inhibited oxidation is provided by comparison of the measured and calculated rates after 12 000 s for curve 1, Fig. 1. Provided most of the hydroperoxide is formed in reaction [6] (which is then followed by reaction [7] or other chain-terminating steps in which hydroperoxide is not formed) then the amount of hydroperoxide produced in a given time, t, should equal half the number of reaction chains started in that time, i.e.,

$$[ROOH]_t = ek_1[I_2]t.$$

At 12 000 s, therefore,

$$[ROOH] = 0.65 \times 1.8 \times 10^{-5} \times 4.33 \times 10^{-3} \times 12\,000 = 7.2 \times 10^{-4} \text{ mole/l.}$$

If the hydroperoxide from styrene has the same effect on the rate as tetralin hydroperoxide then, from Fig. 2, this quantity of hydroperoxide should produce a rate of 1.8×10^{-6} mole/l s. This value is in perfect agreement with the measured rate at this time. This result implies that very little hydroperoxide is formed in the normal chain propagation sequence. This last conclusion is further borne out by the fact that under the experimental

[3]*Since a significant fraction of the initiator was consumed in 12 000 s, the linearity of the 2,6-di-t-butyl-4-methylphenol and PAN oxygen absorption curves implies that there is just sufficient autocatalysis to balance the loss of initiator.*

[4]*In view of the importance of reaction [10] it is possible that reaction [−6] is of less importance in determining the overall kinetics for diarylamines than for phenols. However, if reaction [10] is followed by:*

$$[-11] \qquad AO\cdot + ROOH \rightarrow AOH + RO_2\cdot$$

$$[11] \qquad RO_2\cdot + AOH \rightarrow AO\cdot + ROOH$$

then an equation that is formally similar to [I] will be obtained at long chain lengths. The referee has pointed out that in this case the k_{-6}/k_7 values given in Table I do not have quite the same meaning for the amines as for the phenols. On the other hand, if the nitric oxide radicals were mainly responsible for the autocatalysis it is difficult to see why the three amines studied in this work should show such different degrees of autocatalysis.

conditions of curve 1 ((initial rate = 7.65×10^{-7} mole/l s), pre-oxidation of the styrene with 0.25 mole/l O_2 before the addition of the diphenylamine increased the rate to only 2.3×10^{-6} mole/l s. This rate is equal to that obtained with 1.6×10^{-3} mole/l of tetralin hydroperoxide (see Fig. 2). It therefore seems likely that only $1.6 \times 10^{-3} \times 100/0.25 = 0.64\%$ of the absorbed oxygen formed hydroperoxide in the uninhibited reaction. The autocatalysis of the inhibited oxidation must arise mainly from the hydroperoxide formed in the primary inhibition process.

Since the unsubstituted phenoxy radical is known to react rapidly with hydroperoxide (2, 4) it seemed likely that phenol should also show autocatalytic behavior in styrene. Curve 4 in Fig. 1 shows that this is indeed the case although the degree of autocatalysis is rather less than for the amine under the same conditions, which probably accounts for our previous failure to observe this phenomenon (1). In Fig. 2 the phenol-inhibited rate is shown to be proportional to the square root of the added tetralin hydroperoxide concentration. The measured rate for curve 4 at 12 000 s is 4.4×10^{-6} mole/l s, in satisfactory agreement with a value of 5.0×10^{-6} mole/l s obtained from Fig. 2. Incidentally, the slope of the straight lines in this figure can be used to calculate k_{-6}/k_6k_7 (4). For phenol a value of 2.65×10^{-9} mole s/l is obtained. If k_6 is taken as 4.9×10^3 l/mole s for phenol in styrene at 65° (4), $k_{-6}/k_7 = 1.3 \times 10^{-5}$, which is rather smaller than the value of 5.15×10^{-5} obtained previously with tetralin hydroperoxide in tetralin at 65 °C (4). The lower value in styrene may be due to a decrease in k_{-6} resulting from increased hydrogen bonding between the hydroperoxide and the substrate, i.e., styrene forms stronger hydrogen bonds than aralkyl hydrocarbons with hydroxylic compounds (1). The lower extent of autocatalysis for phenol compared with diphenylamine at the same concentration may also perhaps be partly related to hydrogen bonding. That is, the more rapid oxidation with phenol will give more polyperoxide and this will tend to form strong hydrogen bonds with the hydroperoxide. For diphenylamine the results in Fig. 2 give $k_{-6}/k_6k_7 = 2.2 \times 10^{-10}$ mole s/l.

The oxygen absorption curves for the phenyl-β-naphthylamine inhibited reaction are less autocatalytic than those for DPA but more autocatalytic than those for phenol under the same conditions. The inhibited oxidation is accelerated by tetralin hydroperoxide and the rate has the expected dependence on the square root of the hydroperoxide concentration with $k_6/k_{-6}k_7 = 5.8 \times 10^{-11}$ mole s/l. Under the same experimental conditions as those used for DPA in Fig. 1, the initial PBN-inhibited rate is 3.0×10^{-7} mole/l s and the rate at 12 000 s is 6.5×10^{-7} mole/l s. The calculated rate at this time (based on a hydroperoxide concentration of 7.2×10^{-4} mole/l) is 7.3×10^{-7} mole/l s. Pre-oxidation of the styrene before the addition of the inhibitor indicated that about 0.7% of the absorbed oxygen was present as hydroperoxide.

Phenyl-α-naphthylamine was not noticeably autocatalytic under the usual experimental conditions. However, tetralin hydroperoxide did have a small accelerating effect on the inhibited reaction, k_{-6}/k_6k_7 having a value of 5.1×10^{-12} mole s/l.

Kinetics

The initial rate of the diphenylamine inhibited oxidation has been plotted in Fig. 3 as a function of the DPA concentration. At low initiator concentrations (1.3×10^{-4} mole/l) the rate is proportional to $[DPA]^{-1.0}$ but at a higher concentration (4.3×10^{-3} mole/l) this simple proportionality is only applicable to a rather limited range of DPA concentrations.[5] The decrease in order at low DPA concentrations can probably be ascribed to the

[5]*The rate over the entire DPA concentration range could be represented almost as well by a straight line of slope −0.7 as by the curve shown in Fig. 3.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

increasing importance of reaction [5] as a chain-ending process, i.e., the rate approaches a limiting value of 5×10^{-5} mole/l s as the DPA concentration approaches zero. A decrease in order at high DPA concentrations would arise if chain transfer with the styrene (reaction [8]) were important (2–4). In this case, the rate may approach a limit if chain termination occurs by reaction [9] (4) or, in theory at least (2), the rate may go through a minimum if reaction [−6] is important and chain termination occurs by reaction [7]. However, all the kinetic expressions which have so far been derived indicate that when the order in [AH] is between −1.0 and 0, then the order in $[I_2]$ will be between 1.0 and 0.5. This is not observed with diphenylamine, i.e., the rate is accurately proportional to $[I_2]^{1.0}$ over a wide range in the diphenylamine concentration (see Fig. 4). We are therefore inclined to ascribe the decrease in the kinetic order with increasing inhibitor concentration to non-ideal behavior of the diphenylamine at high concentrations, i.e., to a reduced activity coefficient for the DPA at high concentrations. However, the possibility that chain transfer contributes in a minor way to the observed behavior cannot be entirely ruled out. Moreover, there may be a contribution towards the low kinetic order from a direct chain-initiating reaction between amine and oxygen at high DPA concentrations (cf. 11–13, 27). However, such a process is probably not very important in our system since low rates were obtained in the absence of AIBN when high concentrations of DPA were added to the styrene.

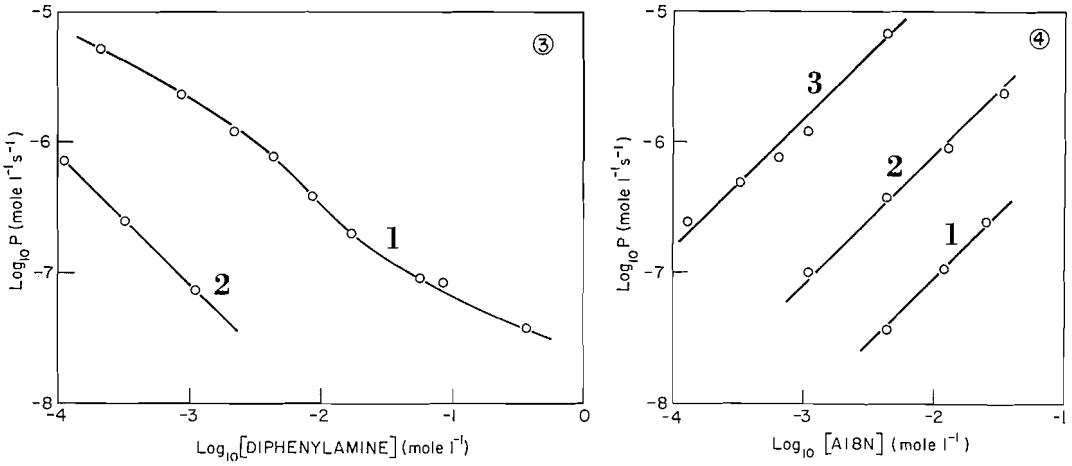

FIG. 3. Rate of oxidation of 7.24 *M* styrene initiated with AIBN as a function of the diphenylamine concentration. Curve 1, [AIBN] = 4.33×10^{-3} mole/l; 2, [AIBN] = 1.3×10^{-4} mole/l.

FIG. 4. Rate of oxidation of 7.24 *M* styrene inhibited with diphenylamine as a function of the AIBN concentration. Curve 1, 3.5×10^{-1}; 2, 8.66×10^{-3}; 3, 3.25×10^{-4} mole/l diphenylamine.

The diphenylamine-inhibited oxidation rate is first order in styrene from 7.24 to 0.72 mole/l. Under conditions where reaction [5] is completely suppressed, the overall kinetics can be represented by the simple equation (1, 4)

$$[II] \qquad P = \frac{ek_1[I_2]k_3[RH]}{k_6[AH]}$$

provided the DPA concentration is less than about 3×10^{-2} mole/l.[6] In the region where

[6]*Incidentally, the order in* [AH] *was reduced to about −0.7 by the addition of* 6×10^{-3} *mole/l of tetralin hydroperoxide. This can probably be attributed to a change from kinetics governed by eq. [II] to kinetics described by eq. [I]. It implies that the simple kinetics of eq. [II] would not be readily observed with DPA in a substrate which gave a hydroperoxide as its major oxidation product.*

this simple equation applies, the measured rates give $k_3/k_6 \approx 9.0 \times 10^{-3}$, from which $k_6 \approx 2.0 \times 10^4$ l mole^{-1} s^{-1} (taking $k_3 = 178$ l mole^{-1} s^{-1} for styrene at 65 °C (28)). This is much larger than the value of 3.3×10^2 l mole^{-1} s^{-1} at 65 °C obtained by Buchachenko *et al.* (10) for the reaction of DPA with the peroxy radicals from 2,4,6-trimethylheptane. The discrepancy may be due to the fact that trimethylheptyl peroxy radicals will be sterically more hindered than styryl peroxy radicals. In connection with our relatively high rate constant for inhibition (see Table I) it is perhaps worth pointing out that kinetic studies of the type described in this paper become more difficult as the inhibitor becomes more efficient. That is, it is necessary for a measurable amount of oxygen to be absorbed without any significant fraction of the inhibitor being used up. A very efficient inhibitor would suppress virtually all oxidation until it was completely consumed and so reaction kinetics could not be based on rates of oxygen absorption. Although this problem is not too critical for DPA in styrene, it would become important in a less readily oxidizable substrate, i.e., in a substrate for which k_3 was much smaller. The major experimental difficulty with DPA in styrene was the autocatalytic nature of the oxygen absorption curves. This necessitated the measurement of initial rates even when only a small fraction of the inhibitor was consumed during the experiment.

The kinetics described by eq. [II] seem to apply to phenyl-β-naphthylamine. That is, $P \propto [AH]^{-1.0}$ over a range from 5×10^{-4} to 2×10^{-2} mole/l PBN at AIBN concentrations of 1.3×10^{-2} and 4.3×10^{-3} mole/l. Similarly, $P \propto [I_2]^{1.0}$ over a range from 1×10^{-4} to 1×10^{-2} mole/l AIBN at a PBN concentration of 5×10^{-4} mole/l. The rate is also first order in styrene from 0.72 to 7.24 mole/l. The rate constant for inhibition is given by $k_6 = 5.0 \times 10^4$ l mole^{-1} s^{-1}. Equation [II] also applies to phenyl-α-naphthylamine over similar ranges in reactant concentrations. For this amine $k_6 = 7.0 \times 10^4$ l mole^{-1} s^{-1}.

Deuterium Isotope Effects

We have shown previously that deuterium isotope effects for reaction [6] are most easily measured by a comparison of the oxidation rates obtained with the system saturated with H_2O and with D_2O (1, 4, 21). The results of such experiments with diphenylamine as the inhibitor are shown in curves 2 and 3 in Fig. 1. The higher rate in the presence of D_2O implies that k_6 is smaller for $(C_6H_5)_2ND$ than for $(C_6H_5)_2NH$. Values of $(k_6)_H/(k_6)_D$ are given in Table I for the three amines studied in this work. Each value represents the average of at least four determinations at various initiator and inhibitor concentrations in the region where eq. [II] is valid. The isotope effect for diphenylamine contrasts with the results of MacLachlan (22) but, as was mentioned in the Introduction, the present result provides a much more logical picture of the inhibition process for amines.

The values found for k_6 are also included in Table I together with values for k_{-6}/k_7, which provides a measure of the susceptibility to autocatalysis by hydroperoxide of

oxidations inhibited by the three amines. The results suggest that simple first-order kinetics, eq. [II], are unlikely to be obtained with diphenylamine in any substrate in which hydroperoxide is the major oxidation product (see e.g. refs. 4–6, 8). In such a system, eq. [II] is most likely to be applicable to phenyl-α-naphthylamine (see e.g. ref. 15).

Phenols exhibit a considerably larger deuterium isotope effect in reaction [6] than is found with amines. This can probably be attributed to the fact that transfer of a hydrogen atom between two identical atoms should, in general, proceed through a transition state in which the zero-point energy of the hydrogen is lost (29). Under these conditions the isotope effect will tend to be a maximum (29). The slightly larger isotope effect found for PAN compared with the other two amines may result from some steric hindrance for hydrogen abstraction from this amine (30).

STUDIES ON HYDROGEN–OXYGEN SYSTEMS IN THE ELECTRIC DISCHARGE

I. THE REACTIONS OF HYDROGEN ATOMS WITH HYDROGEN PEROXIDE

NORISUKE HATA[1] AND PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec, Québec

Received September 2, 1965

ABSTRACT

Hydrogen gas partly dissociated in an electrodeless discharge was mixed downstream with hydrogen peroxide vapor at low pressure (0.1 mm Hg) in a liquid nitrogen trap. The reaction products condensed readily on the wall as a clear, yellowish glass resembling that from dissociated water vapor and other related systems. A manometric study of the warming-up process has revealed four distinct steps. The first two, in which only traces of gas are given off, look like the recombination of trapped free radicals. The major evolution of oxygen upon crystallization of the glassy deposit at 160 °K is ascribed to the decomposition of hydrogen peroxide under the influence of some unidentified species generated in the electric discharge through hydrogen. Experimental evidence for this is presented. In any case the stoichiometry cannot be reconciled with the formation of a metastable intermediate, such as the hypothetical polyoxide H_2O_4.

In the last step beginning around 215 °K more peroxide is decomposed during the eutectic melting of the solid. Qualitatively these phenomena are similar to those shown by the condensate from dissociated water vapor.

INTRODUCTION

Ever since the early investigations of Geib and Harteck (1) on the electric discharge through water vapor, considerable effort and ingenuity have been spent in attempting to elucidate the reaction occurring in this system and in other hydrogen–oxygen systems and in determining the nature of the solid products condensed therefrom; cf. ref. 2 for a review of the question up to 1961. Besides the usual techniques of chemical kinetics (3) and stoichiometry (4), a variety of physical methods have been applied to this problem, such as calorimetry (5), thermal analysis (6), magnetic susceptibility (7), electron spin resonance (8), molecular spectroscopy (4, 9), and X-ray (10) and electron diffraction (11). For all that, the situation is not completely understood, and some aspects of it, like the often postulated formation of hydrogen polyoxides (H_2O_3 and H_2O_4), are still controversial.

Previous claims for the synthesis of these hydrogen polyoxides have rested mainly on the evolution of gaseous oxygen that accompanies crystallization of the glassy condensate at 160 °K. This is particularly abundant in the system atomic hydrogen – liquid ozone (4, 12). We have suggested elsewhere (2) that the origin of this phenomenon is the decomposition of hydrogen peroxide present in the frozen condensate under the influence of some impurity introduced through the electric discharge. Accordingly, we suspected that the same effect could be reproduced, at least qualitatively, by trapping together hydrogen peroxide vapor at low pressure and a stream of hydrogen gas issuing from an electric discharge. Winkler and his co-workers (13) have shown that this same system at room temperature gives water and oxygen.

EXPERIMENTAL

The apparatus (Fig. 1) was basically the same as used before in producing deuterium peroxide (14). The inlet system was changed to take in a gas (hydrogen, Matheson, electrolytic grade) instead of a liquid (heavy water). A flowmeter, A, indicated the gas input, and the pressure was read on a mechanical manometer, B, "Molecular Vacuum Gage" (General Electric Model No. C-148 388). An aneroid manometer, C,

[1]*National Research Council Postdoctorate Fellow, 1962–1964.*

(Wallace and Tiernan, No. FA-141) served to follow the evolution of gas on warming. The effective "load" in the discharge was measured with a wattmeter in the output tank circuit of the r.f. generator. The useful range extended from a maximum of 500 W down to 300 W, at which point the discharge became unstable. A rough calibration of the wattmeter had already been made by visual comparison of the light intensity of a pair of 500 W electric bulbs, one of which was excited by the r.f. discharge. The efficiency of this type of discharge in dissociating water vapor has been discussed elsewhere (15). Since it was not essential for our purpose to know the concentration of hydrogen atoms in the discharged gas stream, no attempts were made to measure it. Here are a few relevant data (for the larger input, 26 mmoles H_2 h^{-1}): rate of flow, 75 cm s^{-1}; volume of gas put through, 1.1 l s^{-1} at the operating pressure of 0.1 mm Hg. Although the discharge was concentrated mainly inside the r.f. coil, the red glow of the Balmer lines extended all the way down the cold trap. No coating was used on the inner wall of the Pyrex discharge tube to avoid contamination of the peroxide.

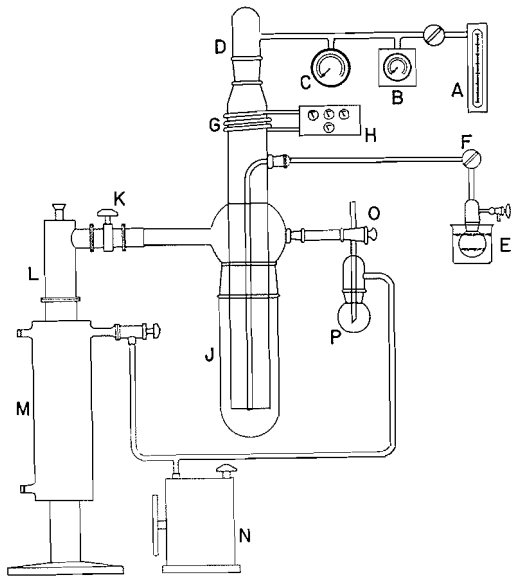

FIG. 1. Diagram of the electric discharge apparatus.

The sample of hydrogen peroxide 99.3% (Buffalo Electro-Chemical Co.) was thoroughly deaerated by repeated freezing and melting under vacuum. It was stored in a thermostated bulb, E, connected through a metering valve, F, with the inlet tube. The latter, 8 mm i.d., entered the large discharge tube laterally some 20 cm below the high-frequency coil, and terminated flush with the bottom of the discharge tube. Blank runs confirmed that the peroxide vapor in the inlet tube was in no way affected by the electric discharge. Likewise, blank runs *without the electric discharge* showed that the decomposition of hydrogen peroxide, by heterogeneous reactions through the whole series of operations, amounted to less than 5%. After a run (usually 4 h) the trapped material was isolated by closing the main valve, K, and the liquid nitrogen was removed from the Dewar flask. The temperature was measured with a tiny thermocouple, copper–constantan, cemented to the outer wall of the glass trap near the bottom. Because of the slow warming rate (0.6–0.7 deg min^{-1}), the readings must have followed closely the true temperature of the condensate except, perhaps, during the exothermic reaction at 160 °K. Once at room temperature the liquid products were distilled under reduced pressure into a small flask, P, for weighing and analysis of the peroxide content by refractive index measurement.

RESULTS

Preliminary tests indicated that it was possible to get a glassy deposit with this system provided the flow of peroxide vapor was small enough (less than 2 g h^{-1}), and was turned on only while the electric discharge in hydrogen was operating. Otherwise the peroxide froze in the inlet tube. In physical appearance this deposit was quite like that produced from dissociated water vapor and other similar systems; that is, a clear glass with a light yellow tint which was particularly noticeable at the bottom of the trap. Its behavior on warming is represented in Fig. 2 for a typical run (No. 5 in Table I). Four distinct

TABLE I

Experimental data for a few typical runs

Run No.	Electric power (W)	H_2 input (mmoles h^{-1})	H_2O_2 input (mmoles h^{-1})	Condensate				
				% H_2O_2	% wt. loss	H_2O_2 (mmoles h^{-1})	H_2O (mmoles h^{-1})	O_2 evolved (mmoles h^{-1})
1	300	26	9.5	89.7	6	8.1	1.7	0.01
2	350	26	14	76.5	17	9.0	5.1	0.03
3	400	26	18	57.5	23	7.8	10.9	0.05
4	400	26	52	61.0	25	23.5	28.5	0.37
5	400	2.7	48	65.7	23	24	23.5	0.42
6	500	2.7	6.5	16.4	42	0.6	6.0	~0.002
7	500	26	10.5	7.0	45	0.4	10.1	~0.001

steps are discernible. The first two correspond to very small pressure increases (note the change in pressure scale at arbitrary unit 1.0). About twice as much gas is released in step 1 (from 90 to 130 °K) as in step 2 (from 140 to 150°K). During the latter the yellow color gradually fades out. Essentially this is similar to what is observed in the dissociated water vapor system.

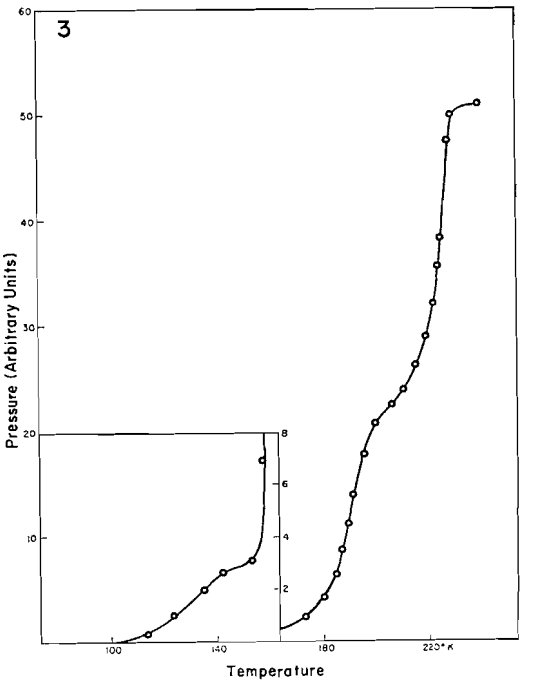

FIG. 2. Warming curve of the condensed products in the system hydrogen atoms – molecular peroxide.
FIG. 3. Warming curve of the condensate from dissociated water vapor (same pressure scale and about 80% as much condensate as in Fig. 2).

For the next step, however, the two systems differ somewhat. Although crystallization begins at the same point in both, namely 160 °K, the process is not so sharp in the case of dissociated water vapor (Fig. 3), and more oxygen, roughly three times, is evolved. Furthermore, only in the latter case does the gas have a strong ozone smell. Again in the last step quite a lot more oxygen is produced during melting of the deposit from dissociated water, and the phenomenon begins at 200 °K, some 20° lower than in the present system. The final products in both cases are rather unstable, as evidenced by streams of oxygen bubbles, even after one distillation.

Table I summarizes the most significant data for a few typical runs, in which the input of both reagents as well as the electric power were varied. The following relationships may be noted.

(*a*) The fraction of input peroxide lost as non-condensible products varies linearly with the power dissipated in the discharge (Fig. 4).

(*b*) The amounts of peroxide decomposed and of water produced (Fig. 5) increase both with the input of hydrogen atoms (runs 1–3) and that of peroxide (runs 3–4).

(*c*) The amount of oxygen evolved from the glassy deposit on crystallization depends on the input of hydrogen atoms (runs 1–3) and, to a greater extent, on the amount of hydrogen peroxide in the deposit (runs 4–5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*d*) Decreasing the input of molecular hydrogen in the discharge causes only minor changes in the composition of the condensate (compare runs 4–5 and 6–7).

(*e*) Increasing the ratio of hydrogen atoms to that of peroxide input, as in runs 6 and 7, leads eventually to complete destruction of the peroxide.

(*f*) The balance of material (oxygen) in all cases fits the stoichiometry of the overall reaction

[1] $$2H_2O_2 = 2H_2O + O_2$$

within the accuracy of the analyses.

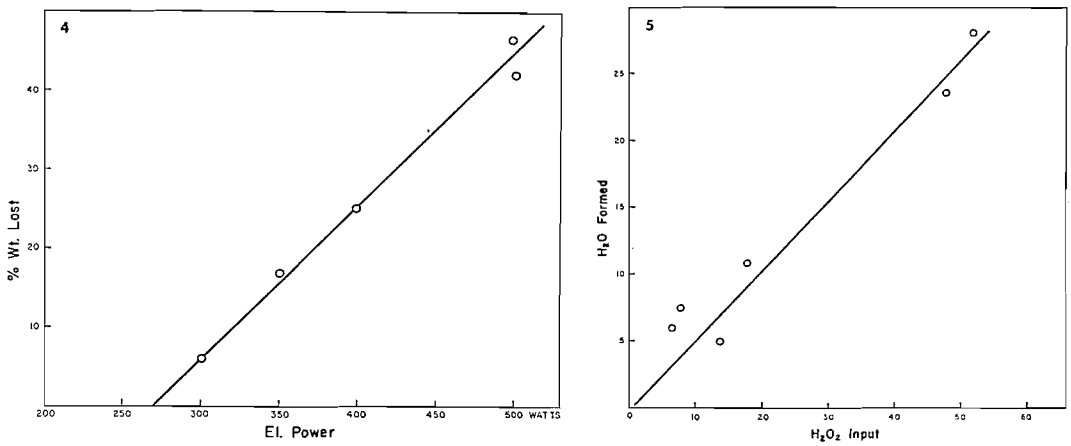

FIG. 4. Relationship between the "load" in the r.f. discharge and the fraction of input material lost.
FIG. 5. Dependence of water formation on peroxide input.

DISCUSSION

It seems appropriate to consider first the reaction kinetics in the present system, even if this was not our main purpose. The bulk of the experimental evidence from a number of related systems, in particular the much studied hydrogen–oxygen reaction (16, 17), the homogeneous decomposition of hydrogen peroxide, either alone (18–20), or in the presence of hydrogen (21, 22), leads to the following mechanism as the most important, if not the unique one, for the gas phase reactions in the present case.

[2] $$H_2O_2 + H = H_2O + OH$$

[3] $$H_2O_2 + OH = H_2O + HO_2$$

[4] $$HO_2 + HO_2 = H_2O_2 + O_2$$

On thermodynamic grounds [2] appears much more likely than the other alternative

[5] $$H_2O_2 + H = H_2 + HO_2$$

for the primary step (17). Recent kinetics studies also support this view (23). As for reaction [3] its high efficiency in chain termination process is well established. The choice between [4] and the other possibility

[6] $$HO_2 + OH = H_2O + O_2$$

for the last step is not so clear cut, but this is of little consequence here. It should be noted, however, that the steady state concentration of OH radicals was certainly very low in our system because of the presence at all times of an excess of hydrogen peroxide over hydrogen atoms. Accordingly the cold wall reaction

[7] $$OH + OH = H_2O_2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which is responsible for the production of peroxide from dissociated water vapor, was unimportant. The same is true of the chain reaction

[8] $$H_2 + OH = H_2O + H.$$

On the other hand, free radicals in low concentrations were certainly trapped in the glassy condensate, and their recombination by diffusion must account for at least part of the unidentified gas evolved in the first two steps. With that hypothesis and from reaction [4], the maximum concentration of trapped HO_2 radicals turns out to be of order of a few parts per thousand, which agrees well with the results of electron spin resonance (e.s.r.) studies (8, 24). At any rate the bleaching of the yellow color in step 2 coincides with the fading away of the e.s.r. signal. Incidentally we have shown that the yellow color in our experiments was not due to atmospheric contaminations nor to impurities from the electric discharge. No yellow color was observed (and no peroxide was formed) in the glassy solid condensed from water vapor and discharged hydrogen. Similarly prolonged bombardment, up to 3 h, of a film of glassy hydrogen peroxide by discharged hydrogen failed to produce any detectable color, and when the film was warmed only minute traces of gas were given off in a continuous fashion (curve B in Fig. 6).

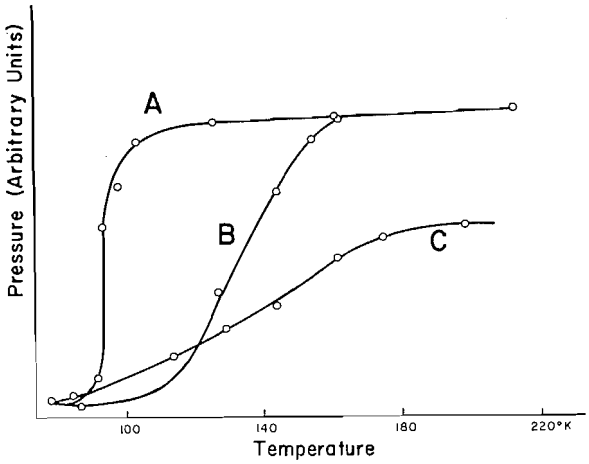

FIG. 6. Gas evolution on warming the condensed products from various systems: A, H_2O_2 and traces of SiH_4; B, glassy H_2O_2 bombarded with H atoms; C, discharge through hydrogen gas.

The most significant aspect of our results is the stoichiometry, in particular the fact that the percent loss of input material, mostly oxygen, is directly proportional to the electric power, that is the hydrogen atom input. Therefore, the bulk of the chemical action is the homogeneous decomposition of part of the hydrogen peroxide following reaction with dissociated hydrogen. This is in opposition to a proposed scheme (4, 12, 25) involving formation of a metastable intermediate by recombination of free radicals at low temperature according to the equation

[9] $$HO_2 + HO_2 = H_2O_4.$$

Presumably the decomposition of this intermediate would be the source of the gas evolved upon crystallization of the glassy deposit,

[10] $$H_2O_4 = H_2O_2 + O_2.$$

If such were the case, then the amount of evolved oxygen should be proportional, *other*

things being equal, to the input of hydrogen atoms, contrary to observation; compare, for instance, runs 1 and 7. As suggested before (2), a more rational, albeit more prosaic, explanation of these phenomena is based on the decomposition of part of the hydrogen peroxide caused by some impurities trapped from the discharged gas. The nature of that reaction is still uncertain, although from various indications it appears to be stoichiometric rather than catalytic. Indeed, various authors have found a constant ratio of evolved oxygen to residual peroxide in series of experiments with the same system and the same type of apparatus. Furthermore, the extent of decomposition is independent of the rate of warming of the condensate (25). Also the main reaction terminates rather abruptly, at least in the present case (Fig. 2). It is not ruled out, however, that some catalysis also takes place.

As for the impurities generated in the electric discharge, there is now a good deal of experimental evidence for their existence, to wit:

(*a*) Thirty-five years ago Hiedemann (26) showed that the unusual reactivity of electrically discharged hydrogen gas could be due to formation of traces of silane.

(*b*) In experiments on the trapping in a solid matrix of hydrogen atoms from discharge tubes the e.s.r. spectrum exhibited a very intense four-line signal even with the purest hydrogen gas (27). Recently the same spectrum was reproduced in the ultraviolet photolysis of silane (28).

(*c*) Redox analysis of the condensate from dissociated water vapor has shown a greater oxidizing and reducing power than that of the same material after melting (29).

(*d*) The well-known "clean up" of atomic hydrogen, leading to progressive "hardening" of hydrogen discharge tubes, has always been interpreted as a surface interaction. The same explanation was invoked even in the photochemical decomposition of hydrogen (30).

(*e*) Definite identification of traces of silane in a stream of hydrogen gas dissociated by a microwave discharge in quartz or Pyrex tubes was achieved recently by mass spectrometry (31).

(*f*) In this laboratory we have observed repeatedly that, after the preparation of large quantities of deuterium peroxide in the electric discharge, the wall of the trap always became covered with a white powder, presumably silica. What is more, this fine powder can be "cleaned up" entirely by passing for a while a stream of discharged hydrogen gas.

We propose to investigate this matter further. Already we have shown that hydrogen peroxide, frozen in liquid nitrogen along with traces of silane, reacts on warming, but in a manner entirely different from the glassy deposit (Fig. 6). Also, warming the condensed products from a prolonged (4 h) discharge in hydrogen evolves traces of an unidentified gas between 100 and 160 °K. From the present results it would appear that more contamination is produced in dissociated water, Fig. 3, (including probably some ozone) than in dissociated hydrogen (Fig. 2). According to the work of Winkler *et al.* (13) on the influence of the trapping temperature, the yield of evolved oxygen from dissociated water or hydrogen peroxide vapor increases linearly as the temperature is lowered, beginning around 120 °K. Yet the formation of peroxide in the solid begins some 30° lower. In our hypothesis this could mean that 120° is the critical trapping temperature for the impurities in these systems.

Finally, the release of oxygen in step 4 must be simply another instance of decomposition of hydrogen peroxide during melting, as reported formerly (32). Further confirmation of this is seen in the fact that in the present case, the crystalline deposit began melting at about the temperature of the lower eutectic in the binary system water–peroxide (33). In contrast, the deposit from dissociated water begins melting at a lower temperature,

around 200 °K, at the metastable eutectic (34), because no hydrogen peroxide is present in the gas phase before condensation, and the hydrate $H_2O_2 \cdot 2H_2O$ is not formed in the solid.

Received April 22, 1965

ABSTRACT

Seven mixed hydroxides of magnesium and aluminium were prepared, and phase and structural changes accompanying their dehydration were investigated by differential thermal analysis, thermogravimetric analysis, and X-ray diffraction techniques. The differential thermal analysis curves possess 2 peaks corresponding to those of parent hydroxides together with a new peak, and the thermogravimetric analysis curves show slight inflections. X-ray diffraction patterns of the mixed hydroxides possess the characteristic lines of the parent hydroxides together with three to five new intense lines which might indicate the formation of a double hydroxide. When the mixed hydroxides are progressively heated they give rise to products possessing patterns which first become diffuse and ultimately pass mainly into the spinel pattern.

Adsorption isotherms of cyclohexane and benzene were measured on the mixed hydroxides and their dehydration products. Specific surface areas calculated by the application of the Brunauer, Emmett, Teller (B.E.T.) equation are in general in good agreement for the two adsorbates. The surface area increases with rise of dehydration temperature to a maximum at 500–600 °C and then decreases with further rise in temperature. This behavior is common to crystalline oxide systems and may be ascribed to the intermingling of decomposition, recrystallization, and sintering processes. Variations in the molecular ratio of the mixed oxides (as much as 20-fold), and in the method of preparation, do not much alter the surface area.

INTRODUCTION

Mixed oxides have lately become important catalysts, and the study of their surface properties is therefore of special interest in view of the close relation between the latter and catalytic activity. The mixed oxides which have been studied most extensively are silica–alumina cracking catalysts. The surface properties and reactivity of several other oxide mixtures have been investigated, but no work is known to the authors on the adsorptive properties of the $MgO–Al_2O_3$ system, although the individual components have been the subject of numerous studies.

The object of this work was to study the adsorption of cyclohexane and benzene on mixed hydroxides of magnesium and aluminium as well as on their dehydration products formed at various temperatures *in vacuo*, i.e. under continuous pumping conditions. Phase and structural changes accompanying the dehydration of the mixed hydroxides were also investigated.

EXPERIMENTAL

(i) Materials

Seven mixed hydroxides were prepared.

Mixed hydroxide I was prepared by coprecipitation from a mixture of equal volumes of 0.4 *M* aluminium nitrate solution and 0.2 *M* magnesium nitrate solution by the slow addition of an equal volume of 1.6 *M* carbonate-free sodium hydroxide solution. The precipitate was freed from nitrate ions by decantation and then by washing with 1% ammonia solution, and was finally dried at 110 °C to constant weight. Chemical analysis gave the composition $MgO.0.96Al_2O_3.4.28H_2O$.

Mixed hydroxides II–V were prepared in the same manner with appropriate concentrations of magnesium, aluminium, and hydroxyl ions. Their compositions are indicated by the following:

Mixed hydroxide II: $MgO.0.443Al_2O_3.3.21H_2O$.
Mixed hydroxide III: $MgO.2.01Al_2O_3.7.45H_2O$.
Mixed hydroxide IV: $MgO.0.336Al_2O_3.2.86H_2O$.
Mixed hydroxide V: $MgO.7.83Al_2O_3.22.11H_2O$.

[1]*Present address: Department of Physical Sciences, the American University of Cairo, Cairo, U.A.R.*

Mixed hydroxide M was prepared by mechanically mixing suspensions of $Mg(OH)_2.H_2O$ and $Al_2O_3.3H_2O$ in approximately equimolecular quantities. Magnesium hydroxide was prepared by slowly running carbonate-free 0.4 *M* sodium hydroxide solution into an equal volume of 0.2 *M* magnesium nitrate solution in the cold. Aluminium hydroxide was prepared by the slow addition of approximately 1.2 *M* ammonia solution to an equal volume of 0.4 *M* aluminium nitrate solution in the cold. Both precipitates were freed from nitrate ions by decantation and washing with 1% ammonia solution. When the parent hydroxides were dried at 110 °C they gave the composition $MgO.1.02H_2O$ and $Al_2O_3.2.91H_2O$, and the diffraction patterns of brucite and bayerite respectively. Mixed hydroxide M has the composition $MgO.1.12Al_2O_3.3.57H_2O$.

Mixed hydroxide A was obtained by the addition of 0.2 *M* magnesium nitrate solution to sodium aluminate solution prepared by the interaction of 0.4 *M* aluminium nitrate solution with 1.6 *M* carbonate-free sodium hydroxide solution in slight excess. Chemical analysis gave the composition $MgO.0.825Al_2O_3.4.3H_2O$.

Several dehydration products were prepared by heating the mixed hydroxides *in vacuo* for 5 h at suitable temperatures. The ultimate limit of vacuum during dehydration was 10^{-4} mm.

Cyclohexane and benzene were prepared in a pure state by standard methods.

(ii) Apparatus and Technique

The adsorption isotherms were determined with a conventional volumetric apparatus in which mercury cut-outs were used in place of stopcocks to eliminate contamination with grease (see, for example, ref. 1). In the procedure adopted the adsorbent was flushed with the vapor of the adsorbate and the latter was then pumped off during 3 h at a temperature 100 °C below the temperature of dehydration; this procedure was not used for the mixed oxides formed at 800 °C and 1 000 °C when degassing was conducted at 600 °C. This treatment was found satisfactory to ensure reproducible results by minimizing further loss of the water content at the lower temperatures, and sintering at the higher temperatures, when duplicate experiments were carried out.

Differential thermal analysis curves were obtained with an automatic recording apparatus supplied by Linseis, Prüfgerätebau Kg., Selb Bayern, G.F.R. Thermogravimetric analysis curves were recorded with an apparatus manufactured by Gebrüdernetzsch, ABT, Prüfgeräte, Selb, Bayern, G.F.R. In both cases the rate of heating was 6 deg per minute. X-ray diffraction patterns were obtained with a Philips 114.6 mm Debye-Scherrer powder camera with Ni-filtered Cu radiation.

RESULTS AND DISCUSSION

(i) Differential Thermal Analysis and Thermogravimetric Analysis

The results of typical experiments of differential thermal analysis and thermogravimetric analysis are illustrated in Fig. 1.

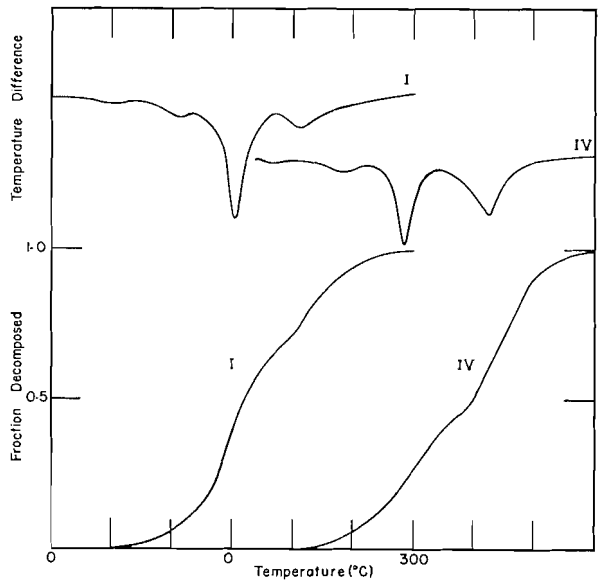

FIG. 1. Typical differential thermal analysis and thermogravimetric analysis curves. Mixed hydroxides I and IV.

PLATE I

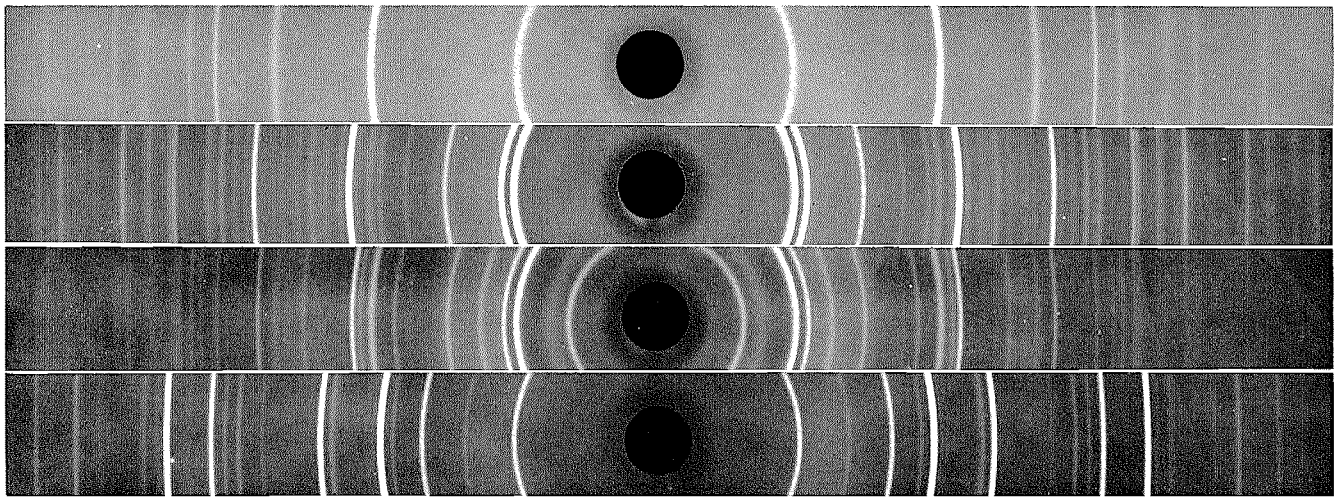

FIG. 2. Typical X-ray diffraction patterns. (*a*) Magnesium hydroxide dried at 110 °C; (*b*) aluminium hydroxide dried at 110 °C; (*c*) mixed hydroxide M dried at 110 °C; (*d*) spinel formed at 1 000 °C.

The mixed hydroxides, except mixed hydroxide V, give differential thermal analysis curves which are characterized by the presence of four endothermic peaks, namely, a very small peak at about 100 °C, a small one at 180–220 °C, and two pronounced peaks at 280–300 °C and 380–420 °C. The first peak presumably results from the loss of adsorbed water, and the last two peaks correspond to the endothermic dehydration of aluminium hydroxide (300 °C) and magnesium hydroxide (400 °C). The second peak is attributed to the dehydration of a partially formed double hydroxide (*vide infra*). The thermal effects of the last two peaks, as measured by the areas they enclose, are found to correspond approximately to the relative amounts of the parent individual hydroxides present in the mixed hydroxides. With mixed hydroxide V, however, the peak at 400 °C was masked by the strong endothermicity associated with the dehydration of the high content of aluminium hydroxide.

Thermogravimetric analysis curves exhibit small inflections marking the separate dehydration processes of the parent hydroxides of aluminium and magnesium. The position of this inflection is found to correspond nearly to the composition of the mixed hydroxide. However, when the rate of heating is increased, the dehydration processes overlap and give rise to almost continuous smooth curves.

(ii) X-Ray Investigation

X-ray diffraction patterns of the mixed hydroxides exhibit the lines characteristic of the parent individual hydroxides. Furthermore, except in the case of mixed hydroxide V, all the patterns also show three to five relatively intense lines which are not found in the patterns of the parent hydroxides or spinel $MgAl_2O_4$. The new lines give *d*-values of 7.56, 3.78, 2.58, 2.30, and 2.03 Å, and *I*-values up to 100, 80, 80, 60, and 60 respectively, but they do not appear in the patterns of intimate mixtures of dry magnesium hydroxide and aluminium hydroxide, which in fact are found to be the addition of the patterns of the two hydroxides. Typical patterns are shown in Fig. 2.

The presence of new lines in the diffraction patterns of mixed hydroxides of magnesium and aluminium might indicate the partial development of a new structure. The formation of a hydrated spinel was assumed by Abich (2) to take place when ammonia is added to a solution of equimolecular parts of magnesium and aluminium salts containing enough ammonium chloride to keep magnesium in solution. It is more likely, however, that a double hydroxide, analogous to tricalcium aluminate hexahydrate described by Flint, McMurdie, and Wells (3), is partially formed. The presence of most of the lines of the parent hydroxides in the diffraction patterns of the mixed hydroxides, as a result of incomplete reaction or excess of one component or the other, makes it difficult at present to determine the structure and the dimensions of the unit cell. However, there is indication that the double hydroxide very likely possesses a cubic lattice similar to that of $3CaO.Al_2O_3.6H_2O$. Attempts are being made at the moment to have the reaction go to completion and to grow crystals so as to enable the elucidation of the exact nature and the structure of this product.

It is worth mentioning that mixed hydroxides of magnesium and iron exhibit a similar behavior when investigated by X-rays and differential thermal analysis (4).

X-ray diffraction patterns of the products of dehydration formed at 200 °C retain some of the lines of the original mixed hydroxides, but the product formed at 300–400 °C gives practically no patterns. Diffuse lines of spinel begin to appear in the diffraction patterns of the mixed oxides prepared by dehydration at 500 °C. As the temperature of dehydration rises, the lines in the patterns become sharper, and, ultimately, the product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

formed at 1 000 °C possesses very clear lines of spinel together with faint lines of periclase and γ-alumina, depending on the component present in excess of stoichiometry. The partial synthesis of spinel from magnesium and aluminium oxides by heating a mixture of equimolecular quantities above 700 °C was ascertained by Budnikov and Zlochevskaya (5). The lower temperatures of spinel formation recorded in the present investigation are ascribed to the high surface activity and intimate admixture of the two oxides.

(iii) Adsorption Measurements

Adsorption–desorption isotherms of cyclohexane and benzene were determined at 35 °C on mixed hydroxide I and its dehydration products formed by heating *in vacuo* for 5 h at eight temperatures between 200 °C and 1 000 °C, and also on mixed hydroxides II–V, M, and A, and their dehydration products prepared by heating at 600 °C *in vacuo*.

The adsorption of cyclohexane is physical in nature, and the isotherms on all the preparations and their dehydration products are type II of Brunauer's classification (6). Desorption isotherms form hysteresis loops which close at relative vapor pressures depending on the particular preparation. The hysteresis loops may be described as type A combined with little of type E of de Boer's classification (7), and thus indicate a broad pore spectrum. A typical set of isotherms is represented in Fig. 3. It is clear that the monolayer capacity increases with rise of temperature of thermal treatment to a maximum at 600 °C, and then decreases with further rise in temperature.

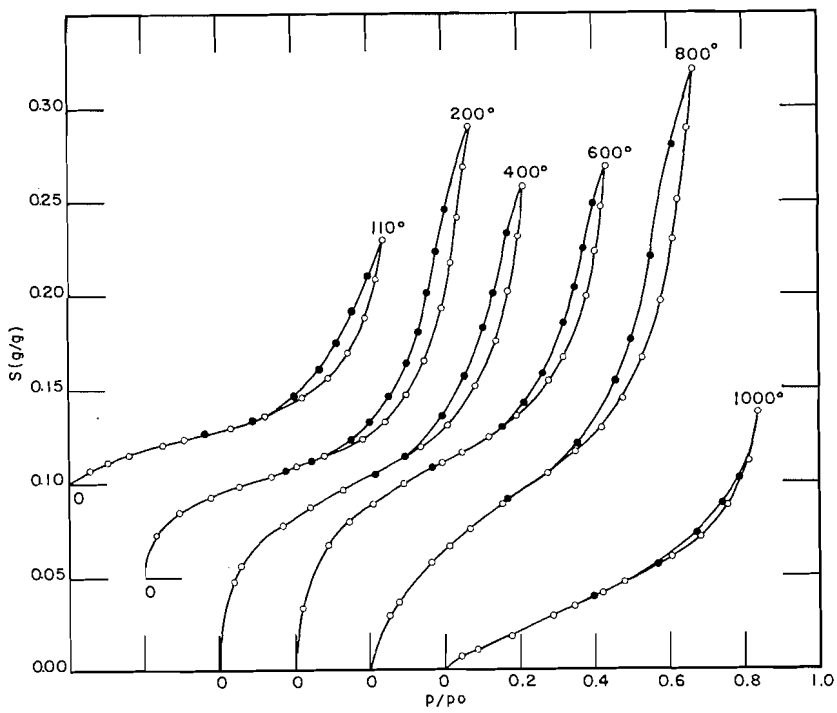

FIG. 3. Adsorption–desorption isotherms of cyclohexane vapor on mixed hydroxide I and its dehydration products formed at 200°, 400°, 600°, 800°, and 1 000 °C. Solid points represent desorption.

Adsorption isotherms of benzene vapor closely resemble those of cyclohexane. The results of typical experiments are illustrated in Fig. 4.

Adsorption values of cyclohexane and benzene vapors on the various preparations of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixed hydroxides and their dehydration products are found to give satisfactory Brunauer, Emmett, Teller (B.E.T.) linear plots in most cases. Specific surface areas were calculated taking 39 Å² and 32.3 Å² as cross-sectional areas of cyclohexane (8) and benzene (9) respectively. Earlier work in this laboratory on oxides of magnesium (10) and iron (11) has shown that the adsorption of cyclohexane can be satisfactorily used for evaluating the specific surface area of such systems. The specific surface areas calculated from the adsorption isotherms of the two vapors are found to be in good agreement for most of the products of dehydration (Figs. 5 and 6), but some discrepancies are encountered especially with the original mixed hydroxides. It is noteworthy that the adsorption of the two vapors on the parent mixed hydroxides is found to be sensitive to slight variations in the method of preparation, and duplicate experiments gave mixed hydroxides possessing surface areas which sometimes vary by as much as 50%. But the effect is much smaller in the case of the dehydration products, and the areas are in agreement within 5–10%.

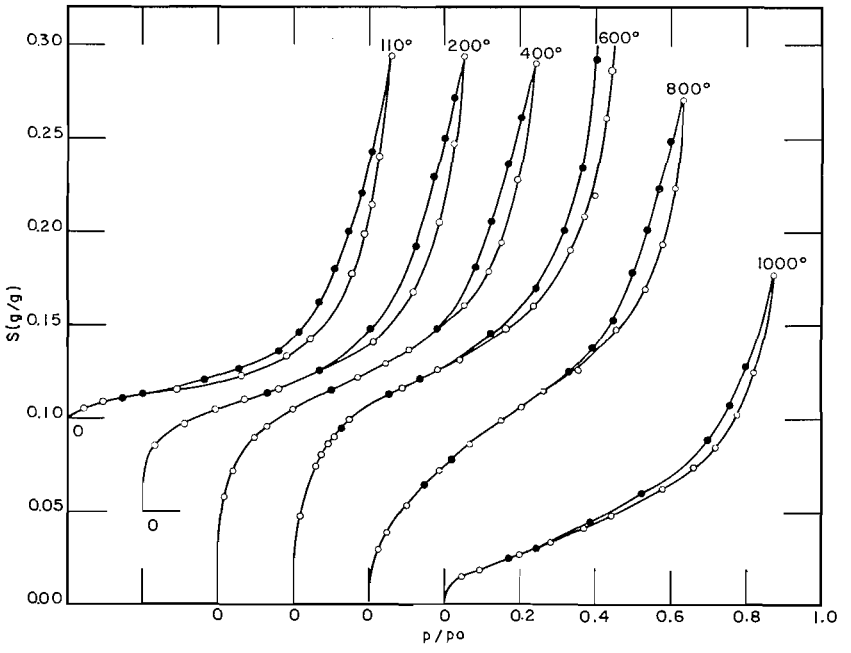

FIG. 4. Adsorption–desorption isotherms of benzene vapor on mixed hydroxide I and its dehydration products formed at 200°, 400°, 600°, 800°, and 1 000 °C. Solid points represent desorption.

The effect of the temperature of dehydration on the specific surface area of the products formed from mixed hydroxide I calculated from the adsorption isotherms of cyclohexane and benzene is shown in Fig. 5. The rise of temperature of dehydration increases the specific surface area to a maximum of about 236 m² per g obtained in the case of the product formed at 600 °C. A further rise of temperature reduces the surface area. This behavior is in harmony with the results of earlier work on the surface properties of magnesium hydroxide (10), ferric hydroxide (11), and aluminium hydroxide (12), and their dehydration products.

The development of surface area on dehydration may be attributed to (*a*) the formation of voids and cracks produced by the loss of water and the destruction of the lattice, although the solid might keep its structure for some time in the form of a pseudo-lattice, and (*b*) the breaking up of the metastable pseudo-lattice and its recrystallization into a

For personal use only.

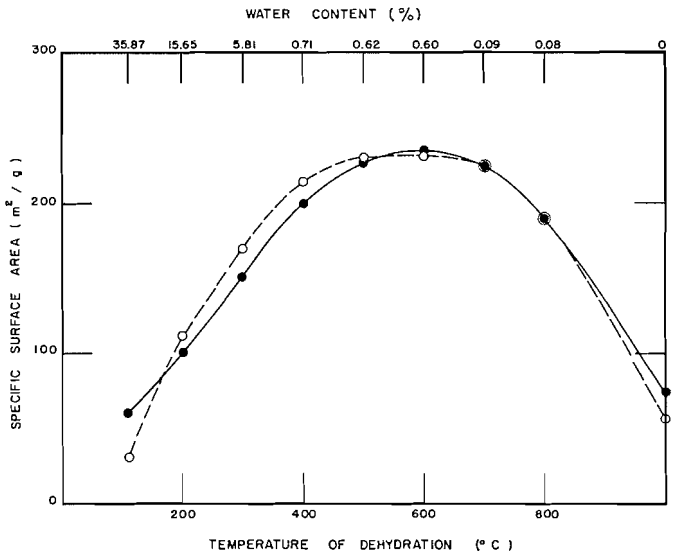

FIG. 5. Effect of temperature of thermal treatment on the specific surface area of mixed hydroxide I and its dehydration products, as calculated from the adsorption of cyclohexane (●) and benzene (○).

new structure developed in strained conditions. At the lower temperatures of dehydration, the evolution of the surface area is mainly caused by the first process, for the increase of the surface area is approximately proportional to the decrease in the water content. But at the higher temperatures of dehydration, especially between 400 °C and 600 °C, the second process predominates, and the development of the surface area is much more than that expected from the increase in the degree of dehydration, thus indicating the occurrence of activation. It is interesting to note that it is in this range of thermal treatment that diffuse lines of the spinel diffraction patterns first make their appearance.

On the other hand, the decrease in surface area which accompanies the thermal treatment above 600 °C is considered to result from sintering effects. The surface area diminishes considerably as the temperature of dehydration is raised to 1 000 °C when spinel structure becomes well developed. This is in agreement with the observation of Jander and Pfister (13) that the catalytic ability of $MgO–Al_2O_3$ mixtures in the carbon monoxide – oxygen reaction decreases strongly at 920 °C when spinel crystals are formed.

The variation of the specific surface area of the mixed hydroxides and oxides with composition is represented in Fig. 6, in which the surface area is plotted as a function of the mole % MgO in the nonvolatile content of the seven preparations. In general there is satisfactory agreement between the specific surface areas of the mixed oxides when calculated from the adsorption isotherms of cyclohexane and benzene, except in the case of mixed oxide M when the two values differ by about 20%. However, marked differences are observed in the case of the parent mixed hydroxides except mixed hydroxide M, and the surface areas calculated from the adsorption of benzene are much lower than the corresponding values calculated from the cyclohexane isotherms. It is difficult at present to find a satisfactory explanation of this result, but reference has been made to the experimental fact that the surface area of mixed hydroxides is highly sensitive to conditions of preparation. In particular, the state of the surafce might play an important role in the relative amounts adsorbed, and it is possible that on the surface of the hydroxides the molecules of cyclohexane and benzene occupy areas different from those on the dehydrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

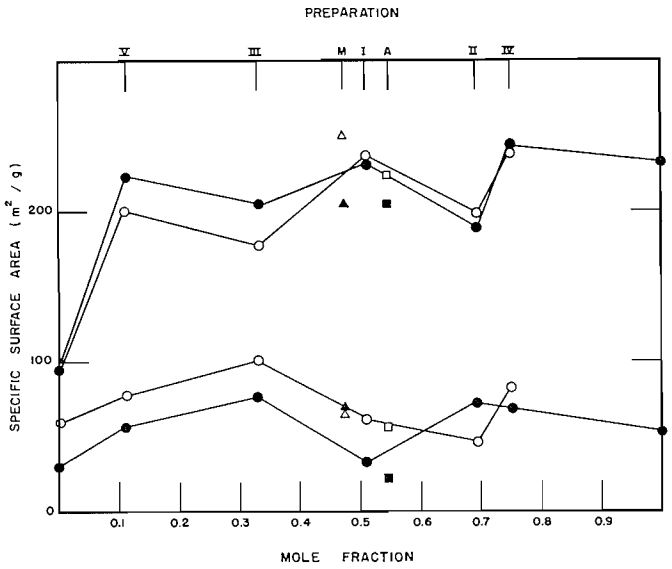

FIG. 6. Variation of the specific surface area of mixed hydroxides (lower curves) and mixed oxides (upper curves) with composition and method of preparation. Surface areas from cyclohexane adsorption: (○) mixed hydroxides and oxides I–V, (△) mixed hydroxide and oxide M, (□) mixed hydroxide and oxide A. Surface areas from benzene adsorption: (●) mixed hydroxides and oxides I–V, (▲) mixed hydroxide and oxide M, (■) mixed hydroxide and oxide A.

surface, although there appears to be no simple correlation between the calculated surface area values and the water content or nonstoichiometry of the mixed hydroxides. It is therefore important to note that the values of the specific surface area of the parent mixed hydroxides calculated from the adsorption of cyclohexane and benzene have to be considered with reserve.

Figure 6 also shows that over a range of 20-fold variation of composition (*a*) the specific surface area of the mixed oxides does not change in a regular manner with composition, (*b*) no mixed oxide of magnesium and aluminium with a markedly high surface area is formed, and (*c*) the specific surface areas of the mixed oxides formed at 600 °C are considerably higher than the values of the corresponding parent mixed hydroxides. Finally, variations in the method of preparation do not bring about basic changes in the surface properties of the mixed oxides.

ACKNOWLEDGMENT

The authors thank Dr. L. E. Copeland for valuable discussions relevant to the structure of the double hydroxide.

NUCLEAR RECOIL REACTIONS IN CYCLOPENTADIENYLMANGANESE TRICARBONYL[1]

T. COSTEA AND IRINA NEGOESCU
Institute of Atomic Physics, Bucharest, Romania

Received November 19, 1965

ABSTRACT

The first stages in an intensive study of Szilard–Chalmers recoil reactions in a covalent metal-organic compound are described. The radioactive manganese-56 is found, as expected, as inorganic manganese (75–80%), as the parent compound (12–20%), and as one or other of two hitherto unidentified, unstable compounds depending on whether anhydrous paper chromatography or paper ionography is used as the separation method (5–7%). Some data are given showing the effect of room-temperature annealing following irradiation at −196 °C. In particular, the yield of one of the unidentified compounds increases markedly (to ~15%) while that of the other compound remains nearly unaffected.

Thin-layer chromatography in anhydrous benzene was used as separation method in thermal annealing studies. They show two hitherto unreported phenomena: The apparent retention increases considerably and then decreases again as annealing continues, and the annealing reaction at two temperatures in the liquid and one in the solid phase are qualitatively very similar. These results are interpreted as indicating the presence of another species, the "pseudoparent", which is not distinguished chromatographically from the parent. Some discussion is given as to possible mechanisms.

It is over thirty years since the discovery by Szilard and Chalmers (1) that atoms having captured a neutron recoil with sufficient energy to break their chemical bonds. A great deal of work has been done (2, 3) in attempting to discover the nature of the chemical reactions following this recoil. However, while much has been learned about the ultimate results of the recoil, the chemistry of the process as it occurs in condensed states remains unknown in detail, largely because of the ephemeral nature of the compounds and atomic states remaining after the recoil. One tantalizing difficulty is the virtual impossibility of observing the primitive atom, since the methods of investigation used to date have always involved dissolution of the sample under observation and subsequent chemical processing. Thus the species observed are those remaining after some quite drastic changes have occurred in the physical and chemical surroundings of the recoil atoms.

One technique which has been used to approach the primitive atom more closely is that of annealing the crystals in one way or another before the chemical processing begins. Although several types of annealing, such as crushing and treatment with γ-rays, light, ultrasonic energy, and high-energy electrons, have been found to have an effect on the recovery of the recoil species, the most usual method is isothermal heating. This method has been used quite extensively, with the result that several quite fundamental hypotheses have been postulated to describe the chemical and physical influences which affect the behavior of the displaced atom. Most work on thermal annealing has been done on ionic compounds (3) and little has been reported on metal-organic compounds. The results

[1]*This work was done in part at Carleton University and at Chalk River Nuclear Laboratories (P. V.'s M.Sc. Thesis, 1965) and in part at IFA in Bucharest, where D. R. W. was a Visiting Scientist during the summer of 1965.*

[2]*Present address: University Chemical Laboratory, Lensfield Road, Cambridge, England.*

obtained so far have mostly shown simple first-order approach to a maximum value or to a pseudoplateau with a very gentle slope. The postulated mechanisms, too, have been based upon first-order kinetics, primarily diffusion mechanisms.

In an attempt to get a closer picture of the reactions occurring in at least one instance, we are undertaking a series of investigations of reactions in a single compound: cyclopentadienylmanganese tricarbonyl, $C_5H_5Mn(CO)_3$. This compound, easily obtainable in a pure state, is straightforward to work with, offers convenient nuclear properties, and presents a reasonably small variety of possible interactions which must be studied. The first stage of this study, which is described here, involves an investigation of the gross features of the recoil and its products. In particular, we were looking for other products than the parent compound and "inorganic" manganese. The second stage, also reported here, is a study of the effect of thermal treatment of neutron-irradiated cyclopentadienylmanganese tricarbonyl, and in particular a comparison of the effects in the solid and liquid states.

EXPERIMENTAL

Target Material

Cyclopentadienylmanganese tricarbonyl was obtained from Ethyl Corporation (U.S.A.) and was sublimed *in vacuo* before use. The reagents used were the purest obtainable grade.

Irradiations

Neutron irradiations were performed in the NRX reactor at Chalk River, Canada, and in the IFA reactor at Bucharest, Romania. Flux and other characteristics in the various irradiation positions used are given in Table I. Freshly-sublimed samples sealed in nylon capsules were used for most irradiations in NRX, while for

TABLE I

Characteristics of irradiation positions*

Position	Thermal flux ($n\ cm^{-2}\ s^{-1}$)	Fast flux ($n\ cm^{-2}\ s^{-1}$)	Dose rate ($rad\ h^{-1}$)	Temperature (°C)
S-6-1	1.4×10^{12}	0.2×10^{10}	1×10^{6}	50
J-Rod	0.6×10^{13}	5×10^{10}	7×10^{6}	50–90
X-Rod	1×10^{14}	2×10^{12}	90×10^{6}	100–120
Self-serve	1×10^{13}	5×10^{10}	6.5×10^{6}	50–90
CT2	1.2×10^{11}	6.3×10^{9}	4.2×10^{6}	30–50
CT3	8.8×10^{8}	3.1×10^{5}	6.4×10^{4}	25–35

*Data obtained through the courtesy of Dr. A. W. Boyd (NRX) and Ing. L. Mantescu (IFA).

low-temperature irradiations in NRX and all irradiations at IFA resublimed material was sealed *in vacuo* in quartz ampoules. Irradiations at −196 °C were done in liquid nitrogen using quartz Dewar flasks. All other irradiations were done at reactor temperature. This leaves some question as to the actual temperature of the sample during irradiation. In NRX, most irradiations lasted 1.0 min, during which time they would not likely reach the ambient temperature. In no case was the melting temperature (77 °C) of the sample reached. Irradiations in CT2 were of 3 min and in CT3 of 60 min duration.

Sample Measurement

Following chromatography or ionography, the strips were cut into small sections and the 0.845 MeV γ-ray was counted with a Na(Tl)I scintillation counter. Background, decay, and coincidence loss corrections were made.

Separation Methods

Solvent extraction was found to give very poor reproducibility, which was traced to extensive adsorption on the glass surfaces and to apparent decomposition of the $C_5H_5Mn(CO)_3$ during the extraction. This method was therefore not used in this study. We regard this adsorption, as also that in the case of ferrocene (4), as indicative of the presence of fragments of molecules (or perhaps ions or radicals) which attain a degree of chemical stability through adsorption on the glass walls.

Paper chromatography.—Ascending paper chromatography in anhydrous benzene was performed in the usual manner except that in all experiments air and moisture were carefully excluded. Whatman No. 1 paper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was used in these experiments. Many of the experiments were performed in a nitrogen-filled dry-box. The benzene used was dried over anhydrous calcium chloride overnight and filtered, and the filtrate was distilled twice over $LiAlH_4$.

Ionography (paper electrophoresis).—This separation procedure was effected using Whatman 3MM paper, with a solution of 0.2 *M* $NaClO_4$ and 0.1 *M* $HClO_4$ as background electrolyte. The irradiated compound, dissolved in alcohol containing a few drops of the background electrolyte, was spotted on paper strips 2 cm × 57 cm. These strips were clamped between Teflon-insulated, water-cooled brass plates. The d.-c. potential applied was about 500 V, giving a potential gradient of about 11 V/cm. The air-free water used was prepared by boiling redistilled water, cooling under vacuum, and storing under nitrogen.

Thin-layer chromatography.—Thin-layer chromatography in an anhydrous, oxygen-free system was used to process all samples irradiated at IFA. After irradiation, the quartz ampoules were crushed, the sample was dissolved in a few drops of dry benzene, and the vial containing the solution was tightly stoppered with a silicone serum port. This procedure was carried out entirely in a nitrogen-filled glove bag. Separation of the recoil species was done by thin-layer chromatography, using the prepared sheets of powdered SiO_2 on a polyester backing (Eastman Chromagram Sheets type K301R2). The chromatography was done in a vacuum-dried, nitrogen-filled vessel, as shown in Fig. 1. Transfer of the solution was done with syringes, allowing essentially no contact with air or moisture. The solvent used for chromatography was benzene,

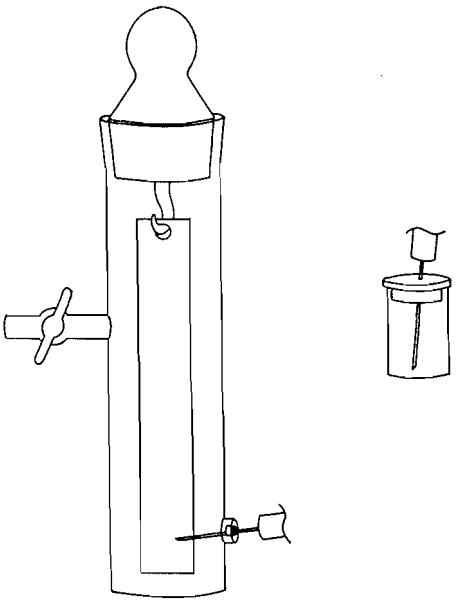

FIG. 1. Apparatus used for controlled-atmosphere chromatography.

distilled and dried over Linde No. 4A molecular sieve. Under these conditions, the resolution was good, and reproducibility in parallel runs was excellent. This technique is very quick and convenient, and we recommend it for use in all cases of chromatography of air-sensitive substances.

Annealing Experiments

Thermal treatment was done by placing the irradiated quartz ampoules into an oven adjusted to the proper temperature. The temperature was reproducible from one experiment to another to within ±0.5°. Heating and cooling times may introduce an uncertainty of ±0.1 min in the annealing times. Temperatures used ranged from 55° to 155°. Gross decomposition did not occur at any temperature, as was shown by (*a*) the absence of macroquantities of manganese in the first strips of the chromatograms and (*b*) by the sharpness of the solidification temperature following heating at temperatures above the melting point.

RESULTS

Species Observed

A typical paper chromatogram is shown in Fig. 2. The large peak at the zero position is clearly inorganic manganese, which we shall assume to be Mn^{2+}. The peak labelled $C_5H_5Mn(CO)_3$ was identified by observation of the behavior of macroscopic quantities of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the parent compound. It was also found that both manganocene and dimanganese decacarbonyl show similar behavior. Thus the purity of the species in this peak cannot be assured. The peak labelled compound A was present in all chromatograms, and although it is small in size it is statistically significant.[3] Figure 3 shows a typical ionogram. The peak labelled $C_5H_5Mn(CO)_3$ may, of course, contain other uncharged species. The ionographic behavior of Mn^{2+} was checked by the use of manganese-54 as Mn^{2+}. Again a small but distinct third peak, labelled compound B, is observed.

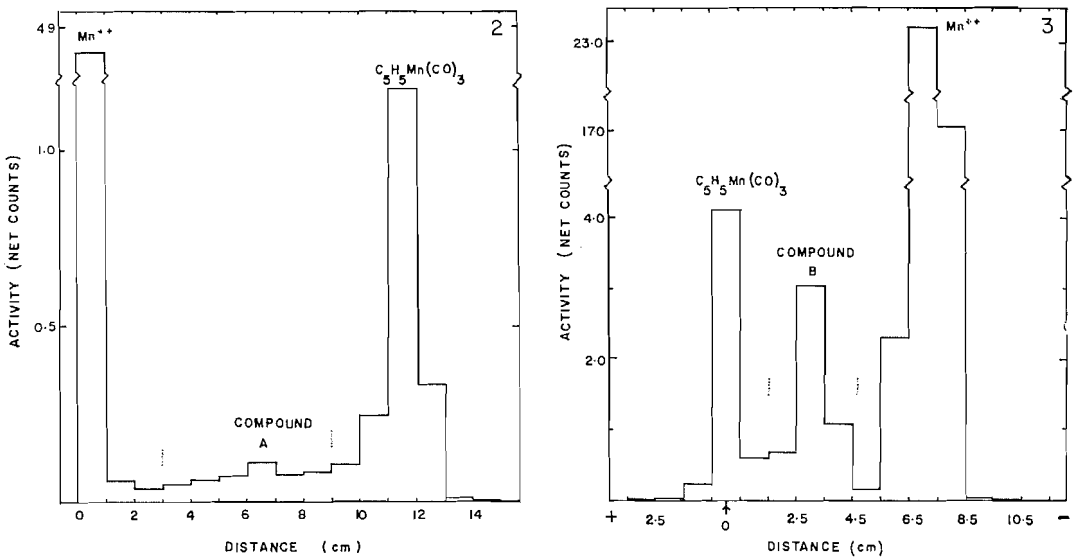

FIG. 2. Typical paper chromatogram for X-rod irradiation.
FIG. 3. Typical paper ionogram for J-rod irradiation.

The compounds A and B have not been identified as yet but some description of their nature and behaviour can be given. In the first place, compound A is likely an uncharged molecule while B seems to be a 1+ (or possibly 2+) cation. That they are related is shown by the following experiment:

The section of a paper chromatogram containing compound A was cut out, dried in nitrogen, and inserted into a paper strip for ionography; of the activity present, most appeared as Mn^{2+}, but some was found as a peak at the position of compound B, and some remained as a molecular compound at the position of the original spot. It is evident from the rapid conversion of this apparently molecular species to ionic species that compound A is unstable in water.

The chemical instability of compound B was shown by aerating a solution of the irradiated parent compound for a few minutes just before ionographic separation. Compound B all but disappeared (1.2% was found compared to 8.6% found in a simultaneous non-aerated control test). Dissolution and chromatography in hexane or in another solvent, as was done by Baumgärtner, Zahn, and Seeholzer (5) for dibenzene chromium, was not possible in this case because of the insufficient solubility of the parent compound.

No positive identification of compounds A and B can be made at present. However, it seems certain that they are constituted from remnants of the original molecule or fragments encountered on the recoil path. Identification of compounds A and B by standard

[3]*On nine observations the activity at the peak of compound A was larger than the mean of nearby activity by an average of 4.5 times the standard deviation of the nearby activity.*

For personal use only.

methods is not possible since we have a total of only about 10^{10} molecules to work with. Since in this case alkyl manganese compounds are not stable, the only likely fragments are the cyclopentadiene ring and the carbonyl group. Some plausible compounds are suggested in Table II. It is hoped that experiments now under way using carbon-14 as an additional

tracer will enable us soon to make unequivocal identification. A typical thin-layer chromatogram for a CT-2 or CT-3 irradiation is shown in Fig. 4. The important result to be noted immediately is the absence of compound A in the CT-2 and CT-3 experiments. The reason for this is not known, but may originate with the difference in chromatographic techniques used.

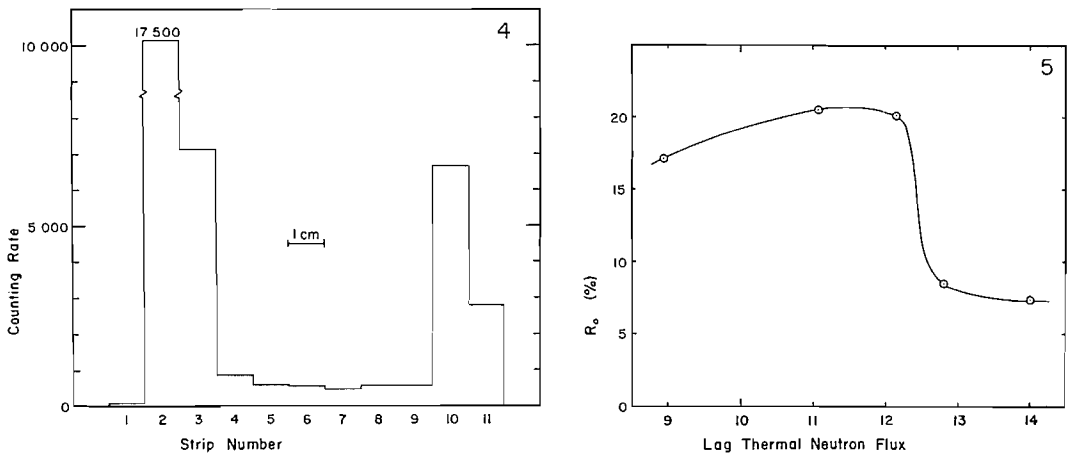

FIG. 4. Typical thin-layer chromatogram for CT2 and CT3 irradiations.
FIG. 5. Dependence of the initial parent yield (R_0) on neutron flux.

It was found in all ionograms that roughly 75–80% of the ^{56}Mn appeared as Mn^{2+}, while in the paper chromatograms and the thin-layer chromatograms a like amount was found as a benzene-insoluble species. Moreover, some 12–20% of the activity appeared as the parent compound in both types of experiment. While these amounts could not have been predicted with confidence, the results are not surprising, and are quite comparable to the results of studies on other metal-organic compounds (4–7).

The yields observed for the various species are summarized in Table III. The rather high relative uncertainties shown for compounds A and B and for $C_5H_5Mn(CO)_3$ are likely due to the chemical instability of these species in solution. One interesting feature of these data is the evident flux-dependence of the yield of the parent compound, as is shown in Fig. 5. The data are not, of course, strictly comparable, since the duration of the irradiations differed, as did the probable temperatures. Thus, the true origin of this effect cannot be identified from the present experiments. In this connection, it seems quite possible that the appearance of compound A in NRX irradiations and not in IFA experiments may be a result of a similar effect if not, in fact, the same reaction.

Thermal Annealing

The results of thermal treatment of the irradiated samples are given in Table IV and are shown in Figs. 6*a* and 6*b* for CT3 and CT2 irradiations, respectively. In considering these data it is important to note that the melting point of the starting compound is 77 °C.

Low-Temperature Irradiations

Some experiments were done in which the irradiation was carried out at liquid nitrogen temperature. Irradiations were done in the J-rod self-serve position of NRX. Chemical separation of the irradiated samples was done at 25 °C after varying lengths of time. Processing at low temperatures was attempted, but the insolubility of the target compound made such experiments impracticable. Results obtained are shown in Table V. The data of Table V are not strictly comparable to those of Table III, since the neutron flux and gamma-ray intensities were different. However, there are some striking features. In the

first place, the yield of the parent compound is seen to increase markedly with annealing at 25°. This result is a convincing demonstration of the importance of irradiation at controlled temperatures, since the sample temperature is undoubtedly higher than 25° under the usual irradiation conditions. The second interesting feature of these data is the distinct difference in the behavior of compounds A and B. The yield of compound A is increased somewhat on annealing, but is generally little affected either by annealing or by the temperature of irradiation. The yield of compound B, on the other hand, is greatly enhanced in the low-temperature irradiation, and seems to be further increased by the annealing. This difference suggests that these compounds, whatever their ultimate nature, arise from quite different reactions in the solid.

DISCUSSION

A number of interesting features are shown by the curves of Figs. 6*a* and 6*b*, some of which have not been observed in systems studied previously. In the first place, there is a good deal of recombination occuring in the liquid state, as is seen clearly in the results of the 88° experiments. While this is not the first time that "annealing" has been observed in the liquid state (8), it is, we believe, the first time that the solid and liquid states have been found to be so similar. Secondly, the form of the curves is not the simple first-order approach to a final value as is usually found, but shows a higher-order process which increases in rate from a slow beginning. In fact, at 65° there seems to be an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

induction period of ~20 min before much change occurs. A further interesting feature is the decrease in retention which occurs after a maximum value has been reached. As the temperature of annealing is increased, the maximum value of the retention increases, and the time required to reach this maximum decreases. This fact suggests that two or more temperature-sensitive competitive reactions are in progress. In this case, of course, it cannot be a solid-state phenomenon, and is thus more likely a molecular displacement or exchange mechanism. The fact that the retention value appears in some cases to increase once more is quite interesting, but unfortunately we have too few data to be sure of this phenomenon.

It is important to note that a different batch of samples, prepared, as far as possible, in exactly the same way but stored for some months at room temperature before irradiation, gave somewhat different results. Qualitatively the trends in retention values as a function of heating time were the same, but some quantitative differences were noted. Thus, in addition to the effects reported here, there is some subtle effect due to sample history. This is a common and tantalizing observation which may result from, among other possibilities, lattice stress (9).

One important result of this work is the discovery that the results of annealing are the same in the liquid and the solid state, for samples irradiated as solids. Mechanisms currently used for explaining recombination involve processes such as short-range diffusion and electron detrapping, both of which will likely proceed to completion almost instantly on melting of the crystal. Thus, it seems that none of the existing mechanisms is likely to apply in the present case. The one exception may be the induction period seen in the 65° CT3 experiment; this induction period could well be a slow detrapping of electrons, to produce molecular or ionic species which subsequently form the species recovered.

The form of the curves, too, seems inconsistent with present mechanisms, in that the usual first-order increase in retention gives way to a more complicated shape. This complexity of shape undoubtedly indicates the occurrence of a series of consecutive and perhaps competitive reactions. After the induction period, which is discernible in only the one case, comes an increase in retention followed by a decrease to approximately the initial value. A further increase, indicated in some cases, is too uncertain to warrant much discussion.

Generally, annealing curves showing a maximum may be interpreted in terms of competitive reactions (10). These reactions may be of several kinds, including micro (11, 12) and gross (13, 14) decomposition and chemical (15, 16) and electronic (17) reduction. The decrease in retention following the maximum in the present work is very considerable, and amounts to roughly 50% in the 120° cases. The fact that this decrease is not accompanied by a corresponding gross decomposition of the sample, coupled with the observation that the same form is shown by the curves for the two phases, suggests that the decrease is due neither to decomposition nor to the type of microrecrystallization postulated by Dimotakis (12). Likewise, the two reduction processes seem not to be relevant to the present system. It is, moreover, difficult to imagine any sort of defect mechanism which would persist when the solid is melted. One is thus led to the conclusion that the observations do not represent an increase in true retention, but an increase in concentration of either an excited state of the parent molecule which decomposes on further heating, or a different compound, fleetingly stable, formed from the available fragments, and not chromatographically distinguished from the parent compound. In view of the relatively long times involved, the second of these alternatives seems the more likely. An analogous hypothesis was invoked by Miller and Dodson (18) in their work on carbon tetrachloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

If this is the case—that the retention curves show the formation and subsequent decomposition of some compound other than the parent compound—then it is useful to speculate further about the general nature of the reactions in the solid and in the liquid. In the first place, from the similarity of retention values before and after the hump, one concludes that formation of the parent compound occurs very rapidly before the first observations and thereafter slowly, if at all, even at 120°. On the other hand, the changing values and times at the maximum apparent retention suggest that the reaction leading to the formation of this other compound, which we shall call the "pseudoparent," is quite temperature sensitive and that the decomposition reaction is slightly less so.

One can thus construct the following series of reactions:

[1] $$\text{Recoil} \rightarrow \text{Mn}^{\ddagger} + \text{fragments}$$

where $Mn^{\ddagger}$ represents a labile manganese-56 atom, perhaps recombined into an unstable molecular form, which undergoes reactions as follows.

[2] $$\text{Mn}^{\ddagger} + \text{fragments} \rightarrow \text{C}_5\text{H}_5\text{Mn}^*(\text{CO})_3$$

[3] $$\text{Mn}^{\ddagger} \xrightarrow{\text{dissolution}} \text{Mn}^{2+}$$

[4] $$\text{Mn}^{\ddagger} \xrightarrow{\text{heating}} (\text{Mn}^*)$$

The quantity (Mn*) is a postulated unstable molecular species which reacts further.

[5] $$(\text{Mn}^*) \xrightarrow{\text{dissolution}} \text{pseudoparent}$$

[6] $$(\text{Mn}^*) \xrightarrow{\text{heating}} \text{Mn}^* \xrightarrow{\text{dissolution}} \text{Mn}^{2+}$$

Reaction [4] followed by either [5] or [6] gives rise to the observed annealing effects. It appears that reaction [4] is accelerated at higher temperatures, while reaction [6] is less sensitive to heating. Unfortunately no reasonable estimates of activation energy can be made from the present data.

It is not intended to imply that (Mn*) and the stable pseudoparent are necessarily different species, although this is likely the case. It is important, moreover, to emphasize the probable role of the dissolution reactions in converting species metastable in the solid state into other species stable in solution. Doubtless this is the origin of compounds A and B.

The identities of the pseudoparent and of the metastable (Mn*) are not known. Both manganocene and dimanganese dekacarbonyl have chromatographic behavior similar to that of the parent compound. Of these, manganocene is the more likely to be the pseudoparent compound, since the probability of assembling the dekacarbonyl molecule is surely very small.

The similarity of the liquid and solid systems suggests that reaction [5] does not occur as result of diffusion back to the initial site, since diffusion processes would presumably show much greater differences between the two phases. Reaction [5] could be, among others, exchange between (Mn*) and inactive manganese atoms produced by local destruction on the recoil path.

Since the "fragments" involved in reaction [2] may quite well involve radiolysis products, or recoil-produced fragments modified by further radiolysis, the effect of flux on the initial retention and on the compounds A and B is rationalized. We thus have the generalized reaction below.

[2*a*] $$\text{Mn}^{\ddagger} + \text{fragments} \rightarrow \text{other products}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

We are continuing our studies of recoil reactions in this compound, in an attempt to identify the molecular species produced and to isolate, if possible, reactions at the initial site from those occurring at the end of the recoil path.

In conclusion we may enumerate the species we have observed: In all cases we found activity attributable to the parent compound and to inorganic manganese. In addition, by three different techniques we have found, directly or indirectly, three other species. We call these compound A, compound B, and the pseudoparent, as observed by, respectively, paper chromatography, paper electrophoresis, and thin-layer chromatography. While it is true that the compounds we actually saw most likely are different, how they originate is unknown. Thus it may well be that all come from a single activated atomic or molecular species in the solid. There is low-temperature annealing evidence to suggest that compounds A and B may perhaps be of different origin. It is possible that compound A and the pseudoparent are the same compound, even though they show different chromatographic behavior, since the chromatographic media were different. Research programs currently under way may help to elucidate these questions.

ACKNOWLEDGMENTS

We express our gratitude to Academician H. Hulubei, Director of the Institute of Atomic Physics, Bucharest, for his support of this project and for his permission for D. R. W. to work at the Institute, and to Drs. R. H. Betts and J. P. Butler of the Chalk River Nuclear Laboratories for much assistance and advice. The President of Carleton University provided a travel grant for D. R. W. and the National Research Council of Canada provided financial assistance.

ABSORPTION SPECTRA AND CONFIGURATION OF SOME AMINE COMPLEXES OF COPPER(II) ACETATE

GOPAL NARAIN
Department of Chemistry, Lucknow University, Lucknow, U.P., India

Received August 31, 1965

ABSTRACT

Coordination complexes of copper(II) acetate, ammonia, aliphatic amines, and pyridine have been prepared. Molecular formulae on the basis of percentage of constituent elements were found to be $Cu(OAc)_2(am)_2$, where OAc represents acetate ion and am any amine used. Conductivity measurements in nitrobenzene and formamide indicate that the complexes are nonelectrolytes and thus it is suggested that acetate ions are also coordinated. Molecular weight measurements in the same solvents confirm this. Visible absorption measurements in formamide show a single band at about 635 mμ.

INTRODUCTION

A survey of the literature shows that a large number of amine complexes of bivalent copper have been prepared with almost all possible inorganic salts. Very little work has been done, however, with the organic salts (1, 2), although dimeric $Cu_2(OAc)_4.2H_2O$ and a number of ammonia and long chain aliphatic amine complexes of monomeric copper(II) acetate have been prepared (3–7). Since then no definite attempt towards preparation and the assignment of structures to these has been made.

The present communication relates to the synthesis and visible absorption measurements of a series of amine complexes of copper(II) acetate. The object of the work was to study whether the acetate ion, besides neutralizing the charge on the metal, is also coordinated to it.

EXPERIMENTAL

(A) Syntheses

(1) Copper(II) acetate.—This was prepared by dissolving the commercial 'neutral' salt in dilute acetic acid, filtering hot, cooling, washing the crystals well with water, and drying the air-dried solid *in vacuo* over phosphoric oxide until fresh desiccant extracted no more water.

The complexes were prepared by the following two methods:

(*X*) Finely powdered copper(II) acetate (500 mg) was placed in a calcium chloride tube fitted with a cotton wool plug at the bottom. This tube was attached to the neck of a flask containing amine, thereby exposing the blue solid to the vapors of amine for 4 h. The complex was formed, and the tube was taken out and left over calcium chloride to remove and absorb excess amine. The complex was dried over phosphorus pentoxide.

(*Y*) Copper(II) acetate (500 mg) was suspended in 15 cc of benzene. A little more than the calculated quantity of amine was added and the solution was refluxed for 2 h. The resulting complex (reaction mixture) was kept overnight and filtered the next morning. The precipitate was washed repeatedly with benzene, and dried first over calcium chloride and then over P_2O_5.

(2) Biacetato, biaminocopper(II).—Prepared by method *X*.
Anal. Found: Cu, 29.20; N, 12.75. $C_4H_{12}O_4N_2.Cu$ requires Cu, 29.47; N, 13.0.

(3) Biacetato, bi(methylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 26.31; N, 11.80. $C_6H_{16}O_4N_2.Cu$ requires Cu, 26.08; N, 11.5.

(4) Biacetato, bi(ethylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 23.50; N, 10.56. $C_8H_{20}O_4N_2.Cu$ requires Cu, 23.38; N, 10.31.

(5) Biacetato, bi(isopropylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 20.95; N, 9.23. $C_{10}H_{24}O_4N_2.Cu$ requires Cu, 21.2; N, 9.35.

(6) Biacetato, bi(n-propylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 20.86; N, 9.18. $C_{10}H_{24}O_4N_2.Cu$ requires Cu, 21.2; N, 9.35.

(7) Biacetato, bi(isobutylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 19.16; N, 8.73. $C_{12}H_{28}O_4N_2.Cu$ requires Cu, 19.39; N, 8.55.

(8) Biacetato, bi(n-butylamino)copper(II).—Prepared by method *X*.
Anal. Found: Cu, 19.0; N, 8.66. $C_{12}H_{28}O_4N_2.Cu$ requires Cu, 19.39; N, 8.55.

(9) Biacetato, bi(pyridino)copper(II).—Prepared by method *Y*.
Anal. Found: Cu, 18.98; N, 8.02. $C_{14}H_{16}O_4N_2.Cu$ requires Cu, 18.71; N, 8.25.

(B) Determination of Total Bases

The bases were estimated by treating 500 mg of a complex with $N/10$ sulfuric acid for $\frac{1}{2}$ h and titrating unreacted acid with $N/10$ sodium carbonate. A blank experiment was also done with 500 mg of $CuOAc_2$. The difference in volume of acids in the two cases gave the volume of acid neutralized by the amine, and the percentage was calculated on the assumption that two molecules of amine react with one molecule of acid.

(C) Molecular Weight Measurements

Molecular weights were determined by the method of freezing point depression, with nitrobenzene and formamide as solvents. Since the complexes dissolve only to a limited extent, a Beckmann thermometer with a scale of only 1 °C was used. The thermometer was extremely sensitive to supercooling and hence a modified apparatus was constructed. A glass vessel containing the freezing point tube was placed in a copper cylinder filled with water maintained at −5 °C with constant stirring by a mechanical stirrer. This cylinder was surrounded by another well-lagged copper cylinder containing ice.

(D) Conductivity Measurements

Measurements were done in nitrobenzene and formamide at a concentration of 10^{-3} M. The cell used had a cell constant = 0.0245.

(E) Purification of Solvents

Nitrobenzene was purified by steam distillation followed by distillation at reduced pressure. Formamide was distilled at reduced pressure.

(F) Spectral Measurements

The spectra were recorded on a Unicam S.P.500 spectrophotometer.

RESULTS AND DISCUSSION

The percentages of constituent elements and the synthesis of the complexes have been given in the Experimental section. The results of total base, molecular weight, conductivity, visible absorption measurements, and colors of the complexes are given in Table I.

On the basis of percentages of metal, nitrogen, and total base, the molecular formulae are $Cu(OAc)_2(am)_2$. These complexes are violet or green in color. They do not melt, but if heated or warmed with acids they decompose and become black in color. Their solubility is extremely low and they are soluble only in nitrobenzene and formamide.

The molar conductances in nitrobenzene and formamide (10^{-3} M solutions) give a value similar to that of the solvent or a value less than 1. These values indicate that the compounds are nonelectrolytes (8).

The freezing point depressions in formamide give the normal absolute value of molecular weight. These results suggest that acetate ion is also inside the coordination sphere along with amine. Therefore the formulae of the complexes are to be written as $[Cu(OAc)_2(am)_2]^0$. Thus in formamide and nitrobenzene, these compounds are monomeric and presumably planar four coordinate, if solvent interaction in the axial position is ignored.

The arrangement of any four groups around a copper(II) ion has usually been found to be planar. The stabilizing energy calculated from the energy level diagram is greater for a square planar than a tetrahedral structure and hence it is evident that unless a ligand possesses sufficient steric repulsions which can balance the decrease in crystal field stabilization energy, the tetra-coordinated complex will not take a tetrahedral configuration. Although such an arrangement is known to occur in the case of $CuCl_4^{-2}$ (9), the usual configuration for copper complexes is planar.

These complexes, which are themselves blue, violet, or green in color, dissolve in formamide to give blue solutions which exhibit a single band at about 635 mμ.

The position of this band depends on the intensity of the ligand field around the metal. Thus for the $[Cu(H_2O)_4]^{+2}$ ion the band is observed at 800 mμ. The successive replacement of water ligands by amines shifts the band from 800 mμ to 600 mμ for $[Cu(am)_4]^{+2}$. This bathochromic effect is due to the stronger ligand field environment produced around the metal, which causes the absorption band to shift to shorter wavelength.

THE RELATIVE ACCEPTOR POWER OF BORON TRIHALIDES TOWARD ACETONITRILE BY PROTON NUCLEAR MAGNETIC RESONANCE MEASUREMENTS[1]

J. M. MILLER[2] AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, McGill University, Montreal, Quebec
Received August 31, 1964

ABSTRACT

Proton nuclear magnetic resonance spectra of BF_3, BCl_3, and BBr_3 adducts of acetonitrile have been measured in nitrobenzene solution. Single peaks were observed in each case and chemical shifts relative to tetramethylsilane decreased in the order $BBr_3 > BCl_3 > BF_3$, suggesting that this is the order of acceptor activity toward acetonitrile. Linear relationships exist between methyl proton chemical shifts of $CH_3CN.BX_3$ and the heats of formation, dipole moments, and infrared vibrational shifts of the same or related adducts.

INTRODUCTION

In a previous article (1) we reported that proton nuclear magnetic resonance (n.m.r.) chemical shifts of $(CH_3)_3N.BX_3$ (where X = H, F, Cl, or Br) relative to tetramethylsilane decrease in the order $BBr_3 > BCl_3 > BH_3 > BF_3$, and that proton resonance peaks are singlets in $(CH_3)_3N.BF_3$ and $(CH_3)N.BH_3$ but quartets in $(CH_3)_3N.BCl_3$ and $(CH_3)_3N.BBr_3$. It was suggested that the quartet splitting resulted from coupling of methyl protons to ^{11}B (spin 3/2) only when there is appreciable steric hindrance to free rotation about the B—N bond, which appears from Courtauld molecular models to be true in $(CH_3)_3N.BCl_3$ and $(CH_3)_3N.BBr_3$ but not in $(CH_3)_3N.BF_3$ and $(CH_3)_3N.BH_3$. However, our failure to observe splitting of methyl protons in $(CH_3)_3N.BF_3$ was probably due to a lack of sensitivity of our spectrometer, as has been pointed out recently by Heitsch (2). He found that under high resolution the methyl proton peak consists of a decet due to coupling of protons with ^{11}B and ^{19}F nuclei. Similarly, Banister and Greenwood (3) attributed broadening of the methyl proton peak of dimeric dimethylaminoboron difluoride to ^{19}F-proton and ^{11}B-proton coupling.

To obtain more information about ^{11}B-proton coupling in boron trihalide complexes we have measured the ^1H n.m.r. spectra of $CH_3CN.BX_3$ adducts (where X = F, Cl, or Br). It was also of particular interest to determine whether proton chemical shifts could be correlated with the acceptor power order $BBr_3 > BCl_3 > BF_3$, which has been inferred from heats of formation of $CH_3CN.BX_3$ adducts (4, 5).

RESULTS AND DISCUSSION

The ^1H chemical shifts of $CH_3CN.BX_3$ adducts in nitrobenzene solution (1.0 mole %) are compared in Table I with the corresponding ^1H chemical shifts of $(CH_3)_3N.BX_3$ adducts* in nitrobenzene and chloroform solution (1.0 mole %) and with other physical

**After reporting our measurements on* $(CH_3)_3N.BX_3$ *adducts (1), we prepared* $(CH_3)_3N.BI_3$ *and found that its* ^1H *spectrum in chloroform solution consists of a quartet centered at 201.6 c.p.s. with a* ^{11}B—^1H *coupling constant of 3.3 c.p.s. and a profile almost the same as those previously observed for* $(CH_3)_3N.BCl_3$ *and* $(CH_3)_3N.BBr_3$. *Thus, in the series of* $(CH_3)_3N.BX_3$ *complexes, proton chemical shifts decrease in the order* $BI_3 > BBr_3 > BCl_3 > BF_3$. *It is also noteworthy that in the same series proton chemical shifts are directly proportional to* ^{11}B—^1H *coupling constants. When an attempt was made to prepare* $CH_3CN.BI_3$ *by adding* BI_3 *to a nitrobenzene solution of* CH_3CN, *an explosion occurred.*

data regarding BX_3 adducts. In the $(CH_3)_3N$ and CH_3CN series of adducts chemical shifts decrease in the order $BBr_3 > BCl_3 > BF_3$. The same order is also indicated by the heats of formation of $CH_3CN.BX_3$ and by dipole moments and infrared carbonyl shifts of related adducts. Moreover, as shown in Fig. 1, ^1H chemical shifts of $CH_3CN.BX_3$ are

directly proportional to: (i) heats of formation of $CH_3CN.BX_3$, (ii) dipole moments of $C_5H_5N.BX_3$ and $(CH_3)_3N.BX_3$, (iii) infrared carbonyl shifts of xanthone.BX_3. These correlations strongly suggest that all four measurements depend mainly upon the same fundamental property which we believe to be the strength of the donor–acceptor bond. It has not yet been possible to relate heats of formation, dipole moments, and carbonyl shifts directly to donor–acceptor bond strengths. In spite of this, these measurements have invariably been interpreted as indicating that the order of acceptor power is $BBr_3 > BCl_3 > BF_3$. While each of these measurements strongly suggests this order, none proves it conclusively. This is now also true of our proton chemical shifts of $CH_3CN.BX_3$ adducts. Nevertheless, we consider that the most reasonable explanation of the observed trend in proton chemical shifts of $CH_3CN.BX_3$ complexes is that the acceptor power toward acetonitrile decreases in the order $BBr_3 > BCl_3 > BF_3$.

This order also applies to N,N-dimethylformamide as reference electron-pair donor, as evident from the methyl proton resonance measurements of Kuhn and McIntyre (9). More recently, Gates, McLauchlin, and Mooney (10) measured ^{11}B chemical shifts of $L.BX_3$ complexes, where L = benzophenone, pyridine, and triethylamine, and X = F, Cl, Br, and I. They found that the difference between ^{11}B chemical shifts of complexed and free boron trihalide decreased in the order $BI_3 > BBr_3 > BCl_3 > BF_3$. This order correlates well with infrared and thermochemical data for acetophenone and pyridine complexes, respectively, strongly suggesting that this order is also that of the relative acceptor power.

Proton resonance peaks of $CH_3CN.BX_3$ complexes were sharp singlets, clearly indicating that there was little, if any, coupling of protons to ^{11}B, ^{19}F, and ^{14}N nuclei. Although ^{11}B-proton coupling was detected in $(CH_3)_3N.BX_3$ complexes, it is probably too weak to be observed in $CH_3CN.BX_3$ complexes because of the additional carbon atom between the ^1H and ^{11}B nuclei. The proton resonance peak of free CH_3CN at 123 c.p.s. was not observed in 1.0 mole % nitrobenzene solutions of $CH_3CN.BCl_3$. In the presence of a large excess of CH_3CN only a single peak occurred at 127 c.p.s. and its position varied with concentration.

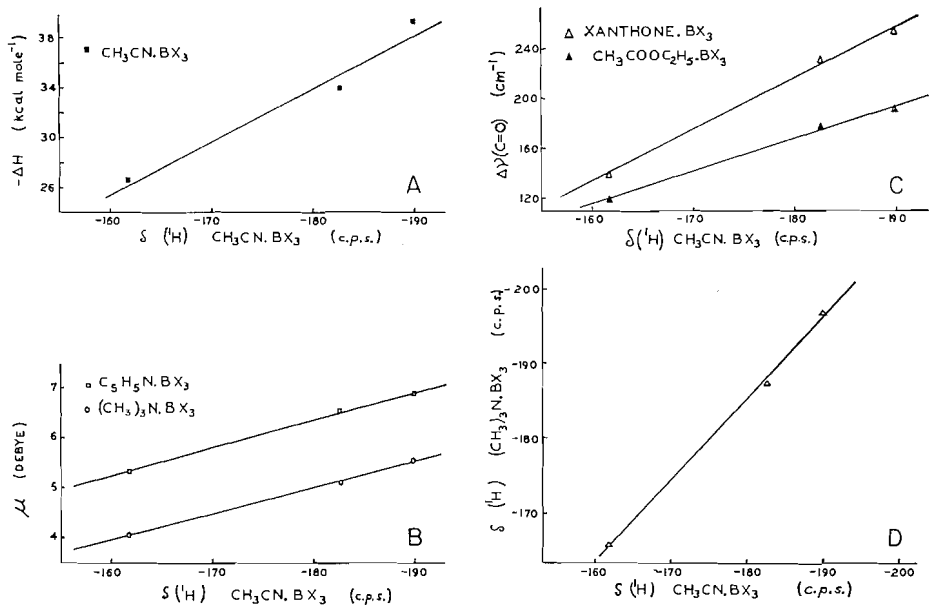

FIG. 1. Correlation of methyl proton chemical shifts of $CH_3CN.BX_3$ with: (A) heat of formation of $CH_3CN.BX_3$, (B) dipole moments of $C_5H_5N.BX_3$ and $(CH_3)_3N.BX_3$, (C) infrared carbonyl shifts of $CH_3COOC_2H_5.BX_3$ and xanthone.BX_3, and (D) ^{1}H n.m.r. shifts of $(CH_3)_3N.BX_3$.

These results confirmed that a fast exchange of BF_3 occurs between free and complexed CH_3CN. This was not true for $(CH_3)_3N.BCl_3$ in excess $(CH_3)_3N$ (1), presumably because of the greater stability of $(CH_3)_3N.BCl_3$ compared with $CH_3CN.BCl_3$ in nitrobenzene solution. Fast exchange in the $CH_3CN.BCl_3 - CH_3CN$ system would be expected to mask any splitting or broadening due to long range ^{11}B—^1H coupling.

Infrared spectra of $CH_3CN.BX_3$ complexes as 1.0 mole % solutions in nitrobenzene confirmed that they are only slightly dissociated ($< 5\%$) in this solvent. The spectrum of each complex contained a small peak at 2 250 cm^{-1} characteristic of the C≡N stretching vibration of pure CH_3CN, in addition to a strong, sharp, and narrow band due to "C≡N stretching" in complexed CH_3CN; these occurred at 2 360, 2 330, and 2 320 cm^{-1} in the BF_3, BCl_3, and BBr_3 complexes, respectively. Beattie and Gilson (11) have shown by normal coordinate analysis of $CH_3CN.BX_3$ that it is not possible to describe a pure "C≡N stretching" frequency in these complexes. It is not surprising, therefore, that "C≡N stretching" frequency shifts do not correlate with the observed ^{1}H chemical shifts.

EXPERIMENTAL

Materials

Acetonitrile complexes of BF_3, BCl_3, and BBr_3 were prepared by combining, in a standard high vacuum apparatus, the purified boron trihalide with acetonitrile previously dried over CaH_2. The component taken in excess was removed by distillation at 0° and the remaining white solid complex was pure after resublimation (for $CH_3CN.BF_3$: found m.p. 132–136°, lit. (4) 135°; for $CH_3CN.BCl_3$: found m.p. 195–201°, lit. (4) 195–200°; for $CH_3CN.BBr_3$: found m.p. 233–235°, with decomposition). Trimethylamine adducts of BF_3, BCl_3, and BBr_3 were prepared and purified as described previously (1). Nitrobenzene was purified by distillation over CaH_2. Tetramethylsilane (Anderson) was used without further purification.

Apparatus and Methods

Proton n.m.r. spectra were measured as described previously (1). Measurements were made on 1.0 mole % solutions of $CH_3CN.BX_3$ in nitrobenzene. To prevent hydrolysis of the adducts, solutions were prepared and transferred in a nitrogen-filled dry box. Measurements were also made on 1.0 mole % solutions of $(CH_3)_3N.BX_3$ in nitrobenzene. Infrared spectra were recorded on a Perkin–Elmer model 421 grating spectrometer.

THE REACTIVITY OF METAL–METAL BONDS

I. THE Sn–Sn BOND[1]

H. C. CLARK,[2] J. D. COTTON,[3] AND J. H. TSAI[4]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 15, 1965

ABSTRACT

The reactions of a series of fluorinated olefins with hexamethylditin have been investigated, under conditions which favor the formation of $(CH_3)_3Sn\cdot$ radicals. Two principal types of products have been isolated, namely (polyfluoroalkyl)trimethyltin compounds, e.g. $(CH_3)_3SnCF_2CF(R)H$, and insertion products of the type $(CH_3)_3SnCF_2CF(R)Sn(CH_3)_3$, where R = F or CF_3. These results are consistent with the formation of intermediate radicals such as $(CH_3)_3SnCF_2C(R)F\cdot$ which then participate either in hydrogen abstraction or in the formation of the insertion products. Reactions of hexamethylditin with $CF_2{=}CFH$, $CF_2{=}CH_2$, $CF_2{=}CFCl$, $CF_2{=}CFBr$, and C_2H_4 are also discussed. The direction of attack of the $(CH_3)_3Sn\cdot$ radical on the olefins indicates that the former has a high degree of nucleophilic character. A more detailed study of the reactions of the cyclic hexamers of dimethyltin and diphenyltin with tetrafluoroethylene shows that some addition does occur, but that the products are of indeterminate composition. The reaction of hexameric dimethyltin with trifluoroiodomethane has also been examined.

INTRODUCTION

Although numerous compounds have now been reported containing metal–metal bonds, few investigations have been made of the chemical reactivity of such bonds. We have become interested in such studies because of the considerable interest, from structural and theoretical viewpoints, in metal–metal bonds, and also because of the possible synthetic routes they provide to new organometallic compounds. In this paper we report on the chemical behavior of the Sn—Sn bond, as found in hexamethylditin, towards a series of fluorinated olefins; in later papers, other metal–metal bonded systems will be examined. Olefins have been chosen as the first set of standard reactants, since their high reactivity towards metal–metal bonds has been amply demonstrated, for example, by the catalytic properties of a platinum–tin complex in the homogeneous hydrogenation of ethylene and acetylene (1). The use of fluorinated olefins makes the application of ^{19}F nuclear magnetic resonance spectroscopy possible as an additional tool to follow the course of the reactions.

Hexaorganoditin compounds are well characterized, and the work of Kraus and Sessions (2) revealed the reactivity of the tin–tin bonds which they contain towards oxygen, chlorine, and sulfur. Interestingly, hexamethylditin reacts with mercury(II) chloride (2) to give mercury and trimethyltin chloride, showing the electropositive nature of the trimethyltin group. Although magnetic measurements (3) have shown that the $(CH_3)_3Sn$ group does not exist as the monomer in dilute benzene solution, other studies have provided indirect evidence of the free radical behavior of this group. Hexamethylditin is cleaved by trifluoroiodomethane (4, 5) according to the equation

$$(CH_3)_3Sn{-}Sn(CH_3)_3 + CF_3I \rightarrow (CH_3)_3SnCF_3 + (CH_3)_3SnI.$$

The most favorable conditions, requiring ultraviolet irradiation of the reactants at 25° for 6 h, are much milder than those usually required for free-radical formation from

trifluoroiodomethane. It was thus suggested (6) that a radical–chain mechanism might be operating, probably involving homolytic fission of the Sn–Sn bond as the first step. Other workers (7) have interpreted the photolytic behavior of hexaethylditin in terms of homolytic fission of the Sn–Sn bond, in addition to rupture of the Sn–C bond, and the formation of new Sn–Sn bonds in polymeric organotin compounds.

This high reactivity of the Sn–Sn bond under free radical conditions suggested that ready addition across the olefinic double bond might also occur. This was supported by a preliminary study (8) of the reaction of hexamethylditin with tetrafluoroethylene, although the reaction products were not fully characterized.

RESULTS AND DISCUSSION

The reaction of hexamethylditin with tetrafluoroethylene was studied most fully, and in a typical reaction, equimolar quantities were irradiated with a 200 W Hanovia lamp at 75° for 4 h. Based on the recovery of hexamethylditin, the reaction was then about 60% complete. Of the ditin consumed, 13% appeared as decomposition products, mainly tetramethyltin which must result from the photochemical decomposition of hexamethylditin (7). This is consistent with the observed formation of a deeply colored, involatile residue, shown spectroscopically to contain polymeric organotin compounds. The other decomposition product, produced in as high as 28% yield, was trimethyltin fluoride, which must result from an α-fluorine atom elimination from fluorocarbontin compounds (5, 9). It was observed in all of the following reactions.

Two distinct types of products were formed as colorless liquids, namely the adducts, $(CH_3)_3Sn(CF_2CF_2)_nSn(CH_3)_3$, and polyfluoroalkyl trimethyltin compounds, $(CH_3)_3Sn(CF_2CF_2)_nH$. The compounds $(CH_3)_3Sn(CF_2CF_2)_nH$, $n = 1$ and 2, were fully characterized but the adducts could not be completely separated and were identified spectroscopically.

From a series of experiments summarized in Table I, in which controlled variations were made in the reaction conditions, several conclusions become apparent. Firstly, the extent of the reaction was approximately doubled when performed in a silica tube (transparent to radiation of wavelength $>2\,200$ Å) as compared with the use of a Pyrex tube (transparent for wavelength $>3\,000$ Å). Secondly, the reaction proceeded much further towards completion with irradiation at 75°, rather than 25°, although no reaction occurred in an experiment performed at 100° without irradiation. Thirdly, at 75° with irradiation, the yields of $(CH_3)_3SnCF_2CF_2H$ and the 1:1 adduct were markedly higher than at 25°, at which temperature the relative abundance of adducts containing several C_2F_4 units was much increased although the overall reaction was less complete.

The accelerating influence of the lower wavelength radiation is understandable in terms of the ultraviolet absorption maxima of ditin derivatives. Van der Kerk *et al.* (10) have reported a maximum at 247 mμ for hexaphenylditin, which they associated with the Sn—Sn bond system. We observe a similar maximum for hexamethylditin $\leqslant 210$ mμ, so that $(CH_3)_3Sn\cdot$ radicals may be formed under ultraviolet irradiation. If the reaction occurs principally in the gas phase, the increased rate at higher temperatures may arise from the consequent increase in the partial pressure of hexamethylditin (b.p. 182°).

The formation of the above products suggests that two principal reactions must occur, both involving the radical $(CH_3)_3SnCF_2CF_2\cdot$. It is reasonable to assume that this species is formed by the attack of $(CH_3)Sn\cdot$ radicals on tetrafluoroethylene. The resultant radical then either participates in hydrogen abstraction, presumably from methyl groups, or attacks another hexamethylditin molecule giving the 1:1 adduct and another $(CH_3)Sn\cdot$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

radical. Both of these steps may alternatively be preceded by combination of $(CH_3)_3SnCF_2CF_2\cdot$ with one or more C_2F_4 molecules giving higher molecular weight radicals. The overall reactions can be described by the following scheme.

$$(CH_3)_3Sn{-}Sn(CH_3)_3 \xrightarrow{\text{ultraviolet}} 2(CH_3)_3Sn\cdot$$

Initiation: $(CH_3)_3Sn\cdot + CF_2{=}CF_2 \rightarrow (CH_3)SnCF_2CF_2\cdot$

Propagation: $(CH_3)_3SnCF_2CF_2\cdot + CF_2{=}CF_2 \rightarrow (CH_3)_3SnCF_2CF_2CF_2CF_2\cdot$, etc.

Chain transfer:

(*a*) $(CH_3)_3Sn(CF_2CF_2)_n\cdot + (CH_3)_3Sn{-}Sn(CH_3)_3 \rightarrow (CH_3)_3Sn(CF_2CF_2)_nSn(CH_3)_3 + (CH_3)_3Sn\cdot$, etc.

or

(*b*) $$(CH_3)_3Sn(CF_2CF_2)_n\cdot + \diagdown\!\!\!\!\diagup C{-}H \rightarrow (CH_3)_3Sn(CF_2CF_2)_nH + \diagdown\!\!\!\!\diagup C\cdot, \text{ etc.}$$

Clearly the higher proportion of olefin in the gas phase at 25° will favor the propagation reaction (i.e. formation of products where n is large), while in agreement with observation, the increased vapor pressure and hence higher proportion of hexamethylditin at 75° will favor the chain transfer reactions. It is possible that at much higher temperatures, the products with $n = 1$ might be formed almost exclusively, but under these more vigorous conditions, decomposition to trimethyltin fluoride and fluorocarbons would probably be extensive.

We must stress that the above evidence does not exclude a molecular, four-center type of mechanism. Moreover, assuming a radical mechanism is involved, these results provide no information on the direction of radical attack. Some such information could well be obtained by examining the reactions of hexamethylditin with unsymmetrical fluoroolefins.

In several reactions of hexamethylditin with perfluoropropene, the only observed products, apart from the photochemical decomposition products from the ditin, were 1,1,2,3,3,3-hexafluoropropyltrimethyltin, $(CH_3)_3SnCF_2CF(CF_3)H$, and 1,2-bis-(trimethyltin)hexafluoropropane, $(CH_3)_3SnCF_2(CF_3)Sn(CH_3)_3$. These colorless liquids were characterized analytically and spectroscopically, and the latter data will be described fully elsewhere. When the reaction was performed at 90° rather than 70°, the yield of the 1:1 adduct was reduced markedly because of decomposition, while at 25° the formation of this adduct was almost negligible.

The hexafluoropropyl derivative has two possible isomeric forms, namely

$$(CH_3)_3SnCF_2CF(CF_3)H \quad \text{and} \quad (CH_3)_3SnCF(CF_3)CF_2H,$$

I II

of which only isomer I was observed in four experiments. The reaction therefore proceeds by the attack of $(CH_3)_3Sn\cdot$ radicals exclusively on the $F_2C{=}$ group of the propene.

$$(CH_3)_3Sn{-}Sn(CH_3)_3 \xrightarrow{\text{ultraviolet}} 2(CH_3)_3Sn\cdot$$

$$(CH_3)_3Sn\cdot + CF_2{=}CFCF_3 \rightarrow (CH_3)_3SnCF_2CF(CF_3)\cdot$$

and

$$(CH_3)_3SnCF_2CF(CF_3)\cdot + \diagdown\!\!\!\!\diagup C{-}H \rightarrow (CH_3)_3SnCF_2CF(CF_3)H + \diagdown\!\!\!\!\diagup C\cdot \text{ etc.}$$

or

$$(CH_3)_3SnCF_2CF(CF_3)\cdot + (CH_3)_3Sn{-}Sn(CH_3)_3 \rightarrow (CH_3)_3SnCF_2CF(CF_3)Sn(CH_3)_3 + (CH_3)Sn\cdot \text{ etc.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Products arising from the propagation step:

$$(CH_3)_3SnCF_2CF(CF_3)\cdot + CF_2{=}CFCF_3 \rightarrow (CH_3)_3SnCF_2CF(CF_3)CF_2CF(CF_3)\cdot \text{ etc.}$$

were not observed.

Radical addition to fluoro-olefins has been investigated by several groups of workers (11–13), and in particular the direction of addition to unsymmetrical olefins has been discussed by Haszeldine *et al.* (11). They point out that hexafluoropropene is very sensitive to nucleophilic attack, and that such attack is exclusively on the $F_2C{=}$ group. The more nucleophilic the attacking radical, therefore, the more should radical attack be oriented towards the $F_2C{=}$ group. A comparison of our results with those of Haszeldine *et al.* thus shows that the $(CH_3)_3Sn\cdot$ radical is as specific as the $(CH_3)_3Si\cdot$ and the $(CH_3)_2SiH\cdot$ radicals in directing attack to the $F_2C{=}$ group, and possesses considerable nucleophilic character.

Temperatures of 85–105° with ultraviolet irradiation favored the reaction of hexamethylditin with trifluoroethylene, leading to similar series of products, $(CH_3)_3Sn(C_2F_3H)_nH$ and $(CH_3)_3Sn(C_2F_3H)_nSn(CH_3)_3$, as well as decomposition products of the ditin. On the basis of spectroscopic evidence, products formulated as $(CH_3)_3SnCFHCF_2H$, $(CH_3)_3SnCFHCF_2CFHCF_2H$, and $(CH_3)_3SnCF_2CFHCF_2CFHSn(CH_3)_3$ were identified, and were probably formed by a series of reactions similar to those for tetrafluoroethylene and perfluoropropene, and involving radicals such as $(CH_3)_3SnCFHCF_2\cdot$ and $(CH_3)_3Sn(CFHCF_2)_nCFHCF_2\cdot$. The presence in the hydrogen abstraction products of terminal $-CF_2H$ groups rather than $-CFH_2$ groups strongly suggests that addition of $(CH_3)_3Sn\cdot$ is predominantly to the $=CFH$ group of trifluoroethylene, as for other radical additions (14, 15).

An increase in the concentration of hexamethylditin should reduce the extent of the propagation reaction

$$(CH_3)_3SnCFHCF_2\cdot + CF_2{=}CFH \rightarrow (CH_3)_3SnCFHCF_2CFHCF_2\cdot, \text{ etc.}$$

When hexamethylditin in 40% excess was irradiated with trifluoroethylene at 90°, a mixture of *both* the 1:1 adduct, $(CH_3)_3SnCFHCF_2Sn(CH_3)_3$ and the 1:2 adduct in an approximate ratio 2:1 was identified spectroscopically. Moreover, neither of these products was formed in a reaction carried out at 100° in the absence of radiation, although considerable decomposition of hexamethylditin to metallic tin, tetramethyltin, and some hydrogen was observed. Similarly, with hexamethylditin and 1,1-difluoroethylene, both hydrogen abstraction products, $(CH_3)_3Sn(CH_2CF_2)_nH$ ($n = 1$ or 2), and adducts $(CH_3)Sn(CF_2CH_2)_nSn(CH_3)_3$ were formed. Spectroscopic evidence showed conclusively that the hydrogen abstraction products contained terminal $-CF_2H$ groups, again demonstrating that the most probable mechanism involves attack of $(CH_3)_3Sn\cdot$ radicals on the CH_2 group of 1,1-difluoroethylene. This agrees with other data relating to radical attack on this olefin by $CF_3\cdot$ (16), $Br\cdot$ (17), and $PH_2\cdot$ (11).

It is clear, then, that the nucleophilic character of $(CH_3)_3Sn\cdot$ does not play too important a role in its reactions with trifluoroethylene and 1,1-difluoroethylene, since products arising from the intermediate radicals $(CH_3)_3SnCF_2CFH\cdot$ and $(CH_3)_3SnCF_2CH_2\cdot$ would otherwise have been formed. These results, however, agree with previous conclusions (11) that the difference in stability of the possible intermediate radicals is sufficient to determine the position of radical attack of the fluoro-olefin, e.g.

$(CH_3)_3SnCH_2CF_2\cdot$ formed rather than $(CH_3)_3SnCF_2CH_2\cdot$

$(CH_3)_3SnCFHCF_2\cdot$ formed rather than $(CH_3)_3SnCF_2CFH\cdot$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

With perfluoropropene the difference in stability of the two possible radicals $(CH_3)_3SnCF_2CF(CF_3)\cdot$ and $(CH_3)_3SnCF(CF_3)CF_2\cdot$ is apparently not great, so that the nucleophilic character of $(CH_3)_3Sn\cdot$ is the determining factor.

Somewhat different reactions occurred between hexamethylditin and trifluorochloroethylene or trifluorobromoethylene. With trifluorochloroethylene, only the hydrogen abstraction product, $(CH_3)_3SnCF_2CFHCl$, and secondary products such as tetramethyltin, trimethyltin chloride, and trimethyltin fluoride were formed. No adduct could be detected by careful spectroscopic examinations of the reaction mixtures. Apparently, the radical $(CH_3)_3SnCF_2CFCl\cdot$ is formed by attack of $(CH_3)_3Sn\cdot$ on the CF_2 group of CF_2CFCl. The orientation of this attack is in good agreement with other systems e.g. $CF_3\cdot$ and $CCl_3\cdot$ (18), $Br\cdot$ (19), $SiCl_3\cdot$ (15), and $PH_2\cdot$ (11). In all these cases, the direction of radical attack was attributed to the difference in stability of the radicals, $RCF_2CFCl\cdot > RCFClCF_2\cdot$, because of the powerful stabilizing effect of the chlorine atom (14). The formation of both trimethyltin chloride and trimethyltin fluoride could be due to the decomposition of either the alkyltin compounds

$$(CH_3)_3SnCF_2CFHCl \rightarrow (CH_3)_3SnF \text{ (or Cl)} + CF_2{=}CHCl \text{ (or F)}$$

or of an unstable and unobserved adduct

$$[(CH_3)_3SnCF_2CFClSn(CH_3)_3] \rightarrow (CH_3)_3SnF \text{ (or Cl)} + (CH_3)_3SnCF{=}CFCl \text{ (or F)}.$$

However, no vinyltin compounds could be identified among the products.

With trifluorobromoethylene, reaction occurred under irradiation at room temperature, to give perfluorovinyltrimethyltin, tetramethyltin, trimethyltin fluoride, and trimethyltin bromide, in addition to involatile polymeric forms of organotin compounds. Neither hydrogen abstraction products nor adducts could be detected even under these mild conditions. These results suggest the following reaction sequence.

$$(CH_3)_3Sn{-}Sn(CH_3)_3 \xrightarrow{\text{ultraviolet}} 2(CH_3)_3Sn\cdot$$

$$(CH_3)_3Sn\cdot + CF_2{=}CFBr \rightarrow [(CH_3)_3SnCF_2CFBr\cdot] \rightarrow (CH_3)_3SnCF{=}CF_2 + Br\cdot$$

$$Br\cdot + (CH_3)_6Sn_2 \rightarrow (CH_3)_3SnBr + (CH_3)_3Sn\cdot, \text{ etc.}$$

This is consistent with the ease of formation of the reactive $Br\cdot$ radical under irradiation (11, 14, 19, 20). However, an alternative sequence cannot be eliminated:

$$(CH_3)_3Sn{-}Sn(CH_3)_3 + CF_2{=}CFBr \rightarrow [(CH_3)_3SnCF_2CFBrSn(CH_3)_3] \rightarrow (CH_3)_3SnCF{=}CF_2 + (CH_3)_3\,SnBr.$$

In the reaction of tetramethyldiarsine with trifluorobromoethylene, both the adduct, $(CH_3)_2AsCF_2CFBrAs(CH_3)_2$, and its decomposition products, $(CH_3)_2AsCF{=}CF_2$ and $(CH_3)_2AsBr$, have been observed (21).

Finally, in view of the successful addition of acetylenes to organotin hydrides to give compounds of the type $R_3SnCH_2CH_2SnR_3$ (22), it was hoped that 1,2-bis(trimethyltin)-ethane might be formed by the reaction of hexamethylditin with ethylene. Even after prolonged periods of irradiation at 25°, no adducts could be detected. This is in sharp contrast to the sequence given by Haszeldine and Osborne (17) for the ease of radical attack, i.e.

$$C_2H_4 \sim CH_2{=}CHCH_3 \sim CH_3CH{=}CHCH_3 > CH_2{=}CF_2 > CF_2{-}CHCl > CF_2{=}CFCl > CF_2{=}CHCF_3 > CF_2{=}CFCF_3.$$

However, this order was established by the use of $Br\cdot$ and $CF_3\cdot$ radicals which must behave more as electrophiles than the $(CH_3)_3Sn\cdot$ radical. Although $Br\cdot$ and $CF_3\cdot$ should readily attack the electron-rich carbon atoms of ethylene, the more nucleophilic $(CH_3)_3Sn\cdot$ may very much more readily attack the electron-poor carbon atoms of tetrafluoroethylene.

In our preliminary communication (8), in addition to the reaction of hexamethylditin with tetrafluoroethylene, we described the reaction of diphenyltin with tetrafluoroethylene. Since that time, the constitution and polymeric complexities of diorganotin compounds, $[R_2Sn]_n$, have been examined by several workers. The linear polymers $[(CH_3)_2Sn]_x$ where $x = 12$–20, and the cyclic hexamer $[(CH_3)_2Sn]_6$ have been synthesized and distinguished on the basis of their infrared and proton magnetic resonance spectra (23). The constitution of the various forms of diphenyltin has been established by the work of Neumann and Konig (24) and the structural study of Olsen and Rundle (25). Since these developments have made it possible to work with homogeneous and well-defined forms of specific diorganotin compounds, we have repeated the earlier work, hoping to characterize the products more fully.

We chose to work chiefly with the cyclic hexameric forms of dimethyltin and diphenyltin. The former was obtained firstly by the method described by Brown and Morgan (23) involving the reduction by lithium aluminium hydride of dimethyltin dichloride in diethyl ether in the presence of triethylamine. The results of Brown and Morgan were readily reproduced, with respect to the general characteristics of the products and to the major features of the infrared and proton magnetic resonance spectra. It was clear, however, as Brown and Morgan had shown, that this method gives predominantly the cyclic hexamer with varying amounts of linear polymers. An alternative preparation involving the decomposition of dimethyltin dihydride with pyridine in the presence of a trace of dimethyltin dichloride was therefore also used. This method has been most recently applied by Neumann (26) to the preparation of $[(C_6H_5)_2Sn]_6$ and $[(C_2H_5)_2Sn]_6$, and the available evidence shows that formation of the cyclic hexamer $[(CH_3)_2Sn]_6$ is essentially quantitative by this method. Similarly, the cyclic hexamer of diphenyltin was obtained (24) by reduction of diphenyltin dihydride with pyridine, and for comparisons with earlier results (8), the product obtained by the reduction of diphenyltin dihydride with methanol was also used in certain reactions. This latter "white modification" was originally considered by Kuivila and Jakusik (27) to be another form of polymeric diphenyltin, but Neumann has shown it to be H—$[(C_6H_5)_2Sn]_6$—H which loses the remaining hydrogen, for example on treatment with pyridine or dimethylformamide, to give the cyclic hexamer.

Reactions of polydimethyltin with tetrafluoroethylene were carried out firstly with heating to 105°. The olefin underwent some polymerization (~25%) and extensive decomposition of the dimethyltin was observed, but no fluorocarbon-tin derivative could be detected. Ultraviolet irradiation of dimethyltin (obtained by the lithium aluminium hydride reduction method) with tetrafluoroethylene in a silica tube at 60° led to extensive polymerization of the olefin with some decomposition of the organotin, and again no fluorocarbon-tin appeared to be formed. When reactions of dimethyltin (prepared by reduction of the dihydride with pyridine) with tetrafluoroethylene were carried out in benzene solution, under ultraviolet irradiation in either Pyrex or silica reaction tubes, there was apparently some uptake of the olefin, other than in polymerization. All the products, however, were resinous substances which solidified on exposure to air. The infrared spectra showed shifts of about 30 cm^{-1} to higher frequencies for the Sn–C stretching vibrations, compared with those of dimethyltin, and also C—F stretching vibrations different from those of polymerized tetrafluoroethylene. However, no products could be obtained in a form suitable for characterization.

Similarly, from reactions of diphenyltin with tetrafluoroethylene, usually carried out in benzene solution under ultraviolet irradiation, only small quantities of yellow oils were obtained, except when the product mixtures were allowed to oxidize in air when unidentified white solids resulted. The consumption of olefin was always small compared with that

required for complete reaction with the diphenyltin, and although the infrared spectra of the oils showed features similar to those reported previously (8), identifiable substances could not be obtained. In summary, after a very careful examination, under rigorously controlled conditions, of the reactions of dimethyl- and diphenyl-tin with tetrafluoroethylene, it is clear that at best only a low proportion of the Sn—Sn bonds are broken and that identifiable species cannot be obtained. The solid material described previously (8) is presumably some type of oxidation product, in which fluorocarbon groups are present, and in which terminal hydrogen atoms of the starting material are probably replaced by chlorine atoms from the solvent.

Finally, we have examined the reaction of dimethyltin (prepared from the dihydride by reduction with pyridine) with trifluoroiodomethane under ultraviolet irradiation in a silica tube at room temperature. The less volatile fractions of the reaction mixture were shown to be mixtures, and from the infrared and proton magnetic resonance spectra, four components were identified. Two of these, from known data, were trimethyltrifluoromethyltin, and trimethyltin iodide. The remaining two were presumably dimethyl bis(trifluoromethyl)tin and dimethyltrifluoromethyltin iodide. The reaction residue contained dimethyltin diiodide. None of these could be obtained as pure compounds because of their similar volatilities and because several of them readily decomposed on gas chromatographic columns. Our evidence does confirm again, however, that trifluoroiodomethane adds across the Sn—Sn bond.

EXPERIMENTAL

Standard high vacuum techniques were used throughout these reactions for the manipulation of volatile compounds. Infrared spectra were recorded with Perkin-Elmer model 137 and model 21 spectrophotometers. Proton spectra were recorded on a Varian A60 spectrometer, and fluorine magnetic resonance spectra at 56.4 Mc s^{-1} with a Varian V-4300 spectrometer. Gas chromatographic separations were performed on a Beckman GC-2A gas chromatograph with helium as the carrier gas.

Reactants

Hexamethylditin was prepared according to the procedure described by Clark and Willis (5). Tetrafluoroethylene was prepared by the pyrolysis of Teflon chips in a silica tube at ~600° and was purified by vacuum fractionation. All other olefins were obtained commercially and were purified by vacuum fractionation.

Reactions of Hexamethylditin with Tetrafluoroethylene

(*a*) Hexamethylditin (7.0 g, 21.4 mmoles) and tetrafluoroethylene (2.2 g, 22 mmoles) in a silica tube at 75° were exposed to ultraviolet radiation for 4 h. The volatile products were separated under vacuum into fractions condensing at −196°, −126°, −78°, −46°, and 0° to leave a brown liquid in the reaction tube. The −196° fraction (0.10 mmole) was mainly tetrafluoroethylene with some perfluoropropane, both identified by infrared spectrometry and chromatography. The −126° fraction was perfluoro-1,3-butadiene (0.15 mmole; mol. wt. calcd. 162, observed 159), unambiguously identified (28) by the characteristic infrared bands at 1 780 (s), 1 330 (vs), 1 190 (s), 1 140 (s), and 965 (s) cm^{-1}. The −78° fraction was tetramethyltin (0.3 g, 1.7 mmole), identified by comparison of its gas chromatographic retention time and its infrared spectrum with those of a standard sample. The −46° fraction was separated chromatographically (preparative dinonyl phthalate column at 140°, with 15 p.s.i. of helium) into 1,1,2,2-tetrafluoroethyl trimethyltin (0.12 g, 0.45 mmole) and 1,1,2,2,3,3,4,4-octafluorobutyltrimethyltin (0.08 g, 2.22 mmole). The former was characterized analytically and by comparison of its infrared and proton magnetic resonance spectra with those of dimethylbis(tetrafluoroethyl)tin (29, 30).

Anal. Calcd. for $C_5H_{10}F_4Sn$: C, 22.6; H, 3.9; mol. wt. 265. Found: C, 22.6; H, 4.1; mol. wt. 251.

The second chromatographic fraction (retention time 6.8 min) was the octafluorobutyltrimethyltin. This was characterized by its infrared and proton magnetic resonance spectra. The latter showed, in addition to the methyl absorptions, a tripleted triplet at −5.97 p.p.m. with respect to internal TMS. This contrasts with the tripleted triplet at −5.51 p.p.m. observed for the SnC_2F_4H group. Both spectra will be discussed more fully elsewhere.

The 0° fraction was combined with the brown liquid, and distillation under reduced pressure (22 mm Hg) at 78° gave unchanged hexamethylditin (2.6 g, 37% recovery). Ether extraction of the residue left a white solid which was treated first with carbon tetrachloride followed by hot methanol. There remained a white solid (0.35 g) whose infrared spectrum was identical to that of polymerized tetrafluoroethylene. Evaporation of the methanol solution gave trimethyltin fluoride (1.3 g, 7.1 mmoles).

Anal. Calcd. for C_3H_9FSn: C, 19.8; H, 4.9. Found: C, 19.7; H, 4.03.

TABLE I

Product distribution in reactions of hexamethylditin with C_2F_4

		Expt. 1	Expt. 2	Expt. 3	Expt. 4
Reactants (mmoles)	$(CH_3)_6Sn_2$	18.3	20.8	21.9	21.4
	C_2F_4	18.5	21.7	22.0	22.0
Conditions	Carius tube	Pyrex	Pyrex	Silica	Silica
	Temperature (°C)	25	25	25	75
	Time (h)	17	60	31	4
% recovery	$(CH_3)_6Sn_2$	77	56	63	37
	C_2F_4	43	35	5	Trace
Products (mmoles)	$(CH_3)_4Sn$		0.18	0.91	1.70
	$(CH_3)_3SnCF_2CF_2H$	0.72	0.19	0.19	0.45
	$(CH_3)_3SnCF_2(CF_2)_2CF_2H$	0.85	0.27	0.27	0.22
	$(CH_3)_3SnCF_2(CF_2)_4CF_2H$*		0.43	0.43	1.30
	$(CH_3)_3SnCF_2CF_2Sn(CH_3)_3$*		Trace	0.23	0.70
	$(CH_3)_3SnCF_2(CF_2)_2CF_2Sn(CH_3)_3$*				0.55
	$(CH_3)_3SnCF_2(CF_2)_{12}CF_2Sn(CH_3)_3$	0.29	0.49	~0.1	
	$(CH_3)_3SnF$	0.44			7.1
	Polymerized C_2F_4		2 g	1 g	0.35

*Quantities of these compounds were estimated from spectroscopic (n.m.r. and infrared) and chromatographic data.

Oxygen was bubbled through the ether extract and the last trace of hexamethylditin was removed by filtration as the tin oxide. Evaporation of the ether left a viscous oil, which was separated by distillation *in vacuo* (10^{-3} mm Hg) into fractions boiling in the 40–60° (1.2 g), 60–80° (0.5 g), and >80° (~1 g) ranges. All three fractions gave complex infrared spectra which show bands attributable to C—H stretching, C—F stretching, CH_3—Sn rocking, and Sn—C stretching vibrations. No further characterization of the 60–80° and >80° fractions was achieved. The 40–60° fraction was a colorless liquid.

Anal. Calcd. for $C_8H_{18}F_4Sn_2$: C, 22.5; H, 4.25; F, 17.7. Calcd. for $C_{10}H_{18}F_8Sn_2$: C, 22.8; H, 3.42; F, 28.8. Calcd. for $C_9H_{10}F_{12}Sn$: C, 23.2; H, 2.15; F, 49.0. Found: C, 22.0; H, 3.45; F, 30.0.

The proton magnetic resonance spectrum of this fraction showed three methyl peaks at −0.42, −0.40, and −0.34 p.p.m. with respect to TMS, as well as a tripleted triplet at −6.08 p.p.m., with ^1H–^{19}F coupling constants of 51.8 and 5.1 c.p.s. The ^{19}F spectrum showed seven peaks in the region +25.8 to +53.3 p.p.m. with respect to trifluoroacetic acid, the peak at +53.3 p.p.m. being a doublet with an ^1H–^{19}F coupling constant of 52 c.p.s. This confirms the presence of a terminal $—CF_2H$ group. The infrared spectrum showed C—F stretching absorptions at 1 205 (s,br), 1 150 (s,br), 1 080 (s), 1 040 (s), and 1 020 (s). An attempted gas chromatographic separation suggested the presence of three components in the approximate ratio of 1:3:1 with retention times of 12, 21.5, and 37 min (dinonyl phthalate column), but the very low volatilities prevented a macro separation, and there was also some evidence of decomposition on the column. It seems probable from this evidence that one component was $(CH_3)_3SnCF_2(CF_2)_4CF_2H$ and that the other two could well be $(CH_3)_3SnCF_2CF_2Sn(CH_3)_3$ and $(CH_3)_3SnCF_2(CF_2)_2CF_2Sn(CH_3)_3$. Species containing longer fluorocarbon chains would give a much higher fluorine analysis and more peaks in the ^{19}F spectrum than were observed.

(*b*) Hexamethylditin (6.1 g, 18.3 mmoles) and tetrafluoroethylene (1.85 g, 18.5 mmoles) in a Pyrex Carius tube were irradiated with ultraviolet light at 25° for 17 h. Vacuum fractionation of the volatile products gave fractions which condensed at 0°, −46°, and −196°, leaving a liquid–solid mixture. The −196° fraction was tetrafluoroethylene (43% recovery). Calcd. mol. wt. 100. Found mol. wt. 100. The −46° fraction was separated chromatographically, and the components were identified, as described above, as 1,1,2,2-tetrafluoroethyltrimethyltin (0.19 g) and 1,1,2,2,3,3,4,4-octafluorobutyltrimethyltin (0.31 g). The 0° fraction was unchanged hexamethylditin (2.1 g). The involatile mixture was extracted several times with ether to leave a white solid (A), and from the ether extract more hexamethylditin was recovered by distillation (2.6 g, total recovery 77%). The white solid (A), after several extractions with hot carbon tetrachloride followed by evaporation and recrystallization from carbon tetrachloride, gave white crystals (0.3 g) with the following analytical results.

Anal. Calcd. for $C_{20}H_{18}F_{28}Sn_2$: C, 23.4; H, 1.7; F, 51.8; Sn, 23.1. Found: C, 23.1; H, 1.6; F, 51.0; Sn, 23.9.

This is consistent with a mixture of adducts averaging to the formula $(CH_3)_3Sn(C_2F_4)_7Sn(CH_3)_3$. The white solid (B) remaining after the carbon tetrachloride extraction was treated with hot methanol and left a trace (0.05 g) of a white solid whose infrared spectrum was identical with that of polymerized tetrafluoroethylene. From the methanol solution, trimethyltin fluoride (0.08 g, 0.44 mmoles) was recovered.

Other reactions were carried out with irradiation of the reactants, in Pyrex or silica tubes, over much longer periods. For example, an experiment performed with a silica tube and ultraviolet irradiation at 25° for 31 h gave the same products as in reaction (*a*) above. However, 63% of the hexamethylditin was recovered,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and while the same relative quantities of trimethyltin fluoride and polymerized C_2F_4 were isolated as in reaction (*a*), the yields of all other products were much smaller.

Reactions of Hexamethylditin with Perfluoropropene

Hexamethylditin (7.2 g, 22 mmoles) was allowed to react with perfluoropropene (3.84 g, 25.6 mmoles) in a silica tube at 70° under ultraviolet irradiation for 8 h. Vacuum fractionation gave fractions at −126°, −78°, −46°, and 0°, and a dark brown liquid–solid mixture remained in the reaction tube. The −126° fraction was shown by gas chromatography to be 95% pure perfluoropropene, with a trace of a second component. The infrared spectrum of this fraction was that of the original propene with several additional weak bands including one at 1 752 cm^{-1}. Apparently a trace of a second olefin was produced. The −78° fraction was shown chromatographically to be composed of tetramethyltin (0.75 g, 4.2 mmole) and 1,1,1,2,3,3,3-heptafluoropropane (0.1 mmole). Calcd. for C_3F_7H: mol. wt. 170. Found: mol. wt. 176. The latter was also identified by its infrared spectrum.

The −46° fraction, on chromatography (dinonylphthalate column) gave hexamethylditin and 1,1,2,3,3,3-hexafluoropropyltrimethyltin, $(CH_3)_3SnCF_2CF(CF_3)H$ (1.2 g, 3.8 mmoles).

Anal. Calcd. for $C_6H_{10}F_6Sn$: C, 22.9; H, 3.2; mol. wt. 315. Found: C, 22.7; H, 3.0; mol. wt. 305.

This was also completely characterized by its ^1H and ^{19}F magnetic resonance spectra which will be discussed fully elsewhere. The 0° fraction was identified spectroscopically as unchanged hexamethylditin (0.7 g).

Carbon tetrachloride was added to the brown reaction mixture, and oxygen was bubbled through the solution for 30 min. The white suspension (3.4 g) which formed was removed by centrifugation and from its infrared spectrum was found to be a mixture of methyltin oxides and trimethyltin fluoride. The carbon tetrachloride solution was reduced to a small volume, and transferred to a special vacuum distillation apparatus. The fraction which distilled at 40–80° and 10^{-3} mm Hg was 1,2-bis(trimethyltin)hexafluoropropane, $(CH_3)_3SnCF_2CF(CF_3)Sn(CH_3)_3$ (1.2 g, 2.5 mmoles).

Anal. Calcd. for $C_9H_{18}F_6Sn_2$: C, 22.6; H, 3.8; F, 23.85; mol. wt. 476. Found: C, 22.3; H, 3.5; F, 23.87; mol. wt. 486.

The proton magnetic resonance spectrum indicated the presence of other species, probably trimethyltin chloride formed during the oxidation in carbon tetrachloride solution, and also higher molecular weight adducts, but in amounts too small to affect the analytical figures.

A tar (~1 g) remained in the distillation apparatus and was not examined further.

Two other reactions at room temperature and under ultraviolet irradiation, were carried out in Pyrex and silica tubes for 50 and 11 h respectively. Both experiments yielded 0.1–0.15 g of the hexafluoropropyltrimethyltin but gave only a trace of the 1:1 adduct.

Reactions of Hexamethylditin with Trifluoroethylene

(*a*) Hexamethylditin (7.9 g, 24.0 mmoles) and trifluoroethylene (1.96 g, 24.0 mmoles) were irradiated at 85° in a silica tube for 4 h. By means of vacuum fractionation and gas chromatography as described above, the volatile products were shown to be trifluoroethylene (0.43 g, 22% recovery), tetramethyltin (0.35 g, 1.95 mmole), hexamethylditin, and a fraction (0.15 g) which condensed at −46°. The latter could not be purified chromatographically because of decomposition on the column, but its proton magnetic resonance spectrum showed, in addition to three methyl peaks at −0.2 (hexamethylditin), −0.25, and −0.30 p.p.m., a complex absorption centered at −5 p.p.m. with respect to internal TMS. This signal appeared essentially as a doublet with secondary splittings. Such a peak at low field, taken into account with the volatility of this fraction, suggested that the fraction contains species such as hexamethylditin, $(CH_3)_3SnCFHCF_2H$, $(CH_3)_3SnCFHCF_2CFHCF_2H$ etc., and not the bis(trimethyltin)fluorocarbon adducts.

Part of the unreacted hexamethylditin was recovered from the involatile material by distillation at 76° and 20 mm Hg (total recovery 2.7 g, 35%) and the residue was extracted with carbon tetrachloride. Oxygen was bubbled through the resulting solution to remove the last traces of hexamethylditin as tin oxides, and after removal of the solvent in a stream of dry air the remaining oil was separated by vacuum distillation into fractions which distilled in the ranges 45–60° and 60–90° respectively. In this experiment, both fractions gave identical infrared spectra and hence were combined (1 g). The proton magnetic resonance spectrum showed two methyl absorptions at −0.334 and −0.30 p.p.m. and a weak peak at −0.20 p.p.m. due to hexamethylditin, as well as an unresolved band centered at −5.0 p.p.m. This with analytical data, identified the compound as >95% pure 1,4-bis(trimethyltin)-1,1,2,3,3,4-hexafluorobutane, $(CH_3)_3SnCF_2CFHCF_2CFHSn(CH_3)_3$.

Anal. Calcd. for $C_{10}H_{20}F_6Sn_2$: C, 24.4; H, 4.1; mol. wt. 490. Found: C, 24.7; H, 3.5; mol. wt. 477.

The ^{19}F magnetic resonance spectrum showed absorptions centered at +163, +138, +52, +46, +41, +36, +31, and +25 p.p.m. with respect to trifluoroacetic acid. In the formulation

$$(CH_3)_3Sn\overset{1}{C}F_2\overset{2}{C}FH\overset{3}{C}F_2\overset{4}{C}FHSn(CH_3)_3$$

there are two types of CH_3 group, accounting for the two methyl peaks in the proton spectrum. Since the unshielding of a fluorine atom is affected by the amount of charge the F atom is able to draw from a carbon atom, the +163 and +138 p.p.m. peaks of the ^{19}F spectrum may be assigned to fluorine atoms 4 and 2 respectively. The peaks in the +25 to +52 p.p.m. region possibly result from the overlapping of the two quartets of fluorine atoms 1 and 3, which in turn arise from the asymmetry of carbon atoms 2 and 4.

(*b*) Hexamethylditin (21.0 g, 64.2 mmole, 40% excess) and the olefin (3.6 g, 46 mmole) were irradiated at 95° for 8 h. The distribution and nature of the products obtained were the same as in (*a*) except that vacuum distillation of the final oily liquid, followed by spectroscopic examination, showed the presence of several components. The fractions which distilled in the 45–60° and 60–90° ranges gave infrared and n.m.r. spectra identical with those obtained in experiment (*a*). The fraction which distilled at 35–45°, however, in addition to the peaks expected from experiment (*a*) for $(CH_3)_3SnCF_2CFHCF_2CFHSn(CH_3)_3$, showed in the proton spectrum two quartets at −6.5 p.p.m. which might be assigned to the internal proton of $(CH_3)_3SnCFHCF_2Sn(CH_3)_3$. This was consistent with the appearance in the ^{19}F spectrum of three new peaks at +160, +151, and +47 p.p.m., of which the former may be assigned to the fluorine atom of —CFH— and the lower field peaks may be components of the quartet arising from the F atoms of the $—CF_2—$ group.

Reactions of Hexamethylditin with 1,1-Difluoroethylene

Hexamethylditin (20.4 g, 62.2 mmole, 40% excess) and 1,1-difluoroethylene (2.84 g, 44.4 mmole) were exposed to ultraviolet irradiation for 7 h at 92°. Vacuum fractionation gave unreacted olefin (0.81 g, 32% recovery), tetramethyltin (0.6 g, 3.4 mmole), and a fraction which condensed at −46° in addition to involatile material. Chromatographic separation of the −46° fraction gave three components, the first of which was identified spectroscopically (31) as monofluoroethylene. Calcd. for C_2H_3F: mol. wt. 46. Found: mol. wt. 58.2. The second component (retention time 11.0 min) was tentatively identified as $CF_2HCH_2CF{=}CH_2$. Calcd. for $C_4H_5F_3$: mol. wt. 110. Found: mol. wt. 108.5. These two products must have arisen by the thermal decomposition on the column of products of the type $(CH_3)_3Sn(CH_2CF_2)_nH$. The third component was hexamethylditin.

Centrifugation of the involatile material led to the separation of a white solid (4.2 g) which was shown spectroscopically to be chiefly trimethyltin fluoride with some fluorocarbon polymers. Distillation of the remaining involatile liquid (76° at 20 mm Hg) gave hexamethylditin (12.5 g, total recovery 57%). Further distillation at 10^{-3} mm Hg gave a fraction which distilled at 30–60° to leave a brown gum as residue (3.7 g). The 30–60° fraction showed infrared absorptions associated with fluorocarbon groups at 1 380 (m), 1 188 (vs,br), 1 120 (s), 1 033 (s), 996 (s), 950 (s,br), and 876 (m,br) cm^{-1}. The ^1H and ^{19}F n.m.r. spectra showed the resonances indicated in Table II. Clearly one of the components must have a terminal $—CF_2H$ group which is responsible for the −6.3 p.p.m. ($^1H_2$ spectrum) and +34.6 p.p.m. (^{19}F spectrum) resonances (30). This, together with the fact that only three resonances of unequal intensity were observed in the ^{19}F spectrum suggested the presence of

$$\underset{\text{I}}{(CH_3)Sn\overset{1}{C}H_2\overset{2}{C}F_2\overset{3}{C}H_2\overset{4}{C}F_2H} \quad \text{and} \quad \underset{\text{II}}{(CH_3)_3SnCH_2CF_2Sn(CH_3)_3}$$

and the n.m.r. spectra can be assigned on this basis. The −1.62 p.p.m. (^1H) and +16.2 p.p.m. (^{19}F) resonances can be assigned to the internal protons and fluorine atoms respectively of II. The −1.65 p.p.m. resonance (^1H) might be assigned to the protons of $\overset{1}{C}H_2$ of I because of the similar environment to that of the internal $—CH_2—$ group of II. The −2.7 and −6.3 p.p.m. resonances in the proton spectrum may then be assigned to the $—\overset{3}{C}H_2—$ and $—\overset{4}{C}F_2H$ protons of I respectively. In the ^{19}F spectrum the +34.6 p.p.m. resonance can be assigned to the $\overset{4}{C}F_2H$ fluorine atoms leaving the +11.5 p.p.m. multiplet as arising from the $—\overset{2}{C}F_2—$ fluorine atoms.

Reactions of Hexamethylditin with Trifluorochloroethylene

(*a*) Hexamethylditin (7.6 g, 22.9 mmole) and trifluorochloroethylene (2.64 g, 22.61 mmole) were exposed to ultraviolet irradiation at 90° for 4 h. Vacuum fractionation led to the separation of unreacted olefin (1.64 g, 63%) and tetramethyltin (0.52 g, 2.8 mmole), as well as a 0° fraction which rapidly turned brown in sunlight. From the latter fraction a clear liquid was separated by centrifugation. This gave a complex infrared spectrum, while the proton magnetic resonance spectrum showed four absorptions in the CH_3 region at −0.01, −0.20, −0.33, and −0.62 p.p.m. The first, second, and last peaks can be assigned to the methyl proton resonances of tetramethyltin (32), hexamethylditin (33), and trimethyltin chloride (34). At lower field, eight lines of equal intensity were observed, centered at −6.3 p.p.m. These could be defined as a doublet–doublet–doublet pattern (J_1 = 48.5 c.p.s., J_2 = 8.1 c.p.s., and J_3 = 7.0 c.p.s.), suggesting the presence of a

$$—\overset{\alpha}{C}F_2\overset{\beta}{C}FClH$$

group in which the signal of H_β is split into a large doublet because of coupling with the F_β nucleus and each component is further split into a doubleted doublet because of interaction with the two non-equivalent F_α atoms which in turn arises from the asymmetry of the β-carbon atom. Since the relative intensity of this H_β resonance and the peak at −0.33 p.p.m. is approximately 1:10, and the chemical shift of the latter is characteristic for the $(CH_3)_3Sn$ group directly bonded to a $—CF_2—$ group (35), these resonances at −0.32 and −6.2 p.p.m. are thought to arise from the same species, probably $(CH_3)_3SnCF_2CFHCl$.

TABLE II

Nuclear magnetic resonance spectrum for ^1H and ^{19}F

		CH_3 region			Lower field region			
^1H	Chemical shift (p.p.m., TMS)	−0.3	−0.32	−0.34	−1.62	−1.65	−2.7	−6.3
	Coupling constant (c.p.s.)				Triplet 23.3	Triplet 23.5	Multiplet 15.2 6.1 4.0	Tripleted triplet 55.1 4.5 4.5
	Intensity ratio	1.0	1.5	1.5	1.5	1.0	1.0	0.5
^{19}F	Chemical shift (p.p.m., TFA)	+11.5		+16.2	+34.6			
	Coupling constant (c.p.s.)	Multiplet		Triplet 25.0	Tripleted doublet 54.5 12.0			
	Intensity ratio	1.0		1.5	1.0			

From the involatile residue, hexamethylditin (5 g, 66% recovery) and trimethyltin fluoride were isolated. Neither in this experiment, nor in a second in which the reactants were irradiated in pentane solution at 25° for 70 h, was there any evidence for the presence of adducts. In this latter experiment the identified products were again trimethyltin fluoride, trimethyltin chloride, and $(CH_3)_3SnCF_2CFHCl$.

Reactions of Hexamethylditin with Trifluorobromoethylene

Hexamethylditin (7.2 g, 21.8 mmole) and trifluorobromethylene (3.6 g, 22 mmole) were irradiated at 25° for 27 h. An orange solid appeared in the reaction tube after 10 h; after completion of the irradiation, the liquid phase turned orange on standing overnight. Vacuum fractionation gave unreacted olefin (2.7 g, 75% recovery), tetramethyltin (0.78 g, 4.4 mmole), a trace of an unidentified volatile fluorocarbon, colorless liquids which condensed at −46° and 0°, and an involatile material.

The −46° fraction was identified as trimethyl perfluorovinyltin, by comparison of its infrared spectrum and gas chromatographic retention time with those of a known sample (35).

The 0° fraction, which became yellow and finally brown on standing, was shown to contain unreacted hexamethylditin containing some tetramethyltin, both of which were also present in the involatile material. From the latter, by extraction first with carbon tetrachloride and then methanol, trimethyltin fluoride was separated. The remaining solid, from its infrared spectrum, contained fluorocarbon polymers.

From a similar experiment in which the reactants were irradiated for only 14 h, the same products were obtained.

Reaction of Hexamethylditin with Ethylene

Hexamethylditin (7.2 g, 22 mmole) and ethylene (0.62 g, 22 mmole) were irradiated in a silica tube at 25° for 1 week, with no changes in appearance. Vacuum fractionation gave unreacted ethylene (0.56 g, 90% recovery), a fraction (0.4 g) which condensed at −78°, and unreacted hexamethylditin (6.8 g, 95% recovery). Gas chromatographic examination of the −78° fraction showed it to contain 90% tetramethyltin, 5% hexamethylditin, and traces of three unidentified compounds.

Preparation of Polydimethyltin

All preparations were carried out either on the vacuum line or in closed systems under nitrogen. Manipulations of diorganotin compounds were always performed in a nitrogen-filled dry-box.

(*a*) Dry triethylamine (10 ml) was added to a slurry of dimethyltin dichloride (10.4 g) in 50 ml anhydrous ether under a nitrogen atmosphere. A slurry of lithium aluminium hydride (2.88 g) in anhydrous ether (250 ml) was added with stirring over 45 min at 0°. The mixture was stirred under nitrogen for a further $3\frac{1}{2}$ h, after which a whitish precipitate was filtered off. The ether was removed under vacuum from the yellow filtrate, which was very air-sensitive, to give an oily liquid. On standing, this liquid slowly separated, with the evolution of gas, into an upper colorless layer and a lower yellow layer. After 48 h gas evolution had ceased, and the lower yellow layer had become solid. The latter was extracted with hot benzene. Several such preparations were conducted and the proton magnetic resonance spectra of the resulting benzene solutions were in general agreement with that obtained by Brown and Morgan (23) for dodecamethylcyclohexatin.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*b*) Dimethyltin dihydride (2.47 mmole), prepared as described previously (29), together with dimethyltin dichloride (5 mg), was stirred in pyridine (5 ml) for 3 h at 30–40°. Gas evolution gradually decreased over this period, and on removal of the pyridine, a yellow solid was obtained. From a number of such preparations, it was established that the quantity of hydrogen evolved was 92–100% of that calculated. The proton resonance spectra of benzene solutions of these products were again very similar to that reported by Brown and Morgan for the dodecamethyl cyclohexatin (after Brown and Morgan's terminology), although weak absorption peaks due to linear forms of dimethyltin were also observed.

Reactions with Tetrafluoroethylene

Typical reactions were carried out as follows:

(*a*) Dimethyltin (1.45 mmole), prepared by method (*a*) above, and tetrafluoroethylene (4.38 mmole) were sealed in a Pyrex tube and heated in the dark at 105° for 18 h. After this period, the color had changed from yellow to brown and a metallic mirror had formed. Vacuum fractionation gave unreacted tetrafluoroethylene (3.38 mmole) and tetramethyltin (0.14 mmole), identified spectroscopically. Characterization of the insoluble and involatile residue was not possible although clearly metallic tin was present.

(*b*) Dimethyltin (1.45 mmole), prepared by method (*a*) above, and tetrafluoroethylene (5.94 mmole) were sealed in a silica tube and irradiated for 30 min at 60° under a 200 W ultraviolet lamp. During this period, the tube became coated with a white powder. Vacuum fractionation gave unreacted olefin (0.96 mmole), a trace of tetramethyltin, and a trace of hexamethylditin identified by its melting point and infrared spectrum. The white residue on heating gave tetrafluoroethylene, and its infrared spectrum showed absorption bands at 1 240 (s), 1 180 (s), 636 (m), 624 (sh), 554 (m), and 523 (m) in agreement with those of a solid semipolymerized sample of tetrafluoroethylene.

(*c*) Dimethyltin (2.90 mmole), prepared by method (*b*) above, with tetrafluoroethylene (9.89 mmole), was dissolved in benzene (20 ml) in a Pyrex Carius tube. The mixture was irradiated at 45–60° for 43 h. The volatile fractions were only olefin (5.48 mmole) and benzene, and a resinous material remained. This gave an infrared spectrum which showed absorptions due to fluorocarbon groups and benzene, and moreover the doublet in the 500 cm^{-1} region characteristic of dimethyltin itself had almost disappeared, being replaced by a new doublet at 530 and 515 cm^{-1}. The product solidified rapidly in air.

(*d*) Dimethyltin (2.47 mmole), prepared from the dihydride, tetrafluoroethylene (2.56 mmole), and Spectrograde benzene (15 ml) were irradiated in a silica tube at 50–60° for 17 h to give a brown solution. Vacuum fractionation gave some tetrafluoroethylene (0.06 mmole) which was shown spectroscopically to contain also hexafluoropropene, trifluoromethane, and benzene, and left a yellow oil. Even under prolonged pumping, benzene could not be removed completely. The infrared spectrum of the product, and of those from a number of reactions, were generally similar, typically showing C—F absorptions at 1 185 (m), 1 165 (sh), 1 074 (sh), 1 060 (s), 1 020 (sh), and new Sn—C stretching absorptions at 532 (s), and 518 (sh). A molecular weight determination in benzene (vapor pressure osmometer) gave a value of 1 990. Calcd. for $[(CH_3)_2SnC_2F_4]_8$: 1 984.

Reactions of Diphenyltin with Tetrafluoroethylene

(*a*) Diphenyltin dihydride (6.85 mmole) dissolved in ether in a silica tube was decomposed with methanol (10 ml) over 30 h. Removal of ether and methanol left a yellow-white solid. Carbon tetrachloride (20 ml) and tetrafluoroethylene (16.2 mmole) were added, and the sealed tube was irradiated under a 100 W ultraviolet lamp at 30° for 47 h. The yellow color disappeared and a white solid was deposited. Vacuum fractionation of the more volatile products gave tetrafluoroethylene (12.7 mmole) and a mixture of chloroform and carbon tetrachloride. Polymerized olefin was removed from the remaining carbon tetrachloride solution by filtration and the filtrate was treated with oxygen for 1 h in an attempt to remove unreacted diphenyltin. A white solid (0.07 g) was formed, whose infrared spectrum showed no C—F absorptions, but still showed phenyl—Sn absorptions. Evaporation of the remaining solution gave a yellow oil, which showed C—F absorptions at 1 215 (s), 1 191 (s), 1 157 (s), 1 145 (sh), 1 125 (m), 1 115 (sh), and 1 105 (sh). The Sn—H absorption of the linear polymer (1 824 cm^{-1}) was not detected in the product.

(*b*) Diphenyltin dihydride (4.77 mmole) in ether was decomposed with 6 ml of pyridine in a silica tube. Pentane (12 ml) and tetrafluoroethylene (5.50 mmole) were distilled onto the hexamer, and the sealed tube was irradiated at 50° for 89 h. The volatile products were pentane and tetrafluoroethylene (3.8 mmole) containing some hexafluoropropene. The involatile residue was extracted with warm benzene, leaving insoluble polymerized olefin (1.8 mmole). Evaporation of the benzene gave a cream solid with C—F absorptions at 1 190 (m), 1 169 (m), 1 157 (sh), and 1 100 cm^{-1}. Further extraction with pentane gave a reddish gum showing stronger but broader C—F infrared absorptions centered at 1 168 and 1 101 cm^{-1}.

(*c*) Diphenyltin dihydride (4.77 mmole) in ether was decomposed with 10 ml of methanol over 48 h in a silica tube to give linear polydiphenyltin. Pentane (22 ml) and tetrafluoroethylene (10.72 mmole) were distilled in, and the sealed tube was irradiated at 30° for 90 h. The volatile products were pentane and unreacted olefin (5.22 mmole). The residue was extracted with pentane to leave on evaporation a pale-yellow oil. This showed C—F absorption bands at 1 193 (m), 1 170 (s), 1 130 (w), 1 097 (vs,br), 1 072 (m), 1 038 (w), 1 022 (w). The proton resonance spectrum of a solution in pentane of this oil showed weak, broad absorption in the range 4.6–5.2 τ suggesting the presence of $—C_2F_4H$ groups. The pentane-insoluble material could be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dissolved in benzene which on evaporation gave a cream solid with similar, but relatively weaker C—F absorptions.

In all of the above experiments, attempts to convert the oily products to solids by treatment with various solvents were unsuccessful.

Reaction of Dimethyltin with Trifluoroiodomethane

Dimethyltin (16.9 mmole), prepared by the pyridine reduction of the dihydride, was irradiated with a large excess of trifluoroiodomethane (111.5 mmole) in a silica tube at 30° for 48 h. Vacuum fractionation gave unreacted trifluoroiodomethane (103.2 mmole) and a mixture of fluorocarbon–tin compounds which condensed in traps at −78°, −46°, and −13°. White crystals remained in the reaction tube and were identified spectroscopically as dimethyltin diiodide. The components of the mixture could not be separated completely by further fractionation and gas chromatographs taken at 78° and 117° on a 30% Ucon 50 on firebrick column, showed extensive broadening and tailing of the peaks due to decomposition. However, the components could be distinguished from the infrared and proton magnetic resonance spectra as shown in Table III.

TABLE III

Identification by infrared and proton magnetic resonance spectra

Component	τ*	J for $^{119}SnCH_3$	J for ^{117}–$SnCH_3$	Sn—C stretch (cm^{-1})	Ref.
A	9.59	60.4	57.6	542, 516†	(30)
B	9.23	65.7	62.4	[557, 530]	
C	9.13	57.7	54.9	540, 511	(34, 36)
D	8.85	64.1	61.3	[552, 522]	
E				547, 511	(36)

*Relative to internal TMS.
†Observed from known sample.

On this basis, components A and C were unambiguously identified as trimethyltrifluoromethyltin and trimethyltin iodide. Since volatility appeared to decrease from A to D, and from the data in Table III, it was concluded that component B was probably dimethyl bis(trifluoromethyl)tin, and component D dimethyltrifluoromethyl tin iodide. From the infrared and n.m.r. intensities the ratio of A:B:C:D was approximately 1:10:4:40. The total amount of these products indicated that approximately 30% of the dimethyltin had been consumed.

ACKNOWLEDGMENTS

The financial support of the National Research Council, in form of grants-in-aid (to H. C. C.) and a Postdoctorate fellowship (to J. D. C.), and the award (to J. H. T.) of a Graduate Fellowship of the University of British Columbia are gratefully acknowledged. We are also grateful for gifts of chemicals from M. and T. Corporation.

THE ENERGY OF HYDROGEN BONDING IN THE SYSTEM: ACETONE–BROMOFORM

A. N. CAMPBELL AND E. M. KARTZMARK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received October 8, 1965

ABSTRACT

A study of the equilibrium freezing-point diagram for the system acetone–bromoform shows that no solid-phase compound forms between acetone and bromoform. The diagram is of the simple eutectic type, the eutectic lying at −101° and 84 mole % acetone. The enthalpies of mixing have been determined for various compositions of mixture and the numerical value of ΔH (per mole of acetone or bromoform) extrapolated to infinite excess of bromoform or of acetone, to obtain the value for completely undissociated complex. This figure is −1.3 kcal per mole of complex (assumed mole to mole). The dipole moments, excess volumes of mixing, viscosities, and total and partial vapor pressures of the system have been measured. From these data, the excess free energy and excess entropy and other thermodynamic functions have been evaluated.

INTRODUCTION

In a previous paper (1) dealing with the system acetone–chloroform, we demonstrated that an equimolar compound, stable in the solid state, at its melting point of −160°, exists, and we evaluated the energy of hydrogen bonding to be 2.7 ± 0.1 kcal. The existence of hydrogen bonding in this system, as well as in the system acetone–bromoform, has been demonstrated by nuclear magnetic resonance and infrared techniques and it has been shown qualitatively that the enthalpy of mixed association is greater in the acetone–chloroform system than in the acetone–bromoform system (2).

It was suggested to us by our colleague, Dr. H. Gesser, that it would be of interest to repeat our studies on the system acetone–bromoform and also evaluate the energy of hydrogen bonding in this system. Since a knowledge of total and partial vapor pressures enables one to calculate the excess free energies and entropies of the hydrogen bonding, we have added these determinations to those previously made.

EXPERIMENTAL

This is for the most part described in our previous communication (1), as far as the determinations of freezing point, density, viscosity, and heats of mixing are concerned. The excess volume of mixing was determined directly, since the determination from density measurements calls for a very high order of accuracy. For this purpose we used the apparatus of Brown and Smith (3), which is itself a modification and simplification of that of Keyes and Hildebrand (4). The only modification we introduced was to replace the ground glass plug by a stopcock. This apparatus works admirably and gives high accuracy, if sufficient care is taken with the calibration of the capillary. Mixtures of different compositions are obtained by varying the amount of mercury in the apparatus.

Refractive indices were determined with an Abbe refractometer, with thermostatic control. An electric sodium lamp was used as the source of illumination, so that all refractive indices refer to the sodium doublet. For our measurements of dielectric constant we used the Sargent Oscillometer, a great improvement on the somewhat crude homemade apparatus of our previous work. We enclosed the capacity cells in an air space within a liquid thermostat, so that constancy of temperature was preserved to 25° ± 0.1°. For the measurement of total vapor pressure we used a simple, large bore, mercury manometer. The apparatus for the determination of vapor composition and hence partial pressures is more complex and is described in detail in our work with Gieskes (5).

The acetone and bromoform used were both Fisher certified chemicals. It was found that distillation of bromoform, even under reduced pressure, yielded a slightly brown product. It was therefore thought better to use freshly opened bottles of the product as it came from the manufacturers. In any case, it seems to us that bromoform is more stable with time than chloroform, which requires repurification every 2 weeks. The physical constants, viz. density and refractive index, were in good agreement with the accepted values.

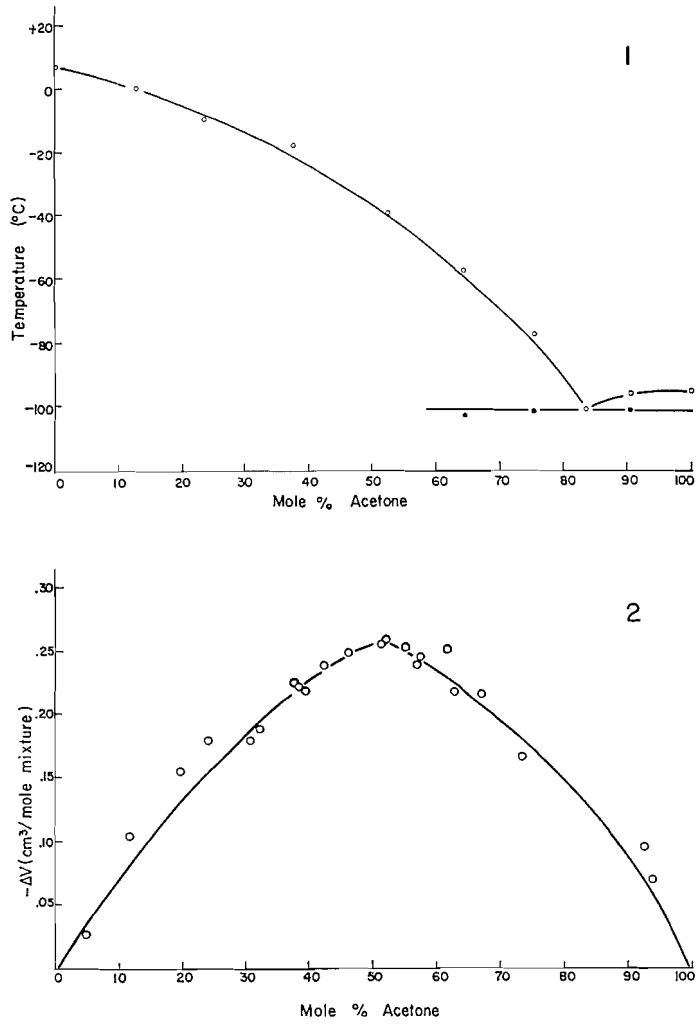

FIG. 1. Equilibrium diagram, freezing point vs. mole % acetone, for acetone-bromoform system.
FIG. 2. Plot of excess volumes of mixing vs. mole % acetone.

The equilibrium diagram, freezing point versus mole % acetone, is represented in Fig. 1. There is no indication of a compound between acetone and bromoform existing in the solid state. (Cf. the corresponding diagram in our previous publication (1).) The single eutectic lies at $-101°$ and 84 mole % acetone.

Figure 2 is a graphical representation of the excess volumes of mixing (all are negative) versus mole % acetone. A maximum contraction of about 0.25 cc occurs at about 50 mole % acetone. Figure 3 represents partial molal excess volumes, derivable from Fig. 2. They are of necessity negative. (Molal volumes are accurately obtained by adding observed excess volumes to the ideal molal volume. These are plotted against mole fraction and tangents taken to give the partial molal volume. The difference $\bar{V} - V^0$ is the excess partial molal volume.)

The relative viscosities and fluidities are reproduced in Fig. 4. The dielectric data for mixtures of acetone and bromoform are given in Table I.

Solutions were also made up containing various proportions of acetone and bromoform and a fixed quantity, namely 91 mole % of benzene. The dielectric data of these solutions are given in Table II. The "molar polarization in absence of benzene" is calculated in the usual way on the assumption that the polarizability of benzene in solution is the same as in the free state.

The figures of the last column of Table II, "molar polarization in absence of benzene", as well as the figures for molar refraction (distortion polarization, Table I) were now plotted against mole % bromoform

and interpolations made for 10 mole % intervals. Finally, the molar polarizations for each 10% bromoform were plotted against benzene content of solution (0 and 91 mole % respectively) and straight line extrapolations made to infinite dilution (100% benzene). In each case, the corresponding molar refraction was subtracted to obtain the "orientation polarization". Each solution was now treated on the (obviously incorrect) assumption that equimolecular proportions of acetone and bromoform were combined to form a

compound and the excess (acetone or bromoform) was 'free'. Again on the assumption that the 'free' acetone or bromoform possessed the same orientation polarization as in the pure liquid state, multiplication of this figure by the mole fraction of 'free' acetone or bromoform gave the orientation polarization of a known mole fraction of 'compound'. This, when converted to mole fraction unity, gave the dipole moment of the so-called compound. The results are given in Table III.

TABLE III

Dipole moment of 'compound'

The enthalpy of mixing is negative for all proportions of acetone and bromoform. The results are expressed graphically in Fig. 5, in three ways, viz. ΔH per mole of mixture (circles), ΔH per mole of acetone (triangles), and ΔH per mole of bromoform (squares).

Table IV gives the vapor pressures, total and partial, for various compositions of bromoform–acetone mixtures.

DISCUSSION

The equilibrium diagram (Fig. 1) shows that the compound between bromoform and acetone, if such exists, does not appear as a solid phase. The diagram is of the simplest type, with a eutectic at $-101°$ and at 84% acetone.

Work shortly to be published by Campbell, Kartzmark, and Chatterjee on the system acetone–chloroform, in which there is undoubted compound formation (mixed association), shows that here the excess volumes are small and negative (maximum $V^E = -0.152$ cc/mole) over the larger part of the concentration range and become slightly positive for concentrations of acetone greater than 68 mole %. In the present system, however, the excess volume is larger and negative over the whole range (-0.25 cc/mole, maximum).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

On a first consideration, this behavior might be considered to indicate interaction, but if there is mixed association in this system, the equilibrium

$$CHBr_3 + (CH_3)_2O \rightleftarrows CHBr_3.(CH_3)_2O$$

must be very far to the left, for equimolar proportions. The result is more surprising, since Murthy (6) finds a weak monomer–dimer equilibrium for bromoform in cyclohexane. Presumably the dissociating effect of acetone would tend to produce expansion. Staveley's (7) work, however, indicates that the value of V^E is determined by the magnitude of other thermodynamic functions, and therefore it is not in itself conclusive evidence for compound formation. The graph of viscosity vs. composition shows negative deviation from additivity.

We have treated our dielectric data by the method outlined under Experimental and assumed the existence (by analogy with the system acetone–chloroform (1)) of a mole to mole compound, stable in the presence of infinite excess of either bromoform or acetone. Such a line of reasoning gives the dipole moment of the hypothetical compound as 3.18 D. The sum of the dipole moments of the constituents is 3.88. We found a similar decrease with the system acetone–chloroform, where a compound is undoubtedly formed. In the past, attempts were frequently made to determine the degree of dissociation of the compound from such results but it is now realized that such calculations have no validity. Nevertheless, the result may be accepted as qualitative evidence for association between the two substances.

The enthalpies of mixing, though negative, are much less than those of the corresponding system acetone–chloroform. If the line of argument of the preceding paragraph is valid, then by the method of calculation of our previous paper (1), the enthalpy of hydrogen bonding in this system becomes $-700 - 625 = -1325$ cal, say -1.3 kcal. The line of argument does seem valid because with a very large excess of either component it is almost inconceivable that the few molecules of the lesser component are not hydrogen bonded to the other component, even if the amount of 'compound' in an equimolar solution is extremely small.

When the total vapor pressures of Table IV are plotted against composition, it is seen that the mixture exhibits positive deviation from Raoult's law from 0 to 75 mole % acetone, and after that slight negative deviation. The same is of course true of the partial pressures.

Our partial pressure data, together with the heats of mixing, permit the calculation of numerous derived data. We have calculated, in Table V, the activities, activity coefficients, partial molal excess free energies, and total excess free energy (free energy of mixing). Finally, from these results, the product TS^E and the excess entropy (S^E) have been calculated. It would then be possible to obtain a great many thermodynamic relations and to 'classify' the system in various ways, but we are ourselves sceptical of the value of this kind of thing. In any case, from the data of this paper it is possible for the reader to make these calculations. We content ourselves with pointing out that while the excess entropy (entropy of mixing) is always negative and passes through a numerical maximum at 50 mole % concentration, the excess molal free energy decreases steadily with increasing acetone concentration from a value of $+203.8$ cal at 10.15 mole % acetone to a value of -37.0 cal at 89.6 mole %. A similar behavior is observed with the excess enthalpy, a quantity which is always negative. This indicates that the nature of the process when a small quantity of acetone is added to a large excess of bromoform is not the same as when a small quantity of bromoform is added to a large quantity of acetone. If it is true

that bromoform in the pure state is partially dimerized, dissociation might become complete in the presence of a large excess of acetone, an effect which would not be predominant when the circumstances were reversed.

THE ELECTROLYTIC CONDUCTANCES OF SODIUM CHLORATE AND OF LITHIUM CHLORATE IN WATER AND IN WATER–DIOXANE

A. N. CAMPBELL, E. M. KARTZMARK, AND B. G. OLIVER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received November 22, 1965

ABSTRACT

The conductances, densities, and viscosities of aqueous solutions of sodium chlorate were determined over the complete range of concentration at 25 °C and at 35 °C. An attempt was made to reproduce the results at 25 °C with the viscosity-corrected Falkenhagen–Leist and Wishaw–Stokes equations. The limiting equivalent conductances of sodium chlorate at 25 °C and 35 °C in water were also determined.

The conductances, densities, and viscosities of sodium chlorate at 25 °C and 35 °C were determined in a solvent consisting of 64.5% dioxane, 35.5% water. The limiting equivalent conductances of sodium chlorate at 25 °C and 35 °C and of lithium chlorate at 25 °C in this solvent were determined by analyzing the data with the Fuoss–Onsager equation for associated electrolytes.

Finally, conductances of sodium chlorate and lithium chlorate at 25 °C were determined in a solvent consisting of 90% dioxane, 10% water.

Because of the preoccupation of this laboratory with molten lithium chlorate and sodium chlorate, their conductances and physical properties generally (1–4), we thought an investigation of the conductivity of these salts in media of low dielectric constant, such as dioxane-water mixtures, might throw some light on the structure of the melt. The specific conductance of molten lithium chlorate is of the same order of magnitude as that of lithium chlorate in 90% dioxane.

With the method of Fuoss and Accascina (5), we have calculated the degree of association (ion-pair formation) of the two electrolytes in various dioxane–water mixtures. We also determined the conductivity of sodium chlorate in water alone, over the entire concentration range, as an obvious comparison with the work of Campbell and Paterson (6) who determined the conductance of lithium chlorate in water.

EXPERIMENTAL

Purity of Materials

Salts

Fisher Certified sodium chlorate received no other purification than drying at 120 °C for 48 h. Lithium chlorate was prepared and purified by the method of Campbell and Griffiths (7). We observed a melting point of 127.9 °C as against 127.6 °C formerly reported by Campbell and Griffiths.

Solvents

Conductance water was obtained by passing distilled water through a mixed resin demineralization column and then purging with purified nitrogen. The specific conductance of water prepared in this way was between 0.9×10^{-7} and 2×10^{-7} mhos.

Spectroscopically pure dioxane was further purified by the method of Hess and Frahm (8). After purification, the refractive index and dielectric constant were found to be 1.4202 (n_D at 25 °C) and 2.21 respectively. Frey and Gilbert (9) report a refractive index of 1.42025 and Critchfield, Gibson, and Hall (10) an identical dielectric constant.

The thermostat was controlled at 25.00 ± 0.005 °C. The conductance apparatus for exact measurement is well known. We used a Jones bridge, with an oscilloscope as detector, tuned amplifier, frequency filter, and all the usual refinements. Resistance measurements could be made to well within 1 Ω in 10 000. Pyrex glass cells of the type recommended by Jones and Bollinger (11) were used for the more concentrated solutions and a cell of the Shedlovsky type (12) for the very dilute region. Cell constants were determined from the equation for the conductances of dilute solutions of potassium chloride, at 25 °C, given by Lind, Zwolenik, and Fuoss (13), viz.

$$\Lambda = 149.93 - 94.65C^{1/2} + 58.74C \log C + 198.4C.$$

Preparation of Solutions

Concentrated Solutions

These were made up by weight and the molar concentration determined from the density and these weights.

Dilute Solutions

These solutions were prepared by successive additions of salt, in platinum cups, to a known amount of water in the conductance cell. These additions were made in a nitrogen-filled drybox to exclude carbon dioxide from the solution. In each case, at least 0.02 g of salt was weighed to the nearest μg, on a Mettler M-5 balance. Thus the weight concentration was known to 0.01%. Molar concentrations were calculated on the assumption that the density of the solution was the same as that of the pure solvent.

Viscosity

A viscometer of the Cannon and Fenske type (14), having negligible drainage and kinetic energy corrections, was calibrated with water at 25 °C and 35 °C.

RESULTS AND DISCUSSION

The direct experimental results are contained in Tables I–V.

Aqueous Solutions of Sodium Chlorate at 25 °C and 35 °C

The data of Tables I and II are expressed graphically in Fig. 1. The existence of a maximum in such curves is a fairly common phenomenon and is due either to a rapid increase in viscosity, or to ion-pair formation, or both. In the present case and in that of lithium chlorate (6), the composition of the maximum does not change with temperature. It happens also that in both cases the composition at the maximum is 5.2 *M*.

In Fig. 2, equivalent conductances, at 25 °C and 35 °C, have been plotted against the square root of concentration. These curves have the normal shape. As usual we have attempted to fit our results for 25 °C to the (viscosity-corrected) equations of Falkenhagen–Leist and Wishaw–Stokes (see ref. 6 for literature and method). The results are expressed graphically in Fig. 3. In contradistinction to the behavior of lithium chlorate, both equations reproduce the results with only fair accuracy up to about 0.1 *M*. At higher concentrations, both equations fail rather badly.

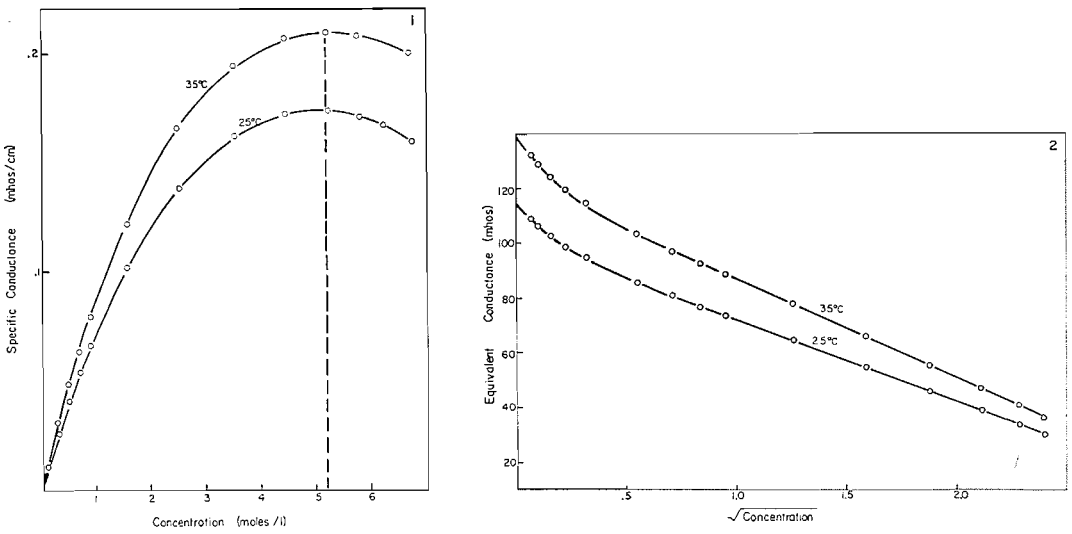

FIG. 1. Specific conductance vs. concentration of sodium chlorate in water.
FIG. 2. Equivalent conductance vs. square root of concentration for sodium chlorate in water.

For personal use only.

Fluidity versus concentration graphs are given in Fig. 4. The graphs are linear over the entire concentration range at both temperatures.

The activation energies both of conductance and of viscosity were calculated from the formula

$$\Delta E_{\text{cond}} = \frac{2.303RT_1T_2}{T_2 - T_1} \log_{10} \frac{\Lambda_2}{\Lambda_1}$$

and the corresponding formula for ΔE_{visc} and are reproduced in Table VI. The ratio of the two energies is sensibly unity, at least in the dilute region. This effect is commonly observed with aqueous solutions. This suggests that, although conductance involves ionic migration within the solution, and viscosity is a shearing movement of the solution as a whole, there must be a resemblance between the two processes. Although it is admitted that a satisfactory conductance equation, if one is ever obtained for the concentrated region, must contain a viscosity term, in practice no advance has been made towards a theoretical solution of the problem.

The limiting equivalent conductances of sodium chlorate in water at 25 °C and 35 °C were obtained by the Kohlrausch method (Fig. 5). Experience has convinced us that this is the most reliable method, where it is applicable. For the straight line portion of the graph, the method of least squares was used to get the best slope. Λ_0 for sodium chlorate at 25 °C was thus found to be 114.7 mhos. The experimental slope of the straight line plot (87.32) was slightly greater than the Onsager tangent ($\alpha\Lambda_0 + \beta$), which has the value 86.49 $cm^2\ ohm^{-1}\ equiv^{-1}$. Our value for Λ_0 agrees exactly with the sum of the individual limiting ionic conductances, as reported in the literature (12, 15).

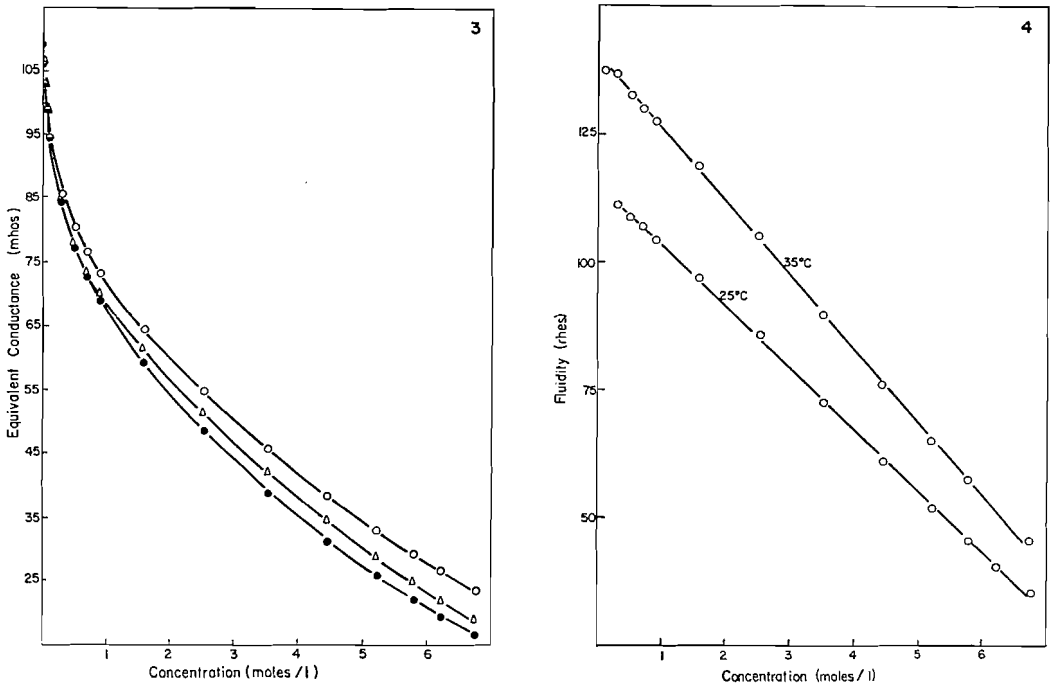

FIG. 3. Experimental and calculated conductances of sodium chlorate at 25°. (○) Experimental, (●) calculated from Wishaw–Stokes equation, (△) calculated from Falkenhagen–Leist equation.

FIG. 4. Fluidity vs. concentration for sodium chlorate in water.

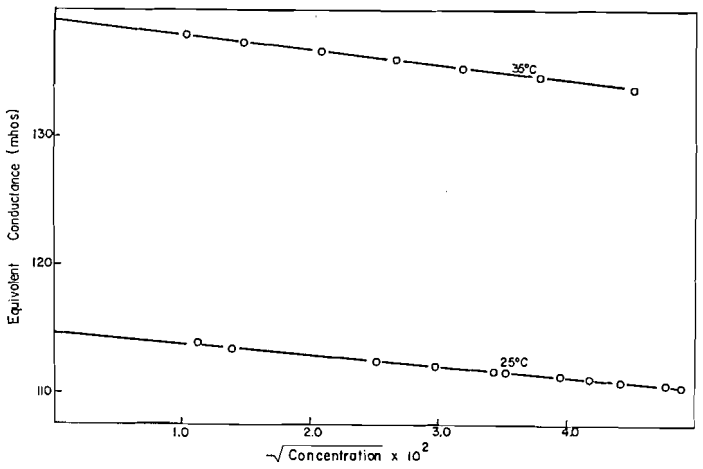

FIG. 5. Limiting equivalent conductance of sodium chlorate in water by the Kohlrausch method.

The same method applied to the 35 °C data yielded a limiting equivalent conductance 139.26 mhos. The slope of the straight line is 120.75 and the Onsager tangent 107.70. Thus, to use the language of Fuoss (16), the phoreogram of sodium chlorate at 35 °C is catabatic to the Onsager tangent, indicating ion association.

Solutions of Sodium Chlorate and of Lithium Chlorate in a Solvent Consisting of 64.5% Dioxane and 35.5% Water at 25 °C and 35 °C

Graphs of equivalent conductance versus the square root of the concentration of sodium chlorate, at 25° C and at 35 °C, and of lithium chlorate in dilute solution at 25°, are given in Fig. 6. Because of the limited solubility, the maximum in the specific conductance is no longer observed. Fluidity is plotted against concentration in Fig. 7. Table VII gives the values of the activation energies of conductivity and of viscosity. Both are greater than the corresponding energies with water as solvent. This may be connected with the fact that the dioxane molecule is much larger than the water molecule, their respective molar volumes being 85 and 18 ml. Greater energy will be required to form a "hole" in dioxane than in water. This, of course, assumes a "hole" mechanism for both conductance and viscosity.

It is no longer believed that a, the distance of closest approach, contact distance, or center-to-center distance, has a physical meaning. It is merely an empirical parameter. It can only be said that the a values (in Å units) are of the order of magnitude which might be expected for solvated ions.

TABLE VIII

Derived quantities for the mixture 64.5% dioxane, 35.5% water

Salt and temperature	D	$J(a)$	a	K_A	Λ_0
Sodium chlorate at 25 °C	23.4	1 690	3.80	16.6	46.69
Sodium chlorate at 35 °C	22.1	2 257	3.77	17.0	58.21
Lithium chlorate at 25 °C	23.4	1 724	3.93	26.2	43.10

TABLE IX

Walden products

Salt and temperature	$\Lambda_0\eta_0$ in water	$\Lambda_0\eta_0$ in 64.5% dioxane, 35.5% water
Sodium chlorate at 25 °C	1.025	0.901
Sodium chlorate at 35 °C	1.017	0.884
Lithium chlorate at 25 °C	0.923	0.832

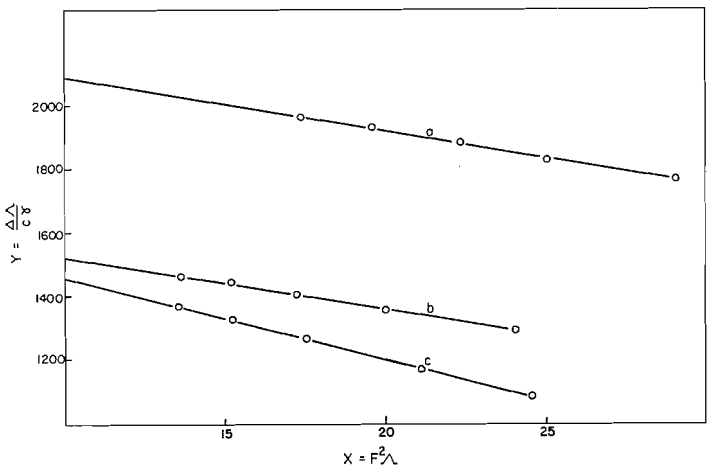

FIG. 8. Plot of y vs. x for the solvent 64.5% dioxane, 35.5% water. (a) Sodium chlorate at 35 °C, (b) sodium chlorate at 25 °C, (c) lithium chlorate at 25 °C.

In Table IX, the so-called Walden product, $\Lambda_0\eta_0$, is compared for both electrolytes in both solvents. Apparently, $\Lambda_0\eta_0$ decreases with decreasing dielectric constant.

Conductances of Sodium Chlorate and of Lithium Chlorate in a Mixture of 90% Dioxane and 10% Water at 25 °C

Plots of equivalent conductance against the square root of the concentration are presented in Fig. 9. The graphs are curved, even in the extremely dilute region. Even the y vs. x plots are curved, making it almost impossible to find Λ_0 by this method. A fair approximation to Λ_0 can be obtained, however, from Walden's rule, using the known

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

viscosity of the solvent. It is then possible to obtain an approximation to K_A, the association constant, by a method given by D'Aprano and Fuoss (18). According to these authors, a plot of log K_c($K_c = \Lambda_0^2F^2/\Lambda_0^2f^2C$) against C should be linear and extrapolate to K_A at zero concentration. Such plots of log K_c versus C are shown in Fig. 10. The plots are linear, except for the most dilute point. The values of K_A and Λ_0 thus obtained are presented in Table X.

TABLE X

Association constants and limiting conductances in a solvent of 90% dioxane, 10% water at 25 °C (dielectric constant = 6.07)

Salt	Λ_0 by Walden's rule	K_A (association constant)
Sodium chlorate	68.0	6.0×10^6
Lithium chlorate	62.8	2.6×10^6

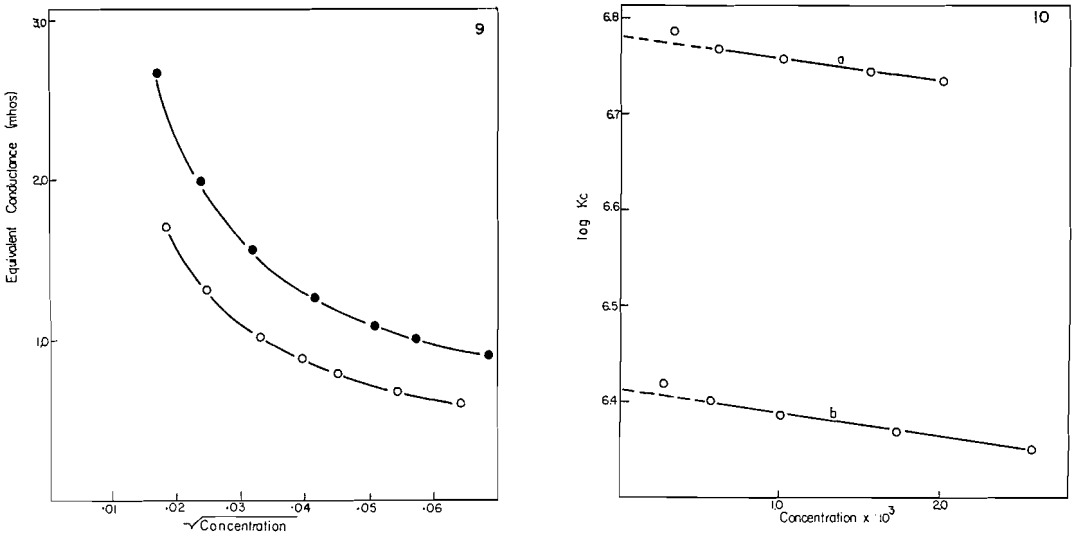

FIG. 9. Equivalent conductance vs. square root of concentration. (○) Sodium chlorate in a solvent consisting of 90% dioxane, 10% water; (●) lithium chlorate in a solvent consisting of 90% dioxane, 10% water.

FIG. 10. Log K_c vs. concentration for 90% dioxane and 10% water mixture. (*a*) Sodium chlorate at 25 °C, (*b*) lithium chlorate at 25 °C.

Figure 9 shows that in 90% dioxane, lithium chlorate has a higher conductance than sodium chlorate, at corresponding concentrations. The reverse is true in the other solvents, which contain more water.

An examination of the association constants shows that in 90% dioxane, sodium chlorate is more associated than lithium chlorate, whereas the reverse is true in 64.5% dioxane.

The original intent of this work was to throw some light on the structure of the melt. One important result emerges. The specific conductance of lithium chlorate in 90% dioxane (dielectric constant = 6.07), at 25 °C, is of the same order of magnitude as that of the anhydrous melt at 130°, both being very low. From Table X, it is obvious that the low conductance in 90% dioxane is due to ion-pair formation, very few free ions being present;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the viscosity of the solution is low. On the other hand, the low conductance of the melt, despite the fact that it is at a temperature 105 deg higher, is unquestionably due, in large part, to the enormous viscosity (6).

As far, at least, as lithium chlorate is concerned, our previous work (1–4) leads us to doubt the view that the melt is highly, or completely, ionized. We are inclined to the view that some sort of coordinate linkage exists in molten lithium chlorate.

THE SYSTEMS SODIUM CHLORATE – WATER – DIOXANE AND LITHIUM CHLORATE – WATER – DIOXANE, AT 25°

A. N. CAMPBELL, E. M. KARTZMARK, AND W. B. MARYK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received November 22, 1965

ABSTRACT

The phase diagrams of the systems sodium chlorate – water – dioxane and lithium chlorate – water – dioxane have been determined at 25 °C.

The sodium chlorate – water – dioxane diagram is relatively simple, anhydrous sodium chlorate being the only solid phase. The occurrence of two liquid layers in contact with sodium chlorate is found between dioxane concentrations of 67.7 and 88.8%.

The lithium chlorate – water – dioxane system exhibits both complex formation and a ternary miscibility gap. The lithium chlorate hydrate, $LiClO_3.\frac{1}{4}H_2O$, exists from 0 to 2.2% dioxane. A mole to mole compound of lithium chlorate and dioxane, $LiClO_3.C_4H_8O_2$, exists from 2.2% dioxane to 100% dioxane. There exists a ternary miscibility gap between dioxane concentrations of 81.5 and 93.6%

The X-ray powder data for anhydrous lithium chlorate, its quarter hydrate, and the compound of lithium chlorate and dioxane have been obtained.

This work arose as a side issue to the work of Campbell, Kartzmark, and Oliver (1) on the conductances of sodium and of lithium chlorates in water–dioxane mixtures. It was thought that the nature of the solid phases might throw some light on the nature of the ions in solution and, indeed, the fact that lithium chlorate forms a compound with dioxane, whereas sodium chlorate does not, would indicate some difference in the solvation of the two cations in dioxane–water mixtures.

EXPERIMENTAL

Materials

Lithium chlorate was prepared by the method of Campbell and Griffiths (2). We found the melting point to be 127.9° ± 0.1° in comparison with the value of 127.8° reported by Campbell and Griffiths. Dioxane was purified by the method of Hess and Frahm (3). Our product boiled at 101.3° (p = 760 mm). The boiling point, density (d^{25} = 1.0278), and refractive index (n_D^{25} = 1.4201) were in close agreement with the results of Frey and Gilbert (4) and of Schott (5). Water distilled in an electric still and having a specific conductance of 5×10^{-6} mhos was used. The sodium chlorate was Fisher certified reagent and received no other purification than drying at 130°.

Determination of Solubility and Methods of Analysis

Both the methods of the "wet residue" and total composition of complex were used to determine the nature of the equilibrium solid phase. After separation of the saturated solution from the wet solid phase, weighed samples of both were submitted to distillation and the distillate analyzed refractometrically for dioxane content. The residue, consisting either of sodium chlorate or of lithium chlorate, was weighed. A complication occurs with lithium chlorate, in that decomposition occurs when dioxane–water mixtures of dioxane content greater than 10% are distilled from lithium chlorate. Hence, such solutions were previously diluted with a weighed amount of water to ensure a dioxane concentration less than 10%.

Since sodium chlorate is not hygroscopic, it was possible to determine the content of sodium chlorate simply by weighing the residue from distillation. The content of lithium chlorate was determined by estimating chlorate radical by a method described by Vogel (6) and by Talbot (7), in which iodine liberated from potassium iodide by the chlorate is titrated with thiosulfate.

X-Ray Powder Photographs

These were taken on anhydrous lithium chlorate, lithium chlorate quarter hydrate, and on the compound of lithium chlorate and dioxane. Because of the hygroscopic nature of the samples containing lithium chlorate, it was necessary to enclose them in fine glass capillaries and mount them in this form in the camera. The capillaries were filled in a drybox and exposed to the X-rays for a period of 10 h.

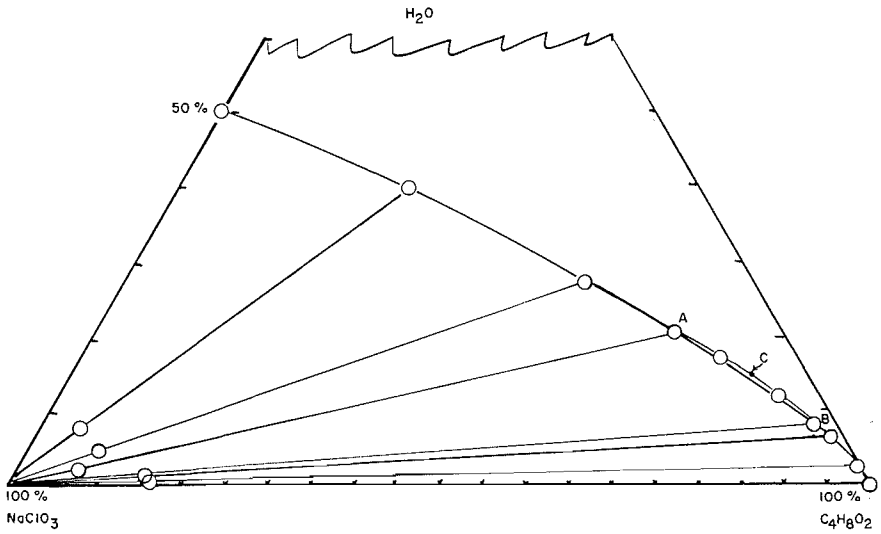

FIG. 1. The system sodium chlorate – water – dioxane, at 25 °C.

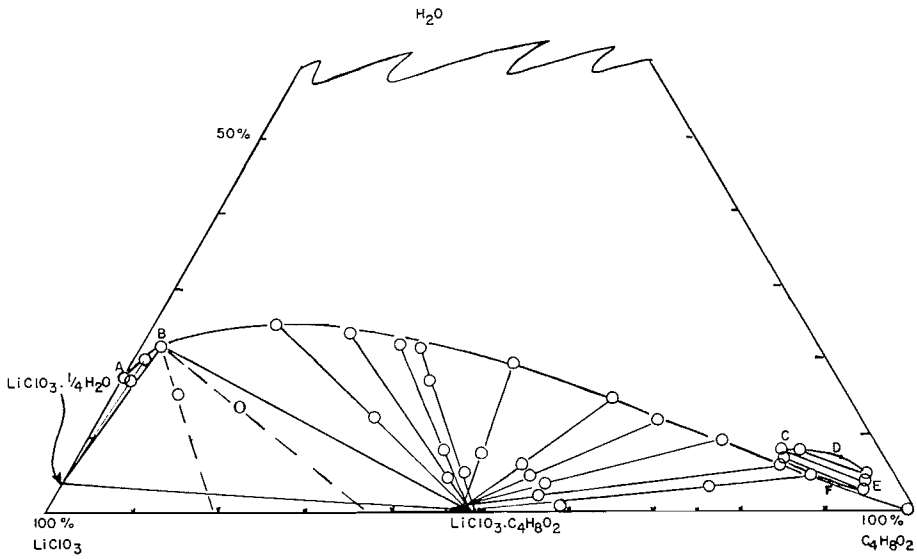

FIG. 2. The system lithium chlorate – water – dioxane, at 25 °C.

RESULTS

The system sodium chlorate – dioxane – water, at 25°, is represented graphically in Fig. 1, and the corresponding system lithium chlorate – dioxane – water, at 25°, in Fig. 2. The X-ray data have been communicated to the American Society for Testing Materials.

DISCUSSION

The sodium chlorate – dioxane – water system (Fig. 1) is relatively simple. No complex formation occurs, the only solid phase being anhydrous sodium chlorate at this temperature. Occurrence of two liquid layers in contact with solid sodium chlorate is found in that region of the diagram where the dioxane concentration is between 67.7 and 88.8%.

For personal use only.

The triangular area, A–$NaClO_3$–B, is an invariant triangle, there being two liquid phases and a solid in equilibrium at constant temperature and pressure, and hence zero degree of freedom. The region of stable existence of two liquid layers, in the absence of solid phase, is very small; the two liquid layers disappear upon addition of a few percent of water. The plait point or critical composition is estimated to be 81.0% dioxane, 5.0% water, and 14.0% sodium chlorate.

The lithium chlorate – water – dioxane system, Fig. 2, exhibits both compound formation and a ternary miscibility gap. As the results of Campbell and Griffiths (2) indicate, a one-quarter hydrate, $LiClO_3.\frac{1}{4}H_2O$, exists at 25° in the binary system lithium chlorate – water. Our results show that the region of existence of this hydrate is very limited in the ternary system: it exists only up to concentrations of 2.2% dioxane. Point B (Fig. 2) is an isothermally invariant point, and it represents this limit. At B, the three phases in equilibrium are solid $LiClO_3.\frac{1}{4}H_2O$, solid compound ($LiClO_3.C_4H_8O_2$), and saturated solution of composition (by weight) 75.5% lithium chlorate, 2.0% dioxane, and 22.5% water. The triangular area, B–$LiClO_3.\frac{1}{4}H_2O$–$LiClO_3.C_4H_8O_2$, is thus an invariant triangle.

The rest of the continuous curve, BF (Fig. 2) represents solutions in equilibrium with a solid of composition 49.3% dioxane and 50.7% lithium chlorate, i.e. a mole to mole compound. The tie lines intersect and spread over a range of 48 to 50% dioxane; this is not surprising because of the great experimental difficulties encountered in this region. The X-ray pattern, however, gives convincing proof of the existence of this compound. A brief summary of the strongest lines is as follows: anhydrous $LiClO_3$: 3.907, 3.767, and 2.803 Å; $LiClO_3.\frac{1}{4}H_2O$: 7.865, 4.103, and 3.751 Å; compound: 4.073, 3.587, and 3.348 Å. Similar dioxanates have been found with other salts.

There exists a ternary miscibility gap in the region where the dioxane concentration is between 81.5 and 93.6%. The gap is small and the lower limit of the gap approaches so near to the solid solubility curve that it was at first difficult to determine whether the two liquids could exist in the presence of solid or not. Accordingly, a large amount of solution containing water, dioxane, and lithium chlorate and unsaturated with respect to lithium chlorate, and such that the mixture consisted of approximately equal volumes of the two liquid layers, was prepared. To this mixture anhydrous lithium chlorate was added. After the mixture was stirred briefly, the two liquid layers disappeared, solid remaining in equilibrium with a single liquid. A further quantity of the two-liquid mixture was added and the system kept at 25° for 24 h. The two liquid layers disappeared. On decanting off the homogeneous liquid and adding a minute amount of water, the two liquid layers reappeared instantaneously and remained even after prolonged stirring. It is, therefore, certain that the miscibility gap in the ternary system lithium chlorate – dioxane – water does not exist in the presence of solid phase, at 25°.

The upper critical composition point is 88.7% dioxane, 4.5% lithium chlorate, and 6.8% water; the lower critical composition point is 88.3% dioxane, 7.3% lithium chlorate, and 4.4% water.

A REFINEMENT OF THE CRYSTAL STRUCTURES OF $(NH_4)_2TeBr_6$ AND Cs_2TeBr_6

A. K. DAS AND I. D. BROWN
Department of Physics, Hamilton College, McMaster University, Hamilton, Ontario

Received December 1, 1965

ABSTRACT

$(NH_4)_2TeBr_6$ and Cs_2TeBr_6 crystals have the cubic K_2PtCl_6 structure with space group: $Fm3m(O_h^5)$ with $a_0 = 10.728 \pm 0.003$ Å and 10.918 ± 0.002 Å respectively. The positional coordinate of the bromine atom, and the anisotropic temperature factors of all atoms in the unit cell, have been refined for both crystals by a full matrix least-squares analysis of the three dimensional X-ray diffraction data ($R = 0.08$). The Te—Br distance, corrected for probable thermal motions of atoms forming the bond, is 2.70 ± 0.01 Å in both crystals.

INTRODUCTION

In a previous paper, one of us (I. D. B.) reported the crystal structure of K_2TeBr_6 (1), which possesses a distorted K_2PtCl_6 structure (2). To examine the influence of the cation on the bonding within the $TeBr_6^{2-}$ ion, we have now refined the structures of $(NH_4)_2TeBr_6$ and Cs_2TeBr_6, both of which possess the undistorted K_2PtCl_6 structure at room temperature.

Accurate lattice parameters for both crystals have already been determined by Swanson and his co-workers (3, 4). The unit cell and space group of $(NH_4)_2TeBr_6$ have been determined by Manojlović (5) and the structure of Cs_2TeBr_6 crystal has been reported by Bagnall *et al.* (6). In the present work, new X-ray diffraction data have been obtained and more accurate values of Te—Br bond distances are reported.

EXPERIMENTAL

Bright-red crystals of $(NH_4)_2TeBr_6$ and Cs_2TeBr_6 were prepared by methods similar to those described for K_2TeBr_6 and $(NH_4)_2TeCl_6$ in Inorganic Syntheses (7). Powder photographs of these crystals with Ni-filtered Cu radiation were used to calculate accurate lattice parameters, and their densities were measured pycnometrically with CCl_4 at 25 °C. The crystal data thus obtained are listed in Table I together with the reported lattice parameters (3, 4), which are in good agreement with the present measurements.

Visually estimated intensity data were collected from a single crystal ($0.39 \times 0.15 \times 0.08$ mm) of $(NH_4)_2TeBr_6$ in five layers parallel to the largest face (001) of the crystal with precession photographs taken with Zr-filtered Mo radiation. The intensities were corrected for the Lorentz and polarization effects but not for absorption. Because of the cubic symmetry of the crystal, some of the reflections in higher layer

lines were equivalent to those in lower layers and thus the data from different layers could be scaled to each other. However, it was not possible to scale odd and even layers together. We assumed that the crystal has the K_2PtCl_6 structure (2) and refined the positional coordinate of the bromine atom and the anisotropic temperature factors of all atoms in the unit cell by a full matrix least-squares analysis* of the three dimensional data. Each reflection was weighted individually according to an estimate of its reliability. The atomic scattering factors for all the atoms except hydrogen, which was not included in the refinement, were taken from International Tables (8). The observed and calculated structure factors are given in Table II and the atomic parameters after the final cycle of refinement are listed in Table IV. The weighted R index given by

$$R = \{\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2\}^{1/2}$$

for these parameters was 0.079.

A similar procedure was followed in the refinement of the structure of Cs_2TeBr_6. The crystal used had the dimensions 0.23 × 0.15 × 0.06 mm. Integrated precession photographs were taken in four layers parallel to the largest face (011) of the crystal and the intensity of each reflection was measured with a microdensitometer. After refinement of the structural parameters, the weighted R index was 0.082. Table III lists the observed and calculated structure factors and Table IV the final positional coordinates and anisotropic temperature factors of Cs_2TeBr_6.

TABLE IV

‡The value of x given by Bagnall *et al.* (6) is 0.24.

RESULTS AND DISCUSSION

Both crystals possess the K_2PtCl_6 structure which is based on a face-centered cubic array of the octahedral $TeBr_6^{2-}$ ions oriented with the Te—Br bonds along the principal cube axes. The cations occupy the tetrahedral holes between 4 neighboring anions and are surrounded by 12 bromine atoms, 3 from each anion.

The Te—Br bond lengths are given in Table V. A correction can be made for the apparent shortening of the bond due to thermal motion (9) on the assumption that the $TeBr_6^{2-}$ ion is librating about the central tellurium atom. If this is done, the mean Te—Br bond length in both crystals becomes 2.70 Å. Owing to the uncertainty in the absolute values of the amplitudes of thermal motion and the proper way to correct for them, the standard error in this bond distance is estimated to be about 0.01 Å. Thus, the Te—Br bond is not significantly different in two structures nor does it differ significantly from the value (2.71 Å) found in K_2TeBr_6 (1). It is apparent that the cations do not have a large influence on the structure of the anion.

TABLE V

Cs—Br distance (3.89 Å) is the same as that predicted (3.90 Å) but the NH_4—Br distance (3.82 Å) is considerably longer than expected (3.66 Å). On the other hand, the Br—Br separation between anions, which one might expect to be the same in both crystals, is shorter in $(NH_4)_2TeBr_6$ (3.84 Å) than in Cs_2TeBr_6 (3.94 Å). In the latter case, the distances are determined by the fact that the cesium and bromine atoms are in contact so that the anions are just separated (Fig. 1*a*). In $(NH_4)_2TeBr_6$ it is the bromine atoms in different anions that are in contact (Fig. 1*b*). The ammonium ion is smaller than the cavity which is formed by the 12 bromine atoms which surround it, and, as discussed in a previous paper (1), this should lead to a distortion at low temperatures. At −52 °C, $(NH_4)_2TeBr_6$ transforms to a lower symmetry (11), which is probably tetragonal. A mechanism for such a distortion has been proposed by Morfee *et al.* (12) for the analogous $(NH_4)_2SnBr_6$ compound. The anions rotate about the (001) direction with alternate anions rotating in an opposite sense. Such a rotation, which has the effect of reducing the anion–cation separation, has been found at room temperature in K_2SnBr_6 (13) and K_2TeBr_6 (1). At temperatures close to the transition temperature, the $TeBr_6^{2-}$ ions would be expected to be librating with a rather large amplitude. This would be manifested in the X-ray investigation as an anisotropy in the thermal motions of the bromine atoms. Such an anisotropy is indeed observed in K_2TeBr_6 and $(NH_4)_2TeBr_6$ (Table V). It is significant that although the same anisotropy is also present in Cs_2TeBr_6, it is very much less marked. We are presently continuing this work by investigating the changes which occur in $(NH_4)_2TeBr_6$ below room temperature.

MOLECULAR MOTION IN WEAK CHARGE TRANSFER COMPLEXES[1]

D. F. R. GILSON[2] AND C. A. MCDOWELL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received November 8, 1965

ABSTRACT

"Wide line" nuclear magnetic resonance studies of several charge transfer complexes are reported. Line width transitions and comparisons of theoretical and experimental second moments indicate that molecular rotation occurs in several of these complexes. Estimates of the barriers to reorientation in the complexes show these to be lower than those observed for the corresponding pure compounds.

INTRODUCTION

The structural details of a number of so-called "weak" charge transfer complexes in the solid state are now well known, due largely to the work of Hassel and his co-workers (1). Apart from such structural studies these complexes have received little attention when compared with the extent of electronic spectral investigations of aromatic charge transfer systems in solution (2). A notable feature of some complexes in the solid state is the occurrence of endless chains of alternating molecular species. In one such complex, between 1,4-dioxane and dinitrogen tetroxide, Groth and Hassel (3) have recently reported that a statistical distribution of the dioxane methylene group positions was evident from the X-ray data and that a proton magnetic resonance study revealed a line width transition above −40 °C. Molecular reorientation has also been observed in complexes between dioxane and silver perchlorate (4, 5) and benzene and silver perchlorate (6).

Because of the evidence we had earlier found for the rotation of the benzene molecule in the benzene–silver perchlorate complex (6) it seemed of interest to study other charge-transfer complexes by nuclear magnetic resonance methods. One would wish to know if, for example, intramolecular motions of the components of charge transfer complexes were of general occurrence. It was also obviously of some interest to discover what were the magnitudes of the potential energy barriers which controlled the extent and frequency of such intramolecular motions.

It is of interest to note that Voigt and Reid (7) have suggested that there may be a mutual rotation of the two components of the tetracyanoethylene-parasubstituted benzenes complexes in solution to account for the intensities of the charge transfer absorptions.

EXPERIMENTAL

Proton and fluorine nuclear magnetic resonance spectra were recorded at 30 Mc/s and at 40 Mc/s. The 40 Mc/s spectra were obtained using a Varian Dual Purpose spectrometer with a 12 in. magnet. While these studies were in progress a wide line spectrometer was constructed (8), employing essentially Varian units with a 6 in. magnet, and measurements were continued at 30 Mc/s.

Variable temperature control was achieved by passing around the sample either heated air or tank nitrogen cooled by liquid nitrogen or dry ice/acetone mixture. For measurements at temperatures below the lower limit of the flow system the sample was immersed directly in liquid nitrogen, air, or oxygen. Temperatures were measured with copper/constantan thermocouples placed upstream and downstream from the sample.

Complexes of 1,4-dioxane with mercuric chloride and silver perchlorate were prepared by recrystallization, the latter from acetone as described by Comyns and Lucas (9). Other complexes were prepared by weighing equimolar quantities of the components into sample tubes, which were then sealed, heated above the melting points of the components, and cooled slowly. Reagent grade chemicals were used except for hexafluorobenzene which was obtained from Imperial Smelting Co. Ltd. and further purified by vapor chromatography.

RESULTS AND DISCUSSION

1,4-Dioxane Complexes

Experimental second moments at 77 °K and at room temperature (298 °K) are given in Table I. The theoretical intramolecular second moment of dioxane, calculated from the carbon atom positions in the bromine complex (10) and assuming a C—H bond length of 1.09 Å and tetrahedral angles, is 15.5 gauss^2. The methods used in estimating the theoretical values of the second moments were identical with those given in refs. 18, 19, 23, and 24. From the parameters obtained by Davies and Hassel in their electron diffraction study of dioxane vapor (11) a second moment of 14.5 gauss^2 is obtained. The lower value results from an increase in the C—H bond length to 1.10 Å. The second moment of the "boat" as opposed to "chair" form falls within this same range. For reorientation about the oxygen–oxygen axis the intramolecular second moment is reduced to 1.2–1.3 gauss^2. In the complexes with bromine and mercuric chloride the dioxane molecule is fixed at room temperature. The low values of the experimental second moment for the complexes with antimony trichloride and silver perchlorate show that rotation or a reorientation occurs.[3] In the latter case, rotation was suggested on the basis of the X-ray structural investigation (4). While the present studies were in progress the temperature dependences of the proton resonance line width and second moment of the benzene–silver perchlorate complex were reported by Kawamori and Sakiyama (5). Below 14 °C the dioxane molecules are fixed but above this temperature undergo rotation, first about the oxygen–oxygen axis and then isotropically. Powell (12) has suggested that rotation affords better packing in the crystal; a similar argument might apply to the antimony trichloride complex, the structure of which has not been reported.

TABLE I

Second moments of dioxane complexes

Complex	Second moment (gauss^2) At 298°K	At 77 °K
Dioxane–Br_2	18.7±0.3	18.9±0.5
Dioxane–$HgCl_2$	18.5±0.2	19.0±0.4
Dioxane–$AgClO_4$	1.5±0.2	20.9±0.4
Dioxane–$SbCl_3$	3.6±0.3	18.6±0.4

Benzene Complexes

The temperature dependences of the line width and second moment of both ^1H and ^{19}F resonances for the 1:1 benzene–hexafluorobenzene complex (13) are shown in Figs. 1 and 2. Line width and second moment transitions occurred for both resonances. The fluorine resonance line exhibited some structure over the transition temperature range of 110–145 °K, Fig. 3. As the temperature was increased, the narrow line grew in intensity at the expense of the broader component.

The calculated intramolecular second moments of benzene and hexafluorobenzene are 3.1 gauss^2 and 1.7 gauss^2, respectively. These values will be reduced by a factor $\frac{1}{4}$ for rotation about the sixfold axes, to 0.8 gauss^2 and 0.4 gauss^2. The crystal structure of this

[3]*It is difficult to decide from n.m.r. studies alone if a molecule or a group rotates continuously, or undergoes a rapid reorientation. The narrowing of nuclear magnetic resonance lines only requires frequencies of rotation (or orientation) of the order of magnitude of the line widths expressed in frequency units, i.e. usually about* 10^4–10^5 *c/s.*

complex has not been reported, but by analogy with other aromatic complexes (14) it is probable that the two molecular species are stacked alternately in columns with their molecular planes parallel. Reorientations about the sixfold axes are thus the most probable causes of the transitions. The structure shown by the ^{19}F resonance can be explained if two resonance lines are present arising from C_6F_6 molecules which are stationary and rotating, respectively.

The line width and second moment of the proton resonance of the benzene – carbon tetrabromide complex are plotted against temperature in Fig. 4. The structure of this complex is not known but probably resembles that of the *p*-xylene – carbon tetrabromide complex determined by Strieter and Templeton (15). Each aromatic ring has a bromine atom on each face and zig-zag strings of alternate carbon tetrabromide and *p*-xylene molecules run parallel to the *c* azis of the crystal. The distance from the bromine atom to the center of the aromatic ring is 3.34 Å, which is 0.2 Å less than the sum of the van der Waals radii. A transition occurs in the benzene – carbon tetrabromide complex below

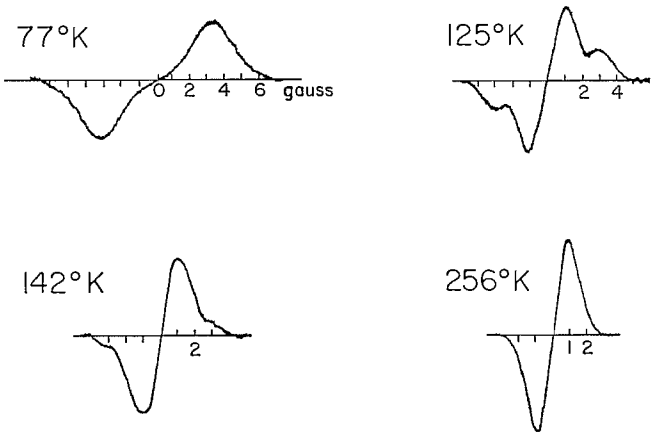

FIG. 3. Line shape derivative curves of the fluorine resonance in the complex $C_6H_6.C_6F_6$ at different temperatures.

100 °K and is not complete at 77 °K. This transition, resulting again from rotation about the sixfold axis, is probably responsible for the disappearance of the ^{81}Br nuclear quadrupole resonance between 77 and 90 °K (16).

The second moment of the proton resonance of the benzene – antimony trichloride complex increases only slightly from 0.82 ± 0.03 gauss² at room temperature to 0.86 ± 0.05 gauss² at 77 °K. The X-ray structure has not been determined, but Daasch (17) has suggested two possibilities, having C_{2v} and C_{3v} symmetry, from an infrared investigation. While the present results do not enable one to decide between these structures, the fact that reorientation still occurs at the lowest temperature studied favors the more symmetrical structure, which is preferred also by Daasch.

Mesitylene–Hexafluorobenzene Complex

The proton second moment and line width below 90 °K were 9.26 gauss² and 5.50 gauss respectively. These values decreased to 1.56 gauss² and 2.47 gauss at room temperature. The fluorine second moment and line width at 77 °K were 1.33 gauss² and 2.60 gauss, respectively, decreasing to 0.61 gauss² and 1.81 gauss at room temperature.

The calculated intramolecular second moment for a mesitylene molecule with fixed methyl groups is 19.7 gauss². It has been shown that methyl group rotation (or tunnelling) in methyl-substituted benzenes occurs down to very low temperatures (18, 19). In hexamethylbenzene the experimental second moment at 1 °K is less than the calculated value for a completely rigid molecule (20). Calculation of theoretical second moments in rotating molecules can be made using the formulae of Andrew and Eades (24). For a mesitylene molecule with rotating methyl groups the calculated intramolecular second moment becomes 4.75 gauss². At room temperature the experimental second moment is reduced to a value less than that calculated for methyl group rotation alone and therefore some further molecular motion must occur. Reorientation about the threefold axis normal to the aromatic ring is most likely. It is assumed that the second moment is this case will be reduced by a factor of $\frac{1}{4}$, i.e. that the internuclear vectors are effectively all normal to the axis of rotation, to give a value of 1.2 gauss², which is compatible with the experimental second moment.

Mesitylene itself has been studied by Andrew *et al.* (19) who report a continuous reduction in second moment from 4 °K to the melting point at 220 °K. The second moment at 220 °K was 8.0 gauss² and there is no evidence of rotation about the threefold axis. The

FIG. 5. Temperature dependence of the proton second moment of pure durene and in complexes of durene: ○, durene; △, C_6F_6–complex; ●, CBr_4–complex.

low value of the fluorine resonance second moment shows that in the complex the hexafluorobenzene molecule is still reorienting at 77 °K.

Durene Complexes

The temperature dependence of the proton second moments of durene complexes with carbon tetrabromide and hexafluorobenzene are shown in Fig. 5. The calculated rigid intramolecular contribution is 23.3 gauss^2 which is reduced to 5.7 gauss^2 by methyl group rotation. For durene itself the experimental second moment at 77 °K is 8.74 gauss^2, decreasing smoothly to 8.14 gauss^2 at 353 °K (m.p.). Thus methyl group reorientation must occur in durene and the complexes at 77 °K.

The behavior of the second moments, and also the line shapes, with temperature is remarkably similar for both of these complexes. The second moments decrease slowly as the temperature is increased from 77 °K, but then fall rapidly from 250 °K (C_6F_6) and 230 °K (CBr_4) to the melting points; 328 °K and 357 °K, respectively. The line shapes at 77 °K were simple but became quite complicated at higher temperatures. Derivative curves of the durene – hexafluorobenzene complex proton resonance absorption at different temperatures are shown in Fig. 6. This structure of the resonance absorption cannot arise from the three-spin system of a rigid methyl group since the second moments are too low. However, a similar line shape was observed previously (20) for the thiourea adduct with durene and, therefore, appears to be a property of the "isolated" durene

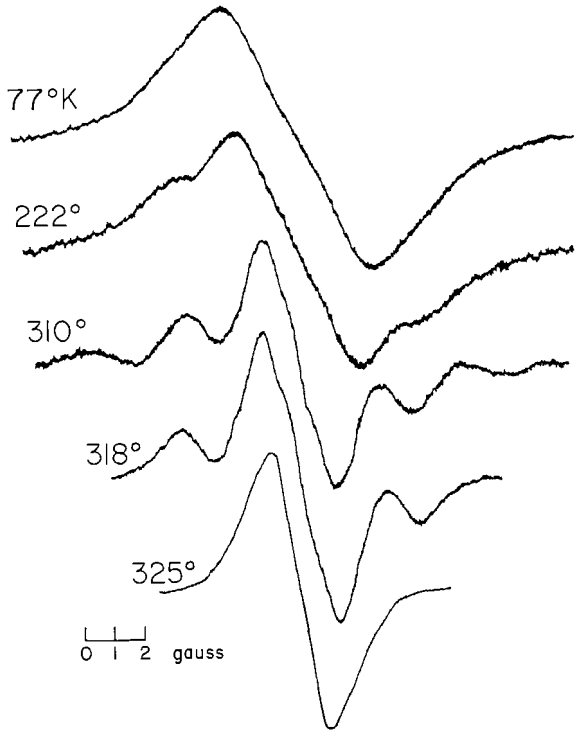

FIG. 6. Line shape derivative curves of the proton resonance in the complex durene–hexafluorobenzene at different temperatures.

molecule. The resonance line shape of pure durene does not show this structure because of the increased intermolecular dipolar interactions in the pure compound.

The reductions in second moments at higher temperatures indicate further molecular motion. This is probably some form of rotational oscillation since there is no evidence of a plateau in the second moment versus temperature plot at about 2 gauss^2. Such a plateau would be expected if the motion were complete reorientation about an axis normal to the molecular plane. These results are of interest in connection with the bromine nuclear quadrupole resonance studies of carbon tetrabromide in the durene complex (21). In this complex the resonances of the two crystallographically inequivalent bromine atoms merged together and then disappeared about 50° below the melting point of the complex. This suggested that their environment had become indentical. The nuclear magnetic and nuclear quadrupole resonance results indicate weakening of the crystal lattice with considerable disorder and molecular motion. It must be emphasised that the motions investigated by these techniques are of low frequency, $\sim 10^4$–10^5 c/s; the long range crystal structure is maintained, therefore, to a much higher temperature.

The fluorine resonance in the durene–hexafluorobenzene complex has second moments of 3.97 gauss^2 and 0.70 gauss^2 at 77 and 298 °K respectively. For a rigid molecule a total second moment of about 5 gauss^2 would be expected and thus molecular reorientation still occurs at 77 °K.

Barriers to Rotation

The line width changes can be related via the theory of Bloembergen, Purcell, and Pound (22), as modified by Gutowsky and Pake (23), to a correlation frequency, ν_c, for the motion responsible for the change.

[1] $$\nu_c = \frac{\alpha\gamma\delta H}{2\pi} \Big/ \tan\frac{\pi}{2}\frac{(\delta H)^2 - B^2}{B^2 - C^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where δH is the line width, γ is the magnetogyric ratio, B is the rigid lattice line width, and C is the limiting value of the line width above the transition. The line widths are expressed in gauss. The factor α arises from uncertainties in the limits of integration used in obtaining eq. [1] and is rather ill-defined. The correlation frequency can be used in the expression

$$[2] \qquad \nu_c = \nu_0 \exp(-E/RT)$$

to give an activation energy E for the molecular reorientation. Since α will affect ν_0 rather than E, it can be incorporated as $(\alpha\nu_0)$.

There are objections to this treatment of correlation frequencies. It assumes that a single correlation frequency, rather than a distribution, may be used to describe the motion. Changes in line shape are ignored, as are the relative magnitudes of the inter- and intra-molecular contributions to the line width. Despite these difficulties fruitful comparisons between similar systems can still be made (19, 25–29). The values of E and $\alpha\nu_0$ obtained from eqs. [1] and [2] were used to calculate theoretical line width versus temperature plots as shown in Figs. 1, 2, and 4. In the complexes of benzene with hexafluorobenzene and carbon tetrabromide the proton resonance line width had not reached a limiting rigid lattice value at 77 °K. Comparison with the benzene – silver perchlorate complex (6) and with benzene itself (24), where the rigid lattice line widths were 8.2 gauss and 9.1 gauss respectively, suggested extreme limits of 7 and 10 gauss. These limits were used to calculate possible ranges of E.

For benzene in the benzene–hexafluorobenzene complex the barrier to rotation ranged from 1.6 to 1.9 kcal/mole. For the hexafluorobenzene molecule, barriers were calculated for both the broad and narrow components of the resonance line. The values obtained were in quite close agreement, 1.3 and 1.5 kcal/mole respectively. In the benzene – carbon tetrabromide complex the barrier ranged from 2.1 to 2.3 kcal/mole depending on the value chosen for the rigid lattice line width. The barriers in these complexes may be compared with those obtained from line width changes for the pure compounds. For benzene Andrew (24) and Eades obtained 3.5 kcal/mole, and in hexafluorobenzene a line width transition between 85 and 100 °K gave a value of 4.5 kcal/mole (20). We are unable to suggest a satisfactory explanation as to why our values for these activation energies should be somewhat lower than those found by Andrew and his co-workers. It is possible, however, that the different crystal symmetries at the respective sites for rotation or reorientation may play some part in determining the magnitude of the activation energies.

THE Hg $6(^3P_1)$ PHOTOSENSITIZED DECOMPOSITION OF METHYLENECYCLOBUTANE VAPOR

G. R. De Maré, O. P. Strausz, and H. E. Gunning
Department of Chemistry, University of Alberta, Edmonton, Alberta

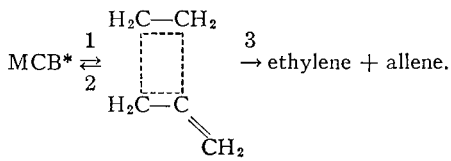
Received October 22, 1965

ABSTRACT

The main mode of decomposition, in which at least two biradicals are involved, is a molecular split into ethylene and allene. The pressure dependence of the reaction exhibits some unusual features which may be interpreted by a stepwise collisional removal of vibrational energy from one of the transient biradicals.

INTRODUCTION

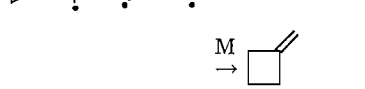
Nangia and Benson (1) have proposed the following general mechanism for the pyrolysis of small ring compounds



[A] $$\text{ring}^* \underset{2}{\overset{1}{\rightleftarrows}} \text{biradical} \xrightarrow{3} \text{olefin (one or more).}$$

The biradicals involved are believed to have short lifetimes (10^{-10} to 10^{-11} s); therefore their collisional deactivation at subatmospheric pressures should be unimportant.

For methylenecyclobutane (MCB) this mechanism may be written



[B] $$\text{MCB}^* \underset{2}{\overset{1}{\rightleftarrows}} \text{1,4-biradical, 2-methylenebutane} \xrightarrow{3} \text{ethylene} + \text{allene.}$$

An alternate, although less likely but experimentally unrefuted mechanism is

[C] 

The 1,4-biradical, 2-methylenebutane intermediate has been postulated also in the mercury sensitization of spiropentane (2) as a precursor of the final products, ethylene + allene and methylenecyclobutane.

[D] 

[E] 

The intervention of the same biradical would also be expected in the mercury sensitization of MCB. Both sequences, [B] for the thermal reaction of MCB and [E] for the mercury sensitization of spiropentane, could be further substantiated if the nature of the mercury-photosensitized reaction of MCB would be consistent with this expectation. The present study was undertaken for this reason.

EXPERIMENTAL

The reaction system and the method used to determine the amount of light absorbed in the cell have been described in a previous paper (3).

The light intensity, measured by propane actinometry at 730 Torr propane pressure, was 1.7×10^{15} quanta/s.

MCB (Aldrich) was found to be 70% pure and was purified by several passages on the diisodecyl phthalate column previously described (3). Methylcyclobutane (MB) was prepared by the mercury-photosensitized decomposition of molecular hydrogen in the presence of MCB. It was purified by gas chromatography (g.c.) and identified by mass and nuclear magnetic resonance (n.m.r.) spectroscopy. Isoprene (IP) (Eastman) and 1,4-pentadiene (PD) (prepared by Mr. L. G. Walker of this department by the thermal decomposition of 1,5-pentanediol diacetate) were used without further purification. Nitric oxide (Matheson C.P.) and ethane-d_6 (Merck) were purified as previously described (3). Methyl mercaptan (Matheson) was purified by g.c. on the above column. Oxygen (Airco assayed reagent) was used without purification.

Analysis of the noncondensable products was identical with that described in the previous paper (3). Good resolution of the ethylene, allene, MB, IP, PD, and MCB peaks was obtained on the diisodecyl phthalate column at ambient temperature.

Ethylene and allene were identified by their mass spectra. MB, IP, and PD were identified by comparison of mass spectra and g.c. retention times with those of authentic samples.

The small quantities of MB, IP, and PD formed in the experiments makes the determination of their quantum yields very inaccurate. Thus the detector response for MCB was used, since it would not increase the experimental error involved in their determination.

RESULTS

The reaction products which were identified (with their respective quantum yields at 40 Torr substrate pressure in parentheses) are ethylene (0.50), allene (0.50), hydrogen (0.02), MB (0.004), IP (0.002), and PD (0.01). The high efficiency of the step(s) forming ethylene and allene and the low yields of hydrogen and MB suggested that the total yield of C_{10} products must be very low; this was verified experimentally.

Vinylcyclopropane, cyclopentene, and *cis*- and *trans*-1,3-pentadiene have retention times similar to that of the substrate on the column used. It was therefore imperative to show that no products were eluting with the substrate. A sample of MCB was subjected to very extensive decomposition by successive reuse after removal of the known products at reasonably short reaction times. The n.m.r. spectrum of this MCB (trapped from the g.c. effluent) was identical with the published one (4) and thus indicated that no products with combined quantum yields > ca. 0.05 were hidden under the substrate peak.

Three series of experiments were carried out.

I. The product yields were determined as a function of reaction time at a substrate pressure of 40 Torr. All yields were found to be independent of reaction time up to 90 min. Mass spectral analysis of the C_2 fraction formed in a 90 min run showed the presence of a trace of acetylene, indicating that secondary decomposition of the ethylene had begun. The hydrogen yield appeared to be slightly higher but was still within experimental error of being unchanged. The yield of IP became measurable only after 30 min reaction time.

II. The quantum yields of ethylene, allene, hydrogen, PD, and MB were examined as a function of substrate pressure at 10 min reaction time. The results are shown in Fig. 1. The yield of MB was too small to provide reliable kinetic data and it is excluded from the figure. The yields of the other products decrease sharply with increasing substrate pressure, indicating that they are formed from an excited molecule which can be deactivated.

III. The various effects of adding a few percent of nitric oxide, or methyl mercaptan, or oxygen, or a large excess of ethane-d_6 to the reaction were studied. Nitric oxide appeared to have no effect on any of the products (hydrogen was not measured). The addition of 1.3 Torr methyl mercaptan to 42 Torr MCB caused a 50% increase in $\Phi(H_2)$ to 0.033 and a

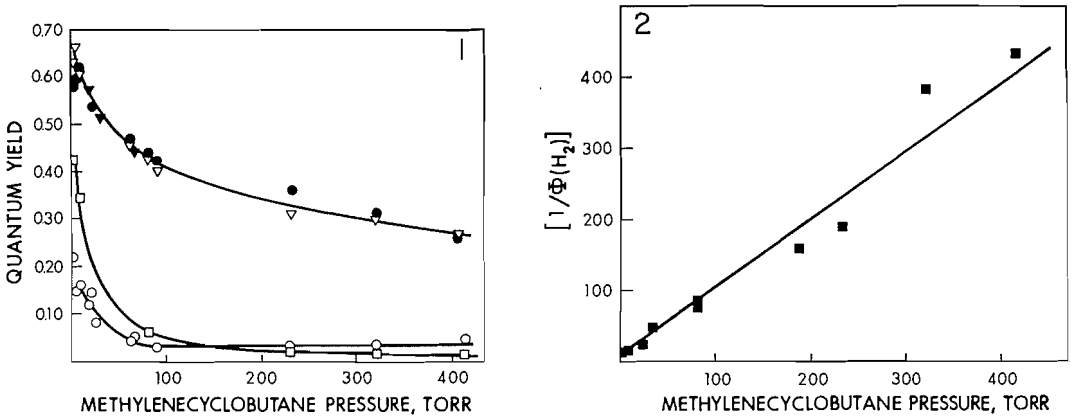

FIG. 1. Quantum yield of formation as a function of methylenecyclobutane pressure: $\Phi(C_2H_4)$, ▽; $\Phi(C_3H_4)$, ●; $5 \times \Phi(H_2)$, □; $3 \times \Phi(PD)$, ○; and $\Phi(C_2H_4) = \Phi(C_3H_4)$, ▼.
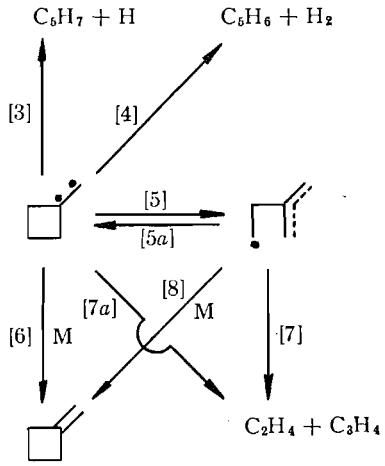
FIG. 2. $1/\Phi(H_2)$ as a function of methylenecyclobutane pressure.

ninefold increase in Φ(MB) to 0.028. The addition of 76 Torr ethane-d_6 to 6.5 Torr MCB had no effect on the product yields. This is probably due to the cancelling of two opposing effects; increased absorption due to pressure broadening of the absorption line and increased deactivation of the excited MCB. No HD was detected, indicating that either the hydrogen is formed as H_2 or that abstraction from MCB is favored by a factor of 10 or more over abstraction from ethane-d_6. Molecular oxygen was added to 42 Torr MCB in concentrations up to 45%. Competitive quenching was corrected for using σ_Q^2(MCB) = 48 Å^2 and $\sigma_Q^2(O_2)$ = 13 Å^2 (5). Transmission through the reaction vessel was measured continuously and was found to increase rapidly at higher O_2 concentrations. The yield of allene[1] was corrected for this change in absorption. The collisional deactivating efficiency of O_2 was assumed to be equal to that of MCB. After application of these three corrections the yield of allene was below the expected value by as much as 12%.[2]

DISCUSSION

The dependence of the yields of the major products of the photosensitization of methylenecyclobutane on substrate pressure indicates that the major primary step of the reaction is the formation of an excited molecule

[1] Hg 6($^3P_1$) +  → Hg 6($^1S_0$) + 



where  is a methylenecyclobutane molecule in a vibrationally excited triplet state. A second primary step which might occur is

[2] Hg 6($^3P_1$) +  → Hg 6($^1S_0$) + $C_5H_7\cdot$ + H.

[1]*Quantitative measurements of* CO, CO_2, *and* C_2H_4 *were not attempted.*
[2]*The largest decrease, 12%, was found at the highest added oxygen pressure, 45%. The decrease could be caused by the reaction of oxygen atoms with the product allene or be the effect of an error in the quenching cross-sections, or perhaps the collisional deactivating efficiency of* O_2 *is greater than that of methylenecyclobutane.*

Excluding the formation of the isomers, the species formed in steps [1] and [2] may lead to the following reactions:

and

[9] $H + \square\!\!\diagup\!\!\diagup \rightarrow \square\!\!\diagup\!\!\cdot$

[10] $\rightarrow H_2 + C_5H_7\cdot$

[11] $\square\!\!\diagup\!\!\cdot + \square\!\!\diagup\!\!\diagup \rightarrow \square\!\!\diagup + C_5H_7\cdot$

[12] $2\,\square\!\!\diagup\!\!\cdot \rightarrow \square\!\!\diagup + \square\!\!\diagup\!\!\diagup$

[13] $\square\!\!\diagup\!\!\cdot + C_5H_7\cdot \rightarrow \square\!\!\diagup + C_5H_6$

Radical–radical and radical–substrate reactions for which product evidence has not been found have been excluded. It is assumed that the biradicals will not react with the substrate to any appreciable extent.

The formation of each product will now be considered.

Hydrogen

If step [4] is neglected, steady-state treatment (s.s.t.) of the mechanism for $\Phi(H_2)$ gives

$$[14] \qquad \Phi(H_2) = \frac{\alpha}{I_a}\left(\frac{k_{10}}{k_9 + k_{10}}\right) + \frac{\beta}{I_a}\left(\frac{k_3}{k_3 + k_5 + k_6P}\right)\left(\frac{k_{10}}{k_9 + k_{10}}\right)$$

where α/I_a and β/I_a are the fractions of the primary reaction proceeding via steps [2] and [1] respectively; I_a is the absorbed light intensity and P is the substrate pressure. Thus steps [2] and [3] are kinetically distinguishable as possible sources of the H-atoms in the sensitization since $\Phi(H_2)$ from hydrogen atoms formed in [2] should be independent of substrate pressure and is therefore $\leqslant 0.002$. Thus, at low pressures (< 100 Torr) the first term of eq. [14] may be neglected. Setting $\beta/I_a \simeq 1.0$ and inverting, one obtains

$$[15] \qquad 1/\Phi(H_2) = \left(\frac{k_3 + k_5}{k_3}\right)\left(\frac{k_9 + k_{10}}{k_{10}}\right) + \left(\frac{k_9 + k_{10}}{k_3 k_{10}}\right) k_6 P.$$

Figure 2, a plot of $1/\Phi(H_2)$ vs. P, shows that a straight line fits the data within experimental error even at pressures well above 100 Torr. Step [2] will therefore be omitted from subsequent steady-state calculations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

If only [3] and [4] are considered as the possible sources of H-atoms and molecular hydrogen respectively, s.s.t. yields

$$[16] \qquad \Phi(H_2) = \left(\frac{k_3 k_{10}}{[k_3 + k_4 + k_5 + k_6 P][k_9 + k_{10}]}\right) + \left(\frac{k_4}{k_4 + k_3 + k_5 + k_6 P}\right).$$

Thus a linear dependence of $1/\Phi(H_2)$ on substrate pressure would be observed if [3] alone or [4] alone take part in the formation of hydrogen.

It may be argued that [4] should be considered as a possible step because of the absence of HD as a product of the reaction in the presence of ethane-d_6. Elimination of molecular hydrogen from the excited methylenecyclobutane should yield methylenecyclobutene and it is not likely to be important. Step [3], on the other hand, must occur. The formation of methylcyclobutane in the photosensitization of the pure substrate and the increased yields of H_2 and methylcyclobutane when methyl mercaptan (a good source of abstractable hydrogen) is added dictate the presence of H-atoms.[3] From the relative yields of hydrogen and methylcyclobutane in the methyl mercaptan experiment and from the low yields of C_{10} compounds in the pure substrate reaction, it appears that the ratio of abstraction to addition is nearly one, which is much greater than that obtained for similar reactions with other olefins (cf. the value for cyclohexene = 0.23 (6)). This high ratio for methylenecyclobutane as well as the resistance of cyclohexene to both abstraction and addition (7) explain why in the presence of ethane-d_6 and under similar conditions the mercury photosensitization of cyclohexene yields hydrogen which is 12% HD, 88% H_2, whereas the photosensitization of methylenecyclobutane yields hydrogen in which only H_2 was detectable. Steps [3] and [10] are therefore considered to be the source of H_2.

Ethylene and Allene

Step [7] satisfactorily explains the equality of $\Phi(C_2H_4)$ and $\Phi(C_3H_4)$ over the pressure range studied. Figure 3 shows the comparison of the yield of ethylene from the methylenecyclobutane photosensitization and the yield of hydrogen from the photosensitization of ethylene. Although both reactions have the same efficiency at 10 Torr substrate pressure the ethylene reaction is much more easily suppressed, indicating that the species involved in the formation of acetylene and hydrogen from ethylene are either longer lived or require fewer collisions to be deactivated than the species involved in the formation of ethylene and allene from methylenecyclobutane.

$1/\Phi(C_2H_4)$ plotted against P in Fig. 4 shows a lower than first order pressure dependence. This is an unusual feature of the methylenecyclobutane system because most of the olefinic triplet state reactions obey second order and none lower than first order kinetics.

From the general mechanism it is possible to obtain kinetic expressions by s.s.t. for $1/\Phi(C_2H_4)$ ranging from less than first order to second order on pressure, depending on the elementary steps chosen. For example, s.s.t. of a mechanism comprised of steps [5] to [7] yields

$$1/R(C_2H_4) = \frac{A + BP}{C + DP},$$

and that comprised of steps [5] to [8] yields

$$1/R(C_2H_4) = \frac{A + BP + CP^2 + DP^3}{E + FP + GP^2},$$

where $A, \ldots G$ are complex functions of the elementary rate constants.

[3]H-*atoms formed by quenching of excited mercury by* CH_3SH *could not explain the relatively small increase in* $\Phi(H_2)$ *in comparison with the increase in* Φ*(methylcyclobutane).*

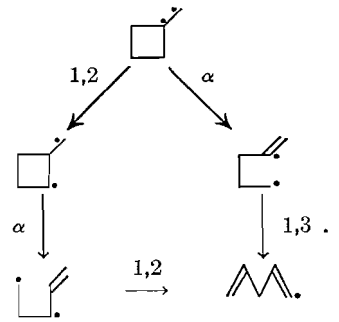
FIG. 4. $1/\Phi(C_2H_4)$ as a function of methylenecyclobutane pressure.



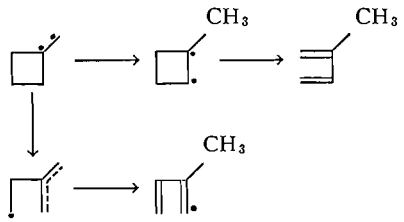
An alternative and perhaps more likely explanation for the low order of pressure dependence is a stepwise deactivation mechanism. If step [6] proceeds slower than the gas kinetic collision frequency some of the excess vibrational energy of the ethylenic triplet biradical (and perhaps of the 1,4-biradical, 2-methylenebutane) may be removed and a lowering of the overall decomposition rate will result.

The 1,4-biradical, 2-methylenebutane has also been postulated as reactive intermediate in the thermal decomposition of methylenecyclobutane (1). The reaction is truly unimolecular and the first order rate constant has been reported as $k = 2 \times 10^{15} \exp(-62/RT)$ s^{-1} (8).

If we estimate the ethylenic (π,π^*) triplet state in methylenecyclobutane to lie at ca. 70 kcal/mole, decomposition may occur even from the ground vibrational level of the triplet state ($E_a \sim 62$ kcal/mole (8)) and this could leave a vibrational energy span of over 40 kcal/mole to be removed in a number of collisions. This stepwise deactivation is contrary to the generally accepted view of a single step mechanism consistent with the kinetic behavior of all other olefinic triplet state reactions in mercury sensitization.

1,4-Pentadiene

The formation of the additional major reaction product 1,4-pentadiene from the triplet methylenecyclobutane seems to require either a 1,2 hydrogen shift followed by an α-ring cleavage and a second 1,2 hydrogen shift or, alternately, an α-ring cleavage and subsequent 1,3 hydrogen shift, as indicated by the sequence,



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The quantum yield of PD first falls rapidly with pressure (from about 0.07 at 2 Torr to ca. 0.01 at 90 Torr) but becomes invariant between 90 and 420 Torr (cf. Fig. 1) (indicating that one of the two (or more) processes responsible for its formation is pressure dependent, the other is not). This is at variance with the general behavior of olefinic triplet state isomerization reactions, in which the isomer yield is a maximum function of pressure (whereas in the present case the percentage yield of isomer is a minimum function). The existence of this maximum in the pressure function can be rationalized in terms of the necessity for a collisional stabilization of the initially hot isomerization product. It is unlikely that the PD product in the present system does not require this pressure stabilization; its apparent lack is probably due to the overriding suppressing effect of pressure on the isomerization reaction itself. The controversy could be resolved by the assumption that PD arises only from the upper vibrational states of the triplet methylenecyclobutene, which is very efficiently relaxed by collision (with the exception of the small pressure invariant portion).

It has been suggested that internal H-atom transfers in triplet state olefins are favored in the order 1,4 > 1,3 > 1,2 (9). This order of reactivity is valid for open chain molecules, where steric, structural, or conformational hindrances are minimal. In triplet MCB 1,4 translocations could not take place because of the spacial separation of the 4-(C—H) bond and the 1-(C) p_π orbital. Even the 4 → 2 shift would not be expected to proceed readily because the 4-(C—H) sp^3 bond points away from the 2-(C) p_π orbital.

Isoprene

The formation of this minute product could proceed via a 1,3 hydrogen shift in the triplet MCB molecule before C—C bond cleavage or in the 1,4-biradical, 2-methylenebutane,

A 1,2 shift from position 3 to 2 in the triplet MCB would more likely give rise to PD and 1,2 shift in the 1,4-biradical, 2-methylenebutane from position 3 to 2 to vinylcyclopropane. (The presence of this latter compound in small quantities among the reaction products cannot be entirely ruled out (cf. Results).) The 1,2 shift seems less likely than the 1,3 shift for two reasons: firstly, because of the empirical rule (*vide supra*), and secondly, because the 1,3 shift involves the translocation of a hydrogen from a secondary to a primary position, whereas in the 1,2 shift the translocation would be from a secondary to a tertiary position (10).

Effect of Added Radical Traps

(i) Nitric Oxide

The absence of any effect on the yields of ethylene and allene again proves that nitric oxide does not react chemically with the triplet states of olefins or with biradicals. The absence of an effect on the yield of methylcyclobutane was unexpected. Perhaps the nitroso compound formed by the reaction of nitric oxide with 1-radical, methylcyclobutane is unstable or very susceptible to secondary photolysis, giving back the starting materials and thus giving the radical another chance to abstract.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(ii) Oxygen

As previously mentioned, the decrease in the yield of allene (the only product measured) was small and well within experimental error. Setser *et al.* (11) have reported a larger effect of oxygen on the ethylene reaction. Thus it appears that the triplet biradicals formed in the methylenecyclobutane reaction are more stable and also more resistant towards oxygen than the triplet biradicals in the ethylene system.

CONCLUSIONS

(i) The major primary step in the photosensitization is the formation of a vibrationally excited triplet state molecule for which the kinetic evidence indicates a stepwise deactivation mechanism.

(ii) The excited molecule decomposes by at least two modes, one of which yields H-atoms, the other 1,4-biradical, 2-methylenebutane (and a possible third mode giving $C_2H_4 + C_3H_4$ directly without the intervention of the 1,4-biradical, 2-methylenebutane).

(iii) The 1,4-biradical, 2-methylenebutane is formed with a quantum efficiency of ca. 0.70 to 0.75. The fate of the biradical is decomposition to ethylene and allene.

(iv) The identity of the final decomposition products and the interpretation of the kinetic data, although far from being free of ambiguity, lend support to the postulated mechanism for the thermal reaction of MCB (1) and the mercury photosensitization of spiropentane (2).

(v) Neither nitric oxide nor oxygen have any effect on the excited molecule or on the 1,4-biradical, 2-methylenebutane.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY SPECTROSCOPIC METHODS

PART IX. THE ULTRAVIOLET ABSORPTION SPECTRUM OF 3-TRIFLUOROMETHYL-2-NITROPHENOL[1]

A. Balasubramanian and W. F. Forbes

ABSTRACT

The ultraviolet and infrared spectra of 3-trifluoromethyl-2-nitrophenol (I) and of a number of reference compounds have been determined. The transitions which give rise to the observed absorption bands, as well as the effect of steric and electronic interactions on these transitions, are discussed.

Remarkable spectral changes are observed for compound I on altering the solvent from cyclohexane to polar solvents such as ether, ethanol, and water. In cyclohexane solution, there is evidence for steric interactions and for relatively weak intramolecular hydrogen bonding. In polar solvents, rupture of the intramolecular hydrogen bond occurs because solvent molecules attach themselves to the functional groups, and particularly to the phenolic OH group. This, in turn, causes the NO_2 group to be twisted out of the plane of the benzene ring.

INTRODUCTION

In a previous paper (1) it was noted that the molar absorptivities of all the main absorption bands in the electronic spectrum of 3-methyl-2-nitrophenol were drastically reduced on changing the solvent from cyclohexane to ether or ethanol. The unusual nature of this phenomenon prompted us to investigate the spectra of related compounds. One of these was 3-trifluoromethyl-2-nitrophenol (I), the spectral properties of which were even more unusual than those of 3-methyl-2-nitrophenol.

I

EXPERIMENTAL

The ultraviolet spectra were determined by standard methods using a Cary model 14 and a Beckman model DU spectrophotometer. The accuracy of λ_{max} values is estimated to be ± 1 mμ, and the precision of molar absorptivities $\pm 5\%$ or better. Absorptivity values were reproducible to $\pm 2\%$. For each compound, at least two independent sets of observations were made.

The infrared spectra were determined on a Beckman model IR 9 spectrophotometer, as previously described.[1] The solute concentration was usually between 0.01 and 0.02 *M*, unless otherwise stated.

The compounds used were normally prepared and purified by standard methods as described in the literature. Generous gifts of 3-trifluoromethyl-2-nitrophenol were received from Professor Manning A. Smith of Bucknell University and from Dr. G. C. Finger of the Illinois State Geological Survey, and of 3-methyl-4,6-di-*t*-butyl-2-nitrophenol from Dr. G. E. P. Smith, Jr. of the Firestone Tire and Rubber Company, Akron, Ohio.

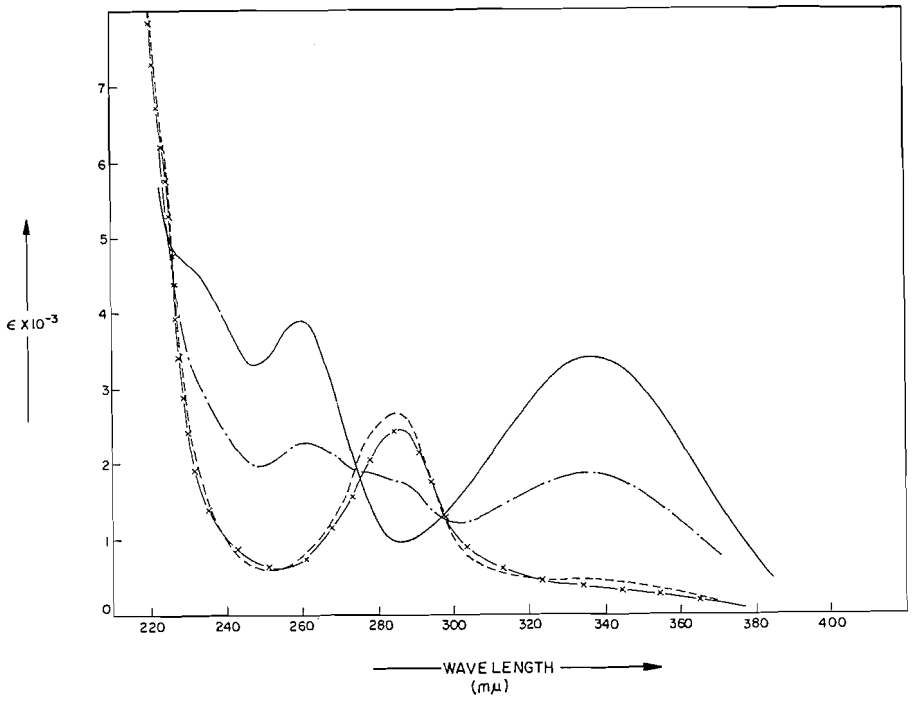

FIG. 1. The spectrum of 3-trifluoromethyl-2-nitrophenol in cyclohexane (—), in 5% ether/cyclohexane (—·—·), in ether (— — —), and in ethanol (—×—×) solutions.

The band at 259 mμ in cyclohexane solution is taken, by analogy with the spectra of nitrobenzene and 2-nitrophenol, to correspond to nitrobenzene *B*-band absorption whereas the 338 mμ band is believed, by analogy with the spectrum of 2-nitrophenol, to be a *C*-band. The latter band is not as pronounced in nitrobenzene, probably because of the greater symmetry in that molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The *B*-band of I differs from that of 2-nitrophenol in two respects: it is of lower molar absorptivity, so much so that it is only slightly more intense than the *C*-band; and it occurs at appreciably shorter wavelength. The first difference, which is also observed in the other substituted nitrobenzenes listed in Table I, can be related to the well-known observation that increased steric hindrance in a molecule causes a decrease in molar absorptivity of the *B*-band, but not necessarily of the *C*-band. This explains the progressive decrease in molar absorptivity of the nitrobenzene-type *B*-band on passing from 2-nitrophenol through 3-methyl-2-nitrophenol to 3,4-dimethyl-2-nitrophenol. Since the covalent radius of fluorine (0.72 Å) is greater than that of hydrogen (0.30 Å), the CF_3 group would be expected to exert a larger steric effect on the NO_2 group than does the CH_3 group; this is, in fact, observed and even the presence of a buttressed 3-methyl group as in 3,4-dimethyl-2-nitrophenol is apparently less effective sterically than the 3-CF_3 group, as judged from the molar absorptivities given in Table I.

The inductive properties of the CF_3 group (3) presumably contribute to these spectral effects, by withdrawing electrons from the NO_2 group. As an illustration, it is pointed out that the *B*-band of 3-trifluoromethylnitrobenzene is at 247 mμ (4), while that of nitrobenzene occurs at 260 mμ (5). Such interactions would be expected to weaken the double-bond character of the *N*-aryl bond, thus increasing the transition energy of the *B*-band and in addition causing the NO_2 group to be twisted more readily out of the plane of the benzene ring. This then can account for both the observed hypsochromic displacement and for the reduced absorption intensity. The sensitivity of the nitrobenzene *B*-band to changes in double-bond character is also indicated by the spectrum of 3-trifluoromethyl-4-nitrophenol (see Table I), where the hydroxy substituent strengthens the double-bond character of the *N*-aryl bond so that a considerably more intense *B*-band is obtained (cf. also the intense *B*-band in 4-nitrophenol (5)).

In addition, the electron-withdrawing effect of the CF_3 group can cause a weakening of the intramolecular hydrogen bond in I. It may be noted that in 2-nitroanisole or 2-trifluoromethylnitrobenzene which contain no intramolecular hydrogen bond, absorption occurs at 250 mμ and near 235 mμ respectively, but that hydrogen-bonded compounds, such as 3-methyl-2-nitrophenol, absorb intensely at longer wavelength (see Table I).

The electronic, as distinct from the steric, effects of the CF_3 group have previously been discussed (cf. refs. 6–8). Concerning the spectroscopic effects of fluoro substituents, a number of workers have collected infrared data (9; cf. also 10, 11) which show that a carbon-bonded fluorine atom does not form strong hydrogen bonds of type C—F---H—O. This is also borne out by the ultraviolet spectrum of benzotrifluoride which undergoes no unusual spectral change on altering the solvent from cyclohexane to ethanol (12). Comparing the spectra of trifluoromethyl-substituted compounds with methyl-substituted analogues, there are examples where no appreciable spectral changes are observed (see refs. 13–15). If a significant spectral change is observed, the introduction of the trifluoromethyl group is frequently accompanied by a hypsochromic displacement, that is, by a spectral change similar to that observed for compound I with respect to 2-nitrophenol (12 mμ; see Table I). Part of the reason for such a displacement is presumably the electron-withdrawing effect of the trifluoromethyl substituent on neighboring atoms, and frequently the operation of steric interactions.

SOLVENT EFFECTS ON THE SPECTRUM OF 3-TRIFLUOROMETHYL-2-NITROPHENOL

The main absorption maxima of I in various solvents are given in Table II, and some of the spectra are shown in Fig. 1. The most remarkable feature of these spectra is the pronounced bathochromic displacement of the main absorption band which occurs on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

passing from inert to polar solvent (see Fig. 1). Such a displacement is unusual in simple aromatic compounds in which an electron-donating substituent is not situated in the para position with respect to an electron-attracting substituent. For example, although appreciable displacements (*B*-bands, cyclohexane to ether and cyclohexane to ethanol respectively) are observed for 4-nitrophenol (13 mμ, 28 mμ) and 4-hydroxyacetophenone (7.5 mμ, 17.5 mμ), the same solvents have far less effect on the spectra of 2- and 3-disubstituted benzenes: 2-nitrophenol (0 mμ, 1.5 mμ), 3-nitrophenol (6.5 mμ, 11 mμ), 2-hydroxyacetophenone (0.5 mμ, 1 mμ), and 3-hydroxyacetophenone (3.5 mμ, 10 mμ). Next, while generally the effect of ethanol is greater than that of ether, the main absorption band of I is displaced to the same extent by ether and ethanol.

*Band assignment doubtful.

The present solvent effect can be explained by assuming that the band at 286 mμ in the spectrum of I in ethanol does not correspond to the *B*-band at 259 mμ in cyclohexane solution, but is primarily a phenol-type *C*-band, probably with some contribution from nitrobenzene-type *B*-band transitions. For 3-methyl- and 3,4-dimethyl-2-nitrophenol, the observed drastic hypochromic effect of polar solvents has previously been attributed (1) to intermolecular hydrogen bonding breaking the intramolecular hydrogen bond; consequently, the NO_2 group is free to take up the position of minimum steric stress, that is one not coplanar with the benzene ring. This non-coplanarity is further enhanced because of the increased effective size of the functional groups caused by hydrogen bonding to solvent molecules. Since the spectral changes are similar in ethanol and ether solutions, intermolecular hydrogen bonding involving the phenolic OH group is sufficient to bring about the observed changes. However, ethanol is also able to interact with the NO_2 group, which increases the effective size of that group, thereby giving rise to the slightly lower ϵ value in ethanolic solution. In either case, the conjugation between the NO_2 group and the benzene ring is reduced, and this in turn decreases the transition probability of the delocalized π-electron system of the nitrobenzene chromophore. As this loss of conjugation increases, the NO_2 group contributes less and less to the observed spectrum.

Evidence for phenol-type absorption has been noted in the spectrum of 3-methyl-2-nitrophenol in ethanol (16). For compound I (where the NO_2 group is more readily displaced from the plane of the benzene ring, and where probably the intramolecular hydrogen bond is more readily broken) it seems likely that in hydrogen-bonding solvents, conjugation of the NO_2 group with the ring is even less, leaving 3-trifluoromethylphenol as the

absorbing species. The spectrum of 3-trifluoromethylphenol in ethanol, in fact, resembles the spectrum of I in ethanol (cf. Tables II and III). The location of the band of I at 286 mμ, ϵ_{max} = 2 500 in ethanol, is, of course, typical of a *C*-band of a substituted phenol. Moreover, the spectrum of I in aqueous alkali (see Table II) is similar to that of 3-trifluoromethylphenol in alkaline medium (λ_{max} = 239 mμ, ϵ_{max} = 9 100, and λ_{max} = 298mμ, ϵ_{max} = 3 050 in 50% ethanol – 50% 0.01 *N* sodium hydroxide (17)). Evidence for phenol-type *C*-band absorption is also provided by the occurrence of only one pronounced absorption band in the 240–360 mμ region of the spectrum of compound I in ethereal or ethanolic solution (see Fig. 1); that is, the *C*-band in the region of 340 mμ, associated with *o*-nitrophenol-type absorption, has virtually disappeared. Against the interpretation of predominant phenol-type absorption, it may be argued that the observed bands are featureless (see Table II), which is characteristic of nitrobenzene *B*-band absorption (18) but not of phenolic *C*-band absorption (19). However, not all substituted-phenol spectra possess the same amount of fine structure; for example, for 2-trifluoromethylphenol in cyclohexane solution the *C*-band fine structure is less pronounced than for many other phenols (17). Hence, *both* types of transitions are believed to contribute to the observed absorption band. For example, in 3,4-dimethyl-2-nitrophenol both the nitrobenzene-type *B*-band and the phenol-type *C*-band would be expected to be near 280 mμ, and it is probable that residual *C*-band absorption, as well as *B*-band absorption, contributes to the observed absorption band. Generally, as illustrated in Table III, the spectra of related compounds fit in well with present band assignments. That is, as larger groups are substituted in the 3-position in 2-nitrophenol, there is a gradual decrease in molar absorptivity of the nitrobenzene *B*-band, while the *C*-band undergoes a variety of changes.

A similar phenomenon has been observed by Wepster (20), who showed that as the steric forces on the *N*,*N*-dimethylamino group in *p*-nitro-*N*,*N*-dimethylaniline were increased by 2- and 2,6-substitution, the absorption band corresponding to *p*-nitro-*N*,*N*-dimethylaniline steadily decreased, while that corresponding to nitrobenzene steadily increased.

It may be noted here that the *B*-band of 2-nitroanisole occurs at shorter wavelength than does that of 2-nitrophenol (see Table III) or even that of 3-nitrophenol, which occurs at λ_{max} = 258.5 mμ, ϵ = 6 100 in cyclohexane solution (2). The effect of ethanol on the *B*-band of 2-nitroanisole is a bathochromic shift of 7 mμ, typical of the effect of a polar solvent on a *B*-band (see also the spectra of 2-trifluoromethylnitrobenzene). If, however, a group such as Cl or OCH_3 is inserted in the 3-position of 2-nitroanisole, absorption occurs at some 30 mμ longer wavelength, which is ascribed to predominantly anisole-type *C*-band absorption. This seems more satisfactory than to assume that the *B*-band is displaced bathochromically by some 30 mμ (see Table III).

Next, the spectrum of 3-hydroxy-2-nitrophenol may be rationalized by assuming two intramolecular hydrogen bonds which cause this compound to absorb at longer wavelength in cyclohexane solution, both directly because of the presence of additional hydrogen bonding and indirectly by keeping the NO_2 group more planar. In ethanol, competitive intermolecular hydrogen bonding is probably not sufficient to destroy completely the intramolecular hydrogen bonds, and thus some *B*-band absorption remains.

The infrared spectra clearly show the intermolecular hydrogen bonding between the phenolic OH group and ether molecules; the data are consistent with an intramolecularly hydrogen-bonded molecule changing to an intermolecularly hydrogen-bonded molecule on addition of polar solvent (see Table IV and note the very broad absorption bands (ca. 600 cm^{-1}) suggesting overlap of different O—H stretching bands). The presence of

two distinct species is also suggested by the ultraviolet spectra in cyclohexane–ether solvent mixtures which almost pass through an isosbestic point (see Fig. 1).

Two additional comments may be made. First, although intramolecular hydrogen bonding is assumed to be present in compound I in inert solution, such bonding has been assumed to be weaker than in other 2-nitrophenols. Such weakening in intramolecular hydrogen bonding is inferred from the appropriate infrared results which are shown in Table IV. Table IV shows that for compound I in carbon tetrachloride solution, the O—H stretching frequency is relatively high whereas the N—O stretching frequencies are relatively low compared with these bands in 2-nitrophenol and 3-methyl-2-nitrophenol. For 3,5-di-*t*-butyl-2-nitrophenol the O—H stretching band occurs at higher frequency, but for this compound the ultraviolet absorption spectrum in cyclohexane solution also indicates an even weaker hydrogen bond than in compound I. The infrared spectra are therefore consistent with the interpretation put forward in this paper.

NOTES

THE PHOTOLYSIS OF PERFLUOROAZOETHANE AT ROOM TEMPERATURE

J. R. Dacey, W. C. Kent, and G. O. Pritchard[1]

This note deals with experiments carried out at room temperature and at a wavelength of 3 660 Å. The photodecomposition of simple aliphatic azo-compounds under these conditions follows a very simple mechanism in which decomposition competes with collisional deactivation steps.

$$A + h\nu = A^*$$
$$A^* \xrightarrow{k_a} \text{products } (N_2 + 2 \text{ radicals})$$
$$A^* + A \xrightarrow{k_b} A + A$$

A* represents a molecule of azo-compound with sufficient energy to decompose, and A a molecule with insufficient energy for decomposition to occur. The original investigations of Wieninger and Rice (1) on azoethane and Durham and Steacie (2) on azoisopropane showed a marked pressure dependence for Φ_{N_2}, in accord with the mechanism. These results have been substantiated in careful re-investigations of both compounds by Kutschke and his co-workers (3, 4). For azomethane $\Phi_{N_2} = 1$ below 1 atm, but above this pressure Φ_{N_2} does in fact fall below unity (5). It is generally accepted (1–5) that although the primary photochemical excitation is mainly electronic the mechanism of decomposition involves conversion into vibrational energy, with its eventual accumulation in a particular bond; thus collisional deactivation processes will increase in importance as the number of degrees of vibrational freedom in a molecule increases, in agreement with observation (1–4). We (6) have extended Φ_{N_2} determinations to hexafluoroazomethane, and found a stronger pressure dependence than was obtained with azoethane (3), which was explained by the greater number of effective oscillators in the fluorine-containing compound (6). Herein we report some experiments with perfluoroazoethane.

The apparatus and the preparation and purification of perfluoroazoethane have been previously described (7), as well as the analysis and purity checks on the N_2 and C_4F_{10} (from C_2F_5 recombination) formed in the reaction system (7). The 3 660 Å radiation was isolated by solution filters (8), and actinometry was performed by the modified Parker method (9). The transmitted intensity, when the reaction cell was under *vacuo*, was 12.3×10^{15} quanta/s.

The results of the experiments are recorded in Table I (27.5 ± 2.5 °C represents the temperature range of the experiments, and not the temperature variation in any one run). The percentage decomposition of the azo-compound was usually less than 2%, based on N_2 produced. The quantum yields of N_2 and C_4F_{10} both decrease with increasing pressure, and, except at low pressures, $\Phi_{C_4F_{10}} < \Phi_{N_2}$. This is expected because of the successive addition of two C_2F_5 radicals to the —N=N—,

$$C_2F_5N{=}NC_2F_5 \xrightarrow{C_2F_5} (C_2F_5)_2N{-}NC_2F_5 \xrightarrow{C_2F_5} (C_2F_5)_4N_2,$$

[1]*Department of Chemistry, University of California, Santa Barbara, California.*

to produce a hydrazine. The C_4F_{10} formed in the reaction was roughly equal to $\Delta P(V/RT)$, where ΔP was the pressure increase in the reaction volume V. This indicated the absence of tetrazine, $(C_2F_5)_6N_4$, formation, when smaller values of ΔP were observed. Tetrazine formation would not in any case be expected from steric considerations (6). In preliminary photochemical experiments with perfluoroazoethane Young and Dresdner (10) report N_2, C_4F_{10}, and a hydrazine as the only products; the hydrazine was a liquid, with boiling point about 118 °C. In the Ward-Still separation of our reaction mixture we observed a liquid product which condensed in the gas buret at a total pressure of about 1 cm at room temperature, which would be the approximate hydrazine vapor pressure at 25 °C.

After collection of the C_4F_{10} and azo-fraction at −104 °C for vapor phase chromatographic analysis, the remaining perfluoroazoethane was fractionated at −80 °C, and reused in subsequent runs. This led to a slight contamination of the perfluoroazoethane with C_4F_{10}, accounting for the high C_4F_{10} yield in the run at 2.71 cm. The main purpose of this investigation was to examine Φ_{N_2} as a function of pressure; the N_2 analyses are accurate to 1%.

In the steady state we have $1/\Phi_{N_2} = 1 + (k_b/k_a)[A]$ and a plot of $1/\Phi_{N_2}$ versus azo pressure is given in Fig. 1, where we have arbitrarily drawn the line through $1/\Phi_{N_2} = 1$ at

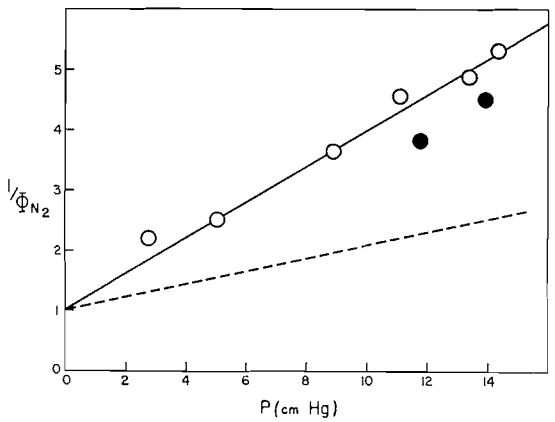

FIG. 1. (○) Plot of $1/\Phi_{N_2}$ versus pressure (cm) of perfluoroazoethane; (●) less accurate data (see text); (- -) plot for hexafluoroazomethane, ref. 6.

$P = 0$ cm. The two shaded points at higher pressures represent experiments in which the actinometer solution was underexposed for an accurate photon count. In the subsequent experiments at higher pressures the exposure time was increased by a factor of 5. The experimental slope $k_b/k_a = 5.6 \times 10^5$ cc mole^{-1}, which is $2\frac{1}{2}$ times the slope obtained for $CF_3N_2CF_3$, 2.3×10^5 cc mole^{-1} under the same conditions (6) (see Fig. 1).

The comparable values of k_b/k_a for the H-containing azo-compounds are 0.8 and 1.0×10^5 for azoethane (3, 11), 7.6×10^5 for azoisopropane (4), 9.1×10^5 for 1-propylazoethane (11), and 2.2×10^6 for azopropane (11), all in units of cc mole^{-1}. The flash photolysis work (11) appears to yield slightly bigger values than are obtained from the direct photolysis data (3, 4), for a particular molecular weight. However, unity intercepts at $P = 0$ cm were chosen in the flash work (11) for azoethane and azopropane, although the very careful direct photolysis investigations on azoethane and azoisopropane (3, 4) indicate intercepts greater than unity, leading to lesser slopes for $1/\Phi_{N_2}$ versus P. The intercepts are accounted for (3, 4) by an interval conversion process

$$A^* \rightarrow A,$$

where A is incapable of dissociation. The significant occurrence of any radiative processes has been ruled out (3, 4). It is not apparent from our data whether such a process contributes to the mechanism in perfluoroazoethane photolysis.

It is seen that the values of k_b/k_a for the azo-compounds discussed do vary in the qualitative way that would be expected from the changes in effective oscillators in the molecules. Specific values of k_a will depend, to some extent, on the C—N bond dissociation energies, which show small variations (12). Values of k_b will be a function of the collision numbers and the magnitude of the vibrational quanta transferred on collision. Any comparison of k_b/k_a values for different molecules must take these factors into account. Although not strictly valid, it is commonly assumed (1, 3, 6) that $k_b = Z$, the collision number, in evaluation of k_a, assuming collision efficiencies of unity, with respect to deactivation.

QUINOLINE N-OXIDE COMPLEXES OF TITANYL, ZIRCONYL, AND THORIUM PERCHLORATES

V. KRISHNAN AND C. C. PATEL

Heterocyclic N-oxides have recently been used as complexing agents. The complexes of quinoline N-oxide have not been investigated, however, except for a report on the preparation and magnetic susceptibility determinations of some copper complexes (1). The study on quinoline N-oxide complexes of titanyl, zirconyl, and thorium perchlorates is given here.

EXPERIMENTAL

Materials

Quinoline N-oxide dihydrate (2) and crystalline titanyl (3), zirconyl (4), and thorium (5) perchlorates were prepared as described earlier.

Preparation and Analyses of the Complexes

The complexes were prepared by mixing the respective perchlorate (1 g) dissolved in about 50 ml of anhydrous ethanol with quinoline N-oxide (3 g) in about 50 ml of the same solvent. After about 12 h, the precipitated complex was filtered off, washed with ethanol, dried over phosphorus pentoxide in vacuum, and analyzed.

Titanium, zirconium, and thorium were analyzed as their dioxides, perchlorate by Kurz's method (6), and nitrogen by the semimicro method of Dumas.

Anal. Calcd. for $TiO.5(C_9H_7NO)(ClO_4)_2$: Ti, 4.84; ClO_4, 20.13; N_2, 7.08. Found: Ti, 4.78; ClO_4, 20.04; N_2, 6.81.

Anal. Calcd. for $ZrO.6(C_9H_7NO)(ClO_4)_2$: Zr, 7.75; ClO_4, 16.91; N_2, 7.14. Found: Zr, 7.61; ClO_4, 17.02; N_2, 6.90.

Anal. Calcd. for $Th.6(C_9H_7NO)(ClO_4)_4$: Th, 15.46; ClO_4, 26.53; N_2, 5.87. Found: Th, 15.52; ClO_4, 26.41; N_2, 5.86.

PROPERTIES

All the complexes are hygroscopic. The titanyl complex is brownish yellow, zirconyl pale yellow, and thorium dark brown. The complexes are soluble in polar solvents and insoluble in nonpolar solvents. Differential thermal analysis (7) study showed that titanyl, zirconyl, and thorium complexes decompose at 210, 295, and 330 °C respectively.

The electronic absorption spectra of quinoline N-oxide dihydrate and the complexes in pure dry acetonitrile, as shown in Fig. 1, were taken with a Hilger Uvispeck spectrophotometer. The infrared spectra of the quinoline N-oxide dihydrate and the complexes were taken with a Perkin–Elmer 521, double-beam grating instrument using KBr disc technique. The results are given in Table I.

DISCUSSION

The titanyl, zirconyl, and thorium complexes decompose at 210, 295, and 330 °C respectively. These decomposition temperatures are slightly higher than the temperatures at which the respective metal perchlorates start decomposing (8, 9). It seems that the oxygen released during the decomposition of the perchlorate is responsible for the oxidation of the ligand molecules.

Quinoline N-oxide dihydrate (Fig. 1) has a π–π^* absorption maximum at 340 mμ (ϵ = 7 470). On complex formation, this band undergoes a hypsochromic shift, similar to pyridine N-oxide complexes, showing bonding through oxygen of NO. In titanyl, zirconyl, and thorium complexes, this band occurs at 335, 330, and 320 mμ respectively. This shows that the π-electrons in the N—O group of the complexes are held in the following increasing strength: titanyl < zirconyl < thorium.

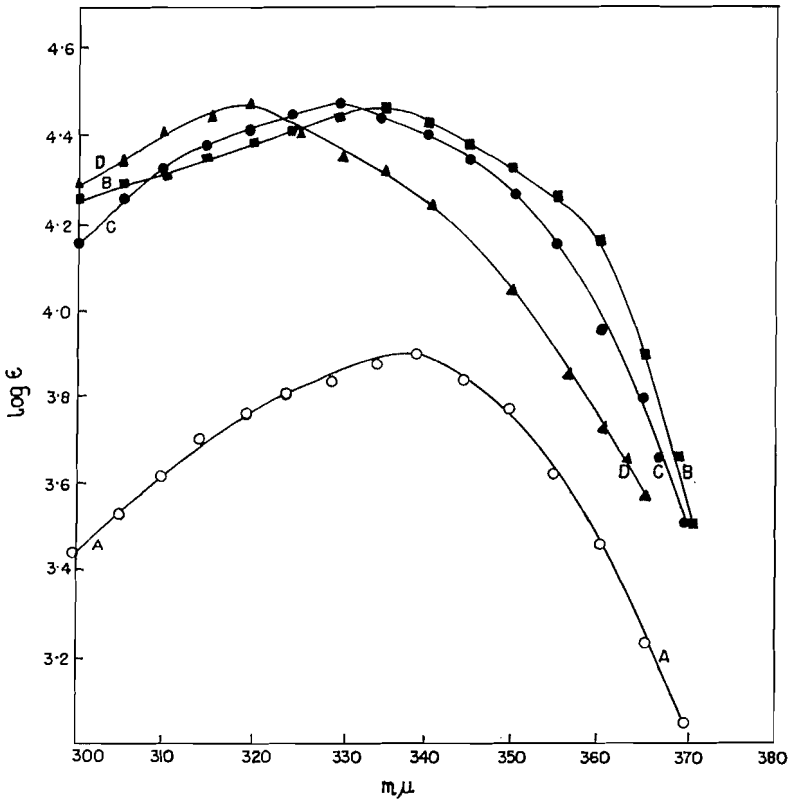

FIG. 1. Electronic absorption spectra of (A) $C_9H_7NO.2H_2O$, (B) $TiO.5(C_9H_7NO)(ClO_4)_2$, (C) $ZrO.6(C_9H_7NO)(ClO_4)_2$, and (D) $Th.6(C_9H_7NO)(ClO_4)_4$ in acetonitrile.

Earlier workers (10–14) assigned a system of infrared bands of quinoline N-oxide dihydrate to N—O stretching in the region 1 350 to 1 250 cm^{-1}. In the present study, the band at 1 230 cm^{-1} of quinoline N-oxide dihydrate is assigned to N—O stretching by comparison of the spectra of naphthalene and quinoline. In the complexes studied, this band is reduced in intensity and a strong new band appears at about 1 125 cm^{-1}. This shows that the band at 1 230 cm^{-1} of quinoline N-oxide is not due to N—O stretching only; it may be due to an overlap of CH in-plane deformation and N—O stretch. The pure N—O band for titanyl, zirconyl, and thorium complexes occurs at 1 122, 1 125, and 1 125 cm^{-1} respectively, making the comparison of the bond strength between the metal and ON< difficult. By comparison of the spectra of pyridine N-oxide (16), dipyridyl N,N′-dioxide (15), and quinoline (17), the NO bending for quinoline N-oxide is assigned at 885 cm^{-1}. This band does not undergo any shift on complex formation, as happens with the NO bending frequency of pyridine N-oxide complexes (18, 19). The perchlorate band ν_3 at 1 090 cm^{-1} and a split band ν_4 at 640 cm^{-1} of the complexes suggest a lowering of the T_d symmetry of the perchlorate, mainly due to crystal field effects.

Titanyl, zirconyl, and thorium complexes have their usual coordination numbers 6, 7, and 6 respectively.

ACKNOWLEDGMENT

The authors are thankful to Prof. M. R. A. Rao for his kind interest in this work.

INVESTIGATIONS ON SOME AMINE COMPLEXES OF IRON(III) PHTHALIMIDE. INFRARED SPECTROSCOPIC MEASUREMENTS

GOPAL NARAIN

INTRODUCTION

The preparation of a series of amine complexes of iron(III) phthalimide and some preliminary investigations on them dealing with analysis, molecular weight, and conductivity have been reported (1). It has been pointed out that the nonelectrolytic nature of the complexes shows that three phthalimide ions are also coordinated along with the amine ligands and that the coordination of the phthalimide ion to the metal could be either through the negatively charged nitrogen or through the oxygen of the carbonyl group. Infrared spectroscopic measurements were obtained in order to provide further confirmation and to establish that both the amine and the phthalimide ligands are coordinated to the iron atom.

EXPERIMENTAL

The spectra were taken as Nujol mulls, on a Perkin–Elmer infrared spectrophotometer model 21 with a sodium chloride prism.

RESULTS AND DISCUSSION

The spectra were examined throughout the entire infrared range from 600 to 3 500 cm^{-1}. The various bands obtained for individual complexes are listed in Table I.

As has been mentioned earlier, it is possible that the phthalimide ion can be coordinated to the metal atom either through the nitrogen or through the oxygen of the carbonyl group. It is not expected that the infrared spectra will make a sharp distinction between these two conditions because any change in phthalimide nitrogen which is directly linked to the carbonyl group will alter the molecular environment and accordingly the frequency of the latter, even if it is not coordinated (2); but on the basis of the *Lewis* concept it is expected that the nitrogen which is negatively charged has better possibilities of being coordinated than the oxygen (3).

The spectra were examined throughout the entire infrared range from 600 to 3 500 cm^{-1}. The various bands obtained for individual complexes are listed in Table I.

As has been mentioned earlier, it is possible that the phthalimide ion can be coordinated to the metal atom either through the nitrogen or through the oxygen of the carbonyl group. It is not expected that the infrared spectra will make a sharp distinction between these two conditions because any change in phthalimide nitrogen which is directly linked to the carbonyl group will alter the molecular environment and accordingly the frequency of the latter, even if it is not coordinated (2); but on the basis of the *Lewis* concept it is expected that the nitrogen which is negatively charged has better possibilities of being coordinated than the oxygen (3).

TABLE I

Infrared bands of amine complexes

Sample No.	Complex	Infrared bands
1	Phthalimide	645 w, 715 s, 792 w, 815 w, 1 070 w, 1 090 w, 1 140 s, 1 185 w, 1 310 s, 1 380 s, 1 465 s, 1 605 w, 1 744 w, 3 180 s
2	Iron(III) phthalimide	645 w, 712 s, 855 w, 1 050 m, 1 085 m, 1 145 w, 1 180 w, 1 310 m, 1 380 s, 1 465 s, 1 605 m, 1 725 s, 1 765 m, 3 140 m
3	Triphthalimido-triaminoiron(III)	670 m, 710 s, 855 w, 1 075 m, 1 130 s, 1 185 m, 1 225 m, 1 290 s, 1 315 s, 1 460 s, 1 510 w, 1 525 m, 1 610 m, 1 705 s, 3 270 s
4	Triphthalimido-tri(methylamino)-iron(III)	675 m, 712 s, 940 m, 780 w, 855 m, 955 w, 1 070 w, 1 130 s, 1 185 s, 1 220 w, 1 265 s, 1 310 s, 1 380 s, 1 465 s, 1 105 w, 1 710 s, 3 266 m
5	Triphthalimido-tri(ethylamino)-iron(III)	675 s, 720 s, 850 m, 1 055 m, 1 075 s, 1 130 s, 1 180 s, 1 285 m, 1 310 s, 1 380 s, 1 460 s, 1 303 s, 1 605 s, 1 710 s, 3 280 s
6	Triphthalimidotri-(propylamino)iron(III)	670 m, 722 s, 855 m, 1 055 w, 1 075 m, 1 107 m, 1 180 m, 1 210 w, 1 295 w, 1 310 m, 1 380 m, 1 265 s, 1 605 m, 1 640 s, 1 715 m, 3 285 s
7	Triphthalimido-tri(butylamino)-iron(III)	670 m, 725 m, 850 w, 1 130 m, 1 180 m, 1 315 m, 1 380 s, 1 460 s, 1 510 w, 1 520 w, 1 560 w, 1 580 w, 1 703 s, 3 280 m
8	Triphthalimidotri-(dimethylamino)-iron(III)	670 m, 715 s, 740 m, 780 m, 860 m, 960 w, 1 075 s, 1 090 s, 1 140 w, 1 185 m, 1 220 w, 1 295 w, 1 305 s, 1 380 m, 1 460, 1 500 w, 1 700 s, 3 310 s
9	Triphthalimidotri-(diethylamino)iron(III)	675 m, 710 s, 740 m, 825 w, 855 s, 950 m, 1050 m, 1 090 w, 1 125 s, 1 180 s, 1 225 w, 1 265 w, 1 310 s, 1 375 s, 1 460 s, 1 605 m, 1 705 s, 3 300 m

All complexes show a single sharp absorption band in the vicinity of 3 300 cm^{-1}, which is assigned to the NH stretching frequency band. In free ammonia and in aliphatic amines the band occurs at 3 414 cm^{-1} and 3 400 cm^{-1}, respectively. This negative shift of the frequency is a result of the coordination of the amine to the iron atom, with the formation of a highly covalent M—N bond which weakens the NH bond.

The band observed in the carbonyl stretching frequency region is of interest. In phthalimide the band occurs at 1 745 cm^{-1}, in iron phthalimide it shifts to 1 725 cm^{-1}, whereas in complexes it shifts in the vicinity of 1 700 to 1 710 cm^{-1}. The cause of this negative shift of frequency appears to be the electron density at nitrogen. In the case of iron(III) phthalimide, which is supposed to possess a partial covalent character, the band shifts only by 25 cm^{-1}. The negative charge on nitrogen increases from phthalimide to iron phthalimide and to amine complexes. This increase brings about a corresponding decrease in frequency.

AQUEOUS SOLUTIONS OF "SODIUM PERNITRITE" FROM ALKALINE HYDROGEN PEROXIDE AND NITRIC OXIDE

GIANNA L. PETRICONI AND HENRY M. PAPEE

Relatively little information about the formation and properties of "alkali metal pernitrites" is, at present, available in the literature. Neither "pernitrous acid" nor its alkaline salts have, so far, been isolated. Although it appears to be customary to assign the "acid" a simple peroxy-formula of the type H—O—O—N=O, it was suggested that the compound may actually be an acid nitrosyl peroxide $NO^+HO_2^-$. Solutions of "alkali-metal pernitrite" are usually prepared in the laboratory (1, 2) by the reaction of alkali nitrite dissolved in water with acidified hydrogen peroxide and by a fast alkalization of the resulting mixture. They, furthermore, can be obtained by the action of ozone on aqueous solutions of alkali azides (3), and they are also formed when aqueous alkaline nitrates, at high pH values, are photolyzed with ultraviolet light (4). Alkaline solutions of the "pernitrous acid" are known to be very powerful inorganic oxidants, since they decompose to yield free $OH^\cdot$ radicals (2, 5).

An investigation which extends work on ultraviolet photolysis of nitrates (quoted in refs. 4 and 6) is presently being carried out in this laboratory; the results obtained so far show that when solutions of concentrated alkali metal nitrates are irradiated with ultraviolet light at acid *or alkaline* pH values, gaseous oxygen and *oxides of nitrogen* are formed in the liquid and can be carried away from the solution in a stream of nitrogen. It was hence suspected that one of the mechanisms of "pernitrite" formation may proceed through the action of $OH^\cdot$ radicals on nitric oxide and (or) nitrogen dioxide in solution, and therefore an attempt was made to prepare this oxidant from hydrogen peroxide and the above-mentioned oxides of nitrogen.

When *gaseous* nitrogen dioxide is introduced, at room temperature, into aqueous solutions of hydrogen peroxide, a fast reaction of oxidation at the interphase becomes immediately visible. The bubbles of gas become almost instantly discolored as they rise through the liquid, and a dense white fog, probably due to the formation of N_2O_5, forms above the surface. The process lasts as long as hydrogen peroxide is present in solution; a similar formation of fog takes place when nitric oxide is used instead of NO_2, but no change in the color of the bubbles of gas is noticeable. The introduction, under vigorous stirring, of *nitric oxide* into solutions of about 1% hydrogen peroxide and at pH 12.5–13.5 results in the formation of fairly substantial amounts of the "pernitrous" compound (up to 6×10^{-3} mole/l), which can easily be identified by its reactions and rates of decomposition (4). This synthesis does not occur when nitrogen dioxide is used; no "pernitrite" can, in fact, be detected by analytical methods previously outlined (4), even when several milliliters of liquid and purified N_2O_4 are introduced, under stirring, into a 1% solution of H_2O_2 at a pH of 13 and at 0 °C.

The experiments aimed at establishing the best conditions at which "sodium pernitrite" could be formed from NO and H_2O_2 were carried out with reagent grade Merck's products throughout, and the nitric oxide used was prepared in a standard laboratory manner and in a closed vessel from dilute nitric acid and copper metal. The gas was passed slowly through a dry ice – acetone spiral trap, and subsequently dissolved in concentrated sulfuric acid, under vigorous stirring and in the presence of 99.9% pure oxygen, which was

simultaneously bled into the acid; concentrations of the nitrosyl-sulfuric acid thus formed (7) were evaluated by titration with permanganate (8). The acid was introduced drop-by-drop into a spherical flask which contained crushed ice made from distilled water and suspended, under strong mechanical stirring, in alkaline hydrogen peroxide. In a typical run, for example, 250 ml of 50.0% NaOH was precooled to about 0 °C in a thermostat, added with 10.0 cc of 32.5% hydrogen peroxide and with about 500 g of ice; 60 ml of ice-cold sulfuric acid which contained 3.2×10^{-2} mole of nitric oxide, as calculated on the basis of the well-known reaction

[1] $$2HNOSO_4 + H_2O \rightarrow 2H_2SO_4 + NO + NO_2,$$

was then added slowly and under stirring to the mixture described above. The resulting yellow solution was slightly warmed and brought to a volume of 1 l, at 20 °C, and the "pernitrite" determined colorimetrically. The amounts of reactants were so chosen that a fairly uniform range of pH values (13.0–13.5) could be obtained after the reactants were mixed and brought to volume and to the temperature of 20 °C; similarly, the amount of ice used was so adjusted as to maintain the reacting mixture at low temperatures until the mixing was completed.

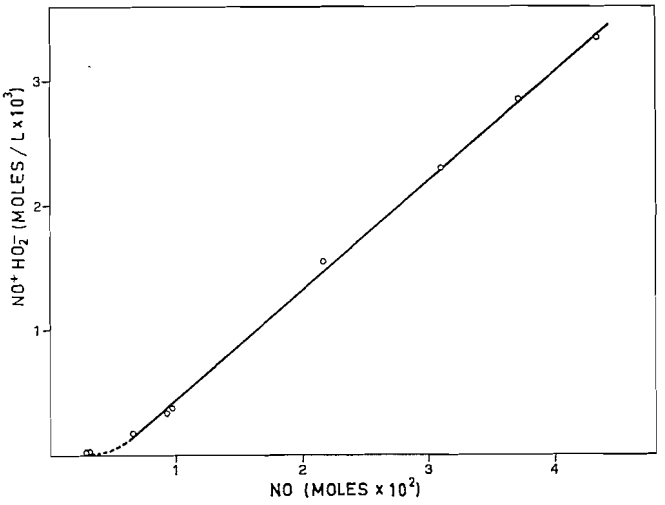

FIG. 1. Yield of "sodium pernitrite" upon addition of increasing aliquots of a nitrosyl-sulfuric acid solution in concentrated H_2SO_4 to 250 ml of NaOH at 50% containing 0.096 mole of H_2O_2. Solid line was fitted by least squares.

Figure 1 illustrates the formation, under our experimental conditions, of the "pernitrous" compound obtained when the reactants are mixed in different proportions; the process appears to be slightly inhibited at low values of NO, in agreement with previous observations by Rius and Foz (9), which indicate that decomposition of the peroxy-compound is favored by an excess of hydrogen peroxide. In fact, when 25 ml aliquots of nitrosyl-sulfuric acid solutions in concentrated H_2SO_4, containing a total of about 7×10^{-3} mole of NO, are oxidized with increasing amounts of H_2O_2 in the presence of NaOH and under conditions previously described, an increase of "pernitrite" formation is observed until the ratio of reactants $H_2O_2/NO = 10$ is arrived at; at this ratio the "pernitrous" compound reaches a concentration of 5×10^{-4} mole/l. A sharp decrease in the formation of the

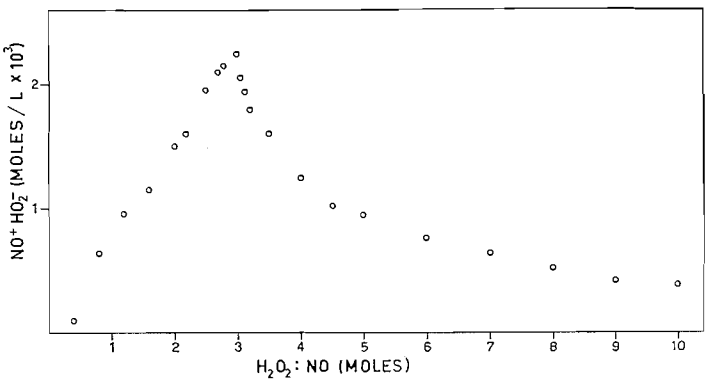

FIG. 2. Yield of "sodium pernitrite" upon reaction of a solution of nitrosyl-sulfuric acid in concentrated H_2SO_4 with alkaline hydrogen peroxide.

peroxy compound occurs as the amount of hydrogen peroxide is increased; yields of "pernitrite" are practically nil here at ratios over 35.

Figure 2 shows the result of a series of experiments which were carried out by Job's (10) method of "continuous variations"; varying amounts of hydrogen peroxide were mixed with solutions of nitrosyl-sulfuric acid under conditions analogous to those previously described except that the sum of H_2O_2 + NO was kept constant and equal to 1.26×10^{-1} mole/l. The sharp maximum in Fig. 2 suggests an optimum ratio of 3.0 for the coefficients in the overall reaction between hydrogen peroxide and components released according to eq. [1]. Changes in concentration of sodium sulfate, of solutions prepared, or the increase of the NaOH content by a factor of about 2 did not have any appreciable effect on the experimental values obtained.

In an extension of our previous work (4) which dealt with the formation of "pernitrite" during ultraviolet photolysis of alkaline nitrates in concentrated aqueous solutions, we found that substantial amounts of oxides of nitrogen (NO and NO_2) are liberated both during and after irradiation, and may be found in the gas carrier. The process can be monitored if the reaction is carried out under vigorous stirring in a closed vessel and in a fast current of nitrogen or oxygen, with unfiltered light obtained from a high-pressure mercury 450 W Hanovia immersion lamp. This result appears to us to be of some importance, in that it may extend similar reactions obtained during the radiolysis of nitric acid (11) and solutions of nitrates (12), where formation of the radical $NO_3^{\cdot}$ (see for example ref. 13 for further references) was reported, to the ultraviolet photolysis of nitrates dissolved in water. Furthermore, it appears to be relevant that this process occurs here at intensities of light which are less than those recently used by other workers for research on formation of $NO_3^{\cdot}$ in solution (14, 15). Since we have also found that formation of "pernitrite" and nitrite occurs when vapors of N_2O_5 carried in a stream of $O_2 + O_3$ and hence containing $NO_3^{\cdot}$ (16–21) are led into concentrated NaOH, it is thought that the process of "pernitrite" formation, under conditions discussed in this note, proceeds through and is due to steps which involve reactions of the transient $NO_3^{\cdot}$ radical in solution. Conversely, the acid nitrosyl peroxide $NO^+HO_2^-$ (Abel's formula for "pernitrous acid" (22)) appears to decompose, at suitable conditions, yielding $NO_3^{\cdot}$, which may be driven out of solution in a gas stream before its decomposition is completed.

We are grateful to Professor V. Caglioti for his interest in this work, and to Mr. C. Luttazzi for his technical help.

EVIDENCE FOR THE INFLUENCE OF TRACES OF HYDROGEN HALIDES IN HALOGEN EXCHANGE REACTIONS

MYRON J. RAND AND FREMONT REIZMAN

We have studied the kinetics of the halogen exchange between germanium tetrachloride and boron tribromide in the liquid phase at room temperature, with the $GeCl_4/BBr_3$ ratio about 10^3. Such anhydrous halide systems are of practical importance in the deposition of thin films of doped semiconductors or oxides from the vapor phase. Considerations of vapor pressure and thermodynamic stability may dictate the use of a mixed halide system, but if rapid halogen exchange occurs the low-concentration halide is essentially completely altered at equilibrium. It is thus difficult to maintain control of the dopant concentration in the reaction zone, to say nothing of the deposited film itself.

For sufficient sensitivity the progress of the exchange reaction was followed by long-path infrared spectrophotometry (1). With a 10 cm sample path 10^{-5} mole fraction boron tribromide in germanium tetrachloride can be detected, and concentration changes in the intermediates BBr_2Cl and $BBrCl_2$ may also be followed. The method permits measurement of the concentration of any component of the solution having absorption bands in the 2 to 10 μ range, including some common trace impurities detectable to a few parts per million. As a consequence it was discovered that the exchange mechanism is unexpectedly complicated. The nature of the reactions competing with direct exchange, which is the chief subject and purpose of this report, suggests that they are by no means unique to the system studied, and may indeed be rate-controlling in exchange reactions among moisture-sensitive halides.

EXPERIMENTAL

Electronic-grade germanium tetrachloride (Sylvania Electric Products Co.) was distilled through a 15-valve Young column in a closed all-glass apparatus, with generous fore- and after-run fractions discarded. The still was continuously flushed with dry nitrogen. The receiver was the spectrophotometer cell, a 10 cm section of 30 mm outside diameter Pyrex tubing with end windows of Irtran-2 (Eastman Kodak Co.) sealed on with Araldite epoxy resin (Ciba Co.). Filler tubes near each end of the cell terminated in O-ring joints to which caps could be clamped tightly. Cell volume was about 50 cc. Cells were never entirely filled, in order that the contents could be mixed by rocking a gas bubble back and forth.

A Perkin–Elmer 221 spectrophotometer with a calcium fluoride prism was used to scan the range 2 to 9 μ. The reference beam was attenuated to produce a transmission reading near 90% in a region with no absorption bands. The spectrum of the pure germanium tetrachloride, as distilled, was taken first; there was no 2.76 μ absorption and only a trace of 3.5 μ absorption, and thus both hydroxyl and hydrogen chloride concentration were < 20 p.p.m. (1). The boron tribromide, from a freshly opened ampoule (Eagle–Picher Co.), was added under the surface of the germanium tetrachloride with a 50 μl syringe. Initial boron tribromide concentration was 0.132% by weight (0.00113 mole fraction). The reaction temperature was 24 ± 1 °C. Concentrations were followed for 150 h after mixing. The reaction vessel was the cell itself.

RESULTS

Addition of boron tribromide to germanium tetrachloride gave rise to many new absorption bands. The BBr_3 itself has several; the intermediate BBr_2Cl and $BBrCl_2$ became visible as exchange proceeded, and eventually also the bands of boron trichloride. ^{10}B–halogen (20%) and ^{11}B–halogen (80%) vibrations were easily separated. There were also two strong absorptions which could only be boron–oxygen vibrations from a hydrolysis product of boron halides. (It is impossible to keep the cell contents perfectly anhydrous, since there is slow moisture desorption from the O-ring seals or even from the glass itself. Boron tribromide is an excellent moisture scavenger, and the long-liquid-path technique is so sensitive that the minute but regularly increasing concentration of the hydrolysis product was easily seen. From its spectrum this substance is neither B_2O_3 nor H_3BO_3. It probably contains the B—O—B linkage.)

Assignment of absorption bands was made with the help of literature reports on the spectra of the boron mixed halides (2), boron trichloride (3), boron tribromide (4), and germanium tetrachloride (1). In addition the spectrum of boron trichloride (C. P. grade, Matheson Co.) dissolved in germanium tetrachloride was studied. Without exception it was found that the absorption maxima in germanium tetrachloride solution agreed closely with those reported for the pure liquid compounds, and were 0.06 to 0.10 μ higher than those for the pure vapors.

The 5 to 6.5 μ region shows the stepwise transformation of boron tribromide to boron trichloride most clearly. Spectrum changes at selected intervals are illustrated in Fig. 1.

Figure 2 summarizes concentration changes with time. The ordinate, log (I_0/I), is the absorbance, which is proportional to the concentration. Since the proportionality constant (the absorptivity) may differ for each boron species, Fig. 2 cannot be used to compare concentrations of different compounds, but it does show the relative amount of a given compound present at any time. It is evident that an exchange does occur, since boron tribromide is converted slowly to boron trichloride via BBr_2Cl and $BBrCl_2$ intermediates. But the mechanism is not solely direct exchange: HCl and HBr are involved.

DISCUSSION

If the exchange proceeded by consecutive replacements of bromine atoms, the first step, the disappearance of boron tribromide, would be pseudounimolecular and first order kinetically because of the overwhelming excess of $GeCl_4$. Thus a plot of absorbance versus time would not be linear. In fact, Fig. 2 shows a linear decrease of boron tribromide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

3	— —	45.5 h after mixing
4	— · —	53.5 h after mixing
5	— —	69.7 h after mixing

concentration with time throughout. The reaction velocity is therefore independent of the reactant concentration and kinetically the reaction is of zero order. This unusual result suggests that the rate is actually determined by the amount of some catalyst present. Furthermore, a direct exchange model does not give the observed initial slopes for the intermediates, and cannot account for their rather rapid decay after slower buildup. Finally, this model has no provision at all for the behavior of HCl and HBr. While direct $GeCl_4$—BBr_3 exchange cannot be ruled out, it is certainly not the only process occurring and probably not even the dominant one.

In the "catalytic" mechanism we propose, a trace of HCl arises from

[1] $$GeCl_4 + H_2O \rightleftarrows Ge(OH)Cl_3 + HCl$$

and is the intermediary which transfers chlorine from $GeCl_4$ to BBr_3. The HCl is converted to HBr by

[2] $$BBr_3 + HCl \overset{k_1}{\rightleftarrows} BBr_2Cl + HBr$$

[3] $$BBr_2Cl + HCl \overset{k_2}{\rightleftarrows} BBrCl_2 + HBr$$

[4] $$BBrCl_2 + HCl \overset{k_3}{\rightleftarrows} BCl_3 + HBr.$$

The HBr in turn exchanges with $GeCl_4$ to regenerate the HCl by

[5] $$HBr + GeCl_4 \overset{k_4}{\rightleftarrows} HCl + GeBrCl_3$$

and the cycle continues until all the BBr_3 has been converted to BCl_3. Finally any HBr reverts to HCl and reaction ceases with the original amount of HCl (which may be very small) still present.

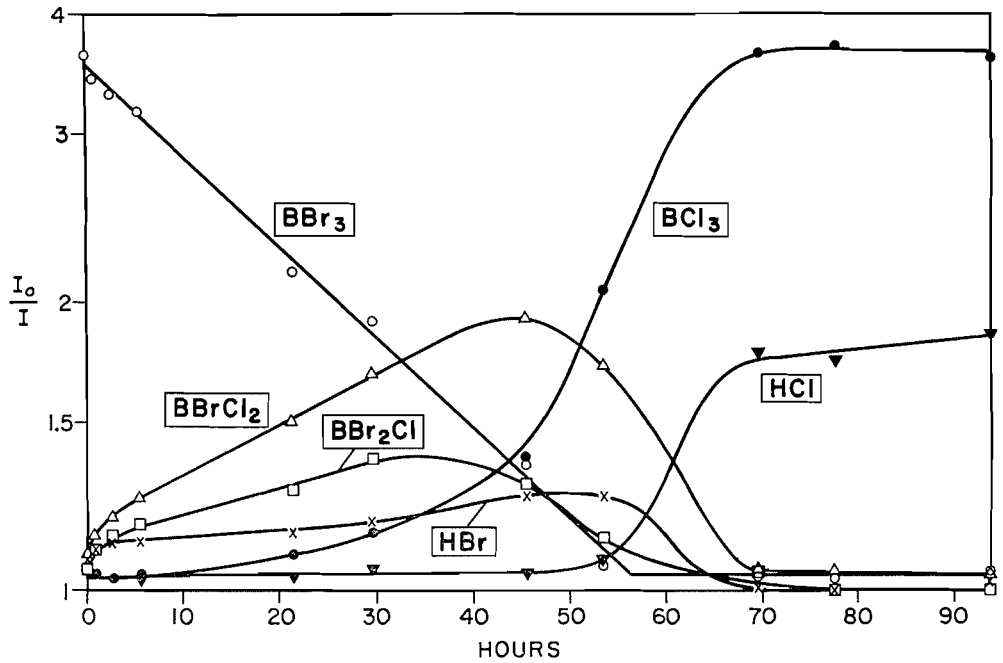

FIG. 2. Concentration changes with time. The absorption bands are: (○) $^{11}BBr_3$ ($2\nu_3$), 6.18 μ; (□) $^{11}BBr_2Cl$ ($\nu_1 + \nu_4$), 5.82 μ; (△) $^{11}BBrCl_2$ ($\nu_1 + \nu_4$), 5.55 μ; (●) $^{11}BCl_3$ ($2\nu_3$), 5.30 μ; (▼) HCl, 3.53 μ; and (×) HBr, 3.98 μ.

Rate equations were written for reactions [1]–[5], and $[HCl]_{init}$ and the four k's varied in an attempt to obtain the best fit to the experimental results. The calculated concentration curves were generated by an iterative numerical integration procedure with an IBM 1620 computer. It was soon discovered that one slight refinement to the model was advantageous. The clue is seen in the behavior of HCl in Fig. 2: the concentration continues to rise slowly after all reaction is completed. This suggests a slow, continuous injection of HCl, due perhaps to desorption of moisture from the rubber O-ring seals. Confirmation of adventitious moisture contamination is easily obtained by a blank run in which pure $GeCl_4$ is allowed to stand in the reaction cell for many days. The spectrum soon develops hydroxyl absorption which strengthens slowly and steadily. This feature was allowed for simply by adding a constant term to the equation for d[HCl]/dt, the value chosen to give the proper final slope to the HCl curve. This small correction produced a significantly better fit in the curves for both intermediates and those for BBr_3 and HBr as well.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Even with the assumption $k_1 = k_2 = k_3 = k_4$, the HCl-exchange model is able to reproduce closely many features of the experimental curves. The initial transients, the shapes and positions of maxima of the curves for the intermediates, and the shapes of the HCl and HBr curves are all accounted for. The curve for BBr_3 concentration is still not linear, but it is much more nearly so than is the exponential decay predicted by the direct $GeCl_4$—BBr_3 exchange model.

The success of the "catalytic" exchange model, together with the very low steady-state concentration of HCl, suggests that the HCl—BBr_3 reaction is rapid compared with $GeCl_4$—BBr_3, a thermodynamically and kinetically credible hypothesis.

The importance of hydrogen chloride in the exchange was demonstrated experimentally with a sample of $GeCl_4$ which had been exposed to the atmosphere: both hydroxyl and HCl contamination developed by reaction [1]. From the spectrum the HCl concentration was of the order of 100 p.p.m. Eight minutes after adding 0.1% BBr_3 the HCl content was only a fifth of its original value, and HBr had appeared prominently in the spectrum.

To support the proposed mechanism the effect of varying the initial concentration of hydrogen chloride should be studied. For convenient reaction speeds, however, the preparation and analysis of $GeCl_4$ with only a few p.p.m. HCl are required; the experimental difficulties became prohibitive.

Moisture contamination of the mixed halide system ultimately results in highly selective hydrolysis. After the 0.1% BBr_3 addition in the experiment described above, the hydroxyl band (2.76 μ) had disappeared, and strong B—O absorption developed near 7.7 μ. This reaction is believed to be

[6] $$Ge(OH)Cl_3 + BBr_3 \rightarrow GeBrCl_3 + \text{hydrolysis product } (+ HBr?)$$

so that [6] competes with [2] for the removal of BBr_3, and is evidently rapid. When germanium tetrachloride containing 1 000 p.p.m. of either boron tribromide or boron trichloride was gassed with wet nitrogen, the boron halide absorption bands completely disappeared in a few minutes.

It has not been possible to find a single mechanism which will exactly reproduce all the features illustrated in Fig. 2. The evidence is nevertheless very strong that halogen exchange between metal halides may proceed rapidly via hydrogen halide intermediates, thus masking the true exchange rate, if any. These catalysts are effective in amounts so minute that conventional purification and handling techniques may not be adequate to exclude the moisture responsible for their presence. Furthermore, one halide may be preferentially hydrolyzed (as is boron tribromide in germanium tetrachloride) so that small amounts of moisture will have a disproportionately large effect on its concentration.

ACKNOWLEDGMENT

We acknowledge with thanks the helpful comments of Ernest M. Grunwald on the reaction mechanism. The computations were programmed and carried out by Mrs. F. P. Crabtree.

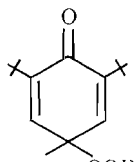
THE OXIDATION OF PHENOLS

III. THE STOICHIOMETRIES FOR THE OXIDATION OF SOME SUBSTITUTED PHENOLS WITH PEROXY RADICALS[1]

E. C. HORSWILL, J. A. HOWARD, AND K. U. INGOLD



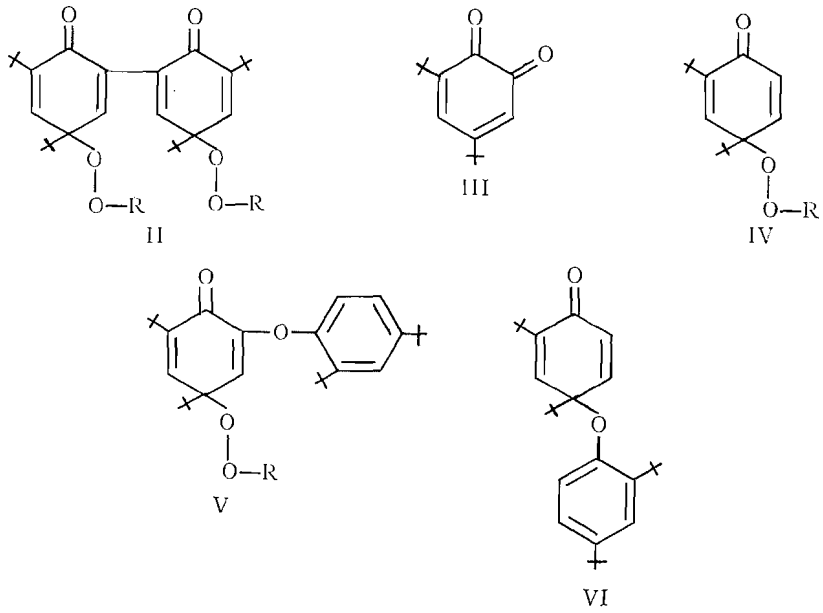
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 29, 1965

ABSTRACT

The stoichiometries for the oxidation of some substituted phenols with cumyl peroxy radicals at 65 °C have been measured. The results can be correlated generally with the expected phenolic oxidation products. Phenols with one or two unsubstituted ortho positions can react with more than 2 peroxy radicals per molecule. A maximum stoichiometry of 2.6 peroxy radicals was obtained with 2,4-dimethylphenol. 2,4,6-Tri-substituted phenols generally have stoichiometric factors of 2.0 or less.

It has been shown by previous workers that the oxidation of 2,6-di-*t*-butyl-4-methylphenol (BMP) with peroxy radicals requires either 2 or 3 radicals per molecule of phenol depending on whether the product is a peroxycyclohexadienone (I) (stoichiometric factor (n) = 2.0) or a stilbenequinone (n = 3.0).[2] The nature of the product depends



I

on the attacking peroxy radical and, probably, also on the temperature and the particular method used for the oxidation. The identification of alkyl benzoquinones and diphenoquinones as the main products formed in the oxidation of 2,6-dialkylphenols under conditions which give the peroxycyclohexadienone from BMP (1) suggests that these phenols will react with just 2 peroxy radicals per molecule. In contrast, the various fully oxidized products from 2,4-di-*t*-butylphenol (see part II in this series (2)) imply specific stoichiometric factors of 3 (compound II) and 2 (compounds III, IV, and V), whereas a simple phenoxy radical dimer (e.g. VI) would give a n value of only 1.0.

[1]*Issued as N.R.C. No. 8879.*

[2]*See part I in this series (1) for a full discussion of the previous work.*

The relative yields of the different products obviously depend on the radical concentrations and on the relative rates of the numerous radical–radical coupling reactions. The measured value of n must therefore depend on the experimental conditions. The present work, which covers a wide variety of substituted phenols, was undertaken to investigate the effect of structure on n, since this is of obvious importance in the evaluation of oxidation inhibitors. That is, both a fast reaction with peroxy radicals and a high molar efficiency are among the more important properties of a commercial antioxidant.

EXPERIMENTAL

The stoichiometries of the phenols were determined at 65 °C by the induction-period method of Boozer *et al.* (3). Pure, undiluted cumene (Phillips research grade) was generally used as the oxidizable substrate since even weak inhibitors produce quite sharp breaks in the oxygen absorption curves (4). The cumene was passed through alumina immediately before use. α,α'-Azo-bis-isobutyronitrile (AIBN) was used as the initiator at a concentration of 2.86×10^{-2} mole/l. All the phenols were carefully purified, and were generally used at a concentration of about 2.4×10^{-3} mole/l.

RESULTS AND DISCUSSION

Inhibitor stoichiometries determined by the induction-period method show variations with both the nature of the oxidizable substrate (5) and the solvent (5–7) which so far remain largely unexplained. For example, in highly polar solvents such as acetonitrile and nitromethane the usual assumption that $n = 2$ for BMP[3] would sometimes lead to the conclusion that the rate of radical production by AIBN is more than twice its rate of decomposition (6, 7). However, under a standard set of conditions in a relatively nonpolar medium (i.e. pure cumene) the induction periods for different phenols should be directly comparable. With the experimental conditions employed in this work the induction period for BMP (2.40×10^{-3} mole/l) was 8 420 s. This implies that the efficiency (e) of chain initiation from the AIBN is 0.55, provided $n = 2.0$ for BMP. The basis for this assumption was checked by measuring the yields of the isobutyronitrile peroxy and cumyl peroxy

[3]*See ref. 1 and references therein for a discussion of the experimental basis for this assumption.*

derivatives of BMP, i.e. I with R = $(CH_3)_2CCN$ (hereafter referred to as IBN-1) and with R = $C_6H_5C(CH_3)_2$ (hereafter referred to as CUM-1). The analysis of compounds of this type by thin-layer chromatography has been described previously (1).

The cumene was oxidized for 9 250 s, at which point 1.5×10^{-2} mole O_2/l had been absorbed. The yields of the two products (based on the initial BMP concentration) were 21 ± 4%[4] for IBN-1 and 53 ± 9%[4] for CUM-1. Similar results were also obtained for solutions of cumene in *n*-heptane, *t*-butanol, and acetonitrile (Table I). The overall yield of compounds with structure I is similar to the previously determined yield of IBN-1 in chlorobenzene, i.e. 62–71%[5] (1), but is somewhat less than the value of 95 ± 10% found for tetralin at 40 °C (1). The difference does not seem to be due to the decomposition of IBN-1 or CUM-1 during the reaction, since both compounds were quite stable at 65° for 16 h in toluene containing both the usual concentration of AIBN and 0.2 mole of cumene hydroperoxide/l. The different yields might, however, be due to the fact that a hydrogen atom is much less readily abstracted from cumene than from tetralin. This factor might also be responsible for the measured difference in the initiation efficiencies in the two hydrocarbons (i.e. 0.55 in cumene and 0.64 in tetralin).

TABLE I

Induction periods and product yields at 65 °C ([AIBN] = 2.86×10^{-2} mole/l, [BMP] = 2.40×10^{-3} mole/l)

Solvent	Cumene concentration (moles/l)	Induction period (s)	Product yield (%)		
			IBN-1	CUM-1	Total
n-Heptane	3.6	9 050	16	52	68
None	7.2	8 420	21	53	74
t-Butanol	3.6	7 750	15	63	78
CH_3CN	3.6	5 900	15	54	69

The expected yields of IBN-1 and CUM-1 can be calculated by comparing the rate of chain initiation ($2ek_1$[AIBN] = 5.7×10^{-7} mole/l s) with the amount of oxygen absorbed by the end of the induction period (1), i.e. about 3×10^{-3} mole/l. If the rate of chain initiation equals the rate of production of isobutyronitrile peroxy radicals, then $8\,420 \times 5.7 \times 10^{-7} = 5 \times 10^{-3}$ mole of these radicals/l will have been formed in this time. The calculated yields are therefore roughly $\frac{5}{8}$ (~60%) IBN-1 and $\frac{3}{8}$ (~40%) CUM-1. The measured yield of IBN-1 is therefore much less than that predicted. The present results support our previous suggestion that isobutyronitrile peroxy radicals are not the only radicals initiating oxidation chains in systems of this type (1).

The phenol stoichiometries which are given in Tables II and III have been calculated with the assumption that $n = 2.0$ for BMP, since the yields of CUM-1 and IBN-1 indicate that it cannot differ significantly from this figure. A value of $n < 1.9$ or $n > 2.1$ indicates a significant change in the usual stoichiometry, since the induction periods were reproducible to better than 5%. The present results can be compared with the stoichiometries reported by Boozer *et al.* (3) for the following phenols in a cumene (2 ml) – chlorobenzene (4 ml) mixture at 62.5 °C: phenol and 4-*t*-butylcatechol, 2.0; *o*- and *p*-cresol, 2.2; 2,5-di-*t*-butylhydroquinone, 0.85; β-naphthol, 2.1.

[4]*95% confidence limits. These results are the average of three determinations for each of two separate experiments.*

[5]*This value is probably about 10–20% too low, as some of the IBN-1 may have been pumped off along with the chlorobenzene. A repeat of this experiment in* CCl_4 *(which was removed with a water pump after the reaction was complete) gave a yield of 80% of IBN-1. In the present work, the cumene was pumped off at 0 °C since blank experiments showed that no IBN-1 or CUM-1 was lost under these conditions.*

Stoichiometric factors of 2.0 for the 2,6-dialkylphenols are not unexpected in view of the importance of benzoquinones and diphenoquinones in the products from these phenols (1). Rather surprisingly, the n factors are also quite close to 2.0 for many other compounds, such as 2-alkylphenols, resorcinol, 3,5-di-*t*-butylcatechol, *α*-naphthol, 4-methoxyphenol, and even phenol itself. The 2,4-dialkylphenols have the largest n factors, which suggests that *o*,*o*′-phenoxy radical coupling (leading to products similar to II) is important in nearly all these compounds. However, it is clear that an unsubstituted ortho position does not, in itself, insure that $n > 2.0$.

It can be seen from Table II that a *t*-butyl group in the para position is less effective than a methyl group. This phenomenon is also generally true of the inhibiting power of 2,4-di- and 2,4,6-tri-alkylphenols (8), and we have shown that it can be attributed to a combination of polar (9, 10) and steric (10) factors. In the case of 2,4,6-tri-*t*-butylphenol, the low n factor suggests that some of the initially formed phenoxy radicals couple through a molecule of oxygen to give bis-(1,3,5-tri-*t*-butyl-2,5-cyclohexadien-4-one) peroxide (cf. ref. 11).

The three phenols listed in Table II which contain a 4-methoxy group all have n factors

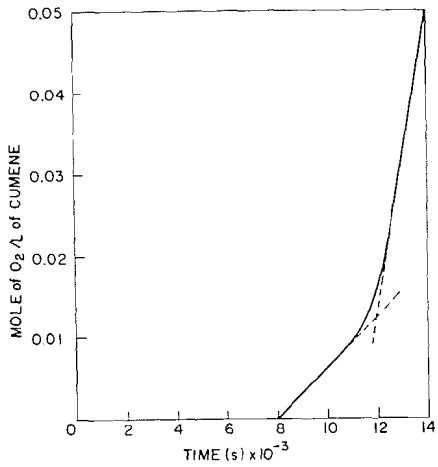
of about 2.0. This result emphasizes the difference between the n factor and the rate of the primary inhibition step, in which the phenolic hydrogen atom is abstracted since the p-methoxy group is highly activating for abstraction (9). In the ortho position the methoxy group reduces n to 1.3–1.4, a reduction which is probably connected with the strong internal hydrogen bond in these phenols. In contrast, catechol and 4-t-butylcatechol, which have a free OH group as well as an internal hydrogen bond, have n factors of 2.2–2.3 (see also nordihydroguaiaretic acid). With regard to catechol itself, the primary induction period, during which a negligible quantity of oxygen is absorbed, is followed by a period of retardation, during which oxygen is absorbed at a rate which is only 70% of the expected rate. This implies that one or more of the catechol oxidation products can also react with peroxy radicals, but at a very much lower rate than most phenols. Relatively low rates after the induction period were also observed with several other phenols, as is noted in Tables II and III.[6] Propyl gallate, a commonly used food antioxidant, is of particular interest in this respect. Its oxygen absorption curve is shown in Fig. 1. The initial induction period corresponds to a n factor of 2.0, but the rate after this point is only 15% of the expected rate. A second break occurs at $n = 3.0$, and the rate then rises to its uninhibited value. This general type of behavior has previously been reported by Boozer *et al.* for 2,5-di-t-butylhydroquinone in a mixture of cumene and chlorobenzene (3), and for 4-t-butylcatechol in a mixture of 1-methylcyclohexene, 2,2,4-trimethylpentene-1, and chlorobenzene (5). In both cases there were two stages to the inhibition, the first break occurring with a n factor of about 1.0. Under our conditions, the n factor of 4-t-butylcatechol was 2.2, and that of 2,5-di-t-butylhydroquinone could not be determined since the compound did not show any sharp break in its oxygen absorption curve. Both hydroquinone and 2-t-butylhydroquinone had low n factors. The low value for the latter compound (i.e. 1.1) cannot be due to the formation of an unreactive quinhydrone, since the addition of an equimolar concentration of 2-t-butyl-p-benzoquinone did not affect the stoichiometric factor of the 2-t-butylhydroquinone.



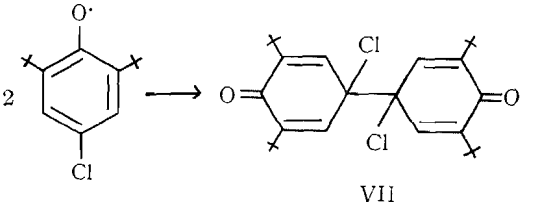


FIG. 1. Oxygen absorption by cumene containing 2.27×10^{-3} mole propyl gallate/l and 2.86×10^{-2} mole AIBN/l.

[6]*A referee has suggested that this retardation after the induction period may be connected with the formation of quinones by the beta cleavage of labile 4-substituents from 4-substituted-4-peroxy-2,5-cyclohexadien-1-ones. Most benzoquinones are retarders of autoxidation.*

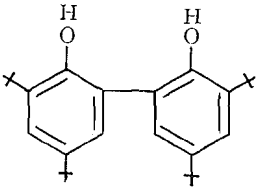
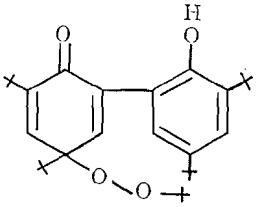
Very weak inhibitors such as 4-cyanophenol and its 2-*t*-butyl derivative gave oxygen absorption curves in which the rate increased smoothly with time, thereby preventing any determination of the stoichiometric factor. Slightly stronger inhibitors, such as phenol itself, allowed oxidation to occur at a significant rate from the start of the reaction but showed a definite break after a certain time. In these cases, the induction period was taken to be the time at which a linear extrapolation of the initial and final portions of the oxygen absorption curve intersected (3).[7] In addition to phenol, the following compounds allowed a noticeable initial rate of oxygen absorption: 2-methylphenol, 2-*t*-butylphenol, 4-*t*-butylphenol, 4-chlorophenol, 2-methyl-4-chlorophenol, 2,6-dimethyl-4-chlorophenol, 2,6-di-*t*-butyl-4-chlorophenol, 2,6-dimethyl-4-cyanophenol, 2,6-di-*t*-butyl-4-cyanophenol, 3-hydroxyphenol, 2-methoxy-4-methylphenol, 2,6-dimethoxyphenol, β-naphthol, and compound IX.



The *n* factor of 1.0 for 2,6-di-*t*-butyl-4-chlorophenol can probably be attributed to phenoxy radical coupling to give bis-(1-chloro-3,5-di-*t*-butyl-4-oxo-2,5-cyclohexadienyl-1).



VII

This relatively stable product is easily formed from the starting phenol by oxidation with sodium ferricyanide, or from the 2,4,6-tri-*t*-butyl phenoxy radical (13). We have previously observed a similar stoichiometry in the oxidation of this phenol with *t*-butoxy radicals in CCl_4 at 122 °C (14). The fact that the other *p*-chlorophenols have low *n* factors suggests that similar products may also be formed from these compounds.

The two dimeric phenolic oxidation products prepared by the oxidation of 2,4-di-*t*-butylphenol with *t*-butyl peroxy radicals (2), i.e. compounds VIII and IX, probably

VIII

IX

owe their low *n* factors both to the steric effect of the *t*-butyl groups in the para position and to the internal hydrogen bonding of the phenolic hydrogens (2).

After this work was completed, a paper by Lloyd and Zimmerman (15) appeared which described the measurement of the induction periods in the uninitiated oxidation of cumene at higher temperatures (110–160 °C) produced by several phenols that we had also studied. The relative inhibitor stoichiometries found by these workers differ quite markedly from the values given in Table II. This is hardly surprising in view of the expected instability

[7]*This type of curve is also obtained with a strong inhibitor in a readily oxidizable substrate, e.g. styrene (12).*

at high temperatures of peroxidic products similar to I, II, IV, V, and IX. For those phenols common to both studies the following stoichiometries were obtained at 132 °C: BMP, 2.0 (assumed); 2,4-dimethyl-6-*t*-butylphenol, 4.0; 2,4,6-trimethylphenol, 3.0; 2-hydroxy-4-*t*-butylphenol, 1.7; 2-methyl-4-*t*-butylphenol, 1.6; pyrogallol, 1.5; and hydroquinone, 1.0.

EXOCELLULAR ALGINIC ACID FROM AZOTOBACTER VINELANDII[1]

P. A. J. GORIN AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received December 7, 1965

ABSTRACT

Azotobacter vinelandii produces a partly acetylated exocellular polysaccharide which consists mainly of D-mannuronic acid units and a small proportion of L-guluronic acid units. It resembles alginic acid since it contains 4-*O*-linked mannuronosyl residues and guluronosyl residues which are 4-*O*- and (or) 5-*O*-linked. The specific rotation of bacterial sodium alginate is close to that of its algal counterpart, thus suggesting that the glycosidic configurations are similar.

Several species of *Azotobacter* are known to form capsules, and some produce exocellular polysaccharides. Parikh and Jones have isolated exocellular polysaccharides from *Azotobacter indicum* and, after fractionation, obtained an acidic component which consisted predominantly of *O*-D-glucopyranuronosyl-(1 → 3)-*O*-D-glucopyranosyl-(1 → 2)-*O*-D-glycero-D-mannoheptopyranosyl repeating units (1). The capsular polysaccharides of *Azotobacter chroococcum* were isolated by Lawson and Stacey (2) and methylated, and a neutral portion of the methylated polysaccharide was hydrolyzed to 2,3,6- and 2,4,6-tri-*O*-methyl-D-glucose, 2,3-di-*O*-methyl-D-glucose, and 2,4,6-tri-*O*-methyl-D-galactose. From an acidic methylated polysaccharide fraction 2,4,6-tri-*O*-methyl-D-glucose, 2,3-di-*O*-methyl-D-glucuronic acid, and a partly methylated glucose derivative were obtained. These two methylated fragments were also obtained from the acidic exocellular polysaccharide of *Azotobacter indicum*, thus suggesting that the two acidic polysaccharides may be similar in structure.

These acidic polysaccharides differ from those formed exocellularly by *Azotobacter vinelandii*. Cohen and Johnstone reported that hydrolysis in aqueous acid gave rise to galacturonic acid, smaller amounts of D-glucose and rhamnose, and possibly a trace of mannuronolactone (3). Another component was later characterized by Claus as 2-*keto*-3-deoxygalactonic acid (4). A closely related *Azotobacter* species, *A. agilis*, did not produce exocellular slime, and it was concluded that this difference strengthened the designation of two distinct species, *A. agilis* and *A. vinelandii* (5). The composition of the capsule of *A. agilis* was different from that of the exocellular polysaccharide of *A. vinelandii* and contained galactose and rhamnose units and a thiobarbituric acid positive moiety (5). The structure of a possible exocellular polygalacturonide formed by *A. vinelandii* was of interest and required further investigation.

A. vinelandii was grown on Burk's medium, and produced exocellular polysaccharides which were isolated by precipitation with ethanol. Hydrolysis of the precipitate with hot aqueous acid gave hexuronic acid and smaller amounts of glucose, arabinose, ribose, and rhamnose on paper chromatograms. This hydrolysis pattern suggested that a polysaccharide consisting exclusively of hexuronic acid residues was present; purification was effected by precipitation from the concentrated culture filtrate by acidification with hydrochloric acid. The polyuronide was soluble in dilute aqueous sodium hydroxide and had a saponification equivalent of 152 compared with 176 required for a hexuronic acid polymer. This discrepancy was explained on examination of a solution of the polysaccharide in

[1]*Issued as N.R.C. No. 8882.*

deuterium oxide containing sodium deuteriooxide by nuclear magnetic resonance spectroscopy. A well-defined uncoupled C-methyl signal was obtained which corresponded to sodium acetate; this assignment was confirmed by preparation of S-benzyl thiouronium acetate after saponification. Based on a C-methyl analysis the polyuronide contained one acetyl group per 5.2 anhydrohexuronic acid units. Cohen and Johnstone report that exocellular polysaccharides of some strains of *A. vinelandii* contain *O*-acetyl groups (3).

The polyuronide, although not readily soluble in hot aqueous acid, could be hydrolyzed with aqueous acid after solubilization and partial degradation with 80% sulfuric acid (6). Examination of the product by paper electrophoresis in borate according to the method of Haug and Larsen (7) showed the presence of mannuronic acid and a trace of guluronic acid.[2] More evidence for two hexuronic acid components was obtained by methanolyzing the polyuronide to methyl ester methyl glycosides. These were reduced with sodium borohydride to methyl hexosides, which were hydrolyzed to mannose and a trace of gulose. Sodium borohydride reduction of the mixed hexoses gave polyols, which were acetylated to mannitol, and sorbitol hexaacetates which were present in the ratio of 11 to 1 as shown by gas–liquid chromatography (g.l.c.). Fractional crystallization of the mixture gave D-mannitol hexaacetate, which arose from mannuronic acid units in the polysaccharide.

Information on the configuration of the guluronic acid moieties at C-5 and the positions of the glycosidic linkages in the polyuronide was obtained by periodate oxidation studies. Oxidation kinetics were studied at 4° on a solution that was prepared by dissolution of the partly acetylated natural product in dilute alkali followed by adjustment of the pH to 3.7. These conditions were similar to those used by Drummond *et al.* (10), who observed that alginic acid from *Laminaria digitata* was oxidized rapidly in the initial stages. The bacterial polysaccharide rapidly consumed 0.46 mole of oxidant/sugar unit and was oxidized slowly thereafter (Table I). The uptake of periodate was only fractionally less than that for alginic acid. In a larger scale experiment the deacetylated bacterial polysaccharide was oxidized with periodate for 24 h at room temperature, and the product reduced with sodium borohydride to a polyalcohol. This was hydrolyzed to give mannuronic acid, D-erythrono-γ-lactone, and threonolactone. Erythrono-γ-lactone was isolated as crystals, and L-threonolactone was converted into a crystalline phenylhydrazide. Isolation of the L-isomer showed that the guluronic acid units have the L-configuration and are glycosidically linked in the 4- and (or) 5-positions. Similarly, the isolation of erythrono-γ-lactone shows that the oxidized mannuronosyl units are 4-*O*- and (or) 5-*O*-linked.

The immunity to oxidation of some of the uronic acid residues in alginic acid from marine sources contrasts with methylation experiments in which only the 2,3-isomer of di-*O*-methyl-D-mannuronic acid has been characterized (11). Hirst and his colleagues have considered the possibility of 3,6-lactone residues in alginic acid, but infrared absorption at

TABLE I

Periodate oxidation kinetics of alginic acids

Time (h)	1	2	5	11	23	47
Mole oxidant consumed by *A. vinelandii* polyuronide	0.27	0.38	0.45	0.47	0.50	0.56
Mole oxidant consumed by algal alginic acid	0.29	0.41	0.50	0.52	0.53	0.58

[2]*A high ratio of mannuronic acid to guluronic acid (M/G) has been found in a polysaccharide isolated from a mucoid Pseudomonas sp. by Linker and Jones (8). The alginic acids isolated from several species and samples of seaweed have M/G ratios varying from 0.37 to 1.82 (9).*

1 745 – 1 750 cm^{-1} corresponded more closely to ester linkages, which could arise from association of the carboxyl groups of one chain with the C-2 or C-3 hydroxyls of another chain (10). The presence of 1,2- or 1,3-furanosyl or 1,3-pyranosyl uronic acid units can also be considered as another possible reason for resistance to periodate oxidation. However, these linkages were shown to be absent from the bacterial polyuronide by the following methylation experiment carried out on the derived polyalcohol.

The fully methylated polyalcohol was hydrolyzed, and the hydrolysate was examined on a paper chromatogram with *p*-anisidine hydrochloride spray to give one pink spot. The product could have the 2,3-, 3,4-, 2,4-, 2,5-, or 3,5-di-*O*-methyl mannuronic acid structure. A series of characterization experiments was therefore carried out. The di-*O*-methyl mannuronic acid was converted by treatment with methanolic hydrogen chloride into methyl ester methyl mannuronosides, which were reduced with sodium borohydride. Hydrolysis of the product with acid gave a di-*O*-methyl mannose which ran more slowly than the 3,4-isomer on a paper chromatogram. Reduction of the di-*O*-methyl mannose to a di-*O*-methyl mannitol followed by oxidation with periodic acid gave 2,3-di-*O*-methyl erythrose (paper chromatogram), which could only arise from 2,3-di-*O*-methyl mannuronic acid. 2,3-Di-*O*-methyl-D-erythrose was also prepared by sodium borohydride reduction of the methyl ester of the di-*O*-methyl mannuronic acid to di-*O*-methyl mannitol, which was then oxidized with periodic acid. Sodium borohydride reduction of the *O*-methyl tetrose gave 2,3-di-*O*-methyl erythritol, which was converted into its crystalline bis-*p*-nitrobenzoate. The absence of 2,4-di-*O*-methyl arabinose as a periodic acid oxidation product eliminated 2,4- and 3,5-di-*O*-methyl mannuronic acids as possibilities. 2,5-Di-*O*-methyl and 2,4-di-*O*-methyl mannuronic acids were not present, since sodium borohydride reduction of the methylated fragment gave a di-*O*-methyl mannonic acid which did not lactonize (infrared data) when it was heated at 100° *in vacuo*. The above data therefore establish that the bacterial polyuronide polyalcohol contains only 4-*O*-pyranosyl and (or) 5-*O*-furanosyl mannuronic acid units.

Since the periodate and methylation results did not distinguish between 4-*O*-pyranosyl and 5-*O*-furanosyl uronic acid residues in the polyuronide, an attempt was made to reduce the polyuronide to a neutral polymer. The polyuronide was converted into its propionate derivative (12), which was reduced with diborane (13). Hydrolysis of the de-esterified reduction product showed that mannose units were present. Some were 1,4-*O*-linked since hydrolysis of the derived polyalcohol gave erythritol, as shown by paper chromatograms and g.l.c. of the derived acetate. Mannose was also formed, in small amounts, but was not structurally significant since it may have arisen from mannose units substituted at C-2 or C-3 by interchain ester linkages. Gulose and threitol were not detected.

Although the polyuronide from *A. vinelandii* has a higher M/G ratio than algal alginic acids, common features, such as the periodate oxidation kinetics and the presence of 4-*O*-D-mannuronosyl (14) and 4-*O*- or 5-*O*-L-guluronosyl units, indicate that the polymers are closely related.

EXPERIMENTAL

Evaporations were carried out under reduced pressure, and specific rotations were measured at 25°. Nuclear magnetic resonance spectra were obtained on a Varian HA-100 nuclear magnetic resonance spectrometer with tetramethylsilane as standard. Paper chromatography was carried out, unless otherwise stated, in solvent A (*n*-butanol–ethanol–water (40:11:19 v/v/v)) or solvent B (ethyl acetate – acetic acid – water (9:2:2 v/v/v)).

Cultural Methods for Polysaccharide Production

Azotobacter vinelandii (Canada Department of Agriculture, Ottawa, No. 534) was maintained on slants of Burk's nitrogen-free medium (15) solidified with 2% agar. Inoculum was produced in 500 ml Erlenmeyer

flasks containing 100 ml Burk's medium/flask, inoculated from the slants, and incubated for 2–3 days at 25° on a rotary shaker (eccentricity 1 inch, operated at 230 r.p.m.). These cultures were used to inoculate 3 l of Burk's medium contained in 5 l stirred fermentors, which were operated at 400 r.p.m. and 25° with an air flow rate of 1 l/min per fermentor. After 4–5 days the cultures were harvested, the cells were removed by centrifugation, and the supernatant liquid was concentrated by evaporation.

Isolation of Polyuronide

Direct precipitation from the culture medium with 3 volumes of ethanol gave a polysaccharide (0.95 g/l) containing 0.73% nitrogen. Hydrolysis with *N* sulfuric acid at 100° for 18 h gave a pink spot on paper chromatography (solvent B, *p*-anisidine hydrochloride spray) running slightly faster (R_{gal} 1.0) than that of galacturonic or glucuronic acid. Smaller amounts of sugars corresponding to glucose, arabinose, ribose, and rhamnose were detected in solvents A and B.

A pure sample of polyuronide could be obtained on evaporation of an 18 l batch of culture filtrate to 2 l and addition of concentrated hydrochloric acid (100 ml). The precipitated polyuronide (22.0 g) was washed with water and then methanol. It was insoluble in water, but dissolved in aqueous 1% sodium hydroxide to give a solution with $[\alpha]_D$ −125° (*c*, 1.0).

Hydrolysis of Polyuronide and Analysis of Components

The polyuronide had a saponification equivalent of 152 and contained 2.81% C-methyl. A spectrum in D_2O containing NaOD gave an uncoupled C-methyl signal in the nuclear magnetic resonance at 2.36 p.p.m. corresponding to sodium acetate. The polyuronide (1.19 g) was dissolved by shaking it for 18 h in water (200 ml) containing sodium hydroxide (1.0 g), and the solution was acidified with sulfuric acid and distilled. The distillate was titrated with 0.1 *N* sodium hydroxide to pH 8 and found to contain 0.89 meq of acid. The sodium salt was converted into S-benzyl thiouronium acetate, which, after two recrystallizations from water, had m.p. 148–149°; yield 51 mg. Its X-ray diffraction pattern was identical with that of an authentic specimen.

The polysaccharide (50 mg) was solubilized and partly hydrolyzed in 80% sulfuric acid (5 ml) at room temperature for 5 h. The solution was diluted with water until the sulfuric acid was 2 *N*, and hydrolysis was completed by heating the solution at 100° for 5 h. The solution was neutralized ($BaCO_3$), filtered, and evaporated to a residue which was examined by paper electrophoresis in borate buffer (7), *p*-anisidine hydrochloride being used as the spray reagent. Mannuronic acid and a trace of guluronic acid were detected as reddish-brown spots. Hydrolysis, under similar conditions, of practical alginic acid (Matheson Coleman & Bell, P6856) prepared from *Laminaria digitata* and a small amount of *Laminaria cloustoni* gave a much higher proportion of guluronic acid. Haug and Larsen (9) report M/G values of between 1.16 and 1.58 for various samples from *Laminaria digitata*.

Hydrolysis of the polyuronide was repeated on a 1 g scale and the resulting mixture of acids heated for 18 h at 100° *in vacuo*. The partly lactonized product was fractionated on a cellulose column, *n*-butanol one-quarter saturated with water being used as solvent. D-Mannurono-γ-lactone was isolated and crystallized from ethanol to give material with m.p. 160–161° and $[\alpha]_D$ +75 → +92° (18 h; constant value *c*, 1.0 in H_2O). Although the specific rotation corresponded to that of D-mannuronolactone (16), the melting point differed from those previously reported. Since the closest melting point was 145° as reported by Spoehr (16), this component was characterized by conversion of the polyuronide into D-mannitol hexaacetate.

The polyuronide (70 mg) was refluxed overnight in 5% methanolic hydrogen chloride (20 ml), and partial dissolution took place. The hydrolysate was neutralized (Ag_2CO_3), filtered, and evaporated to a syrup which consisted of a mixture of methyl ester methyl hexuronosides. This was reduced at room temperature with sodium borohydride (50 mg) in methanol (5 ml) containing 0.1 *N* methanolic sodium methoxide (0.5 ml). After 18 h the solution was evaporated and the reagents removed. The methyl glycosidic mixture was hydrolyzed with *N* hydrochloric acid (5 ml) at 100° for 3 h, neutralized (Ag_2CO_3), filtered, and evaporated to a syrup. Examination on a paper chromatogram (*p*-anisidine hydrochloride spray) in solvent B gave a spot corresponding to mannose. In methyl ethyl ketone – acetic acid – water (9:1:1 v/v/v) saturated with boric acid (10), a trace of gulose was detected.

The hexose-containing mixture was reduced with sodium borohydride (50 mg) in water (1 ml). After 3 h the reagent was removed and the mixture of polyols acetylated by heating it at 100° in acetic anhydride (5 ml) containing pyridine (5 ml). The product was examined by g.l.c. with 2% neopentyl glycol succinate on Chromosorb W (80–100 mesh) (packing A) and 2% nitrile silicone gum XE-60 on Chromosorb W (80–100 mesh) (packing B) in 8 ft × ¼ inch outside diameter copper tubes at 210°, with helium as the carrier gas. Peaks corresponding to mannitol and sorbitol hexaacetates were obtained with packing B, which can resolve the hexaacetates of galactitol (retention time (R_t) 7.3 min), sorbitol (R_t 8.0 min), and mannitol (R_t 6.0 min). For quantitative purposes packing A was used, since it gave a superior resolution of mannitol and sorbitol hexaacetates (R_t 21.5 min and 25.0 min, respectively). The g.l.c. unit was of conventional design with thermal conductivity detectors. Derivatives having retention times identical with those of the hexaacetates of mannitol (92%) and sorbitol (8%) were detected. Crystallization of the product from ethanol gave D-mannitol hexaacetate (32 mg) with m.p. and mixed m.p. 123–124° and $[\alpha]_D$ +19° (*c*, 1.3 in AcOH). Patterson and Todd (17) report m.p. 126° and $[\alpha]_D$ +18.8° (AcOH) for this compound. The X-ray diffraction pattern of the product was identical with that of D-mannitol hexaacetate.

Periodate Oxidation of the Deacetylated Polyuronide

A 100 mg sample of polyuronide was dissolved by shaking it overnight in water (20 ml) containing sodium hydroxide (0.10 g). The pH of the solution was adjusted to 3.7 and the solution made up to 50 ml. A 20 ml sample was treated with 0.1 *M* sodium metaperiodate (10 ml) at 4° and the oxidation kinetics recorded (Table I). A sample of alginic acid from *Laminaria digitata* and a little *Laminaria cloustoni* was oxidized simultaneously. The pH of the solutions after 48 h was 3.8.

Preparation and Hydrolysis of the Polyalcohol

The polyuronide (11.0 g) was shaken for 18 h in water (1 l) containing sodium hydroxide (10 g), the solution adjusted to pH 3.7 with acetic acid, and sodium metaperiodate (20 g) added. After 24 h at room temperature acetic acid (5 l) was added and the precipitated oxypolysaccharide isolated by filtration. The product was dried *in vacuo* and shaken for 3 h in water (1 l) containing sodium borohydride (10 g). The solution was adjusted to pH 7 with acetic acid and evaporated to dryness. Boric acid was removed by refluxing the residue in methanol, and the polyalcohol was precipitated by addition of 3 volumes of ethanol to an aqueous solution of the polymer; yield 9.3 g.

The polyalcohol (0.94 g) was hydrolyzed in *N* sulfuric acid (20 ml) at 100° for 3 h. The solution was neutralized ($BaCO_3$), filtered, and treated with Amberlite IR-120 to remove cations. Examination by paper electrophoresis in borate (7) with *p*-anisidine hydrochloride spray gave a reddish-brown spot corresponding to mannuronic acid and a faster moving yellow spot, possibly tetruronic acid(s). The solution was evaporated and heated at 100° *in vacuo* to promote lactonization, and the resulting syrup was examined on a paper chromatogram in solvent A (ammoniacal silver nitrate spray). Mannuronolactone, erythrono-γ-lactone ($R_{glycerol}$ 1.1), and threono-γ-lactone ($R_{glycerol}$ 1.3) were detected, and fractionation on a cellulose column (eluant: benzene–ethanol–water (300:50:1 v/v/v)) gave a mixture of erythrono- and threonolactones (0.18 g). These were separated on paper sheets (solvent A) to give erythrono-γ-lactone (34 mg) which, after crystallization from acetone, had m.p. and mixed m.p. 105°. Its X-ray diffraction pattern was identical with that of an authentic specimen. The L-threonolactone had $[\alpha]_D$ +25° (*c*, 1.0 in H_2O); it was converted into L-threonic acid phenylhydrazide, which had m.p. 160–161° when crystallized from ethanol and $[\alpha]_D$ +39° (*c*, 0.4 in MeOH). D-Threonic acid phenylhydrazide has m.p. 157° (18) and $[\alpha]_D$ −45° (*c*, 1.0 in MeOH). The X-ray diffraction pattern of the product was identical with that of D-threonic acid phenylhydrazide.

Methylation of the Polyuronide Polyalcohol

The polyalcohol (2.0 g) was methylated by dropwise addition of dimethyl sulfate (40 ml) to an aqueous solution (80 ml) containing sodium hydroxide (40 g). After 1 day this process was repeated, and the following day another methylation was carried out with dimethyl sulfate (100 ml) and sodium hydroxide (100 g) in water (200 ml). The solution was neutralized with acetic acid, dialyzed against tap water for 3 days, and evaporated. The residue was again methylated by the above methylation procedure. One-half of the product was hydrolyzed at 100° for 24 h in 4 *N* sulfuric acid (25 ml), and the solution was neutralized ($BaCO_3$) and evaporated. Examination on a paper chromatogram in solvent B showed the presence of a pink spot running at 1.2 times the rate of rhamnose (*p*-anisidine hydrochloride spray). Only traces of other spots were detected. The hydrolysate was purified on a Dowex-1 column (acetate form) and the di-*O*-methyl mannuronic acid eluted with 10% acetic acid. A pure fraction (0.28 g), which had $[\alpha]_D$ +17° (*c*, 1.2 in MeOH), and a fraction (0.21 g) containing di-*O*-methyl mannuronic acid and small amounts of impurities were isolated.

Characterization of Di-O-methyl Mannuronic Acid

The di-*O*-methyl mannuronic acid (30 mg) was treated with refluxing 3% methanolic hydrogen chloride (5 ml) for 2 h; then the solution was neutralized (Ag_2CO_3), filtered, and evaporated. The resulting methyl ester methyl mannuronosides were reduced at room temperature for 18 h in methanol (2 ml) containing 0.1 *N* methanolic sodium methoxide (0.3 ml) and sodium borohydride (30 mg). The solution was evaporated and cations were removed by the addition of Amberlite IR-120 in water. The resin was filtered off, the solution evaporated to dryness, and boric acid removed by repeated evaporations of methanol. The product, which contained methyl di-*O*-methyl mannosides, was hydrolyzed at 100° for 3 h in *N* hydrochloric acid, and the hydrolysate was neutralized (Ag_2CO_3), filtered, and evaporated to a syrup. The product gave a brown spot on a paper chromatogram in solvent A (*p*-anisidine hydrochloride spray) which ran at 0.95 times the rate of 3,4-di-*O*-methyl mannose (yellow-brown spot).

The di-*O*-methyl mannose was reduced with sodium borohydride by the method used above, and the resulting di-*O*-methyl mannitol was oxidized for 2 h in an aqueous solution (2 ml) containing periodic acid (200 mg). The oxidant was neutralized ($BaCO_3$), excess acetone added, and the solution filtered and evaporated. On a paper chromatogram (solvent A, *p*-anisidine hydrochloride spray) a yellow-brown spot was detected which ran at the same rate as that of 2,3-di-*O*-methyl erythrose (19). No 2,4-di-*O*-methyl arabinose, reported to run more slowly than the available 2,3-isomer (20), was detected.

Di-*O*-methyl-D-mannuronic acid (30 mg) in methanol (5 ml) was treated with ethereal diazomethane to give an ether-soluble methyl ester with $[\alpha]_D$ +17° (*c*, 1.8 in EtOH). It moved at 1.6 times the rate of glycerol on a paper chromatogram in solvent A and gave a pink spot with *p*-anisidine hydrochloride spray. The methyl ester was reduced with sodium borohydride in methanol (for the method see the reduction of α,β-methyl 2,3-di-*O*-methyl mannuronoside methyl ester) to give di-*O*-methyl mannitol ($[\alpha]_D$ 0° (*c*, 0.8 in EtOH)) moving

at 1.16 times the speed of glycerol in solvent A (ammoniacal silver nitrate spray). Oxidation with periodic acid gave 2,3-di-*O*-methyl erythrose as the only product detectable with *p*-anisidine hydrochloride spray. It was characterized after sodium borohydride reduction to 2,3-di-*O*-methyl erythritol. This was converted into its crystalline bis-*p*-nitrobenzoate which, when crystallized from ethyl acetate, had m.p. and mixed m.p. 178–180° and gave a X-ray diffraction pattern identical with that of an authentic specimen.

Authentic 2,3-di-*O*-methyl erythritol was prepared by sodium borohydride reduction of 2,3-di-*O*-methyl-D-erythrose (30 mg) (19). The 2,3-di-*O*-methyl erythritol was converted into its bis-*p*-nitrobenzoate (29 mg), m.p. 177–180° after crystallization from ethyl acetate.

Anal. Calcd. for $C_{20}H_{20}O_{10}N_2$: C, 53.57; H, 4.50. Found: C, 53.14; H, 4.61.

Sodium borohydride reduction of 2,3-di-*O*-methyl mannuronic acid gave 4,5-di-*O*-methyl mannonic acid, which was heated overnight at 100° *in vacuo*. No lactone was detected in the infrared, only absorption at 1 605 cm^{-1} being detected.

Diborane Reduction of the Polyuronide

The polyuronide (2.0 g) was dissolved in formamide (500 ml) by heating the mixture overnight on a steam bath; after the solution was cooled a mixture of propionic anhydride and pyridine (50 ml of each) was added with stirring. After 18 h the reaction mixture was poured into ice water (3 l), and concentrated hydrochloric acid (10 ml) was added. The precipitated polyuronide propionate (2.3 g) was isolated by centrifugation, washed with water, and dried *in vacuo*.

The propionate was reduced with diborane by using 3 times the quantities of reagents cited by Wolfrom *et al.* (21) in the reduction of acetylated heparin (1.5 g). The product was depropionated by the addition of an excess of aqueous sodium hydroxide and then dialyzed for 3 days. The polysaccharide solution was evaporated to a small volume and the reduced polysaccharide precipitated with excess ethanol. Hydrolysis of the product with 2 *N* sulfuric acid at 100° overnight gave mainly hexuronic acids on paper chromatograms. Less-intense spots corresponding to mannose and a trace amount of gulose were detected.

Periodate Oxidation of Reduced Polyuronide

The reduced polyuronide (0.20 g) was oxidized with sodium periodate (0.50 g) for 24 h in aqueous solution (20 ml) at pH 3.7. The oxidized polysaccharide was precipitated by the addition of acetic acid (150 ml) and was isolated by filtration. It was reduced to a polyalcohol for 3 h in an aqueous solution of sodium borohydride (0.20 g in 20 ml). Excess reagent was destroyed by adjusting the pH to 7 by the addition of acetic acid, the solution was evaporated to dryness, and boric acid was removed by refluxing the residue in methanol; yield 0.14 g. Hydrolysis of the polyalcohol in *N* hydrochloric acid at 100° for 18 h gave on a paper chromatogram a small amount of mannose as the only reducing sugar (*p*-anisidine hydrochloride spray). With the ammoniacal silver nitrate spray a spot corresponding to erythritol was obtained. Examination of the acetylated hydrolysate by g.l.c. at 160° with a 4 ft column of 2% nitrile silicone gum XE-60 on Chromosorb W (80–100 mesh) indicated that erythritol tetraacetate (R_t 7.9 min) was present. No threitol tetraacetate (R_t 9.7 min) was detected.

STEROIDS AND STEROIDASES

I. LONG-RANGE EFFECTS AND THE PREPARATION OF A-HOMOSTEROIDS

J. Bryan Jones and Philip Price

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario

Received October 14, 1965

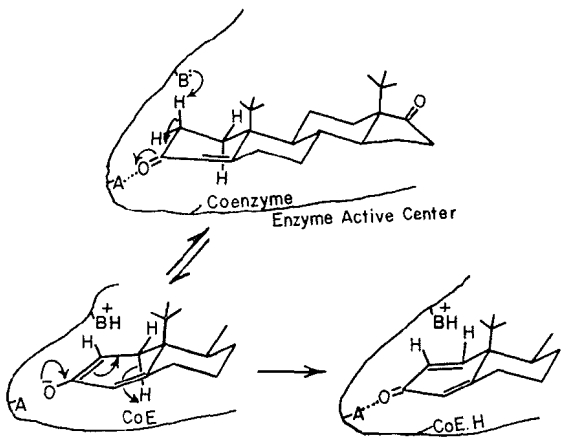
ABSTRACT

The direction of the diazomethane ring enlargement of 17β-hydroxy-5α-androstan-3-one (I, R = OH) appears to be controlled by the long-range effect of the 17β-hydroxyl group, and proceeds with migration of the C_3—C_4 bond to give the A-homo-3-one III (R = OH). This is in direct contrast to the rearrangement of 5α-cholestan-3-one (I, R = C_8H_{17}), which gives the A-homoketone II (R = C_8H_{17}) as a result of C_2—C_3 bond migration. An analogous directing effect was not observed for the reaction of diazomethane with 17β-hydroxy-5β-androstan-3-one (VII). Oxidation of the A-homo-17β-alcohols gave the corresponding diones III (R = =O), X, and XI.

The need to prepare various A-homosteroids arose from the initiation of investigations designed to evaluate the electronic and structural specificities of the enzymes of steroid metabolism. The main objective of the programme is to gain further information on the mechanism of action of various steroidases, and on the structural and other features of steroids which contribute to biological activity. In addition, it is hoped that the factors responsible for the carcinogenic properties of certain steroids will become apparent.

Until recently, very little information was available concerning the stereochemical and mechanistic pathways of reactions catalyzed by steroidases. However, studies during the past 10 years by several groups have provided evidence regarding some of the steps involved in oxygenation (1, 2), isomerization of Δ^5-3-ketones (2, 3), and dehydrogenation (2).

Studies on the stereochemical pathway for Δ^1-dehydrogenation were carried out independently by several workers (2); after an elegant series of experiments, Ringold *et al.* (4) were able to describe the stereochemical pathway for the Δ^1-dehydrogenase of *Bacillus sphaericus* in terms of the mechanism summarized in Fig. 1, in which A represents an acidic or electrophilic binding site at the active center, and B a basic amino acid side chain.



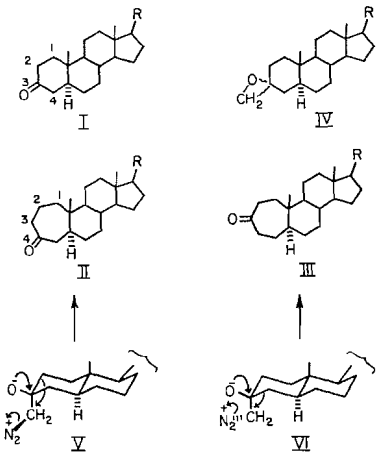


FIG. 1. Mechanism of action of Δ^1-dehydrogenase of *Bacillus sphaericus* (after Ringold *et al.* (4)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

When the present investigation was contemplated, the mechanistic pathway was not known in such detail for any other steroidase. Accordingly, the Δ^1-dehydrogenase of *Bacillus sphaericus* was selected for the initial specificity studies, as it was considered that the structural factors important in the binding and orientation of ring A of steroidal substrates at the active center could be analyzed in terms of the mechanism formulated in Fig. 1.

The aspect of structural specificity that was considered initially was the influence, on binding and catalysis, of variation of the size of ring A; thus, as the first stage of a systematic survey, the synthesis of some androstanes having ring A seven-membered has been effected.

A survey of the literature showed that, in contrast to studies on the expansion of ring D of steroids, relatively little had been reported on the preparation of A-homosteroids (5).

In 1943, Goldberg and Kirchensteiner (6) reported the enlargement of ring A of 17β-acetoxy-5α-androstan-3-one (I, R = OAc) and 5α-cholestan-3-one (I, R = C_8H_{17}) by means of the Tiffeneau–Demjanov rearrangement, which involves conversion of the ketone into the cyanohydrin, followed by reduction to the primary amine and treatment with nitrous acid. The products in both cases were the corresponding A-homo-4-ones II (R = OAc and C_8H_{17}) arising from migration of the C_2—C_3 bond of I. During the course of their investigations on A-homosteroids, Nelson and Schut (7) confirmed the tentative structural assignments of Goldberg and Kirchensteiner for A-homo-5α-cholestan-4-one (II, R = C_8H_{17}) by its synthesis via an independent route. The ring enlargement of 5α-cholestan-3-one (I, R = C_8H_{17}) with diazomethane was also studied by Nelson and Schut (7), and the major product (50% yield) was again the A-homo-4-one II (R = C_8H_{17}) resulting from C_2—C_3 bond migration as under the Tiffeneau–Demjanov reaction conditions. However, a smaller amount (10% yield) of the product of C_3—C_4 migration, A-homo-5α-cholestan-3-one (III, R = C_8H_{17}), was detected. Neither group reported the isolation of an A-homo-3-one III from the Tiffeneau route.

The formation of the same product on ring expansion from both the Tiffeneau and diazomethane reactions was expected (7), as the intermediates and reaction mechanisms involved in the rearrangement step are presumably similar (cf. refs. 8 and 9). Accordingly, in an attempt to prepare 17β-hydroxy-A-homo-5α-androstan-4-one (II, R = OH), diazomethane ring expansion conditions similar to those resulting in C_2—C_3 bond migration in the 5α-cholestane series (7) were applied to 17β-hydroxy-5α-androstan-3-one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(I, R = OH). Gas–liquid chromatographic analysis showed the product to be a mixture of at least six compounds, with one predominating to the extent of 85%. Column chromatographic purification yielded the major component, m.p. 212°, $[\alpha]_D^{24}$ −57.1°, which was obviously different from the expected product II (R = OH), m.p. 197°, $[\alpha]_D^{26}$ +112°, obtained by Goldberg and Kirchensteiner (6). The structural assignment of II (R = OH) by the latter authors was not unambiguous, but it was independently confirmed recently by the preparation of II from 17β-hydroxy-A-homo-5α-androst-1-en-4-one via catalytic hydrogenation (10). The infrared absorption at 1 695 cm^{-1} of the product whose melting point was 212° indicated the presence of a seven membered ring carbonyl, and the elemental analysis and molecular weight (mass spectrum) were in accord with an A-homo-ketone structure. This evidence led inescapably to the conclusion that in the diazomethane ring enlargement of 17β-hydroxy-5α-androstan-3-one (I, R = OH), in contrast to the 5α-cholestane series (which differs only in the nature of the substituent at C_{17}), C_3—C_4 bond migration predominates to give the A-homo-3-one III (R = OH). The many attempts to isolate II (R = OH), the product of C_2—C_3 migration, from the reaction mixture were all unsuccessful. Gas–liquid chromatographic analyses of the reaction mixture showed that the amount of each of the other products expected, the A-homo-4-one II (R = OH), the epoxide IV (R = OH), and A-bishomo compounds, was not greater than 3%.

Investigation of the optical rotatory dispersion (o.r.d.) curve of III (R = OH) confirmed its structure. A comparison of its o.r.d. curve, which shows a strongly negative Cotton effect, with that of A-homo-5α-cholestan-4-one (II, R = C_8H_{17})* is given in Fig. 2*a*.

The observed strongly negative Cotton effect (*a* = −91) of III (R = OH) is in agreement with that quoted (*a* = −60) in ref. 11 for A-homo-5α-cholestan-3-one (III, R = C_8H_{17}). The o.r.d. of 17β-hydroxy-A-homo-5α-androstan-4-one has not been reported, but the circular dichroism spectrum (10) shows a positive maximum, as would be expected by analogy with the positive Cotton effect observed for the o.r.d. curve of II (R = C_8H_{17}).

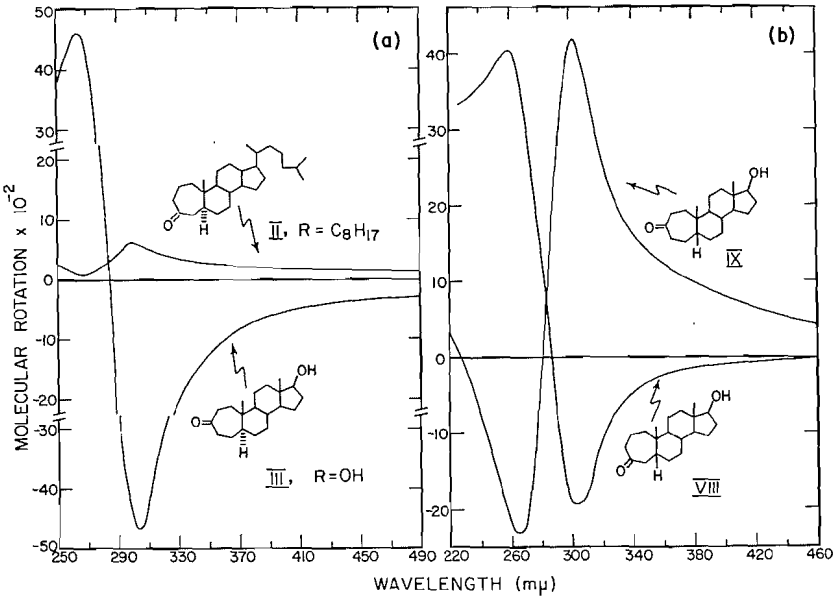

FIG. 2.

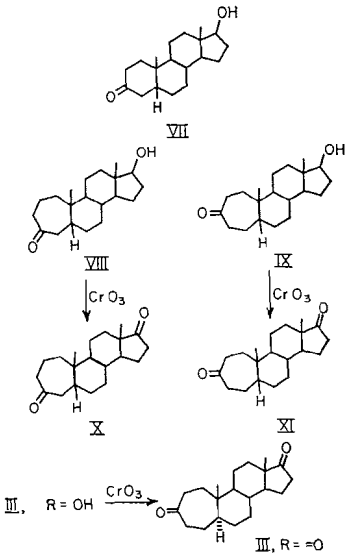

**We thank Drs. G. D. Meakins and D. J. Morris, University of Oxford, for providing us with a pure sample of this compound.*

That the change in the direction of ring enlargement is due to the effect of the hydroxyl group alone, and is not in some way associated with differences between the androstane and cholestane skeletons, has been confirmed by the observation that, for 5α-androstan-3-one (I, R = H), diazomethane ring enlargement proceeds mainly with C_2—C_3 migration, as in the cholestane series, to give 80% of A-homo-5α-androstan-4-one (II, R = H) (a = +94) (12).

The marked influence of the hydroxyl group at C_{17} on the direction of diazomethane ring enlargement appears to be another example of the long-range effects that substituents may exert across widely separated areas of the steroid nucleus (13). As the direction of ring enlargement is almost completely reversed when the polar hydroxyl group replaces the nonpolar substituents at C_{17}, this effect is one of the most powerful yet observed.

At present, the factors determining the direction of ring enlargement, in both the diazomethane and Tiffeneau reactions, are not well defined. Explanations for the differences in bond migration, based either on equatorial nucleophilic attack of the steroid-3-ketone leading to one migration, and axial addition to the other, or on differences in conformations of the intermediate arising by axial attack of the nucleophile, e.g. V and VI for C_2—C_3 and C_3—C_4 migration, respectively, are not completely satisfactory. The latter rationale is suggested from a consideration of the data available on the stereochemistry of additions of nucleophiles, with steric dimensions similar to those of diazomethane and cyanide ions, to cyclohexanones in general (14). It seems probable that axial addition (product development control (15)) should predominate; further experiments designed to provide information on this point, and on the nature of the long-range effect exerted by the hydroxyl group on the nucleophilic addition and subsequent rearrangement steps, are in progress.

As A-homo-androstanes with an A/B *cis* ring fusion were also required for the specificity studies, the reaction of 17β-hydroxy-5β-androstan-3-one (VII) with diazomethane was carried out. Ring expansion to the A-homo compounds occurred in 72% yield, but no overriding influence of the 17β-hydroxyl on the direction of migration was observed in this reaction and the products of both C_2—C_3 and C_3—C_4 migration, VIII and IX,

For personal use only.

respectively, were formed in equivalent amounts. The properties of 17β-hydroxy-A-homo-5β-androstan-3-one (IX) were in agreement with those reported by Müller (11) for IX obtained by hydrogenation of 17β-hydroxy-A-homo-androst-4*a*-en-3-one. The o.r.d. curve showed a positive Cotton effect (Müller reports a positive circular dichroism curve), whereas that for the isomeric A-homo-4-one VIII showed a strongly negative Cotton effect (see Fig. 2*b*). Oxidation of both alcohols with chromium trioxide gave the corresponding diones X and XI in quantitative yields. Oxidation of 17β-hydroxy-A-homo-5α-androstan-3-one (III, R = OH) with chromium trioxide also gave the corresponding diketone III (R = =O) in good yield.

Since enzymes are, in general, stereospecific in their catalytic action, before any meaningful specificity and inhibition studies of the A-homo-androstanes with the Δ^1-dehydrogenase of *Bacillus sphaericus* can be carried out, it is necessary to establish the conformation of the seven-membered ring. A discussion of the conformation of ring A of A-homosteroids will be reported shortly.

EXPERIMENTAL

Infrared spectra were obtained on a Beckmann model 11 spectrometer, and optical rotations on a Bendix–Ericsson polarimeter. Optical rotary dispersions were measured on a Jasco–Durrum ORD 5 spectropolarimeter. Melting points were determined on a Fisher–Johns apparatus and are corrected. All solvents for column chromatography were distilled before use; alumina refers to British Drug Houses chromatographic alumina deactivated by shaking with 5% of its own weight of 10% acetic acid. Gas–liquid chromatographic analyses were effected with columns containing 3.8% SE 30 on silanized "Diatoport S" and 1% QF-1 on silanized "Chromosorb G" by using a F and M model 400 biomedical unit. Merck silica gel G was used as the thin-layer chromatography adsorbent, and benzene – 50% ether as the developing solvent. The spots were visualized by spraying the chromatograms with 50% aqueous toluene – *p*-sulfonic acid followed by heating them at 100°. All compounds that are described were purified until no impurity could be detected by thin-layer chromatography or by gas–liquid chromatography on both SE 30 and QF-1 columns.

17β-Hydroxy-5α-androstan-3-one (I, R = OH)

17β-Hydroxyandrost-4-en-3-one was reduced with lithium in liquid ammonia as described by Brutcher and Bauer (16). The crude product (80% yield) was purified by column chromatography on alumina prepared in petroleum ether, b.p. 40–60°, and was eluted with benzene. Recrystallization from acetone gave needles, m.p. 181–182° (lit. m.p. 181.5–182.5° (17)).

Reaction of 17β-Hydroxy-5α-androstan-3-one with Diazomethane

Potassium hydroxide (14.2 g) followed by 17β-hydroxy-5α-androstan-3-one (10 g) was dissolved in methanol (400 ml) and anhydrous ether (300 ml). N-Nitrosomethylurea (10.6 g) was added in portions during 20 min to the stirred, cooled (0°) solution; after the addition was complete, stirring was continued for a further 5 h. Hydrochloric acid (200 ml, 2 *N*) was then added, the mixture filtered, and the solid material washed well with ether. The combined filtrate and ether washings were concentrated under reduced pressure to remove the organic solvents, and the resulting mixture was extracted with ether (3 × 75 ml). The ether solution was washed with water (50 ml), dried ($MgSO_4$), and evaporated. The residual solid (10.8 g) was chromatographed on alumina (300 g), and elution with benzene – 10% ether gave 17β-hydroxy-A-homo-5α-androstan-3-one (III, R = OH) (8.4 g). Repeated chromatography followed by recrystallization from acetone gave needles (5.1 g), m.p. 212–213°, $[\alpha]_D^{25}$ −57.1° (*c*, 0.7 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 3 600 (hydroxyl) and 1 695 cm^{-1} (seven membered ring carbonyl); nuclear magnetic resonance ($CDCl_3$) δ 0.73 and 0.80 (C_{18}, C_{19}, CH_3, singlets), 1.9 (OH, singlet), and 3.65 p.p.m. (C_{17}—α-H, triplet); o.r.d. (Fig. 2*a*) (*C*, 0.004 in CH_3OH) 24°; $[\phi]_{700}$ −166°; $[\phi]_{589}$ −227°; $[\phi]_{304}$ −4 489°; $[\phi]_{260}$ +4 599°; $[\phi]_{220}$ +444°.

Anal. Calcd. for $C_{20}H_{32}O_2$ (304.5): C, 78.90; H, 10.59. Found: C, 78.88; H, 10.51; mol. wt. (mass spectrum) 304.

A-Homo-5α-androstan-3,17-dione (III, R = =O)

17β-Hydroxy-A-homo-5α-androstan-3-one (450 mg) was dissolved in the minimum amount of acetone (60 ml), and 8 *N* chromic acid (Jones' reagent (18)) was added dropwise to the stirred, cooled (5°) solution until the solution just retained the brown-orange color of the chromic acid. After the mixture was stirred for a further 30 min at 5°, it was poured into water (600 ml) and extracted with ether (3 × 100 ml). The combined ether extracts were washed first with saturated sodium bicarbonate and then with water, and dried ($MgSO_4$). Evaporation of the ether gave a solid (450 mg) which, on recrystallization from hexane,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yielded A-homo-5α-androstan-3,17-dione as needles (430 mg), m.p. 112.5–113.5°, $[\alpha]_D^{25}$ 22.5° (*c*, 0.8 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 1 735 (five membered ring carbonyl) and 1 698 cm^{-1} (seven membered ring carbonyl).

Anal. Calcd. for $C_{20}H_{30}O_2$ (302.5): C, 79.42; H, 9.99. Found: C, 79.20; H, 9.96; mol. wt. (mass spectrum) 302.

17β-Hydroxy-5β-androstan-3-one (VII)

17β-Hydroxy-5β-androstan-3-one was prepared in 95% yield by catalytic hydrogenation of 17β-hydroxy-androst-4-en-3-one in the presence of potassium hydroxide, based on the procedure described by Djerassi *et al.* (19). After purification by chromatography on alumina and recrystallization from cyclohexane, a product with m.p. 141–142° was obtained (lit. m.p. 139–141° (20)).

Reaction of 17β-Hydroxy-5β-androstan-3-one with Diazomethane

Potassium hydroxide (3.6 g) was added to 17β-hydroxy-5β-androstan-3-one (5 g) in methanol (200 ml) and anhydrous ether (150 ml), and the resulting solution was cooled to 0°. N-Nitrosomethylurea (2.7 g) was added, with stirring, during 20 min, and the cold mixture was stirred for a further 5 h at 0°. Hydrochloric acid (50 ml, 2 *N*) was then added, and the insoluble material filtered off and washed with ether. The combined filtrate and ether washings were evaporated under reduced pressure, and the residue was extracted with ether (3 × 50 ml). The ether solution was washed with water (50 ml), dried ($MgSO_4$), and evaporated, and the crude product (5.0 g) was then chromatographed on alumina (500 g). Elution with benzene – 1% ether gave 17β-hydroxy-A-homo-5β-androstan-4-one (VIII) (1.6 g) which, after repeated recrystallization from *n*-hexane, gave needles, m.p. 172.5–173°, $[\alpha]_D^{25}$ 12.7° (*c*, 0.8 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 3 597 and 3 436 (hydroxyl), and 1 695 cm^{-1} (seven membered ring carbonyl); o.r.d. (Fig. 2*b*) (*C*, 0.004 in CH_3OH) 24°; $[\phi]_{700}$ +1°; $[\phi]_{589}$ 44°; $[\phi]_{303}$ −1 932°; $[\phi]_{260}$ +4 049°; $[\phi]_{220}$ +3 660°.

Anal. Calcd. for $C_{20}H_{32}O_2$ (304.5): C, 78.90, H, 10.59. Found: C, 78.87; H, 10.46.

Subsequent elution with benzene – 10% ether gave 17β-hydroxy-A-homo-5β-androstan-3-one (IX) (1.6 g). Repeated recrystallization from *n*-hexane gave needles, m.p. 162–162.5° (lit. m.p. 156–157° (11)), $[\alpha]_D^{25}$ 84.8° (*c*, 0.6 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 3 597 and 3 436 (hydroxyl), and 1 698 cm^{-1} (seven membered ring carbonyl); o.r.d. (Fig. 2*b*) (*C*, 0.003 in CH_3OH) 24°; $[\phi]_{700}$ +150°; $[\phi]_{589}$ +177°; $[\phi]_{302}$ +4 160°; $[\phi]_{264}$ −2 314°; $[\phi]_{220}$ +362°.

Anal. Calcd. for $C_{20}H_{32}O_2$ (304.5): C, 78.90; H, 10.59. Found: C, 78.93; H, 10.43.

A-Homo-5β-androstan-4,17-dione (X)

17β-Hydroxy-A-homo-5β-androstan-4-one (150 mg) was dissolved in acetone (10 ml), and 8 *N* chromic acid (Jones' reagent (18)) was added dropwise, with stirring, to the cooled (ice bath) solution until a permanent brown color remained. After the solution was stirred for a further 30 min, it was poured into water (100 ml) and extracted with ether (3 × 50 ml). The ethereal extract was washed with saturated sodium bicarbonate and then with water. The dried ($MgSO_4$) ether solution was evaporated and the residue (150 mg) was recrystallized several times from petroleum ether (b.p. 40–60°) to give A-homo-5β-androstan-4,17-dione as needles (98 mg), m.p. 127–128°, $[\alpha]_D^{21}$ 85.7° (*c*, 0.25 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 1 733 (five membered ring carbonyl) and 1 695 cm^{-1} (seven membered ring carbonyl).

Anal. Calcd. for $C_{20}H_{30}O_2$ (302.5): C, 79.42; H, 9.99. Found: C, 79.36; H, 9.95.

A-Homo-5β-androstan-3,17-dione (XI)

17β-Hydroxy-A-homo-5β-androstan-3-one (150 mg) was oxidized with Jones' reagent as described above to give a quantitative yield of A-homo-5β-androstan-3,17-dione, which, after several recrystallizations from petroleum ether (b.p. 40–60°), gave rhombs (94 mg), m.p. 80–81° (lit. m.p. 87–88° (11)), $[\alpha]_D^{24}$ 150.7° (*c*, 0.35 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 1 736 (five membered ring carbonyl) and 1 698 cm^{-1} (seven membered ring carbonyl).

Anal. Calcd. for $C_{20}H_{30}O_2$ (302.5): C, 79.42; H, 9.99. Found: C, 79.53; H, 9.94.

ACKNOWLEDGMENTS

Financial support of this work by the National Research Council, the National Cancer Institute of Canada, and the Petroleum Research Fund is gratefully acknowledged. We also thank Dr. A. D. Cross for a generous gift of 17β-hydroxy-androst-4-en-3-one, and Dr. D. B. MacLean for the mass spectra.

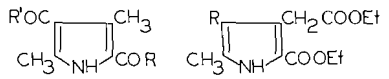
PREPARATION AND REACTIONS OF SOME PYRRYLTHIOL ESTERS

E. Bullock, T.-S. Chen, and C. E. Loader
Department of Chemistry, Memorial University, St. John's, Newfoundland
Received December 16, 1965



ABSTRACT

Two syntheses and some reactions of pyrrylthiol esters are described. The value of the thiol ester residue as a protecting group in the synthesis of complex pyrroles and their derivatives is considered. A simplified synthesis of a pyrrole related to the uroporphyrins is reported.

The synthesis of complex pyrromethanes and porphyrins requires the use of protecting groups. The literature contains numerous examples, but among the most favored groups are the carboxylic esters of ethyl (e.g. ref. 1), benzyl (e.g. ref. 2), and *t*-butyl (e.g. ref. 3) alcohols. One disadvantage of the ester grouping is that it is frequently necessary to remove it by de-esterification and decarboxylation, to free the specific pyrrole ring position for further synthetic operations.

When considering methods of simplifying classical syntheses of pyrroles and pyrromethanes, we investigated the properties of pyrrylthiol esters. The thiol ester group is potentially valuable since it is easily converted into formyl by treatment with an appropriate grade of Raney nickel.

Pyrrylthiol esters can readily be prepared by ring synthesis, and ethyl acetothiolacetate can be used in Knorr-type syntheses wherever the oxygen analogue has been employed. To test the scope of the synthesis, the three possible thiol ester variants on the Knorr pyrrole (I*a*–I*c*) were prepared. It might be expected that the use of zinc dust in the condensation step would lead to some desulfurization and reduced yields. However, a

Ia R = SEt; R' = OEt
Ib R = OEt; R' = SEt
Ic R = R' = SEt

IIa R = CH_2CH_2COOEt
IIb R = COSEt
IIc R = CHO
IId R = CH=CHCOOEt

comparison between a modified Knorr method (2) and the variant with sodium dithionite as reducing agent (4) showed that the former gave superior yields, which were comparable with those obtained in the synthesis of the analogous oxygen compound.

A second successful synthesis of pyrrylthiol esters involves the use of preformed pyrrole rings. Phenyl isothiocyanate reacts with alkylated pyrroles in α- or β-positions to give very high yields of thiocarbanilides (5). By analogy with the thiobenzanilides, the pyrrylthiocarbanilides were readily S-alkylated by dimethyl sulfate (with or without added base), or by alkyl halides and base. Hydrolysis of the S-alkylthioanilides with very dilute mineral acid gave good yields of the corresponding thiol esters. The products isolated by this method were difficult to purify for analysis (possibly as a result of partial hydrolysis), but behaved as expected in subsequent reactions.

Conversions of the thiol ester group into hydroxymethyl (6) or into aldehyde (7) have been reported. By use of the appropriate grade of Raney nickel we have converted

pyrrylthiol esters into the corresponding formyl derivatives. To obtain simple products it is necessary to prepare the nickel strictly according to the published method (8).

As an example of the use of a thiol ester in synthesis we have prepared a pyrrole (II*a* (9)) related to the uroporphyrins. A Knorr-type condensation of ethyl acetothiolacetate with nitrosated diethyl acetonedicarboxylate (10) gave the thiol ester II*b*. The product was desulfurized with W-2 Raney nickel by a novel technique to give the aldehyde II*c* in about 80% yield. Condensation of II*c* with ethyl hydrogen malonate in pyridine (11) gave a good yield of the acrylic ester II*d*, and this was reduced almost quantitatively to II*a* by hydrogen over Adams' catalyst.

Pyrrylthiol esters behave very much like their oxygen analogues. They are generally colorless and can be purified by crystallization or sublimation. Ethyl 2,4-dimethylpyrrole-5-thiolcarboxylate was compared closely with the corresponding ester, and in some of the common reactions of pyrrole synthesis (e.g. acylation, formylation, and Houben–Hoesch reaction) gives yields and products analogous to those obtained from the oxygen compound.

EXPERIMENTAL

Infrared spectra were recorded on a Perkin–Elmer 237B instrument, ultraviolet spectra on a Beckmann DK-2A, and nuclear magnetic resonance (n.m.r.) spectra on a Varian A-60. Melting points were taken in capillaries and are uncorrected. Analyses are by A. Bernhardt (Mülheim, Germany). Ultraviolet spectra were recorded for solutions in 95% ethanol. Petroleum ether refers to the fraction boiling at 60–80 °C.

Ethyl Acetothiolacetate

Two methods of preparation were used. Claisen condensation (12) of ethyl thiolacetate (13) gave a reasonable yield, but a preparation from diketene is simpler.

(*a*) Ethanethiol (100 g) and anhydrous sodium acetate (0.5 g) were mixed in ligroin (300 ml, b.p. 80–90°); diketene (135 g; T. Schuchardt GMBH, Munich) was added dropwise over 4 h. The reagents were protected against moisture and allowed to stand overnight at room temperature. The solvent was removed by distillation under reduced pressure, and the ester isolated by fractional distillation. The fraction distilling at 92–94° and 12 mm weighed 89 g (38%). This reaction is accompanied by the formation of a large amount of dehydracetic acid.

(*b*) Ethanethiol (15 g) and triethylamine (3 drops) were dissolved in ligroin (100 ml) and treated dropwise with diketene (21 g), with stirring, under gentle reflux. After the solution had been allowed to stand at room temperature overnight, it was poured into ice water. The layers were separated and the aqueous layer was washed twice with ether. The combined organic phases were washed with warm (30–35°) sodium bicarbonate solution and then with water, and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the thiol ester (19.5 g, 55%) was distilled at 92–94° and 12 mm.

Ethyl 2,4-Dimethyl-3-ethylthiolcarbonylpyrrole-5-carboxylate (Ib)

(*a*) To ethyl acetoacetate (1.3 g) in acetic acid (1.2 ml) was added sodium nitrite (0.7 g, in the minimum volume of water) dropwise, with stirring. The stirring was continued for another 4 h at room temperature, after which the solution was neutralized (Universal indicator paper) with 20% sodium hydroxide solution. Ethyl acetothiolacetate (1.4 g) was added, followed by sodium dithionite (2.6 g (4)), the mixture being kept neutral (by adding 20% caustic soda) and the temperature of the solution being maintained at about 40 °C. After addition of the dithionite the mixture was stirred for another hour at 40 °C and then made alkaline to phenolphthalein. After the solution had stood for 12 h, crystals separated out. The mixture was diluted with water and extracted with ether (3 × 25 ml). The ether extract was washed and dried (Na_2SO_4), and evaporation of the solvent gave a gummy solid which slowly crystallized. Recrystallization from ethanol–water gave colorless needles (0.85 g, 40%), m.p. 112–113 °C, identical with the material described in method *b* below.

(*b*) Sodium nitrite (0.22 g) in water (0.3 ml) was added dropwise to a solution of ethyl acetoacetate (0.4 g) in acetic acid (0.9 ml) at 5 °C, with stirring. The solution was left to stand for 1 h, and then added dropwise to a stirred mixture of ethyl acetothiolacetate (0.41 g), acetic acid (1.4 ml), and zinc dust (0.6 g) at 60°. The temperature of the mixture rose to 100°; this temperature was maintained (steam bath) for 1½ h, and the mixture left to stand overnight at room temperature. The product was isolated as in method *a* above and yielded colorless needles (0.45 g, 57%), m.p. 112–113 °C after crystallization from chloroform – petroleum ether. The product was sublimed (100° at 15 mm) for analysis. Ultraviolet absorption, maxima at 231, 247, and 285.5 mμ ($\log_{10} \epsilon_{max}$ 4.28, 4.16, and 4.14, respectively). The infrared spectrum (KCl disk) showed maxima (*inter alia*) at 1 634 and 1 669 cm^{-1}.

Anal. Calcd. for $C_{12}H_{17}NO_3S$: C, 56.44; H, 6.71; N, 5.49; S, 12.59. Found: C, 56.14; H, 6.65; N, 5.37; S, 12.34.

Ethyl 2,4-Dimethyl-3-ethoxycarbonylpyrrole-5-thiolcarboxylate (Ia)

This compound was prepared by method *b* above, on the same scale. In this case the ethyl acetothiolacetate was nitrosated and added to ethyl acetoacetate in the reducing mixture. The product formed very pale yellow needles when crystallized from chloroform – petroleum ether, m.p. 143–144 °C (0.51 g, 60%). Ultraviolet absorption, maxima at 232 and 302 mμ ($\log_{10} \epsilon_{max}$ 4.27 and 4.35, respectively). The infrared spectrum (KCl disk) included peaks at 1 675 and 1 619 cm^{-1}.

Anal. Calcd. for $C_{12}H_{17}NO_3S$: C, 56.44; H, 6.71; N, 5.49; S, 12.59. Found: C, 56.26; H, 6.53; N, 5.60; S, 12.45.

Diethyl 2,4-Dimethylpyrrole-3,5-dithiolcarboxylate (Ic)

The dithiol ester was prepared by method *b* above, except that in this case both halves of the potential pyrrole ring were derived from ethyl acetothiolacetate. The product formed colorless needles, m.p. 107–108 °C (0.59 g, 66%) when crystallized from chloroform – petroleum ether. Ultraviolet absorption, maxima at 237 and 308 mμ ($\log_{10} \epsilon_{max}$ 4.26 and 4.38, respectively). The infrared spectrum (KCl disk) included maxima at 1 650 and 1 594 cm^{-1}.

Anal. Calcd. for $C_{12}H_{17}NO_2S_2$: C, 53.10; H, 6.32; N, 5.16. Found: C, 53.05; H, 6.23; N, 5.30.

Methyl 2-Methylpyrrole-5-thiolcarboxylate

2-Methylpyrrole-5-thiocarbanilide (12 g (5)) was rapidly stirred with caustic soda (3 *N*, 24 ml) and dimethyl sulfate (7 ml) on a steam bath. The two-phase mixture was cooled and treated with ammonium hydroxide (6 *N*, 30 ml) to decompose excess dimethyl sulfate. The mixture was extracted with ether (3 × 50 ml), and the combined extracts were washed with water and dried (Na_2SO_4). Removal of the ether gave a yellowish oil which was crude 2-methylpyrrole-5-(S-methyl)-thiocarbanilide (12 g). This material was used without purification.

The oily product (above) was suspended in hydrochloric acid (1 *N*, 240 ml) and stirred at 100° for 2 h. Crystalline material was deposited and removed (after the mixture had been cooled in ice) by filtration. The filtrate was again heated until no more crystalline material accumulated. The combined precipitates (6.5 g, 75% based on the thioanilide) were recrystallized from chloroform – petroleum ether to give colorless needles, m.p. 126–127°. A sample was sublimed for analysis. Ultraviolet absorption, maxima at 283 and 311.5 mμ ($\log_{10} \epsilon_{max}$ 4.34 and 3.67, respectively). Infrared absorptions (Nujol mull) included a band at 1 620 cm^{-1}. The n.m.r. spectrum (CH_2Cl_2) showed peaks at τ 3.02 and 4.15 (pseudo triplets, ring proton absorptions), 7.58 (S-methyl), and 7.67 (ring methyl).

Anal. Calcd. for C_7H_9NOS: C, 54.17; H, 5.81; N, 9.02; S, 20.66. Found: C, 54.19; H, 5.90; N, 9.20; S, 20.57.

Ethyl 2-Methylpyrrole-5-thiolcarboxylate

This compound was prepared in a manner similar to the above, except for the formation of the S-ethyl-thiocarbanilide. 2-Methylpyrrole-5-thiocarbanilide (6 g (5)) was added to a stirred mixture of sodium hydroxide solution (3 *N*, 24 ml) and ethyl bromide (4 ml). The mixture was boiled under reflux for 4 h, cooled, and extracted with ether (3 × 30 ml). The ether extract was worked up as above to give an almost quantitative yield of the crude S-ethylthioanilide. This compound could be crystallized from aqueous ethanol or chloroform – petroleum ether to give yellow plates, m.p. 49.5–51°, but this was unnecessary for a successful preparation of the ester. The S-ethyl thioanilide (3 g) was hydrolyzed in the same way as the S-methyl compound to give the ethyl thiol ester as colorless needles (1.8 g, 84%), m.p. 88–90 °C. The infrared spectrum showed a maximum at 1 616 cm^{-1} (thiol ester carbonyl).

By analogous reactions, 2,4-dimethylpyrrole-5-(S-ethyl)-thiocarbanilide, m.p. 69.5–70.5°, and ethyl 2,4-dimethylpyrrole-5-thiolcarboxylate, m.p. 111.5–113°, were prepared.

Methyl 2-Methyl-3-formylpyrrole-5-thiolcarboxylate

Methyl 2-methylpyrrole-5-thiolcarboxylate (2.8 g) was added to a cooled mixture of dimethylformamide (6 g) and phosphorus oxychloride (2 ml) while the temperature was maintained below 0°. The red solution was warmed on an oil bath at 35° for 30 min (aldimine hydrochloride begins to crystallize at this point), cooled, and poured into an ice-cold solution of sodium hydroxide (4 g) in water (8 ml). After 10 min the solution was brought to pH 6 with cold 3 *N* hydrochloric acid, and after 10 min more the pinkish precipitate was filtered off. Crystallization of the aldehyde from aqueous ethanol gave off-white needles (2.78 g, 85%), m.p. 179–181°. Ultraviolet spectrum, maxima at 229, 272.5, and 307 mμ ($\log_{10} \epsilon_{max}$ 4.30, 4.04, and 4.26, respectively).

Anal. Calcd. for $C_8H_9NO_2S$: C, 52.50; H, 4.96. Found: C, 52.25; H, 4.98.

Methyl 2,4-dimethyl-3-formylpyrrole-5-thiolcarboxylate, m.p. 145–146°, was prepared in an analogous manner.

Methyl 2-methyl-3-(ethylglyoxalyl)pyrrole-5-thiolcarboxylate, m.p. 167.5–169°, was prepared by a Houben–Hoesch reaction (14) between ethyl cyanoformate and methyl 2-methylpyrrole-5-thiolcarboxylate.

Ethyl 2,4-Dimethyl-3-acetylpyrrole-5-thiolcarboxylate

(*a*) Ethyl 2,4-dimethylpyrrole-5-thiolcarboxylate (0.25 g) in a mixture of acetic acid (2 ml) and acetic anhydride (1 ml) was treated with 70% perchloric acid (5 drops). After 15 min the reddish solution was

poured into ice-cold water. The solid precipitate was collected and crystallized from aqueous ethanol to give colorless crystals, m.p. 123–124°, in an almost quantitative yield. Infrared bands (Nujol mull) at 1 666 and 1 594 cm^{-1} (*inter alia*).

Anal. Calcd. for $C_{11}H_{15}NO_2S$: C, 58.64; H, 6.48; N, 6.22; S, 14.23. Found: C, 58.54; H, 6.75; N, 6.41; S, 14.14.

(*b*) A Knorr-type, ring synthesis reaction between nitrosated ethyl acetothiolacetate (see above) and acetylacetone gave a product identical (melting point, mixed melting point, and spectra) with that prepared by method *a* above.

Desulfurization Experiments

W-2 Raney nickel (8) was used as the standard desulfurization material. It was deactivated with boiling acetone for various periods of time, depending on the activity required. In a typical batchwise desulfurization, Raney nickel (2.8 g) was deactivated by refluxing it with acetone (6 ml) for 1 h. Methyl 2-methylpyrrole-5-thiolcarboxylate (0.25 g) was added, followed by acetone (2 ml) and water (2 ml). The mixture was boiled under reflux for another hour, cooled, and filtered through diatomite. Removal of the solvent *in vacuo* yielded an oily product which rapidly crystallized when treated with a drop of methanol. The crystalline product, 2-methyl-5-formylpyrrole, after sublimation, had m.p. 68.5–69.5° (lit. (15) m.p. 68°) and formed an oxime, m.p. 151–152° (lit. (15) m.p. 153°). The n.m.r. spectrum (CCl_4) showed absorptions at τ 0.69 (singlet, formyl), 3.13 and 3.98 (pseudo triplets, ring protons), and 7.57 (singlet, methyl).

Diethyl Acetonedicarboxylate

The commercial acid (Eastern Chemical Corp., Pequannock, New Jersey) was esterified (10) in very high (81.5%) yield, b.p. 119–124° at 6 mm.

Ethyl 5-Carbethoxy-4-carbethoxymethyl-2-methylpyrrole-3-thiolcarboxylate (IIb)

Freshly distilled amyl nitrite (57 g) was added during 1 h at 20° to a stirred, cooled mixture of ethyl acetonedicarboxylate (97 g) and concentrated hydrochloric acid (0.8 ml). The mixture was allowed to warm up to room temperature spontaneously, and then was heated at 40° for 2 h. The mixture was treated with sodium acetate (1.0 g) and then added (over 30 min) to a vigorously stirred mixture of ammonium acetate (75 g), acetic acid (500 ml), ethyl acetothiolacetate (70 g), and zinc dust (25 g) which was cooled in ice water. During the addition of the nitroso compound, zinc dust (50 g) was added in small portions. After the initial temperature rise had ceased, the reaction mixture was slowly heated to 90°, with continued stirring, during 2 h. The hot solution was decanted from excess zinc into stirred ice water (6 l). The zinc was washed with a little hot 50% acetic acid, and the washings were added to the aqueous mixture. After 2 h the precipitate was collected, washed with 50% aqueous ethanol (200 ml), and crystallized from absolute ethanol to yield colorless, flat prisms (75 g, 48%), m.p. 102–103°. The n.m.r. spectrum (CCl_4) showed absorptions at τ −0.27 (broad, NH), 5.73 and 5.88 (O—CH_2, quartets), 5.81 (—CH_2—CO), 7.02 (S—CH_2, quartet), 7.69 (CH_3), and 8.63, 8.69, and 8.76 (ester CH_3, triplets).

Anal. Calcd. for $C_{15}H_{21}O_5NS$: C, 55.04; H, 6.47; N, 4.29; S, 9.80. Found: C, 55.10; H, 6.47; N, 4.40; S, 9.68.

Ethyl 2-Methyl-3-formyl-4-carbethoxymethylpyrrole-5-carboxylate (IIc)

(*a*) W-2 Raney nickel (50 g) was added to acetone (150 ml) and heated under reflux for 2 h with magnetic stirring. A solution of the above thiol ester (IIb, 3.72 g) in acetone (100 ml) and methanol (50 ml) was added, and the mixture was refluxed for another 2 h. The catalyst was removed and the filtrate evaporated to dryness *in vacuo*. The residue was recrystallized from methanol to give white needles (2.16 g, 71%), m.p. 153–154.5° (lit. (9) m.p. 154°).

(*b*) When the foregoing reaction was repeated with the thiol ester (IIb, 0.75 g) and Urushibara nickel-B (10 g (16)), the aldehyde IIc was again isolated (0.52 g, 85%), m.p. 153–154.5°.

(*c*) W-2 Raney nickel (65 g) and silica gel (100 g) were mixed well and packed into a chromatographic column (25 × 500 mm). Acetone (100 ml) was allowed to percolate through the column at about 2–3 ml/min. The exterior of the column was warmed with a water jacket at 50°, and a solution of the thiol ester (IIb, 4.95 g) in methanol (180 ml) and acetone (20 ml) was run through the column at about 2 ml/min. Fractions were collected and the amount of aldehyde present in each was estimated from the n.m.r. spectrum. When the emerging solution showed gross contamination with starting material and a by-product, the earlier fractions were combined and yielded almost pure aldehyde (3.1 g, 77%) as white needles, m.p. 153–154.5°.

Ethyl 3-Carbethoxymethyl-4-(2′-carbethoxyvinyl)-5-methylpyrrole-2-carboxylate (IId)

A mixture of the foregoing aldehyde (IIc, 3.0 g), ethyl hydrogen malonate (1.8 g), pyridine (10 ml), and piperidine (8 drops) was heated at 90° for 6 h, and then refluxed for another 3 h. The mixture was poured into ice water and neutralized with dilute hydrochloric acid. After 3 h the precipitate was collected, washed with water, and recrystallized from aqueous methanol and then hexane to give colorless prisms, m.p. 88–89° (2.3 g). The filtrate and mother liquors were combined and extracted with ether to yield a further crop of the vinyl ester (0.5 g, total yield 74%).

Anal. Calcd. for $C_{17}H_{23}O_6N$: C, 60.51; H, 6.88; N, 4.16. Found: C, 60.45; H, 6.85; N, 4.14.

The n.m.r. spectrum (CCl_4) showed absorptions at τ −0.25 (broad, NH), 2.40 and 4.10 (olefinic CH, AB quartet, J = 16.5 c.p.s.), 5.77 (quartet, O—CH_2), 6.01 (singlet, —CH_2—CO), 7.71 (CH_3), and 8.68 (triplet,

ester CH_3). The ester signals were not resolved in the spectrum of this compound and the signals for the $O—CH_2—CH_3$ groups are broad. Integrated areas for all the peaks are in accord with structure II*d*.

Ethyl 3-Carbethoxymethyl-4-(2'-carbethoxyethyl)-5-methylpyrrole-2-carboxylate (IIa)

A solution of the vinyl ester (II*d*, 2.0 g) in 95% ethanol (50 ml) was shaken for 1 h with Adams' catalyst (50 mg) under hydrogen (at 50 lb/sq. in.) at room temperature. The platinum was removed and the solvent distilled off *in vacuo*. The residue was crystallized from cyclohexane to give white needles (1.91 g, 95%), m.p. 63–64° (lit. (9) m.p. 63.5°).

ACKNOWLEDGMENTS

ÉTUDE QUANTITATIVE DES RÉACTIONS D'OZONOLYSE

II. OZONATION DU *trans*-STILBÈNE

S. FLISZÁR, D. GRAVEL ET E. CAVALIERI
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 10 décembre 1965

ABSTRACT

The ozonolysis of 1 mole of *trans*-stilbene (in CCl_4) by a stream of O_2–O_3 leads to the formation of 0.677 mole of stilbene ozonide, 0.468 mole of benzaldehyde, and 0.089 mole of benzaldehyde diperoxide. This ratio, observed for 80–100% ozonizations, is independent of the olefin concentration, the ozone flow rate, and the temperature (in the range 25–45 °C). These observations are explained, if one assumes that the reaction between two zwitterions can follow two courses: (*a*) formation of a dimer peroxide (55%), and (*b*) elimination of oxygen with the formation of two molecules of benzaldehyde (45%).

Depuis que Criegee *et al.* (1) ont décrit la préparation de l'ozonide du *trans*-stilbène, l'ozonation de cette oléfine a fait l'objet de plusieurs travaux (2); on a notamment pu mettre en évidence que la production de fortes proportions d'aldéhyde benzoïque accompagne la formation de l'ozonide (3).

Par ailleurs on a pu montrer que la formation d'ozonides est toujours accompagnée de la production d'aldéhydes. Ainsi, par exemple, on a pu reconnaître et doser l'aldéhyde benzoïque (ozonation du styrène (4)), le formol (ozonation du styrène (4), de l'estragole (4), de l'*o*-méthyleugénol (5) et de l'eugénol (6)), l'aldéhyde acétique (ozonation des anétholes *cis* et *trans* (4*b*), de l'*o*-méthylisoeugénol (7, 4*b*) et de l'isoeugénol (6)), à côté des aldéhydes aromatiques correspondants. De même, le glyoxylate d'éthyle a pu être mis en évidence lors de l'ozonation de trois esters oléfiniques: les maléate, fumarate et cinnamate d'éthyle (8). Il est à souligner que cette production d'aldéhydes se manifeste toujours dès le début de la réaction d'ozonation, et que nous avons vérifié que la présence d'aldéhydes dans le mélange réactionnel ne peut être attribuée à une scission des ozonides. Ces observations peuvent être expliquées en admettant qu'une partie des molécules zwitterion engendrées lors de la scission de l'ozonide primaire[1] réagit avec d'autres molécules zwitterion pour former des peroxydes; ainsi, une partie de l'aldéhyde engendré lors de la scission de l'ozonide primaire n'étant pas consommé par le zwitterion pour donner l'ozonide stable, cette proportion d'aldéhyde se retrouve finalement dans le mélange réactionnel.

Nous nous proposons, dans nos travaux, d'étudier plus en détail le comportement du zwitterion et la formation de peroxydes par la polymérisation de molécules zwitterion. Dans le cas du stilbène, on peut montrer par des expériences très simples que les fragments carbonylé et zwitterion jouissent d'une indépendance marquée (en regard d'un "mécanisme de cage" proposé par Criegee (10)), appuyant ainsi bien les vues de Criegee (11) sur la scission de l'ozonide primaire.

Une première série d'expériences a permis de déterminer, à différents degrés d'avancement de la réaction, les quantités d'aldéhyde benzoïque et d'ozonide formés lors de l'ozonation de 20 ml de solution d'oléfine 0.1 *M* dans CCl_4 (Fig. 1). Ainsi, à 25 °C, on obtient pour le rapport aldéhyde formé/ozonide formé la valeur 0.20 mmole/0.13 mmole = 1.54 pour un degré d'avancement de la réaction d'environ 13.5%; ce rapport décroît à 0.75 (pour 76.5% de réaction) et, pour l'ozonation complète, à 0.59. Le fait que l'aldéhyde se forme

[1]*Le mécanisme d'ozonolyse de Criegee est brièvement résumé en réf. 9.*

principalement au début de la réaction montre clairement, d'une part, que la probabilité de réaction associée à une rencontre entre deux molécules zwitterion pour former un peroxyde est avantagée par rapport à la probabilité de réaction se rapportant à une rencontre entre une molécule zwitterion et une molécule d'aldéhyde pour donner l'ozonide, et, d'autre part, que les fragments zwitterion et aldéhyde issus de la scission de l'ozonide primaire sont en large mesure indépendants. On note, en effet, que les rendements en ozonide, très faibles en début de réaction, vont en augmentant avec l'avancement de la réaction (~37% à 6% de réaction et ~75% à la fin de la réaction) du fait que l'accumulation progressive de l'aldéhyde favorise la formation de l'ozonide.

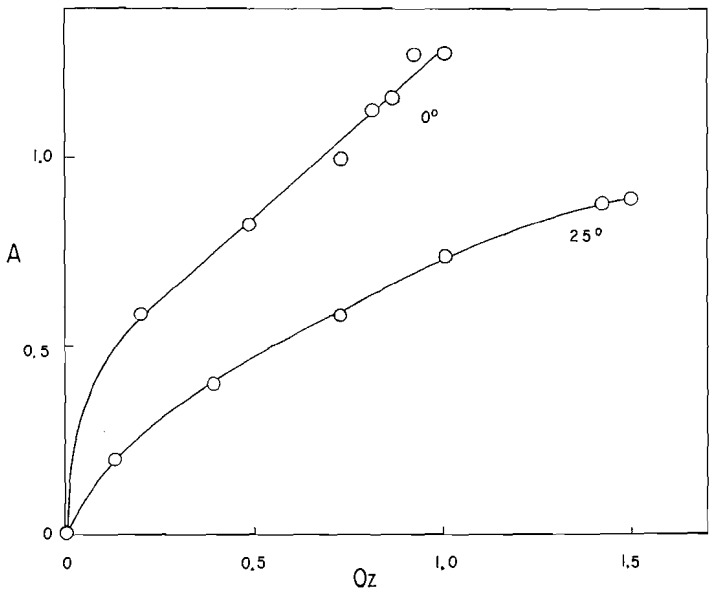

FIG. 1.

Ce phénomène est encore plus accusé aux basses températures. On note, en effet, à 0 °C (Fig. 1) les grandes proportions d'aldéhyde formé au début de la réaction, contrastant avec la production relativement faible d'ozonide; ainsi on a un rendement en ozonide de seulement 31% (rapporté à l'oléfine consommée) pour une consommation de 32% de l'oléfine initialement présente, ce rendement en ozonide étant encore bien plus faible aux phases initiales de la réaction.[2]

Nous nous sommes d'ailleurs assurés que la forte production d'aldéhyde benzoïque n'est pas due à une décomposition des produits engendrés par l'ozonation: ozonide et peroxyde dimère (I). Une solution 0.05 *M* d'ozonide de *trans*-stilbène dans CCl_4, chauffée à reflux pendant 5 h, ne montre que des traces d'aldéhyde benzoïque; une solution 0.05 *M* (dans CCl_4) de diperoxyde de benzaldéhyde (I), chauffée pendant 5 h à reflux, n'a pas engendré d'aldéhyde benzoïque en quantité décelable. Ces constatations sont importantes, particulièrement en ce qui touche la stabilité du diperoxyde de benzaldéhyde, lorsqu'on examine les bilans de production d'aldéhyde.

[2]*Les valeurs reproduites dans la Fig. 1 pour l'ozonation à* 0 °C *ont été obtenues au moyen de deux séries d'expériences indépendantes; dans d'autres cas (pour des raisons que nous n'avons pas pu éclaircir) les rendements en ozonide ont été encore bien plus faibles.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

En vue de faciliter la discussion, définissons le rapport: r = (aldéhyde plus ozonide formés)/stilbène consommé, qui représente la quantité totale d'aldéhyde (soit sous forme libre, soit sous forme d'ozonide) engendré par mole d'oléfine ozonée. Or, dans toutes les expériences d'ozonation du stilbène, on trouve $r > 1$ ($r = 1.19$ à 25° et $r = 1.14$ à 0° dans les expériences rapportées à la Fig. 1) bien que l'ozonolyse du stilbène engendre en un premier temps des quantités égales d'aldéhyde et de zwitterion, soit 1 mole de chaque produit par mole d'oléfine consommée (Tableau I).

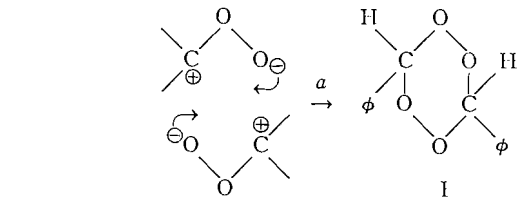

TABLEAU I

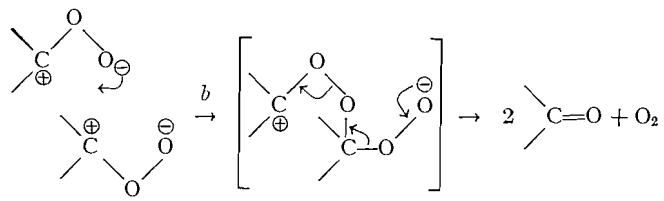
Ozonation de 2.0 mmoles de stilbène dans 20 ml de CCl_4 à 25 °C, en présence de CH_3OH (0.5 M)



O_3 consommé	Stilbène consommé	ϕ CHO formé	Hydroperoxide formé
0.53	0.51	0.50	0.52
1.08	1.09	1.08	1.10
1.48	1.49	1.49	1.50
1.85	1.83	1.84	1.82

NOTONS: Débit O_3: 0.046 mmole/min. Les quantités sont indiquées en millimoles.

Par conséquent, puisque ni l'ozonide ni le diperoxyde de benzaldéhyde ne se décomposent pour engendrer de l'aldéhyde benzoïque, et puisqu'au départ (à la suite de la scission de l'ozonide primaire) il se forme 1 mole d'aldéhyde par mole d'oléfine consommée, on est conduit à admettre que la formation excessive de benzaldéhyde intervient au stade de la réaction entre zwitterions,[3] cette réaction pouvant soit engendrer un peroxyde dimère (I) par la voie a, soit aboutir à la formation d'aldéhyde benzoïque avec élimination d'oxygène par la voie b.

I

II

On note la similitude de ces conclusions avec celles exposées au sujet de l'ozonation du tétraphényléthylène (9), sauf que pour cette dernière oléfine la décomposition en composé carbonylé ne prenait d'importance qu'aux températures plus élevées (~80 °C) ou encore en présence d'un agent réducteur (I^- en solution acétique), tandis que dans le cas du

[3] *Une possibilité de réaction entre deux molécules d'ozonide primaire, qui (du point de vue de la stoïchiométrie) pourraient engendrer quatre molécules d'aldéhyde et une molécule d'oxygène, ne semble pas devoir être retenue, du fait de la très grande instabilité des ozonides primaires.*

stilbène cette décomposition spontanée est très rapide, même à 25 °C. Ceci peut être interprété en observant que la présence dans l'intermédiaire II de deux atomes d'hydrogène (cas du stilbène) en lieu de deux noyaux phényles (cas du tétraphényléthylène) diminue la délocalisation des charges positive et négative dans cet intermédiaire, favorisant ainsi le mécanisme de type "push–pull" représenté en II.

En vue d'évaluer en quelles proportions la voie *b* est suivie, nous avons procédé à une série de déterminations, résumées dans le Tableau II.

On remarque que, même sujets à quelques fluctuations, les rendements en ozonide sont inférieurs aux températures $\leqslant 0°$ par rapport aux températures plus élevées ($\geqslant 25°$); dans tous les cas les valeurs calculées pour r sont supérieures à l'unité, et proches de 1.14 pour les températures $\geqslant 25°$. Ces chiffres représentent en fait un grand excès de production d'aldéhyde, par rapport à la production qui aurait été observée en absence d'un mécanisme de décomposition (voie *b*). Par exemple, l'ozonation complète à 25° de 20 ml de solution 0.1 *M* de stilbène a engendré 1.40 mmoles d'ozonide; donc $2.00 - 1.40 = 0.60$ mmole de benzaldéhyde n'ont pas été utilisées pour la formation de l'ozonide et devraient se retrouver dans le mélange réactionnel; en fait, on trouve 0.88 mmole d'aldéhyde, soit près de 50% de plus que la quantité attendue.

Pour évaluer le pourcentage de zwitterion se décomposant en aldéhyde plus oxygène par rapport à la totalité du zwitterion non utilisé pour la formation d'ozonide, on a avantage à procéder comme suit, ce calcul tenant compte de l'ensemble des résultats obtenus.

Posons (en millimoles) A = aldéhyde et Oz = ozonide formés pour S = stilbène consommé; f = proportion de zwitterion se décomposant en aldéhyde plus oxygène par rapport à la quantité de zwitterion non utilisé pour former l'ozonide. En absence d'un mécanisme de décomposition, le bilan d'ozonation s'écrirait comme suit: 1 mmole de stilbène ozoné $\rightarrow Oz/S$ (ozonide) + $(1 - Oz/S)$ (aldéhyde) + $(1 - Oz/S)$ (zwitterion). La quantité d'aldéhyde formé par millimole de stilbène ozoné étant A/S, l'excès $A/S - (1 - Oz/S)$ représente l'aldéhyde formé par décomposition de zwitterion, soit le nombre de millimoles de zwitterion que s'est décomposé par millimole de stilbène ozoné, donc pour $1 - Oz/S$ millimole de zwitterion non utilisé pour la formation d'ozonide. Alors, par définition, $f = (A/S + Oz/S - 1)/(1 - Oz/S)$, une expression que peut s'écrire comme suit: $S/A = [1/(f + 1)] + Oz/A$.

La Fig. 2, qui reproduit les valeurs de S/A et de Oz/A calculées d'après les résultats résumés dans le Tableau II, montre bien que la relation que nous venons de déduire est satisfaite pour $f \simeq 0.45$; en trait pointillé est indiqué le résultat auquel on aurait du s'attendre pour $f = 0$, c'est-à-dire s'il n'y avait pas de formation d'aldéhyde à partir de zwitterion.

Le calcul de f a été effectué sur les résultats (Tableau II) se rapportant aux expériences faites aux températures $\geqslant 25°$ et $\leqslant 45°$; l'estimé des déviations relatives nous a conduit à rejetter les 2 valeurs marquées d'un astérisque, manifestement entachées d'erreurs expérimentales (Fig. 2), et à accepter les autres 11 résultats,[4] d'après lesquels $f = 0.451$ avec l'écart type 0.0166; exprimé avec une limite de confiance de 95%, on obtient $f = 0.451 \pm 0.037$. Pour simplifier la discussion nous admettrons $f = 0.45$, ce qui signifie qu'environ 45% du zwitterion n'ayant pas réagi avec l'aldéhyde pour former l'ozonide se décompose en aldéhyde benzoïque plus oxygène (voie *b*), les autres 55% se retrouvant sous forme de diperoxyde de benzaldéhyde. Ce dernier point est confirmé par des expériences exposées plus loin.

[4]*Concernant les règles pour le rejet de valeurs douteuses, voir, par exemple, réf. 11, p. 173.*

NOTONS: Débit O_3: millimole/minute. Les quantités (stilbène, ϕCHO et ozonide formés) sont indiquées en millimoles.

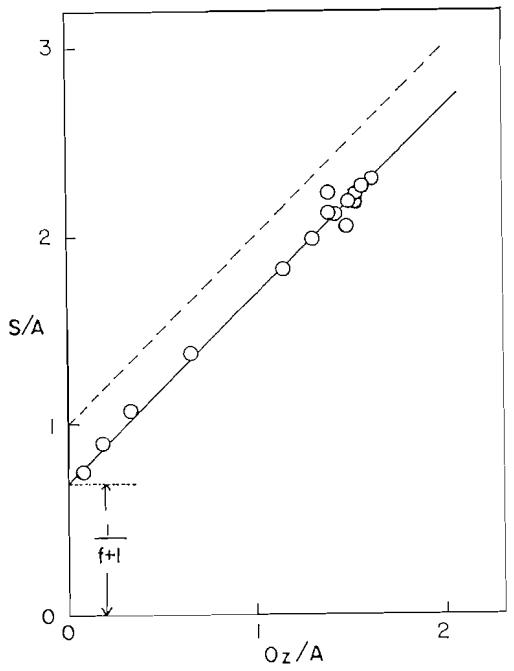

FIG. 2.

En ce qui concerne les rendements en ozonide (rapportés aux quantités d'oléfine consommée), l'analyse statistique des résultats du Tableau II ne permet pas de conclure à une différence significative de ces rendements à 25°, 35° et 45°. Par conséquent, sans faire de distinction quant à la température, le calcul conduit au résultat suivant, exprimé avec une limite de confiance de 95%: rendement en ozonide (rapporté à l'oléfine consommée) = 67.7 ± 1.3%, pour une consommation de 80–100% de l'oléfine initialement présente.

D'après les résultats obtenus, le bilan de l'ozonation du stilbène, en solution dans du CCl_4, s'établit donc comme suit, aux températures comprises entre 25 et 45 °C: 1.0 mole d'oléfine engendre 1.0 mole d'ozonide primaire, qui se scinde en 1.0 mole d'aldéhyde benzoïque plus 1.0 mole de zwitterion. C'est le processus de Criegee, confirmé par les expériences effectuées en présence de CH_3OH. Dans une deuxième étape, 0.677 mole de zwitterion réagit avec une égale quantité d'aldéhyde benzoïque pour former 0.677 mole d'ozonide; restent donc 0.323 mole de benzaldéhyde et 0.323 mole de zwitterion non utilisés. Finalement, 45% du zwitterion non utilisé pour former l'ozonide réagit selon la voie *b* avec formation de 0.145 mole de benzaldéhyde, et 55% réagit selon la voie *a* en engendrant un peroxyde stable. Il s'est ainsi formé complessivement 0.323 + 0.145 = 0.468 mole d'aldéhyde benzoïque[5] par mole de stilbène ozoné, soit près de 1.45 fois la quantité attendue en absence d'une décomposition du zwitterion.

Nous nous sommes encore assurés de la constance de f dans le cas de réactions moins avancées, alors que les rendements en ozonide sont inférieurs à 67.7% (Tableau III). De même nous avons dosé approximativement le diperoxyde de benzaldéhyde en l'isolant de solutions ozonées à 100% et en le séparant de l'ozonide par des recristallisations fractionnées dans du CH_3OH; dans trois expériences nous avons ainsi obtenu des rendements correspondant à 55, 65 et 69% par rapport à la quantité attendue, soit 0.089 mmole par

[5]*Ce rendement en aldéhyde benzoïque peut être obtenu directement en formant la moyenne des quantités A/S observées dans les 11 expériences retenues dans l'établissement de ce bilan.*

For personal use only.

millimole de stilbène ozoné; des rendements variant entre 50 et 70% ont été également obtenus lors de l'isolement de ce diperoxyde à partir de mélanges artificiels d'ozonide et de diperoxyde. Ces observations portent à croire que les 55% du zwitterion non engagé dans la formation d'ozonide engendrent (du moins en majeure partie) du diperoxyde de benzaldéhyde.

TABLEAU III

Ozonation de 20 ml de solution 0.1 *M* de *trans*-stilbène à 25 °C

S	*A*	*Oz*	*f*
0.268	0.20	0.13	0.442
0.673	0.40	0.40	0.460
1.134	0.58	0.73	0.435

NOTONS: *S*, *A* et *Oz*: millimoles.

Quant aux expériences effectuées aux températures $\leqslant 0$ °C, on note $r > 1$ (donc qu'il y a une décomposition du zwitterion en benzaldéhyde) et que les rendements en ozonide sont inférieurs à ceux trouvés aux températures $\geqslant 25$ °C. Ces expériences étant toutesfois difficilement reproductibles, nous nous limiterons pour l'instant à ces constatations.

PARTIE EXPÉRIMENTALE

La technique d'ozonation, le dosage de l'ozone et des hydroperoxydes ont été décrits précédemment (9). L'aldéhyde benzoïque et l'ozonide ont été dosés par voie spectrographique infrarouge d'après les densités optiques de la bande de vibration du groupement carbonyle à 1 705 cm^{-1} pour l'aldéhyde et de la bande à 1 053 cm^{-1} de l'ozonide (3); l'ozonide[6] (p.f. 74 °C) ayant servi à l'établissement des courbes de calibration a été préparé selon Criegee (1). Les dosages du *trans*-stilbène (Eastman Kodak, scintillation grade) ont été effectués par spectrophotométrie en ultraviolet à 312 mμ; nous nous sommes assurés que cette bande disparaît complètement par ozonation à 100%. Le diperoxyde de benzaldéhyde isolé du mélange réactionnel (et purifié par plusieures cristallisations fractionnées dans du CH_3OH) a été reconnu identique par son point de fusion et le point de fusion du mélange à un échantillon préparé selon réf. 12, p.f. 202 °C, confirmant ainsi une expérience de Criegee (1). Ce produit possède dans son spectre infrarouge (en solution dans du CCl_4) deux bandes faibles vers 1 023 et 1 006 cm^{-1}, et n'absorbe pas à 1 053 cm^{-1}; par conséquent sa présence ne gêne nullement les mesures d'intensité de la forte bande de l'ozonide (1 053 cm^{-1}).

REMERCIEMENTS

Nous sommes reconnaissants à M. le Professeur C. Sandorfy, Directeur du Laboratoire de Spectroscopie chimique, pour toutes les facilités qu'il nous accorde dans nos recherches expérimentales. Nous remercions également M. G. Bélanger de son assistance technique précieuse, et le Conseil National de Recherches du Canada pour une subvention qui a permise ces recherches.

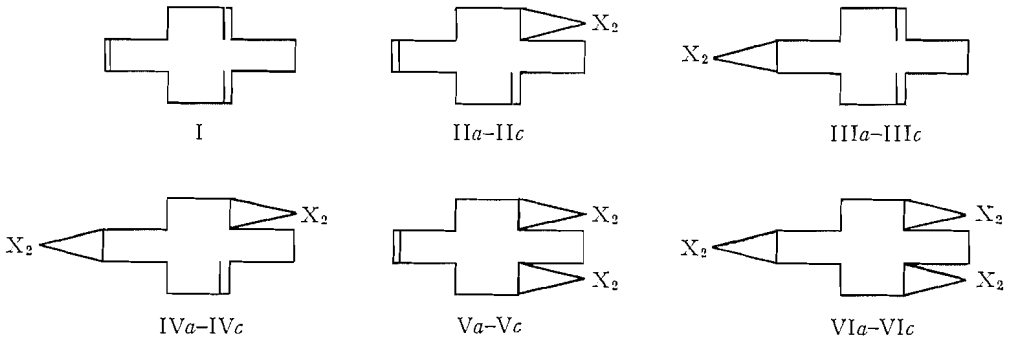
THE STEREOSELECTIVE ADDITION OF DIHALOCARBENES TO *cis,trans,trans*-CYCLODODECA-1,5,9-TRIENE AND THE SYNTHESIS OF CYCLOTRIDECANONE



H. NOZAKI, S. KATÔ, AND R. NOYORI
Department of Industrial Chemistry, Kyôto University, Kyôto, Japan
Received December 21, 1965

ABSTRACT

The addition reactions of dibromo- and dichloro-carbenes to *cis,trans,trans*-cyclododeca-1,5,9-triene (I) followed a stereoselective scheme analogous to that of other reagents forming a three-membered ring on addition to an olefinic bond. The carbenes attacked preferentially one of the *trans* double bonds of I and then added to the *cis* double bond of the resulting bicyclic *cis,trans* dienes. Skattebøl's ring cleavage of dihalocarbene adducts of *cis*-cyclododecene as well as of the monoadducts of I, followed by several steps, gave cyclotridecanone in fairly good yields.

In a continuation of the work on 12-membered homocyclic systems (1), the addition reactions of dihalocarbenes to *cis,trans,trans*-cyclododeca-1,5,9-triene (I) and *cis*-cyclododecene (VII) were examined, and the resulting adducts were transformed into cyclotridecanone in fair yields.

The chemistry of the addition of dihalocarbenes to the triene I is described first.[1] Treatment of the triene I with bromoform and potassium *t*-butoxide gave a mixture of the monoadducts (II*a*, III*a*) of dibromocarbene as a viscous oil. Similarly, reaction of the triene I with dichlorocarbene, as produced by thermal decomposition of sodium trichloroacetate in diglyme or by treatment of chloroform with potassium *t*-butoxide, gave the corresponding adducts (II*b*, III*b*) in good yields. Reduction of these dihalocarbene adducts with metallic sodium dissolved in liquid ammonia (3) yielded an isomeric mixture of bicyclo[10.1.0]tridecadienes (II*c*, III*c*) smoothly. Reduction of all of the dihalomethylena-

a X = Br *b* X = Cl *c* X = H

tion products yielded a mixture of mono- (II*c*, III*c*), bis- (IV*c*, V*c*), and tris-cyclopropane derivatives (VI*c*). All of the halogen-free cyclopropanes were identified by comparison of the retention times on gas–liquid chromatography (g.l.c.) with those of the specimen

[1]*Preferential addition of dichlorocarbene to a trans double bond of I was very recently recorded independently (2).*

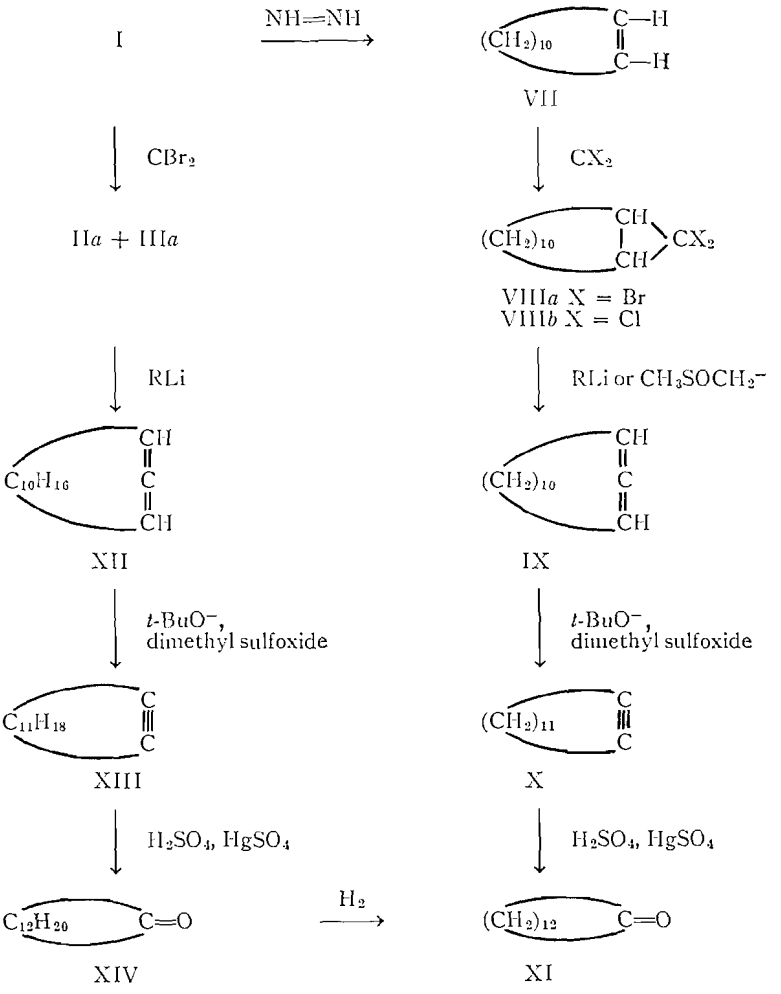
previously synthesized by means of the Simmons–Smith reaction (1*b*). The isomer distributions of the cyclopropane hydrocarbons should be regarded as reflecting those of the parent dihalocarbene adducts and are summarized in Table I.

TABLE I

Stereoselectivity of the addition of dihalocarbenes to *cis,trans,trans*-cyclododeca-1,5,9-triene

Carbene	Method of generation	Reaction temperature (°C)	Monoadduct II/III	Bisadduct* IV/V
CBr_2	$CHBr_3$–KOBu-*t*	−10 to 25	89:11	84:16
CCl_2	$CHCl_3$–KOBu-*t*	−5 to 25	91:9	87:13
CCl_2	CCl_3COONa	80 to 90	85:15	72:28
$(ICH_2)_2Zn \cdot ZnI_2$†		35	97:3	81:19

*The ratios were calculated on the basis of the peak areas in g.l.c. (high-vacuum silicone grease (2 m), He). Polyethylene glycol 6000 treated with silver nitrate as the stationary phase gave practically the same results.
†The results obtained in the previous work (1*b*) are reproduced.



The *trans* double bond of the triene I appears to be much more susceptible to the electrophilic attack of dihalocarbenes, even the selectivity being comparable to that of the Simmons–Smith reagent (4). Further attack of the carbene on the respective monoadducts occurs at the *cis* bond rather than at the *trans* bond, with poorer preference. Such a behavior of carbenes is closely analogous to that previously observed in the epoxidation (5) and the Simmons–Smith reaction (1*b*), all proceeding with closure of a three-membered ring. In contrast, however, the recorded *cis* additions of the triene I that yield monocyclic products, viz. diimide reduction, etc., occur predominantly at the *trans* bonds even in the second stage of the addition.[2]

The next problem is concerned with the synthesis of cyclotridecanone (XI) (6) from the triene I via the dihalocarbene monoadducts. Diimide reduction (1*a*) of the triene I gives selectively *cis*-cyclododecene (VII), which has been used as the starting material in the first synthesis. Treatment of VII with dibromocarbene as produced from bromoform and potassium *t*-butoxide gave the adduct VIII*a* as an oil in 70% yield based on the amount of VII consumed. Ring enlargement by the method of Skattebøl (7) resulted in the formation of cyclotrideca-1,2-diene (IX) in 76% yield. The corresponding dichlorocarbene adduct VIII*b* could also be dehalogenated with *n*-butyllithium to give IX, whereas methyllithium proved to be inactive toward VIII*b*. Treatment of the dibromocarbene adduct VIII*a* with sodium methylsulfinyl carbanion (8) in dimethyl sulfoxide gave the allene IX in 46% yield. These samples of the allene IX were found to be contaminated with 10–20% of the acetylenic isomer X,[3] but IX was so easily autoxidized that this could not be isolated in an analytically pure form. The oily product consisting largely of IX was immediately subjected to isomerization caused by potassium *t*-butoxide in dimethyl sulfoxide, to yield cyclotridecyne (X). Other bases such as potassium *t*-butoxide in *t*-butanol, potassium hydroxide in ethanol, methyllithium, and basic alumina failed to effect this isomerization.[4]

The cyclic allene IX showed characteristic infrared absorptions at 1 950 and 870 cm^{-1}, whereas the cycloalkyne X showed no absorption around 2 200 cm^{-1}. Hydration of X by the action of dilute sulfuric acid containing mercuric sulfate gave the desired ketone XI as a crystalline solid, m.p. 26–30°. The yield of XI based on I amounted to about 25%.

[2]*Previous data were summarized in ref. 1b.*
[3]*The analysis was performed by g.l.c. (polyethylene glycol 6000 treated with silver nitrate, He). For acetylene formation as by-products in this kind of reaction, see ref. 7.*
[4]*For allene–acetylene equilibration in cyclic systems, see ref. 9.*

For personal use only.

In the second process, a similar sequence of reactions was applied to the dibromocarbene monoadducts (II*a*, III*a*) of the triene I; cyclotridecadienone (XIV) was obtained in about a 20% yield based on I. Final catalytic reduction of XIV upon palladium–charcoal gave XI in an almost quantitative yield.

Although the yields of XI that were realized were not very high, the ready availability of the starting material I and the simplicity of each preparative step would give the present routes precedence over the known ones (6).

EXPERIMENTAL

All temperatures were uncorrected. Microanalyses were performed at the Elemental Analyses Centre, Kyôto University.

13,13-Dibromo-trans-bicyclo[10.1.0]trideca-cis-4,trans-8-diene (IIa)

To a stirred mixture of I (57.0 g; 0.35 mole), potassium *t*-butoxide (77.5 g; 0.70 mole), and dry *n*-hexane (40 ml) was added freshly distilled bromoform (127 g; 0.50 mole) at −10 to 0° during 4 h under a nitrogen atmosphere. After an additional 5 h of stirring at room temperature, the mixture was treated with water and extracted with methylene chloride. Distillation *in vacuo* gave the unchanged triene I (18 g) and then the dibromocarbene adduct (a mixture of II*a* and III*a*) (58.5 g; 73% yield based on the amount of the triene I

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

consumed) as a viscous oil, b.p. 103–107° at 0.07 mm. Infrared absorptions (neat): 970 s (*trans* double bon d and 700 cm^{-1} (a closely separated twin peak, *cis* double bond).

Anal. Calcd. for $C_{13}H_{18}Br_2$: C, 46.7; H, 5.4. Found: C, 46.8; H, 5.7.

13,13-Dichloro-trans-bicyclo[10.1.0]trideca-cis-4,trans-8-diene (IIb)

To a slurry of potassium *t*-butoxide (33.6 g; 0.30 mole) in the triene I (32.4 g; 0.20 mole) and dry *n*-hexane (30 ml) kept at −5 to 0°, freshly distilled chloroform (36.0 g; 0.30 mole) was added dropwise during 3 h under a nitrogen atmosphere; the mixture was then allowed to stand at room temperature for 20 h. Distillation *in vacuo* gave the unchanged triene I (9.5 g) and the dichlorocarbene monoadduct (a mixture of II*b* and III*b*) (31.5 g; 91% yield based on the amount of I consumed) as a colorless oil, b.p. 115–118° at 1 mm. Infrared absorptions (neat): 970 (*trans* double bond) and 700 cm^{-1} (*cis* double bond).

Anal. Calcd. for $C_{13}H_{18}Cl_2$: C, 63.7; H, 7.4. Found: C, 63.9; H, 7.6.

A mixture of the triene I (8.1 g; 0.05 mole) and dried sodium trichloroacetate (14.8 g; 0.08 mole) in anhydrous diglyme (30 ml) was heated at 80–90° until the evolution of carbon dioxide had ceased. The reaction mixture was treated as usual and distilled *in vacuo* to give the dichlorocarbene adduct (a mixture of II*b* and III*b*) (6.4 g; 83% yield based on the amount of I consumed), b.p. 112–117° at 1 mm, besides the unchanged triene I (3.0 g).

Reduction of the Dihalocarbene Adducts with Sodium in Liquid Ammonia (3)

To a solution of metallic sodium (2.3 g; 0.1 g-atom) in liquid ammonia (80 ml) kept at −60°, an ethereal solution containing the dichlorocarbene monoadduct (a mixture of II*b* and III*b*) (4.9 g; 0.02 mole) was added dropwise during 30 min; the mixture was then stirred for an additional 5 h. After treatment with ammonium hydroxide solution, the mixture was extracted with ether. Distillation *in vacuo* gave a mixture of *cis*- and *trans*-bicyclo[10.1.0]tridecadiene (II*c* and III*c*) (3.1 g; 88% yield), b.p. 110–113° at 10 mm. A similar treatment of the isomeric mixture of the dibromocarbene adducts (II*a* and III*a*) gave the hydrocarbon mixture (II*c* and III*c*) in 86% yield.

The g.l.c. analyses of the cyclopropane hydrocarbons II*c* and III*c* of various origins are given in Table I.

Dehalogenation of the distillation residue of the dihalocarbene monoadducts or of the crude addition products directly without isolation of each component gave a hydrocarbon mixture, which was subjected to g.l.c. analyses. The isomer distributions of the bis-cyclopropane fraction (IV*c*, V*c*) are given in Table I. Traces of the tris-cyclopropane fraction (VI*c*) were definitely detected.

13,13-Dibromo-cis-bicyclo[10.1.0]tridecane (VIIIa)

To a suspension of potassium *t*-butoxide (77.5 g; 0.70 mole) in *cis*-cyclododecene (VII) (1*a*) (57.8 g; 0.35 mole) and dry *n*-hexane (40 ml) cooled at −10°, freshly distilled bromoform (127 g; 0.50 mole) was added dropwise, with stirring, during 4 h; the mixture was then allowed to stand at room temperature for 5 h. The reaction was carried out under a nitrogen atmosphere, and the addition at temperatures below 0°. The reaction mixture was treated with water and extracted with methylene chloride. The combined extracts were washed with 2 *N* hydrochloric acid, sodium bicarbonate solution, and water; dried over calcium chloride; and concentrated *in vacuo*. Distillation of the residue gave unchanged cyclododecene (17.5 g) and the dibromocarbene adduct VIII*a* (59.4 g; 70% yield based on the amount of olefin VII consumed) as a viscous pale-yellow oil, b.p. 110–115° at 0.08 mm.

Anal. Calcd. for $C_{13}H_{22}Br_2$: C, 48.2; H, 6.6. Found: C, 48.4; H, 6.5.

13,13-Dichloro-cis-bicyclo[10.1.0]tridecane (VIIIb)

A suspension of potassium *t*-butoxide (prepared from 6.0 g (0.15 g-atom) of potassium and freed from *t*-butanol) in *cis*-cyclododecene (VII) (24.9 g; 0.15 mole) and *n*-hexane (20 ml) was kept below 10° under nitrogen. To this, chloroform (17.8 g; 0.15 mole) was added dropwise, with stirring, during 3 h. After the reaction mixture was allowed to stand at room temperature for 1 h, it was treated with water and extracted with *n*-hexane. The extracts were combined, washed, dried, and concentrated *in vacuo*. Distillation of the residual oil gave the dichlorocarbene adduct VIII*b* (23.2 g; 81% based on the amount of VII consumed), b.p. 94–98° at 0.1 mm, besides unchanged VII (5.5 g).

Anal. Calcd. for $C_{13}H_{22}Cl_2$: C, 62.7; H, 8.9. Found: C, 62.9; H, 8.9.

Cyclotrideca-1,2-diene (IX) by Debromination of VIIIa with Methyllithium

To a solution of the *gem*-dibromide VIII*a* (67.6 g; 0.20 mole) in anhydrous ether (200 ml) kept below −40° under a nitrogen atmosphere, an ethereal solution of methyllithium (50 ml; 0.20 mole) was added, with stirring, during 3 h. Then the mixture was stirred at room temperature for an additional 3 h. Distillation of the product *in vacuo* gave crude IX (27.0 g; 76% yield), b.p. 83–85° at 3 mm. Infrared absorptions (neat): 1 950 and 870 cm^{-1}. Gas chromatography ($AgNO_3$ – polyethylene glycol 6000, He) showed that this contained ca. 20% of the acetylenic isomer X. The relative retention times of IX and X were 1.00 and 1.25 min, respectively. Microanalyses did not give reproducible results, probably because of the high sensitivity of the products to air.

Cyclotrideca-1,2-diene (IX) by Debromination of VIIIa with Sodium Methylsulfinyl Carbanion[5]

Sodium methylsulfinyl carbanion solution was prepared by dissolving sodium hydride (1.5 g; 0.06 mole)

[5]*This procedure was based on the successful debromination of 9,9-dibromobicyclo[6.1.0]-4-nonene observed by Mr. T. Aratani of this laboratory independently from Professor Gardner's group (8c).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in freshly distilled dimethyl sulfoxide (30 ml) under a nitrogen atmosphere according to Corey and Chaykovsky (*8a*). A solution of the *gem*-dibromide VIII*a* (10.0 g; 0.03 mole) in dimethyl sulfoxide (10 ml) was added dropwise during 30 min with cooling (an ice-water bath), when an exothermic reaction occurred. The reaction mixture was allowed to stand overnight at room temperature, diluted with water, and extracted with several portions of *n*-hexane. The extracts were washed with water until neutral, dried over sodium sulfate, and concentrated *in vacuo*. Distillation of the residual oil gave crude IX of 85% purity (2.4 g; 46% yield), b.p. 84–87° at 3 mm.

Cyclotrideca-1,2-diene (IX) by Dechlorination of VIIIb with n-Butyllithium

To a solution of the dichlorocarbene adduct VIII*b* (6.0 g; 0.02 mole) in anhydrous ether (60 ml) kept at −40° under nitrogen was added an ethereal solution containing *n*-butyllithium (50 ml; 0.04 mole) during 1 h; the mixture was then allowed to stand overnight. The product was purified by passing it through an alumina column, and then distilled to give crude IX (3.2 g; 75% yield), b.p. 83–86° at 3 mm, whose content as estimated by g.l.c. was ca. 83%.

Cyclotridecyne (X)

To a solution of potassium *t*-butoxide (3.3 g; 0.03 mole) in freshly distilled dimethyl sulfoxide (70 ml) was added in one portion the crude IX (5.6 g; 0.03 mole) as obtained above. The reaction mixture was stirred under a nitrogen atmosphere at room temperature for 12 h, diluted with water, and extracted with *n*-hexane. Distillation *in vacuo* gave cyclotridecyne (X) (5.0 g; 89% yield) as a colorless oil, b.p. 84–86° at 3 mm. The absence of infrared absorptions at 1 950 and 870 cm^{-1} indicated complete conversion, which was also confirmed by g.l.c.

Anal. Calcd. for $C_{13}H_{22}$: C, 87.6; H, 12.4. Found: C, 87.5; H, 12.4.

The allene–acetylene interconversion with potassium *t*-butoxide could not be effected in refluxing *t*-butanol.

Cyclotrideca-1,2,cis-6,trans-10-tetraene (XII)

A solution of the *gem*-dibromide II*a* (68.5 g; 0.21 mole) in dry ether (200 ml) was cooled at −30° under nitrogen, and an ethereal solution containing methyllithium (100 ml; 0.42 mole) was added during 3 h. The mixture was stirred at room temperature for an additional 3 h and treated with water. Distillation *in vacuo* gave the crude allene (mainly XII) (21.7 g; 60% yield) as a colorless oil, b.p. 84–85° at 3 mm. Infrared absorptions (neat): 1 950 and 870 (allenic linkage), 960 (*trans* double bond), and 700 cm^{-1} (a doublet, *cis* double bond). Although the allene XII was fairly sensitive to air and could not be obtained in an analytically pure form, gas chromatography indicated the presence of less than 5% impurities. The crude allene was subjected immediately to the following isomerization.

Cyclotrideca-5,9-dien-1-yne (XIII)

To a solution of potassium *t*-butoxide (8.0 g; 0.07 mole) in dimethyl sulfoxide (200 ml) under nitrogen was added the allene XII (8.0 g; 0.05 mole) in one portion; then the mixture was stirred at room temperature for 12 h, poured into water, and extracted with *n*-hexane. Distillation *in vacuo* gave the dienyne XIII (6.2 g; 78%) as a colorless oil, b.p. 84–86° at 3 mm. Complete isomerization was shown by the disappearance of the 1 950 and 870 cm^{-1} bands in the infrared spectrum. Gas–liquid chromatography ($AgNO_3$ – polyethylene glycol 6000, He) gave several peaks, one of which accounted for ca. 70%. The mixture, however, gave correct analyses for XIII. Infrared absorptions (neat) at 970 s (*trans* double bond) and 690 cm^{-1} (*cis* double bond) suggested XIII consisting of mainly the *cis,trans* isomer.

Anal. Calcd. for $C_{13}H_{18}$: C, 89.6; H, 10.4. Found: C, 89.4; H, 10.6.

Prolonged treatment in this medium caused further isomerization to give a complex mixture, the infrared spectrum of which showed a strong new band at 740 cm^{-1} and no absorption in the 960–970 cm^{-1} region.

Cyclotridecadienone (XIV)

To a solution of the acetylenic hydrocarbon XIII (9.2 g; 0.05 mole) in 80% ethanol (150 ml) was added mercuric sulfate (1 g) and a few drops of concentrated sulfuric acid. The mixture was heated at reflux under vigorous stirring for 10 h, cooled, diluted with water, and extracted with ether. Distillation *in vacuo* gave a colorless oil (7.8 g), b.p. 85–100° at 3 mm, which was subjected to chromatography on an alumina column. Elution with *n*-hexane gave unchanged XIII (3.7 g), and elution with a 1:1 mixture of benzene and ether gave cyclotrideca-4,8- (and (or) -5,9-) dienone(s) (3.5 g; 58% yield based on the amount of XIII consumed) as a colorless oil. Redistillation *in vacuo* gave an analytical sample, b.p. 107–110° at 6 mm. Infrared absorptions (neat): 1 720 (ketone), 970 (*trans* double bond), and 690 cm^{-1} (*cis* double bond). Gas–liquid chromatography ($AgNO_3$ – polyethylene glycol 6000, He) gave a broad single peak. These data may suggest that the ketone XIV thus obtained consisted largely of a *cis,trans* dienone.

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.2; H, 10.5. Found: C, 81.5; H, 10.5.

The ketone XIV gave a 2,4-dinitrophenylhydrazone, m.p. 117–118° when crystallized from ethanol.

Anal. Calcd. for $C_{19}H_{24}N_4O_4$: C, 61.3; H, 6.5. Found: C, 61.4; H, 6.6.

Cyclotridecanone (XI) by Hydration of Cyclotridecyne (X)

To a solution of cyclotridecyne (X) (16.6 g; 0.09 mole) in 60% dioxane (200 ml) containing mercuric sulfate (1.0 g) was added a few drops of concentrated sulfuric acid; then the mixture was heated at reflux for 10 h under vigorous stirring. Distillation of the ethereal extracts *in vacuo* gave a colorless oil (14.3 g), b.p.

For personal use only.

80–100° at 3 mm, which was subjected to chromatography on an alumina column. Elution with *n*-hexane gave unchanged X (5.1 g), and then elution with a 1:1 mixture of benzene and ether gave cyclotridecanone (8.2 g; 65% yield based on the amount of X consumed), m.p. 26–30° (lit. (6*d*) m.p. 26–29°). The following derivatives of XI were prepared: oxime, m.p. 102–103° (lit. (6*a*) m.p. 106°); semicarbazone, m.p. 210–211° (lit. (6*a*) m.p. 208°); and 2,4-dinitrophenylhydrazone, m.p. 114–115° (lit. (6*e*) m.p. 118–119°). All gave correct analyses.

The attempted hydration of the allene IX (10) under similar conditions gave the ketone XI in very poor yield.

Cyclotridecanone (XI) by Hydrogenation of XIV

An ethanolic solution of the dienone XIV was shaken with 10% palladium on charcoal in a hydrogen atmosphere at ordinary pressure to give cyclotridecanone XI in a nearly quantitative yield. Identification was established by comparing the infrared spectrum and gas chromatogram with those of the above specimen.

ACKNOWLEDGMENTS

The authors thank Professor K. Sisido for help and encouragement. They are also indebted to Mr. H. Katô for technical assistance.

POLAROGRAPHIC HALF-WAVE POTENTIALS OF SOME 1,4-NAPHTHOQUINONES[1]

D. J. Currie and H. L. Holmes

Chemistry Section, Defence Research Board, Suffield Experimental Station, Ralston, Alberta

Received September 8, 1965

ABSTRACT

The half-wave potentials for the reduction of 103 substituted 1,4-naphthoquinones were measured in 75% v/v aqueous ethanol containing buffer components. In general, if two constants were assigned, one characteristic of monosubstitution and the other characteristic of disubstitution, it was possible, by assuming additivity of the constants, to predict the half-wave potentials of the compounds within the experimental accuracy of the polarographic method.

INTRODUCTION

The effect of substituents on the polarographic half-wave potentials or the oxidation–reduction potentials (1) of substituted 1,4-naphthoquinones has been the subject of several recent papers (2, 3). Our interest in the bacteriostatic activity of substituted 1,4-naphthoquinones as related to half-wave potentials prompted this further investigation, emphasis being placed on the 1,4-naphthoquinones formed when amines and thiols react with the naphthoquinones. At the same time, an attempt was made to find a relationship between structure and half-wave potential for disubstituted 1,4-naphthoquinones.

EXPERIMENTAL

The polarograms of the 1,4-naphthoquinones and related compounds, the preparation and purity of which will be reported elsewhere, were recorded on a Sargent model XV polarograph; the experimental technique was essentially the same as that of Vladimertsev and Stromberg (2). Stock solutions of the naphthoquinones were made up in ethanol, and determinations were made on 25 ml samples of a 75% v/v aqueous ethanolic solution, 8×10^{-4} *M* in the reducible substance, containing buffer components as the supporting electrolyte. Two buffer solutions were used: (*i*) 0.10 *M* acetic acid and 0.10 *M* sodium acetate, and (*ii*) 0.10 *M* ammonium hydroxide and 0.10 *M* ammonium chloride. The pH values of the ethanolic buffers as measured with a glass electrode were 6.60 and 8.70 units, respectively. The half-wave potentials at two pH values measured against a saturated calomel electrode were used to check the change of half-wave potential with pH. The cell resistance with the ethanolic acetic buffer was ~6 800 Ω, and with the ethanolic ammonium buffer ~5 200 Ω. Methylene blue thiocyanate (0.001%) was used as a maximum suppressor. The drop mass, *m*, was 2.68 mg/s and the drop time, *t*, was 3.27 s in both buffers; from these figures $m^{\frac{2}{3}}t^{\frac{1}{6}} = 2.35\ \text{mg}^{\frac{2}{3}}\ \text{s}^{-\frac{1}{2}}$.

RESULTS

The half-wave potentials, $E_{\frac{1}{2}}$, of some 2-substituted and 2,3-disubstituted 1,4-naphthoquinones, of 6-methyl-1,4-naphthoquinones, and of 6,7-dimethyl-1,4-naphthoquinones in both buffers are tabulated in Tables I–III. The half-wave potentials of some related compounds are shown in Table IV. These tables have been placed in The Depository of Unpublished Data.[2] The values are the average of at least two successive determinations on the same sample, and the differences in the two determinations rarely exceeded 5 mV. On different samples the accuracy was $\sim\pm 10$ mV; moreover, $E_{\frac{1}{2}\ \text{acetic buffer}} - E_{\frac{1}{2}\ \text{ammonia buffer}}$ except for the hydroxy derivatives varied by the same amount.

Where duplication of compounds exists, the values of the half-wave potentials obtained by Vladimertsev and Stromberg (2) agree well with those of this work. The diffusion

currents for soluble 1,4-naphthoquinones were somewhat variable, the values lying between 3 and 6 μA. The results were not corrected for the iR drop across the cell,[3] and therefore a combined error of $\sim\pm 25$ mV is placed on the values reported in the tables.

DISCUSSION

The effects of substituents on the half-wave potentials of quinones have been discussed by Zuman (3), and although the theoretical basis for his treatment is well founded, the use of σ constants is of little help in accurately predicting the half-wave potentials of disubstituted 1,4-naphthoquinones. The assignment of shifts of oxidation–reduction potentials, m, for substituents in monosubstituted derivatives was done by Fieser and Fieser (4). An examination of the results obtained in this work revealed that the shifts in the half-wave potentials of disubstituted 1,4-naphthoquinones, $E_{\frac{1}{2}\,XY}$, from that of the unsubstituted 1,4-naphthoquinone, $E_{\frac{1}{2}\,H}$, were not the algebraic sum of the shifts for the substituents in monosubstituted derivatives, i.e. $E_{\frac{1}{2}\,XY} \neq E_{\frac{1}{2}\,H} + m_X + m_Y$. However, it was also observed, for example, that the sum of half the shifts in the half-wave potentials of 2,3-dimethoxy- and 2,3-dimethyl-1,4-naphthoquinone is very close to the shift observed for 2-methyl-3-methoxy-1,4-naphthoquinone. Similarly, the sum of the shifts in the half-wave potentials of 2-methyl-3-*n*-butylamino- and 2-methyl-3-*n*-butylthio-1,4-naphthoquinone minus the shift in the half-wave potential of 2,3-dimethyl-1,4-naphthoquinone is close to the shift observed for 2-*n*-butylamino-3-*n*-butylthio-1,4-naphthoquinone. After a consideration of other such combinations, it was apparent that, by assigning another constant characteristic of disubstitution, d, to a substituent, and by assuming the relationship $E_{\frac{1}{2}\,XY} = E_{\frac{1}{2}\,H} + d_X + d_Y$, the half-wave potentials of disubstituted 1,4-naphthoquinones could be predicted, in general, to within ± 0.025 V, i.e. within experimental error.

The constants for substituents on the benzene ring were assumed to be additive and independent of substituent effects on the quinonoid side of the naphthoquinone, i.e. $E_{\frac{1}{2}} = E_{\frac{1}{2}\,H} + m$ or $\sum d$ (2- or 2- and 3-substituted) + m or $\sum d$ (6- or 6- and 7-substituted), thereby allowing the prediction of the half-wave potentials of 6-methyl- and 6,7-dimethyl-1,4-naphthoquinones. The empirical values of m and d for various substituents are given in Table V. The observed and calculated values of the shifts of half-wave potential with respect to 1,4-naphthoquinone are given in Tables I–III.

A correlation performed on 90 compounds yielded ($E_{\frac{1}{2}\,X}$ or $E_{\frac{1}{2}\,XY}$) $- E_{\frac{1}{2}\,H} = 0.98(m$ or $\sum d) - 1.5$, where $E_{\frac{1}{2}}$, m, and d are expressed in millivolts. The regression coefficient was 0.99, and the standard errors of the estimate and the regression coefficient were 14 and 0.02, respectively.

The necessity for the two constants m and d seems to be due only to neighboring substituent interactions not directly involving, but indirectly affecting, the carbonyl or hydroxy groups.

This type of approach can be extended to the oxidation potentials of 1,4-naphthoquinones with other substituents. Moreover, a cursory examination of a series of 1,4-benzoquinones reveals that, by using m and d, it is possible to predict their oxidation–reduction potentials with reasonable success by assuming that each side of the quinonoid ring can be treated independently as either mono- or di-substituted, e.g. $E_{\frac{1}{2}}$ (2,5,6-trisubstituted) = $E_{\frac{1}{2}\,H} + m$ (2-substituted) + $\sum d$ (5,6-disubstituted). This is in agreement

[3]*The Russian workers (2) did not correct their results for the iR drop across the cell. The correspondence between the standard oxidation–reduction potentials determined by the polarographic method and those determined by the potentiometric method is made worse if such a correction is applied.*

POLAROGRAPHIC HALF-WAVE POTENTIALS OF SOME β-NITROSTYRENES AND RELATED COMPOUNDS[1]

R. F. SILVER AND H. L. HOLMES

Chemistry Section, Defence Research Board, Suffield Experimental Station, Ralston, Alberta

Received September 8, 1965

ABSTRACT

The polarographic half-wave potentials of a number of β-nitrostyrenes, β-nitropropenylbenzenes, and β-nitrobutenylbenzenes have been determined in aqueous ethanolic solution at an apparent pH of 6.54. A linear relationship exists between these values and Hammett sigma constants, but not with their ultraviolet absorption maxima or with their dipole moments.

The polarographic wave of 11 diethyl benzalmalonates, under the same conditions, was masked by the hydrogen wave.

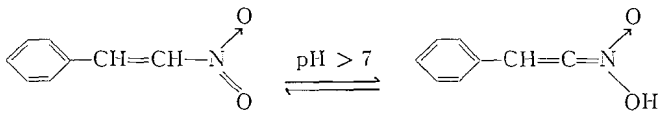
Nitro groups are reducible at the dropping-mercury cathode, and their half-wave potentials depend upon the solvent[2] and upon whether it is an isolated or an aromatic nitro group. Holleck and Jannakoudakis (2) state that the nitro group of β-nitrostyrene shows some properties characteristic of the above two classes.

In an acid medium nitroalkanes exhibit only one polarographic wave, which varies little with pH (−0.75 to −0.89 V over a range of 5 pH units); at pH 4.5 a second wave starts at −1.5 V which is obscured by the hydrogen wave (1). In an alkaline medium the diffusion current of the nitroalkanes falls with time because of equilibration with the non-reducible *aci*-form (1). Reduction of the nitro group at the dropping-mercury electrode is an irreversible, four-electron process which leads to the respective hydroxylamine. The second wave, at more negative potentials, involves the reduction of the alkylhydroxylammonium ion to the alkylammonium ion and is a two-electron process (1).

Aromatic nitro compounds, except for the *o*- and *p*-nitroanilines, the *o*- and *p*-nitrophenols, and the *o*- and *p*-dinitrobenzenes, behave similarly, except that the half-wave potential changes linearly with pH over at least part of the pH scale. At pH < 5 nitrobenzene gives two waves involving four electrons and two electrons to give the respective phenylhydroxylamine and aniline.[3] The exceptions noted above are abnormal, because the resulting phenylhydroxylamine can lose water to give a reducible quinonoid structure (1, 3). Introduction of one or two methyl groups into the benzene ring has little effect upon the half-wave potential of the nitrobenzene unless the two methyl groups are both ortho to the nitro group (see Table II),[4] when the half-wave potential is shifted to more negative values (1). Such effects are noted when the functional group, such as nitro, can undergo a marked mesomerism with the aromatic ring, and when both the functional group and the ortho substituents are bulky (1, 4). The nitro group then should, and does, behave more like an aliphatic nitro group toward polarographic reduction (1). It has been stated (4) that differences in the half-wave potentials of ortho- and para-substituted members of this series give an insight into the nature and extent of certain types of ortho

[1]*Issued as Suffield Technical Paper No. 319, D.R.B. project No. D52-20-20-28.*

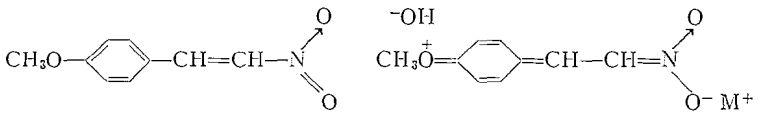
[2]*In 50% ethanol the half-wave potentials of the nitrotoluenes are approximately 0.35 V more negative than when 8% aqueous ethanol is the solvent (1).*



[3]*The nitro group of the 2-nitrofurans and 2-nitrothiophenes behaves similarly (25–28). The order of increasing difficulty of reduction is 2-nitrofuran < 2-nitrothiophene < nitrobenzene (23–25).*

[4]*Tables I and II have been placed in The Depository of Unpublished Data. Photocopies may be obtained, upon request, from: The Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada.*

effects. The half-wave potentials of para-substituted nitrobenzenes appear to bear a linear relationship with Hammett sigma constants (1, 5). Differences in the half-wave potentials of certain ortho- and meta-substituted derivatives have been ascribed to differences in the reduction mechanism rather than to hydrogen bonding (4).



Phenylhydroxylamine is the reduced form of the polarographically reversible system nitrosobenzene $\rightleftharpoons$ phenylhydroxylamine (6–8). The reduction of nitrosobenzene is a two-electron process (6, 7, 9) in which the half-wave potential is dependent upon pH. The shift per pH unit in water is 0.053 V (8) to 0.058 V (7) whereas in ethanol it is 0.0603 V (7). The reduction of an aromatic nitroso group occurs at a much more positive half-wave potential than does an aromatic nitro group (1, 7), and it has been stated (8) that the position of the nitroso group in substituted nitrosobenzenes has no effect upon its half-wave potential.

Between pH 1 and pH 11 β-nitrostyrene is reduced by a four-electron, one-step process, and over the pH range 1–3 a second, two-electron process occurs (2, 11). In analogy with nitrobenzene the half-wave potential of β-nitrostyrene in 10% aqueous methanol varies linearly with pH over the pH range 1–7 (2, 10), and against the saturated calomel electrode can be expressed as $E_{\frac{1}{2}} = -0.023 - 0.063\text{pH}$ (2). Above pH 7 the half-wave potential is constant at about −0.46 V. Holleck and Jannakoudakis (2) considered that the four-electron process led to β-hydroxylaminostyrene and the two-electron process to β-aminostyrene, whereas Masui and Sayo (10, 11) have advanced evidence that the reduction product of the four-electron process was the oxime of phenylacetaldehyde, a product isolated also from the reverse lithium aluminium hydride reduction of β-nitrostyrene (12). The two-electron process is considered to be the reduction of the derived oxime to β-hydroxylaminoethylbenzene (10). The observation that oximes are reduced directly to an amine (13) by a four-electron process (13–17) would appear to negate the process advanced by Masui and Sayo for the reduction of β-nitrostyrene. At pH 7 the waves for β-nitrostyrene decreased with time and three new ones appeared. These new waves were identified as waves of a polymer (−0.7 V against the saturated calomel electrode), of nitromethane (−0.9 V), and of benzaldehyde (−1.4 V) (2). Besides these, it is claimed that the non-reducible *aci*-form (II) of nitrostyrene (I) is formed in an alkaline medium (2).

I II

The energy required to form a cumulated system of double bonds as in structure II must cast some doubt on such a structure. The non-reducible form of 4-methoxy-β-nitrostyrene (III) might better be represented by structure IV.

III IV

If the non-reducible *aci*-form is represented by IV, then it would appear that electron-donating groups in the ortho and para positions should, and do, make reduction more difficult. In fact, Platford and Kerr (18) have shown that, when potassium chloride (pH 7.2) and tetramethylammonium bromide (pH 7.5) are the electrolytes, the half-wave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

potentials for two of the waves of the substituted β-nitrostyrenes vary linearly with Hammett sigma constants. In the present work, a buffered acid medium (pH 6.54) was used and only one wave appears. Except for the aryl nitro derivatives, the half-wave potentials of the β-nitrostyrenes, the β-nitropropenylbenzenes, and the β-nitrobutenylbenzenes vary linearly with sigma constants (20, 21).

One difference appears in the half-wave potentials of the ortho- and para-substituted β-nitropropenylbenzenes and β-nitrobutenylbenzenes on the one hand, and the β-nitrostyrenes on the other. Except for the small fluoro group, the half-wave potentials of the C_2-substituted β-nitropropenylbenzenes are considerably more negative than the C_4-substituted analogues. The reverse is true for the β-nitrostyrenes. This may reflect a certain degree of interference between the ortho substituent and the beta methyl group in the β-nitropropenylbenzenes. This is particularly evident with the 2,4- and 2,6-dichloro derivatives of β-nitrostyrene and β-nitropropenylbenzene. Similar effects are also present to a lesser extent in the β-nitrobutenylbenzenes.

Since the ultraviolet absorption maxima for the β-nitrostyrenes and β-nitropropenylbenzenes do not bear a linear relationship to Hammett sigma constants,[5] then a linear relationship between polarographic half-wave potentials and ultraviolet absorption maxima is not to be expected. Indeed, no linear relationship was observed. This agrees with the observation of Wheeler and Covarrubias (19) that no simple relationship exists between these two properties for the substituted cinnamic acids. The same appears to be true when the half-wave potentials of the β-nitrostyrenes and β-nitropropenylbenzenes are plotted against their dipole moments (22).

The half-wave potentials of the nitrobenzenes (Table II) are more negative than those of their vinylogs (Table I). Also the half-wave potential of β-nitroethylbenzene is much more negative than that of β-nitrostyrene. The identical values for the half-wave potentials of β-nitrostyrene dibromide and β-bromo-β-nitrostyrene suggest that the former is readily converted into the latter in the acetate buffer. Because of the greater participation of a furyl group in conjugation over that of a phenyl group, the half-wave potential of 2-(2′-nitrovinyl)-furan should be, and is, more negative than that of β-nitrostyrene (10). In fact, the half-wave potential of 2-(2′-nitrovinyl)-furan is identical with that of 4-methoxy-β-nitrostyrene. The value for 9-nitromethylenefluorene is surprisingly low.

The polarographic reduction of diethyl benzalmalonates in a buffered aqueous ethanolic solution has already been studied (29, 30). Under the conditions used for the β-nitrostyrenes it is found that the polarographic wave is masked by the hydrogen wave.

EXPERIMENTAL

The polarograms of the β-nitrostyrenes, β-nitropropenylbenzenes, β-nitrobutenylbenzenes, and diethyl benzalmalonates were recorded in a Sargent model XV polarograph and against a saturated calomel electrode. The compound (5×10^{-5} mole) was dissolved in 40 ml of ethanol, and to 16 ml of this solution was added 6.25 ml of sodium acetate – acetic acid buffer (pH 4.67) and 0.25 ml of 0.01% ethanolic methylene blue solution. The solution, when diluted to 25 ml with ethanol, had an apparent pH of 6.54 against a glass electrode.

The solution was deaerated by bubbling nitrogen through it for 10 min before the polarogram was recorded at 25 °C. A second polarogram was recorded on the same solution after a second 10 min sweep with nitrogen. The half-wave potentials recorded in Tables I and II are the averages of values obtained from the two polarograms. The half-wave potentials listed in Tables I and II are accurate to ±0.004 V.

Under the conditions employed here, the polarograms of the diethyl benzalmalonates were masked by the hydrogen wave and no half-wave potentials could be determined. Multiwave polarograms were obtained for the β-nitrostyrenes and their β-alkyl homologues when they contained an aryl nitro group. The additional half-wave potentials are listed in parentheses in Tables I and II.[4]

ABSTRACT

The concept of additive constants to predict the partition coefficient of a compound has been developed and applied to 244 compounds. Some of the limitations of such a concept are discussed.

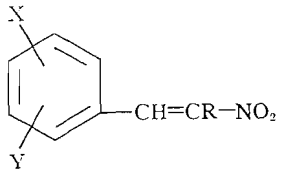
INTRODUCTION

In a series of recent papers, Fujita, Iwasa, and Hansch (1–3) have developed a new substituent constant, π, derived from partition coefficients. They used as the reference system 1-octanol–water, a system which, although useful in correlating biological activity with chemical constitution, is not altogether satisfactory in assessing the effects of very polar groupings in systems with a less-polar phase. The constant π was defined by these authors as $\pi = \log K_X - \log K_H$, where K_H is the partition coefficient of benzene or a monosubstituted benzene between two solvents, and K_X is that for a derivative. Our results indicate that values of π can be given more general significance and can be used to predict within an order of magnitude the partition coefficients of a variety of different compounds. Although no attempt was made in this work to examine the effect of the electronic environment of the same grouping in different compounds, an attempt was made to deal with neighboring group effects. An empirical approach has been used throughout, and therefore, like the Hammett σ constants, succeeding determinations of partition coefficients may change the values of π reported here.

EXPERIMENTAL

The concentrations of the compounds partitioned, the preparation and purity of which will be reported elsewhere, were determined on a Cary model 15 spectrophotometer. The solvents used were Fisher spectranalyzed cyclohexane, Fisher certified reagent 1-octanol, and distilled water. When the two phases were 1-octanol and water, the 1-octanol was saturated with distilled water, and the distilled water was saturated with 1-octanol. When cyclohexane and water were used, no prior equilibration was felt to be necessary. The volume ratios of the two phases were 1:50, 1:1, or 50:1 (organic phase : aqueous phase), and were chosen so that, in general, there was a measurable difference in the optical density of the solution (initially 10^{-3} to 10^{-4} M in the compound) before and after partitioning. Only the concentration of the sample in one phase was measured, this phase being the one which easily dissolved the compound; the concentration in the other phase was calculated by difference.

The partition coefficients were calculated from the expression $K = C_{\text{organic phase}}/C_{\text{water}}$ and the compounds were assumed to be neither associated nor dissociated in either phase. Each determination was done at least twice, the phases remaining in contact for 10 min and 30 min, with periods of shaking of 10 min and 15 min, respectively. The difference between the two log K values rarely exceeded 0.06 log unit, and the average value of these determinations is recorded. The temperature at which partitioning was done was 25 $\pm$ 5 °C.



RESULTS

Table I gives the logarithm of the partition coefficients in the cyclohexane–water system of 36 β-nitrostyrenes, 40 β-nitropropenylbenzenes, and 20 β-nitrobutenylbenzenes. The partition coefficients of 33 compounds more or less related to the nitrostyrenes, and the partition coefficients of 86 substituted 1,4-naphthoquinones are tabulated in Tables II and

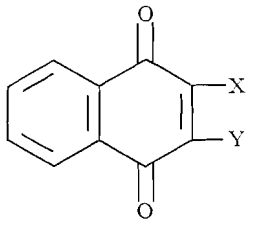
III, respectively. The effect of increasing the length of an alkyl chain on the partition coefficient is shown in Table IV (26 compounds).

In addition to the results given above, the partition coefficients of 41 of the compounds were measured in the 1-octanol–water system, and the results are given in Table V.

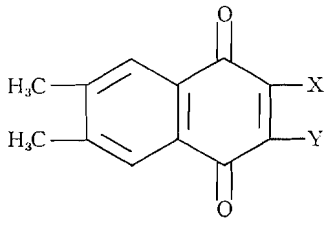
DISCUSSION

The System Cyclohexane–Water

The assumption was made that the logarithm of the partition coefficient of any compound could be expressed as the algebraic sum of the π values of the component groupings of the molecule (eq. [1]).



$$[1] \qquad \log K = m \sum \pi + b$$



Our results were empirically fitted to this expression with $m = 1$ and $b = -1.30$, and the self-consistent π values of the component groupings that were derived are given in Table VI. This table made possible the calculation of the partition coefficient of many of the compounds (see example 1). It was soon apparent, however, that when two polar groupings were attached to the same carbon atom, or to adjacent carbon atoms, the calculated values of the partition coefficients did not agree with the measured values. To obviate this, an

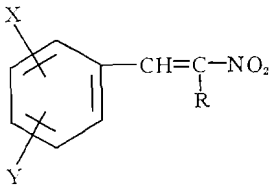
interaction parameter, π interaction, was assigned, where possible, to each polar group and was used in the expression shown in eq. [2].

$$[2] \qquad \log K = \sum \pi + \sum \pi \text{ interaction} - 1.30$$

The assumption was made that each interacting group could be assigned its own constant, i.e. that

$$\pi \text{ interaction}_{CXY} = \pi \text{ interaction}_{CXCY} = \pi \text{ interaction}_X + \pi \text{ interaction}_Y.$$

The use of eq. [2] is demonstrated in example 2.



The principle of additivity of π values was applied to the π values of several classes of functional groupings, i.e. it was possible to derive generalized π constants for the groupings OR, C(O)R, C(O)OR, OC(O)R, SR, NHR, and NR_2 where R = alkyl or aryl. The application of this concept is treated in examples 3 and 4. When R = hydrogen, the measured log K values were understandably different from those predicted by the generalized constants, and appropriate constants were defined for the $—NH_2$ and —OH functions. The reaction of water with these groupings to form $—NH_3^+$ and $—O^-$ is expected to nullify the use of the π values reported here, i.e. for the compounds 2-methyl-3-hydroxy- and 2,6,7-trimethyl-3-hydroxy-1,4-naphthoquinone. The same is true for the functions RNH— and R_2N— and the species RNH_2^+— and R_2NH^+—, i.e. for dibenzylamine.

*R = alkyl or aryl.
†These are bifunctional groups attached in the positions indicated between the two columns.
‡In compounds containing the structure C_6H_5X and $C_6H_5CH_2X$ where $X \neq$ alkyl and where, in addition, no alkyl groups are directly attached to the ring, π_{phenyl} = +3.65 and +3.00, respectively.

1,4-Naphthoquinone presented special difficulties in the choice of component groups, and it was decided to give this compound its own π value of +2.50. The interaction parameter for the carbonyl groups in the naphthoquinone series was assumed to be zero; with a few notable exceptions, e.g. 2-acetamido-1,4-naphthoquinone, this assumption appeared to be justified. It is recognized, however, that our method of calculation of the π values may partially have obscured this interaction. A deviation from the additivity of π interaction values for X and Y might be expected in systems in which three or more groups are involved, e.g. —CXYZ, —CX—CYZ, and —CXCYCZ— (see, however, example 5).

Compounds of the form  were given a π value of −0.15, and again no attempt was made to separate the components. The compound in which R = H was treated separately and given a π value of −1.25.

The gross agreement between our results and those of Fujita, Iwasa, and Hansch implies that the π values derived in this work for compounds of the form $XC_6H_4CH{=}C{=}$ would apply equally well to compounds of the form $XC_6H_4CH_2$— or XC_6H_5. A comparison of the logarithm of the partition coefficients of benzene, monosubstituted benzenes, and benzyl derivatives with the calculated values indicated that a more positive π value for the phenyl group in these compounds would be more appropriate. Therefore, in compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

containing the structure C_6H_5X and $C_6H_5CH_2X$ where X $\neq$ alkyl and where, in addition, no alkyl groups are directly substituted on the phenyl ring, different values of π_{phenyl} were used. The logarithms of the partition coefficients of benzene (+2.36), phenol (−0.85), aniline (+0.01), nitrobenzene (+1.69), benzonitrile (+1.15), and ethylbenzoate (+1.40) in cyclohexane–water are accommodated by $\pi_{phenyl} = +3.65$. The values for phenylacetonitrile (+1.31), ethyl phenylacetate (+2.40), and some compounds in Table IV are accommodated by $\pi_{phenyl} = +3.00$. This effect is also present to an extent in the 6-methyl- and 6,7-dimethyl-1,4-naphthoquinones. In these two series, the calculated values were derived from the expression $\pi_{1,4\text{-naphthoquinone}} + \pi_{methyl}$ (or $2\pi_{methyl}$) − 1.30.

The π value for benzene, expressed as $6\pi_{methyl} - 12\pi_{hydrogen} - 1.30 = +2.60$, is even more positive than that indicated by the measured value of log K; therefore, since the logarithms of the partition coefficients of hydrocinnamonitrile (+1.35), ethyl hydrocinnamate (+3.11), and other examples in Table IV show that unsaturation has little effect on the partition coefficient, a term involving a different neighboring group effect has been incorporated in π_{phenyl}. This effect, which gives rise to different values of π_{phenyl} in compounds of the form $C_6H_5(CH_2)_nX$, is likely to be associated with the ease of solvation, and therefore the flexibility of the aralkyl system as a whole. The value of the partition coefficient of 4-nitro-5-phenyl-1-cyclohexene and the values of $\pi_{C_4H_4}$ for naphthalene derivatives are in accord with this explanation. The partition coefficient of vitamin K_1 is much less than the estimated value, and in solution the long hydrocarbon chain is flexible enough to blanket some of the functional groups of the molecule. Because of insufficient data on related compounds, no estimates were made of the $\sum \pi - 1.30$ values of phenanthrenequinone or 2,6,7-trimethyl-3-anilino-4-phenylimino-1-naphthoquinone.

A correlation yielding $\log K = 0.907(\sum \pi - 1.30) + 0.07$ was performed on 223 compounds, excluding those log K values expressed, for example, as $\geqslant +4.4$ and omitting dibenzylamine, 2-methyl-3-hydroxy-1,4-naphthoquinone, 2,6,7-trimethyl-3-hydroxy-1,4-naphthoquinone, vitamin K_1, and those compounds for which no π values were calculated. The regression coefficient was 0.95, and the standard errors of the estimate and of the regression coefficient were 0.50 and 0.02, respectively. Although an examination of Table VI indicates that, in general, the π values for a given substituent on an alkyl or alkenyl chain or in any position on a phenyl ring are for all practical purposes the same, nevertheless the inequalities which are apparent indicate that the electronic environment of a substituent cannot be ignored completely.

The System 1-Octanol–Water

The π values derived for the cyclohexane–water system were of limited value in predicting the partition coefficients of compounds in the 1-octanol–water system. A comparison of the π values of Fujita, Iwasa, and Hansch (2) with those derived in this work shows that the agreement is excellent for all but the polar groups. It is apparent, therefore, that either different parameters for polar groups have to be used for other solvent systems (the 1-octanol–water π values of Fujita, Iwasa, and Hansch were partially successful in correlating our data in this system without the use of interaction parameters), or a linear relationship has to be scrapped in favor of a continuous nonlinear one. The latter is perhaps more convenient, since other solvent pairs are likely to be investigated.

Examples

(1) 2-Chloro-β-nitropropenylbenzene

$\log K = \sum \pi - 1.30$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$= \sum (3\pi_{\text{methyl}} + \pi_{\text{phenyl}} + \pi_{\text{nitro}} + \pi_{o\text{-chloro}} - 5\pi_{\text{hydrogen}}) - 1.30$$
$$= 3(+0.65) + 2.75 - 0.95 + 0.80 - 5(0) - 1.30$$
$$= +3.25 \text{ (calculated)}.$$

The measured value of K gives a value of $\log K = +3.31$.

(2) 4-Hydroxy-3-methoxybenzalmalononitrile

$$\log K = \sum \pi + \sum \pi \text{ interaction} - 1.30$$
$$= \sum (2\pi_{\text{methyl}} + 2\pi_{\text{cyano}} + \pi_{\text{phenyl}} + \pi_{p\text{-hydroxy}} + \pi_{m\text{-methoxy}} - 7\pi_{\text{hydrogen}}) + \sum (\pi \text{ interaction}_{\text{hydroxy}} + \pi \text{ interaction}_{\text{methoxy}} + 2\pi \text{ interaction}_{\text{cyano}}) - 1.30$$
$$= 2(+0.65) + 2(-1.25) + 2.75 - 3.50 + 0.20 - 7(0) + 2.05 - 0.25 + 2(+0.75) - 1.30$$
$$= +0.25 \text{ (calculated)}.$$

The measured value of K gives a value of $\log K = +0.30$.

(3) n-Butylamino Group

$$\pi_{n\text{-butylamino}} = \pi_{\text{NHR}} + 4\pi_{\text{methyl}} - 3\pi_{\text{hydrogen}}$$
$$= -1.40 + 4(+0.65) - 3(0)$$
$$= +1.20.$$

(4) Furfuryl Group

$$\pi_{\text{furfuryl}} = \pi_{\text{OR}} + 4\pi_{\text{methyl}} - 8\pi_{\text{hydrogen}}$$
$$= -0.50 + 4(+0.65) - 8(0)$$
$$= +2.10.$$

(5) Ethyl α-Carbethoxy-β-anilino-β-phenylpropionate

$$\log K = \sum \pi + \sum \pi \text{ interaction} - 1.30$$
$$= 6\pi_{\text{methyl}} + 2\pi_{\text{C(O)OR}} + 2\pi_{\text{phenyl}} + \pi_{\text{NHR}} - 6\pi_{\text{hydrogen}} + 2\pi \text{ interaction}_{\text{C(O)OR}} + \pi \text{ interaction}_{\text{NHR}} - 1.30$$
$$= 6(+0.65) + 2(-0.80) + 2(+2.75) - 1.40 - 6(0) + 2(-0.15) - 0.85 - 1.30$$
$$= +3.95 \text{ (calculated)}.$$

The measured value of K gives a value of $\log K = +4.22$.

ACKNOWLEDGMENTS

The authors thank Dr. G. Feniak for supplying samples of all the compounds in Table IV with the exception of benzene and the monoalkylbenzenes, and Dr. J. B. Reesor for his suggestions concerning the apparent differences in π_{phenyl} for aryl derivatives. Mrs. A. Linderman assisted in the measurement of the partition coefficients, and Mr. D. Park and Mr. F. McClusky assisted with the computations.

THE SPECIFICITY OF HYDROGEN BOND FORMATION BETWEEN DERIVATIVES OF NUCLEIC ACID BASES AND SOME ANALOGUES[1]

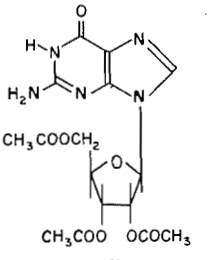
ABSTRACT

Hydrogen bonding between pairs of derivatives of the base constituents of nucleic acids and their analogues has been studied in chloroform solution by infrared spectrophotometry. The strongest interactions occur between derivatives of guanine and cytosine. The introduction of the additional ring nitrogen atom in the pharmacologically active 5-azacytosine and 6-azacytosine derivatives does not change the complexing behavior. The positions of the N—H stretching bands in the infared spectra indicate that these complexes have a structure similar to that of the complexes formed between the corresponding pairs of bases in the naturally occurring desoxyribonucleic acid chain.

INTRODUCTION

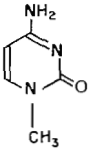
The stability of double-stranded nucleic acids depends on the interplay of van der Waals and electrostatic interactions and on selective hydrogen bonding between specific pairs of purine and pyrimidine base units. There is considerable interest in the incorporation of other bases into nucleic acids; to understand the biochemical and pharmacological action of these groups, means must be devised to distinguish among the different types of stabilizing forces. It is particularly important to isolate the stabilizing effects of specific hydrogen bonding; this may be done by examining model structures in which these forces may be expected to predominate.

In proteins, the ability of amide–amide hydrogen bonds to stabilize specific conformations of peptides has been demonstrated by studies in nonpolar solvents (1, 2); the same methods can be applied to nucleic acids. Although the overall environment of the complexing groups in a nonpolar solvent differs from that in a biologically active system, the more immediate environment of the hydrogen bonds is not necessarily so different; in aqueous media the structurally functional hydrogen bonds tend to be shielded from surrounding water molecules by the skeletal structure.



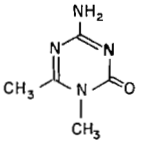
In nucleic acids, interactions between the stacked base groups not only shield the hydrogen bonds, but also actively stabilize the structures. Ts'o *et al.* (3) have shown that the attractions between the stacked base units can be studied in dilute aqueous solution, where the hydrogen bonding between bases is least effective. Conversely, the hydrogen bonding forces should dominate in nonpolar media.

The insolubility of the free bases, and of their simpler derivatives and analogues, restricts studies of this kind. Krackov *et al.* (4), in a search for more soluble model substances, used 2-pyridone and its sulfur and selenium analogues to investigate specific hydrogen bonding in benzene and dioxane solutions. They were able to show that specific complexing did occur in these compounds, and although the analogy with the natural



[1]*Issued as N.R.C. No. 8904.*
[2]*National Research Council Postdoctorate Fellow.*

nucleoside bases is somewhat remote, their results lend support to the conventional picture of hydrogen bond stabilization in nucleic acid systems. More recently, while our own work was in progress, Hamlin *et al.* (5) have shown spectroscopically that complex formation occurs between 9-ethyladenine and 1-cyclohexyluracil in deuteriochloroform solution.



In this paper we demonstrate specific hydrogen bonding between 2′,3′,5′-tri-*O*-acetylguanosine (I) and 1-methylcytosine (II) in chloroform. The introduction of an additional nitrogen atom into the cytosine ring to form 5-aza- and 6-aza-cytosine derivatives is of considerable interest, since these compounds have been shown to possess cancerostatic and bacteriostatic activity (6, 7). We have been able to show that derivatives of these bases (III, IV) complex specifically with 2′,3′,5′-tri-*O*-acetylguanosine (I), and that the complexes have a structure similar to that of the complexes formed between I and II.

EXPERIMENTAL

The preparation of the substances I–VIII used in this investigation has been described (Table I). Complex formation was detected by infrared spectrophotometry with 2 cm long, brass-walled cells having sodium chloride windows, thermostatted at 32°. The spectra were measured over the range 3 570 – 3 330 cm^{-1}, limited by the chloroform cutoff. A Perkin–Elmer model 521 spectrophotometer was used, with the wavenumber scale calibrated against ammonia vapor (8) and the transmittance scale checked with rotating sectors. The chloroform solvent was freed from antioxidants and dried by shaking with phosphorus pentoxide followed by distillation. Chloroform prepared in this manner is unstable and develops a band at 3 486 cm^{-1}, presumably by photolysis in the spectrometer beam or catalysis from the metal cell walls. Solutions were prepared by boiling the solvent and solute together under reflux, and residual traces of water were removed by isothermal distillation. Molal concentrations in the range 1.2×10^{-4} to 2.5×10^{-4} *m* were employed. The solubility of I is less than 1.2×10^{-4} *m*, at 25°, but supersaturated solutions were readily obtained. The solubility of II is also very low and its solutions are light sensitive, resulting in the deposition of a precipitate which is probably a hydrochloride. This can be avoided by careful handling of the solution and the use of freshly prepared chloroform.

RESULTS

The solutions of the individual substances exhibited the absorption bands listed in Table I, which are typical of the N—H stretching vibrations (9, 11). In compounds II–VIII these bands were narrow; their peak intensity – concentration dependence followed

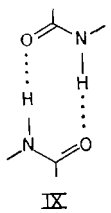

TABLE I

Band positions of N—H stretching vibrations (chloroform solutions)

Substance	ν_{max} (cm^{-1})	Method of preparation
I	3 510, 3 408	Ref. 23
II	3 531, 3 418	Ref. 24
III	3 541, 3 423	Ref. 25
IV	3 521, 3 405	Ref. 26

Beer's law within the accuracy of the measurements. This excluded any significant degree of self-association over the concentration range examined. The spectrum of I did show slight asymmetry on the low wavenumber side of both bands at room temperature, but

IX

the peak absorbances remained linearly dependent on the concentration over the accessible range (7.3×10^{-5} to 2.2×10^{-4} *m*). Complexing through hydrogen bonding to the N—H groups of primary amines would be expected to produce a new band within the measured wavenumber range. Complexes not involving primary amino groups, such as the dimerization V → IX, would yield new bands outside the measured range, but this should be accompanied by the disappearance or diminution of the bands of free species. It is known that such complexes are only formed at concentrations higher by several orders of magnitude than those used in our experiments (5, 10).

The spectra of binary solutions of I–V, I–VI, I–VII, II–V, II–VI, II–VII, II–VIII, IV–VIII, V–VI, V–VII, and VI–VII were examined in varied proportions at a total concentration of 1.5×10^{-4} *m*, and exhibited only the bands of the monomeric species. The spectra of binary solutions of I–II, I–III, and I–IV, however, when measured in the same concentration range, each exhibited one prominent new band at 3 489, 3 488, and 3 472 cm^{-1}, respectively. The system I–III was studied over the temperature range 30–45°, and the band showed reversible intensity changes typical of an equilibrium system. It is inferred that the new band is associated with the spectrum of a complex, and is the higher N—H stretching vibration of a hydrogen-bonded primary amine group, the lower component of which is obscured by chloroform absorption (11). Analysis of the band intensities showed that, within the limits of experimental precision, only 1:1 complexes are formed. The spectral changes for the I–II system are illustrated in Fig. 1, and the continuous variation graph (12) for the I–IV pair is shown in Fig. 2. The corresponding spectra and graphs for the other pairs are qualitatively similar. Since the intensity of the bands associ-

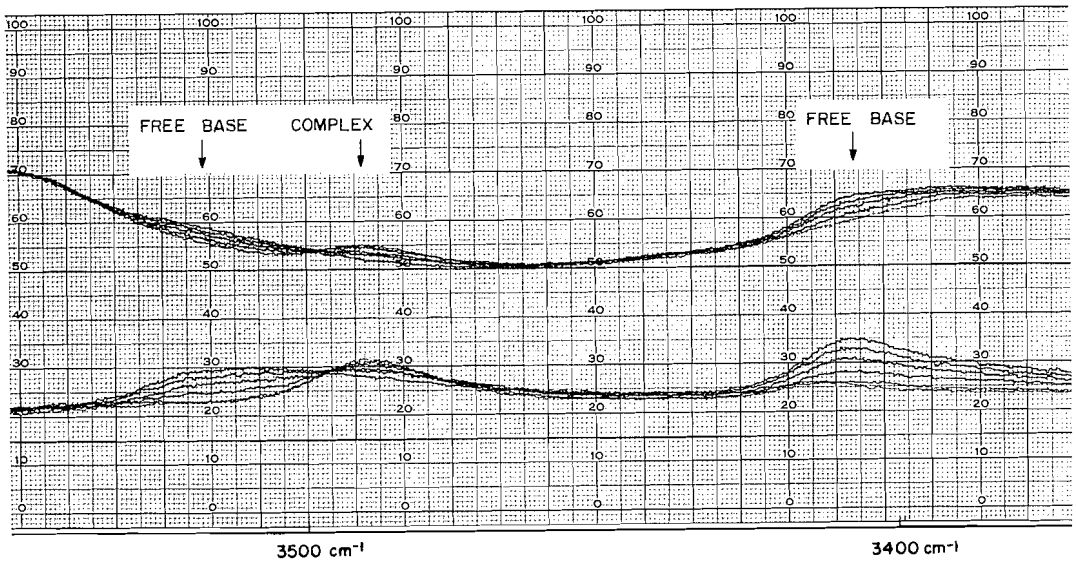

FIG. 1. Infrared spectra in chloroform solution. Formation of complex between guanine and cytosine derivatives (I–II). Upper spectra obtained without compensation; lower spectra compensated for chloroform absorption. ated with the free amino groups of both components diminishes on complex formation, it is presumed that both amino groups participate in complex formation. The instability of the solutions prevented an accurate evaluation of the equilibrium constants, but the analysis by the continuous variation method suggested values of the order of 10^5 l $mole^{-1}$ for the equilibrium constant of the I–II system, and a somewhat lower value for the I–IV system. Under the conditions of our experiments we should have been able to observe complex formation, provided the equilibrium constant was not less than 10^4 l $mole^{-1}$. These findings are consistent with those of Hamlin *et al.* (5), who reported that the equilibrium constant for complex formation between 9-ethyladenine and 1-cyclohexyluracil is of the order of 10^3. In our experiments the system most closely corresponding to this is V–VII, in which the cyclohexyl group of Hamlin's uracil derivative is replaced by 2′,3′,5′-tri-*O*-acetylribose; as stated above, we failed to detect complex formation under our experimental

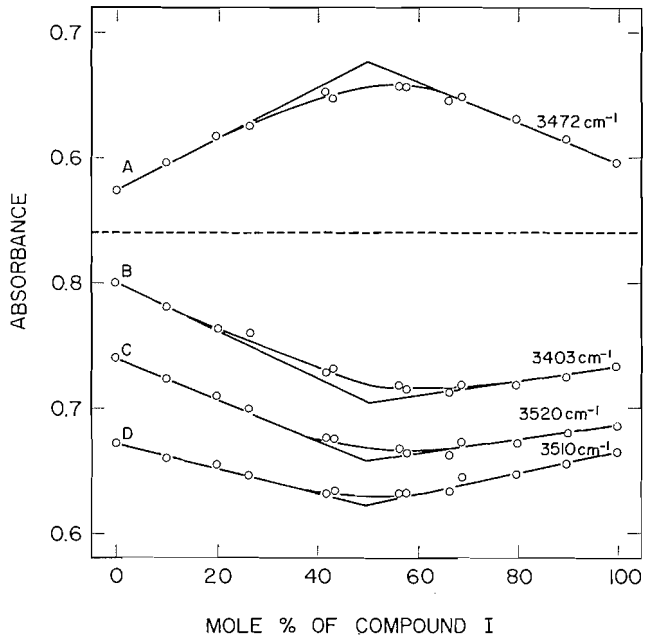

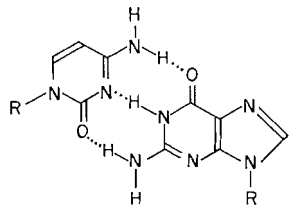

FIG. 2. Continuous variation graph for the I–IV mixture. The absorbance values are for measurements obtained without compensation. Total molality 2.5×10^{-4}.

conditions for this system, which would indicate that the equilibrium constant must be less than 10^4.

DISCUSSION

Since the amino groups of both the guanine and cytosine moieties are involved in the guanine–cytosine type complexes (I–II, II–III, and I–IV), these would appear to have structure X as in desoxyribonucleic acid. This mode of association is apparently very

X

stable, and has been shown to occur in crystalline complexes modelled on the guanine–cytosine base pair (13–15). Studies on polynucleotides (16) indicate that 2:1 complexing can also occur, but this is unlikely at the high dilutions we used; in no case did we observe any evidence for it.

Equilibrium constants of the order of 10^5 l mole^{-1} indicate that the structural stability of these complexes is remarkably high. Three hydrogen bonds are formed per pair, and the presence of all three seems to be essential, since replacement of the guanosine derivative (I) by the corresponding inosine derivative (VIII) reduced the stability of the complex below our limit of detection. The extremely high stability of the guanine–cytosine type

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

complexes may be illustrated by the fact that the equilibrium constant for simple dimeric association of the amide group in ϵ-caprolactam is 1.5 l mole^{-1} (1); for complex formation between aniline and dimethylacetamide an equilibrium constant of 6.0 l mole^{-1} has been reported (17). Substitution in the ring system of complexing pairs can induce large changes in other physical behavior: thus aza substitution at position 6 in cytidine lowers the basicity by a factor of 10 (18); nevertheless, the complexing facility remains virtually unchanged.

This evidence for the high stability of guanine–cytosine pairs, as contrasted with adenine–uracil or adenine–thymine pairs, is consistent with the generally accepted view, based on experimental studies of nucleic acids and on quantum mechanical calculations (19). One might infer from our results that the aza analogues should be incorporated extensively into nucleic acids, but this is not supported by experiment. 6-Azacytidine is known to inhibit enzyme reactions that precede the nucleic acid synthesis (6), and the ability of 5-azacytidine to be incorporated is partially concealed by its rapid hydrolysis (20–22). Nevertheless, we see that 5-azacytidine type substances do exhibit a specificity to complex with guanine; this offers some support for the hypothesis (20) that the cancerostatic and bacteriostatic actions of 5-azacytidine involve modification of the nucleic acid structure. This might be brought about by its hydrolysis subsequent to its incorporation into the nucleic acid chain. Lastly, it must be remembered that the formation of specific hydrogen bonds is only one factor determining nucleic acid stability, and differences in the interactions between adjacent stacked base groups must also be considered.

STRUCTURAL COMPONENTS IN METHYL VINYL SULFONE MODIFIED COTTON CELLULOSE[1]

S. P. ROWLAND, V. O. CIRINO, AND A. L. BULLOCK

Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, United States Department of Agriculture, New Orleans, Louisiana

Received January 5, 1966

ABSTRACT

Methylsulfonylethyl cellulose was prepared at a low degree of substitution (0.11), which is conventional for the chemical modification of cotton, by the Michael addition of methyl vinyl sulfone to cotton fabric. The distribution of substituents in the anhydroglucose units was determined by hydrolysis of the molecular chain to glucose units, selective concentration of the substituted glucose components, gas–liquid chromatographic analyses of the methylsulfonylethylglucoses, and comparison with authentic samples of 2-*O*-, 3-*O*-, and 6-*O*-methylsulfonylethylglucoses in the form of trimethylsilyl ethers. The validity of each of these steps for quantitative analyses has been examined. The ratio of the 2-*O*-, 3-*O*-, and 6-*O*-monomethylsulfonylethylglucoses was found to be 0.20:0.03:1.0. No evidence was found for the presence of di- or tri-substituted glucoses.

INTRODUCTION

The sites of reaction and the distributions of substituents on the 2-*O*, 3-*O*-, and 6-*O*-positions of the anhydroglucose units of cellulose have been well characterized for a number of etherification reactions, primarily methylation (1, 2), ethylation (3), hydroxyethylation (4), carboxymethylation (5), and carbamoylethylation (6). However, aside from studies of trimethylolmelamine-treated (7) and divinyl sulfone treated cottons (8), etherifications which are of interest in the chemical modification and cross-linking of cotton cellulose have received little attention, and in neither of these cases has the distribution of substituents been delineated.

Unambiguous characterizations of the structural components of chemically modified celluloses depend upon molecular degradation of the polymer to glucose units, quantitative recovery of the components, and identification of the modified glucoses. The direct approach to identification of the structural components, which has been applied very successfully by Croon and co-workers (1–5) for celluloses modified to a degree of substitution in the range of 0.5–1 or higher, becomes more demanding when applied to chemically modified cottons for which the cross-linking or modifying agent seldom exceeds 10% of the composition or an apparent average degree of substitution of 0.15.

This paper describes the substituent group distribution resulting from the base-catalyzed Michael addition reaction of methyl vinyl sulfone with cotton cellulose under conditions approximating those for cross-linking cotton with divinyl sulfone. Special attention is devoted to the development of techniques having a degree of general applicability for the facile characterization of chemically modified cottons, and to the verification of the quantitative validity of these techniques. Gas–liquid chromatography has been employed extensively throughout this study.

EXPERIMENTAL

Materials

The cotton cellulose was in the form of desized, scoured, bleached 80 × 80 print cloth weighing 3.3 oz./yd. Methyl vinyl sulfone was obtained from K and K Laboratories, Incorporated,[2] β-cellobiose (white label

[1]*Presented in part before the Joint Chromatography Symposium of the Division of Cellulose, Wood, and Fiber Chemistry and the Division of Carbohydrate Chemistry at the winter meeting of the American Chemical Society, Phoenix, Arizona, January 1966.*

grade) from Eastman Kodak Company, α-glucose from the National Bureau of Standards, trimethylchlorosilane from General Electric Company, and hexamethyldisilazane from Peninsular Chemresearch. Reagent grade pyridine was dried over sodium hydroxide pellets. The syntheses of authentic samples of 2-*O*-, 3-*O*-, and 6-*O*-monomethylsulfonylethylglucoses are described elsewhere (9).

Apparatus

The gas–liquid chromatographic unit was a F & M model 1609 equipped with a hydrogen flame ionization detector. The gas–liquid chromatographic columns were based on a solid phase of acid-washed dimethyldichlorosilane-treated Chromosorb W of 80–100 mesh from Johns–Mansville Corporation. The liquid phases consisted of SE-52, Apiezon M, XE-60, and QF-1 from Wilkens Instrument and Research, Incorporated. The columns were prepared in ¼ inch outside diameter tubing and are identified as follows: 3% SE-52, 6 ft stainless steel column; 10% Apiezon M, 2 ft aluminium column; 8.5% XE-60, 2 ft aluminium column; and 3% QF-1, 5.5 ft aluminium column.

Procedure

Methyl Vinyl Sulfone Modified Cotton Cellulose

Methyl vinyl sulfone was caused to react with cotton print cloth under conditions generally similar to those described by Tesoro and Oroszlan (10). The extent of reaction was measured by weight gain and sulfur analysis (Schoeniger combustion method (11)). The samples of methylsulfonylethyl cellulose which were studied contained 1.97% sulfur (ca. 6.5% weight gain), corresponding to a degree of substitution of 0.11.

Hydrolysis of Cottons to Glucose and Substituted Glucoses

Cotton celluloses were hydrolyzed with sulfuric acid by the general procedure of Hägglund (12) as modified by Abend (8). One gram of fabric from a supply of material homogenized as small (ca. 0.25 cm^2) squares was covered with 15 g of 72% sulfuric acid and was subjected to mild agitation at room temperature under an atmosphere of nitrogen for 8 h. The homogeneous solution was diluted to 7.7 *N* with 20 ml of distilled water, and mild agitation was continued under a nitrogen blanket for 16–20 h. At this time the solution was diluted to 1.5 *N* with 120 ml of water and refluxed for 6 h under nitrogen. Barium hydroxide was utilized to adjust the pH between 5.6 and 6.0, the barium sulfate was removed, the filtrate was concentrated under vacuum below 40 °C, and the concentrate was freeze-dried to a solid product.

Hydrolyses of cotton celluloses with 90% formic acid by the procedure of McGilvray (13) was accomplished with 42 ml of formic acid for 2 g of air-dried fabric. After a 5 h period on a boiling water bath, insoluble cellulose (A-1) was removed by centrifugation and filtration. The filtrate was evaporated to dryness and the evaporation process was repeated three times (or until all the free formic acid was removed), with the addition of ca. 50 ml of water each time. The product which contained formate groups was hydrolyzed to free saccharides (B-1) by reflux for 4 h with 1 *N* or 2 *N* sulfuric acid. Neutralization and removal of acid were conducted as described above. The cellulose fraction (A-1) which remained undissolved after the 5 h treatment in formic acid was retreated with fresh formic acid (42 ml) for 9 h and subsequently hydrolyzed to the free saccharide (B-2) with dilute sulfuric acid. A 2.02 g sample of unmodified cotton yielded 0.2920 g of fraction B-1 and 0.2380 g of B-2. A 2.0157 g sample of methylsulfonylethyl cellulose yielded 0.3279 g of fraction B-1 and 0.2416 g of fraction B-2. Insoluble fraction A-1 contained 0.93% sulfur. A 2.0101 g sample of methylsulfonylethyl cellulose, ball-milled to show a completely noncrystalline X-ray diffractogram, yielded only the soluble fraction B-1.

Removal of Glucose from Chemically Modified Glucoses

A 1.0 g sample of the hydrolysate of cotton fabric was dissolved in 20 ml of water together with 0.2 g of dried yeast. Fermentation was allowed to proceed at ambient temperature until no more microbubbles appeared. The solution was filtered and freeze-dried to a solid product. The hydrolyzed cotton or glucose yielded less than 0.1 g of residual nonvolatile product; methylsulfonylethyl cellulose yielded 0.25 g of product.

Gas–Liquid Chromatographic Analyses

Trimethylsilyl ethers of saccharides were prepared for gas–liquid chromatographic analyses by the method of Sweeley *et al.* (14), which employs approximately 10 mg of sample, 1.0 ml of anhydrous pyridine, 0.2 ml of hexamethyldisilazane, and 0.1 ml of trimethylchlorosilane. Heating for 5–15 min at 90–95 °C was necessary to insure conversion of cellobiose into the trimethylsilyl ether.

RESULTS

Hydrolysis and Concentration of Structural Components from Modified Cotton

During these studies it was found that gas–liquid chromatography of methylsulfonylethylglucoses (either as pure isomers or as hydrolysates from methylsulfonylethyl cellulose) in the form of trimethylsilyl ethers required high temperatures for both the injection port and the columns. Column temperatures in the range of 190–250 °C produced the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

best results. Although a variety of liquid phases was investigated, only the following were found to be suitable: SE-52, Apiezon M, XE-60, and QF-1. The limitation of other more polar columns was the inability to desorb the methylsulfonylethylglucoses at suitable operating temperatures and (or) the tendency to catalyze rearrangement of the blocking groups introduced into these molecules for synthesis purposes (9, 15).

Direct hydrolyses of cotton and wood celluloses to glucose have been achieved under a variety of conditions (12), but invariably with the requirement of a strong acid, unless the modified cellulose was uniquely soluble in the hydrolyzing medium. The process commonly employed in preceding studies involves dissolution in 72% sulfuric acid at room temperature followed by hydrolysis of the cellulose at higher levels of dilution. This procedure, when applied to cotton under an inert atmosphere, yielded a light-colored hydrolysate. The effectiveness of the hydrolysis in our hands is indicated by chromatograms of the trimethylsilyl ethers of the hydrolysate of the unmodified cotton cellulose (curve A, Fig. 1). Chromatograms of pure glucose and cellobiose are shown for comparison

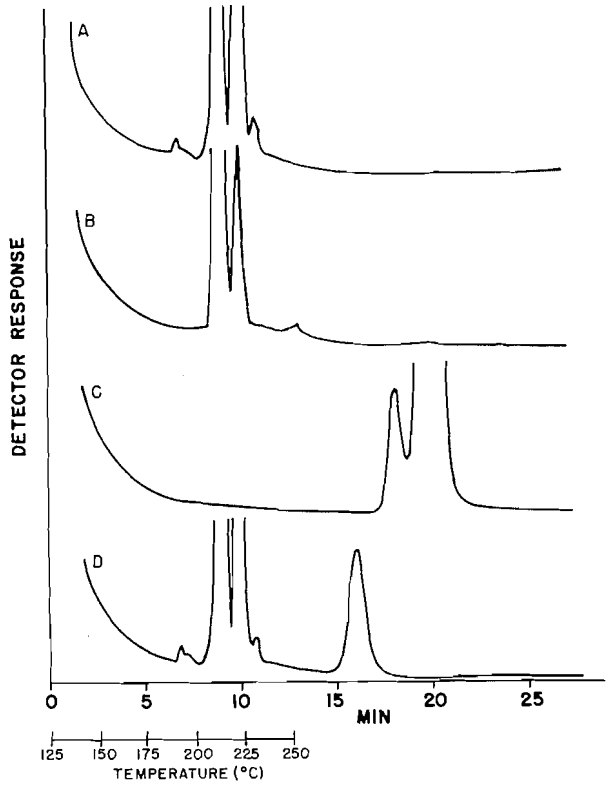

FIG. 1. Chromatograms of trimethylsilyl derivatives on SE-52 liquid phase with temperature of column programmed at 10 °C/min from 125 to 250 °C. Curve A is the hydrolysate of cotton; curve B is α-glucose; curve C is β-cellobiose; curve D is the hydrolysate of methylsulfonylethyl cellulose.

(curves B and C). Comparison of the peaks and retention times for the cotton hydrolysate with those of glucose and cellobiose indicates that the hydrolysate contains no cellobiose or higher oligomer. Glucose is indicated in a high state of purity, with the traces of impurities in minute peaks at retention times of $6\frac{3}{4}$ and 11 min.

This hydrolytic procedure, when applied to methylsulfonylethyl cellulose, results in total hydrolysis and high recovery of the hydrolysate (97–100% of theory) without significant loss in sulfur content (93–100% recovery). Chromatograms of the trimethylsilyl ethers of the hydrolysate of methylsulfonylethyl cellulose are shown in curve D of Fig. 1. In addition to the major peak corresponding to glucose, a new peak is observed intermediate in retention time between those of glucose and cellobiose. The new peak is attributed to methylsulfonylethylglucoses; no evidence for methyl vinyl sulfone or methyl 2-hydroxyethyl sulfone was found in the chromatogram of the hydrolysate.

Since Croon and Lindberg (1) observed a decrease in optical rotation amounting to 3–5% for methyl ethers of glucose treated under conditions very similar to those employed in this study, the effect of 72% sulfuric acid upon the individual methylsulfonylethylglucoses (see later section) has been examined together with the effect of milder conditions of hydrolysis for methylsulfonylethyl cellulose. McGilvray (13) found that a completely methylated cellulose was hydrolyzed much faster in 90% formic acid than under the more drastic conditions involving sulfuric acid. No demethylation occurred when he subjected 2,3,6-tri-*O*-methylglucose to this hydrolytic procedure.

When the formic acid hydrolysis was applied to cotton, 14% of the cellulose was dissolved in the period (5 h) which McGilvray found to be sufficient to hydrolyze methyl cellulose completely. An additional 9 h of hydrolysis solubilized 12% of the original cotton, leaving aggregates of material not unlike hydrocellulose (16). The soluble fraction of cellulose was found by gas–liquid chromatography to be present as a complex mixture of formates of glucose and higher saccharides. Upon hydrolysis with 1 *N* sulfuric acid, this formate fraction showed the presence of minor amounts of cellobiose together with major amounts of glucose.

Methylsulfonylethyl cellulose was hydrolyzed selectively in 90% formic acid; 53% of the sulfur-containing components was removed in 26% of the total sample. Ball-milled methylsulfonylethyl cellulose was solubilized completely and hydrolyzed rapidly without selectivity, under the same conditions used in the reaction with formic acid. Hydrolysis of solubilized carbohydrate formates with 2 *N* sulfuric acid was employed to remove formate groups and to convert cellobiose and higher saccharides into glucose units. Chromatograms of this hydrolysate showed a ratio of peak areas of modified glucoses to glucose equivalent, within experimental variation, to the ratio observed for the product from hydrolysis with 72% sulfuric acid. This indicates that the loss of methylsulfonylethyl substituents during hydrolysis is small, if it occurs at all.

To establish the extent to which the peaks under consideration as methylsulfonylethylglucoses from hydrolyzed methylsulfonylethyl cellulose represent complete detection of these components in gas–liquid chromatography, the response of the flame ionization detector to glucose and to 3-*O*-methylsulfonylethylglucose (9) was calibrated against cellobiose as an internal standard (17). By applying correction factors (1.07 for glucose and 2.0 for 3-*O*-methylsulfonylethylglucose) to specific peak areas before normalization of the total peak areas, it appears that the methylsulfonylethylglucose fraction constitutes 15.2% of the hydrolysate. This is in good agreement with the expectation, on the basis of sulfur analysis together with the reasonable assumption that only monosubstitution occurs within the anhydroglucose unit, that modified glucose components amount to 15.6% of the hydrolysate.

The small fraction of modified glucoses in the hydrolysate imposes limitations upon the resolution of peaks of the unknown components. Fermentation proved to be the simplest

and most effective method for removal of the unmodified glucose. Except for the appearance of glycerol and traces of components near the retention time for glucose, the chromatograms of the concentrate were free of interference in the region of the methylsulfonylethylglucose fraction. Chromatograms and analyses indicate that the methylsulfonylethylglucoses constitute 70% of the concentrate. The effectiveness of removal of glucose is apparent from curves A and B of Fig. 2.

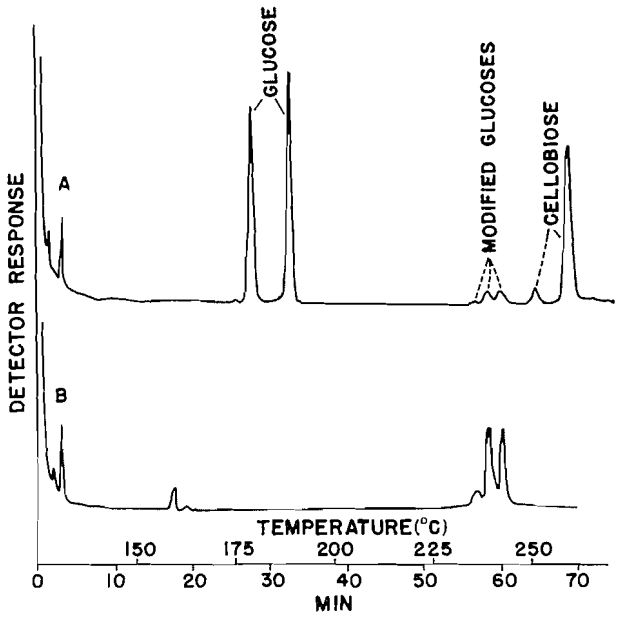

FIG. 2. Chromatograms of trimethylsilyl derivatives on SE-52 liquid phase programmed at 2 °C/min from 125 to 250 °C. Curve A is the hydrolysate of methylsulfonylethyl cellulose containing cellobiose as an internal reference; curve B is the concentrate of the hydrolysate after fermentation.

2-O-, 3-O-, and 6-O-Monomethylsulfonylethylglucoses

Individual samples of 2-*O*-, 3-*O*-, and 6-*O*-methylsulfonylethylglucoses, whose syntheses are described elsewhere (9), were subjected to the 72% sulfuric acid treatment employed for the hydrolysis of cottons; no detectable change was observed in the chromatograms, confirming earlier evidence for the complete stability of the ether linkage between the glucose and methylsulfonylethyl groups.

Methylsulfonylethylglucoses in the form of trimethylsilyl ethers were characterized by gas–liquid chromatography on several columns with glucose or cellobiose as internal reference for relative retention values (Table I). In each case the methylsulfonylethylglucose was resolved into two peaks representing anomeric forms. To facilitate comparisons of the relative retention values for the anomeric forms of the pure methylsulfonylethylglucoses, we have assigned to the reference materials relative retention values which are consistent with a relative retention value of 1.0 for the peak of the second anomer of 6-*O*-methylsulfonylethylglucose. Ratios of the areas of the two anomeric peaks were characteristic for each position isomer and are as follows: 2-*O*-methylsulfonylethylglucose, 0.43:0.57; 3-*O*-methylsulfonylethylglucose, 0.50:0.50; and 6-*O*-methylsulfonylethylglucose, 0.49:0.51.

Ratio of Isomeric Monomethylsulfonylethylglucoses in Methylsulfonylethyl Cellulose

Chromatograms of the concentrated methylsulfonylethylglucose fraction from the hydrolysis of methylsulfonylethyl cellulose with 72% sulfuric acid are reproduced in Fig. 3 together with markers which designate positions at which the anomers of the pure

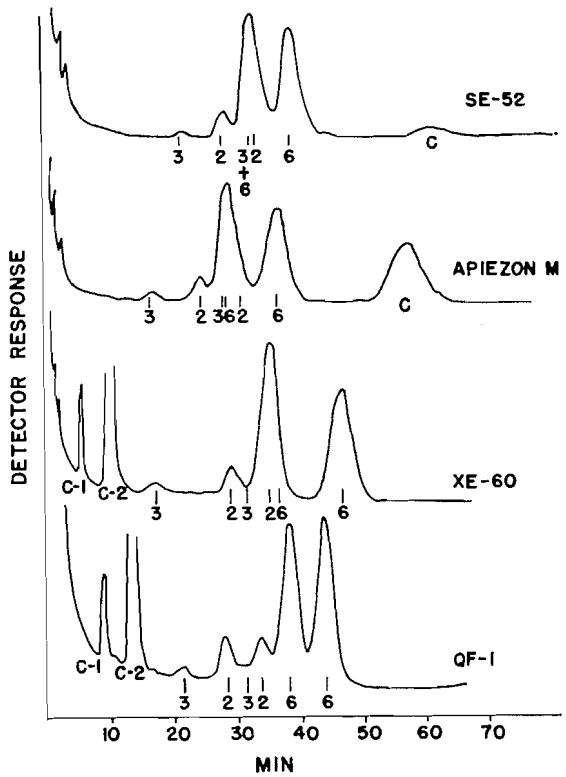

FIG. 3. Chromatograms of the trimethylsilyl derivatives of the concentrate from the hydrolysis of methylsulfonylethyl cellulose with 72% sulfuric acid. Isothermal operation; XE-60 operated at 190 °C; all other columns operated at 200 °C. Vertical markers indicate the positions of peaks of anomers of the individual 2-*O*-, 3-*O*-, and 6-*O*-monomethylsulfonylethylglucoses. Cellobiose (C) is an internal standard.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

monomethylsulfonylethylglucoses appear in the chromatogram. On SE-52 and Apiezon M columns, one anomer of each isomeric substituted glucose is resolved separately, and the other anomers (i.e. the second anomer of 2-*O*- and 3-*O*- together with the first anomer of 6-*O*-methylsulfonylethylglucose) are unresolved and appear together in a single peak. The separation is less satisfactory on the XE-60 column and most effective on the QF-1 column, where only the second anomeric peak of the 3-*O*-methylsulfonylethylglucose is secluded between two other peaks.

The ratio of peak areas (product of retention time and peak height) on QF-1 for the 2-*O*-, 3-*O*-, and 6-*O*-isomers is 0.20:0.03:1.0. The ratios obtained from gas–liquid chromatography on SE-52, Apiezon M, and XE-60, if the ratios of the peak areas for the anomers of each individual position isomer are taken into consideration, are 0.21:0.03:1.0, 0.21:0.036:1.0, and 0.17:0.03:1.0. The ratios of peak areas from triangulation or planimetry measurements were generally less consistent, extending over the following range: 0.18–0.25 : 0.03–0.06 : 1.0. We conclude that the best data are represented in the ratio 0.20:0.03:1.0, which is preferably expressed with the value of unity assigned to the 6-*O*-methylsulfonylethylglucose. The assignment of a value of unity to the 3-*O*-isomer, which is present in the smallest amount and subject to the largest inaccuracies, accentuates errors and impedes comparisons.

DISCUSSION

The base-catalyzed reaction of an alcohol with an activated olefin is a reversible nucleophilic attack of an alkoxide ion on the vinyl group (18, 19). The mechanism of the reaction of methyl vinyl sulfone with an alkoxide ion is considered to be similar to that of acrylonitrile in cyanoethylation or acrylamide in carbamoylethylation. The distribution of methylsulfonylethyl groups among the 2-*O*-, 3-*O*-, and 6-*O*-positions of the anhydroglucose unit in the ratio 0.20:0.03:1.0 is similar to that which Touzinsky (6) has reported recently (Table II) for carbamoylethyl groups from calculations of equilibrium constants by a modification of Spurlin's equations (20).

TABLE II

Distributions of substituents in cellulose ethers

Reagent	Ratio of substituents			Reference
	2	3	6	
Methyl vinyl sulfone	0.20	0.03	1.0	—
Acrylamide	0.47	0.05	1.0	6
Methyl chloride	2.5	0.5	1.0	2
Dimethyl sulfate	1.75	0.5	1.0	1
Ethyl chloride	2.25	0.5	1.0	3
Sodium chloroacetate	0.8	0.4	1.0	5
Ethylene oxide	0.3	0.1	1.0	4

In contrast to the major reaction at the 6-hydroxyl group for these Michael reactions involving small molecular species, the related reactions of large molecules proceeding through similar activated sulfone intermediates with cellulose are less well defined; Stamm (21) has indicated that reaction of a dye, 1-amino-9,10-dihydro-4[*p*[(2-sulfatoethyl)sulfonyl]anilino]9,10-dioxo-2-anthracenesulfonic acid, with cellulose or α-methylglucoside occurs mainly at the 2-hydroxyl group, a conclusion reached on the basis of the structure of methylglucoses isolated subsequent to complete methylation and removal of the dye substituent. Chekalin (22), studying the same reaction with rayon, cellobiose, and

α-methylglucoside and employing diagnostic reactions with triphenylmethyl chloride, periodate, and phenylhydrazine, found evidence for 65–75% of the substituent in the 6-*O*-position, with the major portion of the rest in the 2-*O*-position. It is not clear, therefore, to what extent molecular size, conditions of reaction, or methods of analyses have contributed to these differences.

The marked preference of methyl vinyl sulfone for reaction at the 6-hydroxyl group is distinctly different from the results of nucleophilic substitution reactions involving an alkyl halide or sulfate with cellulose in the presence of alkali (see Table II). Since the Michael reaction is reversible, the distribution of substituents among the different types of hydroxyl groups is controlled by the relative equilibria of the individual reactions. On the other hand, the nucleophilic substitution reactions with alkyl halides are not reversible; the distribution of substituents in the latter case is controlled by the rates of reactions. In these rate-controlled reactions the 2-hydroxyl group is the predominant point of attack. It is interesting, also, that the ratios of distribution of substituent groups between the 2- and 3-hydroxyls for methylsulfonylethylation (1.0:0.15) and carbamoethylation (1.0:0.11) appear to be generally different from those observed for rate-controlled reactions (1.0 : 0.20–0.33). An exception is carboxymethylation (1.0:0.5), for which the relative reactivity at the 3-position appears to be uniquely high among nucleophilic substitution reactions with cellulose; this reaction is also unique in that an electrostatic interference is indicated between substituent and reagent at the 2- and 3-positions for polysubstitution of an anhydroglucose unit (5).

It is now recognized that reactions employed for the modification or cross-linking of cotton cellulose may be rate controlled or equilibrium controlled, and that each class of reaction may exhibit a different pattern of distribution of substituents among the hydroxyl groups of the anhydroglucose unit. It further appears that each specific reagent may differ from another of the same class, but that the contribution of steric and electronic factors of the reagent, solubility of reagent, and conditions of reaction remain to be clarified.

ACKNOWLEDGMENTS

The authors are indebted to Mr. C. H. Mack and Mr. E. R. Cousins for technical contributions. We thank Mr. P. F. Pittman for analyses and Mr. G. I. Pittman for preparation of the line drawings.

CARCINOGENICITY OF LACTONES

I. THE REACTION OF 4-METHYLBUTENO- AND 4-METHYLBUTANO-γ-LACTONES WITH PRIMARY AMINES

J. Bryan Jones and John M. Young

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario

Received December 1, 1965

ABSTRACT

As the first stage in the investigations of the mechanisms of action of carcinogenic lactones, the reactions of 4-hydroxypent-2-enoic acid lactone (II, R = CH_3), which is a carcinogen, and of the non-carcinogenic 4-hydroxypent-3-enoic (III, R = CH_3) and 4-hydroxypentanoic (IV, R = CH_3) acid lactones with methylamine and benzylamine have been studied. As expected, the carcinogenic lactone reacts to give the Michael addition products, whereas both inactive lactones undergo ring opening by nucleophilic attack at the carbonyl group. From the relative rates of reaction of the amines with the lactones it is concluded that the induction of tumors by II (R = CH_3) does not involve alkylation of biological primary alkylamino groups. The proton magnetic resonance spectra of the products enable the different reaction pathways to be distinguished readily, and may provide the basis for rapid physicochemical screening of alkylation agents that are potential carcinogens.

The wide range of biological activity exhibited by lactones has been well known for many years (1). In particular, unsaturated lactones are able to inhibit selectively both tissue growth and seed germination, and many of them possess antibiotic, cardiac, anthelmintic, hemorrhagic, and insecticidal activity (1). Recently, their ability to act as chemical carcinogens was also demonstrated (2).

In contrast to the extensive data on the biological effects of unsaturated lactones, of which refs. 1 and 2 are merely illustrative, there appears to be relatively little known about the chemical mechanisms of action involved. As the active lactones are all alkylating agents, their biological effect is probably due to an in vivo modification of the nucleophilic groups either of proteins (including enzymes) or of deoxyribonucleic (DNA) and ribonucleic (RNA) acids (2–4). However, many of the studies which have been carried out (1, 2) in attempts to verify this supposition, and to determine the nature of the most reactive biological nucleophile and hence the probable in vivo site of alkylation, were of necessity carried out without the aid of modern spectroscopic analytical methods. As a result, many conclusions have been drawn which cannot be regarded as satisfactory when the often rather meagre data are reexamined from the standpoint of the current knowledge of the mechanisms of organic and biochemical reactions.

Accordingly, a systematic survey of the reactions of a series of active lactones, representing a wide variation of biological effects, with the nucleophilic groups present in proteins and in DNA and RNA has been initiated. It is hoped that such a study of all the possible sites of alkylation and a determination of their mechanism of reaction with the active lactones, together with a comparison of the *relative* rates of combination, will enable the probable site of alkylation in the cell to be identified.

The results reported in this communication represent the preliminary investigations in the aspect of this programme concerned with the carcinogenesis of certain unsaturated lactones (2). This area is of importance for several reasons. Lactones, which have subsequently been shown to be carcinogenic, are in widespread use as antibiotics, food preservatives, sterilization agents, etc., and a knowledge of their reaction with proteins and nucleic acids would result in an increased margin of safety in their application. Also,

apart from being of interest with regard to current theories of chemical carcinogenesis (3–5), the results of this survey could enable guidelines to be laid down for distinguishing carcinogenic from non-carcinogenic alkylating agents on a chemical basis. This would obviate the tedious and expensive biological testing which at present precludes the examination of many potential carcinogens in general use.

Before 1961, the examination of lactones as carcinogens had largely been neglected, apart from fairly extensive studies on β-propiolactone (2). Since then, largely due to Dickens and Jones (2), a broad range of lactones and related compounds has been evaluated. Dickens and Jones were able to demonstrate a correlation between carcinogenic activity and structure, and they classified the various types into groups on this basis, as illustrated in Diagram 1. Compounds of the structural type represented by groups 1 and 2 were found to be carcinogenic whereas the related lactones of group 3 failed to produce tumors.

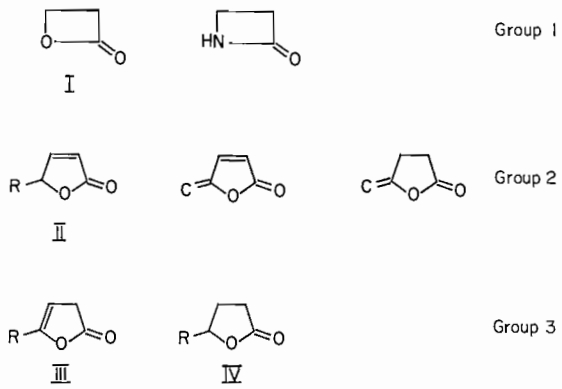

DIAGRAM 1.

The reactions of β-propiolactone (I) (group 1) with nucleophiles have been well documented (2–4, 6). Nucleophilic attack with a wide variety of nucleophiles occurs exclusively at the β-carbon atom, with alkyl–oxygen fission to give β-substituted propionic acids (V) as shown in Diagram 2. In contrast, the data available on the corresponding reactions of the lactones of groups 2 and 3 are very limited. Lactones II (R = CH_3), III (R = CH_3), and IV (R = CH_3) were selected as typical examples of the carcinogenic and non-carcinogenic compounds of these groups. The possible pathways for the reactions of these lactones with nucleophiles are summarized in Diagram 2.

The nucleophile considered first was the primary amino group. The NH_2 group is present in the DNA and RNA bases (adenine, guanine, and cytosine) and is the basic terminal group of all open-chain proteins. In addition, it is present in the side chain of the basic amino acids lysine (an essential amino acid), hydroxylysine, ornithine, and α,ε-diaminopimelic acid. To simplify the interpretation of the proton magnetic resonance (p.m.r.) spectra of the products of the first experiments, and thereby facilitate the elucidation of the reaction pathways, simple primary amines were used as models for the nucleic acid bases and for peptides containing the primary amino group.

The reactions of the simplest model amine, methylamine, with lactones II (R = CH_3), III (R = CH_3), and IV (R = CH_3) have been studied widely (7–11). However, the results obtained from these independent investigations were not consistent with one another, and different conclusions regarding the structures of several of the products were

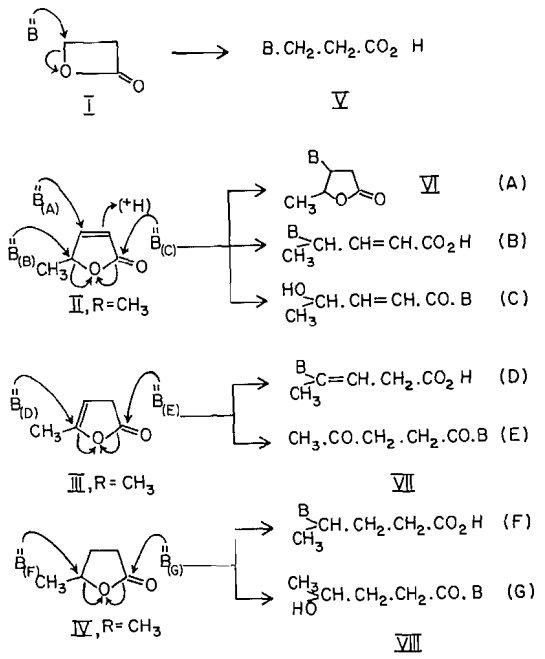

DIAGRAM 2.

drawn by the various groups. In view of the importance of the above reactions with respect to the objectives of this study, they have been reinvestigated to resolve the controversies regarding the nature of the products and the reaction pathways involved.

When aqueous methylamine and 4-hydroxypent-2-enoic acid lactone (β-angelica lactone)[1] (II, R = CH_3) were mixed in equivalent amounts at 20°, reaction occurred during 25 min to give a product which, when worked up at temperatures below 20°, was shown by p.m.r. to contain 80% of the Michael addition product VI (B = $NHCH_3$). It was not possible to obtain a pure sample of VI (B = $NHCH_3$) because, when the temperature was raised, and particularly during distillation, a reverse Michael reaction occurred to give a mixture containing the starting lactone II (R = CH_3) as the major component. These results contrast with those of Lukes *et al.* (*7c*), who reported that methylamine and the lactone II (R = CH_3) did not react by addition across the double bond but gave, instead, the 3-pyrroline-2-one X. However, the readiness with which VI (B = $NHCH_3$) undergoes a reverse Michael reaction on distillation accounts for the absence of this compound in the products obtained by Lukes from reactions carried out at elevated temperatures for relatively extended periods.

The reaction of 4-hydroxypent-3-enoic acid lactone (α-angelica lactone)[1] (III, R = CH_3) with methylamine proceeded rapidly at 0° in aqueous solution. When the reaction mixture was worked up at temperatures below 20° a product was obtained, the infrared (1 685 cm^{-1}, pyrrolidinone carbonyl) and p.m.r. (Fig. 1*a*) spectra of which were consistent with structure XI (R = CH_3). This shows that the initial attack by methylamine is at the carbonyl group of III (R = CH_3), and that the intermediate keto amide VII (B = $NHCH_3$) which is produced cyclizes spontaneously to the pyrrolidinone. These results confirm the most

[1]*Many difficulties have arisen in the literature (2, 7–11) from the anomalous α and β nomenclature of angelica lactones. Systematic nomenclature has been used in this communication to avoid further confusion.*

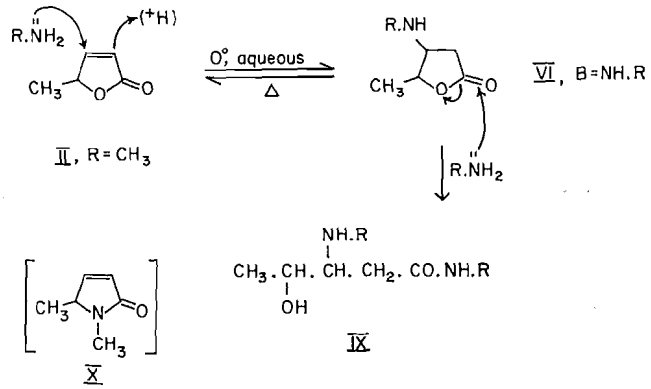

DIAGRAM 3.

recent conclusions reached by Lukes *et al.* (7*c*) in a review of his own and other data. Attempts made to dehydrate XI (R = CH_3) by distillation and by acid catalysis resulted in the formation of unresolvable mixtures. The presence of the pyrrolinone XII, reported by Lukes *et al.* (7*c*) to be formed under these conditions, was excluded by the absence of olefinic proton peaks in the p.m.r. spectrum.

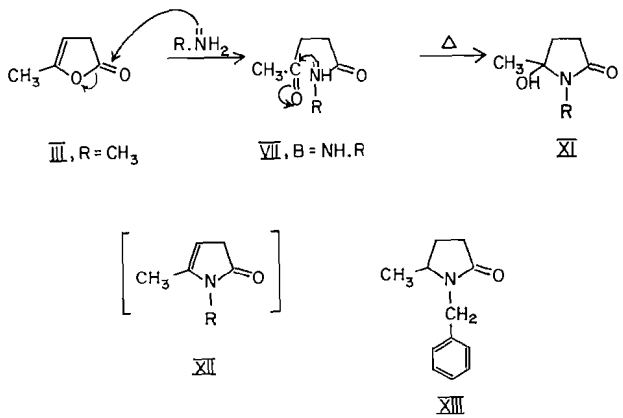

DIAGRAM 4.

In contrast to the extremely rapid reactions of the unsaturated lactones with methylamine, that of 4-hydroxypentanoic acid lactone (IV, R = CH_3) was slow. Isolation of the hydroxyamide VIII (B = $NHCH_3$) as the major product showed that nucleophilic attack at the carbonyl group had occurred (p.m.r. spectrum in Fig. 1*b*).

Because of the complications encountered when methylamine was used as a model biological nucleophile, other primary amines were considered. An amine of sufficient steric bulk to prevent cyclization of the initial products to pyrrolidine derivatives was desirable, and it was felt that aniline might satisfy this condition. Aniline possessed the added advantage that its protons would be sufficiently far downfield in the p.m.r. spectra of the products that no overlap with lactone-derived protons would occur. However, it was found that aniline and the lactones II (R = CH_3) and IV (R = CH_3) did not react, even when heated to 180°. This was not unexpected, because aniline, with a pK_a of 4.69,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is approximately one million times less basic than a typical primary alkylamine (12). The reaction of aniline with the β,γ-unsaturated lactone III (R = CH_3) yielded the keto amide VII (B = NHC_6H_5) as reported by Walton (8) and by Lukes and his collaborators (7*b*). No cyclization to the pyrrolidinone XI (R = C_6H_5) was observed.

The model nucleophile finally adopted was benzylamine, which combined aliphatic amine reactivity with the advantage that the aromatic protons would not cause confusion in the interpretation of the p.m.r. spectra. Also, the increase in steric dimensions from those of methylamine was found to be effective in inhibiting to a large extent the cyclization of the products. The reactions were first carried out under nonaqueous conditions to facilitate product identification, since there was evidence from some of the methylamine experiments that secondary reactions with water had delayed formulation of the primary product. Subsequently, the reactions were repeated in aqueous solutions approximating in vivo biological conditions more closely. When reactions occurred very slowly at or below 37° (human body temperature) the mixtures were heated until reaction did occur. This was done to obtain an estimate of the relative rates at which the active and inactive lactones reacted. (Even when a distinction between active and inactive lactones can be made on the basis of different mechanisms of reaction, the relative rates at which alkylations occur may well be of greater biological significance.)

As for methylamine, the reaction of benzylamine with the α,β-unsaturated lactone II (R = CH_3) resulted in the formation of the Michael addition product VI (B = $NHCH_2C_6H_5$) (p.m.r. spectrum in Fig. 1*c*), under both nonaqueous and aqueous conditions. When the reaction was carried out for 15 min at 20° the yield of VI (B = $NHCH_2C_6H_5$) reached 75% (before purification), but when the reactants were kept for longer periods at room temperature, increasing amounts of the amino amide IX (R = $CH_2C_6H_5$) (p.m.r. spectrum in Fig. 1*d*) were produced. In contrast to the Michael addition product formed in the analogous methylamine reaction, the benzylamino lactone VI (B = $NHCH_2C_6H_5$) could be distilled, and when pure was stable indefinitely. On suspension in water it gradually equilibrated to give a 1:1 mixture of IX (R = $CH_2C_6H_5$) and the starting lactone II (R = CH_3), presumably by a reverse Michael reaction as indicated in Diagram 3. (An alternative pathway involving opening of the lactone ring as the first step followed by addition of methylamine to the resulting α,β-unsaturated amide could also account for the formation of IX (R = $CH_2C_6H_5$), but this route is considered to be less credible than that suggested in Diagram 3.) Lukes *et al.* (7*c*) reported only the formation of the secondary product IX (R = $CH_2C_6H_5$). When 2 equivalents of benzylamine was mixed with the lactone II (R = CH_3), a 90% yield of IX (R = $CH_2C_6H_5$) was isolated.

Since most biological processes, particularly those involving enzymes, are stereospecific (13), the stereochemistry of the addition to the double bond is of interest in that it gives an indication of the preferred direction of approach of the nucleophile. Infrared spectroscopic and chemical evidence enabling the configurations of the diastereomers of lactones VI (B = $NHCH_3$) and VI (B = $NHCH_2C_6H_5$) to be distinguished has been presented by Lukes *et al.* (7*c*). However, the compounds were not obtained directly from addition of the amine across the double bond of the lactone II, and, for the benzylamine products, the results were not unambiguous, as it was necessary to assign configurations mainly by analogy with those proposed for the methylamine addition compounds. To clarify this biologically important point, the hydrobromide and hydrochloride salts of the benzylamino lactone VI (B = $NHCH_2C_6H_5$) were prepared and are currently being examined by X-ray diffraction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Lukes *et al.* (7*c*) reported that the β,γ-unsaturated lactone III (R = CH_3) reacted with benzylamine to give the keto benzylamide VII (B = $NHCH_2C_6H_5$). The yield obtained was only 18%, and thus the keto amide could not be regarded as the major product under the conditions applied. A reinvestigation of this reaction confirmed that the first step in the reaction of lactone III (R = CH_3) with benzylamine, under both nonaqueous and aqueous conditions, was nucleophilic attack at the carbonyl group (path E, Diagram 2). The reaction mixture was found to contain the keto amide VII (B = $NHCH_2C_6H_5$) (p.m.r. spectrum in Fig. 1*e*) as reported by Lukes *et al.* (7*c*), together with varying amounts of the cyclized product, the benzylpyrrolidinone XI (R = $CH_2C_6H_5$). When the temperature was maintained at 0–5° during reaction and work-up, the keto benzylamide VII (B = $NHCH_2C_6H_5$) was obtained in yields of up to 90%. Purification by standard recrystallization from benzene greatly diminished the proportion of keto amide, and from the filtrates was recovered an oil which was shown to be the pyrrolidinone XI (R = $CH_2C_6H_5$) by its p.m.r. spectrum (Fig. 1*f*). The AB pattern at δ 4.42 p.p.m. was found to be characteristic of the benzyl methylene protons in the cyclized products. The difference in chemical shifts of the benzyl methylene protons arises from the asymmetric environment produced by the nitrogen atom with three dissimilar substituents. The cyclic structure appears to restrict the inversion of nitrogen sufficiently that the AB pattern is observable at room temperature in contrast to the analogous open-chain compounds, such as N-benzyl-O,N-dimethylhydroxylamine, for which Griffith and Roberts observed an AB-type spectrum only when it was cooled to −40° (14). The keto benzylamide VII (B = $NHCH_2C_6H_5$) was shown by its infrared spectra (1 723 cm^{-1}, 1 670 cm^{-1}, no hydroxyl absorption) to exist in the open-chain form both in the solid state and in freshly prepared solution in various solvents. When the solutions were kept at room temperature gradual equilibration with the pyrrolidinone occurred. Refluxing in water produced a 1:1 mixture of open-chain and cyclic forms. Partial equilibration also occurred during the attempted purification of both isomers by chromatography and by distillation. For this reason it was not possible to obtain a completely pure sample of 1-benzyl-5-hydroxy-5-methylpyrrolidin-2-one (XI, R = $CH_2C_6H_5$).

As with methylamine, nucleophilic attack by benzylamine on the saturated lactone IV (R = CH_3) occurred at the carbonyl group to give the hydroxybenzylamide VIII (B = $NHCH_2C_6H_5$) (p.m.r. spectrum in Fig. 1*g*). The reaction was extremely slow at room temperature under nonaqueous conditions, and proceeded only a little more rapidly when water was present. A measure of the rate was provided by the fact that the reaction was incomplete even after the reaction mixture had been refluxed under aqueous conditions for 48 h. In an attempt to ascertain the conditions necessary to achieve complete reaction, the lactone IV (R = CH_3) and benzylamine were heated at 190° for several days. These vigorous conditions resulted in much decomposition, but some starting lactone was always recovered. On one occasion a trace amount of 1-benzyl-5-methylpyrrolidin-2-one (XIII), arising from cyclization of the hydroxyamide VIII (B = $NHCH_2C_6H_5$), was formed. Restriction of nitrogen inversion (imposed by cyclization) was again indicated by the appearance of the benzyl methylene protons as an AB quartet in the p.m.r. spectrum (Fig. 1*h*).

CONCLUSIONS

From the above results it is apparent that, as expected, there is a marked difference in the mode of reaction of the carcinogenic and non-carcinogenic lactones with the amino group. Both inactive lactones, III (R = CH_3) and IV (R = CH_3), react by nucleophilic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

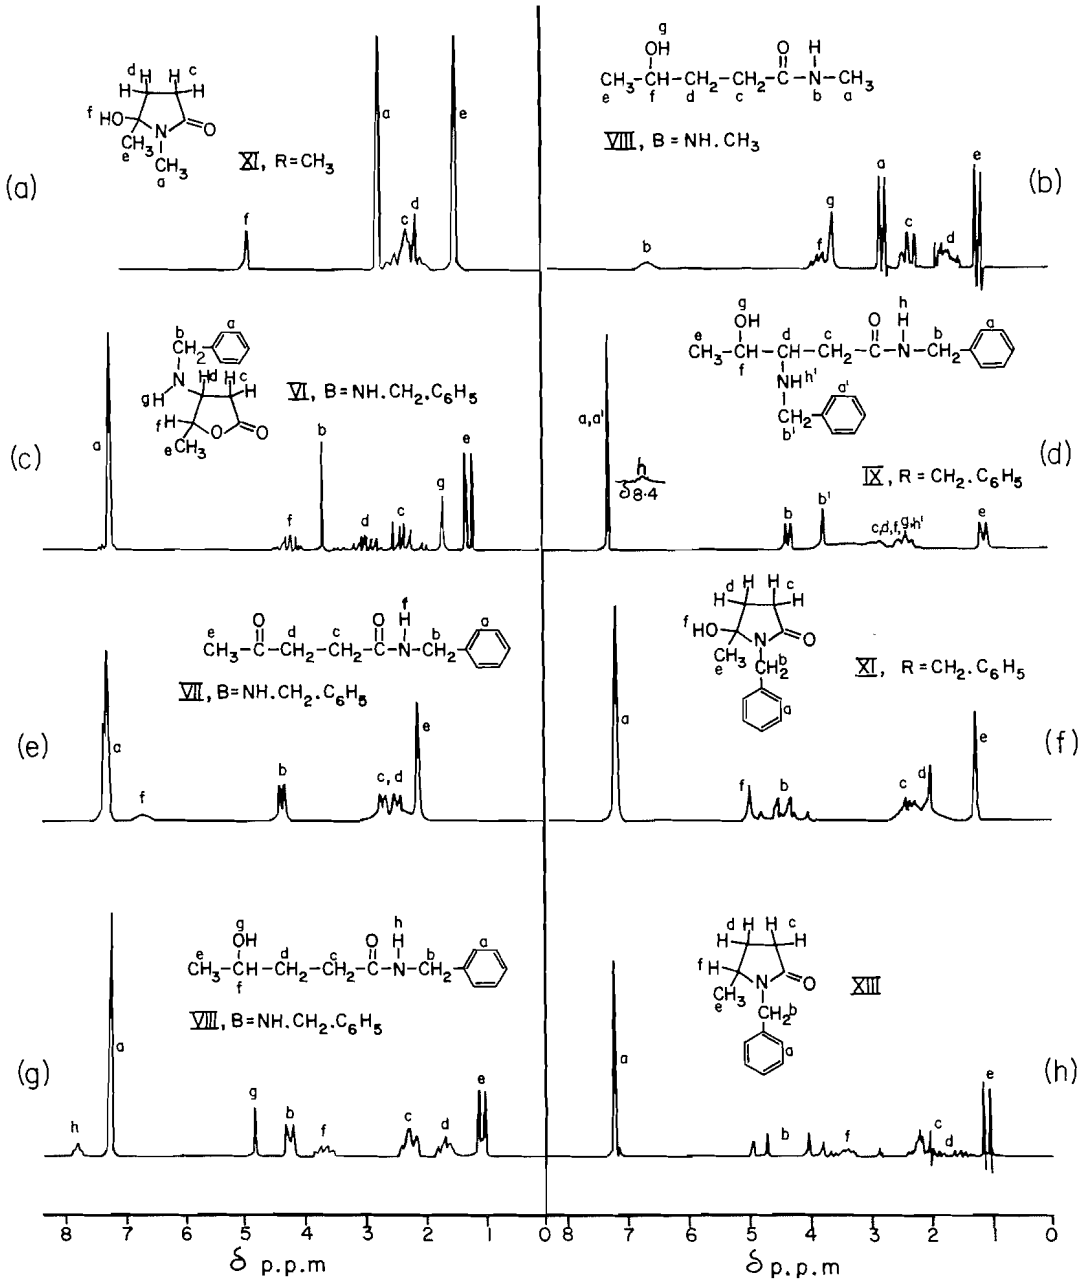

FIG. 1. Comparison of the p.m.r. spectra of products from carcinogenic (II, R = Me) and non-carcinogenic (III (R = Me) and IV (R = Me)) lactones.

attack at the carbonyl group (paths E and G, respectively, Diagram 2) whereas the active lactone II (R = CH_3) undergoes Michael addition preferentially (path A, Diagram 2).

The terminal and side-chain amino groups present in peptides and proteins have pK_a's of 7.5 to ~11 (12) and, in the lower range of physiological pH, the amino groups

would be present mainly as their conjugate acids. However, many enzymes (13) are active at pH > 8, at which sufficient concentrations of the non-protonated amino groups would be available for alkylation by such facile reagents as II (R = CH_3) and III (R = CH_3). A qualitative comparison of the relative rates of the reactions studied gives the order of reactivity as III $\geqslant$ II $\ggg$ IV. The fact that the *inactive* lactone III (R = CH_3) reacts most rapidly is regarded as evidence against the amino group being an important in vivo site at which the carcinogenic lactones effect their modification. This was not an unexpected result, because the role of a nucleophile at the active site of an enzyme has not yet been ascribed to the primary amino group (13). The model amines studied cannot be regarded as representative of this group in the nucleic acid bases. However, studies with other carcinogenic alkylating agents (4) have not implicated the primary amino groups of adenine, guanine, and cytosine.[2] The reactions of the DNA and RNA bases and associated compounds with the active and inactive lactones will be reported in a future communication.

It might well be significant that treatment of the biologically active lactone with amines yields an unstable Michael addition product which appears to be capable of undergoing a reverse reaction, whereas the inactive lactones give rise to the much more stable amide derivatives.

The p.m.r. spectra of the various products reproduced in Fig. 1 show how readily they enable the different mechanisms of reaction to be distinguished. They give hope that this approach may eventually provide the basis of a rapid non-biological screening method for distinguishing carcinogenic from non-carcinogenic alkylating agents.

EXPERIMENTAL

The p.m.r. spectra were obtained at 60 mc.p.s. with tetramethylsilane as internal standard; the melting points were determined on a Fisher–Johns apparatus and are corrected. All solvents used for chromatography were redistilled; aqueous solutions were prepared from carbon dioxide free, distilled water which was saturated with nitrogen before use.

4-Hydroxypent-3-enoic Acid Lactone (III, R = CH_3)

The commercial product (Aldrich Chemical Co.) was redistilled, b.p. 48–50° at 10 mm (lit. (15) b.p. 52° at 10 mm); $\nu_{max}^{CCl_4}$ 1 806 and 1 687 cm^{-1} (lactone carbonyl); p.m.r. (CCl_4) δ 1.97 (3H, essentially singlet), 3.10 (2H, multiplet), and 5.15 p.p.m. (1H, multiplet).

4-Hydroxypent-2-enoic Acid Lactone (II, R = CH_3)

Isomerization of 4-hydroxypent-3-enoic acid lactone with triethylamine as described by Thiele (15) gave the lactone II (R = CH_3) in 70% yield, b.p. 99–100° at 18 mm (lit. (19) b.p. 89° at 15 mm); $\nu_{max}^{CCl_4}$ 1 782 and 1 765 cm^{-1} (lactone carbonyl); p.m.r. (CCl_4) δ 1.41 (3H, doublet, J = 6.5 c.p.s.), 5.10 (1H, multiplet), 6.01 (1H, doublet, J = 5.5 c.p.s.), and 7.58 p.p.m. (1H, multiplet).

Reaction of 4-Hydroxypent-2-enoic Acid Lactone with Aqueous Methylamine

Methylamine (1.13 g of a 29% aqueous solution, 1 mole) was added dropwise, with stirring, during 5 min at 0° to 4-hydroxypent-2-enoic acid lactone (1.96 g, 1 mole); the mixture was allowed to warm to room temperature and then stirred for a further 15 min. The solution was rotary evaporated at room temperature to give a yellow oil (2.5 g), shown by the p.m.r. spectrum to contain 80% of 4-hydroxy-3-methylaminopentanoic acid lactone (VI, B = $NHCH_3$): δ 1.32 (CH_3, doublet, J = 6.5 c.p.s.), 1.95 (N—H, singlet), 2.05–3.25 (C_2,C_3—H, complex multiplet), 2.32 (N—CH_3, singlet), and 4.32 p.p.m. (C_4—H, multiplet). A pure sample of the amino lactone could not be obtained since, on distillation, a facile reverse Michael reaction occurred to give the starting lactone II (R = CH_3).

Reaction of 4-Hydroxypent-3-enoic Acid Lactone with Aqueous Methylamine

4-Hydroxypent-3-enoic acid lactone (5 g, 1 mole) was cooled to 0°, and methylamine (5.4 g of a 29% aqueous solution, 1 mole) was added dropwise, with stirring, during 10 min. The aqueous solvent was then removed by rotary evaporation at 20° to give an orange solid (6.5 g), shown by infrared and p.m.r. spectra

[2]*The pK_a of this group in nucleosides and related compounds is in the range 1.6–4.4.*

For personal use only.

to contain 95% of 1,5-dimethyl-5-hydroxypyrrolidin-2-one (XI, R = CH_3). A sample that had been recrystallized five times from ether yielded colorless rhombs, m.p. 69° (lit. (7*a*) m.p. 71°); $\nu_{max}^{CHCl_3}$ 3 610, 3 440 – 3 330 (hydroxyl), and 1 685 cm^{-1} (pyrrolidinone carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*a*) δ 1.48 (3H, singlet), 1.9–3.0 (4H, multiplet), 2.79 (3H, singlet), and 5.65 p.p.m. (1H, singlet).

Reaction of 4-Hydroxypentanoic Acid Lactone with Aqueous Methylamine

4-Hydroxypentanoic acid lactone (1 g, 1 mole) and methylamine (0.57 g of a 29% aqueous solution, 1 mole) were kept at 20° for 3 h. The mixture was then concentrated *in vacuo* and distilled to give 4-hydroxy-N-methylpentanoamide (VIII, B = $NHCH_3$) (1 g), b.p. 104° at 0.1 mm; $\nu_{max}^{CHCl_3}$ 3 490 and 3 330 (hydroxyl, amide) and 1 668 cm^{-1} (amide carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*b*) δ 1.19 (3H, doublet, J = 6.5 c.p.s.), 1.4–2.0 (2H, complex multiplet), 2.1–2.6 (2H, complex multiplet), 2.78 (3H, doublet, J = 5 c.p.s.), 3.5–4.0 (1H, complex multiplet), and 6.6 p.p.m. (1H, broad multiplet).

Anal. Calcd. for $C_6H_{13}NO_2$ (129.2): C, 55.78; H, 10.15; N, 10.85. Found: C, 55.59; H, 9.99; N, 10.52.

N-Phenyl-4-oxopentanoamide (VII, B = NHC_6H_5)

Aniline (0.94 g, 1 mole) and 4-hydroxypent-3-enoic acid lactone (0.98 g, 1 mole) were heated to 180° for 5 min. Recrystallization of the mixture from benzene – petroleum ether (b.p. 70–90°) gave the anilide (1.36 g) as needles, m.p. 101° (lit. (7*b*, 11) m.p. 101°); $\nu_{max}^{CHCl_3}$ 3 480 (amide), 1 720 (ketone carbonyl), and 1 695 cm^{-1} (amide carbonyl); p.m.r. ($CDCl_3$) δ 2.15 (3H, singlet), 2.69 (4H, quartet, J = 4.5 c.p.s.), 7.0–7.7 (5H, multiplet), and 8.4 p.p.m. (1H, broad multiplet).

Reaction of 4-Hydroxypent-2-enoic Acid Lactone (II, R = CH_3) with Benzylamine

A. Nonaqueous Conditions

4-Hydroxypent-2-enoic acid lactone (2.95 g, 1 mole) and benzylamine (3.22 g, 1 mole) were kept at 20° for 2 h. The mixture was then distilled and the fraction boiling at 134–138° and 0.04 mm was collected to give 3-benzylamino-4-hydroxypentanoic acid lactone (0.87 g); $\nu_{max}^{CCl_4}$ 3 350 (amino hydrogen) and 1 785 cm^{-1} (γ-lactone carbonyl); p.m.r. (CCl_4) (Fig. 1*c*) δ 1.24 (3H, doublet, J = 6 c.p.s.), 1.67 (1H, singlet), 2.32 and 2.98 (2H and 1H, ABX multiplet), 3.64 (2H, singlet), 4.24 (1H, multiplet), and 7.20 p.p.m. (5H, singlet).

Anal. Calcd. for $C_{12}H_{15}NO_2$ (205.3): C, 70.22; H, 7.36; N, 6.82. Found: C, 70.20; H, 7.41; N, 7.02.

The hydrobromide was obtained by treatment with aqueous hydrobromic acid. Recrystallization from methanol gave rhombs, m.p. 186°.

Anal. Calcd. for $C_{12}H_{16}BrNO_2$ (286.2): C, 50.37; H, 5.72; Br, 27.93; N, 4.90. Found: C, 50.67; H, 5.82; Br, 28.27; N, 5.03.

The hydrochloride was prepared in an analogous manner, separating as rhombs from ethanol, m.p. 179–181° (lit. (7*c*) m.p. 179–181°).

B. Aqueous Conditions

4-Hydroxypent-2-enoic acid lactone (2 g) was dissolved in water (2 ml) and a solution of benzylamine (2.16 g, 1 mole) in water (2 ml) was added dropwise, with magnetic stirring, during 5 min at 20°. Stirring was continued for a further 10 min, the solvent was then removed by rotary evaporation at 20°, and the crude product (3.9 g) was chromatographed on Florisil (120 g). Elution with chloroform–acetone (3:1) followed by distillation yielded 3-benzylamino-4-hydroxypentanoic acid lactone as a colorless oil (1.4 g), b.p. 136° at 0.12 mm, the properties of which were identical with those described above.

3-Benzylamino-4-hydroxy-N-benzylpentanomide (IX, R = $CH_2C_6H_5$)

A. A solution of 4-hydroxypent-2-enoic acid lactone (1 g, 1 mole) and benzylamine (2.13 g, 2 moles) in water (2 ml) was heated to 80° for 10 min, and the water was then removed in a rotary evaporator. The resulting white solid (3 g) was recrystallized from benzene to give 3-benzylamino-4-hydroxy-N-benzylpentanoamide as needles (2.7 g), m.p. 126.5–127° (lit. (7*c*) m.p. 127–128°); $\nu_{max}^{CHCl_3}$ 3 460 (hydroxyl, amide NH) and 1 668 cm^{-1} (amide carbonyl); p.m.r. (dimethyl sulfoxide-d_6) (Fig. 1*d*) δ 1.06 (3H, doublet, J = 6.5 c.p.s.), 2.3 (4H, multiplet), 2.78 (1H, multiplet), 3.27 (1H, multiplet), 3.72 (2H, singlet), 4.28 (2H, doublet, J = 6 c.p.s.), 7.24 (10H, singlet), and 8.48 (1H, multiplet).

Anal. Calcd. for $C_{19}H_{24}N_2O_2$ (312.4): C, 73.05; H, 7.74; N, 8.97. Found: C, 73.18; H, 7.91; N, 9.08.

B. A suspension of 3-benzylamino-4-hydroxypentanoic acid lactone (0.5 g) in water (2 ml) was kept at room temperature (20°) for 2 weeks. The solid that was produced was filtered off (0.23 g) and recrystallized from benzene to give the amino amide IX (R = $CH_2C_6H_5$) as needles (0.1 g), the properties of which were identical with those of the sample obtained above.

Reaction of 4-Hydroxypent-3-enoic Acid Lactone (III, R = CH_3) with Benzylamine

A. Nonaqueous Conditions

A mixture of 4-hydroxypent-3-enoic acid lactone (1 g, 1 mole) and benzylamine (1.06 g, 1 mole) was kept at 20° for 1 h. The N-benzyl-4-oxopentanoamide (VII, B = $NHCH_2C_6H_5$) (2.06 g) that was produced was then recrystallized from benzene to give needles (1.29 g), m.p. 79.5–80° (lit. (7*c*) m.p. 82–83°); $\nu_{max}^{CHCl_3}$ 3 550 (amide NH), 1 723 (ketone carbonyl), and 1 670 cm^{-1} (amide carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*e*) δ 2.10 (3H, singlet), 2.55 (4H, A_2B_2 quartet, J = 5.5, 9.0, and 5.5 c.p.s.), 4.32 (2H, doublet, J = 6 c.p.s.), 6.59 (1H, broad multiplet), and 7.25 p.p.m. (5H, singlet).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

B. Aqueous Conditions

Benzylamine (3.24 g, 1 mole) in water (5 ml) was cooled to 0°, and a suspension of 4-hydroxypent-3-enoic acid lactone (2.97 g, 1 mole) in water (5 ml) was added dropwise, with stirring, during 15 min. The mixture was then rotary evaporated at 20° and the yellow solid (6 g) was recrystallized from benzene. N-Benzyl-4-oxopentanoamide separated as needles (3.5 g) which were identical in all respects with the sample obtained above under nonaqueous conditions. Evaporation of the benzene mother liquid yielded an oil (2.4 g), which was estimated spectroscopically to contain 80% of the cyclized product 1-benzyl-5-hydroxy-5-methylpyrrolidin-2-one; $\nu_{max}^{CHCl_3}$ 3 400 (hydroxyl) and 1 680 cm^{-1} (pyrrolidinone carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*f*) δ 1.26 (3H, singlet), 1.85–2.70 (4H, complex multiplet), 6.42 (2H, AB quartet, J_{AB} = 15.7 c.p.s., $\nu_A - \nu_B$ = 24.4 c.p.s.), 5.01 (1H, singlet), and 7.19 p.p.m. (5H, singlet). The crude product decomposed on distillation, and all attempts to effect purification by chromatography were unsuccessful because partial equilibration of the open-chain (VII, B = $NHCH_2C_6H_5$) and cyclic (XI, R = $CH_2C_6H_5$) isomers occurred on the column.

A pure sample of the keto amide VII (B = $NHCH_2C_6H_5$), m.p. 80°, underwent 50% conversion into the pyrrolidinone XI (R = $CH_2C_6H_5$) when it was refluxed in water for 2 days.

Reaction of 4-Hydroxypentanoic Acid Lactone with Benzylamine

A. Nonaqueous Conditions

4-Hydroxypentanoic acid lactone (5 g, 1 mole) and benzylamine (6.2 g, 1 mole) were heated at 140° under nitrogen for 48 h. The product was dissolved in chloroform (50 ml), and the chloroform solution was washed with 2 *N* hydrochloric acid (25 ml), then with saturated aqueous sodium hydrogen carbonate (25 ml), and finally with water (10 ml). The dried ($MgSO_4$) solution was evaporated and the red oil (6.3 g) was chromatographed on Florisil. Elution with benzene–acetone (20:1) followed by distillation gave N-benzyl-4-hydroxypentanoamide (3.8 g), b.p. 179–180° at 0.02 mm; $\nu_{max}^{CHCl_3}$ 3 490 and 3 350 (hydroxyl, amide NH) and 1 668 cm^{-1} (amide carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*g*) δ 1.05 (3H, doublet, J = 6 c.p.s.), 1.68 (2H, triplet, J = 6.5 c.p.s.), 2.25 (2H, triplet, J = 6.5 c.p.s.), 3.67 (1H, quartet, J = 6 c.p.s.), 4.24 (2H, doublet, J = 6 c.p.s.), 4.81 (1H, singlet), 7.17 (5H, singlet), and 7.74 p.p.m. (1H, broad multiplet).

Anal. Calcd. for $C_{12}H_{17}NO_2$ (207.3): C, 69.54; H, 8.27; N, 6.76. Found: C, 69.33; H, 8.24; N, 6.57.

On one occasion, after the above hydroxybenzylamide was heated at 190° for 3 days, some cyclization to 1-benzyl-5-methylpyrrolidin-2-one was observed; $\nu_{max}^{CHCl_3}$ 1 670 cm^{-1} (pyrrolidinone carbonyl); p.m.r. ($CDCl_3$) (Fig. 1*h*) δ 1.09 (3H, doublet, J = 6 c.p.s.), 1.20–2.45 (4H, complex multiplet), 3.10–3.65 (1H, complex multiplet), 4.37 (2H, AB quartet, J_{AB} = 15.0 c.p.s., $\nu_A - \nu_B$ = 53.4 c.p.s.), and 7.19 p.p.m. (5H, singlet).

B. Aqueous Conditions

Benzylamine (5.4 g, 1 mole) and 4-hydroxypentanoic acid lactone (5 g) were refluxed in water (10 ml) under nitrogen for 48 h. Work-up as described above gave N-benzyl-4-hydroxypentanoamide (5.4 g), b.p. 173–174° at 0.015 mm, identical with the product obtained above under nonaqueous conditions.

ACKNOWLEDGMENTS

We express our appreciation to the National Cancer Institute of Canada for their generous support of this work. The award of a Province of Ontario Graduate Fellowship to one of us (J. M. Y.) is gratefully acknowledged.

SYNTHESIS OF 6′-SUBSTITUTED MALTOSES

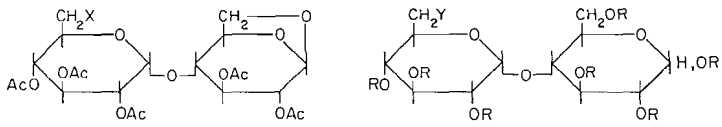
G. G. S. DUTTON AND K. N. SLESSOR[1]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 9, 1964

ABSTRACT

Derivatives of maltose substituted at position 6′ have been prepared by the replacement of a 6′-*O*-*p*-toluenesulfonate ester by various reagents. Tritylation of 1,6-anhydro-β-maltose followed by acetylation and detritylation yielded 2,3,2′,3′,4′-penta-*O*-acetyl-1,6-anhydro-β-maltose, which gave the 6′-*O*-*p*-toluenesulfonate in good yield. Replacement of the sulfonate ester with iodide led to a derivative from which 6′-deoxy-maltose was prepared by reduction, acetolysis, and deacetylation. 6′-Deoxy-6′-mercapto-maltose was prepared by replacement of the sulfonate with thiolacetate followed by acetolysis and deacetylation. 6′-Amino-6′-deoxy-maltose was prepared in low yield by azide replacement of the sulfonate, deacetylation, reduction, and mild acid hydrolysis.

Attempts to prepare 6-substituted derivatives from benzyl 4′,6′-*O*-benzylidene-β-maltoside were unsuccessful. The possible explanations for the unreactivity of position 6 are discussed.

Specifically substituted disaccharides are important not only as reference compounds in partial hydrolyses of substituted polysaccharides (1–3), but also as substrates in studies on the action of carbohydrases. The information gained in such specificity studies may be useful when applied to the action of these enzymes on oligo- and poly-saccharides.



Because of the difficulty of synthesizing α-linked glucosidic disaccharides from their monosaccharide constituents, the modification of a naturally occurring disaccharide containing an α-linkage was undertaken. Maltose was chosen for two reasons. Firstly, this disaccharide is the most common α-linked glucopyranosyl glucose, and secondly, information obtained in specificity studies would be of interest in the interpretation of the action of enzymes on starches. An earlier paper (4) described the catalytic oxidation of benzyl β-maltoside to yield maltobiouronic acid (4-*O*-[α-D-glucopyranosyluronic acid]-D-glucose).

The preparation of specifically substituted derivatives is dependent on the use of reagents which show high selectivity in their reactions. Thus, sulfonation (*p*-toluenesulfonyl or methanesulfonyl chloride in pyridine) of 1,6-anhydro-β-maltose gave a complex mixture of products, as shown by thin-layer chromatography. Tritylation, however, yielded only the 6′-*O*-trityl derivative. Acetylation of this material followed by detritylation with aqueous acetic acid gave a pentaacetate with only the 6′-hydroxyl free (III). Subsequent *p*-toluenesulfonation yielded 2,3,2′3′,4′-penta-*O*-acetyl-1,6-anhydro-6′-*O*-*p*-toluenesulfonyl-β-maltose in high yield (IV).

Replacement of the sulfonate with iodide followed by reduction gave the 6′-deoxy derivative (VI). Acetolysis with 1% sulfuric acid as the catalyst permitted opening of the 1,6-anhydro ring without cleavage of the disaccharide linkage. Deacetylation yielded 6′-deoxy-maltose (VII), which was characterized as the β-hepta-acetate (VIII). Acid hydrolysis yielded glucose and material chromatographically identical with 6-deoxy-D-glucose prepared by the method of Fischer and Zach (5). Sodium borohydride reduction followed by hydrolysis yielded two compounds, which were identified chromatographically as 6-deoxy-D-glucose and sorbitol. Although benzyl 6′-deoxy-β-maltoside has been prepared (6), the free sugar was not reported.

(VIII) Y = H, R = Ac
(X) Y = SAc, R = Ac
(XI) Y = SH, R = H
(XIII) Y = NH_2, R = H

6'-Derivatives of maltose

Replacement of the sulfonate with thiolacetate (7) yielded the 6′-*S*-acetyl derivative (IX) which, upon acetolysis, gave hepta-*O*-acetyl-6′-*S*-acetyl-6′-deoxy-α-maltose (X). Deacetylation with sodium methoxide in methanol gave a product which oxidized very rapidly in contact with air. The free thiol was regenerated by the addition of excess 2-mercaptoethanol. Hydrolysis of 6′-deoxy-6′-mercapto-maltose yielded two compounds chromatographically identical with D-glucose and 6-deoxy-6-mercapto-D-glucose (8). Hydrolysis of the borohydride-reduced disaccharide gave 6-deoxy-6-mercapto-glucose and sorbitol, as indicated by paper chromatography.

Replacement of the sulfonate with azide yielded 2,3,2′,3′,4′-penta-*O*-acetyl-1,6-anhydro-6′-azido-6′-deoxy-β-maltose (XII). Reduction of the azide in this molecule led to an amorphous mixture, presumably caused by *O*- to *N*-migration of the acetates. Deacetylation followed by reduction led to the desired 6′-amino-1,6-anhydro-6′-deoxy-β-maltose. The ability of the 6-amino group to hinder acid hydrolysis (9) would be expected to stabilize the glycosidic linkage of a 6-amino-glucose, which has, in fact, been reported by Cramer and co-workers (10). Thus mild acid hydrolysis should open the 1,6-anhydro ring without cleavage of the disaccharide, thereby yielding 6′-amino-6′-deoxy-maltose. After hydrolysis of the amino anhydride with 0.15 *N* hydrochloric acid for 13 h at 100°, chromatography indicated the presence of two ninhydrin-positive materials, the slower of which gave a positive test with *p*-anisidine trichloroacetate spray and was shown to be 6′-amino-6′-deoxy-maltose (XIII). The faster running, ninhydrin-positive material was chromatographically identical with the starting material. *p*-Anisidine trichloroacetate spray revealed, in addition to 6′-amino-6′-deoxy-maltose, a relatively large proportion of glucose. Both sprays, however, failed to indicate the presence of any 6-amino-6-deoxy-glucose, which should have been produced in an amount equal to that of glucose by hydrolysis of the disaccharide.

It has been suggested that these results may indicate that 6-amino-6-deoxy-D-glucose is more easily destroyed by acid than is D-glucose (11). Such degradations of amino sugars are known. For example, Paulsen has reported the ease with which 5-amino-5-deoxy sugars are transformed into pyridine derivatives (12).

Attempts to prepare 6-substituted derivatives of maltose by preferential reaction of the single, free, primary hydroxyl group on benzyl 4′,6′-*O*-benzylidene-β-maltoside were unsuccessful. *p*-Toluenesulfonation yielded three major products, as indicated by thin-layer chromatography. Two of these products travelled at a rate corresponding to that of monotosylates, the other travelling at a rate corresponding to that of a ditosylate. Methanesulfonation yielded a mixture of starting material and monosubstituted material. Disubstituted material was formed when reaction times were increased. Tritylation was attempted, and thin-layer chromatography indicated that no reaction had occurred even after 3 days at room temperature.

The isolation of both uronic acids from the catalytic oxidation of methyl β-maltoside (13) is contrasted with the isolation of only maltobiouronic acid from the oxidation of benzyl β-maltoside (4, 14). Partial tritylation of either maltose or benzyl β-maltoside leads to the 6′-*O*-trityl derivative (6, 15). The acid chromate oxidation of position 6 was found to be much more difficult than the oxidation of position 6′ in the synthesis of pseudo-cellobiouronic and cellobiouronic acids (16). Results presented in this work further demonstrate the difference in reactivity of the two primary hydroxyl groups in maltose.

Whereas a disaccharide may appear to be composed of two identical sugar residues, it must be realized that the glcycose residue is substituted (e.g. at C-4 in maltose and cellobiose) whereas the glycosyl portion is not. It therefore follows that seemingly identical positions in the two residues may well be subjected to different electronic effects and hence have different reactivities.

In addition, the presence of a bulky aglycone in the β-anomeric position may exert a marked steric effect upon substitution at position 6. For these reasons the selectivity normally associated with certain typical monosaccharide reactions may undergo marked change when applied to disaccharides.

EXPERIMENTAL

Evaporations were carried out under reduced pressure at a bath temperature of 40–45°. Optical rotations are equilibrium values measured on a Bendix–Ericson ETL-NPL automatic polarimeter (type 143A) at 21 ± 2°. Molecular weights were determined on a M.S.9 spectrometer. Melting points quoted are uncorrected. Chromatograms were run by the descending technique in the following solvents: (*a*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4), (*b*) 1-butanol–ethanol–water (4:1:5), and (*c*) ethyl acetate – acetic acid – water (18:7:8). The sulfonate replacement reactions and acetolyses of 1,6-anhydro rings were followed by thin-layer chromatography on silica gel with solvent *d* (ethyl ether – toluene (2:1)).

Sugars were detected on paper chromatograms by the *p*-anisidine trichloroacetate spray (17) for reducing sugars and the periodate–permanganate spray (18) for nonreducing sugars. Detection of sugars on thin-layer plates was accomplished by spraying the plates with concentrated sulfuric acid and heating them at 150–200°.

1,6-Anhydro-β-maltose

To a suspension of hexa-*O*-acetyl-1,6-anhydro-β-maltose (19) (7 g, 1) in methanol (95 ml) was added a solution of 0.1 *M* sodium methoxide in methanol (5 ml). After 4 h the acetate had dissolved, and after a further 14 h the solution was neutralized with Amberlite IR 120 (H^+) ion-exchange resin. The solution was filtered and evaporated to give a sirup which was dissolved in refluxing methanol (50 ml). The hot solution was thinned with ethyl acetate (100 ml) and allowed to cool. The crystals (3.2 g) were filtered off, and then recrystallized in the same manner to give 1,6-anhydro-β-maltose, m.p. 156–158°, $[\alpha]_D$ 108° (*c*, 7.3 in H_2O) (lit. (20) m.p. 150°, $[\alpha]_D$ 79°).

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.17. Found: C, 44.02; H, 5.93.

1,6-Anhydro-6′-O-trityl-β-maltose

To 1,6-anhydro-β-maltose (2.2 g, powdered and dried over P_2O_5 *in vacuo*) was added freshly distilled pyridine (25 ml). The mixture was warmed to effect solution and cooled to room temperature. Recrystallized trityl chloride (2.85 g, 1.5 mole equivalents) was added and the solution was left at room temperature for 5 h. The pyridine solution was added dropwise to ice water (500 ml) with continuous stirring. The mixture was then extracted with chloroform (2 × 100 ml), and the chloroform extracts were amalgamated and filtered through Celite. The clear solution was thinned with an equal volume of petroleum ether (30–60°) and the precipitate (1.9 g) collected by filtration. The trityl ether was recrystallized three times from ethanol–water (1:2, 75 ml/g) to yield 1,6-anhydro-6′-*O*-trityl-β-maltose melting at 141–142°, $[\alpha]_D$ 40.8° (*c*, 2.53 in MeOH).

Anal. Calcd. for $C_{31}H_{34}O_{10}\cdot H_2O$: C, 63.70; H, 6.16. Found: C, 63.78; H, 6.26.

Penta-O-acetyl-1,6-anhydro-6′-O-trityl-β-maltose (II)

To 1,6-anhydro-6′-*O*-trityl-β-maltose (1.5 g) dissolved in pyridine (15 ml) was added acetic anhydride (15 ml), and the solution was left overnight at room temperature. Dropwise addition of the acetylation solution to ice water (1 000 ml) gave the acetylated ether (2.2 g). Recrystallization from ethanol–water (3:1, 50 ml/g) gave penta-*O*-acetyl-1,6-anhydro-6′-*O*-trityl-β-maltose melting at 101–102°, $[\alpha]_D$ 55.0° (*c*, 1.55 in $CHCl_3$).

Anal. Calcd. for $C_{41}H_{44}O_{15}$: C, 63.40; H, 5.67. Found: C, 62.98; H, 5.67.

2,3,2′,3′,4′-Penta-O-acetyl-1,6-anhydro-β-maltose (III)

Penta-*O*-acetyl-1,6-anhydro-6′-*O*-trityl-β-maltose (1 g) was dissolved in 80% aqueous acetic acid (40 ml) and the solution was kept for 3 h at 50°. To the warm solution was added water (90 ml), and the mixture was kept at 5° for 18 h. The precipitate was collected by filtration and washed with 25% aqueous acetic acid (10 ml). The combined filtrates were evaporated to a sirup. Crystals (665 mg) were obtained by dissolving the sirup in hot 2-propanol (25 ml). Recrystallization from the same solvent (40 ml/g) gave 2,3,2′,3′,4′-penta-*O*-acetyl-1,6-anhydro-β-maltose melting at 82–83°, $[\alpha]_D$ 43.4° (*c*, 2.43 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{30}O_{15}$: C, 49.44; H, 5.62; mol. wt. 534. Found: C, 49.50; H, 5.70; mol. wt. 534.

Penta-O-acetyl-1,6-anhydro-6′-O-p-toluenesulfonyl-β-maltose (IV)

To the pentaacetate (4 g) dissolved in dry pyridine (18 ml) was added *p*-toluenesulfonyl chloride (7.5 g). After 5 h at room temperature, water (3 drops) was added to hydrolyze excess *p*-toluenesulfonyl chloride and the solution was poured into ice water (80 ml). This mixture was extracted with chloroform (3 × 100 ml), and the chloroform extracts were combined and washed with water (7 × 100 ml). The solution was dried with calcium chloride, filtered, and evaporated to give a sirup which, when dissolved in hot 2-propanol (155 ml), gave the crystalline tosylate (4.25 g). Recrystallization from the same solvent (36 ml/g) gave penta-*O*-acetyl-1,6-anhydro-6′-*O*-*p*-toluenesulfonyl-β-maltose melting at 170–171°, $[\alpha]_D$ 55.7° (*c*, 1.00 in $CHCl_3$).

Anal. Calcd. for $C_{29}H_{36}O_{17}S$: C, 50.58; H, 5.23; S, 4.65. Found: C, 50.48; H, 5.11; S, 4.36.

Penta-O-acetyl-1,6-anhydro-6′-deoxy-6′-iodo-β-maltose (V)

To a solution of the 6′-*O*-*p*-toluenesulfonate (1.2 g) in *N*,*N*-dimethylformamide (50 ml) was added finely powdered sodium iodide (4 g). The solution was heated on a steam bath for 1½ h. The cooled solution was diluted with water (100 ml), and extracted with chloroform (4 × 50 ml). The combined chloroform extracts were washed with water (6 × 100 ml), dried over calcium chloride, filtered, and evaporated. The sirup that was obtained was dissolved in hot 2-propanol (100 ml), from which crystals (1.04 g) were obtained. Recrystallization from the same solvent (100 ml/g) gave penta-*O*-acetyl-1,6-anhydro-6′-deoxy-6′-iodo-β-maltose melting at 194–195°, $[\alpha]_D$ 42.0° (*c*, 1.03 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{29}O_{14}I$: C, 40.99; H, 4.50. Found: C, 41.09; H, 4.58.

Penta-O-acetyl-1,6-anhydro-6′-deoxy-β-maltose (VI)

To a solution containing penta-*O*-acetyl-1,6-anhydro-6′-deoxy-6′-iodo-β-maltose (0.5 g) and pyridine (0.1 ml) in ethanol (10 ml) was added 10% palladium on charcoal (0.5 g). The mixture was kept at 60° and a stream of hydrogen was introduced through a capillary. After 4 h the catalyst was filtered off and the solution evaporated. The resulting sirup was dissolved in chloroform (30 ml), and the solution was washed with 1% sodium thiosulfate (15 ml) and finally with water (4 × 30 ml). The chloroform solution was dried over calcium chloride and evaporated to give a faintly yellow sirup. The sirup was dissolved in hot 2-propanol (25 ml) and the solution, when cooled, gave the crystalline deoxy sugar (252 mg). Recrystallization from 2-propanol (40 ml/g) gave penta-*O*-acetyl-1,6-anhydro-6′-deoxy-β-maltose melting at 141–142°, $[\alpha]_D$ 44.5° (*c*, 0.86 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{30}O_{14}$: C, 50.96; H, 5.77. Found: C, 50.87; H, 5.89.

6′-Deoxy-maltose (VII)

Penta-*O*-acetyl-1,6-anhydro-6′-deoxy-β-maltose (485 mg) was dissolved in the acetolysis mixture (10 ml; sulfuric acid – acetic anhydride – acetic acid, 1:70:30). The optical rotation changed from 89.2° (5 min) to 138.8° (2 h), after which time it was constant. The flask was cooled in ice after 3 h and ice (5 g) was added. The sulfuric acid was neutralized by the addition of 1% barium acetate, and the precipitate was removed by centrifugation. The solution was evaporated to give a sirup which was evaporated to dryness with ethanol (3 × 10 ml). The hepta-*O*-acetate could be obtained as an amorphous powder on precipitation from alcohol–water. The sirupy acetate was dissolved in methanol (10 ml), and a solution of 0.1 *M* sodium methoxide in methanol (2 ml) was added. After 17 h at room temperature the solution was neutralized with Amberlite IR 120 (H^+), filtered, and evaporated to a sirup. The sirup, which was chromatographically pure, could not be induced to crystallize even after chromatography on Dowex 50WX2 (Li^+) ion-exchange resin (21). After hydrolysis of a sample of the sugar with 2 *N* sulfuric acid, the presence of glucose and material identical with 6-deoxy-glucose (5) was indicated by chromatography. A second sample, which had been reduced with sodium borohydride before hydrolysis, consisted of sorbitol and 6-deoxy-glucose. The 6′-deoxy-maltose had $[\alpha]_D$ 112.7° (*c*, 2.77 in H_2O).

Anal. Calcd. for $C_{12}H_{22}O_{10}\cdot H_2O$: C, 41.86; H, 6.93. Found: C, 41.39; H, 6.96.

Hepta-O-acetyl-6′-deoxy-β-maltose (VIII)

A portion of the 6′-deoxy-maltose (23.3 mg) was dissolved in pyridine (1 ml), and acetic anhydride (4 ml) was added. The solution was left for 30 h at room temperature, poured into ice water (40 ml), and extracted with chloroform (3 × 30 ml). The combined chloroform extracts were washed thoroughly with water (6 × 50 ml), dried over calcium chloride, filtered, and evaporated. The resulting sirup was dissolved in hot ethanol (2 ml) and the solution, when cooled, yielded crystalline hepta-*O*-acetyl-6′-deoxy-β-maltose, m.p. 183–185°, $[\alpha]_D$ 64° (*c*, 0.68 in $CHCl_3$).

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.80. Found: C, 50.58; H, 6.12.

Penta-O-acetyl-6′-S-acetyl-1,6-anhydro-6′-deoxy-β-maltose (IX)

To a solution of penta-*O*-acetyl-1,6-anhydro-6′-*O*-*p*-toluenesulfonyl-β-maltose (500 mg) in *N*,*N*-dimethylformamide was added potassium thiolacetate (220 mg). The mixture was heated on a steam bath for half an hour. To the cooled solution was added water (50 ml), and the mixture was extracted with chloroform (4 × 50 ml). The combined chloroform extracts were thoroughly washed with water (7 × 100 ml), dried over calcium chloride, filtered, and evaporated to a sirup. The sirup was dissolved in hot 2-propanol (45 ml), and the solution, when cooled, gave crystals (300 mg) of the *S*-acetate. Recrystallization of this material from 2-propanol (80 ml/g) yielded penta-*O*-acetyl-6′-*S*-acetyl-1,6-anhydro-6′-deoxy-β-maltose melting at 219–220°, $[\alpha]_D$ 34.6° (*c*, 0.72 in $CHCl_3$).

Anal. Calcd. for $C_{24}H_{32}O_{15}S$: C, 48.66; H, 5.41; S, 5.41. Found: C, 48.74; H, 5.57; S, 5.24.

Hepta-O-acetyl-6′-S-deoxy-α-maltose (X)

Penta-*O*-acetyl-6′-*S*-acetyl-1,6-anhydro-6′-deoxy-β-maltose (150 mg) was dissolved in the acetolysis mixture (3 ml; sulfuric acid – acetic anhydride – acetic acid, 1:70:30). After 3 h at room temperature the solution was added dropwise to ice water (25 ml). The white powder so obtained was filtered and a portion recrystallized from ethanol–water (1:3, 100 ml/g). Further recrystallization did not remove a small amount of the β-anomer which was shown to be present by thin-layer chromatography in solvent *d*. Hepta-*O*-acetyl-6′-*S*-acetyl-6-deoxy-α-maltose had m.p. 73–75° and $[\alpha]_D$ 113° (*c*, 0.79 in $CHCl_3$).

Anal. Calcd. for $C_{28}H_{38}O_{18}S$: C, 48.42; H, 5.49. Found: C, 48.67; H, 5.79.

6′-Deoxy-6′-mercapto-maltose (XI)

To hepta-*O*-acetyl-6′-*S*-acetyl-6′-deoxy-α-maltose (120 mg) in methanol (4 ml) was added a solution of 0.1 *M* sodium methoxide in methanol (1 ml). After the solution had been kept at room temperature overnight, it was neutralized with Amberlite IR 120 (H^+), filtered, and evaporated to a sirup. Chromatography in solvent *a* indicated two products (R_f 0.018 and 0.23), which were the disulfide and free thiol, respectively. When excess 2-mercaptoethanol and 1 drop of concentrated ammonia were added, only the more mobile compound was present. Chromatography of the acid hydrolysate of 6′-deoxy-6′-mercapto-maltose indicated the presence of glucose and 6-deoxy-6-mercapto-glucose. Borohydride reduction followed by hydrolysis yielded sorbitol and 6-deoxy-6-mercapto-glucose. Attempts to crystallize the chromatographically pure disaccharide were unsuccessful. Insufficient material was recovered to obtain suitable analyses. The 6′-deoxy-6′-mercapto-maltose had $[\alpha]_D$ 137.6° (*c*, 2.02 in H_2O).

Penta-O-acetyl-1,6-anhydro-6′-azido-6′-deoxy-β-maltose (XII)

Penta-*O*-acetyl-1,6-anhydro-6′-*O*-*p*-toluenesulfonyl-β-maltose (1.5 g) dissolved in *N*,*N*-dimethylformamide (75 ml) was heated on a steam bath with sodium azide (1.5 g) for 1 h. The cooled solution was poured into an equal volume of water and the mixture was extracted with chloroform (4 × 100 ml). The combined chloroform extracts were thoroughly washed with water (8 × 200 ml), dried over calcium chloride, filtered, and evaporated to a sirup. The sirup was dissolved in hot 2-propanol, and the solution was cooled to give crystals (1.06 g) of the 6′-azide. Recrystallization from the same solvent (50 ml/g) yielded penta-*O*-acetyl-1,6-anhydro-6′-azido-6′-deoxy-β-maltose melting at 151–152°, $[\alpha]_D$ 47.9° (*c*, 2.53 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{29}O_{14}N_3$: C, 47.23; H, 5.19; N, 7.51; mol. wt. 559. Found: C, 47.68; H, 5.34; N, 7.38; mol. wt. 559.

6′-Amino-6′-deoxy-maltose (XIII)

To a solution of penta-*O*-acetyl-1,6-anhydro-6′-azido-6′-deoxy-β-maltose (560 mg) in methanol (20 ml) was added 0.1 *M* sodium methoxide in methanol (4 ml). After 18 h at room temperature, the solution was neutralized with Amberlite IR 120 (H^+) and evaporated to a sirup which plainly showed an infrared absorption band near 2 100 cm^{-1} characteristic of the azide group (22). The sirup was dissolved in ethanol (15 ml), and 10% palladium on charcoal (300 mg) was added. The mixture was maintained at 65° while a fine stream of hydrogen was bubbled through the solution. After 45 min the solution was made slightly acidic with 3% hydrogen chloride in methanol and the hydrogenation was continued for a further 2 h. The catalyst was removed by filtration, and the solution was evaporated to give a chromatographically pure sirup, R_f 0.054 (solvent *b*, detected with ninhydrin). This material was dissolved in 0.015 *N* hydrochloric acid and heated in a sealed tube for 13 h at 100°. The hydrolysate was neutralized with silver carbonate, filtered, and adjusted to pH 5 with 0.3 *N* hydrochloric acid. Chromatography in solvent *b* indicated only two ninhydrin-positive materials, R_f 0.041 and 0.054. However, *p*-anisidine trichloroacetate spray indicated the presence of glucose, the material showing R_f 0.041, and slower running degradation products. The presence of glucose was indicated by comparison with standards in solvent systems *a*, *b*, and *c*, and also by thin-layer chromatography (23). Preparative paper chromatography on Whatman 3MM paper in solvent *b* gave a small amount (10 mg) of the R_f 0.041 material. Hydrolysis of a sample of this material yielded glucose and 6-amino-6-deoxy-glucose, identical with material prepared by the method of Cramer and co-workers (10). This indicated that the R_f 0.041 material was 6′-amino-6′-deoxy-maltose, $[\alpha]_D$ 88° (*c*, 0.3 in H_2O).

Anal. Calcd. for $C_{12}H_{23}O_{10}N \cdot HCl$: N, 3.70. Found: N, 3.97.

The very low yield prevented any attempts to prepare suitable derivatives.

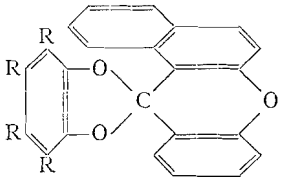
CARBONYL AND THIOCARBONYL COMPOUNDS

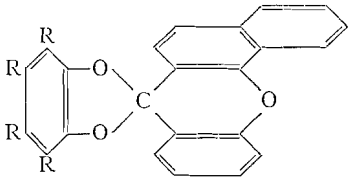
X. SYNTHETIC EXPERIMENTS WITH COUMARIN-2-THIONE AND BENZOXANTHIONES

N. LATIF AND I. FATHY
National Research Center, Dokki, Cairo, United Arab Republic



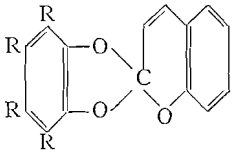
Received July 6, 1965

ABSTRACT



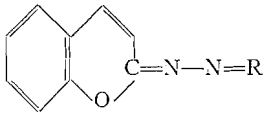
The benzoxanthene ethers I*a*–II*b* are obtained in good yields by the action of tetrachloro- and tetrabromo-*o*-benzoquinone on 1,2- and 3,4-benzoxanthione, respectively. The benzopyran analogues III*a*–III*b* are obtained by the interaction of the corresponding haloquinone and coumarin hydrazone. The latter, which is now readily obtained by the action of hydrazine hydrate on coumarin-2-thione, condenses with thioketones to give coumarin azines. The benzopyran ethers III*a* and III*b* are cleaved by malononitrile, cyanoacetic ester, hydrazine hydrate, phenylhydrazine, and benzoylhydrazine, yielding the unsaturated nitriles (V*a*–V*b*) and the corresponding hydrazones, respectively.

1,2-Benzoxanthione reacts with 9-diazoxanthene, diphenyldiazomethane, and diphenylenediazomethane to give the ethylene sulfides VI–VIII, respectively. However, coumarin-2-thione reacts with the diazo compounds in a different manner; it gives the ethylenes X and XI directly, together with the symmetrical thiiranes XII and XIII, in the cases of diphenyldiazomethane and 9-diazoxanthene, respectively, whereas the cyclopropane derivative XIV is produced in the case of diphenylenediazomethane. XIV is also obtained by the photochemical interaction of coumarin itself and the diazo compound.

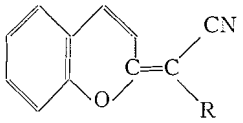


Tetrahalo-*o*-benzoquinones react with xanthione and thioxanthione to give the corresponding methylene ethers (1, 2). It is now shown that benzoxanthiones readily undergo this quinone–thione reaction to give the analogous benzoxanthene ethers. Thus, I*a*–II*b* are obtained, in good yield, by the action of tetrachloro- and tetrabromo-*o*-benzoquinone on 1,2- and 3,4-benzoxanthione, respectively, in boiling dry benzene. The products are identical with the benzoxanthene ethers previously obtained by the reaction of 1,2- and 3,4-benzoxanthone hydrazone with the corresponding tetrahalo-*o*-benzoquinone (3, 4). When the reaction was applied to coumarin-2-thione, tetrachloro-*o*-benzoquinone gave the spiropyran III*a* (1), whereas tetrabromoquinone oxidized the thione mainly to

I*a*, R = Cl
I*b*, R = Br



II*a*, R = Cl
II*b*, R = Br

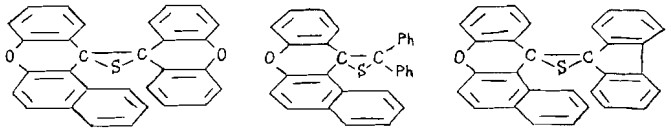


III*a*, R = Cl
III*b*, R = Br

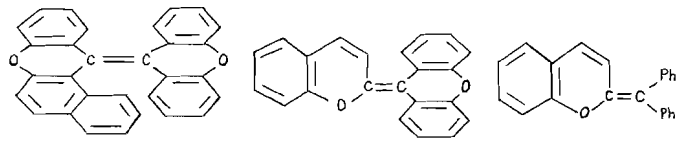
coumarin. Both III*a* and III*b* are now readily obtained by the interaction of coumarin hydrazone with the corresponding tetrahalo-*o*-benzoquinone, possibly through the intermediate formation of an unstable diazo derivative (5). Although hydrazine hydrate opens the lactone ring of coumarin (6), it condenses readily with coumarin-2-thione to give coumarin hydrazone. The latter reacts with thioketones, e.g. thiobenzophenone, thiofluorenone, xanthione, and 1,2-benzoxanthione, to give the coumarin azines IV*a*–IV*d*, respectively, which are identical with the products obtained by the condensation of coumarin-2-thione with the corresponding ketohydrazones. The structure given for III*b*

is based on analogy, and is supported by the following facts: (*i*) it is colorless and does not contain sulfur, (*ii*) it is hydrolyzed by mineral acids to give coumarin and tetrabromocatechol, and (*iii*) its infrared spectrum lacks the stretching frequency band characteristic of the lactone carbonyl group.

IV*a*, R = diphenylmethylene
IV*b*, R = diphenylene
IV*c*, R = xanthylene
IV*d*, R = 1,2-benzoxanthylene



V*a*, R = CN
V*b*, R = $COOC_2H_5$



The ethers III*a* and III*b* are cleaved by active hydrogen compounds to yield the corresponding unsaturated benzopyran derivatives and tetrahalocatechol. Thus, III*a* reacts readily with hydrazine hydrate, phenyl- and benzoyl-hydrazine, malononitrile, and cyanoacetic ester to give coumarin hydrazone, phenyl- and benzoyl-hydrazone, and the unsaturated nitriles V*a* and V*b*, respectively, possibly through a β-elimination process of an intermediate semiether (7). A similar uncatalyzed cleavage of xanthene ethers by active hydrogen compounds has been reported (3, 7). Authentic samples of the products are obtained by condensing coumarin-2-thione with the appropriate active hydrogen compound.

Reaction of 1,2-Benzoxanthione and Coumarin-2-thione with Diazo Compounds

9-Diazoxanthene reacts with xanthione, thioxanthione (8), and 3,4-benzoxanthione (4) to give the corresponding ethylene sulfides. It is now found that 1,2-benzoxanthione reacts with 9-diazoxanthene and diphenyl- and diphenylene-diazomethane in a similar manner to give the ethylene sulfides VI–VIII. However, coumarin-2-thione reacts with the diazo compounds in a different manner. Thus, diphenyldiazomethane and 9-diazoxanthene give the ethylenes X and XI directly, together with the symmetrical thiiranes XII and XIII, respectively, whereas 9-diazofluorene gives the cyclopropane derivative XIV. Constitution of the sulfides VI–VIII is based on analogy (4, 8), lack of color, and the fact that, upon treatment with copper powder, the corresponding ethylene is obtained, e.g. VI gives IX. The structures of X and XI are supported by analytical data, lack of the stretching frequency band characteristic of the lactone carbonyl group in their infrared spectra, and the fact that they are readily cleaved by thionyl chloride or sulfur. Thus, for example,

XII XIII XIV

R = 9-fluorenyl

XV XVI

the ethylene X gives coumarin and xanthone when it is allowed to react with boiling thionyl chloride, and gives coumarin-2-thione and xanthione upon fusion with sulfur. It has been reported (9) that, at higher temperatures, certain ethylenes, such as dixanthylene and dithioxanthylene, acquire ionic betaine structures which are susceptible to cleavage by thionyl chloride or sulfur. It is assumed, in the case of X and XI, that the presence of an unshared electron pair on the oxygen of the benzopyran residue enhances the stabilization of heteropolar structures (cf. XV) through resonance. Production of the ethylenes X and XI in this reaction may proceed through the intermediate formation of an unstable ethylene sulfide (cf. Reaction Scheme 1), which splits off sulfur under the reaction conditions. The latter reacts immediately with the diazo compound to give the symmetrical thiiranes XII and XIII, respectively. 9-Diazoxanthene and diphenyldiazomethane react with sulfur, at room temperature, to give XII and XIII in good yields (8), whereas 9-diazofluorene undergoes this reaction very slowly.

REACTION SCHEME 1.

The structure of XIV is supported by the fact that the product is soluble in aqueous alkali, and by its infrared spectrum, which shows a strong stretching frequency band at 5.75 μ (Nujol) characteristic of the carbonyl group of a saturated δ-lactone (cf. ref. 10). Nuclear magnetic resonance spectral data also exclude the possible structure XVI; the two protons attached to the cyclopropane ring gave rise to the AB system around δ 3.5 p.p.m.

EXPERIMENTAL

Melting points were not corrected. Microanalyses were performed by A. Bernhardt, Germany, and by the Microanalysis Unit, National Research Center, Cairo. Infrared spectra were measured on a Perkin–Elmer infracord 137, and the nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer.

Preparation of 9,9-(Tetrachloro-o-phenylenedioxy)1,2-benzoxanthene (Ia)

A solution of tetrachloro-*o*-benzoquinone (1 g) and 1,2-benzoxanthione (1 g) in dry benzene (20 ml) was heated under reflux for 3 h, filtered while hot, and evaporated to dryness under reduced pressure. A few milliliters of ether was added to the residue, and the solid that formed was filtered off, washed with acetone, and crystallized from xylene to give 9,9-(tetrachloro-*o*-phenylenedioxy)1,2-benzoxanthene (I*a*) (1.35 g), m.p. 333–334 °C (undepressed when admixed with an authentic sample (3)). Its infrared spectrum was identical with that of an authentic sample.

Preparation of 9,9-(Tetrabromo-o-phenylenedioxy)1,2-benzoxanthene (Ib)

Tetrabromo-*o*-benzoquinone (2 g) and 1,2-benzoxanthione (1.4 g) were allowed to react as in the case of the chloro analogue. The product that was obtained (2.52 g) was recrystallized from benzene to give 9,9-(tetrabromo-*o*-phenylenedioxy)1,2-benzoxanthene (I*b*), m.p. 344 °C (decomp.). Its infrared spectrum is identical with that of an authentic sample (3).

Preparation of 9,9-(Tetrachloro-o-phenylenedioxy)3,4-benzoxanthene (IIa)

Tetrachloro-*o*-benzoquinone (1 g) and 3,4-benzoxanthione (1 g) were allowed to react together as in the case of I*a*. The product that was obtained was crystallized from benzene to give II*a* (1.04 g) as colorless crystals, m.p. 305 °C (undepressed when admixed with an authentic sample (4)). The product and the authentic sample have identical infrared spectra.

When the reaction was carried out with tetrabromo-*o*-quinone, 9,9-(tetrabromo-*o*-phenylenedioxy)3,4-benzoxanthene (II*b*) was obtained as colorless crystals, m.p. 306 °C (decomp.). Its infrared spectrum is identical with that of an authentic sample (4).

Preparation of Coumarin Hydrazone

A solution of coumarin-2-thione (11) (2 g) and hydrazine hydrate (99–100%; 0.6 ml) in absolute alcohol (50 ml) was heated under reflux for 3 h. The solution was filtered while hot and evaporated to dryness under reduced pressure, and the residue was extracted with boiling petroleum ether (40–60°). The extract was concentrated and cooled, and the solid that separated out was recrystallized from methanol to give coumarin hydrazone (1.3 g) as yellow crystals, m.p. 85–86 °C.

Anal. Calcd. for $C_9H_8ON_2$: C, 67.50; H, 5.00; N, 17.5. Found: C, 67.78; H, 4.94; N, 17.69.

Preparation of 2,2-(Tetrachloro-o-phenylenedioxy)benzopyran (IIIa)

Coumarin hydrazone (0.8 g) was added in portions, at room temperature (25 °C), to a dry ethereal solution of tetrachloroquinone (2.5 g). After each addition, a reaction, with evolution of gas, occurred. When all the hydrazone had been added, the reaction mixture was evaporated to dryness under reduced pressure. A few milliliters of acetone was added to the residue that was obtained, and the solid that separated out was recrystallized from the same solvent to give 2,2-(tetrachloro-*o*-phenylenedioxy)benzopyran (III*a*) (1.2 g), m.p. 214 °C (undepressed when admixed with an authentic sample (1)). The filtrate was evaporated to dryness and extracted with methanol, and the extract was poured onto ice-cold water, and acidified. The solid that formed was dried and added to acetic anhydride, and the mixture was heated under reflux for 30 min and then poured onto ice. The solid that separated out was crystallized from methanol, and proved to be the diacetate of tetrachlorocatechol (melting point and mixed melting point).

Preparation of 2,2-(Tetrabromo-o-phenylenedioxy)benzopyran (IIIb)

Tetrabromo-*o*-benzoquinone (2.1 g) and coumarin hydrazone (0.4 g) were allowed to react as in the case of III*a*. The solid that was obtained was crystallized from acetone to give III*b* (0.65 g) as colorless crystals, m.p. 222–224 °C.

Anal. Calcd. for $C_{15}H_6O_3Br_4$: Br, 57.70. Found: Br, 56.91.

Hydrolysis of IIIb

The cyclic ether (0.2 g) was added to a solution of concentrated hydrochloric acid (specific gravity 1.19; 1 ml) in dioxane (5 ml), and the mixture was heated under reflux for 30 min and poured onto ice. The precipitate that formed was filtered off, dried, and shown to be tetrabromocatechol (identified as its diacetate). The filtrate was left to evaporate slowly at room temperature (25 °C). The colorless crystals that formed were recrystallized from petroleum ether (30–50°), and proved to be coumarin (m.p. and mixed m.p. 70 °C).

Preparation of Coumarin Azines

General Procedure A

A mixture of coumarin hydrazone (0.01 mole), the thioketone (0.01 mole), and yellow mercuric oxide

(2 g) in absolute alcohol (30 ml) was boiled under reflux for 3 h. The reaction mixture was filtered while hot, concentrated, and left to cool. The precipitate that formed was filtered off and recrystallized from the appropriate solvent (Table I).

General Procedure B

A suspension of coumarin-2-thione (0.01 mole), the appropriate ketohydrazone (0.01 mole), and yellow mercuric oxide (2 g) in absolute alcohol (30 ml) was heated under reflux for 6 h, filtered while hot, and cooled. The azines IV*a*–IV*e* were obtained, and proved to be identical with the products obtained from procedure A.

TABLE I

Reaction of coumarin hydrazone with thioketones

Thioketone used	Coumarin azine, color, and yield	Solvent of crystallization	Melting point (°C)	Analysis (%)
Thiobenzophenone*	IV*a*, yellow, 60%	Acetone	157–158	Calcd. for $C_{22}H_{16}N_2O$: C, 81.48; H, 4.93; N, 8.61. Found: C, 81.50; H, 5.07; N, 8.90.
Thiofluorenone*	IV*b*, orange-yellow, 65%	Acetone	170–171	Calcd. for $C_{22}H_{14}N_2O$: C, 81.98; H, 4.38; N, 8.69. Found: C, 81.92; H, 4.78; N, 8.79.
Xanthione	IV*c*, orange-yellow, 45%	Benzene	176–177	Calcd. for $C_{22}H_{14}N_2O_2$: C, 78.1; H, 4.14; N, 8.28. Found: C, 77.98; H, 4.13; N, 8.64.
1,2-Benzoxanthione	IV*d*, orange-yellow, 42%	Acetone–alcohol	140–141	Calcd. for $C_{26}H_{16}N_2O_2$: C, 80.41; H, 4.12; N, 7.21. Found: C, 80.34; H, 4.42; N, 7.56.

*The reaction was carried out in a carbon dioxide atmosphere.

Preparation of Coumarin Benzoylhydrazone

A mixture of coumarin-2-thione (0.5 g), benzoylhydrazine (0.5 g), yellow mercuric oxide (1 g), and absolute alcohol (20 ml) was boiled under reflux for 6 h. The reaction mixture was filtered while hot, concentrated, and cooled. The product that separated out (0.48 g) was recrystallized from acetone to give coumarin benzoylhydrazone as pale yellow crystals, m.p. 160–161 °C.

Anal. Calcd. for $C_{16}H_{12}N_2O_2$: C, 72.72; H, 4.54; N, 10.60. Found: C, 72.40; H, 4.66; N, 11.06.

Preparation of 2H-1-Benzopyran-Δ2,α-malononitrile (Va)

A mixture of the thione (1 g), malononitrile (0.5 g), and yellow mercuric oxide (1 g) in dry toluene (20 ml) was heated under reflux for 6 h and filtered while hot. The solution was concentrated and cooled, and the solid that separated out was crystallized from benzene to give V*a* (0.92 g) as yellow crystals, m.p. 167–168 °C.

Anal. Calcd. for $C_{12}H_6N_2O$: C, 74.22; H, 3.09; N, 14.43. Found: C, 74.43; H, 3.23; N, 14.82.

Preparation of 2H-1-Benzopyran-Δ2,α-cyanoacetic Ester (Vb)

Coumarin-2-thione and ethyl cyanoacetate were allowed to react as above, when V*b* was obtained as yellow crystals (from methanol), m.p. 141–142 °C.

Anal. Calcd. for $C_{14}H_{11}NO_2$: C, 69.71; H, 4.57; N, 5.80. Found: C, 70.22; H, 4.59; N, 6.04.

Reaction of 2,2-(Tetrachloro-o-phenylenedioxy)benzopyran (IIIa) with Hydrazine Hydrate

A mixture of III*a* (0.5 g) and hydrazine hydrate (99–100%; 0.2 ml) in alcohol (30 ml) was heated under reflux for 3 h, filtered while hot, and evaporated to dryness under reduced pressure. The residue was extracted with boiling petroleum ether (40–60°), and the extract was concentrated and cooled. The product that separated out (0.15 g) was shown to be coumarin hydrazone (m.p. and mixed m.p. 85°). The residue, after extraction with petroleum, was shown to contain tetrachlorocatechol as usual.

Reaction of IIIa with Phenylhydrazine

The reaction was carried out as above, and the solution was left to cool. Coumarin phenylhydrazone (0.23 g), m.p. 143 °C (undepressed when admixed with an authentic sample (11)), was obtained.

When benzoylhydrazine was used instead of phenylhydrazine, coumarin benzoylhydrazone, m.p. 160 °C (0.35 g), was obtained.

Reaction of IIIa with Malononitrile

The cyclic ether III*a* (0.5 g) and malononitrile (0.25 g) in ethanol (25 ml) were heated under reflux for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

6 h. The solid which separated when the solution was allowed to cool was recrystallized from benzene to give 2*H*-1-benzopyran-Δ2,α-malononitrile (*Va*) (0.2 g), m.p. 167–168 °C.

When the reaction was carried out in *n*-butanol with cyanoacetic ester, *Vb* was similarly obtained.

Reaction of Diazo Compounds with 1,2-Benzoxanthione

The thione (0.01 mole) was added in portions to the ethereal solution of the diazo compound. A vigorous reaction, with evolution of gas, took place after each addition. When all the thione had been added, the reaction mixture was left at room temperature (25 °C) for 30 min. The product that separated out was filtered off, washed with ether, and crystallized from acetone to give the corresponding episulfide as colorless crystals (Table II).

Action of Copper Bronze on VI

The episulfide VI (0.5 g) and copper bronze (0.3 g) in xylene (20 ml) were heated under reflux for 1 h. The reaction mixture was filtered while hot, concentrated, and cooled, and the product that separated out was recrystallized from benzene to give the ethylene IX as colorless crystals, m.p. 312–314 °C, in an almost theoretical yield.

Anal. Calcd. for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42. Found: C, 86.94; H, 4.41.

TABLE II

Reaction of 1,2-benzoxanthione with diazo compounds

Diazo compound	Episulfide, % yield, and melting point	Analysis (%)
9-Diazoxanthene	VI, 90%, 188–190°	Calcd. for $C_{30}H_{18}O_2S$: C, 81.44; H, 4.07; S, 7.23. Found: C, 80.98; H, 4.24; S, 7.47.
Diphenyldiazomethane	VII, 80%, 168–170°	Calcd. for $C_{30}H_{20}OS$: C, 84.11; H, 4.67; S, 7.47. Found: C, 84.06; H, 4.54, S, 7.99.
9-Diazofluorene	VIII, 85%, 184–186°	Calcd. for $C_{30}H_{18}OS$: C, 84.5; H, 4.22; S, 7.5. Found: C, 83.87; H, 4.44; S, 6.54.

Reaction of 9-Diazoxanthene with Coumarin-2-thione

Coumarin-2-thione (0.95 g) was added to a solution of 9-diazoxanthene (1.45 g) in dry ether (30 ml), and the reaction mixture was left for 1 h at room temperature (25 °C). The product that separated out was crystallized from acetone as colorless crystals (0.6 g), which were proved to be dispiro(xanthene-9,2′-thiirane-3′,9″-xanthene) (XII) (m.p. and mixed m.p. 206°). The filtrate was evaporated to dryness under reduced pressure, and a few milliliters of methanol was added. The solid that separated out was filtered off and recrystallized from methanol–acetone to give X (0.7 g) as orange-yellow crystals, m.p. 137 °C.

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.16; H, 4.51. Found: C, 84.86; H, 4.24.

Reaction of X with Thionyl Chloride

A solution of X (0.5 g) in thionyl chloride (10 ml) was heated under reflux for 6 h, left to cool, and poured onto ice. The solid that formed was filtered off, washed with water, and crystallized from methanol to give xanthone (m.p. and mixed m.p. 174°). The aqueous filtrate was left to evaporate slowly at room temperature, and the colorless crystals that separated out were recrystallized from petroleum ether (40–60°) and proved to be coumarin (m.p. and mixed m.p. 70°).

Reaction of X with Sulfur

A mixture of X (0.8 g) and powdered sulfur (0.15 g) was heated for 2 h at 270–275° (bath temperature), while a stream of dry carbon dioxide was passed through. The reaction mixture was left to cool and then extracted with methanol, the extract was concentrated and cooled, and the product that separated out (0.17 g) was proved to be coumarin-2-thione (melting point and mixed melting point). The alcohol-insoluble residue was crystallized from benzene, and proved to be xanthione (melting point and mixed melting point) (0.23 g).

Reaction of Diphenyldiazomethane with Coumarin-2-thione

The reaction was carried out as in the case of 9-diazoxanthene. The colorless product which separated out after 30 min was filtered off, and proved to be epithiotetraphenylethane (XIII) (m.p. and mixed m.p. 178°). The mother liquor was left overnight, and a yellow product separated out. It was recrystallized from acetone to give XI as yellow crystals, m.p. 132 °C.

Anal. Calcd. for $C_{22}H_{16}O$: C, 89.18; H, 5.4. Found: C, 89.11; H, 5.6.

For personal use only.

Reaction of 9-Diazofluorene with Coumarin-2-thione

A solution of 9-diazofluorene (1.9 g) and coumarin-2-thione (1.6 g) in dry ether (30 ml) was kept at room temperature for 24 h. The product that separated out was recrystallized from acetone to give XIV (1.2 g) as colorless crystals, m.p. 286 °C. The product is soluble in 5% aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.16; H, 4.51. Found: C, 85.16; H, 4.56.

Photochemical Reaction of 9-Diazofluorene and Coumarin

A solution of equimolecular amounts of 9-diazofluorene and coumarin in dry benzene was exposed to sunlight for 15 days (May), in a pyrex glass tube which was sealed, while a stream of carbon dioxide was passed through the mixture. The product that separated out was recrystallized from acetone, and proved to be XIV (m.p. and mixed m.p. 286 °C). Its infrared spectrum was identical with that of an authentic sample.

ACKNOWLEDGMENTS

The authors thank Professor F. G. Baddar, Faculty of Science, A'in Shams University, Cairo, for determination of the infrared spectra, and Dr. U. Scheidegger, Research Chemist, Varian AG, Switzerland, for determination of the nuclear magnetic resonance spectrum.

NOTES

CHEMISTRY OF TETRAHYDROFURANONE DERIVATIVES II. A CONVENIENT PROCEDURE FOR THE SYNTHESIS OF 3-ALKYL-SUBSTITUTED FURANS[1]

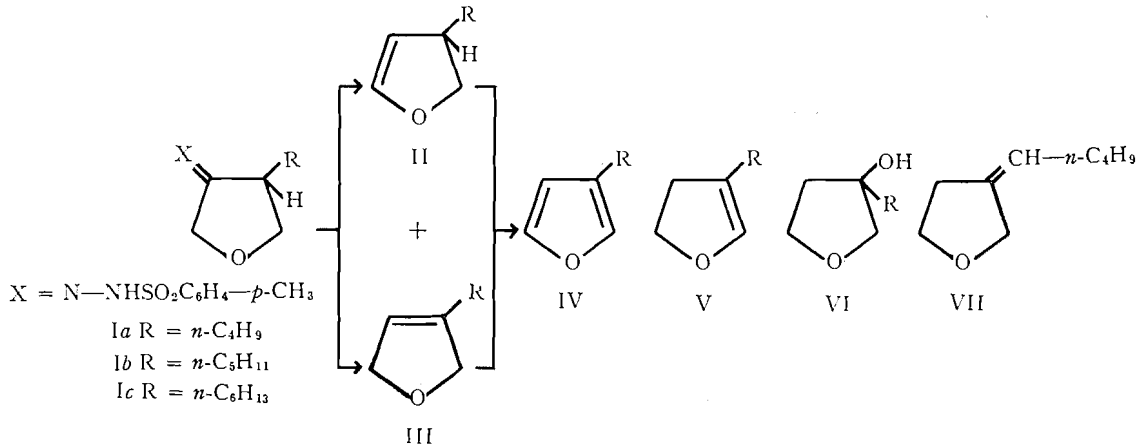
M. A. GIANTURCO AND P. FRIEDEL

A variety of isoprenoid products of plant origin contain a 3-alkyl-substituted furan nucleus (1, 2). Moreover, this structural unit has recently been found to be present in dendrolasin, an odorous substance isolated from ants; this appears to be the first furan derivative ever found in the animal kingdom (3, 4).

Although a few of these natural products have been synthesized (1, 5–7), no convenient procedure for the preparation of 3-alkyl-substituted furans seems to have been reported in the literature. In fact, the best synthesis of compounds of this class appears to be the one based upon the reaction of 3-furoyl chloride with the appropriate alkylcadmium, followed by Wolff–Kischner reduction of the resulting ketone (4, 8).

However, the above procedure is laborious and inefficient, primarily because of the unavailability of a good synthetic method for 3-furoic acid. Prugh has recently reported (9), indeed, that the method of Gronowitz, which leads to 3-furoic acid in 5% overall yield, is the best of the published procedures for the synthesis of this key intermediate (1, 10–12).

The present note describes a convenient approach to 3-alkyl-substituted furans, by a method which should be of fairly general applicability and does not require the preparation of 3-furoic acid.



In a previous communication (13), it has been shown that high yields of mixtures of 2,3- and 2,5-dihydrofurans are obtained when the tosylhydrazones of the now easily available tetrahydrofuranones (14) are treated with sodium dissolved in ethylene glycol (Bamford–Stevens reaction). The ratios of the 2,3- and 2,5-isomers were found to depend upon the position of the alkyl substituent on the ring, being approximately 8:1 and 24:1, respectively, when the tosylhydrazones of 2-methyltetrahydrofuran-3-one and 2-methyltetrahydrofuran-4-one were reacted, and approximately 2:1 when the reaction was carried out with the 3-methyltetrahydrofuran-4-one derivative.

In the course of the present work, application of the Bamford–Stevens reaction to the tosylhydrazones of 3-*n*-butyl-, 3-*n*-pentyl-, and 3-*n*-hexyl-tetrahydrofuran-4-one (I*a*–I*c*) has led to the isolation of the appropriate mixtures of dihydrofurans in yields higher than 90%; in all three cases, the ratios II*a*/III*a*, II*b*/III*b*, and II*c*/III*c* were approximately 3:2.

Subsequent treatment of each of the three above dihydrofuran mixtures with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone gave, after 45 min at room temperature, the corresponding furans (IV) in yields slightly higher than 50%. Besides the solvent (benzene), the desired furan, and traces of starting materials, no other volatile product could be detected in the reaction mixtures by gas–liquid partition chromatography. When the reaction was followed chromatographically to determine its optimal time, it was found that yields of at least 40% could actually be obtained after only 10 to 15 min. Reaction

[1]*For part I of this series, see ref. 13.*

times longer than 1 h, or the use of other quinones as dehydrogenating agents (*o*-chloranil, *p*-chloranil, and phenanthrenequinone) did not improve the yields.

To establish definitely which one of the two isomers (II or III) is best suited for the conversion into the corresponding furan, the mixture of II*b* and III*b* obtained from I*b* was separated into its components by preparative gas–liquid partition chromatography, and II*b* and III*b* were treated separately with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. Although the maximum yield of 3-*n*-pentylfuran (IV*b*) which could be obtained from 3-*n*-pentyl-2,3-dihydrofuran (II*b*) was somewhat lower than 50%, the reaction of 3-*n*-pentyl-2,5-dihydrofuran (III*b*) with the above quinone at room temperature for 1 h resulted in the formation of IV*b* in yields higher than 80%.

When the ease of quinone dehydrogenation of the third possible type of 3-alkyl-substituted dihydrofuran was tested by reacting 4-*n*-pentyl-2,3-dihydrofuran (V*b*) with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, it was found that this isomer gave only extremely low yields of the corresponding furan (IV*b*).

4-*n*-Pentyl-2,3-dihydrofuran (V*b*) was isolated by preparative gas–liquid partition chromatography from the mixture obtained by copper sulfate dehydration of 3-hydroxy-3-*n*-pentyltetrahydrofuran (VI*b*). The above mixture, unsuitable for quinone dehydrogenation to IV*b*, was found to contain 30% V*b*; the remaining 70% consisted of an unidentified compound, accompanied by some III*b* (infrared evidence). The unidentified substance, which co-chromatographs with III*b* on two columns of different polarity, may be the product (VII) of the loss of water between the OH and the extranuclear α-methylene of VI*b*.

These results suggest an explanation for Wynberg's previous report (15) that 3-alkyl-2,5-dihydrofurans are extremely stable in the presence of dehydrogenating agents. Since the starting materials employed by the above investigator had been prepared by the method of Yur'ev *et al.* (16), i.e. iodine-catalyzed dehydration of 3-alkyl-3-hydroxytetrahydrofurans, it seems probable, in fact, that they were not 3-alkyl-2,5-dihydrofurans but rather mixtures analogous to the one obtained in this laboratory by copper sulfate dehydration of VI*b*.

In view of the above, it appears that the position of the double bond in the ring and that of the substituent with respect to the double bond play a dominant role in determining the success or failure of the quinone dehydrogenation of 3-alkyl-substituted dihydrofurans to the corresponding furan.

For personal use only.

A full account of our attempts to employ quinone dehydrogenation of dihydrofurans for the synthesis of monoalkyl- and polyalkyl-substituted furans will be reported in due time. However, the data given in the Experimental section are typical of the general procedure.

EXPERIMENTAL

The infrared data refer to dilute CCl_4 solutions of the compounds; only the most significant bands are reported. The nuclear magnetic resonance spectra were measured at 60 Mc.p.s., with tetramethylsilane as internal standard. Only the seven most intense mass spectral peaks are reported (ionizing voltage, 150 eV; source temperature, 150°). Retention times (R_T) refer to the following chromatographic conditions: 6 m × $\frac{3}{8}$ inch SE-30 column, 30% on 45–60 mesh Chromosorb W, 200°, 120 cc He/min.

Potassium Salt of 3-Carbomethoxytetrahydrofuran-4-one

To a 13.2 g portion of 85% powdered KOH dissolved in 3 ml H_2O and 45 ml 96% ethanol was added, with stirring and external ice cooling, 28.8 g (0.2 mole) of freshly distilled 3-carbomethoxytetrahydrofuran-4-one, prepared as previously described (14). After the addition of 10 ml ether, the pasty precipitate was centrifuged out immediately, washed once with 10 ml ice-cold 96% ethanol and then with 40 ml ether, and vacuum-dried to yield 36.4 g (100%) of crude product. The material so obtained was suitable for further reactions.

3-n-Pentyl-3-carbomethoxytetrahydrofuran-4-one

To a stirred suspension of the above potassium salt (36.4 g, 0.2 mole) in dimethyl sulfoxide (300 ml) was added, in one lot and at room temperature, *n*-pentyl iodide (79.2 g, 0.4 mole). After all the material had dissolved (30 min), stirring was continued for an additional 3 h (negative $FeCl_3$ test); the solution was then poured into ice water (300 ml), salted, and extracted with ether. Distillation yielded, after a forerun consisting chiefly of *n*-pentyl iodide, 35.94 g (84% yield) of the alkylated ester. A sample that was redistilled for analysis had the following physical properties: b.p. 78–79° at 0.2 mm; $n_D^{22.3}$ 1.4555; infrared: $\lambda_{C=O}$ at 5.62 and 5.72 μ.

Anal. Calcd. for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47. Found: C, 61.62; H, 8.46.

3-n-Pentyltetrahydrofuran-4-one

A stirred solution of the above ester (33.5 g, 0.156 mole) in a mixture of 150 ml 20% H_2SO_4 and 150 ml acetic acid was refluxed until the theoretical amount of carbon dioxide had evolved (4 h). After cooling, the solution was brought to pH 10 with NaOH, salted, and extracted with ether. The usual work-up and distillation yielded, after a small forerun, 20.15 g of ketone (82.7% yield). A sample that was redistilled for analysis had the following physical properties: b.p. 78° at 6 mm; $n_D^{25.3}$ 1.4426; infrared: $\lambda_{C=O}$ at 5.65 μ, λ_{C-O-C} at 9.38 μ.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 68.95; H, 10.32.

3-n-Pentyl-2,3-dihydrofuran (IIb) and 3-n-Pentyl-2,5-dihydrofuran (IIIb)

The tosylhydrazone (m.p. 115–116°) of the above ketone was obtained in 80% yield by the usual procedure (13). Heating the solution of this derivative in diethylene glycol (in which sodium had previously been dissolved) according to the previously described procedure (13) gave a mixture of II*b* and III*b* (57.5% II*b* and 42.5% III*b*, by gas–liquid partition chromatography) in 94.3% yield. The mixture (b.p. 45–60° at 12.5 mm) was used as such for conversion into IV*b*; its components, separated from each other by preparative gas–liquid partition chromatography, had the physical properties given below.

3-n-Pentyl-2,3-dihydrofuran (IIb)

R_T 10.5 min; n_D^{28} 1.4372; infrared: 3.22 (w), 6.18 (s), 6.22 (m), 6.80 (s), 8.78 (vs), 10.83 μ (s); nuclear magnetic resonance: absorptions at δ = 0.88 (triplet, 3H), 1.28 (8H), 2.85 (broad signal, 1H), 3.65 to 4.45 (complex multiplet of sharp lines, 2H), 4.80 (triplet, 1H), 6.15 (triplet, 1H); mass spectrum: m/e = 69 (100%), 41 (17%), 140 (molecular ion, 9%), 39 (8%), 27 (6%), 70 (6%), 68 (5%).

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 76.85; H, 11.47.

3-n-Pentyl-2,5-dihydrofuran (IIIb)

R_T 14.2 min; n_D^{28} 1.4480; infrared: 6.00 (w), 6.80 (m), 9.30 (vs), 11.08 μ (vs); nuclear magnetic resonance: absorptions at δ = 0.91 (deformed triplet, 3H), 1.36 (band envelope, 6H), 2.08 (distorted triplet, 2H), 4.44 (complex multiplet, 4H), 5.4 (1H); mass spectrum: m/e = 69 (100%), 41 (96%), 55 (83%), 39 (53%), 29 (50%), 27 (48%), 56 (37%), 140 (molecular ion, 16%).

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 76.85; H, 11.59.

3-n-Pentylfuran (IVb)

To a stirred and cooled suspension of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (12.95 g, 0.057 mole) in anhydrous benzene (50 ml) was added, in small portions, the mixture of II*b* and III*b* described above (7.98 g, 0.057 mole). After the mixture was stirred for 1 h, it was centrifuged, the solid was washed with 250 ml pentane, and the combined solutions were passed through a 30 cm × 2 cm column of neutral alumina, which was then washed with more pentane. The bulk of the solvents was distilled off at normal pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

through an efficient column. A vacuum was then applied and IV*b* was obtained in 52% yield as the fraction boiling at 77–79° and 83 mm (146–148° at 760 mm); R_T 9.1 min; $n_D^{25.5}$ 1.4445; infrared: 6.38 (w), 6.62 (m), 6.80 (m), 8.58 (s), 9.38 (m), 9.73 (s), 11.43 μ (s); mass spectrum: m/e = 82 (100%), 81 (50%), 95 (20%), 138 (molecular ion, 18%), 53 (11%), 27 (7%), 41 (7%).

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.21. Found: C, 78.37; H, 10.50.

4-n-Pentyl-2,3-dihydrofuran (Vb)

Heating the previously described (16) 3-*n*-pentyl-3-hydroxytetrahydrofuran (V*b*) over anhydrous $CuSO_4$ at 160–180° (bath temperature), while the dehydration products were being swept out in a stream of nitrogen through a short column, yielded a mixture containing 30% V*b* (see text). This compound, separated by preparative gas–liquid partition chromatography from the accompanying III*b* and from another unidentified substance (which co-chromatographs with III*b*), had the following physical properties: R_T 12.2 min; n_D^{25} 1.4452; nuclear magnetic resonance: absorptions at δ = 0.91 (distorted triplet, 3H), 1.10 to 1.70 (band envelope, 6H), 2.02 (2H), 2.47 (broadened triplet, 2H), 4.20 (triplet, 2H), 5.92 (1H); mass spectrum: m/e = 83 (100%), 55 (20%), 41 (17%), 140 (molecular ion, 12%), 27 (11%), 39 (10%).

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 77.00; H, 11.35.

A GENERAL METHOD OF PREPARATION OF SUBSTITUTED 2-HYDROXY-1,4-QUINONES

T. R. Kasturi and T. Arunachalam

6-Methoxy-1-naphthol (I), required in connection with a projected synthesis of oxasteroids, has earlier been prepared in very low yield either by the dehydrogenation of 6-methoxy-1-tetralone (II) with sulfur (1) or by the diazotization of 6-methoxy-1-naphthylamine (III) (2, 3). Hence, an alternative simple and better method of preparation of I was desirable.[1]

Recently, Crowshaw and his co-workers (4) reported the conversion of an unsaturated cyclic ketone (IV) into the corresponding phenol (V) by treating the former with potassium *t*-butoxide in *t*-butanol, in an atmosphere of oxygen. Mechanistic considerations[2] suggested that a similar reaction with 6-methoxy-1-tetralone (II) may give rise to the naphthol I. When compound II was treated with potassium *t*-butoxide in *t*-butanol, in an atmosphere

[1]*We have already synthesized I by a simple method which will be published later.*
[2]*We thank Dr. N. A. J. Rogers of the University of Birmingham for helpful discussions.*

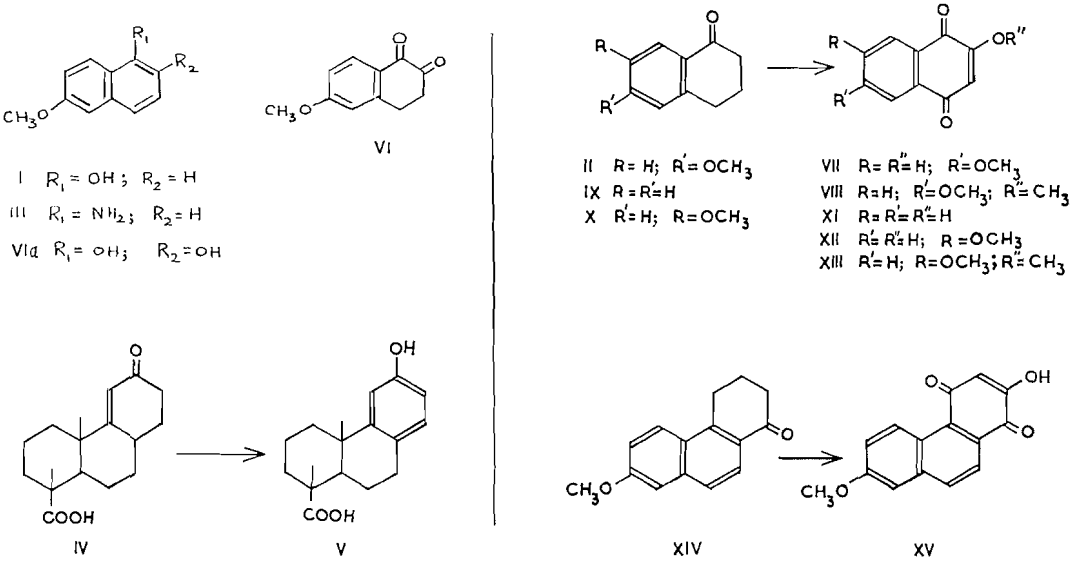
A GENERAL METHOD OF PREPARATION OF SUBSTITUTED 2-HYDROXY-1,4-QUINONES

T. R. Kasturi and T. Arunachalam

6-Methoxy-1-naphthol (I), required in connection with a projected synthesis of oxasteroids, has earlier been prepared in very low yield either by the dehydrogenation of 6-methoxy-1-tetralone (II) with sulfur (1) or by the diazotization of 6-methoxy-1-naphthylamine (III) (2, 3). Hence, an alternative simple and better method of preparation of I was desirable.[1]



Recently, Crowshaw and his co-workers (4) reported the conversion of an unsaturated cyclic ketone (IV) into the corresponding phenol (V) by treating the former with potassium *t*-butoxide in *t*-butanol, in an atmosphere of oxygen. Mechanistic considerations[2] suggested that a similar reaction with 6-methoxy-1-tetralone (II) may give rise to the naphthol I. When compound II was treated with potassium *t*-butoxide in *t*-butanol, in an atmosphere

[1]*We have already synthesized I by a simple method which will be published later.*
[2]*We thank Dr. N. A. J. Rogers of the University of Birmingham for helpful discussions.*

For personal use only.

of oxygen, it rapidly absorbed 2 moles of oxygen per mole of ketone II to give a high-melting, yellow, crystalline solid in 80% yield. This product was different from the expected naphthol I or the α-diketone[3] VI, which could presumably be isolated as 1,2-dihydroxy-6-methoxynaphthalene (VI*a*).

The above-mentioned yellow solid dissolved readily in sodium bicarbonate solution to give a red solution, and its elemental analysis corresponded to $C_{11}H_8O_4$. It showed peaks at 3 257 (enolic OH), 1 669 (C=O), 1 645 (C=C), and 840 and 794 cm^{-1} (trisubstituted double bond) in the infrared spectrum; in the electronic spectral region it showed λ_{max} at 278 and 294 mμ with high intensity, and a broad absorption around 380 mμ. In the presence of alkali the band at 380 mμ was shifted to a longer wavelength at 470 mμ which is characteristic of 2-hydroxy-1,4-quinones (8). The aforementioned solid, on methylation with diazomethane, gave the corresponding methyl ether, analyzed as $C_{12}H_{10}O_4$. Based on the foregoing data, the yellow solid was assigned the structure of 2-hydroxy-6-methoxy-1,4-naphthaquinone (VII), and the corresponding ether that shown by VIII.

The melting point of the yellow solid was undepressed on admixture with an authentic sample of VII prepared by an unambiguous method (9), and the infrared spectra of the two were superimposable. The authentic sample VII obtained by us via the method of Buu-Hoi and Cagniant (9) melted at 217–218°, though the melting point reported by these authors was only 197–200°.

With a view to finding out the generality of this reaction,[4] we carried out the oxygenation with α-tetralone (IX), 7-methoxy-1-tetralone (X), and 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene (XIV), when good yields of the corresponding quinones, viz. 2-hydroxy-1,4-naphthaquinone (XI), 2-hydroxy-7-methoxy-1,4-naphthaquinone (XII), and 2-hydroxy-7-methoxy-1,4-phenanthrequinone (XV), were obtained, as proved by the ultraviolet and infrared absorption data given in Table I. The spectral data of the methyl ethers VIII and XIII, corresponding to the 2-hydroxyquinones VII and XII, respectively, are also recorded in Table I.

[3]*Oxygenation of ketones under these conditions is known to give α-diketones (5–7).*

[4]*This reaction was not applied to cyclohexenone, as Dr. N. A. J. Rogers and his co-workers are presently engaged in this study (4).*

In agreement with the generality of this reaction, Anderson and his co-workers (10) have recently also reported the formation of 2-hydroxy-5,6,7,8-tetramethoxy-1,4-naphthaquinone under similar conditions from 5,6,7,8-tetramethoxy-1-tetralone in 28% yield. Therefore, we feel that this is a general and simple method for the preparation of 2-hydroxy-1,4-quinones.[5,6]

EXPERIMENTAL[7]

2-Hydroxy-6-methoxy-1,4-naphthaquinone (VII)

A solution of 0.704 g (0.004 mole) of 6-methoxy-1-tetralone (II) (11) in 10 ml of dry *t*-butanol was added to a solution of potassium *t*-butoxide prepared from 0.39 g (0.01 g-atom) of potassium in 12 ml of dry *t*-butanol; the resulting solution was stirred at room temperature in an atmosphere of oxygen for 2 h, at the end of which period the initial rapid absorption of oxygen had ceased. The absorption of oxygen corresponded to 2 moles per mole of II. The mixture was acidified with 4 *N* hydrochloric acid and then extracted with ether. The ether extract was washed with 10% sodium bicarbonate solution; the alkali extract, on acidification, gave 0.65 g (80%) of VII, which was crystallized from ethanol as yellow needles, m.p. 217–218° (lit. m.p. 197–200° (9)).

Anal. Calcd. for $C_{11}H_8O_4$: C, 64.70; H, 3.95. Found: C, 64.70; H, 3.99.

[5]*Prof. Thomson and his co-workers have also found this reaction to be a general one (private communication). We thank Prof. Thomson, Aberdeen, Scotland, for giving us this information before its publication, and also for his valuable comments on this manuscript.*

[6]*This oxygenation reaction may be a normal ketone autoxidation in basic solution in the presence of oxygen, and may proceed via the α-diketone VI.*

[7]*All melting points are uncorrected. The ultraviolet spectra were determined in ethanol on a Beckmann DU spectrophotometer. The infrared spectra were recorded with a Perkin–Elmer model 137 B infracord spectrophotometer. The microanalyses were carried out by Mr. B. R. Seetharamia of our department, and by the CIBA Research Centre, India.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The above reaction was repeated with 0.704 g (0.004 mole) of 6-methoxy-1-tetralone (II) in 10 ml of *t*-butanol containing potassium *t*-butoxide (0.005 mole) prepared from 0.19 g of potassium and 6 ml of *t*-butanol; 0.308 g (37.8%) of VII, m.p. 217–218°, and 0.325 g of II, m.p. 76–77°, were obtained.

2-Hydroxy-1,4-naphthaquinone (XI)

A solution of 0.292 g (0.002 mole) of α-tetralone (IX) in 5 ml of dry *t*-butanol was added to a solution of potassium *t*-butoxide prepared from 0.234 g (0.006 g-atom) of potassium in 8 ml of dry *t*-butanol; the reaction was carried out as before to give 0.215 g (61.8%) of XI, which was crystallized from ethanol as brown needles, m.p. 190–191° (lit. m.p. 188–190° (12)).

Anal. Calcd. for $C_{10}H_6O_3$: C, 68.96; H, 3.47. Found: C, 68.93; H, 3.73.

2-Hydroxy-7-methoxy-1,4-naphthaquinone (XII)

The foregoing oxygenation was carried out with 0.704 g (0.004 mole) of 7-methoxy-1-tetralone (X) (13), in a solution of potassium *t*-butoxide prepared from 0.39 g of potassium in 12 ml of dry *t*-butanol, to yield 0.61 g (74.8%) of XII, which was crystallized from ethanol as light-brown needles, m.p. 214–215° (lit. m.p. 214° (14), 220–222° (15)).

Anal. Calcd. for $C_{11}H_8O_4$: C, 64.70; H, 3.95. Found: C, 64.75; H, 3.94.

2-Hydroxy-7-methoxy-1,4-phenanthrequinone (XV)

The above reaction was repeated with a solution of 0.340 g of 7-methoxy-1-keto-1,2,3,4-tetrahydrophenanthrene (XIV) (16) in 5 ml of *t*-butanol, in the presence of a solution of potassium *t*-butoxide prepared from 0.156 g of potassium in 6 ml of dry *t*-butanol, to yield 0.3 g (78%) of XV (9),[8] which was crystallized from ethanol as orange needles, m.p. 226–227°.

Anal. Calcd. for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96. Found: C, 70.81; H, 3.98.

2,6-Dimethoxy-1,4-naphthaquinone (VIII)

An ethereal solution of diazomethane, prepared from 0.5 g of nitrosomethylurea, was added to a chilled solution of 0.204 g of VII with occasional swirling, and the mixture was left at 0° for 0.5 h. The excess of diazomethane was decomposed with acetic acid, and the ether layer was separated and washed with 5% sodium hydroxide and water. Removal of the ether gave 0.2 g (91%) of VIII, which was crystallized from ethanol as yellow needles, m.p. 232–233°.

Anal. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62. Found: C, 66.11; H, 4.71.

2,7-Dimethoxy-1,4-naphthaquinone (XIII)

Similarly, 0.204 g of XII was methylated with an ethereal solution of diazomethane to give 0.2 g (91%) of XIII, which was crystallized from ethanol as light-brown needles, m.p. 217–218°.

Anal. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62. Found: C, 66.25; H, 4.74.

ACKNOWLEDGMENTS

The authors thank Prof. D. K. Banerjee for his keen interest in this problem and for his helpful suggestions. We are grateful to Dr. T. R. Govindachari of the CIBA Research Centre for providing the microanalytical data of a few compounds reported here. We also thank Dr. S. R. Ramadas for helpful discussions. One of the authors (T. A.) thanks the Indian Institute of Science, Bangalore, for the award of a predoctorate fellowship.

PREPARATION OF *cis*- AND *trans*-OCIMENE FROM CATALYTIC PYROLYSIS OF LINALYL ACETATE

BERNARD M. MITZNER,[1] SEYMOUR LEMBERG, AND ERNST T. THEIMER

cis-Ocimene (I) and *trans*-ocimene (II) have recently been reported as occurring in nature (1, 2).[2] They can be prepared in the laboratory by the acid-catalyzed dehydration of linalool (III), presumably by the mechanism shown in Reaction Scheme 1. This rationale allows for formation of dipentene (VII), myrcene (VI), and terpinolene (VIII). The products of a typical linalool dehydration are shown in Table I.

REACTION SCHEME 1.

Unfortunately, the dehydration of linalool is not a practical method for the preparation of quantities of pure *cis*- and *trans*-ocimene, since it is extremely difficult to separate the ocimene from the dipentene via distillation.

The thermal pyrolysis of linalyl acetate (IX) has been investigated by the authors, but temperatures in excess of 300° are necessary to crack the ester, and under these

TABLE I

Linalool dehydration		Linalyl acetate pyrolysis	
Compound	%	Compound	%
Myrcene (VI)	32.3	Myrcene (VI)	43
Dipentene (VII)	23.3	*cis*-Ocimene (I)	20
cis-Ocimene (I)	13.7	*trans*-Ocimene (II)	35
trans-Ocimene (II)	25.5	Dipentene (VII)	2 (approximately)
Terpinolene (VIII)	5.3		

conditions the *cis*-ocimene is quickly converted into alloocimene (3) and relatively large quantities of dipentene are formed. We have, however, developed a catalytic pyrolysis procedure that allows linalyl acetate, in the vapor state and in contact with acid-washed Chromosorb, to undergo catalytic pyrolysis. The path of the reaction can be rationalized as shown in Reaction Scheme 2. By this proposed mechanism, myrcene (VI), *cis*-ocimene

REACTION SCHEME 2.

(I), and *trans*-ocimene (II) are formed as the major products. The actual percentages of terpenes are recorded in Table I.

EXPERIMENTAL

Catalytic Pyrolysis

The thermal catalytic pyrolysis of linalyl acetate is carried out by passing linalyl acetate through a copper tube ($\frac{3}{4}$ inch outside diameter × $\frac{11}{16}$ inch inside diameter, packed with 40–60 mesh Chromosorb P (acid washed and supplied by Johns–Manville Co.), and heated to 140 °C) at a rate of 5 ml/min, with a nitrogen flow rate of 250 ml/min. The resulting pyrolysate is neutralized with K_2CO_3 and distilled via a 4 ft protruded packed column.

Gas chromatographic measurements were carried out with a copper column ($\frac{1}{4}$ inch outside diameter × $\frac{3}{16}$ inch inside diameter, 10 ft long, and packed with 10% Carbowax 20M on 60–80 mesh silane-treated Celite) at a column temperature of 100 °C and an inlet pressure of 20 p.s.i., with a helium flow rate of 90 ml/min.

Procedure temperatures of only 140–150 °C are required.

Because of the relatively low amount of dipentene formed (approximately 2%) quantities of *cis*- and *trans*-ocimene can be prepared as described and can be distilled pure. (See Fig. 1 for a comparison of the vapor phase chromatographic curves of the dehydration and pyrolysis.)

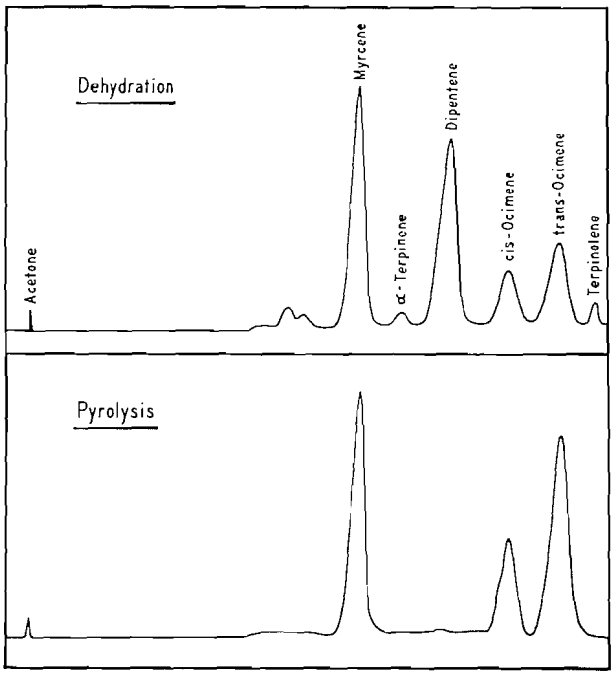

FIG. 1. Gas–liquid chromatographic comparison of the elimination reactions.

Dehydration of Linalool

A mixture of 175 g $KHSO_4$ (analytical grade) and 3 000 g linalool (99% pure as indicated by vapor phase chromatography) was heated and stirred at 128–160 °C liquid temperature, under a vacuum of 150 mm Hg, in a flask fitted with a thermometer, stirrer, and 6 inch distillation column. In this manner, 2 715 g of oil and 278 g of water were collected. The oil was fractionated via a 28 inch P.P. column; the ocimene-rich section, b.p. 70–72 °C at 60 mm Hg, n_D^{20} 1.478, amounted to 773 g and had the analysis shown in Table I.

SYNTHESIS OF CHLORINATED 2-(3-BENZOFURANYL)PHENOLS

E. C. M. COXWORTH

An interest in *o*-hydroxybenzophenones prompted us to repeat the reaction of β,β-dichloro-α,α-bis(3,5-dichloro-2-hydroxyphenyl)ethane with potassium hydroxide in refluxing methanol, which was reported by Riemschneider and his co-workers (1) to

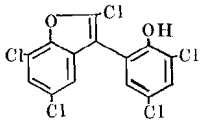
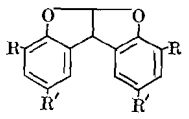
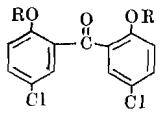
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



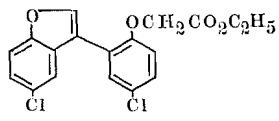
yield 2,2′-dihydroxy-3,3′,5,5′-tetrachlorobenzophenone (I). The product we obtained (A) conformed with that of Riemschneider with respect to melting point and the melting points of its acetate and its methyl ether. However, the analytical and spectroscopic data led us to conclude that the product A is actually 2-(5,7-dichloro-3-benzofuranyl)-4,6-dichlorophenol (II*a*).



I



II a R=R′=Cl
II b R=H, R′=Cl



III

IV a R=R′=Cl
IV b R=H, R′=Cl

V a R=$CH_2CO_2C_2H_5$
V b R=CH_2CO_2H

VI

The following evidence led us to the conclusion that A has structure II*a* and not structure I.

(*i*) The analytical data for the experimental product A and its acetate and methyl ether are in good agreement with those for II*a* and its derivatives; they do not agree with those for I and its derivatives. Riemschneider and his co-workers (1) found a percentage chlorine for A close to the calculated value for I, but since II*a* has a similar percentage chlorine, this analytical data will not distinguish between the two structures.

(*ii*) The nuclear magnetic resonance spectrum of the acetate of A had peaks at 7.89 τ (singlet, 3H), 2.61 τ (doublet, 2H), 2.49 τ (triplet, 2H), and 2.22 τ (singlet, 1H). On the basis of the acetate of structure II*a* these peaks may be assigned, respectively, to an acetate CH_3, benzene H's, benzene H's, and the H on the α-carbon of the furan ring. The diacetate of structure I would be expected to show peaks for six acetate H's and four benzene H's, and no other peaks.

(*iii*) The ultraviolet spectrum of A showed λ_{max} 296, 287, and 253 mμ, but there was no absorption in the region 325–450 mμ where *o*-hydroxybenzophenones have been reported (2) to show a strong absorption maximum. In corroboration of this, a sample of 5,5′-dichloro-2,2′-dihydroxybenzophenone (3) had λ_{max} 344, 259, and 223 mμ. (Attempts to synthesize 2,2′-dihydroxy-3,3′,5,5′-tetrachlorobenzophenone by the unambiguous route (3) used to synthesize 5,5′-dichloro-2,2′-dihydroxybenzophenone were not successful.)

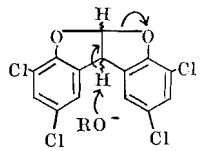
(*iv*) The infrared spectrum of A had absorption bands at 1 610 and 1 582 cm^{-1} but only of medium intensity, and a sharp band in the OH stretching region at 3 500 cm^{-1} suggestive of an unchelated phenolic hydroxyl group. In contrast, 5,5′-dichloro-2,2′-dihydroxybenzophenone had an intense, broad band at 1 630 – 1 615 cm^{-1} (both the position and intensity being typical of chelated *o*-hydroxyphenyl ketones (4)), and a broad hydroxyl peak at 3 340 cm^{-1}.

When the literature was now checked for references concerning the synthesis of 2-(3-benzofuranyl)phenols, it was found that Riemschneider and Lange (5) had reported recently that treatment of α,α-bis(3,5-dichloro-2-hydroxyphenyl)-β,β,β-trichloroethane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with refluxing aqueous potassium hydroxide gave the potassium salt of 4,6-dichloro-2-(2,5,7-trichloro-3-benzofuranyl)phenol (III). However, in their report, no mention was made of previous reactions of this kind.

One other relevant synthesis of 2-(3-benzofuranyl)phenols was noted. Dischendorfer (6) had reported that treatment of the inner acetal of bis(2-hydroxy-1-naphthyl)acetaldehyde with hot alcoholic sodium hydroxide, or with acetic acid containing hydrochloric acid, gave 4-(2-hydroxy-1-naphthyl)naphtho[2′,1′,2,3]furan. Now, in the original paper which prompted our investigation, Riemschneider (1) had reported that the phenolic product A mentioned previously could also be obtained by treatment of the inner acetal of bis(3,5-dichloro-2-hydroxyphenyl)acetaldehyde (IV*a*) with either hot alcoholic potassium hydroxide or hot 10% sulfuric acid. Our proposal that the phenolic product A has the structure II*a* thus makes the reactions of the acetal IV*a* with acid or base analogous to the reactions described by Dischendorfer (6). The inner acetal IV*a* was obtained by treating β,β-dichloro-α,α-bis(3,5-dichloro-2-hydroxyphenyl)ethane with cold alcoholic potassium hydroxide (1). The acetal may thus be considered a possible intermediate in the reaction of this dichloroethane compound with hot alcoholic potassium hydroxide, which leads directly to II*a*.



Since II*a* could not be prepared by the unambiguous route of Moshfegh *et al.* (3), it was of interest to determine the effect of hot alcoholic potassium hydroxide on the known acetal IV*b* (1), since the product from this reaction could be compared directly with the available 5,5′-dichloro-2,2′-dihydroxybenzophenone. The benzophenone was not obtained from this reaction; the product (B) which was obtained is considered to be the benzofuranyl phenol II*b*, on the basis of analytical and spectroscopic data (see Experimental section). The structure of II*b* was proven by the independent synthesis of the carbethoxymethyl ether in the following fashion, the method of approach being modelled on the work of Johnson and Robertson (7):

The reaction of 5,5′-dichloro-2,2′-dihydroxybenzophenone (3) with ethyl bromoacetate gave the diester V*a*, which was converted readily into the diacid V*b*. Ring closure of V*b* was effected by heating the diacid in acetic anhydride containing sodium acetate. The crude product from the ring closure, apparently a mixture of anhydride and acid (ν 1 850 and 1 780 cm^{-1}, with a prominent shoulder at 1 750 cm^{-1}), was converted directly into the desired ethyl ester by refluxing in ethylene chloride containing ethanol and a trace of toluenesulfonic acid. The ethyl ester VI so obtained was identical (by mixed melting point and infrared spectrum) with the product obtained by treating the experimental product B with ethyl bromoacetate.

The reactions of acetals such as IV*a* with acids to yield enol ethers, of which II*a* would be a special type, are well known (10). However, the reactions of acetals with bases, as exemplified by the transformation IV*a* → II*a* (as the potassium salt), seems more unusual, since acetals are generally considered not to react with bases. Some ethers have been reported to undergo E2-type elimination reactions in the presence of strong bases such as NaPh in aprotic solvents (11), but the types of base and solvent are quite different from the reagents employed in the reactions under consideration here. It is suggested that a possible mechanism for these base–acetal reactions is a normal E2 elimination process, which would be favored in this type of acetal by the following characteristics: the considerable acidity of the β-hydrogen, the stabilization of the incipient double bond by the benzofuran system being formed, the ease of accommodation of the negative charge on the leaving phenoxide ion, and the favorable geometry. By analogy to the physostigmine ring system (12), the ring fusion between the two dihydrofuran rings in acetals such as IV*a*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is probably *cis*. Thus the β-hydrogen and the acetal oxygen would be in a *trans* relationship to each other, favorable for an E2 elimination to occur.

Further work on the reaction of these types of acetals with base is in progress. This will include attempts to distinguish between the E2 elimination process and the alternative E1*cb* process.

EXPERIMENTAL

The infrared spectra were all recorded as Nujol mulls. The ultraviolet spectra were measured in methanol. The nuclear magnetic resonance spectra were all taken in carbon tetrachloride, with tetramethylsilane as internal standard. Melting points are uncorrected.

Reaction of β,β-Dichloro-α,α-bis(3,5-dichloro-2-hydroxyphenyl)ethane with Potassium Hydroxide in Refluxing Methanol

This reaction was carried out as described by the previous authors (1). The product obtained (A) had m.p. 185–187° (reported (1) m.p. 185–186°).

Anal. Calcd. for $C_{13}H_6Cl_4O_3$ (I): C, 44.40; H, 1.72. Calcd. for $C_{14}H_6Cl_4O_2$ (II*a*): C, 48.31; H, 1.73. Found: C, 48.16; H, 1.83.

The acetate of A had m.p. 128.5–130.5° (reported (1) m.p. 126°).

Anal. Calcd. for $C_{17}H_{10}Cl_4O_5$ (diacetate of I): C, 46.9; H, 2.31; mol. wt. 436. Calcd. for $C_{16}H_8Cl_4O_3$ (acetate of II*a*): C, 49.26; H, 2.06; mol. wt. 390. Found: C, 49.37; H, 2.21; mol. wt. 402.

The methyl ether of A had m.p. 107.5–108.5° (reported (1) m.p. 107°).

Anal. Calcd. for $C_{15}H_{10}Cl_4O_3$ (dimethyl ether of I): C, 47.4; H, 2.65. Calcd. for $C_{15}H_8Cl_4O_2$ (methyl ether of II*a*): C, 49.8, H, 2.22. Found: C, 49.6; H, 2.40.

The nuclear magnetic resonance spectrum of the methyl ether of A showed peaks at 6.40 τ (singlet, 3H), 2.57 τ (multiplet, 3H), 2.41 τ (doublet, 1H), and 1.97 τ (singlet, 1H). On the basis of the methyl ether of II*a*, these peaks were assigned, respectively, to a methoxy CH_3, benzene H's, a benzene H, and the H on the α-carbon of the furan ring.

Reaction of the Inner Acetal IVb with Potassium Hydroxide (Preparation of B)

The inner acetal IV*b* was prepared as described by previous authors (1). The acetal (0.584 g) in ethylene glycol (9.0 g) containing potassium hydroxide (1 g) was heated at 100–115° for 3 h with occasional swirling. The resultant clear yellow solution was cooled and diluted with water (30 ml), and the solution was filtered. The filtrate was acidified with hydrochloric acid and the resultant oil extracted with benzene. The benzene solution was washed three times with water, and then film evaporated to remove benzene and moisture. The residue was a viscous oil (0.586 g) that crystallized to a product of m.p. 80–92°. Recrystallization from *n*-hexane gave prisms, m.p. 89–91°, but further crystallizations from *n*-hexane gave needles, m.p. 109.5–110° (B). The compound had the following ultraviolet spectrum: λ_{max} 293 (ε 8 200), 285 (ε 7 400), 260 (ε 12 800), 254 (ε 15 000), 248 (ε 14 950), and 242 mμ (ε 15 800); λ_{min} 289 (ε 6 900), 278 (ε 6 490), 259 (ε 12 300), 252 (ε 13 800), and 246 mμ (ε 14 000). The general shape of this spectrum was similar to that of the spectrum of II*a*. The infrared spectrum showed peaks at 1 619, 1 600, 1 580, and 3 520 cm^{-1}, all of medium intensity.

Anal. Calcd. for $C_{14}H_8O_2Cl_2$ (II*b*): C, 60.23; H, 2.88. Found: C, 60.46; H, 3.13.

The acetate was prepared by refluxing product B for 3 h in acetic anhydride containing sodium acetate. The acetate of B had m.p. 119–120°; the nuclear magnetic resonance spectrum of the acetate had peaks at 8.04 τ (singlet, 3H), 2.41–2.98 τ (multiplet, 6H), and 2.31 τ (singlet, 1H), assigned, respectively, on the basis of the acetate of II*b*, to an acetate CH_3, benzene H's, and the H on the α-carbon of the furan ring.

Anal. Calcd. for $C_{16}H_{10}O_3Cl_2$ (acetate of II*b*): C, 59.8; H, 3.14. Found: C, 59.6; H, 3.16.

The carbethoxymethyl ether of B was prepared by the same method as was used to prepare V*a*. The product had m.p. 132–133°, mixed m.p. with authentic VI 131.5–133.5°. The infrared spectrum was identical with that of VI.

5,5′-Dichloro-2,2′-dihydroxybenzophenone

The procedures and relative molar quantities of reagents that were used were according to the method of Moshfegh *et al.* (3). However, the methyl ether was used instead of the ethyl ether as a protecting group. Thus, 5,5′-dichloro-2,2′-dihydroxydiphenylmethane was converted into 5,5′-dichloro-2,2′-dimethoxydiphenylmethane (8), which was oxidized to 5,5′-dichloro-2,2′-dimethoxybenzophenone (9). The dimethoxy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

benzophenone was demethylated to give the desired 5,5′-dichloro-2,2′-dihydroxybenzophenone, m.p. 151.5–153.5° (reported (2) m.p. 152–155°); λ_{max} 344, 259, and 223 mμ; λ_{min} 290 and 245 mμ.

5,5′-Dichloro-2,2′-dihydroxybenzophenone, Bis(carbethoxymethyl Ether) (Va)

In 100 ml dry acetone were placed 5,5′-dichloro-2,2′-dihydroxybenzophenone (2.69 g, 0.0095 mole), ethyl bromoacetate (5.0 g, 0.030 mole), and freshly ground anhydrous potassium carbonate (8.3 g, 0.060 mole). The mixture was refluxed, with the exclusion of atmospheric moisture, for 5 h. The reaction mixture was cooled and filtered, and the filtrate was film evaporated to remove the acetone. The residue from the film evaporation was dissolved in diethyl ether (40 ml) and filtered to remove the insoluble material; the insoluble material was washed with diethyl ether (10 ml). The combined filtrates were film evaporated to remove the solvents. The gummy residue from the film evaporation was stirred with *n*-hexane (20 ml) to yield a white solid, which was removed by filtration, washed with *n*-hexane, and dried to yield 3.14 g (73.5%) of *Va*, m.p. 86.5–87.5°. Recrystallization from *n*-hexane gave colorless plates, m.p. 88.5–89.5°, ν 1 770 and 1 675 cm^{-1}.

Anal. Calcd. for $C_{21}H_{20}Cl_2O_7$: C, 55.39; H, 4.42. Found: C, 55.30; H, 4.47.

5,5′-Dichloro-2,2′-dihydroxybenzophenone, Bis(carboxymethyl Ether) (Vb)

The diester *Va* (2.63 g, 0.0058 mole) was refluxed for 45 min in a mixture of ethanol (100 ml) and water (70 ml) containing potassium hydroxide (4.5 g). The solution was then film evaporated to remove most of the ethanol. After removal of the ethanol the solution was cooled, filtered, and extracted once with diethyl ether. The aqueous layer was then acidified with dilute hydrochloric acid to precipitate the product as a white solid. The product was removed by filtration, washed with water, and dried to yield 2.14 g (93%) of *Vb*, m.p. 217–218°, ν 1 752 (intense shoulder at 1 729) and 1 684 cm^{-1}. Recrystallization from ethanol–water gave material of m.p. 218–221°.

Anal. Calcd. for $C_{17}H_{12}Cl_2O_7$: C, 51.14; H, 3.03. Found (crude product): C, 51.34; H, 3.37.

Ring Closure of Vb and Preparation of 2-(5-Chloro-3-benzofuranyl)-4-chlorophenol Carbethoxymethyl Ether (VI)

The diacid *Vb* (2.03 g, 0.0051 mole), acetic anhydride (20 ml), and fused sodium acetate (5.0 g) were mixed, and the mixture was then refluxed (bath temperature 150–155°) for 50 min. After the reaction mixture was cooled, it was poured into water (200 ml) and stirred for 2 h. The white precipitate so formed was removed by filtration, washed with water, and dried. This material (1.86 g) had m.p. 85–98°; ν 1 850 and 1 780 (anhydride) with a prominent shoulder at 1 750 (acid), and 1 619 and 1 576 cm^{-1}, no bands between 1 750 – 1 620 cm^{-1}. The product was partially soluble in dilute sodium hydroxide.

The crude product (0.45 g) was dissolved in ethylene dichloride (10 ml) containing ethanol (1.3 ml) and toluenesulfonic acid (30 mg), and the solution refluxed for 6 h. The solution was cooled, diluted with chloroform, washed with water and then sodium bicarbonate, and dried over sodium sulfate. Film evaporation left a crystalline product, 0.41 g, m.p. 125–131°. Recrystallization from *n*-hexane gave VI, m.p. 132–133°; ν 1 759, 1 618, and 1 572 cm^{-1}.

Anal. Calcd. for $C_{18}H_{14}Cl_2O_4$ (VI): C, 59.19; H, 3.86. Found: C, 58.96; H, 3.98.

STEROIDS AND RELATED NATURAL PRODUCTS XXIX. SODIUM BOROHYDRIDE – BORON TRIHALIDE REDUCTION OF 3-OXO-4-OXA-5α-CHOLESTANE[1]

GEORGE R. PETTIT[2] AND WILLIAM J. EVERS

A variety of esters have conveniently been reduced to the corresponding ether derivatives by a complex metal hydride – boron trifluoride (1) or diborane – boron trifluoride (1*g*) reagent. In the metal hydride procedure, the required diborane was generated from a large excess of boron trifluoride. Since the generally useful Lewis acid, aluminium chloride, in combination with sodium borohydride, failed (1*g*) to effect ester → ether conversion, it was desirable to determine whether other boron halides would replace or prove to be superior to boron trifluoride. To explore this area, 3-oxo-4-oxa-5α-cholestane (I) was again (1*g*) selected for model experiments.

Reduction of lactone I to 4-oxa-5α-cholestane (II) was previously accomplished with lithium aluminium hydride – boron trifluoride (1*g*, 1*i*).[3] Here, the more practical sodium borohydride – boron trifluoride procedure (1*e*) was first utilized for transforming lactone I into tetrahydropyran II. Reduction was conducted during a 2 h period at ice-bath temperature to approximate the conditions that were anticipated to be necessary with boron tribromide and boron triiodide. Depending on the mode of initiating the reaction, yields of pure tetrahydropyran II varied from 44 to 58%. The best conversion into ether II was obtained by adding the lactone – boron trifluoride mixture to the hydride (see ref. 1*e*).

Under similar conditions, with boron trichloride in place of the trifluoride, the yields of ether II varied from 3 to 64%. When the reduction was repeated with boron tribromide and again with boron triiodide, conditions approximating those giving the poorest result (hexane–diglyme solvent system) with boron trichloride were used to decrease the concomitant attack on both solvent and product.[4] Comparably poor yields (less than 5%) of ether II were obtained in both cases. Boron triiodide rapidly attacked diethylene glycol dimethyl ether, and a substantial quantity of 1,2-diiodoethane accompanied the expected products. The experiments did demonstrate, however, that the presence of fluorine or boron trifluoride was not a necessary requirement of ester → ether reduction.

I II III

The preceding experiments also suggested that other periodic group III*a* hydrides or related hydrides from groups IV*a* or V*a* in combination with a boron halide might prove to be unique, and perhaps useful, reducing agents. Of the various possibilities, preliminary

examination of stannane (group IV*a*) and phosphine (group V*a*) was undertaken. Phosphine has already been used for reduction of aromatic nitro compounds (4), and of the two appeared to be the more promising. Under reaction conditions analogous to those employed in the case of diborane – boron trifluoride, neither phosphine nor stannane with boron trifluoride reduced lactone I. Reaction of such hydride systems as diborane–phosphine with various other functional groups, or under more vigorous conditions with esters, offers interesting possibilities but was not considered of further importance in evaluating the ester → ether reaction.

In summary, diborane in combination with a boron trihalide yields a hydride reagent unique in its manner of attacking esters.[5]

EXPERIMENTAL[6]

Sodium Borohydride – Boron Trihalide Reduction of 3-Oxo-4-oxa-5α-cholestane (I)

A. Boron Trifluoride

Boron trifluoride etherate (2.4 g) in diglyme (10 ml) was added over a 15 min period to a cold (ice bath) solution of lactone I (0.20 g) and sodium borohydride (0.04 g) in diglyme (15 ml). Before the slow addition of water (10 ml) followed by 2 *N* hydrochloric acid (10 ml), stirring (with cooling) was continued for an additional 2 h. The mixture was extracted with diethyl ether, and the combined ethereal extracts were washed with water and concentrated to a crystalline residue. A hexane solution of the crude product was chromatographed on activated alumina (6.0 g). After elution with the same solvent (200 ml) and recrystallization of the resulting fraction from hexane, a 0.09 g yield (44%) of 4-oxa-5α-cholestane melting at 90–91.5° was obtained. Melting points of 90–91° and 93–94° have been reported (1*h*–1*i*, 2*b*) for ether II.

In an earlier experiment, the usual technique (I*e*), i.e. adding a mixture of the lactone (I) and boron trifluoride etherate to the hydride solution, was employed and a 58% yield of ether II was obtained.

B. Boron Trichloride

To a cool (ice bath) solution composed of sodium borohydride (0.20 g), lactone I (2.0 g), and diglyme (20 ml) was added, with stirring, over a 15 min period a solution of boron trichloride (18.5 g, The Matheson Company, Inc., chemically pure grade) in hexane (8 ml). After 2 h, water (40 ml) was added, and the mixture extracted with diethyl ether. The combined ethereal extracts were washed successively with water, 10% sodium bicarbonate, and water. Removal of solvent *in vacuo* led to a semicrystalline residue, which was dissolved in benzene and chromatographed on activated alumina. Elution with the same solvent gave a 0.34 g fraction. Continued elution with chloroform–methanol (20:1) led to 0.49 g of diol III. Two recrystallizations from methanol yielded a sample of the diol (III) melting at 137.5–138.5°. A melting point of 136–137° has been reported (1*g*, 2*b*). Concurrently, the benzene fraction (0.34 g) was rechromatographed on activated alumina, and the substance that was eluted with hexane was recrystallized from the same solvent to yield ether II (0.07 g) melting at 91–91.5°.

In another experiment boron trichloride (10 g) was condensed at 0° and allowed to evaporate into a reaction flask containing a cool (ice bath) solution of lactone I (1.0 g) in diglyme (30 ml). Next, a solution of sodium borohydride (0.1 g) in diglyme (15 ml) was added, with stirring, over a 20 min period. One hour later the mixture was diluted with water (70 ml) and extracted with diethyl ether. The combined ethereal extracts were washed with water and concentrated *in vacuo* to a crystalline solid. Isolation of tetrahydropyran II (0.64 g, m.p. 91.5–92.5°) was conducted essentially as described in the preceding paragraph.

C. Boron Tribromide

To a cool (ice bath) solution of sodium borohydride (0.20 g) and lactone I (2.0 g) in diglyme (15 ml) was added, during 15 min, a solution of boron tribromide (37 g, Metro Industries) in hexane (20 ml). After the addition was complete, stirring with cooling was continued for 2 h; then the products were isolated as

[5]*Diborane (alone) reacts with esters to yield hemiacetal derivatives*[1] *(1g), and in combination with aluminium chloride (1g) results in reduction to the alcohol level, as generally observed in the case of lithium aluminium hydride. The useful variation in reducing properties offered by diborane and derived reagents suggests that a procedure utilizing diborane will eventually replace many of the now commonly employed metal hydride techniques. The recent introduction of commercial (Metal Hydrides Division, Ventron Corp.) 1 M diborane in tetrahydrofuran solution has greatly simplified experimentation utilizing diborane.*

[6]*A description of reagents, solvents, and chromatographic techniques has been summarized in the introduction to the Experimental section of part XXVIII in this series.*[1]

A Kofler melting point apparatus was used for melting point determinations (corrected). Optical rotation (chloroform solution) and microanalytical values were determined, respectively, in the laboratories of Dr. P. Demoen, Janssen Pharmaceutica, Beerse, Belgium, and Dr. A. Bernhardt, Mülheim, Germany. The infrared spectra (potassium bromide) were recorded by Dr. R. A. Hill, University of Maine, Orono, Maine.

The identity of each substance isolated from the reduction reaction sequences was established by mixture melting point determination and infrared spectral comparison with an authentic specimen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

illustrated in experiment B. After two recrystallizations from hexane, ether II weighed 0.03 g and melted at 91–91.5°. In addition, a 0.45 g specimen, m.p. 135–137°, of diol III was isolated.

D. Boron Triiodide

The preceding experiment (C) was repeated with boron triiodide (6.0 g) in hexane (20 ml) and a solution composed of lactone I (0.2 g), sodium borohydride (0.04 g), and diglyme (12 ml). In this case the lactone-containing mixture was added dropwise to the boron triiodide solution to insure an excess of halide. Upon contact, an immediate and vigorous reaction was observed. The crude crystalline product was isolated essentially as described in experiment A, and triturated with hexane. The hexane solution was chromatographed on activated alumina. Elution with the same solvent gave 1,2-diiodoethane (0.73 g, m.p. 81.5–82°)[7] and 0.02 g of impure (m.p. 55–63°) ether II. After three recrystallizations from acetone, the latter specimen melted at 88–90.5° and weighed 5 mg.

Attempted Reduction of 3-Oxo-4-oxa-5α-cholestane (I)

(a) Phospine – Boron Trifluoride

Phosphine generated (5) by treating lithium aluminium hydride with phosphorous trichloride (11.0 g), in diethyl ether, was swept with nitrogen during 2.5 h into a reaction mixture composed of lactone I (1.0 g), boron trifluoride etherate (11 g), and diethyl ether (20 ml). The experiment was performed (see above) at ice-bath temperature and terminated by sweeping the system with nitrogen and slowly adding water (20 ml). The aqueous phase was discarded and the ethereal layer was successively washed with water, potassium carbonate (10%), and water. Removal of solvent gave 0.82 g of lactone I melting at 115–117°.

(b) Stannane – Boron Trifluoride

The attempted reaction between lactone I (1.0 g), boron trifluoride etherate, and stannane (generated (6) by allowing stannic chloride (3.4 g) in diethyl ether (40 ml) to react with lithium aluminium hydride (0.6 g) in diethyl ether (40 ml) at −40°) was conducted at ice-bath temperature as described in experiment *a* for phosphine – boron trifluoride. In this example, a 0.92 g recovery of starting material melting at 116–118° was observed.

ACKNOWLEDGMENTS

This investigation was supported in part by Public Health Service research grants CA-04074-06 and CA-04074-07 from the National Cancer Institute, and by Smith, Kline, and French Laboratories. Grateful acknowledgment is also extended by G. R. P. to Professor Carl Djerassi and the Department of Chemistry, Stanford University, for providing facilities during the initial preparation of this manuscript.

THERMAL ISOMERIZATION OF HEXACHLOROCYCLOPROPANE

W. F. HALE

The thermal decomposition of hexachlorocyclopropane (I) has been examined to study the effect of halogen substitution on the isomerization of cyclopropane and, in addition, as a possible route to polydichloromethylene. Considerable literature exists (1 and references therein) concerning the nature of the thermal isomerization of cyclopropanes to propenes. Although not supported by unequivocal evidence, it has been generally assumed that the transition state possesses some diradical character. Since it was known (2) that substitution of halogen for hydrogen stabilizes methyl radicals, ring opening of I with linear coupling to form a polymer was considered to be possible. Recently, a similar approach was outlined (3) in the attempted preparation of polydiphenylmethylene via hexaphenylcyclopropane.

Several recent reports (4) have discussed the preparation and properties of I. We have found that the addition of dichlorocarbene to tetrachloroethylene according to the procedure of Fields and Meyerson (4*c*) is a convenient synthetic method providing about a 10% yield of I.

Pyrolyses were carried out in the vapor phase in a flow system under reduced pressure. A weighed quantity of I was sublimed into a flowing stream of argon, which served as the carrier gas. The mixed vapor stream was then allowed to pass through an electrically heated furnace in an unpacked Vycor tube under the conditions indicated in Table I.

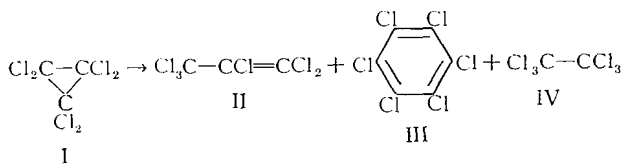

TABLE I

Pyrolysis of hexachlorocyclopropane

Temperature (°C)	Pressure (mm)	Flow rate (g/h)	Product distribution

300	100	0.50	20	80	—	—	—
400	2.8–4.0	1.00	—	100	—	—	—
500	3.0–4.0	0.20	—	35	30	25	10

*Unresolved mixture with infrared bands characteristic of CCl_4 and $Cl_2C{=}CCl_2$.

The products (as shown in the equation) were identified by physical properties, infrared spectra, and gas chromatography. As previously noted by Tobey and West (4*d*), I was stable at 200 °C. At 300 and 400 °C, facile conversion into hexachloropropene (II) occurred,[1] with no evidence of polymer formation. This result parallels the structural isomerization observed with cyclopropane (1,5,6) and, to a lesser extent, hexafluoro-

[1]*Fields and Meyerson (4c) noted 15% conversion into II when the inlet system for a mass spectrum determination was set at 250 °C.*

cyclopropane (7) at somewhat higher temperatures. At 500 °C, additional compounds were found which could have resulted from rearrangement, decomposition, and coupling reactions (8) of either the initially generated II or I directly. Again, products of the direct coupling of hexachlorotrimethylene, such as perchlorocyclohexane and polydichloromethylene, were not detected. It would appear that either chlorine substitution does not sufficiently stabilize the proposed diradical intermediate or the transition state has little diradical character.

Attempts to trap the intermediate by inclusion of maleic anhydride or styrene in the sublimate were unsuccessful. Starting materials and II were recovered from pyrolyses at 250 and 400 °C in a flow system. Treatment of I in a sealed tube at 200 °C with maleic anhydride or tetracyanoethylene yielded only starting materials and II.

EXPERIMENTAL

Melting points were measured in a Thomas–Hoover bath and are uncorrected. Infrared spectra were obtained on a Beckman IR-5 spectrophotometer. Gas chromatographic separations were accomplished with a F. and M. No. 502 dual-column instrument equipped with a 4 m column of QF-1 fluorosilicone (liquid phase) on 80 × 100 mesh, acid-washed, dimethyldichlorosilane-treated Johns–Manville Chromosorb P (height equivalent to a theoretical plate, ~0.6 mm).

Hexachlorocyclopropane (I)

The decomposition of sodium trichloroacetate in dimethoxyethane in the presence of tetrachloroethylene according to the procedure of Fields and Meyerson (4*c*) gave a 10.2% yield of I, m.p. 102.5–104° (reported (4*d*) m.p. 102.5–103.5°).

Pyrolysis of Hexachlorocyclopropane (I)

All pyrolyses were carried out in a horizontally oriented, 74 cm × 2.4 cm inside diameter Vycor tube which was heated in the center portion with a 27 cm Hevi-Duty Heating Equipment Co. electric furnace. The pyrolysis temperatures listed in Table I were recorded by a chrome–alumel thermocouple in the center of the furnace. No packing was used in the tube and an argon sweep was provided through a capillary opening before the sublimation zone. Samples of I (1.00 g per run) were contained in a combustion boat in the sublimation zone, which was maintained at 40–120 °C (depending on the pressure and desired flow rate) with an externally wrapped heating tape. A water-cooled condenser and a dry ice trap were connected in series to the Vycor tube following the furnace such that the air-cooled zone for product condensation was about 20 cm in length. The pyrolysis products which collected in the various cool zones were characterized as follows: I by melting point, mixed melting point, infrared spectrum, and gas chromatographic retention time; II by boiling point, refractive index (n_D^{20} 1.5491; reported (9) n_D^{20} 1.5491), infrared spectrum, and gas chromatographic retention time; III by melting point (223°; reported (10) m.p. 226–227°), mixed melting point, and infrared spectrum; IV by melting point (185–186°; reported (10) m.p. 187°) and infrared spectrum; and V by characteristic infrared absorption bands.

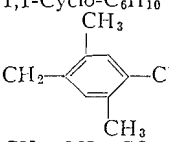
POTENTIAL ANTICANCER AGENTS
III. URETHANE-TYPE NITROGEN MUSTARDS OF SOME SYNTHETIC ESTROGENS

I. NICULESCU-DUVĂZ, V. FEYNS, E. GRANT, AND E. TĂRNĂUCEANU

While studying the anticancer activity of the urethane-type nitrogen mustards, we prepared a number of compounds of this type from synthetic estrogens, with the purpose of establishing a relationship between the estrogenic activity of the bis-hydroxyphenyl derivatives and the anticancer action of their nitrogen mustard carbamates. Since compounds I and II that had previously been prepared (1) exhibited 50–60% inhibitions on Walker carcinosarcoma 256 (2), it seemed to be of interest to extend the series of these substances.

I



II

The urethane-type nitrogen mustards were obtained by condensation of the bis-hydroxyphenyl derivatives with di-(2-chloroethyl)-carbamyl chloride in pyridine (3) followed, after pyridine removal, by crystallization from ethanol. The nitrogen mustards thus obtained are summarized in Table I.

TABLE I

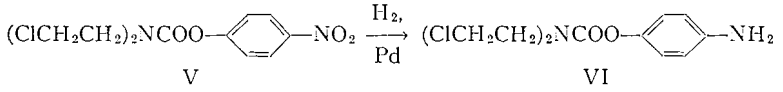
Some of the carbamates prepared in this way were obtained as gums which could not be purified by crystallization. Column chromatography on alumina was employed, the urethane group not being split as reported by Nogrady for N-di-(2-chloroethyl)-D-1-glucopyranosyl carbamate (4).

Thus, in the case of bis(4-(N,N-di-(2-chloroethyl)-carbamyl)phenyl)disulfide (III), after pyridine removal, the residue was extracted first with benzene and then with benzene – methylene chloride mixtures (from 1:1 to 1:9). The extracts were chromatographed over alumina. The carbamate was recovered from the light-yellow benzene eluate, the other fractions containing small quantities of unidentified dark-colored resinous substances. The chromatography of 1,1-bis(4-(N,N-di-(2-chloroethyl)-carbamyl)phenyl)-cyclohexane (IV) was similarly performed, except that residue extraction, column development, and elution were carried out with benzene and benzene–methanol mixtures (from 99:1 to 90:10). Here also, the carbamate was found in the benzene eluate.



III

IV

For the same reason (an impossibility to purify), 1,2-bis(4-(N,N-di-(2-chloroethyl)-carbamyl)phenyl)methylenimine (VIII) was synthesized according to the reaction sequence shown in Reaction Scheme 1.

V VI

VII

VIII

REACTION SCHEME 1.

The carbamates of *p*-hydroxynitrobenzene (V) and *p*-hydroxybenzaldehyde (VII) were prepared by common procedures (3); amine VI was obtained in good yield by the catalytic hydrogenation of the nitro derivative V with palladium chloride on carbon at room temperature.

Biological evaluation of the compounds is in progress. The estrogenic activity of some of the bis-*p*-hydroxyphenyl derivatives used as precursors in the present work and in ref. 1, and the antitumor activity of their bis(N,N-di-(2-chloroethyl)carbamyl) derivatives against Walker carcinosarcoma 256 are shown in Table II. Mention should also be made that preliminary tests showed compounds V and VI (not tabulated) to be inactive against Walker carcinosarcoma 256.

Structural evidence for the new compounds was provided by infrared absorbtion spectra.

EXPERIMENTAL

4-(N,N-Di-(2-chloroethyl)-carbamyl)nitrobenzene (V)

Di-(2-chloroethyl)-carbamyl chloride (7.8 g, 0.038 mole) in 20 ml of pyridine was added to 5 g (0.036 mole) of *p*-nitrophenol. After the solution was allowed to stand for 3 days at room temperature, pyridine hydrochloride separated out and was filtered off. The filtrate was evaporated to dryness *in vacuo* to give a residue, which was triturated with toluene and again evaporated to dryness *in vacuo*. The procedure was repeated 3 times until all the pyridine had been removed; 9.2 g (83%) of V was obtained (after recrystallization from ethanol, m.p. 85–86 °C). Infrared (KBr): ν_{max} carbamate (amide I band) 1 732 cm^{-1}.

Anal. Calcd. for $C_{11}H_{12}Cl_2N_2O_4$: C, 42.99; H, 3.90; N, 9.12. Found: C, 42.97; H, 3.94; N, 9.09.

4-(N,N-Di-(2-chloroethyl)-carbamyl)benzaldehyde (VII) was similarly prepared. The residue after pyridine was removed failed to crystallize and was extracted with benzene; the benzene solution was evaporated to dryness *in vacuo* to give the desired product (viscous yellow oil) of analytical purity. Infrared: ν_{max} carbamate (amide I band) 1 735 cm^{-1}.

Anal. Calcd. for $C_{12}H_{13}Cl_2NO_3$: C, 49.65; H, 4.48; N, 4.82. Found: C, 49.65; H, 4.50; N, 4.78.

4-(N,N-Di-(2-chloroethyl)-carbamyl)aniline (VI)

V (7.9 g, 0.026 mole) was dissolved in 250 ml ethanol and hydrogenated in the presence of 2 g of 5% palladium chloride on carbon catalyst at atmospheric pressure and room temperature, the theoretical amount of hydrogen (1 730 ml) being consumed during 4 h. The catalyst was filtered off and the solvent was removed by distillation under reduced pressure. The residue was dissolved in ether, and dry hydrogen chloride was passed into the solution to give 7.3 g (91%) of the hydrochloride of VI (m.p. 182–183 °C). Infrared (KBr): ν_{max} carbamate (amide band I) 1 730 cm^{-1}.

Anal. Calcd. for $C_{11}H_{15}Cl_3N_2O_2$: C, 42.10; H, 4.78; N, 8.93. Found: C, 42.14; H, 4.80; N, 8.98.

1,2-Bis(4-(N,N-di-(2-chloroethyl)-carbamyl)phenyl)methylenimine (VIII)

Aldehyde VII (3.3 g, 0.011 mole) was added to a solution of 2.9 g (0.011 mole) of amine VI in 110 ml of ethanol. After the solution was allowed to stand for 2 days at room temperature with occasional shaking, a solid was collected and recrystallized from ethanol to give 2.2 g (38%) of pure VIII (see Table I).

SUMMARY

The synthesis of new urethane-type nitrogen mustards from the following bis-hydroxyphenyl derivatives is reported: 1,2-bis(*p*-hydroxyphenyl)ethane; 2,2-bis(*p*-hydroxyphenyl)-propane; 2,2-bis(*p*-hydroxyphenyl)butane; 3,3-bis(*p*-hydroxyphenyl)pentane; 1,1-bis-(*p*-hydroxyphenyl)cyclopentane; 1,1-bis(*p*-hydroxyphenyl)cyclohexane; 2,5-bis(*p*-hydroxybenzyl)-*p*-xylene; *p*,*p*′-dihydroxychalcone; 1,2-bis(*p*-hydroxyphenyl)methylenimine; *p*,*p*′-dihydroxybenzalazine; 1,2-bis(*p*-hydroxyphenyl)disulfide; 2,4′-dihydroxydiphenyl sulfone.

Antitumor activities against Walker carcinosarcoma 256 are given for some of the new compounds.

ACKNOWLEDGMENTS

The authors thank Mr. Filip Chiraleu for performing infrared measurements and Miss Maria Stănescu for technical assistance. The cancerostatic screening was done by Dr. V. Dobre. We thank him for making the screening data available to us.

A GRAVIMETRIC STUDY OF HYDRATION OF POLYNUCLEOTIDES[1]

MICHAEL FALK

Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia

Received December 6, 1965

ABSTRACT

The hydration of soluble ribonucleic acid, of two forms of polyriboadenylic acid, and of nucleohistone was determined gravimetrically as a function of relative humidity (r.h.). The curves are smooth functions of r.h., similar to those obtained earlier for deoxyribonucleic acid. The general similarity of the hydration curves of the polynucleotides so far investigated is in agreement with the suggestion that the ionic phosphate groups are the primary hydration sites in polynucleotides. The hydration data fit the Brunauer–Emmett–Teller equation up to about 75% r.h. and the Harkins–Jura equation at higher values. Both equations yield a value of about 2.0 molecules of H_2O per nucleotide for the "monolayer content" for all the polynucleotides investigated.

INTRODUCTION

Polynucleotides are highly hygroscopic. For example, deoxyribonucleic acid (DNA) takes up its own weight of water at 90% relative humidity (r.h.); its degree of hydration rapidly tends to infinity as r.h. increases towards 100%. The study of the degree of hydration as a function of r.h. is particularly important in view of the structural changes that occur in many polynucleotides at certain values of r.h. Such structural changes are well known for DNA (1–3) and have recently been observed also for ribonucleic acid (RNA) (4) and for several synthetic polynucleotides (5). The knowledge of hydration of nucleic acids in the solid state is additionally useful because it appears to be related to their hydration in aqueous solution, which is of importance in biology. There is a correlation between the hydration of DNA in the solid state (6) and in solution (7–9).

In the present study the hydration of soluble RNA, of two forms of polyriboadenylic acid (poly-A), and of nucleohistone was measured gravimetrically as a function of r.h. and was compared with the hydration of DNA, measured earlier by the same technique (6).

EXPERIMENTAL

Materials

Poly-A was purchased as the potassium salt from the California Corporation for Biochemical Research, Los Angeles. This material had been prepared by the method of Beers (10). The material as received was in the "neutral" form, corresponding to pH 7. The "acid" form was prepared by titration of a concentrated aqueous solution with HCl to pH 4, followed by lyophilization. The absorption spectra were identical with the previously published infrared (11) and ultraviolet (12) spectra of the two forms of poly-A. The X-ray diffraction patterns of fibers made from the samples at pH 7 and pH 4 agreed with those reported in the literature (13, 14).

Soluble RNA from yeast was prepared by the method of Holley (15) and was the sodium salt. The infrared and ultraviolet spectra were identical with those recorded in this laboratory for many samples of soluble RNA from several sources (4, 5) and with the spectra reported elsewhere (16, 17).

Nucleohistone, isolated from calf thymus, was purchased from the California Corporation for Biochemical Research. Its infrared spectrum was identical with that reported by Bradbury *et al.* (18).

[1]*Issued as N.R.C. No. 8920.*

Methods

Several specimens of each sample, 30 to 50 mg, were exposed to atmospheres of constant r.h. and were weighed to within 0.05 mg until constant weights were obtained, which usually required 3 to 6 days. The constant relative humidity was maintained by a saturated solution of an appropriate salt contained in a Petri dish. The r.h. values for most of the solutions were taken from the data of Wink and Sears (19) and were estimated to be accurate to ±0.5% or better. The temperature was kept at 21.0 ± 0.4°, except for a part of the study on poly-A in which it was controlled to ±1°. Several cycles of hydration and dehydration were performed for each specimen. At the end of each series of measurements the dry weight was obtained by drying to constant weight in a vacuum of 10^{-3} Torr at 25, 50, and 80°. None of the samples showed any additional loss of weight between 50 and 80° and it was assumed for the purpose of the calculations that all of the adsorbed water was expelled from the samples.

RESULTS AND DISCUSSION

The results, averaged from several hydration–dehydration cycles, are presented in Table I as moles water per mole nucleotide. The average deviation was ±0.15 mole H_2O per mole. To convert weights to moles the following molecular weights "per nucleotide" were used: DNA, 331; nucleohistone, 662; poly-A at pH 4, 403; poly-A at pH 7, 367; RNA, 345. The above values for DNA, nucleohistone, and RNA are based on 1:1:1:1 base ratios (they are not very sensitive to the exact value of the ratios) and the value for calf-thymus nucleohistone on the assumption of a 50% DNA content (20, 21); the value for poly-A at pH 4 was based on the assumption of the addition of 1 mole of HCl per adenylate unit. The values of hydration for nucleohistone are plotted in Fig. 1.

TABLE I

Hydration and dehydration of polynucleotides in moles H_2O per mole of nucleotide

Relative Humidity(%)	RNA		Poly-A, pH 7		Poly-A, pH 4		Nucleohistone		DNA (ref. 6)

Hydration of Different Polynucleotides

The curves of hydration and dehydration were smooth functions of relative humidity for all the compounds investigated and had the same form as the corresponding curves for DNA (6). The absence of distinct plateaux, such as occur for some compounds of low molecular weight which contain the phosphate group (22), indicates the absence of well-defined hydrates. Hydration–dehydration hysteresis occurred for all of the substances investigated and was of the order of 1 mole H_2O per mole nucleotide, as indicated in Table I. The discussion which follows neglects hysteresis and is based on the data for hydration, which are more extensive than for dehydration.

The polynucleotides listed in Table I differ from one another in their secondary structure and in the nature of the cation. The general similarity of their hydration curves is therefore in agreement with the suggestion that the hydration of polynucleotides is largely controlled by the phosphate groups (1, 3, 22, 23), and is not strongly affected by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

nature of the cation and by the detailed secondary structure. The similarity of the hydration curves of the sodium and lithium salts of DNA (6) also shows that the hydration is not strongly dependent upon the cation.

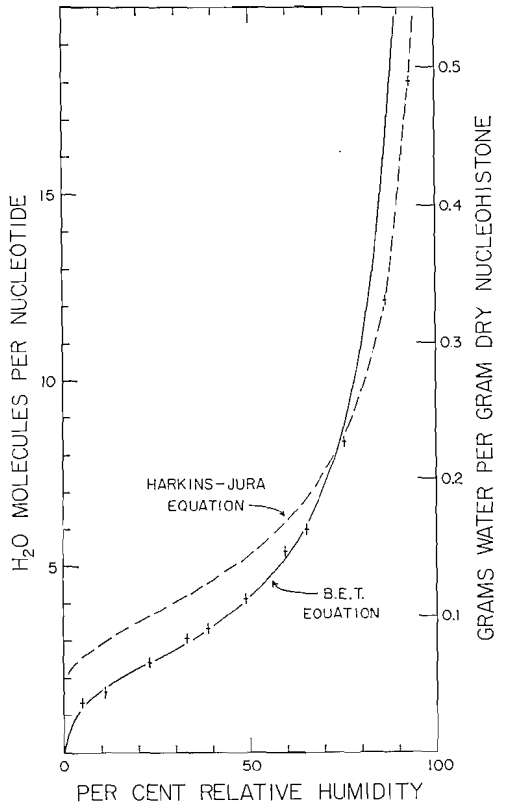

FIG. 1. Plot of the values of hydration for nucleohistone.

The small differences in the hydration of the individual polynucleotides are too complex to be interpreted in detail, but may be at least partly due to the differences of accessibility of the phosphate groups to water. For example, the hydration of polynucleotide double helices may be expected to be higher than that of the single-stranded structures as a result of the efficient way in which the phosphate groups are exposed to water on the outside of the double helix. This expectation is fulfilled in the case of RNA, which has an incomplete double helix and a lower hydration than native DNA. The hydration of denatured DNA, which also has an incomplete double helix, is about the same as that of RNA (5). On the other hand, the hydration of the pH 4 form of poly-A (which is known to be a double helix) would be expected to be higher than that of the pH 7 form of poly-A (which is known to be single-stranded), but below about 80% r.h. it is actually lower.

DNA in the form of sodium salt undergoes reversible structural transitions at about 80% r.h. (2) and at about 65% r.h. (3). These transitions do not cause detectable discontinuities in the hydration curve of DNA. It would be of interest to determine whether the structural transitions in RNA (4) and in the pH 4 form of poly-A (5), which occur near 98% r.h., affect the hydration curves of these compounds in a discontinuous manner.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

However, the determination of hydration above about 93% r.h. is difficult and has not been attempted in the present study.

The Brunauer–Emmett–Teller and Harkins–Jura Equations

It is of interest to test the present data for a fit with the Brunauer–Emmett–Teller (B.E.T.) equation (24). This equation is of the form $A = BCx/(1 - x + Cx)(1 - x)$, where A is the total amount of water adsorbed at relative humidity x, and B and C are adjustable parameters which have some physical significance (6). The hydration data for all the substances investigated fit the B.E.T. equation within experimental error up to about 75% r.h. At higher relative humidities the observed hydration is lower than that calculated, as shown for nucleohistone in Fig. 1. For all four polynucleotides investigated, the best fit with the B.E.T. equation corresponds to the following approximate values of the two parameters: $B = 1.9$ H_2O molecules per nucleotide and $RT \ln C = 1.8$ kcal/mole. These values are of the same magnitude as those obtained for DNA (6).

It is also of interest to test the data for a fit with the Harkins–Jura equation (25, 26). This equation is applicable to a liquid-like phase condensed upon a solid surface of limited area and has previously been shown to fit the hydration of proteins (27, 28) and of cellulose (29) at high r.h. In the present notation this equation is of the form $\log x = D - B^2/A^2$, where D is an adjustable parameter and x, A, and B are the same as in the B.E.T. equation. The present hydration data were found to fit the Harkins–Jura equation above about 75% r.h. (Attempts to find a Harkins–Jura fit below 75% r.h. lead to a negative value of D, and hence to imaginary values of A over some part of the range.) At lower relative humidities the observed hydration is lower than that calculated from the parameters D and B found at high r.h. This is shown for nucleohistone in Fig. 1. The values of the parameter B, the "monolayer content", derived from the high relative-humidity portion of the hydration data, are about 2 molecules of H_2O per nucleotide for the various polynucleotides. The data for the sodium salt of DNA (6) gave $B = 2.3$. The agreement between the values of the parameter B derived from the data at lower r.h. by the B.E.T. equation and at higher r.h. by the Harkins–Jura equation is within 20% for the various polynucleotides. This agreement is interesting as the two equations are based on very different physical models and make use of different portions of the hydration data. It appears that strong binding of approximately 2 water molecules to each phosphate group may be common to all polynucleotides, and may be largely independent of the cation.

The part of the hydration curves up to about 75% r.h., which fits the B.E.T. equation, probably corresponds to the adsorption of further layers of water molecules, also largely around the phosphate groups. The part of the curves at higher r.h., which fits the Harkins–Jura equation, probably corresponds to a gradual transition of the adsorbed layer to a condensed film with properties which approach those of liquid water.

ACKNOWLEDGMENTS

I wish to thank Professor R. F. Beers for a sample of poly-A, Professor R. W. Holley for the sample of RNA, Dr. J. T. Finch for recording and interpreting X-ray diffraction patterns of two samples of poly-A, and Dr. Karl A. Hartman, Jr. for the preparation of one sample of pH 4 poly-A. The work on poly-A was begun at the Spectroscopy Laboratory, Massachusetts Institute of Technology, and was supported by a grant (No. A-2262 (C3) from the National Institutes of Health) to Professor R. C. Lord.

ABSOLUTE RATE CONSTANTS FOR HYDROCARBON AUTOXIDATION

III. α-METHYLSTYRENE, β-METHYLSTYRENE, AND INDENE[1]

J. A. HOWARD AND K. U. INGOLD

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received December 21, 1965

ABSTRACT

Absolute rate constants for the copolymerization of α-methylstyrene and oxygen have been measured from 13 to 50 °C. The propagation and termination rate constants can be represented by

$$k_p = (6.6 \pm 0.7) \times 10^6 \exp(-(8\,070 \pm 800)/RT) \text{ l mole}^{-1} \text{ s}^{-1}$$
$$k_t = (1.6 \pm 0.7) \times 10^8 \exp(-(3\,700 \pm 1\,600)/RT) \text{ l mole}^{-1} \text{ s}^{-1}.$$

Experiments with 2,6-di-*t*-butyl-4-methylphenol at 65 °C have shown that $C_6H_5C(CH_3):CH_2$ and $C_6H_5C(CD_3):CD_2$ have the same propagation rate constant but that chain termination involves a deuterium isotope effect $(k_t)_H/(k_t)_D \simeq 1.5$.

Absolute rate constants for the copolymerization of oxygen with β-methylstyrene and with indene at 30 °C showed that a significant fraction of the oxidation chains were terminated by a kinetically first order process (rate constant k_x). The rate constants for β-methylstyrene and indene at 30 °C are $k_p = 51$ and 142 l mole^{-1} s^{-1}, $k_t = 1.6 \times 10^7$ and 2.5×10^7 l mole^{-1} s^{-1}, and $k_x = 0.61$ and 1.2 s^{-1}, respectively. The propagation rate constant for indene can be separated into a rate constant for the copolymerization with oxygen ($k_{add} = 128$ l mole^{-1} s^{-1}) and a rate constant for hydrogen atom abstraction ($k_{abstr} = 14$ l mole^{-1} s^{-1}). In the presence of heavy water the first order process for indene had a deuterium isotope effect $(k_x)/(k_x)_{D_2O} \simeq 3$.

INTRODUCTION

The effects of temperature and solvents on the absolute rate constants for the autoxidation of styrene, i.e., for its copolymerization with oxygen, were described in the first paper in this series (1). The second paper gave the absolute rate constants for four deuterium-labelled styrenes and a number of ring-substituted styrenes (2). The present paper extends this work to α- and β-methylstyrene and indene. Both α-methylstyrene and indene have been shown to copolymerize with oxygen in thermally initiated oxidations (3, 4). α-Methylstyrene is of particular interest since it yields a tertiary peroxy radical. The mechanism of chain termination for compounds giving tertiary peroxy radicals has been under very active study in the past 2 or 3 years (5–9) but absolute rate constants have been measured in only a few cases, i.e., for chain propagation (k_p) and chain termination (k_t) in the autoxidation of cumene (9–12) and 2,4,6-trimethyl heptane (13) and for the mutual destruction of *t*-butylperoxy radicals derived from *t*-butylhydroperoxide (9). α-Methylstyrene is also interesting in that the rate of the α,α′-azo-bis-isobutyronitrile (AIBN) thermally initiated oxidation has been reported to increase very noticeably as the oxygen pressure is increased, e.g., the rate at 50° with 0.01 mole/l AIBN is 0.076, 0.12, and 0.13 mole l^{-1} h^{-1} at 100, 750, and 3 200 mm oxygen pressure, respectively (3). This variation in the rate with the oxygen pressure has been attributed to a contribution from crossed chain termination, involving aralkyl ($R^\cdot$) and aralkylperoxy ($RO_2^\cdot$) radicals, to the overall rate of chain termination at oxygen pressures below 3 200 mm (3).

This paper describes the effects of temperature on the absolute rate constants for the oxidation of α-methylstyrene. The results of a few measurements on the deutero-α-methylstyrene, $C_6H_5C(CD_3):CD_2$, are also included. In addition, the inhibition with 2,6-di-*t*-butyl-4-methylphenol (BMP) of the thermally initiated autoxidation of α-methylstyrene has been studied.

EXPERIMENTAL

The experimental technique and theory of the rotating sector method has been described previously (1, 2). α,α'-Azo-bis-cyclohexylnitrile (ACHN) was used as the photo-initiator. The deutero-α-methylstyrene, $C_6H_5C(CD_3):CD_2$, was obtained from Merck, Sharp and Dohme of Canada, Limited. Mass spectrometric analysis showed it to be 89% $C_9H_5D_5$ and 11% $C_9H_6D_4$.

Indene (Eastman) was purified by crystallization and distillation. β-Methylstyrene (Aldrich) was purified by distillation.

It is nearly impossible to assign a specific error to each of the absolute rate constants reported in this paper and in the other papers in this series. We have previously discussed the sources of some of the errors involved in rotating sector measurements (1). The errors will be increased under the following circumstances: (i) when there are concurrent first and second order chain termination reactions, (ii) when the reaction is autocatalytic or autoretarding, and (iii) when the chain length is relatively short. On the whole, it is probably safe to assume that all the values for k_t should be accurate to within a factor of 2 and all the values for k_p should be accurate to within ±50%. Under ideal conditions, and when a large number of measurements have been made (as for all our work on deuterium-labelled hydrocarbons), the results should be a great deal more accurate.

RESULTS AND DISCUSSION

Uninhibited Oxidation of α-Methylstyrene

The ACHN-photosensitized oxidation of α-methylstyrene is self-retarding.[2] That is, the rate decreases as the reaction proceeds to a greater extent than can be accounted for by the consumption of ACHN and the hydrocarbon. This has also been observed in the AIBN thermally initiated oxidation (3) but the effect is more pronounced in the photochemical reaction, apparently because a reaction product absorbs some of the 365 mμ initiating radiation. Thus, for example, the oxidation of 1.78 mole/l of α-methylstyrene in chlorobenzene containing 6.7×10^{-3} mole/l ACHN with 0.04 mole/l O_2 increased the ultraviolet absorption at this frequency by a factor of more than 4. This increase in absorption can probably be attributed to the acetophenone which is formed in large amounts in both the thermal (3) and photochemical[3] oxidation. This problem renders the determination of absolute rate constants rather difficult, it being necessary to correct for the changing rate of chain initiation during each experiment.

The results given in Table I contrast with those of Miller and Mayo in that oxygen pressure in the range 100–680 mm had no significant effect on the oxidation rate or, more correctly,[4] on $k_p/(2k_t)^{1/2}$. The lower temperature of the present experiments as well as the smaller pressure range which was covered probably accounts for this discrepancy.

At 40 and 50 °C, α-methylstyrene showed no sign of the first order chain-terminating process that was observed in styrene at these temperatures (1, 2). Its absence reinforces our previous conclusion, drawn from studies of the deuterium isotope effect (2), that the α-hydrogen atom in styrene is involved in this process.

The rate constants in Table I can be represented by:

$$k_p/(2k_t)^{1/2} = (3.5 \pm 0.2) \times 10^2 \exp(-(6\,170 \pm 300)/RT)\ (\text{l mole}^{-1}\ \text{s}^{-1})^{1/2}$$
$$k_p = (6.6 \pm 0.7) \times 10^6 \exp(-(8\,070 \pm 800)/RT)\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_t = (1.6 \pm 0.7) \times 10^8 \exp(-(3\,700 \pm 1\,600)/RT)\ \text{l mole}^{-1}\ \text{s}^{-1}.$$

[2]*In the absence of ACHN the photo-oxidation is autocatalytic but very slow, the rate being only about 1/6 of that found for styrene under similar conditions, c.f., the self-initiated thermal oxidation (3).*

[3]*For example, the absorption of 0.1 mole/l O_2 in a photochemical autoxidation of 1.78 mole/l of α-methylstyrene in chlorobenzene at 50° and 680 mm O_2 gave a 70% yield of acetophenone and a 16% yield of a methanol insoluble polymer, $(C_9H_{10}O_2)_n$. These yields are based on the assumption that 0.1 mole/l of the α-methylstyrene had reacted. The chain length in this oxidation was about 80.*

The α-methylstyrene was only very slightly oxidized during most of our kinetic measurements (<0.01 mole/l O_2.) We have therefore assumed that the small amounts of formaldehyde which must have been formed in the reaction did not interfere with the determination of k_t and k_p for the α-methylstyrene.

[4]*Throughout this work the measured rate of chain termination is taken to be $2k_t$ since two oxidation chains are ended, i.e.,*

$$RO_2\cdot + RO_2\cdot \xrightarrow{2k_t} \textit{Inactive products.}$$

The small activation energy for the chain termination of tertiary peroxy radicals is in agreement with the recent electron spin resonance studies of Thomas (9) on the chain-terminating interaction of *t*-butylperoxy radicals ($E = 10.2 \pm 1$ kcal/mole) and cumylperoxy radicals ($E = 0 \pm 1$ kcal/mole from the oxidation of cumene and 2 ± 1 kcal/mole from the decomposition of cumene hydroperoxide). Vichutinskii (12) has also reported obtaining an activation energy of 2.3 ± 0.3 kcal/mole for the mutual destruction of cumylperoxy radicals, the reaction being followed by the method of chemiluminescence. The actual rate constant for the chain termination is larger than for *t*-butylperoxy radicals ($k_t = 3.1 \times 10^2$ l mole^{-1} s^{-1} at 30 °C (9)), cumylperoxy radicals[5] ($k_t = 1.9 \times 10^4$ l mole^{-1} s^{-1}), or the peroxy radicals from 2,4,6-trimethylheptane ($k_t = 1.8 \times 10^5$ l mole^{-1} s^{-1} at 40–80° (13)). It is, perhaps, specifically worth pointing out that the rate of oxidation of α-methylstyrene is about twice as great as the rate of oxidation of styrene under comparable conditions even though both k_p and k_t are smaller for the former compound than for the latter.[6] It is clear that structural influences on oxidation rates cannot be easily interpreted unless both rate constants are known.

The deutero-α-methylstyrene, $C_6H_5C(CD_3):CD_2$, oxidized slightly more rapidly at 30° than the undeuterated compound ($k_p/(2k_t)^{1/2} = 1.6 \times 10^{-2}$ (l mole^{-1} s^{-1})$^{1/2}$). At this temperature the measured rate constants (5 and 5×10^4 l mole^{-1} s^{-1} for k_p and k_t, respectively, at a $C_6H_5C(CD_3):CD_2$ concentration of 0.57 mole/l) indicated an unbelievably large isotope effect for both propagation and termination. A rather different experimental approach involving measurement of the rates of oxidation at 65 °C in the presence of 2,6-di-*t*-butyl-4-methylphenol (see below) indicated that $(k_p)_H/(k_p)_D = 1.0 \pm 0.05$. This suggests that the entire variation in $k_p/(2k_t)^{1/2}$ is due to a change in k_t. That is, $(k_t)_H/(k_t)_D = (1.6)^2/(1.3)^2 = 1.5$, this isotope effect being calculated from oxidations with a chain length of 15 for the normal and 18.5 for the deutero-α-methylstyrenes (see ref. 7). These isotope effects are in fair agreement with the values obtained by Boozer *et al.* (14) from the oxidation of cumene and $C_6H_5C(CD_3)_2H$, i.e., $rate_H/rate_D \simeq 0.88$. This deuterium

[5]*This value is derived from the results of Melville and Richards (10) and Vichutinskii (12). Melville and Richards give values for $2k_t$ of 2.8 and 3.3×10^4 l mole^{-1} s^{-1} at 50 and 65 °C, respectively. These values have been corrected by a factor of 1/0.6 to allow for the fact that the efficiency of chain initiation from ACHN is not equal to 1.0, i.e., $(k_t)_{50°} = 2.8/(0.6 \times 2.0) = 2.35 \times 10^4$ l mole^{-1} s^{-1}. Extrapolation to 30 °C gives $k_t = 1.88 \times 10^4$ l mole^{-1} s^{-1}. Vichutinskii's value for $2k_t$ of 3.3×10^4 l mole^{-1} s^{-1} at 20 °C combined with this activation energy also gives $k_t = 1.88 \times 10^4$ l mole^{-1} s^{-1} at 30 °C. Howard and Robb's (11) value is significantly higher than this, i.e., 9×10^4 l mole^{-1} s^{-1} at 56 °C.*

In connection with these calculations, extrapolation of Thomas' data (9) and Vichutinskii's data (12) to 60 °C gives $k_t = 1.42 \times 10^8$ l mole^{-1} s^{-1} for t-butylperoxy radicals and $k_t = 2.65 \times 10^4$ l mole^{-1} s^{-1} for cumylperoxy radicals. The ratio of these two rate constants is 18.7, in excellent agreement with the ratio of 16 determined by Traylor and Russell at this temperature (7).

[6]*For example, for styrene at 30 °C $k_p = 41$ l mole^{-1} s^{-1} and $k_t = 2.1 \times 10^7$ l mole^{-1} s^{-1} (1).*

isotope effect in chain termination has been explained by Traylor and Russell (7) as arising from a secondary isotope effect in the reaction,

$$C_6H_5C(CH_3)_2O\cdot \rightarrow CH_3\cdot + C_6H_5COCH_3$$

and a primary isotope effect in the reaction

$$CH_3OO\cdot + ROO\cdot \rightarrow CH_2O + O_2 + ROH.$$

Inhibited Oxidation of α-Methylstyrene

In previous communications from this laboratory (15) we have shown that the highly hindered phenol 2,6-di-*t*-butyl-4-methylphenol (BMP) inhibits the AIBN thermally initiated oxidation of styrene and tetralin with very simple overall kinetics. The self-termination reaction of two peroxy radicals is replaced by hydrogen atom abstraction from the phenol, AH, i.e.,

$$RO_2\cdot + AH \xrightarrow{k_{inh}} ROOH + A\cdot$$

the oxidation rate, P, being given by

$$P = \frac{R_i k_p[RH]}{2k_{inh}[AH]}$$

where R_i is the rate of chain initiation and RH represents the substrate. It is inconceivable that deuteration of the substrate could have any significant effect on k_{inh}. A comparison of the BMP-inhibited rates of oxidation of a deuterated and undeuterated substrate should therefore reveal any isotope effect in k_p.

The BMP-inhibited oxidation of pure α-methylstyrene at 65 °C showed the expected first order kinetics. That is, at an AIBN concentration of 3×10^{-3} mole/l, $P \propto [AH]^{-1.0}$ in the range $10^{-4} - 5 \times 10^{-3}$ mole/l, and at a BMP concentration of 1.2×10^{-3} mole/l, $P \propto [AIBN]^{1.0}$ in the range $3 \times 10^{-4} - 3 \times 10^{-2}$ mole/l. The measured rates gave $k_p/k_{inh} = 2.7 \times 10^{-3}$ for neat α-methylstyrene and 5.0×10^{-3} for 1.78 *M* α-methylstyrene in chlorobenzene. Extrapolation of the data in Table I gives $(k_p)_{65°} = 40$ l mole^{-1} s^{-1}. Hence, $k_{inh} = 8.0 \times 10^3$ l mole^{-1} s^{-1} for α-methylstyrene in chlorobenzene and 1.5×10^4 l mole^{-1} s^{-1} for neat α-methylstyrene (if it is assumed that k_p is unaffected by the chlorobenzene, see Part IV).

The normal and deutero-α-methylstyrene were compared in dilute solution (1.87 *M*) in dimethylsulfoxide (DMSO) as a solvent. This procedure was employed because DMSO increases the inhibited rate by a factor of about 5 compared with chlorobenzene and it thus made possible the accurate measurement of inhibited rates with only 1 ml of the α-methylstyrenes. This accelerating effect of the DMSO is chiefly due to a reduction in k_{inh} since the solvent effect on k_p is quite small (see Part IV). Using 2×10^{-3} mole/l AIBN and 1.5×10^{-3} mole/l BMP, we obtained identical oxygen absorption curves for the two compounds. Within the limit of accuracy of the measurements $(k_p)_H/(k_p)_D = 1.0 \pm 0.05$ (see footnote[7]).

β-Methylstyrene

The oxidation of this compound does not appear to have been studied previously. Benzaldehyde was one of the main products (~40%) from the photochemically initiated

[7]*This result contrasts with the small positive isotope effect of 1.05–1.27 obtained by Boozer et al. (14) from the rates of the 4-nitrophenol- and 2,4-dichlorophenol-inhibited oxidation of cumene and* $C_6H_5C(CD_3)_2H$ *and also contrasts with the small positive isotope effect of (~10–20%) from our absolute measurements of* k_p *for styrene,* $C_6H_5CD{:}CH_2$ *and* $C_6H_5CD{:}CD_2$ *(2).*

oxidation of a 0.89 *M* solution in chlorobenzene at 30 °C. It is presumably formed together with acetaldehyde, by the depolymerization of an oxygen–β-methylstyrene copolymer. The polymer could be precipitated from benzene with petroleum ether.

β-Methylstyrene oxidizes more rapidly than styrene. The presence of a kinetically first order chain termination process (rate constant k_x) in addition to the usual bimolecular termination renders the accurate determination of k_p and k_t quite difficult. We have previously observed concurrent first and second order termination processes in the oxidation of styrene (1, 2). However, the first order process is a more important source of chain termination in β-methylstyrene and, moreover, its importance increases slightly as the oxidation proceeds. The measured rate constants for styrene and β-methylstyrene at 30 °C are compared in Table II. The slightly larger value of k_p for the latter compound suggests that electron release by the methyl group more than outweighs the expected steric effect which would tend to hinder the addition of the peroxy radical.

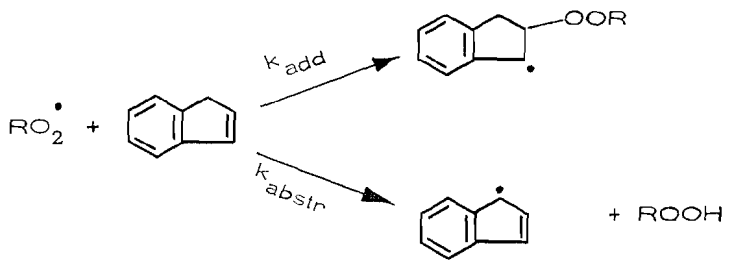

TABLE II

Absolute rate constants for styrenes in chlorobenzene at 30 °C

Substrate	Concentration (mole l^{-1})	k_p ($l\ mole^{-1}\ s^{-1}$)	$k_t \times 10^{-7}$ ($l\ mole^{-1}\ s^{-1}$)	k_x (s^{-1})
Styrene (ref. 1)	2.01	41	2.1	0.24
β-Methylstyrene	0.89	51	1.6	0.61
Indene	0.67	142	2.5	1.24

Indene

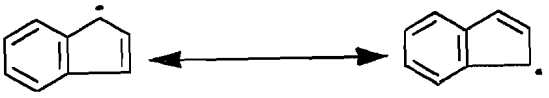
The AIBN thermally initiated oxidation of indene involves both addition and abstraction by the chain-propagating peroxy radicals (4). Addition gives a 1:1 copolymer of indene and oxygen (rate constant k_{add}) while abstraction results in chain transfer and the formation of a hydroperoxide (rate constant k_{abstr}).

In the present experiments at 30° with photochemical initiation of a 0.67 *M* solution of indene in chlorobenzene 10% of the absorbed oxygen is present as readily titratable hydroperoxide (4), i.e., $k_{add}/k_{abstr} = 9$.

There is a very pronounced first order chain termination process which renders the accurate determination of k_p and k_t for indene extremely difficult. At 30 °C the measured rate constants for 0.67 *M* indene in chlorobenzene were $k_p = 85\ l\ mole^{-1}\ s^{-1}$, $k_t = 8.2 \times 10^6\ l\ mole^{-1}\ s^{-1}$, and $k_x = 1.24\ s^{-1}$. If the first order process had been neglected an apparent $k_t = 4 \times 10^8$ would have been obtained.

We have shown previously that the first order process in styrene is strongly suppressed by the addition of heavy water (2).[8] With this in mind, absolute rate constants were

[8]*This was attributed to the replacement of readily abstractable, labile hydrogen atoms by much less readily abstractable deuterium atoms. The suggested mechanism involves hydroxylation of aromatic nuclei by hydroxyl radicals to give, eventually, phenols which are primarily responsible for the first order termination.*



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

measured for indene under the same conditions as above except that a large excess of D_2O was added to the reactants. The following values were obtained: $k_p = 142$ l mole^{-1} s^{-1}; $k_t = 2.5 \times 10^7$ l mole^{-1} s^{-1}, and $k_x = 0.34$ s^{-1}. Neglect of the first order process would give $k_t = 6.7 \times 10^7$ l mole^{-1} s^{-1}. These propagation and bimolecular termination rate constants are probably a great deal more reliable than those obtained in the absence of D_2O since the first order termination has become much less important. They are compared with the constants for styrene and β-methylstyrene in Table II. The deuterium isotope effect on k_x, i.e., $k_x/(k_x)_{D_2O} \approx 3$ is in fair agreement with the value of $\geqslant 4.5$ found previously for styrene at 50 °C (2).

The overall propagation rate constant, k_p, can be divided into two parts, i.e.,

$$k_{add} = 142 \times 0.9 = 128 \text{ l mole}^{-1} \text{ s}^{-1}$$
$$k_{abstr} = 142 \times 0.1 = 14 \text{ l mole}^{-1} \text{ s}^{-1}.$$

Indene is about three times as reactive as styrene towards the addition of the corresponding peroxy radicals. This enhanced reactivity can probably be at least partly attributed to the fact that electron release by the methylene group is not accompanied by an opposing steric effect as was the case in β-methylstyrene. The rate constant for hydrogen abstraction is about 40% larger than the value found for allylbenzene at this temperature (see Part IV). This is probably caused by the greater stability of the indenyl radical which results from the two resonance structures (4).

ABSOLUTE RATE CONSTANTS FOR HYDROCARBON AUTOXIDATION

IV. TETRALIN, CYCLOHEXENE, DIPHENYLMETHANE, ETHYLBENZENE, AND ALLYLBENZENE[1]

J. A. HOWARD AND K. U. INGOLD

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received December 21, 1965

ABSTRACT

Absolute rate constants have been measured for the autoxidation of five hydrocarbons under a variety of conditions. The propagation (k_p) and termination (k_t) rate constants at 30 °C (in l mole^{-1} s^{-1}) are: tetralin in chlorobenzene 6.3 and 3.8×10^6 respectively, cyclohexene in chlorobenzene 6.1 and 2.8×10^6, diphenylmethane 4.8 and 8.0×10^7, ethylbenzene 0.11 and 2.0×10^7, and allylbenzene 10 and 2.2×10^8. Measurements on tetralin, α-methylstyrene, and allylbenzene in different solvents indicate that the effect of solvents on oxidation rates is mainly connected with changes in the rate of termination rather than propagation. Experiments with α,α-d_2-diphenylmethane gave isotope effects $k_H/k_D \sim 5.1$ for k_p and ~ 1.4 for k_t. The rate constant for hydrogen atom abstraction from 2,6-di-*t*-butyl-4-methylphenol by peroxy radicals decreases in the order expected if steric effects are important, i.e., primary peroxy > secondary peroxy > tertiary peroxy radical.

The co-oxidation method of estimating chain termination constants is criticized on the grounds that it can only be used to distinguish the fairly large changes in k_t commonly encountered between hydrocarbons giving tertiary peroxy radicals and those giving secondary or primary radicals.

The effect of hydrocarbon structure on bimolecular chain termination rate constants is reviewed. There is a gradation in k_t from $\sim 2 \times 10^8$ l mole^{-1} s^{-1} for primary peroxy radicals, through the range 8×10^7 to 1×10^6 for secondary radicals, to the range from 3×10^5 to 3×10^2 for tertiary peroxy radicals.

INTRODUCTION

The present paper extends our measurements of absolute rate constants for autoxidation from substances which copolymerize with oxygen (1, 2) to substances from which a benzylic and (or) allylic hydrogen atom is abstracted. Attention has again been devoted to deuterium isotope effects on the propagation and termination rate constants (k_p and k_t) with measurements being made on perdeutero tetralin and α,α-d_2-diphenylmethane. Solvent effects on k_p and k_t for tetralin suggest that the increase in oxidation rates in polar solvents is due more to a decrease in k_t than to an increase in k_p. The present data are in quite good agreement with previous determinations of k_t for cyclohexene (3–5) and tetralin (6).

The propagation and termination rate constants for allylbenzene have been measured. This compound is particularly interesting in that the initially formed benzyl radical isomerizes to a cinnamyl radical. Chain termination must involve the mutual interaction of cinnamyl peroxy radicals (7).

$$C_6H_5CH_2CH{=}CH_2 \xrightarrow{RO_2\cdot} C_6H_5\dot{C}HCH{=}CH_2 \rightarrow C_6H_5CH{=}CH\dot{C}H_2 \xrightarrow{O_2} C_6H_5CH{=}CHCH_2OO\cdot$$

The rates of oxidation of mixtures of tetralin and allylbenzene have been measured at 65 °C. The present results illustrate the difficulties which are inherent in this method of comparing rate constants for chain termination.

The 2,6-di-*t*-butyl-4-methylphenol inhibited oxidation of several substrates in chlorobenzene and dimethyl sulfoxide (DMSO) has been examined. It was found that the rate constant for inhibition depends on the nature of the peroxy radical.

[1]*Issued as N.R.C. No. 8893.*

The rate constants for bimolecular chain termination found in the present work have been combined with other reliable values from the literature to give an overall picture of the variation in k_t with hydrocarbon structure.

EXPERIMENTAL

Perdeuterotetralin was obtained from Merck, Sharpe and Dohme. Analysis by mass spectrometry gave 83.5% $C_{10}D_{12}$, 14.0% $C_{10}D_{11}H$, and 2.5% $C_{10}D_{10}H_2$. We are indebted to Dr. L. C. Leitch for a generous sample of α,α-d_2-diphenylmethane ($C_{13}D_2H_{10}$ 91%, $C_{13}DH_{11}$ 9%). None of the hydrocarbons used in this work contained more than 0.5% of impurities as determined by vapor phase chromatography.

All the absolute rate constants given in the tables are averages of at least two independent experiments consisting of not less than two, and usually three or four, measurements of k_t.

RESULTS AND DISCUSSION

Tetralin

Absolute rate constants for the autoxidation of pure tetralin from 13 to 50 °C and of 1.69 *M* tetralin in chlorobenzene from 22 to 50 °C are presented in Table I. At temperatures of 30 °C and above, the reaction shows fairly pronounced autocatalysis which is due to thermal, rather than photochemical, decomposition of tetralin hydroperoxide. This increasing thermal contribution to chain initiation as the reaction proceeds complicates the determination of k_p and k_t. Two methods were employed to overcome this difficulty. Firstly, a fresh sample of tetralin was used for each rate measurement. Secondly, a number of rate measurements were made in a single run, but the thermal contribution was determined after each pair of photochemical experiments, i.e., repeated rate measurements were made in the order, (i) steady illumination, (ii) intermittent illumination, (iii) no illumination. This second method gave somewhat more reproducible results but the agreement between the two methods was quite satisfactory. No kinetically first order chain terminating process could be detected at any temperature (1, 2) and the rate was independent of the oxygen pressure in the range 100–700 mm.

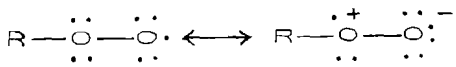
TABLE I

Absolute rate constants for the autoxidation of tetralin

Tetralin concentration (moles/l)	Temp. (°C)	$(k_p/(2k_t)^{1/2}) \times 10^3$ $(l\ mole^{-1}\ s^{-1})^{1/2}$	k_p $(l\ mole^{-1}\ s^{-1})$	$k_t \times 10^6$ $(l\ mole^{-1}\ s^{-1})$
7.34	13	1.14	2.2	1.9
1.69*	22	1.66	3.8	2.6
7.34	30	2.2	6.2	3.8
1.69*	30	2.3	6.4	3.8
7.34	40	2.8	8.5	5.0
1.69*	40	3.4	7.6	2.5
7.34	50	4.0	13.6	6.0
1.69	50	4.0	12.9	5.3

*In chlorobenzene.

Since the absolute rate constants appear to be identical in pure tetralin and in the chlorobenzene solution, the results of both sets of measurements were combined to determine the temperature coefficients.



$$k_p/(2k_t)^{1/2} = (44 \pm 2) \exp -(6\,000 \pm 300)/RT\ (l\ mole^{-1}\ s^{-1})^{1/2}$$
$$k_p = (5.7 \pm 0.6) \times 10^6 \exp -(8\,300 \pm 800)/RT\ l\ mole^{-1}\ s^{-1}$$
$$k_t = (4.3 \pm 1.5) \times 10^9 \exp -(4\,300 \pm 1\,500)/RT\ l\ mole^{-1}\ s^{-1}$$

The measured activation energy for termination may be too large because of the uncertainties in k_t at the higher temperatures. The average value of k_t over the whole

temperature range is 4×10^6 l mole^{-1} s^{-1}, in moderately good agreement with Bamford and Dewar's estimate of 1.1×10^7 l mole^{-1} s^{-1} at 25 °C.

Current interest in solvent effects on rates of hydrocarbon autoxidation (see e.g. 1, 8, 9) prompted us to examine the effect of *n*-decane, acetonitrile, and DMSO on the absolute rate constants for the oxidation of tetralin at 30 °C. The data are given in Table II together with the results obtained for α-methylstyrene in DMSO and chlorobenzene and for allylbenzene in DMSO and as the pure material. The data suggest that the solvents influence k_t to a much greater extent than k_p. This result contrasts with our previous results in styrene at 13 °C (1).[2] It lends support to Hendry and Russell's proposal (9) that the solvent effect is connected with the fact that peroxy radicals have some polar character in their ground state, i.e.,

which is destroyed in termination. It is possible that some of the variation in k_t with the different solvents may be due to changes in the viscosity of the medium. However, this effect is probably not very large since acetonitrile has a lower viscosity than chlorobenzene and DMSO a higher viscosity.

The use of DMSO as a solvent in autoxidations may appear somewhat unusual in view of the well known reactions between sulfur-containing compounds and hydroperoxides which were first described by Denison (10). However, DMSO does not affect the yield of hydroperoxide formed during the oxidation of tetralin at 65 °C (see Table III). The slightly greater than theoretical yields of hydroperoxide noted in this table are almost certainly due to the oxidation that occurs after the absorption measurements are completed while the sample is being removed from the reaction vessel for analysis. It is clear that DMSO acts as an "inert" solvent under the conditions of these experiments.

In a preliminary experiment a small sample of the perdeuterotetralin was oxidized at 65 °C. The rate was unexpectedly low, being only about 8% of the rate for normal tetralin[3] instead of an expected 20% (11). Only three very minor impurities totalling less than 0.5% were detected in the deuterotetralin by gas chromatography on a 150 ft Golay capillary column at 120 °C. However, when the deuterotetralin was washed with concentrated D_2SO_4 the acid layer turned black. The washing was repeated many times until the acid layer became only a pale yellow. The deuterotetralin was then washed with D_2O, passed through alumina, dried with calcium hydride, and distilled. The final product ($C_{10}D_{12}$ 76.8%, $C_{10}D_{11}H$ 19.8%, $C_{10}D_{10}H_2$ 3.4%) showed no detectable impurities by gas chromatography and had an identical ultraviolet spectrum to that of undeuterated tetralin. However, the result of all this "purification" was to *reduce* the rate at 65° to only 5% of the value for pure tetralin. Rotating sector experiments on this "purified" material at 30 °C and a chain length of about 5 ([RD] = 7.34 mole/l) gave the following.

$$k_p/(2k_t)^{1/2} = 5.7 \times 10^{-5}\ \text{l}^{1/2}\ \text{mole}^{-1/2}\ \text{s}^{-1/2}$$
$$k_p = 1.1 \times 10^{-1}\ \text{l mole}^{-1}\ \text{s}^{-1}$$
$$k_t = 2.0 \times 10^{6}\ \text{l mole}^{-1}\ \text{s}^{-1}$$

[2]*However, DMSO was not used as a solvent in the styrene experiments and a great deal of the observed variation in rate with solvent was due to a change in the rate of chain initiation, R_i. Thus, at 13 °C, $k_p/(2k_t)^{1/2}$ was constant in benzene, chlorobenzene, and acetonitrile (2.7×10^{-3} l$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$) although it was slightly smaller in t-butylbenzene (2.3×10^{-3}) and quite a bit smaller in n-decane (1.2×10^{-3}). In DMSO the rate of chain initiation is lower than in chlorobenzene (see Table II).*

[3]*The oxidation was initiated with 5.72×10^{-2} mole/l AIBN. The rates were 5.35×10^{-5} and 4.5×10^{-6} mole l^{-1} s^{-1} for $C_{10}H_{12}$ and $C_{10}D_{12}$ respectively.*

2.0	DMSO	14.3	2.36	2.4	102

*Sample refluxed in isopropanol containing potassium iodide and acetic acid for 10 min under nitrogen. The liberated iodine was titrated with sodium thiosulfate. Recrystallized tetralin hydroperoxide titrated to about 98% of theory. There was no significant blank correction when chlorobenzene and DMSO were treated with 0.01 *M* AIBN and oxygen at 65 °C for the same lengths of time as the corresponding tetralin oxidations.

The isotope effect on k_p (>50) is completely out of line with previous work on the isotope effect in a similar oxidation (11) and with our own results for diphenylmethane which are described below. Under these circumstances the observed isotope effect on k_t (~ 2) can hardly be meaningful. We can only suppose that some undetected and hard to remove impurity was present in the deuterotetralin.

Cyclohexene

The photochemically initiated autoxidation of cyclohexene at 30 °C showed fairly pronounced autocatalysis which was mainly due to the thermal decomposition of the hydroperoxide. For this reason, the absolute rate constants were measured on a dilute solution of cyclohexene in chlorobenzene. There was no detectable first order chain termination.

In Table IV the propagation and termination rate constants obtained in this work are compared with previously reported values for pure cyclohexene (which have been extrapolated to 30 °C). The rate constant for the reaction of cyclohexenylperoxy radicals with 2,6-di-*t*-butyl-4-methylphenol at 30 °C are also compared in this table.

$$RO_2\cdot + AH \xrightarrow{k_{inh}} ROOH + A\cdot \text{ (see footnote [4])}$$

On the whole, the agreement between different workers is quite satisfactory.

Diphenylmethane

The oxidation of this compound is autocatalytic at 30 °C. There is no detectable first order chain termination. Absolute rate constants for the pure unlabelled and pure α,α-d_2-diphenylmethane are given in Table V. The deuterium isotope effects for $k_p/(2k_t)^{1/2}$, k_p, and k_t are all of the expected order of magnitude (11). The isotope effect for termination (~ 1.4) provides further support for the view that one of the α-hydrogen atoms is abstracted in the chain-terminating interaction of secondary peroxy radicals (1, 11).

Ethylbenzene

Although this compound is quite resistant to oxidation at 30 °C it was found that a

[4]*Since the reaction of the phenoxy radical with* $RO_2\cdot$, *i.e.*,

$$RO_2\cdot + A\cdot \rightarrow ROOA$$

is very rapid, two chains are terminated for each primary step of inhibition. The inhibited rate P_{inh} *is therefore given by (12)*

$$P_{inh} = (k_p[RH]R_i)/(2k_{inh}[AH]).$$

The values of k_{inh} *quoted in refs. 4 and 5 have therefore been divided by 2 after extrapolating to 30 °C.*

TABLE V

Absolute rate constants for the autoxidation of diphenylmethane at 30 °C

	$(k_p/(2k_t)^{1/2}) \times 10^4$ (l mole^{-1} s^{-1})$^{1/2}$	k_p (l mole^{-1} s^{-1})	$k_t \times 10^7$ (l mole^{-1} s^{-1})
$(C_6H_5)_2CH_2$	3.8	4.8	8.0
$(C_6H_5)_2CD_2$	0.88	0.94	5.7
k_H/k_D	4.3	5.1	1.4

reasonable chain length (~13) could be obtained by reducing the light intensity to 13% of its maximum value. In the pure hydrocarbon at 30 °C

$$k_p/(2k_t)^{1/2} = 2.0 \times 10^{-4} \text{ (l mole}^{-1} \text{ s}^{-1})^{1/2}$$
$$k_p = 1.1 \text{ l mole}^{-1} \text{ s}^{-1}$$
$$k_t = 1.6 \times 10^7 \text{ l mole}^{-1} \text{ s}^{-1}.$$

This chain termination rate constant is in good agreement with the value of $(9.5 \pm 2.0) \times 10^6$ l mole^{-1} s^{-1} reported by Tsepalov and Shlyapintokh (13) using the rotating sector method in the range 50–90° and is in even better agreement with the value of $(2.0 \pm 0.3) \times 10^7$ l mole^{-1} s^{-1} reported by Vichutinskii (14) using the chemiluminescence method in the range 30–60 °C.

Allylbenzene

Absolute rate constants for the oxidation of allylbenzene at 30 °C have been given in Table II for the pure hydrocarbon and for a 1.74 *M* solution in DMSO. The reaction was neither autocatalytic nor autoretarding and there was no detectable first order chain termination.

It is clear that the comparatively low rate of oxidation of allylbenzene is not due to a low rate of propagation but instead is due to the very high rate of termination of the *primary* cinnamyl peroxy radicals.

The differences found in this work for the chain termination rate constants of allylbenzene and the three secondary hydrocarbons was a little unexpected. It led us to re-examine a currently popular indirect method of estimating chain termination rate constants known as competitive oxidation.

Competitive Oxidations

In 1955 Russell published a paper on the competitive oxidation of cumene and tetralin which was of fundamental importance to the whole field of autoxidation (15). Russell found that mixtures of cumene and tetralin, containing only small amounts of the more reactive compound, tetralin, are oxidized at rates considerably below those observed for either of the pure hydrocarbons. This decrease in the rate stems from the fact that a relatively high concentration of tetralylperoxy radicals is formed in solutions containing mostly cumene. Tetralylperoxy radicals terminate much more readily than cumylperoxy radicals and a lower rate of oxidation is observed for the mixture than for pure cumene because of the lowered steady-state concentration of peroxy radicals. Small amounts of other reactive hydrocarbons that produce secondary peroxy radicals were also shown to retard the oxidation of cumene. The limitations of this method for estimating k_t were clearly realized at this time, although they seem to have been overlooked in recent years. That is, a well defined minimum rate can only be obtained when the second hydrocarbon has a larger k_t *and* is oxidized at a greater rate than the first. It must therefore have a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

very much larger k_p. If this condition is not met, plots of rate against mixture composition may be curved but they will not exhibit a minimum.

Russell's original observation that primary and secondary peroxy radicals terminate more rapidly than tertiary has been repeatedly confirmed. However, the co-oxidation method seems quite incapable of distinguishing even the grossest variations in k_t for hydrocarbons giving primary and secondary peroxy radicals. For example, Balacéanu and co-workers (16, 17) have based a fairly extensive compilation of k_t values on the fine details of a large number of co-oxidation rate curves. Cumene, cyclohexene, and tetralin were used as reference hydrocarbons with values of $2k_t$ taken (from the literature) to be 3×10^4 (18), 1×10^6 (3), and 2 (or 4) $\times 10^7$ (6) l mole^{-1} s^{-1}, respectively. However, the data we have presented above show that k_t is virtually the same for cyclohexene and tetralin. One might perhaps be tempted to be wise after the event and draw this same conclusion from the almost linear co-oxidation rate vs. composition curve which is shown for these two hydrocarbons in ref. 16*a*, except for the fact that hydrocarbons with widely different k_t's also give nearly linear plots. Thus, Balacéanu (16*d*) has taken Tsepalov and Shlyapintokh's recent measurement of $2k_t$ for ethylbenzene (i.e., 1.9×10^7 l mole^{-1} s^{-1} (13) see above) to confirm the validity of the co-oxidation method of estimating k_t since ethylbenzene and tetralin ($2k_t$ taken as 2×10^7 (6)) give an exactly linear relation between rate and mixture composition. In conjunction with our present value of k_t for tetralin this linear relation actually provides one of the best pieces of evidence that the co-oxidation method of estimating k_t is not at all accurate. Further evidence along these lines is provided by Balacéanu's conclusion that $2k_t > 2 \times 10^7$ l mole^{-1} s^{-1} for cyclohexane (16*d*); a direct determination by McCarthy and Maclachlan, using a pulse radiolysis method, gave $2k_t = 2.8 \times 10^6$ l mole^{-1} s^{-1} (19). This latter value is in line with our own determination of $2k_t$ for cyclohexene and tetralin (two other hydrocarbons with six membered rings, see below). It would appear that the co-oxidation method is too insensitive to detect any but the very largest changes in the chain termination rate constants.

To check this conclusion we have examined the co-oxidation of tetralin ($k_t \approx 4 \times 10^6$ l mole^{-1} s^{-1}) and allylbenzene ($k_t \approx 2 \times 10^8$ l mole^{-1} s^{-1}). Russell (20) has shown that there is little or no curvature in the plots of rate against concentration for the oxidation of mixtures of indan with the following compounds at 90 °C (0.02 *M* *t*-butyl perbenzoate as initiator): dibenzyl ether, tetralin, allylbenzene, diphenylmethane, and methyl phenylacetate, these compounds being arranged in order of decreasing rate with indan lying between tetralin and allylbenzene. In spite of the very large differences in k_t we should therefore not expect much curvature in the co-oxidation of tetralin and allylbenzene, nor in fact do we find very much (see Fig. 1).

Inhibited Oxidations at 65 °C

The hindered phenol, 2,6-di-*t*-butyl-4-methylphenol (AH), inhibits the oxidation of hydrocarbons by replacing the normal bimolecular chain termination process by the following reactions.

$$RO_2\cdot + AH \xrightarrow{k_{inh}} ROOH + A\cdot$$

$$RO_2\cdot + A\cdot \xrightarrow{fast} ROOA$$

The inhibited rate, P_{inh}, can be very simply represented.

$$P_{inh} = k_p[RH]\frac{R_i}{2k_{inh}[AH]}$$

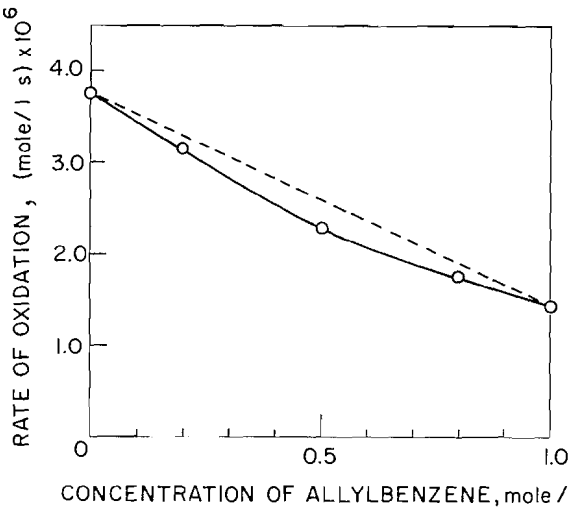

FIG. 1. The co-oxidation of tetralin and allylbenzene in *o*-dichlorobenzene at 65 °C with 0.01 mole/l AIBN as initiator. The total reactant concentration was kept at 1.0 *M* to reduce purely solvent effects on the rate which might be brought about by changes in the relative concentrations of the two reactants. The measured rate has been corrected for nitrogen evolution by the AIBN.

It follows that, for the same rate of chain initiation, the ratio of the inhibited rate to the uninhibited rate (P_0) is given by the following equation.

$$\frac{P_{\text{Inh}}}{P_0} = \left(\frac{R_i}{2}\right)^{1/2} \frac{k_t^{1/2}}{k_{\text{Inh}}[\text{AH}]}$$

We have previously suggested (1, 21) that, in a given solvent (8), k_{Inh} might be nearly independent of the nature of the peroxy radical. If k_{Inh} is indeed constant then measurement of P_{Inh}/P_0 will give k_t directly provided both the inhibited and the uninhibited[5] reactions conform to the simple kinetic equations. This method of obtaining k_t looked promising for compounds for which the rotating sector method could not be readily applied, e.g., fluorene, which absorbs quite strongly at 365 mμ, and dibenzyl ether, which is strongly autoretarding in chlorobenzene.

Several readily oxidizable compounds were examined at 65 °C as 2.0 *M* solutions in chlorobenzene (Table VI) and DMSO (Table VII). These solvents were used to reduce any variation in the strength or extent of phenol–solvent hydrogen bonding from one substrate to another. In calculating the data for these tables the rate constant for decomposition of AIBN was taken to be 1.8×10^{-5} s^{-1} and its efficiency of chain initiation[6] was taken to be 0.65. The first five substrates in the two tables have been arranged in order of decreasing k_t. It is quite clear that k_{Inh} is not independent of the nature of the peroxy radical. In fact, the results suggest a steric effect on the reaction rate since k_t decreases from the primary radical (allylbenzene), through the secondary radials to the tertiary radical (α-methylstyrene). The rather low value of k_{Inh} for α-methylstyrene in chlorobenzene, which is obtained from k_t at 30 °C, may be due to the relatively large activation energy for termination observed with this compound (2).

[5]*Obviously this method will not give k_t for styrene (1) or indene (2) since the uninhibited oxidations are terminated by both first and second order processes.*

[6]*This is smaller than the value of 0.8 used previously in chlorobenzene which partly accounts for the lower values of $k_p/(2k_t)^{1/2}$ for styrene and α-methylstyrene compared with the previously given values of $k_p/k_t^{1/2}$ (8) The remaining difference is probably due to the higher substrate concentrations employed in the present work.*

†Autocatalytic.
‡1.0 *M* solution.

While it is obviously impossible to assign accurate k_t values by this method it does provide rough numbers which seem fairly reasonable. Thus, taking $k_{inh} = 1.2 \times 10^4$ l mole^{-1} s^{-1} in chlorobenzene for compounds which give a secondary peroxy radical, we obtain $k_t = 2.1 \times 10^7$ l mole^{-1} s^{-1} for fluorene (in good agreement with the values found for styrene (1) and indene (2) in chlorobenzene) and $k_t = 1.0 \times 10^7$ l mole^{-1} s^{-1} for dibenzyl ether. Similarly, taking $k_{inh} = 2 \times 10^3$ l mole^{-1} s^{-1} in DMSO we obtain $k_t = 5 \times 10^6$ l mole^{-1} s^{-1} for fluorene (cf. allylbenzene and tetralin in DMSO, Table II) and $k_t = 1.0 \times 10^7$ for dibenzyl ether. The results suggest that k_t for dibenzyl ether is relatively unaffected by the solvent.

Summary of Bimolecular Chain Termination Constants for Hydrocarbon Autoxidation

The bimolecular chain termination rate constants found in the present work have been combined in Table VIII with values from our previous work (1, 2) and with other reliable values from the literature so as to give an overall picture of the variation in k_t with hydrocarbon structure. Rate constants for alcohols and aldehydes have not been included because there are too few values presently available for useful comparisons to be made with the hydrocarbons. Octene-1 has been placed with allylbenzene since it almost certainly gives mainly primary peroxy radicals (22). The value given in the table was obtained by the pulse radiolysis of octene-1 in the presence of oxygen (19). However, when this technique is used for a compound in which the hydrogen atoms are not all equivalent, some question must always remain as to whether the peroxy radicals whose decay kinetics are observed are the same as the peroxy radicals formed in the thermal chain process. The anomalous position of octene-1 in Table VIII strongly suggests that this pulse radiolysis value for k_t is at least an order of magnitude too small.

Table VIII does not include the numerous k_t values reported by Bateman and co-workers (3, 23–25) for olefinic hydrocarbons since, where comparison is possible, their values are very much smaller than those found by other workers. For example, they give values of 4.8×10^5 and $0.8–1.5 \times 10^5$ l mole^{-1} s^{-1} for cyclohexene (3) and octene-1 (23) respectively. In addition, their internal consistency was not very good, e.g., the reported values of k_t for ethyl linoleate vary from 1.5×10^5 (23, 24) to 1.5×10^7 l mole^{-1} s^{-1} (25) and the values reported for digeranyl vary almost as much. Table VIII includes a recent determination of k_t for the simplest peroxy radical, namely the hydroperoxy radical, HOO· (26).

The results in Table VIII show that there is a continuous gradation in k_t over a range of about 10^6 as the peroxy radical is changed from the primary cinnamylperoxy (from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

allylbenzene), through the secondaries, to the tertiary butylperoxy radical. The data for the secondary peroxy radicals suggest that k_t has a median value of about 2×10^7 for fairly unhindered benzylic peroxy radicals. This value is enhanced in diphenylmethane, presumably because the radical center is activated by a second phenyl group and is depressed in tetralin because the radical center is part of a six membered ring. In the latter case, steric hindrance to chain termination is expected since the peroxy (or alkoxy) group in one radical must be in the highly unfavorable axial position (19). This is, of course, also true of cyclohexene and cyclohexane. In this connection it is interesting to note that Robb and Shahin (27) obtained low k_t values for three methyl cyclohexenes, viz. 4.3×10^5, 1.7×10^6, and 1.4×10^6 l mole^{-1} s^{-1} for the 1-methyl-, 4-methyl-, and 4,5-dimethyl-cyclohexenes. Incidentally, our own attempt to measure k_t for cyclohexane was frustrated by its low rate of oxidation. The idea that steric factors may be important in chain termination provides a tentative explanation for the very high k_t value found for allylbenzene since steric effects would be at a minimum for this primary peroxy radical. The high k_t value for this compound may also be partly due to the greater resonance stabilization which is possible for the cinnamyl system relative to the benzyl system.

The variation in k_t for the tertiary peroxy radicals can probably be attributed to variations in the stabilities of their alkoxy radicals. That is, the termination of tertiary peroxy radical chains seems to proceed mainly through the formation and subsequent β-scission of the corresponding alkoxy radicals (30). The radical ejected in the β-scission adds oxygen to form a primary (or secondary) peroxy radical which can terminate chains much more readily than the main chain carrying tertiary peroxy radicals (15).

TABLE VIII

Bimolecular chain termination rate constants for hydrocarbon autoxidation (data refer to pure hydrocarbon or to the hydrocarbon in chlorobenzene solution)

Parent hydrocarbon		k_t* (l mole^{-1} s^{-1})	References
	H_2	1.0×10^6†	(26)
Primary radicals	Allylbenzene	2.2×10^8	This work

A CRITIQUE OF PAULI REPULSIONS AND MOLECULAR GEOMETRY

R. F. W. BADER[1] AND H. J. T. PRESTON
Burke Chemical Laboratories, Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 30, 1965

ABSTRACT

A theoretical method, which allows one to determine the effect of the Pauli exclusion principle on the electron density distribution, is used to test the concepts underlying the electron pair repulsion theory of molecular geometry. It is shown that pictures of overlapping orbitals frequently do not correspond to the actual effect which the Pauli principle has on the three-dimensional charge density. An alternative electrostatic approach, involving the concept of a binding region for a polyatomic molecule, is proposed to account for the observed molecular geometries.

INTRODUCTION

A theory of molecular geometry has been advanced "on the idea that the arrangement of all the electron pairs (bonding pairs and lone pairs) in the valency shell of the central atom is determined by the operation of the Pauli exclusion principle (1)". This theory relates the electron distribution in three-dimensional space and thus the molecular geometry to "Pauli repulsions" between pairs of electrons, the pairs being in bond or lone pair orbitals. Lone pairs of electrons, since they are considered to be in the field of principally one nucleus, are considered as occupying a more diffuse orbital than the bonding electron pairs. Thus one speaks of lone pair – lone pair repulsions as being greater than lone pair – bond repulsions which in turn are more important than bond–bond repulsions. It is the purpose of the present work to find a theoretical basis for the concept of "Pauli repulsions" when applied in this manner.

The Pauli principle in its most general form demands that a wave function be antisymmetric with respect to permuting the space and spin coordinates of all the electrons present in the system. When an orbital approximation to the wave function is employed, the demands of the Pauli principle are met if no more than two electrons with opposite spins are placed in any one space orbital when these orbitals form an *orthogonal* set. Indeed, within the orbital approximation, this is an alternative statement of the Pauli principle. The important feature for the present discussion is that the Pauli principle demands that the set of orbitals, atomic or molecular, used to describe the system be orthogonal,

$$\int \phi_i \phi_j \, d\tau = \delta_{ij}. \qquad [1]$$

Thus for a system of N electrons requiring a minimal set of $N/2$ space orbitals (or $(N + 1)/2$ if N is odd), the Pauli principle is in reality an orthogonality restraint imposed in an $(N/2)$- or $((N + 1)/2)$-dimensional mathematical space. This is the source of confusion regarding "Pauli repulsions" which are treated as occurring in the three-dimensional physical space of the molecular system. To state that the Pauli principle gives rise to repulsions between filled orbitals in three-dimensional space is *not* the same as requiring these orbitals to be orthogonal in the many-dimensional space required to define the orbitals. The only function of the electronic coordinates which can be pictured in three-dimensional space is the one-electron density distribution, not the orbitals. Thus to determine what effect the Pauli principle has on molecular shape or the electronic

[1]*A. P. Sloan Research Fellow.*

arrangement in physical space, one must ask the question "what effect does the requirement of orthogonality of the orbitals in the many-dimensional orbital space have on the electron density distribution of three-dimensional space?" The answer to this problem is not obvious and does not in general follow from pictures of colliding orbitals in physical space. It is possible to formulate a technique which does show the effect of the orthogonality requirements of the Pauli principle on the three-dimensional electron density distribution. We shall illustrate this method with a number of examples.

The one-electron density distribution is the probability of finding electronic charge at some point in real space. Thus it is obtained by first squaring the total wave function

$$\psi^*\psi \, d\tau_1 \, d\tau_2, \ldots d\tau_N$$

which then gives the N-electron density function. This function gives the probability of electron 1 being in its volume element $d\tau_1$ when simultaneously electron 2 is in its volume element $d\tau_2$, etc. This is a function in $3N$-dimensional space. If this expression is integrated over the coordinates of all the electrons but one, we will have the probability of any one electron being at some point in its three-dimensional space. Since all the electrons are equivalent, multiplication of the integral by N gives the total one-electron density at each point in space designated by $\rho(\bar{r})$

$$[2] \qquad \rho(\bar{r}) = N \int \psi^*\psi \, d\tau_2 \, d\tau_3 \ldots d\tau_N$$

It is the density $\rho(\bar{r})$ which is responsible for the scattering of X-rays and electrons and which determines the electrical properties of the molecule such as the dipole moment and the electric field and field gradients within the molecule. For a molecule in a stationary state, the electron density distribution can be interpreted as a *static* distribution of negative charge, rather than as a probability function. For an orbital approximation to a wave function, eq. [2] takes the particularly simple form

$$[3] \qquad \rho(\bar{r}) = \sum_i n_i \phi_i^2$$

where the ϕ_i's are an orthogonal set of orbitals and the n_i's are the occupation numbers equal to one or two.

When the orbitals are orthogonal, the Pauli principle is satisfied and there are no Pauli repulsion effects. To determine the effect of the Pauli principle on a wave function or a density, one must start with an orbital set which is orthogonal because of some restraint. The restraint may be artificial or be the result of a large separation between the orbitals. Then the effects of the nonorthogonality are determined when the restraint is removed. For example, we may consider the effects of the Pauli exclusion principle on the electron density distribution obtained when two helium atoms approach one another. Let ϕ_a and ϕ_b be doubly occupied atomic orbitals on atoms a and b. When the atoms are widely separated, the overlap between the orbitals is zero and the electron density is then simply

$$\rho_0 = 2(\phi_a^2 + \phi_b^2).$$

The same expression would hold for the density for small values of the internuclear distance if the orbitals did not overlap. However, since they do overlap, the Pauli exclusion principle demands the corrected form

$$[4] \qquad \rho = \rho_0 + \Delta\rho.$$

The quantity $\Delta\rho$ is the change in the electron density which arises from the orthogonality

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

requirements of the Pauli exclusion principle. Longuet-Higgins and Salem (2)[2] have shown that when ρ is expressed in the form of eq. [4], $\Delta\rho$ has the form

$$\Delta\rho = -4S\phi_a\phi_b + 2S^2(\phi_a^2 + \phi_b^2) \quad [5]$$

where S is the overlap integral between ϕ_a and ϕ_b. Expression [5] for $\Delta\rho$ is correct to the order S^2 and goes to zero as S goes to zero. It is seen that $\Delta\rho$ is negative in some parts of space, giving a total density ρ less than that of the original atomic densities, and positive, in others, giving in these regions a total density which is greater than the original atomic densities. The integration of ρ over all space must yield the total number of electrons, four in this case, and this is given by the integration of ρ_0 itself. Thus the integration of $\Delta\rho$ must yield zero,

$$\int \Delta\rho \, d\bar{r} = 0.$$

The positive and negative regions of $\Delta\rho$ exactly balance so that the decrease in density in certain regions from the value given by ρ_0 must be equal to the increase over the ρ_0 values in other regions. The quantity $\Delta\rho$ thus gives a three-dimensional picture of the charge density which is transferred relative to the original set of orbitals because of the operation of the Pauli principle. In this simple example where ϕ_a, ϕ_b, and S are all positive, the expression for $\Delta\rho$ shows that charge of total amount $4S^2$ must be removed from regions where ϕ_a and ϕ_b overlap and transferred to regions where ϕ_a^2 and ϕ_b^2 are large. Figure 1 shows a plot of $\Delta\rho$ in the molecular plane. The plot shows dramatically the operation of the Pauli exclusion principle on two overlapping, doubly filled orbitals, or if one wishes, the effect of Pauli repulsions. Wherever the overlap of the original atomic orbitals is large, $\Delta\rho$ is negative, showing that electron density has migrated away from this region. The density is transferred to the regions behind each nucleus. The region between the nuclei is one of low potential energy, and is the region where charge density must be concentrated to achieve a stable chemical bond. This is the origin of the Pauli repulsions. The operation of the Pauli exclusion principle requires that density be removed from the region of low potential energy and be placed in less favored regions. The electronic energy is thus raised above that of the separated atoms and a repulsive force results. Thus while there are no Pauli repulsive forces as such, the Pauli exclusion principle does place restraints on the distribution of the electronic charge and this in turn determines the electronic energy of the system.

Actually, the energy is not related to the one-electron density distribution in any simple way.[3] However, the forces acting on the nuclei are explicable in terms of classical electrostatics and are determined by the one-electron density distribution (4). Therefore, the change in stability brought about by the charge which is transferred as a result of the Pauli principle is best discussed in terms of the forces acting on the nuclei. For example, in the case of the two He atoms, it is easily shown[4] that for any finite value of the internuclear separation the density distribution obtained from the overlap of the original atomic densities ρ_0 results in net forces of repulsion on both nuclei. For a diatomic molecule one can define a region, called the binding region, in which charge must be concentrated

[2] *The general theorem for $\Delta\rho$ was contributed by H. C. Longuet-Higgins.*

[3] *The energy is determined by the second-order or two-electron probability distribution (3).*

[4] *According to Gauss' law the electric field resulting from a spherical charge distribution acts as though all the charge were concentrated at its origin, and only that charge within the sphere defined by the bond length is effective. Thus for any finite value of the internuclear distance, where each nucleus has penetrated the density of the other, each experiences a force of repulsion due to two units of positive charge and an attractive force equivalent to something less than two negative charges.*

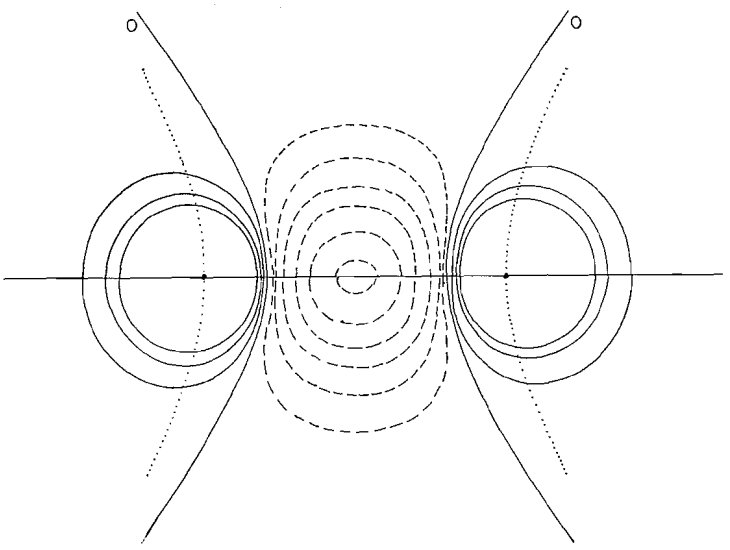

FIG. 1. A plot of $\Delta\rho$ for two He atoms at an internuclear separation of 2.5 atomic units (a.u.). The solid contours represent positive $\Delta\rho$ values, increasing in steps of 0.002 a.u. from the zero line. The dashed contours are negative $\Delta\rho$ values, decreasing in steps of 0.002 a.u. from the zero line. The dotted lines through the nuclei are the boundary curves which separate the binding and antibinding regions.

to overcome the nuclear forces of repulsion and achieve electrostatic equilibrium (5). This region is illustrated in Fig. 1 for a homonuclear diatomic molecule. Any charge density placed between the two boundary curves exerts an attractive force on both nuclei along the axis. Any charge outside these two curves exerts a greater force on one nucleus than on the other and leads to a separation of the molecule into atoms. Charge density on the boundary curves exerts equal forces on both nuclei along the bond axis. It is evident from Fig. 1 that $\Delta\rho$ is primarily negative in the binding region and positive in the antibinding regions. Since the sum of the original atomic densities, ρ_0, was insufficient to bind the nuclei, the density transferred because of the operation of the Pauli exclusion principle $\Delta\rho$ will clearly lead to an increase in the force of repulsion on both nuclei. That is, $\Delta\rho$ leads to a decrease in the charge density in the binding region over that present in the original atomic distribution which was itself insufficient to balance the forces of nuclear repulsion.

In this simple example of two He atoms, the form of $\Delta\rho$ fits in well with the concept of "Pauli repulsions" as they are usually applied (1). In a sense the orbitals do collide. However, it should be remembered that the resulting instability is an electrostatic one, resulting from the forced migration of charge from the binding region and the consequent increase in the nuclear forces of repulsion. For more complicated examples with more orbitals the analogy of $\Delta\rho$ with that of colliding orbitals in real space breaks down.

The expression for $\Delta\rho$ (2) and the concept of a binding region (6) can be extended to a polyatomic system. For any molecular system we can first determine $\Delta\rho$, the charge which is transferred because of the Pauli principle, and secondly, determine what effect this transfer of charge has on the stability of the system by noting whether or not it corresponds to an accumulation in the binding region. The general expression for $\Delta\rho$ for doubly occupied orbitals is (2)

$$[6] \qquad \Delta\rho = \sum_{i<j} \left(-4S_{ij}\phi_i\phi_j + 2S_{ij}^2[\phi_i^2 + \phi_j^2]\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the total density is

$$\rho = 2 \sum_i \phi_i^2 + \Delta\rho. \qquad [7]$$

There is a contribution to $\Delta\rho$ from every pair of overlapping orbitals which is identical in form to that obtained for the two He atoms. The form of $\Delta\rho$ is determined by the initial choice for the set of orbitals ϕ_i. If they are chosen as an orthogonal set, then $\Delta\rho$ is zero at every point in space. However, in discussions of chemical bonding, comparisons between different systems are often employed, either between the separated atoms and the molecule, or between different members of an isoelectronic series. For example, we may consider the classic case of the ten-electron Ne atom and what effect the Pauli principle has on the relationship between its electron density distribution and that of the isoelectronic molecules H_2O, NH_3, and CH_4.

An Analysis of the Assumed Pauli Repulsions in H_2O and NH_3

Sidgwick and Powell (7) were the first to point out that molecules with four pairs of electrons in the valency shell were either tetrahedral in shape (CH_4) or were related to the basic tetrahedral geometry, e.g., the nearly tetrahedral bond angles found in NH_3 and H_2O. Lennard-Jones demonstrated (8) that the antisymmetrization requirements of the Pauli principle forces the electrons of an inert gas atom, such as neon, to dispose themselves so that those of the same spin subtend tetrahedral angles at the nucleus. He also showed that there was no correlation between the two tetrahedra resulting from the electrons with α and β spin. Pople (9) postulated that as one considered the withdrawal of successive protons from the Ne nucleus to form HF, H_2O, NH_3, and CH_4 respectively, the motion of the two tetrahedra would become correlated so as to concentrate a pair of electrons with opposite spin along each bond to a hydrogen atom. In this way the electron densities in these molecules were directly related to the tetrahedral hybridization (sp^3) of Ne and thus one accounted for the nearly tetrahedral bond angles in NH_3 and H_2O.[5] In their original paper Gillespie and Nyholm (1) also consider the orbital descriptions of H_2O and NH_3 to be sp^3 and related to that of Ne. They accounted for the fact that the bond angle in NH_3 is actually slightly less than tetrahedral by postulating that the repulsions between the lone pair and bond orbitals is greater than those between the bond orbitals themselves. Similarly in the case of H_2O, the extraction of two protons from the Ne nucleus changes the four equivalent orbitals into two lone pairs and two bonding pairs. Here the lone pair – lone pair "repulsion" causes an even greater decrease in the originally tetrahedral angle between the bonding pairs. In both these examples the important assumptions are the essentially tetrahedral arrangement of the electron pairs and the effects of the Pauli repulsions on these pairs as the original equality of the orbitals is perturbed by the change in the number of bonded protons. We shall investigate the physical basis of this theory by first determining $\Delta\rho$ and comparing this with the assumed repulsions between the orbitals, and secondly, by determining the stability of the tetrahedral density arrangement by means of the concept of a binding region. It will be shown that the polarizations made necessary by the presence of the protons are indeed of crucial importance.

In Ne the electron density is given by (ignoring the inner 1s electrons)

$$\rho = 2 \sum_i \phi_i^2$$

[5]*Sinanoglu has pointed out that to consider these molecules as distortions from the basic tetrahedron of* Ne *is a gross oversimplification. Such a theory "recognizes only the exclusion principle-type hybridization (in* Ne*), but not the polarization-type hybridization due to the protons (10)".*

where each ϕ_i may be considered as an sp^3 hybrid orbital. These form an orthogonal set and $\Delta\rho$ is zero. The density ρ is of course spherical. We now consider the effects of perturbing this density distribution by extracting three protons from the Ne nucleus, one into each of three of the sp^3 hybrids. This results in a tetrahedral NH_3 molecule and destroys the orthogonality between the original Ne orbitals. The resulting $\Delta\rho$ will be directly determined by the effects of the Pauli exclusion principle arising from this nonorthogonality. The final molecular density distribution for tetrahedral NH_3 expressed in terms of equivalent molecular orbitals is

$$\rho = 2(\phi_1^2 + \phi_{b1}^2 + \phi_{b2}^2 + \phi_{b3}^2) + \Delta\rho_{1b} + \Delta\rho_{bb}.$$

Where ϕ_1 is an original unperturbed Ne orbital (the lone pair) and the ϕ_{bi} are bonding orbitals of the form[6]

$$\phi_{bi} = \lambda[(1/2)s + (\sqrt{3}/2)p_i] + \mu h_i ,$$

λ/μ being a polarity factor and p_i a nitrogen 2p orbital directed at the hydrogen orbital h_i. The term in brackets defines an sp^3 orbital. The λ/μ ratio must be unity or less to obtain the correct order of magnitude for the molecular dipole moment (11) and was taken as one in the present calculations. In any event, the variation of this ratio over a wide range of reasonable values does not alter the conclusions discussed below. Since the total $\Delta\rho$ is constructed of terms from pairs of overlapping orbitals, we may divide it into contributions, one due to the lone pair orbital overlapping with the bonding orbitals and one due to the bond orbitals overlapping each other. In this way we may determine separately the lone pair – bond "repulsions" and the bond–bond "repulsions". These two expressions have the forms respectively

$$\Delta\rho_{1b} = -4S_{b1}\left(\sum_i \phi_1\phi_{bi}\right) + 2S_{b1}^2\left(\sum_i (\phi_{bi}^2 + \phi_1^2)\right) \qquad [8]$$

$$\Delta\rho_{bb} = -4S_{bb}\left(\sum_{i<j} \phi_{bi}\phi_{bj}\right) + 2S_{bb}^2\left(2\sum_i \phi_{bi}^2\right) \qquad [9]$$

where S_{b1} and S_{bb} are the overlap integrals between the lone pair orbital and a bond orbital and between two bond orbitals respectively. Figure 2 is a plot of $\Delta\rho_{1b}$. The figure shows that the charge migration which results from the finite overlap of the lone pair and bonding orbitals corresponds to a depletion in the density above the N nucleus and to its accumulation below, between the three hydrogen nuclei. The reason for the form of the charge migration is easy to understand in terms of the nonorthogonalities. The whole of S_{b1} arises from the overlap of ϕ_1 with the hydrogen orbitals in the ϕ_{bi} only, since the nitrogen sp^3 orbital contributions to the ϕ_{bi} are still orthogonal to the sp^3 orbital which comprises ϕ_1.

$$S_{b1} = \mu[(1/2)S_2 - (1/2\sqrt{3})S_3].$$

(S_2 and S_3 are respectively the overlap integrals of a 2s and 2p on nitrogen with a hydrogen orbital.) S_{b1} in this case equals +0.06381. Since S_{b1} is positive, the first set of terms in eq. [8] will decrease the density where the product $\phi_1\phi_{bi}$ is positive and increase it where this product is negative. The orbital ϕ_1, since it has a 2p orbital contribution, is positive above the nitrogen and negative below it. The second term in $\Delta\rho_{b1}$ is positive in all regions.

[6]*The atomic orbitals employed in the calculations of the density distributions are Slater functions. We have previously demonstrated (6) that the use of Slater functions rather than the Hartree-Fock expressions does not alter the appearance or the general characteristics of the calculated electron density plots.*

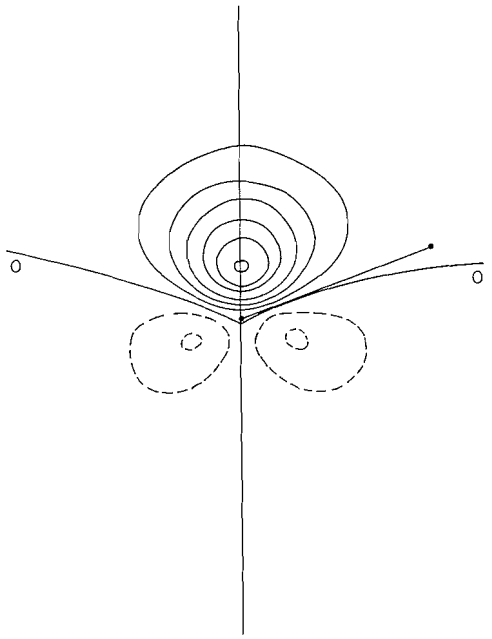

FIG. 2. A plot of the density shift, $\Delta\rho_{lb}$, due to the interaction of the lone pair with the bonding orbitals in tetrahedral NH_3. This and the subsequent diagrams are plotted in the plane parallel to the threefold symmetry axis and along an N–H bond. The vertical line is the threefold symmetry axis. The $\Delta\rho_{lb}$ contours increase and decrease in steps of 0.01 a.u. from the zero line.

Figure 3 shows a plot of $\Delta\rho_{bb}$, the density which is transferred because of the nonorthogonality between the bonding orbitals. This plot is close to the reverse of that found for $\Delta\rho_{lb}$, as it shows a decrease in density in the region below the N nucleus and its concentration above. The bond–bond interaction is greater than the bond – lone pair interaction, however, since the value of S_{bb} (0.1284) is greater than that of S_{b1}. The nonorthogonality between two bonding orbitals is again due entirely to the hydrogens,

$$S_{bb} = \mu^2 S_1 + 2\lambda\mu[(1/2)S_2 - (1/2\sqrt{3})S_3],$$

the first term arising from the overlap of two hydrogen orbitals and the second from the overlap of the hydrogen in one orbital with the sp^3 hybrid from another. The bonding orbitals will overlap one another most strongly in the region between all four nuclei and thus $\Delta\rho_{bb}$ is negative in this region. The net result of the lone pair – bond and bond–bond overlap is shown in Fig. 4 which is a plot of the total charge migration as determined by the orthogonality requirements of the Pauli principle. Charge density is removed from above and below the N nucleus along the symmetry axis and is concentrated in the region of each H nucleus. Figure 4 thus shows the effect of the Pauli exclusion principle on the three-dimensional electron density distribution for the NH_3 molecule when this distribution is related to an idealized tetrahedral one. The question now to be asked is whether the form of $\Delta\rho$ is such that it will lead to a decrease in the tetrahedral bond angle. In order that the bond angle decrease, electron density must be concentrated in the region below the nitrogen nucleus, between the three hydrogen nuclei. Such a charge migration would exert attractive forces on the three protons, drawing them together. The form of $\Delta\rho$ does not meet this requirement. There is a greater amount of charge placed above the

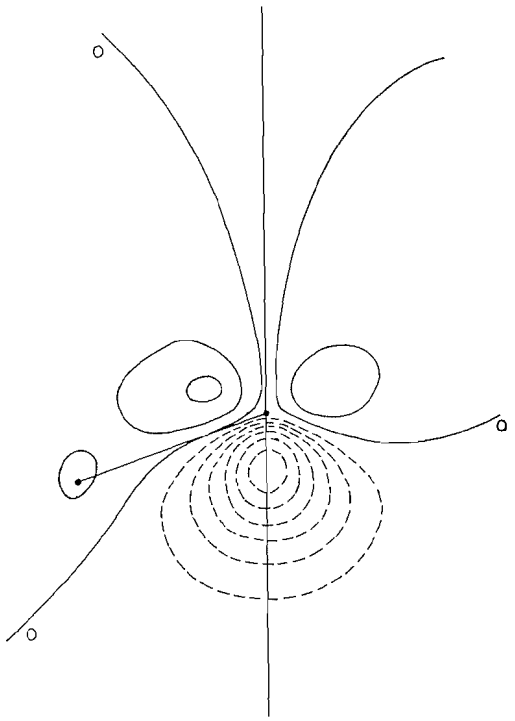

FIG. 3. A plot of the density shift, $\Delta\rho_{bb}$, due to the bond–bond interactions in tetrahedral NH_3. The contours are in steps of 0.01 a.u.

proton along the H—N bond axis than below it and the charge is depleted in regions between all four nuclei. Thus one finds that the basic assumptions of the electron pair repulsion theory are not met. The interactions between the bonding orbitals are larger than those involving the lone pair orbital, and the overall migration of the charge density due to the "Pauli repulsions" is such as to lead to an increase rather than the predicted decrease in the tetrahedral bond angle.

The application of this type of analysis to the water molecule leads to similar conclusions. Consider first the distribution to be tetrahedral in character and derived from neon by the removal of two protons from the neon nucleus. Since the two lone pair orbitals in the resulting water molecule would remain orthogonal, $\Delta\rho_{11}$, the density transferred because of the overlap of the two lone pair orbitals would be zero. Thus there are no Pauli repulsions at all between the lone pairs in the water molecule when its electron density is related to that of neon. The same result would be obtained by relating the density distribution to that of methane. The fact that the two lone pair orbitals in the water molecule overlap one another when pictured in three-dimensional space does not preclude the possibility that their total overlap is still zero, i.e.

$$\int \phi_{11}\phi_{12}\,d\tau = 0.$$

Thus a pair of electrons can coexist in both orbitals with no shift in electron density as the Pauli exclusion principle is satisfied. The electron density distribution in certain regions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of real space will contain contributions from both of the lone pair orbitals. This is permissible as long as the orbitals are orthogonal in the orbital space.[7] The forms of $\Delta\rho_{1b}$ and $\Delta\rho_{bb}$ are similar to those calculated for ammonia, resulting in a total charge migration which would increase rather than decrease the tetrahedral bond angle. In addition, there is no charge migration due to the interaction of the lone pairs. i.e. $\Delta\rho_{11}$ is zero. Thus the concept that the bond angle in the water molecule is less than the tetrahedral value because of Pauli repulsions between the lone pairs is incorrect.

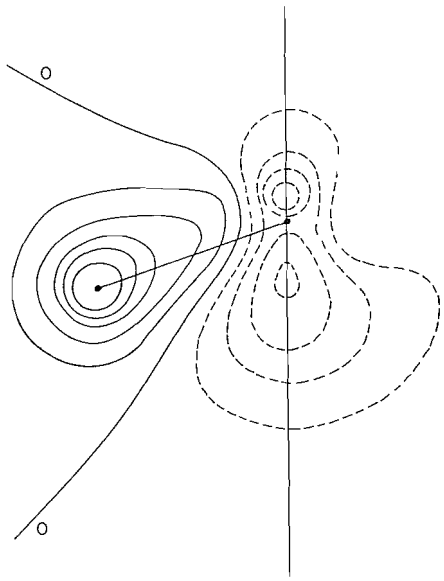

FIG. 4. A plot of the total charge migration as required by the Pauli exclusion principle for tetrahedral NH_3 with sp^3 hybridization. The contours are in steps of 0.002 a.u.

The identification of "Pauli repulsions" between filled orbitals with shifts in the electronic charge density has demonstrated that their interpretation in terms of overlapping orbitals in real space can be misleading. In the simple case of two He atoms where the overlapping orbitals are centered on different atoms, the form of $\Delta\rho$ does fit in with the simple interpretation. However, when a number of the orbitals are centered on one nucleus, such as in H_2O or NH_3, this is no longer true. The order of magnitude of the shifts $\Delta\rho_{bb} > \Delta\rho_{1b} > \Delta\rho_{11}$ is in contradiction with the proposals of the electron pair repulsion theory and, more important, $\Delta\rho_{11}$ is actually zero. The latter point is especially important in emphasizing that the overlap of orbitals when pictured in real space does not preclude the possibility they are orthogonal and hence satisfy the Pauli principle. Furthermore, the density shift arising from the requirements of the Pauli principle as calculated for the tetrahedral distribution does not predict a decrease in the tetrahedral bond angle. Thus the second basic assumption of the theory, that the electron density distribution in these molecules can be related to a tetrahedrally oriented set of orbitals, is incorrect. This conclusion is necessary not only because $\Delta\rho$ does not lead to a decrease in the bond angle, but for an even more fundamental one. The concept of a binding region discussed previously for a diatomic molecule can be extended to a polyatomic molecule (6). One can

[7]*Lone pair – lone pair Pauli repulsions will never exist between equivalent lone pair orbitals centered on the same nucleus. They will always be orthogonal by definition.*

determine a spatial region in a polyatomic molecule in which the electron density binds all the nuclei simultaneously and is the region in which electron density must be concentrated in order to achieve electrostatic equilibrium in terms of the forces exerted on the nuclei. We shall demonstrate below that tetrahedral density distributions for water and ammonia do not concentrate density in the binding region, and for this reason are unacceptable.

Analysis of the Charge Distributions for H_2O and NH_3 in Terms of Their Binding Regions

The binding region for the ammonia molecule is indicated by the dotted line in Fig. 5. It is derived on the basis that the charge distribution for the ammonia molecule must reflect the threefold symmetry of the nuclear framework. Thus one must consider the forces exerted on the nuclei by a symmetrically equivalent set of charge points in deriving the binding region. This set of symmetrically equivalent points reduces to a single one for charge along the threefold axis, to a set of three for charge in the symmetry planes, and to a set of six for charge placed in any other regions. Any such set of symmetrically equivalent charge points placed below the boundary curve will exert forces on the nuclei such as to decrease all of the internuclear separations. Charge density outside of this boundary curve will tend to separate the molecule into either a diatomic molecule and two atoms or into four atoms.[8] Charge density must be concentrated in the binding region if the molecule is to achieve electrostatic equilibrium. The existence and shape of the binding region and the necessity of concentrating charge in this region illustrates the importance of the requirements imposed on the density distribution by the presence of the protons. The shape of the binding region will in fact determine the polarization-type hybridization induced by the protons which was referred to by Sinanoglu (10).

The question as to how much charge must be placed in the binding region can be determined by choosing a standard distribution which is known to be insufficient from the point of view of the amount of charge it places in the binding region. The density difference between the molecular charge distribution of interest and this standard one is then determined. A distribution with a positive difference in the binding region is a possible one. A distribution with a negative difference in the binding region is unacceptable since it places less charge density in the binding region than does the standard distribution which is known to be insufficient in this regard. The standard density distribution is the one obtained by placing the nuclei at the positions they have in the molecule, each with its original atomic charge distribution. By arguments similar to those employed in the case of the approach of the two He atoms, there are net forces of repulsion acting on all the nuclei for a charge distribution composed of the overlap of atomic charge densities. This is a general result (6). We shall label this type of density difference $\Delta\rho_m$ to distinguish it from the $\Delta\rho$ due to the Pauli principle.

$$\Delta\rho_m = \rho(\text{molecule}) - \rho(\text{atomic})$$

Figure 5 shows a plot of $\Delta\rho_m$ for the tetrahedrally based density distribution for NH_3. There is less charge density between every pair of nuclei than in that obtained from the simple overlap of atomic densities. Thus there would be large forces of repulsion acting on all the nuclei. In particular, the large accumulation of charge density above the nitrogen and its depletion below would result in large forces tending to increase the bond

[8]*One can also construct a binding region by considering the forces exerted on the nuclei by only a single charge point at a time. The binding region thus obtained is equivalent to the superposition of all the possible diatomic boundary curves. Such a region has been given previously for the water molecule (6) and corresponds to the region between all three nuclei defined by an angular boundary curve subtended at the oxygen nucleus with an angle less than the bond angle. A similar less extended binding region for an ammonia molecule would be pyramidal in shape, enclosed within the region of all four nuclei with its apex at the nitrogen nucleus.*

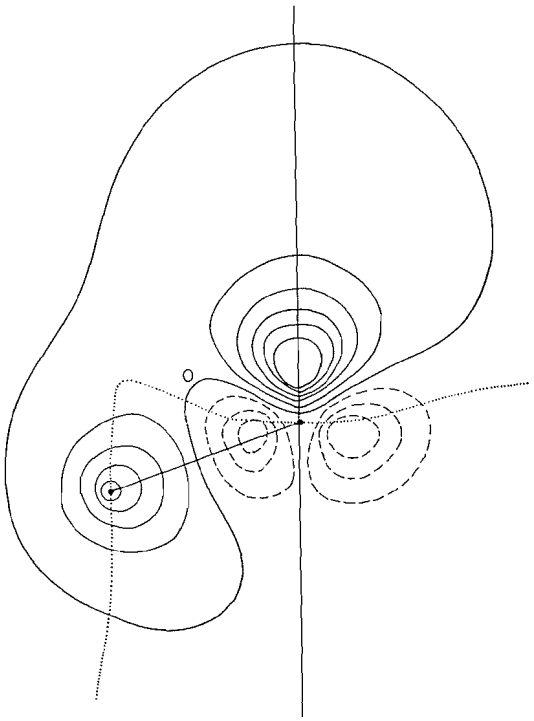

FIG. 5. A plot of $\Delta\rho_m$ (molecular density – atomic density) for tetrahedral NH_3 with sp^3 hybridization. The contours are in steps of 0.05 a.u. in this and the following diagram. The dotted line divides the binding region (below the line) from the antibinding region.

angle. Thus not only does the form of $\Delta\rho$, the density shift due to Pauli repulsions, predict an increase in the bond angle for a tetrahedral distribution, but the form of the distribution itself predicts even larger forces of repulsion on the nuclei.

A plot of $\Delta\rho_m$ for a tetrahedral density distribution for the water molecule has been given previously (6) and illustrates the same general features as those noted for the ammonia molecule. The value of $\Delta\rho_m$ is negative in the binding region and in the regions between all three nuclei, and is large and positive in the antibinding region above the oxygen nucleus. The large decrease in the electron density in the binding regions found for the tetrahedral distributions is due to the sp^3 hybridization assumed for the lone pair electrons. When an sp^3 hybrid orbital is squared, there is a contribution to the electron density of $(\sqrt{3}/2)sp$ per electron. This term is positive above the nodal plane of the p orbital (where it leads to an increase in the electron density) and negative below it (where it leads to a decrease in ρ). In Ne the four cross terms are all equally weighted and a spherical density distribution is obtained. In ammonia, the lone pair orbital contributes a term $\sqrt{3}sp_l$, which increases the density in the antibinding region above the nitrogen nucleus at the expense of density in the binding region. However, the density in a bonding orbital is shared between the nitrogen (a fraction equal to $\lambda^2 \sim 0.5$) and a hydrogen (a fraction equal to μ^2). Thus the bonding orbitals in ammonia contribute $3\lambda^2\sqrt{3}sp_i$ rather than the $3\sqrt{3}sp_i$ necessary to *just* balance the charge migration due to the lone pair. It is clear that hybridization of the lone pair must be reduced and must approach pure s character in order to concentrate charge density in the binding region in the water and ammonia molecules. At the same time, the demands of the Pauli principle require the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

bonding orbitals to acquire more p character from the nitrogen or the oxygen as the lone pair becomes more s-like. Figure 6 is a plot of $\Delta\rho_m$ for the ammonia molecule in which the molecular density possesses a lone pair in a pure 2s orbital and the bonding orbitals are close to pure 2p in character from the nitrogen. The bonding orbitals contain a small amount of 2s character but it is of negative sign. This distribution does accumulate charge density in the binding region and does balance all of the forces exerted on the nuclei (11). In addition, the values calculated for the other physical properties which depend upon the one-electron density are in excellent agreement with experiment. A density distribution for the water molecule which does concentrate density in the binding region and which does balance the forces on all the nuclei is similar in character to that found for the ammonia molecule (12). The oxygen contributions to the bond orbitals are of almost pure 2p character and the lone pair orbitals are sp hybrids. (The lone pair may also be viewed as one orbital of pure 2s character and another of pure 2p, perpendicular to the molecular plane.) A plot of $\Delta\rho_m$ for this type of distribution for the water molecule has been given previously (6).

One can envisage a whole spectrum of possible hybridizations for the nitrogen and oxygen atoms in the ammonia and water molecules, extending from the one extreme of sp^3 hybrids to the other in which the lone pair is pure 2s (and in water, a second of pure 2p, perpendicular to the molecular plane) and the bonds pure 2p. The analysis of the resulting charge distributions in terms of the amount of charge shifted to the binding region has shown that only the latter of the extremes of hybridization is satisfactory in this respect. Thus a theory which assumes that the charge distribution in these molecules arises from a perturbed neon-like distribution will be unsatisfactory as the unperturbed density is chosen from the wrong end of the hybridization spectrum. Rather, the charge distribution should be considered as arising from a perturbation of the original ground state electronic densities for the nitrogen and oxygen atoms. This is, of course, more realistic on energetic grounds as well. In both the water and ammonia molecules an orbital angle less than the bond angle is necessary to concentrate density in the binding region and along the bonds in three-dimensional space. In a sense one must have "bent orbitals" in these molecules in order to obtain chemical bonds in terms of the density distribution in real space.

Interestingly enough, the acceptable density distributions for the H_2O and NH_3 molecules (with the 2s lone pairs) concentrate density above the heavy nucleus to almost identical extents as do the distributions with sp^3 lone pairs. However, in the distributions with the 2s lone pair this increase is not due to the lone pair. The lone pair density, in fact, cancels out in the determination of $\Delta\rho_m$ as the 2s orbital is unchanged from the atomic distribution. Instead, the increase in $\Delta\rho_m$ above the nitrogen or oxygen nucleus arises from the density contained in the bonding orbitals. A 2p orbital concentrates density on both sides of the nucleus it is centered on. Thus bonds formed from 2p orbitals will necessarily place density above and below the nitrogen nucleus. In addition, the negative 2s character found in the bonding orbitals also contributes to this build-up of charge above the heavy nucleus. However, the fact that there is an increase in the electron density above the nitrogen and oxygen nuclei over that found in the atomic cases indicates that the ammonia and water molecules do possess directed lone pairs. In fact an excellent definition of a lone or unshared pair would be the concentration of electron density in an antibinding region. The fact that the positive $\Delta\rho_m$ values in the antibinding regions arise from the density in the bonding orbitals is irrelevant. An infinite number of choices as to the forms of the orbitals is possible and to express the density (which is invariant to an

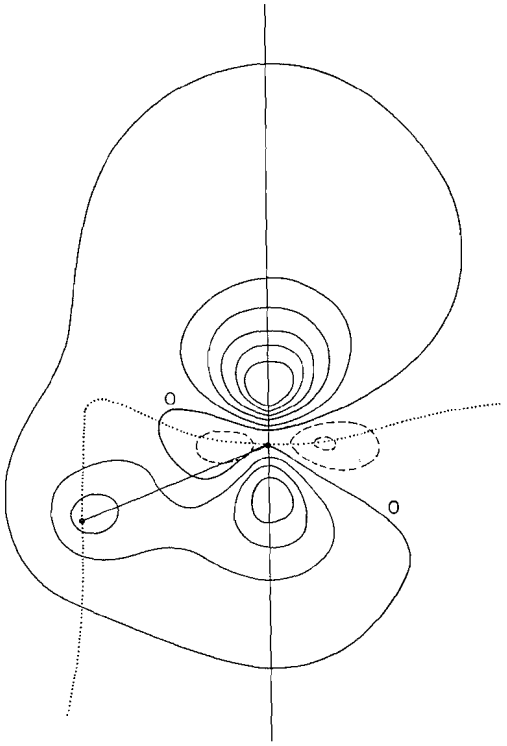

FIG. 6. A plot of $\Delta\rho_m$ for NH_3 with the experimental bond angle of 107.3° for the density distribution which balances all the forces on the nuclei and has the correct dipole moment (11).

orthonormal change in the basis set) in terms of equivalent orbitals as done here is but one of many possibilities. Only the total density distribution is of significance and the concentration of charge density in the antibonding region, where by definition it plays no role in binding the nuclei together, must correspond to the existence of a lone pair. The results of self-consistent field (S.C.F.) calculations, when expressed in terms of equivalent orbitals (11, 12), exhibit the same characteristics as determined by the present considerations of concentrating density in the binding regions. Thus one finds for these variationally determined functions that the bonding orbitals are primarily of 2p character with negative 2s contributions, that the orbital angle is less than the bond angle, and that the lone pairs approach the limiting 2s form. This has also been pointed out by Peters (13) for the diatomic hydride functions of Ransil (14). Ruedenberg and Edmiston (15) have shown that when the molecular orbitals describing these wave functions are transformed into a new set, one which minimizes the overall interorbital coulombic and exchange interactions, bonding orbitals are obtained which now contain 2p and 2s character of the same sign and the lone pair orbitals are directed behind the heavy nucleus. However, the definition of a lone pair orbital is now changed, for the orbitals labelled as lone pairs by Ruendenberg no longer consist of atomic orbitals centered only on the heavy atom. Rather, they contain contributions from the hydrogen orbitals as well, with negative coefficients. In fact, Ruedenberg ascribes the origin of nonbonded interactions to the antibonding nature of these lone pair orbitals. A definition of a lone pair based on the final density distribution avoids the ambiguities associated with an orbital definition. There is but one density distribution but many possible orbital descriptions of it.

One can give an electrostatic interpretation as to why the ammonia and water molecules are pyramidal and bent, respectively. In a planar ammonia molecule the unshared pair of electrons would necessarily be placed in a 2p orbital perpendicular to the plane of the molecule. A p_π orbital is very inefficient at screening a nucleus, since density is placed above and below the bond axis or the molecular plane. By bending the bonds out of the plane the lone pair takes on an increasing amount of s character. The electrons in a 2s orbital are much more efficient at screening a nucleus, since the density is distributed spherically about it. In addition, the 2s orbital is easily polarized (by the admixture of 2p) to place density in the binding region below the nitrogen nucleus in a pyramidal molecule. Thus the total density between the nuclei obtained from s–p hybrid bonds and a p_π lone pair in the planar molecule is *less* than that obtained from bonds composed of p orbitals and a 2s lone pair for the pyramidal geometry. In the case of the water molecule one lone pair remains in a p_π orbital (perpendicular to the molecular plane) whether the molecule is linear or bent. The second lone pair, however, changes from a p_π orbital in the linear case through a range of s–p hybridizations to the limiting form of an s orbital when the bonding orbitals are pure p and the molecule is bent. Again one finds that to achieve maximum screening of the heavy nucleus and to achieve the maximum electron density along the bonds, the bonding orbitals must be approximately pure p orbitals and one lone pair must be placed in an s orbital. This corresponds to the bent geometry. The $\Delta\rho_m$ plots for the tetrahedral density distributions again illustrate the importance of considering the total density distribution. The sp^3 bonding orbitals in a tetrahedral density distribution for NH_3 or H_2O do concentrate a maximum amount of density along the bonds. However, the orthogonality restraints of the Pauli exclusion principle demand that the lone pair must be strongly s–p hybridized when the bonds are s–p hybrids. The result of the forced hybridization of the lone pair is the removal of more density from the binding region and from between the nuclei than was concentrated by the sp^3 bonding orbitals. The net effect is a distribution which places less charge density between the nuclei than that obtained from the simple overlap of the atomic densities. Thus the presence or absence of lone pairs does affect the geometry of a molecule, but not in the sense of exerting Pauli repulsions. Rather, the geometry can be interpreted as being determined by the molecule attaining a density distribution which provides a maximum screening of the nuclei and places a maximum of electron density along the bonds.

We have shown that the effects of the Pauli exclusion principle on the density distributions of simple molecules is not what is commonly pictured. However, one is still faced with the fact that the electron pair repulsion theory is remarkably successful. In recent papers Gillespie (see for example ref. 16) has purposely avoided any reference to the degree of hybridization. Instead, the distortions from the most probable arrangement of a given number of initially equivalent pairs of electrons is determined by arguments based on the relative sizes of the orbitals. Thus orbitals which are lone pairs in the molecule become more diffuse and less directional and occupy a larger volume of space. In terms of the argument put forward in this paper this would correspond to an increase in the s character of the lone pair orbitals. Similarly the bonding orbitals are stated to be contracted and polarized by the presence of the ligands. This description coincides with the predicted increase in the p character of the bonding orbitals found here. However, the present approach arrives at these conclusions by a determination of which distribution places the maximum density in the binding region, and not by arguments based on orbital repulsions. It will be of interest to determine whether or not the parallelism between the two approaches noted above will continue to hold in the non-hydride molecules as well.

ACKNOWLEDGMENT

The authors are indebted to Professor R. J. Gillespie for the many valuable discussions held with him regarding this work.

SORPTION OF HYDROGEN AND OXYGEN BY CADMIUM OXIDE

M. J. D. Low and A. M. Kamel
School of Chemistry, Rutgers, The State University, New Brunswick, New Jersey

Received May 31, 1965

ABSTRACT

The sorptions of hydrogen and of oxygen on freshly prepared and on gas-treated cadmium oxide were measured from 0 to 250 °C. The data suggest that hydrogen chemisorption predominates near 26°, where it is the precursor of water formed on the surface. Surface reduction occurs at temperatures as low as 50°. At least two types of oxygen sorption exist. The isobar has a minimum near 50°. Chemisorption occurs below 50° and the sorption kinetics indicates the presence of two types. The incorporation of oxygen into the bulk may account for the observed increased sorption above 150°.

SORPTION OF HYDROGEN AND OXYGEN BY CADMIUM OXIDE

The relatively large deviations from stoichiometry of cadmium oxide and its behavior as degenerate electronic semiconductor have prompted a considerable amount of work on the electronic properties of that substance. Some effects of oxygen pressure on conductivity or thermoelectric power have been noted, but quantitative sorption experiments have not been reported. In view of the importance of surface effects to semiconductor behavior, and the possibility of comparison of data with those of zinc oxide, we have undertaken the present study.

EXPERIMENTAL DETAILS

Gas sorptions were measured by following the decrease in pressure within a high-vacuum system of conventional design equipped with mercury and dibutylphthalate manometers. Hydrogen was purified by diffusion through hot palladium. Tank oxygen was passed over hot CuO and through a trap filled with glass wool at −196°. Helium and nitrogen were purified by passage through glass-wool-filled traps at −196°. Water was degassed by alternate freezing and thawing *in vacuo*.

A reproducible adsorbent was prepared by the decomposition of $CdO{\cdot}1.65H_2O$ to $CdO_{0.80}$ *in vacuo* (1). A sample of the hydroxide was placed in the sample chamber of the adsorption system and evacuated at room temperature. A furnace, preheated to 500°, was then placed around the sample chamber. A pressure of approximately 10^{-5} mm Hg was reached within about 15 min. The furnace was removed after 40 min, a second preheated furnace was installed, and the sample was then held at some previously chosen temperature. Dead spaces were measured by the expansion of helium. The nitrogen B.E.T. surface area (2) of the oxide prepared as described remained constant at 5.2 m^2/g *in vacuo* for 12 h. The analysis of several samples yielded the formula $CdO_{0.80}$ and indicated that the decomposition of the hydroxide was complete (1). Amounts of gas sorbed are given as ml N.T.P./g $CdO_{0.80}$.

EXPERIMENTS AND RESULTS

To obtain information about sorption on gas-treated as well as on freshly prepared surfaces, several series of experiments were made. Each series was isothermal, and was made with a freshly prepared sample weighing ~1 g. In one series, an adsorbent sample was prepared as described, and was then exposed to hydrogen at an initial pressure of 206 mm Hg. The isothermal gas sorption was followed for some time. Each of the plots of Fig. 1 of the amount sorbed, q, versus time shows such data. After some time, marked with arrow N in Fig. 1, a Tesla coil discharge was started in the tubing near the sample chamber. The discharge was stopped at time F, and the hydrogen uptake followed for a further period. The sample chamber was then opened to the pumps for 15 min. Oxygen at an initial pressure of 188 mm Hg was then introduced, and the sorption was followed for some time. Oxygen uptake data are shown in the plots of Fig. 2. At time N, a Tesla coil discharge was started and continued to time F. The experiment was stopped after a further period of time, and the sample was discarded. This sequence of operations was

then repeated with a freshly prepared sample at each of the temperatures given in Figs. 1 and 2.

The surface area of a sample was occasionally measured after the 15 min degassing prior to exposure to oxygen. The total amounts of hydrogen sorbed in ml N.T.P. and the surface areas in m^2/g were: 0, 5.2; 0.394, 5.1; 1.098, 4.5; 1.579, 4.6; and 2.278, 4.9, respectively.

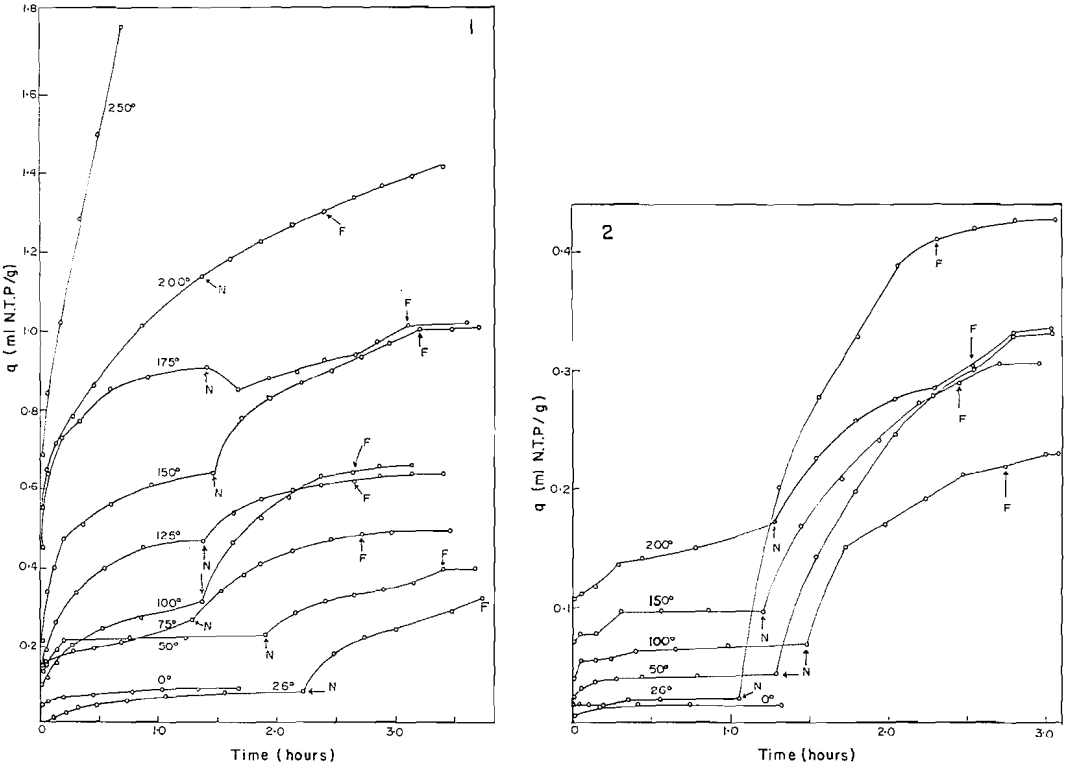

FIG. 1. Hydrogen sorption on fresh surfaces.
FIG. 2. Oxygen sorption on hydrogen-treated surfaces.

As the changes in surface areas were small, and therefore no major changes in adsorbent texture occurred, the possible effects of small changes in area brought about by interaction of the oxide with hydrogen were disregarded.

Some of the data of Fig. 1 are shown in Fig. 3 as plots of amounts of hydrogen sorbed after various specific times as functions of temperature. As the q vs. t plots below 200° of Fig. 1 show that gas sorptions were nearing completion after ~1 h, the 60 min plot of Fig. 3 approximates an initial-pressure isobar, and can be taken to be analogous to a true isobar. The general shape of the plot indicates at least two modes of sorption, a change in the nature of the uptake being indicated by the minimum near 26°.

A second series of experiments on hydrogen sorption by oxygen-treated surfaces was made as follows. A freshly prepared adsorbent sample was exposed to oxygen at an initial pressure of 188 mm Hg, and the isothermal sorption was followed (Fig. 4). The sample was then degassed for 15 min and exposed to hydrogen at an initial pressure of 206 mm Hg (Fig. 5). The adsorbent was then discarded. This sequence was repeated with freshly prepared samples at each of the temperatures indicated in Figs. 4 and 5. The data of Fig. 4 are replotted in Fig. 6 in the manner described for hydrogen sorption.

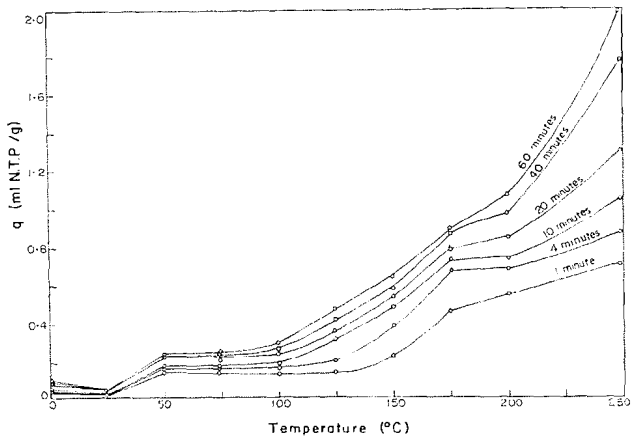

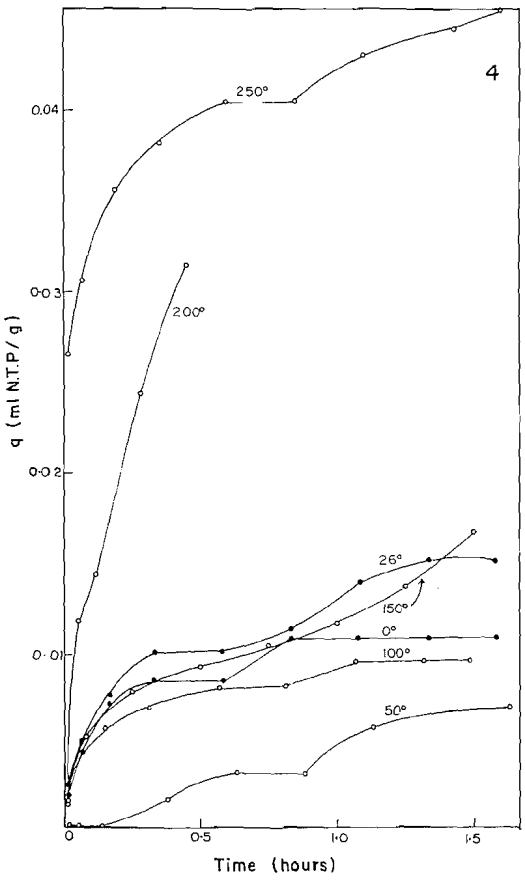

FIG. 3. Hydrogen sorption on fresh surfaces.

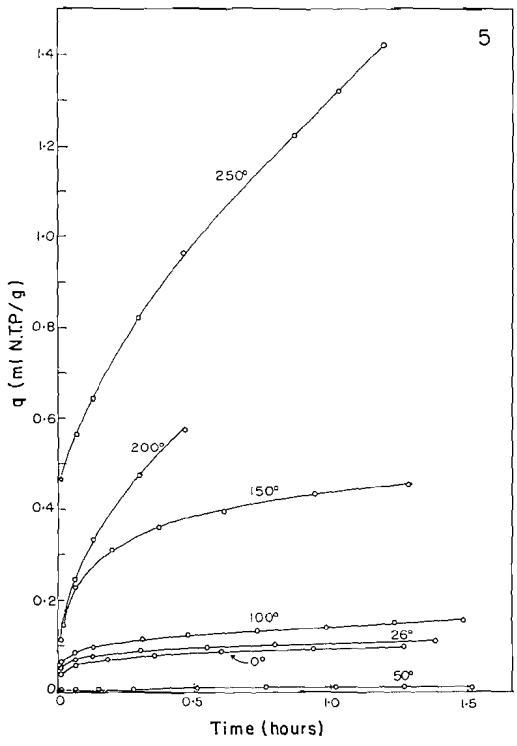

FIG. 4. Oxygen sorption on fresh surfaces.
FIG. 5. Hydrogen sorption on oxygen-treated surfaces.

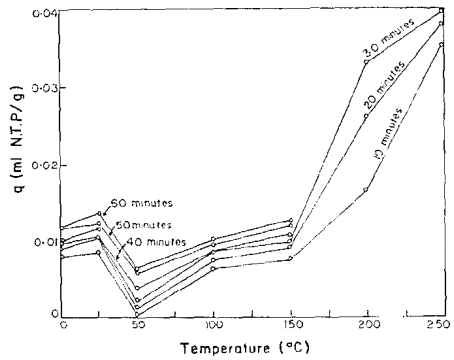

FIG. 6. Oxygen sorption on fresh surfaces.

Pretreatment of the adsorbent with one gas had marked effects on the subsequent uptake of a second gas. The potential desorption of a fraction of the first gas during the pumping step between the two gas sorptions precludes a quantitative treatment, but useful comparisons can be made. Corresponding data of Figs. 1 and 5 show that treatment of the adsorbent with oxygen caused marked changes in the subsequent hydrogen sorption, the pretreatment effects being noticeable mainly as changes in the initial rapid gas sorption. The effects were complex. For example, on computing the change in hydrogen sorption after 30 min caused by oxygen pretreatment, there was a decrease of about 10 ml H_2/g per ml of oxygen pre-adsorbed at $\geq 50°$. There was little change at 0°, but an increase of 4 ml H_2/g per ml of oxygen pre-adsorbed occurred at 26°. The changes in the hydrogen sorption caused by small amounts of pre-adsorbed oxygen (these being taken as the final values of each of the plots of Fig. 4) especially up to $\sim$100°, cause the initial-pressure isobar for hydrogen sorption on the oxygen-treated adsorbent to resemble that of the oxygen isobar of Fig. 6. Similar complex changes in oxygen sorption were caused by hydrogen pretreatment. Comparison of corresponding data of Figs. 2 and 4 shows the oxygen sorption to be enhanced by the hydrogen treatments. The rapid initial oxygen sorption was increased by an order of magnitude, and small increases occurred in the slow sorption. The enhancement, however, was inefficient. The oxygen sorption after 30 min, for example, was increased by $\sim$0.07 ml O_2/g per ml of hydrogen pre-sorbed.

A number of other experiments were made, each with a fresh sample of adsorbent. Voluminous and irreversible oxygen sorptions such as those of Fig. 2 could be caused by Tesla coil discharges during oxygen sorption on clean surfaces. Oxygen sorption did not cause a change in surface areas. Some other experiments were made with hydrogen-treated surfaces. In one experiment, a 1 g sample of fresh adsorbent was exposed to hydrogen at 30 cm Hg and 26° and was heated to 250° in 30 min. A total of 0.904 ml of hydrogen had been taken up when 250° was reached. The sample was then degassed for 15 min at 250° to $\sim 3 \times 10^{-6}$ mm Hg and cooled to 50°. Hydrogen at 31 cm Hg and 50° was introduced but was not taken up. The sample was then raised to 100° in the presence of the gas, but no sorption was found. The sample was then degassed at 100° for 15 min and heated to 150°. Some sorption of hydrogen then occurred. The adsorbent was then heated to 200° in the presence of hydrogen. A further sorption of hydrogen occurred, but the sorption was smaller than that occurring with a freshly prepared surface, i.e., exposure to hydrogen deactivated the surface.

Similar experiments were made with water-treated surfaces. For example, a fresh

For personal use only.

sample was exposed for 2 min to water vapor at 8 mm Hg. After pumping for 15 min to a pressure of about 3×10^{-6} mm Hg to remove excess water, the sample was exposed to oxygen, all steps being carried out at 26°. It was not possible to measure the amount of water taken up (3). Comparison of results with those of oxygen sorption on fresh surfaces showed that water pretreatment had an enhancing effect on oxygen sorption. The total oxygen uptake was increased by ~80% at 26° and 100°, but voluminous initial sorptions similar to those observed with hydrogen-treated surfaces were not found. Other experiments showed that hydrogen sorption was almost totally inhibited by pre-adsorbed water.

Numerous attempts were made to obtain infrared spectra of the surface species at room temperature, using a Perkin-Elmer model 521 spectrophotometer. The relatively high conductivity and consequent high infrared absorption as well as the high light scattering of the pressed oxide pellets and evaporated films did not permit meaningful transmission measurements to be made in many cases. Samples transmitting about 2% of the incident radiation could on occasion be prepared but, in numerous trials, surface OH and CdH groups analogous to OH and ZnH groups found on ZnO surfaces (4) were never observed. This indicates that such groups, if formed, are few in number or have a transient existence on the surface.

DISCUSSION

The hydrogen sorption below the temperature region of the minimum of the isobar of Fig. 3 is ascribed predominantly to chemisorption. This is based on the low probability of physical adsorption at such relatively high temperatures and, more significantly, on the enhancement of oxygen sorption by hydrogen pretreatment. This effect indicates that below the isobar minimum at least a portion of the hydrogen must have been strongly bound to the surface in order to be able to affect the subsequent sorption of oxygen. The relatively rapid increase in q from 26° to 50°, the relatively small difference between q at 50° and at 75°, and the increasing coverage with time at $\geq 50°$ indicate a second process. Some evidence for this comes from the shape of the plots of Fig. 1. The 50° plot quickly rises to an almost constant q value. The sorption at 75° occurs more slowly but continues to a higher value than at 50°, indicating a decline in predominance of one process and transition to a second one, as do the more rapid and voluminous sorptions at $\geq 100°$.

The various data show that strong interactions occurred between hydrogen and the oxide over the entire temperature range studied. This supplements rather than conflicts with the statement (5) that cadmium oxide reduction starts at 95° and that bulk reaction occurs at 120°, or the similar observation (6) that reduction begins in the range 221–254°, based on experiments designed to establish the reduction threshold through the detection of free water. Failure to detect unbound water, however, does not exclude the possibility that reduction had occurred but the water formed was retained by the oxide surface, as suggested by the present data. For example, hydrogen sorption was inhibited by water and also by hydrogen treatment of the surface until the temperature was raised, so that water desorption could occur near 150° as indicated by previous work (7), thus suggesting a self-poisoning of hydrogen sorption through the formation of water at low temperatures. Also, as it had been shown that temperatures in the vicinity of 200° were required to degass cadmium oxide prior to surface area measurements (1, 7), it is likely that the decline and subsequent increase in surface areas on hydrogen treatment were an artifact: water formed at low temperatures could partially block the pore system of the adsorbent and thus cause an apparent reduction in area until desorption took place. Also, water as well as hydrogen enhanced oxygen sorption, again suggesting the formation of water at low temperatures.

For personal use only.

The various effects are in agreement with a postulated mechanism involving a chemisorption predominant near 26°, which is the precursor to water formation on the surface. Chemisorbed hydrogen could be slowly converted to adsorbed water, some water formation occurring as low as 50°. The surface mobility of hydrogen atoms or ions and of bound water species as well as the rate of conversion or reduction is increased with increasing temperature, most of the water formed being retained by the surface below ~150°.

The shapes of the plots of Fig. 6 indicate that at least two processes were involved in the sorption of oxygen between 0° and 250°. As the sorption of oxygen influenced the subsequent hydrogen sorption, the region of the isobar below 50° can be ascribed to an oxygen chemisorption, at least in part. Similarly, a second chemisorption can be invoked to account for the region of the isobar above 50°. The plots of Fig. 4, however, with the exception of the short experiment at 200°, show the rate of oxygen sorption to decelerate markedly and then to accelerate after a short period of quiescence. A second deceleration then occurs below 150°. The general kinetic behavior indicates the occurrence of two processes and points to a conversion of one chemisorption into a second type. The dual effect of oxygen in enhancing hydrogen sorption at 26° but inhibiting it at higher temperature also suggests two modes of oxygen sorption. The relatively more voluminous oxygen sorption above 150° as shown by Figs. 4 and 6 may involve a diffusion of oxide ions from the surface into the bulk of the adsorbent to fill vacancies in the anion sublattice. Support for this comes from the work of Haul, Just, and Dümbgen (8, 9), who studied the disorder and oxygen transport in cadmium oxide by measuring the ^{16}O–^{18}O exchange between gaseous oxygen and cadmium oxide crystals from 630° to 855°. Their results furnished strong evidence for a transport mechanism involving vacancies in the anion sublattice. However, the exact nature of the surface species and the mechanism of the enhancing effect of the discharges, as well as a detailed explanation of the various poisoning effects, are unknown and speculative in the absence of simultaneous measurements of gas sorption and electronic behavior of the adsorbent.

THE DIELECTRIC CONSTANT OF ETHYL CHLORIDE ADSORBED ON POROUS SILICA GLASS TREATED TO REMOVE SILANOL GROUPS

R. SHIGEISHI[1] AND R. MCINTOSH
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 4, 1965

ABSTRACT

The real and imaginary parts of the complex dielectric constant of the composite system ethyl chloride adsorbed on porous glass have been determined over a range of temperature, namely −20 to −190 °C in the frequency range 1 000 to 4 000 Mc/s. The porous glass was treated to remove the majority of the silanol groups. The dielectric constants of the adsorbate are also reported. The major finding was that removal of the silanol groups eliminated the second linear section (of lower slope) of the usual plots. The behavior of the polar adsorbate is then shown to be quite similar to that of polar adsorbates on nonporous rutile. Loss curves as functions of frequency and temperature are given and discussed. There is insufficient evidence to discriminate between Debye-type loss and that of an oscillator or resonator.

A method is given of obtaining the dielectric parameters from the standing wave data with greater accuracy than can be obtained from use of Von Hippel plots.

INTRODUCTION

Almost from the earliest publications concerning the dielectric behavior of adsorbates in such solids as silica gel and porous glass, there has been reported the existence of two linear sections of the primary data as a function of quantity adsorbed (1–6). The relative slopes of these two sections of the dielectric constant or capacitance change plots have depended upon the adsorbate in some instances. Thus Higuti (2) reported the second linear section to have the higher slope for propanol in titania gel, except at the highest temperature of his experiments when that section had the lower slope. For the system nitrobenzene – silica gel the slope of the second section was the higher (3). McIntosh, Johnson, Hollies, and McLeod (4) found the second linear section to have the lower slope for ethyl chloride and butane, among other adsorbates, using silica gel as adsorbent. Kurbatov (5) reported the same situation for water and acetone in silica gel. As further experience was gained and it was learned that the temperature coefficients of these slopes might differ, attention was directed to the underlying cause of the sudden change of dielectric property rather than to the absolute value of the polarization which is directly related to the value of these slopes. A frequent suggestion was that the change of dielectric behavior corresponded with the completion of the first layer of adsorbate, which was expected to be firmly bound and to have reduced orientational polarizability in comparison with bulk liquid or higher layers. This explanation could account for a change to a higher slope, but did not seem to offer a reason for a change to a lower slope. Moreover, the position of the abrupt change of slope did not correlate particularly well with the monolayer volume, V_m, deduced from the usual Brunauer, Emmett, Teller plots. In this respect, and in the fact that the second linear section frequently had a lower slope, the behavior of adsorbates in rigid gels differed from the behavior of adsorbates on the nonporous adsorbent rutile, which until very recently was the only nonporous adsorbent examined (7). Because of the poor correlation between V_m and the kink of the relevant plots and because a nonpolar adsorbate such as butane behaved similarly to polar adsorbates, McIntosh, Rideal, and Snelgrove (8) suggested that the phenomenon is probably universal in porous adsorbents and also pointed out that an abrupt change of the density of the adsorbate could account for the

For personal use only.

experimental results. This latter explanation was soon proved untenable because the required density was too low to permit adsorption of the quantities taken up by porous glass (9).

Another relevant fact to be considered in explaining the dielectric behavior was the observed shift of the position of change of slope with the water content of a silica gel (8); still another that the activation energy of the process causing dielectric loss was shown by Waldman (10) in Professor Freymann's laboratory to change abruptly at the volume adsorbed corresponding to the B.E.T. monolayer volume. However, all the relevant facts and suggestions need not be repeated here. It is sufficient to summarize the situation by pointing out that at least three reasonable explanations have been offered. The first was the completion of the first layer of adsorbate. The second was the onset of capillary condensation. The third was a new environment of the adsorbate in which the electrical field experienced by the adsorbate differed from that to which molecules in the initial adsorption range were exposed.

While the information referred to above was being accumulated through dielectric studies, evidence of the existence of chemisorbed hydroxyl groups was being obtained by the determination of infrared spectra (11, 12). Such adsorbed groups, called silanol groups, were found to have an influence on the spectra of adsorbates, and in turn to have their own spectra perturbed by adsorbate (13). Means to remove these silanol groups were invented. Thus heating to high temperatures such as 800 °C with pumping was shown to be quite effective. The treatment of the glass with a fluoride and subsequent heating and evacuation also proved valuable (14).

In the present study a porous glass sample which had been evacuated at 800 °C and had not appreciably sintered was used as the adsorbent and ethyl chloride as the adsorbate. A temperature range from −20 to −190 °C was utilized along with a frequency range of 1 000 to 4 000 Mc/s. These conditions served to extend the observations of Chapman and McIntosh (15) and at the same time permitted the examination of a silica glass substrate from which most of the silanol groups had been removed. The treatment is shown to have eliminated the second linear region of lower slope in the dielectric plots. Moreover, results at these frequencies and temperatures are now quite similar to those found for polar adsorbates on nonporous rutile. As it is believed that improvements in the experimental techniques of measuring the dielectric constants are also worth describing, these are reported. An improved procedure of converting the standing wave data to the real and imaginary parts of the complex dielectric constant was also developed and is given in Appendix I.

EXPERIMENTAL

Dielectric constants were obtained by the shorted coaxial line method described by Von Hippel (16). In essence, a standing wave is established in a coaxial line by propagating an electromagnetic wave between two concentric channels of a coaxial cell containing the dielectric sample and terminated by a metallic short. Determination of the node position and the voltage standing wave ratio yields the dielectric constant of the adsorbate–adsorbent system.

The coaxial cell along with the ancillary components of the inner and outer cell housings are shown in Fig. 1. The dimensions of the coaxial cell and of the tapers leading to the UG30C/U connector were chosen to present an impedance of 50.0 Ω to the microwave.

The inner cell housing fitted over the coaxial cell and the connector and was gasketed to the main brass plate with indium. Evacuation and admission of gas to the sample were accomplished by a narrow Monel Metal tube and a pinhole in the outer conductor. A 5 in. diameter outer cell housing was gasketed with indium to the top plate. The region between the inner and outer cell housings was evacuated through glass to metal Kovar seals soldered to the brass plate.

To obtain desired temperatures in the cell, heating coils were wrapped around a copper cylinder placed around the bottom of the inner cell housing, which was filled with brass filings to improve thermal conduction.

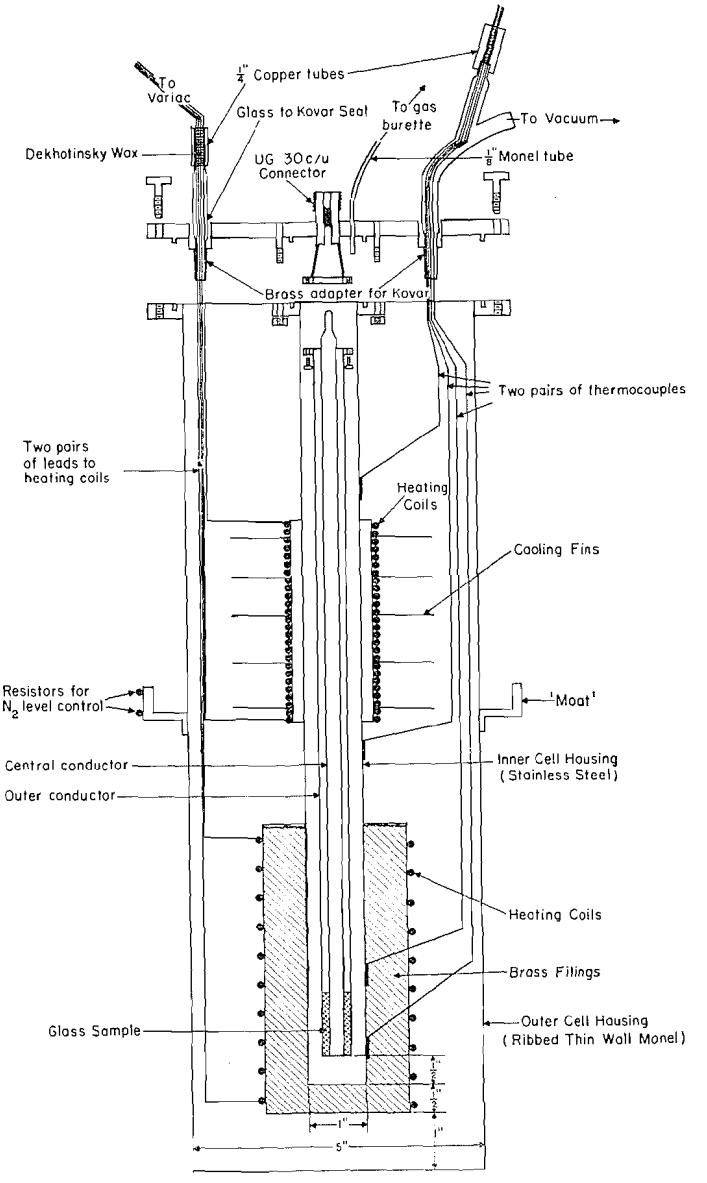

FIG. 1. Coaxial dielectric cell and jackets.

Another heating jacket was placed somewhat higher on the housing. This second heating jacket provided heating coils and in addition circular copper vanes. When no current was passed through this heater, the vanes had the effect of making the top part of the cell cooler than the bottom. By adjusting the currents in the heating coils temperature gradients spanning the length of the porous glass sample were reduced to less than 0.5 °C.

Temperatures were measured by copper–constantan thermocouples placed at various points along the inner cell housing. They gave the temperature of the sample, the temperature gradient along the sample, and the temperature gradients spanning the entire cell. The latter measurements were required in the calculation of the quantities adsorbed. Both the thermocouples and the leads to the heating coils were passed into the vacuum region via copper tubes soldered to the Kovar of the glass-to-metal seal. The glass end was joined to another glass-to-metal seal which was soldered into the brass plate. A vacuum seal was obtained by filling the channels in the copper tubes with Dekhotinsky wax.

A large Dewar placed around the entire cell contained liquid nitrogen as the coolant. The level of the liquid nitrogen in the Dewar was automatically controlled between two desired levels by a device which regulated the solenoid valve through which the air to the storage vessels of liquid nitrogen passed (17). Two carbon resistors which formed a part of the controlling device were strapped one above the other to a rectangular funnel-shaped device designated 'moat'. The controller worked in such a way that the level of the liquid nitrogen never rose above the height of the top resistor and never fell below that of the bottom resistor. The 'moat' kept the level of the liquid nitrogen in contact with the outer cell housing at a constant level despite the fall and rise of the liquid nitrogen level in the Dewar. By these means the temperature could be controlled to ±0.3 °C.

Admissions of gas to the sample were made when the sample was at −20 °C. The temperature of the sample was then adjusted to that desired and appropriate corrections were applied for adsorption from the gas phase when these were significant. A standard gas burette and mercury manometer system were employed and need not be described.

The ethyl chloride, obtained in cylinders from the Matheson Co., contained water as its main impurity. This was removed by slowly passing the ethyl chloride from the cylinder through ~20 ft of glass tubing which contained particles (activated Linde type 13X) acting as a molecular sieve into a distillation trap kept at 0.0 °C. The molecular sieve had previously been heated to 180 °C and evacuated for 3 d. The ethyl chloride was then subjected to trap-to-trap distillations.

Adsorbed water and the majority of surface hydroxyl groups were eliminated from the adsorbent by placing the porous glass sample (Corning glass No. 7930) in a Vycor tube connected to a vacuum rack. A heating jacket of Kanthal A was placed around this tube, and the sample was heated to 800 °C and evacuated for 5 h. An amount of ethyl chloride sufficient to immerse the glass was condensed into the cooled Vycor tube, and the tube was closed off and removed from the vacuum line. It was subsequently placed in a dry-box along with the coaxial cell and a polyethylene bag. When the humidity in the dry-box had dropped to zero, the Vycor tube was broken, the sample was taken out and inserted into the cell, and the cell was placed in the polyethylene bag. The cell was mounted as quickly as possible in a dry nitrogen atmosphere and slowly evacuated at room temperature.

To determine the extent of removal of hydroxyl groups, infrared spectra were taken of thin glass samples placed in a quartz cell and evacuated at temperatures between 25 and 850 °C. To determine whether the procedure for loading the cell was effective in preventing hydroxyl groups from the water in the atmosphere reforming during the short time the sample was exposed to the atmosphere, spectra were taken of samples accorded the same treatment as the actual sample used except that they were not immersed in liquid ethyl chloride.

The general procedure for obtaining the dielectric data has been outlined previously (18). The coaxial lines were manufactured by Hewlett-Packard. Amplification of signals was achieved by a Guildline photocell amplifier and the microwave signals were rectified by matched silicon crystal diodes of the type 1N21CM.

An extensive calibration of the empty cell was done for the frequency and temperature ranges employed in the measurements for the adsorbate–adsorbent system. These calibrations were required since the short position changed with the temperature of the cell. The empty cell showed a small loss and the ambient temperature affected the node positions. Furthermore, corrections were applied to the rectified signal outputs to account for contact potentials in the external d.-c. circuit.

ARITHMETIC PROCEDURE

The relation between the primary data and the propagation factor of the adsorbate–adsorbent system is

$$\frac{\tanh \gamma_2 d}{\gamma_2 d} = -j\frac{\lambda_1}{2\pi d}\left[\frac{\frac{E_{\min}}{E_{\max}} - j\tan\frac{2\pi X_0}{\lambda_1}}{1 - j\frac{E_{\min}}{E_{\max}}\tan\frac{2\pi X_0}{\lambda_1}}\right] = C\,e^{-j\zeta}$$

where $E_{\min}/E_{\max}$ is the inverse standing wave ratio, λ_1 the wave length, d the length of the glass sample, X_0 the distance of the first minimum from the surface of the glass (defined as the position $X = 0$), and γ_2 the propagation factor; C and ζ are found from the primary data. Thus if $\gamma_2 d = Te^{j\tau}$, T and τ can be evaluated from charts drawn by Von Hippel (16). It can then be shown that

$$\frac{\epsilon^*}{\epsilon_v} = -\left(\frac{\lambda_1}{2\pi d}\right)^2 (T\,e^{j\tau})^2$$

where ϵ^* is the complex dielectric constant of the composite system and ϵ_v that of free space.

To overcome the errors inherent in this procedure which were pointed out by McCowan, a program for the 1620 IBM computer was written which obtained T and τ accurately. See Appendix I.

RESULTS

The infrared spectra of thin glass samples which were evacuated at temperatures between 25 and 800 °C are shown in Fig. 2*a*. The relatively sharp peak at 3 760 cm^{-1} obtained for glass heated to 800 °C is attributed to the fundamental stretching frequency of a surface OH group which is oriented in such a way that it cannot interact with its surroundings (12, 19). The broad band obtained for glass evacuated at lower temperatures is attributed to a composite spectrum of the peak at 3 760 cm^{-1} and one at a lower frequency. The latter peak is thought to be caused by a hydrogen bonding of the OH groups among themselves.

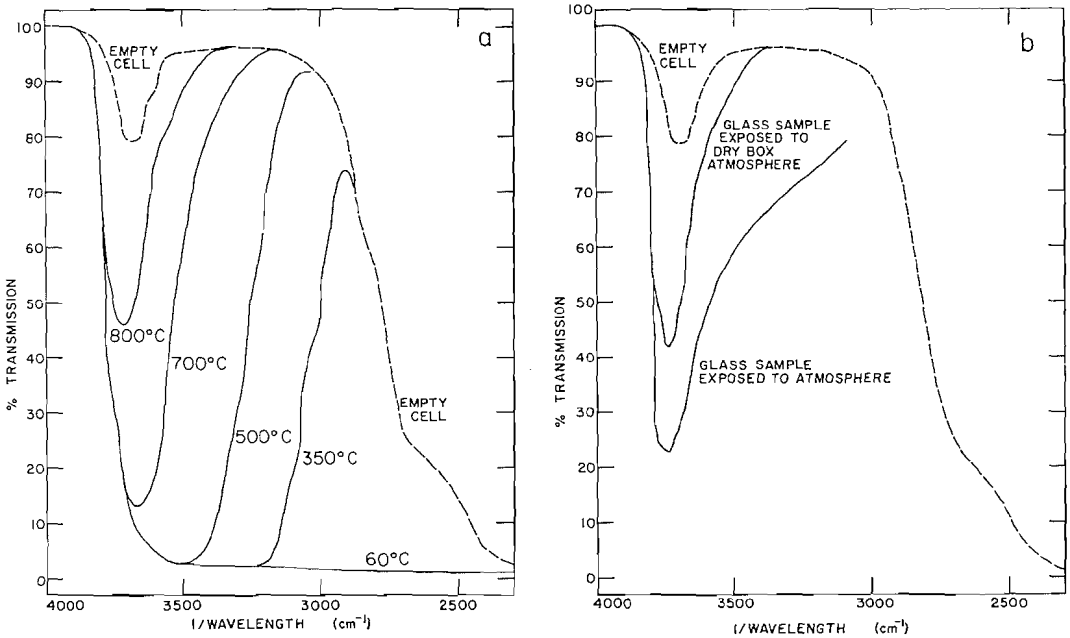

FIG. 2. Infrared spectra of glass samples (*a*) evacuated at several temperatures (*b*) exposed to atmosphere of dry-box and of room.

Figure 2*b* shows the spectra of glass samples heated to 800 °C and exposed for 30 min to the atmosphere inside and outside the dry-box used to transfer the actual sample to the cell. The spectrum for the former case reveals no significant increase of the peak height or width and hence this method was effective in preventing OH groups from reforming on the surface.

An isotherm is shown in Fig. 3. This is typical for ethyl chloride adsorbed on porous glass except for the initial amounts adsorbed (18). For glass containing hydroxyl groups there is initially a sharp rise in amount adsorbed with equilibrium pressure. The lesser adsorption at low pressure of the treated sample is another indication of the greatly reduced OH content of the glass and indicates a lesser heat of adsorption.

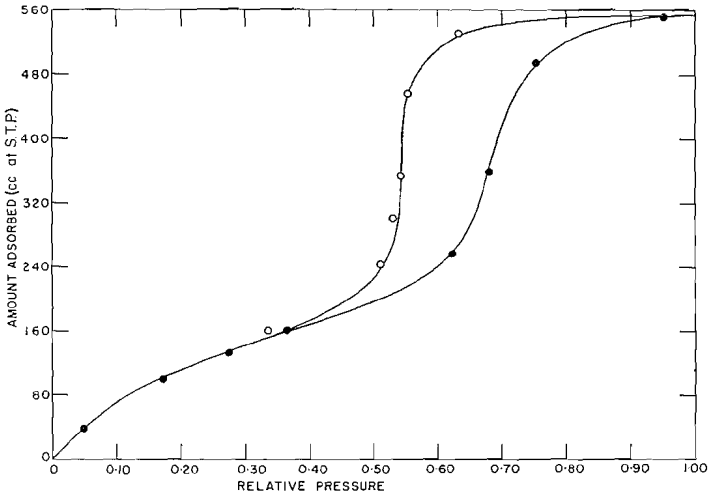

FIG. 3. Adsorption isotherm at −20 °C of ethyl chloride in porous silica glass from which silanol groups have been removed.

Both parts of the dielectric constant for the bare glass (ϵ_0', ϵ_0'') indicate that there is no consistent variation with frequency. At any temperature the smallest and largest values of ϵ_0' differ by approximately 4%. The deviation from the mean is 1%. The ϵ_0'' values, although showing a relatively large overall fluctuation with frequency, are divided into two groups. For the four lowest frequencies there is little or no loss, the highest value being 0.005. At the three highest frequencies ϵ_0'' is three to four times this value.

It is felt that these changes with frequency are not significant but are a reflection of a frequency-dependent error inherent in the cell and the measuring apparatus. These arise from cell and line characteristics which vary with frequency and from the frequency-dependent corrections applied in the calculations to account for the attenuation in the line and its coaxial fittings. A similar but larger fluctuation was reported by McCowan (18) in his work which encompassed the same frequency range and employed General Radio coaxial lines. It had been hoped that the use of improved Hewlett-Packard lines would eliminate these fluctuations. Unfortunately they have only been reduced. These fluctuations, however, would be expected to be less important as the dielectric constant of the system increased since the corrections would be a smaller percentage of the total measured change.

The variation of ϵ_0' and ϵ_0'' with temperature is consistent. Both quantities rise as the temperature is decreased. The change in ϵ_0' in going from −20 to −191 °C is approximately 2%. The preceding remarks apply equally to the dielectric constant of the glass phase (ϵ_1' and ϵ_1'') obtained by the Böttcher method (20).

Figures 4a, 4b, 5a, and 5b show typical plots of ϵ' and ϵ'' as a function of volume adsorbed.

Three points of particular interest are shown by these plots. First, the dielectric isotherms at −20 and −60 °C and the three lowest frequencies at −100 °C show only one linear section. Second, those for −140 °C and the remaining frequencies at −100 °C show two linear sections with the second having a higher slope than the first. These observations are in contrast to previous results for the same adsorbent–adsorbate system where a kink was found at all temperatures and the second linear section had a lower slope

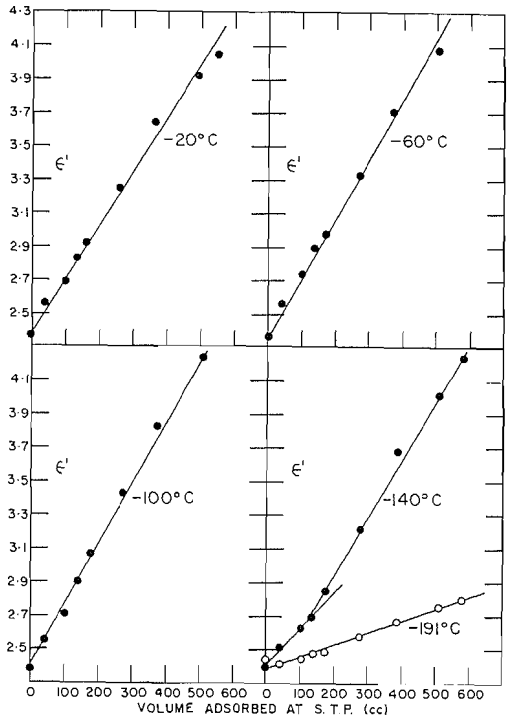

FIG. 4a.

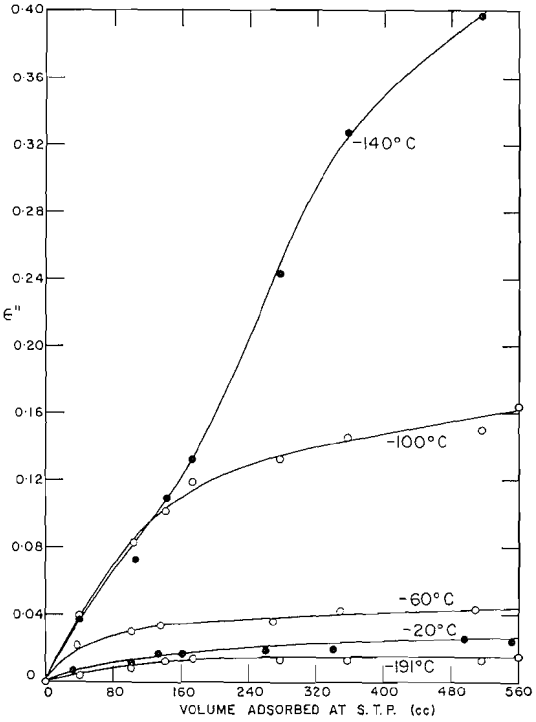

FIG. 4b.

FIG. 4. (*a*) ϵ' (composite system) and (*b*) ϵ'' (composite system) as a function of volume adsorbed for various temperatures and 1 000 Mc/s.

than the first. Third, the plots at −191 °C show that ϵ' for the first admission always falls below that of the glass alone and from this point increases linearly with the volume adsorbed. This is confirmation of a similar observation first made by Chapman (15) in the frequency range 3 kc/s to 4 Mc/s. In that case, however, the anomalous behavior began at approximately −170 °C.

Evidence of dispersion at all temperatures is given by the ϵ'' versus volume adsorbed plots in Figs. 4*b* and 5*b*. At high temperatures these show a rapid rise for initial amounts adsorbed followed by a region of less rapid rise as the amount adsorbed is increased. As the temperature is lowered the curves tend to become linear till at −140 °C the behavior is reversed from that at high temperatures. Here, the slope of the curve is less for the initial amounts than for the later quantities adsorbed. Hence at the higher temperatures the multilayers are showing less loss than the monolayer while at −140 °C this is reversed.

Plots of ϵ' and ϵ'' versus temperature, Figs. 6*a* and 6*b*, show the existence of loss peaks for the composite system which shift to lower temperatures as the amount adsorbed is increased. This is accompanied by a similar shift in the peaks of ϵ' versus temperature.

The dielectric behavior of the adsorbate itself is shown in typical plots of ϵ_2' and ϵ_2'' versus temperature for 100, 300, and 500 cc adsorbed (Figs. 7*a*, 7*b*, 8*a*, and 8*b*). These show more explicitly the difference in behavior of the initial and later amounts adsorbed; the loss for the initial amounts shows a peak while for greater quantities adsorbed the loss continues to increase as the temperature is lowered. From the former plots a definite negative temperature coefficient for ϵ_2' can be seen. Its value $d\epsilon_2'/dT = -0.01$, although

well below that for liquid ethyl chloride (−0.05), agrees well with that reported by Chapman. In his investigation, however, the multilayers showed a temperature coefficient almost twice that for the monolayer. In this research the difference was smaller.

Although the frequency range is limited and the results not as consistent as those obtained with temperature as a variable, plots were drawn of ϵ_2'' versus frequency for 100 and 300 cc adsorbed. These are shown in Figs. 9*a* and 9*b*.

DISCUSSION

The mean value of the real part of the dielectric constant of the glass phase is 3.41, in good agreement with the values obtained by both Chapman and Petrie (3.4 and 3.6) for glass samples evacuated at 350 and 120 °C respectively. Although the value is low compared with that for fused silica (3.75), this is not surprising in view of the fact that the Böttcher method of extraction is not completely satisfactory. McCowan obtained the high value of 5.2. His sample, however, was evacuated at 60 °C, and at this temperature porous glass contains physically adsorbed water, which is polar and may be expected to contribute to the dielectric polarization. This could explain the high result.

The shape of the initial part of the isotherms, the small heat of adsorption, and the high loss values for initial amounts adsorbed are evidence that ethyl chloride prefers the OH to the Si or O sites. Previous work on systems such as ammonia-porous glass (21) indicates that a hydrogen bond is formed between the surface hydroxyl groups and the ammonia. Evidence presented here suggests that the chlorine of the ethyl chloride and the silanol group may form a bond.

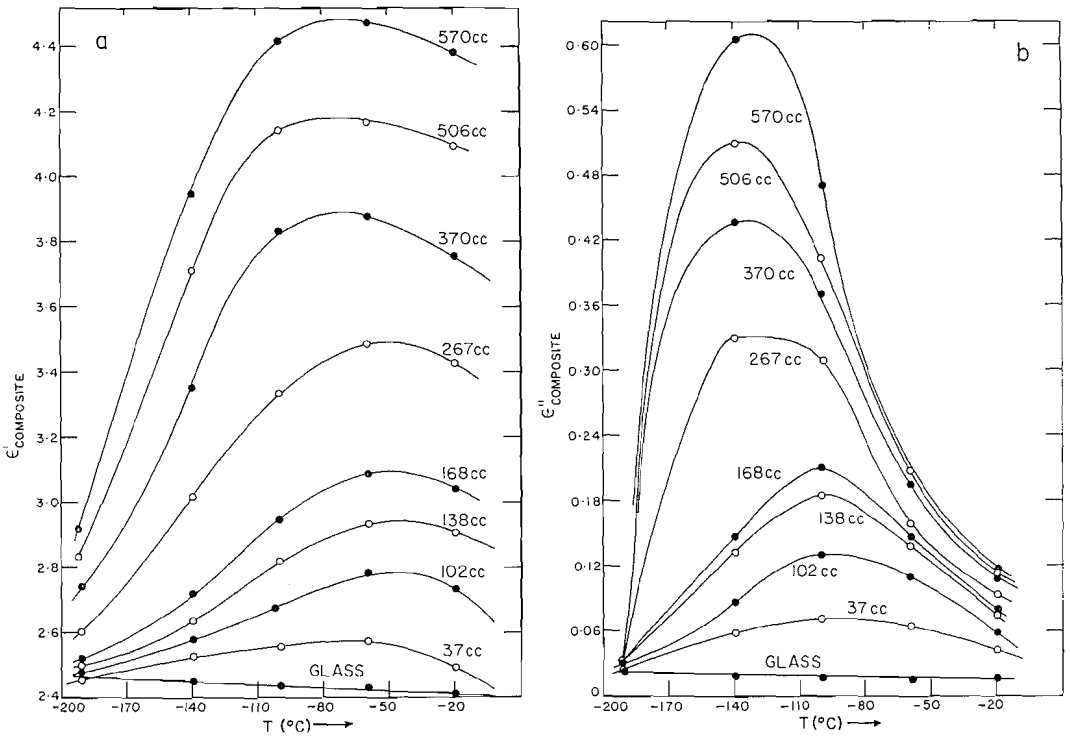

FIG. 6. (*a*) ϵ' (composite system) and (*b*) ϵ'' (composite system) as a function of temperature for several quantities adsorbed and a frequency of 4 000 Mc/s.

The marked effect of such a complex on the dispersion characteristics of the adsorbent–adsorbate system is clear from the data at −191 °C. At this temperature ϵ' is less after the first admission of gas than for the glass alone. Consistent with this apparent anomaly is the high value of the loss for the adsorbate. At such low temperatures it would be expected that the dipoles would be immobile and that the dielectric constant of the adsorbate would have a value given by $\epsilon' = \Delta\epsilon + n^2$, where n is the refractive index and $\Delta\epsilon$ is the elastic displacement of the dipoles. Since the first term is very small, ϵ' should be approximately equal to the square of the refractive index. The value of n^2 was 2.3 as estimated from tables of molar refraction while that of ϵ_2' at −191 °C was 2.44. Hence the dipoles are not free to rotate and the adsorbed ethyl chloride should show no loss. It was found, however, that the average value for ϵ_2'' for the first admission was 0.17 (bulk ethyl chloride shows no loss at −191 °C). It can then be inferred that the complex has different dispersion properties than adsorbed ethyl chloride and that this complex might explain the apparent anomaly at −191 °C.

Further evidence that the complex is responsible for the anomaly was obtained by Chapman (15) from his work on *n*-butane which would not form a hydrogen bond with the OH group adsorbed on porous glass at −180 °C. In this case ϵ' was always larger than that for glass alone and the adsorbate showed no loss.

The elimination of the kink point in the plot of ϵ' versus volume adsorbed for the higher temperatures is a significant observation. The occurrence of a kink and especially the lower slope of the second linear section for porous adsorbents have never been satisfactorily explained. Although no definite answer is given here, certain worthwhile suggestions may be offered with regard to its occurrence.

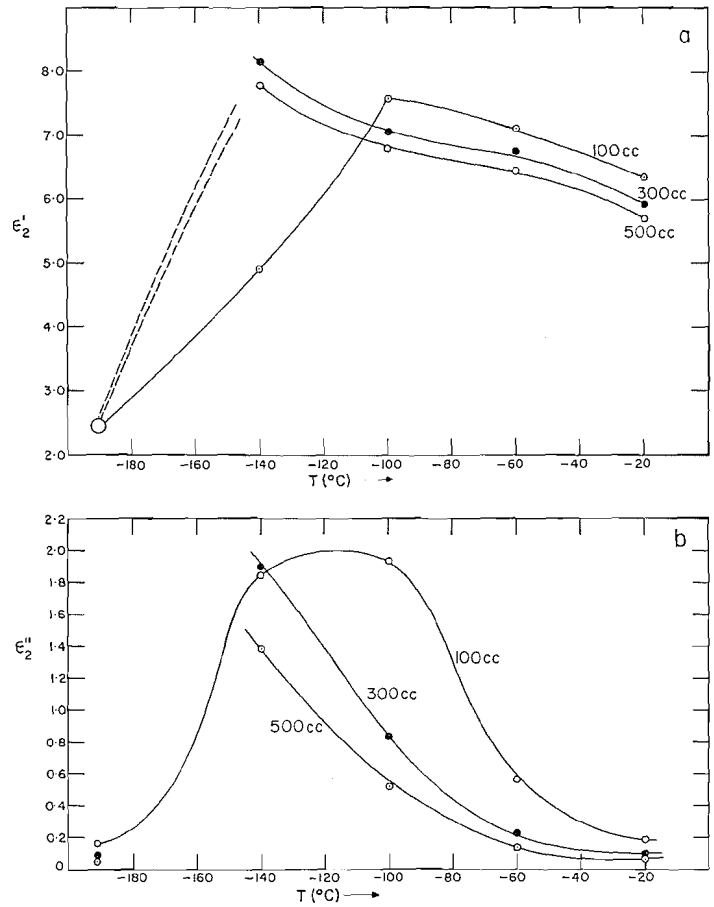

FIG. 7. The variation of (*a*) the real part and (*b*) the imaginary part of the dielectric constant of adsorbate with temperature for a measuring frequency of 1 000 Mc/s.

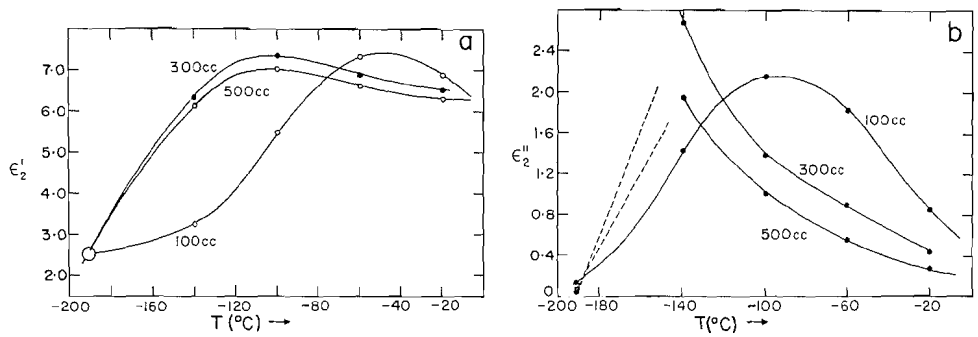

FIG. 8. The variation of (*a*) the real part and (*b*) the imaginary part of the dielectric constant of adsorbate with temperature for a measuring frequency of 4 000 Mc/s.

Two linear sections in the Böttcher equation imply a combination of one or more of three things, occurring at the kink point. These are a change in the adsorbate density, a change in the polarizability of the adsorbate, or a change in the internal field. From studies on *n*-butane on porous glass Petrie (9) was able to conclude that the density change

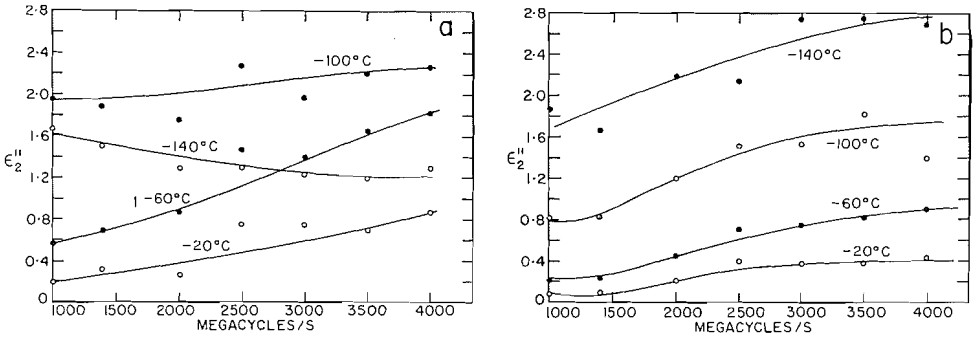

FIG. 9. The imaginary part of the dielectric constant of the adsorbate as a function of frequency for several temperatures and (*a*) 100 cc adsorbed (*b*) 300 cc adsorbed.

was not responsible, since the low density required to bring values of polarization up to those of the first section was not consistent with the available pore volume. She also reasoned that there was no cause for the polarizability to undergo a sudden large change. At first glance, the fact that ethyl chloride may form a complex with OH groups could be a possible answer since the complex may have a different polarizability from adsorbed ethyl chloride. However, since *n*-butane on porous glass also shows two linear sections this again must be discarded. The cause of the second linear section must therefore be due to a change in the internal field.

It has been shown recently by Yates (22) that nonporous rutile has bound to its surface OH groups which have a somewhat different absorption peak than those adsorbed on silica, namely 3 680 cm^{-1} rather than 3 760 cm^{-1}. Also, there appears to be a greater variation in the number and absorption frequency of the OH groups on the rutile. Nevertheless, one would suppose that such groups would also be capable of forming hydrogen bonds with appropriate adsorbates. One should therefore attempt to compare the dielectric behavior on the three adsorbents which are, nonporous rutile containing OH groups, porous glass containing OH groups, and porous glass with most of the OH groups removed. By so doing one would seek to answer the question whether or not the number of hydroxyl groups is responsible for the different behaviors or whether the hydroxyl groups must be associated with a porous structure to bring about the effects. Unfortunately the relative numbers of OH groups on the surfaces of the adsorbents are not known and an unequivocal answer to the query is not possible. At the same time some analysis and discussion is warranted.

In summary, a nonpolar adsorbate on rutile shows a single dielectric constant over the range of adsorption up to 3 or 4 V_m, and thus there is no indication of a changed local field over the range of adsorption studied. All polar adsorbates show two values of dielectric constant. The first region shows the lower value and one which changes little with temperature. The second region shows a dielectric constant more nearly equal to that of bulk liquid and its temperature coefficient is negative. The sudden change from one value to the other occurs at an amount adsorbed corresponding quite well with V_m. Thus, first-layer material has been interpreted as quite firmly bound and as undergoing oscillatory motion.

The OH-free porous glass shows a dielectric constant for ethyl chloride independent of coverage at temperatures down to about −100 °C, and of value about 6.5 to 7.5 throughout the temperature range whereas bulk liquid varies from 12.1 to 19.3. This range for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

adsorbate agrees with the values of ethyl chloride along the first linear section of porous glass having many OH groups on the surface (15) and for adsorbate within the first adsorbed layer on rutile (23). Thus on all three surfaces the first quantities of ethyl chloride appear to be firmly bound and have the small temperature coefficient of dielectric constant associated with oscillators. As the quantity of adsorbed ethyl chloride is increased on the OH-free porous glass, there is no evidence of greater orientational freedom. Thus the matter adsorbed above the beginning of the hysteresis loop is still only one layer in thickness or the pore structure is reducing its rotational freedom.

The ethyl chloride adsorbed below the hysteresis loop is less firmly bound on the OH-free surface than on the porous glass containing OH groups as is shown by the shape of the isotherm or the lower value of C obtained from B.E.T. plots. This is further evidence that apparent dielectric constants are quite insensitive to changes in the heat of adsorption, which must be the case for a constant value during the filling of the first layer.

As the temperature of the OH-free surface is lowered, it is seen that dispersion begins in the adsorbate below the hysteresis loop for the comparatively high measuring frequencies employed in this investigation. Thus the binding of this material to the surface is stronger than that of the "capillary-condensed" material. The plots for these lower temperatures now resemble those for nonporous rutile and ethyl chloride, although it must be remembered that the adsorbate taken on at higher relative pressures does not behave like bulk liquid as is the case for multilayer material on rutile.

Ethyl chloride adsorbed above the inception of the hysteresis loop on glass containing OH groups has a low apparent dielectric constant. Since the heat of adsorption for the low range of adsorption is increased by the presence of the OH groups without reducing the apparent value of the dielectric constant, the reduction of ϵ_2 for the capillary-condensed material remains unexplained. The effect is apparently not related to orientational contributions to the polarization because it is found also with normal butane. Hydroxyl groups on rutile do not prevent high values of dielectric constant for the adsorbate in the higher layers. One is therefore led to speculate that in some way hydroxyl groups in the porous solid create within the pores an internal field which leads to a lesser apparent value of polarization.

In reaching the conclusion above, it is clear that the different nature of OH groups on the rutile and silica surfaces has been ignored. The unknown effect of the relative number of OH groups situated on the two surfaces has also been neglected. Neither of these two simplifications is strictly justifiable. However, the experimental effect arising from the three factors is a gross effect, and the gross difference between adsorbents is the porosity of the glass. It is therefore possible to associate this difference, namely the porosity (in conjunction with OH groups), with the experimental observation.

At low temperatures, both the appearance of a second linear section with a slope larger than the first (ϵ' versus volume adsorbed) and the increased loss for the later quantities adsorbed are interesting since these observations have never been made for porous glass. These facts and the plots of ϵ_2' and ϵ_2'' versus temperature for 100, 300, and 500 cc adsorbed show that the dielectric properties of the initial and later quantities adsorbed are different. A qualitative explanation of this in terms of the strength of binding to the surface may be made.

Dielectric loss is due to a phase difference between the polarization and the electric field. If the dipole cannot follow the field at high frequency, at low temperature, or because of some hindering mechanism, such a phase difference results and dielectric loss occurs. Thus the initial amounts adsorbing on the high-energy sites should have a larger relaxation time and should show loss at lower frequencies and higher temperatures than the adsorbate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

taken up at the higher relative pressures. It must be noted here that this case is complicated by the fact that much of this high initial loss is due to the complex between ethyl chloride and the residual OH groups. These complexes have different dispersion properties than ethyl chloride adsorbed on Si and O sites, as is shown by the drop in ϵ' for the composite system at -191 °C below that of the glass alone and was shown earlier by Chapman (15).

When the temperature is lowered, the movement of the dipoles becomes more restricted and the loss will rise for all quantities adsorbed until at some temperature it is a maximum. Lowering the temperature still further will then decrease the loss since the adsorbate will approach the condition where orientation of dipoles is negligible. The quantities adsorbed on the high-energy sites show a maximum at a higher temperature then matter adsorbed on sites of lower binding energy. In Figs. 7*b* and 8*b* it is seen that for 100 cc adsorbed the maximum occurs at approximately -100 to -120 °C depending on the frequency, while for 300 and 500 cc the loss is still rising at -140 °C and does not show a maximum. Similarly ϵ_2' should show a maximum at higher temperatures for initial amounts adsorbed. This is seen in Figs. 7*a* and 8*a*. Furthermore, below the temperature at which ϵ_2'' has a maximum for 100 cc adsorbed the difference in ϵ_2' between initial and later quantities adsorbed should become larger, since ϵ_2'' for the former has passed its maximum while it is still rising for the latter. When the difference in ϵ_2' values between initial and later quantities adsorbed becomes sufficiently large, it is manifest in the appearance of a kink in the primary plots of ϵ' versus volume adsorbed, with the second section having a higher slope.

Despite the limitations of the frequency range it can be seen that the temperature of the maximum of ϵ_2' and ϵ_2'' shifts to lower values as the frequency is lowered. This is to be expected since at constant temperature the dipole can follow the field more easily when the frequency is lower so that the loss will be lower. In addition, a noticeable difference in ϵ_2' values between initial and later quantities adsorbed occurs at lower temperatures for lower frequencies. For example, a comparison of the curves for 4 000 and 1 000 Mc/s shows that for the former, a relatively large difference is noted at -100 °C, while for the latter, such a comparable difference does not occur till -140 °C. Thus at -100 °C only the higher frequencies show a kink in the plots of ϵ' versus volume adsorbed. At -140 °C the difference is large for all frequencies and hence all plots show kinks. It is surprising, however, that at -100 °C the division of the frequencies that show kinks and those that do not is so sharp. No doubt this is in part caused by the judgment that must be exercised in deciding whether a kink exists or not since the kinks are not as clear as they are at -140 °C.

Chapman's results also show the shifting of the loss to lower temperatures as the volume adsorbed is increased. He did not observe the marked rise in values for later quantities adsorbed because of the high concentration of OH groups and the fact that the losses in his case never showed a maximum when plotted against temperature. Although the temperature range he employed was large, he used low frequencies so that significant losses did not occur till -130 °C. Thus the conditions of the investigation were comparable to those above -60 °C in this work.

The curves for ϵ_2' in Figs. 7*a* and 8*a* show that ϵ_2' is smaller for larger amounts adsorbed at the high temperatures. This observation is not consistent with the explanations just offered, since the orientational polarization should increase with amount adsorbed. Whether ϵ_2' rises or falls with quantity adsorbed is dependent on which of two methods is used to compute these values from given data. A discussion of this point need not be given here, as the results differ significantly only in this one respect. In view of the earlier discussion the procedure giving increasing values of ϵ_2' with amount adsorbed seems preferable.

Plots of ϵ_2'' versus frequency for 100 and 300 cc adsorbed are shown in Figs. 9*a* and 9*b*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

It is evident that the amount of scatter in the values of ϵ_2'' at any temperature is much larger than in comparable plots of ϵ_2'' versus temperature at constant frequency. However, definite trends can be seen which are consistent with the conclusions reached from ϵ_2'' versus temperature plots. Thus for 300 cc adsorbed and for the higher temperatures the loss curves seem to be far removed from the loss peaks while at the lower temperatures the loss curves are closer to the peaks, i.e. the loss peaks have shifted to lower frequencies for the lower temperatures. At all temperatures the frequency maximum is beyond the range used in this work. The absence of loss peaks precludes any conclusions regarding the mode of motion of the adsorbate from these data. The fact that ϵ_2'' increases for decreasing temperature can be explained by a shift in the peak position of the Debye type of dispersion curve or equally by the increased peak level of resonance absorption (24).

The plots for 100 cc adsorbed are more interesting. The curve at -140 °C indicates that at this temperature the loss peak occurs at a frequency lower than 1 000 Mc/s while the curve at -100 °C indicates that a loss peak occurs in the frequency range employed here.

Of the three criteria one might wish to use to discriminate between resonant and Debye-type systems, only two appear to be available because of the limited range of frequency employed in the measurement. The first is the absolute value of the real part of the dielectric constant ϵ_2'. It is appreciably less than that of bulk liquid at equivalent temperatures, but much greater than expected for distortion polarization alone. The second is the temperature coefficient of ϵ_2', which is smaller than for liquid. Both these findings are consistent with the behavior of rotational oscillators. The shape of the loss curves as a function of frequency and the changes in these curves with temperature are not well enough defined to provide useful evidence. When it is recalled that a Debye loss curve stretches over about six decades in the frequency, the small factor of four in frequency in the present investigation is seen to represent too small a section of the curve. On the basis of present evidence, therefore, it would seem that a description of the adsorbed ethyl chloride as a rotational oscillator is still acceptable on a provisional basis.

ACKNOWLEDGMENT

The authors are very much indebted to Professor R. A. Stairs, Trent University, Peterborough, for suggesting the method of obtaining ϵ' and ϵ'' from the standing wave data, and for outlining a less rigorous procedure, which itself was not successful but which led to the method described in Appendix I.

APPENDIX I

The Evaluation of ϵ' and ϵ'' from the Experimentally Determined Characteristics of the Standing Wave

Von Hippel (16) develops the equation

$$\frac{\tanh \gamma_2 d}{\gamma_2 d} = \frac{(-j\lambda_1/2\pi d)(E_{\min}/E_{\max} - j \tan (2\pi X_0/\lambda_1)}{1 - j(E_{\min}/E_{\max}) \tan (2\pi X_0/\lambda_1)}$$

where γ_2 is the complex propagation factor of the wave in medium 2, d is the thickness of the sample, X_0 its distance from the first minimum of the standing wave, and λ_1 the wavelength in the air part of the guide. The right-hand side may be expressed as $C \exp(-j\zeta)$ where C and ζ are obtained from experimental data. The term $\gamma_2 d$ may be expressed as $T \exp(j\tau)$. Charts provided by Von Hippel (16) give values of T and τ for values of C and ζ. Knowing T and τ we may evaluate ϵ' and ϵ'' from the definition of γ_2 and the relations which thus exist, namely

$$\epsilon' = -KT^2 \cos 2\tau$$
$$\epsilon'' = KT^2 \sin 2\tau$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where $K = \epsilon_0\lambda_1^2/(2\pi d)^2$ and ϵ_0 is here the dielectric constant of vacuum.

The value of K arises in the following way:

$$\gamma = \alpha + j\beta = j\omega(\epsilon\mu)^{1/2},$$

where α is the attenuation factor and β the phase factor of the standing wave. In the coaxial line system, where the air part of the guide is designated as medium 1 and the dielectric as medium 2,

$$z_1 = (\mu_1/\epsilon_1)^{1/2} \text{ and } z_1\gamma_1 = j\omega\mu_1.$$

Similarly

$$z_2\gamma_2 = j\omega\mu_2$$

and for nonmagnetic materials this means $z_1\gamma_1 = z_2\gamma_2$.

$$\gamma_2^2/\gamma_1^2 = \epsilon_2/\epsilon_1.$$

For medium 1, assumed lossless,

$$\gamma_1 = j\beta_1 = j2\pi/\lambda_1$$

and

$$\epsilon_1 = \epsilon_1' = \epsilon_0.$$

Hence

$$\epsilon_2 = -\gamma_2^2\lambda_1^2\epsilon_0/4\pi^2.$$

Since we have defined

$$\gamma_2 d = T\exp(j\tau),$$
$$\gamma_2^2 = T^2(\cos 2\tau + j\sin 2\tau)/d^2,$$

so that

$$\epsilon_2 = -\lambda_1^2\epsilon_0 T^2(\cos 2\tau + j\sin 2\tau)/(2\pi d)^2$$

and

$$K = \lambda_1^2\epsilon_0/(2\pi d)^2.$$

Because of the forms of the functions, interpolation between curves on the charts is not always easy and some accuracy of the primary data is readily lost. A solution may be obtained to the equation below which can be programmed for an IBM 1620 computer.

$$[\tanh(T\exp(j\tau)) - C\exp(-j\zeta)T\exp(j\tau)]^2 = 0$$

Calling $\tanh(T\exp j\tau) = u + jv$ and $C\exp(-j\zeta)T\exp(j\tau) = x + jy$, we wish to solve the equation

$$G = (u - x)^2 + (v - y)^2 = 0,$$

where

$$u = \frac{\sinh(2T\cos\tau)}{\cosh(2T\cos\tau) + \cos(2T\sin\tau)} \qquad v = \frac{\sin(2T\sin\tau)}{\cosh(2T\cos\tau) + \cos(2T\sin\tau)}$$

$$x = CT(\cos(\tau - \zeta)) \qquad y = CT(\sin(\tau - \zeta))$$

G is thereby given by the equation

$$G = C^2T^2 + \frac{\cosh(2T\cos\tau) - \cos(2T\sin\tau)}{\cosh(2T\cos\tau) + \cos(2T\sin\tau)} - 2CT\frac{[\cos(\tau - \zeta)\sinh(2T\cos\tau) + \sin(\tau - \zeta)\sin(2T\sin\tau)]}{\cosh(2T\cos\tau) + \cos(2T\sin\tau)}.$$

Since any values other than the best ones cause the function G to increase, it was assumed that the function could be represented as a paraboloid of the form

$$G = A(T - T_0)^2 + B(T - T_0)(\tau - \tau_0) + D(\tau - \tau_0)^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

near the values T_0 and τ_0 which are the best values of the solution of the equation. The quantities A, B, D, may be eliminated and T_0 and τ_0 evaluated through the relations

$$\tau_0 = \tau - \left(\frac{\partial^2 G}{\partial T \partial \tau} \cdot \frac{\partial G}{\partial T} - \frac{\partial^2 G}{\partial T^2} \cdot \frac{\partial G}{\partial \tau}\right) \Big/ \left[\left(\frac{\partial^2 G}{\partial T \partial \tau}\right)^2 - \frac{\partial^2 G}{\partial \tau^2} \cdot \frac{\partial^2 G}{\partial T^2}\right]$$

$$T_0 = T - \left(\frac{\partial^2 G}{\partial T \partial \tau} \cdot \frac{\partial G}{\partial \tau} - \frac{\partial^2 G}{\partial \tau^2} \cdot \frac{\partial G}{\partial T}\right) \Big/ \left[\left(\frac{\partial^2 G}{\partial T \partial \tau}\right)^2 - \frac{\partial^2 G}{\partial \tau^2} \cdot \frac{\partial^2 G}{\partial T^2}\right].$$

Preliminary values of T and τ are read from the charts and first values of τ_0 and T_0 obtained. The process is repeated until values of τ_0 and T_0 within acceptable limits of the answer are obtained.

Analytical expressions for the first and second derivatives of the function G are very cumbersome. An attempt to obtain a solution by approximating these derivatives through small increments in the G function due to small increments in τ and T was not successful, as the computer gave answers which oscillated in value. It thus became mandatory to use the exact functions for these terms; these are set out below.

Derivatives of the Function G with respect to T and τ

$$\frac{\partial G}{\partial T} = [4(AD) - 2C(AX)(AA) - 4CT(AB)]\frac{1}{(AA)^2} + 2C^2T$$

$$\frac{\partial G}{\partial \tau} = [4T(AE) - 2CT(AF)(AA) + 4CT^2(AC)]\frac{1}{(AA)^2}$$

$$\frac{\partial^2 G}{\partial T \partial \tau} = [4(AE)(AA) - 2C(AF)(AA)^2 - 8T[\sin Q \sinh P(AA) - 2(AD)(AG)] + 4CT(AC)(AA) - 8CT^2[-(AZ)(AA) + 2(AB)(AG)]]\frac{1}{(AA)^3}$$

$$\frac{\partial^2 G}{\partial T^2} = [8(\cos Q \cosh P)(AA) - 16(AD)(AH) - 8C(AB)(AA) - 8CT[(AY)(AA) - 2(AB)(AH)]]\frac{1}{(AA)^3} + 2C^2$$

$$\frac{\partial^2 G}{\partial \tau^2} = [-4T(AD)(AA) + 8T^2[\cos Q \cosh P(AA) + 2(AE)(AG)] + 2CT(AX)(AA)^2 - 4CT^2(AB)(AA) - 8CT^3[(AY)(AA) - 2(AC)(AG)]]\frac{1}{(AA)^3}$$

$$(AA) = (\cosh P + \cos Q)$$
$$(AB) = (\cos Z + \cos Z \cos Q \cosh P + \sin Z \sin Q \sinh P)$$
$$(AC) = (\sin Z + \sin Z \cos Q \cosh P - \cos Z \sin Q \sinh P)$$
$$(AD) = (\sin \tau \sin Q \cosh P + \cos \tau \cos Q \sinh P)$$
$$(AE) = (\cos \tau \sin Q \cosh P - \sin \tau \cos Q \sinh P)$$
$$(AF) = (\sin Q \cos R - \sin R \sinh P)$$
$$(AG) = (\sin \tau \sinh P + \cos \tau \sin Q)$$
$$(AH) = (\cos \tau \sinh P - \sin \tau \sin Q)$$
$$(AX) = (\sin Q \sin R + \cos R \sinh P)$$
$$(AY) = (\cos R \cos Q \sinh P - \sin R \sin Q \cosh P)$$
$$(AZ) = (\cos R \sin Q \cosh P + \sin R \cos Q \sinh P)$$

where $P = 2T \cos \tau \qquad Q = 2T \sin \tau \qquad R = \tau - \zeta$

REACTION OF $N_2(A^3\Sigma_u^+)$ WITH ATOMIC NITROGEN[1]

ROBERT A. YOUNG
Stanford Research Institute, Menlo Park, California

Received October 26, 1965

ABSTRACT

Attempts to measure the actual lifetime of $N_2(A^3\Sigma_u^+)$ in active nitrogen resulted only in a very small upper limit of $\approx 5 \times 10^{-4}$ s. This result is consistent with quenching of the $A^3\Sigma_u^+$ state by atomic nitrogen in an atom–atom interchange process,

$$N + N_2(A^3\Sigma_u^+, v = 0) \rightarrow N_2(X^1\Sigma_g^+, v = 25) + N,$$

having a rate coefficient of $\gtrsim 2 \times 10^{-10}$ cm^3/molecule s. It is suggested that similar processes are involved in determining the distribution of excited states observed in atom association.

I. INTRODUCTION

Although Berkowitz *et al.* (1) showed that atomic nitrogen was the predominant reactive species in active nitrogen, several investigators (2) studying chemical reactions in discharged nitrogen have found it necessary to hypothesize other energy-rich species. In almost all instances this additional component of active nitrogen has been assumed to be the $A^3\Sigma_u^+$ state of N_2. However, emission from this state has never been detected in the reacting gas. In fact, spectrographic tests for its presence have been avoided except in one case (3) in which none was detected.

Usually these chemical reaction studies are done near the discharge ($\approx$0.1 s in travel time) which forms active nitrogen. It is known that large quantities of vibrationally excited N_2 exist just beyond the discharge (4) ($\approx$0.05 s) and probably are the major energy reservoir powering the pink nitrogen afterglow (5). Furthermore, their collisional deactivation rate coefficient (6) is $\approx 10^{-16}$ cm^3/s. In the light of this information it would appear that vibrationally excited N_2 is responsible for most of the observed chemical effects which require an excited species other than atomic nitrogen.

Experiments have indicated that the $A^3\Sigma_u^+$ state of N_2 has a radiative lifetime of $\tau \approx 20$ s and is not deactivated by nitrogen (7) ($k_Q < 10^{-18}$ cm^3/s). If this is correct there should be a detectable concentration of $A^3\Sigma_u^+$ molecules maintained by the recombination of atomic nitrogen. The flux of the 1st positive band of nitrogen whose lower state is $A^3\Sigma_u^+$ represents a lower bound to this rate of population. For example, if radiation is the only loss of $N_2(A^3\Sigma_u^+)$, and the recently measured (8) chemiluminescent recombination rate of N is applied to a steady state situation with [N] $\approx 10^{15}$ atoms/cm^3 and [N_2] $\approx 10^{17}$ molecules/cm^3, then

$$k[N]^2 = 10^{-17}[10^{15}]^2 = \frac{1}{\tau}[N_2(A^3\Sigma_u^+)]$$

and gives $[N_2(A^3\Sigma_u^+) = 2 \times 10^{14}$ molecules/cm^3 emitting 10^{13} photons/s cm^3 in the Vegard–Kaplan bands. If, however, processes other than radiation remove this species, then its steady state density will be lower and fewer metastable molecules could survive from the discharge to cause chemical effects.

It is of crucial interest to spectroscopically verify the presence or absence of large amounts of $N_2(A^3\Sigma_u^+)$ in discharge nitrogen within $\approx$0.1 s of the discharge and to obtain

For personal use only.

some limits on its rate of removal in a typical experimental situation. As the environment near the discharge is complicated by the pink glow, a study of the concentration further from the discharge seems more likely to give results analyzable into elementary processes. This experiment was performed.

II. EXPERIMENT

Nitrogen of various purities (starting from gas purified by passing over heated Ti–Zr turnings to which known amounts of impurities were added) was passed through a 100 W microwave discharge in a flow system previously described (9). The gas was viewed after ≈0.5 s through the quartz window of a 10 cm diameter, 100 cm long tube by a crossed-grating echelle spectrograph of ≈6 Å/mm plate factor and $f/1.0$ aperture. The nitrogen atoms were measured by NO titration and the spectrograph was calibrated for intensity when [O] = [N] by obtaining spectrograms of the NO bands excited in the process

[1] $$N + O + (M) \rightarrow NO^* + (M)$$

whose rate has been previously measured (9). Hence each experiment consisted of the following steps: (*a*) establish a stable pressure and determine the purity of the flowing gas, (*b*) establish a stable discharge (the microwave oscillator was incorporated into a power supply which regulated the cathode current to 0.1%), (*c*) titrate with NO to obtain $[N]_0$, (*d*) re-establish the conditions before titration, (*e*) time the long spectrographic exposure, (*f*) adjust the NO flow until [N] = (O), (*g*) take a sequence of timed spectrographic exposures, and (*h*) titrate with NO to again obtain $[N]_0$.

III. DATA REDUCTION

If reciprocity failure of the film (103 a-0) is not considered, if the time necessary to obtain an image of the (0,5) Vegard–Kaplan band (one of the strongest from $v' = 0$) is t_1, and if the exposure time to obtain an equally dense image of the $\gamma(0,3)$ NO band is t_2, then

$$I_{VK}(0,5) \approx k_1(\gamma(0,3))\frac{[N]_0^2}{4}\frac{t_2}{t_1} = \frac{[N_2(A^3\Sigma_u^+)_{v=0}]}{\tau}\frac{I_{VK}'(0,5)}{\sum_{v''} I_{VK}'(0,v'')}$$

where $I_{VK}'(0,v'')$ are the intensities of these bands in any uniform set of arbitrary units. A lower bound to the rate of $A^3\Sigma_u^+$ formation is the rate of emission of the first positive bands. This can be represented as

$$P = k_2[N]^2$$

where k_2 refers[2] to

[2] $$N + N + (M) \rightarrow N_2 + (M) + h\nu$$

If the rate of loss of $N_2(A^3\Sigma_u^+, v = 0)$ is $(A/\tau)[N_2(A^3\Sigma_u^+, v = 0)]$, then in a steady state

[3] $$fk_2[N]_0^2 \approx \frac{A}{\tau}\left(\frac{\tau\sum_{v''} I_{VK}'(0,v')}{I_{VK}'(0,5)}\right)k_1(\gamma(0,3))\frac{[N]_0^2}{4}\frac{t_2}{t_1}$$

or

[4] $$\frac{A}{\tau} \gtrsim \left(\frac{4k_2}{k_1(\gamma(0,3))}\right)\left(\frac{t_1}{t_2}\right)(f)\left(\frac{I_{VK}'(0,5)}{\tau\sum_{v''} I_{VK}'(0,v'')}\right)$$

where f is the fraction of all radiation which eventually leads to $A^3\Sigma_u^+$, $v = 0$, and $A/\tau = 1/\tau + k_Q[Q]$: k_Q is the rate coefficient for a reaction between Q and $N_a(A^3\Sigma_u^+)$. The last parenthesis of eq. [4] is $\approx 1/6\tau$ (11).

[2] *Young and Black (8) report values of* $k_{N_2} = 8 \times 10^{-18} + 1.2 \times 10^{-34}[N_2]$ *cm³/molecule-s;* $k_{N_2} = 5 \times 10^{-16} + 3.8 \times 10^{-33}[IIe]$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

If vibrational relaxation occurs before emission, $f \approx 1$. If electronic deactivation occurs more rapidly than vibrational relaxation, then $f \approx 0.3$ (12). Assuming the latter, we have

$$[5] \qquad \frac{A}{\tau} \gtrsim \frac{10^{-2}k_2}{k_1(\gamma(0,3))}\frac{t_1}{t_2}.$$

Corrections must still be applied because of film reciprocity failure.

Note that the actual value of [N] is not involved in eq. [5] because of the calibration procedure used. For a similar reason the spatial distribution of [N] and [O] is relatively unimportant—decay down the tube affects both the production rate and calibration of the spectrograph. If $A/\tau < 10$, this equation will not be applicable because a steady state has not yet been established.

IV. RESULTS

Under no circumstances were the Vegard–Kaplan bands ever observed in active nitrogen. The longest exposure was 240 h in 1% N_2 in He at 6 mm Hg with [N] $\approx 10^{13}$ atoms/cm^3 and [O] $\approx 10^{11}$. The $\gamma(0,3)$ band was detected in 1 min. Exposures of 50 h in 100% N_2 at 2 mm Hg with [N] $\approx 10^{15}$ atoms/cm^3 and [O] $\approx 10^{13}$ were also unsuccessful in obtaining any record of the Vegard–Kaplan bands when the $\gamma(0,3)$ NO band was detected in 30 s for [N] = [O]. Other combinations of parameters gave a similar result. Equation [5] gives $A/\tau \gtrsim 2.5 \times 10^2$/s for the 50 h exposure after correction for reciprocity failure (≈ 5), and substitution of $k_2 \approx 2 \times 10^{-17}$ cm^3/molecule s (8), $k_1\gamma(0,3) \approx 10^{-18}$ cm^3/molecule s.[3] Similar treatment of the 240 h exposure gives $A/\tau \gtrsim 2 \times 10^3$ with $k_2 = 1.3 \times 10^{-15}$, $k_1(0,3) \cong 10^{-18}$, and a correction factor of 10 for reciprocity failure. These results indicate that significant vibrational relaxation probably does not occur before electronic deactivation; hence the $v' = 0$ level of the $A^3\Sigma_u^+$ state is significantly populated only by direct emission from the $B^3\pi_g$ state.

V. DISCUSSION

The large value of A/τ derived from our measurements must be due to a gas collision process—diffusion of $N_2(A^3\Sigma_u^+)$ to the walls of the flow system cannot account for the measured A/τ, nor can such a large value result from an incomplete approach to a steady state. Since N_2 and He are inefficient quenchers of $N_2(A^3\Sigma_u^+)$, the most likely reaction removing this species is

$$[6] \qquad N + N_2(A^3\Sigma_u^+, v = 0) \rightarrow N_2(X^1\Sigma, v = 25) + N$$

i.e., atom–atom interchange. The maximum lower bound to the rate of this process can then be deduced from the He experiment

$$\frac{A}{\tau} \approx 2 \times 10^3 = k_6[N] = k_6[10^{13}]$$

i.e., $k_6 \gtrsim 2 \times 10^{-10}$ cm^3/s.

For any reaction other than [6] to account for the measured A/τ requires the presence of an unsuspected impurity in concentrations at least comparable to that of atomic nitrogen and probably much higher in view of the large value found for k_6. From past experience (8–10) this is considered extremely unlikely.

A review of the literature (7, 13) pertaining to observations of the Vegard–Kaplan bands revealed an inverse correlation of these bands and significant concentrations of

[3] *Young and Sharpless (10) report values of*

$$k\gamma(0,3) = 8.2 \times 10^{-19} + 2.4 \times 10^{-36}[N_2];\ k\gamma(0,3) = 8.2 \times 10^{-19} + 5 \times 10^{-37}[He].$$

For personal use only.

nitrogen atoms. Reaction [6] implies just this. The correlation found between a high intensity of the Vegard–Kaplan bands and the need for high purity nitrogen probably is due to the correlation between high purity and low atom production (14) rather than to direct quenching by impurities.

Reaction [6] is probably fast since selection rules are less restrictive for atom–atom interchange than in other processes and large internuclear distance changes between reactants and products are anticipated since this is a reaction coordinate. Reaction [6] may be another example where excess energy goes into vibration of a newly formed bond (15).

For initial vibrational levels higher than $v' = 6$ other electronic states (16) may be formed in reaction [6], although at room temperature one would expect as major products those states whose potential well was outside the reactant's potential well. The distribution of product states will, of course, be determined by the level structure of the unstable N_3 collision complex and the initial levels populated.

Other excited N_2 molecules can probably undergo reactions similar to [6], i.e.,

$$N + N_2(\alpha) \rightarrow N_2(\beta) + N$$

where energy and momentum are conserved but large changes in internuclear distance can occur. Such mechanisms are probably extremely important in determining the observed population of excited states in active nitrogen. Furthermore, since this mechanism may lead preferentially to the electronic ground state, it may account for the small number of electronically excited molecules found in atomic association in nitrogen, oxygen (10), and other diatomic molecules.

ACKNOWLEDGMENTS

The importance of atom-atom interchange reactions in removing $N_2(A^3\Sigma_u^+)$ was jointly realized by Dr. D. M. Hunten of the Kitt Park National Observatory and the author. I wish to thank Dr. Hunten for a stimulating discussion of it.

CHARGE TRANSFER IN THE RADIOLYSIS OF BINARY HYDROCARBON MIXTURES[1]

J. A. STONE, A. R. QUIRT,[2] AND O. A. MILLER
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario
Received October 5, 1965

ABSTRACT

The radiolysis of dilute solutions of ethane-d_6, propane-d_8, and *n*-butane-d_{10} in liquid hydrocarbons at 195 °K results in the production of D_2 and HD in amounts which are determined by the relative ionization potentials of solvent and solute. Solvents of higher ionization potential enhance the production of D_2 and HD from deuterated solutes of lower ionization potential. When the ionization potentials are in the reverse order the yields are diminished. This solute–solvent interaction, which is ionic in nature, is a general phenomenon in the radiolysis of mixtures of saturated hydrocarbons in the liquid phase and is consistent with charge transfer between solvent and solute.

INTRODUCTION

The radiolysis of saturated hydrocarbons yields hydrogen as a major product. The use of deuterated hydrocarbons (cyclohexane-d_{12} and methylcyclohexane-d_{14}) as aids to the study of the mechanism of hydrogen formation has been described by Dyne and Denhartog (1). They showed that the yield of deuterium (HD + D_2) from dilute solutions (~5 electron %) of a deuterated hydrocarbon in a hydrocarbon solvent was not governed solely by the concentration of the deuterated species. The solvent exerted a major effect on the yields, e.g., with *n*-pentane as solvent the yield of D_2 was ten times and the yield of HD was eight times greater than when *n*-decane was the solvent. Hardwick (2) showed that this effect of solvent could be correlated with the relative ionization potentials of the deuterated solute molecules and the solvent molecules. Taking the standard value as the yield of D_2 from a dilute solution of cyclohexane-d_{12} in cyclohexane, enhanced yields of D_2 were observed for solvents with ionization potentials greater than that of cyclohexane, while diminished yields were observed for solvents of lower ionization potential. This correlation with ionization potential was interpreted by Hardwick in terms of a charge transfer mechanism. However, the ionization potentials of the two deuterated hydrocarbons used by Dyne and Denhartog, methylcyclohexane-d_{14} (9.85 ± 0.03 eV) and cyclohexane-d_{12} (9.88 ± 0.02 eV) are essentially the same (3), while the range in ionization potentials of the hydrocarbon solvents used is small (~0.5 eV). The lower hydrocarbons, ethane, propane, and *n*-butane, have wide and clear-cut differences in ionization potentials, viz. ethane 11.65 eV, propane 11.08 eV, and *n*-butane 10.63 eV (4). Using these hydrocarbons as solvents and their deuterated analogues as solutes, we have determined that this effect of solvent on the radiolysis of dilute solutions of hydrocarbon solute is a general phenomenon in the radiolysis of saturated hydrocarbons in the liquid phase. However, although our results are qualitatively in agreement with Hardwick's theory, we did not obtain quantitative agreement with the simple theory.

For the series of hydrocarbons chosen the most convenient temperature for carrying out experiments in the liquid phase is that of a solid CO_2/ethanol mixture (195 °K).

EXPERIMENTAL

Materials and Sample Preparation

The deuterated hydrocarbons, ethane-d_6, propane-d_8, and n-butane-d_{10}, all with a minimum isotopic purity of 98 atom % D, were from Merck Sharp & Dohme of Canada Ltd. The hydrocarbons ethane, propane, butane, cyclopentane, n-hexane, and methylcyclohexane were Phillips Research Grade.

Solutions of from 1.5 to 18 electron % deuterated hydrocarbon were made up in protiated hydrocarbons so that the liquid sample sizes were ~1.5–2.0 ml at 195 °K. The hydrocarbons were degassed by trap-to-trap distillation before being passed into the irradiation vessels. These were cylindrical Pyrex tubes 4 ml in volume with long necks (15 cm of narrow-bore tubing) which were sealed off at their upper ends after the sample was introduced.

Irradiation and Product Analysis

The samples were irradiated at 195 °K in a ^{60}Co γ-source at a dose rate of 2.3×10^{22} eV/l h (as measured in the Fricke dosimeter taking $G(Fe^{3+}) = 15.5$) to a total dose of 4.6×10^{22} eV/l. The cells were opened for analysis by breaking the narrow neck of the sample tube by means of flexible bellows attached to the analytical vacuum line. The hydrogen produced was removed from the frozen samples and measured by conventional methods. Solid nitrogen traps ensured that only hydrogen and methane were collected and measured. The total hydrogen content and the isotopic composition of this hydrogen were determined mass spectrometrically.

RESULTS

The yields of hydrogen from the radiolysis of liquid ethane, propane, and n-butane at 195 °K and a total dose of 4.6×10^{22} eV/l are shown in Table I.

TABLE I

Hydrogen yields from liquid ethane, propane, and n-butane at 195 °K (4.6×10^{22} eV/l)

Hydrocarbon	$G(H_2)$
Ethane	3.75±0.15
Propane	4.25±0.25
n-Butane	4.00±0.15

Gillis (5) found that $G(H_2)$ for liquid ethane at 195 °K was constant over the dose range $2 \times 10^{22} - 10 \times 10^{22}$ eV/l. The value of 3.75 in Table I is consistent with the value of 3.60 given by Gillis for 3 MeV X-rays. However, he reported a value of 3.36 for ^{60}Co gammas but could offer no explanation for the difference between the two values.

The addition of small quantities (from 1.5 to ~4.5 electron %) of the deuterated hydrocarbons to any of the above hydrocarbons resulted in the production of HD and D_2 in addition to H_2. In these very dilute solutions the yields of HD and D_2 were, within experimental error, linear up to ~4.5 electron % of deuterated solute. In the case of n-butane-d_{10} in ethane, which system showed the highest yields of D_2 and HD for a given electron fraction of deuterated solute, this linearity did not extend much above 3 electron % solute. Typical results are shown in the first two figures. Figure 1 shows the D_2 yields from dilute solutions of n-butane-d_{10} in ethane, propane, n-butane, cyclopentane, methylcyclohexane, and n-hexane. Figure 2 shows the corresponding HD yields.

Using the notation of Dyne and Denhartog (1), $G(D_2)$ extrapolated to 100 electron % deuterated hydrocarbon will be defined as $G_1(D)$ while the corresponding extrapolated value of $G(HD)$ will be defined as $g(HD)$. The results for all experiments in which low concentrations of deuterated solutes in protiated solvents were used are summarized in Table II. The ionization potentials, P_1, of the various solvents shown in the fifth column are from photoionization determinations of Watanabe (4).

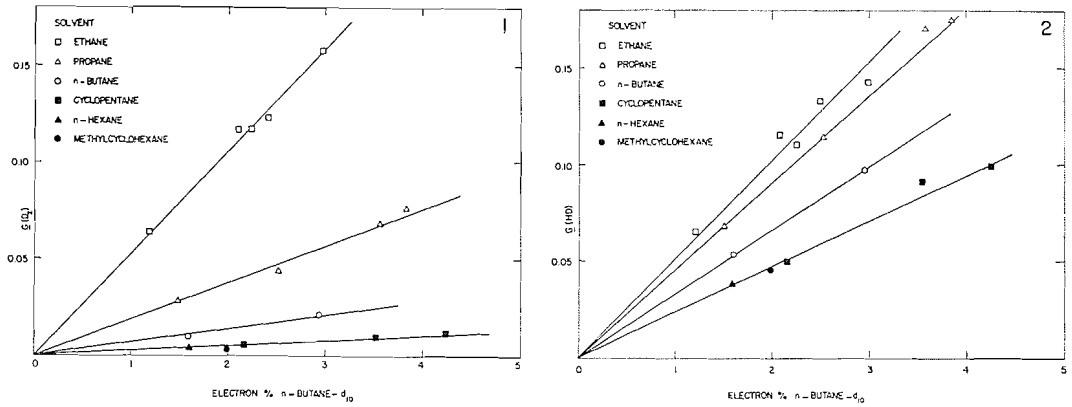

FIG. 1. D_2 yields from dilute solutions of n-butane-d_{10} in various hydrocarbons at 195 °K.
FIG. 2. HD yields from dilute solutions of n-butane-d_{10} in various hydrocarbons at 195 °K.

TABLE II

G_i(D) and g(HD) for deuterated solutes in protiated solvents

Solute	Solvent	G_i(D)	g(HD)	P_i of solvent, eV
C_2D_6	C_2H_6	0.75	2.40	11.65
C_2D_6	C_3H_8	0.35	2.18	11.08
C_3D_8	C_2H_6	3.05	4.73	11.65
C_3D_8	C_3H_8	0.50	3.25	11.08
C_3D_8	n-C_4H_{10}	0.35	2.40	10.63
n-C_4D_{10}	C_2H_6	5.28	5.17	11.65
n-C_4D_{10}	C_3H_8	1.92	4.57	11.08
n-C_4D_{10}	n-C_4H_{10}	0.70	3.33	10.63
n-C_4D_{10}	c-C_5H_{10}	0.28	2.40	10.09

The results of single experiments with n-butane-d_{10} in n-hexane and methylcyclohexane (shown in Figs. 1 and 2) were essentially the same as those obtained with cyclopentane as solvent.

As the concentration of solute is increased, the HD and D_2 yield curves must depart from linearity. This is shown in Figs. 3 and 4 where the yields of D_2 and HD from all three deuterated solutes in ethane as solvent are plotted over the solute concentration range 1–18 electron %.

To gain further insight into the mechanism of the solvent–solute interaction two further experiments were performed.

(i) The addition of 0.32 electron % ammonia to a solution containing 3.8 electron % n-butane-d_{10} in ethane reduced G(HD) to 0.114 from 0.190 and $G(D_2)$ to 0.053, also from 0.190.

(ii) The addition of 0.98 electron % sulfur hexafluoride to a solution of 3.00 electron % n-butane-d_{10} in ethane in the liquid phase at 195 °K resulted in a lowering of the total hydrogen yield from 3.75 to 2.36. This lowered yield was composed of $G(H_2) = 2.25$, G(HD) = 0.091, and $G(D_2) = 0.024$.

DISCUSSION

A true measure of the effect of solvent on the radiolytic yields of D_2 and HD could be obtained if it were possible to measure these yields in a system where no solvent–solute interaction of the type under study occurred. Such a system probably does not exist.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

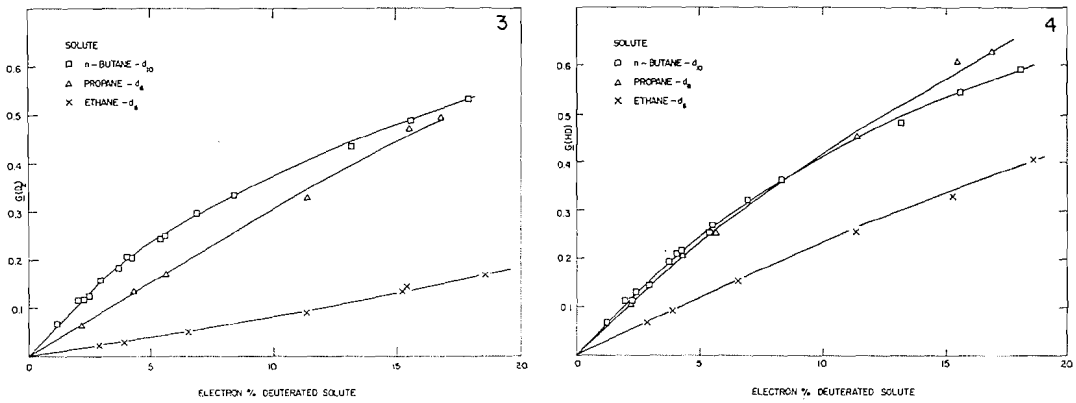

FIG. 3. D_2 yields from n-butane-d_{10}, propane-d_8, and ethane-d_6 in ethane at 195 °K.
FIG. 4. HD yields from n-butane-d_{10}, propane-d_8, and ethane-d_6 in ethane at 195 °K.

However Table II shows that when a deuterated solute is irradiated in the corresponding protiated hydrocarbon e.g. n-butane-d_{10} in n-butane, then the values of $G_1(D)$ and $g(HD)$ are similar for the three solutes used. $G_1(D)$ ranges from 0.50 to 0.75 and $g(HD)$ from 2.40 to 3.33. For purposes of comparison between the different solutes, we have therefore taken these values of $G_1(D)$ and $g(HD)$ as the standard values, e.g. for propane-d_8 the standard values are 0.50 and 3.25. Any deviations from these standard values with change of solvent will be used to assess the effect of solvent on the radiolysis of the deuterated solute. By this choice of standard states we do not wish to imply that the systems used to define the states are ideal and obey the "mixture law". The similarity of the standard values for all these deuterated solutes is indicative of similar modes of hydrogen formation. Intercomparisons of the radiolysis of these three deuterated solutes in different solvents should therefore be meaningful.

$G_1(D)$ and $g(HD)$ for all three deuterated solutes depart significantly from their standard values with change of solvent. Table III shows the differences, $\Delta G_1(D)$ and $\Delta g(HD)$, between the values of $G_1(D)$ and $g(HD)$ in a given solvent and the standard values for the solute used. The values of ΔP_i, the difference in ionization potential between solvent and solute, are given in the last column. We have computed these differences on the assumption that the ionization potential of a deuterated molecule is the same as that of the corresponding protiated molecule. The limitation of this assumption is discussed later.

An immediate general conclusion is that the results are consistent with Hardwick's prediction: when the solvent has the higher ionization potential, $\Delta G_1(D)$ and $\Delta g(HD)$

TABLE III

Changes in $G_1(D)$ and $g(HD)$ with change of solvent

Solute	Solvent	$\Delta G_1(D)$	$\Delta g(HD)$	ΔP_i, eV
C_2D_6	C_2H_6	0	0	0
C_2D_6	C_3H_8	−0.40	−0.22	−0.57
C_3D_8	C_2H_6	2.55	1.48	0.57
C_3D_8	C_3H_8	0	0	0
C_3D_8	n-C_4H_{10}	−0.15	−0.85	−0.45

For personal use only.

are both positive, but when the solute has the higher ionization potential, they are both negative.

Three facts lead us to the conclusion that the observed solvent–solute interaction is ionic in nature.

(i) The relative ionization potentials of solvent and solute tell whether "activation" or "deactivation" of the deuterated solute occurs.

(ii) The enhanced yields of D_2 and HD from *n*-butane-d_{10} in ethane are depressed by the addition of ammonia, which is known to have a very high proton affinity in the gas phase (6) and has also been shown to be effective in inhibiting the cationic polymerization of cyclopentadiene in the liquid phase via a proton transfer mechanism (7). Williams (8) has discussed the competition between proton transfer and charge neutralization in the case of the radiolysis of liquid cyclohexane containing ammonia-d_3. His arguments should be equally applicable to the present case with the additional possibility of charge transfer between hydrocarbon molecular ions and ammonia (photoionization potential = 10.23 eV (4)).

(iii) The addition of sulfur hexafluoride, an efficient electron scavenger (9), depresses $G(H_2)$ for ethane but at the same time inhibits the effect of this solvent on the radiolytic production of D_2 and HD from *n*-butane-d_{10}. For 0.98 electron % SF_6, $G_1(D) = 0.80$ and $g(HD) = 3.03$. Even allowing for a reduction in total hydrogen yield from 3.75 to 2.36, these values are much closer to the standard values for *n*-butane-d_{10} ($G_1(D) = 0.70$ and $g(HD) = 3.33$) than those obtained in the absence of SF_6 ($G_1(D) = 5.28$, $g(HD) = 5.17$).

In the region of low solute concentration shown in Figs. 1 and 2, G(total hydrogen) i.e. $G(H_2 + HD + D_2)$ remained constant within experimental error and was equal to $G(H_2)$ for the pure solvent. At higher solute concentrations G(total hydrogen) did decrease measureably as might be expected since $G(D_2 + HD)$ for the pure deuterated solutes was ~3.1. The enhanced yields of HD and D_2 found in the "activating" solvents are therefore obtained at the expense of H_2 production from the solvent. The enhanced yields do not arise from excited solvent species which do not lead to hydrogen formation in the radiolysis of the pure solvent. These results are qualitatively in agreement with Hardwick's mechanism outlined by reactions [1] to [6] i.e. charge transfer competing with charge neutralization. Charge transfer is assumed to occur with 100% efficiency when the appropriate reactants collide, i.e. it is governed by the normal laws of diffusion in the liquid phase.

[1] $$R_1H \rightsquigarrow R_1H^+ + e$$

[2] $$R_2D \rightsquigarrow R_2D^+ + e$$

[3] $$R_1H^+ + R_2D \rightarrow R_1H + R_2D^+$$

[4] $$R_2D^+ + R_1H \rightarrow R_2D + R_1H^+$$

[5] $$R_1H^+ + e \rightarrow [R_1H]^* \rightarrow H_2 \text{ or HD}$$

[6] $$R_2D^+ + e \rightarrow [R_2D]^* \rightarrow D_2 \text{ or HD}$$

Reactions [5] and [6] are written to show that the solvent–solute interaction we are studying affects both the first and second order yields of hydrogen i.e. affects both H_2 and D_2 produced in first order processes and H_2 and HD produced in second order processes (we neglect a second order yield of D_2 at the low concentrations of deuterated solutes employed). Dyne (10) has concluded that the enhanced yields of D_2 and HD from cyclohexane-d_{12} in various solvents arise from a common precursor, namely, the

cyclohexane-d_{12} molecular ion. The effect of ammonia and sulfur hexafluoride on the yields of HD and D_2 from *n*-butane-d_{10} in ethane is consistent with such a designation.

Reactions [1] and [2] have been written with the implication that only molecular ions are of importance in the solvent–solute interaction. Fragment ions of general formula $C_nH^+_{2n+1}$ have ionization potentials too low for charge transfer with solvent molecules to be exothermic.

Reactions [3] and [4] are of course mutually exclusive for a given solvent–solute system, only that reaction which is exothermic being allowed.

The results may be conveniently divided into two groups (see Table III) according to whether (*a*) the solvent increases $G_1(D)$ and $g(HD)$ above the standard values (activating solvents) or (*b*) the solvent decreases $G_1(D)$ and $g(HD)$ below the standard values (deactivating solvents).

(a) Activating Solvents

Only three systems were studied in which activation of the solute occurred, viz, *n*-butane-d_{10} in ethane, *n*-butane-d_{10} in propane, and propane-d_8 in ethane. These were of course the only systems used in which the solvent had the higher ionization potential. The results are qualitatively consistent with the charge transfer mechanism outlined by eqs. [1]–[6] but are not quantitatively in agreement with such a simple mechanism.

In an activating solvent an electron is transferred to the solvent ion from the solute, which is in low concentration (reaction [3]). Charge transfer as outlined by reactions [1] to [6] will depend simply upon the diffusion rates of the reacting species and the sign of the difference in ionization potential between solvent and solute. The absolute magnitude of the difference in ionization potential plays no part. The results obtained are not consistent with such a simple behavior.

(i) It would be expected that two deuterated solutes irradiated in the same activating solvent would yield very similar values of $G_1(D)$ and $g(HD)$. However, *n*-butane-d_{10} gives higher yields of D_2 and HD ($G_1(D) = 5.28$ and $g(HD) = 5.17$) than does propane-d_8 ($G_1(D) = 3.05$ and $g(HD) = 4.73$) in the same solvent, ethane. It would appear then that charge transfer to *n*-butane-d_{10} is about twice as efficient as to propane-d_8. The greater diffusion rate of propane-d_8 in ethane should actually lead to slightly higher values of $G_1(D)$ and $g(HD)$ than those for *n*-butane-d_{10} (the plotting of Figs. 1 and 2 in terms of electron fraction compensates for the difference in geometrical size between the two solute molecules).

(ii) $G(D_2 + HD)$ is much greater for the radiolysis of *n*-butane-d_{10} in ethane than in propane. The diffusion rates of the reactants in ethane will be greater than those of the reactants in propane but this will probably not be sufficient to account for the large difference in yields.

(iii) Throughout this discussion we have assumed that the ionization potential of a deuterated molecule is exactly the same as that of the corresponding protiated molecule. This is certainly not the case for methane and methane-d_4 which have photoionization potentials of 12.71 and 12.87 eV respectively (11). The ionization potentials of the deuterated molecules we used have not been determined but presumably they show similar small differences from those of the corresponding protiated hydrocarbons. This means that in theory any protiated hydrocarbon should be a deactivating solvent for the corresponding deuterated hydrocarbon. However, we have shown that for all three deuterated hydrocarbons the values of $G_1(D)$ and $g(HD)$ can be reduced in deactivating solvents below the standard values. This implies that small differences in ionization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

potential (~0.1 eV) may not be sufficient to ensure that charge transfer occurs at every collision.

Libby (12) has discussed the role of the Franck–Condon principle in determining the rates of electron transfer between aqueous ions in different valence states. On the basis of his argument, resonance charge exchange between a hydrocarbon ion and the same hydrocarbon molecule, both in the ground state, is forbidden (13). Vibrational excitation of the ion will help to overcome the Franck–Condon restriction as will a difference in ionization potential between electron donor and acceptor molecules. Most ions will be formed in vibrationally excited states but relaxation soon occurs. The extent to which charge transfer occurs in a given system will therefore be governed by the difference in ionization potential of donor and acceptor molecules and the extent of vibrational excitation of the ion at the instant that charge transfer occurs.

In activating solvents at low solute concentrations the absolute difference in ionization potential will play the major role in overcoming the Franck–Condon restriction. Since relaxation is rapid, the contribution from ionic excitation assumes importance only as the concentration of the solute increases. Figures 3 and 4 show that at low solute concentrations $G(D_2 + HD)$ for *n*-butane-d_{10} in ethane is greater than that for propane-d_8 in ethane because of the more favorable difference in ionization potentials. At ~20 electron % solute, when each solvent molecule is in contact with at least one solute molecule, charge transfer can occur before ionic relaxation. In this case the values of $G(D_2 + HD)$ are practically the same for both systems. Similarly, the difference in yield of $(D_2 + HD)$ for low concentrations of *n*-butane-d_{10} in propane and ethane reflects the differences in ionization potential between solvent and solute, ionic excitation playing a minor role. These results are in agreement with those reported by Guarino and Hamill (14), who found that the degree of positive charge transfer from an organic glass to different solutes in low concentration depended upon the magnitudes of the differences in ionization potential between solvent and solute.

(b) Deactivating Solvents

In the deactivating solvents used, charge transfer from solute to solvent is always favored, since the difference in ionization potential is significant ($\leqslant$0.45 eV) and the vibrationally excited solute ion is surrounded by eligible electron donors. Charge transfer therefore readily competes with charge neutralization. Figures 1 and 2 show that when *n*-butane-d_{10} is irradiated in solvents of lower ionization potential the yields of HD and D_2 are practically the same regardless of the solvent. That the yield of D_2, which is produced in a first order reaction, is not zero in these deactivating solvents means that it must be produced in a process (or processes) not susceptible to charge transfer, e.g. molecular elimination from excited, non-ionized molecules.

As stated before, a protiated hydrocarbon solvent should be a deactivating solvent for the corresponding deuterated solute. However, deactivation is not complete. Even though excitation of the solute ion favors charge transfer, the free energy requirements are not fully met in all cases. It would appear that in deactivating solvents, for small differences in ionization potential between solvent and solute, the degree of charge transfer is dependent to a great extent on the absolute magnitude of ΔP_1. When $\Delta P_1 \simeq 0.45$ eV this dependence vanishes.

EXCESS VOLUMES, VAPOR PRESSURES, AND RELATED THERMODYNAMIC PROPERTIES OF THE SYSTEM ACETONE–CHLOROFORM–BENZENE, AND ITS COMPONENT BINARY SYSTEMS

A. N. Campbell, E. M. Kartzmark, and R. M. Chatterjee
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received October 28, 1965

ABSTRACT

The volume changes on mixing of the three binary mixtures, acetone–chloroform, benzene–chloroform, acetone–benzene, and the ternary mixture, acetone–chloroform–benzene, and their molar refractivities and viscosities, were determined.

Determinations of total and partial vapor pressures were made. The systems acetone–chloroform and benzene–chloroform show negative deviations from Raoult's law. The system acetone–benzene shows positive deviations.

The excess Gibbs free energies of mixing have been calculated for all systems. By combining these data with previously measured heats of mixing (1), the excess entropy has also been calculated. The curves representing zero excess volume, zero heat of mixing, zero excess free energy of mixing, and zero excess viscosity as functions of composition in the ternary system do not coincide. It, therefore, must be concluded that they result from compensating effects and do not represent ideality.

INTRODUCTION

Campbell, Kartzmark, and Friesen (1) found a curve of zero heat of mixing in the system acetone–chloroform–benzene at 25°. We have now determined the volume changes on mixing to find whether the curve of zero volume of mixing coincided in composition with the former curve. The total and partial vapor pressures were determined at 25°. These measurements in conjunction with the previous heat of mixing data complete the thermodynamic description of the system. The excess Gibbs free energy and the product TS^E, where S^E is the excess entropy, are obtained by standard methods. Since a compound is known to be formed in the system acetone–chloroform, it was thought advisable to determine also the densities, refractive indices, and viscosities over the whole ternary system.

EXPERIMENTAL

Purification of Materials

Acetone

Spectranalyzed acetone (A.C.S.) from the Fisher Scientific Company was dried with calcium chloride and then subjected to distillation after adding potassium permanganate to remove any nonaqueous impurities. The distillate collected was again dried by means of calcium chloride and distilled once again without adding potassium permanganate. Care was taken to avoid unnecessary exposure to air and freshly distilled acetone was used for each measurement.

Chloroform

Chloroform (A.C.S.) from the Fisher Scientific Company was purified to remove ethanol. Repeated extraction with concentrated sulfuric acid and final washing with distilled water removed ethanol completely. Chloroform was dried over anhydrous calcium chloride and then finally distilled from anhydrous phosphorus pentoxide, twice, in air. The purified reagent was stored in the dark. The sample purified in this manner could not be kept for more than a week. Fresh treatments were made every week.

Benzene

Thiophene-free benzene (A.C.S.) from the Fisher Scientific Company was frequently shaken with concentrated sulfuric acid until the yellow color in the acid layer disappeared. It was then washed with a solution of sodium bicarbonate and water, and the product then dried with anhydrous sodium sulfate and sodium. Finally it was distilled twice from sodium.

Method of Analysis

Theoretically, the composition of a ternary mixture may be obtained from a knowledge of any two physical properties. It is necessary first to prepare calibration curves of the physical properties for all proportions,

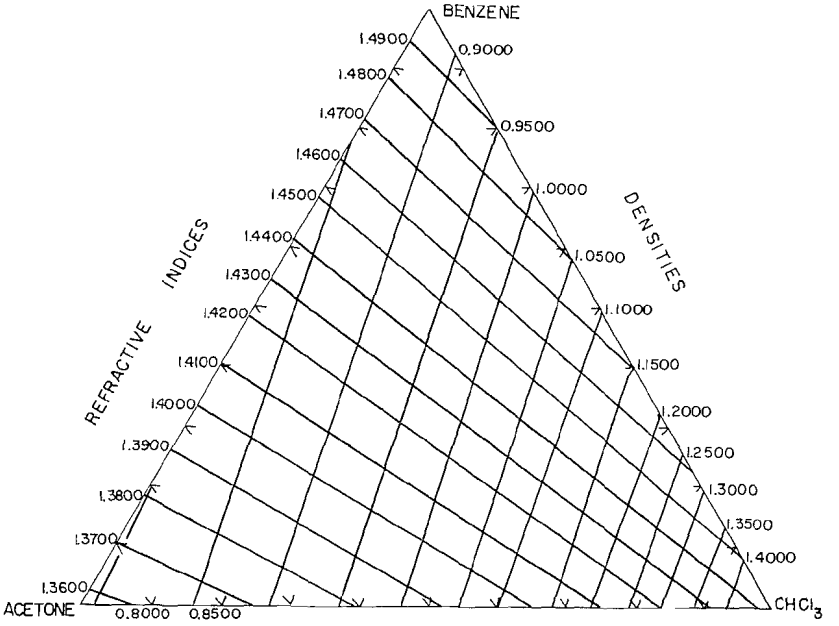

FIG. 1. Curves of equal density and refractive index. System acetone–chloroform–benzene at 25 °C.

and express the results on a triangular diagram in the form of curves of equal values. In practice, the physical quantities chosen must: (*a*) be easily and accurately determinable, (*b*) vary largely for small changes in concentration, and (*c*) exhibit a graphical behavior such that curves of the different properties intersect one another at a sharp angle. We found refractive index and density to satisfy these requirements. Figure 1 reproduces the data. Our densities are accurate to ±0.0001 g/cc. Densities and refractive indices were measured on 55 ternary mixtures as well as on 47 binary mixtures, in order to obtain the calibration plot of Fig. 1. The accuracy of the refractive index measurements was ±0.0001.

Volume Change on Mixing

The change in volume on mixing is very small and attempts to determine this from density measurements result in serious error. We therefore used the method of Brown and Smith (2), which measures V^E directly. We modified their apparatus by introducing a 2 mm bore stopcock at the filling end of the apparatus, instead of the ground stopper used by them. The advantage of this is that several cells are no longer required to cover the whole composition range, since with the stopcock the mercury can be adjusted at different levels in the two limbs. The accuracy of the method is about ±0.003 cc/mole.

Vapor Pressure, Vapor Composition, and Partial Pressure

The air saturation method was used for the determination of the composition of the equilibrium vapor but not for the determination of total vapor pressure, since the precautions to be taken and the corrections applied are extensive when the method is used for this purpose. Total vapor pressure was therefore determined manometrically, to ±0.1 mm. Details of the method are given in a paper by Campbell, Kartzmark, and Gieskes (3).*

Viscosity

Viscosities were determined with Cannon- and Fenske-type viscometers.

Refractive Index and Molar Refraction

An Abbe refractometer with temperature control at 25° ± 0.1° and a sodium arc lamp were used.

RESULTS

The experimental data are so extensive that they have been compiled in the following tables which are to be found in the depository.†

**For more complete details see the M.Sc. theses of J. M. T. M. Gieskes (1962) and R. M. Chatterjee (1965), University of Manitoba.*

Table I. Excess volumes in binary systems at 25 °C.

Table II. Partial molar volumes in the binary systems.

Table III. Excess volume data for the system acetone–chloroform–benzene at 25 °C.

Table IV. Viscosity data at 25 °C in the system acetone–benzene–chloroform.

Table V. Partial pressures obtained with Von Zawidski's treatment in the system acetone–chloroform at 25 °C.

Excess Volume

The quantities $\bar{V}^E = (\bar{V} - \bar{V}^0)$ have an uncertainty of ± 0.01 cc/mole.

To find the excess volumes for the ternary system, solutions of chloroform and of acetone in a fixed amount of benzene were mixed. In this way, we found V^E's for pseudobinary systems containing respectively 0.10, 0.20, 0.25, 0.30, 0.40, 0.50, 0.60, and 0.70 mole fraction benzene. From these and the data for the true binary systems, it is possible to calculate two curves of zero excess volume of mixing. These are shown in Fig. 2, on which also the curve of $G^E = 0$, as well as the curve of $H^E = 0$, are expressed as dotted curves.

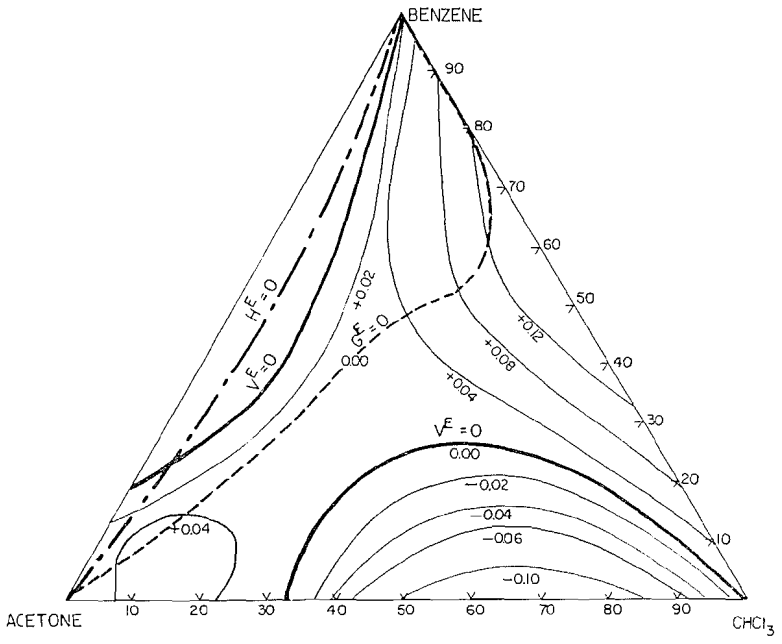

FIG. 2. Curves of equal excess volume. System acetone–benzene–chloroform at 25 °C.

Viscosity

Figure 3 is a ternary plot of lines of equal excess viscosity, including that of $\eta^E = 0$.

Vapor Pressure

For the calculations of activity coefficients and total excess free energies in Table VI the following formulae were used:

$$\mu^E_{\text{acetone}} = RT \ln \frac{P_{\text{acetone}}}{x_{\text{acetone}} P^0_{\text{acetone}}}$$

$$G^E = x_{\text{acetone}} \mu^E_{\text{acetone}} + x_{\text{chloroform}} \mu^E_{\text{chloroform}}$$

The H^E values of Campbell and Kartzmark (4) and the values of TS^E calculated from $TS^E = H^E - G^E$ have been obtained.

These three excess quantities for acetone–chloroform are represented graphically in Fig. 4. The partial pressure data have been treated by the Zawidzki method (5). For the calculation of the constants α and β the total pressure data were used and approximations applied until the values satisfied the experimental results. Observed and calculated partial pressures were compared. Figures 5 and 6 show the excess thermodynamic functions in the systems benzene–chloroform and acetone–benzene. Table VII gives the total and partial pressures for the system benzene–acetone–chloroform and the activity coefficients and total excess Gibbs free energy for the system. From the data for total excess Gibbs free energy, the curve of $G^E = 0$ has been interpolated and is given in Fig. 2.

DISCUSSION

A. The System Acetone–Chloroform

Volume contraction on mixing occurs up to about 68 mole % acetone, after which V^E changes sign. A maximum value of V^E of $+0.05$ cm³/mole occurs at 86 mole % acetone and a minimum of -0.152 cm³/mole at 32 mole % acetone. The partial molal excess volume of acetone passes through a maximum and that of chloroform through a minimum when the molar ratio is approximately unity. These results are in agreement with those of Hubbard (6).

This system shows marked positive deviation of viscosity with a maximum at 60 mole % chloroform. The total vapor pressure also shows the greatest deviation at this concentration. Beckmann and Faust (7) agree with our viscosity findings but state that the maximum disappears at higher temperatures. Our data for compositions of equilibrium liquid and vapor show that this system exhibits azeotropic behavior at 25°. The strong negative deviations from Raoult's law imply that G^E is strongly negative, as is found to be the case.

Figure 4 shows that the curves for all thermodynamic excess functions are unsymmetrical. Haase (8) has pointed out that experimental results in general seem to indicate that the function $V^E(x)$ has a behavior similar to that of $S^E(x)$. Clearly this is not true of the system acetone–chloroform. Gieskes (9) has recently reported a similar deviation in the system acetic acid – chloroform and Scott *et al.* (10) for the system 1-hydro-*n*-perfluoroheptane – acetone. Scott and his co-workers observed a very large positive V^E and a negative S^E.

Campbell and Kartzmark (4) have proved the existence of a 1:1 compound between acetone and chloroform and it is probably the formation of this compound that accounts for the negative deviation from Raoult's law and the considerable heat of mixing. The contraction of volume on mixing, however, can scarcely be attributed to this cause, since Campbell and Kartzmark (in press) find a much more pronounced negative V^E in the system bromoform–acetone, where the tendency to compound formation is certainly less, whereas Stavely, Tupman, and Hart (11) and Hubbard (6) found that for the present system the volume contraction increases with rising temperature, despite the fact that the dissociation of the compound must also increase.

B. The System Benzene–Chloroform

This system exhibits an increase of volume on mixing. The excess partial molar volume curves are not symmetrical.

The viscosity shows a minimum at 33 mole % chloroform but no conclusion can be drawn from this.

When the results of Table VI are plotted it is apparent that there is no azeotropic point in this system, but a slight negative deviation from Raoult's law. According to Reeves and Schneider (12) large total shift of the chloroform proton signal in benzene solution is indicative of complex formation between chloroform and the aromatic hydrocarbon, but Campbell, Kartzmark, and Friesen (1) failed to detect compound formation in the solid state in their study of the freezing point diagram.

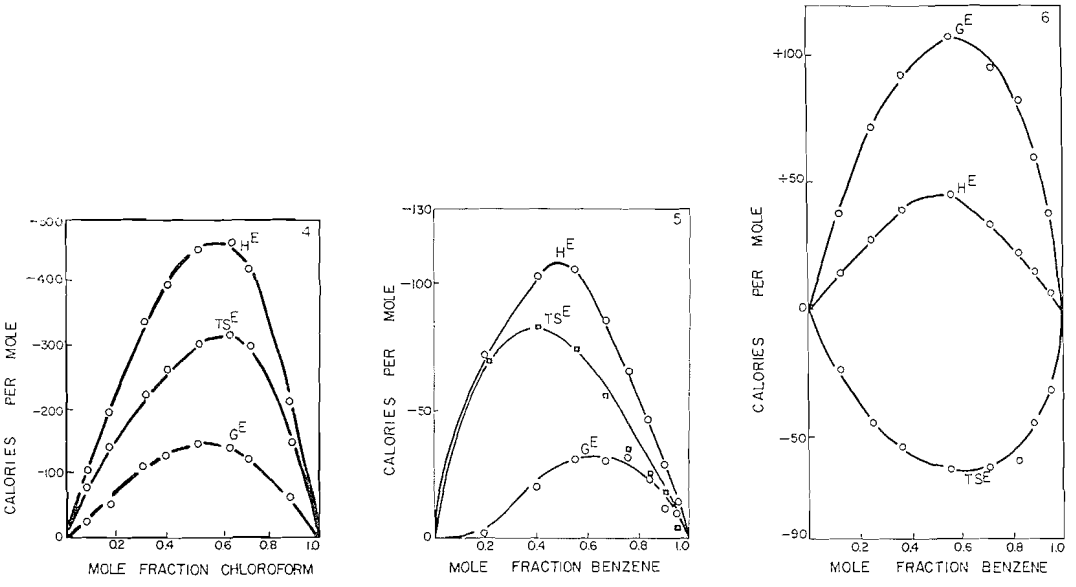

FIG. 4. Excess thermodynamic functions. System acetone–chloroform at 25 °C.
FIG. 5. Excess thermodynamic functions. System benzene–chloroform at 25 °C.
FIG. 6. Excess thermodynamic functions. System acetone–benzene at 25 °C.

All the thermodynamic functions of Fig. 5 are negative but V^E is positive throughout. Our values are in disagreement with the results of Schmidt (13) who used a pycnometric method.

C. The System Acetone–Benzene

This system shows contraction on mixing up to relatively high acetone concentration, followed by expansion over a small region of concentration: the region of positive V^E has not previously been observed. The results of Harms (14), of McCombie, Roberts, and Scarborough (15), and of Ebersole (16), as well as measurements of Brown and Smith (17), are in reasonably good agreement with ours. None, however, has observed the region of positive ΔV. In the case of Brown and Smith, who used the same direct method as ourselves, this is due to their not having pushed their measurements beyond 88.8 mole % acetone.

The viscosity shows negative deviation from straight line behavior. When the data of Table VI are plotted, in the usual way, it is apparent that the vapor pressures show positive deviation from Raoult's law, but no azeotrope.

D. The System Acetone–Chloroform–Benzene

Figure 2 shows that in the ternary system there are two curves, along which the excess volume, V^E, is equal to zero. The curve of zero heat of mixing obtained by Campbell, Kartzmark, and Friesen (1) does not coincide with either of the $V^E = 0$ curves. Neither semi-ideality nor pseudo-ideality exists in this system. The existence of curves of zero excess volume must be due to opposing deviations from ideality in the constituent binary systems. The partial and total vapor pressures show both negative and positive deviation (Table VII). The excess Gibbs free energy has been calculated and the interpolated curve of $G^E = 0$ appearing in Fig. 2 shows the compensating effects of the binary systems. The concentrations for which $G^E = 0$ do not coincide either with those for which $H^E = 0$ or $V^E = 0$ or $\eta^E = 0$. The obvious conclusion is that the $V^E = 0$, $H^E = 0$, $G^E = 0$, and $\eta^E = 0$ curves occur in the ternary system as a result of compensating effects of the respective functions in the respective binary systems. Since they do not coincide, the system cannot be considered as even semi-ideal. The ternary freezing point diagram of Campbell, Kartzmark, and Friesen (1) shows that the compound between acetone and chloroform continues to exist in the ternary system.

The excess viscosity is plotted in Fig. 3 in the form of curves of equal excess viscosity. A curve of $\eta^E = 0$ is shown. The excess viscosity is defined as the actual viscosity minus the $\sum x_i \eta_i^0$, where x_i = mole fraction and η_i^0 = viscosity of pure liquid.

THE KINETICS OF THE THERMAL DECOMPOSITION OF PYRITE

A. W. COATS[1] AND NORMAN F. H. BRIGHT
Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada
Received December 16, 1965

ABSTRACT

The kinetics of the thermal decomposition of purified pyrite to pyrrhotite and sulfur in a dynamic argon atmosphere have been studied over the temperature range 600 to 653 °C. The reaction was followed by the rate of weight loss as indicated by a quartz spring balance and also by the rate of progression of the pyrite/pyrrhotite interface into a cylindrical, compressed, polycrystalline pellet. The temperature coefficient of the reaction was found to be 69.5 ± 5.9, 64.7 ± 3.3, and 66.9 ± 5.1 kcal mole^{-1}, when the results were processed in three different ways. The pyrite/pyrrhotite interface was found to progress at a linear rate into the pellet at a given temperature; equations were derived to express the variation of reaction rate with temperature. Attempts to follow the early nucleation stage of the decomposition, using massive mineral crystals, proved unsuccessful.

INTRODUCTION

The thermal decomposition of the mineral pyrite (FeS_2) to yield pyrrhotite (FeS_{1+z}) and sulfur has been made the subject of many investigations (1–13); this work has recently been reviewed by Kullerud and Yoder (1). Most studies have been made by measuring sulfur vapor pressure values (p_S) under equilibrium conditions over a range of temperatures. The enthalpy, ΔH, of the reaction, obtained from these measurements, has given values ranging from 39 to 104 kcal mole^{-1} for various investigators, most values lying in the 65 to 85 kcal mole^{-1} range. Most workers employed static conditions at less than 1 atm pressure; Kullerud and Yoder (1), however, extended their measurements to higher pressures. The only investigation to be made under the dynamic conditions of a flow of inert gas appears to be that of Udintseva and Chufarov (12), who used both single crystals and polycrystalline cubes of pyrite.

The difficulties associated with the study of this reaction arise from two sources: (*a*) variability of composition of the resultant pyrrhotite, which is a nonstoichiometric body; Bog and Rosenqvist (9) expressed the reaction by the equation

$$\left(\frac{2}{1-x}\right) FeS_2 \rightarrow \left(\frac{2}{1-x}\right) FeS_{1+z} + S_{2(g)} \qquad [1]$$

for temperatures of 500 to 550 °C, where x varies with temperature; (*b*) Wunderlich (13) has pointed out that the degree of association of the sulfur also varies with temperature, higher pressures and lower temperatures of reaction favoring the formation of S_8 and S_6 molecules over the S_2 indicated in eq. [1].

In the present study, the conditions employed were those of constant gas flow similar to those that might be expected to obtain in an industrial manufacturing process for sulfur from pyrite. The aim of this work was to determine the kinetic parameters for the reaction of small, polycrystalline cylindrical pellets of pyrite that would approximate in size the pieces of ore that would be used in the industrial process. In addition, this type of study was amenable to the same type of analytical treatment as that employed by McKewan (14) in the reduction of iron oxide pellets by hydrogen.

[1]*NRC Postdoctorate Fellow (1964–1965), assigned to the Mines Branch, Department of Mines and Technical Surveys, Ottawa; present address: High-Temperature Chemistry Division, Central Electricity Research Laboratories, Cleave Road, Leatherhead, Surrey, England.*

Initially, an attempt was made to study the nucleation processes occurring in the very earliest stages of the decomposition; no success was, however, achieved in this objective. This work is mentioned in the Appendix.

EXPERIMENTAL TECHNIQUE AND RESULTS

The pyrite used in this work was a mineral sample from Eastman, Quebec. It was crushed, washed with dilute acid to remove any pyrrhotite, and then washed with water. The product ($-40 + 100$ mesh) was found to contain an appreciable amount of quartz. Accordingly, it was crushed to -200 mesh and the quartz removed as far as possible by heavy-liquid separation with tetrabromoethane. The final product, on analysis, corresponded to the formula $FeS_{1.99}$; spectrographic analysis showed no significant impurity other than 0.3% Si, presumably as unliberated quartz. The powder was pressed into cylindrical pellets of 0.25 in. diameter and height at 160 000 lb in^{-2}. The pellets weighed approximately 0.86 g, corresponding to a bulk density of about 4.27 g cm^{-3} or about 85% theoretical density. The apparatus in which the decomposition was studied consisted of a vertical quartz tube, a portion of which was heated by a Kanthal-wound furnace. Temperatures were maintained constant in the hot zone of the furnace to within ± 0.5 °C, both in respect of location and of time. Samples were suspended in a light quartz stirrup at the end of a fine platinum wire, the upper end of which was attached to a calibrated helical quartz spring of sensitivity 5.39 cm g^{-1}. This spring was well above the top of the furnace and was, in turn, attached to a fine gold chain that was used for raising and lowering the sample by a suitable windlass mechanism. The extension of the spring was measured with a cathetometer. Sample temperatures were measured with a Pt : Pt 10% – Rh thermocouple, sheathed in a fine quartz tube and placed not more than 0.25 in. below the sample and still well within the hot zone of the furnace. Argon flows of approximately 180 ml min^{-1} were used in the decomposition runs. The gas flow was maintained for 10 min before the pellet was lowered into the hot zone of the furnace; at the completion of a run, the sample was raised out of the hot zone and the gas flow maintained for 15 min before opening the apparatus.

Pellets were sectioned laterally, mounted, and polished by the usual metallographic procedures. A partly decomposed pellet exhibited a well-defined reaction interface having surfaces parallel to the external faces of the pellets. The diameter of the unreacted material was measured at two locations at right angles on both top and bottom faces of the sectioned surface; the mean of these four values was taken to represent the extent to which the decomposition had proceeded. Cathetometer readings were taken at regular 5 min intervals, so that the change in reading formed a measure of the bulk rate of decomposition.

The results were treated in two ways:

(*a*) Straight lines were obtained when the diameter of unreacted pyrite was plotted against time for a given temperature. An Arrhenius plot of $\log_{10} k_0$ against $1/T$ °K, where k_0 is the velocity of advance of the interface in cm min^{-1} at a temperature of T °K, also gave a straight line. Least squares treatment was applied to this plot to obtain the equation of the best line through the points. The equation obtained was:

$$\log_{10} k_0 = 14.3 - \frac{15.18 \times 10^3}{T}. \qquad [2]$$

(*b*) In McKewan's treatment (14), eq. [3] was assumed and, from it, eq. [4] was derived for spherical and for cylindrical pellets with equal height and diameter,

$$dw/dt = k_1 A \qquad [3]$$

$$r_0 d_0[1 - (1 - R)^{1/3}] = k_2 t, \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where dw/dt = rate of weight loss, A = interfacial area between reactant and product, r_0 = initial radius of pellet, d_0 = initial density of pellet, k_1 and k_2 = rate constants, t = time, R = fraction of reactant decomposed at time t, = (% wt. lost at time t)/(% wt. lost at end of reaction) ($0 < R < 1$).

In the present work, results were available to test the validity of eqs. [3] and [4]. In eq. [3], dw/dt is directly proportional to the difference in successive cathetometer readings (Δx), taken at 5 min intervals. A, the area of the interface between the pyrite and the pyrrhotite, is directly proportional to the square of the diameter (d^2) of the unreacted pyrite in the case where the initial height and diameter are equal and where the height and diameter of the unreacted material remain equal throughout the reaction, i.e. where the rate of progress of the reaction into the pellet can be considered as isotropic. This requirement was, in fact, satisfied in the present case, as evidenced by many observations of the height and diameter of unreacted material made on sectioned pellets at various stages during the course of the decomposition. Thus, a plot of Δx against d^2 for various temperatures should give a series of straight lines of slope k_1, where k_1 varies with temperature according to an Arrhenius equation. Again, applying a least squares fit to the values of log k_1 plotted against $1/T$ °K, the following equation was obtained.

$$[5] \qquad \log_{10} k_1 = 12.8 - \frac{14.14 \times 10^3}{T}.$$

In eq. [4], values of R can be calculated from the weight of the pellet at a known time; this can be obtained either by direct weighing after a known reaction time or, alternatively, by computation from the cathetometer readings. In this work, the former method was used. In the calculation of R, a value of 23.0% was taken as the total percentage weight loss in the reaction. The use of this value will be further commented upon later. Plots of $[1 - (1 - R)^{1/3}]$ against t gave straight lines of slope k_2, where k_2 varies with temperature according to an Arrhenius equation. As in the other cases, the application of the least squares method to the plot yielded the equation

$$[6] \qquad \log_{10} k_2 = 14.0 - \frac{14.63 \times 10^3}{T}.$$

DISCUSSION OF RESULTS

A calculation of the activation energy (E) from eqs. [2], [5], and [6] gave the following results:

METHOD	E (KCAL MOLE^{-1})
From diameter–time plot (eq. [2])	69.5±5.9
From area-of-interface plot (eq. [5])	64.7±3.3
From weight-loss plot (eq. [6])	66.9±5.1

The tolerance values quoted here were calculated for 90% confidence limits (15). From these results, it would appear that there is no significant difference in the value of E obtained from the three different plots.

In the terms of absolute rate theory, where the rate constant k_3 is given by the equation

$$[7] \qquad k_3 = \frac{kT}{h} e^{\Delta S/R} e^{-\Delta H/RT},$$

where the symbols have their usual significance, the value of E should be equivalent to ΔH. A comparison of the values obtained in the present work with those of earlier workers shows that the values of Bog and Rosenqvist (9) and of D'Or (5) fall within the 90% confidence limits obtained in this work.

Of the two methods used to determine the kinetic parameters of the reaction, that based on the direct measurement of the unreacted material appears to be simple to perform and involves no assumptions. The method can show whether the interface is advancing at a linear rate; however, many experimental runs would be required. The method based on the work of McKewan, on the other hand, can be evaluated from far fewer experiments, since the weight changes can be obtained directly from the changes in the extension of the quartz spring or from some similar method. However, this method does incorporate a number of assumptions, e.g. that the rate is proportional to the interfacial area (eq. [3]), and that the stoichiometry of the reaction is exactly known. A complete verification of the validity of eq. [3] would require practically the same quantity of results as would be needed for the former method; however, if eq. [4] is found to hold, then this would constitute a verification of the validity of eq. [3]. In this particular reaction, the exact stoichiometry is *not* known, since the composition of the resultant pyrrhotite is a function of temperature. In this work, the value of 23.0% decomposition, which was taken as representing the end point of the reaction, had to be an approximation. This was based upon the form of the decomposition/time curves and showed that the reaction was completed after 75 min at the highest temperatures studied, and that the sample weight at this time corresponded to a 23.0% loss. This value of 23.0% would imply a formula approximating to Fe_7S_8 for the reaction product, pyrrhotite. This is reasonable when the known range of composition of this compound is considered.

CONCLUSIONS

1. The temperature coefficient of the decomposition of pyrite in a dynamic argon atmosphere is 69.5 ± 5.9, 64.7 ± 3.3, and 66.9 ± 5.1 kcal $mole^{-1}$ when the experimental results are processed in three different ways.
2. The equations of McKewan can be used to represent this decomposition reaction.
3. The pyrite/pyrrhotite interface advances at a linear rate; equations were obtained expressing the variations of the reaction rate with temperature.

ACKNOWLEDGMENTS

The authors would like to express their thanks to the scientific and technical staff of the Mineral Sciences Division, Mines Branch, for help and advice at various stages of the investigation. One of us (A. W. C.) wishes to express his thanks to the National Research Council of Canada for the grant of a Postdoctorate Research Fellowship.

The authors would also like to express their gratitude for useful discussions to Dr. T. R. Ingraham, Extraction Metallurgy Division, Mines Branch, who, with his collaborators, has, in recent years, studied the kinetics of thermal decomposition of numerous polycrystalline inorganic compounds employing the "advancing interface" technique.

APPENDIX

Preliminary Investigation of the Nucleated Decomposition of Natural Pyrite Crystals

At the commencement of this investigation, we hoped to study the decomposition of pyrite by investigating the rate of development of nuclei of decomposition on the surfaces of crystals of the mineral and also the rate of growth of these nuclei, possibly in various crystallographic directions. We hoped to correlate this information with the bulk rate of decomposition as determined by other methods, described in the main portion of this paper. There was also the possibility that the rates of decomposition in various directions could be correlated with the crystal structure in the same way as was done by one of us (N. F. H. B.) (16) for the dehydration of certain salt hydrates several years ago.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The study was conducted on small natural pyrite crystals (approximately 0.25 in. cubes). The crystals were heated *in vacuo* and observed with a low-power microscope. No individual nuclei could be observed up to a temperature of 550 °C but, on removal of the crystal from the vacuum enclosure after cooling, it was obvious that some decomposition had taken place, since the crystal was then black in color in contrast to its original brassy hue. Oblique illumination of the crystal with colored light also failed to reveal the formation of any discrete nuclei on heating.

On closer examination, blue-grey areas which appeared at first to increase and then to decrease in size could be observed. This effect could possibly be due to interference colors caused by a very thin film of pyrrhotite over the surface of the crystal, the appearance and disappearance of the colors being associated with the varying film thickness.

Other problems encountered with the use of natural pyrite crystals were: inhomogeneity of the interior of the crystal, the presence of impurities, and the variation in weight, size, and composition from crystal to crystal. These problems could best be eliminated by using polycrystalline, pelletized material. As no discrete nuclei had been observed, the aim of the work thereafter was directed towards studying the kinetics of the post-nucleation reaction.

This preliminary work did, however, imply that the surface of the crystal was very quickly covered by a thin film of reaction product and that the formation and growth of individual nuclei was unlikely to be the rate-controlling step in the decomposition, but rather the rate of movement of the pyrite/pyrrhotite interface into the crystal.

The fact that the polycrystalline pellets used in the main portion of this study had 85% of theoretical density implies that the amount of open porosity in the pellets must have been small. It is, then, not surprising that the rate of movement of the pyrite/pyrrhotite interface in both the single crystal and compressed polycrystalline pellet should be the rate-controlling step in the decomposition, and that similar kinetics, therefore, would govern both cases.

THE SULFURIC ACID SOLVENT SYSTEM

PART VII. SOLUTIONS OF SOME TIN(IV) AND LEAD(IV) COMPOUNDS

Received November 15, 1965

ABSTRACT

Solutions of tetramethyl tin, trimethyl tin sulfate, di-*n*-butyl tin diacetate, tetraphenyl tin, and triphenyl tin hydroxide in 100% sulfuric acid have been investigated by cryoscopic and conductimetric methods. Tetramethyl tin reacts with sulfuric acid with the evolution of methane and the formation of trimethyl tin hydrogensulfate. Trialkyl tin hydrogensulfates and dialkyl tin dihydrogensulfates behave as strong bases. It is probable that the cationic species formed are protonated hydrogensulfates rather than "stannonium" ions. Phenyl-substituted tin compounds are cleaved in sulfuric acid with the formation of benzene sulfonic acid and the complex hexa(hydrogensulfato) stannic acid, $H_2Sn(HSO_4)_6$, and its anions. Lead tetraacetate gives yellow solutions containing hexa(hydrogensulfato) plumbic acid, $H_2Pb(HSO_4)_6$, and its anions.

INTRODUCTION

Little work has been reported previously concerning the behavior of stannic compounds dissolved in sulfuric acid. Stannic oxide and stannic sulfate are almost insoluble in concentrated sulfuric acid. Salts of sulfatostannic acid, $H_2Sn(SO_4)_3$, have, however, been prepared by several workers. Weinland and Kuhl (1) prepared $K_2Sn(SO_4)_3$ by evaporating a solution containing 1 mole of stannic acid and 1.5 moles of potassium sulfate in sulfuric acid. They also prepared a number of other related salts such as $Rb_2Sn(SO_4)_3$ and $PbSn(SO_4)_3.3H_2O$. The potassium and calcium salts were also obtained by Druce (2) by the reaction of a chlorostannate, e.g. K_2SnCl_6 with sulfuric acid. He also prepared complex sulfatostannates of the anilinium and related cations. More recently Brubaker (3) has studied solutions of Sn(IV) in aqueous solutions of sulfuric acid of various strengths. He concluded that in dilute aqueous acid tin is present as a cation such as Sn^{4+} or SnO^{2+} (presumably solvated) and in very strong acid as an anion $Sn(SO_4)_3^{2-}$. There appears to have been no previous investigation of the cryoscopic and conductimetric behavior of organotin compounds in 100% sulfuric acid.

The preparation of plumbic sulfate, $Pb(SO_4)_2$, has been reported by several workers. For example, it was prepared by Brauner (4) from PbF_4 and concentrated sulfuric acid and by Hutchinson and Pollard (5) from lead tetraacetate and sulfuric acid. In the present work $Pb(SO_4)_2$ was prepared by the latter method and in agreement with the results of Hutchinson and Pollard and other early workers it was found to be only slightly soluble in sulfuric acid and dilute oleums. The more usual method of preparation of $Pb(SO_4)_2$ is by the electrolysis of sulfuric acid with lead electrodes (6). Dolezalek and Finkh (7), and Esche (8), suggested that the solutions in sulfuric acid from which $Pb(SO_4)_2$ is obtained, and the greenish-yellow solutions obtained by the electrolysis of sulfuric acid using lead electrodes, contain "hydrotrisulfato" plumbic acid, $H_2Pb(SO_4)_3$, since the potassium and ammonium salts, $K_2Pb(SO_4)_3$ and $(NH_4)_2Pb(SO_4)_3$, could be obtained from the solutions. Elbs and Fischer (6) prepared several insoluble alkali metal

salts such as $K_2Pb(SO_4)_3$ by treating an acid solution of $Pb(SO_4)_2$ with a solution of the metal sulfate in sulfuric acid. We have prepared the potassium salt and confirmed its very low solubility in 100% sulfuric acid.

The results of the present cryoscopic and conductimetric measurements on solutions of lead tetraacetate in sulfuric acid have already been reported in a preliminary communication (9); they are given now in detail.

EXPERIMENTAL

The freezing-point depression and electrical conductivities of solutions were measured by methods described previously (10–12). *Tetramethyl tin* was prepared by the method of Edgill and Ward (13) from methyl magnesium iodide and stannic chloride in *n*-butyl ether as solvent. It was purified by fractional distillation (b.p. 77.2 °C, $n_D^{25} = 1.4410$). *Trimethyl tin sulfate*, $[(CH_3)_3Sn]_2SO_4$, was prepared by dissolving tetramethyl tin in 100% sulfuric acid. Methane was evolved and addition of a small amount of water to the solution precipitated the sulfate, which was filtered off and washed with acetone and then with dry ether. *Di-n-butyl diacetate* was a sample obtained from Allbright and Wilson Ltd. *Tetraphenyl tin* was prepared by the method of Chambers and Scherer (14) by the reaction of phenyl zinc chloride with stannic chloride in toluene as solvent and under an inert atmosphere. The crude product was extracted with ether to remove chlorostannanes and recrystallized from toluene (m.p. 225–226°). *Triphenyl tin hydroxide* was prepared from the chloride (Eastman Kodak) by hydrolysis in alkaline solution. The product was extracted into ether and crystallized from the ether solution by cooling to ice temperature. It was recrystallized from petroleum ether (m.p. 118–120°). *Lead Tetraacetate* was obtained from the G. F. Smith Co. and was recrystallized from a mixture of acetic acid and acetic anhydride (m.p. 176°). The preparation of the 100% sulfuric acid solvent has been described previously (10, 11).

RESULTS AND DISCUSSION

The results of the freezing-point and conductivity measurements are given in Table I in the form of values at round concentrations. These were obtained by interpolation from plots of the results of at least two separate experiments on each compound in each of which a number of separate additions of the solute were made. Values of ν, the total number of moles of particles (molecules or ions) formed by the reaction of 1 mole of solute with sulfuric acid, were obtained from the expression

$$\nu = \Theta(1 + 0.002\Theta - 0.098\, ms)/6.12\, m_d/m$$

where Θ is the freezing-point depression calculated from the hypothetical freezing-point of undissociated sulfuric acid, i.e. 10.625°, m is the molality of the solute, m_d is the molality of the self-dissociation products, and s is the number of moles of solvent used up in the reaction of 1 mole of the solute (15). Values of γ, the number of moles of hydrogensulfate ions formed by the ionization of 1 mole of solute, were obtained by comparing the concentrations of solutions of the solute with those of an appropriate fully ionized reference base such as $KHSO_4$, H_2O, or CH_3CO_2H (15).

Tetramethyl Tin and Trimethyl Tin Sulfate

Tetramethyl tin dissolves rapidly in sulfuric acid with the evolution of methane according to the equation

$$[1] \qquad (CH_3)_4Sn + H_2SO_4 = (CH_3)_3Sn.HSO_4 + CH_4 \quad .$$

A similar reaction has been observed between tetramethyl tin and concentrated aqueous solutions of hydrogen halides (16).

A concentrated solution of tetramethyl tin in 100% sulfuric acid was prepared and the reaction allowed to go to completion. The solution was then added to 100% sulfuric acid in the conductimetric and cryoscopic cells. Values of ν and γ slightly greater than 2.0 and 1.0 respectively were obtained, in substantial agreement with the formation of trimethyl tin hydrogensulfate according to eq. [1] and its ionization to give a trimethyl tin cation

$$(CH_3)_3Sn.SO_4H = (CH_3)_3Sn^+ + HSO_4^-, \quad \nu = 2.0, \gamma = 1.0,$$

assuming that all of the methane produced in reaction [1] is evolved from the solution. The fact that the observed values of ν and γ are slightly greater than predicted can be explained by the production of small amounts of methane sulfonic acid and water.

$$CH_4 + 2H_2SO_4 = CH_3SO_3H + H_3O^+ + HSO_4^-$$

For trimethyl tin sulfate the experimental results are $\nu = 4$ and $\gamma = 2$, in agreement with the ionization

$$[(CH_3)_3Sn]_2SO_4 + H_2SO_4 = 2(CH_3)_3Sn^+ + 2HSO_4^-,$$

and confirm the results for tetramethyl tin.

On the basis of the cryoscopic and conductimetric measurements alone it is not possible to distinguish between solvated species such as $(CH_3)_3Sn.SO_4H_2^+$ and $(CH_3)_3Sn(SO_4H_2)_2^+$ and the "stannonium" ion $(CH_3)_3Sn^+$. In aqueous solution it has been shown that trialkyl tin cations exist in solvated forms, e.g. $R_3SnOH_2^+$, rather than as the planar R_3Sn^+ ion. The formation of the latter would lead to racemization of optically active methyl ethyl *n*-propyl tin sulfate, and it has been shown that no racemization occurs, since the camphorsulfonate has been resolved from aqueous solution (16). Recently, infrared studies of solid trimethyl tin salts such as the perchlorate, nitrate, and carbonate have led to the conclusion that these compounds do not contain $(CH_3)_3Sn^+$ cations (17–19) and that the anions are covalently bound to tin to give a five-coordinated trigonal bipyramidal configuration around tin. X-ray studies of $(CH_3)_3SnF$ show that there is a trigonal bipyramidal coordination of tin in a structure involving fluorine bridges (20). It has also been reported (18) that the tetrafluoroborate ion in $(CH_3)_3SnBF_4$ is covalently bound to tin in a polymeric chain structure containing five-coordinated tin. Henceforth in this paper we will write all alkyl tin cations in their more probable solvated forms.

Di-n-butyl Tin Diacetate

This compound reacts with sulfuric acid to give 3 hydrogen sulfate ions per solute molecule ($\gamma = 3$). Reaction according to the equation

$$(n\text{-Bu})_2Sn(OAc)_2 + 4H_2SO_4 = (n\text{-Bu})_2Sn(HSO_4)_2 + 2AcOH_2^+ + 2HSO_4^-,$$

for which $\gamma = 2$, might be expected by analogy with the behavior of dialkyl silicon compounds (12), but the observed γ value of 3 is consistent only with the formation of a singly charged tin cation, e.g.

$$(n\text{-Bu})_2Sn(OAc)_2 + 5H_2SO_4 = [(n\text{-Bu})_2Sn(HSO_4)_2]H^+ + 2AcOH_2^+ + 3HSO_4^- \quad .$$

Ionization to give a doubly charged cation is also inconsistent with the experimental results.

$$(n\text{-Bu})_2Sn(OAc)_2 + 6H_2SO_4 = [(n\text{-Bu})_2Sn(HSO_4)_2]H_2^{2+} + 2AcOH_2^+ + 4HSO_4^-, \quad \gamma = 4.0.$$

Similar reactions in which tin anions are formed are also inconsistent with the conductimetric results.

$$R_2Sn(OAc)_2 + 4H_2SO_4 = R_2Sn(HSO_4)_3^- + 2AcOH_2^+ + HSO_4^-, \quad \gamma = 1.0,$$

$$R_2Sn(OAc)_2 + 4H_2SO_4 = R_2Sn(HSO_4)_4^{2-} + 2AcOH_2^+, \quad \gamma = 0.$$

Tetraphenyl Tin and Triphenyl Tin Hydroxide

The cryoscopic and conductimetric results are only explicable if complete cleavage of the Sn—C bonds occurs. Thus the reaction of aryl tin compounds is quite similar to that of aryl silicon compounds (12). The experimental ν and γ values for triphenyl tin hydroxide of 10.4–9.9 and 2.3–2.1 respectively are in reasonably good agreement with the formation of $HSn(HSO_4)_6^-$ and $Sn(HSO_4)_6^{2-}$.

$$Ph_3Sn.OH + 13H_2SO_4 = H_2Sn(HSO_4)_6 + 3PhSO_3H + 4H_3O^+ + 4HSO_4^-, \quad \nu = 12, \gamma = 4,$$

$$Ph_3Sn.OH + 12H_2SO_4 = HSn(HSO_4)_6^- + 3PhSO_3H + 4H_3O^+ + 3HSO_4^-, \quad \nu = 11, \gamma = 3,$$

$$Ph_3Sn.OH + 11H_2SO_4 = Sn(HSO_4)_6^{2-} + 3PhSO_3H + 4H_3O^+ + 2HSO_4^-, \quad \nu = 10, \gamma = 2.$$

For tetraphenyl tin ν has an approximately constant value of 10.5 and γ decreases from 2.6 to 2.3 with increasing concentration.

These results are in approximate agreement with the formation of $HSn(HSO_4)_6^-$ and

$Sn(HSO_4)_6^{2-}$ according to the following equations

$$Ph_4Sn + 14H_2SO_4 = H_2Sn(HSO_4)_6 + 4PhSO_3H + 4H_3O^+ + 4HSO_4^-, \quad \nu = 13, \gamma = 4,$$

$$Ph_4Sn + 13H_2SO_4 = HSn(HSO_4)_6^- + 4PhSO_3H + 4H_3O^+ + 3HSO_4^-, \quad \nu = 12, \gamma = 3,$$

$$Ph_4Sn + 12H_2SO_4 = Sn(HSO_4)_6^{2-} + 4PhSO_3H + 4H_3O^+ + 2HSO_4^-, \quad \nu = 12, \gamma = 2.$$

The low value of ν suggests that some polymerization of the sulfato tin anion may be occurring as was previously found for the $Si(HSO_4)_6^{2-}$ anion (12). However, it is not clear why there is no indication of polymerization in the results obtained with triphenyl tin hydroxide. Because of the large ν values and the variety of probable products it is not possible to interpret these results with complete certainty. $H_2Sn(HSO_4)_6$ is clearly a relatively strong acid of the sulfuric acid solvent system but it is not possible to give any quantitative estimate of its strength.

Lead Tetraacetate

Both ν and γ vary with increasing concentration of solute, from 8.2 to 7.5 and 3.4 to 2.5 respectively, over the concentration range 0.005 *m* to 0.055 *m*.

The results are consistent with the reaction of lead tetraacetate to give a solution containing hexa(hydrogensulfato) plumbic acid, $H_2Pb(HSO_4)_6$, and its anions.

$$Pb(OAc)_4 + 10H_2SO_4 = H_2Pb(HSO_4)_6 + 4AcOH_2^+ + 4HSO_4^-, \quad \nu = 9, \gamma = 4,$$

$$Pb(OAc)_4 + 9H_2SO_4 = HPb(HSO_4)_6^- + 4AcOH_2^+ + 3HSO_4^-, \quad \nu = 8, \gamma = 3,$$

$$Pb(OAc)_4 + 8H_2SO_4 = Pb(HSO_4)_6^{2-} + 4AcOH_2^+ + 2HSO_4^-, \quad \nu = 7, \gamma = 2.$$

An estimate of the dissociation constants of the acid $H_2Pb(HSO_4)_6$ was obtained from the conductivity data in the following manner. For very dilute solutions it was assumed that the concentration of $Pb(HSO_4)_6^{2-}$ is negligible. We then have

$$[H_2Pb(HSO_4)_6] = \gamma - 3 \text{ and } [HPb(HSO_4)_6^-] = 4 - \gamma.$$

Hence the limiting value at low concentrations for $K_{b_1} = [HPb(HSO_4)_6^-]/[H_2Pb(HSO_4)_6][HSO_4^-]$ was found to be 48 moles kg^{-1}. For relatively concentrated solutions it was assumed that the concentration of un-ionized acid is small so that to a good approximation

$$[HPb(HSO_4)_6^-] = \gamma - 2 \text{ and } [Pb(HSO_4)_6^{2-}] = 3 - \gamma.$$

Hence the mean value of $K_{b_2} = [Pb(HSO_4)_6^{2-}]/[HPb(HSO_4)_6^-][HSO_4^-]$ was found to be 7.4 moles kg^{-1}.

The acid dissociation constants K_{a_1} and K_{a_2} of hexa(hydrogensulfato) plumbic acid are related to the basic dissociation constant K_{b_1} and K_{b_2} by the relationship

$$K_a = K_b K_{ap}$$

where K_{ap} is the autoprotolysis constant of sulfuric acid. K_{ap} has the value 2.4×10^{-4} $mole^2\ kg^{-2}$ at 25 °C (22). Thus for $H_2Pb(HSO_4)_6$

$$K_{a_1} = 1.2 \times 10^{-2} \text{ mole kg}^{-1}$$

and

$$K_{a_2} = 1.8 \times 10^{-3} \text{ mole kg}^{-1}, \text{ at 25 °C.}$$

These values are slightly different from those reported earlier (9) because of the use of an improved value for K_{ap}. The first dissociation constant of $H_2Pb(HSO_4)_6$ is of a similar magnitude to the acid dissociation constant of $H_2S_2O_7$ (21).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Solutions containing hexa(hydrogensulfato) plumbic acid are not stable above $\sim 100°$; decomposition occurs to give oxygen and a precipitate of plumbous sulfate.

$$H_2Pb(HSO_4)_6 \rightarrow PbSO_4 + H_2S_2O_8 + 3H_2SO_4$$

$$2H_2S_2O_8 \rightarrow 2H_2S_2O_7 + O_2$$

Lead tetraacetate was also found to be soluble in selenic, fluorosulfuric, and chlorosulfuric acids, giving yellow solutions which may contain the acids $H_2Pb(HSeO_4)_6$, $H_2Pb(FSO_3)_6$, and $H_2Pb(ClSO_3)_6$ respectively. On heating all the solutions decomposed, the yellow color faded, and oxygen was evolved. Plumbic oxide, PbO_2, precipitated by adding lead tetraacetate to water and dried at 120° was found to be insoluble in sulfuric acid. However, slightly moist PbO_2 was found to dissolve slowly on warming with sulfuric acid to give a yellow solution.

THE SULFURIC ACID SOLVENT SYSTEM

PART VIII. SOLUTIONS OF SOME PHOSPHORUS(V) AND VANADIUM(V) COMPOUNDS

R. J. GILLESPIE AND R. KAPOOR

Received November 15, 1965

ABSTRACT

It is shown that a number of phosphates ionize in sulfuric acid to give the $P(OH)_4^+$ ion. Triphenyl phosphine and triethyl phosphate are fully protonated but phosphorus oxyfluoride and phosphorus oxychloride are shown to be nonelectrolytes.

Ammonium metavanadate and vanadium pentoxide give the acid $H[VO(HSO_4)_4]$ and there is evidence that the dimer $H[V_2O_3(HSO_4)_6]$ and possibly higher polymers are present in increasing amounts with increasing concentration.

PHOSPHORUS(V) COMPOUNDS

Arlman (1) prepared the compound $H_3PO_4.HClO_4$ and suggested that it was an ionic perchlorate $P(OH)_4^+.ClO_4^-$. To obtain more definite evidence for $P(OH)_4^+$, and other possible oxy-cations of phosphorus, we have investigated solutions of KH_2PO_4, $K_4P_2O_7$, $Na_2H_2P_2O_7$, $K_5P_3O_{10}$, $Na_5P_3O_{10}$, $(C_6H_5)_3PO$, $(C_2H_5O)_3PO$, POF_3, and $POCl_3$ in sulfuric acid by cryoscopic and conductimetric measurements.

The results of the cryoscopic and conductimetric studies are given in Table I, and the conductivities are plotted in Fig. 1. They show that all the phosphates are converted quantitatively to the $P(OH)_4^+$ ion according to the following equations:

[1] $$KH_2PO_4 + 2H_2SO_4 = P(OH)_4^+ + K^+ + 2HSO_4^-, \quad \nu = 4, \gamma = 2,$$

[2] $$K_4P_2O_7 + 7H_2SO_4 = 2P(OH)_4^+ + 4K^+ + HS_2O_7^- + 5HSO_4^-, \quad \nu = 12, \gamma = 5,$$

[3] $$Na_2H_2P_2O_7 + 5H_2SO_4 = 2P(OH)_4^+ + 2Na^+ + HS_2O_7^- + 3HSO_4^-, \quad \nu = 8, \gamma = 3,$$

[4] $$M_5P_3O_{10} + 10H_2SO_4 = 3P(OH)_4^+ + 5M^+ + 2HS_2O_7^- + 6HSO_4^-, \quad \nu = 16, \gamma = 6.$$

The polyphosphates all dehydrate sulfuric acid to give the $P(OH)_4^+$ ion and there is no evidence that any other cation of phosphorus is present in the solutions. Triphenyl phosphine and triethyl phosphate are protonated to give the cations $(C_6H_5)_3POH^+$ and $(C_2H_5O)_3POH^+$, respectively.

[5] $$(C_6H_5)_3PO + H_2SO_4 = (C_6H_5)_3POH^+ + HSO_4^-, \quad \nu = 2, \gamma = 1,$$

[6] $$(C_2H_5O)_3PO + H_2SO_4 = (C_2H_5O)_3POH^+ + HSO_4^-, \quad \nu = 2, \gamma = 1.$$

Phosphorus oxyfluoride and phosphorus oxychloride both behave as nonelectrolytes, although solutions of the former are not completely stable.

VANADIUM(V) COMPOUNDS

Early workers obtained a compound having the composition $V_2O_5.3SO_3$, or $(VO)_2(SO_4)_3$, from solutions of vanadium pentoxide in concentrated sulfuric acid (2). Hayek and Engelbrecht (3) reported the formation of $V_2O(SO_4)_4$ from the reaction of $VOCl_3$ with SO_3. Woolf (4) formulated this compound as $(VO)_2S_4O_{13}$. More recently Mishra and Symons

(5) have studied solutions of V_2O_5 in 65% oleum and in sulfuric acid. In 65% oleum they state that their results are consistent with the reaction

[7] $$V_2O_5 + 9H_2S_2O_7 = 2VO(HS_2O_7)_3 + 6H_2SO_4$$

and exclude the formation of species such as VO_2^+ and $V(OH)_4^+$. In sulfuric acid their conductivity measurements give approximately 2.4 for γ, the number of hydrogensulfate ions formed from 1 molecule of V_2O_5, and they conclude that this results from a combination of the reactions:

[8] $$V_2O_5 + 9H_2SO_4 = 2VO(HSO_4)_3 + 3H_3O^+ + 3HSO_4^-$$

and

[9] $$V_2O_5 = 5H_2SO_4 = 2VO(OH)(HSO_4)_2 + H_3O^+ + HSO_4^-.$$

We now report the results of cryoscopic and conductimetric measurements on solutions of ammonium metavanadate and vanadium pentoxide in 100% sulfuric acid and dilute oleum.

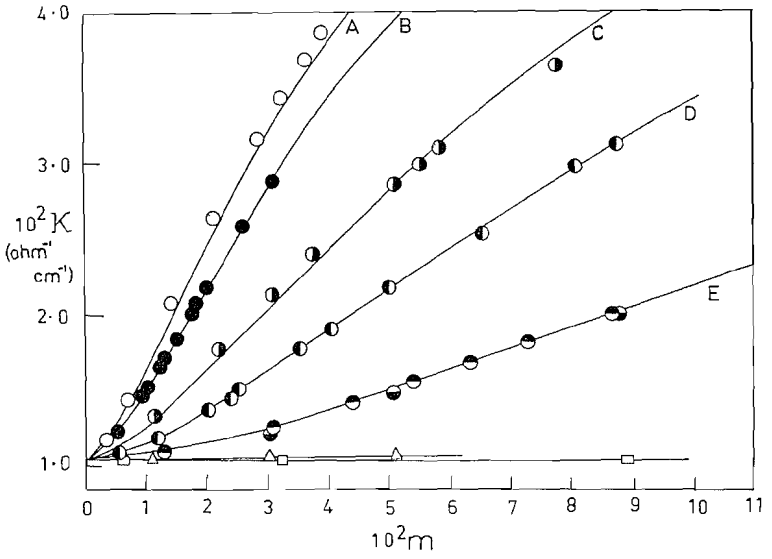

FIG. 1. Electrical conductivities of solutions of phosphorus(V) compounds at 25 °C. (A) $6KHSO_4$, (B) $5KHSO_4$, (C) $3NaHSO_4$, (D) $2KHSO_4$, (E) $KHSO_4$, (○)$K_5P_3O_{10}$, (●) $K_4P_2O_7$, (◑) $Na_2H_2P_2O_7$, (◐) KH_2PO_4, (◓) $(C_6H_5)_3PO$, (◒) $(C_2H_5O)_3PO$, (△) POF_3, (□) $POCl_3$.

Solutions in 100% H_2SO_4

The freezing-point results for ammonium metavanadate (Table II) show that ν is approximately 6. At first sight this might be taken to indicate an ionization similar to that of potassium nitrate (6, 7), i.e.

[10] $$KNO_3 + 3H_2SO_4 = K^+ + NO_2^+ + H_3O^+ + 3HSO_4^-$$

[11] $$NH_4VO_3 + 3H_2SO_4 = NH_4^+ + VO_2^+ + H_3O^+ + 3HSO_4^- \quad .$$

However, this ionization cannot account for the fact that the value of ν is initially greater than 6 and decreases with increasing concentration to a value that is definitely less than 6, nor for the observation that the conductivity results (Table II) give a γ value that is considerably less than the expected value of 3 and decreases with increasing concentration.

Since vanadium is known to form numerous compounds of the type VOX_3, it seems reasonable to postulate the following reaction

[12] $$NH_4VO_3 + 6H_2SO_4 = NH_4^+ + VO(HSO_4)_3 + 2H_3O^+ + 3HSO_4^-$$

for which $\nu = 7$ and $\gamma = 3$. It is possible that $VO(HSO_4)_3$ is a weak acid in which case the following equilibrium would be set up,

[13] $$VO(HSO_4)_3 + HSO_4^- \leftrightharpoons VO(HSO_4)_4^- \quad .$$

Complete formation of the $VO(HSO_4)_4^-$ anion would give the overall reaction

[14] $$NH_4VO_3 + 6H_2SO_4 = NH_4^+ + VO(HSO_4)_4^- + 2H_3O^+ + 2HSO_4^-$$

for which $\nu = 6$ and $\gamma = 2$.

The anion $VO(HSO_4)_4^-$ is derived from the acid $H[VO(HSO_4)_4]$, which differs from $VO(HSO_4)_3$ only by a solvent molecule. The formula $H[VO(HSO_4)_4]$ probably represents the neutral species in solution better than does $VO(HSO_4)_3$.

The equilibrium constant for [13] is given by

[15] $$K_b = [HVO(HSO_4)_4][HSO_4^-]/[VO(HSO_4)_4^-] = (\gamma - 2)\gamma m/(3 - \gamma).$$

Using the results from 0.01 to 0.05 m NH_4VO_3 we find $K_b = (2.9 \pm 0.2) \times 10^{-2}$ mole kg^{-1}, and since

[16] $$K_a = [VO(HSO_4)_4^-][H_3SO_4^+]/[HVO(HSO_4)_4],$$

we have

[17] $$K_a = K_{ap}/K_b = 0.8 \times 10^{-2} \text{ mole kg}^{-1}$$

for the acid dissociation constant of $HVO(HSO_4)_4$ at 25°, since K_{ap} has the value 2.4×10^{-4} $mole^2$ kg^{-2} at this temperature (8).

TABLE II

Freezing points and conductivities of solutions of NH_4VO_3 and V_2O_5 in 100% H_2SO_4 with calculated ν and γ values

Compound	$10^2 m$	f.p. (°C)	ν	$10^2 \mathscr{K}$ (ohm^{-1} cm^{-1})	γ	$\nu - \gamma$

	4	9.118	5.89	2.024	2.25	3.64
	5	8.772	5.81	2.300	2.18	3.63
	6	8.420	5.74	2.575	2.15	3.59
V_2O_5	1	10.111	6.68	1.156	2.15	4.53
	2	9.788	6.19	1.338	1.92	4.27
	3	9.456	5.92	1.520	1.71	4.21
	4	9.128	5.74	1.700	1.61	4.13
	5	8.808	5.56	1.886	1.55	4.06
	6	8.490	5.38	2.067	1.50	3.88

The above equilibria require that $(\nu - \gamma) = 4.0$ and the observed results are in fair agreement with this. However, ν decreases to values of less than 6, γ to values less than 2, and $\nu - \gamma$ is always somewhat less than 4 and decreases with increasing concentration. The simplest explanation of this is that the dimeric species $V_2O_3(HSO_4)_4$ and its anion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

$V_2O_3(HSO_4)_5^-$, or their solvated forms, are formed in increasing amounts at higher concentrations. The corresponding equations are

[18] $2NH_4VO_3 + 9H_2SO_4 = [VO(HSO_4)_2]_2O + 2NH_4^+ + 3H_3O^+ + 5HSO_4^-, \quad \nu = 5.5, \gamma = 2.5, (\nu - \gamma) = 3,$

and

[19] $2NH_4VO_3 + 9H_2SO_4 = V_2O_3(HSO_4)_5^- + 2NH_4^+ + 3H_3O^+ + 4HSO_4^-, \quad \nu = 5.0, \gamma = 2.0, (\nu - \gamma) = 3.$

The results of the cryoscopic and conductimetric measurements on solutions of vanadium pentoxide in 100% H_2SO_4 (Table II) can be accounted for by reactions similar to those proposed for ammonium metavanadate. The value of ν decreases from 6.7 in dilute solutions to 5.4 at higher concentrations, whereas the conductimetric γ factor decreases from approximately 2.0 to about 1.5 over the same concentration range. The results are reasonably consistent with the formation of $HVO(HSO_4)_4$ in equilibrium with $VO(HSO_4)_4^-$, i.e. with reaction according to the equations

[20] $V_2O_5 + 11H_2SO_4 = 2HVO(HSO_4)_4 + 3H_3O^+ + 3HSO_4^-, \quad \nu = 8, \gamma = 3, (\nu - \gamma) = 5,$

and

[21] $V_2O_5 + 9H_2SO_4 = 2VO(HSO_4)_4^- + 3H_3O^+ + HSO_4^-, \quad \nu = 6, \gamma = 1, (\nu - \gamma) = 5.$

In this case the equilibrium constant for [13] is given by

[22] $$K_b = (\gamma - 1)\gamma m/(3 - \gamma),$$

and using the results from 0.01 to 0.05 m V_2O_5, we find $K_b = (2.9 \pm 0.2) \times 10^{-2}$ and hence $K_a = 0.8 \times 10^{-2}$ mole kg^{-1}, in excellent agreement with the value found from the ammonium vanadate results.

However, ν decreases below 6 and $\nu - \gamma$ is somewhat smaller than expected and also decreases with increasing concentration. Again these results are consistent with the formation of an increasing amount of dimer with increasing concentration.

[23] $V_2O_5 + 6H_2SO_4 = V_2O_3(HSO_4)_4 + 2H_3O^+ + 2HSO_4^-, \quad \nu = 5, \gamma = 2, \nu - \gamma = 3,$

[24] $V_2O_5 + 6H_2SO_4 = V_2O_3(HSO_4)_5^- + 2H_3O^+ + HSO_4^-, \quad \nu = 4, \gamma = 1, \nu - \gamma = 3.$

Solutions in Dilute Oleum

The freezing points of solutions of NH_4VO_3 and V_2O_5 in dilute oleum, which are shown in Table III and Fig. 2, lend support to the above conclusions.

The freezing point rises on addition of NH_4VO_3 to oleum and the slope of the freezing-point curve corresponds to $\Delta\nu = -1$, as expected for the reaction

[25] $$NH_4VO_3 + \underbrace{3H_2S_2O_7}_{\nu \simeq (3 \times 1.3)} = \underbrace{NH_4^+ + HVO(HSO_4)_4 + HS_2O_7^-}_{\nu = 3} \qquad \Delta\nu \simeq -1 \ .$$

Since 1 mole of NH_4VO_3 reacts with 3 moles of $H_2S_2O_7$ to give $HVO(HSO_4)_4$, and since the initial concentration of $H_2S_2O_7$ in the experiment was 0.30 m, the freezing point would be expected to rise until the concentration $m_{NH_4VO_3} = 0.30/3 = 0.10\ m$, and at this point the freezing-point depression should correspond to $\nu = 3$. The maximum is observed experimentally at 0.095 m, which is very close to the expected value, and the freezing-point depression gives $\nu = 3.1$, in good agreement with the formation of $HVO(HSO_4)_4$. Similarly on addition of V_2O_5 to oleum the freezing point rises and the slope of the curve corresponds to $\Delta\nu = -2$, in accord with the reaction

[26] $$V_2O_5 + \underbrace{3H_2S_2O_7}_{\nu \simeq (3 \times 1.3)} + 2H_2SO_4 = \underbrace{2HVO(HSO_4)_4}_{\nu = 2} \qquad \Delta\nu \simeq -2 \ .$$

On addition of ammonium metavanadate to dilute oleum the conductivity decreases and passes through a minimum when the ratio of the number of moles of added NH_4VO_3 to the initial number of moles of $H_2S_2O_7$ = r = 0.35 to 0.36 (Table III and Fig. 2).

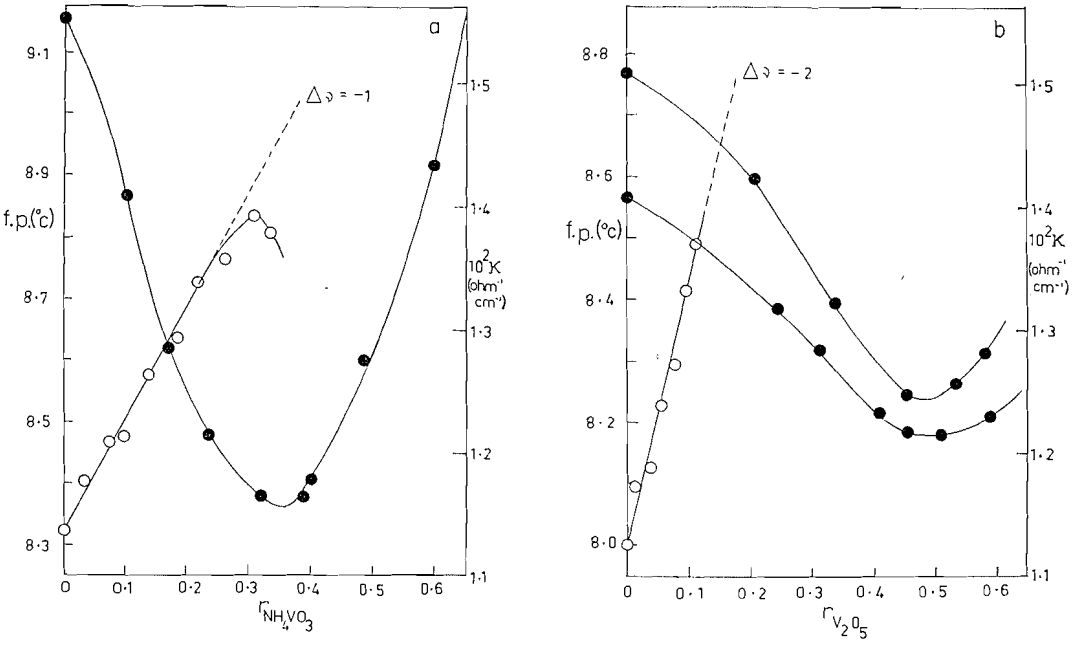

FIG. 2. Freezing points (○), and conductivities (●), of solutions of (*a*) NH_4VO_3, and (*b*) V_2O_5, in dilute oleum.

Ammonium metavanadate behaves in sulfuric acid as

[27] $$2H_2O + NH_4HSO_4 + HVO(HSO_4)_4$$

(see eq. [14]), and we can look at the titration in terms of adding these species to a solution containing $H_2S_2O_7$. Thus the following reactions are expected to occur,

[28] $$H_2O + H_2S_2O_7 = 2H_2SO_4$$

[29] $$NH_4HSO_4 + H_2S_2O_7 = NH_4^+ + HS_2O_7^- + H_2SO_4$$

[30] $$NH_4HSO_4 + HVO(HSO_4)_4 = NH_4^+ + VO(HSO_4)_4^- + H_2SO_4 \quad .$$

If the initial concentration of $H_2S_2O_7$ is n_a, and n_b moles of NH_4VO_3 are added to give a conductivity minimum ($r = n_b/n_a$), then $2n_b$ moles of $H_2S_2O_7$ are used up in reaction [28], leaving $n_a - 2n_b$ moles of $H_2S_2O_7$ to take part in reaction [29]. Suppose n_c moles of NH_4HSO_4 react with $H_2S_2O_7$ in reaction [29] to give a conductivity minimum, then since the conductivity minimum occurs at r = 0.56 in the titration of a strong base with $H_2S_2O_7$ (9),

[31] $$n_c/(n_a - 2n_b) = 0.56.$$

Thus $n_b - n_c$ moles of NH_4HSO_4 are left to give a conductivity minimum in reaction [30].

A conductivity minimum is predicted at r = 0.44 in the titration of a weak acid, K_a 1×10^{-2}, with a strong base (9), i.e.

[32] $$(n_b - n_c)/n_b = 0.44, \text{ i.e. } n_c = 0.56n_b.$$

0.616	1.597		

*r = ratio of moles of NH_4VO_3 or V_2O_5 to initial $H_2S_2O_7$.

Thus from eqs. [31] and [32] we have

[33] $$n_b/n_a = 0.33,$$

which is close to the observed minimum.

Addition of V_2O_5 to dilute oleum also gives a minimum in the conductivity–concentration curve at $r = n_b/n_a = 0.48$ to 0.50 (Table III and Fig. 2).

V_2O_5 behaves in sulfuric acid as

[34] $$3H_2O + 2HVO(HSO_4)_4$$

(see eq. [20]) and we can consider the titration in terms of adding these species to $H_2S_2O_7$. The following reactions will occur,

[35] $$H_2O + H_2S_2O_7 = 2H_2SO_4$$

and

[36] $$HVO(HSO_4)_4 + H_2O = H_3O^+ + VO(HSO_4)_4^- \quad .$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

If the initial concentration of $H_2S_2O_7$ is n_a it will react with n_a moles of water, so that at the conductivity minimum, when n_b moles of V_2O_5 have been added, the system contains $2n_b$ moles of $HVO(HSO_4)_4$ and $3n_b - n_a$ moles of water.

For the titration of a weak acid, such as $HVO(HSO_4)_4$ ($K_a \simeq 1 \times 10^{-2}$), with water a conductivity minimum is expected at $r = n_{H_2O}/n_{HA}$, the number of moles of added water to moles of acid = 0.42 (9) so that for an initial concentration of the acid $HVO(HSO_4)_4 = 2n_b$

[37] $$n_{H_2O}/n_{HVO(HSO_4)_4} = (3n_b - n_a)/2n_b = 0.42.$$

Hence $$r = n_b/n_a = 0.46,$$

which is quite close to the observed minimum.

Thus in both the titration of NH_4VO_3 with dilute oleum and in the titration of V_2O_5 with dilute oleum the positions of the conductivity minima are consistent with the formation of $HVO(HSO_4)_4$, a weak acid with $K_a \simeq 1 \times 10^{-2}$ mole kg^{-1}, and thus confirm the previous results.

The results obtained in oleum do not give any evidence for the dimer $V_2O_3(HSO_4)_4$. This is consistent with the fact that the equilibrium

[38] $$2VO(HSO_4)_3 + H_2O \leftrightharpoons V_2O_3(HSO_4)_4 + 2H_2SO_4$$

would be expected to lie well over to the left-hand side in oleum.

EXPERIMENTAL

The method of carrying out cryoscopic and conductivity measurements and the methods of calculating ν and γ have been described previously (10).

V_2O_5 and NH_4VO_3 were commercial samples of at least 99% purity (Anderson Chemical Company) and the phosphorus compounds were also obtained from commercial sources (Alpha Inorganics Inc.). The compounds were dried at 120°.

AUTOMATIC DIRECT ANALYSIS OF A_2B_2 NUCLEAR MAGNETIC RESONANCE SPECTRA

T. K. Lim, A. Taurins, and M. A. Whitehead
Theoretical Chemistry Laboratory, McGill University, Montreal, Quebec
Received December 3, 1965

ABSTRACT

A method for complete direct analysis of A_2B_2 n.m.r. spectra is described. The number of possible combinations of spectral lines is reduced from 1 663 200 to 128 by classifying the lines into six pairs. The method is equally effective in analyzing both overlapping and non-overlapping line systems. The n.m.r. spectra of phenazine, 2,3-dimethylquinoxaline, thianthrene, naphthalene, and *o*-dichlorobenzene are analyzed; they give theoretical spectra which agree well with the observed spectra.

INTRODUCTION

The interpretation of A_2B_2 n.m.r. spectra has been discussed (1–3) for cases in which the chemical shift and the coupling constants are of comparable size, so that strong coupling is possible. With the spin coupling constants given as J_{AA}, J_{AB}, etc., two constants K and M were defined as $K = J_{AA} + J_{BB}$ and $M = J_{AA} - J_{BB}$ and the assumption was made that $K = -M$.

When the solution of the secular equation was considered in detail, practical equations correlating the spectrum and parameters were developed, and these gave analyses of A_2B_2 spectra which reproduced the experimental spectra quite well (4–9). When the 24 spectral lines do not overlap, the computer program by Whitman (10) can be used to solve the spectra, but it presents ambiguities in choosing and extracting the experimental lines, especially when they are closely spaced.

The method described herein extends the correlation between the spectrum and parameters, and permits a complete direct mechanical analysis of A_2B_2 spectra. The number of possible combinations of spectral lines is reduced from 1 663 200 to 128, by classifying six pairs of lines instead of four groups. Assigning six pairs is much easier, and since these lines are close together or overlapping, less ambiguities occur than when four groups are considered. The present method also allows several best assignments for each compound, thus avoiding the influence of experimental errors.

THEORY

An A_2B_2 system, under the selection rule, gives a symmetrical theoretical spectrum of 28 lines, of which 4 are combination transitions corresponding to the change of spin of three or four nuclei simultaneously. This type of transition is always weak, and can be neglected. The remaining 12 possible transitions of the half spectrum are summarized in Fig. 1 (1–4).

The 24 fundamental transitions are summarized in Fig. 2 according to their components of angular momentum, while the corresponding transition energies and intensities are shown in Table I.

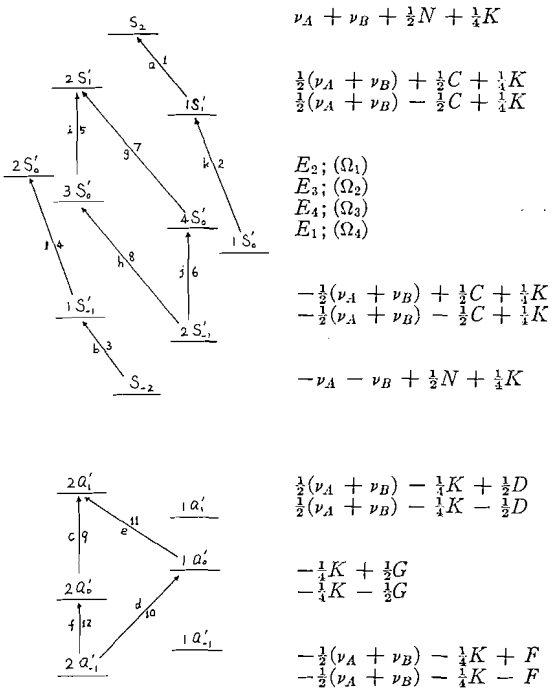

FIG. 1. The 12 permitted transitions and corresponding energies of the A_2B_2 half-spectrum. The numbers are the Pople notation, while the letters are the Dischler notation.

*The total sum of intensity of the half-spectrum is 8.
†If M takes negative value, then D and F interchange and i, e, c, and d lines interchange as well as e and f lines.

In the figures and tables, the following nomenclature is used: A and B are the protons, and J_{AA}, J_{AB}, etc. are the spin coupling constants,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$N = J_{AB} + J_{AB}', \qquad K = J_{AA} + J_{BB} \geqslant 0,$$
$$L = J_{AB} - J_{AB}' \geqslant 0, \qquad M = J_{AA} - J_{BB} \geqslant 0;$$
$$\nu_0\delta = |\nu_A - \nu_B|,$$

where ν_A and ν_B are the line frequencies in the absence of spin coupling and $\nu_0\delta$ is the chemical shift in cycles per second.

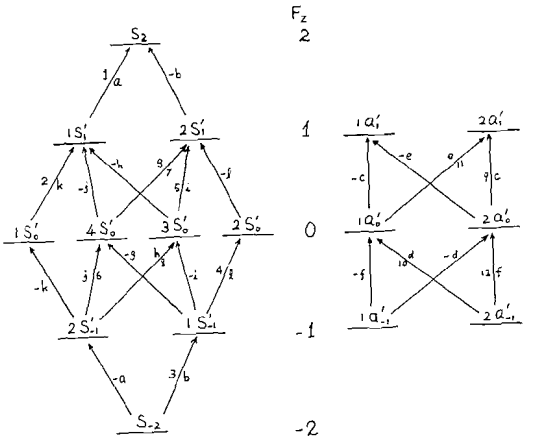

FIG. 2. The 24 possible transitions of the A_2B_2 system according to their components of angular momentum. The symmetric transitions are shown on the left half of the figure and the antisymmetric transitions on the right.

$$C = \sqrt{[(\nu_0\delta)^2 + N^2]}$$
$$D = \sqrt{[(\nu_0\delta + M)^2 + L^2]}$$
$$F = \sqrt{[(\nu_0\delta - M)^2 + L^2]}$$
$$G = \sqrt{(M^2 + L^2)}.$$

Four angles are defined in terms of which the energies E_n and wave functions ζ_n of the system can be expressed.

$$\sin\theta = \sqrt{[(1/2)(1 - M/G)]}$$
$$\sin\chi = \sqrt{\{(1/2)[1 - (\nu_0\delta - M)/F]\}}$$
$$\sin\Psi = \sqrt{\{(1/2)[1 - (\nu_0\delta + M)/D]\}}$$
$$\sin\Phi = \sqrt{[(1/2)(1 - \nu_0\delta/C)]}\,\frac{N}{|N|}.$$

The Ω_i s in Fig. 3 are the eigenvalues of the 4×4 S_0 submatrix, whereas the A_i s are their corresponding eigenvectors; by definition, $\Omega_1 \geqslant \Omega_2 \geqslant \Omega_3 \geqslant \Omega_4$ (4).

In the interpretation of A_2B_2 spectra by Pople *et al.* (2), the difficulty of solving the 4×4 S_0 submatrix was avoided by making all the interpretations from transitions other than those involving S_0 states, and by assuming that $K = -M$. The correlations between spectrum and parameters are as follows:

[1] $$N = a - b$$

[2] $$\nu_0\delta = \sqrt{(4ab)}$$

[3] $$c + e = \sqrt{[(\nu_0\delta + M)^2 + L^2]}$$

[4] $$c - e = \sqrt{(M^2 + L^2)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

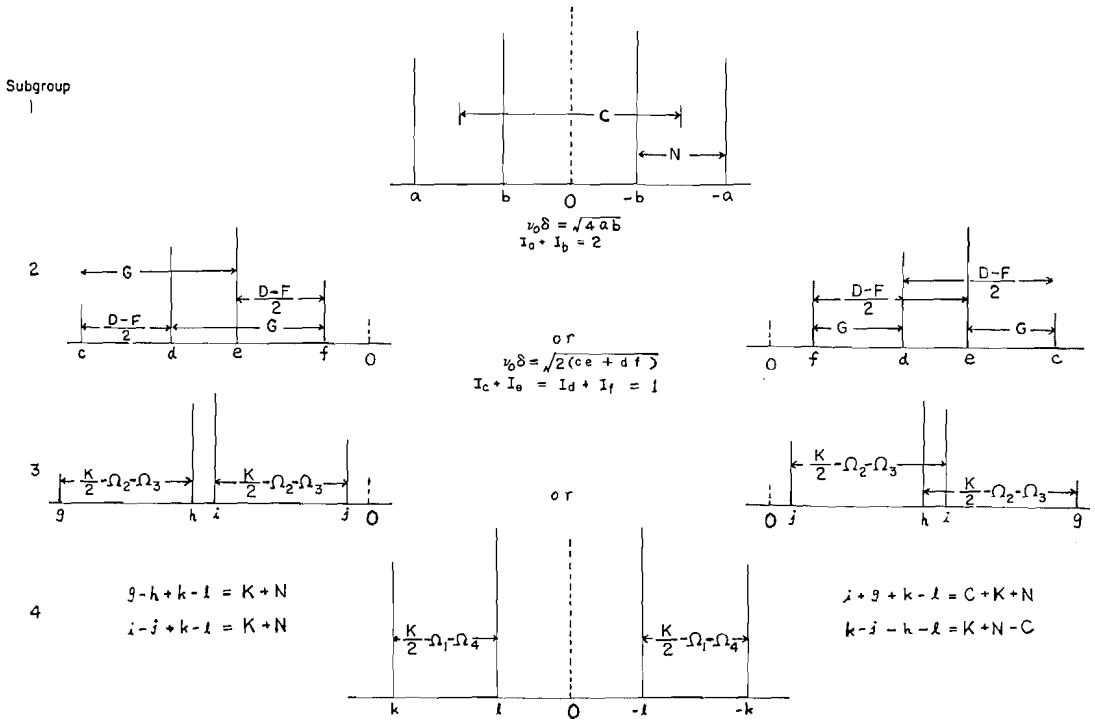

FIG. 3. The correlation of lines and parameters of the A_2B_2 spectrum.

$$M = \frac{2ce}{\nu_0\delta} - \frac{\nu_0\delta}{2} \quad [5]$$

$$L = \sqrt{[(c-e)^2 - M^2]} \quad [6]$$

$$K = -M. \quad [7]$$

Dischler *et al.* (4, 5) avoided the assumption that $K = -M$, by dividing the half-spectrum into four groups and expressing K explicitly. The resulting correlations were:

$$N = a - b \quad [1]$$

$$\nu_0\delta = \sqrt{(4ab)} = \sqrt{[2(ce + df)]} \quad [8]$$

$$M = \frac{ce - df}{\nu_0\delta} \quad [9]$$

$$L = \sqrt{[(c-e)^2 - M^2]} = \sqrt{[(d-f)^2 - M^2]} \quad [10]$$

$$K = k - l - N + \tfrac{1}{2}(g - h + i - j) \quad [11]$$

$$c \geqslant d \geqslant e \geqslant f \quad [12]$$

$$g \geqslant h \geqslant i \geqslant j \quad [13]$$

$$I_a : I_b = b : a \quad [14]$$

$$I_a + I_b = 2 \quad [15]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[16] $$I_c + I_e = I_d + I_f = 1$$

[17] $$2 \geqslant I_g + I_h + I_i + I_j \geqslant 1$$

[18] $$2 \leqslant I_k + I_c \leqslant 3$$

where eqs. [14] through [18] are intensity correlations: eqs. [12] and [13] are incorrect, for Dischler's equations (5, 6) are:

$$c - e = d - f \geqslant 0 = G,$$
$$c + f = d + e \geqslant 0 = \tfrac{1}{2}(D + F),$$
$$c - d = e - f \geqslant 0 = \tfrac{1}{2}(D - F).$$

Hence while it is true that $c \geqslant d$ and $e \geqslant f$, the relationship between d and e is not specified and d could be greater than, equal to, or less than e. This is also true of h and i. We shall therefore use eqs. [12a] and [13a] in this paper.

[12a] $$c \geqslant d, \qquad e \geqslant f$$

[13a] $$g \geqslant h, \qquad i \geqslant j$$

These four characteristic groups possess 4, 8, 8, and 4 lines, respectively, and can be further divided symmetrically into A and B parts with an equal number of lines. The assignment of the groups is given in Fig. 3.

To correlate the lines and parameters, the mean value of equivalent sets is taken rather than the absolute value of either set (5), and the half-spectrum is divided into six pairs. The correlation between these six pairs and the four groups is given in Fig. 4.

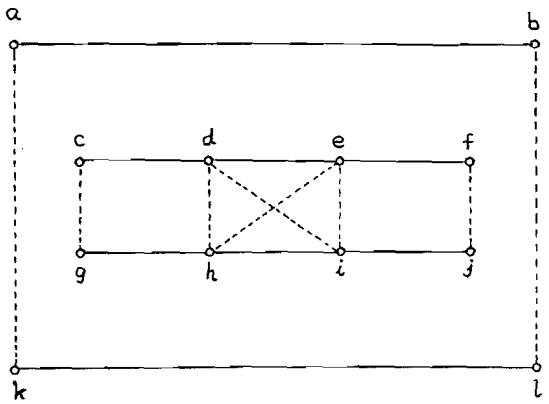

FIG. 4. Correlation between the classification of six pairs of lines in the present work and the four groups of Dischler. Each solid line represents one group while each dashed line represents one pair. The pairing in the center part of the figure should be either $d \ldots h$ and $e \ldots i$ or $d \ldots i$ and $e \ldots h$.

The possible permutations of the assignment of each spectrum using four groups are $2^3 \cdot C_2^{12} \cdot C_4^{10} \cdot C_4^6 = 1\,663\,200$; the number reduces to $2^7 = 128$ using six pairs. This greatly facilitates the interpretation and the calculation of the spectrum.

Besides the arrangement shown in Fig. 3, the possibility also exists of interchanging a and b, and k and l simultaneously, since N is positive or negative according to whether a is greater or less than b. Interchange of d and e, and h and i, is also possible, since we have the possibility of h greater or less than i depending on their values. Thus there are four possible arrangements similar to that in Fig. 3, all of which must be calculated separately and compared with the experimental results, as they cannot be distinguished in the course of the computer program.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The complete set of equations becomes:

$$[19] \qquad \nu_0\delta = \frac{\sqrt{(4ab)} + \sqrt{[2(ce - df)]}}{2}$$

$$[20] \qquad C = (\tfrac{1}{4})(2a + 2b + g + h + i + j)$$

$$[21] \qquad N = \pm\sqrt{[C^2 - (\nu_0\delta)^2]}$$

$$[9] \qquad M = \frac{ce - df}{\nu_0\delta}$$

$$[22] \qquad K = k - l - N + \frac{C}{2} + \frac{1}{4}(g - 3h + i - 3j)$$

$$[23] \qquad L = \sqrt{\left[\left(\frac{c - e + d - f}{2}\right)^2 - M^2\right]}$$

$$[12a] \qquad c \geqslant d, \qquad e \geqslant f$$

$$[13a] \qquad g \geqslant h, \qquad i \geqslant j$$

with the same intensity correlation equations, eqs. [14–18], as before.

The change to equations [12*a*] and [13*a*] is made because there is no reason to assume that d must be greater than e, or that h must be greater than i. For example if G is less than $(D - F)/2$, then e must be greater than d (Fig. 3 subgroup 2). Equation [10] was replaced by eq. [23] because if $c - e$ is equal to $d - f$, then it is more reasonable to adjust the experimental error by considering all the 4 lines in group 2 rather than only two lines. Equation [22] was used to adjust the experimental error. This equation is easy to derive from Fig. 3 by adding or subtracting the expressions of subgroup 4.

The method used to assign the six pairs of lines in the spectrum is as follows (see Fig. 3).

Step 1.—The first pair assigned has the highest intensity of the six pairs and, depending on whether N is positive or negative, will consist of the lines b and l or a and k.

Step 2.—Another intense pair of lines is then chosen and will consist of the two lines not assigned to the first pair, namely a and k or b and l. The intensity of this pair and of the pair assigned below in step 6 is often very close. Therefore the intensity sum is of importance. The total intensity of one line from step 1 and one line from step 2 should equal 2, the sum of the remaining two lines being nearly 2. Furthermore from eq. [8] it is known that this second pair of lines should be two or three pairs away from the first pair.

Step 3.—The innermost lines (those nearest to the center of the spectrum) are then assigned as the lines f and j; they are generally of low intensity.

Step 4.—The outermost lines (those furthest from the center of the spectrum) are assigned as c and g; they are the least intense lines.

Step 5.—The remaining two pairs are of medium to high intensity; one pair lies between the two high intensity lines assigned in steps 1 and 2 above and possesses several possible assignments such as (d,h) or (d,i) for $i > h$ or $h > i$ when $e > d$, or such as (e,h) or (e,i) for $i > h$ or $h > i$ when $d > e$.

Step 6.—The only remaining pair of lines will also possess several possible assignments such as (e,h) or (e,i) when $e \geqslant d$ and (d,h) or (d,i) when $d > e$.

The initial assignment of the lines under these conditions is arbitrary, but the computer program considers each arbitrary assignment and calculates the correct assignment.

MECHANICAL CALCULATION

The computer program for the IBM 7040 was coded for complete direct analysis of A_2B_2 spectra. There are 128 possible permutations of the 12 lines in each spectrum. Defining

$$\Delta_i = |\sqrt{[2(c_i e_i + d_i f_i)]} - \sqrt{(4a_i b_i)}|,$$

where the subscript i stands for the ith permutation, then the permutation with the smallest Δ_i is chosen as the best assignment. To avoid the influence of experimental error, the permutation j, if any, is also considered as a "possible best" permutation if the difference $\Delta_j - \Delta_i$ is within the range of 0.02 c/s. (This value is adjustable when necessary.) After the "possible best" permutations have been assigned, four different cases, (1) $N > 0$ and $h > i$, (2) $N > 0$ and $i > h$, (3) $N < 0$ and $h > i$, and (4) $N < 0$ and $i > h$, are considered simultaneously. Note that the cases for $d > e$ or $e > d$ have been automatically defined during the sorting procedure of the "possible best" assignments. Before calculating these four cases, the parameters K, L, M, N and the chemical shift $\nu_0\delta$ are calculated from the required equations given above. When the values of the chemical shift and the parameters have been calculated, a subprogram consisting of

(i) the calculation of the Hamiltonian matrix,

(ii) the diagonalization,

(iii) the sorting of the energy levels and their corresponding eigenvectors, and

(iv) the calculation of intensities and positions is used for each case, and the calculated results are listed and compared with the observed spectrum. The corresponding values of chemical shifts, parameters, and coupling constants for the four cases are printed. Finally, the theoretical and experimental spectra can be plotted if desired.

RESULTS AND DISCUSSION

The method has been used to investigate the spectra of the following A_2B_2 compounds: phenazine, 2,3-dimethylquinoxaline, thianthrene, naphthalene, and *o*-dichlorobenzene. The theoretical calculations compare well with the observed spectra. Only the spectrum of *o*-dichlorobenzene does not involve the overlap of the spectral lines, so that the method was tested on both overlapping line and non-overlapping line systems, and appears equally valid for both systems. See Tables II and III.

The spectra of phenazine, 2,3-dimethylquinoxaline, thianthrene, and naphthalene were measured on the Varian A-60 spectrometer in these laboratories; the *o*-dichlorobenzene spectrum is from the published work of Whitman (10).

The experimentally observed spectra are not labelled in the tables; this is because the lines take the sequence of letters appropriate to the case to which the observed spectra is being compared.

As stated, the calculations were made in two main steps (i) the calculation of the parameters $\nu_0\delta$, J_{AA} etc. and (ii) the calculation of the frequencies and intensities. The formulae for calculating the frequencies and intensities are essentially the same as in the Dischler method and therefore the results should be nearly the same, as they are. The most important difference between this method and that of Dischler is that this method provides a possible way of carrying out a mechanical calculation of all the parameters, so that all possible assignments can be fully considered and analyzed; this seems very difficult to do in Dischler's method. Pople's method using the $K = -M$ approximation usually gives worse correlation results for a few lines although generally the results seem good. Table IV gives the comparable results from these three methods, all the calculations being made on the same spectra, in this laboratory, using the formulae in the text.

*The order of the observed lines is governed by the assignment of the lines in the correct column of N and h,i values. Thus since $N > 0$ and $h > i$ are the correct assignments, the observed lines are labelled *g*, *c*, *a*, *k*, *h*, *d*, *i*, *e*, *b*, *l*, *j*, and *f*. This leaves two choices within the experimental error, but when $\Delta_i = 0.249$ $h_{theory} = 9.631$, $h_{exp} = 10.040$ and $d_{theory} = 9.906$ while $d_{exp} = 9.700$; when $\Delta_i = 0.258$ the sequence is correct.

†Sequence of line designations as in appropriate column of energies.

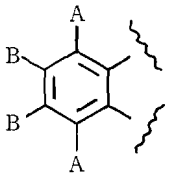
*Calculated from the mean value method of Dischler and Pople's formulae as given in the text.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The calculation on *o*-dichlorobenzene gives two possible best assignments within the limit $\Delta_i < 0.3$ c/s. Their chemical shifts and coupling constants are given in Table V as A and B.



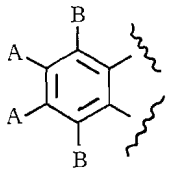
It should be noted that equations

$$K = J_{AA} + J_{BB} \geqslant 0, \qquad M = J_{AA} - J_{BB} \geqslant 0$$

are used in this paper instead of Pople's equations

$$K = J_{AA} + J_{BB} \geqslant 0, \qquad M = J_{AA} - J_{BB} \leqslant 0.$$

Therefore Pople's assumption of $K = -M$ (i.e., $J_{AA} = 0$) becomes $K = M$ (i.e. $J_{BB} = 0$) when the equations of this new method are used. This results in the exchange of the nuclei A and B. For example, the positions of nuclei A and B in *o*-disubstituted benzene for Pople's paper and the present paper are respectively



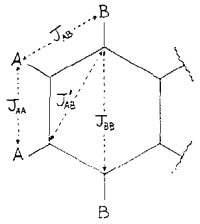


TABLE V

Assignments of chemical shift and coupling constants

Compounds	$\nu_0\delta$	J_{AA}	J_{BB}	J_{AB}	J_{AB}'
(A) *o*-Dichlorobenzene	15.212	7.300	0.092	8.063	1.720
(B) *o*-Dichlorobenzene	15.217	7.483	0.286	8.114	1.506
(C) 2,3-Dimethylquinoxaline	19.809	6.836	0.675	8.407	1.726
(D) Phenazine	23.904	6.295	0.202	8.819	1.596
(E) Thianthrene	15.502	7.542	0.115	7.713	1.631
(F) Naphthalene	23.098	6.738	0.036	8.572	1.629

A and the first part of Table II are calculated with $\Delta_i = 0.249$ c/s, while B and the second part of Table II are calculated with $\Delta_i = 0.258$ c/s. The comparison of the theoretical and experimental results are given in Table II. It is clear that the results for the $N > 0$ and $h > i$ case are preferable. Although the theoretical results of both assignments are within the range of experimental error, assignment B in Table V is preferable because the h and d lines are in the same sequence of energies in the theoretical and experimental spectra, whereas in assignment A in Table V the h and d lines are in the reverse sequence of energies in the experimental and theoretical spectra. These are the cases $N > 0$ and $h > i$ in Table II.

In the other four compounds, only one best assignment is found for each compound: 2,3-dimethylquinoxaline $\Delta_i = 0.182$ c/s, phenazine $\Delta_i = 0.412$ c/s, naphthalene $\Delta_i = 0.135$ c/s, and thianthrene $\Delta_i = 0.662$ c/s, and their spectra all have overlapping lines.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The assignments of these compounds are given in Table III. In all cases the best assignment requires $N > 0$ and $h > i$ as was assumed by Dischler.

The experimental spectra of 2,3-dimethylquinoxaline, phenazine, and thianthrene, as well as the theoretically calculated spectra, are shown in Figs. 5–7.

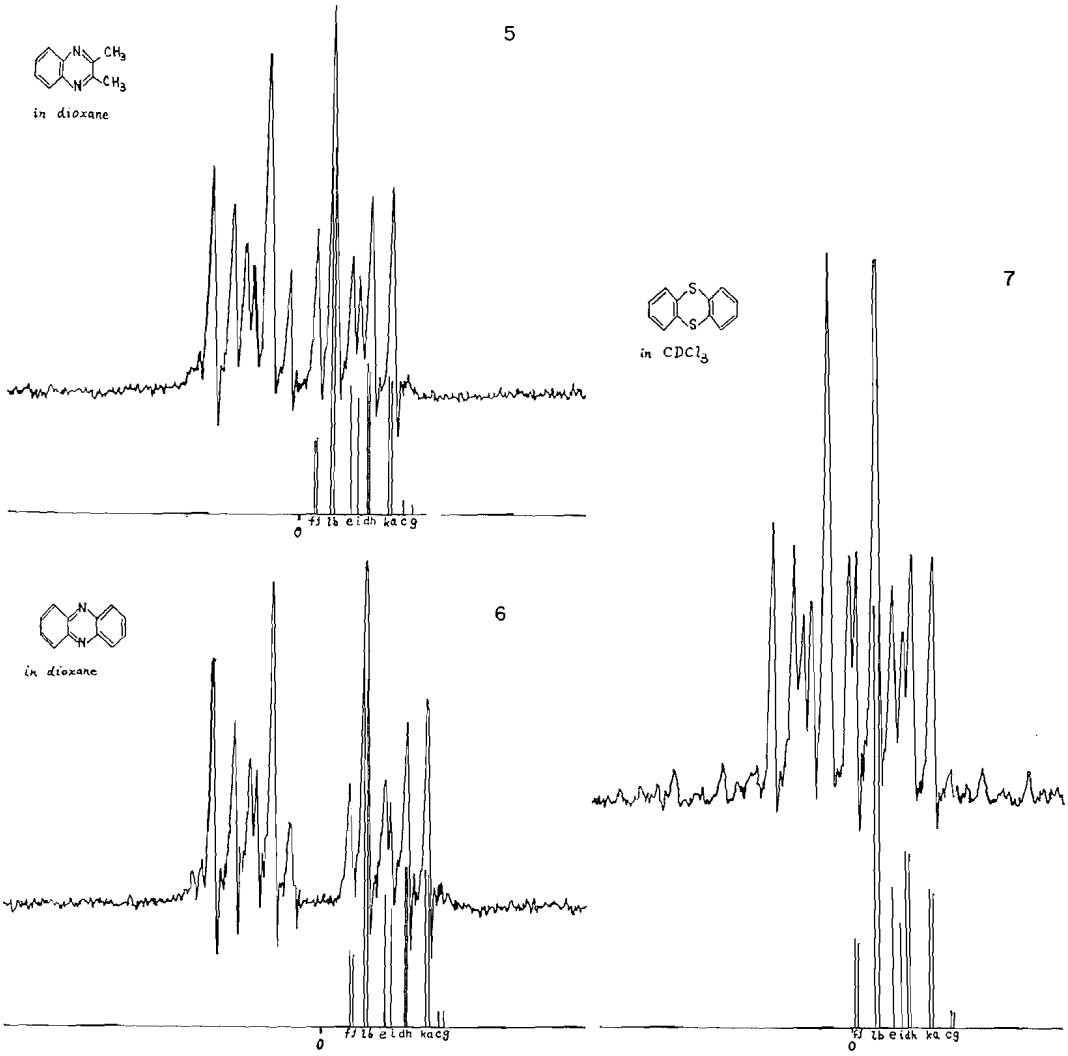

FIG. 5. Experimental and theoretical spectra of 2,3-dimethylquinoxaline.
FIG. 6. Experimental and theoretical spectra of phenazine.
FIG. 7. Experimental and theoretical spectra of thianthrene.

NOTES

DIMETHYLTRIFLUOROACETYLARSINE AND RELATED COMPOUNDS

W. R. Cullen and G. E. Styan

Although fluoroacyl derivatives of transition metals have been known for some time, little work has been done on the analogous derivatives of other metals and metalloids (1). Therefore, since compounds with Sn—Sn and As—As bonds are readily cleaved by fluoroalkyl iodides to give fluoroalkyl derivatives of tin or arsenic (2–4),

$$CF_3I + (CH_3)_3Sn{-}Sn(CH_3)_3 \rightarrow (CH_3)_3SnCF_3 + ISn(CH_3)_3,$$

it was of interest to see whether these bonds would react similarly with active trifluoroacetyl derivatives of the type $CF_3C(O)X$.

Tetramethyldiarsine is readily cleaved by trifluoroacetyl chloride at 20° to give a good yield of the pale-yellow liquid dimethyltrifluoroacetylarsine. With trifluoroacetic anhydride, however, the main products are dimethyltrifluoromethylarsine and dimethyltrifluoroacetoxyarsine.

$$(CH_3)_2As{-}As(CH_3)_2 \xrightarrow{CF_3C(O)Cl} (CH_3)_2AsC(O)CF_3 + ClAs(CH_3)_2$$

$$(CH_3)_2As{-}As(CH_3)_2 \xrightarrow[[CF_3C(O)]_2O]{} (CH_3)_2AsCF_3 + (CH_3)_2AsOOCCF_3 + CO$$

The last reaction may proceed through initial formation of the trifluoroacetyl compound followed by decarbonylation.

$$(CH_3)_2AsC(O)CF_3 \rightarrow (CH_3)_2AsCF_3 + CO$$

This process occurs slowly on heating the pure trifluoroacetylarsine but the reason for its ready occurrence in the anhydride reaction is obscure.

In the transition metal field it has been found that the fluoroacyl derivatives usually decarbonylate when heated, giving the fluoroalkyl compound, and some are so unstable that they cannot be isolated at ordinary temperatures (1).

$$LiCo(CO)_4 + CF_3C(O)Cl \rightarrow CF_3Co(CO)_4 + CO + LiCl$$

Apparently a similar situation is found when trifluoroacetyl iodide is mixed with hexamethylditin. Carbon monoxide is evolved and the main products are trimethyltrifluoromethyltin and, probably, trimethyltin iodide.

$$CF_3C(O)I + (CH_3)_3Sn{-}Sn(CH_3)_3 \rightarrow (CH_3)_3SnCF_3 + CO + ISn(CH_3)_3$$

The reaction of the ditin compound with trifluoroacetic anhydride at 60° follows a different route, the main products being tetramethyltin (instead of $(CH_3)_3SnCF_3$ or $(CH_3)_3SnC(O)CF_3$), trimethyltin trifluoroacetate, and carbon monoxide. The tetramethyltin does not arise through thermal decomposition of trimethyltrifluoromethyltin, since this yields trimethyltin fluoride and difluorocarbene (2).

Irradiation of a mixture of trifluoroacetyl chloride and hexaethylditin gives triethyltin chloride and diethyltin dichloride as the major tin-containing products. In this case the acid chloride seems to be acting mainly as a source of halogen. Similar reactions of

hexaethylditin with compounds such as benzoyl chloride and ethyl bromide have been described (5, 6).

We have also found that dimethyltrifluoroacetylarsine is obtained in low yield by reacting dimethylarsine with trifluoroacetyl chloride.

$$(CH_3)_2AsH + CF_3C(O)Cl \rightarrow (CH_3)_2AsC(O)CF_3 + HCl$$

Other products including chlorodimethylarsine are obtained. Dimethylarsine and acetyl chloride are reported to react similarly (7).

EXPERIMENTAL

The techniques used in this investigation have been described previously (4) and all known compounds were identified, at least, by their infrared spectra.

Reaction of Tetramethyldiarsine with Trifluoroacetyl Chloride

The diarsine (5.4 g) and trifluoroacetyl chloride (7.7 g) were left at 20° for 3 days. Unreacted acetyl chloride (4.5 g) was recovered. The remaining material could not be separated by distillation and all came over in the range 98–101°. Separation was effected by vapor phase chromatography (v.p.c.) (10 ft dinonyl phthalate column at 100°). Some dimethyltrifluoromethylarsine (~ 0.5 g) was collected and identified by its molecular weight of 174 (calcd. 174). The second component, a pale-yellow liquid (~ 4.3 g, 96% yield), was identified as *dimethyltrifluoroacetylarsine.*

Anal. Calcd. for $C_4H_6AsF_3O$: C, 23.8; H, 3.0; As, 37.1; F, 28.2. Found: C, 23.7; H, 3.1; As, 36.9; F, 28.5.

Infrared spectrum (vapor): 3 024 (m), 2 940 (m), 2 832 (w), 1 839 (w), 1 720 (s), 1 431 (m), 1 277 (vs), 1 204 (vs), 1 161 (vs), 909 (vs), 854 (m), 727 (s) cm^{-1}. Nuclear magnetic resonance data: ^1H spectrum, singlet at 1.00 p.p.m. downfield from external tetramethylsilane; ^{19}F spectrum, singlet at 0.38 p.p.m. downfield from external trifluoroacetic acid. The third component (~ 3.6 g) was identified as chlorodimethylarsine.

A sample of the acetylarsine was heated to 120° (18 h) and some decomposition took place. After 17 h at 150° decomposition was more extensive (~ 20%) and the major product was found to be dimethyltrifluoromethylarsine. The acetylarsine seemed to decompose readily on a mercury surface.

Reaction of Tetramethyldiarsine with Trifluoroacetic Anhydride

The diarsine (5.3 g) and the anhydride (8.0 g) were left at 20° for 28 days. A noncondensable gas was produced which was identified as carbon monoxide by its molecular weight of 28 (calcd. 28.0). Distillation of the least volatile fraction gave dimethyltrifluoromethylarsine, b.p. 56–60° (lit. 58° (8)), and dimethyltrifluoroacetoxyarsine, b.p. 136° (lit. 136–137° (9)) (4.3 g, 78% yield).

Reaction of Dimethylarsine with Trifluoroacetyl Chloride

The arsine (1.1 g) and acid chloride (4.6 g) were left at 20° (10 days). Trap-to-trap distillation gave hydrogen chloride (0.3 g) and unreacted trifluoroacetyl chloride (2.6 g). The least volatile fraction (1.5 g) could not be separated into its constituents by this means, but v.p.c. (10 ft dinonyl phthalate column at 110°) gave three main components. The first was identified as dimethyltrifluoroacetylarsine; the second was a mixture of compounds containing C, H, As, F, and O; the third was identified as chlorodimethylarsine. The relative area of the three peaks on the chromatogram was 1:4:2 in order of elution.

Reaction of Hexamethylditin with Trifluoroacetyl Iodide

The iodide (6.25 g) and the ditin compound (4.3 g) were left at 20° for 4 h. Noncondensable gas was evolved. Trap-to-trap distillation gave a trace of fluoroform, trifluoroiodomethane (0.5 g), trifluoroacetyl iodide (2.4 g), tetramethyltin (0.6 g), and trimethyltrifluoromethyltin (2.3 g, 74% yield). The tin compounds were also identified by comparison of their retention times on 6 ft silicone and 10 ft Apiezon J v.p.c. columns with those of authentic samples. The involatile residue was found to contain 46.5% iodine, determined as silver iodide (calcd. for $(CH_3)_3SnI$: I, 45.3%).

Reaction of Hexamethylditin with Trifluoroacetic Anhydride

When the tin compound (6.0 g) and the anhydride (4.8 g) were heated at 60° (15 h), a considerable amount of carbon monoxide of molecular weight 28 (calcd. 28) was produced. The volatile contents of the tube consisted of a trace of fluoroform, trifluoroacetyl fluoride (0.5 g) of molecular weight 116 (calcd. 116), unreacted anhydride (1.0 g), and tetramethyltin (2.5 g) of molecular weight 178 (calcd. 179). The tetramethyltin was also identified by its retention times as described in the preceding experiment. The solid residue (5.6 g) was identified as slightly impure trimethyltin trifluoroacetate, m.p. 90–100° decomp. (lit. m.p. 122–124° decomp. (10)).

Anal. Calcd. for $C_5H_9F_3SnO_2$: C, 21.7; H, 3.2. Found: C, 21.1; H, 2.8.

Reaction of Hexaethylditin with Trifluoroacetyl Chloride

Hexaethylditin (9.7 g) and the acetyl chloride (12 g) were irradiated with ultraviolet light (10 cm from a 100 W G.E. lamp) for 66 h. The least volatile fraction contained only triethyltin chloride (~ 7 g) and diethyltin dichloride (~ 4.5 g), which were separated by v.p.c. (Ucon Polar column at 135°). Ethane (0.4 g) was also isolated.

A NEW SYNTHESIS OF GERMYL IODIDE

James E. Griffiths and Alexander L. Beach

The versatility of silyl iodide in the preparative chemistry of the silicon hydrides arises from its position far to the left in MacDiarmid's silver salt conversion series (1). Attempts to establish such a series for the preparation of germyl compounds have been frustrated in part by the relatively poor stability of some of the materials (2). It has not always been clear, however, whether this is a problem of intrinsic instability (2) or of impurity-catalyzed decomposition.* In any case, the availability of a convenient synthesis of germyl iodide seems desirable if the chemistry of the germyl group is to be studied effectively. Although it is true that the germane iodine reaction produces germyl iodide (3–5), it is also generally true that the germane–halogen reaction is highly exothermic and rather difficult to control. A new method is presented here which takes advantage of the pseudo-halogen nature of trifluoromethyl iodide and effectively circumvents the disadvantages of the other method.

Trifluoromethyl iodide and germane react at a range of temperatures (25 to 235 °C) in a sealed tube forming germyl iodide and fluoroform. The reaction is very slow at room temperature taking up to 2 months to proceed to an appreciable extent but proceeds at a convenient rate near 130 °C. Some conversion of germyl iodide into less desirable products (probably GeH_2I_2, $GeHI_3$, and GeI_4 since no H_2 or HI was detected) occurs at these elevated temperatures but condensation of the products outside of the hot zone can quite

**Apiezon greases appear to promote decomposition of germyl compounds, whereas polymeric chlorofluorocarbon greases and waxes give much better results.*

A NEW SYNTHESIS OF GERMYL IODIDE

James E. Griffiths and Alexander L. Beach

The versatility of silyl iodide in the preparative chemistry of the silicon hydrides arises from its position far to the left in MacDiarmid's silver salt conversion series (1). Attempts to establish such a series for the preparation of germyl compounds have been frustrated in part by the relatively poor stability of some of the materials (2). It has not always been clear, however, whether this is a problem of intrinsic instability (2) or of impurity-catalyzed decomposition.* In any case, the availability of a convenient synthesis of germyl iodide seems desirable if the chemistry of the germyl group is to be studied effectively. Although it is true that the germane iodine reaction produces germyl iodide (3–5), it is also generally true that the germane–halogen reaction is highly exothermic and rather difficult to control. A new method is presented here which takes advantage of the pseudo-halogen nature of trifluoromethyl iodide and effectively circumvents the disadvantages of the other method.

Trifluoromethyl iodide and germane react at a range of temperatures (25 to 235 °C) in a sealed tube forming germyl iodide and fluoroform. The reaction is very slow at room temperature taking up to 2 months to proceed to an appreciable extent but proceeds at a convenient rate near 130 °C. Some conversion of germyl iodide into less desirable products (probably GeH_2I_2, $GeHI_3$, and GeI_4 since no H_2 or HI was detected) occurs at these elevated temperatures but condensation of the products outside of the hot zone can quite

*Apiezon greases appear to promote decomposition of germyl compounds, whereas polymeric chlorofluorocarbon greases and waxes give much better results.

likely minimize this effect. Although the latter point has not been demonstrated directly in the sealed tube experiments subsequent work under different conditions leads one to this conclusion. The reaction is quite rapid above 200 °C forming germyl iodide, fluoroform, and copious amounts of yellow-orange solids which may well include GeI_4. No hydrogen or hydrogen iodide was produced.

For larger scale preparations, several experiments have shown that a flow system through a heated container also is feasible and affords a more convenient method for synthesis. If a mixture of germane and CF_3I is passed through a heated glass bulb (195 to 260 °C) at moderate pressure (nominally 10 cm Hg) at various flow rates, the yield of GeH_3I varies between 15 and 37% based upon the CF_3I consumed. The lowest yield reflects a low flow rate of reactants or, in other words, the longer the desired product is in the hot zone, the greater its decomposition.

EXPERIMENTAL AND RESULTS

Trifluoromethyl iodide,* germane (6), and germane-d_4 (7) were prepared by standard methods and were purified by fractional vaporization and condensation in an all glass vacuum system. Criteria of purity were molecular weight (±1), tensimetric homogeneity (±0.3 mm Hg), and the absence of impurity bands in the infrared spectrum. The last was recorded on a Beckman IR-12 spectrophotometer.

In a typical experiment, 2.01 mmoles of GeD_4 and 1.00 mmoles of CF_3I were sealed in an evacuated tube and heated at 130 °C for 2 h. Yellow solid deposits appeared on the tube walls. Reactants and products were individually separated by repeated fractional condensation and vaporization in U-type vacuum traps maintained at −45 °C to separate GeD_2I_2 and less volatile products, −95 °C to isolate GeD_3I, −126 °C to stop CF_3I, and at −196 °C to recover GeD_4 and CF_3D. The deuterium compound GeD_4 rather than GeH_4 was used for many of the experiments so that infrared spectra could be employed to monitor the effectiveness of the separations of products and reactants. The deformation modes of the GeD_3 group (ν_2 and ν_5) or ν_4 of GeD_4 do not overlap with other absorption bands and in the spectrum of CF_3D a strong doublet band well isolated from all others appears at 974 cm^{-1} (8). The latter served as a useful criterion for establishing to what extent CF_3D and GeD_4 were separated. Since the initial separation was not entirely successful, the contents of the trap which had been cooled to −196 °C (see above) were repeatedly passed through a trap held at −160 °C into a trap cooled to −196 °C until the former fraction contained only CF_3D and the latter contained mainly GeD_4 with a small amount of CF_3D. By making up known mixtures an infrared calibration was possible.

The result of all of the vacuum manipulations was to collect 0.33 mmole of GeD_3I (molecular weight, 206, calcd. 205.5; vapor pressure at 20.2 °C, 56 mm), 0.373 mmole of CF_3I (molecular weight 195.9, calcd. 195.9), 0.629 mmole of CF_3D, and 0.746 mmole of GeD_4. Molecular weight measurements on mixtures of CF_3D and GeD_4 are not useful criteria of purity. The conversion into GeD_3I based upon initial amounts of GeD_4 and CF_3I was 17 and 31% respectively. Based upon reactants actually used up in the reaction the yields were 82 and 53% respectively. Solid deposits left in the reaction tube and traces of volatile materials trapped at −45 °C were not treated further. It is assumed that the bulk of this was germanium tetraiodide.

Separations and identification of various compounds in all subsequent experiments were done similarly and details are not given except when necessary.

When 1.01 mmoles of GeD_4 and 2.00 mmoles of CF_3I were heated together in a sealed tube at 135 to 140 °C during 4.5 h, 0.216 mmole of GeD_3I, 0.401 mmole of CF_3D, 0.746

Peninsular Chemresearch Inc., Gainesville, Florida.

mmole of GeD_4, and 1.60 mmoles of CF_3I were recovered, representing a yield of GeD_3I of 85 or 54% respectively based upon the amounts of GeD_4 or CF_3I actually used up in the reaction.

When 8.1 mmoles of GeH_4 and 8.8 mmoles of CF_3I were heated rapidly to about 230 to 240 °C, reaction proceeded vigorously with immediate deposition of bright orange solids. After about 40 min at these temperatures, 1.00 mmole of GeH_3I (molecular weight, 203, calcd. 202.5; vapor pressure at 19.1 °C, 53 mm) could still be recovered but only about 1 mmole of unconsumed CF_3I remained. The only other volatile product was CF_3H. All of the germane was used.

Several flow system experiments are reported in which products were removed from the hot zone and two types of glass apparatus were used. In the first an equimolar mixture (16 mmoles) of GeH_4 and CF_3I was passed through a 1 in. diameter glass tube at 185 °C at a flow rate of 5 mmoles/h. No products were detected but at 220 °C a small amount (0.1 mmole) of GeH_3I (identified by its infrared spectrum) could be isolated. No solid deposits were noted. In this type of experiment, however, the gases passed through the hot zone at very low pressure and the results are not particularly reproducible.

In the next series of experiments the reactant gases were passed through a 1 l glass bulb heated with a heating mantle and fitted with inlet and outlet tubes. Instead of allowing the gases to pass slowly through the hot zone at low pressure, a nominal pressure of 5 or 10 cm Hg was maintained and the overall flowrate was much increased. The results are summarized in Table I. The GeH_3I and CF_3I were isolated after the reaction, but CF_3H was not separated from GeH_4 because of the great deal of effort required to separate them.

TABLE I

Flow reaction of GeH_4 with CF_3I

Taken*		Recovered*		Temp.	Flow rate	Pressure
GeH_4	CF_3I	GeH_3I	CF_3I	(°C)	(mmole/min)	(cm Hg)
6.16	5.37	0.6 (201.9)†	3.84 (196.6)†	195	1.15	10.0
4.36	4.63	0.5 (202.1)	1.51 (196.3)	225	0.30	10.0
9.71	9.74	1.5 (201.9)	5.37 (196.6)	260	0.97	5.1

*Amounts in mmoles.
†Observed molecular weights in parenthesis.

In summary, germyl iodide can be conveniently prepared by methods outlined above and is moderately stable in a static system at temperatures near 135 °C. A flow system with the reactants at moderate pressures (5 to 10 cm Hg) and rather high temperatures (200 to 260 °C) offers some advantages over the sealed hot tube method. Specifically, rapid removal of products from the hot zone and better control of the total pressure is easier to accomplish. Furthermore, the limited data available in this work indicate that further scale-up of the reaction would be profitable and also that germyl iodide is not nearly as unstable thermally as was previously thought.

REACTIONS OF ACTIVE NITROGEN WITH ORGANIC SUBSTRATES. IV. ISOPRENE[1]

TERUKYO HANAFUSA[2] AND NORMAN N. LICHTIN

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Some time ago we (1) communicated the very limited results of an initial cursory examination of the reaction of isoprene with active nitrogen. This reaction has now been subjected to more extensive investigation but, because of its complexity and in spite of considerable effort, relatively few conclusive results have been obtained and the investigation has been terminated.

Reactions were carried out in a fast flow system at autogenous temperature (ca. 60°), at pressures of 2.0 to 2.5 Torr and linear flow rates of 4.0 to 4.6 m s^{-1}. The molar ratio of isoprene to $N(^4S)$ was 10 ± 2. The use of a large excess of isoprene minimizes secondary attack of active nitrogen on the products. A glow discharge supported by 2 450 Mc microwaves was used to generate the reagent and the pyrex walls of the system were not poisoned.

Products were divided into three categories (2) on the basis of volatility. Those trapped at −78° but volatile at 10^{-2} Torr and 60° are hereafter designated as "monomeric"; those trapped at −78° but not volatile at 10^{-2} Torr and 60° are called "polymeric"; and those trapped at −196° but not at −78° are called "degradative". Gas chromatography was employed to isolate and purify individual products (cf. Experimental). Except for HCN, quantitative yields were not determined.

Nine compounds besides recovered isoprene were identified in the "degradative" fraction. Propane, the least abundant of these, was identified only by its gas-chromatographic retention time. Hydrogen cyanide was identified by its reaction with test paper (American Cyanamide Co.) and was determined quantitatively by titration of the total "degradative" product by Liebig's method (cf. ref. 3). The other seven were identified by comparison of both their infrared spectra and gas-chromatographic retention times with those of authentic samples. The most prominent "degradative" hydrocarbon under the conditions employed is propylene. Ethylene appears to be the next most abundant, whereas yields of ethane, acetylene, propyne, 2-methylbutene-1, and 1,3-butadiene are smaller. All of these products except 2-methylbutene-1 are degradative in the structural sense. The present data are too few to provide an independent test of the mechanistic model which has been suggested (2, 4) to rationalize products of the reaction of active nitrogen with butadiene. They are, however, not inconsistent with the postulate that they are formed as a result of various modes of decomposition of complexes of substrate with $N^4(S)$.

All the "degradative" products obtained from isoprene except 2-methylbutene-1 were also obtained in the reaction with 1,3-butadiene. This compound probably is formed by addition of hydrogen to isoprene. 1,3-Butadiene may have been formed directly in the decomposition of the primary adduct, along with $CN + H_2$ or $HCN + H$, or indirectly by combination of molecular fragments analogous to the "resynthesis" of propylene (5).

With the concentration of $N(^4S)$ (as determined by emission titration with NO (6)) equal to $6 \pm 1 \times 10^{-7}$ *M*, 27% of N was converted to HCN. This percentage conversion

[1]*Research supported principally by the U.S. Army Research Office (Durham) under grant No. 31-124-G171. The technical assistance of Mr. M. S. Puar in some of this work was supported by grant No. 702A of the Petroleum Research Fund of the American Chemical Society.*

[2]*Present address: The Institute of Scientific and Industrial Research, Osaka University, Osaka, Japan.*

is, within experimental precision, identical with the values found for butadiene (4) and propylene (7) under similar conditions with substrate in excess over N(^{4}S). The weight ratio of the yield of HCN to the total yield of monomeric products to the total yield of polymeric products was approximately 1.2:1:1.2.

The "monomeric" fraction contained at least 16 compounds, only 4 of which were unequivocally identified by infrared spectrometry, 3 by comparison of their spectra with those of authentic samples and the fourth, *beta*-methylpyrrole, by comparison with data in the literature (8). The formation of the latter product from isoprene is analogous to the formation of pyrrole from 1,3-butadiene. This compound constitutes a much smaller fraction of the total monomeric product from isoprene than does pyrrole from 1,3-butadiene, however. Its relative yield based on peak areas uncorrected for differences in area factors is only about 8% compared with the value of 26% found for pyrrole. The reason for this difference is not apparent. The reaction of isoprene also provides a small yield of pyrrole (2% on the above basis). In view of the large excess of isoprene employed and the small yield of 1,3-butadiene, it is improbable that this product is formed by secondary attack on butadiene. Presumably it is formed from the initial addition complex (2, 4) with loss of a methyl group.

Ammonia constituted about 3% of the "monomeric" product. It has not been detected among the products from 1,3-butadiene and its formation in significant yield is apparently associated with the presence of a methyl group in the molecule. Enhancement of ammonia yields is associated with the presence of methyl groups in a number of other substrates (9, 10) and has been explained (9) on the basis of simultaneous abstraction of two or three hydrogen atoms from one methyl group.

The fourth product, 1-cyanoisoprene, was isolated from the products of one experiment but not from those of several others. This compound is the analog of the *cis*-1-cyanobutadiene-1,3 obtained from 1,3-butadiene. These products presumably arise from attack of the cyanogen radical on substrate.

In spite of extensive gas chromatography of fractions of the "monomeric" product and, in a few cases, of mass-spectrometric analysis,* no other pure product was isolated and identified. One unresolved fraction appeared to contain primary amines, on the basis of infrared bands at 3 300 – 3 400 cm^{-1}. A number of fractions contained one or more unsaturated nitriles, on the basis of infrared absorptions in the 2 215 – 2 235 cm^{-1} region.

Examination of the "polymeric" product involved fractionation on the basis of solubility and volatility under vacuum, vapor phase chromatography, ultraviolet and infrared spectrometry, elemental analysis, and attempted formation of picrates as described under Experimental. All five fractions which were obtained had very similar infrared spectra. Absorption bands observed at 2 800 – 3 000, 1 450, and 1 375 cm^{-1} are presumably due to aliphatic CH_2 and CH_3; those near 2 200 cm^{-1} indicate the presence of nitrile groups. Broad absorption at 3 200 – 3 300 and bands around 1 625 – 1 650 suggest the presence of amino groups. This suggestion is consistent with the solubility of several fractions (all which were tested) in 2 *M* aqueous HCl. Elemental analyses of two fractions (cf. Experimental) correspond to the atomic ratios $C_{3.0}H_{4.3}N_{1.00}$ and $C_{3.0}H_{5.0}N_{1.00}$ respectively. C, H, and N constituted only 89.2 wt. % of the former fraction and 79.9 wt. % of the latter, however. Gas chromatography on Carbowax 20 M at 75–200° of two CCl_4-soluble fractions indicated that both were complex mixtures of many components, but the possibility that fragmentation of the "polymer" took place on the column was not investigated.

EXPERIMENTAL

Apparatus and procedures were essentially the same as previously described (2, 4). The pyrex walls of the system were not poisoned but were conditioned before each experiment by evacuating overnight with a mercury diffusion pump and then by passing molecular nitrogen for 20 min at the pressure of the experiment and active nitrogen for 30 min before isoprene was introduced into the reactor 30 cm downstream from the glow discharge. The flow rate of isoprene was controlled by thermostatting its reservoir.

Emission titration of active nitrogen with NO (6) was carried out to a visual end point periodically during the course of the work. The selectivity of the NO titration for $N(^4S)$ is still controversial (11–13) but the uncertainty inherent in this controversy (12) only has the effect of rendering the ratios of isoprene to $N(^4S)$ quoted in this paper minimum possible values of the true quantities: i.e. there is no question that isoprene was in large excess.

An F and M model 500 instrument equipped with a model 720 temperature-programmed oven was used for most of the gas chromatography reported here. Some preliminary separations of "monomeric" products were carried out on a Aerograph Autoprep model A-700.

The "degradative" fraction was separated into its components on an 8 ft × $\frac{1}{4}$ in. outside diameter diisodecyl phthalate column at room temperature with a helium flow of 20 cc min^{-1}. The separated fractions were collected at −196° and rechromatographed on an 8 ft × $\frac{1}{4}$ in. outside diameter silica gel column temperature programmed from 50 to 250 °C at 4 deg min^{-1} with a helium flow rate of 30 cc min^{-1}. Individual fractions were rechromatographed to homogeneity as needed. Each purified fraction was transferred to a 10 cm gas cell for measurement of its infrared spectrum on a Perkin–Elmer model 237 instrument.

The "monomeric" fraction was first chromatographed on an 8 ft preparative silicone 550 column programmed at 50 to 200 °C at 2.9 deg min^{-1} with a helium flow rate of 40 cc min^{-1}. This procedure cleanly separated out NH_3 and the small portion of the recovered isoprene collected in the "monomeric" fraction. The other, poorly resolved fractions were individually rechromatographed on an 8 ft preparative Carbowax 20 M column programmed from 50 to 200 °C at 2.9 deg min^{-1} with a helium flow rate of 40 cc min^{-1}. The components corresponding to individual peaks were collected and their infrared spectra measured in CCl_4 solution in a 2 mm cell on a Perkin–Elmer model 237 spectrometer.

The "polymeric" fraction was extracted with refluxing methylene chloride and the insoluble residue was completely dissolved by refluxing pyridine. The solvents were then removed by distillation under reduced pressure. The methylene chloride soluble fraction was then extracted with CCl_4. The tan insoluble residue melted at 116–128°, was soluble in chloroform, ethanol, acetone, and 2 *M* aqueous HCl, as well as in methylene chloride and pyridine. Its infrared spectrum was measured in Nujol mull and in methylene chloride solution. Its elemental analysis was C, 58.9; H, 7.36; N, 23.0. A picrate formed by reaction with picric acid in ethanol did not have a sharp melting point. After removal of solvent from the carbon tetrachloride extract, the residue was fractionally distilled at 0.07 Torr to yield two fractions, b.p. 75–82° and 82–105°. The two fractions were then gas chromatographed on a 6 ft × $\frac{1}{4}$ in. Carbowax 20 M column programmed from 75 to 200 °C at 4 deg min^{-1} with a helium flow rate of 30 cc min^{-1}. Infrared spectra of the two fractions and the residue from distillation were determined with liquid films. The 75–82° fraction had an ultraviolet absorption maximum at 206–210. The dark pyridine-soluble fraction of the "polymeric" product was found to be soluble in glacial acetic acid and 2 *M* aqueous HCl. Its infrared spectrum was determined in Nujol. Its elemental analysis was C, 52.3; H, 7.28; N, 20.3. The material had a wide melting range above 130°.

Nitrogen was Matheson Co. prepurified grade. Isoprene was Matheson Co. research grade. Solvents were reagent or spectroscopic grade. Authentic 1-cyanoisoprene was prepared by the method of Snyder (14).

THE COPPER/SELENIUM SYSTEM

R. D. HEYDING

The copper-rich region of the copper/selenium phase diagram is well established (1), and room temperature phase relationships at higher selenium concentrations have been reported by Borchert and Patzak (2). Apparently no comprehensive examination has been made of the selenium-rich region, although the 'hypothetical' diagram proposed by Gattow and Schneider (3) is remarkably accurate. The crystal structures of the compounds stable at room temperature are known, with the exception of the low temperature Cu_2Se modifications. The structure of Cu_2Se reported by Borchert (4) was not observed by Boettcher *et al.* (5) or by Kotovich and Frank-Kamenetskii (6). Boettcher, on the other hand, observed seven distinct electron diffraction patterns for thin films of $Cu_{1.9}Se$ between 20 and 320 °C.

A series of alloys with 27 to 70 atomic % selenium have been prepared in our laboratory and examined by differential thermal analysis (d.t.a.) and by room temperature and high temperature X-ray diffraction techniques. A phase diagram to 880 °C has been obtained, crystal structures have been examined, and enthalpies of transformation have been estimated.

EXPERIMENTAL

Samples were prepared by the reaction of copper and selenium (both Asarco 59) in sealed evacuated Vycor tubes in the usual manner. When the formation reactions were complete, specimens were annealed for various periods depending on the rate at which apparent equilibrium was attained, and either slowly cooled in the annealing furnace or quenched in ice/water mixtures.

One gram samples for d.t.a. were sealed *in vacuo* in Vycor tubes with reentrant thermocouple wells. Nickel sponge was used as the standard specimen. Heating rates (not programmed) were between 2° and 3 deg/min, and free cooling rates varied from 5 deg/min at 800 °C to 3 deg/min at 130 °C. Indium (39_5), cadmium (59), zinc (69), and antimony (69) as primary standards, and sulfur (59) and selenium (59) as secondary standards, were used to calibrate the instrument with respect to temperature and the area of the differential signal. The high vapor pressure of selenium at the strain point of Vycor imposed an upper limit of 880 °C on the analysis.

Diffraction patterns of three specimens (Cu_2Se, Cu_3Se_2, and CuSe) were obtained in a 19 cm Unicam high temperature Debye–Scherrer camera. Room temperature powder patterns were obtained in 11.46 cm cameras. Nickel-filtered copper radiation ($\lambda_{K\alpha}$ = 1.54050 Å) was used throughout.

RESULTS AND DISCUSSION

The phase diagram is shown in Fig. 1. Transformation temperatures are considered to be accurate to ±1 °C. The monotectic at 523 °C is inferred; no direct evidence was sought for the two phase liquid field.

The diselenide $CuSe_2$ melts peritectically at 342 °C, forming CuSe and a liquid phase. The reverse reaction is slow. On cooling through the transformation point at 3 deg/min, less than 10% of the stoichiometric quantity of $CuSe_2$ is formed. The compound has the C18 marcasite structure reported by Gattow (7), although the unit cell volume of our specimens is 5% smaller than that of Gattow's single crystal (cf. Table I).

The monoselenide CuSe undergoes a rapid and reversible polymorphic transformation at 53 °C, and decomposes at 382 °C to $Cu_{2-x}Se$ and a liquid phase. The low temperature modification, αCuSe, has the B18 covellite structure. The diffraction data are in good agreement with published intensities and cell dimensions for klockmannite (8, 9). The high temperature modification, βCuSe, has been indexed on an orthorhombic cell (Table I) based on observed splittings in low order αCuSe reflections. In this setting the transformation appears to involve a small decrease in the a/b ratio from the orthohexagonal

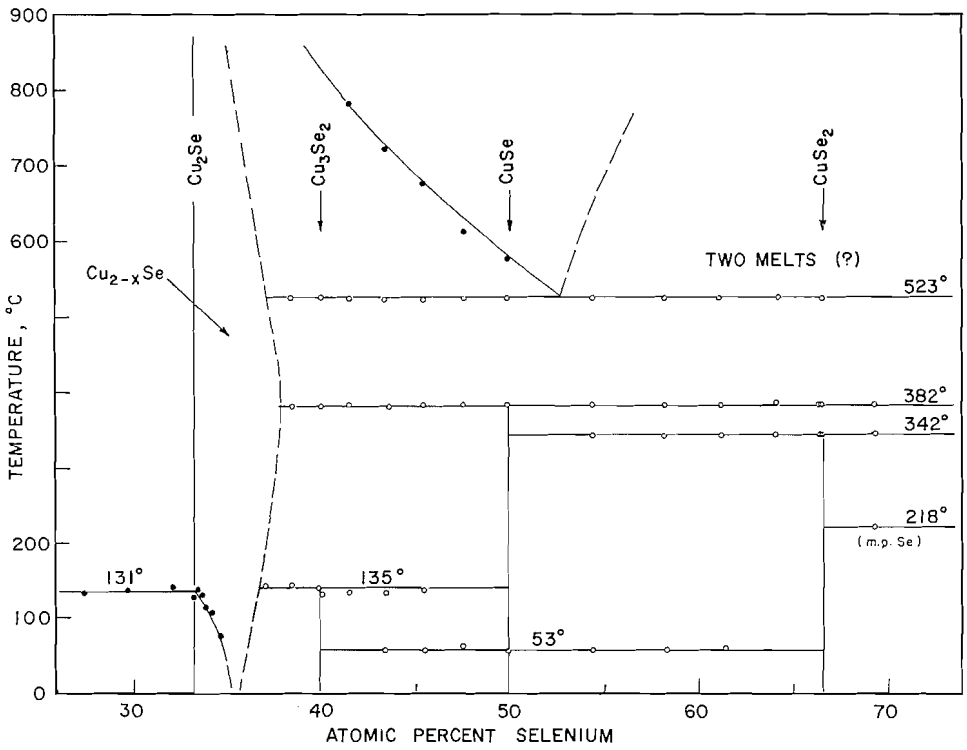

FIG. 1. Phase diagram of the copper/selenium system: (○) differential thermal signal, heating cycle; (●) differential thermal signal, cooling cycle.

value. The high temperature diffraction patterns of this compound were of indifferent quality, and it must be emphasized that this assignment is tentative.

The compound Cu_3Se_2 disproportionates at 135 °C to $Cu_{2-x}Se$ and βCuSe. The reaction of the latter two compounds below 135 °C to form Cu_3Se_2 is exceedingly slow. On the other hand, specimens with this composition quenched rapidly from 360 °C contain Cu_3Se_2 and, in many instances, only traces of the end-members. Normally one would infer from these observations that Cu_3Se_2 is a high temperature phase. However, careful examination of specimens of Cu_3Se_2 in the high temperature camera has confirmed the disproportionation at 135 °C, the $Cu_{2-x}Se/\beta$CuSe field between 135 and 382 °C, and the $Cu_{2-x}Se$/liquid field above 382 °C. (Once heated above 135 °C, the Cu_3Se_2 phase did not reappear in the camera.) Moreover, specimens in this concentration range showed consistent d.t.a. patterns before and after long annealing periods between 300 and 390 °C in the d.t.a. furnace itself.

It is uncommon for a phase to appear on quenching from well above its stability field when the rate of transformation just below the transformation temperature is very slow. In this instance an explanation can be based on the assumption that the selenium-rich limit of the homogeneous $Cu_{2-x}Se$ phase moves to higher selenium concentrations with increasing temperature, as indicated by the dotted line in Fig. 1. On quenching from the $Cu_{2-x}Se/\beta$CuSe field, Cu_3Se_2 may be formed by a precipitation mechanism imposed by the decreasing number of Cu vacancies in the $Cu_{2-x}Se$ solid solution.

The tetragonal unit cell dimensions of Cu_3Se_2 obtained in quenched specimens are only slightly smaller than those of the mineral umangite (10).

βCuSe§	Orthorhombic (?)	—	$6.81_3 \pm 0.01$	$4.01_5 \pm 0.01$	$17.09_5 \pm 0.02$
$CuSe_2$	Orthorhombic	$Pnnm$	$5.01_7 \pm 0.01$	$6.19_8 \pm 0.01$	3.741 ± 0.005

*In the presence of αCu_2Se.
†In the presence of αCuSe.
‡In the presence of $Cu_{2-x}Se$ and CuSe.
§Specimen temperature 63 ± 2 °C.

The cubic C1 $Cu_{2-x}Se$ phase has a very narrow homogeneity range at room temperature centered at ca. $Cu_{1.8}Se$, within the limits $0.18 \leq x \leq 0.25$ (Table I). When x is zero, the cubic phase is not stable below 131 °C. Between 131 and 440 °C no phases other than the cubic C1 phase were observed in the high temperature camera.

The symmetry of the low temperature Cu_2Se phase (which will be called αCu_2Se in accord with the nomenclature used for other low temperature 2:1 IB/VIA compounds) is not yet known. The diffraction pattern is in substantial agreement with that recorded by Kotovich (6), provided the cubic $Cu_{2-x}Se$ reflections are deducted from the Kotovich pattern. The reflections cannot be indexed using the tetragonal cell proposed by Borchert (4). The compound does not appear to be isomorphous with Cu_2S III (11), αCu_2Te (12), Ag_2S (13), or αAg_2Se (14), or, indeed, any of the copper and silver chalicides in the same composition region.

Recently Sharma (15) studied thin films of Cu_2Se and failed to observe a transformation at 110 °C reported in an early paper by Rahlfs (16). Sharma suggested that if the transformation occurs in films it must do so at much higher temperatures than in bulk specimens. Since the film was cubic at room temperature and was therefore $Cu_{1.8}Se$ and not Cu_2Se as Sharma believed, no transformation was to be expected below ca. 900 °C. The structural properties of the film and of our bulk specimens appear to be identical.

The enthalpies associated with the transformations have been estimated from the areas of the d.t.a. signals observed during the transformations. These data are compared in Table II with values calculated from room temperature enthalpies of formation reported by Gattow and Schneider (3). Even with very generous allowances for the semiquantitative d.t.a. data, the agreement is so unsatisfactory that some discussion is required.

TABLE II

Enthalpies of transformations in the Cu/Se system

Compound	ΔH_f^{298}* (kcal/mole)	Transformation	T (°C)	Products	$\Delta H_{calcd}{}^T$† (kcal/mole)	$\Delta H_{obs}{}^T$‡ (kcal/mole)
αCu_2Se	−13.01	α,β	131	$Cu_{2-x}Se$	—	$+4.9 \pm 1.0$
Cu_3Se_2	−23.64	Decomposition	135	$Cu_{2-x}Se$ + βCuSe	$+0.3 \pm 2.5$	$+4.6 \pm 0.9$
αCuSe	-9.4_5	α,β	53	βCuSe	—	$+0.33 \pm 0.09$
βCuSe	—	Decomposition	382	$Cu_{2-x}Se$ + Se (1)	$+2.3 \pm 0.8$	$+3.4 \pm 0.8$
$CuSe_2$	−10.3	Decomposition	342	βCuSe + Se (1)	$+2.4 \pm 1.0$	$+2.9 \pm 0.7$

*Gattow and Schneider (3).
†Calculated from ΔH_f^{298}, with ΔH_{liq} for Se = +1.30 kcal/mole, and assuming ΔH_{trans} α,βCuSe = +0.33 kcal/mole; $C_p\,dT$ terms neglected. Uncertainties in $\Delta H_{calcd}{}^T$ indicate the result of a 5% uncertainty in ΔH_f^{298}.
‡Estimated from the area of the differential thermal signal during the transformation.

Obviously small errors in the enthalpies of formation will invoke disproportionately large errors in calculated heats of reaction. Gattow and Schneider obtained their data by direct calorimetric determination of heats of reaction of powdered copper and selenium. Incomplete reaction in the calorimeter was observed in several instances, particularly in the Cu_3Se_2 composition range. It is difficult to estimate what uncertainties incomplete reaction might impose on the results. The uncertainties assigned in Table II for purposes of comparison are based on an uncertainty of 5% in the enthalpies of formation. With this assumption the calculated and observed heats of decomposition of $CuSe_2$ and βCuSe are within the assigned limits. The enthalpy of formation of Cu_3Se_2 is based on an assumption which implies that the disproportionation of Cu_3Se_2 involves little or no change in enthalpy. (The value of 0.3 kcal/mole in Table II arises solely from the α,βCuSe transition.) This supposition is not supported by d.t.a. The quantities of Cu_3Se_2 formed in the calorimeter may have been less than the authors appreciated.

The enthalpy of the $\alpha Cu_2Se/Cu_{2-x}Se$ transformation is larger than one would expect for a simple polymorphic change. It is quite possible that the low temperature phase is not a polymorphic form of the cubic $Cu_{2-x}Se$ phase, but a new phase, slightly richer in copper than the tentative formula indicates.

Powder diffraction patterns of $CuSe_2$ and βCuSe have been submitted to the ASTM Index, and to the Depository of Unpublished Data.*

ACKNOWLEDGMENTS

I am indebted to Prof. F. A. Hames, Department of Metallurgy, for the use of his high temperature camera, and to Mr. V. Lawetz for assistance in preparing samples and obtaining diffraction patterns. An operating grant from the Ontario Research Foundation is gratefully acknowledged.

NOTE ADDED IN PROOF: In a recent paper, Gattow (17) has reported the atom positions in $CuSe_2$, and has given 350 °C as the temperature at which this compound decomposes.

THE REACTION OF HYDROGEN AND ETHYLENE IN THE GAS PHASE

M. C. LIN

Recent measurements of the chain initiation and termination steps in the thermal decomposition of ethane (1) led to the conclusion that the combination of ethyl radicals was the main termination step and that the unimolecular decomposition of the ethyl radical was in its pressure-dependent region in the range of temperatures and pressures covered by the experiments. On the basis of these facts the mechanism for the homogeneous hydrogenation of ethylene in a similar region of temperature and pressure was reexamined, and a mechanism is proposed which is consistent with the new values for the rates of the elementary reactions.

Early work by Pease (2) showed that with mixtures of hydrogen and ethylene in the ratio 3:1 the main product was ethane and its rate of formation was first order with respect to both hydrogen and ethylene. The rate constant for the formation of ethane was given by the expression

$$k = 5.90 \times 10^{13}\, e^{-44800/RT} \text{cc mole}^{-1}\, \text{s}^{-1}$$

in the temperature range 475–550 °C. It is apparently well established that the reaction occurs by a free radical chain mechanism. For example, from the reaction of D_2 with C_2H_4 at temperatures between 550 and 660 °C large amounts of C_2H_3D were formed, and C_2H_5D and $C_2H_4D_2$ were the major deuterated ethanes produced (3). The following mechanism was proposed by Rice and Herzfeld (4):

[1] $$H_2 + C_2H_4 \rightarrow H + C_2H_5$$

[2] $$C_2H_5 + H_2 \rightarrow H + C_2H_6$$

[3] $$H + C_2H_4 \rightarrow C_2H_5$$

[4] $$H + C_2H_5 \rightarrow C_2H_6 \text{ or } H_2 + C_2H_4 \quad .$$

The rate of production of ethane is then

[5] $$d[C_2H_6]/dt = (k_1k_2k_3/k_4)^{1/2}[H_2][C_2H_4].$$

This expression is, however, inconsistent with the measurements of the related elementary reactions in the thermal decomposition of ethane in the following ways:

(*a*) The chain termination step

[6] $$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \text{ or } C_2H_4 + C_2H_6$$

can be shown to be faster than reaction [4] under the conditions of the experiments. If the chain length is long, the relative rates of reactions [4] and [6] may be expressed as follows

[7] $$R_4/R_6 = [H]/[C_2H_5] = k_2[H_2]/k_3[C_2H_4],$$

where k_4 is assumed to be equal to k_6. Neither k_2 nor k_3 is well known but they may be calculated from the rate constants of the reverse reactions and the corresponding equilibrium constants. For 900 °K the following data were used: $K_2 = k_{-2}/k_2 = 1.4 \times 10^3$ (5); $K_3 = k_{-3}/k_3 = 6.2 \times 10^{-10}$ mole/cc (5); $k_{-2} = 7.6 \times 10^{10}$ cc/mole s (6); $k_{-3} = 1.1 \times 10^4$ s^{-1} at 500 mm (1). Thus

[8] $$R_4/R_6 = 3.1 \times 10^{-6}\, [H_2]/[C_2H_4].$$

The combination of ethyl radicals must therefore be the predominant chain-ending step.

(*b*) The overall activation energy predicted by eq. [5] may be calculated by using the following values, in kcal/mole: $E_1 = 66.5$; $E_2 = 12.5$ (both calculated from taking $D(C_2H_5—H) = 97.5$, $D(H—H) = 103.2$, and $E_{-2} = 6.8$ (6)); $E_4 = 0$. E_3 may be obtained from the measured value for E_{-3}, the activation energy for reaction [−3], combined with the heat of the reaction $C_2H_5 \rightleftharpoons C_2H_4 + H$ of 38.6 kcal/mole (5). The decomposition of the ethyl radical has been shown to be pressure dependent at temperatures from 430–620 °C and pressures below 600 mm (1, 7). The order of the decomposition is about 1.4 at 600 mm and 1.7 at 60 mm. E_{-3} was found to be 32.7 kcal/mole over the range of pressures and temperatures studied (1). Thus

$$E_3 = 32.7 - 38.6 = -5.9 \text{ kcal/mole}$$

and

$$E_{\text{overall}} = \tfrac{1}{2}(E_1 + E_2 + E_3 - E_4) = 36.5 \text{ kcal/mole},$$

which is much lower than the value of 44.8 kcal/mole obtained by Pease.

To overcome these difficulties the following mechanism is proposed in which initiation occurs by the bimolecular reaction of ethylene and termination by the combination of ethyl radicals, i.e.

[9] $$C_2H_4 + C_2H_4 \rightarrow C_2H_3 + C_2H_5$$

[2] $$C_2H_5 + H_2 \rightarrow C_2H_6 + H$$

[3] $$H + C_2H_4 \rightarrow C_2H_5$$

[6] $$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \text{ or } C_2H_4 + C_2H_6 \quad .$$

The rate of ethane production is then

[10] $$d[C_2H_6]/dt = k_2(k_9/k_6)^{1/2}[C_2H_4][H_2].$$

The reaction is thus correctly predicted to be first order in both ethylene and hydrogen.

The activation energy of reaction [9] may be estimated by assuming a value of 103 ± 3 kcal/mole for $D(C_2H_3—H)$ (8). If E_{-9} is taken as 0 then $E_9 = 64$ kcal/mole. Thus $E_{\text{overall}} = E_2 + \frac{1}{2}(E_9 - E_6) = 44.5$ kcal/mole. This is in agreement with the experimental value.

ACKNOWLEDGMENT

The author would like to express his indebtedness to Dr. M. H. Back for continued discussions and also to Professor K. J. Laidler for valuable comments.

CONFIGURATION OF DIELS–ALDER ADDUCT OF FURAN AND ACETYLENE DICARBOXYLIC ACID[1]

J. KALLOS AND P. DESLONGCHAMPS[2]

Research Laboratory, Department of Pathology, St. Mary's Memorial Hospital, Montreal, Quebec

Received December 9, 1965

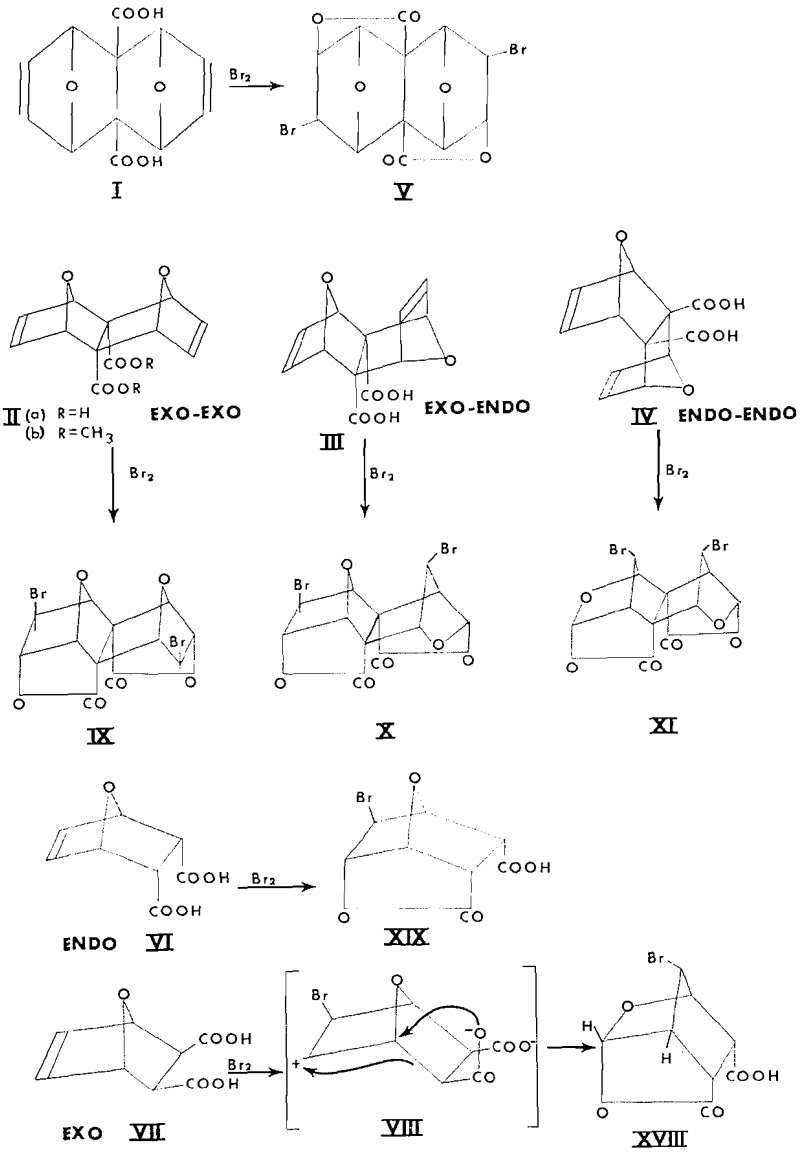
ABSTRACT

The configuration of the Diels–Alder adduct (I) of furan and acetylene dicarboxylic acid was established by chemical and spectroscopic methods and found to be *exo–exo* (II*a*).

In 1931, Diels and Alder (1) reported the preparation of an adduct (I) obtained by reacting furan (2 moles) with acetylene dicarboxylic acid (1 mole). Theoretically this adduct could have three possible configurations: *exo–exo* (II*a*), *endo–exo* (III), or *endo–endo* (IV). This communication presents experimental evidence that the stereochemistry of this adduct is *exo–exo*.

Diels and Olsen (2) obtained a dibromodilactone by reacting the diester of the adduct (I) with bromine in chloroform; they proposed a planar formula (V) for this dibromodilactone but did not present any proof for the configuration of the adduct. However, if the dibromodilactone derivative possesses the Diels–Olsen formula (V), the configuration of the adduct has to be *exo–exo* (II*a*).

In 1948, Woodward and Bear (3) showed that bromolactonization of the carboxylic acid derivatives of 7-oxa-bicyclo[2.2.1]hept-2-ene occurs with the *exo* type (VII) as well as the *endo* type (VI). They also showed that the *exo* compound reacts via a Wagner–Meerwein rearrangement as shown (VIII). In view of these findings the planar formula suggested for the dibromodilactone required further investigation. In fact, three formulae are possible for this compound; these are as represented in IX, X, and XI.



In 1961, iodolactonization of the diacid I was investigated by Stockman (4). He concluded that the adduct was a mixture of 4% *exo–exo* (II*a*) and 96% *endo–exo* (III). However, his argument is based on the specificity of iodolactonization, which in our view cannot be conclusive.

The stereochemistry of the adduct was elucidated by the following sequence of reactions. Iodolactonization (5) of the diacid II*a* in potassium carbonate solution with iodine gave iodolactone acid XII*a*; infrared: 1 775 and 1 715 cm^{-1}. On esterification with diazomethane the corresponding iodolactone acid methyl ester (XII*b*) was formed; infrared: 1 785 and 1 745 cm^{-1}. Iodolactonization usually occurs only with *endo* derivatives (5). This was confirmed when the iodolactone acid XII*a* was reconverted into the starting diacid II*a* by zinc – acetic acid treatment. This eliminated the possibility of the *endo–endo* configuration.

The diacid II*a* was transformed into the lactone acid XIII*a* by the action of hydrobromic acid in acetic acid solution; infrared: 1 765 – 1 770 and 1 715 – 1 735 cm^{-1}. On esterification with diazomethane the corresponding lactone acid methyl ester (XIII*b*) was obtained; infrared: 1 780 and 1 720 – 1 740 cm^{-1}. The fact that no rearrangement occurs during lactonization was proven by a direct correlation of lactone acid XIII*a* with iodolactone acid methyl ester XII*b*. Hydrogenation of lactone acid XIII*a* yielded the dihydrolactone acid XIV*a* which, after esterification, gave dihydrolactone acid methyl ester XIV*b*; carbonyl absorption: 1 790 and 1 730 – 1 750 cm^{-1}. The same compound (XIV*b*) was obtained from a hydrogenolysis of iodolactone acid methyl ester XII*b* with Raney nickel – pyridine and was shown to be identical in every respect.

Lactone acid XIII*a* was saponified with methanolic potassium hydroxide, and the resulting dipotassium salt (XV) was brominated. Two compounds were isolated: an insoluble bromodilactone (XVI) (infrared: 1 785 cm^{-1}) and a bromohydroxylactone acid, obtained as its methyl ester (XVII) (infrared: 3 390, 1 765, and 1 745 cm^{-1}). As expected, the bromodilactone derivative (XVI) was also obtained by a direct bromination of lactone acid XIII*a*. In this manner, monolactone acid derivatives XIII*a* and XVII were obtained; these have a lactone across one or the other bicyclic ring system with the same carboxyl group.

That no skeletal rearrangement occurs during the bromolactonization was shown by the following: the hydroxylactone acid methyl ester XVII was transformed into lactone acid methyl ester XIII*b* by the action of zinc – acetic acid; the insoluble bromodilactone XVI yielded lactone acid XIII*a* after treatment with zinc – acetic acid.

The nuclear magnetic resonance spectra of two model compounds were first examined. The first one (XVIII), the rearranged bromolactone from *exo*, gave two interesting signals as expected: a proton at 8.42 τ and the proton of the hemiacetal at 3.92 τ. The second compound (XIX), the bromolactone from *endo*, did not have proton signals in these positions. Since hemiacetal protons are in a distinct position in the nuclear magnetic resonance spectrum, these findings indicate that this method can be used to differentiate between the *exo* and the *endo* forms after bromolactonization.

The nuclear magnetic resonance spectra of the soluble lactones were examined. For iodolactone acid methyl ester XII*b* in CF_3COOD, the two olefinic hydrogens appeared, respectively, as doublets (J = 6 c.p.s.) at 3.05 and 3.50 τ; from 4.40 to 4.82 τ, a complex multiplet evaluated for five hydrogens corresponded to the lactone hydrogen (—COO—*CH*$\langle$) and the four bridgehead ether protons, and at 5.82 τ a singlet for one hydrogen represented the proton of the $\rangle$CHI group. Finally, a singlet (three hydrogens) attributed to the methoxyl resonance was found at 6.34 τ.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Lactone acid methyl ester XIII*b* in $CDCl_3$ exhibited two separate doublets ($J = 6$ c.p.s.) at 3.09 and 3.62 τ, representing the two olefinic protons, and a complex multiplet from 4.77 to 5.50 τ integrating for five hydrogens, which represented the lactone proton and the four bridgehead ether protons. The methoxyl group appeared as a singlet (three hydrogens) at 6.34 τ, and the methylene group is shown as a broad singlet at 8.02 τ.

Hydroxybromolactone acid methyl ester XVII in CF_3COOD showed a complex multiplet of six protons from 4.33 to 5.23 τ attributed to the four bridgehead ether protons, the lactone proton, and the secondary alcohol groups (>CH—OH). The methoxyl and the hydrogen of the >CH—Br group appeared together as a singlet with a slight shoulder at 6.04 τ (four hydrogens), and the methylene group was shown as a broad singlet integrating for two protons at 7.92 τ. All three spectra showed no signal in the hemiacetal absorption region.

In conclusion, we first have proved the structure of the diacid II*a* by a series of chemical transformations, and then have independently confirmed it by nuclear magnetic resonance spectral analysis.

During this work, reactions of the dibromodilactone derivative IX were investigated. From the reaction of phenylmagnesium bromide on the dibromodilactone, two compounds were isolated: 1,1-diphenyl-1,4-butanediol (6) and 1-phenyl-1,4-butanediol (7). This unusual fragmentation might be explained by a retro Diels–Alder reaction to give furan which then reacted with the Grignard reagent to yield the two diols. This was confirmed by reacting the Grignard reagent with furan, which yielded the same two diols. The zinc – acetic acid reaction of the insoluble dibromodilactone IX resulted in the formation of succinic acid in a high yield. Clearly, this also indicates a retro Diels–Alder reaction to give acetylene dicarboxylic acid which was then hydrogenated to succinic acid.

EXPERIMENTAL

Melting points were recorded on a Kofler micro hot stage melting point apparatus and are uncorrected. The infrared spectra were measured on a Perkin–Elmer "Infra Cord" spectrophotometer. The nuclear magnetic resonance spectra were measured with tetramethylsilane as internal standard.

Hexahydro-1,4;5,8-dioxonaphthalene-9,10-dicarboxylic Acid (IIa) (2–6)

A modified procedure of the Diels and Alder method was employed. Acetylene dicarboxylic acid (15 g, 132 mmoles) and furan (20.5 g, 307.5 mmoles) were dissolved in ether (75 ml) and the solution was left at room temperature for 2 weeks, after which the material crystallized out. The crystals were filtered off and washed with isopropyl alcohol (95%) and finally with ether (14.3 g, 65% yield, m.p. 157–160 °C).

The analytical sample was prepared by recrystallization from isopropyl alcohol (90%), m.p. 160–162 °C (reported m.p. 158 °C (1)).

Anal. Calcd. for $C_{10}H_{10}O_6$: C, 57.60; H, 4.02. Found: C, 57.55, 57.35; H, 3.92, 3.82.

Diacid Dimethyl Ester IIb

(a) From Diacid IIa

The diacid (250 mg, 1 mmole) was dissolved in methanol and the solution cooled in an ice–salt bath. An excess of diazomethane in ether was added and the solution was immediately evaporated *in vacuo*. The crystalline material (278 mg) was recrystallized from ethanol, m.p. 154–156 °C (reported m.p. 148 °C (1)).

Anal. Calcd. for $C_{14}H_{14}O_6$: C, 60.04; H, 5.07; O, 34.50. Found: C, 59.95; H, 5.21; O, 34.70.

(b) From Iodolactone Acid XIIa

To the iodolactone acid (48.7 mg, 0.13 mmole) dissolved in glacial acetic acid (5 ml) was added zinc dust (76 mg), and the mixture was magnetically stirred at room temperature for 1 h. Then, a second portion of zinc (33 mg) was added. After 1 h, the undissolved material was filtered off and the solution evaporated to dryness. The foamy residue was dissolved in water (15 ml) and stirred with Amberlite IR-120 (H^+) resin (7.5 g) for 1 h, after which the resin was removed by filtration and the solution evaporated *in vacuo* with a water bath (temperature 35 °C). The material (37 mg) was esterified in methanol with diazomethane at a low temperature (0 °C), and the resulting mixture was purified by preparative thin-layer chromatography with silica gel G as absorbent and methanol in chloroform (1%) as eluent; the spots were developed with iodine in chloroform (0.5%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The band in the chromatogram having a R_f value from 0.25 to 0.50 was eluted. It gave a crystalline compound (17.4 mg, 55% yield, m.p. 154–156 °C) which was recrystallized from ethanol. A mixed melting point with the compound obtained by procedure *a* showed no depression, and its infrared curve was also identical.

Iodolactone Acid XIIa

The diacid (850 mg, 4.0 mmoles) was dissolved in water (5 ml) and neutralized with sodium hydroxide (20%). Sodium bicarbonate solution (5%, 8 ml), methanol (1 ml), and water (5 ml) were added. To this mixture, an iodine solution (6.1 ml; 5 g of iodine and 10 g of KI in 30 ml of water) was added dropwise, with stirring.

After acidification (to Congo) with hydrochloric acid (3 *N*), crystallization occurred. The crystals were filtered off, washed with water, and dried (1.03 g, 80% yield, m.p. 200–205 °C (decomp.)). The analytical sample was prepared by crystallization from methanol, m.p. 205–210 °C.

Anal. Calcd. for $C_{12}H_9O_6I$: C, 38.30; H, 2.41; O, 25.50; I, 33.80. Found: C, 38.34; H, 2.52; O, 25.53; I, 33.85.

Iodolactone Acid Methyl Ester XIIb

Iodolactone acid (400 mg, 1.06 mmoles) was partly dissolved in methanol (15 ml), cooled in an ice bath, and magnetically stirred. The mixture was saturated with an ethereal solution of diazomethane. After 15 min, it was evaporated to dryness *in vacuo* and a crystalline material was obtained. The analytical sample was prepared by recrystallization from ethyl acetate or acetonitrile, m.p. 231–233 °C.

Anal. Calcd. for $C_{13}H_{11}O_6I$: C, 40.00; H, 2.83. Found: C, 40.14; H, 3.07.

Lactone Acid XIIIa

The diacid (5 g, 2 mmoles) was dissolved in a solution of hydrobromic acid in acetic acid (100 ml of a saturated solution of hydrobromic acid in acetic acid mixed with 200 ml of acetic acid) while cooled in an ice bath. The reaction mixture was stirred at room temperature for 1.5 h. The hydrobromic acid was removed *in vacuo* (water pump) and the acetic acid distilled off. The dried black crystalline material was dissolved in a minimum amount of methanol and allowed to crystallize in the cold. The crystals were filtered off and washed with methanol (2.575 g, 51.5% yield, m.p. 242–245 °C).

Anal. Calcd. for $C_{12}H_{10}O_6$: C, 57.6; H, 4.00; neutral equiv. 250.2. Found: C, 57.41; H, 4.15; neutral equiv. 246.

Lactone Acid Methyl Ester XIIIb

(a) From Lactone Acid XIIIa

Lactone acid (300 mg, 0.6 mmole) was dissolved in methanol (10 ml) and cooled in an ice bath. To this solution was added an excess of diazomethane in ether. The solvent was evaporated and the residue was crystallized from methanol (235 mg, m.p. 248–250 °C).

Anal. Calcd. for $C_{13}H_{12}O_6$: C, 59.10; H, 4.58. Found: C, 59.34, 58.95; H, 4.59, 4.70.

(b) From Bromodilactone XVI

Bromodilactone (60 mg, 0.182 mmole) was mixed with glacial acetic acid (8 ml) and zinc dust (78 mg), and refluxed for 3 h. Another portion of zinc dust was added and refluxing was continued for another 3 h. The solution was filtered and evaporated to dryness (101 mg). The residue was dissolved in water (10 ml) and stirred with Amberlite IR-120 (H^+) resin (4 g). After the resin was filtered off, the aqueous solution was evaporated to dryness. This material was dissolved in methanol (10 ml), cooled in an ice bath, and esterified with diazomethane. After evaporation, a crystalline material was obtained. This material was purified by preparative thin-layer chromatography with silica gel G as absorbent and methanol in chloroform (3%) as eluent.

The material having a R_f value from 0.64 to 0.77 was eluted. Its infrared spectrum was identical with that of an authentic sample (from procedure *a*). After crystallization from methanol, it had m.p. 248–250 °C. The material showed no depression on a mixed melting point determination.

(c) From Bromohydroxylactone Acid Methyl Ester XVII

Bromohydroxylactone acid methyl ester (15.4 mg, 0.042 mmole) was dissolved in acetic acid (2 ml) and mixed with zinc dust (24 mg). This mixture was refluxed for 3 h, then another portion of zinc dust (38 mg) was added, and refluxing was continued for an extra 3 h. The acetic acid solution was filtered and evaporated to dryness. The residue was dissolved in water (3 ml) and extracted with five portions of chloroform (5 ml). The dried chloroform solutions were evaporated to dryness (9.1 mg).

This material was purified by preparative thin-layer chromatography as described in procedure *b*. The resulting crystalline material (3 mg, m.p. 248–250 °C) was shown to be identical with an authentic sample (from procedure *a*) by comparison of infrared spectra. Also, the material showed no depression on a mixed melting point determination.

Dihydrolactone Acid Methyl Ester XIVb

(a) From Lactone Acid XIIIa

Lactone acid (92 mg, 0.35 mmole) was dissolved in methanol (25 ml) and hydrogenated with pre-reduced platinum oxide (20 mg). The hydrogen consumption stopped after 6 min, the catalyst was removed by filtration, and the solvent was evaporated to dryness. The residue was dissolved in methanol and esterified with an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ethereal solution of diazomethane. The solution was evaporated to yield a crystalline material (92 mg). After recrystallization from methanol, it had m.p. 260–262 °C.

Anal. Calcd. for $C_{13}H_{13}O_6$: C, 58.7; H, 4.95. Found: C, 58.76, 58.52; H, 5.13, 5.18.

(b) From Iodolactone Acid Methyl Ester XIIb

Iodolactone acid methyl ester (60 mg, 0.154 mmole) was dehalogenated and hydrogenated in ethanol (75 ml) in the presence of pyridine (0.06 ml) and Raney nickel (about 300 mg) for 4 h in an atmosphere of hydrogen at normal pressure. The solution was filtered and evaporated to dryness. The solid mixture (46.6 mg) was purified by preparative thin-layer chromatography with silica gel G as absorbent and methanol in chloroform (1%) as eluent. The material (R_f value 0.5) was eluted (36.5 mg) and crystallized from methanol, m.p. 252–255 °C. The infrared spectrum of this compound was identical with that of the compound from procedure *a*. A mixed melting point determination showed no depression.

Bromodilactone XVI

(a) From Lactone Acid XIIIa

Lactone acid (165 mg, 0.66 mole) was dissolved in a sodium bicarbonate solution (1.91 mmoles, 11 ml), cooled in an ice bath, and stirred magnetically. Bromine was added until a persistent bromine color remained. The reaction was left for 50 min at room temperature. The solution was acidified with dilute hydrochloric acid (to Congo); the resulting precipitate was filtered off, washed with water and then methanol, and dried (180 mg, 84% yield). Recrystallization from dimethylformamide gave the analytical sample, m.p. 355–365 °C.

Anal. Calcd. for $C_{12}H_9O_6Br$: C, 43.8; H, 2.75; O, 29.2; Br, 24.3. Found: C, 43.91; H, 2.79; O, 28.98; Br, 24.31.

(b) Bromodilactone XVI and Bromohydroxylactone Acid Methyl Ester XVII from the Dipotassium Salt XV

Lactone acid (250 mg, 1 mmole) was mixed with methanol (60 ml) containing potassium hydroxide (179 mg, 3.2 mmoles). This mixture was refluxed until all the solid was dissolved (0.5 h), and then left for 2 h. This solution was evaporated *in vacuo* and water (20 ml) was added. To this solution was added an excess of bromine (0.1 ml, 298 mg, 1.88 mmoles). After the solution was stirred at room temperature (30 min), the resulting precipitate was filtered off, washed with boiling water, and dried (87.5 mg). A mixed melting point determination with bromodilactone from the previous experiment showed no depression. The infrared spectrum was also identical.

The mother liquor was acidified (to Congo) with hydrochloric acid solution (*N*) and extracted overnight with ether. The dried ether solution was evaporated to dryness (173.2 mg). This material was partly dissolved in methanol, saturated with an ethereal solution of diazomethane, and then evaporated to dryness (174.7 mg). The resulting crystalline mixture was separated by chromatography with silica gel (5.1 g). Elution with chloroform in benzene (25%) yielded two fractions (40 mg and 91 mg). The second fraction (91 mg) was recrystallized from acetonitrile (48.3 mg, m.p. 250–255 °C (melts, resolidifies at 275°, and remelts at 330–340 °C)).

Anal. Calcd. for $C_{13}H_{13}O_7Br$: C, 43.30; H, 3.60; O, 31.1; Br, 22.10. Found: C, 43.48, 43.22; H, 3.71, 3.69; O, 31.07; Br, 22.09.

Dibromodilactone IX

The diacid (1 g, 4.03 mmoles) was dissolved in an aqueous solution (50 ml) of sodium bicarbonate (715 mg, 8.50 mmoles). This solution was cooled in an ice bath and bromine (1.3 g, 8.2 mmoles) was added until a persistent bromine color remained. This solution was acidified (to Congo) with hydrochloric acid (*N*), and when cooled, crystallization occurred. The crystals were filtered off and washed with water, methanol, and ether (1.59 g, 97% yield). The compound was recrystallized from dimethylformamide or ethyl acetate. It sublimed slowly from 300 to 360 °C.

Anal. Calcd. for $C_{12}H_8O_6Br_2$: C, 35.4; H, 1.98; Br, 39.3. Found: C, 35.47; H, 2.04; Br, 39.01.

Zinc – Acetic Acid Reaction on Dibromodilactone IX

Dibromodilactone (400 mg, 0.98 mmole) was mixed with glacial acetic acid (100 ml) and zinc dust (150 mg), and the mixture refluxed for 11 h. After the second (200 mg), the fourth (400 mg), and the fifth hour (400 mg), fresh portions of zinc dust were added. The zinc residue was removed by filtration and the solution evaporated to dryness. The foamy residue (1.4 g) was dissolved in water (40 ml). A portion (20 ml) of this aqueous solution was mixed with Amberlite IR-120 (H^+) resin (5 g). After removal of the resin by filtration, the aqueous solution was evaporated to dryness *in vacuo* (water bath temperature 35 °C) and yielded a crystalline residue (46.7 mg). After sublimation *in vacuo*, a crystalline material (34 mg, 60% yield, m.p. 185 °C) was obtained and identified as succinic acid by comparison of its infrared spectrum with that of an authentic sample. Also, a mixed melting point determination showed no depression.

Grignard Reaction on Dibromodilactone IX

The phenylmagnesium bromide reagent was prepared in the usual way by mixing magnesium turnings (729 mg, 30.0 mg-atoms) with bromobenzene (4.70 g, 30.0 mmoles) in dry ether (10 ml.). A solution of dibromodilactone (204 mg, 0.5 mmole) in dry tetrahydrofuran (130 ml) was dropped slowly into the Grignard reagent solution and the reaction mixture was refluxed for 1 day with magnetic stirring. The tetrahydrofuran

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solvent was replaced by benzene by the distillation technique. This benzene solution was cooled in an ice bath and an ammonium chloride solution (25%, 5 ml) was dropped in slowly. The benzene layer was separated, and the aqueous solution was acidified with hydrochloric acid and extracted with ether. The benzene–ether phase was washed with sodium hydroxide solution (*N*) and water. The dried organic phase was evaporated to dryness (1.09 mg). This mixture was chromatographed on Florisil (25 g).

Elution with benzene yielded a compound (550 mg) which was identified as biphenyl. Elution with benzene–chloroform (50%) gave a compound (108 mg) which was crystallized from toluene (50.2 mg), m.p. 106–107 °C. This crystalline material was found to be 1,1-diphenyl-1,4-butanediol by comparison of its infrared curve with that of an authentic sample (6). Also, a mixed melting point showed no depression.

Elution with pure chloroform yielded a semicrystalline material (120 mg) which was mixed with a solution of chloroform – carbon tetrachloride (1:9) and the insoluble crystals filtered off (73.1 mg). Recrystallization from toluene yielded a compound with m.p. 60–64 °C. The infrared spectrum of this compound was identical with that of 1-phenyl-1,4-butanediol (7). A mixed melting point determination showed no depression.

Grignard Reaction on Furan

This experiment was performed under the exact conditions described above, except that dibromodilactone was replaced by furan (300 mg). The same work-up gave both compounds: 1,1-diphenyl-1,4-butanediol (10 mg) and 1-phenyl-1,4-butanediol (90 mg).

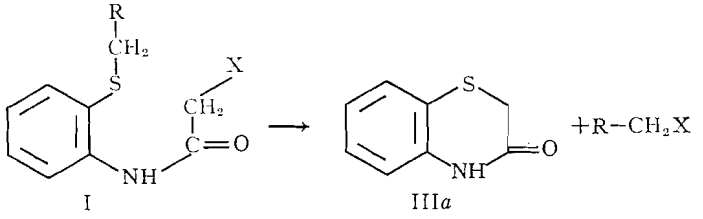
CHEMISTRY AND SYNTHESIS OF SOME DIHYDRO-2*H*-1,4-BENZOTHIAZINE DERIVATIVES

RAJ NANDAN PRASAD[1] AND KARIN TIETJE
Research Department, Abbott Laboratories Limited, Montreal, Quebec



Received October 13, 1965

ABSTRACT

The formation of 3-oxo-3,4-dihydro-2*H*-1,4-benzothiazine (III*a*) by cyclization of alkyl 2-haloacetamidophenyl sulfides (I) was investigated; it is proposed that the reaction proceeds via a six-membered sulfonium halide. The preparation of 4-alkyl derivatives of III*a* and of 4-alkyl and 4-acyl derivatives of its reduction product 3,4-dihydro-2*H*-1,4-benzothiazine (V*a*) is described. Acylation of V*a* was shown to proceed without opening of the thiazine ring. Preparation of the O-benzoyl, N-benzoyl, and O,N-dibenzoyl derivatives of 2-(β-hydroxyethylmercapto)aniline (VIII) has permitted clarification of the confusion in the literature with respect to the derivatives of V*a* and VIII. Compound XVIII, the 1,1-dioxide of III*a*, undergoes C-alkylation at the 2-position when treated with alkyl halides, rather than O-alkylation as previously suggested.

The formation of 3-oxo-3,4-dihydro-2*H*-1,4-benzothiazine (III*a*) when the distillation of 2-(α-chloroacetamido)phenyl methyl sulfide (I*a*) was attempted was reported recently by Davis *et al.* (1). It was observed in this laboratory that the reaction is general for 2-(α-chloroacetamido)phenyl alkyl (and aralkyl) sulfides (Table I), and that when the

*See ref. 1.
†The halide that was isolated was phenethyl iodide.
NOTE: A, heating at 180–200 °C, under water aspirator pressure; B, heating at 140–180 °C, under water aspirator pressure (8 mm); C, refluxed for 3 h with an equivalent amount of sodium iodide in acetone; D, refluxed for 3 h in acetone only; E, refluxed for 3 h with an equivalent amount of sodium bromide in acetone; F, stirred at room temperatu re for 3 h in dimethyl sulfoxide; G, stirred in dimethyl sulfoxide at 60° for 3 h; H, stirre d in dimethyl sulfoxide at 60° for 3 h with an equivalent amount of sodium bromide.

[1]*To whom inquiries concerning this paper should be sent.*

aralkyl group was benzyl or phenethyl, the corresponding halide was isolated in good yield. This suggests the possibility that the elimination of these halides proceeds through a six-membered cyclic sulfonium halide (II).

I II IIIa

Refluxing 2-(α-bromoacetamido)phenyl phenethyl sulfide (I*f*) with an equivalent amount of sodium iodide in acetone gave III*a* in 51% yield. Instead of phenethyl bromide, however, phenethyl iodide was obtained in 43% yield as the second product. 2-(α-Iodoacetamido)phenyl phenethyl sulfide was prepared in 78% yield by stirring the bromo compound with an equivalent amount of sodium iodide in acetone at room temperature for 20 min. The iodo derivative, when it was refluxed in acetone for 3 h, gave only a 20% yield of III*a*; however, when sodium bromide was added the yield was increased to 49%.

The reaction probably proceeds in two stages. In the slow or rate-determining step, the sulfonium ion (II) is formed. The rate of sulfonium ion formation appears to be dependent on the polarity of the solvent. Because charged moieties are being formed in the transition state, the addition of sodium bromide can be expected to accelerate the reaction by providing additional charge stabilization (2).

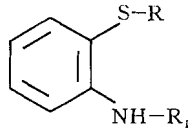
Distillation of 2-(α-chloroacetamido)anisole under similar conditions proceeded normally with no decomposition or elimination of methyl chloride, thus showing the lesser nucleophilic reactivity of oxygen compared with that of sulfur.

The 2-(α-haloacetamido)phenyl alkyl or aralkyl sulfides (I) were prepared according to the method of Davis *et al.* (1) from 2-alkyl- or 2-aralkyl-mercaptoanilines (Table II).

The 6-chloromethyl (3) and 6-trifluoromethyl (4) derivatives (III*b* and III*c*) were prepared by reductive cyclization of the corresponding *o*-nitrophenylthioglycolic acids (5, 6). It was found that the reduction was more conveniently performed with sodium hydrosulfite than with the other reagents previously described in the literature.

Treatment of III with alkyl or aralkyl halides in alcoholic potassium hydroxide or in dimethylformamide containing sodium hydroxide gave the new N-alkyl or N-aralkyl derivatives (IV) (Table III). When III*a* was allowed to react with ethyl chloroacetate, the use of sodamide gave better results than the standard method with sodium hydride.

The reduction of III*a* with $LiAlH_4$ in ether by the procedure of Angelini *et al.* (7) gave 3,4-dihydro-2*H*-1,4-benzothiazine (V*a*) in 80% yield, but was unsatisfactory for large-scale preparation because of the low solubility of III*a* in ether. The use of tetrahydrofuran according to the procedure of Hromatka *et al.* (8) repeatedly resulted in a violent and uncontrollable reaction towards the end of the addition period; when the addition was performed at reflux temperature, the reduction could be accomplished without difficulty. III*b* was reduced smoothly by $LiAlH_4$ in ether solution to V*b* (9). III*c* was more conveniently reduced with diborane in tetrahydrofuran solution to V*c*.



Several of the N-alkyl derivatives (IV) were reduced by $LiAlH_4$ in ether to give the N-alkyl dihydrobenzothiazines (VI) (Table IV). The carbethoxymethyl substituent in IV*d* was reduced during the reaction to a β-hydroxyethyl group (VI*c*).

†The particular halogen analyzed is indicated in parentheses.
‡The distilled product was cloudy; hence it was reduced to VI*b* without elemental analysis.
§The yield varied depending on the method used: 42% by method A and 62% by method B.
‖The halide that was used was allyl or propargyl bromide.

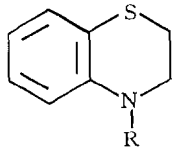
REACTION SCHEME 1.

Treatment of the unsubstituted dihydrobenzothiazine (V*a*) with acyl halides and pyridine in ether gave a number of new N-acyl dihydrobenzothiazines (VII) (Table IV).

The N-benzoyl derivative (VII*d*) was reduced by diborane to the corresponding N-benzyl derivative (VI*d*). This reduction could not be effected by $LiAlH_4$, which caused cleavage of the benzoyl group (cf. Nystrom and Brown (10)).

In contrast, the N-acetyl derivative (VII*a*) was readily converted by $LiAlH_4$ into the N-ethyl derivative (VI*b*).

An alternative approach to the N-alkyl derivatives (VI) was the direct alkylation of V*a*; this method was applied successfully in the preparation of the N-benzyl and N-methyl derivatives.



It is interesting to note that none of the acylation reactions of V*a* showed signs of thiazine ring opening. Acylation of several substituted 3,4-dihydro-2*H*-1,4-benzothiazines in an alkaline medium has also been reported by Lowrie (11) to occur without ring opening. The suggestion that the heterocyclic ring in dihydrobenzothiazines is readily opened (12, 13) would thus appear to be incorrect. Some of the confusion in the earlier literature arises from the reported synthesis of V*a* (Fusco and Palazzo (14)) from *o*-nitrochlorobenzene and 2-mercaptoethanol. Fusco and Palazzo isolated the dibenzoyl derivative (IX) when their product was benzoylated, and therefore concluded that ring cleavage had occurred; however, it has been shown (8, 15) that their initial product was, in fact, 2-(β-hydroxyethylmercapto)aniline (VIII). The interconversions of the O-benzoyl,

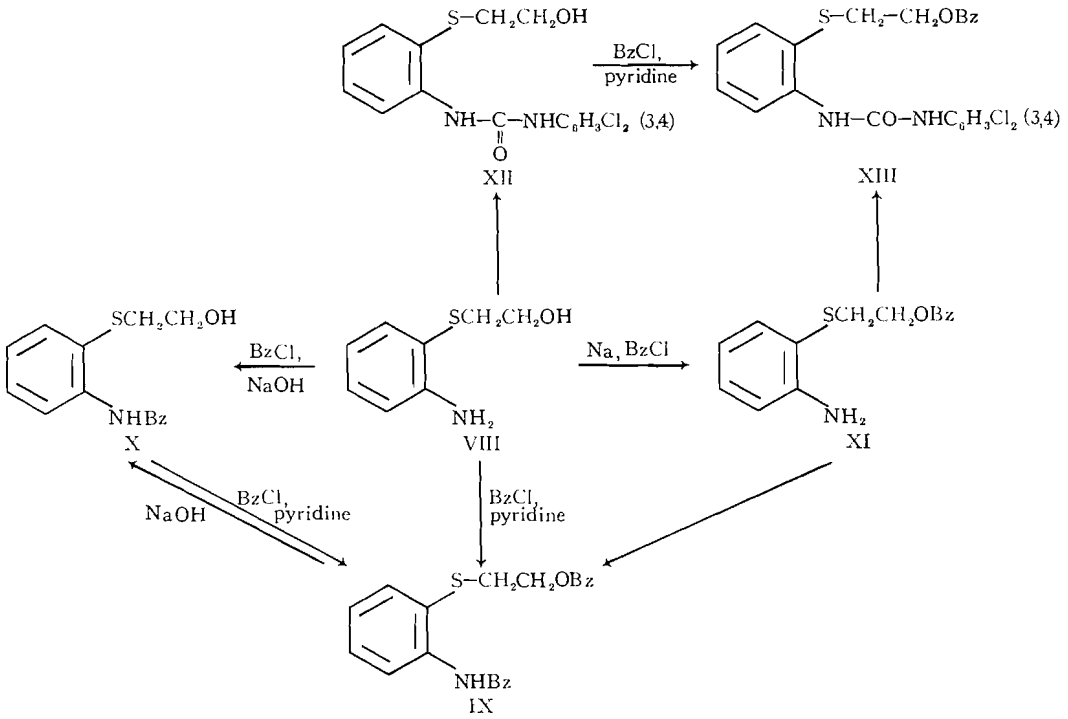
*Yields given are those of the crude solid or the once-distilled liquid.

†Recrystallization solvents: A, ethanol; B, benzene; E, ether; M, methanol; PE, petroleum ether (30–60°); W, water.

‡The particular element analyzed is indicated in parentheses.

§For reported physical data, see refs. 7–9, 23, and 28.

‖The pinkish-white hydrochloride (m.p. 162–165 °C) was obtained from V*a* and dry HCl gas, in ether containing a little methanol. Fusco and Palazzo (14) report that the hydrochloride salt was hygroscopic and gave no melting point, etc.



¶65.5% from IV*a* and $LiAlH_4$.

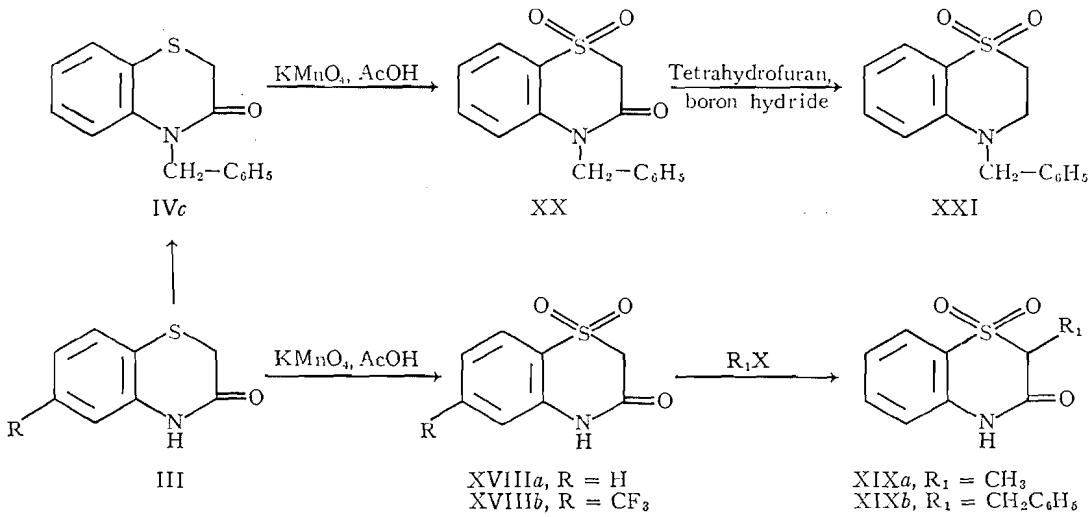
**Formed a picrate, m.p. 132–133° (decomp.) when crystallized from aqueous ethanol.

Anal. Calcd. for $C_9H_{11}NS{\cdot}C_6H_3N_3O_7$: C, 45.68; H, 3.58; N, 14.21. Found: C, 45.82; H, 3.79; N, 14.16.

††Yield varied from 0 to 80% depending on the method used: 80% from IV*c* and diborane; 70% from VII*d* and diborane; 0% from VII*d* and $LiAlH_4$; 52% from V*a*, benzyl chloride, and potassium iodide.

N-benzoyl, and O,N-dibenzoyl derivatives of VIII are shown in Reaction Scheme 2. The O-benzoyl derivative (XI) may be prepared by the gradual addition of 1 equivalent of benzoyl chloride to a suspension of the sodium salt of VIII in toluene.

REACTION SCHEME 2.



Reaction of XI with 3,4-dichlorophenylisocyanate gives XIII, which could also be obtained from XII and benzoyl chloride. Refluxing VIII with acetic anhydride gave the N,O-diacetyl derivative (XIV) in a quantitative yield. The latter, when boiled with aqueous alcoholic potassium hydroxide for 5 min, gave 2-(β-hydroxyethylmercapto)-acetanilide (XV) in 96% yield.

Nitrosation of V*a* gave 3,4-dihydro-4-nitroso-2*H*-1,4-benzothiazine (XVI) as an oil, which was reduced to 4-amino-3,4-dihydro-2*H*-1,4-benzothiazine (XVII) (characterized as the hydrochloride). The two methylene groups of XVII gave signals centered at τ 6.36 and 6.85 in the nuclear magnetic resonance spectra (in dimethyl sulfoxide). This establishes that nitrosation of V*a* does not involve thiazine ring opening.

Oxidation of III*a* with potassium permanganate in glacial acetic acid gave the sulfone XVIII*a*, which was previously prepared by Claasz (16) by the reductive cyclization of 2-nitrobenzenesulfonylacetic acid. The compound shows strong infrared absorption bands at 3 300 and 1 700 cm^{-1}, which suggests the predominance of the oxo form (XVIII*a*). The sulfone could not be reduced by diborane or $LiAlH_4$. However, the 4-benzyl sulfone (XX) (prepared from IV*c* and potassium permanganate) could be reduced by diborane to 4-benzyl-3,4-dihydro-2*H*-1,4-benzothiazine-1,1-dioxide (XXI).

Benzylation of XVIII*a* in the presence of a base gave a benzyl derivative (XIX*b*) which was different from XX. Infrared absorption bands indicated the presence of NH (3 200 cm^{-1}) and C=O (1 680 cm^{-1}) groups in XIX*b*. The nuclear magnetic resonance spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

REACTION SCHEME 3.

(in deuteriochloroform) showed the expected singlet at low field (τ 0.25) for the NH hydrogen (which disappeared on treatment with deuterium oxide), and a typical ABX pattern with a quadruplet centered at τ 5.79 for a methine group and a multiplet centered at τ 6.64 for a methylene group. Thus benzylation of XVIII*a* caused substitution on the 2-carbon atom to give 2-benzyl-3-oxo-3,4-dihydro-2*H*-1,4-benzothiazine-1,1-dioxide (XIX*b*).

Methylation of XVIII*a* with methyl iodide in a basic medium produced the known (Claasz (17)) methyl derivative (XIX*a*). The infrared absorption spectrum of XIX*a* had peaks at 1 670 cm^{-1} (C=O) and 3 220 cm^{-1} (NH). Its nuclear magnetic resonance spectrum (in dimethyl sulfoxide) had a signal at τ 0.22 (NH) which disappeared when D_2O was added, as well as a quadruplet at τ 5.25 and a doublet at τ 8.50 which indicated the presence of a CH—CH_3 grouping.

On the basis of this evidence, the methylation product of XVIII*a* has the structure XIX*a*. The original suggestion by Claasz that the methylation of XVIII*a* gives the O-alkylated product, 3-methoxy-2*H*-1,4-benzothiazine-1,1-dioxide, is therefore incorrect.

EXPERIMENTAL

Melting points, determined with a Thomas Hoover capillary melting point apparatus, are corrected. Infrared spectra were obtained with a Beckman IR-8 spectrophotometer. Analyses were carried out by the Abbott Microanalytical Laboratory, Chicago, Illinois.

2-Phenethylmercaptoaniline

Phenethyl bromide (185.0 g, 1.0 mole) was added dropwise to a solution of 2-aminobenzenethiol (125.1 g, 1.0 mole) and sodium hydroxide (44.0 g, 1.1 moles) in 90% ethanol (700 ml) at a rate sufficient to maintain a gentle reflux. After the addition was complete the reaction mixture was refluxed for an additional hour. The solution was concentrated to half its volume, and the residue was diluted with water and extracted with ether. The ethereal extract was washed with water, dried, and distilled to give the product, b.p. 149–155° at 0.2 mm, yield 185.0 g (81%). The analytical sample distilled at 150° and 0.2 mm.

The above method was used for the preparation of 2-isopropylmercaptoaniline and the known 2-methylmercaptoaniline (1), 2-ethylmercaptoaniline (18), 2-*n*-propylmercaptoaniline (19), 2-*n*-butylmercaptoaniline (18), and 2-benzylmercaptoaniline (1, 20).

2-(α-Haloacetamido)phenyl Alkyl or Aralkyl Sulfides (I)

All compounds in this series were made according to the method of Davis *et al.* (1), and are recorded in Table II.

2-(α-Iodoacetamido)phenyl Phenethyl Sulfide (Ig)

A solution of sodium iodide (8.6 g, 0.057 mole) in acetone (200 ml) was stirred with a solution of I*f* (20.0 g, 0.057 mole) in acetone (70 ml) for 20 min at room temperature. The precipitated sodium bromide (5.6 g, 97%) was removed by filtration, and the filtrate was evaporated under reduced pressure in a bath at 30° to give the product melting at 82.5–84°. One crystallization from ether – petroleum ether (30–60°) gave the analytical sample, m.p. 83–84°.

6-Chloro-3-oxo-3,4-dihydro-2H-1,4-benzothiazine (IIIb)

Sodium hydrosulfite (15.6 g, 0.09 mole) was added in portions to a solution of 4-chloro-2-nitrophenylthioglycolic acid (7.4 g, 0.03 mole) (which was being stirred at 45°) in water (500 ml) containing sodium hydroxide (5.2 g, 0.13 mole). The reaction was exothermic and the temperature was held at 90° for 5 min after the addition of the hydrosulfite was complete. The hot reaction solution was treated with norite, filtered, and acidified while hot to give 4.0 g (66%) of the product, m.p. 205–206°; infrared absorption (Nujol mull): 3 200 cm^{-1} and 1 655 cm^{-1}.

4-Methyl-3-oxo-3,4-dihydro-2H-1,4-benzothiazine (IVa)

Method A, Table III

A solution of III*a* (40.0 g, 0.242 mole) (22–25), methyl iodide (52.0 g, 0.40 mole), and potassium hydroxide (13.6 g, 0.243 mole) in ethanol (400 ml) was refluxed for 5 h. The mixture was filtered and the filtrate was evaporated to dryness. The residue was extracted with ether (leaving some unchanged starting material), and the ether solution was washed with aqueous sodium thiosulfate, dried, and evaporated. The product was obtained by distillation, b.p. 119–122° at 0.5 mm, m.p. 53.5–55.5° (lit. (26) m.p. 55–56°).

4-Benzyl-3-oxo-3,4-dihydro-2H-1,4-benzothiazine (IVc)

Method B, Table III

A solution of III*a* (33.0 g, 0.2 mole) in dimethylformamide (200 ml) was added to a suspension of sodium hydride (9.6 g, 50% NaH, 0.2 mole) in dimethylformamide (100 ml) without external cooling, and the mixture was stirred for 90 min. A solution of benzyl chloride (25.3 g, 0.2 mole) in benzene (50 ml) was added dropwise without external cooling, and the temperature was held at 100° for 1 h.

The reaction mixture was diluted with water, and extracted with benzene (200 ml). The benzene extract was evaporated and crystallized from petroleum ether to give the product, m.p. 84–85°, yield 31.5 g (62%).

4-Carbethoxymethyl-3-oxo-3,4-dihydro-2H-1,4-benzothiazine (IVd)

A suspension of sodium amide (23.0 g, 0.623 mole) in toluene (1 300 ml) and a solution of III*a* (100 g, 0.605 mole) were mixed and refluxed for 17 h. Ethyl chloroacetate (85.5 g, 0.7 mole) was then added to the cooled reaction mixture, followed by further refluxing for 4.5 h.

The reaction mixture was cooled and diluted with water (500 ml). The organic layer was separated, washed with water, dried, and distilled to give 29.0 g (19%) of the product, b.p. 148–158° at 0.2–0.3 mm, which solidified on standing. The analytical sample was obtained by crystallization from ether – petroleum ether (30–60°), m.p. 48.5–50.5°.

3,4-Dihydro-2H-1,4-benzothiazine (Va)

The procedure of Hromatka *et al.* (8) was modified by performing the addition of the 3-oxo compound (III*a*) to the $LiAlH_4$ in tetrahydrofuran at reflux temperature instead of 0°, thereby preventing a violent reaction at the end of the addition period.

6-Trifluoromethyl-3,4-dihydro-2H-1,4-benzothiazine (Vc)

3-Oxo-6-trifluoromethyl-3,4-dihydro-2*H*-1,4-benzothiazine (III*c*, m.p. 200–202° (lit. (4) m.p. 185–186°)) was reduced with diborane by the procedure described below for the preparation of VI*d*, yield 67%, m.p. 88–89° when crystallized from petroleum ether.

Anal. Calcd. for $C_9H_8F_3NS$: C, 49.31; H, 3.65; N, 6.39. Found: C, 49.11; H, 3.57; N, 6.40.

4-(β-Hydroxyethyl)-3,4-dihydro-2H-1,4-benzothiazine (VIc)

IV*d* (21.7 g, 0.086 mole) in ether (200 ml) was added dropwise to a suspension of $LiAlH_4$ (7.27 g, 0.19 mole) in ether (500 ml) at a rate sufficient to maintain a gentle reflux. After the addition was complete (1 h), the mixture was refluxed for an additional 2 h, and cooled; then ethyl acetate (34 g, 0.38 mole) was added dropwise, followed by water (58 ml). The precipitate was filtered, and the filtrate dried and distilled to give the product, b.p. 125–143° at 0.15–0.18 mm, yield 13.3 g (79%). The analytical sample distilled at 151° and 0.4 mm.

Reduction of IV*a*, IV*b*, and IV*e* by the above procedure gave VI*a*, VI*b*, and VI*e*, respectively.

4-Benzyl-3,4-dihydro-2H-1,4-benzothiazine (VId)

A solution of IV*c* (12.75 g, 0.05 mole) in tetrahydrofuran (100 ml) was added dropwise to a 1 *M* diborane (27) solution (100 ml) in tetrahydrofuran, and the temperature was held at 0°. The reaction mixture was then refluxed for 1 h, cooled, hydrolyzed by 10% aqueous hydrochloric acid (60 ml), and concentrated to one-fourth of its volume. The residue was made strongly alkaline and extracted with chloroform. The chloroform

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

extract was washed with water, dried, and evaporated to give the product, m.p. 90–93°, yield 7.4 g (62%). Crystallization from ether – petroleum ether (30–60°) gave the analytical sample, m.p. 96.5–97.5°.

Another method for the preparation of VI*d* was by refluxing a mixture of V*a* (7.55 g, 0.05 mole), benzyl chloride (6.32 g, 0.05 mole), and potassium iodide (8.3 g, 0.05 mole) in absolute ethanol (200 ml) for 16 h, filtering the hot mixture, and evaporating the filtrate. The residue, on crystallization from ether–petroleum ether (30–60°), gave the product, yield 6.35 g (52%).

VI*a* was similarly obtained (66% yield, b.p. 104° at 0.17 mm) by refluxing V*a* (30.2 g, 0.2 mole), methyl iodide (42.63 g, 0.3 mole), and anhydrous potassium carbonate (15.2 g, 0.11 mole) in methanol (300 ml) for 4.5 h.

4-Benzoyl-3,4-dihydro-2H-1,4-benzothiazine (VIId)

Benzoyl chloride (14.1 g, 0.1 mole) in ether (50 ml) was added, with stirring, to a solution of V*a* (15.1 g, 0.1 mole) in ether (250 ml) containing pyridine (8.3 g, 0.105 mole) at −5°. After the reaction mixture was stirred for 4 h at room temperature, it was filtered and the filtrate washed with 10% aqueous hydrochloric acid and water. The dried ethereal extract was evaporated and the residue crystallized from ether – petroleum ether (30–60°) to give the product, m.p. 86–89°, yield 19.0 g (79%). One recrystallization from the same solvent gave the analytical sample, m.p. 88–89.5°; infrared absorption (Nujol mull): 1 645 cm^{-1} (C=O).

All other 4-acyl derivatives of V*a* were synthesized by this method, and all had the characteristic infrared absorption band in the 1 635 – 1 660 cm^{-1} region.

The 4-benzoyl derivative was also obtained under Schotten–Baumann conditions, but the yield was somewhat inferior.

Reduction of VIIa and VIId

VII*a* was reduced by $LiAlH_4$ in ether by the procedure described for the reduction of IV*d*. For the reduction of VII*d*, however, the procedure employing diborane, described for the reduction of IV*c*, had to be followed.

4-Amino-3,4-dihydro-2H-1,4-benzothiazine (XVII)

Sodium nitrite (13.8 g, 0.2 mole) in 20 ml water was added to V*a* (30.2 g, 0.2 mole) in 5% hydrochloric acid (250 ml) at −5°. The solution was basified and extracted with chloroform, and the chloroform solution was washed with water and saturated sodium chloride, dried, and evaporated. The nitrosated product (XVI) could not be distilled without decomposition; accordingly, it was reduced with $LiAlH_4$ in ether in the usual way. The 4-amino derivative thus obtained was treated with hydrogen chloride in ether to give the hydrochloride, m.p. 174° (decomp.) when crystallized from methanol.

Anal. Calcd. for $C_8H_{11}ClN_2S$: C, 47.37; H, 5.47; N, 13.83; S, 15.82; Cl, 17.49. Found: C, 47.81; H, 5.61; N, 13.27; S, 15.26; Cl, 17.63.

2-(β-Hydroxyethylmercapto)aniline (VIII) (9, 21)

Treatment of 2-aminobenzenethiol with ethylene oxide in the presence of alcoholic potassium hydroxide gave VIII in an almost quantitative yield. Culvenor *et al.* (21) claimed to have prepared V*a* by this reaction.

2-(β-Acetoxyethylmercapto)acetanilide (XIV)

A mixture of VIII (46.0 g, 0.275 mole) and acetic anhydride (100 ml) was slowly distilled for 2 h at atmospheric pressure in a bath at 150–170°. The residue was fractionally distilled to give the product, b.p. 184–186° at 1.1 mm, as a colorless liquid which slowly solidified on standing. The product, when refluxed with 5% dilute ethanolic potassium hydroxide, gave 2-(β-hydroxyethylmercapto)acetanilide (XV), b.p. 176° at 0.5 mm.

2-(β-Benzoxyethylmercapto)benzanilide (IX) (14)

Benzoyl chloride (13.3 g, 0.094 mole) was added dropwise to VIII (8.0 g, 0.047 mole) in pyridine (180 ml), and the mixture was stirred overnight at room temperature. Dilution with water yielded the crude product, which was purified by crystallization from methanol, m.p. 81–83°, yield 14.0 g (78%); infrared absorption (Nujol mull): 3 390 cm^{-1} (NH), 1 725 cm^{-1} (ester), and 1 685 cm^{-1} (C=O).

The same product was obtained by the reaction of either X or XI with benzoyl chloride in pyridine, as described above.

2-(β-Hydroxyethylmercapto)benzanilide (X)

Benzoyl chloride (8.3 g, 0.059 mole) was added to a stirred mixture of VIII (10.0 g, 0.059 mole) in 100 ml of 3.3% aqueous potassium hydroxide solution. After being stirred vigorously for 10–15 min, the mixture was extracted with ether. The ethereal extract was washed with water and evaporated, and the residue was crystallized from ether to give 11.0 g (68%) of the product, m.p. 88.5–90°; infrared absorption (Nujol mull): 3 430 cm^{-1}, 3 330 cm^{-1}, and 1 665 cm^{-1}.

2-(β-Benzoxyethylmercapto)aniline (XI)

A solution of VIII (17.0 g, 0.1 mole) in toluene (100 ml) was added to a vigorously stirred mixture of sodium (2.3 g, 0.1 mole) in 300 ml boiling toluene, under a dry nitrogen atmosphere. After the addition was complete (15 min), the mixture was refluxed for 1½ h and then cooled to room temperature, and benzoyl chloride (14.0 g, 0.1 mole) in toluene (50 ml) was slowly added. The mixture was stirred for another 30 min

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

at room temperature, and then 200 ml water was added at 15°. The organic layer was separated, washed with water, dried, and evaporated under reduced pressure in a bath below 40°. Part of the oily residue was dissolved in ether, and hydrogen chloride was added to give the product as the hydrochloride, m.p. 176–180°.

The free base was obtained from the hydrochloride as a viscous, honey-colored liquid which solidified (m.p. 43–46°) when it was allowed to stand overnight. Recrystallization from warm ethanol gave the analytical sample, m.p. 44.5–46°; infrared absorption (Nujol mull): 3 460 cm^{-1}, 3 360 cm^{-1} (primary sorpamine), and 1 710 cm^{-1} (ester).

N-(2-(β-Hydroxyethylmercaptophenyl))-N'-(3',4'-dichlorophenyl)urea (XII)

3,4-Dichlorophenylisocyanate (18.8 g, 0.1 mole) in ether (500 ml) was added to VIII (15.1 g, 0.1 mole) in ether (500 ml); after the mixture had been stirred for 1 h at room temperature, it was refluxed for over 2½ h. The crude product (24.5 g) was filtered off and crystallized from acetone–ether, m.p. 156–157°; infrared absorption (Nujol mull): 3 550 cm^{-1} (OH), 3 330 cm^{-1} (NH), and 1 700 cm^{-1} (C=O).

N-(2-(β-Benzoxyethylmercaptophenyl))-N'-(3',4'-dichlorophenyl)urea (XIII)

A solution of XI (2.0 g, 0.0073 mole) in ether was mixed with an equivalent amount (1.4 g) of 3,4-dichlorophenylisocyanate in ether. The clear solution was refluxed for 30 min and then left for 2 days at room temperature. The crystalline solid (1.7 g, 50%) was filtered off and crystallized from 15 ml absolute ethanol to give the product, yield 0.9 g, m.p. 153–154°; infrared absorption (Nujol mull): 3 350 cm^{-1} (NH), 3 280 cm^{-1} (NH), 1 720 cm^{-1} (ester), and 1 655 cm^{-1} (amide).

The same product (XIII) was also obtained from XII (10.0 g, 0.028 mole) and benzoyl chloride (3.9 g, 0.028 mole) in pyridine.

4-(3',4'-Dichlorophenylcarbamyl)-3,4-dihydro-2H-1,4-benzothiazine (XXIIa)

Equivalent amounts of V*a* and 3,4-dichlorophenylisocyanate in benzene were refluxed for 1½ h, and then the solvent was removed to give the product in a quantitative yield. One recrystallization from 360 ml boiling ethanol gave colorless needles, m.p. 159–161°; infrared absorption (Nujol mull): 3 260 cm^{-1} and 1 655 cm^{-1}. The mixed melting point of XXII with XII was 128–146°.

Other ureas (XXII*b*–XXII*e*) were similarly prepared by refluxing equivalent amounts of V*a* and the corresponding isocyanate for 1½ h in ether. The final products were isolated by the addition of petroleum ether (30–60°) to the reaction solution.

3-Oxo-3,4-dihydro-2H (4H) -1,4-benzothiazine-1,1-dioxide (XVIIIa)

A solution of III*a* (33.0 g, 0.2 mole) in glacial acetic acid (500 ml) was added to potassium permanganate (45 g, 0.28 mole) in water (1 000 ml) over a 15 min period. The temperature was allowed to rise to 42° during the addition. After 1.5 h at room temperature, sodium bisulfite (24.0 g, 0.23 mole) was added at 15–20°. The solution was concentrated to 200 ml under reduced pressure, and the product separated out when the concentrate was cooled, yield 31.9 g (81%), m.p. 195–202°. Recrystallization from methanol–benzene raised the melting point to 208–209° (lit. (16) m.p. 207–208°); infrared absorption (KBr pellet): 3 300 cm^{-1} (NH) and 1 700 cm^{-1} (C=O).

The 6-trifluoromethyl analogue (XVIIIb) was prepared in the same way, m.p. 256–257° (decomp.) when crystallized from acetone – petroleum ether, yield 60%.

Anal. Calcd. for $C_9H_6F_3NO_3S$: C, 40.75; H, 2.26; F, 21.50; S, 12.07. Found: C, 40.94; H, 2.53; F, 21.54; S, 12.29.

The 4-benzyl derivative (XX) was similarly prepared from IV*c*, m.p. 140–141° when crystallized from chloroform – petroleum ether, yield 64%.

Anal. Calcd. for $C_{15}H_{13}NO_3S$: C, 62.71; H, 4.52; N, 4.87; O, 16.72. Found: C, 63.03; H, 4.66; N, 5.18; O, 16.37.

2-Benzyl-3-oxo-3,4-dihydro-2H-1,4-benzothiazine-1,1-dioxide (XIXb)

A solution of XVIII*a* (9.85 g, 0.05 mole) in 50% aqueous ethanol (50 ml) containing sodium hydroxide (2.0 g, 0.05 mole) was refluxed for 1 h. The cooled reaction mixture was extracted first with petroleum ether (to remove unreacted benzyl chloride) and then with ether. The ethereal extract was washed with water, dried, and evaporated. The residue was crystallized from ether – petroleum ether (30–60°) to give 9.0 g (62%) of the product, m.p. 144–147°. Two recrystallizations from the same solvent gave the analytical sample, m.p. 147–148°; infrared absorption (Nujol mull): 3 200 cm^{-1} and 1 685 cm^{-1}.

Anal. Calcd. for $C_{15}H_{13}NO_3S$: C, 62.71; H, 4.52; N, 4.77; S, 11.15. Found: C, 62.69; H, 4.50; N, 4.64; S, 11.31.

4-Benzyl-3,4-dihydro-2H-1,4-benzothiazine-1,1-dioxide (XXI)

Treatment of 4-benzyl-3-oxo-3,4-dihydro-2*H*-1,4-benzothiazine-1,1-dioxide with diborane in tetrahydrofuran as described for the preparation of VI*d* gave the product, m.p. 127–128° when crystallized from aqueous methanol, yield 60%.

Anal. Calcd. for $C_{15}H_{15}NO_2S$: C, 65.93; H, 5.49; N, 5.12; O, 11.72; S, 11.72. Found: C, 65.86; H, 5.31; N, 5.18; O, 11.94; S, 11.57.

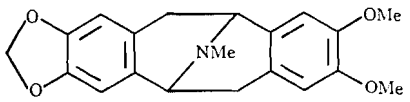
THE ALKALOIDS OF PAPAVERACEOUS PLANTS

LV. A NEW ALKALOID, ESCHSCHOLTZIDINE, AND ITS STRUCTURE

RICHARD H. F. MANSKE AND KJU HI SHIN
Research Laboratories, Dominion Rubber Co. Ltd., Guelph, Ontario



Received February 10, 1966

ABSTRACT

A very small amount of a new alkaloid, eschscholtzidine, present in *E. californica*, was shown to be eschscholtzine in which a methylenedioxy group is replaced by two methoxyls.

The present authors have recorded the isolation of a number of alkaloids from *Eschscholtzia californica* Cham. (1). The fraction which yielded eschscholtzine has now yielded a new base, eschscholtzidine, which so far has not been crystallized either free or in the form of salts. It was ultimately purified by means of column chromatography, and its purity checked by the thin-layer technique (R_f 0.51 on silica gel with cyclohexane–chloroform–diethylamine (7:2:1)).

That this alkaloid was related to eschscholtzine (2) was suspected because of its chemical behavior and its source. The nuclear magnetic resonance spectrum confirmed this close relation, and in fact indicated the structure shown by I.

I

Its nuclear magnetic resonance spectrum was superposable on that of eschscholtzine, except that now two methoxyls (τ 6.18 (3H) and 6.27 (3H)) and a methylenedioxy group (τ 4.23 (2H)) were evident. Hence it appeared to have structure I. This was readily confirmed by first demethylenating the alkaloid to the corresponding dihydroxy base followed by methylation with diazomethane. The product was identical with a specimen of argemonine kindly supplied by Dr. T. O. Soine.

EXPERIMENTAL

The final mother liquors, from which no further alkaloids could be crystallized either as free bases or as salts (hydrochloride, nitrate, and hydrobromide) (from 270 kg of *E. californica*), were combined, dissolved in dilute hydrochloric acid, and filtered. The solution was then extracted with several portions of chloroform. The alkaloids were regenerated from the fraction that was extracted with chloroform, dissolved in ether, and dried with potassium hydroxide.

The solution was then passed through a long column of alumina (250 g, pH 8.15, activity 0.98) and eluted with dry ether. The first fraction colored on exposure to air and was discarded. The large middle fraction was again passed through a second column, and its middle fraction proved to be chromatographically pure; yield 3 g. For analysis a portion was distilled at 180° and 1 mm.

Anal. Calcd. for $C_{20}H_{21}O_4N$: C, 70.78; H, 6.24; N, 4.13. Found: C, 70.65; H, 5.88; N, 3.92.

It is optically active ($[\alpha]_D^{24}$ +194.2° (*c*, 1.56 in methanol)). This value is almost exactly equal to the arithmetic mean between the values for argemonine and eschscholtzine. The ultraviolet spectrum shows λ_{max}^{EtOH} 291 mμ (log ϵ 4.08).

Conversion into Argemonine

A solution of 0.4 g of eschscholtzidine in 10 ml of 58% sulfuric acid plus 1 g of phloroglucinol was heated to boiling and digested on a steam bath for 1 h. The cooled and diluted solution was filtered and the filtrate was

extracted with three successive portions of ether, basified with ammonia, and again exhausted with ether. The residue from the latter ether extract was dissolved in methanol and left overnight with an excess of ethereal diazomethane. Removal of the solvent left a residue which was extracted with dilute aqueous oxalic acid; then the filtered solution was thoroughly extracted with ether. The aqueous phase was then basified with ammonia and extracted once more with ether. The residue from the latter extract was a colorless oil which crystallized at once when seeded with a crystal of argemonine. When recrystallized from dry ether the base consisted of colorless, stout polyhedra which melted sharply at 155°;* in admixture with a specimen of argemonine it melted at 154–155°.

NOTE ADDED IN PROOF: The phenolic alkaloid melting at 254° but not further characterized, reported as present in *E. californica* (1), has been identified as bisnorargemonine (m.p. 256°, mixed m.p. 254°), a specimen of which was kindly supplied by Dr. T. O. Soine. The infrared spectra of the two alkaloids in potassium bromide pellets were superimposable; λ_{max}^{EtOH} 288.5 mμ.

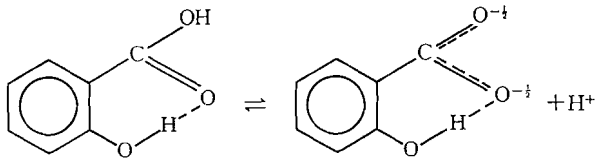
EFFECT OF INTRAMOLECULAR HYDROGEN BONDING ON IONIZATION CONSTANTS OF SUBSTITUTED SALICYLIC ACIDS

G. E. DUNN AND FEI-LIN KUNG
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received December 14, 1965

ABSTRACT



Ionization constants at 25 °C have been determined by a spectrophotometric method for 17 substituted salicylic acids. These have been fitted to the simple Hammett relationship and to the extended one proposed by Jaffe, which takes into account the transmission of substituent effects by the *o*-hydroxy group. The results with Jaffe's equation show that substituent effects on acidity are transmitted only slightly, if at all, through the intramolecular hydrogen bond of a chelate ring. Possible interpretations of the results are discussed.

Salicylic acid is well known to be a decidedly stronger acid than benzoic or the other monohydroxybenzoic acids. The relevant ionization constants are shown in Table I, where it may be seen that the second *o*-hydroxy group in 2,6-dihydroxybenzoic acid has an even greater effect than the first. Since the hydroxy group normally has a strong resonance effect of electron release, a hydroxy group in the ortho position might have been expected

TABLE I
Ionization constants of hydroxybenzoic acids in water at 25 °C (1)

Substituent	$K \times 10^5$	$K/K_{benzoic}$
Benzoic	6.30	1.0
m-Hydroxy	8.33	1.32
p-Hydroxy	2.62	0.42
o-Hydroxy	105	16.7
2,6-Dihydroxy	6 000	952

to decrease the strength of a benzoic acid just as it does when in the para position. The anomalous increase in acid strength produced by an *o*-hydroxy group is commonly attributed to intramolecular hydrogen bonding between the phenolic hydroxyl and the carboxyl group (2–8). Among the hydroxybenzoic acids, chelation is possible only for the ortho isomer and, since it would be expected to be stronger in the anion than in the unionized acid, it should stabilize the anion more than it does the acid and so cause increased ionization.

If the above argument is correct, then a substituent in the 4- or 5-position of salicylic acid should influence the ionization constant by two paths. For example, an electron-withdrawing group, such as nitro, in the 5-position should exert its normal acid-strengthening influence on the carboxyl group by way of the usual combination of

inductive, field, and resonance effects, as in the corresponding nitrobenzoic acid. This effect would be represented in terms of the Hammett relationship (9) by

$$[1] \qquad \log K/K_0 = \rho_1\sigma_1,$$

where K is the ionization constant of 5-nitrosalicylic acid, K_0 is that of salicylic acid, σ_1 is the Hammett substituent constant for the *m*-nitro group, and ρ_1 is Hammett's reaction constant for the ionization of salicylic acids under the conditions concerned. Second, the substituent should have a similar but larger effect on the acidity of the phenolic group, thus increasing the strength of the chelating hydrogen bond and so exerting a further acid-strengthening influence on the carboxyl group. This second effect would be represented by

$$[2] \qquad \log K/K_0 = \rho_2\sigma_2^-,$$

where σ_2^- is the Hammett *p*-nitro substituent constant for use with phenols and amines (Hammett's σ^*), and ρ_2 is a Hammett reaction constant representing the susceptibility of the ionization of salicylic acids to subsequent influences by way of the chelate hydrogen bond. Jaffe (10) has shown that influences through the two paths should be additive, so that the overall effect of a substituent should be given by

$$[3] \qquad \log K/K_0 = \rho_1\sigma_1 + \rho_2\sigma_2^-.$$

He found (10) that, in the case of the salicylic acids, eq. [3] was not an improvement over eq. [1]. Jaffe attributed this to the fact that the six substituents for which data were available (11) were such that σ_1 and σ_2 are linearly related, so that for these substituents eqs. [1] and [3] become indistinguishable. He proposed that eqs. [1] and [3] can be distinguished only when the correlation coefficient between σ_1 and σ_2 is less than 0.9.

Since there was available in our laboratory a collection of sixteen 4- and 5-substituted salicylic acids prepared in connection with a study of their decarboxylation (12), it appeared to be worthwhile to determine their ionization constants, both for comparison with their rates of decarboxylation and for a test of eq. [3]. The fact that the correlation constant between σ_1 and σ_2^- for the 16 acids is 0.723 makes them particularly suitable for the latter purpose. The present paper reports the results of these determinations.

EXPERIMENTAL

Materials

The 5-methyl-, 4-nitro-, 5-nitro-, 4-hydroxy, 5-hydroxy-, 5-bromo-, 4-ethoxy-, 5-chloro-, and 5-iodosalicylic acids, as well as salicylic acid itself, were commercial products. The 4-methoxy- and 5-methoxysalicylic acids were prepared by methylating the corresponding hydroxy acids (12). All the acids were purified to constant melting point by one or more recrystallizations from water or aqueous ethanol; the melting points reported are for the recrystallized acids. All melting points were determined with a Hershberg melting point apparatus (13) by using calibrated Anschütz thermometers, and are expressed in degrees Centigrade.

3-Methylsalicylic Acid

A product sold commercially under the name 2,4-cresotic acid (m.p. 166.8–168.0°) and consequently supposed to be 4-methylsalicylic acid (2-hydroxy-4-methylbenzoic acid) was found to have an ionization constant which, according to the Hammett parameters derived from the other salicylic acids, was inconsistent with its supposed structure. Decarboxylation of the acid with copper powder in hot quinoline gave a cresol which was converted into the dibromo derivative by the usual method (14). This derivative produced no depression in the melting point when mixed with the dibromo derivatives prepared from an authentic sample of *o*-cresol. The "2,4-cresotic acid" must therefore have its methyl and hydroxyl groups ortho to each other. Its large ionization constant (0.962×10^{-3}) shows that the carboxyl and hydroxyl groups are also ortho to each other, so that the acid must be 3-methylsalicylic acid (2-hydroxy-3-methylbenzoic acid). Melting points of the *p*-bromophenacyl, *p*-nitrobenzyl, acetyl, and dinitro derivatives confirm this structure. Its ionization constant is therefore reported in Table III under the heading 3-methylsalicylic acid.

4-Methylsalicylic Acid

This acid was prepared by treating 4-methylanthranilic acid with nitrous acid. A solution of 7.6 g of 4-methylanthranilic acid in 33 ml concentrated sulfuric acid and 45 ml water was cooled to 0–5° and stirred while 4 g sodium nitrite in 10 ml water was added dropwise over a period of 10 min. The mixture was stirred for another 15 min, and then poured into 200 ml boiling water. When this solution was cooled, 4-methylsalicylic acid precipitated out; after two recrystallizations from water 1.1 g (14.5%) melting at 177.0–177.8° (lit. (15) m.p. 172°) was recovered.

4-Cyanosalicylic Acid

This acid was prepared from 4-aminosalicylic acid by the Sandmeyer reaction. A solution of 10.0 g of 4-aminosalicylic acid in 30 ml of concentrated sulfuric acid and 60 ml water was cooled to 0–5° and stirred while 20 g sodium nitrite in 100 ml water was added slowly until the mixture gave a positive test with starch–iodide paper. The cold solution was poured into 200 ml water containing 14.5 g cuprous cyanide and enough potassium cyanide to keep the latter in solution. The mixture was warmed to 60° for half an hour, and then filtered. The residue was extracted with three 200 ml portions of ether, and 4-cyanosalicylic acid was recovered from the ether. After several recrystallizations from water the yield was 0.2 g (2%) melting at 228.0–229.0° (lit. (16) m.p. 227–229°).

5-Cyanosalicylic Acid

This compound has not previously been reported in the literature. The cyano group was introduced by the method of Friedman and Schechter (17). A solution of 11.9 g 5-iodosalicylic acid and 4.65 g cuprous cyanide in 50 ml dimethylformamide was refluxed for 2 days. The resulting brown mixture was cooled and poured into a solution of 10 g ferric chloride hexahydrate in 30 ml concentrated hydrochloric acid and 30 ml water. This mixture was heated on a steam bath for half an hour, and then extracted with three 200 ml portions of ether. The extract was washed with aqueous sodium bisulfite, dried, and evaporated. The residue, after several recrystallizations from water, yielded 3.1 g (43%) of 5-cyanosalicylic acid melting at 224.0–225.0°. The characteristic nitrile band in the infrared spectrum of the acid was present at 2 230 cm^{-1}.

Anal. Calcd. for $C_8H_5NO_3$: C, 58.90; H, 3.09; N, 8.59. Found: C, 58.90; H, 3.12; N, 8.77.

Method

A spectrophotometric method was chosen for the determination of the ionization constants because it had been used previously in this laboratory on anthranilic acids (18) and could be extended, if desired, to include the overlapping ionization constants of the zwitterionic aminosalicylic acids.

For the ionization of a monoprotic acid in water,

$$HB \rightleftarrows H^+ + B^-,$$

the ionization constant may be expressed by

$$K = \frac{[H^+][B^-]}{[HB]},$$

where the quantities in brackets represent molar concentrations or, at high ionic strengths, activities. If the total concentration of acid (ionized plus un-ionized) is C, then

$$K = \frac{[H^+][B^-]}{C - [B^-]} = \frac{[H^+](C - [HB])}{[HB]},$$

so that

$$[B^-] = \frac{KC}{[H^+] + K} \quad \text{and} \quad [HB] = \frac{C[H^+]}{[H^+] + K}.$$

Since hydronium ion does not absorb in the visible or ultraviolet regions, the total absorbance, A, of the equilibrium solution of HB is given by

$$A = A_{HB} + A_B,$$

where A_{HB} is the absorbance of the equilibrium concentration of un-ionized acid HB, and A_B is the absorbance of the equilibrium concentration of anion B^-. For a 1 cm cell the Beer–Lambert relationship converts the preceding equation into

$$A = \epsilon_{HB}[HB] + \epsilon_B[B^-],$$

where ϵ = molar absorptivity.

When the expressions for [HB] and $[B^-]$ derived above are introduced, this becomes

$$A = C \times \frac{\epsilon_{HB}[H^+] + \epsilon_B K}{[H^+] + K}. \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Since A, $[H^+]$, and C are observable quantities, eq. [4] contains only three unknowns: K, ϵ_{HB}, and ϵ_B.

In principle, ϵ_{HB} and ϵ_B can be determined experimentally by measurements made in strongly acidic and strongly basic solutions, respectively. However, these strongly acidic and basic solutions will have much larger ionic strengths than are necessary in the equilibrium region, and it is desirable to make all measurements at the same low ionic strength. Hence, in the present work the absorbances were measured at one wavelength for several (usually 16) different values of $[H^+]$ in the equilibrium region at an ionic strength of 0.01, and all three unknowns were obtained by fitting the data to eq. [4] by the least squares method (19). All measurements were made at the same total concentration of a substituted salicylic acid, so that the actual value of C is unimportant provided it is such as to give absorbances suitable for measurement. It varied from acid to acid, but averaged about 10^{-4} M.

The apparatus and procedure for choosing appropriate wavelengths, concentrations, and pH ranges, as well as for making the measurements of pH and absorbances, are the same as those previously described (18).

RESULTS

Figure 1 shows the ultraviolet absorption spectra of salicylic and 5-nitrosalicylic acids at pH values of about 0, 3, and 9. The spectra of all the other acids resembled that of salicylic

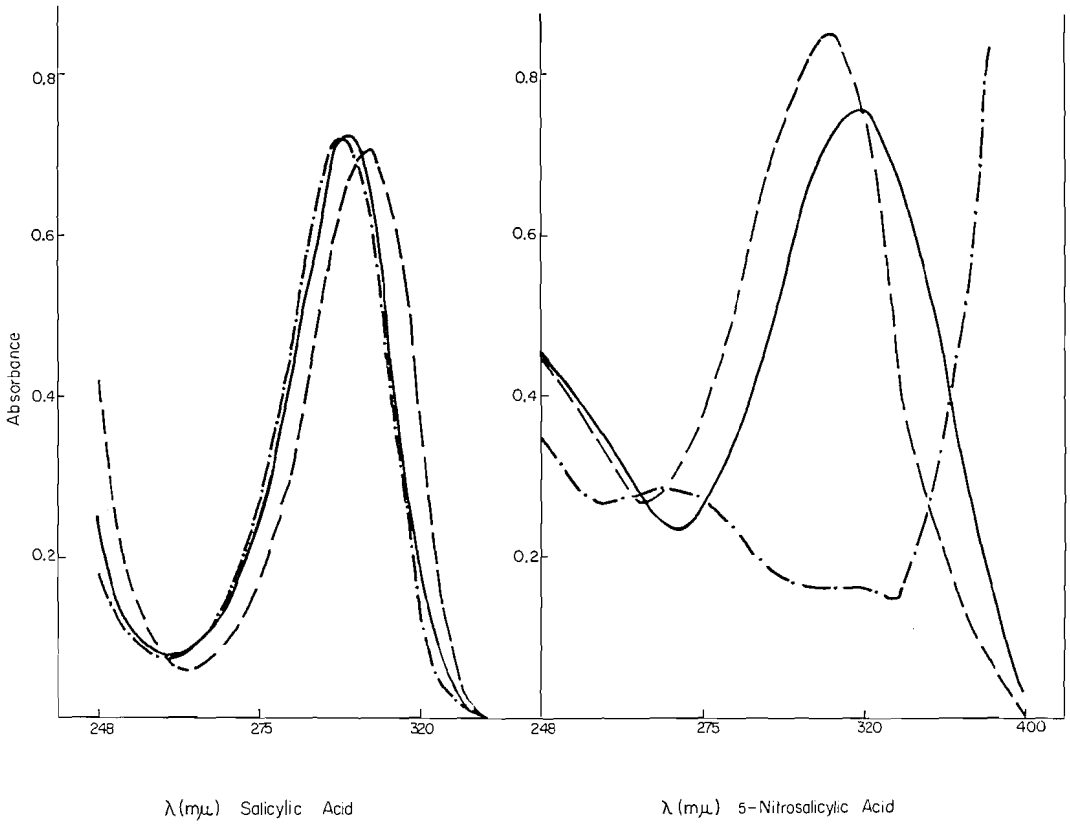

FIG. 1. Effect of pH on the ultraviolet spectra of salicylic acids. LEGEND: —, formate buffer (pH ~ 3); — —, 1 N hydrochloric acid; —·—, ammonia buffer (pH ~ 9).

acid, with small shifts in wavelength and absorptivity as the substituents varied. The 5-nitro acid is distinctly different from the others, no doubt because the p-nitro substituent activates the phenolic group to the point where it is significantly ionized at pH 9.

The absorbance and pH data obtained for salicylic and 5-nitrosalicylic acids are reported in Table II. In Fig. 2, the experimental points are compared with the curves calculated by using the data of Table II to solve eq. [4]. The measurements in 1 N hydrochloric acid and ammonia buffers (shown as the first and last items of Table II) were used to provide the

preliminary estimates of $C\epsilon_{HB}$ and $C\epsilon_B$ required for fitting eq. [4]. They were not included among the points to be fitted because they were obtained at ionic strengths greater than 0.01, but they are reported for comparison with the values of $C\epsilon_{HB}$ and $C\epsilon_B$ obtained from eq. [4]. For salicylic acid they may be compared with the calculated values $C\epsilon_{HB} = 0.653$

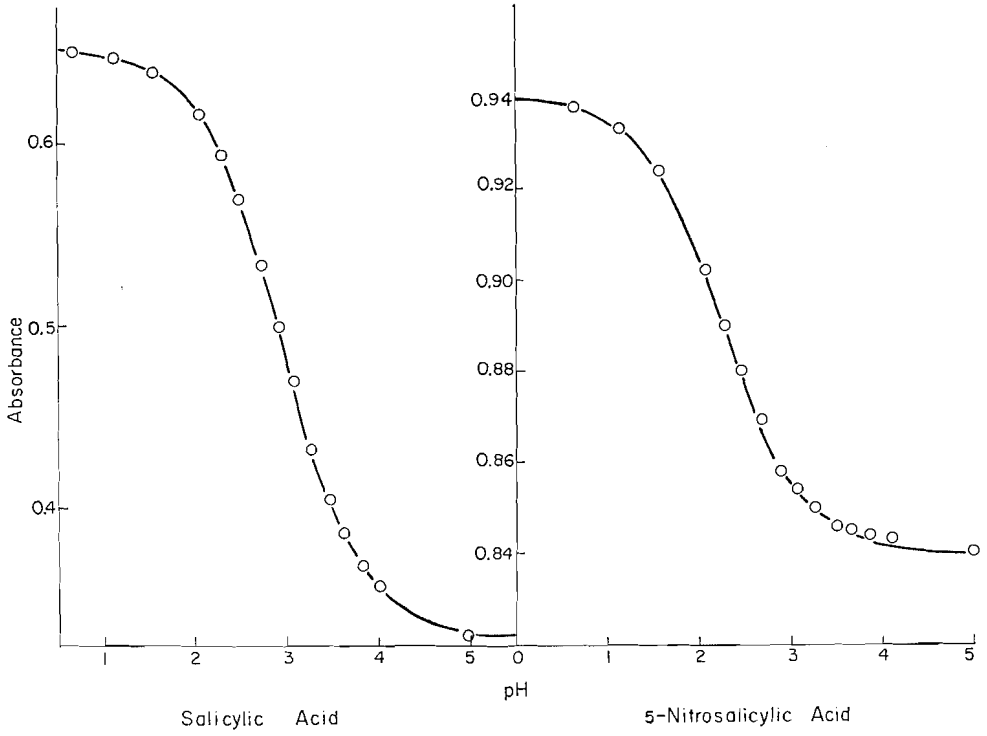

FIG. 2. Determination of ionization constants. LEGEND: O, experimental points; —, line calculated from eq. [4] by using the least squares values of K, $C\epsilon_{HB}$, and $C\epsilon_B$.

$\pm$ 0.005 and $C\epsilon_B = 0.328 \pm 0.003$; the agreement is equally good for all the other acids except the 5-nitro acid. For this acid eq. [4] gives $C\epsilon_{HB} = 0.940 \pm 0.008$ and $C\epsilon_B = 0.840 \pm 0.004$, which are in good agreement with the data of Table II at pH $\sim$ 0 and 6, respectively, but not with that in ammonia. This is further evidence that the phenolic group of 5-nitrosalicylic acid is significantly ionized at pH $\sim$ 9.

Table III shows the ionization constants of the various substituted salicylic acids and their standard deviations obtained from the least squares fit of the data to eq. [4]. Also

shown are the wavelengths and concentrations at which the absorbance and pH measurements were made. The last column of Table III gives literature values for the ionization constants of those acids for which they are available. For comparison with these, thermodynamic ionization constants were estimated from our observed ionization constants by multiplying each by 0.929, the activity of the unsubstituted salicylate ion at an ionic strength of 0.010 reported by Kielland (20).

It is seen that our calculated thermodynamic ionization constants agree reasonably well with the literature values except for the nitro acids. Here the 4-nitro acid is stronger than the 5-nitro, where previous workers found the opposite order. The earlier results were obtained by a conductometric method, and it appears that they could be too high because of the phenolic ionization which our spectra show to be strongly activated in the 5-nitro acid by the *p*-nitro group. It may be noted that only one of the literature values was considered to be sufficiently reliable to be included in the I.U.P.A.C. tabulations of dissociation constants, although all but one were available when the compilation was made (1).

DISCUSSION

Jaffe has proposed (10) that eqs. [1] and [3] can be distinguished only when σ_1 and σ_2 have a correlation coefficient less than 0.9. For the 16 acids used in the present work, this correlation coefficient is 0.723. The σ values were taken from Hine's tables (8) by using σ^- for σ_2 when dealing with the 5-nitro and 5-cyano acids.

The data of Table III were fitted by the least squares method (19) to eq. [1] in the form

$$\log K = \rho_1\sigma_1 + \log K_0.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Since the standard deviations of log K were very similar for all substituents, the points were weighted equally. The calculated value of ρ_1 is 0.889 ± 0.061, and of log K_0 is -2.989 ± 0.025 (observed, -2.991 ± 0.013). The external estimate of error* (s_{ext}) is 0.0524. Figure 3 shows the data and the calculated line as a plot of log K against σ_1. The fit appears to be as good as that found in most other Hammett plots.

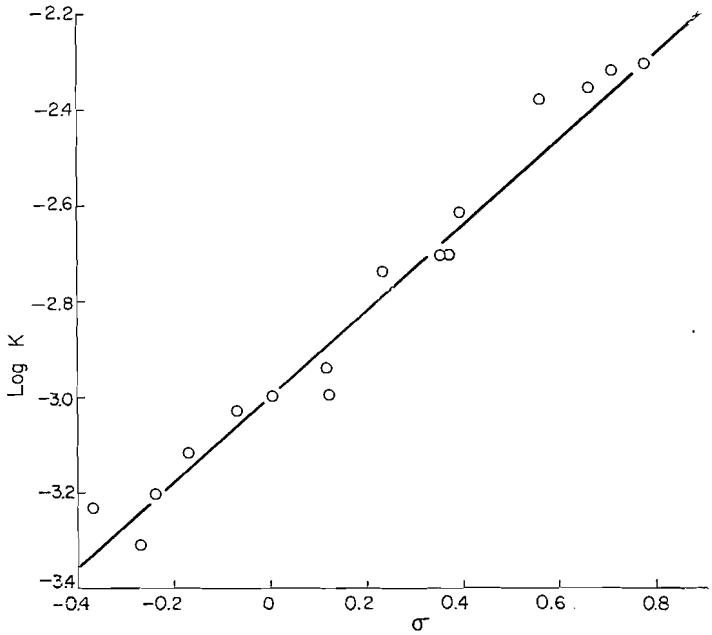

FIG. 3. Hammett plot of σ vs. the data from Table III.

The least squares fit (19) of the same data to eq. [3] in the form

$$\log K = \rho_1\sigma_1 + \rho_2\sigma_2 + \log K_0$$

gives $\rho_1 = 0.820 \pm 0.038$, $\rho_2 = 0.101 \pm 0.046$, log $K_0 = -2.997$, and $s_{ext} = 0.0454$. It is seen that ρ_2 is very small (only about double its standard deviation). The Student's t test (19) indicates that ρ_2 differs from zero only at the 95% confidence level (conditions under which Jaffe considers eq. [3] to be not significantly better than eq. [1] (10)). Consequently, we may conclude that the electronic effects of substituents upon the ionization constants of salicylic acids are transmitted only very slightly, if at all, through the phenolic hydroxyl group.

The reason for the failure of the chelate ring to transmit a substituent effect to the carboxyl group is not obvious. Comparison of the ionization constants reported in Table III with those in Table I shows that the range of ionization constants produced by changing substituents in salicylic acid is one-fourth as large as the difference in the ionization constants of salicylic and *p*-hydroxybenzoic acids. If the latter difference is produced entirely by chelation, it is surprising that the former one is independent of chelation. Several possible interpretations present themselves, but none is unequivocal.

For example, it might be argued that the variation in phenolic acidity produced by substituents is not large enough to affect the strength of the intramolecular hydrogen bond
