Infrared spectra of DMA complexes have in general been measured in the solid phase and assignments have been made for only C—O stretching modes (1, 5). In this work spectra have been measured both in the solid phase and in solution in methylene chloride. Table II shows the spectrum of DMA as a liquid film. Assignments were made by comparison with the spectra of other amides (19, 20) and by analogy with assignments for N-methylacetamide based on a normal coordinate analysis (21). The frequencies of the C—N and C—O stretching modes for the complexes are shown in Table III. Considerable differences exist between solution spectra and solid phase spectra.

DISCUSSION

The p.m.r. spectrum of an oxygen-bonded DMA complex might be expected to differ radically from that of a nitrogen-bonded compound. In the latter, stabilization of resonance form (1) would reduce the C—N bond order and change the hybridization of the nitrogen

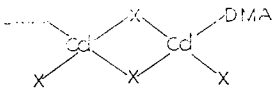
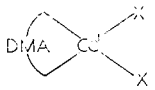
*sh = shoulder.



atom from sp^2 to sp^3. The N-methyl groups would then be equivalent, since free rotation about the C—N bond could occur and a single N-methyl resonance would replace the doublet observed for free DMA. The collapse of the N-methyl resonances into a single peak on protonation of N,N-dimethylformamide and N,N-dimethylacetamide has been explained in this way (23).

Analytical data suggest that the indium halide and cadmium halide adducts may contain bidentate DMA. For the indium complexes structures of type III have been envisaged in which both mono- and bi-dentate DMA are present.



III

It should be noted, however, that many cadmium halide complexes are dimers involving halogen bridges and species such as IV may be more realistic than molecules involving bidentate DMA as in V.

IV

V

For the perchlorate complexes only monodentate DMA seems possible.

Infrared Spectra

Spectra of the solid complexes show that considerable lowering of the carbonyl frequency of DMA occurs on complexing. The frequency shift varies between 40 cm^{-1} and 80 cm^{-1} but no regular correlation between shift and cation or anion was detected. Small shifts to higher frequency were noted for the C—N stretching mode and absorptions at 730 cm^{-1} and 960 cm^{-1} in free DMA were greatly increased in intensity in the complexes. Apparently these modes which involve stretching and bending of the DMA skeleton become more infrared active on coordination.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In solution, all perchlorate complexes exhibit two C—O frequencies in the 1 600 cm^{-1} region. With halide complexes two bands were also observed; however, the $ZnX_2.2DMA$ adducts show two carbonyl absorptions in the solid phase. Bull *et al.* (1) have suggested that coupling of two C—O vibrations via the metal to which both are coordinated or the existence of nonequivalent ligands in the crystal lattice may account for the solid phase spectra. Fermi resonance is also a common cause of doubling of carbonyl absorptions (22).

Addition of excess ligand to solutions of the complexes caused an increase in intensity of the higher frequency carbonyl band relative to that at lower frequency. It is concluded that on dissolution partial dissociation of the metal complex occurs giving both bonded and free DMA in solution. An equilibrium of this type is illustrated for $In(ClO_4)_3.6DMA$.

$$In(ClO_4)_3.6DMA \rightleftarrows In(ClO_4)_3.(6 - x)DMA + xDMA$$

Further coordination of the dissociated species by solvent molecules may occur.

In summary, infrared data provide no evidence for nitrogen-bonded or bidentate DMA, since lowering of the C—O stretching frequency and raising of the C—N stretching frequency are consistent with an increased contribution of resonance form (II) to the ground state of the DMA molecule.

Proton Magnetic Resonance Spectra

The similarity in the spectra of all the complexes of In, Zn, Cd, and Sn suggests only oxygen-bonded DMA in acetone-d_6 solution at 36°. Neither the indium nor cadmium halide compounds mentioned above showed any evidence for bidentate DMA in solution.

Addition of excess DMA to solutions of the complexes produced only one set of resonance peaks, suggesting rapid exchange between bonded and unbonded DMA, the resonance positions in such a system being a weighted average of the resonances of the free and complexed DMA.

Traces of perchloric acid in the perchlorate complexes resulted in p.m.r. spectra having only one broad N-Methyl resonance. As previously stated, free rotation about the C—N bond and an sp^3-hybridized nitrogen atom are prerequisites for the equivalence of the N-methyl groups of DMA. Protonation of the nitrogen atom of the amide might be expected to produce such an effect. As pointed out by Berger *et al.* (24), a very small concentration of the nitrogen-protonated form is sufficient to bring about a collapse of the N-methyl resonances.

Complex formation results in low field shifts for all the protons in DMA. Deshielding can be attributed to a flow of electron density from the donor molecule to the acceptor and would be expected to fall off with increasing number of intervening bonds. Hence shifts for the C-methyl protons are larger than shifts for the N-methyl protons. Shifts are influenced both by cation and anion. For halide ions the order is $I^- > Br^- > Cl^-$ for each metal and for cations the larger the charge on the cation, the larger the downfield shift. Thus $Sn^{4+} > In^{3+} > Zn^{2+} \geqslant Cd^{2+}$. However, the lack of data concerning the structures of the coordinated ions in solution prevents any firm conclusions being drawn as to the relative acceptor properties of the metal halides and perchlorates. Further work is now in progress to determine the exact nature of the species in solution for each complex.

The low temperature resolution of both N-methyl and C-methyl resonances of the indium trihalide complexes is more difficult to explain. At similar temperatures the zinc, cadmium, and tin halide complexes show only signal broadening due to viscosity effects. $InI_3.1.5DMA$ and $InBr_3.1.5DMA$ at −30° show four N-methyl signals and two C-methyl resonances, the ratio of the signals at low field to those at high field being 1:2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The frequency separation of the C-methyl resonances at this temperature was 9 c.p.s. for $InI_3.1.5DMA$ and 7 c.p.s. for $InBr_3.1.5DMA$. For $InCl_3.2.5DMA$ resolution was incomplete even at $-30°$. The lack of data concerning the species in solution prevents any firm conclusions being drawn as to the origin of these spectra but the existence of two types of coordinated DMA is not impossible. A more intensive study of low temperature spectra is now in progress.

ACKNOWLEDGMENT

The author wishes to thank Dr. Eric Bullock for many helpful discussions during this work.

CALCULATIONS OF KINETIC ISOTOPE EFFECTS FOR THE IODIDE EXCHANGE AND FOR THE SOLVOLYSIS OF METHYL IODIDE[1,2]

ALFRED V. WILLI[3]
Chemistry Department, Brookhaven National Laboratory, Upton, New York

Received February 11, 1966

ABSTRACT

Kinetic deuterium and carbon-13 isotope effects are calculated for the S_N2 exchange reaction of CH_3I with $*I^-$(131) and for the CH_3I solvolysis in water. The normal vibrational frequencies of CH_3I and of the transition state $I\cdots CH_3\cdots X$ (X = I or OH_2) are evaluated from force constants by solving the secular equation with an IBM 7094 computer. Values for force constants of the planar CH_3 moiety (with an sp^2 C atom) in the transition state are obtained by comparison with suitable stable molecules. For the iodide exchange reaction, there is not much dependence of the calculated D isotope effect on the particular choice of f_{CI} and f_{12} (interaction between CI stretches) if these force constants are within reasonable limits. The bending force constant $f_{HCI}(\neq)$ may then be adjusted to reproduce the experimental D isotope effect.

Based on the simple transition state model $CH_3^{\delta+}\cdots I^{\delta-}$, it is not possible to obtain agreement with the experimental D effect in the solvolysis reaction without assuming an extremely high value of f_{HCI}. If must be concluded that a water molecule is probably involved in the transition state. On the basis of the model $I\cdots CH_3\cdots OH_2$, the experimental D effect may be reproduced with a suitable choice of f_{HCI} and f_{HCO}. It is shown that, under favorable circumstances, experimental temperature dependence data may be applied for a distinction between different sets of f_{CH}, f_{HCH}, and f_{HCI} (or f_{HCO}) which reproduce the experimental isotope effect at one temperature.

INTRODUCTION AND GENERAL PROCEDURE

In recent years, refined methods have been developed for the theoretical calculation of kinetic isotope effects within the transition state theory framework (1–3). It has become possible to carry out complete calculations of vibrational frequencies of reactants and transition states by solving the secular equation with an electronic digital computer (2, 3). Some calculations have been done for particular mechanistic problems (4–6). In this work, these methods are applied to a theoretical study of some nucleophilic substitution reactions of methyl iodide in order to gain an understanding of the causes of the isotope effect and to investigate the conclusions, with respect to the transition state, which may be drawn from experimental isotope effect data. For these systems, results of some previous calculations have been reported which do not involve complete solutions of the secular equations of the 6, 7, or 8 atomic transition states (7, 8).

Experimental data are available for the kinetic isotope effects of the following four S_N reactions of methyl iodide: (*a*) $CH_3I + *I^-$, (*b*) $CH_3I + CN^-$, (*c*) $CH_3I + OH^-$, and (*d*) the solvolysis of CH_3I in water. For *b* and *c* the ^{13}C isotope effect has been measured (9), and, for *a* and *d* the D effect (rate of CH_3I divided by rate of CD_3I) is known (8, 10). Experimental data on ^{14}C isotope effects in four S_N reactions of CH_3I (11) are also available. In this paper, calculations for reactions *a* and *d* are discussed in detail. Results of calculations for reactions *b* and *c* will be reported elsewhere.

The harmonic vibrational frequencies (and isotope effects thereon) of the reactants and of the corresponding transition state were calculated with an IBM 7094 computer from

reasonable values of the force constants, with the use of programs which are modifications (2) of those of J. H. Schachtschneider (12). Effects of anharmonicity were neglected in this work.

The most important causes of the isotope effect are force constant changes which take place when the transition state is formed from the reactants (2). One possible procedure in these calculations would be as follows: usual values are introduced for the force constants of CH stretching, CI stretching, HCH bending, and HCI bending in the reactant.

With the aid of sample calculations, we may find out how some of these force constants must be changed in the transition state in order to obtain a fit with experimental isotope effect data. However, there is no set of these 4 force constants which leads to a good agreement between calculated and observed values of all six vibrational frequencies of methyl iodide. If we intend to keep the model for methyl iodide as close to reality as possible we must include interaction force constants ("off-diagonal" elements of the F matrix) in the force field. In this study, vibrational frequencies of $^{12}CH_3I$, $^{13}CH_3I$, and $^{12}CD_3I$ are calculated with a set of 13 force constants (see Table I) (including 9 interaction force constants) reported by Fenlon, Cleveland, and Meister (13) which reproduces the experimental values for $^{12}CH_3I$ within 1 wave number. The values of 4 of the interaction force constants which do not involve reacting bonds are also applied to the force field of the transition state (Table I). This must be done to compensate for an artificial isotope effect caused by the presence of these interaction force constants in the force field of the reactant. A fair comparison of force constants of the reactant and of the transition state would not be possible otherwise.

NOTE: Designation of the force constants of CH_3I is the same as in ref. 13.

All data referring to geometry and force constants of methyl iodide and of the transition state are collected in Table I. For the general model of the transition state, $I\cdots CH_3\cdots X$, it is assumed that the CH_3 group is planar with equilibrium CH distances of 1.08 Å and equilibrium HCH angles of 120°. The positions of I and of the first atom of X are on the threefold symmetry axis with bond distances 10% greater (20% greater in the case of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

OH_2) than those of stable CI or CX bonds. Now we must assign values to the force constants of the following motions: CI and CX bond stretching, the interaction (f_{12}) between these two motions, CH stretching, HCH, HCI, and HCX valence angle bending (and a few additional ones if X consists of more than one atom). In these calculations, 4 interaction force constants and a force constant for the CH_3 out-of-plane bending motion (g) are also considered (6). Thus, the situation appears unfavorable at first glance. Values of 12 force constants may be adjusted to obtain agreement with one single experimental value either for k_H/k_D or for k_{12}/k_{13} (or with two experimental data if both isotope effects have been measured). However, there is the possibility of obtaining force constants for the internal motions of the CH_3 moiety in the transition state by comparison with suitable stable molecules. We assume that the valence electrons of the central carbon atom are in an sp^2 configuration and use a CH stretching force constant and an HCH bending force constant corresponding to such bonding in stable molecules (14, 15).[4] (It may be expected that f_{CH} increases by 0.25–0.3 mdyn/Å when the central carbon atom changes from an sp^3 to an sp^2 configuration.)

There remain 5 force constants in the transition state whose values are not yet fixed (designated with asterisks in Table I). Three of these, f_{CI}, f_{CX}, and f_{12}, are directly related to stretching motions of the bonds to be broken or formed. The secular equation of the transition state will have $3n - 7$ positive solutions and one negative or zero solution. The negative (or zero) eigenvalue leads to an imaginary (or zero) frequency $\nu_L^{\ddagger}$ which means that the motion of crossing the potential barrier is aperiodic. If f_{CI}, f_{CX}, and f_{12} are assumed to be equal, $\nu_L^{\ddagger}$ will be zero, and the isotope effect on the frequency of the other stretching mode in the three particle system $I\cdots(CH_3)\cdots X$ will be negligible. (In these calculations the influence of all vibrations is fully considered, however.) The bending force constants f_{HCI} and f_{HCX} may now be adjusted to obtain agreement between the calculated and the experimental isotope effect. It should be mentioned that f_{HCI} and f_{HCX} cannot be evaluated separately from calculations for a single model. There are very many different sets of f_{HCI} and f_{HCX} (the sum of both values being nearly constant) which will reproduce the experimental data.

If f_{CI}, f_{CX}, and f_{12} are chosen in such a way that $f_{CI}f_{CX} - f_{12}^2 < 0$, then $\nu_L^{\ddagger}$ will have an imaginary value. Under these circumstances, the calculated isotope effect differs slightly from that for the case where $\nu_L^{\ddagger} = 0$, and the bending force constants must be adjusted to somewhat different values. Quite fortunately, these differences are small if $\nu_L^{\ddagger}$ remains in a reasonable order of magnitude and if the ratio f_{CI}:f_{CX} does not change much.

THE IODIDE EXCHANGE REACTION

Deuterium Isotope Effect at 298.2°

The most simple situation is the exchange reaction of methyl iodide with labeled iodide ion. In its transition state, as far as it is correct to assume that it is symmetric, f_{CX} equals f_{CI} and f_{HCX} equals f_{HCI}. There are now three free parameters only, viz. f_{CI}, f_{12}, and f_{HCI}. Results of some sample calculations are shown in Table II. Numbers 3–8 have been done to study the influence of f_{CI} and f_{12} on the isotope effect. In the calculations marked with an asterisk the bending force constant f_{HCI} is adjusted to fit the experimental isotope effect, $k_H/k_D = 1.06$.

Since there is a slight dependence of the isotope effect on the magnitude of $f_{CI}^2 - f_{12}^2$ an attempt is made to set the limits for the possible values of those two force constants: Suppose that, at the transition state, the potential energy decreases as the second power

[4]*Detailed information on the out-of-plane bending force constant g may be found in ref. 6.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of ρ, the arithmetic mean of the increase of length (Δr_1) of one CI bond and of the decrease of length ($-\Delta r_2$) of the other CI bond.

[1] $$\rho = \tfrac{1}{2}(\Delta r_1 - \Delta r_2)$$

The potential energy, which is also taken to contain contributions of restoring forces *within* each CI bond, is then given by the equation:

[2] $$\begin{aligned} 2V &= f_{CI}'(\Delta r_1^2 + \Delta r_2^2) - f_{\mp}\rho^2 + \text{other terms (not involving } \Delta r_1 \text{ and } \Delta r_2) \\ &= f_{CI}'(\Delta r_1^2 + \Delta r_2^2) - \tfrac{1}{4}f_{\mp}(\Delta r_1 - \Delta r_2)^2 + \text{other terms.} \end{aligned}$$

This is equivalent to the expression which defines $f_{CI}(= f_{11} = f_{22})$ and f_{12} as elements of the F matrix:

[3] $$2V = f_{CI}(\Delta r_1^2 + \Delta r_2^2) + 2f_{12}\Delta r_1 \Delta r_2 + \text{other terms}$$

[4] $$f_{CI} = f_{CI}' - \tfrac{1}{4}f_{\mp}, \quad f_{12} = \tfrac{1}{4}f_{\mp}.$$

To arrive at the magnitude of $f_{\mp}$ one may proceed as follows: Let us assume that there is little energy change when the iodide ion approaches to within 2.56 Å of the C atom of the CH_3I molecule while the other CI distance is unchanged (2.14 Å). Now eq. [2] is used to describe the energy surface for the formation of the transition state with equal CI distances of 2.35 Å. With an assumed $f_{CI}' = 1.0$ mdyn/Å (in reactant $f_{CI} = 2.25$ mdyn/Å), one obtains $f_{\mp} = 8$ mdyn/Å (as an upper limit) for a barrier height of 20 kcal/mole.

If $f_{\mp}$ is increased from 2.0 to 8.0 mdyn/Å (see Nos. 3, 21, 15, 25 in Table II) while f_{HCI} is held constant at 0.250 mdynÅ, the secondary deuterium isotope effect k_H/k_D then decreases from 1.12 to 1.014 and the primary carbon isotope effect k_{12}/k_{13} increases from 1.047 to 1.061. For each of the four choices of $f_{\mp}$, the HCI bending force constant may now be adjusted to reproduce the experimental deuterium isotope effect (see Nos. 24, 21, 16, 22). The appropriate values of f_{HCI} are between 0.235 and 0.270 mdynÅ which is in the order of one half of the corresponding value for the stable molecule CH_3I, $f_{HCI} = 0.55$ mdynÅ. If the low value of $f_{CH} = 5.05$ mdyn/Å is assumed for the CH stretching force constant in the transition state, the HCI bending force constant must then be adjusted to a value 0.050–0.055 units higher than in the corresponding sample calculations with $f_{CH} = 5.3$ mdyn/Å (see Nos. 23, 18, and 20).

Fit values of f_{HCI} are also evaluated for the two sets of force constants with $f_{CH} = 5.3$ mdyn/Å, $f_{HCH} = 0.525$ mdynÅ, and with $f_{CH} = 5.05$ mdyn/Å, $f_{HCH} = 0.525$ mdynÅ (Nos. 29 and 30). The value assumed for f_{HCH} in those calculations equals that of the corresponding bending force constant in the reactant, and it may be considered as the high limit for the transition state.

Temperature Dependence of the D Isotope Effect

Table II also contains values for the different factors which contribute to the isotope effect, viz. MMI, the ratio of the isotopic ratios of the factor depending on masses and moments of inertia (isotopic ratio for the transition state divided by the isotopic ratio for the reactant); EXC, the ratio of the isotopic ratios of the excitation factor ($\prod(1 - e^{-u_i})^{-1}$); and ZPE, the zero point energy factor ($e^{-\Delta\Delta\Sigma u_i/2} \equiv e^{-\Delta\Delta E_0'/RT}$). In the analysis of experimental data, on the other hand, the isotope effect is usually expressed with the aid of an Arrhenius type equation:

[5] $$\begin{aligned} k_H/k_D &= A \times \exp(-\Delta\Delta E_0'/RT) \\ &= A \times \text{AZPE.} \end{aligned}$$

As suggested by Wolfsberg and Stern (2), eq. [5] is also applied here for the representation of the temperature dependence of the calculated isotope effect within a limited temperature range. For some examples (see Table II), values for the pre-exponential factor A and for the apparent zero point energy factor AZPE for 25 °C are computed from 6 calculated data for k_H/k_D in the temperature range between 293 and 333 °K by the least squares method.

The A value may now be used to draw some conclusions on the relative importance of changes of CH stretching and bending force constants (2). Therefore, it would be highly desirable to have available experimental data on the temperature dependence of the deuterium isotope effect. Though it may not be possible to draw conclusions on the best values for two force constants, f_{CH} and f_{HCH}, the temperature dependence would supply an additional piece of information. If the experimental A value were larger than 1.07 we would be able to conclude that both f_{CH} and f_{HCH} are at their low values. If A were below 0.95 we would conclude that f_{CH} and f_{HCH} are close to their high limits (see Table II). All these deductions, naturally, are valid within the limitations of the assumptions involved in these calculations (i.e., neglect of anharmonicity effects, tunneling, and of solute–solvent interactions).

Carbon-13 Isotope Effect

As can be seen from Table II, the ^{13}C isotope effect does not depend much on f_{CH} or on the bending force constants. But k_{12}/k_{13} significantly increases with increasing $f_{\neq}$. Consequently, the experimental value of the carbon isotope effect will supply information on the curvature of the potential barrier in the transition state. It is fully realized, however, that it would be difficult to obtain precise experimental data of k_{12}/k_{13} for this reaction, even if isotopically pure samples of $^{13}CH_3I$ were available.

Dependence of the Isotope Effects on the Stretching Force Constants f_{CI} and f_{12}[5]

The increase of k_{12}/k_{13} with increasing $f_{\neq}$ may easily be understood on the basis of the simple approximate equation given by Wolfsberg and Stern (2): The greater the difference $f_{CI}^{\circ} - (f_{11} + f_{22} - 2f_{12}) = f_{CI}^{\circ} - 2(f_{CI} - f_{12})$ (f_{CI}° refers to CH_3I) the higher the isotope effect. There is no force constant change at the positions of isotopic substitutions if we consider the dependence of k_H/k_D on $f_{\neq}$. On the basis of the approximate equation, the decrease of k_H/k_D can be explained partially by a decrease of the $\nu_L^{\neq}$ ratio. (For more details see the longer manuscript in the Depository.)

The changes of coupling conditions of the motions of the carbon and the hydrogen atoms can easily be observed by looking at the $\nu_L^{\neq}$ ratios. With increasing $f_{\neq}$, the $\nu_L^{\neq}$ ratio of the carbon isotope effect increases from 1.031 ($\approx \sqrt{(16/15)}$) to 1.035 while the $\nu_L^{\neq}$ ratio of the deuterium isotope effect decreases from 1.09 ($\approx \sqrt{(18/15)}$) to 1.0332. (See Nos. 3–7, 15, 25 in Table II). If in the motion of crossing the potential energy barrier the hydrogen atoms would not move at all with the central carbon atom, the $\nu_L^{\neq}$ ratios would be at the following limiting values: $\sqrt{(13/12)} \approx 1.041$ for the carbon isotope effect and 1.000 for the deuterium isotope effect.

THE SOLVOLYSIS REACTION

Isotope Effect at 343.2°

An inverse deuterium isotope effect, $k_H/k_D = 0.87$ (8), has been found in the solvolysis of methyl iodide in water at 70 °C. For this reaction, three sample calculations have been reported in a previous paper (6). It has become possible now to do much more work with the aid of the IBM 7094 computer. In the previous calculation for the model $CH_3^{\delta+} \cdots I^{\delta-}$,

[5]*The author wishes to express his thanks to Dr. Max Wolfsberg for having drawn his attention to the theoretical relations discussed in this paragraph.*

For personal use only.

the HCI bending force constant was set equal to zero. Thus, the conclusions drawn in the previous paper are still to be supported by some additional calculations with $f_{HCI} > 0$.

In the ion pair model for the transition state, with $r_{CI} = 2.50$ Å, the $CH_3^{\delta+}$ group is also considered to be flat. Values of the force constants are the same as in Table I. The following conclusions may be drawn from the sample calculations of Table III. If among the three transition state force constants f_{CH}, f_{HCH}, and $f_{HCI} + g$, two are kept at their reactant values the third one must always be set equal to a value higher than that of the reactant (the experimental isotope effect could not be reproduced otherwise). Such a transition state must be considered as highly improbable. Presumably, the CI bond would be extended to a higher degree in the transition state of the unimolecular cleavage of CH_3I than in the transition state of the bimolecular reaction of CH_3I with $^*I^-$. In these calculations with the unimolecular model, however, f_{HCI} must always be adjusted to a value considerably larger than that of the transition state $I\cdots CH_3\cdots I$. Consequently, the ion pair model for the transition state of the solvolysis reaction cannot correspond to reality.

The calculations of Table IV are done on the basis of the model $I\cdots CH_3\cdots OH_2$ ($r_{CI} = 2.50$ Å, $r_{CO} = 1.80$ Å, planar CH_3) which had been suggested previously by Llewellyn, Robertson, and Scott (8). (This model does not necessarily represent a nucleophilic attack of H_2O with formation of a covalent bond; the water molecule may merely enter the solvation shell of the carbonium ion being formed.) In contrast to the calculations of the previous paper (6), the force field of the transition state now contains, in addition, the 4 interaction force constants of Table I. Furthermore, the H_2O moiety is formulated as a three-particle group in these calculations, with $r_{OH} = 0.958$ Å, $\sphericalangle$ HOH = 105°, $f_{OH} = 7.66$ mdyn/Å, $f_{Int} = -0.097$ mdyn/Å, $f_{HOH} = 0.703$ mdynÅ (as in water), and with $\sphericalangle$ COH = 105°, $f_{COH} = 0.01$ mdynÅ, $f_{HCOH} = 0.02$ mdynÅ (torsional force constant; 2 torsional coordinates).

There are 5 force constants in the transition state whose values are still undetermined: f_{CI}, f_{CO}, f_{12} (interaction between the CI and CO stretches), f_{HCI}, and f_{HCO}. The two bending force constants f_{HCI} and f_{HCO} cannot be evaluated separately with the aid of the H or C isotope effect. Therefore, f_{HCI} is set equal to 0.205 mdynÅ (a value about 20% smaller than the fit value for the transition state $I\cdots CH_3\cdots I$) which is identical with the value used in the previous paper. Sample calculations are carried out with four different choices of the stretching force constants f_{CI}, f_{CO}, and f_{12}, designated with I, II, III, and IV, as shown in Table IV. I and II correspond to $\nu_L^{\ddagger} = 0$, III and IV lead to an imaginary $\nu_L^{\ddagger}$. In I and II, $f_{CI}f_{CO} - f_{12}^2 = 0$, whereas in III and IV, $f_{CI}f_{CO} - f_{12}^2 = -2.0$ (mdyn/Å)^2. In I and III, $f_{CI} = f_{CO}$; in II and IV, however, $f_{CI} < f_{CO}$ ("unsymmetric" stretching force field). The latter case is considered to be more probable, since in the transition state a dipole–dipole interaction between H_2O and CH_3I goes over to a π bond (positive f_{CO}) while the CI bond is broken (zero or negative f_{CI}).

It can be seen from Table IV that there are no significant differences in the calculated deuterium isotope effect if only f_{HCO} is held constant at 0.400 mdynÅ (Nos. 19, 21, 27, 29). In the calculations for Nos. 25, 26, 31, and 33, f_{HCO} is adjusted to fit the experimental D isotope effect for each of the four sets, I–IV. Since a "symmetric" stretching force field is considered unreal, we may conclude that (with f_{HCI} at 0.205 mdynÅ) f_{HCO} must lie between 0.445 and 0.460 mdynÅ for the transition state under consideration. (It may even be lower if $f_{CI}f_{CO} - f_{12}^2$ were below -2.0(mdyn/Å)^2.) Such a value for the HCO bending force constant of the transition state $I\cdots CH_3\cdots OH_2$ appears to be reasonable. Calculations either with $f_{CH} = 5.05$ mdyn/Å or with $f_{HCH} = 0.525$ mdynÅ would lead to different f_{HCO} values, naturally.

LINEAR FREE ENERGY RELATIONSHIPS CONCERNING EQUILIBRIA IN MODERATELY CONCENTRATED MINERAL ACIDS

A SIMPLE METHOD FOR ESTIMATING pK's OF WEAK BASES[1]

J. F. BUNNETT AND FREDRIC P. OLSEN
Department of Chemistry, Brown University, Providence, Rhode Island

Received March 30, 1966

ABSTRACT

Linear relationships exist between the logarithms of equilibrium quotients, $[SH^+]/[S][H^+]$, of diverse bases as they vary with acid concentration in moderately concentrated mineral acids. For purposes of formulating these linear free energy relationships in standard form, the equilibrium quotient for protonation of a hypothetical aromatic primary amine of pK_a zero has been chosen as horizontal coordinate; this is given by $(-H_0 - \log [H^+])$. Log $([SH^+]/[S]) + H_0$ is plotted against $(H_0 + \log [H^+])$. The slope, ϕ, of the linear plot is a parameter which characterizes the response of the equilibrium quotient to changing acid concentration. The intercept represents the thermodynamic pK_a of the base. This constitutes a general method for estimating the pK_a of any base which undergoes protonation in moderately concentrated mineral acid, with reference to the single acidity function, H_0. For bases of diverse type, pK's estimated by this method are in good agreement with those estimated by the acidity function method. Use of the new correlation procedure as a check on the validity of several acidity functions and its application to equilibria not involving proton gain or loss are also discussed.

Reactions which occur in moderately concentrated sulfuric, hydrochloric, or perchloric acid solution usually manifest changes in rate or state of equilibrium, on change of acid concentration, which are much greater than can be attributed merely to the change in hydrogen ion concentration. An appreciable change in mineral acid concentration constitutes an appreciable change in the medium, and these reaction rates and equilibria are subject to medium effects of considerable magnitude.

Most quantitative treatments of these effects have employed the acidity function approach. This approach, originally due to Hammett (1), has been tested, refined, and extended in recent years by several workers (2–8). The subject has been reviewed (9–12). These studies have considerably widened understanding, but the area of applicability of each acidity function, as currently applied, is rather small.

Medium effects of other kinds have been treated advantageously by means of linear free energy relationships (l.f.e.r.) (13–15), but phenomena in moderately concentrated mineral acids have not been approached within this frame of reference. In this paper, it is shown that equilibria in such systems can be dealt with profitably by the l.f.e.r. approach. The accompanying paper (16) similarly treats kinetic phenomena.

COMPOSITION OF LINEAR FREE ENERGY RELATIONSHIPS

The equilibrium protonation of a substrate (S) may be represented by

$$S + H^+ \rightleftarrows SH^+ \quad . \qquad [1]$$

Ordinarily, the concentration of mineral acid is known and the *ionization ratio*, $[SH^+]/[S]$, often symbolized I, can be measured, usually by spectrophotometry. The *equilibrium quotient*, herein symbolized as Q, is $[SH^+]/[S][H^+]$. This is the reciprocal of the concentration equilibrium constant for acid dissociation of SH^+.

[1]*Presented in part at the 150th meeting of the American Chemical Society, Atlantic City, N.J., Sept. 14, 1965. Preliminary communication: J. F. Bunnett and F. P. Olsen, Chem. Comm. 601 (1965).*

With respect to rate measurements, one normally measures the pseudo-first-order rate coefficient, k_ψ. For reactions involving acquisition of a proton in forming transition state from initial state, it is also appropriate to reckon the second-order rate coefficient, $k_\psi/[H^+]$, which we symbolize as k_2.

We have found that, in general, linear relationships exist between the logarithms of equilibrium quotients and (or) second-order rate coefficients for diverse reactions in

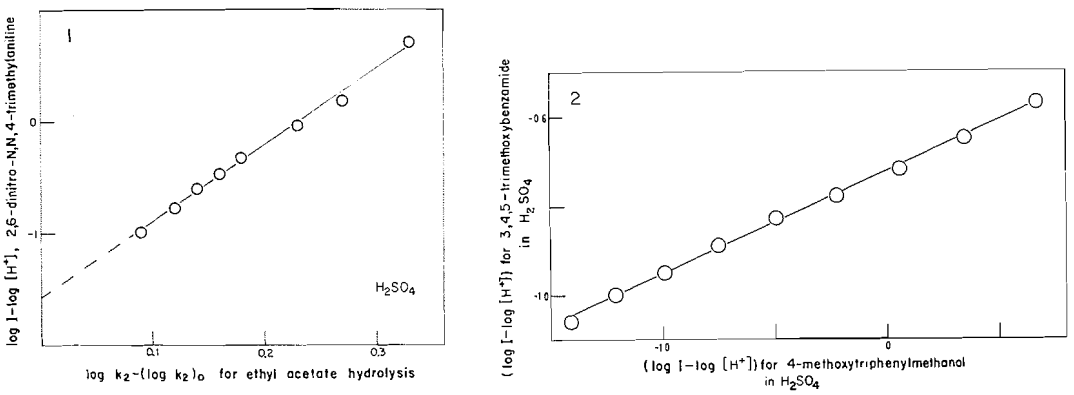

FIG. 1. Plot of log ($[SH^+]/[S][H^+]$) for equilibrium protonation of 2,6-dinitro-N,N,4-trimethylaniline against log k_2 (less log k_2 at infinite dilution) for ethyl acetate hydrolysis, both in H_2SO_4 solutions.

FIG. 2. Plot of (log $[SH^+]/[S][H^+]$) for equilibrium protonation of 3,4,5-trimethoxybenzamide against (log $[Ar_3C^+]/[Ar_3COH][H^+]$) for 4-methoxytriphenylmethanol, both in H_2SO_4 solutions.

solutions of the same mineral acid. For example (Fig. 1), log Q for protonation of 2,6-dinitro-N,N,4-trimethylaniline in sulfuric acid solutions is linearly related to log k_2 for ethyl acetate hydrolysis in sulfuric acid solutions. Each point in Fig. 1 represents log Q for a particular mineral acid concentration plotted against log k_2 at the same mineral acid concentration. Observations at lower sulfuric acid concentrations are at the left in the plot.

An example of a linear correlation between the logarithms of equilibrium quotients of two dissimilar reactions is presented as Fig. 2. One of these reactions is a simple protonation, while the other probably comprises two concurrent, consecutive equilibria.

$$Ar_3COH + H^+ \rightleftarrows Ar_3COH_2^+$$

$$Ar_3COH_2^+ \rightleftarrows Ar_3C^+ + H_2O$$

The overall equilibrium quotient for the latter case could be written as $[Ar_3C^+][H_2O]/[Ar_3COH][H^+]$, but in line with common practice (as in formulating K_W for the autoprotolysis of water) the water concentration factor will be omitted. Therefore, for triarylcarbinol – triarylcarbonium ion equilibria, Q is taken as $[Ar_3C^+]/[Ar_3COH][H^+]$. (This differs from the symbolism used by Deno *et al.* (5).)

The generality of such linear relationships warrants their organization in a standardized fashion. For this purpose, the logarithm of the rate coefficient or equilibrium constant for some standard reaction whose variation expresses the variable under study is chosen as horizontal coordinate. For example, log K for the dissociation of benzoic acids was chosen by Hammett (17) as the horizontal coordinate to represent the electronic effects of meta and para substituents, and log k for solvolysis of *tert*-butyl chloride in various solvents was chosen by Grunwald and Winstein (18) to represent solvent effects on solvolysis rates.

The standard reaction must be one for which an abundance of good data is available, covering the whole range of variation of the chemical variable of interest. A difficulty with respect to reactions in moderately concentrated acids is that the necessary data are not available, to our knowledge, for any real reaction. Data covering at least 0.5–10 M in hydrochloric, sulfuric, and perchloric acids are required. Because of the strong dependence of rates and equilibria on mineral acid concentration, only rarely can rate coefficients or equilibrium quotients be measured with precision over the specified range of acid concentrations. And when they are measurable over a broad range, as in the case of some ester hydrolyses, it is only because k_2 doesn't change much as acid concentration changes. For that very reason, log k_2 in such cases is not an optimum choice as horizontal coordinate.

There is, however, a hypothetical reaction for which an abundance of good data is available. This is the equilibrium protonation of a hypothetical aromatic primary amine (B), for which a plot of log I versus $-H_0$ is linear with slope identically 1.00, and which has pK_{BH^+} zero. The protonation of such an amine obeys the relationship (1):

$$H_0 = pK_{BH^+} + \log ([B]/[BH^+]).$$

It follows that log ($[BH^+]/[B]$) is given by $-H_0$, and log Q for protonation of the hypothetical amine by $(-H_0 - \log [H^+])$.

One may then write, for equilibria,

$$\log ([SH^+]/[S]) - \log [H^+] = (1 - \phi)(-H_0 - \log [H^+]) + \text{constant},$$

where the data on the left pertain to some real reaction and $(1 - \phi)$ is an arbitrary choice of slope parameter. It is convenient, though not necessary, to add $(H_0 + \log [H^+])$ to each side of the equation.

$$\log ([SH^+]/[S]) + H_0 = \phi(H_0 + \log [H^+]) + \text{constant}$$

To evaluate the constant, consider approach to infinite dilution in water. H_0 approaches $-\log [H^+]$; therefore the first term on the right disappears and the left side becomes log Q for the real reaction at infinite dilution in water, or pK_{SH^+}.

[2] $$\log ([SH^+]/[S]) + H_0 = \phi(H_0 + \log [H^+]) + pK_{SH^+}$$

Equation [2] is suggested as the standard formulation of this l.f.e.r., insofar as protonation equilibria are concerned. The slope of a linear plot according to eq. [2] is a parameter, ϕ, which expresses the response of the equilibrium to changing acid concentration. A negative ϕ value means that log ionization ratio for the real base increases, as the acid concentration augments, more rapidly than does $-H_0$. A positive ϕ value means that it increases less rapidly. The intercept of the plot represents pK_{SH^+} for the real base, referred to infinite dilution in water as standard state. Thus these plots offer a way of estimating pK values.

Representative plots according to eq. [2] are presented as Figs. 3 and 4. Figure 3 concerns the protonation of *m*-nitrobenzamide in sulfuric acid solutions (data of Yates, Stevens, and Katritzky (4)); the slope (ϕ) is +0.50 and the intercept (pK_{SH^+}) is −2.03. Figure 4 concerns the 4,4′,4″-trimethyltriphenylcarbinol $\rightleftarrows$ 4,4′,4″-trimethyltriphenylcarbonium ion equilibrium in sulfuric acid solutions (data of Deno, Jaruzelski, and Schriesheim (5)); ϕ is −1.21 and pK_{R^+} is −3.82.

An expression equivalent to eq. [2] is

[3] $$\log ([SH^+]/[S]) - \log [H^+] = (\phi - 1)(H_0 + \log [H^+]) + pK_{SH^+}.$$

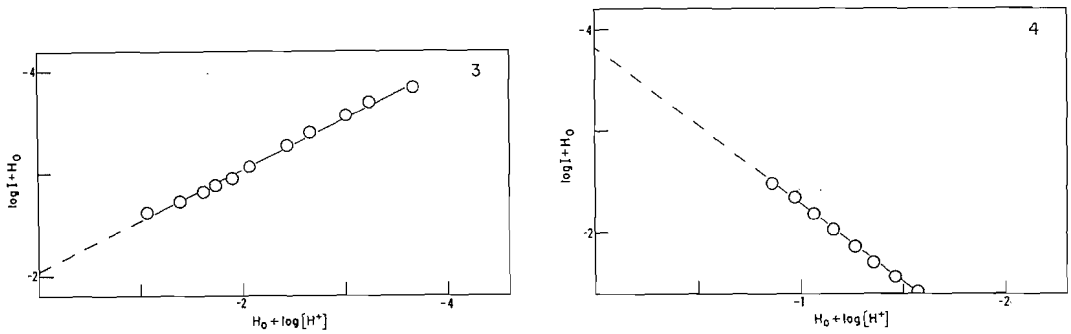

FIG. 3. Correlation of (log $I + H_0$) for *m*-nitrobenzamide in H_2SO_4 solutions with (H_0 + log [H^+]).
FIG. 4. Correlation of (log $I + H_0$) for carbonium ion formation from 4,4′,4″-trimethyltriphenylmethanol in H_2SO_4 solutions with (H_0 + log [H^+]).

If a plot according to eq. [2] is linear, a plot according to eq. [3] is necessarily also linear. Either type of plot may be used to evaluate ϕ and pK values.

Evaluation of pK's according to eq. [3] bears some similarity to an approximate method which has been widely employed (9, 19). This is to plot log Q against molar acid concentration and extrapolate to infinite dilution; the intercept is taken as pK_{SH^+}. Such plots are not linear over a broad range of acid concentrations, but they approximate linearity over short ranges. If the extrapolation is short, this method is serviceable. But the restriction to short extrapolations severely limits its applicability.

CORRELATION OF FOUR REPRESENTATIVE COLLECTIONS OF DATA

In four experimental studies of equilibrium protonation in sulfuric acid solutions, data were obtained which were used to generate four of the principal acidity functions currently available. These are the study of Deno, Jaruzelski, and Schriesheim (5) concerning triarylcarbinol – triarylcarbonium ion equilibria (the H_R function), that of Yates, Stevens, and Katritzky (4) concerning carboxamide protonation (the H_A function), that of Arnett and Mach (7) concerning protonation of aromatic tertiary amines (the H_0''' function), and that of Hinman and Lang (6) concerning protonation of indoles (the H_I function).

We have treated all the data obtained in all four studies by the l.f.e.r. method according to eq. [2], except a few which appear inappropriate for correlation. The data omitted were those in Table IV of Deno *et al.* (5) (identified by them as "less accurate"), sets of data entirely concerned with events at $< 1.1\ M$ mineral acid concentration, and all data at $> 85\%$ H_2SO_4. We have also treated the data of Arnett and Bushick (20, 21), at 30.3°, concerning some of the same triarylcarbinols studied by Deno *et al.* A total of 64 sets of data were examined. Our objective was to determine whether these data actually do give linear correlations according to eq. [2] and whether the pK's estimated from the intercepts agree with the pK's estimated in the acidity function studies. Each set of data was plotted and also subjected to standard linear regression analysis with use of a computer.

The results of the linear regression analysis are presented in Table I. Besides descriptive information, this table reports the slope (ϕ) for each correlation and the intercept, as "pK (l.f.e.r.)". Also reported are the standard deviation of individual points from the linear regression line (σ_y) and the standard deviation of the slopes of the l.f.e.r. plots (σ_{sl}). The pK's of the several substrates as evaluated in the acidity function studies are listed as "pK (a.f.)", and the slope and σ_y for plots of log I versus $-H_0$ are tabulated.

Most of the plots according to eq. [2] were linear to the eye; two are presented as Figs. 3 and 4. Scatter, probably stemming from random experimental error, was evident in many. A few plots suggested some curvature in one direction or the other, but curvature was not regular in its appearance or direction and is probably due to chance patterns of random error. The median standard deviation of points from the line (σ_y) is 0.041 log units, or 10%. This is the order of magnitude of the experimental error in the equilibrium measurements; it does not indicate any inadequacy of correlation according to eq. [2].

It is possible to compare the intercepts from 57 of the plots with pK's estimated by the acidity function (a.f.) method. In seven cases, pK's (although easily obtained by the l.f.e.r. method) could not be estimated by Hinman and Lang because of difficulties inherent in the a.f. method. The median difference in pK's estimated from the same data by the two methods is 0.25 pK unit, which is roughly the order of magnitude of the uncertainty usually imputed to pK values determined by the a.f. method. Possible sources of error in both methods are considered below.

CONCEIVABLE ALTERNATIVE FORMULATIONS OF L.F.E.R.

There are two ways in which correlations according to eq. [2] or [3] can be viewed as l.f.e.r. These differ in the standard states to which activity coefficients refer.

One way involves the unusual choice of each mineral acid solution as the standard state for measurements in that solution. f_{H^+} is defined as unity in each mineral acid solvent, and f_S and f_{SH^+} as unity at infinite dilution in that solvent, a condition closely approached in most photometric measurements of acid–base equilibria. The standard state is a hypothetical solution in that solvent in which H^+, S, and SH^+ are all present at unit concentration (1 M) with unit activity coefficient. Apart from experimental error and a very small correction due to the fact that S and SH^+ are present in finite concentrations, the measured log Q is then the thermodynamic pK_{SH^+} for that substrate in that medium. Since $-\log K_{SH^+} = \log Q = \Delta G^0/2.3RT$, a linear relationship between log Q at constant temperature amounts to a l.f.e.r. With respect to a similar definition of standard states, a linear relationship between log k_2 and log Q is by the same reasoning also a l.f.e.r.

It is evident that the value of log Q at any point on a plot of log Q versus ($H_0 + \log [H^+]$) represents the thermodynamic pK_{SH^+} of the substrate in that solution. To determine pK_{SH^+} for a substrate in a solution of any specified acid concentration, one need only look up the value of ($H_0 + \log [H^+]$) for that solution and determine (graphically or by use of eq. [3]) the value of log Q in that solution. For example, the pK's of 2,3,6-trichlorobenzamide and N,N-diethyl-2,4,6-trinitroaniline in 50% sulfuric acid are reckoned by eq. [3] from data in Table I as -1.71 and -2.13, respectively. These differ by only 0.4 pK unit although the pK's referred to infinite dilution in water differ by 2.6 units (Table I).

More commonly, infinite dilution in water is taken as the standard state for all activity coefficients.[2] One may then write

$$[4] \qquad pK_{SH^+} = \Delta G^0/2.3RT = \log [SH^+]/[S][H^+] + \log f_{SH^+}/f_S f_{H^+}$$

or, equivalently,

$$[5] \quad pK_{SH^+} = \Delta G^0/2.3RT = \log [SH^+] - \log [S] - \log [H^+] + \log f_{SH^+} - \log f_S - \log f_{H^+}.$$

[2]*Rigorously, the standard state is a hypothetical solution in which all activity coefficients are unity (as at infinite dilution) and all solutes are present at unit concentration (1 M).*

Each of the six logarithmic terms on the right side of eq. [5] is algebraically linear with $\Delta G^0/RT$, as is any sum of those terms. In this sense log Q (the sum of the three concentration terms) makes a linear contribution to free energy change. Consequently, linear relationships between log Q may be considered as l.f.e.r. It should be noted that ΔG^0 is now defined as constant; therefore any change in log Q with acid concentration must be offset by an equal and opposite change in log $(f_{SH^+}/f_S f_{H^+})$ (see eq. [4]).

By the same reasoning, log $([SH^+]/[S])$ or log I makes a linear contribution to free energy change, offset by an equal and opposite change in log $(f_{SH^+}/f_S a_{H^+})$. Inasmuch as $-H_0$ may be considered to represent log $([BH^+]/[B])$ for a hypothetical aromatic primary amine of pK_{BH^+} zero, the familiar plots of log I versus $-H_0$ may also be regarded as l.f.e.r.

Grunwald *et al.* (22–24) have postulated that linear relationships exist between log (f_{SH^+}/f_S) for various acid dissociation equilibria in ethanol–water mixtures. This implies (see eq. [4]) that log Q − log f_{H^+} for diverse substrates, as they vary with medium composition, should be linearly related. This postulate cannot be directly tested by experiment because values of f_{H^+} are not known, either in alcoholic solvents or in moderately concentrated mineral acids. The quantities actually related by Grunwald *et al.* were log (Q/Q'), pertaining to substrates S and S′; this allowed the inconvenient log f_{H^+} to be cancelled out. Their observation that linear relationships exist between log (Q/Q'), as they vary with solvent composition, whereas log Q's are not linearly related in ethanol–water media (cf. data in Table IV of Gutbezahl and Grunwald (23)), supports their postulate insofar as ethanol–water solutions are concerned. But when log Q's are linearly related, as in sulfuric acid media, demonstration of linear relationships between log (Q/Q') is trivial.

Let us now consider the hypotheses that linear relationships exist between log Q (or log k_2) and that they exist between log I (or log k_ψ). Let us inquire which type of linear correlation is better justified by available data.

All the data in Table I have been submitted to linear regression analysis according to both types of correlation. The qualities of fit are best judged by comparing σ_y values. Unfortunately, the σ_y values do not provide a clear distinction between the two methods. For the 64 sets of data, the σ_y's are nearly the same ($\Delta\sigma_y \leqslant 0.004$) in 48 sets and the remaining sets divide almost equally between favoring one type of correlation or the other.

The corresponding question concerning kinetic data is whether a better correlation is obtained between (log $k_\psi + H_0$) and (H_0 + log $[H^+]$) or between log k_ψ and $-H_0$. From a detailed inquiry, reported in the accompanying paper (16), a clear decision has emerged: correlations of the former type are much better. Mainly for this reason, l.f.e.r. concerning reactions in moderately concentrated mineral acids are judged to be better composed between (log $I + H_0$) or (log $k_\psi + H_0$) and (H_0 + log $[H^+]$) than between log I or log k_ψ and $-H_0$. Expressed more generally, correlations are better composed between log Q and (or) log k_2 than between log I and (or) log k_ψ.[3]

An ancillary advantage of plots of the favored type is that their intercepts are quantities of considerable interest: pK's or log k_2 values at infinite dilution. The intercepts in plots of log I or log k_ψ versus $-H_0$ represent, of course, the values of these quantities at zero H_0. Because many activity coefficient ratios differ appreciably from unity at zero H_0, an inconvenient correction of the latter intercepts would be necessary in order to evaluate the pK or log k_2 at infinite dilution. A further advantage of the favored correlations is that when a protonation equilibrium is concurrent and consecutive with one not involving proton gain or loss, the slope parameters for the two steps may be combined additively.

[3]*It should be noted that plotting (log $I + H_0$) is equivalent to plotting log Q versus (H_0 + log $[H^+]$); different slopes are obtained, but it is basically the same type of correlation either way.*

CONCERNING ACIDITY FUNCTIONS

Let us consider two bases, L and M, of a structural type other than aromatic primary amines. The condition that must be met if these are to be used in construction of an acidity function is:

$$[6] \qquad \text{d log } ([LH^+]/[L]) = \text{d log } ([MH^+]/[M]).$$

Alternatively, this may be expressed

$$[7] \qquad \text{d log } [LH^+]/[L][H^+] = \text{d log } [MH^+]/[M][H^+].$$

If log Q for L is linear with $(H_0 + \log [H^+])$,

$$[8] \qquad \text{d log } [LH^+]/[L][H^+] = (\phi - 1)\text{d}(H_0 + \log [H^+]).$$

It follows that if a set of bases are to be used to construct an acidity function, (*a*) their protonation reactions must have equal ϕ values or (*b*) $(H_0 + \log [H^+])$ must be zero. The latter special case is approximated in dilute aqueous solution, where the acidity function which prevails is pH. When $H_0 \neq -\log [H^+]$, the requirement of equal ϕ values must be met. This criterion will now be used to judge some of the published acidity functions.

The foregoing criteria for judgment of acidity functions are similar to those advanced by Gutbezahl and Grunwald (23). On the basis of the inequality of m values (which roughly correspond to the present ϕ values) for several bases in ethanol–water systems, they concluded that an acidity function cannot exist in such systems. This conclusion has been widely quoted with the implication that ethanol–water systems are inherently worse than sulfuric acid – water systems insofar as the possibility for existence of acidity functions is concerned. In 1953 it was widely believed that the protonation of all neutral bases "obeyed" the H_0 function in moderately concentrated mineral acids, but this is now known not to be the case. ϕ values for various bases in sulfuric acid solutions differ as much or more than m values in ethanol–water. The experience of Gutbezahl and Grunwald does not exclude the possibility that a set of bases of an appropriately limited structural type may define a proper acidity function in ethanol–water media. Indeed, Yeh and Jaffé (25) found the condition of eq. [6] to be satisfied for azobenzene derivatives in ethanol – water – sulfuric acid solutions. Their acidity function, unfortunately symbolized H_0, appears to be a satisfactory one for that functional class of bases.

In judging published acidity functions, one must bear in mind that errant ϕ values can be caused by random experimental error. Therefore if the bases used to construct an acidity function differ in their ϕ values, it does not necessarily follow that they are inappropriate for construction of an acidity function. On the other hand, unless the ϕ values for a set of bases are substantially equal, a necessary condition for the construction of an acidity function fails to have been satisfied.[4] Also, the manner of constructing acidity functions is such that experimental errors accumulate except as they happen to offset each other.

The H_A Function for Amides (4)

With the exception of 2-pyrrolecarboxamide, the ϕ values (Table I) for the bases used to construct the H_A function lie between +0.42 and +0.55. This is a relatively narrow range; the benzamide derivatives are thus appropriate for construction of an acidity

[4]*However, if there is persistent and regular curvature common to all bases of a functional class in plots of log Q or (log I + H_0) versus (H_0 + log [H^+]), that is, a regular violation of the linear relationships of our present concern, these conclusions do not apply. As discussed below, there are indications of such violations for some types of bases in perchloric acid solutions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

function. However, the H_A function suffers from uncertanty at its beginning. Because no amide was available whose pK could be determined by measurements in dilute solution, the uncomfortable assumption was made that the H_A and H_0 functions coincide up to 16.1% H_2SO_4. Using a ϕ value of +0.48 (the average for the benzamide derivatives in Table I), one reckons that H_A (evaluated as $H_0 - \phi(H_0 + \log [H^+])$) should be −0.50 in 16.1% H_2SO_4 whereas Yates *et al.* (4) assumed −0.78. A further small uncertainty entered from use of 2-pyrrolecarboxamide, whose ϕ is +0.31, to carry the acidity function between 16 and 24% sulfuric acid. The H_A function as a whole appears to be too negative by about 0.3 units; appropriately, this is the direction and order of magnitude of the differences between pK(l.f.e.r.) and pK(a.f.) for the amides in Table I.

The H_0''' Function for Aromatic Tertiary Amines (7)

With a few exceptions, the ϕ values (Table I) for the bases used to construct the H_0''' function lie between −0.33 and −0.48. It is not obvious why five indicators fall outside this range. The two with unusually low negative ϕ values are both diphenylamine derivatives, but three other diphenylamines have ϕ values between −0.33 and −0.48. The generally satisfactory agreement of pK's estimated by l.f.e.r. and a.f. methods (excepting the two errant diphenylamine derivatives) suggests that the H_0''' scale as a whole is fairly accurate.

The H_R Function for Triarylcarbinol – Triarylcarbonium Ion Equilibria (5)

Despite considerable experimental attention, the set of indicators used to establish the H_R function has not been fully demonstrated to satisfy the criterion of eq. [6]; in the studies of Deno *et al.* (5) and of Arnett and Bushick (20, 21) there were gaps of little or no overlap at ca. 25%, 39%, 53%, and 71% H_2SO_4. The less rigorous but nevertheless persuasive criterion of constancy of d log I/d % H_2SO_4 between adjacent indicators was, however, rather well met. The correlations summarized in Table I, based mainly on data of Deno *et al.* but including also the 30.3° data of Arnett and Bushick, show that to a considerable extent the bases employed meet the criterion of equality of ϕ values. The ϕ values, excepting those for the last two triarylcarbinols listed, lie between −1.02 and −1.59 with an average of −1.29. It is not entirely clear whether the extremes are real or represent unusual experimental error; one of the extremes (for 4-methoxytriphenylmethanol) is confirmed by measurements in a second laboratory but another (for triphenylmethanol) is not. The agreement between pK's estimated by the l.f.e.r. and a.f. methods is nearly as good as between those estimated by the a.f. method in two different laboratories.

The ϕ values for 3,3′,3″-trichloro- and 4,4′-dinitro-triphenylmethanols (−0.8) differ sharply from the rest. This could represent unusual activity coefficient behavior in those equilibria or breakdown of the linear relationship between log Q and $(H_0 + \log [H^+])$ at very high acid concentrations. The large discrepancies between pK's estimated by the two methods are, as discussed below, a direct consequence of the deviant ϕ values in these two cases.

The H_I Function for Indoles

Of the 25 indoles investigated by Hinman and Lang (6), 23 fall neatly into categories which link structural type with ϕ value in sulfuric acid. Four indoles unsubstituted in the pyrrole ring have ϕ from +0.04 to +0.26, thirteen indoles carrying a 2- and (or) 3-substituent but no 1-substituent have ϕ from −0.26 to −0.46, and six of eight 1-substituted indoles have ϕ between −0.67 and −0.85. The two errant bases are 1,2,3-trimethylindole (ϕ −0.32) and 1-methylindole-3-acetic acid (ϕ −0.37).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Hinman and Lang also recognized three categories on the basis of d log I/d [H_2SO_4] slope values. One of their categories coincides with the first above (indoles unsubstituted in the hetero ring); properly, they eschewed those four bases in constructing a general acidity function for indoles. Their second category included all the indoles of Table I carrying a 2- and (or) 3-substituent but no 1-substituent as well as five 1-substituted indoles. Their third category included three 1,3-disubstituted indoles. Their second and third categories do not match ours.

Hinman and Lang used data for nine indole derivatives to evaluate the H_I function. These included two (1-methylindole and 1,2-dimethyl-5-nitroindole) whose ϕ values place them in our third category. The set of bases used therefore appears not to have been entirely appropriate; the H_I function of Hinman and Lang is apparently somewhat too negative above 3 M sulfuric acid.

SOURCES OF ERROR IN ESTIMATING pK VALUES

Let us consider Fig. 5, a typical l.f.e.r. plot by means of which the pK of a base (in this case, 2,4,6-trinitro-N,N-diethylaniline) can be estimated. The pK_{SH^+} is estimated as the intercept, which is -5.62 and which may be compared with pK_{SH^+} -5.71 estimated by the a.f. method. The former estimate involves the assumption that the straight line established by the experimental points (in this case at 52–67% H_2SO_4) is linear all the way to infinite dilution in water. Any fault in this assumption introduces an error into the pK estimate. Also, any experimental error which deflects the slope causes an error in the intercept which is larger the longer the extrapolation.

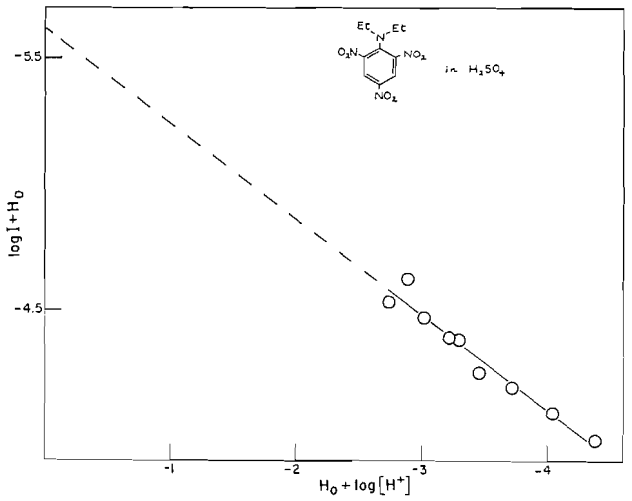

FIG. 5. Correlation of (log $I + H_0$) for N,N-diethyl-2,4,6-trinitroaniline in H_2SO_4 solutions with (H_0 + log [H^+]).

In estimating pK's by the a.f. method, one assumes that the variation of the activity coefficient ratio for a given base, through a series of acid concentrations down to infinite dilution, is the same as the variation of activity coefficient ratio by the indicator bases used to construct the acidity function. Any fault in this assumption introduces an error into the pK estimate. The pK estimate is not very sensitive to experimental error in measurements on the base under study, but errors in measurements on the bases used to

construct the acidity function tend to accumulate in the function itself and to affect all pK estimates based upon it.

pK ESTIMATION WITH REFERENCE TO KINETIC DATA

We have seen that one can, by the l.f.e.r. approach, estimate the pK of any base with reference to H_0 and log [H$^+$], whether or not its protonation "obeys" H_0 in the Hammett sense. It is also possible to estimate pK's without reference to any acidity function, in the usual sense of the term. For this purpose one uses kinetic data instead of (H_0 + log [H$^+$]).

One plots log Q for protonation of the base under study against (log k_2 − log k_2^0) or (log k_ψ − log k_ψ^0) for reaction of, respectively, a weakly or strongly basic substrate. Theoretically, k_2^0 and k_ψ^0 are rate coefficients at infinite dilution in water but in practice they are measured coefficients in dilute solution, say, at pH 2. Figure 1 is such a plot. By reasoning such as employed in the derivation of eq. [2], the intercept is pK_{SH^+}. The intercept in Fig. 1 is −1.58; this agrees well with the pK of 2,6-dinitro-N,N,4-trimethylaniline as estimated by the standard l.f.e.r. (−1.57) and acidity function (−1.66) methods.

EQUILIBRIA IN PERCHLORIC ACID SOLUTIONS

Table II summarizes l.f.e.r. correlations concerning triarylcarbinol – triarylcarbonium ion equilibria (data of Berkheimer (26, 27)) and the protonation of indoles (data of Hinman and Lang (6)) in perchloric acid solutions.

The data are few, but for both types of substrates the (negative) ϕ values at low acid concentrations ($< 2\ M$) are much larger in magnitude than for substrates of similar structural type at higher acid concentrations. (At higher acid concentrations, the ϕ values are similar to those for the same substrates in sulfuric acid media.) Moreover, plots of (log I + H_0) versus (H_0 + log [H$^+$]) for 4-methyl- and 3,3′,3″-trimethyl-triphenylmethanol were smooth curves with slopes varying from ca. −1.5 at 35–38% $HClO_4$ to ca. −0.7 at 44–47% $HClO_4$. The usual pattern of uniformly linear correlations and substantially constant slopes for substrates of similar structure is apparently violated. More extensive data to substantiate or refute these indications would be desirable.

These possible violations of l.f.e.r., even if substantiated by further data, do not necessarily mean that linear relationships between (log I + H_0) and (H_0 + log [H$^+$]) are not of frequent occurrence in perchloric acid. Good linear relationships for diverse equilibria in perchloric acid are presented in Table III. Abundant kinetic data concerning reactions in perchloric acid are available; in general the plots of (log k_ψ + H_0) versus (H_0 + log [H$^+$]) are good straight lines, as reported in the accompanying paper. Among kinetic data there are, however, some reactions which do not afford linear "l.f.e.r." plots. Two examples are hydrolyses of trimethylacetic anhydride (28) and acetylimidazole (29). Such anomalies seem to be more frequent, and more serious, in perchloric than in sulfuric acid solutions.

SOME MISCELLANEOUS ACID–BASE EQUILIBRIA

Some miscellaneous correlations of protonation equilibria are summarized in Table III. These all concern equilibria for which no proper acidity function is available, except by coincidence in two cases, and for which pK's have been estimated by various methods.

For benzamide, pK's of −2.15 (30), −1.85 (33*a*), and −2.16 (33*b*) have been estimated with reference to the H_0 function which, we now realize, is not "obeyed" by amides. pK's of −1.74 and −1.68 have been estimated from different sets of data in sulfuric acid with reference to the H_A function (33*c*). The pK for benzamide in Table III, −1.53, is based on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Moodie's data in perchloric acid (30). If the whole H_A function is considered too negative by perhaps 0.3 unit, this estimate is in fairly good agreement with the (corrected) estimates based on that function.

pK's of the two azo ethers in Table III were estimated as -1.6 and -0.74, respectively, with reference to the H_0 function (31). In view of the large negative ϕ values, it is not surprising that pK's estimated by the l.f.e.r. method differ considerably from the earlier estimates. The agreement between the pK's estimated for 4-(*p*-sulfophenylazo)anisole in two mineral acids is noteworthy. The considerable difference in ϕ value for protonation of the two azo ethers in hydrochloric acid solutions also merits attention.

Schubert and Quacchia (32) noted that the protonation of 1-methoxy-3,5-dihydroxybenzene "follows" H_0 very closely. The pK estimated with reference to the H_0 function, -3.61 (average), should therefore be a good one; it agrees quite well with -3.54 as estimated by the l.f.e.r. method. The less certain ionization ratios for 1,3-dimethoxy-5-hydroxybenzene also indicated obedience to H_0, and again the pK estimated with reference to that function, -3.68 (average), agrees with the l.f.e.r. estimate (-3.72) based on the same data. Schubert and Quacchia noted that protonation of 1,3,5-trihydroxybenzene and its trimethyl ether "obeyed" H_0 less well; it is therefore reasonable that the l.f.e.r. estimates of pK differ appreciably from the (drifting) estimates based on the H_0 function.

Challis and Long (19) estimated the pK of azulene at four temperatures by the extrapolation procedure of Paul and Long (9) and at 25° by an acidity function approach via 1-methylazulene, which is more basic than azulene. Their estimates are more negative than the l.f.e.r. estimates by about 0.1 pK unit at all temperatures; the agreement is good. The consistent variation of ϕ value with temperature is noteworthy.

These diverse correlations illustrate the utility of the l.f.e.r. method for estimating pK's of bases for which no regular acidity function is available.

EQUILIBRIA NOT INVOLVING PROTONATION

A few measurements have been made on equilibria not involving acquisition or loss of a proton between initial and final states (34–36). A general symbolism for such reactions is:

$$\text{S} \overset{K_e}{\rightleftarrows} \text{V} \ (+\text{H}_2\text{O}). \qquad [9]$$

Such reactions often involve covalent addition of water, or the reverse, and we recommend writing them so that dehydration is the forward reaction. The equilibrium constant expression may be written in logarithmic form

$$\log ([\text{V}]/[\text{S}]) = \log (f_S/f_V) + \log K_e \qquad [10]$$

Equations [4] and [10] are similar in form, suggesting that linear relationships may exist between $(H_0 + \log [\text{H}^+])$ and the logarithms of equilibrium quotients such as that in eq. [10]. In the few cases known to us, $\log ([\text{V}]/[\text{S}])$ is indeed linear with $(H_0 + \log [\text{H}^+])$. The correlations are summarized in Table IV. A representative plot is presented as Fig. 6.

TABLE IV

Equilibria not involving proton gain or loss (correlations of log ([V]/[S]) with $(H_0 + \log [\text{H}^+])$)

Such plots have threefold utility. The slopes (ϕ values) are useful to characterize the medium effect on the equilibrium quotient. The intercepts represent log K_c at infinite dilution in water. And for concurrent, consecutive equilibria, the ϕ values for the successive steps may be combined additively. The principle of additive combination is discussed and illustrated in the following paper.

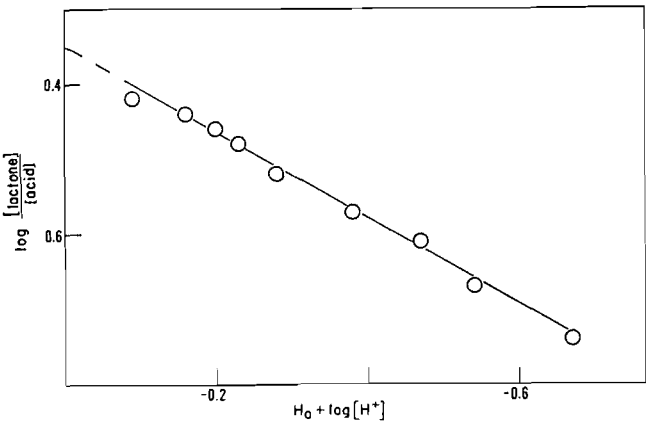

FIG. 6. Correlation of log([lactone]/[acid]) for the γ-hydroxybutyric acid – γ-butyrolactone equilibrium in HCl solutions with (H_0 + log [H^+]).

SIGNIFICANCE OF ϕ VALUES

ϕ values are useful to characterize the response of equilibrium quotients to changing acid concentration. Their utility is similar to that of Hammett *rho* values which characterize the response of reaction rates or equilibria to the polar effects of substituents.

The l.f.e.r. developed in this paper may be viewed as linear relationships between the logarithms of activity coefficient ratios. If the Hammett definition, $h_0 = a_{H^+} f_B/f_{BH^+}$, is algebraically rearranged and logarithms are taken, one obtains

$$H_0 + \log [H^+] = \log f_{BH^+}/f_B f_{H^+}. \quad [11]$$

Substituting for log [H^+] in eq. [4] its equivalent from eq. [11], one obtains

$$\log [SH^+]/[S] + H_0 = \log (f_{BH^+} f_S/f_{SH^+} f_B) + pK_{SH^+}. \quad [12]$$

Substituting from eqs. [11] and [12] into eq. [2], one obtains

$$\log f_{BH^+} f_S/f_{SH^+} f_B = \phi \log f_{BH^+}/f_B f_{H^+}.$$

ϕ is thus a proportionality constant between the logarithms of activity coefficient ratios.

Medium effects on rates and equilibria in moderately concentrated mineral acids have been interpreted in terms of hydration change by many authors (19, 33*c*, 37–42). Hydration change is recognized as a major factor affecting ratios of formal activity coefficients, but other factors probably are also significant. It being difficult to assess just how much of the medium effect is due to hydration change, we shall discuss medium effects in terms of the extreme hypothesis that hydration change is the only factor affecting the magnitude of ϕ values. We do not, however, mean to assert that hydration change is the only relevant factor.

If full account is taken of the hydration of all species, the protonation of a primary aromatic amine indicator base may be written:

$$B(H_2O)_b + H(H_2O)_n^+ \rightleftarrows BH(H_2O)_a^+ + (b + n - a)H_2O.$$

It has been shown (40) that

$$H_0 + \log [H(H_2O)_n^+] = (b + n - a) \log a_{H_2O} + \log f_{BH(H_2O)_a^+}/f_{H(H_2O)_n^+} f_{B(H_2O)_b},$$

if each species is hydrated to a constant extent in any medium. On the extreme hydration change hypothesis, the above ratio of activity coefficients for hydrated species is unity in all media, and the hydration change may be reckoned as $(H_0 + \log [H^+])/\log a_{H_2O}$. It is, however, more realistic to consider that each formal species is represented in solution by several species of differing degrees of hydration, in equilibrium with each other. In that case, the average hydration change is the slope of a plot of $(H_0 + \log [H^+])$ versus $\log a_{H_2O}$ (41). For hydrochloric, sulfuric, and perchloric acids, the slope of said plot is approximately 4.5 from about 3.5 to 7.0 M.

Similarly, the slope in a plot of $(\log ([SH^+]/[S]) + H_0)$ against $\log a_{H_2O}$ would represent the $(p - s - a + b)$, the average hydration change accompanying the hypothetical reaction:

[13] $$SH(H_2O)_p^+ + B(H_2O)_b \rightleftarrows S(H_2O)_s + BH(H_2O)_a^+ + (p - s - a + b)H_2O.$$

Accordingly,

$$\frac{d (\log ([SH^+]/[S]) + H_0)}{d (H_0 + \log [H^+])} = \phi = \frac{(p - s) - (a - b)}{b + n - a}.$$

Thus, according to the hydration change hypothesis in its extreme form, ϕ represents the ratio of average hydration change in the hypothetical reaction of eq. [13] to that in protonation of an aromatic primary amine indicator base. The larger the hydration of SH^+ relative to that of S, the more positive ϕ is. A negative ϕ suggests that $(p - s) < (a - b)$, and is expected when hydration of SH^+ is relatively low. We may estimate, on the extreme hydration change hypothesis, the average change in number of water molecules of hydration through a middle range of acid concentrations as about 4.5ϕ. In order to emphasize this feature, we have sometimes used the parameter w', defined as 4.5ϕ, in discussions (43, 44).

VALUES OF H_0 AND $[H^+]$

In our computations, the H_0 values of Paul and Long (9) were employed except at higher concentrations of sulfuric acid, where the H_0 value of Jorgenson and Hartter (2) were used.

We have taken the molar concentration of hydrogen ion to be equal to the molar concentration of the mineral acid. Vapor pressure data show that hydrochloric acid is > 99% dissociated in solutions as concentrated as 10 M (45). No Raman absorption characteristic of undissociated sulfuric acid is detectable below 14 M, although it is speculated that molecular H_2SO_4 may exist in appreciable concentrations in solutions as dilute as 12 M or even 10 M (46). Nuclear magnetic resonance measurements have been interpreted as showing as little as 80% dissociation of perchloric acid in 9 M concentration (47), but this interpretation has been challenged (48) as seriously underestimating the dissociation constant of $HClO_4$.

The thermodynamic pK_a for the second dissociation of sulfuric acid is 2.0. If the activity coefficient ratio, $f_{H^+}f_{sulfate}/f_{bisulfate}$, increases with acid concentration as such ratios for protonation equilibria usually do, or if it diminishes only slightly from unity, acid dissociation of bisulfate ion is negligible even in 1 M sulfuric acid. The apparent molal volumes of sulfuric acid solutions indicate little dissociation of bisulfate ion in 1 M sulfuric acid (49).

However, Young, Maranville, and Smith (46) have described Raman spectral measurements which they interpret as showing substantial acid dissociation of bisulfate ion at sulfuric acid concentrations as high as 11 M. Their spectra have not been published, and Raman studies on 1–10 M sulfuric acid appear not to have been made in other laboratories. The Raman interpretations of Walrafen and Young (50) in sulfuric acid solutions containing SO_3 are controversial (51, 52). Edward and Wang (53) have interpreted the ultraviolet spectra of sulfuric acid solutions at 190 mμ to indicate substantial dissociation of bisulfate ion as high as 5 M, but their estimates are in quantitative disagreement with those of Young *et al.* unless a special transparency is imputed to sulfate ion at higher acid concentrations.

It is thus not certain to what extent the bisulfate ion dissociates in moderately concentrated sulfuric acid solutions. However, if the interpretations of Young *et al.* are correct, the present l.f.e.r. correlations are not substantially affected. $H_0 + \log [H^+]$, after Young *et al.*, is uniformly higher than $H_0 + \log [H_2SO_4]$ by 0.11

$\pm$ 0.01 log unit through the concentration range 0.1 to 7.8 M sulfuric acid. Therefore ϕ values within this range would not be affected, but intercepts (pK_{SH^+} values) would be increased by 0.11ϕ. Since most ϕ values lie between -1 and $+1$ and the uncertainty in pK estimates is of the order of 0.2 pK units, changing to $(H_0 + \log [H^+])$ based on Young *et al.* would scarcely affect pK estimates.

If the interpretations of Young, Maranville, and Smith are correct, values of $(H_0 + \log [H^+])$ at $> 54\%$ sulfuric acid would differ from those we have used by varying margins. Between 55 and 70% sulfuric acid, $(H_0 + [H_2SO_4])$ changes by 1.74. The correction would tend to extend this change to about 1.82. ϕ values based on measurements within this range would be diminished about 5% in absolute magnitude, a scarcely significant change. pK estimates would also be affected by amounts less than 0.25 unit, the correction in a particular case depending on the ϕ value and the length of the extrapolation involved.

ACKNOWLEDGMENTS

We are grateful to the National Science Foundation for a large measure of financial support, to Drs. R. L. Hinman and R. B. Moodie for supplying unpublished data, and to Mr. R. P. Bell and Profs. E. Grunwald and W. M. Schubert for stimulating correspondence and conversations.

LINEAR FREE ENERGY RELATIONSHIPS CONCERNING REACTION RATES IN MODERATELY CONCENTRATED MINERAL ACIDS[1]

J. F. BUNNETT AND FREDRIC P. OLSEN
Department of Chemistry, Brown University, Providence, Rhode Island

Received March 30, 1966

ABSTRACT

Linear relationships exist between log $k_\psi + H_0$ (for reactions of weakly basic substrates) or log k_ψ (for reactions of strongly basic substrates) and (H_0 + log [H^+]). These are linear free energy relationships. For weakly basic substrates, the correlations obtained are better than in plots of (log $k_\psi + H_0$) versus log a_{H_2O} or of log k_ψ versus $-H_0$. The slopes in plots of log k_ψ or (log $k_\psi + H_0$), as appropriate, against (H_0 + log [H^+]) are taken as parameter, ϕ, which characterizes the response of the reaction rate to changing mineral acid concentration. Values of ϕ for reactions of strongly basic substrates reflect only relationships between protonated substrate and transition state, and may be related to reaction mechanism. ϕ values for reactions of weakly basic substrates reflect both equilibrium protonation of the substrate and transformation of protonated substrate to transition state, and are therefore less directly related to mechanism. However, the ϕ values for the two steps are additive and that for the latter step can be obtained by subtraction if the overall ϕ value and that for equilibrium protonation are known.

The rates and states of equilibrium of reactions in moderately concentrated mineral acid solutions generally vary with the acid concentration. The extent and even the direction of variation differ from reaction to reaction. The description, quantification, and interpretation of these phenomena have occupied the attention of many workers, but understanding remains incomplete.

In the accompanying paper (1) it is shown that linear free energy relationships (l.f.e.r.) exist between the logarithms of equilibrium quotients, [SH^+]/[S][H^+], and (or) second-order rate coefficients for diverse reactions as these quantities vary with acid concentration. These relationships as they pertain to equilibria are considered in that paper. They are now considered as they pertain to rate phenomena.

That l.f.e.r. concerning kinetic data exist is illustrated by Fig. 1 of the accompanying paper and by Figs. 1 and 2 of this one. In the present Fig. 1, the logarithm of the second-order rate coefficient (k_ψ/[H^+], alternatively symbolized k_2) for the enolization of acetophenone (data of Zucker and Hammett (2)) in perchloric acid solutions is plotted against log k_2 for the depolymerization of trioxane (interpolated from data of Bell, Bascombe, and McCoubrey (3)) in perchloric acid solutions. Each point represents measurements at a different acid concentration, points for lower acid concentrations being toward the left of the plot. In Fig. 2, log k_2 for ethyl acetate hydrolysis (interpolated from data of Bell, Dowding, and Noble (4)) is plotted against log k_ψ for hydrolysis of N,N′-diphenylformamidine (data of DeWolfe (5)), both in hydrochloric acid solutions. The latter substrate is strongly basic, essentially fully protonated at all the acid concentrations studied, and one therefore plots log k_ψ rather than log k_2.

For purposes of formulating l.f.e.r. concerning equilibria in standard fashion, the logarithm of the equilibrium quotient for protonation of a hypothetical aromatic primary amine (B) of pK_{BH^+} zero was chosen as horizontal coordinate (1). The logarithm of the

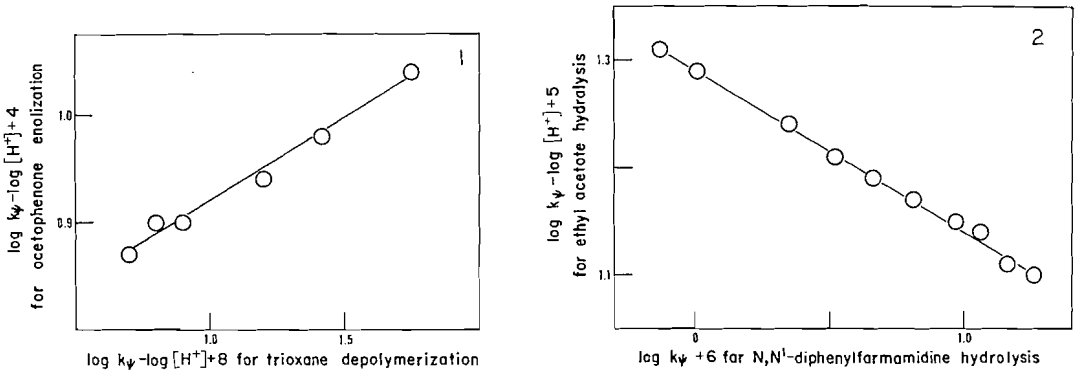

FIG. 1. Correlation of (log k_ψ − log [H⁺]) for acetophenone enolization and trioxane depolymerization in $HClO_4$ solutions.

FIG. 2. Correlation of (log k_ψ − log [H⁺]) for ethyl acetate hydrolysis with log k_ψ for N,N′-diphenylformamidine hydrolysis, in HCl solutions.

equilibrium quotient for this reaction is given by $-H_0$ − log [H⁺]. The same reference reaction will be used in the standardized correlation of kinetic data.

If log k_2 is linear with $-H_0$ − log [H⁺],

$$\log k_\psi - \log [H^+] = (1 - \phi)(-H_0 - \log [H^+]) + \text{constant},$$

where $(1 - \phi)$ is an arbitrary choice of slope parameter. It is convenient, though not necessary, to add $(H_0 + \log [H^+])$ to each side of the equation.

$$\log k_\psi + H_0 = \phi(H_0 + \log [H^+]) + \text{constant}$$

As infinite dilution in water is approached, the first term on the right disappears and the left side of the equation approaches log k_2^0, the logarithm of the second-order rate coefficient at infinite dilution in water; the constant is thus log k_2^0.

$$\log k_\psi + H_0 = \phi(H_0 + \log [H^+]) + \log k_2^0 \qquad [1]$$

Equation [1] is recommended as the standard formulation of this l.f.e.r., insofar as acid-catalyzed reactions of weakly basic substrates are concerned. If the substrate is protonated, in an equilibrium sense, to more than about 5% at the highest acid concentration studied, a different expression must be used.

It is a fact that plots of (log $k_\psi + H_0$) versus $(H_0 + \log [H^+])$ are generally linear, for reactions of weakly basic substrates. Figures 3 and 4 are illustrative.

The slope parameter, ϕ, is useful to characterize the kinetic effect of changing the reaction medium. The intercept represents log k_2 at infinite dilution in water (see eq. [1]).

COMPARISON WITH CORRELATIONS OF OTHER TYPES

An early hypothesis was that log k_ψ for all reactions of weakly basic substrates would be linear with $-H_0$ with unit slope (6). Later, such reactions were considered to fall into two categories in which slopes were unity in plots of log k_ψ against either $-H_0$ or log [H⁺] (7, 8). Since the abandonment of these hypotheses, two systems have been employed to characterize the medium effect on reaction rate. More commonly, the slope of the plot of log k_ψ versus $-H_0$ or some other acidity function has been cited. Alternatively, the slope in a plot of (log $k_\psi + H_0$) versus log a_{H_2O}, the w parameter (9), has been used for this purpose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

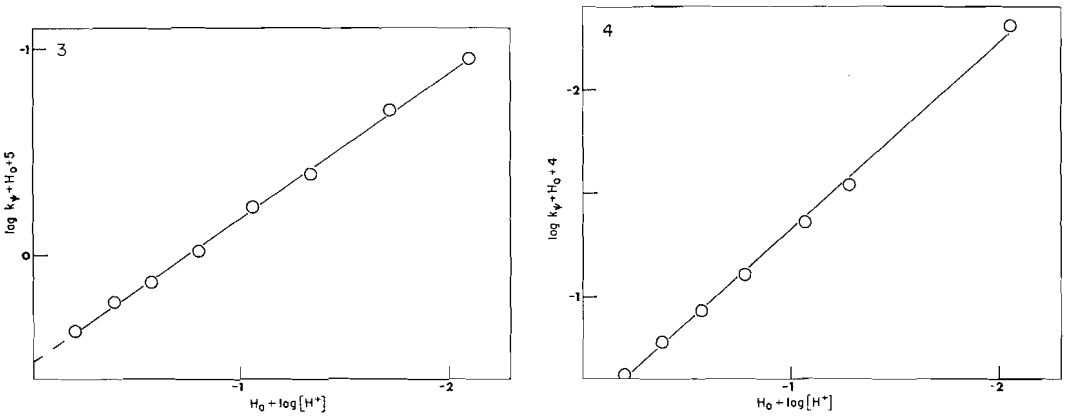

FIG. 3. Correlation of (log k_ψ + H_0) for acetone enolization in HCl solutions with (H_0 + log [H⁺]).
FIG. 4. Correlation of (log k_ψ + H_0) for isonicotinamide hydrolysis in HCl solutions with (H_0 + log [H⁺]).

A difficulty with each method is that the plots in question are not always linear. Departures from linearity appear in plots of log k_ψ versus $-H_0$ when the gradient is appreciably less than unity and in plots of (log k_ψ + H_0) versus log a_{H_2O} when a broad range of acid concentrations is concerned and w differs appreciably from zero. The linear regression "slope" of a curved plot depends on which part of it is examined; the magnitude of the slope parameter therefore depends on how broad a range of acid concentrations was covered by the kinetic experiments.

For the purpose of comparing the quality of correlation according to eq. [1] with correlations by the two foregoing methods, we have reexamined the same large body of kinetic data (nearly all the suitable kinetic data available in 1960) which was correlated by one of us to evaluate w values (9). Correlations according to eq. [1] have been made in all appropriate cases, and correlations of log k_ψ with $-H_0$ in certain test cases selected according to systematic criteria. The criteria were that the set of data comprise six or more points and that Δ log k_ψ between the first and last points be at least 1.6 or the difference in mineral acid concentration at least 5.9 M.

The results of these correlations are summarized in Table I. In addition to correlations of reactions of weakly basic substrates according to eq. [1], Table I presents some correlations of reactions of moderately basic substrates, for which the function plotted against (H_0 + log [H⁺]) is log k_ψ − log ([SH⁺]/[S]$_{st}$) (cf. ref. 10), and some for strongly basic substrates for which the function plotted is log k_ψ. The three functions plotted are designated in Table I by A, B, and C, respectively.

Table I is divided into two parts. Part I comprises reactions for which exactly the same numbers were plotted against (H_0 + log [H⁺]) as were earlier plotted against log a_{H_2O}. Reactions are numbered the same as in Table I of ref. 9, and that table should be consulted for the acid concentration ranges concerned, numbers of experimental points, and citations of original literature.

Part II of the present Table I comprises reactions reckoned on a revised basis. The principal changes are use of Jorgenson–Hartter H_0 values (11) for > 60% sulfuric acid, instead of those of Paul and Long (12), and the plotting of (log k_ψ − log ([SH⁺]/[S]$_{st}$)) instead of log k_ψ − log $h_0/(h_0 + K_{SH^+})$ against (H_0 + log [H⁺]) for most moderately basic substrates. The latter are mainly amides. From recently published amide half-protonation H_0 values and gradients[2] in plots of log ([SH⁺]/[S]) against $-H_0$ (13–17),

[2]*Where no published gradient could be found, a gradient of 0.75 was assumed.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the fraction of amide protonated was reckoned at each acid concentration and log k_ψ − log ($[SH^+]/[S]_{st}$) was computed and plotted. Reactions 57 and 58 were handled similarly.

For each set of data in Table I, the slope of the l.f.e.r. plot is given as the ϕ value, the standard deviation in the y-direction of individual points from the linear regression as σ_y, and the standard deviation of the slope as σ_{sl}. For selected "test case" reactions of weakly basic substrates, the slope in the plot of log k_ψ versus $-H_0$ and the standard deviation of points from the linear regression line are also given. Slopes (w values) and σ_y in plots of functions A, B, and C against log a_{H_2O} for reactions in part I appear in Table I of ref. 9, and for reactions in part II in the footnotes.

For the 42 reactions selected as good test cases for correlation procedures, the quality of correlation in the present l.f.e.r. plots, w plots, and plots of log k_ψ versus $-H_0$ may be compared in terms of the standard deviations of points from the linear regression lines, this statistical parameter being directly indicative of the quality of fit.

[a]The function plotted against (H_0 + log [H^+]) is: *A*, log k_ψ + H_0; *B*, log k_ψ − log (h_0/(h_0 + K_{SH^+})) (in part I) or log k_ψ − log ([SH^+]/[S]$_{st}$) (in part II); *C*, log k_ψ.
[b]Standard deviation of individual points, in the *y* direction, from the least squares line.
[c]Standard deviation of the slope, in ϕ units.
[d]Based on 3 points; two points below 0.5 *M* used in previous calculation (9) now omitted.
[e]Based on revised H_0 values of Jorgenson and Hartter (11).
[f]Revised w = +0.13, σ_y = 0.06.
[g]Revised w = +0.31, σ_y = 0.04.
[h]Revised w = −0.35, σ_y = 0.04.
[i]Revised w = −0.81, σ_y = 0.04.
[j]Revised w = +0.40, σ_y = 0.15.
[k]Based on half-protonation H_0 −1.4 (33), gradient 0.75.
[l]Revised w = +5.04, σ_y = 0.02.
[m]Revised w = +4.78, σ_y = 0.03.
[n]Revised w = +1.60, σ_y = 0.07.
[o]Based on half-protonation H_0 −1.0 (16), gradient 0.75.
[p]Revised w = +2.69, σ_y = 0.09.
[q]Revised w = +2.50, σ_y = 0.08.
[r]Based on half-protonation H_0 −2.15, gradient 0.75 (17).
[s]Revised w = +3.19, σ_y = 0.05.
[t]Revised w = +3.12, σ_y = 0.02.
[u]Revised w = +3.29, σ_y = 0.15.
[v]Revised w = +1.97, σ_y = 0.09.
[w]Based on half-protonation H_0 −1.80 (13, 14), gradient 0.75 (14); revised w = +1.83, σ_y = 0.10.
[x]Based on half-protonation H_0 −3.07 (13), gradient 0.75; revised w = +1.86, σ_y = 0.09.
[y]Based on half-protonation H_0 −3.23 (13), gradient 0.37 (14); revised w = +1.79, σ_y = 0.05; when gradient 0.75 used instead of 0.37, ϕ = +0.78.
[z]Revised w = +0.86, σ_y = 0.08.
[aa]Revised w = +1.07, σ_y = 0.07.
[bb]Based on basicity data of ref. 34.
[cc]Revised w = +3.39, σ_y = 0.10.
[dd]Revised w = +4.72, σ_y = 0.08.
[ee]Revised w = +9.11, σ_y = 0.11.
[ff]Revised w = +1.61, σ_y = 0.04.
[gg]Revised w = +1.38, σ_y = 0.04.
[hh]Revised w = +1.43, σ_y = 0.03.

Comparing l.f.e.r. with w plots, one sees that σ_y is less in l.f.e.r. plots than in w plots in 24 cases, greater in 11 cases, and equal in 7. σ_y is much less (difference of 0.05 or more) in 7 cases but much greater in only 2 cases. The superiority of l.f.e.r. over w plots is evident.

Comparing l.f.e.r. plots with plots of log k_ψ versus $-H_0$, one sees that σ_y is less in l.f.e.r. plots in 24 cases, greater in 7, and equal in 11 cases. σ_y is much less in 15 cases but much greater in only 1 case. The l.f.e.r. plots thus excel plots of log k_ψ versus $-H_0$ even more than they do w plots. Correlation by the l.f.e.r. method is clearly superior.

Among the 160 sets of data in Table I, the median standard deviation of points from the l.f.e.r. linear regression line is 0.03 log units, or 7%. This magnitude of deviation could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reasonably be ascribed to errors in the determination of rate coefficients, in the measurement of mineral acid concentration, and (for moderately basic substrates) in the reckoning of $[SH^+]/[S]_{st}$. Visual inspection of the plots does not suggest any deviation from linearity that cannot reasonably be attributed to random experimental error.

REACTIONS OF MODERATELY AND STRONGLY BASIC SUBSTRATES

It is convenient to represent an acid-catalyzed reaction in generalized fashion:

[2a] $$S + H^+ \rightleftarrows SH^+$$

[2b] $$SH^+ (+ H_2O) \rightleftarrows \ddagger \rightarrow \text{products}$$

In real reactions, additional equilibria, such as reversible addition of water to an unsaturated linkage, may intervene between protonated substrate (SH^+) and transition state. However, the above model still suffices because transition state theory assumes equilibrium between SH^+ and transition state and it does not matter whether that equilibrium comprises one or many steps.

When the substrate is strongly basic, only step [2b] need be taken into account. It is a fact that log k_ψ for reactions of such substrates is linearly related to log k_2 for reactions of weakly basic substrates (see Fig. 2) and to $(H_0 + \log [H^+])$. The latter is demonstrated by Fig. 5 and by the "C" correlations in Table I.

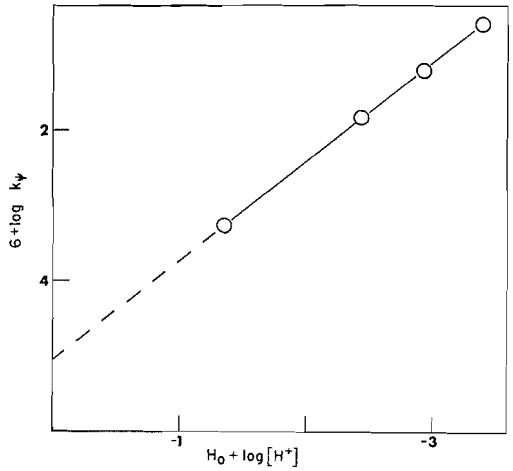

FIG. 5. Correlation of log k_ψ for protodedeuteration of $CH_3NH_2D^+$ in H_2SO_4 solutions with $(H_0 + \log [H^+])$.

With attention to eq. [2b], we may express the rate both phenomenologically and theoretically:

$$\text{rate} = k_\psi[S]_{st} = k[SH^+]f_{SH^+}/f_{\ddagger}.$$

Rearranging and taking logarithms, one obtains

[3] $$\log k_\psi - \log ([SH^+]/[S]_{st}) = \log k + \log f_{SH^+}/f_{\ddagger}.$$

When the substrate is strongly basic, the second term on the left is negligible. Thus the variation of log k_ψ expresses the variation in log $((f_{SH^+}/f_{\ddagger})$. When the substrate is moderately basic the second term on the left cannot be neglected; the variation of log k_ψ − log $([SH^+]/[S]_{st})$ is likewise expressive of variation in log $(f_{SH^+}/f_{\ddagger})$. As shown in Table I,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

part II, good linear correlations of $\log k_\psi - \log([SH^+]/[S]_{st})$ versus $(H_0 + \log [H^+])$ are obtained.

In the 1961 correlations for evaluation of w values (9), the function plotted for moderately basic substrates was $\log k_\psi - \log (h_0/(h_0 + K_{SH^+}))$, this being taken to represent $\log k_\psi - \log ([SH^+]/[S]_{st})$ on the assumption that the equilibrium protonation of substrates "obeyed" H_0. We now realize that assumption to be incorrect in many cases. The original function has been retained for three reactions in Table I, part I, for lack of detailed quantitative information on the protonation equilibria involved.

SIGNIFICANCE OF ϕ VALUES

Equation [3] states that variation of $\log k_\psi - \log ([SH^+]/[S]_{st})$ represents variation in $\log (f_{SH^+}/f_{\neq})$. Equation [11] of the accompanying paper (1) states that variation of $(H_0 + \log [H^+])$ represents variation in $\log (f_{BH^+}/f_B f_{H^+})$. The linear relationship of the left side of eq. [3] to $(H_0 + \log [H^+])$ thus implies a linear relationship between the logarithms of activity coefficient ratios, the proportionality constant being ϕ.

For a weakly basic substrate, the stoichiometric substrate concentration and the unprotonated substrate concentration are virtually identical. Insertion into eq. [3] of the value of $\log ([SH^+]/[S])$ from eq. [12] of the accompanying paper gives

$$[4] \qquad \log k_\psi + H_0 = \log (f_{SH^+}/f_{\neq}) + \log (f_{BH^+} f_S / f_{SH^+} f_B) + \log k + pK_{SH^+}.$$

One could, of course, combine the two logarithms of activity coefficient ratios and cancel out f_{SH^+}. From eq. [11] of the accompanying paper and the present eq. [4], it is evident that the linearity of $(\log k_\psi + H_0)$ with $(H_0 + \log [H^+])$ also implies a linear relationship between the logarithms of activity coefficient ratios.

In terms of the extreme hypothesis that all variations in activity coefficient ratios in moderately concentrated mineral acids are due to hydration changes between initial and final or transition state, the ϕ value can be interpreted as a proportionality constant between the average hydration change in the reaction under study and the average hydration change in equilibrium protonation of a primary aromatic amine indicator base. Letting the average degrees of hydration of S, SH^+, and transition state be s, p, and t, respectively, and employing reasoning detailed elsewhere (18, 19), one infers that ϕ for reactions of moderately or strongly basic substrates represents $(t - p)/(b + n - a)$. ϕ for reactions of weakly basic substrates then represents $[(t - s) - (a - b)]/(b + n - a)$. b, n, and a are, respectively, the average degrees of hydration of primary aromatic amine indicator base, proton, and base conjugate acid.

On the extreme hydration change hypothesis, the value of $(b + n - a)$ over the range of about 3.5–7 M hydrochloric, sulfuric, or perchloric acid is about 4.5 water molecules. Within this concentration range, the average hydration change in a correlated reaction would then approximate 4.5ϕ, which we have sometimes called the w' parameter (20, 21). For reactions of weakly basic substrates, the average hydration change between reactants and transition state, $t - (s + n)$, would approximate $4.5(\phi - 1)$.

Though the hypothesis on which this reckoning is based is almost certainly an oversimplification, it does appear that hydration change is a major factor affecting activity coefficient behavior. ϕ values are useful for the purpose of roughly estimating what the average hydration change would be if the extreme hydration change hypothesis were correct.

It has long been recognized that there is some connection between reaction mechanism and medium effects on kinetic behavior. The Zucker–Hammett hypothesis (7, 8) was an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

early attempt to define the relationship, but numerous exceptions to it are now known. Three categories of reaction mechanism with respect to w values were delineated by Bunnett (22) on the basis of empirical correlations between w values and the generally accepted mechanisms for certain "calibration" reactions. On the basis of the same calibration reactions, these categories are as follows in terms of ϕ values: water not involved in rate-limiting step, $\phi < 0.0$; water involved as nucleophile in rate-limiting step, ϕ +0.22 to +0.56; water involved as proton transfer agent in rate-limiting step, $\phi >$ +0.58. Carboxylic amide hydrolyses, specifically reactions 32–37, inclusive, previously used for calibration purposes, have not been heeded in stating these categories in terms of ϕ values. Although their w values as published in 1961 clustered rather closely, the ϕ values (based on better information regarding equilibrium protonation) range from +0.44 to +0.78, a broad spread which straddles the second and third mechanistic categories.

It is evident from eq. [4] that ϕ values for reactions of weakly basic substrates represent variation in both the kinetic activity coefficient ratio, $f_{SH^+}/f_{\ddagger}$, and the thermodynamic activity coefficient ratio, $f_{BH^+}f_S/f_{SH^+}f_B$. Only the former can be related to reaction mechanism. It is now clear, though it was not in 1961, that the latter ratio can change appreciably as the medium changes. For this reason, mechanistic interpretation of ϕ (or w) values *for reactions of weakly basic substrates* in the absence of quantitative information as to how the thermodynamic activity coefficient ratio varies with medium composition is fraught with uncertainty. This point was made in 1961 (23), but the reservation needs to be stated more strongly today. Mechanistic interpretation of ϕ values for reactions of moderately or strongly basic substrates is not subject to this reservation (see eq. [3]). These reactions therefore offer attractive possibilities for defining further the relationship of ϕ parameters to mechanism.

ADDITIVE COMBINATION OF ϕ VALUES

Let us symbolize the ϕ values of the separate steps [2*a*] and [2*b*] of the generalized scheme presented above as ϕ_e and ϕ_r, signifying "equilibrium" and "reaction", respectively. And let us represent the phenomenological rate coefficient for step(s) [2*b*] as k_r. We may then write for step [2*a*]

$$[5] \qquad \log ([SH^+]/[S]) + H_0 = \phi_e(H_0 + \log [H^+]) + pK_{SH^+}$$

and for step(s) [2*b*]

$$[6] \qquad \log k_r = \phi_r(H_0 + \log [H^+]) + \log k_r^0.$$

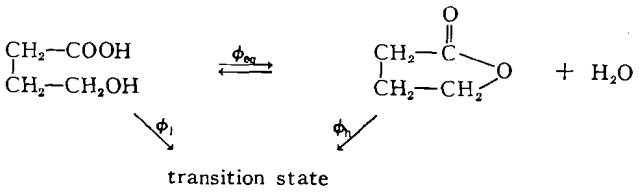
Addition gives

$$[7] \quad \log k_r + \log ([SH^+]/[S]) + H_0 = (\phi_e + \phi_r)(H_0 + \log [H^+]) + pK_{SH^+} + \log k_r^0.$$

Inasmuch as the overall rate is given alternatively by $k_\psi[S]_{st}$ or by $k_r[SH^+]$, it follows that

$$\log k_r + \log ([SH^+]/[S]_{st}) = \log k_\psi.$$

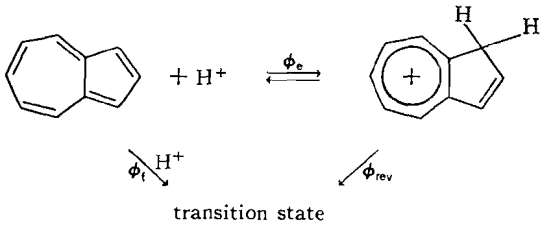
When the substrate is weakly basic, $[S] \approx [S]_{st}$; substitution into eq. [7] gives



$$[8] \qquad \log k_\psi + H_0 = (\phi_e + \phi_r)(H_0 + \log [H^+]) + pK_{SH^+} + \log k_r^0.$$

Comparison with eq. [1] shows that the ϕ value as ordinarily determined is the sum of the ϕ values for the separate equilibrium and "reaction" steps.

The principle of additivity has an important bearing on the problem of relating ϕ



values for reactions of weakly basic substrates to reaction mechanism. Only the ϕ_r value can be related to mechanism. When the substrate is weakly basic, ϕ_r can be obtained by subtracting ϕ_e from the total ϕ value as obtained from kinetic measurements. In some cases, it should be possible to measure ϕ_e directly. In others, ϕ_e may be known for a closely related substrate and one may assume that closely related structures have similar ϕ_e values. There is evidence for the validity of this assumption in several series of bases (1).

The principle of additivity is illustrated by the measurements of Long, Dunkle, and McDevit (24) on the reversible lactonization of γ-hydroxybutyric acid in hydrochloric acid solutions. The ϕ value for the overall equilibrium (ϕ_{eq})

should be equal to the kinetic ϕ value for lactonization (ϕ_l) minus that for lactone hydrolysis (ϕ_h). ϕ_{eq} is -0.57 (Table IV, ref. 1), ϕ is 0.32 and ϕ_h is 0.87 (Table I), all in hydrochloric acid solutions. Thus the expected relationship is realized.

Another illustration concerns the protonation equilibrium and kinetics of proton addition to azulene in perchloric acid, studied by Challis and Long (25).

It is expected that ϕ_e should equal ϕ_f minus ϕ_{rev}. ϕ_e in perchloric acid at 5.7° is -1.54 (Table III, ref. 1). In the same acid at 7.3°, ϕ_f is -0.42 and ϕ_{rev} is 1.11; thus the expected relationship is satisfied. The two kinetic ϕ values are not tabulated in the present paper; the former is based on a plot of log $k_\psi + H_0$ and the latter on a plot of log k_ψ against $(H_0 + \log [H^+])$.

Recently Kresge, O'Ferrall, Hakka, and Vitullo (26) have approached this general problem in a different way. They considered hydrogen isotope exchange reactions of 1,3,5-trihydroxybenzene and its trimethyl ether, which are analogous to the azulene protonation reaction if differences between hydrogen isotopes are disregarded. A parameter α was taken to represent the degree to which the transition state resembles the σ-complex protonation product. α was related to experimentally measurable quantities by the equation

$$k_\psi/[H^+] = k_2^0 K_{SH^+}^{\alpha}([SH^+]/[S][H^+])^{\alpha}.$$

(The symbols of the present paper are employed.) If this equation is written in logarithmic form, substitutions are made from the two l.f.e.r. equations,

$$\log k_\psi - \log [H^+] = (\phi - 1)(H_0 + \log [H^+]) + \log k_2^0$$

$$\log ([SH^+]/[S]) - \log [H^+] = (\phi_e - 1)(H_0 + \log [H^+]) - \log K_{SH^+},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and allowable cancellations are made, there results

$$(\phi - 1) = \alpha(\phi_e - 1).$$

There α parameter therefore amounts to a *proportionality constant* between l.f.e.r. slope parameters. In contrast, we are inclined to relate the *difference* between slope parameters, $\phi - \phi_e$, to reaction mechanism. Time will tell which approach is the more profitable. Notwithstanding, the utility of the α parameter would appear to be limited to cases where the transition state lies between substrate and protonated substrate. The additivity of ϕ values is subject to no such restriction. Moreover, it will be advantageous to compare $(\phi - \phi_e)$ for reactions of weakly basic substrates with ϕ_r determined directly from studies on strongly basic substrates.

We have discussed the additivity of ϕ values for equilibrium [2*a*] and quasi-equilibrium [2*b*]. It is evident that the principle of additivity would likewise prevail if [2*b*] were a true equilibrium; that would be the case of concurrent, consecutive equilibria referred to in the accompanying paper.

SIGNIFICANCE OF NONLINEARITY IN L.F.E.R. PLOTS

The more than 200 l.f.e.r. plots considered in this and the accompanying paper (1) are linear almost without exception. This warrants the conclusion that it is normal or regular for a reaction to give a linear l.f.e.r. plot.

However, not all plots of this type are linear. Plots with severe scatter, severe curvature, and even maxima or minima are known. Most of these "misbehaved" reactions also give nonlinear w plots. Several were mentioned in a 1961 paper (9) and examples have been published by other authors (20, 27–29).

Several causes of deviations from linearity can be recognized:

(*a*) *Experimental error.*—Random errors usually cause scatter, and most of the larger deviations (σ_y) of points from the linear regression line in Table I are of this character. A severe systematic error or certain chance patterns of random error would cause an otherwise linear l.f.e.r. plot to be curved.

(*b*) *Misjudgment of substrate basicity.*—If a substrate treated as weakly basic actually becomes substantially protonated within the acid concentration range of kinetic study, a curved plot results. A probable example has been described by Roth and Bunnett (20).

(*c*) *The inception of a second reaction mechanism.*—If two mechanisms for a reaction are in competition, or if a substrate undergoes two competing reactions, the relative contributions of the two at various acid concentrations depend on their ϕ values. The reaction of lower ϕ value will go relatively faster at higher acid concentrations and the slope of the "l.f.e.r." plot based on overall rate coefficients will decrease. If an intermediate were partitioned between reversion to reactants and progression to products and the ϕ values for the two pathways were different, a curved "l.f.e.r." plot could also result. Examples of competing mechanisms which give rise to curved plots (not shown here) have been discussed by Buchholz and Powell (27) and by Noyce and Jorgenson (30).

(*d*) *Abnormal variation in activity coefficient ratios.*—This would represent departure from the usual linear relationship between the logarithms of activity coefficient ratios. An example concerning the hydrolysis of carboxylic anhydrides has been described by Bunton and Fendler (29), and it is possible that the irregular behavior of acetylimidazole hydrolysis (28) is another. Arnett (31) has cited reasons to expect irregular activity coefficient variation for benzoic acid in sulfuric acid solutions, but no kinetic or protonation equilibrium data are available to bear out his expectations.

For personal use only.

Because l.f.e.r. plots are normally linear, the occasional appearance of a curved plot has diagnostic value. It suggests that one of the above four factors is responsible for the curvature. It alerts the investigator to reexamine his experimental procedures and his assumptions as to substrate basicity, and to consider the possibility that competition between reactions or mechanisms obtains. A curved plot may be a valuable clue.

KINETICS IN MEDIA CONTAINING ORGANIC SOLVENT COMPONENTS

H_0 values have been determined for many mixtures of mineral acid, water, and an organic solvent component such as ethanol, acetic acid, or dioxane (32). In a few cases examined, plots of (log k_ψ + H_0) versus (H_0 + log [HX]) have been found to be straight; these are summarized in Table II. How general such behavior is, we do not know.

COULOMB PARAMETERS IN SIMPLE HUCKEL AND OMEGA TECHNIQUE MOLECULAR ORBITAL METHODS[1]

N. C. BAIRD[2] AND M. A. WHITEHEAD

Theoretical Chemistry Laboratory, Chemistry Department, McGill University, Montreal, Quebec

Received May 2, 1966

ABSTRACT

The well-known similarities of the simple Huckel and omega technique molecular orbital procedures for pi electrons to Pople's self-consistent field method are extended by considering systematic approximations to the latter. From the relationships found, Huckel-method Coulomb integrals and omega values for a variety of atoms (Be, B, C, N, O, F, Mg, Al, Si, P, S, Cl, Ge, As, Se, Sn, Sb, Te) are derived. The Huckel and omega Coulomb integrals are shown to be directly related to a recent definition of orbital electronegativity. The ability of the omega techniques to improve upon the Huckel-method charge distributions is discussed by use of an arbitrary but typical example.

INTRODUCTION

Semi-empirical pi-electron molecular orbital methods, using atomic orbitals as a basis set, continue to be extensively employed in discussions of the structure, stability, reactivity, and spectra of conjugated organic molecules. Three such procedures, the Pariser–Parr–Pople method (1–3), the simple Huckel method (4, 5), and the "omega" technique (5, 6), have been widely applied to such problems (3, 5). The evaluation of the necessary secular determinant matrix elements for the latter two methods is usually empirical, although attempts have been made to estimate the Coulomb integrals from electronegativities, atomic spectral data, and the parameters or results of the Pariser–Parr–Pople technique (7).

In the present study, the well-known similarities among the Huckel, omega, and Pariser–Parr–Pople methods will be considered in some detail, and extended. In particular, quantitative relations between the Coulomb parameters of the three techniques will be derived, and these relationships exploited to provide theoretical estimates of the Coulomb integrals for a wide variety of atoms.

THEORY AND DISCUSSION

All the molecular orbital procedures to be discussed consider only the "pi" electrons of conjugated molecules. The one-electron molecular orbitals (MOs) ψ_i for such electrons are approximated as linear combinations of atomic orbitals (AOs) ϕ_u, with coefficients c_{iu} determined by an energy minimization process; thus

$$\psi_i = \sum_u c_{iu}\phi_u. \qquad [1]$$

The total electronic wave function representing the ground state of a closed shell of pi electrons in a conjugated molecule can normally be accurately expressed as a single Slater determinant of the occupied MOs ψ_i. Pople (2, 8) introduced a simplified self-consistent field procedure to deal with such systems. Various systematic approximations were introduced by Pople (neglect of differential overlap, treatment of the sigma electrons

[3] $$F_{uu} = U_{uu} + \tfrac{1}{2}P_{uu}\gamma_{uu} + \sum_{w \neq u} (P_{ww} - Z_w)\gamma_{uw}$$

and

[4] $$F_{uv} = H_{uv} - \tfrac{1}{2}P_{uv}\gamma_{uv} \qquad (u \neq v),$$

where the bond-order matrix elements P_{uv} are defined as

[5] $$P_{uv} = 2\sum_{i} c_{iu}c_{iv},$$

the summation i being over the occupied MOs only. With the approximation for the overlap integrals S_{uv} that

[6] $$S_{uv} = \delta_{uv} = 1 \quad \text{if } u = v,$$
$$= 0 \quad \text{if } u \neq v$$

the diagonal elements P_{uu} of the bond-order matrix P may be identified with q_u, the total pi-electron charge density in AO u,

[7] $$q_u = P_{uu}.$$

In [3] and [4], the Z_w represent the pi-electron core charge of the atom associated with AO w, and in neutral molecules this is equal to the number of pi electrons (0, 1, or 2) contributed by AO w to the pi system. The γ_{uv} (and γ_{uu}) are the two-electron repulsion integrals

[8] $$\gamma_{uv} = \int\int \phi_u^*(1)\,\phi_v^*(2)\,(1/r_{12})\,\phi_u(1)\,\phi_v(2)\,d\tau(1)\,d\tau(2).$$

The one-center repulsion integrals of [8], γ_{uu}, are normally approximated as (1, 3, 8)

[9] $$\gamma_{uu} = I_u - A_u,$$

where I_u, A_u are the valence-state ionization potential and electron affinity of AO u.

The core integral U_{uu} is associated with the ionization potential I_u by (3, 9, 10)

[10] $$U_{uu} = -I_u.$$

The core resonance integral H_{uv} is normally obtained empirically.

Substitution of the relations [7], [9], [10] into eq. [3] for F_{uu} gives

[11] $$F_{uu} = -I_u + \tfrac{1}{2}q_u(I_u - A_u) + \sum_{w \neq u} (q_w - Z_w)\gamma_{uw},$$

which may be rearranged, by use of the core charge Z_u of AO u, to give

[12] $$F_{uu} = [-I_u + \tfrac{1}{2}Z_u(I_u - A_u)] + [\tfrac{1}{2}(q_u - Z_u)(I_u - A_u)] + \left[\sum_{w \neq u} (q_w - Z_w)\gamma_{uw}\right].$$

This can be shortened to

[13] $$F_{uu} = J(u) + K(u, q_u) + L(u, q_w),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in which J, K, L represent the first, second, and third square brackets on the right-hand side of [12].

The term $J(u)$ represents the F_{uu} of AO u for a molecular charge distribution in which all the AO u charge densities q are exactly equal to the corresponding core charges Z ("neutral" AOs).

The term $K(u, q_u)$ represents the correction to $J(u)$ for a non-neutral charge density in AO u.

The term $L(u,q_w)$ is the correction to $J(u)$ for non-neutral charge densities in all the other atomic orbitals.

In the simple (non-overlap) Huckel and omega technique methods, the same secular determinant [2] is solved with the overlap assumption [6] for the conjugated system. In these methods, the F matrix elements are not defined explicitly as in [3] and [4], but are left as empirical quantities α_u and β_{uv}, the Coulomb and resonance integrals:

$$F_{uu} = \alpha_u = \int \phi_u^* H_{\text{eff}}^0 \, \phi_u \, d\tau, \tag{14}$$

$$F_{uv} = \beta_{uv} = \int \phi_u^* H_{\text{eff}}^0 \, \phi_v \, d\tau. \tag{15}$$

Here H_{eff}^0 is an "effective" Hamiltonian operator for the pi system. For computational purposes, α_u and β_{uv} are normally expressed in terms of a "standard" α^0 and β^0 (5), such that

$$\alpha_u = \alpha^0 + h_u\beta^0, \tag{16}$$

$$\beta_{uv} = k_{uv}\beta^0. \tag{17}$$

The quantitative relationships between Pople's method and the simpler MO techniques (Huckel, omega) will now be investigated by considering a set of systematic approximations to the former, and numerically evaluating the simplified F matrix elements for a variety of atoms.

Approximation Method A

The "Pople" expressions for F_{uu}, [11], [12], and [13], may be rewritten for convenience by introducing ϵ terms defined as

$$\epsilon_{uu} = \tfrac{1}{2}\gamma_{uu} = \tfrac{1}{2}(I_u - A_u), \tag{18}$$

$$\epsilon_{uw} = \gamma_{uw} \qquad (w \neq u) \tag{19}$$

to give

$$F_{uu} = J(u) + \sum_w (q_w - Z_w)\epsilon_{uw}, \tag{20}$$

where the sum over w *includes* u.

In method A, the following approximations will be made:

(*a*)

$$\sum_w (q_w - Z_w)\epsilon_{uw} = 0. \tag{21}$$

(*b*) For $u \neq v$,

$$F_{uv} = 0, \tag{22}$$

unless u, v are "nearest neighbors" in the pi system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*c*) For nearest neighbors u and v, F_{uv} can be expressed in terms of $F_{CC'}$, the nearest neighbor F_{uv} for the ground state of benzene, thus

$$F_{uv} = k_{uv}F_{CC'}, \qquad [23]$$

where k_{uv} is an empirical constant for the pair u, v.

Since for neutral molecules

$$\sum_w (q_w - Z_w) = 0, \qquad [24]$$

approximation *a* would be exact if all the ϵ_{uw} were identical, i.e.

$$\epsilon_{u1} = \epsilon_{u2} = \quad = \epsilon_{uu} = \epsilon. \qquad [25]$$

In this case the equation reduces to

$$\sum_w (q_w - Z_w)\epsilon_{uw} = \epsilon \sum_w (q_w - Z_w) = 0. \qquad [26]$$

The equalities [25] are usually incorrect for real systems; however, the ϵ_{uw} for small ring systems are all of the same order of magnitude. In benzene, for example, Pariser and Parr's (1) empirical γ_{uu}, γ_{uv} integrals give ϵ_{uw} for $u = 1$ of

$$\epsilon_{11} = 5.3 \text{ eV}$$

$$\epsilon_{12} = \epsilon_{16} = 7.3 \text{ eV}$$

$$\epsilon_{13} = \epsilon_{15} = 5.5 \text{ eV}$$

$$\epsilon_{14} = 4.9 \text{ eV}$$

$$\text{i.e. all } \epsilon_{uw} = 6.1 \pm 1.2 \text{ eV}.$$

Approximation *b* is not a drastic one since in the Pariser–Parr–Pople method, the off-diagonal F_{uv} for non-nearest neighbors are assumed to have $H_{uv} = 0$ (1, 2, 3). The remaining term $-P_{uv}\epsilon_{uv}$, of F_{uv} would be expected to be small in most cases.

The F_{uu} for method A is then simply $J(u)$ of [13], or

$$F_{uu} = -\left[I_u + Z_u \frac{(A_u - I_u)}{2} \right]. \qquad [27]$$

The term in square brackets of [27] corresponds exactly to the orbital electronegativity χ_u of the "neutral" AO u using the "molecular orbital" definition of bond electronegativity (11). Three neutral orbital cases are possible, corresponding to vacant, singly occupied, and lone-pair atomic orbitals,

$$F_{uu}\,(Z_u = 0) = -I_u = -\chi_u\,(Z_u = 0), \qquad [28]$$

$$F_{uu}\,(Z_u = 1) = -(I_u + A_u)/2 = -\chi_u\,(Z_u = 1), \qquad [29]$$

$$F_{uu}\,(Z_u = 2) = -A_u = -\chi_u\,(Z_u = 2). \qquad [30]$$

Coulomb integrals have been previously associated with orbital electronegativities for singly occupied ($Z_u = 1$) AOs (3, 12, 13) and the above relations show the association to be a general one.

Numerical values of the terms $J(u)$, evaluated from the valence-state energy data of Hinze and Jaffe (14) for a variety of atoms which could use p_π AOs in a conjugated network are listed in Table I. The $J(u)$ are in electron volts, whereas in simple Huckel

methods it is conventional to express the Coulomb integrals in terms of the standard Coulomb and resonance integrals, α^0 and β^0 for benzene. If one adopts this form of expression,

$$J(u) = J(\mathrm{C}) + h_u F_{\mathrm{CC}'}, \qquad [31]$$

where $J(\mathrm{C})$ and $F_{\mathrm{CC}'}$ represent the $J(u)$ and nearest-neighbor F_{uv} terms for benzene. From [31]

$$h_u = \frac{J(u) - J(\mathrm{C})}{F_{\mathrm{CC}'}}, \qquad [32]$$

which requires the numerical value of $F_{\mathrm{CC}'}$ before the h_u can be evaluated. Now from [4], for the nearest neighbors in benzene,

$$F_{\mathrm{CC}'} = H_{\mathrm{CC}'} - \tfrac{1}{2} P_{\mathrm{CC}'} \gamma_{\mathrm{CC}'}. \qquad [33]$$

For this case, $P_{\mathrm{CC}'}$ is 2/3, and using the Pariser–Parr (1) value of $\gamma_{\mathrm{CC}'}$, 7.30 eV, [33] becomes

$$F_{\mathrm{CC}'} = H_{\mathrm{CC}'} - 2.43 \text{ eV}. \qquad [34]$$

The core resonance integral $H_{\mathrm{CC}'}$ is normally determined empirically from some property of benzene. From the ultraviolet spectrum of benzene, Pariser and Parr (1) derived $H_{\mathrm{CC}'} = -2.39$ eV; from a bond-length correlation function, Chung and Dewar (15) obtain −1.75 eV, and from the resonance energy of benzene these authors obtain −1.92 eV. The observed electron-impact ionization potential of 9.52 eV for benzene (6) can be used to derive $H_{\mathrm{CC}'}$ of −1.50 eV. The magnitude of $F_{\mathrm{CC}'}$ in the cases mentioned above is then −4.82, −4.18, −4.35, and −3.93 eV respectively.

The correspondence between method A and the simple Huckel method can now be demonstrated by showing the one-to-one relation between Huckel h_u values obtained empirically and the h_u calculated by [32] from the valence-state energy data. The only difficulty in such an analysis is the choice of appropriate Huckel h_u to be used. For the purposes of this study, the consistent and widely used "best" values listed by Streitwieser (*7a*) have been adopted. The correlation of these h_u with the term $(J(u) - J(\mathrm{C}))$ is given in Fig. 1. The correlation line is excellent, considering that the "best" h_u are only estimated to within ± 0.25.* The slope of the line, -4.2_3 eV, is within the range of the estimates of $F_{CC'}$ given above.

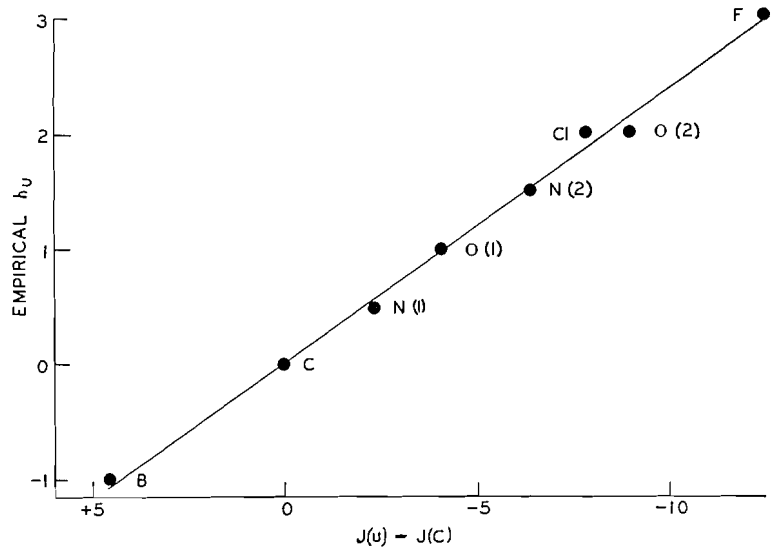

FIG. 1. Plot of $J(u) - J(\mathrm{C})$ against the empirical Huckel h_u. NOTE: The integer in brackets following the atomic symbol represents the core charge Z_u for atoms having more than one value of Z_u listed in Table I.

The quantitative correspondence between the theoretical and empirical h_u gives some insight into the nature of the effective hamiltonian H_{eff}^0 of [14]. The H_{eff}^0 corresponds to the Pople-method hamiltonian for a molecular charge distribution in which all the pi atomic orbitals are neutral (i.e. all $q_u = Z_u$). From this elucidation, the Huckel h_u for a variety of atoms not considered by Streitwieser may be calculated. These h_u, evaluated using $F_{CC'} = -4.23$ eV, are listed in Table I.

Certain trends in the h_u are evident:

(I) Atoms of Groups 2 and 3, the p_π AOs of which are normally vacant, have very low h_u, of the order of -1.

(II) Group 4 atoms have h_u close to zero.

(III) Group 5, 6, and 7 atoms display a wide range of h_u depending upon Group, Period, and pi core charge of the atoms, although in general all the h_u are quite high, and for a given atom $h_u\,(Z_u = 2) > h_u\,(Z_u = 1)$. The term for sulfur $(Z_u = 2)$ is close to that of nitrogen $(Z_u = 2)$ as anticipated (*7a*).

All the atomic energy terms used in the derivation of the $J(u)$ values in Table I were obtained by assuming that the sigma-bonded AOs of the valence shell were "neutral" (that

**The excellent correlation obtained may be due in part to the use of atomic and molecular ionization potential data in deriving some Huckel h_u which would have been considered in arriving at the "best" values.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is, the sigma bonds are completely nonpolar). The close agreement between theoretical and empirical Coulomb integrals in Table I indicates that this "assumption" must be an additional feature of the simple Huckel-method H_{eff}^0.

The explicit dependence of h_u on the net *excess* charge Q_σ of the sigma core, the deviation from neutrality, may be evaluated by using the approximate dependence of I_u and A_u upon Q_σ as previously outlined (16). By use of this dependence, and the energy data of Hinze (14*c*), then the h_u dependence upon Q_σ is

$$h_{\text{C}} = 0.00 + 2.28Q_\sigma + 0.43Q_\sigma^2, \quad [35]$$

$$h_{\text{N}} = 0.56 + 2.43Q_\sigma + 0.49Q_\sigma^2, \quad [36]$$

$$h_{\text{O}} = 0.96 + 3.17Q_\sigma + 0.32Q_\sigma^2 \quad [37]$$

for the $Z_u = 1$ cases of carbon, nitrogen, and oxygen respectively. The dependence of h_u upon the sigma net charge, excess or deficit, is about 2 to 3 units per electron. This dependence will be important for protonated nitrogen and oxygen atoms, for which Streitwieser lists $h_{\text{N}^+} = 2.0$, and $h_{\text{O}^+} = 2.5$. These h_u correspond to Q_σ of about $+0.5$ electron in each case. Such a deficit of less than $+1.0$ electron is acceptable, since the sigma bonds from nitrogen and oxygen will be quite polar in such cases, effectively spreading the positive charge throughout the sigma system.

Approximation Method B

Several attempts have been made to explicitly incorporate a certain amount of electron repulsion as a function of molecular charge distribution into the simple Huckel method (6, 17–20). Streitwieser (6) systematized these attempts into a scheme now known as the omega (ω) technique, in which the Coulomb integral α_u is dependent upon the charge density q_u of the AO u, hence

$$\alpha_u = \alpha^0 + h\beta^0 + (Z_u - q_u)\omega\beta^0. \quad [38]$$

where ω is an empirical constant.

By analogy with the ω technique, the first two terms $J(u)$ and $K(u,q_u)$ of the Pople expression [13] will be considered to yield an appropriate F_{uu} expression in method "B". Approximations *b* and *c* of method A will remain unchanged in this technique.

The approximation to the Pople F_{uu} expression in method B is, therefore, that the term $L(u,q_w)$ of [13] is zero;

$$L(u,q_w) = \sum_{w \neq u} (q_w - Z_w)\gamma_{uw} = 0. \quad [39]$$

By retaining the definition of h_u in [32], the approximate diagonal matrix term F_{uu} then becomes

$$F_{uu} = J(\text{C}) + h_u F_{\text{CC}'} + \omega_u F_{\text{CC}'}(Z_u - q_u), \quad [40]$$

where

$$\omega_u = \frac{\frac{1}{2}(A_u - I_u)}{F_{\text{CC}'}}. \quad [41]$$

Equation [40] may be written directly in terms of I_u and A_u; dropping the last term (see [39]) of eq. [11] gives

$$F_{uu} = -[I_u + \tfrac{1}{2}q_u(A_u - I_u)]. \quad [42]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The term of [42] in square brackets represents the molecular-orbital definition of the bond electronegativity function for AO u (11) with charge density q_u. The method B Coulomb integrals are then directly associated with the bond electronegativities of the pi AOs; in method A this association held only for the "neutral" orbital electronegativities. Klopman (13) has previously noted the correspondence between electronegativity and Coulomb integrals in omega-type methods.

By use of the value of $F_{CC'}$ from method A of -4.23 eV, the terms ω_u for various atomic p_π orbitals u may be evaluated (eq. [41]). These parameters are listed in Table I. Empirical values of ω for carbon have ranged from 0.33 to 1.8 (7*a*), but the widely used and "best" value is $\omega_C = 1.4$ (6, 7*a*, 20). The theoretical value of ω_C in Table I is 1.32, in excellent agreement with the empirical result. Although Pritchard and Sumner (19) derived quite different ω_u for different atoms, the ω value for *all* atoms is normally taken to be the same as that for carbon (6). The widely different ω_u's for different atoms (and different Z_u) listed in Table I indicate that this extension is not justified.

Within each Period, there appears to be a good correlation of ω_u with h_u, ω_u generally increasing with atomic number. Within each Group of the Periodic Table, ω_u decreases as the atomic number increases. For atoms with different possible pi core charges Z_u, ω_u for $Z_u = 2$ is greater than that for $Z_u = 1$.

The relation between ω_u and h_u for the first Period atoms (except Be†) is illustrated in Fig. 2. This relation may be expressed as

[43] $$\omega_u = 0.45h_u + 1.3_0.$$

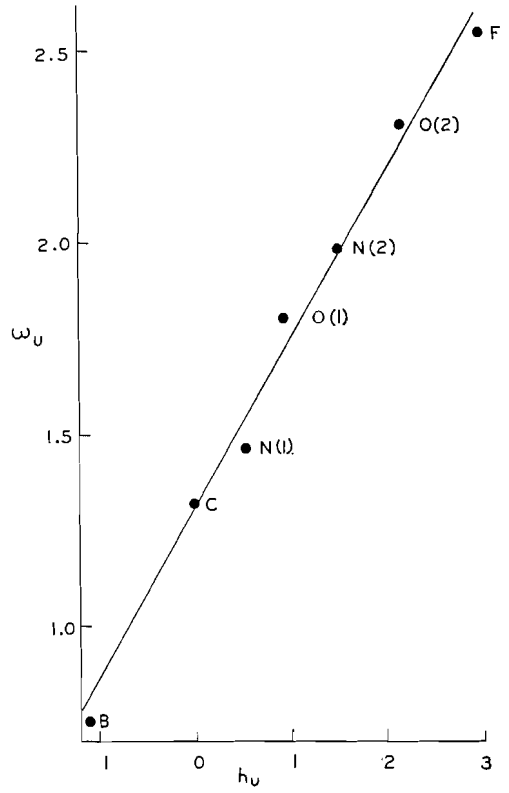

FIG. 2. Plot of ω_u against h_u for atoms of the first Period.

†*The Group 2 elements for the first and second Periods fall significantly off the correlation lines.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The corresponding relation for the second Period atoms may be approximately expressed as

[44] $$\omega_u = 0.42h_u + 0.8_6$$

for the elements Al to Cl. The two correlation lines are almost parallel to each other.

Equations [40], [43], and [44] may be combined to give

[45] $$F_{uu} = J(\mathrm{C}) + h_u{}^* F_{\mathrm{CC}'}$$

with

[46] $$h_u{}^* = h_u + (Z_u - q_u)(0.45h_u + 1.3)$$

for the atoms B, C, N, O, and F, and

[47] $$h_u{}^* = h_u + (Z_u - q_u)(0.42h_u + 0.86)$$

for the atoms Al, Si, P, S, and Cl. In [46] and [47], the h_u are those for the simple Huckel method listed in Table I.

Streitwieser attempted to compare the omega technique with Pople's method by noting that the term $\frac{1}{2}\gamma_{uu}$ of [3] should be numerically identical with $-\omega\beta^0$ of [38] if the omega technique did include only the terms $J(u)$ and $K(u,q_u)$ of [13], and completely neglected the remaining term $L(u,q_w)$ (6). By using $\beta^0 = -2.11$ eV and the $\frac{1}{2}\gamma_{uu}$ (for carbon) of 5.3 eV, he showed that $-\omega\beta^0$ was about 2.9 eV, little more than half the value of the $\frac{1}{2}\gamma_{uu}$ (6). This low value of $-\omega\beta^0$ was taken as evidence that the omega technique in fact allowed for the term $L(u,q_w)$ of [13] in some average way. The value of β^0 used in this analysis (by Streitwieser) was computed by a correlation of experimental molecular ionization potentials with the calculated difference in pi energy between the neutral molecules and their positive ions. The energies were computed by adding the one-electron energies of the occupied MOs. This method of obtaining the total pi energy by adding the one-electron levels is actually inconsistent with the effective inclusion of electron repulsions in the F_{uu} terms, since in self-consistent field MO methods, this simple addition process includes electron repulsions twice (3). The use of a self-consistent field $H_{\mathrm{CC}'}$ value of about -2 eV, giving an $F_{\mathrm{CC}'}$ of about -4.2 eV, leads to a ω_{C} value very close to the empirical estimate when the $L(u,q_w)$ term is completely neglected. There is no averaged correction for this term in empirical omega techniques for this reason. Method B is then computationally equivalent to the omega technique for hydrocarbons.

Comparison of the Methods

Now that methods A and B, corresponding in fact to the simple Huckel and omega procedures, have been outlined, it is instructive to try to compare the actual validities of each method to Pople's scheme. For purposes of the comparison, a typical molecular

system was chosen and calculations were performed to establish the extent to which the omega technique improved the Huckel F_{uu} parameters, during the self-consistent field calculations, towards those required by Pople's method.

The example used is a six-membered ring system containing five carbon atoms, each having a p_π AO (with $h_u = 0$), and one conjugating heteroatom, X, with $h_X = 1.0$. The pi system of the molecule is assumed to contain 6 electrons, and all nearest neighbors are assumed to have F_{uv} equal to that of benzene. For simplicity, the geometry of the ring is taken to be identical to that of benzene, and the heteroatom X is assumed to have all γ_{uX} equal to those of the carbon atoms. The values of the latter integrals were taken from Pariser and Parr's paper (1).

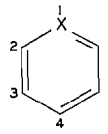

FIG. 3.

The simple Huckel charge distribution based on these assumptions is given in Table II. The ΔF_{uu} listed in the remaining columns of Table II corresponds to the differences between $J(u)$, the simple Huckel F_{uu}, and the F_{uu} for the various methods calculated on the basis of the Huckel charge distribution;

$$\Delta F_{uu} = F_{uu} - J(\mathrm{C}). \qquad [48]$$

The ΔF_{uu}'s corresponding to the omega technique (column 4 of Table II) bear little resemblance in sign, magnitude, or relative order for the different atoms to those required by the Pople method (column 7) for the same charge distribution. The correspondence between the omega ΔF_{uu} and the Pople ΔF_{uu} is not substantially improved by adding nearest-neighbor terms (column 5) and first and second nearest-neighbor terms (column 6) to the ΔF_{uu} of the omega technique. The inclusion of the first, or first and second nearest-neighbor terms has been previously suggested (21, 22) as a means of improving the omega technique. The simple Huckel ΔF_{uu}, all zero of course, are actually closer to those of Pople's method than are the ΔF_{uu} of any other of the techniques.

Since the second iteration F_{uu}'s of the omega techniques are not altered from the Huckel F_{uu}'s in even qualitatively the same manner as those in the Pople method, it is difficult to see why the self-consistent field charges of the ω methods represent an improvement over those of the Huckel method. The ω technique will have the effect of "smoothing out" the net excess charges calculated by the Huckel method, but will not necessarily lead to any improvement in the relative *order* of charge densities among the atoms.

SIMULTANEOUS ANALYSIS OF TWO-COMPONENT SYSTEMS BY DIFFUSE REFLECTANCE SPECTROSCOPY[1]

ABSTRACT

Diffuse reflectance spectroscopy can be used for the analysis of multicomponent systems in the adsorbed state. The Kubelka–Munk theory for diffuse reflection and transmission on light-scattering layers has been applied for this analysis. Simple dye mixtures adsorbed on thin-layer chromatography-grade adsorbents were employed. The method can be adapted directly to the analysis of incompletely separated components on chromatographic adsorbents.

INTRODUCTION

Analytical applications of diffuse reflectance spectroscopy to chromatographic separation procedures (1–4) have stimulated development, by the same techniques, of a method for simultaneous analysis of multicomponent systems. Such a method is analogous to procedures for absorptiometric analysis of multicomponent mixtures in solution and would find application for systems in which incomplete chromatographic separation would ordinarily prevent quantitative evaluation by reflectance spectroscopy. The requirements, of course, are similar to those necessary for successful analysis of mixtures of absorbing substances in solution; no interaction between components should occur and one species should absorb at a wavelength where the others absorb weakly. In addition, the reflectance spectra, or some suitable function of the reflectance, should be additive. For a solid powder system, where the chromophoric species are adsorbed on the surface of a chromatographic adsorbent, it is necessary to adopt a theory which deals with the diffuse reflection and the transmission of light-scattering layers.

The widely accepted theory of Kubelka and Munk (5, 6) proves most appropriate. For an infinitely thick, opaque layer the Kubelka–Munk equation may be written

$$[1] \qquad \frac{(1 - R_\infty')^2}{2R_\infty'} = \frac{k}{s}$$

where R_∞' is the absolute reflectance of the layer, k is the absorption coefficient, and s is the scattering coefficient.

The relative reflectance R_∞, which is measured against a reference standard such as MgO, $CaSO_4$, or $MgCO_3$, is usually used rather than the absolute reflectance R_∞'. The equation then becomes

$$[2] \qquad F(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s}$$

and a linear relationship should be observed between $F(R_\infty)$ and the absorption coefficient k if s is constant. This is achieved by using powders with large particle size in comparison

[1]*Paper presented at the Fifth National Meeting, Society for Applied Spectroscopy, Chicago, June 16, 1966.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the wavelength used for measurement; since adsorbents for thin-layer and column chromatography usually have particle sizes larger than 5 μ, s will be independent of wavelength.

To obtain a straight-line calibration curve from reflectance measurements it is also essential that concentrations of adsorbed components be such that absorption of light is not greater than 50% (11); this can be achieved by dilution of the sample, when necessary, with the adsorbent powder. To exclude specular reflectance, which results in deviations from the Kubelka–Munk law, powder particle size should not be too large (7–9).

For a powder mixture containing n light-absorbing components whose reflectance functions are additive, the Kubelka–Munk function $F(R_\infty)$ can be adapted for simultaneous analysis. The function of the total reflectance R_{∞_T} of the mixture at some wavelength i may be represented as the sum of all individual reflectance functions.

$$[3] \qquad F(R_{\infty_T})_i = \sum_{j=i}^{n} \tau_{ij} C_j$$

where j refers to components and τ is the slope of the Kubelka–Munk plot of $F(R_\infty)$ versus C.

Equation [3] can be written in a more explicit manner by writing as many equations as there are components in the mixture.

$$[4] \qquad F(R_{\infty_T})_1 = \tau_{11} C_1 + \tau_{12} C_2 + \ldots \tau_{1n} C_n$$

$$[5] \qquad F(R_{\infty_T})_2 = \tau_{21} C_1 + \tau_{22} C_2 + \ldots \tau_{2n} C_n$$

These equations are, of course, only valid for a concentration range within that prescribed by the Kubelka–Munk law. At higher concentrations interference due to saturation of the first monomolecular adsorption layer (10) results in marked deviations from linearity and, in extreme cases, gives a calibration curve asymptotic to the horizontal axis. The useful concentration range can, however, be extended by use of the semi-empirical relationship

$$[6] \qquad \frac{(1 - R_\infty)^2}{2R_\infty} = k \log C$$

suggested in an earlier paper (11) which resulted in an almost fivefold extension of the range. Other functions which tend to give linear calibration curves under suitable conditions, $\log R_\infty$ versus C^2, R_∞ versus $\sqrt[3]{C}$ or $\sqrt{(C/(1 - C))}$, have been proposed by Lermond and Rogers (12) and could be applied as well for simultaneous analysis.

EXPERIMENTAL

Reagents

All reagents were of analytical grade and the dye solutions of Orange G, Crystal Violet, Fuchsin, and Brilliant Green were prepared by dissolving weighed amounts in 1:1 ethanol–water. The absorbent was Silicagel G from "Merck Darmstadt", of a grade suitable for thin-layer chromatography, with a particle size ~5 μ.

Apparatus

The diffuse reflectance spectra (400–700 mμ) were measured with an automatic recording Spectronic 505 spectrophotometer equipped with the standard reflectance attachment; barium sulfate was used as the reference standard. Quantitative photometric studies were done with a Beckman DU spectrophotometer, equipped with a reflectance attachment, at wavelengths determined from the reflectance spectra; the reference standard was magnesium carbonate. A "Desaga" variable thickness thin-layer-chromatography applicator was used to prepare the 5 × 20 cm chromatoplates.

Procedure

Stock solutions containing 0.380 mg/ml for Orange G and 0.300 mg/ml for Crystal Violet, Fuchsin, and Brilliant Green were prepared. Dilution series of eight different concentrations (from 0.100 to 0.300 mg/ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

were made up for each dye. The solutions were applied to chromatoplates by means of a 10 μl graduated "Hamilton" microsyringe. The plates were dried for 5 min at 110 °C; each spot was removed from the plate and diluted with silica gel from the same plate until the aggregate totalled 40.0 ± 0.2 mg. The sample was then ground in an agate mortar for two periods of 15 s each to ensure homogeneity and uniform particle size. The sample was packed in a semimicro cell (11) and its reflectance was measured.

RESULTS AND DISCUSSION

The dye pairs Orange G – Crystal Violet and Fuchsin – Brilliant Green were chosen for study. Figures 1 and 2 show the individual spectra of the dyes and the spectra of the

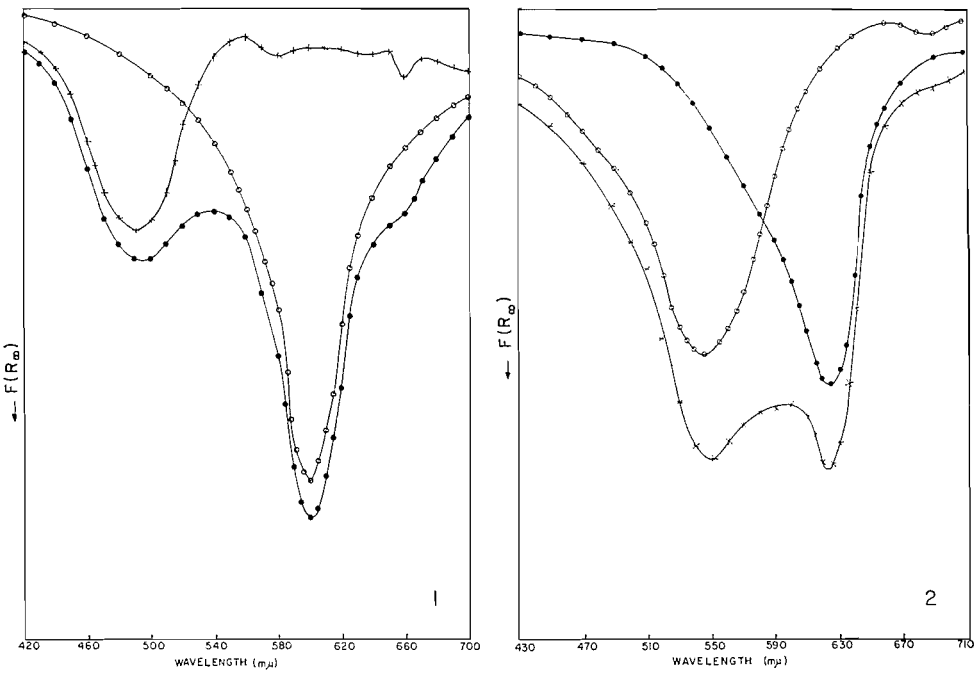

FIG. 1. Reflectance spectra of +, Orange G; ○, Crystal Violet; ●, a mixture of the two.
FIG. 2. Reflectance spectra of ○, Fuchsin; ●, Brilliant Green; ×, a mixture of the two.

mixtures of the two pairs; the theoretically computed total spectra of the pairs (by addition of the individual reflectance functions) are essentially identical with the measured spectra. The absorption maxima for all four dyes did not vary significantly throughout the entire concentration range studied. Figures 3 and 4 show adsorption characteristics and interferences of Fuchsin and Brilliant Green and mixtures of the two dyes; these results show the absence of interferences due to molecular dissociation, association, and abnormal adsorbent–adsorbate interactions and show that the dye systems were satisfactory for further investigation. The absorption maxima determined from Figs. 1–4 (626 mμ for Brilliant Green, 600 mμ for Crystal Violet, 545 mμ for Fuchsin, and 490 mμ for Orange G) were used for quantitative analysis. Calibration plots for the Fuchsin – Brilliant Green pair are shown in Fig. 5. Within the concentration ranges studied, the Kubelka–Munk relationship was valid for all four dyes, and the τ values for the slopes of the Kubelka–Munk curves required for eqs. [4] and [5] were readily obtained.

Sample mixtures were prepared and, to test the reliability of the method, were analyzed as unknowns by students of the junior and senior level. To avoid fluctuations due to temperature, humidity changes, and bleaching effects the dilution series were processed

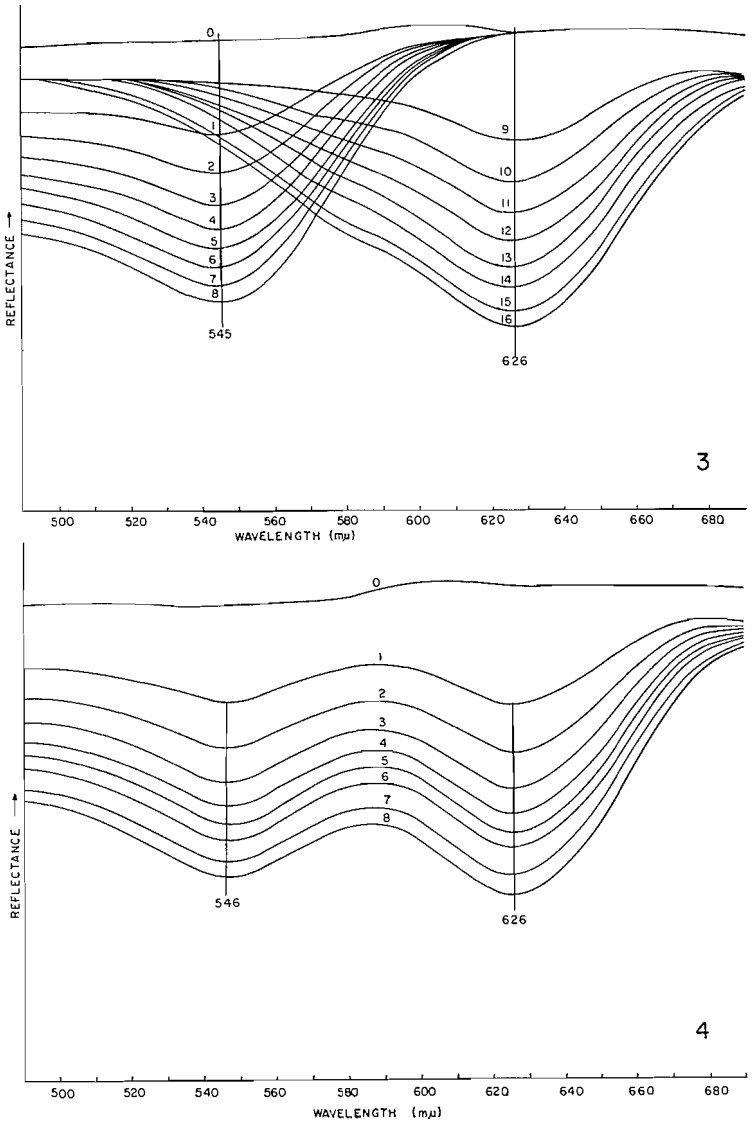

FIG. 3. Reflectance spectra of dilution series of Fuchsin (1–8) and Brilliant Green (9–16) adsorbed on Silicagel G, recorded against a barium sulfate reflectance standard. The zero line is for pure Silicagel G. The concentration of dye in μg per sample is as follows. Fuchsin: (1) 0.3, (2) 0.6, (3) 0.9, (4) 1.2, (5) 1.5, (6) 1.8, (7) 2.4, (8) 3.0. Brilliant Green: (9) 0.3, (10) 0.6, (11) 0.9, (12) 1.2, (13) 1.5, (14) 1.8, (15) 2.4, (16) 3.0.

FIG. 4. Reflectance spectra of dilution series of a mixture of Fuchsin and Brilliant Green adsorbed on Silicagel G, recorded by diffuse reflectance spectroscopy against a barium sulfate reflectance standard. The zero line is for pure Silicagel G. Concentration of each dye in μg per sample: (1) 0.3, (2) 0.6, (3) 0.9, (4) 1.2, (5) 1.5, (6) 1.8, (7) 2.4, (8) 3.0.

simultaneously with the unknowns. Six readings were taken for each calibration curve and four samples of each dye pair were prepared. The students' results are shown below.

Precision (average standard deviation for four sets of four samples) = ±2.4%

Accuracy (average deviation of four samples from true value)

Dye pair 1		Dye pair 2	
Orange G	Crystal Violet	Fuchsin	Brilliant Green
1.9%	3.3%	2.1%	3.1%

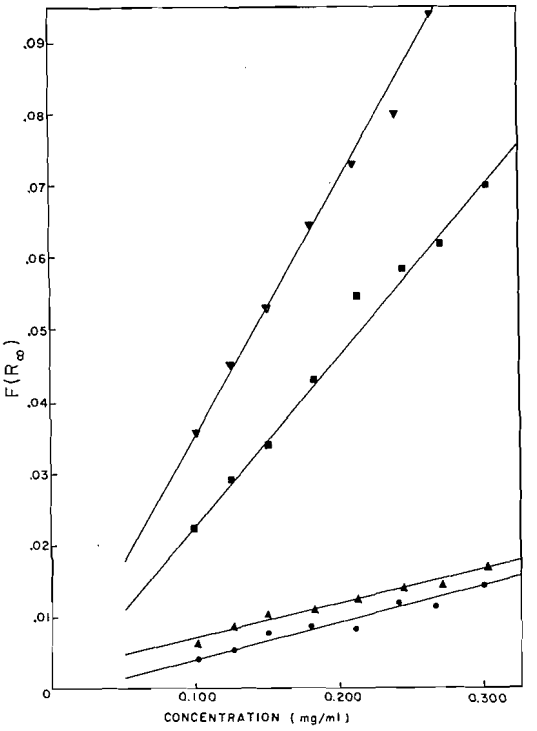

FIG. 5. Kubelka–Munk plots for ▼, Brilliant Green at 626 mμ; ▲, Fuchsin at 626 mμ; ●, Brilliant Green at 545 mμ; ■, Fuchsin at 545 mμ.

The precision is, as expected, somewhat lower than for single component analysis; the factors limiting precision for such simple systems were found to be the packing reproducibility and the homogeneity of the samples, which is in agreement with earlier findings (1). The accuracy is competitive with that obtained from transmission spectroscopy techniques.

CONCLUSIONS

Diffuse reflectance spectroscopy can be applied to the quantitative analysis of mixtures of chromogenic compounds adsorbed on powders. The samples can be analyzed directly on the powder without elution of the adsorbed compounds. The method is relatively simple and inexpensive and can be used in the hands of inexperienced analysts with satisfactory accuracy.[2]

Its major value will be in analysis of mixed zones in chromatography where incomplete separation is encountered. The technique should be useful in thin-layer chromatography, in column chromatography, and in powder electrophoresis. Although this study has been done on simple two-component systems, there is little doubt that the method could be extended successfully to multicomponent systems and to compounds which have to be rendered visible by chromogenic agents or which absorb in the ultraviolet region of the spectrum.

ELECTRON SPIN RESONANCE SPECTRA OF ^{15}N-CENTERED RADICALS AT LOW TEMPERATURES

II. THE RADIOLYSIS OF POTASSIUM SULFAMATE[1]

J. R. MORTON[2] AND D. R. SMITH

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received April 14, 1966

ABSTRACT

Single crystals of potassium sulfamate, KNH_2SO_3, enriched in the isotope ^{15}N, were irradiated, and examined at 77° K by electron spin resonance. Two intermediates, neither of which are present on examination at 300 °K, have been identified as NH_2 and NH_2SO_3. A possible radiolysis mechanism is discussed.

INTRODUCTION

Electron spin resonance (e.s.r.) spectra of single crystals of potassium sulfamate (KNH_2SO_3) γ-irradiated at room temperature reveal the presence of the radicals SO_3^- (1) and $NHSO_3^-$ (2). Two mechanisms may be envisaged as contributing to the radiation damage process in potassium sulfamate. The "cage" effect (3) would favor the formation of $NHSO_3^-$ over the formation of NH_2 and SO_3^-.

[1] $$NH_2SO_3^- \longrightarrow\!\!\!\!\!\sim\!\!\!\!\!\rightarrow NHSO_3^- + H$$

However, the presence of SO_3^- suggests an alternative mechanism involving the intermediate NH_2:

[2a] $$NH_2SO_3^- \longrightarrow\!\!\!\!\!\sim\!\!\!\!\!\rightarrow NH_2 + SO_3^-$$

[2b] $$NH_2 + NH_2SO_3^- \rightarrow NH_3 + NHSO_3^-$$

The purpose of the present study was to determine, if possible, the mechanism of the radiolysis of potassium sulfamate, by carrying out the process at low temperatures with the hope of identifying any intermediates by means of electron spin resonance.

EXPERIMENTAL

To obtain improved resolution of the e.s.r. spectra, potassium sulfamate enriched in the isotope ^{15}N was prepared. Sulfamic acid containing 95% $^{15}NH_3SO_3$, purchased from Merck Sharp and Dohme Ltd., Montreal, was neutralized with aqueous potassium hydroxide solution. Single crystals of potassium sulfamate were grown by slow evaporation of this solution. The crystals are orthorhombic (4), and the unit cell, which contains four molecules of KNH_2SO_3, has dimensions $a = 8.32$ Å, $b = 8.28$ Å, $c = 5.90$ Å, in the space group *Pbma*. The crystals usually formed hexagonal tablets on (001), elongated along [010].

The samples were γ-irradiated at 77 °K in an 18 000 curie ^{60}Co source (Gammacell 220), at a dose rate of 1 Mrad/h. Irradiation at 77 °K was carried out after positioning the crystals in thin-walled quartz (Spectrosil) tubes. The γ-ray induced e.s.r. signal from the quartz was subsequently removed by illumination with a low-pressure Hg lamp. This was found to have no effect on the e.s.r. spectrum of the sample. Dosimetry measurements were made using the ferrous sulfate method (5). The electron spin resonance spectrometer has already been described (6). Conventional methods (7) were used to determine the elements of the hyperfine interaction tensors, an isotropic g-factor of 2.004 being assumed. The total radical concentration was measured in a powdered sample of $K^{14}NH_2SO_3$, using a previously described e.s.r. technique (8). The relative radical concentrations were estimated using a single crystal of $K^{15}NH_2SO_3$. The spectral line-widths of the different radicals were almost equal, and no line-width corrections were applied.

RESULTS

The electron spin resonance spectrum of a crystal of $K^{15}NH_2SO_3$ freshly irradiated at 77 °K is shown in Fig. 1(*a*), for the orientation H_0 parallel to the c-axis. It will be seen that, in addition to $NHSO_3^-$ (C), two other radicals are present (A and B).

[1] *A.E.C.L. No. 2465.*

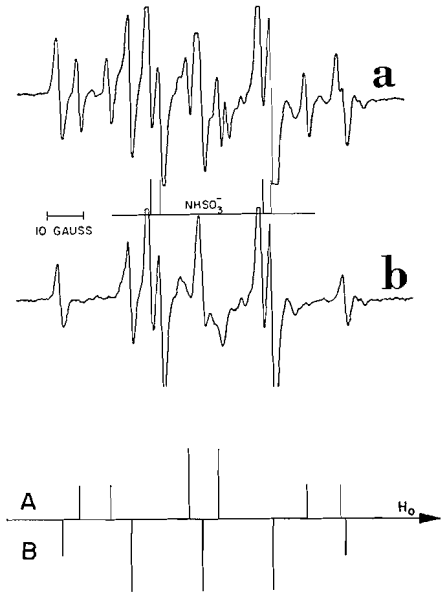

FIG. 1. Electron spin resonance spectra of a crystal of $K^{15}NH_2SO_3$ for the orientation H_0 parallel to c-axis: (a) freshly irradiated at 77 °K; (b) after annealing to 195 °K for 1 min.

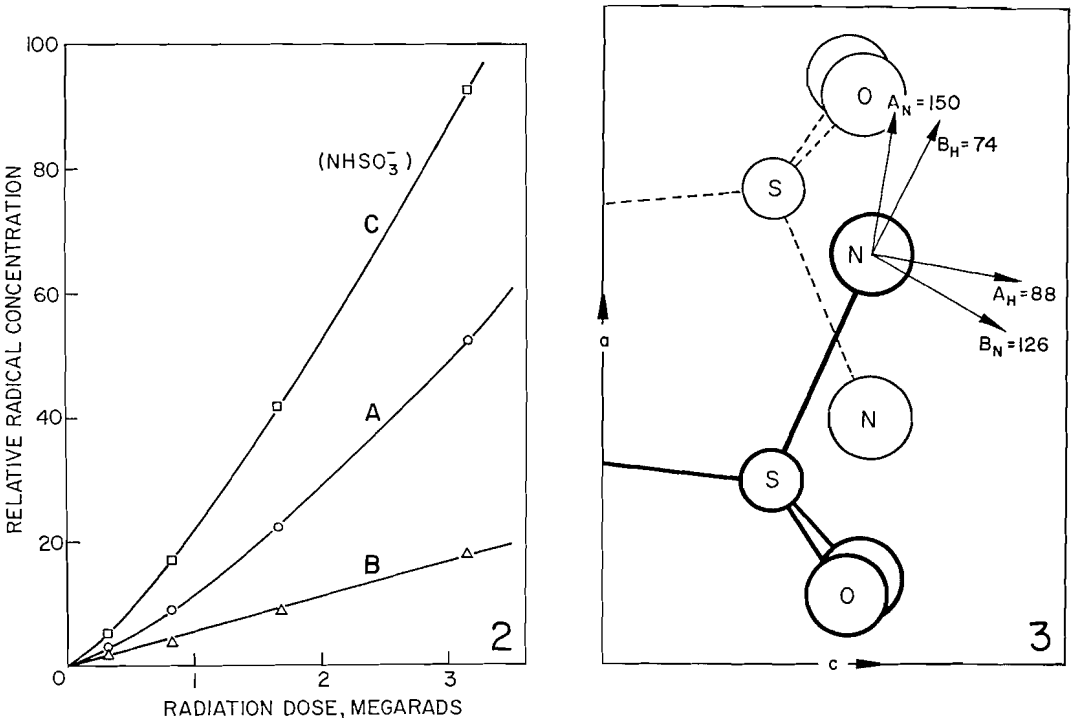

FIG. 2. Relative concentration of radicals A, B, and C in crystals of $K^{15}NH_2SO_3$ as a function of radiation dose.

FIG. 3. Projection on to (010) of part of the unit cell of potassium sulfamate, showing also the directions of certain principal values of the hyperfine tensors of radicals A (NH_2) and B (NH_2SO_3).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The spectra of radicals A and B were both analyzed in terms of hyperfine interaction with three spin $\frac{1}{2}$ nuclei, two of which were equivalent for all crystal orientations. Since the spin of ^{15}N is $\frac{1}{2}$ it seemed a reasonable assumption that both A and B were radicals of the type R—NH_2; in the next section, evidence will be offered suggesting that A and B were NH_2 and NH_2SO_3 respectively.

The estimated buildup of these three radicals as a function of radiation dose in the freshly irradiated crystals is shown in Fig. 2. On annealing the crystal at 195 °K for 1 min the spectrum of radical A had disappeared, as will be apparent from Fig. 1(*b*). On warming to room temperature only the spectra of SO_3^- and $NHSO_3^-$ remained. The total radical concentration after a 1 Mrad irradiation at 77 °K was $(1.0 \pm 0.1) \times 10^{17}$ radicals/g, and $(1.4 \pm 0.1) \times 10^{17}$ radicals/g after warming to room temperature. These figures correspond to a radiation-chemical yield[3] G(total) of 0.16 at 77 °K and 0.22 at room temperature, and estimated yields of 0.03, 0.03, 0.03, and 0.07 for the radicals NH_2, SO_3^-, NH_2SO_3, and $NHSO_3^-$ respectively at 77 °K.

In Table I the ^{15}N and proton hyperfine tensors of radicals A, B, and C ($NHSO_3^-$) determined at 77 °K are listed; the data for radical C ($NHSO_3^-$) are included for the sake of completeness although little is added to those of Rowlands (2).

*These directions have no significance since the tensor has axial symmetry.

DISCUSSION

A. Identification of the Radicals

The species A and B are both nitrogen-centered π-radicals, in which the unpaired electron occupies an orbital to which the dominant contribution is that of the nitrogen $2p_\pi$ atomic orbital. Both radicals exhibit the characteristically (7) large ^{15}N hyperfine interaction when H_0 is perpendicular to the nodal plane of the radical, and very much smaller ^{15}N interactions when H_0 explores this plane. It is reasonable to suppose that one of these radicals be NH_2 and the other NH_2SO_3. Since A is the more labile species, it is tempting to identify it provisionally with NH_2. In the potassium sulfamate crystal

[3]*G = number of radicals formed per 100 eV deposited in the sample.*

(4) the S—N bonds have direction cosines (0.920, 0.000, ±0.392) in the *abc* axis-system. The angle between this direction and that of the 150 Mc/s principal value of the ^{15}N tensor of radical A is $\cos^{-1}$ 0.968 or 14°, and the unique direction of the proton tensor in radical A is inclined $\cos^{-1}$ 0.224 or 77° to the S—N bonds in the crystal. These observations are not unreasonable if A is the radical NH_2 formed by scission of the N—S bond, but are difficult to explain on the postulate that A is NH_2SO_3. The latter radical would be expected to lie in an orientation similar to that of the ion from which it had been formed. It would therefore be anticipated that in the case of NH_2SO_3 the largest principal value of the ^{15}N and proton tensors would be respectively perpendicular and parallel to the S—N bonds in the crystal. The data for radical B fit these criteria: the angle between the S—N bond and the direction of the 126 Mc/s principal value of the ^{15}N tensor being $\cos^{-1}$ 0.129 or 83°, and between the S—N bond and the direction of the 74 Mc/s principal value of the proton tensor being $\cos^{-1}$ 0.998 or 4°. These observations are illustrated in Fig. 3, where arrows representing the directions of the above principal values are superimposed on a projection of part of the unit cell of potassium sulfamate.

The above discussion provides confirmatory evidence that A and B may be identified with NH_2 and NH_2SO_3, respectively. Since both these radicals have bene detected previously by e.s.r. (9–11) a comparison with the earlier data is of interest. In the case of NH_2 in an argon matrix (9) the isotropic proton and ^{14}N interactions were 67.0 and 28.9 Mc/s respectively, the latter corresponding to a ^{15}N interaction of 40.5 Mc/s. These figures are to be compared with those for radical A: 76.5 ± 5 and 52.1 ± 5 Mc/s for the isotropic proton and ^{15}N interactions respectively. The discrepancy between the isotropic nitrogen interactions is not too serious when it is recalled that for ND_2 in an argon matrix the ^{14}N interaction was 33.3 Mc/s, equivalent to 46.6 Mc/s for a ^{15}N nucleus. The isotropic nitrogen interaction in NH_2 is clearly somewhat dependent upon environment. It appears (Table I) that the re-orientation of the NH_2 radical between the two equivalent positions is so rapid that the proton tensor exhibits axial symmetry about the rotation axis which is the two-fold axis of the molecule. The unique direction of the proton tensor (principal value 88 Mc/s) lies in the radical plane, being approximately perpendicular ($\cos^{-1}$ 0.027 or 88°) to the direction of the largest (150 Mc/s) ^{15}N principal value, and approximately parallel ($\cos^{-1}$ 0.999 or 2°) to the direction of the smallest (1 Mc/s) ^{15}N principal value. A similar relationship between the principal values of the proton and ^{13}C tensors was noted in the case of the radical $^{13}CH_2CO_2^-$ (12), in which the CH_2 group was also re-orienting about the two-fold axis.

Within the experimental error (5°) the proton and ^{15}N hyperfine tensors of radical B (NH_2SO_3) are diagonal in a common axis-system: parallel to the nitrogen $2p_\pi$ orbital (B_N = 126 Mc/s, B_H = 51 Mc/s); bisecting the HNH angle and parallel to the S—N bonds in the crystal (B_N = 8 Mc/s, B_H = 74 Mc/s); and the mutually perpendicular direction (B_N = 19 Mc/s, B_H = 27 Mc/s). In this case the re-orientation of the NH_2 group is not rapid enough to eliminate the anisotropy in the proton tensor, although it is rapid enough to render the protons equivalent as far as the resonance is concerned. It will be noted, however, that the *largest* proton hyperfine interaction and the *smallest* ^{15}N interaction are obtained when H_0 is parallel to the bisector of the HNH angle, just as in the case of NH_2 discussed above. Exactly analogous relationships were observed for the radical NH_2SO_3 trapped in sulfamic acid (11), although the principal values of the respective tensors differ somewhat.

B. The Radiolysis Mechanism

The results suggest that the radiolysis mechanism of potassium sulfamate is more complex than the alternatives represented by reactions [1] and [2]. A reaction scheme

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which accounts for many of the present observations is outlined and discussed below. Untrapped electrons and trapped electrons are represented by e^- and e_t^- respectively.

(i) Irradiation at 77 °K.—The following reactions are thought to occur:

[3] $$NH_2SO_3^- \longrightarrow\!\!\!\!\!\sim\!\!\!\!\!\rightarrow NH_2SO_3 + e^-$$

[4] $$NH_2SO_3 + e^- \rightarrow NHSO_3^- + H$$

[5] $$H + NH_2SO_3^- \rightarrow NHSO_3^- + H_2$$

[6] $$NH_2SO_3 + e^- \rightarrow NH_2 + SO_3^-$$

[7] $$e^- \rightarrow e_t^-$$

The primary reaction is thought to be ionization of $NH_2SO_3^-$ [3], and some recombination must occur [4, 6] since NH_2 and $NHSO_3^-$ are detected. It is estimated that reactions [4] and [6] are approximately of equal importance in the recombination of NH_2SO_3 and e^-. Reaction [5] accounts for the absence of trapped hydrogen atoms and gives rise to further $NHSO_3^-$.

(ii) Annealing at 195 °K for 1 min.—

[8] $$NH_2 + NH_2SO_3^- \rightarrow NHSO_3^- + NH_3$$

Since no NH_2SO_3 disappeared, the electrons must remain trapped at this temperature.

(iii) Warming to room temperature.—The untrapping of the electrons

[9] $$e_t^- \rightarrow e^-$$

must be followed by reactions [4], [5], [6], and [8], since only $NHSO_3^-$ and SO_3^- are detected at room temperature. Since the total radical yield at 77 °K did not include $G(e_t^-)$, the total radical yield after warming to room temperature (~298 °K) should increase by this amount. If $G(e_t^-) = G(NH_2SO_3)$, then

$$[G(NHSO_3^-) + G(SO_3^-)]_{298°K} = [G(NH_2SO_3) + G(\text{total})]_{77°K} = 0.19.$$

The increase in total yield from 0.16 at 77 °K to 0.22 at room temperature provides qualitative support for the above mechanism.

ACKNOWLEDGMENTS

The authors are grateful to Dr. L. D. Calvert for determining the unit-cell directions of the crystals by means of X-ray diffraction photographs.

ELECTRON SPIN RESONANCE SPECTRA OF $N_2H_4^+$ AND PF_2[1]

J. K. S. WAN,[2] J. R. MORTON, AND H. J. BERNSTEIN
Divisions of Pure and Applied Chemistry, National Research Council, Ottawa, Canada

Received April 18, 1966

ABSTRACT

The radicals $N_2H_4^+$ and PF_2 have been detected by electron spin resonance in γ-irradiated NH_4PF_6. The radical $N_2H_4^+$ was shown to be formed from NH_3^+ radicals detectable after low-temperature irradiation.

INTRODUCTION

It has recently been shown that the radicals PF_4 and $PF^{\pm}$ can be trapped in irradiated NH_4PF_6 (1). In addition to these fragments, there was evidence of a nitrogen- and hydrogen-containing specie the nature of which was not discussed. The present re-examination of the e.s.r. spectra of irradiated powdered NH_4PF_6 was undertaken in the hope that the nitrogen- and hydrogen-containing specie might prove to be NH_4. This radical has been predicted to be stable (2, 3), but has never been detected experimentally.

It will be shown that the nitrogen- and hydrogen-containing specie is $N_2H_4^+$. In addition, the previously unknown radical PF_2 was discovered during this investigation.

RESULTS

Part of the spectrum of NH_4PF_6 irradiated at 300 °K is shown in Fig. 1. Not shown in this figure are the spectra of PF_4 and $PF^{\pm}$ which extend from 2 000 to 4 500 G (1), but which do not obscure the region 3 300 – 3 500 G. The spectrum of the nitrogen- and hydrogen-containing specie shown in Fig. 1 is seen to consist of nine lines centered at $g = 2.0030$ and separated by equal intervals of 12.0 G. The estimated intensity ratios of the nine lines were approximately 1:6:17:29:36:29:17:6:1.

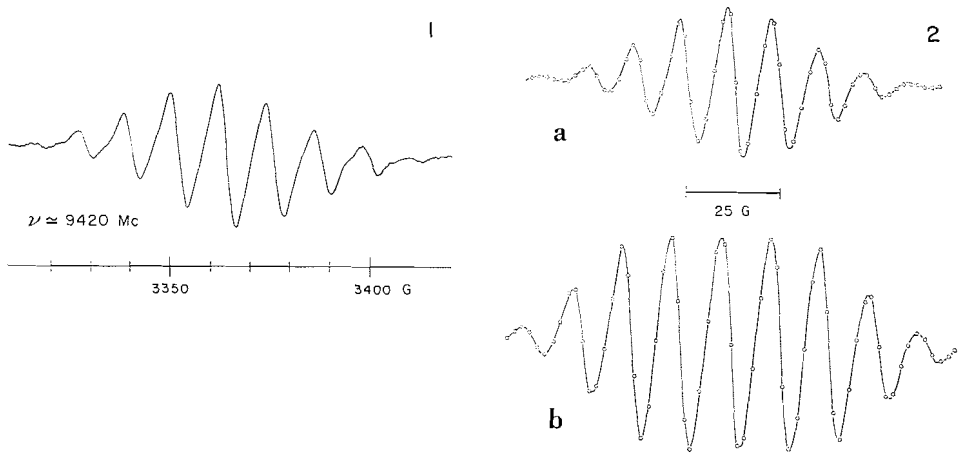

FIG. 1. The e.s.r. spectrum of NH_4PF_6 irradiated at 300 °K, between 3 300 and 3 400 G.
FIG. 2. Calculated e.s.r. spectra of (*a*) $N_2H_4^+$ and (*b*) NH_4 using the parameters quoted in the text.

In attempting to identify the species responsible for this spectrum, several possibilities were considered: NH_2, NH_3^+, NH_4, and $N_2H_4^+$. Of these, only NH_4 has not been identified previously by e.s.r. The available parameters for NH_2 (4) and NH_3^+ (5, 6) eliminate them as possibilities. However, $N_2H_4^+$ in solution has spectral parameters (7) $a_N = 11.5$ G, $a_H = 11.0$ G, and $g = 2.0034$. From these data and a maximum-slope half-width of 4.5 G the calculated spectrum of $N_2H_4^+$ shown in Fig. 2(*a*) was prepared.[3] An analysis of Fig. 1 in terms of NH_4 was also attempted, using $a_N = 24$ G and $a_H = 12$ G. The calculated spectrum in Fig. 2(*b*) was obtained. It is apparent that the evidence favors identification of the radical as $N_2H_4^+$. Experiments with irradiated ND_4PF_6 supported this assignment: the observed spectrum consisted of a broad, almost featureless, absorption due to $N_2D_4^+$ (upon which was superimposed the six-line spectrum of PF_2 discussed later), very similar to the spectrum calculated for $N_2D_4^+$. The spectrum calculated for ND_4 was a well-resolved triplet.

Experiments were carried out also at 77 °K, in the hope of detecting NH_4 at this temperature. Samples of NH_4PF_6 irradiated at 77 °K and examined at either 77 °K or 300 °K revealed a six-line spectrum which was attributed to NH_3^+, by comparison with existing data (5, 6). The reaction

$$2NH_3^+ \rightarrow N_2H_4^+$$

took several days to complete at room temperature, but only 40 min at 120 °C, as illustrated in Fig. 3. By observation of the relative rates of disappearance of NH_3^+ at various temperatures the activation energy for the process (probably diffusion-controlled) was estimated to be 15 ± 2 kcal/mole.

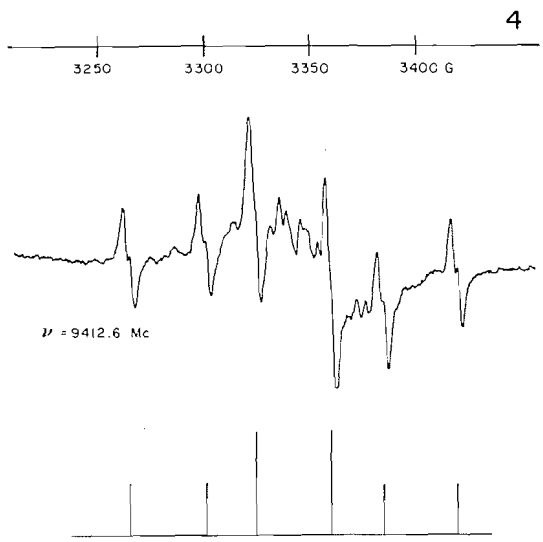

FIG. 3. The e.s.r. spectra at 393 °K of NH_4PF_6 irradiated at 77 °K showing the conversion of NH_3^+ into $N_2H_4^+$: (*a*) 0 min, (*b*) 20 min, (*c*) 40 min at 393 °K.

FIG. 4. The e.s.r. spectrum of PF_2 superimposed on the broad absorption due to $N_2D_4^+$ in irradiated ND_4PF_6.

The spectrum of irradiated ND_4PF_6 (Fig. 4) revealed, in addition to the absorption due to $N_2D_4^+$, a six-line spectrum consisting of a pair of 1:2:1 triplets. This hyperfine structure must be due to interaction with three nuclei of spin $\frac{1}{2}$, two of which are equivalent. In the deuterated material the only nuclei of spin $\frac{1}{2}$ are ^{31}P and ^{19}F, so that the six-line

For personal use only.

spectrum must be due to PF_2, FP_2, F_3, P_3, or a doubly charged analogue of one of these. The most reasonable choice was thought to be PF_2, the spectral parameters being:

$$a_P = 36.0 \pm 0.5 \text{ G}, a_F = 60.5 \pm 0.5 \text{ G}, g = 2.0108 \pm 0.0002.$$

This identification was confirmed by comparing these data with those for NF_2 (8). These 19-electron radicals are expected to be bent (9), and to possess $^2B_1$ ground states.

Several attempts were made to detect PF_2 in irradiated NH_4PF_6. Because of the different g-factors of PF_2 and $N_2H_4^+$ the PF_2 line at lowest field should have been resolved from the $N_2H_4^+$ absorption. In the radiation dose range 1–5 Mrad PF_2 could be detected in ND_4PF_6, but not in similarly processed NH_4PF_6. No explanation can be offered for this strange isotope effect.

EXPERIMENTAL

Ammonium hexafluorophosphate (Ozark-Mahoning Co.) was recrystallized three times from distilled water or 99.95% D_2O. The recrystallized compounds were checked by infrared, n.m.r., and microanalysis for purity. The powder samples were irradiated in a 20 000 Curie source of 1.3 MeV ^{60}Co γ-rays. The dose rate was approximately 2 Mrad/h and the total dose was 1–5 Mrad. Electron spin resonance spectra were obtained with a Varian V-4502-14 spectrometer and auxiliary equipment.

ACKNOWLEDGMENTS

The authors are grateful to Atomic Energy of Canada Limited for use of irradiation facilities and for the computation of e.s.r. spectra.

ULTRAVIOLET, INFRARED, AND RAMAN SPECTRA OF PROTONATED CARBOXYLIC ACIDS

SUMIE HOSHINO, HARUO HOSOYA,[1] AND SABURO NAGAKURA
The Institute for Solid State Physics, The University of Tokyo, Tokyo, Japan
Received January 5, 1966

ABSTRACT

Ultraviolet, infrared, and Raman spectra were measured for acetic acid and propionic acid in sulfuric acid solutions of various acidities. Infrared spectra of acetic acid and benzoic acid were measured in deuterosulfuric acid and aqueous deuterated sodium hydroxide solutions. From the detailed analyses of the ultraviolet absorption change the pK_{BH^+} values of acetic and propionic acids were found to be -6.12 and -6.33, respectively. In the infrared and Raman spectra of the protonated acids, the C=O stretching band at about 1 700 cm^{-1} disappeared and a new strong infrared absorption band appeared at about 1 600 cm^{-1}. The frequency of the latter band, which can be assigned to antisymmetric C—O stretching band, is very similar to that of the carboxylate group. The acidity dependence of these infrared spectra was parallel with that of the ultraviolet absorption. These facts confirm that the protonated carboxyl group has a skeleton $[-C(OH)_2]^+$ similar to the carboxylate group $[-CO_2]^-$.

INTRODUCTION

Aromatic and aliphatic carboxylic acids have been found, from cryoscopic (1) and other chemical studies (2), to be protonated in concentrated sulfuric acid solution:

$$R—COOH + H^+ \rightleftharpoons R—COOH_2^+.$$

The structure of protonated species $R—COOH_2^+$ is important because it is known to be one of the reactive intermediates for the acid-catalyzed esterification of carboxylic acids (3). The basic strengths of the carboxylic acids have been extensively studied by observing the change in ultraviolet absorption spectrum with changing acidity of the medium. The observed basicities, pK_{BH^+}, are of the same order of magnitude as those of analogous aldehydes and ketones (4). Raman spectral measurements showed that protonation occurs at the carbonyl oxygen atom in accordance with the predicted electronic structures (5), while the results of n.m.r. studies show the spectra to be influenced by medium effects as well as by protonation (6). On the other hand, infrared spectra of protonated species in strong acid solutions have never been observed. The purpose of the present series of experiments is to investigate the extent to which the results of these various kinds of spectroscopic measurements, when applied to the same system, accord with and make up for each other.

EXPERIMENTAL

Materials

Acetic acid and propionic acid of G.R. grades were refluxed over potassium permanganate followed by careful distillation. Benzoic acid for analytical purpose specially supplied by the Osaka Industrial Research Institute was used without further purification. Sulfuric acid of G.R. grade (Wako Pure Chemical Industries, Ltd.) and deuterosulfuric acid (Showa Denko K.K., 99% deuterium concentration and 97% acid concentration) were used without further purification. Deuterated sodium hydroxide solution (~6 *N*) was prepared by dissolving carefully the freshly cut sodium metal into deuterated water purchased from Showa Denko K.K.

Measurements

A Cary model 14M recording spectrophotometer was used to measure the ultraviolet absorption spectra of acetic acid and propionic acid in sulfuric acid solutions of various acidities, and the solute concentrations were adjusted as high as $10^{-2}M$. The values of Hammett's acidity functions were taken from the table by Paul and Long (7).

The Raman spectra of acetic and propionic acids were measured in sulfuric acid solutions with a Cary model 81 recording Raman spectrophotometer located at the Government Chemical Industrial Research Institute, Tokyo.[2]

The infrared spectra of acetic and benzoic acids in deuterosulfuric acid and deuterated sodium hydroxide solutions were measured with a Hitachi EPI-2 recording spectrophotometer. Envelope cells were made from two sheets of polyethylene films (8). The cells containing a few drops of the sample solution were pressed by fingers from the bottom to the top in order to get them as thin as possible. Thereafter they were held by commercial cell holders. They were transparent enough for the measurements in the carbonyl-stretching region. Deuterium–hydrogen exchange was observed but was found to be slow enough for accurate infrared absorption measurements.

All the measurements were carried out at a constant temperature, 20 °C.

RESULTS AND DISCUSSION

pK_{BH^+} *Determination of Acetic Acid in Concentrated Sulfuric Acid*

The ultraviolet absorption spectra of acetic acid in water and in 10% sulfuric acid showed an absorption peak at 203 mμ (ϵ = 38, see Fig. 1). This is undoubtedly due to the unprotonated molecule. With the increase of the sulfuric acid concentration, the peak shifted to shorter wavelengths and finally disappeared. For a given wavelength, the plot of the molar extinction coefficient ϵ against the H_0 value of the solvent gave a sigmoid curve (Fig. 2). The pK_{BH^+}, ϵ_B, and ϵ_{BH^+} were found to be −6.12, 36.38, and 3.57, respectively, by applying the least squares method to the observed apparent molar extinction coefficients at 200 mμ:

$$[1] \qquad pK_{BH^+} = H_0 - \log [(\epsilon_{BH^+} - \epsilon)/(\epsilon - \epsilon_B)].$$

This means that acetic acid is half-protonated in 74% sulfuric acid. Details of the method were described elsewhere (3).

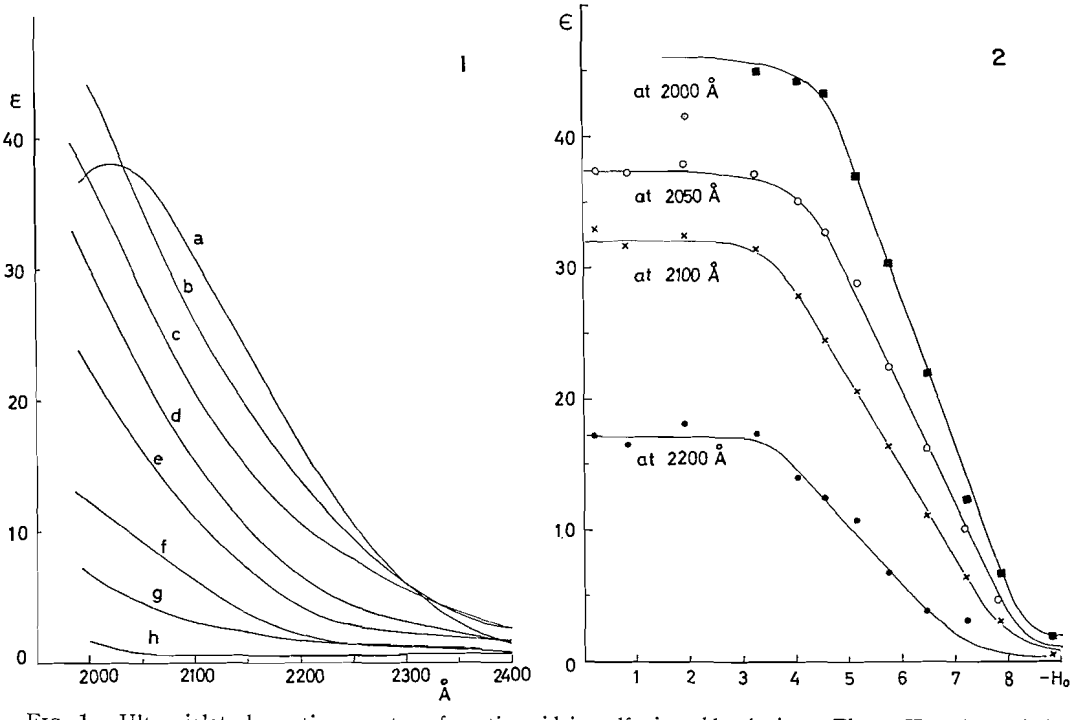

FIG. 1. Ultraviolet absorption spectra of acetic acid in sulfuric acid solutions. The $-H_0$ values of the solvent acid are, respectively: (*a*) 0.84; (*b*) 4.07; (*c*) 5.16; (*d*) 5.78; (*e*) 6.50; (*f*) 7.23; (*g*) 7.86; (*h*) 8.86.

FIG. 2. The change of the apparent molar extinction coefficient of acetic acid in sulfuric acid solutions of various acidities.

[2]*The authors wish to thank Mrs. Michiko Fukuyama for the measurements of Raman spectra.*

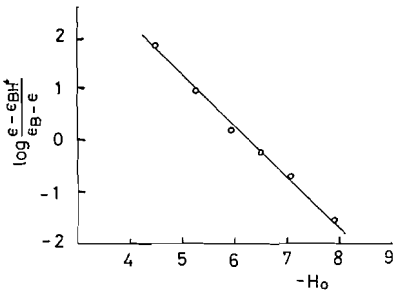
For personal use only.

The following facts lead to the conclusion that acetic acid is really a Hammett base: (i) The plot of $\log [(\epsilon - \epsilon_{BH^+})/(\epsilon_B - \epsilon)]$ against H_0 gave a straight line with a slope of near unity (Fig. 3), and (ii) almost the same pK_{BH^+} values were obtained for several different wavelength plots (3).

The pK_{BH^+} value (−6.33 at 210 mμ) of propionic acid was also determined by the same method (half-protonated in 75% sulfuric acid). The pK_{BH^+} values determined by the present authors for both acids coincide well with those obtained by other authors:[3] −6.10 (9) and −6.20 (7) for acetic acid and −6.8 (10) for propionic acid.



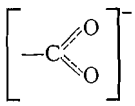


FIG. 3. The plots showing that acetic acid is one of the typical Hammett bases. The ϵ values were taken at 200 mμ.

Structure Determination of the Protonated Carboxylic Group

Raman spectra of the 6 μ region were measured with acetic acid in sulfuric acid solutions of various acidities. The results are shown in Fig. 4. The 1 700 cm^{-1} band due to C=O stretching vibration decreases in intensity with increasing concentration of sulfuric acid and disappears for the 98% sulfuric acid solution. The same tendency was also observed with benzoic acid.[4] The disappearance of the 1 700 cm^{-1} band means that the protonation of acetic acid occurs on the oxygen atom of the carbonyl group, as in the case of the protonation of benzoic acid.

The Raman spectra of the simple carboxylic acids show that the carbonyl-stretching band disappears in the aqueous sodium hydroxide solutions, in which the carboxylate anion is produced (11).

[2] 

The infrared carbonyl-stretching band at 1 715 cm^{-1} in water (1 717 cm^{-1} in methanol) gradually diminishes in intensity and a new band appears at lower frequencies (1 600 cm^{-1}) with the increase of the solvent sulfuric acid concentration. The infrared spectrum of acetic acid in deuterated sodium hydroxide solution has an absorption peak at 1 560 cm^{-1}. This corresponds to the known antisymmetric C—O stretching band at 1 584 cm^{-1} for solid sodium acetate (1 425 cm^{-1} for the symmetric one) (Fig. 5).

For the infrared spectra of benzoic acid, a band appears at 1 603 cm^{-1} in concentrated deuterosulfuric acids (Fig. 6). Although a large number of simple benzene derivatives show weak ring-stretching bands near 1 600 cm^{-1}, the new band must have another origin

[3]*The previous results of the pK_{BH^+} values of acetic acid obtained from the change of the ultraviolet spectrum were not as accurate as the present one. For example, whether or not acetic acid may be regarded as a Hammett base was not checked by the previous authors (7, 9).*

[4]*Although the acidity dependence of the Raman spectrum could not give the accurate pK_{BH^+} value of acetic acid because of its inaccuracy in the absolute intensities, the results given in Fig. 4 show that the pK_{BH^+} value lies in between −5 and −9.*

For personal use only.

but not as [—C(=O)OH_2^+]. The similarity between the structures [2] and [3] gave the similar spectra pertinent to the C—O bonds. It is acceptable that the presence of the two protons is felt by these bonds as a minor perturbation (the mass ratio of O and OH being 0.94). The absence of the 1 600 cm^{-1} bands of the Raman spectra in the acidic and alkaline media can be explained as due to the antisymmetric vibrational mode of their similar skeletons. The symmetric ones are expected to be located at lower frequencies, but they were masked by the strong absorption of the solvent and polyethylene cells.

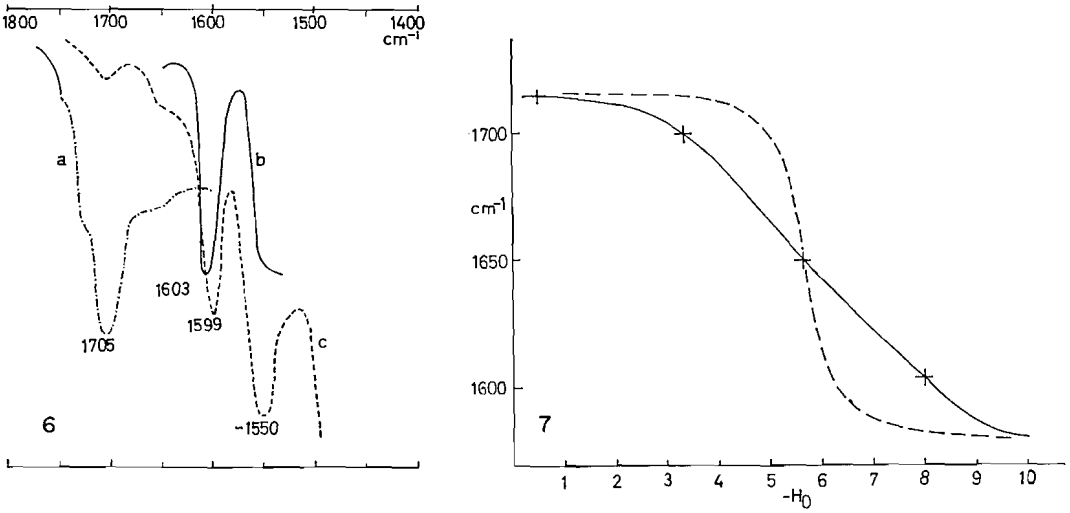

FIG. 6. Infrared absorption spectra of benzoic acid in various solutions. The solvents are: (*a*) methanol; (*b*) concentrated D_2SO_4; (*c*) aqueous NaOD.

FIG. 7. The change of the peak wave number of the infrared absorption spectra of acetic acid in deuterosulfuric acid solutions. The broken line represents a theoretical curve,

$$-5.80 = H_0 - \log [(\nu_{max} - 1\,562)/(1\,728 - \nu_{max})].$$

Since the accurate intensities of the infrared absorption were not obtained, we tried to estimate the pK_{BH^+} value of this compound from the change in the wave number of the absorption peak. The plot of the wave number against the H_0 values of the solvent gave the curve shown in Fig. 7. The general shape of this curve indicates a pK_{BH^+} of about −6 in agreement with the results of ultraviolet spectra.[5]

TOTAL CROSS SECTIONS FOR IONIZATION BY ELECTRON IMPACT

A. G. HARRISON,[1] E. G. JONES, S. K. GUPTA, AND G. P. NAGY
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 17, 1966

ABSTRACT

Total cross sections for ionization by 75 V electrons have been measured for a wide range of molecules. On the whole the results are in agreement with the cross sections reported by Lampe *et al.* rather than those reported by Otvos and Stevenson. The results fit neither a single linear correlation with molecular polarizability nor a simple postulate of additivity of atomic ionization cross sections.

INTRODUCTION

Otvos and Stevenson (1) have reported the cross sections for ionization by electron impact for a number of gaseous molecules and have concluded from their data that the ionization cross section is a constitutive molecular property which can be estimated from suitable atomic ionization cross sections. More recently, Lampe, Franklin, and Field (2) have reported cross sections, determined in a similar manner, which are, in many cases, in disagreement with the values reported by Otvos and Stevenson. Further, Lampe *et al.* (2) showed that the postulate of additivity did not fit their data but rather suggested that the cross sections were linearly related to the polarizability of the neutral molecule.

In the hope of resolving this conflict in experimental results and to provide more extensive tests of the additivity concept and of the correlation with polarizability, we have measured the ionization cross sections for a wide variety of molecules. Our results are, on the whole, in agreement with those of Lampe *et al.* (2), but they fit neither a simple additivity postulate nor a simple correlation with molecular polarizability.

EXPERIMENTAL

As in previous studies (1, 2) the method consisted of measuring as a function of the sample reservoir pressure the total positive ion current to the negatively biased repeller of a mass spectrometer ion source. This total ion current, I_+, is given by the relation

$$I_+ = Q_i I_e d N \qquad [1]$$

where Q_i is the ionization cross-section, I_e is the ionizing electron current, d is the ionizing path length, and N is the concentration of molecules in the ion source. For molecular or effusive flow into and out of the ionization region the concentration of all gases in the ion source will be the same for a given reservoir pressure. Consequently a plot of I_+ versus reservoir pressure should be linear with a slope proportional to the total ionization cross section, and relative cross sections may be obtained by comparison of these slopes.

The present results were obtained using the ion source of a 2 in., 180° magnetic deflection instrument (A.E.I. MS-10). The total ion current to the repeller rose sharply to 4 V repeller bias after which it remained constant; measurements were taken on this plateau region. The current was measured with a General Radio model 1230A electrometer and recorded on a strip chart recorder. Typically, currents were in the range 10^{-10} to 10^{-8} A. The electron accelerating voltage was 75 V and the ionizing current 20 μA.

The reservoir pressure was read by a C.E.C. micromanometer and typically was varied from 5 to 150 μ. The gas admission leak was a porous plug (Metrosil) which tests showed to exhibit effusive flow to pressures of at least 20 mm. Initially some problems were encountered in the gas flow out of the ionization region. Preliminary experiments showed that for condensible gases the measured ion current at constant reservoir pressure was strongly dependent on the temperature of the cold trap, which indicated changes in the effective pumping speed. Therefore a number of baffle plates were placed in the pumping lead directly below the ion source. After this change the ion current was found to change by $<1\%$ for all compounds when the cold trap was cooled from dry ice temperature to liquid N_2 temperature.

Typical ion current versus pressure plots are shown in Fig. 1. The cross sections were measured relative to that of krypton which was run periodically during each day's work. The slope of the krypton plot changed by <1% during the course of a day while cross sections relative to that for krypton were reproducible to ~3%.

All chemicals used were commercially available. The mass spectra were checked for impurities before use and the samples were carefully degassed before admission to the reservoir system.

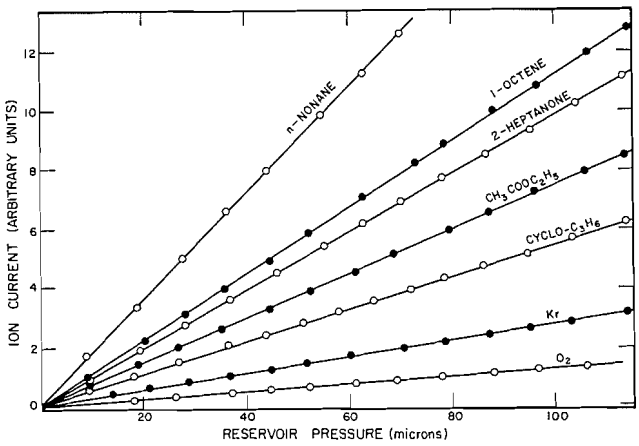

FIG. 1. Typical ion current versus pressure plots.

RESULTS AND DISCUSSION

The ionization cross sections obtained in the present work are compared with previous measurements in Table I. On the whole our results are in satisfactory agreement with the results of Lampe *et al.* (2) although we find significantly lower values for a number of cyclic and unsaturated hydrocarbons. The present results are also in reasonable agreement with the cross sections quoted by Massey and Burhop (3) and the values reported recently by Rapp and Englander-Golden (4). Indeed if we normalized our results to the Q_1(Kr) reported by the latter workers the only significant differences would occur for Ne and Xe. On the other hand, our cross sections, and those of Lampe *et al.* (2) are considerably higher than the values reported by Otvos and Stevenson (1) and the few cross sections reported by De Maria *et al.* (5). This is particularly true for organic molecules.

More extensive results were obtained for homologous series of alkanes, alkenes, alkynes, alkylbenzenes, ethers, aldehydes, ketones, and carboxylic esters. The cross sections are tabulated in Tables II and III. With the exception of those values reproduced from Table I these cross sections have not been previously measured. The upper limit to each series was determined by volatility since the sample reservoir was operated at room temperature.

The results in Tables II and III give numerous examples of structural isomers and show that, within experimental error, the cross sections are independent of structure within a given class of compound. This is particularly evident for the alkylbenzenes and carboxylic esters (Table III) and is shown further by the cross sections for isomeric C_6 alkanes recorded in Table IV. On the other hand isomers belonging to different functional classes in many cases show significantly differing cross sections. This is indicated by the data for a number of isomer pairs collected in Table IV.

The cross sections in Tables I to IV cannot be reproduced by assuming additivity of atomic ionization cross sections and assigning atomic cross sections to C, H, and O. If a

TABLE IV

Effect of structural isomerism on ionization cross sections

Molecule	$Q_i \times 10^{16}$ (cm^2 molecule^{-1})	Molecule	$Q_i \times 10^{16}$ (cm^2 molecule^{-1})
n-C_6H_{14}	20.0	C_3H_6	8.97
2-Methylpentane	19.6	cyclo-C_3H_6	10.4
3-Methylpentane	19.7		
2,2-Dimethylbutane	20.0	C_5H_{10}	14.1
2,3-Dimethylbutane	19.7	cyclo-C_5H_{10}	16.9
C_2H_5OH	8.66	C_6H_{10}	15.0
CH_3OCH_3	9.33	cyclo-C_6H_{10}	15.5
C_2H_5CHO	9.38	C_6H_{12}	16.4
CH_3COCH_3	10.2	cyclo-C_6H_{12}	17.9

The variation in these differences and comparison with $Q_i(O_2) = 3.04 \times 10^{-16}$ cm^2 molecule^{-1} indicates a breakdown of the additivity postulate. By similar reasoning the additivity concept implies that $Q_i(H_2)$ can be evaluated as follows.

$$Q_i(H_2) = Q_i(C_nH_{2n+2}) - Q_i(C_nH_{2n}) = Q_i(\text{alkane}) - Q_i(\text{alkene})$$
$$Q_i(H_2) = Q_i(C_nH_{2n}) - Q_i(C_nH_{2n-2}) = Q_i(\text{alkene}) - Q_i(\text{alkyne})$$

From Table I, $Q_i(H_2) = 1.2_9 \times 10^{-16}$ cm^2 molecule while from Table II the average difference $Q_i(\text{alkane}) - Q_i(\text{alkene}) = 3.1 \times 10^{-16}$ and the average $Q_i(\text{alkene}) - Q_i(\text{alkyne}) = 1.5 \times 10^{-16}$. A further indication of the failure of the additivity concept is, of course, supplied by the differences for the isomer pairs recorded in Table IV.

On the other hand, the cross-sections within an homologous series do fit a modified additivity rule. This is shown graphically in Fig. 2 where for each homologous series the total cross sections are plotted as a function of the number of carbon atoms in the molecule. With the exception of the lower alkanes a satisfactory straight line is obtained for each series, which indicates that increasing the chain length by successive introductions of CH_2 brings about a regular increase in the cross sections. Further, it should be noted that, within experimental error, the slopes of the straight lines are identical; this indicates that for each series the effect of CH_2 introduction is identical. For the alkanes those above C_3 fit a straight line relation while methane, ethane, and possibly propane lie below the straight line. A similar linear correlation with a number of carbon atoms has been noted recently by Schram *et al.* (6) for the ionization cross sections of a limited number of alkanes and alkenes in the electron energy region 1 keV to 12 keV.

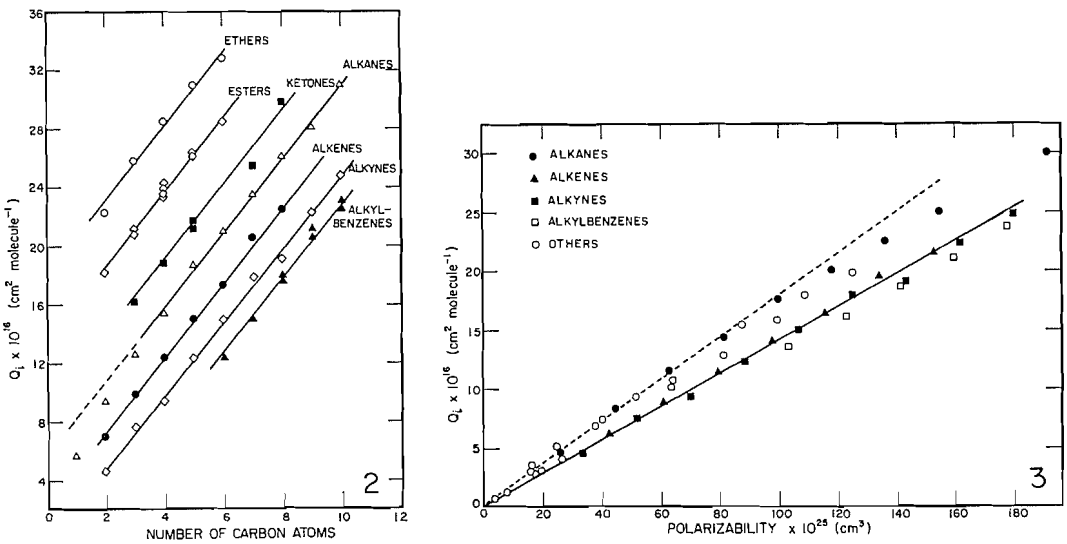

FIG. 2. Total ionization cross sections as a function of the number of carbon atoms. The scales for some series have been shifted for clarity. See Tables for absolute values.
FIG. 3. Total ionization cross sections plotted against polarizability.

The straight line relationships of Fig. 2 permit an estimation of the cross sections of higher members of each series by simple extrapolation. The best fits for the straight lines are given below, where N_C is the number of carbon atoms in the molecule, and the equation for the alkanes applies only for C_4 and higher.

Alkanes	$Q_i \times 10^{16} =$	$4.4_0 + 2.5_4 N_C$
Alkenes	$Q_i \times 10^{16} =$	$1.3_0 + 2.5_4 N_C$
Alkynes	$Q_i \times 10^{16} =$	$-0.2_5 + 2.5_4 N_C$
Alkylbenzenes	$Q_i \times 10^{16} =$	$-1.4 + 2.5_4 N_C$
Alkyethers	$Q_i \times 10^{16} =$	$5.0_0 + 2.5_4 N_C$
Carboxylic esters	$Q_i \times 10^{16} =$	$3.5_0 + 2.5_4 N_C$
Ketones	$Q_i \times 10^{16} =$	$2.6_0 + 2.5_4 N_C$

Lampe *et al.* (2) have suggested on the basis of their results that the ionization cross sections are a linear function of the polarizability of the neutral molecule. With the extensive data now available a more rigorous test of this correlation can now be made. The plot of cross section versus polarizability is shown in Fig. 3. The closed circles represent the data for the alkanes and the open circles the data for other molecules whose polarizabilities are tabulated in Landolt-Bornstein (7). The polarizabilities of the higher alkenes, alkynes, and alkylbenzenes were estimated from the reported values for the first members by assuming the same increment per CH_2 (18.3×10^{-25}) as found for the alkanes; this procedure gives slightly lower polarizabilities than would be obtained by using bond polarizabilities (8).

The data obviously do not fit a single linear relationship. The broken line is the straight line of slope equal to that given by Lampe *et al.* (2) from their correlation. As can be seen it fits the data for the lower alkanes and a number of other molecules. However, the higher alkanes, alkenes, alkynes, and alkylbenzenes fall below this straight line. The alkene and alkyne cross sections fit a single linear correlation with polarizability, but the slope of the line is about 20% lower than the line which fits the lower alkanes. We conclude from Fig. 3 that no single, simple correlation of total ionization cross section with polarizability holds. It might be noted that Lampe *et al.* (2) did not measure cross sections for the higher alkanes, alkenes, and alkynes where the most significant deviations are found.

In summary, it is apparent that molecular ionization cross sections fit neither a simple additivity postulate nor a single linear correlation with polarizability. Stevenson and Schissler (9) reviewing the data available in 1961 reached a similar conclusion concerning the additivity concept and suggested that the correlation with polarizability should be viewed with caution. The present results do show that within any homologous series the data can be correlated with polarizabilities or accommodated by a modified additivity rule. Difficulties arise only when comparing one homologous series with another, indicating that the cross section is determined, in part, by the nature of the functional group.

Stevenson and Schissler (9) have presented arguments suggesting that the additivity rule breaks down for the cases where an appreciable number of collisions lead to excitation rather than ionization. A rather similar explanation has been advanced (10) to explain the isotope effects observed in total ionization experiments. It has been found consistently that total cross sections for ionization of deuterated molecules are greater than for the undeuterated form, regardless of whether this ionization is brought about by collision with metastable atoms (11), beta rays (12), or electrons (13). This has been explained on the assumption that the initial impact process leads, in part, to formation of highly excited (super-excited) neutral molecules which may either undergo neutral dissociation or autoionization and subsequent fragmentation. The replacement of hydrogen by deuterium is considered to retard the neutral fragmentation reactions preferentially and thus lead to a higher ionization cross section.

Such a postulate can explain the present results if we assume that either the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

"super-excited" molecules or the fraction of these which undergo neutral dissociation reactions is dependent on the functional group present. Thus we would suggest, for example, that for the alkenes and alkynes the fraction of electron impact events leading to neutral fragmentation is considerably greater than for the lower alkanes, resulting in deviations from a single correlation with polarizability. In this regard we would note that our measurements give $Q_1(C_2D_6)/Q_1(C_2H_6) = 1.01_3$ compared to $Q_1(C_2D_2)/Q_1(C_2H_2) = 1.04_1$, $Q_1(C_2D_4)/Q_1(C_2H_4) = 1.03_8$, and $Q_1(C_7D_8)/Q_1(C_7H_8) = 1.04_2$. This latter value is identical with the ratio 1.04 reported by Meyerson *et al.* (13). The lower isotope effect for ethane could be taken to indicate that neutral fragmentation events are less important in this case. More extensive investigations of isotope effects particularly among higher members of the series would be of considerable interest.

A CORRELATION OF STEPWISE STABILITY CONSTANT RATIOS AND SOME BONDING PROPERTIES OF TRANSITION METAL AND ZINC COMPLEXES[1]

P. G. MANNING
Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received January 20, 1966

ABSTRACT

Stepwise stability constant ratios for some transition metal and zinc amino acid complexes are analyzed. It is shown that the observed ratios for Cu and Ni amino acid complexes are larger than the calculated ratios by a factor R, the Bjerrum rest effect. It is suggested that the rest effect is due to metal–nitrogen covalency, there being sufficient transfer of charge from ligand to metal in the first association stage to reduce markedly the electrostatic attraction between ligand and metal in the second.

For Zn complexes, the observed and calculated ratios are in excellent agreement. A small rest effect would seem to be present in the Co system, but experimental errors render any conclusions uncertain.

INTRODUCTION

The absolute magnitudes of stepwise stability constants for metal–ligand ion association reactions are useful in choosing the ligands that might be of application in, e.g. the ion-exchange separation of rare earths. However, the stability constants often do not tell us the nature of the species formed. In an earlier publication in this series (1), the ratios of stepwise stability constants for some simple rare earth and cupric ion association systems were analyzed using the Bjerrum relationship (2)

$$P = K_1{:}K_2 = S \times T \times R,$$

where K_1 and K_2 are stepwise stability constants defined by

$$K_n = [\mathrm{ML}_n]/[\mathrm{ML}_{n-1}][\mathrm{L}]$$

where M = metal ion and L = ligand. The S, T, and R factors are as follows.

S factor.—S is purely statistical and can be evaluated from a knowledge of the number of available cation sites and ligand groups. For a bidentate ligand binding to a hexahydrated cation (octahedral), $S = 2 \times 12/5 = 4.8$. The factor 2 arises because the probability of a ligand's leaving the 1:2 associate is twice that of the ligand's leaving the 1:1.

T factor.—This factor is a measure of the work done in bringing a second ligand from infinity to its equilibrium position in the 1:2 (metal:ligand) associate against the repulsive force exerted by the already bound ligand. Therefore, T, being electrostatic in nature, should be independent of the nature of cation and ligand. Table I lists T values derived from experimental P values for rare earth, cupric, and zinc ion association systems. The characterization of certain metal–ligand systems by a given T value would aid considerably in the interpretation of the vast compilations of stability constants, e.g. the Chemical Society publications (3). One of the aims of this work is the analysis of stepwise stability constant ratios for transition metal amino acid complexes in order to determine whether a T value = 1.6 holds for these singly charged ligand systems. The simpler ligands have been studied so as to minimize steric hindrance effects and long-chain hydrocarbon

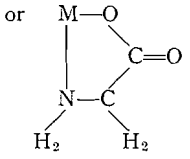
Zn^{2+}	Mandelate	Monodentate	1.5

*R' = organic group.

interactions with the water structure. The latter effect could introduce important entropy changes.

R factor.—R, the rest effect, covers those effects that are neither electrostatic nor statistical. Bjerrum (2) defined R as "the influence of bound ligands on the binding power of the metal ion." In this paper, it is demonstrated that rest effects are present in transition metal amino acid complexes, and the significance of the R term is discussed.



DISCUSSION

The possible reactions between a cation and a simple (primary amino) amino acid (e.g. glycine) may be formulated as follows (4),

[1] $$M + NH_2CH_2COO = M—O·CO·CH_2·NH_2$$

[2] $$\text{or } M—NH_2·CH_2·COO$$

[3] or

The (primary amino) amino acids are generally regarded as being bidentate ligands (4), and this may be readily confirmed from the magnitudes of P_{obs}. The above reactions are analagous to monodentate and bidentate glycolate interaction with Cu, Zn, and the rare earths, so that a value of $T = 1.6$ (Table I) may be postulated for reactions [1], [2], and [3]. The S factors for reactions [1], [2], and [3] are 2.4 ($= 2 \times 6/5$), 2.4, and 4.8 respectively for a cation with six equivalent binding sites. The corresponding P_{calc} values are, therefore, 3.8, 3.8, and 7.7. Table II presents P_{obs} for some (primary amino) amino acid complexes of Cu, Ni, Co, Fe, Mn, and Zn. The P_{calc} and P_{obs} values for Zn are in excellent agreement, indicating that a value of $T = 1.6$ holds for this system and that the ligands are bidentate. The data for Mn and Fe glycine complexes are too few for any unequivocal conclusions to be drawn, but the P_{obs} values would tend to favour bidentate ligandcy. For the leucine and valine complexes of Mn, $P_{obs} < S$. Consequently, the latter systems would seem to warrant reinvestigation.

It was shown in an earlier publication (30) that $T = 1.1$ for singly charged ligands (e.g. chloride) ion pairing with the rare earth hydration sheath. When this T value was corrected for the smaller separation of ligands in a complex, then T (monovalent ligand complexing) $\sim$1.4, a value in good agreement with the directly derived T values listed in Table I. It would seem, therefore, that the metal–oxygen bonding in the complexes listed in Table I is of low covalent character, i.e. mainly ionic. A T value of 1.6 also holds for ferric chloride complexes (31), which are generally regarded as being mainly ionic (32).

*Source of P values, refs. 5–29.

In a recent review article (33), Moeller and co-workers concluded that rare earth – oxygen bonds were mainly ionic. Later in this publication, it is shown that M—L covalency (transfer of charge from M → L) increases the magnitude of P. It would seem, therefore, that the Zn—O and Zn—N bonds in the amino acid systems are of low covalent character.

The observed P values for the Cu and Ni complexes indicate that the value of R is appreciable (Table III). These cations form much stronger complexes with the (primary amino) amino acids than does Zn, showing that the ligands are probably bidentate. The S values for Cu have been computed on the basis of four available cation sites. The Jahn–Teller effect was shown to be operative in the cupric glycolate and acetate systems (1), and the effect has also been observed in the Cu ethylenediamine system (34). Furthermore,

the log K values for the three stages of Cu glycine association (6) are 8.33, 6.97, and <1, while the corresponding figures for Co (6) are 4.61, 3.75, and 2.56. For Co, however, the average P_{obs} value of 10 ± 3 overlaps the P_{calc} value of 7.7 calculated on the basis of $S = 4.8$ and $T = 1.6$.

The value $T = 1.6$ for singly-charged ligand systems covers contributions to the magnitude of P from, e.g. preferential disruption of the hydration sheath in a given stage of ion association and also any solvent structure and dielectric effects. The rest effect may therefore be associated with metal–ligand interaction, notably the bonding properties. Possible reasons for a large R factor are:

(i) The M—L bond length increases as the number of bound ligands increases. Such an effect was not noted in the α-hydroxymonocarboxylate systems listed in Table I, and it is unlikely to be present here. Bjerrum (2) has shown that the M—L bond length does not change upon higher association for simple nitrogen-bonding ligands.

(ii) The ligand is bidentate in the first association stage and monodentate in the second. This possibility has been eliminated earlier in this work.

(iii) The metal–ligand bond is sufficiently covalent that considerable charge is transferred from ligand to metal. The electrostatic attractive force between metal and ligand in the second association stage is then reduced. The greater the covalency of the metal–ligand bond the greater will be R. Copper–oxygen bonds would seem to be mainly ionic, however, as the Cu glycolate data in Table I show ($T = 1.6$). Covalent bonding can therefore be attributed to Cu–N bonds. The magnitude of R shows that the order of metal–ligand covalency for (primary amino) amino acid systems is Cu > Ni > Co $\geqslant$ Fe = Mn = Zn $\sim$ O. This series is in accord with the deductions of Martell and Calvin (4) from the slopes of plots of the second ionization potential of the metal against complex stability, for different oxygen- and nitrogen-bonding ligands. It is of interest to note that the above ordering of metals according to the magnitudes of their R values follows closely the Irving–Williams order (35), which compares the absolute stabilities of complexes. Thus the R factor could be put in the order Mn = Fe $\leqslant$ Co < Ni < Cu > Zn. The Irving–Williams order can be interpreted on the basis of the ability of the cation to accept charge from a ligand, and the sequence can be correlated with the standard electrode potential of the metal (36). The correlation between the magnitude of R and the ability of a metal to accept charge is good. The R sequence also suggests that the R value for Co is significantly greater than 1.0. While the R values could tell us, in principle, the amount of charge transferred to the metal (metal–ligand covalency), the calculation becomes impractical because of the unknowns associated with the M—L distance over which the continuous transfer of charge takes place.

Values of P for the (secondary amino) amino acids (Table IV) suggest that Cu—N

For personal use only.

covalency is small and $R = 1.1$. For Ni, however, the Ni—N bond would seem to be of similar covalency to the primary amino system ($R = 1.7$). It is possible that the coordinating acid oxygen atom of the (secondary amino) amino acid has similar bonding properties to the oxygen atom of water. The (secondary amino) amino acids are therefore capable of displacing all six waters of the Cu^{2+} primary hydration sheath with equal facility. The N atom would bind in the square plane and the O atom either in the square plane or perpendicular to the square plane. For this model, $S = 4.8$, $S \times T = 7.7$ and $R = 1.8$, corresponding to $P_{obs} = 14$. This R value is more consistent with that for Ni. Furthermore, for the Cu—$OOC \cdot CH_2 \cdot N(CH_3)_2$ system (12), $P_{obs} = 9$, whereas for square planar bonding only, $S = 8.0$. For six available Cu sites, $S \times T = 7.7$, giving an R value = 1.2. The R value for the Ni system is 1.4, since $P_{obs} = 11$. It would seem, therefore, that the secondary amino and tertiary amino amino acids can displace all six waters of the Cu^{2+} sheath.

CONCLUSION

Interpretations of the magnitudes of stepwise stability constant ratios for transition metal and zinc amino acid complexes have led us to the following conclusions:

(*a*) The method is capable of giving reliable information on the nature of metal–ligand bonding.

(*b*) Electrostatic repulsion between a bound ligand (in a M—L complex) and a potentially binding ligand contributes a factor of 1.6 to the magnitude of the stepwise stability constant ratio, where L = singly charged ligand and M = transition metal, Zn, or rare earth ion.

(*c*) M—N bond covalency follows the order Cu > Ni > Co $\gg$ Mn = Fe = Zn $\sim$ O.

(*d*) In the Cu^{2+} systems, the (primary amino) amino acids bind in the square plane. The (secondary and tertiary amino) amino acids displace all six waters of hydration.

THE PHOTOLYSIS OF CO_2 AT 1 470 Å[1]

A.-Y. UNG[2] AND H. I. SCHIFF[3]
Upper Atmosphere Chemistry Group, McGill University, Montreal, Quebec

Received March 16, 1966

ABSTRACT

The apparatus used to study the photolysis contained a collimating region which minimized the effect of divergent light, and permitted the temperature of the cell and lamp to be controlled separately. Analytical sensitivity was such that conversions less than 0.2% were possible.

Although CO and O_2 were the only stable products, the CO/O_2 ratios were higher than those required by mass balance. The product yields were found to be independent of CO_2 pressure and to be linear with irradiation time at 25 °C. At higher temperatures the quantum yields decreased and at 200 °C were no longer linear functions of irradiation time. The O_2 yields decreased when CO was added, the effect increasing with temperature. The overall quantum yield was less than unity. Reactions were observed with CH_4, H_2, and N_2O when these were added in small amount. These results indicated the presence of a reactive species, capable of promoting back reactions and of being adsorbed on the walls. A mechanism is suggested which best fits the results and which postulates CO_3 as the reactive species.

The ultraviolet photolysis of CO_2 is of interest for a number of reasons. It has been widely used as an actinometer for determining the quantum yields of other photolyses at short wavelengths. Although it has generally been assumed that the CO quantum yield is unity, this has never been convincingly demonstrated. The photolysis also provides a potential source of metastable $O(^1D)$ atoms, which possesses advantages over alternate sources. Reactions of these metastable atoms play an important role in the chemistry of the earth's atmosphere but have received little study in the laboratory. The photolysis of CO_2 is also of interest in understanding the photochemistry of the atmospheres of Mars and Venus. However, the results obtained by previous investigators have not been satisfactorily interpreted by any mechanism thus far proposed.

A number of investigators (1–3) have found that, although CO and O_2 are the only products detected, oxygen is not recovered in the amounts required for mass balance. Formation of ozone has been postulated by Mahan (1) and by Warneck (3), although Warneck (4) recently claimed to have found evidence for incipient CO_3 formation.

Although Jucker and Rideal (5) concluded that the primary photolytic product is electronically excited CO_2, the consensus now seems to favor the initial production of CO and $O(^1D)$ atoms, in agreement with spectroscopic evidence (6, 7). Yamazaki and Cvetanovic (8–10), however, found that $O(^1D)$ atoms are rapidly quenched by CO_2 and should therefore have negligible lifetimes in systems in which they are generated by CO_2 photolysis.

Finally, no systematic study has yet been reported on the effect of temperature on the photolysis. The present work was undertaken as an attempt to clarify some of these problems. In particular, the results indicated the necessity for considering a back reaction.

EXPERIMENTAL

The essential features of all the glass and quartz apparatus are shown in Fig. 1. The light source was a microwave discharge through Xe operating at the vapor pressure of Xe at 83 °K. To minimize self-absorption the discharge was excited close to the sapphire window by suitable choice of pressure and by tuning of the

[1]*Work supported by the U.S. Army Research Office, Durham, and by the Defence Research Board of Canada.*

microwave cavity. The lamp was connected to a 1 l ballast volume to reduce pressure fluctuations. The sapphire window, 1 mm thick and 38 mm in diameter, was 40% transparent to 1 407 Å radiation and showed a sharp cut-off below 1 420 Å. This arrangement provided essentially monochromatic light at 1 470 Å.

The photolysis cell was separated from the lamp by a thermostatted chamber 28 cm in length and another sapphire window, 1 mm thick and 30% transparent at 1 470 Å. This chamber acted as a collimating region to reduce the divergence of the light beam. Experiments showed that light lost by divergence through the outer walls was 40 times the intensity reaching the cell. The need for collimation has not been fully appreciated by previous investigators and is particularly important when comparisons are made of quantum yields of systems with widely differing absorption.

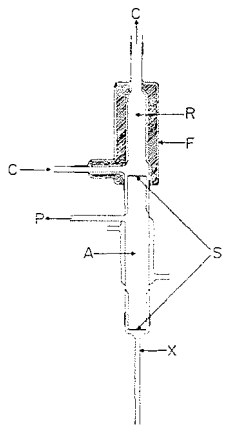

FIG. 1. Schematic diagram of photolysis apparatus: X, the xenon lamp; A, central, thermostatted collimating region; S, sapphire windows; P, to vacuum pump; C, circulating system; F, furnace; R, the photolysis cell.

The chamber also permitted alteration of the cell temperature without affecting the lamp outlet. Conversely, it prevented the lamp from heating the cell window. Finally, the chamber served as an optical shutter when filled with air, which permitted the lamp to be stabilized before the photolysis was initiated.

The cell was 10 cm in length and 34 mm i.d. Circulation of gas through the cell and connecting trap (total volume = 285 ml) to prevent accumulation of products near the entrance window, was effected by a glass-enclosed paddle wheel actuated by an external magnetic field. This reduced the "inner-filter" effect and the complications of secondary reactions at the window. Conversions never exceeded 0.2%.

The experimental procedure consisted of allowing the lamp to operate for at least 15 min with air at 1 atm pressure in the middle chamber. After the lamp had become stabilized the photolysis was begun by rapid evacuation of the middle chamber. Since the photolysis time τ was from 5 to 120 min, the 2 s evacuation time introduced little error. Condensable gases were removed from the products at 83 °K. Non-condensable products were analyzed by means of a gas burette and a gas chromatograph containing a 7 ft column of 5A molecular seive. Analysis of as little as 10^{-10} moles of H_2, O_2, N_2, CH_4, CO, and CO_2 could be effected. The photolysis apparatus was protected from intrusion of Hg vapor from the analytical section by refrigerated traps. Pressures were measured with Bourdon and ionization gauges.

Matheson 'Research' grade CO_2 was used after rigorous degassing and numerous trap-to-trap distillations. All other gases were Matheson 'Research' grade assayed reagents.

RESULTS

CO and O_2 were the only stable products detected. Figure 2 shows the yields of these products as a function of the CO_2 pressure at 25 °C for two different light intensities, and Fig. 3 shows similar results at 200 °C at a still lower light intensity. The plateau behavior at higher pressures indicates complete absorption in this region. The ratios of the CO/O_2 yields, however, are approximately 5.5 instead of 2 as required by mass balance.

Figure 4 shows the product yields as a function of irradiation time at 25 °C for two different light intensities and at a sufficiently high pressure to correspond to complete absorption. The slopes of the CO and O_2 curves are also in the ratio of about 5.5. Figure

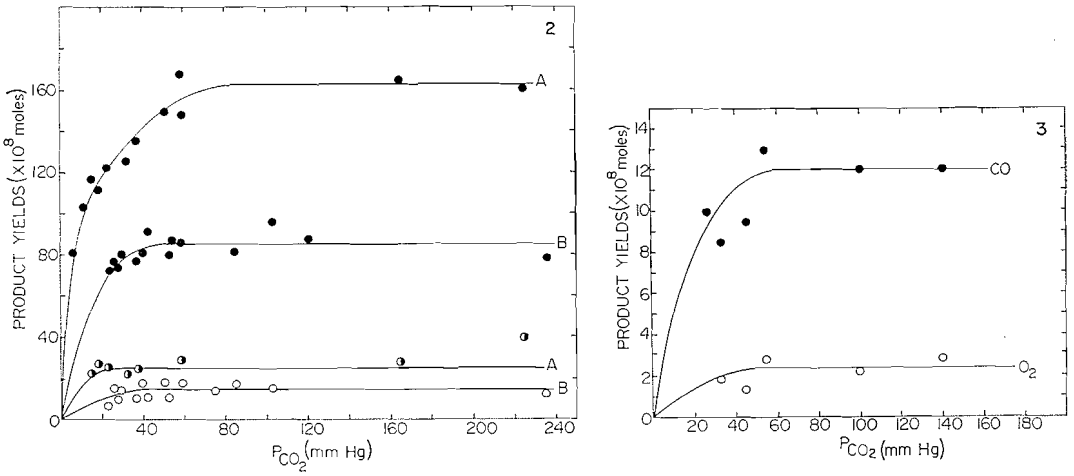

FIG. 2. Product yields as a function of CO_2 pressure at 25 °C for an irradiation time of 30 min: ●, CO; ○ and ◑, O_2; A, high light intensity; B, low light intensity.

FIG. 3. Product yields as function of CO_2 pressure at 200 °C for an irradiation time of 20 min and low light intensity.

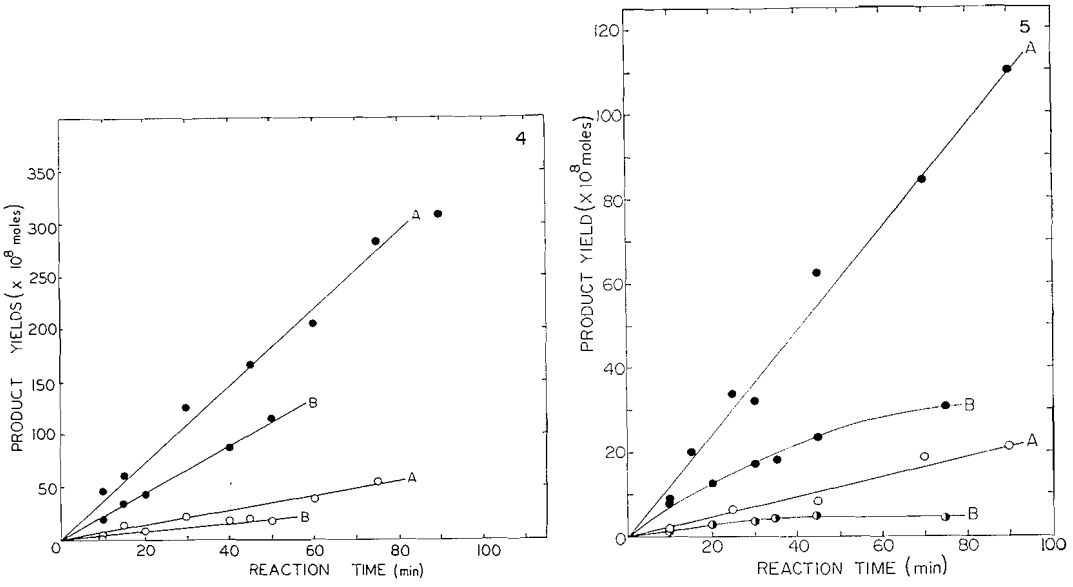

FIG. 4. Product yields as a function of irradiation time at 25 °C for two different light intensities: ●, CO; ○, O_2; A, higher light intensity and P_{CO_2} = 50 Torr; B, lower light intensity, and P_{CO_2} = 54 Torr.

FIG. 5. Product yields as function of irradiation time at two different temperatures for the same light intensity: ●, CO; ○ and ◑, O_2; A, 25 °C and P_{CO_2} = 45 Torr; B, 200 °C and P_{CO_2} = 51 Torr.

5 shows similar plots at constant light intensity but at 25 °C and at 200 °C. The results in Figs. 4 and 5 were obtained in a random order both in reaction time and in temperature which attests to the reproducibility and to the unchanged transparency of the windows. At 200 °C the linear relationship between the product yield and irradiation time no longer applies, while these and other experiments at 25, 110, and 200 °C show that the product yields decrease with increasing temperature.

Table I shows the results of a number of experiments designed to discover the fate of the missing O_2. In series A, clean Pyrex wool was placed alternately in the photolysis cell and just beyond it. Blank experiments showed that there was no detectable adsorption of O_2 by packing. Inclusion of the packing in the cell results in a marked decrease in the O_2 quantum yield.

TABLE I*a*

Experimental Series A—Photolysis of CO_2 in reaction cell packed with Pyrex glass wool; reaction time 120 min

Expt. No.	Reaction temp. (°C)	P_{CO_2} (Torr)	Position of glass wool	O_2 (moles $\times 10^8$)	CO (moles $\times 10^8$)	O_2/CO
1	25	42.0	In the cell	Nil	12	0
2	200	45.5	In the cell	Nil	11	0
3	25	300	In the cell	0.5	11	0.045
4	200	300	In the cell	<0.5	10	<0.045
5	25	300	Beyond the cell	2.7	9	0.30
6	200	300	Beyond the cell	1.0	4.0	0.25

TABLE I*b*

Experimental Series B—Photolysis of CO_2 in reaction cell which was previously saturated with O atoms produced by microwave discharge of O_2 in the system; reaction time 120 min

Exposure time (min)	Reaction temp. (°C)	P_{CO_2} (Torr)	O_2/CO
120	25	37.9	0.60
120	25	38.7	0.76
120	200	40.5	0.68
60	200	37.7	0.15
0	200	37.7	0.10

TABLE I*c*

Experimental Series C—Photolysis of CO_2 with a cylinder of thin gold foil inserted in the center of the reaction cell; reaction temperature 25 °C

Photolysis time (min)	P_{CO_2} (Torr)	CO (moles$\times 10^8$)	O_2 (moles$\times 10^8$)	O_2/CO
120	31.8	6.2	2.6	0.42
120	31.5	6.2	2.6	0.42

In series B the walls of the cell were first conditioned by filling the cell with O_2 at a pressure of 2 Torr, subjecting it to a microwave discharge for the times shown, and then evacuating the cell to a pressure at least as low as 10^{-6} Torr. CO_2 was then put in the cell and photolyzed in the normal way. The O_2/CO quantum yield ratios were observed to increase markedly and even to exceed the theoretical value of 0.5.

In series C a cylinder of thin gold foil, 2 cm in diameter was inserted in the center of the cell. This also produced an increase in the O_2/CO ratio to a value close to 0.5.

Figure 6 shows the effect of adding CO at three different temperatures. The ordinate represents O_2 yields relative to the value obtained in the absence of added CO. These results indicate a decrease in O_2 yield, the effect increasing with temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Figure 7 shows the effect of added H_2 and CH_4 on the yields of CO and O_2 when CO_2 was photloyzed at 25 °C. In both cases the O_2 quantum yield dropped rapidly to zero. The CO quantum yield was increased by addition of CH_4 but not by addition of H_2. No H_2 was observed among the products when CH_4 was added. Reaction was also observed with N_2O when this substance was added in small amounts.

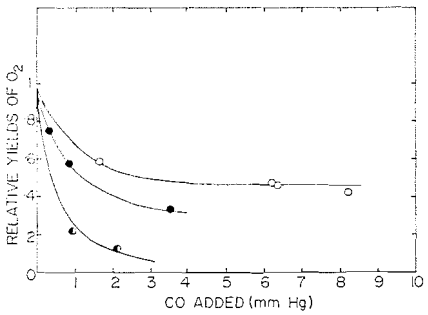

FIG. 6. Effect of added CO on the relative quantum yield of O_2: ○, 25 °C; ●, 110 °C; ◑, 200 °C.

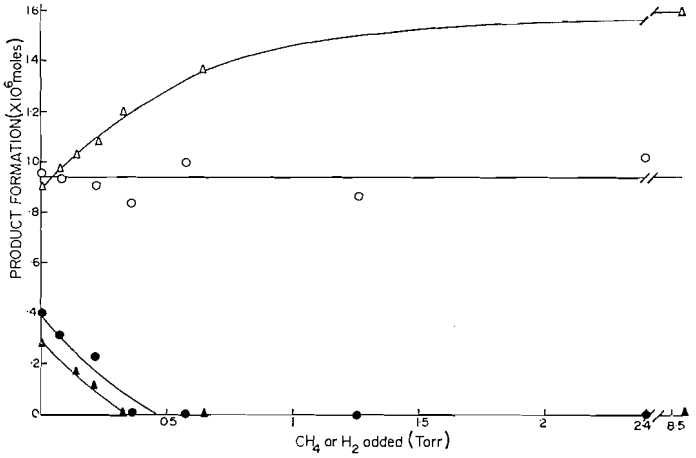

FIG. 7. Effect of added H_2 and CH_4 on product yields for an irradiation time of 15 min and $P_{CO_2} = 35$ Torr: △, yield of CO when methane added; ▲, yield of O_2 when methane added; ○, yield of CO when hydrogen added; ●, yield of O_2 when hydrogen added.

Comparisons were made between the CO and O_2 quantum yields in the photolysis of CO_2 and the quantum yields of CO_2 formed in the photolysis of mixtures of CO and O_2 containing <0.5 mole % O_2 for which the light incident on the cell was absorbed to the extent of 70%. The results are shown in Table II. This table also shows comparisons with the N_2 yields formed in the photolysis of N_2O. Light intensities and other parameters were kept constant throughout these experiments, which were performed in a random order. It is worth noting that the CO_2 quantum yields from the CO–O_2 actinometer did not change with temperature over the range 25–200 °C. This indicates that the temperature effects reported were not the result of a decrease in transparency of the sapphire windows with increasing temperature. Assuming a value of $\varphi_{CO_2} = 2$ for the CO–O_2 actinometer (1), gives $\varphi_{CO} = 0.25$ for the CO_2 photolysis at 25 °C, while a value of $\varphi_{N_2} = 1.4$ for the N_2O photolysis (11, 12) gives $\varphi_{CO} = 0.27$.

Warneck (3) has recently reported that the ratio of the O_2/CO yields increases with elapsed time (up to 60 min) between CO_2 photolysis and product analysis, which was taken as evidence for incipient CO_3 formation. However, in the present work no change in this ratio was ever observed for periods up to 75 min after photolysis.

DISCUSSION

The salient results which require explanation are: (i) the oxygen deficiency in the product yields; (ii) the independence of the product yields on CO_2 pressure; (iii) the linear dependence of the yields on irradiation time at the lower temperatures and the non-linearity at higher temperatures; (iv) the decrease in O_2 yield with added CO, and the increase of this effect with temperature; (v) an overall quantum yield less than unity; and (vi) the reaction with H_2, CH_4, and N_2O when these gases are present in the system in small amount.

The primary photolytic process could be either

[1] $$CO_2 + h\nu \rightarrow CO + O(^1D)$$

or

[1′] $$CO_2 + h\nu \rightarrow CO_2^*$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

If [1] is the predominant process then it could be followed by

[2] $$O + O + M \rightarrow O_2 + M$$

[3] $$O \xrightarrow{\text{wall}} \tfrac{1}{2}O_2$$

The ratio of the CO/O_2 quantum yields should then equal 2 while the present results show values of ~5.5 over a considerable range of pressure and light intensity. Other investigators (1–3) also find high ratios ranging from 3 to 110, although Groth (13) obtained a value close to 2 using a flow system and a gold-plated cell. Mahan (1) and Warneck (3) attributed the missing oxygen to O_3 formation; both detected O_3 in their systems by ultraviolet absorption, but in amounts too small for quantitative estimates.

However, it can readily be shown that O_3 formation cannot account for the magnitude of the missing O_2. If O_3 is formed by the process

[4] $$O + O_2 + CO_2 \rightarrow O_3 + CO_2$$

and destroyed by

[5] $$O + O_3 \rightarrow 2O_2$$

then the maximum amount of O_3 which could be formed is given by the steady state expression

[6] $$[O_3] = \frac{k_4}{k_5}[O_2][CO_2] = \gamma[O_2].$$

For mass balance we must have

[7] $$[CO] = 3[O_3] + 2[O_2]$$

so that

[8] $$\frac{[O_2]}{[CO]} = \frac{1}{3\gamma + 2}.$$

This would be consistent with the O_2 yield being linear with irradiation time if the CO curves were linear, as shown in Fig. 4. However, the expression is not consistent with our observation that the ratio is independent of CO_2 pressure since γ is proportional to $[CO_2]$.

But, most important, the expression is quantitatively incorrect. The most reliable values for k_4 and k_5 reported for these reactions (14) when the O atoms are in the ^3P ground state give a value of $\gamma = 0.12$ at 50 Torr which would result in $CO/O_2 = 2.4$. Values of 5.5 for this ratio would require γ to be an order of magnitude greater than has ever been reported for these reactions, when $O(^3P)$ atoms were involved. For $O(^1D)$ atoms, γ should be even lower since the reaction

[9] $$O(^1D) + O_2(^3\Sigma) \rightarrow O_3(^1A)$$

is spin forbidden, while there is evidence that [5] is faster with $O(^1D)$ than with $O(^3P)$ atoms and can even produce chain decomposition of O_3.

If [1′] is the predominant primary process, as favored by Jucker and Rideal (5), and if the reaction leading to product formation is

[10] $$CO_2^* + CO_2 \rightarrow 2CO + O_2$$

then again the CO/O_2 ratio should be 2.

Recently, Warneck (4) has suggested that the missing O_2 is due to the formation of unstable CO_3 molecules which releases O_2 slowly, based on the observation that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

O_2/CO ratio increases slowly after irradiation. However, no such increase was ever observed in the present work.

A possible explanation for the missing O_2 is adsorption of O atoms on the walls of the reaction cell. This explanation would be consistent with the observation that the O_2/CO ratio approached zero when the cell was packed with glass wool and 0.5 when gold foil was inserted in the cell, similar to the results reported by Groth (13). The results obtained when the cell was previously exposed to relatively large concentrations of O atoms also support this explanation; O_2/CO ratios greater than 0.5 could result from the reaction of O atoms produced by photolysis with atoms adsorbed on the walls.

The linearity of the product yields with irradiation time at 25 °C agrees with the findings of Warneck (3). Mahan (1) also reported a linear relation for CO production but a decrease in the rate of O_2 production with τ. If the fraction of O atoms that recombine on the wall is α (with $1 - \alpha$ the fraction that is adsorbed) then the relationship between the CO and O_2 yields is given by

$$[11] \qquad [CO] = \left(2 + \alpha + 3\frac{k_4}{k_5}[M]\right)[O_2],$$

so that for a given pressure the curves for the CO and O_2 yields should be proportional.

The decrease in quantum yield with added CO could be explained by the back reaction

$$[12] \qquad O(^1D) + CO\ (+M) \rightarrow CO_2\ (+M).$$

Although Groth (13) believed that this reaction was unimportant, he offered no evidence to support this view. DeMore and Raper (15) studied this reaction in liquid CO and concluded that it would be slow in the gas phase. Popov (16), on the other hand, claimed that it occurs readily.

There are, however, a number of difficulties with this mechanism: the temperature dependence of the effect of added CO (Fig. 6), on the yields as functions of irradiation time (Fig. 5), and on the overall quantum yield would require reaction [12] to have an appreciable activation energy. This would seem unlikely if it were a three-body reaction. However, if [12] is bimolecular, difficulties are encountered in trying to explain the independence of the product yields as a function of pressure and simultaneously the linearity of these yields with irradiation time at the lower temperatures. Finally, Cvetanovic (17) has presented rather convincing evidence that $O(^1D)$ atoms have very short lifetimes in the presence of CO_2.

These objections can be overcome if we postulate the conversion of $O(^1D)$ to CO_3 by a rapid reaction

$$[13] \qquad CO_2 + O\ (+M) \rightarrow CO_3\ (+M).$$

The missing oxygen could then be equally well explained by adsorption of CO_3 on the walls. The results of the experiments shown in Table I could be understood simply by substituting CO_3 for O atoms in the explanations offered above. Indeed a strong adsorption might appear more likely for CO_3 than for O because of the possibility of a type of carbonate formation.

The back reaction can take the form

$$[14] \qquad CO_3 + CO \rightarrow 2CO_2.$$

If the other destructive processes for CO_3 are mainly

$$[15] \qquad CO_3 \rightarrow CO + O_2$$

$$[16] \qquad CO_3 \xrightarrow{\text{wall}} CO_3(\text{adsorbed}),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

then steady state treatments for CO_3 and for O atoms leads to the expression

$$[17] \qquad \frac{d[CO]}{dt} = \varphi_1 I_a \left(1 + \frac{k_{15} - k_{14}[CO]}{k_{15} + k_{16} + k_{14}[CO]}\right).$$

It should be noted that the same result is obtained whether [13] is a bimolecular or a three-body reaction. A similar expression can be derived for the rate of O_2 formation in agreement with the findings that the O_2/CO ratios are independent of light intensity and temperature. These expressions are consistent with the observations that the yields are independent of total pressure. At the lower temperatures the linearity of the yields with irradiation time follows if $k_8[CO] < k_{10}$. The effect of temperature on the yields, on the results of addition of CO, and on the drop-off from linearity with τ can be attributed to the activation energy of [14] which would then become increasingly important at the higher temperatures. It appears more plausible to attribute a significant activation energy to a reaction such as [14] rather than to one such as [12].

The only previous measurements on the effect of temperature on CO_2 photolysis was made by Wijnen (18). Four experiments were reported, two at 25 °C and two at 270 °C which indicated a CO quantum yield 1.4 times greater at the higher temperature. These results are, however, in disagreement with our results at 25, 110, and 200 °C in which the quantum yields were found to decrease with temperature.

The importance of wall adsorption can be seen by comparing experiments 1 and 3 in Table I. At the higher pressure diffusion and therefore k_{10} are lower. Similarly, comparison of experiments 1 and 2 shows that the same CO yield is obtained at 25 ° and at 200 °C when the cell is packed with glass wool. Under these conditions all the CO_3 (or O atoms) are adsorbed and no back reaction is possible.

It is interesting to note that a similar expression for the rate of CO production is obtained if one assumes reaction [1′] for the initial process and the main destructive steps for CO_2^* to be

$$[18] \qquad CO_2^* + CO_2 \rightarrow CO_3 + CO$$

$$[19] \qquad CO_2^* + CO_2 \rightarrow 2CO_2.$$

The bracket on the right hand side of the rate equation [17] is then simply multiplied by the factor

$$\varphi_1' I_a \frac{k_{18}}{k_{18} + k_{19}}.$$

However, [1′] is not likely to be the sole primary step since Young[4] has recently found emission when NO is added in small amount, in contrast to the previous results of Mahan (19). This implies the presence of O atoms in the system, and consequently the occurrence of reaction [1].

On the other hand the value of φ_1 cannot be unity, since if it were, the rate expression would lead to a quantum yield greater than unity. The present results show that at 25 °C, $\varphi_{CO} = 0.25$ based on O_2–CO mixtures as the actinometer standard, and $\varphi_{CO} = 0.27$ based on N_2O as a standard. Any errors introduced by the use of these standards are such as to give φ_{CO} upper limits.

This result appears to be in conflict with previous investigations which, with the exception of a value of $\varphi_{CO} = 2$ reported by Jucker and Rideal (5) seem to favor a value of unity. Verhock (20), however, finds that a value of unity is only obtained in a flow system, but is much smaller in static systems.

In their study of the photolysis of N_2O at 1 470 Å Doering and Mahan (21) obtained values for φ_{N_2} greater than 2 if CO_2 was used as an actinometer and φ_{CO} was assumed to be unity. This result is greater than the theoretical upper limit and considerably above the value of 1.4 found by other workers. They explained their results by postulating a reaction between electronically excited and ground state N_2O molecules. A lower value for φ_{CO} would also have been consistent with their result.

More disturbing is the finding by Mahan (1) that $\varphi_{CO} = 1.1$ based on the same reference O_2–CO standard as used in the present work. However, consideration of his experimental conditions reveals that the absorption path lengths were very much larger in the O_2–CO system than in the CO_2 photolysis. With uncollimated light many more quanta would be absorbed by the CO_2 system and result in an overestimation of φ_{CO}. This is felt to be a major source of error in much of the previous work and was the main reason why the central collimating chamber was used in the present work.

More recently, Groth (22) reinvestigated the photolysis of ammonia. He found consistent values for φ_{NH_3} when he used $\varphi_{CO} = 1.1$ from a CO_2 actinometer and $\varphi_{O_3} = 1.9$ from an O_2 actinometer. The pressures used were sufficiently high that collimation should not have been a serious problem.

Nevertheless, quantum yields of unity for CO_2 photolysis would be extremely unlikely if adsorption and back reactions play significant roles, as indicated in the present work. The strongest evidence for the presence of energetic species capable of promoting back reactions is provided by the experiments in which reaction occurred when small amounts of CO, H_2, CH_4, and N_2O were added. None of these gases react at an appreciable rate with ground state $O(^3P)$ atoms.

Although Warneck (23) postulated CO_3 formation to explain the oxygen loss in the system, he maintained that $O(^1D)$ is the reactive species. However, the results of Cvetanovic (17) and of Young[4] strongly suggest a rapid disappearance of $O(^1D)$ in the presence of CO_2. The present results do appear to show a better kinetic fit when CO_3 is assumed to be the reactive species present.

The detailed mechanism for the ultraviolet photolysis of CO_2 cannot, however, be considered to be firmly established. Further work in this direction is in progress in our laboratories. Nevertheless the results do give clear evidence for the existence of reactions which would make the use of this photolysis as an actinometer, with a quantum yield of unity, at best rather questionable. The back reaction is also of considerable aeronomic significance. It could, for example, explain the failure to observe any CO in the atmosphere of Venus (24).

ACKNOWLEDGMENT

The authors would like to thank Dr. Cvetanovic for helpful discussions on this problem.

NOTES

SOME COMPLEXES PRESENT IN AQUEOUS FERRIC CHLORIDE SOLUTIONS

P. G. MANNING

Friedman (1) has shown that $FeCl_4^-$ complexes exist in solutions of ferric ion in 12 *M* HCl, and that the four-coordinate (tetrahedral) species was in equilibrium with a six-coordinate hydrated $FeCl_n$ complex. Friedman (1) concluded his paper by posing the problem as to where in the series of complexes, $FeCl^{2+}$, $FeCl_2^+$, $FeCl_3$, etc., the cation coordination number changed from 6 to 4. Such a structural change would lead to anomalous stepwise stability constant ratios (P), e.g. the Ag—NH_3 system (2). In this work, we have analyzed Lister and Rivington's (3) stability constants for Fe^{3+} complexes with Cl^- and other simple ligands. Since Fe^{3+}—Cl^- bonds are considered to be mainly ionic, then for simple complexes the ratio of stepwise stability constants may be given by (4)

$$P = S \times T, \qquad [1]$$

where S is a statistical factor and T is a measure of the work being done in bringing a second charged ligand from infinity to its equilibrium position in the 1:2 metal:ligand complex. For monovalent ligands associating with a number of different cations, $T = 1.6$ (4).

A stability constant is defined as

$$b_n = [ML_n]/[ML_{n-1}][L], \qquad [2]$$

where M = metal and L = ligand. According to Lister and Rivington (3), the b_1 and b_2 values for the reactions $Fe^{3+} + Cl^- = FeCl^{2+}$ and $FeCl^{2+} + Cl^- = FeCl_2^+$ are 4.1 and 1.5 respectively, so that P(obs.) = 2.7. From eq. [1], P(calcd.) = $2 \times 6/5 \times 1.6 = 3.85$. The agreement between P(obs.) and P(calcd.) is reasonably good, considering the low stability of the complexes.

Lister and Rivington (3) have also reported data for the addition of Cl^- to $FeSCN^{2+}$ complexes, the stability constants being

$$Fe^{3+} + SCN^- = FeSCN^{2+}, \quad b_x = 130 \qquad [3]$$

$$FeSCN^{2+} + Cl^- = FeSCNCl^+, \quad b_y = 2.0 \qquad [4]$$

$$FeSCNCl^+ + Cl^- = FeSCNCl_2, \quad b_z = 0.45 \qquad [5]$$

$$Fe^{3+} + Cl^- = FeCl^{2+}, \quad b_1 = 4.1. \qquad [6]$$

Now P_{yz}(calcd.) = $2 \times 5/4 \times 1.6 = 4.0$, in excellent agreement with P_{yz}(obs.). Furthermore, $b_1{:}b_y$(calcd.) = $6/5 \times 1.6 = 1.9$, a value that compares favorably with $b_1{:}b_y$(obs.). These calculations are based on the premise that $T_{12} = T_{23}$, but it has been shown in an earlier publication (4) that this is the case for some Cu-monodentate ligand complexes.

The corresponding ferric bromide complexes are much weaker, and it would seem that the P(obs.) values are too inaccurate for any clear conclusions to be reached. However, some of the SO_4 and HSO_4 data are of interest. Thus for the reactions

$$Fe^{3+} + SO_4^{2-} = FeSO_4^+, \quad b_s = 170 \qquad [7]$$

$$FeSO_4^+ + HSO_4^- = FeSO_4.HSO_4, \quad b_t = 2.2 \qquad [8]$$

$$Fe^{3+} + HSO_4^- = FeHSO_4^{2+}, \quad b_u = 6. \qquad [9]$$

According to Bjerrum (5), log T is proportional to e_1e_2, where e_1 and e_2 are the ionic charges on the ligands. Hence, $P_{ut} = b_u:b_t(\text{calcd.}) = 6/5 \times 1.6^2 = 3.1$, whereas the observed ratio is 2.7.

Stepwise stability constants for three stages of Fe^{3+}—Cl^- association have been reported by Rabinowitch and Stockmayer (6) and Olerup (7). The $b_1:b_2$ values (3.2 and 2.9) are in agreement with Lister and Rivington's (3). The P_{23}(obs.) values of the two investigations differ, however. Rabinowitch and Stockmayer (6) report a P_{23} value = 32 and Olerup (7) reports a value of 2.3. If the 1:3 chloride complex is octahedral, P_{23}(calcd.) $= 3/2 \times 5/4 \times 1.6 = 2.8$, a value in agreement with Olerup's determination. If Rabinowitch and Stockmayer's (6) P_{23}(obs.) value is indicative of a change in coordination from 6 to 4 in the second association stage, then P_{12}(obs.) would be considerably smaller than calculated; and yet the observed and calculated P_{12} values are in good agreement. Olerup's P_{23}(obs.) value would therefore seem to be the better.

It would appear from our treatment that the complexes $FeCl_2^+$, $FeSCNCl_2$, and $FeSO_4.HSO_4$ are octahedral. Olerup's (7) P_{23}(obs.) value suggests that $FeCl_3$ is also octahedral. It is likely that the transition from six- to four-coordination occurs in either the third or fourth association stage, probably the fourth.

It is of interest to note that Gamlen and Jordan (8) concluded from a comparison of P_{12}, P_{23}, and P_{34} values that the structural change occurred in the fourth chloride association stage. These workers used Rabinowitch and Stockmayer's (6) b_1 and b_2 values together with their own b_3 and b_4 figures. The T_{12} and T_{23} correlated reasonably well, but the T_{34} was extremely high.

PREPARATION OF FREMY'S SALT, POTASSIUM NITROSODISULFONATE

R. P. Singh

This note describes an improved method for the preparation of a stable Fremy's salt, $K_2[ON(SO_3)_2]$, which has been used as an analytical tool for estimating free phenolic hydroxyl groups in isolated lignin (1) and also in lignins present in groundwood pulp (2, 3). The usual methods (4–10) for its preparation consisted essentially in preparing the sodium or potassium salts of hydroxylamine disulfonic acid followed by oxidation with either lead oxide, silver oxide, or potassium permanganate. Fremy's salt prepared from this material is known to be unstable, and the degree of instability has often been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

According to Bjerrum (5), log T is proportional to e_1e_2, where e_1 and e_2 are the ionic charges on the ligands. Hence, $P_{ut} = b_u:b_t(\text{calcd.}) = 6/5 \times 1.6^2 = 3.1$, whereas the observed ratio is 2.7.

Stepwise stability constants for three stages of Fe^{3+}—Cl^- association have been reported by Rabinowitch and Stockmayer (6) and Olerup (7). The $b_1:b_2$ values (3.2 and 2.9) are in agreement with Lister and Rivington's (3). The P_{23}(obs.) values of the two investigations differ, however. Rabinowitch and Stockmayer (6) report a P_{23} value = 32 and Olerup (7) reports a value of 2.3. If the 1:3 chloride complex is octahedral, $P_{23}(\text{calcd.}) = 3/2 \times 5/4 \times 1.6 = 2.8$, a value in agreement with Olerup's determination. If Rabinowitch and Stockmayer's (6) P_{23}(obs.) value is indicative of a change in coordination from 6 to 4 in the second association stage, then P_{12}(obs.) would be considerably smaller than calculated; and yet the observed and calculated P_{12} values are in good agreement. Olerup's P_{23}(obs.) value would therefore seem to be the better.

It would appear from our treatment that the complexes $FeCl_2^+$, $FeSCNCl_2$, and $FeSO_4.HSO_4$ are octahedral. Olerup's (7) P_{23}(obs.) value suggests that $FeCl_3$ is also octahedral. It is likely that the transition from six- to four-coordination occurs in either the third or fourth association stage, probably the fourth.

It is of interest to note that Gamlen and Jordan (8) concluded from a comparison of P_{12}, P_{23}, and P_{34} values that the structural change occurred in the fourth chloride association stage. These workers used Rabinowitch and Stockmayer's (6) b_1 and b_2 values together with their own b_3 and b_4 figures. The T_{12} and T_{23} correlated reasonably well, but the T_{34} was extremely high.

PREPARATION OF FREMY'S SALT, POTASSIUM NITROSODISULFONATE

R. P. Singh

This note describes an improved method for the preparation of a stable Fremy's salt, $K_2[ON(SO_3)_2]$, which has been used as an analytical tool for estimating free phenolic hydroxyl groups in isolated lignin (1) and also in lignins present in groundwood pulp (2, 3). The usual methods (4–10) for its preparation consisted essentially in preparing the sodium or potassium salts of hydroxylamine disulfonic acid followed by oxidation with either lead oxide, silver oxide, or potassium permanganate. Fremy's salt prepared from this material is known to be unstable, and the degree of instability has often been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

attributed to the method of preparation, to the pH of solution, and also to the presence of other ions, particularly manganese and chloride, in solution (6).

A method claiming a pure product in high yield was patented by Teuber (8) and we have found in our laboratory that certain modifications of Teuber's process produce a more stable product. Teuber's process involves

(*a*) reaction of sodium nitrite, acetic acid, and sodium bisulfite to form hydroxylamine disulfonate, $HON(SO_3Na)_2$,

(*b*) oxidative dehydrogenation of the product in *a* with potassium permanganate in the presence of ammonia,

(*c*) separation of the reduction product, manganese dioxide, from the salt solution by repeated filtration, and

(*d*) crystallization of potassium nitrosodisulfonate, $ON(SO_3K)_2$, by addition of the filtrate to a saturated solution of potassium chloride, and separation of the crystals by filtration.

Laboratory experiments showed that severe decomposition can occur during steps $a \rightarrow d$. The following modifications were introduced which resulted in marked improvement in yields and reproducibility; (i) hydroxylamine disulfonate in step *a* was prepared from sodium nitrite, sodium bicarbonate, and sulfur dioxide; (ii) the decomposition in step *b* was minimized by maintaining better pH control; (iii) separation of manganese dioxide by centrifugation before filtration in step *c* largely prevented decomposition and resulted in higher yield of the product; (iv) the final product in step *d* was collected by centrifugation and rapidly treated with potassium hydroxide. This again prevented decomposition in the final stage of preparation and resulted in simplicity of operation.

The solid salt has a yellow-orange color and gives purple solutions, which can easily be analyzed colorimetrically, since their absorptions in the 545 mμ region are directly proportional to their concentrations as measured both by weighing of the orange dimeric solid and by iodine–thiosulfate titration. Solutions in which some decomposition has occurred can still be estimated colorimetrically, though not titrimetrically, since hydrolysis products then interfere. Spectrometric analysis of the salt, obtained by the above method, showed the following traces of impurities.

Element	Percentage Limit
Mn	0.0005
Ba	0.0005
Fe	0.002
Pb	0.001
Si	0.001
Al	0.001
Ca	0.01
Mg	0.0005
Cu	0.001

The product thus obtained could be stored in the cold for several months without decomposition.

EXPERIMENTAL*

Potassium Nitrosodisulfonate

In a 2 l beaker containing distilled water (250 ml) and crushed ice (500 g) were placed 39.6 g of sodium bicarbonate and 33.0 g of sodium nitrite. The mixture was thoroughly mixed with a mechanical stirrer and was externally cooled to −5° by a freezing mixture of salt and ice. Sulfur dioxide was then passed in rapidly, and the temperature of the solution was controlled at −5° to −2°. When the pH of the mixture fell to 2 (approx. 30 min) and the color changed to orange brown, the passage of sulfur dioxide was immediately stopped. The mixture was stirred for an additional 10 min, during which time it became colorless.

**Reagent grade chemicals were used in the entire experiment.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Clean filtered air was then bubbled though the solution for 5 min and the pH of the solution was adjusted to 10.1 with 18% ammonium hydroxide (approx. 10 ml). The solution was stirred at −2° for 30 min and 380 ml of 1 *N* potassium permanganate cooled at −3° was then added to it portion-wise at a rate which did not allow the temperature to rise above 5°. The contents were stirred for 1 h and then allowed to stand at the same temperature. The dark-brown slurry was centrifuged at 1 950 rpm for 5 min and the supernatant violet liquid was passed through a filter paper into a saturated solution of potassium chloride (250 g in 700 ml water at 30°). On cooling, the solution yielded an orange crystalline precipitate which was collected by centrifugation. The material was recrystallized from 1 *N* potassium hydroxide, washed with pure methanol until free from alkali, and stored in vacuum over P_2O_5 in a cold room. The yield of the product was 77.6%, based on sodium bicarbonate.

Anal. Calcd. for $K_2NS_2O_7$: S, 23.90; K, 29.14. Found: S, 23.90; K, 29.38.

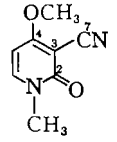
THE ROLE OF β-ALANINE AND OF GLYCERATE IN THE BIOSYNTHESIS OF RICININE[1]

P. R. THOMAS,[2] M. F. BARNES,[2] AND LÉO MARION[3]

Division of Pure Chemistry, National Research Council, Ottawa, Canada



Received September 17, 1965

ABSTRACT

β-Alanine-2-^{14}C has been fed to young *Ricinus communis* L. plants and the radioactive ricinine isolated. The activity of each carbon in the alkaloid molecule was determined. Propionate-2-^{14}C was also fed to young *Ricinus* plants and the radioactivity on carbons 2 and 3 of the isolated ricinine was determined. The pattern of labelling produced by β-alanine-2-^{14}C was very similar to that produced by propionate-2-^{14}C, but was quite distinct from that produced when succinate-2,3-^{14}C or acetate-2-^{14}C was fed to the plant. Whereas with the latter, carbons 2 and 3 of the pyridone ring of ricinine are approximately equally labelled, the ricinine obtained after propionate-2-^{14}C or β-alanine-2-^{14}C was fed contains on carbon 3 almost twice the activity contained on carbon 2.

It has been found that acetate-2-^{14}C is not incorporated into carbon 6 of ricinine. It has also been established that (±)-glycerate-1-^{14}C is incorporated into ricinine only negligibly (0.12%), whereas labelled glycerol is incorporated to the extent of 2.7–3.9%. Glycerate-3-^{14}C, however, is known to be incorporated into the pyridine ring of nicotine; therefore, glyceric acid must undergo decarboxylation before incorporation.

It has been established (1) by feeding experiments with succinate-2,3-^{14}C and acetate-2-^{14}C that these two acids are precursors of carbons 2, 3, and 7 of the alkaloid ricinine (I).

I

More recently it has been found that aspartate is also a precursor of the same three carbons of ricinine, but that it is deaminated and, like succinate and acetate, goes through the Krebs cycle before incorporation (2). Feeding experiments with aspartic acid-^{15}N have shown that the ring nitrogen and the cyano group both carry the same ^{15}N abundance, and consequently that the nitrogen of the aspartic acid must have been split off and become equilibrated with the nitrogen pool before incorporation (2).[4]

[1]*Issued as N.R.C. No. 9068.*

[2]*National Research Council of Canada Postdoctorate Fellow.*

[3]*Present address: Faculty of Pure and Applied Science, University of Ottawa, Ottawa, Canada.*

[4]*Yang and Waller (Phytochemistry, 4, 881 (1965)) have fed aspartate-4-^{14}C,^{15}N to Ricinus plants and observed that the incorporation of ^{14}C into the nitrile group and that of ^{15}N into the pyridone ring were approximately in the ratio of 1:1. From this result they concluded that the ^{14}C and ^{15}N of aspartate were directly incorporated into ricinine. Johns and Marion (2) have found the very same excess of ^{15}N in both the pyridone nitrogen and the nitrile. Were the aspartate incorporated as a unit, it is highly improbable that the nitrile nitrogen could have shown the same ^{15}N abundance as the pyridone nitrogen.*

It was of interest to find out whether the simpler amino acids could also act as precursors of ricinine, and if so, which carbons did they contribute. According to Anwar *et al.* (3) propionate-2-^{14}C was incorporated into ricinine to a larger extent than acetate-2-^{14}C and 25% of the activity of the ricinine was located in the nitrile group, but they did not determine the distribution of the remaining 75% of the activity. The incorporation of activity into the nitrile group, however, is of the same order of magnitude as that observed after acetate-2-^{14}C was fed. It appeared probable, therefore, that β-alanine, which is present in some naturally occurring peptides, could also be a precursor of the alkaloid.

β-Alanine-2-^{14}C was fed by the usual procedure (1) to *Ricinus communis* L. seedlings, and the ricinine was isolated from the plant 3 days after the feeding. The radioactivity of the isolated alkaloid showed an incorporation of 1.4% of the β-alanine-2-^{14}C fed to the plants. The ricinine was degraded by the procedures described previously (1, 4) to isolate each carbon in the molecule and determine the location of the activity in the alkaloid. The results are given in Table I.

TABLE I

Distribution of activity in ricinine

Identity of carbon atom	Isolated as	Activity of $BaCO_3$ from isolated compound (d.p.m./mg)	Percentage of activity of ricinine
2	$C_6H_5{}^{14}CO_2H$	37.2	25.6
3	$Br_3{}^{14}CNO_2$	394	39.5
4	$C_6H_5{}^{14}CO_2H$	3.3	2.1
5	$Br_3{}^{14}CNO_2$	9.6	1.0
6	$C_8H_{11}O_2{}^{14}CH_2C_8H_{11}O_2$	0.9	2.2
7	See text	398*	20.9
N—CH_3	$^{14}CH_3Me_3N^{\oplus}I^{\ominus}$	3.5	1.4
O—CH_3	$^{14}CH_3Me_3N^{\oplus}I^{\ominus}$	3.4	1.4
			Total 94.1

*Activity of decyanoricinine.

For purposes of comparison, propionate-2-^{14}C was also fed to *Ricinus communis* L. seedlings, and the ricinine isolated 3 days after the feeding. The radioactivity of the alkaloid corresponded to an incorporation of 1.3% of the propionate fed, and the activity on carbon 2 was found to be 21.0% of the total activity of the ricinine, whereas that on carbon 3 was 39.8%. As shown in Table I, the feeding of β-alanine-2-^{14}C produces ricinine that contains 25.6% of its activity on carbon 2 and 39.5% on carbon 3. Both propionate and β-alanine therefore produce about the same labelling pattern, which is also in agreement with the pattern of incorporation of β-alanine-2-^{14}C into nicotine, in which approximately 25% of the total activity is found on carbon 2 and approximately 50% on carbon 3 (5).

It is known that acetate-2-^{14}C and succinate-2,3-^{14}C, when fed to *Ricinus* plants, both go through the Krebs cycle before incorporation into the alkaloid, and give rise to a four-carbon dicarboxylic acid in which the radioactivity on carbons 2 and 3 is equilibrated. Hence, the pyridone ring of the ricinine produced in these feeding experiments is always labelled essentially equally on carbons 2 and 3 (1, 4). The same holds true when acetate-2-^{14}C and succinate-2,3-^{14}C act as precursors of nicotine (6) and anabasine (7), and carbons 2 and 3 of the pyridine nucleus of both these alkaloids are also equally labelled.

The labelling pattern produced by both propionate and β-alanine is therefore quite different from that obtained with either acetate or succinate feeding, and it seems that

435706

neither propionate nor β-alanine can be converted into a four-carbon dicarboxylic acid before incorporation.

Within experimental error (eight different determinations are involved), the activities reported in Table I account for all the activity (94.1%) of the ricinine molecule. The percentages of activity located on carbons 4, 5, and 6 and on the two methyl groups are low, and the significant labelling involved carbons 2 and 3 together with the nitrile carbon.

Whether β-alanine is present in the normal *Ricinus* plant does not seem to be known. There is, however, no doubt that β-alanine, when fed to the plant, acts as a precursor of ricinine. The fact that the labelling pattern it produces is so different from that produced by acetate indicates that the biosynthetic pathway through which it is incorporated into ricinine must be very distinct from that involving acetate.

That more than one amino acid present in the normal plant can contribute to the biosynthesis of the same fragment of an alkaloid molecule may account, at least in part, for the fact that the observed incorporation into the alkaloid of a radioactive precursor fed to the plant is always rather low. It seems to suggest that there may be no single synthetic pathway to an alkaloid, but rather several simultaneous pathways from different precursors.

The feeding of acetate-2-^{14}C to *Ricinus* plants has been studied previously (1, 4) and the distribution of radioactivity in the ricinine molecule was determined for all carbons except carbon 6. Although the sums of the activities on carbons 2, 3, 4, 5, and 7 and on the two methyl groups accounted for 99.6% of the total activity, the experimental error inherent in the methods of determination made it possible for some small percentage of activity to be present at carbon 6. A sample of ricinine isolated from *Ricinus* plants fed acetate-2-^{14}C was therefore degraded so as to isolate carbon 6 (2, 4). The results showed that no measurable activity was present at carbon 6, whereas the feeding of β-alanine-2-^{14}C to the plant resulted in the incorporation of 2.4% of the total activity of the isolated ricinine at carbon 6. Hence it can be stated that acetate is a precursor of carbons 2, 3, and 7 of ricinine, but not of the remaining carbons.

Experiments involving the feeding of labelled glycerol to *Ricinus* plants have been reported previously (4). It was observed that glycerol-1-^{14}C gave rise to ricinine labelled at both carbon 4 and carbon 6, whereas glycerol-2-^{14}C produced radioactive ricinine (2.7% incorporation) labelled at carbon 5 (38.8% of the total activity) but not at carbon 4 or carbon 6. The total incorporation of radioactivity into ricinine, however, was appreciably lower than had been obtained with succinate or acetate, and it was assumed that glycerol may not be a direct precursor of carbons 4, 5, and 6, but is likely converted into an intermediate before incorporation. This assumption is supported by the fact that, with both glycerol-1-^{14}C and glycerol-2-^{14}C, labelling of the methyl groups occurs to the extent of 26–35% of the total activity of the ricinine (8) and therefore indicates appreciable breakdown of the molecule.

Leete and Friedman (9), who fed glycerol-2-^{14}C to *Nicotiana glauca*, observed that the anabasine produced by the plant was radioactive (0.36% incorporation) and that 38% of the radioactivity was present in the pyridine ring. The activity on carbon 5 of the pyridine ring, however, was 31.6% of the activity in that ring, and was therefore comparable with that observed with ricinine (38.8%) at the analogous position (4).

In the hope of obtaining a more selective labelling pattern, or an incorporation involving less preliminary breakdown of the precursor, glyceric acid-1-^{14}C, which is related to glycerol but is unsymmetrical, was fed to *Ricinus* plants. The incorporation of radioactivity, however, was only 0.12%. This low incorporation indicates that the carboxylic group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

containing the radioactive carbon was mostly lost as carbon dioxide, probably through pyruvate as an intermediate stage. Griffith and Byerrum (10), who fed glycerate-3-^{14}C to tobacco plants, found a greater incorporation of ^{14}C than when acetate-2-^{14}C was fed, and that 48% of the activity of the isolated nicotine was located in the pyridine ring. They assumed that glycerate was first converted into acetate before incorporation. The low incorporation of glycerate-1-^{14}C into ricinine would tend to support this assumption, although Griffith and Byerrum (10) did not report as supporting evidence the location of the activity around the pyridine ring of nicotine. At any rate, glycerate does not act like glycerol in the biosynthesis of ricinine.

EXPERIMENTAL

All samples were ignited and the carbon dioxide evolved was converted into barium carbonate. The radioactivity was counted on thin layers of barium carbonate on aluminium planchets in a Baird-Atomic end-window proportional counter, and corrections were made for efficiency, background count, and sample self-absorption. β-Alanine-2-^{14}C was supplied by Volk Radiochemical Co., and glyceric acid-1-^{14}C and acetate-2-^{14}C by Merck Sharp & Dohme of Canada Limited.

Growth of Ricinus Plants and Administration of Tracers

Seeds of *Ricinus communis* L. were planted at a depth of ca. 1.3 cm in vermiculite which was kept moist by daily watering. The germinating plants were kept at a temperature of 25° in daytime and 21° during the night. They were fed at the same stage of growth and in the same manner as reported previously (1). β-Alanine-2-^{14}C (9.9 mg, total activity 2.22×10^8 d.p.m.) was fed to 67 plants. Glyceric acid-1-^{14}C (supplied in aqueous solution, about 1 ml, by Merck Sharp & Dohme of Canada Limited; total activity 2.22×10^8 d.p.m.) was fed to 39 plants. Acetate-2-^{14}C (5.8 mg, total activity 2.22×10^8 d.p.m.) was fed to 37 plants. Sodium propionate-2-^{14}C (total activity 2.22×10^8 d.p.m.) was also fed to a number of germinating plants.

Isolation of Ricinine

The isolation of ricinine from the plant and its purification were carried out as described previously (1, 2). From the plants that had been fed β-alanine-2-^{14}C, ricinine (731 mg) was isolated. A sample of this ricinine was ignited and the resulting carbon dioxide was converted into barium carbonate. This salt had an activity of 432 d.p.m./mg, which represents an incorporation of 1.37%. The ricinine (275 mg) isolated from the plants that had been fed glyceric acid-1-^{14}C had an activity of 104 d.p.m./mg of barium carbonate derived from it, corresponding to an incorporation of 0.124%. In accordance with previous results (1), acetate-2-^{14}C was incorporated to the extent of 6%. The ricinine (146 mg) isolated from the plants that had been fed propionate-2-^{14}C had a specific activity of 3.41×10^3 d.p.m./mg, which corresponds to an incorporation of 1.3%.

Ricinine Degradation

All degradations were carried out as reported previously (1, 2), except that tribromonitromethane (bromopicrin), corresponding to carbons 3 and 5, was extracted with ether from its aqueous mixture rather than separating it by centrifugation.

In the degradation of ricinine obtained in the acetate-2-^{14}C feeding experiment, the active ricinine was diluted with inactive ricinine by a factor of approximately 13, thus producing a base with an activity of 151 d.p.m./mg of barium carbonate. Carbon 6 of the alkaloid was isolated as formaldehyde dimedone (4), which gave inactive barium carbonate.

The results of the degradations of ricinine obtained from the plants fed β-alanine-2-^{14}C are given in Table I. For the degradations leading to the isolation of each carbon atom except carbons 6 and 7, diluted ricinine producing barium carbonate with an activity of 124 d.p.m./mg was used. For carbon 6, diluted ricinine producing barium carbonate with an activity of 86.5 d.p.m./mg was used. For the determination of carbon 7, a small sample of undiluted ricinine was hydrolyzed and decarboxylated to decyanoricinine (4-methoxy-*N*-methyl-2-pyridone), which produced barium carbonate with an activity of 398 d.p.m./mg. The percentage of activity at carbon 7 was then obtained by difference.

The ricinine isolated from plants that had been fed propionate-2-^{14}C was divided into two portions. One of the portions, after dilution with inactive ricinine, had a specific activity of 8.21 d.p.m./mg of barium carbonate. Its degradation for the isolation of carbon 2 yielded benzoic acid with a specific activity of 1.97 d.p.m./mg of barium carbonate, equivalent to 21% of the total activity.

The second portion of the ricinine obtained from the propionate experiments, after dilution with inactive alkaloid, had a specific activity of 161 d.p.m./mg of barium carbonate. Its degradation for the isolation of carbon 3 produced bromopicrin having a specific activity of 512 d.p.m./mg of barium carbonate, equivalent to 39.8% of the activity of the alkaloid.

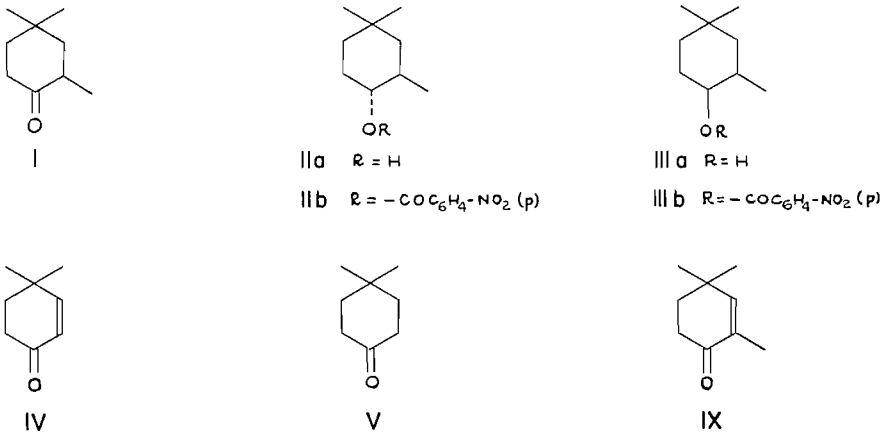
ÉTUDES SUR LA TRIMÉTHYL-2,4,4 CYCLOHEXANONE ET SES PRODUITS DE RÉDUCTION[1]

JEAN-CLAUDE RICHER ET DAVID PERELMAN
Département de Chimie, Université de Montréal, Montréal, Québec



Reçu le 15 mars 1966

RÉSUMÉ

De nouvelles synthèses de la triméthyl-2,4,4 cyclohexanone sont rapportées. La configuration de chacun des produits de réduction de cette cétone est attribuée grâce à leur mode de formation, leur spectre infra-rouge et de résonance magnétique nucléaire et leur vitesse relative d'oxydation chromique.

INTRODUCTION

Dans les cadres d'une étude connexe, il était important pour nous d'avoir une méthode simple de préparer la triméthyl-2,4,4 cyclohexanone (I) et de connaître d'une façon bien définie la stéréochimie des alcools II*a* et III*a* dérivant de cette cétone. Au moment où le présent travail a été entrepris, plusieurs synthèses de la cétone I étaient connues (1–7);

il nous semblait toutefois intéressant d'appliquer d'une part à la diméthyl-4,4 cyclohexen-2 one (IV), et d'autre part à la diméthyl-4,4 cyclohexanone (V), les méthodes, mises au point respectivement par Burn et Petrow (8) et par Ireland et Marshll (9), pour la synthèse des méthyl-2 cyclanones. Ces méthodes sont schématisées dans le Schéma Réactionnel 1. Les résultats obtenus sont rapportés dans la présente publication. De plus, la configuration relative de chacun des alcools II*a* et III*a* est établie d'une manière définitive.

RÉSULTATS

1. Synthèses de la triméthyl-2,4,4 cyclohexanone

1.1. Synthèse par l'intermédiaire des éthers VII a et VII b

La condensation du *p*-thiocrésol (VI*a*) et de la formaldehyde sur la diméthyl-4,4 cyclohexen-2 one (IV) en présence de triéthylamine, suivant les indications de Burn et Petrow (8), conduit au dérivé attendu (VII*a*) avec un rendement de 72%. Les spectres

SCHÉMA RÉACTIONNEL 1.

infra-rouges et ultraviolets de ce produit sont conformes à la structure désignée et s'accordent avec les données des auteurs. La dinitro-2,4 phénylhydrazone dérivée de VII*a* fond à 139 °C. Le spectre de résonance magnétique nucléaire de ce dérivé confirme la structure proposée.

Utilisant les conditions expérimentales de Burn et Petrow (8), l'éther VII*a* a été désulfurisé en présence de nickel de Raney modifié par l'acétone. L'analyse par chromatographie en phase gazeuse, sur le produit distillé, révèle la présence de la triméthyl-2,4,4 cyclohexanone (I) (7.6%), de la triméthyl-2,4,4 cyclohexen-2 one (IX) (83.6%), et des triméthyl-2,4,4 cyclohexanols (II*a* et III*a*) (3.4%). Il s'avérait intéressant d'examiner la possibilité de poursuivre cette réaction au-delà de la désulfurisation initiale; à cette fin une série de réaction fut entreprise dans laquelle la proportion de nickel de Raney par rapport à l'éther VII*a* a été successivement augmentée. Les résultats de ces réactions, rapportés dans le Tableau I, montrent que la désulfurisation peut être amenée à produire en prépondérance soit les triméthyl-2 4,4 cyclohexanols (II*a* et III*a*) soit la triméthyl-2,4,4 cyclohexen-2 one (IX). Les cétones I et IX présentes dans les produits de désulfurisation peuvent être séparées de leurs contaminants par l'intermédiaire de leur semicarbazone; l'hydrogénation, en présence du palladium sur carbonate de calcium, du mélange des cétones récupérées conduit à la triméthyl-2,4,4 cyclohexanone (I) pure.

TABLEAU I

Désulfurisations de l'éther VII*a*

Poids de VII*a* (g)	Poids de catalyseur (g)	Produits obtenus* (%)					
		Non-identifié	I	Non-identifié	IX	III*a*	II*a*
3	26	7.2	1.8	—	—	37.3	53.7
3	17.5	8.5	33.7	—	—	24.6	33.1
3	12	3.4	39.7	11.3	42.8	—	2.8
3	6.6	0.4	12.8	6.8	75.9	2.6	1.7
49.4 (3)	108 (6.5)	1.0	20.0	7.7	65.8	3.8	1.7

*Les résultats rapportés ici ont été déterminés par chromatographie en phase gazeuse, en mesurant les surfaces sous les pics à l'aide d'un planimètre.

De la même manière, la condensation de la diméthyl-4,4 cyclohexen-2 one (IV) avec la formaldéhyde et le thiophénol en présence de triéthylamine fournit l'éther VII*b* avec un rendement de 70%. Le spectre infra-rouge du produit distillé montre les bandes attendues; la dinitro-2,4 phénylhydrazone de cet éther fond à 143.5 °C et le spectre de résonance magnétique nucléaire de ce dernier dérivé est conforme à la structure proposée. La désulfurisation de l'éther en présence d'un excès de nickel de Raney non-modifié conduit à un mélange où l'on retrouve la cétone saturée I (7.5%) et les triméthyl-2,4,4 cyclohexanols *cis* (III*a*) (24.2%) et *trans* (II*a*) (68.3%).

Afin de vérifier si une polysubstitution se produit au cours de la réaction de Burn et Petrow, une désulfurisation a été effectuée sur l'éther VII*b* brut non-distillé; la chromatographie en phase gazeuse des produits obtenus n'indique la présence que des alcools II*a* et III*a*, qui ne sont pas contaminés par des alcools polyméthylés. L'absence de composés tétra- et penta-méthylés montre clairement que la phénylthiométhylation procède seulement sur le carbone éthylénique en position 2 de la diméthyl-4,4 cyclohexen-2 one (IV).

1.2. Synthèse par l'intermédiaire de la butylthiométhylène-2 diméthyl-4,4 cyclohexanone (VIIIb)

L'action du butanethiol sur la formyl-2 diméthyl-4,4 cyclohexanone (VIII*a*) fournit l'éther énolique VIII*b*; les données spectrales (infra-rouge, ultraviolet et résonance magnétique nucléaire) de cet éther sont conformes à la structure proposée. La désulfurisation effectuée selon les indications d'Ireland et Marshall (9) conduit à un produit qui, après distillation, montre par chromatographie en phase gazeuse la présence de trois composés, à savoir la cétone saturée I (8.2%) et les triméthyl-2,4,4 cyclohexanols *cis* (III*a*) (40.7%) et *trans* (II*a*) (51.1%). Ce résultat est inattendu car les auteurs (9) ne signalent aucune formation d'alcool lors de la désulfurisation. Le mélange obtenu est oxydé par la méthode de Brown (10) et conduit à la triméthyl-2,4,4 cyclohexanone (I) pure.

Pour fins de comparaison les cétones saturée (I) et non-saturée (IX) ont été préparées à partir de l'isobutyraldéhyde et de la pentènone-3 en suivant les indications de Yanagita (4). Nous avions ainsi à l'aide des méthodes énumérées plus haut des sources d'accès simples pour obtenir la triméthyl-2,4,4 cyclohexanone (I) et ses alcools (II*a* et III*a*).

2. Propriétés des alcools épimères

La réduction des cétones cyclohexaniques par le sodium dans l'éthanol est la méthode généralement utilisée pour la synthèse des alcools équatoriaux (11). Ce procédé a été appliqué pour la préparation du triméthyl-2,4,4 cyclohexanol *trans* (II*a*). L'analyse chromatographique du produit de la réduction indique la présence de la cétone saturée I (7%) qui n'a pas réagi et des triméthyl-2,4,4 cyclohexanols *cis* (III*a*) (1%) et *trans* (II*a*) (92%). L'alcool *trans* (II*a*) est purifié par l'intermédiaire de son *p*-nitrobenzoate (II*b*), recristallisé jusqu'à point de fusion constant de 66–67 °C. Le composé isolé après saponification de ce dérivé est chromatrographiquement pur.

L'hydrogénation en milieu acide en présence d'oxyde de platine (12) a été utilisée pour la préparation du triméthyl-2,4,4 cyclohexanol *cis* (III*a*). L'alcool obtenu après saponification des acétates est contaminé par 2% de son épimère (II*a*). Ces résultats confirment la proposition de Barton (11), selon laquelle l'hydrogénation en milieu acide fournit principalement un alcool axial. Le triméthyl-2,4,4 cyclohexanol *cis* (III*a*) est isolé à l'état pur après saponification de son *p*-nitrobenzoate, recristallisé jusqu'à point de fusion constant de 82.5–83.5 °C.

Les propriétés des alcools épimères ainsi obtenus sont résumées dans le Tableau II.

Ces résultats présentent plusieurs particularités intéressantes. Selon la règle d'Auwers–Skita, les constantes physiques seraient plus élevées pour l'alcool *cis* que pour l'alcool *trans*. Les indices de réfraction suivent cette règle mais les points d'ébullition montrent la tendance inverse. Cette exception n'est pas unique; en effet, Eliel (13) a rapporté que la règle ne s'applique pas aux alkylcyclohexanols. Deuxièmement, les alcools équatoriaux montrent l'absorption typique dans l'infra-rouge à des fréquences plus élevées que celles des alcools axiaux (14). De plus, les spectres de résonance magnétique nucléaire des alcools II*a* et III*a* sont typiques (15) tant par la forme que par la position des bandes pour des cyclohexanols équatoriaux et axiaux. Les vitesses relatives d'oxydation chromique sont conformes à la théorie de la décompression stérique proposée par Schreiber et Eschenmoser (16), selon laquelle un alcool axial est oxydé plus rapidement que son isomère équatorial. La différence d'énergie libre entre les alcools II*a* et III*a*, telle qu'évaluée à l'aide de leur vitesse d'oxydation et de l'équation proposée par Sipos *et al.* (17), serait de 0.83 kcal/mole.

TABLEAU II

Propriétés physiques des triméthyl-2,4,4 cyclohexanols

Propriétés	*trans* (II*a*)	*cis* (III*a*)
η_D^{22}	1.4567	1.4600
Point d'ébullition	88–89 °C à 20 mm Hg	81–82 °C à 20 mm Hg
Spectres infra-rouges (C—O)	1 050 cm^{-1}	1 018 cm^{-1}
Déplacements chimiques (δ) des hydrogènes carbinoliques	2.98 (bande large)	3.70 (bande étroite)
Vitesses d'oxydation chromiques* ($10^3\ k_2$)	87.2 l $mole^{-1}\ s^{-1}$	384 l $mole^{-1}\ s^{-1}$

*Mesures effectuées par C. Gilardeau.

A l'aide de ces considérations, il est maintenant possible d'attribuer d'une façon définitive les configurations II*a* et III*a* aux alcools dérivant de la triméthyl-2,4,4 cyclohexanone. Ces conclusions permettent de lever l'ambiguité causée par la communication de Yanagita (4), dans laquelle est rapportée la préparation d'un triméthyl-2,4,4 cyclohexanol donnant un *p*-nitrobenzoate de p.f. 61–63 °C. Les auteurs proposaient dans la partie théorique (réf. 4, p. 1724) une configuration *trans* alors que dans la partie expérimentale (réf. 4, p. 1729) ils décrivaient le triméthyl-2,4,4 cyclohexanol *cis*.

PARTIE EXPÉRIMENTALE

Les spectres infra-rouges ont été déterminés sur un spectrophotomètre Beckman modèle IR-8 à double réseau. Les analyses par chromatographie en phase gazeuse ont été effectuées à 125 °C sur un appareil Kromo-Tog modèle K-2 de la compagnie Burrell à l'aide d'une colonne contenant 10% d'Hyprose adsorbé sur Chromosorb P. Les spectres de résonance magnétique nucléaire ont été pris sur un spectromètre modèle A-60 de la compagnie Varian. Le tetraméthylsilane est utilisé comme référence interne. Les points de fusion ont été pris sur un "Hot Stage Apparatus" de la compagnie Reichert (Autriche). Les analyses élémentaires ont été effectuées par le Docteur Claude Daesslé à Montréal.

*1. Dérivé p-tolylthiométhyl-2 diméthyl-4,4 cyclohexanone (VII*a*)*

Selon la méthode de Burn et Petrow (8), un mélange de 50.6 g (0.40 mole) de diméthyl-4,4 cyclohexen-2 one (IV), 74.2 g (0.60 mole) de *p*-thiocrésol, 50 g (0.65 mole) de formaldéhyde 37%, 60 g (0.57 mole) de triéthylamine et 125 ml d'éthanol 95% est chauffé à reflux à 60 °C pendant 48 h. Après les extractions à la façon habituelle, 76.4 g (72% du rendement théorique) du dérivé attendu sont isolés, présentant les caractéristiques suivantes: p.é. 145 °C à 0.7 mm Hg; η_D^{22} 1.5769; infra-rouge: bande à 1 675 cm^{-1} (carbonyle cétonique α,β non-saturé); ultraviolet: λ_{max} dans l'éthanol à 228 (ϵ de 16 820) et 242 mμ (ϵ de 14 920) (litt. (8) λ_{max} à 225 (ϵ de 11 390) et 254.5 mμ (ϵ de 14 300)); la dinitro-2,4 phénylhydrazone de cet éther fond à 139 °C après cristallisation d'un mélange éthanol–chloroforme.

Anal. Calc. pour $C_{23}H_{24}N_4O_4S$: C, 59.98; H, 5.49; N, 12.72; S, 7.25. Trouvé: C, 59.92; H, 5.71; N, 12.87; S, 7.47.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Le spectre de résonance magnétique nucléaire de ce dérivé montre des bandes à 1.03 (singulet, six hydrogènes des groupes méthyles), 1.71 (triplet, deux hydrogènes en position 5), 2.33 (singulet, trois hydrogènes du groupe méthyle du *p*-thiocrésol), 2.65 (triplet, deux hydrogènes en position 6), 3. 81 (singulet, deux hydrogènes du groupe CH_2S), 5.88 (singulet, hydrogène vinylique) et 7.16 p.p.m. (quatre hyrogènes aromatiques).

2. Dérivé phénylthiométhyl-2 diméthyl-4,4 cyclohexanone (VIIb)

Ce dérivé a été préparé à partir de 7.5 g (0.06 mole) de diméthyl-4,4 cyclohexen-2 one (IV), 6.5 g (0.06 mole) de thiophénol, 7.5 g de formaldéhyde 37% et 10 g de triéthylamine dissous dans 50 ml d'éthanol 95%. Après un chauffage à 56 °C pendant 26 h, 10.3 g (70% du rendement théorique) de produit ont été isolés. Le produit obtenu après distillation présente les caractéristiques suivantes: η_D^{22} 1.5802; p.é. 140 °C à 0.9 mm Hg; la dinitro-2,4 phénylhydrazone, plaques oranges fondant à 143.5 °C.

Anal. Calc. pour $C_{21}H_{22}N_4O_4S$: C, 59.14; H, 5.20; N, 13.14; S, 7.48. Trouvé: C, 58.71; H, 5.30; N, 13.36; S, 7.39.

Le spectre de résonance magnétique nucléaire de ce dérivé montre une bande à 1.03 (singulet, six hydrogènes des groupes méthyles), 1.70 (triplet, deux hydrogènes en position 5), 2.61 (triplet, deux hydrogènes en position 6), 3.85 (singulet, deux hydrogènes du groupe CH_2S), 5.93 (singulet, hydrogène vinylique) et 7.30 p.p.m. (cinq hydrogènes aromatiques).

3. Dérivé butylthiométhylène-2 diméthyl-4,4 cyclohexanone (VIIIb)

Un mélange de formyl-2 diméthyl-4,4 cyclohexanone (VIII*a*) (11.1 g), de butanethiol (12.3 g) et de benzène anhydre (80 ml) est chauffé à reflux sous atmosphère d'azote en présence d'acide *p*-toluène sulfonique (100 mg); l'eau formée est séparée par distillation azéotrope et recueillie dans un séparateur Dean–Stark. Le produit désiré (10.9 g, 68.1% du rendement théorique) est isolé selon les indications d'Ireland et Marshall (9). Un échantillon analytique présente les caractéristiques suivantes: η_D^{23} 1.5339; p.é. 122–124 °C à 1.5 mm Hg; infra-rouge: bande carbonyle α,β non-saturée à 1 660 cm^{-1}; ultraviolet: λ_{max} à 315 mμ (ϵ de 15 150) (litt. (9) λ_{max} à 313 mμ (ϵ de 18 000)); le spectre de résonance magnétique nucléaire montre des bandes à 2.93 (triplet, deux hydrogènes du groupe —SCH_2—) et à 7.60 p.p.m. (triplet, hydrogène vinylique).

Anal. Calc. pour $C_{13}H_{22}OS$: C, 68.99; H, 9.79; S, 14.14. Trouvé: C, 69.23; H, 9.75; S, 14.15.

REMERCIEMENTS

Les auteurs remercient le Conseil National de Recherches du Canada et le Ministère de l'Education du Québec pour l'aide financière apportée sous forme d'octroi de recherches (A-1295) et de bourse de perfectionnement (D. P.); la compagnie Pitt-Consol Chemical Library, Pennsylvania, pour le généreux échantillon de *p*-thiocrésol; et le Docteur Claude Gilardeau pour la détermination des vitesses d'oxydation chromique des triméthyl-2,4,4 cyclohexanols.

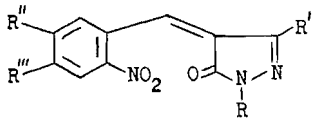
THE PREPARATION OF 9-HYDROXYPYRAZOLO[3,4-*b*]QUINOLINES

R. T. COUTTS AND J. B. EDWARDS
College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

Received March 28, 1966

ABSTRACT

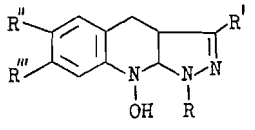
4-(2-Nitrobenzylidene)-2-pyrazolin-5-ones (I) were best prepared by heating *o*-nitrobenzaldehyde and 2-pyrazolin-5-ones in acetic anhydride containing fused sodium acetate (cf. Erlenmeyer azlactone synthesis). Pyrazolones of type I were reductively cyclized with cyclohexene and palladium–charcoal, and gave 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-1*H*-pyrazolo-[3,4-*b*]quinolines (II) which, as expected, were amphoteric compounds. Of the three other methods of reduction used in this study, two (zinc and acetic acid; sodium borohydride and palladium–charcoal) were capable of producing pyrazoloquinolines, but were less reliable. The other method employed (hydrazine hydrate and palladium–charcoal) caused degradation of the pyrazolone molecule in the two cases examined, and in both, bis(2-aminobenzylidene) hydrazine (V) was the reduction product isolated.



In our earlier studies (1–3) we investigated the reduction of aromatic nitro compounds which possessed an ester or an acid group in a position capable of undergoing cyclization, with a view to finding a system of reduction which would give cyclic compounds containing a *N*-hydroxy group. Such compounds were required for pharmacological evaluation.

We have now extended our studies to the reduction of aromatic systems which possess both a nitro group and a lactam carbonyl group in a position capable of undergoing cyclization, to see whether cyclic *N*-oxy or *N*-hydroxy compounds could conveniently be prepared in this way.

o-Nitrobenzaldehyde and its simple derivatives are known (4) to condense with 3-methyl-1-phenyl-2-pyrazolin-5-one to give 4-(*o*-nitrobenzylidene) derivatives. Preparations of 3-methyl-4-(*o*-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (I*a*) and its dimethoxy (I*b*) and methylenedioxy (I*c*) derivatives have been reported (4), and of these three compounds, only one (I*a*) yielded a reduced product (II*a*) which was the result of cyclization at the hydroxylamino stage of reduction.



Compounds having the general formula I were selected, therefore, for our initial investigation of reductive cyclizations involving an amide carbonyl group. Four methods of reduction were chosen, all of which were known to yield *N*-oxy or *N*-hydroxy compounds in certain instances. The four methods were as follows: sodium borohydride in the presence of palladium–charcoal (1–3); zinc and acetic acid (4); hydrazine hydrate and palladium–charcoal (5); and cyclohexene and palladium–charcoal (6).

Attempts by us to prepare I*a* and I*b* by the reported method (4) gave poor yields of products. Heating *o*-nitrobenzaldehyde and 3-methyl-1-phenyl-2-pyrazolin-5-one in ethanol containing a catalytic quantity of piperidine gave a slightly better yield of the

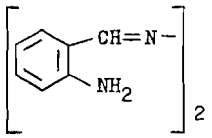
desired product (I*a*), though an appreciable yield of the bis compound, 4,4′-(*o*-nitrobenzylidene)bis(3-methyl-1-phenyl-2-pyrazolin-5-one) (III), was also isolated. 3-Methyl-4-(*o*-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (I*a*) was best prepared by heating *o*-nitrobenzaldehyde and the pyrazolone in acetic anhydride containing anhydrous sodium acetate. By the same method, the related *o*-nitrobenzylidene-pyrazolones (I*b*, I*d*, and I*e*) were also obtained. An attempt to prepare 3-methyl-4-(*o*-nitrobenzylidene)-2-pyrazolin-5-one (I*f*) by this method gave what appeared to be the *N*-acetyl derivative (I*g*). Compound I*f* was obtained by the alternative method of reacting the aldehyde with the pyrazolone in ethanol containing piperidine. An infrared spectrum of the product (I*f*) indicated the presence of hydroxyl and nitro groups and the absence of carbonyl absorption, which suggested that the compound existed in the lactim form (IV) in the solid state.



It has been reported (4) that the reduction of I*a* with zinc and acetic or hydrochloric acid, or with aluminium amalgam, gave 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-

III

IV

V

phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*a*), which was isolated as its yellow hydrochloride, m.p. 251–252°. Treatment of this hydrochloride with ammonia is said (4) to yield the base (II*a*), m.p. 142°, in excellent yield. The product obtained when we reduced I*a* with sodium borohydride and palladium–charcoal depended on the nature of the solvent used. When a mixture of methanol and ethanol was employed, a pale-yellow solid, m.p. 252–254°, slowly precipitated from the acidified filtrate. It analyzed correctly for $C_{17}H_{17}N_3O \cdot HCl$ and was identical with the compound prepared as described by the Indian workers (4). Using their method, we failed to liberate the base (II*a*), but found that it was more conveniently prepared from its hydrochloride by making use of the fact that II*a* is also an acid as well as a base. In agreement with its structure, it was readily soluble in aqueous sodium hydroxide or sodium carbonate. Addition of acetic acid to either solution precipitated II*a*; addition of hydrochloric acid, however, resulted in the precipitation of the sparingly soluble hydrochloride.

Reduction of I*a* with sodium borohydride and palladium–charcoal in dioxane gave only a small amount of II*a* hydrochloride. The main product was a colorless solid which was insoluble in both acidic and basic solutions. Reduction of the related chloro compound (I*d*) in dioxane with the same reducing system gave a similar neutral compound. Evidence from infrared studies indicates that the nitro group was reduced and the carbonyl group retained in both cases. As yet, these products remain unidentified.

The pyrazolone (I*a*) was then reduced with cyclohexene and palladium–charcoal, and the *N*-hydroxypyrazoloquinoline (II*a*) was the major product isolated. A colorless hydrochloride was formed on recrystallization of this product from methanol to which a few drops of hydrochloric acid had been added. Despite the difference in color, this hydrochloride was the same compound as that isolated by the Indian workers.

Reduction of I*a* with zinc and acetic acid containing acetic anhydride yielded the

O-acetyl derivative of II*a*. Such a structure was suggested by elemental analysis and by the insolubility of the product in sodium carbonate solution. Confirmation was obtained when the same compound was produced by acetylating II*a*.

When I*a* was reduced by means of hydrazine hydrate and palladium–charcoal, a pyrazoloquinoline was not obtained. Instead, bis(2-aminobenzylidene) hydrazine (V) was the product isolated. The same compound resulted when both 3-methyl-4-(*o*-nitrobenzylidene)-2-pyrazolin-5-one (I*f*) and *o*-nitrobenzaldehyde were similarly reduced, which indicated that cleavage of the molecule occurred with this treatment. This method of reduction, therefore, was not suitable for the preparation of *N*-hydroxy compounds.

Reduction of 4-(4,5-dimethoxy-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (I*b*) by means of zinc and acetic acid is reported (4) to yield 4-(2-amino-4,5-dimethoxybenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (I*b*, NH_2 replacing NO_2). When I*b* was reduced with sodium borohydride and palladium–charcoal in methanol, or by means of cyclohexene and palladium–charcoal, the amino compound was not obtained. As in the case of the reduction of I*a*, a *N*-hydroxypyrazoloquinoline, namely, 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-6,7-dimethoxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*b*), was isolated as its hydrochloride. Once again, it was converted into the free base by making use of the acidic properties of the *N*-hydroxy group.

It was found that the hydrochloride of II*b* had a variable melting point. Some samples melted at 211–212° whereas others melted as low as 195–197°. Except for very minor differences, the infrared spectra were identical and both samples analyzed correctly for $C_{19}H_{19}N_3O_3 \cdot HCl$.

The reduction of 4-(5-chloro-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (I*d*) followed the same pattern. Reduction by means of zinc and acetic acid, or by means of cyclohexene and palladium–charcoal, gave 6-chloro-3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*d*), which had the same solubility characteristics as II*a*. The reduction of 4-(*o*-nitrobenzylidene)-1,3-diphenyl-2-pyrazolin-5-one (I*e*) by means of cyclohexene and palladium–charcoal gave rise, on acidification, to the hydrochloride of 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-1,3-diphenyl-1*H*-pyrazolo[3,4-*b*]-quinoline (II*e*) which, on the basis of its elemental analysis, was isolated as the monohydrate. The base was readily obtained from the hydrochloride by the method described for the other pyrazoloquinolines. As expected, it was an amphoteric substance which was difficult to purify, and even after repeated reprecipitations and crystallizations it analyzed only indifferently for $C_{22}H_{19}N_3O$.

The insolubility of 4-(*o*-nitrobenzylidene)-3-methyl-2-pyrazolin-5-one (I*f*) in common solvents precluded its reduction.

The results of this investigation contrast with the findings of Narang *et al.* (4). All four pyrazolones (I*a*, I*b*, I*d*, and I*e*) reduced in this study gave cyclic *N*-hydroxy compounds, and in each case, the benzylidene double bond was also reduced. This study has also shown that only reduction with cyclohexene and palladium–charcoal consistently yielded 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-1*H*-pyrazolo[3,4-*b*]quinolines.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra (KBr disks) were recorded on a Beckmann IR.8 spectrophotometer except where stated otherwise. Palladium–charcoal refers to 10% palladium on charcoal.

Preparation of 3-Methyl-4-(o-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (Ia)

Method a

o-Nitrobenzaldehyde (6.0 g) and 3-methyl-1-phenyl-2-pyrazolin-5-one (7.0 g) were reacted by the reported (4) method. The title compound (3.82 g, 31%), m.p. 159–161°, was obtained as a red solid (lit. (4) m.p. 162°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Method b

o-Nitrobenzaldehyde (4.1 g) and 3-methyl-1-phenyl-2-pyrazolin-5-one (4.35 g) were dissolved in ethanol (50 ml) containing piperidine (0.5 ml), and the resulting solution was heated under reflux for ½ h. The title compound (1.44 g) separated as orange-red crystals, m.p. 162°. A further crop (1.08 g), m.p. 259–261°, was obtained by concentrating the mother liquors (total yield 34%). When the concentrate was allowed to stand, a pale-yellow second product (2.65 g), m.p. 203° (decomp.), separated. This was 4,4′-(*o*-nitrobenzylidene)-bis(3-methyl-1-phenyl-2-pyrazolin-5-one) (lit. (7) m.p. 203–205°).

Anal. Calcd. for $C_{27}H_{23}N_5O_4$: N, 14.55. Found: N, 14.48.

Method c

A mixture of *o*-nitrobenzaldehyde (6.7 g), 3-methyl-1-phenyl-2-pyrazolin-5-one (7.0 g), fused sodium acetate (3.8 g), and acetic anhydride (12 ml) was heated on a hot plate until a homogeneous red solution formed (15 min). When cooled, a dark-red solid formed. It was washed with water and cold ethanol, and then recrystallized from ethanol to give the title compound (8.31 g, 61%) as orange-red crystals, m.p. 160–162°.

Preparations of Pyrazolones Ib, Id, and Ie

Under the conditions described for the preparation of I*a* (method *c*), the following compounds were obtained in the yields stated.

4-(4,5-Dimethoxy-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (I*b*) (4.6 g, 40%), m.p. 183–185°, was obtained as a light-brown solid from 4,5-dimethoxy-2-nitrobenzaldehyde (6.6 g) and 3-methyl-1-phenyl-2-pyrazolin-5-one (6.9 g) (lit. (4) m.p. 183°).

4-(5-Chloro-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (I*d*) (4.2 g, 62%), m.p. 140–142°, was obtained as orange-red needles from 3-chloro-6-nitrobenzaldehyde (7.4 g) and 3-methyl-1-phenyl-2-pyrazolin-5-one (7.0 g). The infrared spectrum had absorption peaks at 1 690 (s) (C=O) and at 1 520 (s) and 1 330 (s) (NO_2) cm^{-1}.

Anal. Calcd. for $C_{17}H_{12}ClN_3O_3$: C, 59.75; H, 3.42; Cl, 10.38; N, 12.30. Found: C, 59.50; H, 3.54; Cl, 10.49; N, 12.57.

4-(*o*-Nitrobenzylidene)-1,3-diphenyl-2-pyrazolin-5-one (I*e*) (4.9 g, 74%), m.p. 181–182°, was obtained as red needles from *o*-nitrobenzaldehyde (3.0 g) and 1,3-diphenyl-2-pyrazolin-5-one (5.0 g). The infrared spectrum had absorption peaks at 1 695 (s) (C=O) and at 1 540 (s) and 1 330 (s) (NO_2) cm^{-1}.

Anal. Calcd. for $C_{22}H_{15}N_3O_3$: C, 71.53; H, 4.09; N, 11.38. Found: C, 71.48; H, 4.26; N, 11.31.

Preparation of 3-Methyl-4-(o-nitrobenzylidene)-2-pyrazolin-5-one (If)

Method a

An attempted preparation of the title compound from *o*-nitrobenzaldehyde (4.53 g) and 3-methyl-2-pyrazolin-5-one (3.24 g) as described for the preparation of I*a* (method *c*) gave a dark-brown solid (7.6 g), m.p. 172–175°. The infrared spectrum showed broad absorption at 1 700 (s) (C=O) and at 1 520 (s) and 1 345 (s) (NO_2) cm^{-1}. This product was assumed to be 1-acetyl-3-methyl-4-(*o*-nitrobenzylidene)-2-pyrazolin-5-one (I*g*).

Anal. Calcd. for $C_{13}H_{11}N_3O_4$: C, 57.14; H, 4.06; N, 15.37. Found: C, 57.18; H, 4.18; N, 15.47.

Method b

By using the method described for the preparation of I*a* (method *b*), the title compound (3.1 g), m.p. 243–246° (decomp.), was obtained as a pale-brown solid. The product was insoluble in common organic solvents. It was boiled with alcohol and then acetone before analysis. The infrared spectrum (Unicam SP 200 spectrophotometer) showed broad absorption between 2 400 and 3 300 with a maximum at 2 900 (m) (OH), and peaks at 1 530 (s) and 1 360 (s) (NO_2) cm^{-1}.

Anal. Calcd. for $C_{11}H_9N_3O_3$: C, 57.14; H, 3.92; N, 18.18. Found: C, 56.60; H, 4.15; N, 18.30.

Reduction of 3-Methyl-4-(o-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (Ia)

Method a

A solution of the title compound (1 g) in a mixture of ethanol (80 ml) and methanol (10 ml) was added dropwise over a 15 min period to a solution of sodium borohydride (0.5 g) in water (5 ml) and methanol (10 ml) to which had been added, previously, palladium–charcoal (0.05 g) suspended in water (5 ml). Nitrogen was bubbled through the reaction mixture during the addition of the title compound and for a further 15 min. The solution was filtered and acidified with hydrochloric acid, and a small amount (ca. 50 mg) of a pale-yellow solid, m.p. 107–115°, which was not further investigated, was deposited. The filtrate from this was concentrated and an orange product slowly deposited. It was removed and washed with cold ethanol to yield 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-pheny-1*H*-pyrazolo[3,4-*b*]quinoline (II*a*) hydrochloride as a yellow solid (0.336 g), m.p. 252–254° (lit. (4) m.p. 251–252°).

Anal. Calcd. for $C_{17}H_{18}ClN_3O$: C, 64.65; H, 5.74; Cl, 11.23; N, 13.31. Found: C, 64.30, 64.64; H, 5.58, 5.71; Cl, 11.19; N, 13.26.

Method b

The reduction described under method *a* was repeated on a threefold scale with dioxane (60 ml) as solvent. A slight excess of hydrochloric acid was added to the filtrate, which, on dilution with water, gave an off-white

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solid (2.1 g), m.p. 140–146° with preliminary softening. This was crystallized from aqueous ethanol to give a colorless solid, m.p. 174–176°, the infrared spectrum of which showed absorption peaks at 1 685 (s) (C=O) and at 3 280 (m) and 1 595 (s) (NH?) cm^{-1}.

Anal. Found: C, 71.25; H, 5.68; N, 13.30.

The mother liquors remaining after the removal of the above product slowly deposited II*a* hydrochloride (0.18 g) as pale-orange prisms, m.p. 241–245°.

Method c

The title compound (1 g) was heated under reflux for 24 h in ethanol (10 ml) containing cyclohexene (3 ml) in which was suspended palladium–charcoal (0.1 g). The catalyst was removed by filtration, and the filtrate was evaporated to give a dark-red oil which, on trituration with benzene, solidified. The solid was crystallized from ethanol to yield 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]-quinoline (II*a*) (0.380 g), m.p. 141–142° (lit. (4) m.p. 142°).

Anal. Calcd. for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04. Found: C, 73.00; H, 6.10; N, 15.16.

The above pyrazoloquinoline dissolved readily in aqueous sodium hydroxide. When this solution was acidified with acetic acid, the pyrazoloquinoline, m.p. 142°, was regenerated. When the alkaline solution was acidified with hydrochloric acid, 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]-quinoline (II*a*) hydrochloride was precipitated quantitatively as a colorless solid, m.p. 254–256°. The infrared spectrum of the hydrochloride was identical with that of the hydrochloride obtained by method *a*.

Method d

Zinc dust (1 g) was added in small quantities to a stirred solution of the title compound (2.0 g) in boiling glacial acetic acid (20 ml) until the initially red-colored solution became pale yellow. The solution was filtered and the filtrate was diluted with water (100 ml) to which had been added concentrated hydrochloric acid (2 ml). When the solution was allowed to stand, a pale-yellow flocculant precipitate formed. Recrystallization from methanol to which had been added a few drops of concentrated hydrochloric acid gave 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*a*) hydrochloride (0.43 g) as a yellow solid, m.p. 255–256°. The infrared spectrum was identical with that of the hydrochloride obtained as described under methods *a* and *c*.

Method e

The reduction described under method *d* was repeated with acetic acid containing acetic anhydride (32% v/v). The filtrate was diluted with water to yield 9-acetoxy-3*a*,4,9,9*a*-tetrahydro-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*a*, Ac replaced H) as a flocculant precipitate, which was crystallized from methanol as a white solid (0.115 g), m.p. 207–208°. This solid was insoluble in aqueous sodium hydroxide. The infrared spectrum showed strong absorption at 1 670 (C=O) cm^{-1}.

Anal. Calcd. for $C_{19}H_{19}N_3O_2$: C, 71.01; H, 5.96; N, 13.08. Found: C, 70.46; H, 5.90; N, 13.00.

The same compound was obtained by heating under reflux a solution of II*a* (0.5 g) in acetic anhydride (5 ml) for 1 h. The cooled solution was poured into 5% aqueous sodium hydroxide and stirred until homogeneous; then the alkaline solution was extracted with ether. When evaporated, the dried ether solution gave a brown oil, which was triturated with ethanol to yield the acetyl derivative (0.26 g), m.p. 207–208° when crystallized from ethanol.

Reduction of 4-(4,5-Dimethoxy-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (Ib)

Method a

The title compound (3 g) was reduced with cyclohexene and palladium–charcoal as described for the reduction of I*a* (method *c*). The filtrate, on evaporation, yielded a dark-brown oil (2.85 g) which was dissolved in chloroform. Addition of hydrochloric acid to the chloroform solution (in an attempt to extract basic material) resulted in the formation of an orange solid at the interface. Crystallization from ethanol gave 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-6,7-dimethoxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*b*) hydrochloride (1.12 g) as a pale-brown solid, m.p. 211–212°. The infrared spectrum showed broad absorption from 2 200 to 3 300 (m) (OH) cm^{-1}.

Anal. Calcd. for $C_{17}H_{22}ClN_3O_3$: C, 60.71; H, 5.89; N, 11.18. Found: C, 60.37; H, 5.64; N, 10.86.

Method b

The title compound (3 g) was reduced with sodium borohydride and palladium–charcoal as described for the reduction of I*a* (method *b*). The resulting reddish-brown solid (1.2 g) was crystallized from ethanol as a pale-brown solid, m.p. 195–197°. Except for very minor differences, the infrared spectrum of this compound was identical with that of II*b* hydrochloride prepared as described above.

Anal. Calcd. for $C_{17}H_{22}ClN_3O_3$: C, 60.71; H, 5.89; N, 11.18. Found: C, 61.20; H, 5.92; N, 11.32.

Reduction of 4-(5-Chloro-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (Id)

Method a

The title compound (2 g) was reduced with zinc and acetic acid as described for the reduction of I*a* (method *d*) to give 6-chloro-3*a*,4,9,9*a*-tetrahydro-5-hydroxy-3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]quinoline (II*d*) hydrochloride (1.22 g) as a pale-yellow solid, m.p. 224–225°. The infrared spectrum showed broad absorption from 2 300 to 3 280 with a broad maximum centered at 2 900 (s) (OH) cm^{-1}.

Anal. Calcd. for $C_{17}H_{17}Cl_2N_3O$: C, 58.30; H, 4.89. Found: C, 58.78; H, 5.10.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Method b

The title compound (2 g) was reduced with cyclohexene and palladium–charcoal as described for the reduction of I*a* (method *c*). The resulting red oil (1.7 g) was dissolved in ether, and the ether solution was extracted with 5% aqueous sodium hydroxide. When the aqueous extract was acidified with acetic acid, the pyrazoloquinoline (II*d*) was isolated as a pale-yellow solid (0.48 g), m.p. 108–110° after crystallization from ethanol. This product was identical with II*d* obtained from its hydrochloride as described later.

Method c

The title compound (3 g) was reduced with sodium borohydride and palladium–charcoal as described for the reduction of I*a* (method *b*). The resulting orange-brown solid (1.92 g) was crystallized from dilute acetic acid as a light-brown solid, m.p. 140–142°. The infrared spectrum (Unicam SP 200 spectrophotometer) showed absorption peaks at 1 695 (s) (C=O) and at 1 605 (m) and 3 290 (m) (NH?) cm^{-1}.

Anal. Found: C, 63.51; H, 4.58; N, 13.10.

Reduction of 4-(o-Nitrobenzylidene)-1,3-diphenyl-2-pyrazolin-5-one (Ie)

The title compound (3 g) was reduced by means of cyclohexene and palladium–charcoal as described for the reduction of I*a* (method *c*). An ether solution of the resulting dark-red oil (2.90 g) was extracted with 5% aqueous sodium hydroxide; when this extract was acidified with hydrochloric acid, a pale-brown solid was obtained. Crystallization from ethanol gave 3*a*,4,9,9*a*-tetrahydro-9-hydroxy-1,3-diphenyl-1*H*-pyrazolo-[3,4-*b*]quinoline (II*e*) hydrochloride monohydrate (2.11 g) as an off-white solid, m.p. 182–183°. The infrared spectrum showed broad absorption from 2 200 to 3 200 with a broad maximum centered at 2 860 (s) (OH) cm^{-1}.

Anal. Calcd. for $C_{22}H_{22}ClN_3O_2$: C, 66.74; H, 5.60; N, 10.50. Found: C, 66.83; H, 5.64; N, 10.13.

Isolation of Free Bases (II) from their Hydrochlorides

The hydrochloride was dissolved in aqueous sodium hydroxide; when acetic acid was added, the base precipitated. These amphoteric products were crystallized from methanol or ethanol. When the aqueous solution was acidified with hydrochloric acid, the hydrochloride precipitated. The infrared spectra of the free bases all showed broad absorption in the 2 100 – 3 500 range with maxima (m,s) between 2 850 and 3 090 (OH) cm^{-1}.

The pyrazoloquinoline (II*b*) was a light-brown solid, m.p. 88–90°.

Anal. Calcd. for $C_{19}H_{21}N_3O_3$: N, 12.38. Found: N, 12.01.

The base (II*d*) was a yellow solid, m.p. 109–111°.

Anal. Calcd. for $C_{17}H_{16}ClN_3O$: C, 65.06; H, 5.14; Cl, 11.30; N, 13.39. Found: C, 65.14; H, 5.11; Cl, 11.53; N, 13.49.

The base (II*e*) was a brown solid, m.p. 109–110° after repeated crystallization from ethanol.

Anal. Calcd. for $C_{22}H_{19}N_3O$: C, 77.39; H, 5.61; N, 12.31. Found: C, 76.63; H, 5.36; N, 11.80.

Reductions with Hydrazine Hydrate and Palladium–Charcoal

Reduction of 3-Methyl-4-(o-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (Ia)

The title compound (1 g) was heated under reflux for 30 min in ethanol (40 ml) containing hydrazine hydrate (1.5 ml) and palladium–charcoal (0.1 g). The catalyst was removed, and the filtrate was diluted with water and left to stand overnight. Bis(2-aminobenzylidene) hydrazine (V) (0.41 g) separated as bright-yellow crystals, m.p. 251–252° when crystallized from ethanol (lit. (8) m.p. 248°).

Anal. Calcd. for $C_{14}H_{14}N_4$: C, 70.56; H, 5.92; N, 23.51; mol. wt. 238.3. Found: C, 70.52; H, 5.94; N, 23.39; mol. wt. (vapor pressure) 231.

Reduction of 3-Methyl-4-(o-nitrobenzylidene)-2-pyrazolin-5-one (If)

Reduction of the title compound (1 g) with hydrazine hydrate and palladium–charcoal as described above also gave bis(2-aminobenzylidene) hydrazine (0.48 g), m.p. 251–252°.

Reduction of o-Nitrobenzaldehyde

Reduction of the title compound (1 g) with hydrazine hydrate and palladium–charcoal by the method described above also gave bis(2-aminobenzylidene) hydrazine (0.71 g), m.p. 251–252°.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

XV. THE VOLATILE OIL OF MENTHA ARVENSIS VAR. GLABRATA RAY[1]

E. VON RUDLOFF AND F. W. HEFENDEHL[2]

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received April 28, 1966

ABSTRACT

The volatile oil of the North American wild mint (*Mentha arvensis* L. var. *glabrata*) was found to consist mainly of *d*-pulegone (80–90%) and smaller amounts of α-pinene, β-pinene, sabinene, limonene, 1,8-cineole, 1-octen-3-ol, menthone, isomenthone, piperitone, *cis*- and *trans*-pulegone oxide, and piperitenone. Trace amounts of γ-terpinene, menthofuran, β-caryophyllene, and ε-, δ-, and γ-cadinene were also isolated, and camphene, *p*-cymene, terpinolene, sabinene hydrate, isopulegone or its stereoisomer, β-elemene, and α-terpineol were tentatively identified. A labile autoxidation product of pulegone was also detected.

A study of the seasonal variations in the oil composition showed that significant changes in the quantitative composition occurred only in very young plants. The maximum yield of oil was obtained at the start of flowering. Practically no variation in the composition of the oil was recorded for plants from different localities.

INTRODUCTION

For a biosynthetic study of some of the terpenes found in mint plants, a knowledge of the chemical composition of the oil of local wild mint, *Mentha arvensis* L. var. *glabrata* Ray (syn. *M. arvensis* var. *villosa* (1) and *M. canadensis* L. (2)), was required. This plant differs morphologically from the European *M. arvensis* varieties (1). Gildemeister (2, 3) lists a number of older investigations which indicate that pulegone is a major constituent and that the presence of menthol and isomenthol was suspected. Gage (4) and Kremers (5) report that the main constituent of the oil of *M. canadensis* L. is *d*-pulegone, and *l*-limonene was identified (5). However, Braun (6) could not confirm these findings. In view of these uncertainties and the lack of more modern data, a detailed analysis by means of gas–liquid chromatography (g.l.c.) was undertaken.

The present study was carried out in two parts. Since it is known that the composition of the oil of *Mentha piperita* L. changes during flowering (7), a study of any such variation in *M. arvensis* var. *glabrata* was made first. When the optimum yield and best harvest time for a representative composition of the oil had been determined, a larger amount of the oil was isolated and analyzed in detail. The composition of the oil from local plants was also compared with that of plants from the Cypress Hills and Peace River districts in Alberta to establish whether variation in the composition of the oil exists in plants from different locations.

The g.l.c. techniques used were essentially those described earlier (8–10). However, a number of new liquid phases and experimental parameters were studied in more detail to improve the resolution and to obtain data which could be compared directly with those found in the literature. Thus, Levi *et al.* (11–13) and Hefendehl (14) have reported good resolution of the mint terpenes on sucrose diacetate hexaisobutyrate (SAIB) columns. Previously a sample of this liquid phase had given a poorer separation, especially of some oxygenated monoterpenes (sabinene hydrate, menthofuran, and menthones), in this laboratory. However, when a sample of SAIB from another source was tried, results similar to those reported by Levi *et al.* and Hefendehl were obtained.

EXPERIMENTAL

The g.l.c. analyses were carried out with a F & M model 500 (linear temperature programming; F & M Scientific Instrument Inc.) instrument and with one of conventional design for isothermal operation (15). Preparative g.l.c. was carried out with an Aerograph Autoprep A-700 instrument (Wilkens Instrument and Research Inc.). The carrier gas was helium, and thermal conductivity detectors were employed. For very small samples a model 600-D Aerograph instrument equipped with a flame-ionization detector was used. Retention times were measured from the time of injection to the initial emergence of the peaks (16, 17). The percentage composition of the oil was calculated by summation of the areas under the peaks (triangulation method); the errors were similar to those reported by Janak (18). Infrared spectra were recorded as films between sodium chloride plates on a Perkin–Elmer model 21 (double-beam) spectrophotometer. Ultraviolet spectra were obtained in isooctane on a Bausch and Lomb model 505 spectrophotometer. Nuclear magnetic resonance spectra were determined with a Varian HA-100 instrument, tetramethylsilane being used as the internal standard.

Plant Material

Wild mint plants were collected from the Beaver Creek area (approximately 10 miles south of Saskatoon) and transplanted to experimental plots. The plants were identified as *Mentha arvensis* L. var. *glabrata* by Dr. G. W. Argus, Curator, W.P. Fraser Herbarium, University of Saskatchewan, and an herbarium specimen has been retained by us.

The seasonal variation in the composition of the oil was studied during the main growing season (July to September) of 1964. All other data were obtained from subsequent growth of the same plants. A number of wild plants from the Cypress Hills area just west of the Alberta border and from the Peace River district, Alberta, were collected during August 1965.

Recovery of Oil

The freshly harvested plants were steam-distilled for 3 to 5 h in a glass apparatus. The volatile oil was extracted with ether, washed with a little bicarbonate solution and water, and dried over anhydrous sodium sulfate. When less than 200 g plant material was available, the circulatory distillation apparatus of Kaiser and Lang (19), as modified by Hefendehl (20), was used. The latter apparatus gave a better recovery of monoterpene hydrocarbons.

Gas–Liquid Chromatographic Analyses

Column packings were prepared by the tray method, with nonacid-washed solid supports, including Chromosorb W, Gas Chrom P, and Anakrom ABS (60–80 mesh). Columns were packed by hand with gentle tapping or by applying a vibrator and vacuum. Both methods gave g.l.c. columns with the same resolving power (for the same packing), provided that only moderate vibration was used. Copper tubing was preferred over stainless-steel tubing, since the latter was found to contain an internal coating which was detrimental to the resolution of terpenes (on polar column packings) and which could not be removed easily. Comparison with a glass column of similar dimensions showed the copper column to perform equally well when the common terpenes were analyzed.

Aliquots (1 to 5 μl) of each oil sample were injected (injector at 125–140°) onto a 180 × 0.4 cm inside diameter column containing 15% polyethylene glycol (Carbowax 20M, PEG) on Chromosorb W. Linear temperature programming from 55 to 200° at 4°/min gave a satisfactory resolution of the major and most of the minor components. The percentage compositions of the oil at different stages of plant growth (as calculated from these chromatograms) are shown in Table I. The oils from the plants from both the Cypress Hills and Peace River districts had a composition similar to that of the local plants from August 5 to 13. More detailed analytical data were obtained by use of 300 × 0.3 cm PEG, SAIB (obtained from Wilkens Instrument and Research Inc.), SPEG (10% succinate polyethylene glycol polyester), and QF-1 (15% fluorinated silicone polymer on Anakrom ABS) columns, as well as a 180 × 0.4 cm EGPN (15% ethylene glycol bis-propionitrile on Chromosorb W) column. A typical chromatogram on the PEG column is shown in Fig. 1. Apiezon N, adipate, or succinate polyesters (NGA, APEG, SEG, BDS) and quadrol–SAIB mixtures did not give improved separation.

Prefractionation

The oil (10 g) was chromatographed on silicic acid (100 g, polyethylene glycol modified (9, 21)). Elution with petrol (b.p. 40–60°) gave a hydrocarbon fraction which still contained some of the less-polar oxygenated terpenes. Rechromatography gave an almost pure hydrocarbon fraction (0.8 g). Elution with methanol gave the oxygenated terpenes (9.2 g, by difference). Gas–liquid chromatographic analysis of the latter fraction showed that over three-quarters of peak 35 (see Fig. 1 and Table II) was lost in this procedure. New peaks, corresponding to the products of decomposition, could not be found. Some minor peaks also appeared to decompose.

Individual Components

Aliquots (10 to 50 μl) of the prefractionated terpenes were injected repeatedly onto a 180 or 300 × 0.4 cm PEG column. To facilitate recovery the detector current was reduced from 200 to 100 mA and the helium

flow from 110 to about 50 ml/min. Each peak was collected in a 15 × 0.2 cm inside diameter glass tube at the instrument exit, dry ice being applied at the middle of the tube. The infrared and ultraviolet spectra and physical constants were determined (see Table II), and these were compared with those of known terpenes to identify the individual components of the oil. Each fraction was analyzed on g.l.c. columns to determine the purity and relative retention times. Peaks were designated *a* and *b* if a contaminant was present (see Table II).

β-Pinene and sabinene could not be isolated separately, and their identity was confirmed by permanganate–periodate oxidation (22–24) to nopinone and sabina ketone. The terpene mixture (ca. 10 mg) was shaken vigorously with excess aqueous oxidant (100 mmoles/l, 5 ml) for 1 h. The product was extracted directly with ether (2 ml) and the ethereal solution was dried over anhydrous sodium sulfate. The ether was evaporated in a small vial (at 60–70°) and an aliquot of the residue (ca. 8 mg) was injected onto the PEG column. Two peaks with the same retention times as nopinone and sabina ketone were recorded.

Several sesquiterpene hydrocarbons were present in the oil (Fig. 1, solid black peaks in the peak 20 to peak 30 range). Of these, β-caryophyllene (peak 22), ε-cadinene (peak 26*a*), and γ- and δ-cadinene (peak 29, mixture (8, 10)) were identified by their spectral and retention characteristics. Peak 21*b* had the same retention time as β-elemene; peak 24 could not be correlated with a known sesquiterpene.

Analysis on the SAIB column showed that the menthone fraction (peak 15) contained a small amount of a contaminant with the same retention time as menthofuran. This was collected and had an ultraviolet spectrum similar to that of menthofuran. When the pulegone fraction (peak 23) was analyzed on the QF-1 column, a trace peak with the same retention time as α-terpineol was recorded.

Peaks 14, 18, 20, 30, 31, 35, 39, 40, and 41 appeared to decompose extensively during prefractionation. Attempts to isolate some of these components by g.l.c. directly from the oil met with similar difficulties, indicating that extensive decomposition of these components also takes place during g.l.c. However, enough of fractions 31 and 35 could be collected to record their spectra. The ultraviolet spectra were devoid of characteristic absorption, except for that of carbonyl groups. The infrared spectra showed the isolated fractions to consist mainly of ketones (1 715, 1 675, and 1 707 cm^{-1}, respectively). Weak to medium bands at 3 480 cm^{-1} indicated that contaminants containing hydroxyl groups were present. Absorption bands of variable (weak to medium) intensity near 3 040, 1 245, and 925 cm^{-1} could arise from epoxide groups, but such assignments are only tentative. The broad singlet near 1 375 cm^{-1} indicated that isopropyl or *gem*-dimethyl groups were absent. This suggested that these two components could be the isomeric pulegone oxides (25). The latter were synthesized by oxidation of *d,l*-pulegone with alkaline hydrogen peroxide solution (26) and separated by preparative g.l.c. The identity of the *cis*- and *trans*-isomers was established by their nuclear magnetic resonance spectra (25). If the presence of decomposition products is taken into account, there was good agreement between the spectra of components 31 and 35 and those of the synthetic oxides. Co-injection of the synthetic oxides confirmed the retention data.

In addition to *trans*-pulegone oxide, peak 35 was found to contain an autoxidation product of pulegone. These two components were partially separated on a 10% SPEG column. When the mint oil was allowed to stand in the light (daylight and fluorescent) for 24 h, peak 35*a* increased, with a concomitant decrease in the pulegone peak. When pulegone itself was allowed to autoxidize in the same manner, a second peak with the same retention time as peak 35*a* was recorded. Since polymeric autoxidation products (e.g. dimers) would not be eluted from the g.l.c. columns under the conditions used, the product must be a peroxide of pulegone. Whether this peroxide is formed in the plant or during isolation could not be established. However, the data in Table I suggest that only very small amounts can be present in the freshly distilled oil.

RESULTS AND DISCUSSION

The seasonal variation in the chemical composition of the volatile oil from *M. arvensis* var. *glabrata* is shown in Table I. From the data obtained in the main growing season of 1964, it follows that no significant variation in the chemical composition of the oil occurs just before, during, or after flowering. This is similar to our findings for the oil from *Tanacetum vulgare* L. (10), but contrasts with those reported for the oil from *M. piperita* L. (7, and the literature cited in ref. 20). Battaile and Loomis (27) have reported that the *de novo* synthesis of terpenes occurs only in very young tissues of mint plants and that interconversion (e.g. menthone → menthol → menthyl acetate) takes place only in older ones. Hence, the oil from very young (5–10 cm high) wild mint plants was also investigated. The yield of oil was much lower than that of mature plants, and a markedly different percentage composition was recorded (cf. last column, Table I). Aside from a considerably higher content of monoterpene hydrocarbons (12.5% vs. 1.5 to 2%), the oil from the young plants contained much more menthone and isomenthone. This is surprising, because the

biogenetic sequence advanced by Reitsema (28) and extended by Bataille and Loomis (27) predicts a higher content of the unsaturated ketones (piperitenone, piperitone, and pulegone) in young plants. This is of considerable interest for biogenetic studies, and is being investigated further by us.

It is noteworthy that the oil from mature wild mint plants from the Cypress Hills area (southeastern Alberta, August 1965) and the Peace River district (northwestern Alberta, August 1965) had virtually the same composition as that of the mature plants found locally. This indicates that the composition of the oil from *M. arvensis* var. *glabrata* is relatively stable over a wide geographical area. The yield of oil from the local plants was a maximum at the beginning of flowering (cf. Table I, August 5, 1964), and dropped slowly during and after flowering. Since the chemical composition of the oil did not change to any significant degree during the flowering period, a large amount of plant material was harvested in August 1965, and the oil obtained was analyzed in detail. A typical gas–liquid chromatogram on the PEG column (as shown in Fig. 1 and Table II) lists the percentage composition and the components identified. The composition is very similar to that recorded the previous year, except that the content of component 35 is somewhat higher (1.5 to 2.0% vs. 0.2 to 0.6%). Apparently the content of the pulegone autoxidation product (peak 35*a*; cf. Experimental) was higher in the large batch.

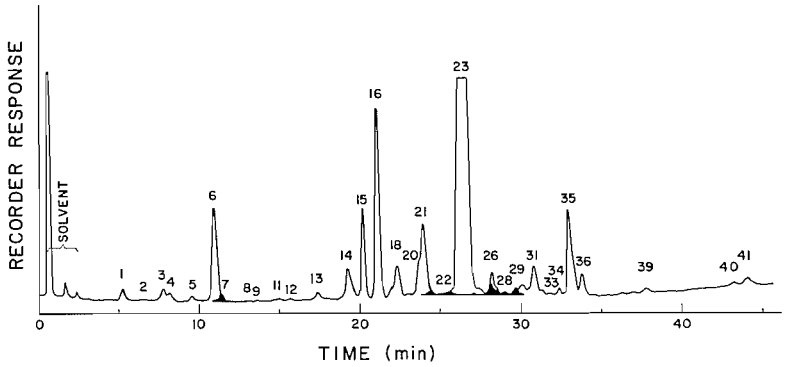

FIG. 1. Gas–liquid chromatogram of the volatile oil of *Menthaa rvensis* L. var. *glabrata* Ray (300 × 0.4 cm polyethylene glycol column, temperature programmed from 55° to 210° at 4°/min). The peaks in solid black were separated by silicic acid column chromatography; the peak identifications are shown in Table II.

Practically all of the components in the monoterpene hydrocarbon range (peaks 1–10) were identified, and α-pinene (peak 1), myrcene (peak 5), limonene (peak 6), and 1,8-cineole (peak 7) were isolated in a fairly pure state. The identity of β-pinene and sabinene (peaks 3 and 4) was confirmed by permanganate–periodate oxidation (22–24) to nopinone and sabina ketone, respectively. The infrared spectrum of peak 8 corresponded closely to that of γ-terpinene, but the optical rotation (+10°) requires the presence of an optically active contaminant. Components 9 and 10 were not obtained in sufficient amounts to record satisfactory spectra, but the retention data indicated these to be *p*-cymene and terpinolene, respectively. Ocimene isomers or phellandrenes were not detected.

The sesquiterpene hydrocarbon fraction makes up less than 0.5% of the oil, and isolation of the individual components was difficult. Peak 21*b* was only tentatively identified as β-elemene (by relative retention times), but β-caryophyllene (peak 22) and ϵ-cadinene (peak 26*a*) were sufficiently pure to permit identification by comparison of their infrared spectra. Component 29 showed an infrared spectrum typical of the mixture of δ- and

γ-cadinene encountered previously (8, 10). Katsuhara *et al.* (29) found in the sesquiterpene fraction of various mint oils β-elemene, β-caryophyllene, and δ- and γ-cadinene (as well as six unidentified trace components), which is in good agreement with the present findings.

All of the major oxygenated terpenes, except for the double peak 20–21, were identified, as were also some of the minor constituents. The trace peak 12 could contain octan-3-ol (relative retention times), but its infrared spectrum showed the presence of major amounts of a ketone (1 710 cm^{-1}). Peak 13*a* was not identified, but peak 13*b* had an infrared spectrum closely resembling that of 1-octen-3-ol. Levi *et al.* (13) reported the presence of 3-octanol and its acetate in mint oils, and 1-octen-3-ol was identified in *M. pulegium* by Naves (30). The menthone fraction (peak 15) was found to contain a small amount of menthofuran (peak 15*b*) by rechromatography on the SAIB column. Isomenthone (peak 16) and pulegone (peak 23), the main constituent of the oil, were readily identified. Rechromatography of the latter indicated that a trace amount of α-terpineol could be present in the oil. Piperitone (peak 26*b*) and piperitenone (peak 36) were also obtained in a fairly pure state. Considerable difficulty was encountered with components 14, 18, 20–21, 31, 35, and 40, since these appeared to decompose or rearrange during isolation. Component 14 appears to be sabinene hydrate, which dehydrates easily to form sabinene. It cannot be ruled out that the oil in the plants contains only sabinene hydrate and that sabinene is an artifact. However, sabinene is frequently found in essential oils and may thus also be a true constituent of the wild mint. Levi *et al.* (13) have shown that sabinyl acetate may be a component of mint oils, but this thujane derivative could not be detected in the oil of our local wild mint. Sabinyl acetate was isolated from *Juniperus sabina* L. by our technique (31); hence, decomposition to sabinene may be ruled out. It is noteworthy that this oil does not contain any acetates in detectable amounts. Peaks 18 and 40, although present in 0.3 to 0.5% amounts, could not be isolated. Difficulties were also encountered with the double peak 20–21. Only the main portion of peak 21 was isolated with any degree of purity. Its infrared spectrum showed strong absorption bands at 1 707, 878, and 1 370 (broad) cm^{-1} and a weak band at 3 080 cm^{-1}. These absorption bands are similar to those expected for isopulegone, but no data for comparison could be found. The presence of isopulegone or its stereoisomer may be expected on biogenetic grounds.

Components 31 and 35 appear to be most interesting from a chemical point of view. Their infrared spectra suggest that these could be epoxides, but the isolated products also showed absorption in the hydroxyl region. It is possible that the epoxide ring is opened during passage through the detector (thermal conductivity type, at 220–250°) and that only part of the isolated fractions is the original oxides. The spectra and retention data suggested that these two components could be *cis*- and *trans*-pulegone oxide, respectively. This was confirmed by preparing the isomeric pulegone oxides (25, 26) and by comparing their properties with those of components 31 and 35. However, evidence was obtained (cf. Experimental) which shows that the *trans*-pulegone oxide (peak 35*b*) was accompanied by an autoxidation product (a pulegone peroxide, peak 35*a*) of pulegone. Since the latter is labile, it was not isolated. Peak 35 was partially resolved into these two components on the SPEG column. This appears to be the first time that these pulegone oxides were found in mint oils.

Shimizu (32) has isolated piperitone oxides from mint oils. These were prepared (26) and their retention data compared with the components of *M. arvensis* var. *glabrata*. The retention times were the same as those of peaks 26 and 27. However, since component 26 was found to consist mainly of ε-cadinene and piperitone, and peak 27 mainly of an unidentified sesquiterpene hydrocarbon, only traces, if any, of the piperitone oxides can be present.

CONCLUSIONS

The chemical composition of the oil of *M. arvensis* var. *glabrata* resembles closely that of the oil of *M. pulegium* and *Hedeoma pulegioides* (American pennyroyal) (13), pulegone being the major constituent and smaller amounts of α-pinene, β-pinene, limonene, 1,8-cineole, menthofuran, menthone, isomenthone, piperitone, and piperitenone being present. However, the latter two oils are reported to contain also 3-octylacetate, linalyl acetate, and menthol (13), which were not found in the local mint oil. Another distinguishing feature appears to be the presence of the two pulegone oxides, the tentatively identified isopulegone, and possibly sabinene and its hydrate (in the oil of the local wild mint). The oils from other *M. arvensis* varieties differ markedly (13, 2, 7) from the local variety.

From the biosynthetic point of view it is noteworthy that ketones are the predominant components and that only traces of alcohols and no acetates were detected. On the basis of the scheme proposed by Reitsema (28) and extended by Bataille and Loomis (27), the hydrogenation step from pulegone to the menthones appears to be somewhat arrested and the reduction of the latter to the menthols may be blocked. This indicates a marked difference in the secondary changes as compared with *M. piperita* L., and may account for the remarkably consistent composition of the oil before, during, and after flowering of the plants.

ACKNOWLEDGMENTS

The authors thank Dr. G. Argus for confirming the identity of the plants, and Mr. M. Granat for technical assistance. The spectra were recorded by Mr. M. Mazurek and Mr. W. C. Haid.

STRUCTURAL BIOCHEMISTRY

II. SYNTHESIS OF 3β-HYDROXY-17β-(L-PROLYL-L-PROLYL)AMINO-5α-ANDROSTANE[1-3]

GEORGE R. PETTIT,[4] ARUN K. DAS GUPTA,[5] AND ROBERT L. SMITH

Received April 22, 1966

ABSTRACT

A practical synthetic route to 3β-hydroxy-17β-amino-5α-androstane (III) was developed and the configuration of the amine substituent established by proton magnetic resonance studies. Condensing amine III with carbobenzoxy-L-proline by means of Woodward's reagent K led to proline derivative IV*a*. Steroidal peptide V*b* was readily prepared by first removing the protecting group from amide IV*a* by palladium-catalyzed hydrogenolysis and then repeating the peptide-forming and hydrogenation steps. Protection of the 3β-hydroxy group proved to be unnecessary, and the presently reported approach to steroidal peptides proved to be reliable and useful.

Presently, the only fully characterized and naturally occurring amino acid linked steroids are the bile acid conjugates. These amides consist of a bile acid, for example, cholic acid, combined with either glycine or taurine (3). Evidence (4) has been accumulating, however, to indicate that steroids interact with human plasma proteins. Considering the binding of steroid proteins and the possibility that steroids linked to peptides might be involved in steroid transport, we began (in 1959) a study of synthetic approaches to steroidal peptides. The possibility that synthetic steroidal peptides might alter, or otherwise interfere with, established hormone production enhanced our interest. At first we also intended to employ certain steroids as platforms for the synthesis of peptides. The hydrocarbon segment would be expected to render peptide intermediates more soluble in nonpolar media and provide more easily purified (e.g. by column chromatography) and crystalline peptide derivatives. The latter objective was discarded in 1963 when Merrifield (5) reported the obviously superior solid-phase peptide technique employing a polymer platform. Thus, to provide steroidal peptides of possible use in advancing knowledge of steroid transport and alteration of hormone properties,[6] we proceeded initially with the synthetic approaches described in the sequel.

For practical purposes, the history of steroidal peptide syntheses begins with the Bondi and Müller (7) preparations (in 1906) of glycocholic and taurocholic acids from cholic acid azide. Later (8) an alternate synthetic route based on the triformyl derivative of cholic acid chloride was employed. More recently, efficient syntheses of bile conjugates by the mixed anhydride technique (9) has provided, for example, glycocholic acid (10) in approximately 80% yield.

[1]*A preceding paper titled "Steroidal Peptides" (1) may be considered as part I in this series. The new serial title "Structural Biochemistry" is intended for our nucleotide and peptide studies and to include overlapping aspects with our steroid program. The present manuscript may thus be considered as part XXXIV of the steroid investigations; for part XXXIII, see ref. 2.*

[2]*This investigation was aided in part by National Science Foundation research grant GB-249, and grants Nos. T-79C to T-79F from the American Cancer Society.*

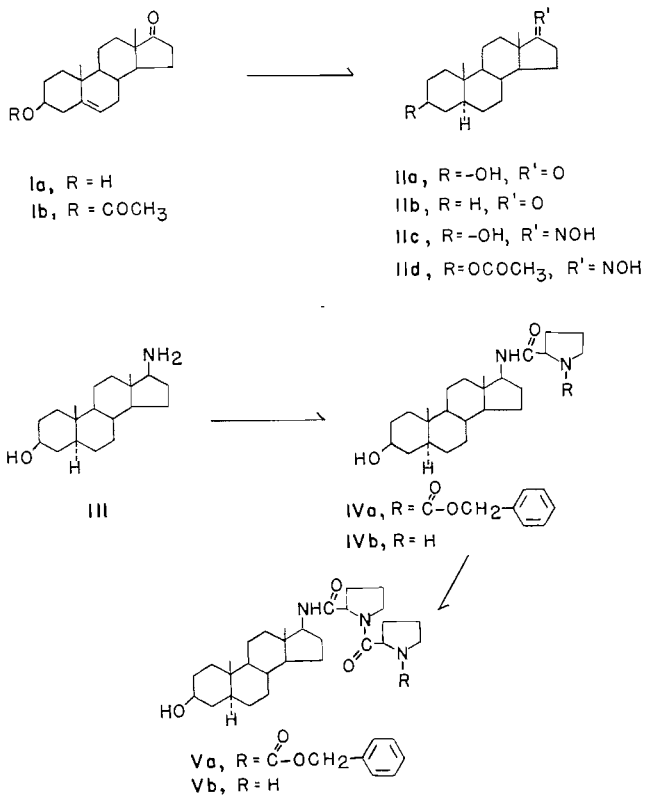
In the last 5 years, several amino acid ester derivatives (e.g. 14–20 unit α-polyglycine mixtures (11*d*)) of hydroxy steroids have been described (11). Part of the present study, concerned with first syntheses of steroidal peptides derived from amino steroids, has been reported in a preliminary communication (1). Meanwhile, the preparation of, for example, the glycyl–glycyl dipeptide derivative of 3α-amino-20-oxo-5α-pregnane has been described (12).

The frequent occurrence of proline in natural peptide hormones (13) such as the hypotensive peptides bradykinin and kallidin (14), both of which contain a diprolyl unit, suggested selection of 3β-hydroxy-17β-(L-prolyl-L-prolyl)amino-5α-androstane (V*b*) as an initial synthetic objective. As noted, prolyl peptide V*b* was of biological interest, and useful synthetic techniques arising from construction of this small peptide could later be extended to yield larger steroidal polypeptides.

Dehydroepiandosterone (I*a*) served as starting material and was hydrogenated in ethanol solution containing 10% palladium on charcoal and perchloric acid to 3β-hydroxy-17-oxo-5α-androstane (II*a*). Hydrogenation of Δ^5-olefins is a routine operation in steroid chemistry, and a large number of such reactions have been conducted in our laboratory. Generally we have found (15) the product (cf. II*b*) of C-3 oxygen–carbon hydrogenolysis to accompany (ca. 5% yields) the principal product expected from 3-hydroxy- or 3-acetoxy-5-ene systems. Chromatographic separation of the dehydroepiandosterone hydrogenation product gave alcohol II*a* and 2–5% yields of ketone II*b*. Next, previously described methods for conversion of alcohol II*a* via oxime II*c* (98% yield) into amine III were also improved. The oxime → amine reduction step (90% yield) was conducted with sodium–ethanol.[7] The synthesis of amine III from 3β-acetoxy-17-oxo-androst-5-ene (I*b*) was also explored. No advantage was offered by the latter route, and amine III was routinely prepared from alcohol I*a*. Reduction of the 17-oxime proceeded in a highly stereoselective manner to give equatorial amine III.[8] Careful chromatographic purification of the reduction product failed to reveal the presence of the 17α-epimer. The appearance of a sharp singlet at 0.60 δ (C-18 angular methyl group) and a broad complex response at 2.53 δ (17α-proton) in the proton magnetic resonance spectrum of amine III verified the 17β-assignment.[9]



To obtain dipeptide V*b* of high optical purity, racemization during the remaining sequence had to be prevented. From a number of possible peptide-forming methods, the azide (20) and Woodward's reagent K (21) procedures were considered the most attractive. Both, particularly the azide technique, generally cause little or no detectable racemization (22). The apparent experimental simplicity with *N*-ethyl-5-phenylisoxazolium 3′-sulfonate (Woodward's reagent K) combined with the prospect that (as with the azide method) protection would probably not be necessary for the 3β-hydroxy group allowed selection of Woodward's reagent K as the condensing agent.[10] Stepwise formation of dipeptide V*b* was considered desirable to reduce racemization and for evaluating biological properties. Hence, the following route to dipeptide V*b* was employed.

[7]*In addition to ethanol (16a–16d), propanol (16e–16g), butanol (16f), pentanol (16h–16j), and isopentanol (16f) have been used as solvent for similar transformations.*

[8]*Beckmann rearrangement (17) of 20-oximino steroids or treatment of 20-oxo-pregnanes with hydrazoic acid – sulfuric acid mixtures (18) also yields 17β-acetamides in good yield (71–95% via Beckmann rearrangement and 80–82% via Schmidt transformation).*

[9]*A proton magnetic resonance study of authentic 3β-hydroxy-17α-aminoandrost-5-ene and the isomeric 17β-derivative provided the basis for this conclusion (19a). We are indebted to Prof. C. H. Robinson for providing the 17α-amino isomer and for informing us of his proton magnetic resonance study before publication (19b).*

[10]*Summaries of more recently devised peptide methods and reviews of now classical approaches are cited in ref. 23. Because proline is generally less sensitive to racemization than primary-type α-amino acids, the procedures selected here were expected to be of greater value in subsequent studies involving arginine steroidal peptides (24).*

Condensing amine III with the active ester formed by reacting Woodward's reagent K with *N*-carbobenzoxy-L-proline gave (70%) proline derivative IV*a*. The reaction was conducted at ice-bath temperature in acetonitrile solution containing triethylamine. Concomitant acylation of the alcohol group was not observed, and the crystalline amide was readily purified. Hydrogenation (with palladium black and with provision for removing carbon dioxide) of carbamate IV*a* was conducted in methanol solution. In this early series of experiments the palladium catalyst was prepared from palladium(II) chloride, but later palladium from Englehard Industries was found to be equally (and routinely) effective. Amine IV*b* was formed in excellent yield (96%). The crystalline amine (IV*b*) easily formed a hydrochloride derivative. Thin-layer or column chromatography of amines III or IV*b* with chloroform generally gave salts unless appropriate precautions (use of ammonia) were taken. Solvate and (or) hydrate formation was encountered with intermediates beginning with oxime II*c*. Analytical specimens generally required prolonged drying (48–72 h at 60–100° over phosphorus pentoxide) to attain constant weight.

Repetition of the peptide-forming sequence and subsequent hydrogenolysis of the protecting group provided, respectively, peptides IV*a* and V*b*. Peptides IV*a* to V*a* were readily purified by column chromatography, neutral alumina or silica gel being used as the solid phase. A pure specimen of dipeptide V*b* was easily prepared by recrystallization from methanol to yield crystals melting, with decomposition, at 213–217°. As with other androstane-containing peptides later prepared in our laboratories, dipeptide V*b* displayed a substantial negative rotation (−142° in methanol) at the sodium D-line.

In summary, the preceding synthetic route to peptide V*b* proved to be a practical one, and has been used to prepare a number of related steroidal peptides (19*a*, 24).

EXPERIMENTAL

Acetonitrile, dimethylformamide (from phosphorus pentoxide), and triethylamine (from potassium hydroxide) were redistilled and stored over Molecular Sieve type 4-A. The methanol used as the hydrogenation solvent was redistilled from potassium hydroxide. All chromatography solvents were also redistilled. Palladium black was either freshly prepared from palladium(II) chloride (Amend Chemical and Drug Co., New York) or used as purchased from Englehard Industries, Inc., Newark, New Jersey. Woodward's reagent K (*N*-ethyl-5-phenylisoxazolium 3′-sulfonate) was obtained from Pilot and later from Aldrich Chemical Co. The commercial product was dried (*in vacuo*) at 20° for 24 h, and employed without further purification. Carbobenzoxy-L-proline was used as received from Nutritional Biochemicals Corp. Solvent extracts of aqueous solutions were dried over magnesium sulfate.

Neutral alumina (E. Merck, A.G. Darmstadt) and silica gel (E. Merck, 0.05–0.20 mm) were used for column chromatography. Thin-layer chromatograms were prepared with silica gel G (E. Merck). Where R_f values are given, the thin-layer chromatography was performed as follows. Silica gel was uniformly spread on microscope slides and activated by heating the slides at 110° for 0.25 h. The plate was then stored over calcium chloride in a desiccator. Thin-layer plates were eluted in a closed cylindrical container (5 cm in diameter × 9 cm in height) containing a vertical paper strip (Whatman filter paper, 2 × 9 cm). All thin-layer plates were developed by either saturation with iodine vapor, or spraying them with concentrated sulfuric acid or phosphomolybdic acid (saturated solution in methanol). With the acid sprays, the plate was heated at 125° for 0.25 to 1 h. All analytical samples exhibited a single spot on a thin-layer chromatogram.

All melting points were recorded on a Kofler apparatus. Mixture melting points were determined in open Kimble glass capillary tubes in a silicone oil bath. Each new compound was colorless, and elemental microanalytical data was provided by Dr. A. Bernhardt, Max-Planck Institute, Mülheim, Germany. Optical rotation values were determined (at 20° in chloroform unless otherwise noted) in the laboratory of Dr. C. Janssen, Beerse, Belgium. R. A. Hill, Department of Chemistry, University of Maine, and P. A. Whitehouse, Arizona State University, recorded the infrared (in potassium bromide) and proton magnetic resonance spectra. The latter were determined in deuteriochloroform solution with a Varian model A-60 spectrometer. Chemical shifts are reported as frequency-independent δ values with respect to tetramethylsilane as internal standard.

3β-Hydroxy-17-oxo-5α-androstane (IIa)

A solution of 3β-hydroxy-17-oxo-androst-5-ene (I*a*, 25.0 g) and 70% perchloric acid (0.25 ml) in absolute ethanol containing 10% palladium on carbon (3.0 g) was shaken in a hydrogen atmosphere (slightly positive pressure) for 3.5 h. When the reaction was terminated, approximately the calculated amount of hydrogen had been consumed. The solution was filtered through a Celite layer, and the filtrate was concentrated *in vacuo* to a crystalline solid. A solution of the residue in chloroform was washed successively with water, 5% aqueous sodium bicarbonate, and water. Removal (*in vacuo*) of solvent gave a solid composed of four components (as indicated by thin-layer chromatography). A solution of the product in chloroform was chromatographed on neutral alumina (400 g). Elution with the same solvent (500 ml) gave impure material (12.0 g). Fractions obtained by continued elution with the same solvent and rechromatography (beginning with 4:1 benzene–chloroform) of the first fraction led to 13.8 g (55%) of alcohol II*a* (fractions melting from 173–174° to 176–177.5° after recrystallization from chloroform–hexane) and 0.43 g (2%) of ketone II*b* melting at 114–116°.

Two recrystallizations from chloroform–hexane (1:2) provided a pure specimen of *3β-hydroxy-17-oxo-5α-androstane* (II*a*) as fine needles: R_f 0.29 in ether–benzene (3:1); m.p. 176–177.5° (sintering from 172°); $[\alpha]_D$ +44.4° (*c*, 0.27); ν_{max} 3 440, 2 920, 1 730, 1 374, 1 308, 1 082, and 1 046 cm^{-1}. Melting points of 174–174.5° and 176–177° have been reported (25) for alcohol II*a*.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.59; H, 10.40; O, 11.01. Found: C, 78.68; H, 10.34; O, 10.93.

After three recrystallizations from hexane an analytical sample of *17-oxo-5α-androstane* (II*b*) was obtained as needles melting at 117–119° (sintering from 108°): R_f 0.77 in ether–benzene (3:1); $[\alpha]_D$ +93.7° (*c*, 1.55); ν_{max} 2 920, 1 745, 1 448, 1 376, 1 060, and 1 012 cm^{-1}. An optical rotation (26) value of $[\alpha]_D^{16}$ +87.8° and melting points of 119–120.5° and 122° have been reported (26) for ketone II*b*.

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.15; H, 11.02; O, 5.83. Found: C, 83.20; H, 11.17; O, 6.00.

The preceding hydrogenation experiment was repeated several times, and yields of ketones II*a* and II*b* of up to 76 and 6%, respectively, were obtained.

3β-Hydroxy-17-oximino-5α-androstane (IIc)

A warm solution of hydroxylamine hydrochloride (8.8 g) in 10:1 ethanol–water (110 ml) was added to a solution of ketone II*a* in pyridine (100 ml). The resulting solution was heated at reflux for 5 h. The hot solution was diluted with warm (60°) water (1 l), and the product which separated was collected and washed successively with water, 5% hydrochloric acid, and water. The crude solid (10.4 g) recrystallized from methanol as needles; yield 9.0 g (85%), m.p. 191–193°. Concentrating the mother liquors led to an additional 1.4 g (13%) of oxime melting from 187–191° to 190–192°. Two recrystallizations from methanol gave a pure sample as sparkling plates: R_f 0.55 in chloroform–methanol (9:1); m.p. 194° (sintering from

140°); $[\alpha]_D$ +17.5° (*c*, 6.18); ν_{max} 3 300 (broad), 2 920, 1 450 (broad with shoulder at 1 468), 1 372, 1 138, 1 046 (shoulder at 1 038), and 930 cm^{-1}. A melting point of 185–186° has been reported (27) for oxime II*c*.

3β-Hydroxy-17β-amino-5α-androstane (III)

Method a

Freshly cut sodium (54.0 g) was added in small increments over a 2 h period to a refluxing solution of oxime II*c* (9.0 g) in absolute ethanol (450 ml). Heating was continued for 1.5 h, and the hot mixture was diluted with warm (50°) water. After 16 h at room temperature, product was collected, washed with water, and dried; yield 7.8 g (90%), m.p. 153–157°. A solution of the straw-colored product in ethanol was treated with Norit A, filtered, and concentrated (*in vacuo*) to a pale-yellow solid. Amine III crystallized from 1:2 benzene–hexane as crystal clusters weighing 4.9 g and melting at 157°. An additional 1.8 g (m.p. 156°) was isolated by concentrating the mother liquors. Recrystallization (Norit A) from benzene–hexane followed by two recrystallizations from ethanol–water yielded a pure specimen as microcrystalline platelets: R_f 0.29 in chloroform (saturated with concentrated ammonium hydroxide);[11] m.p. 158–160° (softens at 150°); $[\alpha]_D$ +10.7° (*c*, 1.41); ν_{max} 3 200, 2 930 (shoulder at 2 860), 1 590 (weak and broad), 1 446, 1 376 – 1 368 (doublet), 1 076, 1 052, and 1 034 cm^{-1}; proton magnetic resonance response at 0.60 (singlet, three protons), 0.78 (singlet, three protons), 2.53 (complex, one proton), and 3.40 (broad, one proton) δ.

Anal. Calcd. for $C_{19}H_{33}NO$: C, 78.30; H, 11.41; N, 4.80. Found: C, 78.45; H, 11.35; N, 4.87.

Amine III has been prepared (29) in 60% yield by using a sodium–propanol reduction sequence.

Method b

The series of experiments beginning above with alcohol II*a* were repeated with 3β-acetoxy-17-oxo-androst-5-ene (I*b*) as starting material. The hydrogenation step (performed by Dr. H. Klinger) gave comparable results, that is, approximately 5% of the product was one (II*b*) resulting from hydrogenolysis at C-3. The major product, 3β-acetoxy-17-oxo-5α-androstane, was converted as described in the case of oxime II*c* into acetate II*d*. Reduction of oxime II*d* (10.0 g) was conducted essentially as described in the preceding experiment (method *a*). One recrystallization from ethyl acetate – methanol gave 8.2 g melting at 153–157°. Two additional recrystallizations from the same solvent gave a pure sample (crystalline rosettes) melting at 164–165°; $[\alpha]_D$ +17.0° (*c*, 0.79 in methanol).

Anal. Found: C, 78.02; H, 11.36; N, 4.74.

Method *b* held no advantage over method *a*. In the reduction step, the use of super dry[12] ethanol or larger molar ratios of sodium or oxime was unnecessary.

3β-Hydroxy-17β-(N^{α}-carbobenzoxy-L-prolyl)amino-5α-androstane (IVa)

Woodward's reagent K (5.1 g) and triethylamine (2.0 g) were added to a cold (ice bath), rapidly stirred solution of *N*-carbobenzoxy-L-proline (4.6 g) in dry acetonitrile (250 ml). The reaction was conducted in a flask equipped with a magnetic stirrer and a calcium chloride drying tube. After the solution was stirred for 2 h at ice-bath temperature, dissolution of reactants was complete. The cold reaction mixture was next treated with amine III (5.8 g) and allowed to warm to room temperature. Before the solvent was removed (at 50°) *in vacuo*, stirring at room temperature was continued for 22 h. The residue was dissolved in chloroform and washed successively with water (100 ml), 5% hydrochloric acid (2 × 50 ml), water (100 ml), 5% sodium bicarbonate (2 × 50 ml), and water (100 ml). The chloroform solution was concentrated to approximately 30 ml and chromatographed on neutral alumina (100 g). Elution with the same solvent (300 ml) gave a colorless foam which separated from chloroform–hexane (1:2) as an amorphous powder; yield 7.3 g (70%), m.p. 187–190°. Crystallization and recrystallizations from chloroform – ethyl acetate (1:4) led to a pure sample as microcrystalline needles: R_f 0.61 in chloroform–methanol (9:1); m.p. 196.5–198° (sintering from 191°); $[\alpha]_D$ −76.9° (*c*, 1.01); ν_{max} 3 320, 2 930, 1 693 – 1 668 (broad shoulder at 1 715), 1 540 (broad), 1 420, and 1 359 cm^{-1}; proton magnetic resonance response at 0.51 (singlet, three protons), 0.76 (singlet, three protons), 4.15 (complex, one proton), 4.91 (singlet, two protons), and 7.01 (singlet, five protons) δ.

Anal. Calcd. for $C_{32}H_{46}H_2O_4$: C, 73.52; H, 8.87; N, 5.36; O, 12.25. Found: C, 73.45, 73.46; H, 8.84, 8.64; N, 5.50, 5.51; O, 12.23.

3β-Hydroxy-17β-L-prolylamino-5α-androstane (IVb)

Method a

Hydrogen was passed (at room temperature for 3 h) through a gas dispersion tube into an Erlenmeyer flask containing a solution of carbamate IV*a* (5.2 g) in methanol (250 ml) and palladium black (0.52 g). The mixture was rapidly stirred with a magnetic stirrer, and generated carbon dioxide was swept (with hydrogen) from the reaction vessel into aqueous barium hydroxide. Additional catalyst (0.5 g) was added and hydrogenation continued for 4 h. The solution was filtered through a Celite layer and the filtrate was evaporated *in vacuo* to a colorless solid. A methanol–chloroform (1:3) extract of the residue was diluted with 5% aqueous sodium bicarbonate, and the resulting chloroform phase was washed with water and concentrated (*in vacuo*) to dryness; yield 3.7 g (96%), decomposition point 226–228° (softening at 216°).

[11]*This general technique has been described by Lábler and Černý (28).*

[12]*Prepared as described by Vogel (30).*

For personal use only.

Because a thin-layer chromatogram indicated the presence of impurities, a solution of the product in chloroform–methanol (19:1) was chromatographed on neutral alumina (100 g). Unreacted carbamate IV*a* accompanied by two unidentified by-products was eluted by the same solvent (150 ml). Continued elution with 19:1 to 4:1 chloroform–methanol led to a crystalline residue exhibiting a positive Beilstein test. The latter fraction was dissolved in chloroform and washed successively with 5% aqueous sodium bicarbonate (25 ml) and water (2 × 100 ml). Removal of solvent and recrystallization of the residue from chloroform–hexane (1:1) gave needles weighing 1.6 g and melting to 238° with decomposition. Further recrystallization from the same solvent gave a pure specimen as sparkling needles: R_f 0.24 in chloroform–methanol (4:1); decomposition point 230–238° (sintering from 223°); $[\alpha]_D$ −52.7° (*c*, 1.99); ν_{max} 3 380 – 3 250 (doublet), 2 920 (shoulder at 2 830), 1 663, 1 560, 1 524, 1 446, 1 078, and 1 038 (shoulder at 1 027) cm^{-1}; proton magnetic resonance response at 0.63 (singlet, three protons), 0.77 (singlet, three protons), and 2.79 (complex, one proton) δ.

Anal. Calcd. for $C_{24}H_{40}N_2O_2$: C, 74.20; H, 10.38; N, 7.20; O, 8.22. Found: C, 74.30, 74.03; H, 10.22, 10.33; N, 7.20; O, 8.44.

Method b

In another experiment 1.6 g of carbamate IV*a* was subjected to hydrogenolysis. The crude product weighed 1.1 g and decomposed at 222–225°. Three recrystallizations from methanol yielded an analytical sample as shiny needles decomposing at 226–228°; $[\alpha]_D$ −55.9° (*c*, 0.41).

Anal. Found: C, 74.03; H, 10.45; O, 8.44 (Calcd.: O, 8.24).

A methanol solution of amine IV*b* (0.18 g) was treated with ethereal hydrogen chloride, and the solid (0.16 g) which separated was recrystallized 3 times from methanol – diethyl ether. By this means, an analytical specimen of *amine IVb hydrochloride* was obtained as needles decomposing at 256° with sintering from 235°: R_f 0.22 in chloroform–methanol (4:1); ν_{max} 3 350, 3 200, 2 900 (shoulders at 2 820, 2 740, and 2 560), 1 672, 1 550, and 1 034 cm^{-1}.

Anal. Calcd. for $C_{24}H_{41}ClN_2O_2$: C, 67.83; H, 9.72; Cl, 8.34. Found: C, 67.91; H, 9.78; Cl, 8.26.

3β-Hydroxy-17β-(N$^{\alpha}$-carbobenzoxy-L-prolyl-L-prolyl)amino-5α-androstane (Va)

Proline derivative IV*b* (1.9 g) was allowed to react with the active ester prepared from *N*-carbobenzoxy-L-proline (1.3 g) and Woodward's reagent K (1.3 g) in the presence of triethylamine (0.5 g) as summarized above for the preparation of carbamate IV*a*. A thin-layer chromatogram (7:3 chloroform–methanol being used as the mobile phase) indicated that dipetitde V*a* was the major product accompanied by two minor by-products. Accordingly, a solution of the crude product in chloroform was chromatographed on a column of silica gel (75 g). Elution with the same solvent gave 1.2 g of peptide V*a*. An analytical sample was prepared by recrystallizing the peptide from methanol – diethyl ether – pentane: yield 0.6 g of crystals melting at 120–123°; $[\alpha]_D$ −142.9° (*c*, 0.35 in methanol).

Anal. Calcd. for $C_{37}H_{53}O_5N_3$: C, 71.69; H, 8.62; N, 6.70. Found: C, 71.66; H, 8.44; N, 6.12.

3β-Hydroxy-17β-(L-prolyl-L-prolyl)amino-5α-androstane (Vb)

Cleavage of the carbobenzoxy protecting group from peptide V*a* (0.70 g) was conducted essentially as described above (see amide IV*b*) with methanol (25 ml) as solvent and palladium black (0.20 g) as catalyst. After 6 h, the evolution of carbon dioxide appeared to be complete and hydrogenation was terminated. A thin-layer chromatogram (7:1 chloroform–methanol being used as the mobile phase) indicated that amine V*b* (0.55 g) was accompanied by a trace of starting material. Three recrystallizations from methanol (with a few drops of diethyl ether) gave pure crystals of peptide IV*b* decomposing at 213–217°; $[\alpha]_D$ −134.1° (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{29}H_{47}N_3O_3$: C, 71.71; H, 9.75. Found: C, 71.29, 71.19; H, 9.51, 9.53.

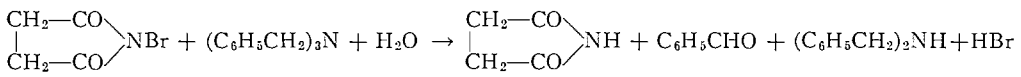
ÉTUDE CINÉTIQUE DE L'OXYDATION DE LA TRIBENZYLAMINE PAR LA *N*-BROMOSUCCINIMIDE[1]

MIKLOS ZADOR
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 23 mars 1966

RÉSUMÉ

L'oxydation de la tribenzylamine par la *N*-bromosuccinimide a été étudiée dans un solvant méthanol–eau. La réaction procède selon deux étapes. La première, celle d'oxydation proprement dite, s'accompagne de la formation d'acide bromhydrique. Elle est suivie par la solvolyse du produit intermédiaire formé et donne lieu au benzaldéhyde.



La catalyse par l'acide bromhydrique et l'inhibition par la succinimide sont interprétées en termes de mécanisme réactionnel faisant intervenir des dérivés hypobromeux.

INTRODUCTION

Les dérivés *N*-bromés des amides, tels que la *N*-bromosuccinimide, agents de bromuration allylique par excellence, se sont récemment avérés efficaces dans l'oxydation de dérivés tels que les alcools et les amines. Ils permettent également l'oxydation sélective d'une de ces fonctions dans une molécule polyfonctionnelle ainsi que la dégradation de molécules complexes.

L'ensemble de ces résultats a fait l'objet de trois articles de revue (1–3). Il en ressort qu'en milieu apolaire les réactions sont de type radicalaire, initiées par les peroxydes et les radiations ultraviolettes. En milieu polaire les initiateurs n'ont pas d'effet et la réaction procède dans ce cas "via brome positif". Bien qu'un très grand nombre de travaux aient été publiés sur l'aspect préparatif de ces réactions, on connaît peu de résultats quantitatifs concernant leur cinétique et leur mécanisme.

L'oxydation de la tribenzylamine par la *N*-bromosuccinimide a été étudiée par Dunstan et Henbest (4) et par Horner *et al.* (5). On peut écrire

ou, pour abréger,[2]

$$SNBr + B_3N + H_2O \rightarrow SNH + C_6H_5CHO + B_2NH + HBr.$$

Dunstan et Henbest (4) ont observé que dans le benzène il y a tout d'abord formation d'un intermédiaire de couleur orange, dont le spectre infrarouge est presque identique à celui d'un mélange des deux réactifs. En présence d'eau celui-ci se décompose pour donner les produits de la réaction.

Les autres auteurs (5) admettent qu'un dérivé bromé de la tribenzylamine, $C_6H_5CHBrN(CH_2C_6H_5)_2$, se forme comme intermédiaire dans la réaction. Cependant, ils ne fournissent pas de preuves expérimentales pour soutenir leur hypothèse.

Dans le présent travail nous nous sommes proposés d'élucider la cinétique et le mécanisme de cette réaction, que nous avons effectué toutefois dans un solvent méthanol–eau pour éviter les complications dues à l'hétérogénéité du mileu benzène–eau utilisé par les auteurs cités.

[1]*Présenté au 33ème congrès annuel de l'Association Canadienne-Française pour l'Avancement des Sciences, Montréal, Québec, novembre 1965.*

[2]*Nous avons préféré d'utiliser le symbole SNBr au lieu de NBS pour la N-bromosuccinimide. Ceci nous permet de symboliser la succinimide par SNH et, de plus, d'écrire une équation stoïchiométrique.*

MÉTHODES EXPÉRIMENTALES

Réactifs

Les solvants utilisés sont le méthanol de pureté analytique et l'eau distillée. La tribenzylamine est recristallisée d'un mélange éthanol–eau, et la succinimide est recristallisée d'un mélange éthanol–benzène. La *N*-bromosuccinimide utilisée est rapidement recristallisée de l'eau distillée bouillante, et on la conserve à l'abri de la luminère. L'analyse iodométrique indique une pureté supérieure à 99%. L'acide bromhydrique est de pureté analytique de composition azéotropique.

Méthodes d'analyse

Les réactions sont suivies par spectrophotométrie et par conductimétrie.

Spectrophotométrie

Le dosage du benzaldéhyde s'effectue à longueur d'onde de 281 mμ, où se situe un maximum d'absorption pour ce composé. La loi de Lambert–Beer est respectée dans les conditions expérimentales, et la valeur du coefficient d'absorption moléculaire est de 1 240 dans le méthanol contenant 5% (v/v) d'eau.

Seul le brome susceptible de se former peut interférer dans ce dosage. Cependant, dans les conditions expérimentales, c'est à dire en présence d'un excès de tribenzylamine, le brome moléculaire se transforme instantanément en dérivés hypobromeux qui n'absorbent pas à cette longueur d'onde.

Conductimétrie

La variation de conductivité, due à la formation d'acide bromhydrique, permet également de suivre la réaction. Un calibrage est effectué dans les conditions expérimentales, pour lesquelles l'acide bromhydrique se trouve sous forme de bromure de tribenzylammonium.

Appareillages

Le spectrophotomètre utilisé est un "Hitachi–Perkin–Elmer model 139", et le conductimètre est un modèle "Radiometer CDM2*d*". Le compartiment à cellules du spectrophotomètre et la cellule conductimétrique sont thermostatés à 25 ± 0.2 °C. Les résultats sont enregistrés sur un "Photovolt model Microcord 44".

Méthode cinétique

La réaction est réalisée dans des solvants mixtes méthanol–eau, pour lesquels on a vérifié que l'oxydation du méthanol est négligeable dans les conditions expérimentales; la formation du benzaldéhyde est par ailleurs quantitative.

A la solution contenant les réactifs (la *N*-bromosuccinimide exceptée), on ajoute au temps initial la quantité appropriée de solution de *N*-bromosuccinimide fraîchement préparée par dissolution du réactif solide. L'homogénéisation du mélange est réalisée par agitation magnétique. Cependant, dans le cas où l'addition des réactifs est faite directement dans les cellules, le mélange est effectué par barbotage d'air pendant quelques secondes. L'oxygène de l'air n'a pas d'influence détectable sur la vitesse des réactions.

La force ionique des solutions n'est pas maintenue constante, étant donné que l'influence de cette dernière est expérimentalement non-significative dans l'étendue de concentration étudiée (jusqu'à $\mu = 0.002$).

La reproductibilité des vitesses initiales est supérieure à 20%, ce qui est relativement médiocre mais permet néanmoins de tirer des conclusions quantitatives. En effet, dans le domaine de concentration considéré la vitesse varie d'un facteur supérieur à 100.

RÉSULTATS ET DISCUSSION

Formation de benzaldéhyde

La formation du benzaldéhyde est illustrée par la Fig. 1, où l'on porte la variation de la densité optique en fonction du temps pour trois expériences caractéristiques. Dans le cas général (courbe *a*) une période d'induction précède l'augmentation de la vitesse de la réaction. Un des produits, l'acide bromhydride, exerce une action catalytique (courbe *b*), tandis que la succinimide a une influence inhibitrice (courbe *c*).

L'ensemble des résultats obtenus par spectrophotométrie ne peut être interprété par un mécanisme simple. Nous avons donc cherché à obtenir des informations supplémentaires en étudiant la variation de conductivité due à la formation d'acide bromhydrique.

Formation d'acide bromhydrique

L'emploi simultané des deux méthodes analytiques nous permet de montrer que la réaction procède par plusieurs étapes. Une expérience caractéristique est présentée dans la Fig. 2. La formation de l'acide bromhydrique (forme réduite) est représentée par la

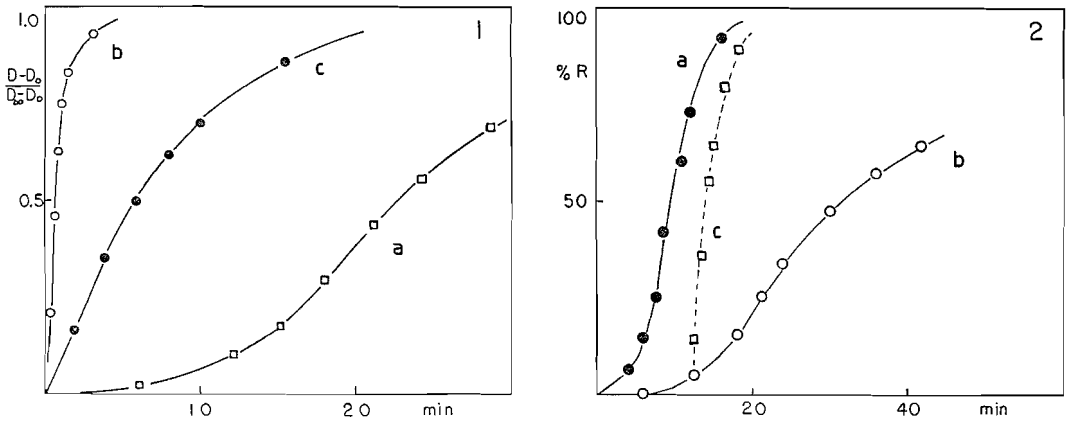

FIG. 1. Formation de benzaldéhyde. Solvant, méthanol contenant 5% (v/v) d'eau; température, 25 °C; $[B_3N] = 1.0 \times 10^{-2}$ mole l^{-1}; $[SNBr] = 5.0 \times 10^{-4}$ mole l^{-1}; courbe *a*, $[SNH] = 5.0 \times 10^{-3}$ mole l^{-1} et $[HBr] = 0$; courbe *b*, $[SNH] = 5.0 \times 10^{-3}$ mole l^{-1} et $[HBr] = 5.0 \times 10^{-4}$ mole l^{-1}; courbe *c*, $[SNH] = 1.0 \times 10^{-1}$ mole l^{-1} et $[HBr] = 5.0 \times 10^{-4}$ mole l^{-1}.

FIG. 2. Formation d'acide bromhydrique et de benzaldéhyde. Solvant, méthanol; température, 25 °C; $[B_3N] = 1.0 \times 10^{-2}$ mole l^{-1}; $[SNBr] = 5.0 \times 10^{-4}$ mole l^{-1}; $[SNH] = 5.0 \times 10^{-3}$ mole l^{-1}; courbe *a*, % HBr formé; courbe *b*, % benzaldéhyde formé; courbe *c*, % benzaldéhyde formé après l'addition de 5% (v/v) d'eau.

courbe *a*; c'est une étape d'oxydation. L'absence de réaction avec l'iodure de potassium montre que le brome oxydant est consommé à la fin de cette étape.

La courbe *b* évoque la formation du benzaldéhyde au cours de la même expérience. Ces résultats montrent clairement que le benzaldéhyde ne se forme que dans une étape postérieure à l'oxydation. L'addition de 5% (v/v) d'eau au mélange réactionnel à un stade où l'oxydation est quasi complète augmente d'une manière très importante la vitesse de formation du benzaldéhyde (courbe *c*); on peut en conclure que cette étape est la solvolyse du produit intermédiaire formé au cours du processus; cela permet en outre de déterminer la constante de vitesse de cette seconde étape.

Etant donné la difficulté d'obtenir du méthanol contenant moins de 10^{-3} mole d'eau/l, il ne nous a pas été possible de montrer qu'il s'agissait d'une hydrolyse plutôt qu'une solvolyse par les deux solvants.

Étude en cinétique initiale

La formation de l'acide bromhydrique a été beaucoup plus facile à étudier de façon significative; en effet cette étape peut être étudiée en cinétique initiale, ce qui évite l'influence de l'acide bromhydrique formé au cours de la réaction. Un certain nombre de résultats sont présentés dans le Tableau I et dans la Fig. 3. Dans cette dernière, les courbes représentent la variation de la vitesse initiale de la réaction en fonction de la concentration initiale en acide bromhydrique pour diverses concentrations en succinimide. Pour une concentration donnée de cette dernière, la vitesse initiale peut être exprimée en fonction de la concentration en acide bromhydrique par éq. [1].

$$[1] \qquad V = [SNBr](k_0 + k_{H^+}[HBr] + k_{HBr}[HBr]^2)$$

La courbe *b* de la Fig. 3 correspond aux valeurs suivantes des constantes: $k_0 = 1.8 \times 10^{-2}$ min^{-1}; $k_{H^+} = 300$ $mole^{-1}$ l min^{-1}; $k_{HBr} = 7 \times 10^5$ $mole^{-2}$ l^2 min^{-1}. Notons que dans les conditions expérimentales l'acide bromhydrique se trouve sous forme de bromure de tribenzylammonium (B_3NH^+). De plus la concentration en protons solvatés

NOTONS: Solvant, méthanol contenant 5% (v/v) d'eau; température, 25 °C; [B_3N] = 1.0×10^{-2} mole l^{-1}.

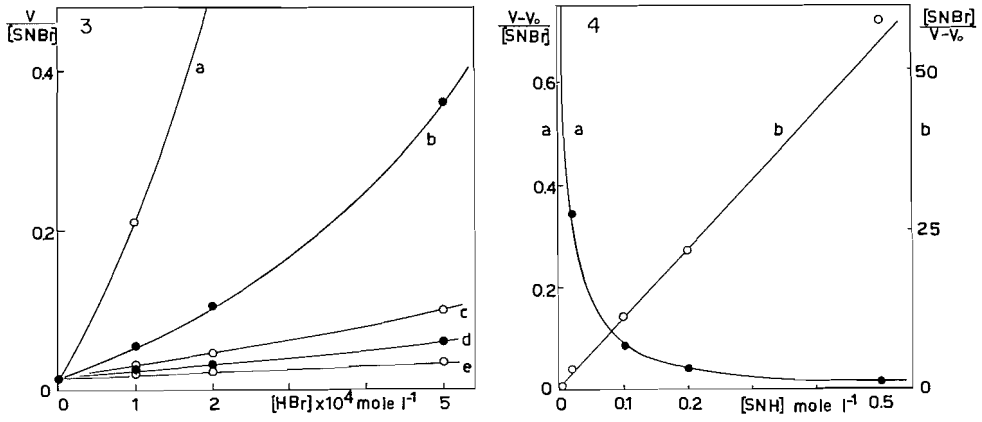

FIG. 3. Effet catalytique de l'acide bromhydrique sur la vitesse d'oxydation. Solvant, méthanol contenant 5% (v/v) d'eau; température, 25 °C; [B_3N] = 1.0×10^{-2} mole l^{-1}; [SNBr] = 5.0×10^{-4} mole l^{-1}; courbe *a*, [SNH] = 5.0×10^{-3} mole l^{-1}; courbe *b*, [SNH] = 2.0×10^{-2} mole l^{-1}; courbe *c*, [SNH] = 1.0×10^{-1} mole l^{-1}; courbe *d*, [SNH] = 2.0×10^{-1} mole l^{-1}; courbe *e*, [SNH] = 5.0×10^{-1} mole l^{-1}. Unité de vitesse, mole l^{-1} min^{-1}.

FIG. 4. Effet inhibiteur de la succinimide sur la vitesse d'oxydation. Solvant, méthanol contenant 5% (v/v) d'eau; température, 25 °C; [B_3N] = 1.0×10^{-2} mole l^{-1}; [SNBr] = 5.0×10^{-4} mole l^{-1}; [HBr] = 5.0×10^{-4} mole l^{-1}. Unité de vitesse, mole l^{-1} min^{-1}.

est, pour ce milieu tamponné B_3NH^+/B_3N, proportionnelle à la concentration en ion B_3NH^+ car la tribenzylamine est prise en grand excès. Dans ces conditions, k_{H^+} et k_{HBr} sont des constantes apparentes.

L'effet catalytique de l'acide bromhydrique varie avec la concentration en succinimide (Fig. 3, courbes *a*–*e*). Pour une concentration donnée en acide bromhydrique l'expression suivante (éq. [2]) permet de rendre compte de manière quantitative des résultats observés.

$$V = V_0 + \frac{k[\mathrm{SNBr}]}{1 + k'[\mathrm{SNH}]} \qquad [2]$$

Dans cette expression le terme V_0 représente la vitesse d'oxydation non-catalysée, qui d'ailleurs n'est pas affectée par la succinimide (ordonnée à l'origine dans la Fig. 3). Le terme suivant représente la vitesse de la réaction catalysée.

L'équation [2] peut être transformée en une relation linéaire (éq. [3]).

$$\frac{[\mathrm{SNBr}]}{V - V_0} = \frac{1}{k} + \frac{k'}{k}[\mathrm{SNH}] \qquad [3]$$

L'accord avec l'expérience est satisfaisant, comme le montre la droite de la Fig. 4, dont la pente donne la valeur de k'/k. Il n'est pas possible de calculer séparément la valeur des deux constantes, étant donné la grande incertitude sur l'ordonnée à l'origine, $1/k$.

Interprétation des résultats

Pour interpréter les résultats nous admettons le mécanisme suivant (éqs. [4]–[7]) pour l'oxydation de la tribenzylamine par la *N*-bromosuccinimide (Y = —OR, HOR ou Br^-; R = $—CH_3$ ou —H).

$$\mathrm{SNBr} + \mathrm{B_3N} + \mathrm{YH} \xrightarrow{k_0} \mathrm{SNH} + \text{Intermédiaire} + \mathrm{HBr} \qquad [4]$$

$$\mathrm{SNBr} + \mathrm{H^+} + \mathrm{Y} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{SNH} + \mathrm{YBr^+} \qquad [5]$$

$$\mathrm{YBr^+} + \mathrm{B_3N} \xrightarrow{k_2} \text{Intermédiaire} + \mathrm{HBr} \qquad [6]$$

$$\text{Intermédiaire} + \mathrm{ROH} \xrightarrow{k_3} \mathrm{C_6H_5CHO} + \mathrm{HN}\diagup\!\diagdown + \mathrm{YR} \qquad [7]$$

La *N*-bromosuccinimide peut oxyder directement la tribenzylamine pour donner un produit intermédiaire et de l'acide bromhydrique (éq. [4]). Elle peut, dans une étape parallèle, réagir selon des vitesse différentes avec les diverses espèces Y pour donner des produits contenant le brome au degré d'oxydation +1 (éq. [5]).

Les diverses espèces YBr^+ échangent le brome entre elles d'après le schéma montré dans éq. [8].

$$\begin{array}{ccc} & \mathrm{CH_3OBr} & \\ \nearrow\!\!\!

Nous négligeons de plus les formes protonées telles que $BrOH_2^+$ et CH_3OHBr^+, dont la concentration devrait être infime (7), mais qui pourront néanmoins intervenir comme agents d'oxydation (8).

Dans l'étape suivante (éq. [6]) les dérivés YBr^+ oxydent, avec des vitesses différentes, la tribenzylamine mais les concentrations relatives des formes intervenant dans l'équilibre montré dans éq. [8] restent inchangées pour les raisons mentionnées auparavant.

Le mécanisme proposé est cohérent avec éq. [1]. En effet, k_0 y représente l'oxydation "spontanée", le terme $k_{H^+}[HBr]$ correspond à la solvolyse, catalysée par H^+, de la *N*-bromosuccinimide et $k_{HBr}[HBr]^2$ est dû à la réaction de cette dernière avec l'ion bromure catalysée par H^+; ces deux dernières réactions, après l'établissement de l'équilibre montré dans éq. [8], sont suivies par l'oxydation de la tribenzylamine par YBr^+.

L'équation [5] explique bien l'influence inhibitrice de la succinimide. Elle réagit avec YBr^+ et diminue ainsi la concentration de cette forme active.

L'application formelle d'un traitement d'état stationnaire pour YBr^+ donne éq. [9],

$$[9] \qquad k_1([SNBr] - [YBr^+]) - k_{-1}[SNH][YBr^+] - k_2[YBr^+] = 0$$

où k_1 et k_{-1} sont les constantes de vitesse apparentes de éq. [5]; de même, k_2 est la constante de éq. [6] qui inclue la concentration en tribenzylamine.

A partir de éq. [9] on obtient la relation suivante (éq. [10]) pour la vitesse d'oxydation via les éqs. [5] et [6].

$$[10] \qquad V = \frac{k_1k_2[SNBr]}{k_1 + k_2 + k_{-1}[SNH]}$$

Pour la vitesse totale d'oxydation on a

$$[11] \qquad V = V_0 + \frac{k_1k_2[SNBr]}{k_1 + k_2 + k_{-1}[SNH]},$$

où V_0 représente la vitesse d'oxydation "spontanée".

Cette expression est la même que éq. [2] en posant $k = k_1k_2/(k_1 + k_2)$, $k' = k_{-1}/(k_1+k_2)$ et $k'/k = k_{-1}/k_1k_2 = 108$ mole^{-1} l min.

Enfin, éq. [7] est l'étape de solvolyse et donne lieu aux produits finals (le benzaldéhyde et la dibenzylamine). Sa constante de vitesse (k_3) a été déterminée par la méthode mentionnée plus haut, et sa valeur est 0.6 min^{-1} dans les conditions expérimentales.

La confirmation directe de ce mécanisme par l'identification des intermédiaires d'oxydation n'est pas possible. Les méthodes d'isolement sont en effet trop lentes par rapport à la solvolyse, tandis que la spectroscopie est inefficace à cause de l'excès de tribenzylamine et la nature du milieu. Comme hypothèse on peut admettre qu'il s'agit des dérivés α-bromés (5) ou α-hydroxylés de la tribenzylamine. Ces derniers peuvent d'ailleurs se former aux dépens des premiers et donneraient, par décomposition, le benzaldéhyde et la dibenzylamine. Cependant, faute de preuve éxperimentale, il n'est pas possible de formuler un mécanisme détaillé pour leur formation.

Il est à noter que le mécanisme proposé s'apparente en partie à celui de Orton *et al.* pour la transposition des *N*-halogéno-acétanilides (9–11).

$$[12] \qquad C_6H_5NXCOCH_3 + HX \overset{\text{Lent}}{\rightleftharpoons} C_6H_5NHCOCH_3 + X_2$$

$$[13] \qquad C_6H_5NHCOCH_3 + X_2 \xrightarrow{\text{Rapide}} XC_6H_4NHCOCH_3 + HX$$

L'équation de vitesse est donnée par éq. [14].

$$[14] \qquad V = k[C_6H_5NXCOCH_3][HX]^2$$

En effet, la catalyse par l'acide bromhydrique (en particulier par l'ion bromure) ne s'explique que par la formation du brome (qui est en équilibre avec les dérivés hypobromeux) comme intermédiaire réactionnel. Les différences entre les équations de vitesse obtenues sont dues à l'importance plus grande de la solvolyse du dérivé *N*-bromé ainsi qu'à l'influence inhibitrice marquée de l'amide formée (succinimide) (éqs. [1], [11] et [14]).

Il est difficile de faire une comparaison avec les études antérieures consacrées à l'oxydation de la tribenzylamine par la *N*-bromosuccinimide (4, 5), étant donné que les conditions expérimentales sont très différentes. Le fait que les vitesses de réaction soient élevées même à basse concentration permet néanmoins de mettre en doute l'intervention du complexe formé entre la tribenzylamine et la *N*-bromosuccinimide dans le benzène comme intermédiaire de réaction (4). En effet, l'acide bromhydrique et le benzaldéhyde ne se forment qu'après l'addition d'eau au mélange réactionnel, et la réaction peut très bien avoir lieu, avec une vitesse très élevée, à ce moment là.

A la lumière de ce travail l'on peut conclure que l'oxydation globale ou sélective d'une fonction particulière dans une molécule polyfonctionnelle serait principalement due au brome et aux dérivés hypobromeux qui se forment, et non pas à la *N*-bromosuccinimide, du moins en milieu organo–aqueux. L'interprétation éventuelle des résultats devrait donc être faite sur cette base.

PYRANOSE–FURANOSE AND ANOMERIC EQUILIBRIA

INFLUENCE OF SOLVENT AND OF PARTIAL METHYLATION[1]

W. MACKIE[2] AND A. S. PERLIN

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received April 25, 1966

ABSTRACT

Sugars possessing the *arabino* (2,3,4-*trans*,*cis*) configuration exist as furanoses to a greater extent in dimethyl sulfoxide than in water. Their 2,3-di-*O*-methyl derivatives show an even stronger preference for a five membered ring structure in both solvents. This is most marked for 2,3-di-*O*-methyl-D-arabinose and 2,3-di-*O*-methyl-D-altrose, which are 65% and 80% furanose, respectively, in dimethyl sulfoxide. Compounds in the *xylo* (2,3,4-*trans*,*trans*) or *lyxo* (2,3,4-*cis*,*trans*) series show little tendency to be furanoses in either solvent. However, α-pyranoses in the *lyxo* series are relatively more stable in dimethyl sulfoxide than in water, whereas the anomeric composition for members of the *xylo* series is the same in both solvents. Some of these variations in the equilibria are attributed to the preferential stabilization of pyranose forms in water. D-Lyxose and D-ribose show nuclear magnetic resonance spectral differences in the two solvents that appear to be due to conformational, as well as tautomeric, equilibrium changes.

An equatorial anomeric hydroxyl proton of a given pair in dimethyl sulfoxide shows a larger spacing (6.5–8.0 c.p.s.) than an axial anomeric hydroxyl proton (4–5 c.p.s.). The signal for the latter proton occurs at higher field than an equatorial OH-1, except when OH-2 is axial.

In a recent study of hydroxyl proton magnetic resonance spectra it was found that certain sugars tend to exist as furanoses to a greater extent in dimethyl sulfoxide than in water (1). D-Arabinose shows this difference very markedly. At equilibrium, virtually no furanose is detected in the aqueous solution, whereas in dimethyl sulfoxide its proportion is one-third of the total (Table I). Galactose behaves similarly, although the final percentage of furanose is not as high. D-Altrose and D-fructose, both of which are configurationally related to these sugars, exist as furanoses to a very considerable extent in water. However, the tautomeric composition of the former (2) is altered significantly in dimethyl sulfoxide, in which it shows an even stronger preference for the five membered ring structure (Table I). The presence of mixed furanose and pyranose forms of D-fructose in water is shown by the fact that, when an aqueous solution of the sugar is concentrated, the resulting syrupy material shows several strong singlets ascribable to OH-2 when freshly dissolved in dimethyl sulfoxide. As equilibration proceeds in this solvent, the main change observed is a decrease in the relative intensity of the signal attributable to OH-2 of the β-pyranose form.

One possible explanation (1) of these compositional differences in the two solvents is that water may preferentially stabilize the pyranoses through hydrogen bonding. This is based on evidence (3) that, when water solvates a sugar molecule possessing a pyranose chair form, the structure of water itself suffers very little disorientation, and intermolecular association can take place readily. Although dimethyl sulfoxide also is strongly hydrogen bonding, there is no apparent relationship of this kind between its linear structure (4) and one specific type of cyclic sugar conformation.

To examine the possibility that water may stabilize pyranoses preferentially, the equilibrium compositions of some 2,3-di-*O*-methyl derivatives of sugars in water and dimethyl sulfoxide were measured. According to Kabayama and Patterson (3), the most

D-Altrose	34‖	44¶
2,3-Di-*O*-methyl-D-altrose	>45	ca. 80

*The measurements were made over prolonged periods (several weeks) until no further change was evident.

†Based on the intensity of the signal ascribed to H-1 of furanose components (α plus β).

‡Based on the intensity of the signal ascribed to OH-1 of furanose components (α plus β).

§The overlap of the doublet ascribed to furanose OH-1 with that of α-pyranose permits only a rough estimate.

‖Based on the combined intensities of the two weakest of four H-1 signals in deuterium oxide (2).

¶Four low-field (OH-1) doublets, all of substantial intensity but of similar chemical shift, are clearly detected when an equilibrated aqueous solution is concentrated and the syrup examined in dimethyl sulfoxide. Since these signals are closely grouped, deuterium oxide was added to the solution and the percentage of furanose estimated from the appropriate H-1 signals (preceding footnote).

effective arrangement for hydrogen bonding in aqueous solutions is that involving the oxygen of water and the hydrogen of a pyranose hydroxyl group, particularly when the latter group is equatorially oriented. Since the ether derivatives contain fewer hydroxyl groups that can bond in this way, solvent stabilization of them should be minimized accordingly. The resulting data are not inconsistent with this rationalization. Thus, 2,3-di-*O*-methyl-D-arabinose (I) shows a considerably higher content of furanose in solution than does D-arabinose itself. In deuterium oxide, I produces at least three H-1 signals, whereas only two significant ones are found for arabinose (1, 2). Although unequivocal assignments have not been made, the intensity of the weakest signal shows that a minimum of 17% of furanose is present in the solution of I. A similar value (20%) is given by the OH-1 signals observed immediately after the mixture is transferred from water to dimethyl sulfoxide (compare Fig. 1A below with Fig. 5B in ref. 2). In this instance, the assignment of a furanose OH-1 signal is more straightforward since there is a corresponding upfield multiplet signal caused by a primary carbinol group (i.e. OH-5) (1, 5), the identity of which is confirmed by the use of 2,3-di-*O*-methyl-D-arabinose-5,5′-d_2 (II), which gives a singlet signal for OH-5 (Fig. 1C).

As with D-arabinose itself (1), the equilibrium composition of I or II changes in dimethyl sulfoxide strongly in favor of a furanose component. Figures 1C and 1D illustrate this change for I and the 5,5′-dideuterated compound (II), respectively, and the equilibrium compositions of the dimethyl ether and D-arabinose are compared in Table I. Corresponding data for 2,3-di-*O*-methyl-D-galactose included in the table show that this configurationally related sugar also tends to exist as a furanose more readily than does D-galactose itself both in water and in dimethyl sulfoxide.

An additional point about the equilibrium composition of 2,3-di-*O*-methyl-D-arabinose may be noted. This compound is an oil and, based on its nuclear magnetic resonance (n.m.r.) spectrum when freshly dissolved in dimethyl sulfoxide, has approximately the same composition as found (Fig. 1C) after it has been transferred from an aqueous solution to dimethyl sulfoxide and then equilibrated. Similarly, the H-1 signal attributed above to a furanose in deuterium oxide solution is much stronger when the spectrum is recorded

For personal use only.

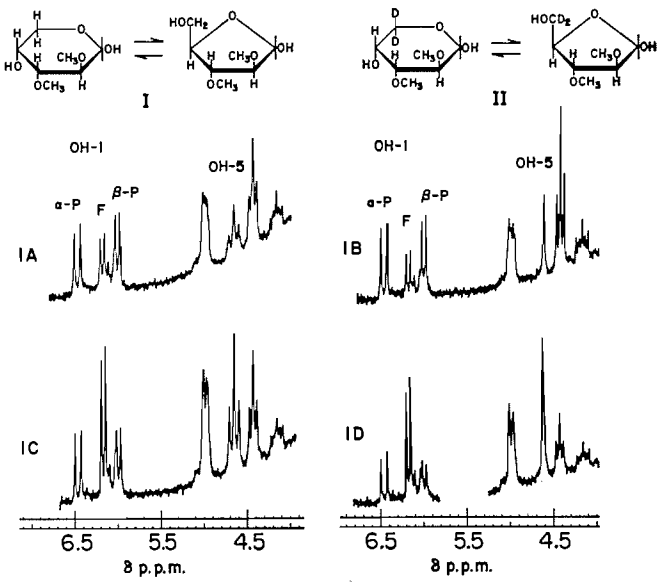

FIG. 1. Partial n.m.r. spectra at 100 Mc.p.s. of 2,3-di-*O*-methyl-D-arabinose (I) and 2,3-di-*O*-methyl-D-arabinose-5,5′-d_2 (II) in dimethyl sulfoxide. A and B are from the spectra of syrupy I and II directly after transfer from an aqueous solution; C and D are from the spectra recorded 2 weeks later. α-P and β-P = α- and β-pyranose; F = furanose.

immediately after the oil has been dissolved.[3] Hence, these observations also show that 2,3-di-*O*-methyl-D-arabinofuranose (most probably the α-anomer) is more stable than either pyranose anomer of I when water is absent.

Since only half of the hydroxyl hydrogens of I are masked, it is not unreasonable that its equilibrium composition in water does not attain the same value as does arabinose itself in dimethyl sulfoxide, i.e. that methylation has only a partial effect in reducing the stability that could be attributed to solvation by water. However, the methyl groups also may exert a different kind of influence. Bishop and Cooper (7) have shown that some partially methylated sugars yield higher proportions of methyl furanosides than do the parent sugars under equilibrating conditions. Particularly pertinent to the present study is their finding that 2,3-di-*O*-methyl-L-arabinose yields 75% of the α,β-furanosides whereas L-arabinose yields only 28%, values close to those for the free sugar equilibria in dimethyl sulfoxide. These authors suggest (7) that methylation promotes relatively stronger repulsive interactions in the pyranosides than in the furanosides by increasing the effective size of the substituents on C-2 and C-3. This idea also helps to explain the current results, although it does not account for the low proportions of furanose found in aqueous solutions. However, changes in the solvation pattern could be a complementary factor. The hydroxyl group of a sugar can form a hydrogen bond with water or dimethyl sulfoxide molecules through either its oxygen or its hydrogen atom, whereas the methoxyl group can form a hydrogen bond through only its oxygen atom. Hence, solvation should

[3]*At 1 min the estimated concentration of furanose is 34%; in 30–40 min the intensity of the signal drops to half this value (i.e. its equilibrium level), although not at a strictly exponential rate. This change provides a measure of the rate of interconversion of furanose into pyranose in water, a type of reaction that rarely has been observed in the absence of a mutarotation catalyst. The mutarotation of* D-*fructofuranose liberated by invertase is the one well-known example of this kind (6).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

increase the effective size of the methoxyl group more than that of the hydroxyl group, thereby destabilizing pyranose forms even more strongly. Similarly, dimethyl sulfoxide can form a hydrogen bond with the hydroxyl group, whereas in solvating the methoxyl group it probably interacts through its sulfur atom with the alkoxyl oxygen atom (8).

Sugars having the *xylo* or *lyxo* configuration appear to exist almost exclusively as pyranoses both in water (2, 9) and in dimethyl sulfoxide (1); accordingly, each exhibits only two anomeric proton or hydroxyl proton signals (see below, however, for an additional comment on D-lyxose). This overwhelmingly greater preference for the pyranose form is also apparent with 2,3-di-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-glucose, and 2,3-di-*O*-methyl-D-mannose, each of which shows only two OH-1 signals[4] when equilibrated in dimethyl sulfoxide.

The relatively high stability of the altrofuranose structure is even more marked with 2,3-di-*O*-methyl-D-altrose (III), which is almost entirely in the furanose form in dimethyl sulfoxide (Table I). As seen in Fig. 2, the general characteristics of its n.m.r. spectrum show that one form greatly predominates in the solution. Although several of the signals are closely grouped together, spin decoupling permitted the chemical shifts of H-4 and H-5 to be estimated. The 6-*O*-trityl derivative of III gives a spectrum similar to that shown in Fig. 2, and permitted the H-5 signal to be located even more readily. With both compounds, irradiation at the respective frequencies of H-4 and H-5, with frequency-swept double resonance, showed that the secondary hydroxyl group proton (at 5.1 p.p.m. in Fig. 2) is coupled with H-5 but not with H-4. Hence, the 5-position of III is not engaged in ring formation, and accordingly the compound can be assigned a furanose structure. The identity of a minor component, detected from Fig. 2, is not known.

One form of 2,3-di-*O*-methyl-D-altrose is also dominant in deuterium oxide, although substantial proportions of two other components are present as well; the relative intensities

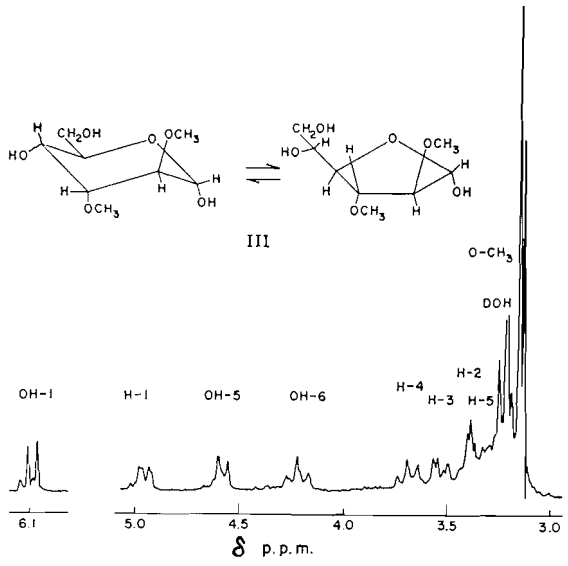

FIG. 2. The n.m.r. spectrum at 100 Mc.p.s. of 2,3-di-*O*-methyl-D-altrose in dimethyl sulfoxide-d_6.

[4]*The data for these signals are presented in Table IV.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the three anomeric proton signals detected are 1.0:2.5:2.0. The major component is likely the α-furanose (IV) since it shows a spacing of less than 0.5 c.p.s., which is characteristic of many 1,2-*trans*-furanoses and 1,2-*trans*-furanosides. Possibly one of the other species detected is the β-furanose, and the total percentage of furanose may be higher than indicated in Table I. This is suggested by the fact that the compound consumes periodate at a rate close to that of known aldohexofuranoses and aldohexofuranosides (Table II). Although cleavage of the C-5,C-6 bond in a compound of this type could be facilitated by rapid displacement of the pyranose–furanose equilibrium, the comparatively slower rate of 2,3-di-*O*-methyl-D-galactose and the relative inertness of 2,3-di-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-D-mannose are in accord with the above information about the furanose concentration of their aqueous solutions. Thus the rate for dimethyl galactose is $\frac{1}{5}$th of that of the known galactofuranoside, whereas the rate for dimethyl glucose is $\frac{1}{36}$th of that of the glucofuranose derivative (Table II). These data also show the marked contrast between the two derivatives of D-mannose substituted at positions 2 and 3, emphasizing the striking influence of the fused five-membered ring in stabilizing the D-mannofuranose structures (1, 10).

TABLE II

Periodate oxidation rates*

Compound	$t_{\frac{1}{2}}$
1,2-*O*-Isopropylidene-D-glucofuranose	40 min
Methyl β-D-galactofuranoside	100 min
D-Mannofuranose 2,3-carbonate	35 min
2,3-Di-*O*-methyl-D-altrose	55 min
2,3-Di-*O*-methyl-D-galactose	8 h
2,3-Di-*O*-methyl-D-glucose	24 h
2,3-Di-*O*-methyl-D-mannose	24 h

*Measured spectroscopically at 223 mμ for highly dilute solutions (see Experimental).
These reactions were also examined directly in the n.m.r. sample tube by noting the rate of liberation of formaldehyde (10). However, at this relatively high concentration, oxidation was frequently too rapid for satisfactory measurement.

The wide differences observed between sugars having the *arabino* configuration on the one hand, and those having the *xylo* or *lyxo* configuration on the other, can be rationalized in a general way on conformational grounds (7, 11–13). Furanose forms of *arabino*-type compounds would be expected to be the more stable since their two-, three-, and four-ring substituents have a *trans,trans* arrangement, whereas one or two vicinal *cis* interactions are found in compounds of the latter two types. In the pyranose series, the relative order of stabilities is probably reversed. This additivity of effects appears to be particularly evident with D-altrose. In either pyranose chair conformation the *altro* configuration should result in substantial instability (11), whereas non-bonded interactions in the furanose forms should be comparatively slight, especially in the all-*trans* α-anomer (IV). According to the current findings, the relative stability of furanose forms of compounds having the *arabino* configuration is enhanced by methylation and also by changing the solvent from water to dimethyl sulfoxide.

Neither of these treatments has a pronounced influence on the energy barrier separating the pyranose and furanose forms in the *xylo* and *lyxo* series. However, the effect of dimethyl sulfoxide on the two classes of compounds is quite different from that of water. In the former solvent there is a marked increase in the ratio of α-pyranose to β-pyranose for

sugars and derivatives having the *lyxo* configuration,[5] whereas those of the *xylo* series attain nearly the same equilibrium composition in both solvents (Table III).

The overall data thus show that a change in solvent from water to dimethyl sulfoxide affects sugar equilibria in two ways. It promotes a displacement in favor of the furanose forms for compounds that would be expected to have relatively stable five membered ring structures (e.g. arabinose and galactose). With certain other sugars (e.g. mannose and lyxose) that would suffer especially unfavorable vicinal interactions as furanoses, there is a shift towards a higher proportion of α-pyranose (axial OH-1).[6] Xylose and glucose, long

L-Rhamnose	33	13

*Based on the relative intensity of the OH-1 signals shown by the compound in dimethyl sulfoxide. These solutions were prepared by rapidly concentrating *in vacuo* an equilibrated aqueous solution of the compound, after which the superficially dry syrup that remained was dissolved immediately in dimethyl sulfoxide. The figures in parentheses in this column are the averages of several literature values determined for aqueous solutions of these sugars by a variety of methods, including n.m.r. spectroscopy (see refs. 12 and 13).

The anomeric designation was deduced by comparison with the spectrum recorded shortly after a known crystalline anomer of the sugar was dissolved in dimethyl sulfoxide (see refs. 1 and 16).

†After the solution described above (preceding footnote) was stored for 8 weeks at room temperature. Some of the solutions were heated at 100 °C for 1–2 h, without any noticeable effect on the anomeric composition. The changes observed in the composition of the *lyxo* compounds were essentially complete within 1 week.

regarded as the most conformationally stable of the pyranoses (11), are not influenced by the solvent change. It was surmised initially that water might selectively stabilize pyranose forms of some of the sugars by hydrogen bonding, and thereby mask the relatively high stability of their furanose forms. More effective hydrogen bonding with water is also regarded as a factor that should stabilize β-pyranoses (equatorial OH-1) more than the α-anomers (3, 12). In attempting to relate the observed changes in equilibrium in the two solvents with such hydrogen-bonding possibilities and with structural features that might be common to, for example, arabinose and mannose, one or two possibilities suggest themselves.

If, as has been suggested (3), axial groups of pyranose chair forms are not effectively solvated by water, then groups such as OH-2 of mannopyranose and OH-4 of arabinopyranose may alternatively form an intramolecular hydrogen bond with the ring oxygen

[5]*In contrast to these observations, it has been suggested recently (14) that* β-D-*mannose is stabilized by complexing with dimethyl sulfoxide. The authors have since found that this suggestion was based on incorrect information (B. Casu, private communication).*

[6]*Somewhat analogous to the effect observed with the arabino-type compounds, the ratio of* α*-anomer to* β*-anomer also increases, even with water as the solvent, when* D-*mannose is partially methylated. Thus, deuterium oxide solutions of 2,3-di- and 2,3,4,6-tetra-O-methyl-*D-*mannose contain only 20% and 14%, respectively, of the* β*-anomer, in contrast to the value of over 30% for* D-*mannose itself (Table III). These figures are based on the relative intensity of two low-field resonance signals in each spectrum that correspond closely, both in chemical shift and spacing, to the H-1 signals of* D-*mannose.*

atoms, for which they appear to be suitably oriented. In dimethyl sulfoxide, the hydrogen-bonding pattern should be different; based on the chemical shifts of hydroxyl protons, both axial and equatorial groups are strongly bonded by this solvent (1, 5, 16, 17). Hence, if the OH-2 group of mannose (or OH-4 of arabinose) were now to be reoriented away from the molecule by association with the solvent, the oxygen orbitals should become directed inwards (3). Molecular models suggest that this arrangement would increase repulsive interactions between these orbitals and the erected para orbital of the ring oxygen (see ref. 3) (and in β-mannose, also with the O-1 orbitals). The less-favorable interaction patterns introduced by these changes presumably are relieved by a shift towards a furanose form, in one instance, or in favor of the α-pyranose form, in another. None of these considerations apply to xylose or glucose, and their equilibrium compositions accordingly are about the same in water and dimethyl sulfoxide.[7]

Some other, relatively minor differences are observed when the n.m.r. spectral properties of certain sugars in water and dimethyl sulfoxide are compared. Thus, although D-lyxose appears to exist exclusively in pyranose forms in water (2, 9), an equilibrated solution of it in dimethyl sulfoxide possibly contains a small percentage of furanose forms. This is suggested by the presence of a minor low-field signal and a shoulder on the α-H-1 signal (Fig. 3A). More striking, however, is the 3.2 c.p.s. spacing of the α-pyranose signal as compared with the 4.2 c.p.s. spacing in water. In contrast, the H-1 spacings for most of the other sugars examined are influenced little by the solvent change (Table IV). If it is accepted that the intermediate size of the 4.2 c.p.s. value reflects a chair–chair interconversion for α-D-lyxopyranose (2, 9), then the position of this equilibrium in dimethyl sulfoxide appears to be shifted strongly in favor of the C1 conformation. Although the 3.3 c.p.s. spacing is much larger than that of the configurationally related α-D-mannose, it differs little from the H-1 spacings for various other α-pyranoses in dimethyl sulfoxide (Table IV). In addition, the OH-1 spacing and chemical shift are close to those of axially oriented OH-1 groups of several other sugars, including α-D-mannose (Table IV). Therefore, the properties of D-lyxose in dimethyl sulfoxide suggest that the compound exists almost entirely as the α-pyranose and in the C1 conformation in this solvent.

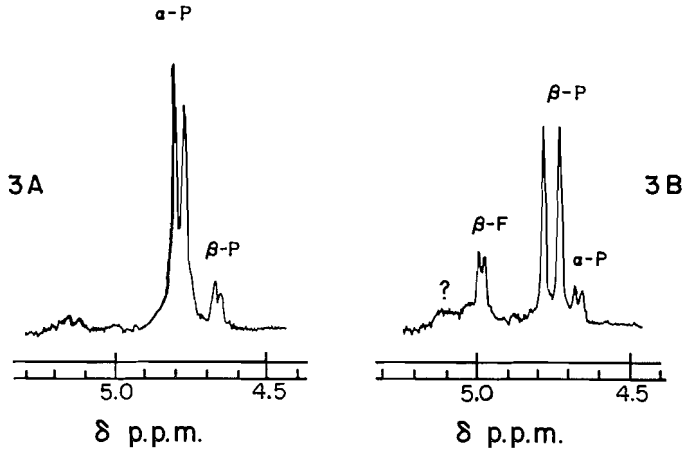

FIG. 3. Partial n.m.r. spectra at 100 Mc.p.s. of D-lyxose (A) and D-ribose (B) equilibrated in dimethyl sulfoxide-d_6 containing a small amount of deuterium oxide. α-P and β-P = α- and β-pyranose; β-F = β-furanose.

[7]*However, in less-polar solvents the composition of glucose shifts in favor of the α-anomer, which is thought to be due to an enhancement of the anomeric effect in such media (13). Since dimethyl sulfoxide possesses a relatively high dielectric constant, the current findings are not at variance with this view.*

The n.m.r. spectrum of D-ribose in dimethyl sulfoxide differs in several respects from that in deuterium oxide. A weak low-field multiplet ascribed by Lemieux and Stevens (2) to H-1 of either the α-furanose or *aldehydo* form is replaced in the spectrum of the dimethyl sulfoxide solution by a broad, ill-defined signal comprising about 18% of the overall integral of the absorption signals in this region (Fig. 3B). The percentage contribution of the α-pyranose signal drops from 20% (2) to 10%, whereas the relative intensities of the β-furanose (21%) and β-pyranose (51%) H-1 signals are altered little. Perhaps most notable are the characteristics of the β-pyranose. There is a decrease in the H-1 spacing from 6.4 c.p.s. in deuterium oxide (2) to 5.3 c.p.s. in dimethyl sulfoxide, and the OH-1 spacing is considerably smaller than those for equatorial anomeric hydroxyl groups of other sugars (Table IV, and see the next paragraph). Hence, it appears to be unlikely that β-D-ribopyranose exists entirely in the C1 conformation in dimethyl sulfoxide, in contrast to its behavior in water (2, 9). Both the H-1 and OH-1 signals for α-D-ribopyranose are consistent with the 1C conformation attributed to this isomer in deuterium oxide (2, 9), although, as shown above by the low percentage detected, its structure is also relatively unstable in dimethyl sulfoxide. Therefore, the overall data suggest that D-ribose equilibrates in dimethyl sulfoxide to a number of forms, each of which incorporates relatively strong destabilizing interactions.

The data in Table IV permit the generalization, which has been proposed also by Casu *et al.* (17), that anomeric pyranose pairs show characteristically different OH-1 spacings. Thus, equatorial group proton signals have relatively large spacings of 6.5–8 c.p.s., whereas the axial group protons show spacings of 4.5–5 c.p.s. Although this is analogous to the fact that the axial OH signal for *cis*-4-hydroxy-*t*-butylcyclohexane has a smaller spacing than that for the equatorial *trans*-isomer (5), secondary axial and equatorial hydroxyl groups of sugars and derivatives are not as readily differentiated (ref. 17 and unpublished observations). However, the size of the hydroxyl proton spacings appears to be indicative of the orientation of the hydroxyl group of 1,4-dioxane type hemialdals (18).

Chemical shift values for anomeric hydroxyl protons also show some consistent trends. When there is an equatorial 2-*O*-substituent, the equatorial OH-1 signal occurs at lower field than that of the axial OH-1 by about 0.4 p.p.m., whereas their relative positions are reversed (by about 0.1 p.p.m.) when the substituent is axial. (Several derivatives of D-mannose, in addition to those listed, containing an *O*-acetyl, *O*-methyl, or *O*-benzyl group at C-2 give results closely similar to that for D-mannose itself.) Since 2-deoxy-D-xylohexose shows $\delta_e - \delta_a$ of 0.4 p.p.m. (17), it may be inferred that an axial oxygen at C-2 promotes increased shielding of an equatorial 1-hydroxyl proton, perhaps by weakening its ability to form a bond with dimethyl sulfoxide.

EXPERIMENTAL

Nuclear magnetic resonance spectra were recorded on a Varian HA-100 high-resolution spectrometer with tetramethylsilane contained in a coaxial capillary as the internal control reference signal. Spin-decoupling operations were carried out with the frequency-sweep mode facility of this instrument.

Except for 2,3-di-*O*-methyl-D-xylose (kindly provided by Dr. E. E. Percival), none of the di-*O*-methyl aldoses used in this study are crystalline. However, each of the syrupy compounds was shown to be pure, as judged by paper chromatography with four different solvent systems. Where possible, the sugar was obtained by acid hydrolysis or acetolysis of a crystalline glycoside.

Methyl 4,6-O-Ethylidene-2,3-di-O-methyl β-D-Mannopyranoside

4,6-*O*-Ethylidene-D-mannose (300 mg) (a gift from Dr. D. H. Ball) was dissolved in warm methanol (1.0 ml), and methyl iodide (10 ml) was added, followed by anhydrous calcium sulfate (2 g) and silver oxide (5 g). The suspension was shaken for 24 h, diluted with chloroform, and filtered; then the filtrate was concentrated. Methyl iodide (10 ml), anhydrous calcium sulfate (2 g), and silver oxide (4 g) were added to the

residue and the mixture was heated under reflux for 48 h. Chloroform-extractable material was recovered, and the second methylation procedure repeated. The chloroform-soluble product (0.37 g) crystallized and, after recrystallization from petroleum ether, melted at 70–71 °C; $[\alpha]$ −95° (*c*, 1.2 in chloroform).

Anal. Calcd. for $C_{11}H_{20}O_6$: C, 53.21; H, 8.06. Found: C, 52.9; H, 8.1.

*2,3-Di-O-methyl-*D*-mannose (19), 2,3-Di-O-methyl-*D*-glucose (20), and 2,3-Di-O-methyl-*D*-galactose (21)*

These were prepared by acid hydrolysis of the appropriate crystalline 4,6-*O*-ethylidene or 4,6-*O*-benzylidene methyl glycoside. For example, methyl 4,6-*O*-ethylidene-2,3-di-*O*-methyl β-D-glucoside (22) (m.p. 107–108°C) (150 mg) was hydrolyzed with 1 *N* sulfuric acid (10 ml) on the steam bath for 7 h. The hydrolysate was neutralized with barium carbonate, and filtered; then the solution was treated with Amberlite IR-120 (H^+) and charcoal, and concentrated *in vacuo* at 50 °C.

*2,3-Di-O-methyl-*D*-arabinose (23) and 2,3-Di-O-methyl-*D*-arabinose-5,5′-d_2*

These were prepared by hydrolysis, for 2 h with hot 0.5 *N* sulfuric acid, of methyl 2,3-di-*O*-methyl-α,β-D-arabinofuranoside and the 5,5′-dideuterated compound, respectively, which were synthesized according to the procedure described recently by Heyns and Muller (24).

*2,3-Di-O-methyl-*D*-altrose*

4,6-*O*-Benzylidene-2,3-di-*O*-methyl α-D-altropyranoside (25) (m.p. 85–86 °C) (160 mg) was dissolved in a 200:1 mixture of acetic anhydride and concentrated sulfuric acid (2 ml), and stored at 3 °C for 72 h (26). After an additional 48 h at room temperature, the solution was added to crushed ice, and carefully neutralized with sodium bicarbonate; then the aqueous suspension was extracted several times with chloroform. The combined extracts were dried and concentrated to yield a syrup (212 mg), which was dissolved in cold sodium methoxide (0.1 *N*, 2 ml). After 18 h at 3 °C the deacetylation mixture was neutralized with carbon dioxide, water was added, and the solution was treated with mixed-bed ion-exchange resins and concentrated. The chromatographically pure syrup (100 mg) had $[\alpha]$ +31° (*c*, 1.4 in water). The n.m.r. spectrum in dimethyl sulfoxide-d_6 (Fig. 2) showed that the product contained three hydroxyl groups: anomeric, secondary, and primary.

Attempts to prepare an anilide and a diphenylhydrazone failed to yield solid derivatives.

The di-*O*-methyl derivative (30 mg) was treated with triphenylchloromethane (70 mg) in dry pyridine (2 ml) for 24 h. Ice water was added, the tacky precipitate was recovered with thorough washing and dissolved in ethanol, and triphenylcarbinol was removed by repeated crystallization. The syrupy residue (52 mg) was shown by thin-layer chromatography (benzene–methanol (9:1)) to consist of one component contaminated with a trace of triphenylcarbinol. The n.m.r. spectrum of this compound, recorded in dimethyl sulfoxide, showed the presence of approximately 15 phenyl protons per 2 hydroxyl protons, consistent with the formulation of this product as 2,3-di-*O*-methyl-6-*O*-trityl-D-altrose.

Periodate Oxidations

An aqueous solution (2 ml) containing about 0.2 μmole of the sugar derivative was diluted with aqueous sodium metaperiodate (2 ml, containing 0.24 μmole of oxidant). Blank periodate and iodate solutions were also prepared by diluting the standard periodate solution (2 ml aliquots) with equal volumes of water or ethylene glycol solutions, according to the modification of Aspinall and Ferrier (27). Each reaction mixture was stored at 22 °C, and its optical density at 223 mμ was measured at chosen intervals.

Some typical periodate uptake data (mole/mole), from which the $t_{\frac{1}{2}}$ values listed in Table II are taken, are as follows.

	Time (min)						
Compound	10	30	60	80	120	240	1440
1,2-*O*-Isopropylidene-D-glucofuranose	0.18	0.41	0.62	0.72			
D-Mannose 2,3-carbonate	0.22	0.46	0.67	0.77			
Methyl α-D-galacto-furanoside	0.10	0.23	0.36	0.44	0.56		
2,3-Di-*O*-methyl-D-altrose	0.14	0.37	0.52	0.62	0.75		
2,3-Di-*O*-methyl-D-galactose					0.12	0.37	0.91
2,3-Di-*O*-methyl-D-glucose						0.11	0.49
2,3-Di-*O*-methyl-D-mannose						0.14	0.51

ACKNOWLEDGMENTS

The authors thank M. Mazurek, who recorded the n.m.r. spectra, and W. Haid, who carried out the microanalyses.

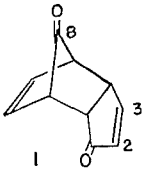
CYCLOADDITIONS

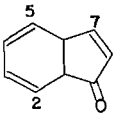
X. KINETICS OF THE THERMAL DECARBONYLATION OF DICYCLOPENTADIENE-1,8-DIONE[1]

JOHN E. BALDWIN
Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois



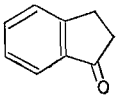
Received May 16, 1966

ABSTRACT

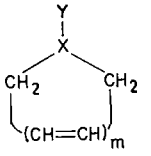


The thermal cycloelimination of carbon monoxide from dicyclopentadiene-1,8-dione is a kinetically well-behaved first-order reaction. At 380 °K the activation parameters for the process are $\Delta H^{\ddagger} = 34.5 \pm 0.8$ kcal mole^{-1} and $\Delta S^{\ddagger} = +9.8 \pm 2.3$ e.u. mole^{-1}. Application of the theoretical proposals of Woodward and Hoffmann indicates that this necessarily disrotatory decarbonylation may be concerted.

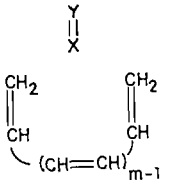
INTRODUCTION



The thermal decomposition of dicyclopentadiene-1,8-dione (I) has been observed at 350° and at 240° to give carbon monoxide and *cis*-bicyclo[4.3.0]nona-2,4,7-trien-9-one (II) or 1-indanone (III) (1, 2). An analogous decarbonylation of a monochloro derivative of the dione I has been clarified (3).



I



II

III

IV

V

The thermal decarbonylation of dicyclopentadiene-1,8-dione is a special case of a general reaction: cycloelimination of carbon monoxide from Δ^3-cyclopentenones (4). Indeed, the later category may be viewed as a special case of a still more general type of reaction: cycloelimination of a small molecule joined to an organic moiety through only one of its atoms, as in IV → V. Examples of this type of reaction with nitrogen, sulfur monoxide, sulfur dioxide, and nitrous oxide have been reported recently (5–8). Such reactions in the opposite direction are known, as in the cycloaddition of sulfur dioxide to 1,3-cycloheptadiene (9).

In common with other cycloaddition and cycloelimination reactions, these "end-on" reactions might proceed by a variety of mechanistic pathways (10, 11). At one extreme, the bonds to be broken (or made) between the reaction partners might be broken (or made) simultaneously or nearly simultaneously in a concerted fashion. At the other extreme, a stepwise process might give, through cleavage (or formation) of only one bond between the reaction partners, a bifunctional intermediate during the reaction.

KINETIC RESULTS

The rate of cycloelimination of carbon monoxide from dicyclopentadiene-1,8-dione (I) could be followed conveniently at 104–125° by nuclear magnetic resonance (n.m.r.) spectroscopy.

In the olefinic proton region of the n.m.r. spectrum, dicyclopentadiene-1,8-dione exhibits a doublet of doublets at τ 2.75 which may be assigned (3) to H-3, and absorption from the other olefinic protons near τ 3.8. As the decarbonylation reaction proceeds, new doublets of doublets centered at τ 2.5 and 3.8 and a complex multiplet at 4.4 become evident. The olefinic n.m.r. absorptions in the product *cis*-bicyclo[4.3.0]-nona-2,4,7-trien-9-one (II) may be assigned as follows: τ 2.5 (1H) to H-7; τ 3.8 (1H) to H-8; and τ 4.4 (4H) to H-2, H-3, H-4, and H-5 (12).

To analyze mixtures of starting dione I and product II, one can compare the integrated absorptions caused by the single protons beta to the intact carbonyl function in both compounds, or convert the ratio (r) of areas from the τ 4.0–4.5 absorptions to those from the τ 3.4–4.0 signals to percentage of dione in the mixture by using the formula: percentage of dione $= 50(4 - r)/(2 + r)$, which takes into account the number of protons from each compound contributing to each area. The kinetic data were processed by a least-squares program for first-order reactions made available to us by Professor S. Smith and Dr. J. Petrovich. Sample kinetic data are given in Table I, and Table II summarizes all the rate constants measured with dioxane as the reaction solvent.

TABLE I

Kinetic data for the decarbonylation of dicyclopentadiene-1,8-dione in dioxane at 118.2°

*Initial concentration of dione I in dioxane at room temperature.
†Points taken from the first three runs, having three different initial concentrations.

From the data in Table II, a least-squares fit to the Arrhenius equation gave $E_a = 35.24 \pm 0.43$ kcal $mole^{-1}$ and $\log_{10} A = 15.47 \pm 0.24$, where the indicated ranges are defined by the calculated probable errors.

Different results were obtained when attempts were made to follow the reaction with deuteriochloroform as solvent. During the initial phase of the reaction, n.m.r. peaks corresponding to product II and undecomposed dione were observed, but at later times the n.m.r. spectra showed that the reaction mixture contained dione I and 1-indanone (III) (13). Mixtures of the dione and indanone could be readily analyzed by n.m.r., for in a mixture of the two the absorptions below τ 3.0 are caused by the four aromatic protons of indanone and one proton of the dione, and the absorptions at τ 3.4–4.0 are caused by the other three olefinic protons of the dione I.

The shift from n.m.r. spectra indicating formation of one product (II) to those indicating formation of another (III) occurred at different points in different samples, from 10 to 30% reaction. This behavior is suggestive of the initial formation of II and carbon monoxide from I, and the subsequent acid-catalyzed rearrangement of II to the more stable 1-indanone. Once decomposition of the solvent yields some acid, the rearrangement of the initially formed product to 1-indanone becomes fast relative to the rate of decarbonylation. The kinetic data obtained in deuteriochloroform at 124.5° (10 points) gave a good first-order plot, with $k = 1.34 \pm 0.04 \times 10^{-4}$ s^{-1}.

DISCUSSION

The decarbonylation of dicyclopentadiene-1,8-dione occurs by a well-behaved first-order process at 104–125°. No significant difference in the rate is effected by changing the reaction solvent from dioxane to deuteriochloroform.

From the Arrhenius parameters for the decarbonylation, one may calculate an activation enthalpy and entropy: $\Delta H^{\ddagger} = 34.5 \pm 0.8$ kcal mole^{-1} and $\Delta S^{\ddagger} = +9.8 \pm 2.3$ e.u. mole^{-1} at 380 °K. Here, the estimated errors in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ have been calculated from the equations developed by Petersen *et al.* (14), with the maximum error in rate constants being taken as 3%.

The large positive entropy of activation for the decarbonylation is suggestive of a transition-state configuration in which both bonds to the carbon of the carbon monoxide unit have been broken, thus permitting the carbon monoxide moiety to rotate about the axes perpendicular to the C—O bond. (Free carbon monoxide has a rotational entropy at 380 °K of +11.74 e.u. mole^{-1} (15, 16).) This conception of the activated complex is equally compatible with either a concerted decarbonylation or a two-step, nonconcerted decarbonylation in which one bond is cleaved first before attainment of the transition state. It views a rate-determining formation of a bifunctional intermediate as incompatible with the observed $\Delta S^{\ddagger}$.

For the generalized decarbonylation reaction of the type being considered (IV → V, where X=Y is C=O), construction of molecular orbital correlation diagrams (17, 18) and application of the theoretical proposals of Hoffmann and Woodward (11) and of Longuet-Higgens and Abrahamson (19) lead to the following conclusions: when m is zero and the reaction products are carbon monoxide and ethane, ethylene, or acetylene, the thermal decarbonylation is nonconcerted; when m is an odd integer, the disrotatory thermal decarbonylation may be concerted; when m is an even integer, the conrotatory thermal decarbonylation may be concerted.

Similar conclusions have been reached independently by Hoffmann (20)[2] and by Lemal and McGregor (5) for decarbonylations and some other "end-on" cycloeliminations.

It should be noted that the conclusions based on molecular orbital correlation diagrams are insensitive to the ordering of the energy levels in carbon monoxide with respect to

[2]*R. Hoffmann, private communication.*

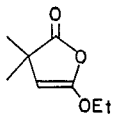
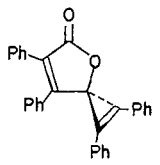
For personal use only.

those of the olefinic cycloelimination product. They may be extended to those photochemical decarbonylations in which the $\pi \rightarrow \pi^*$ excitation of the olefinic moiety is responsible for the reaction; when m is an odd integer, the conrotatory $\pi \rightarrow \pi^*$ photochemical decarbonylation may be concerted; when m is an even integer, the disrotatory $\pi \rightarrow \pi^*$ photochemical decarbonylation may be concerted.

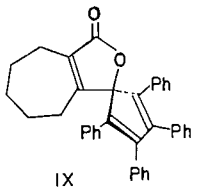


The simple molecular orbital correlation diagrams do not give any direct prediction of nonconcertedness or allowed concertedness for decarbonylations of IV (X=Y is C=O) when the $n \rightarrow \pi^*$ transition leads to reaction, for the π^* orbital of the carbonyl unit correlates with a π^* orbital in carbon monoxide and hence is not involved in the reaction.[3]

The implications of the conclusions based on molecular orbital theory[4] for "end-on" cycloeliminations of carbon monoxide from IV are interestingly reflected in chemical experience.



Thermal decarbonylations of saturated ketones, cyclopropanones, and cyclopropenones are predicted to occur in a stepwise, nonconcerted fashion. Thermolytic decarbonylations of ketones to ethanes are not commonly observed. The products from the reaction of ethyl diazoacetate with dimethylketene, ethyl β,β-dimethylacrylate, carbon monoxide, and the γ-lactone VII have been interpreted in terms of the intermediate formation of a cyclopropanone followed by unimolecular fission of one C—O bond to produce the bifunctional species VI, which either loses carbon monoxide or collapses to form the lactone (23). (Carbon monoxide might also stem from the Δ^3-oxacyclopentenone VII in a thermally allowed process.) More definitive evidence of the thermal decarbonylations of cyclopropanones may become available in the near future (24).



VI

VII

VIII

IX

Breslow and his co-workers have demonstrated (25, 26) that pyrolysis of diphenylcyclopropenone leads to carbon monoxide and diphenylacetylene. Concurrently, a product (VIII) is obtained in which, presumably, a bond adjacent to the carbonyl function has been cleaved and the resultant intermediate has added to the carbonyl of another ketone molecule. The decarbonylation does not follow good first-order kinetics. Cycloheptenocyclopropenone and tetracyclone at 250° give a 1:1 adduct (IX). These observations, of course, require no unique mechanistic interpretation; a precise mechanistic

[3]*Lemal and McGregor hold another opinion; cf. ref. 5, footnote 11.*

[4]*The thermal elimination of sulfur dioxide from 3-sulfolenes has just been shown to be stereospecific, in accord with theory (21, 22).*

description for the reactions leading to VIII and IX is not the issue here. That the two thermal decarbonylations occur with the concomitant formation of VIII and IX, whereas the decarbonylation of I is a smooth first-order process uncomplicated by a similar side-reaction, demonstrates a basic dissimilarity between the two cycloeliminations.

The decarbonylations of Δ^3-cyclopentenones and Δ^3-2-oxacyclopentenones are facile, common, and synthetically useful (4, 27). The kinetic data for the cycloelimination of carbon monoxide from dicyclopentadiene-1,8-dione are consistent with, but do not require, a concerted mechanism for the reaction. Here, geometric constraints demand a disrotatory stereochemical course in the process.

What information is available dovetails with the theoretical predictions based on molecular orbital correlation diagrams, but conclusive evidence of the concerted character of decarbonylations that are allowed to be concerted, and many details of the chemical behavior of ketones whose decarbonylations are predicted to be nonconcerted, remain obvious goals for further experimentation.

EXPERIMENTAL

Analyses were carried out by J. Nemeth and his associates, Urbana. Melting points are uncorrected. A Varian A-60 spectrometer was used for the n.m.r. analyses.

Dicyclopentadiene-1,8-dione (I)

The preparation of dicyclopentadiene-1,8-dione from cyclopentenone by the method of Hafner and Goliash (2) gave material having m.p. 98–101° (decomp.) (lit. (2) m.p. 103–104°) after recrystallization from ethanol. The infrared and n.m.r. spectra of the dione were consistent with published data (2, 3).

When 642 mg of dicyclopentadiene-1,8-dione, 811 mg of 2,4-dinitrophenylhydrazine, 5 ml of diglyme, 1 ml of 95% ethanol, and 3 drops of concentrated hydrochloric acid were mixed at room temperature, a precipitate formed; this 8-2,4-dinitrophenylhydrazone derivative was collected after 5 min to give 1.17 g (85.5% of theory), m.p. 197–198° (decomp.) (strong carbonyl band in the infrared at 1 710 cm^{-1}).

Anal. Calcd. for $C_{16}H_{12}N_4O_5$: C, 56.47; H, 3.55; N, 16.47. Found: C, 54.71, 54.69, 55.84; H, 3.56, 3.36, 3.70; N, 16.67.

This orange 8-2,4-dinitrophenylhydrazone was partially and smoothly rearranged to the red 1-2,4-dinitrophenylhydrazone, m.p. 200–201° (strong carbonyl in the infrared at 1 790 cm^{-1}), by attempted recrystallization from chloroform, nitromethane, or chlorobenzene, or by allowing it to remain in the acidic reaction mixture.

Anal. Found: C, 56.39, 56.35; H, 3.53, 3.49; N, 16.27, 16.55.

Mixtures of the two derivatives were separated by thin-layer chromatography on alumina, with benzene–chloroform (5:1 v/v) as developer (R_f of red 1-derivative, 0.6; of orange 8-derivative, 0.3). Quantitative estimates of the two compounds were conveniently made by infrared spectroscopy in the carbonyl region (28).

Kinetic Methods

Solutions of dicyclopentadiene-1,8-dione in dioxane or deuteriochloroform containing a small percentage of tetramethylsilane were sealed in n.m.r. tubes and heated for appropriate periods in a 40 cm diameter insulated kinetic bath, controlled to ±0.1° with a thermoregulator relay – mercury contactor and stirred by a Lightnin model L mixer. All temperatures were determined with the thermometers calibrated against National Bureau of Standards certified thermometers. The kinetic samples were analyzed by n.m.r. spectroscopy as described above. After a sample was analyzed, it was returned to the kinetic bath for further reaction. Crude kinetic data were processed by a least-squares program for computing first-order rate constants. The kinetic results are summarized in Tables I and II.

cis-Bicyclo[4.3.0]nona-2,4,7-trien-9-one (II)

Three n.m.r. tubes containing approximately 200 mg of *cis*-bicyclo[4.3.0]nona-2,4,7-trien-9-one (as judged by n.m.r. spectroscopy) and undecomposed dione I in dioxane were opened and concentrated by evaporation. Two flash distillations from a bath at 120–125° and 1 mm gave the trienone as a colorless liquid.

Anal. Calcd. for C_9H_8O: C, 81.79; H, 6.10. Found: C, 80.10, 81.43; H, 5.92, 6.27.

The infrared spectrum of the neat liquid showed ν_{max} 1 710 (vs) and 1 790, 1 650, 1 610, 1 595, and 1 585 cm^{-1} (all m). The adduct of the trienone with maleic anhydride had m.p. 239–241° (lit. (29) m.p. 240°).

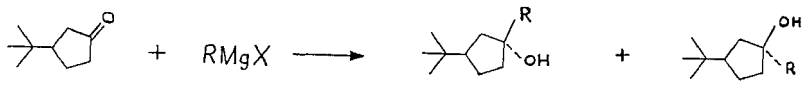
ÉTUDES CONFORMATIONNELLES EN SÉRIE CYCLOPENTANIQUE

II. SUR LA STÉRÉOCHIMIE DES ALCOOLS TERTIAIRES DÉRIVÉS DE LA *t*-BUTYL-3 CYCLOPENTANONE[1]

JEAN-CLAUDE RICHER ET PATRICE BÉLANGER
Département de Chimie, Université de Montréal, Montréal, Québec



Reçu le 31 mars 1966

RÉSUMÉ

La stéréochimie des *t*-butyl-3 alkyl-1 cyclopentanols obtenus par addition d'organomagnésiens sur la *t*-butyl-3 cyclopentanone a été établie grâce à des synthèses stéréospécifiques et aussi en se basant sur les résultats d'oxydation de ces alcools par le permanganate de potassium.

INTRODUCTION

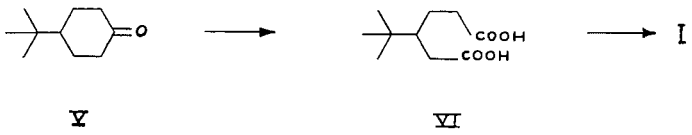
A l'occasion d'un travail précédent (1), la déshydratation d'un mélange de *t*-butyl-3 isopropyl-1 cyclopentanols (III*c* et IV*c*) obtenus par addition du bromure d'isopropylmagnésium (II*c*) sur la *t*-butyl-3 cyclopentanone (I) a été rapportée; la stéréochimie de l'addition du réactif de Grignard n'avait toutefois pas été déterminée. Le présent travail a donc été entrepris dans le but de spécifier la configuration relative des alcools tertiaires qui sont formés.

I II III IV

SCHÉMA RÉACTIONNEL 1. *a*, R = Me; *b*, R = Et; *c*, R = *i*-Pr.

RÉSULTATS

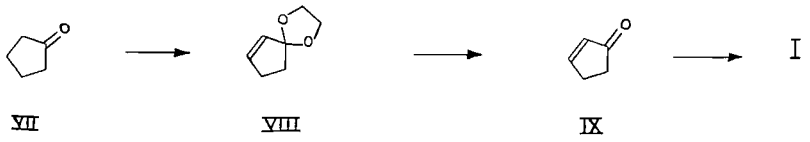
1. t-Butyl-3 cyclopentanone (I)



Au cours d'une étude précédente (1), une synthèse utilisant la *t*-butyl-4 cyclohexanone (V) comme produit de départ a été proposée pour la préparation de I; la série de réactions impliquées est résumée dans le Schéma Réactionnel 2. Dans les cadres du présent travail, une autre synthèse de I a été mise au point, utilisant la cyclopentanone (VII) comme produit de départ; cette méthode, basée sur la transformation de VII en cyclopentène-2 one (IX) suivant le processus expérimental de Garbisch (2) et suivi d'une addition-1,4 du chlorure de *t*-butylmagnésium, est résumée dans le Schéma Réactionnel 3. La cétone ainsi obtenue est en tous points identique à celle décrite précédemment.

2. Addition de réactifs de Grignard sur la t-butyl-3 cyclopentanone (I)

L'addition de réactifs de Grignard sur le groupement carbonyle de I conduit à deux produits principaux: les *t*-butyl-3 alkyl-1 cyclopentanols *cis* (III) et *trans* (IV). Par définition, l'isomère *cis* est celui où les deux groupes alkyles sont du même côté du cycle.



L'addition de l'iodure de méthylmagnésium (II*a*) sur I conduit au mélange des alcools tertiaires attendus (III*a* et IV*a*). Une analyse chromatographique en phase gazeuse montre que l'isomère *trans* IV*a* prédomine légèrement avec un pourcentage de 50.5%. Les alcools tertiaires peuvent être séparés par chromatographie en phase gazeuse préparative. Le

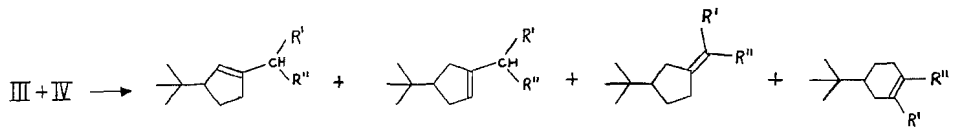
SCHÉMA RÉACTIONNEL 3.

t-butyl-3 méthyl-1 cyclopentanol *cis* (III*a*) est un produit facilement sublimable fondant à 51 °C. Son épimère *trans* IV*a* est aussi un solide facilement sublimable de p.f. 56 °C.

Les *t*-butyl-3 éthyl-1 cyclopentanols *cis* (III*b*) et *trans* (IV*b*) sont préparés par l'addition du bromure d'éthylmagnésium (II*b*) sur la *t*-butyl-3 cyclopentanone (I). Une analyse par chromatographie en phase gazeuse montre la présence des deux alcools attendus; le produit *trans* IV*b* prédomine avec un pourcentage de 56.1%. Séparés l'un de l'autre par chromatographie en phase gazeuse préparative, le *t*-butyl-3 éthyl-1 cyclopentanol *cis* (III*b*) est un liquide distillant à 95 °C sous 45 mm de Hg et possédant un indice de réfraction de 1.4564 à 25 °C; son isomère *trans* IV*b* distille à 95 °C sous 45 mm de Hg et possède un indice de réfraction de 1.4510 à 25 °C.

TABLEAU I



t-Butyl-3 cyclopentanols	Point de fusion (°C)	Point d'ébullition (°C)	n_D^{25}
Méthyl-1 *cis* (III*a*)	51		
Méthyl-1 *trans* (IV*a*)	56		
Éthyl-1 *cis* (III*b*)		95 sous 45 mm Hg	1.4510
Éthyl-1 *trans* (IV*b*)		95 sous 45 mm Hg	1.4564
Isopropyl-1 *cis* (III*b*)		75 sous 28 mm Hg	1.4558
Isopropyl-1 *trans* (IV*b*)		74 sous 28 mm Hg	1.4524

Les *t*-butyl-3 isopropyl-1 cyclopentanols *cis* (III*c*) et *trans* (IV*c*) sont préparés par l'addition du bromure d'isopropylmagnésium (II*c*) sur la *t*-butyl-3 cyclopentanone (I); il est à noter que les alcools tertiaires attendus ne représentent qu'environ 10% des produits de la réaction, qui sont constitués principalement de produits d'aldolisation et de réduction. Les deux alcools désirés peuvent toutefois être obtenus à l'état pur par chromatographie en phase gazeuse préparative; le *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*), qui représente 61% des alcools tertiaires attendus, distille à 74 °C sous 28 mm de Hg et possède un indice de réfraction de 1.4524 à 25 °C, alors que l'isomère *cis* III*c* (39%) distille à 74 °C sous 28 mm de Hg et possède un indice de réfraction de 1.4558 à 25 °C.

3. Préparation des t-butyl-3 alkyl-1 cyclopentènes (X) et des t-butyl-4 alkyl-1 cyclopentènes (XI)

La déshydratation du mélange des *t*-butyl-3 alkyl-1 cyclopentanols III et IV par l'acide sulfurique conduit principalement aux hydrocarbures X et XI attendus (Schéma Réactionnel 4). Dans le cas des alcools de la série éthyle (III*b* et IV*b*) et de la série isopropyle (III*c* et IV*c*) les *t*-butyl-3 alkylidène cyclopentanes (XII) et les *t*-butyl méthyl cyclohexènes

SCHÉMA RÉACTIONNEL 4. *a*, R′ = R″ = H; *b*, R′ = H, R″ = CH_3; *c*, R′ = R″ = CH_3.

(XIII) sont aussi obtenus. Le Tableau II résume la composition des produits de déshydratation des *t*-butyl-3 alkyl-1 cyclopentanols III et IV par l'acide sulfurique. L'examen de ce tableau confirme une fois de plus que le mécanisme de déshydratation se fait par l'intermédiaire d'un carbocation et qu'il y a possibilité de réarrangement, lorsque le carbocation tertiaire peut se réarranger en un deuxième carbocation tertiaire. Les hydrocarbures du type XI et XII ont pu être isolés par chromatographie en phase gazeuse et leur identification s'est faite principalement par les spectres de résonance magnétique nucléaire. Les différentes propriétés physiques de ces hydrocarbures sont rapportées dans le Tableau III.

*Les spectres de résonance magnétique nucléaire ont été déterminés en solution dans le chloroforme deutérié avec le tétraméthylsilane comme standard interne. A, protons du *t*-butyle; B, proton éthylénique.

4. Préparation des alcools tertiaires III et IV par l'intermédiaire d'époxydes

Une méthode simple et rapide pour passer d'un hydrocarbure non-saturé à un alcool consiste à préparer l'époxyde, qu'il ne reste qu'à réduire à l'aide d'un hydrure complexe (Schéme Réactionnel 5); une telle méthode a été utilisée très souvent (3). De plus, la réduction d'un époxyde conduit toujours à l'alcool le plus substitué. Ainsi, l'époxydation d'un *t*-butyl-3 alkyl-1 cyclopentène (X) conduira à la formation des *t*-butyl-3 alkyl-1 cyclopentanols *cis* et *trans* (III et IV). Concernant la stéréochimie de la réaction d'époxydation, Henbest (4) a trouvé lors d'une étude sur le méthyl-4 cyclopentène (XXI*a*) que, par

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

réaction avec un peracide, cet hydrocarbure conduit à un mélange de deux époxydes (XXII*a* et XXIII*a*) où l'isomère *trans* XXII*a* est prédominant. Dans un travail récent (5), une extension de ces résultats a été faite au *t*-butyl-4 cyclopentène (XXI*c*).

Cette méthode a été appliquée aux alcènes du type X, XI et XII. Les époxydations sont effectuées dans le chlorure de méthylène à l'aide d'acide *m*-chloroperbenzoique (XIV) d'après les indications de Rickborn (6). Par chromatographie en phase gazeuse, les

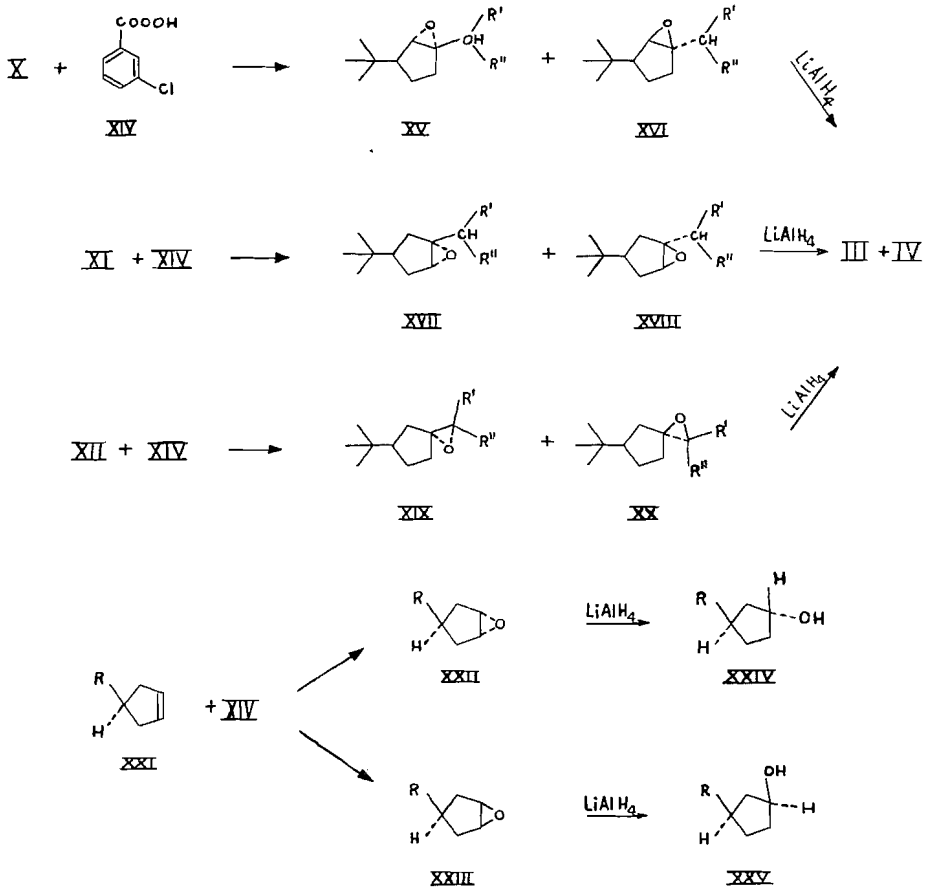

SCHÉMA RÉACTIONNEL 5. *a*, R′ = R″ = H; *b*, R′ = H, R″ = CH_3; *c*, R′ = R″ = CH_3 (se referent aux produits XV à XX). *a*, R = Me; *b*, R = *i*-Pr; *c*, R = *t*-Bu (se referent aux produits XXI à XXV).

pourcentages relatifs des époxydes *cis* et *trans* ont été déterminés; ces résultats sont résumés dans le Tableau IV. La réduction de ces époxydes par l'hydrure double de lithium et d'aluminium dans le tétrahydrofuranne conduit à un mélange de *t*-butyl-3 alkyl-1 cyclopentanols III et IV où l'isomère *cis* (provenant d'une attaque *trans* par rapport au groupe *t*-butyl durant la réaction d'époxydation) est en majorité. Les pourcentages relatifs d'alcools III et IV présents dans les milieux réactionnels sont rapportés dans le Tableau IV.

A l'aide de ces résultats et se basant sur les expériences précédentes de Henbest (4), la configuration relative de chaque alcool tertiaire obtenu par réaction de Grignard sur la *t*-butyl-3 cyclopentanone (I) peut donc être considérée comme établie.

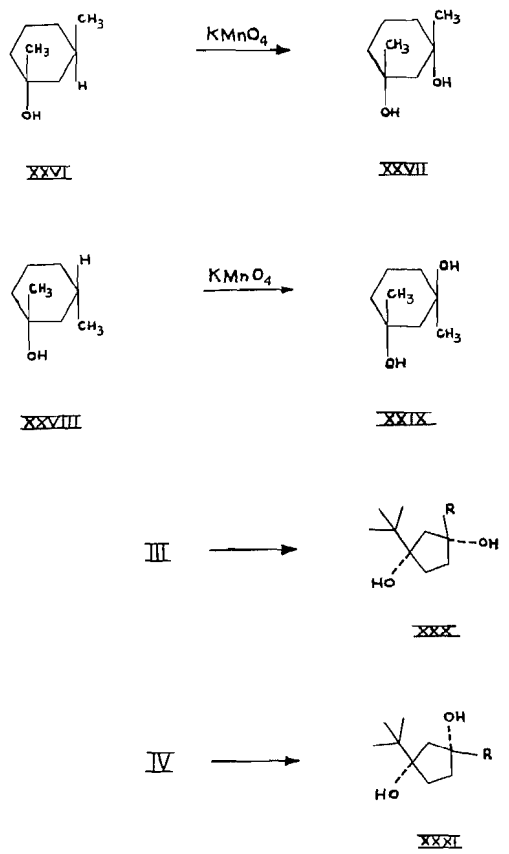
*Les valeurs de ce tableau ont été déterminées par chromatographie en phase gazeuse, en calculant la surface sous les pics à l'aide d'un planimètre.

5. Oxydation permanganique des alcools III et IV



Plusieurs auteurs (7–11) ont montré que les hydrogènes tertiaires peuvent être facilement oxydés par les agents puissants. En particulier, Eastman et Quinn (10) ont noté que l'oxydation du diméthyl-1,3 cyclohexanol *cis* (XXVI) par le permanganate de potassium conduit au diméthyl-1,3 cyclohexanediol-1,3 *cis* (XXVII), lequel réagit avec l'anhydride borique pour former un borate cyclique. De même, l'oxydation du diméthyl-1,3 cyclohexanol *trans* (XXVIII) conduit au diméthyl-1,3 cyclohexanediol-1,3 *trans* (XXIX), lequel ne forme pas de borate cyclique. Les auteurs terminent leur article par la conclusion suivante: "Il existe une similitude formelle entre l'attaque, par le permanganate, d'une liaison π pour donner un glycol *cis*, et l'attaque d'un lien σ d'une liaison C—H pour mener à l'obtention d'un alcool tertiaire avec rétention de configuration du carbone." Il faut remarquer que lors de ces oxydations l'hydrogène tertiaire conduit à un hydroxyle tertiaire de même configuration.

L'application de cette méthode aux alcools tertiaires III et IV a été effectuée (Schéma Réactionnel 6);[2] les propriétés des diols obtenus (XXX et XXXI) sont résumées dans le Tableau V.

Il est maintenant bien établi (12–14) que des ponts hydrogène intramoléculaires peuvent se former lorsque les groupes hydroxyles d'un diol sont placés dans un environnement géométrique favorable. Ainsi, le diméthyl-1,3 cyclohexanediol-1,3 *cis* (XXVII) peut former ce pont hydrogène, qui est facilement détectable dans le spectre infra-rouge. Les *t*-butyl-3 alkyl-1 cyclopentanediols-1,3 *cis* (XXX) peuvent aussi former des ponts hydrogènes, ce qui n'est pas possible avec les isomères *trans* XXXI. Sachant que l'hydrogène tertiaire est oxydé en hydroxyle sans que la configuration du carbone ne soit touchée, il en résulte que les diols III*a* et III*b*, qui montrent la présence de ponts hydrogène intramoléculaires, sont dérivés des alcools tertiaires III*a* et III*b* où les groupes *t*-butyl et R étaient *cis*, l'un par rapport à l'autre. Il est à noter que les conclusions obtenues grâce à cette méthode sont identiques à celles dérivées à l'aide des concepts présentés dans la section précédente.

[2]*Cette méthode n'a pas été appliquée aux alcools tertiaires IIIc et IVc à cause des complications qui auraient pu résulter de la présence de deux types différents d'hydrogènes attachés à des carbones tertiaires.*

*Les rendements indiqués sont des rendements, tenant compte des alcools de départ, qui ont été récupérés.

DISCUSSION

La stéréochimie relative des alcools III et IV a maintenant été établie grâce à des synthèses et des oxydations stéréospécifiques. Ces résultats indiqueraient que l'addition de réactifs de Grignard sur la *t*-butyl-3 cyclopentanone s'effectuerait avec une sélectivité minime mais définie par le côté opposé au groupe *t*-butyle. Cette légère préférence est conforme aux concepts complètement stériques proposés récemment (15) pour l'addition d'agents nucléophiles sur les groupements carbonyles cycliques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Les configurations relatives attribuées aux alcools tertiaires III et IV sont en accord avec le temps relatif de rétention de ces alcools lors de la chromatographie en phase gazeuse. En effet, il est maintenant bien établi (16–18) que lors de chromatographie, tant sur colonne qu'en phase gazeuse, les alcools les plus empêchés sont élués les plus rapidement. Dans le cas présent, les alcools du type IV, qui ont leur groupe OH *cis* par rapport au groupement *t*-butyle et qui par conséquent sont les plus empêchés, sont toujours élués plus rapidement que leurs isomères III, dans lesquels le groupe OH est *trans* par rapport au groupement *t*-butyle.

La spectroscopie infra-rouge confirme de plus la configuration relative attribuée aux alcools tertiaires III et IV. L'utilité de cette méthode physique dans le cas des alcools secondaires est connue depuis les travaux de Jones et ses collaborateurs (19). En série cyclopentanique, Hückel (20) a montré que le cyclopentanol possède des bandes vers 1 070 et 995 cm^{-1}, attribuables à des vibrations C—O. Dans son travail sur les isopropyl-3 cyclopentanols *cis* et *trans* (XXIV*b* et XXV*b*), Hückel (21) obtint pour chacun des isomères des spectres infra-rouges différents; dans le cas du produit *cis* XXV*b* il nota la présence de bande à 1 071 et 994 cm^{-1}, alors que pour l'isopropyl-3 cyclopentanol *trans* (XXIV*b*) la bande à 1 071 cm^{-1} demeure constante mais la bande à 994 cm^{-1} se dédouble en deux bandes à 1 014 et 996 cm^{-1}. Dans le cas des *t*-butyl-3 cyclopentanols XXIV*c* et XXV*c* et des méthyl-3 cyclopentanols XXIV*a* et XXV*a*, des résultats semblables ont été rapportés récemment (5). En faisant la comparaison des spectres infra-rouges des *t*-butyl alkyl-1 cyclopentanols *cis* (III) et *trans* (IV) un dédoublement des bandes dans la région des vibrations C—O a pu être observé. Le Tableau VI résume ces observations, et les résultats confirment une fois de plus les attributions de configurations faites précédemment pour les alcools tertiaires III et IV, obtenus par l'addition de réactifs de Grignard sur la *t*-butyl-3 cyclopentanone (I).

TABLEAU VI

Spectres infra-rouges de quelques cyclopentanols substitués

Alcool	cm^{-1}	cm^{-1}
Méthyl-3 cyclopentanol *cis* (XXV*a*)*	1 068	995
Méthyl-3 cyclopentanol *trans* (XXIV*a*)*	1 065	1 010 et 995

PARTIE EXPÉRIMENTALE

Les spectres infra-rouges ont été pris sur un spectrophotomètre Beckman modèle IR-8 à double réseau; les spectres infra-rouges des *t*-butyl-3 alkyl-1 cyclopentanols *cis* (III) et *trans* (IV) ont été déterminés sur un appareil Perkin–Elmer modèle 21; les mesures de ponts hydrogène ont été faites en solution saturée du diol dans le tétrachlorure de carbone sur un appareil Perkin-Elmer modèle 112 avec prisme de fluorure de lithium. La cellule utilisée mesurait 3 cm de longueur. Les analyses par chromatographie en phase gazeuse ont été effectuées sur un appareil Kromo-Tog modèle K-2 de la compagnie Burrell. Les séparations par chromatographie en phase gazeuse préparative ont été faites sur un appareil Prep-Partitioner modèle 24 de la compagnie Fisher Scientific. Les spectres de résonance magnétique nucléaire ont été pris à l'aide d'un spectromètre modèle A-60 de la compagnie Varian. Les déplacements chimiques (δ) sont exprimés en parties

For personal use only.

par million. A moins d'indication contraire, le solvant utilisé est le chloroforme deutérié, et le tétraméthylsilanne est utilisé comme référence interne. Les points de fusion ont été déterminés sur un appareil Hot Stage de la compagnie Reichert (Autriche), et ne sont pas corrigés. Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre de type Abbé. Les analyses élémentaires ont été faites par Claude Daesslé, Organic Microanalysis, Montréal.

1. t-Butyl-3 cyclopentanone (I)

1.1. Cyclopentène-2 one (IX)

Utilisant la procédure générale de bromuration décrite par Garbisch (2), 67.2 g (0.8 mole) de cyclopentanone (VII) ont conduits à 18.1 g de cyclopentène-2 one (IX): p.é. 78 °C sous 59 mm Hg et n_D^{25} 1.4754 (litt. (2) p.é. 68–69 °C sous 23 mm Hg et n_D^{29} 1.4739).

1.2. Addition de Grignard sur IX

A une solution de chlorure de *t*-butylmagnésium préparée à partir de 46 g de chlorure de *t*-butyl et 11.5 g de magnésium dans 300 ml d'éther, 18 g de cyclopentène-2 one (IX) sont ajoutés à 0 °C; le mélange est ensuite porté à reflux pour une durée de 6 h. Après hydrolyse du complexe par addition d'une solution d'acide acétique 10%, le produit est extrait à la manière habituelle et conduit à 18.4 g (59% du rendement théorique) de *t*-butyl-3 cyclopentanone (I): p.é. 84 °C sous 35 mm Hg et n_D^{25} 1.4512 (litt. (22) n_D^{20} 1.4505). La chromatographie en phase gazeuse de cette cétone à 180 °C à l'aide d'une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P révèle la présence de 2% de la cétone non-saturée IX à l'état d'impureté.

2. Addition des réactifs de Grignard sur la t-butyl-3 cyclopentanone (I)

2.1. Les t-butyl-3 méthyl-1 cyclopentanols cis (IIIa) et trans (IVa)

A une solution d'iodure de méthylmagnésium (II*a*) préparée à partir de 4.4 g de magnésium et de 22 g d'iodure de méthyle, 14 g (0.1 mole) de *t*-butyl-3 cyclopentanone sont ajoutés à 0 °C; après un reflux de 1 h, le complexe est détruit par addition de 100 ml d'une solution 1 *M* d'acide tartrique, et le produit, extrait à la manière habituelle, fournit 14 g (90% du rendement théorique) d'un solide blanc fondant à 38 °C et distillant à 22 °C sous 68 mm Hg.

Anal. Calc. pour $C_{10}H_{20}O$: C, 76.86; H, 12.90. Trouvé: C, 77.01; H, 13.09.

Une chromatographie en phase gazeuse à 110 °C à l'aide d'une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P montre la présence de 50.5% de l'alcool *trans* IV*a* de temps de rétention 55 min, et de 49.5% d'alcool *cis* III*a* de temps de rétention 59 min. Une chromatographie en phase gazeuse préparative à 120 °C à l'aide de huit colonnes contenant 10% d'Hyprose adsorbé sur du Chromosorb P permet d'isoler chacun des alcools, dont les propriétés sont résumées dans le Tableau I.

2.2. Les t-butyl-3 éthyl-1 cyclopentanols cis (IIIb) et trans (IV)

A une solution de bromure d'éthylmagnésium (II*b*) préparée à partir de 5 g de magnésium et de 35 g de bromure d'éthyle, 20 g (0.14 mole) de *t*-butyl-3 cyclopentanone (I) sont ajoutés à 0 °C; après un reflux de 1 h, le produit est isolé à la manière habituelle et fournit 21 g (87% du rendement théorique) d'un liquide jaunâtre distillant à 155 °C sous 185 mm Hg et ayant l'indice de réfraction de 1.4532 à 27 °C.

Anal. Calc. pour $C_{11}H_{22}O$: C, 77.58; H, 13.02. Trouvé: C, 77.52; H, 12.7.

Le spectre infra-rouge de ce produit montre la disparition totale de la bande carbonyle à 1 740 cm^{-1} et l'apparition d'une large bande hydroxyle à 3 400 cm^{-1}. La chromatographie en phase gazeuse à 135 °C montre la présence de 56.1% de l'alcool *trans* IV*b* de temps de rétention 48 min, et de 43.9% de l'alcool *cis* III*b* de temps de rétention 55 min. Une chromatographie en phase gazeuse préparative d'après les conditions déjà décrites dans la section précédente permet d'isoler chacun des constituants, dont les propriétés sont résumées dans le Tableau I.

2.3. Les t-butyl-3 isopropyl-1 cyclopentanols cis (IIIc) et trans (IVc)

A une solution de bromure d'isopropylmagnésium (II*c*) préparée à partir de 3.10 g de magnésium et de 18.6 g de bromure d'isopropyl sont ajoutés 14 g (0.1 mole) de *t*-butyl-3 cyclopentanone (I). Après un reflux de 15 h, le produit est isolé à la manière habituelle et fournit 15.4 g (76% du rendement théorique) d'un résidu jaune qui, lorsque distillé sous vide, se sépare en deux fractions: (*a*) 4.01 g (26% du total), p.é. 87 °C sous 25 mm Hg et n_D^{23} 1.4542; (*b*) 11.3 g (74% du total), p.é. 152 °C sous 2 mm Hg (il s'agit d'un produit jaune foncé très visqueux se solidifiant après quelques semaines).

Une chromatographie en phase gazeuse de la première fraction à 160 °C à l'aide d'une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P montre la présence de trois pics et d'un épaulement. A 35 min 37.6% du produit est élué, et par superposition de pics on peut démontrer que ce produit est la *t*-butyl-3 cyclopentanone (I) qui n'a pas réagi; 26.6% du total est élué à 41 min, et ce produit est le *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*). Le *t*-butyl-3 isopropyl-1 cyclopentanol *cis* (III*c*) et les produits de réduction (*t*-butyl-3 cyclopentanols *cis* et *trans*) sont élués à 47 min et forment 35.8% du total.

Un mélange formé de 1.5 g de la fraction volatile, 5 ml de pyridine et 5 ml d'anhydride acétique est laissé à la température de la pièce pour la nuit. Le mélange réactionnel est alors versé dans l'eau et extrait avec l'éther de pétrole. Le résidu analysé par chromatographie en phase gazeuse dans des conditions décrites plus haut montre la présence des acétates des *t*-butyl-3 cyclopentanols *cis* et *trans* (XXIV et XXV) à 33 min, qui ne sont pas séparés dans les conditions utilisées et qui représentent 15.2% du total; le pic de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

t-butyl-3 cyclopentanone (I, 36.4% du total) apparaît à 35 min; les *t*-butyl-3 isopropyl-1 cyclopentanols *trans* (IV*c*) et *cis* (III*c*), représentant respectivement 28.6 et 19.7% du total, sont élués après 41 et 47 min. Une chromatographie en phase gazeuse préparative à 125 °C à l'aide de huit colonnes contenant 10% d'Hyprose adsorbé sur du Chromosorb P permet la séparation des deux alcools tertiaires, dont les propriétés sont résumées dans le Tableau I.

Anal. Calc. pour $C_{12}H_{24}O$: C, 78.18; H, 13.13. Trouvé: C, 78.42; H, 13.01.

3. Préparation des t-butyl-3 alkyl-1 cyclopentènes (X) et des t-butyl-4 alkyl-1 cyclopentènes (XI)

3.1. t-Butyl-3 méthyl-1 cyclopentène (Xa) et t-butyl-4 méthyl-1 cyclopentène (XIa)

A 15 g (0.1 mole) d'alcools III*a* et IV*a*, 3 gouttes d'acide sulfurique concentré sont ajoutées et le tout porté à ébullition; l'eau formée est distillée au fur et à mesure de sa formation. En continuant le chauffage, le mélange d'hydrocarbures distille à 154 °C sous la pression atmosphérique. L'extraction du produit à la manière habituelle conduit à 10.7 g (77% du rendement théorique) d'un mélange d'hydrocarbures: p.é. 64 °C sous 95 mm Hg et n_D^{26} 1.4388. Le spectre infra-rouge du mélange d'hydrocarbures montre des bandes à 3 050, 1 650, 815 et 790 cm^{-1} toutes caractéristiques de produits non-saturés. Une chromatographie en phase gazeuse à 110 °C sur une colonne de 2 m contenant 20% de Ucon Polar adsorbé sur du Chromosorb P montre la présence de deux pics à 6.5 et 7.2 min dans la proportion de 61 à 39. Le premier pic correspond au *t*-butyl-3 méthyl-1 cyclopentène (X*a*) et le second correspond au *t*-butyl-4 méthyl-1 cyclopentène (XI*a*). Une chromatographie en phase gazeuse préparative à 42 °C à l'aide de huit colonnes contenant 15% de β,β'-oxydipropionitrile adsorbé sur du Chromosorb P permet la séparation de chacun de ces hydrocarbures, dont les propriétés sont résumées dans le Tableau III.

3.2. t-Butyl-3 éthyl-1 cyclopentène (Xb) et t-butyl-4 éthyl-1 cyclopentène (XIb)

A 15 g (0.088 mole) d'une mélange des alcools III*b* et IV*b*, 4 gouttes d'acide sulfurique concentré sont ajoutées, et l'eau qui se forme est éliminée au fur et à mesure par distillation. Les hydrocarbures formés sont extraits à la manière habituelle, et la distillation du produit à 74 °C sous 109 mm Hg conduit à un mélange d'hydrocarbures, dont l'indice de réfraction est de 1.4438 à 25 °C; le spectre infra-rouge de ce mélange indique la disparition complète de la bande hydroxyle à 3 400 et l'apparition de bandes à 3 050 et 1 640 cm^{-1}. Une analyse par chromatographie en phase gazeuse dans les conditions décrites à la section 3.1 montre la présence de 52% de *t*-butyl-3 éthyl-1 cyclopentène (X*b*) à 10.5 min, alors que le pic de *t*-butyl-4 éthyl-1 cyclopentène (XI*b*) apparaît à 12 min et représente 40% du total. A 16 min un pic d'un produit non-identifié avec certitude mais qui pourrait être le *t*-butyl-3 éthylidène cyclopentane (XII*b*) est élué et représente 3% du total. Finalement, le pic du *t*-butyl-4 méthyl-1 cyclohexène (XIII*b*) apparaît à 17.5 min et représente 5% du total. Une chromatographie en phase gazeuse préparative dans les conditions décrites à la section 3.1 permet d'isoler facilement les *t*-butyl-3 éthyl-1 cyclopentène (X*b*) et *t*-butyl-4 éthyl-1 cyclopentène (XI*b*), dont les propriétés sont résumées dans le Tableau III.

3.3. t-Butyl-3 isopropyl-1 cyclopentène (Xc) et ses isomères

A 1 g (5.4 mmoles) d'un mélange d'alcools tertiaires III*c* et IV*c*, 1 goutte d'acide sulfurique concentré est ajoutée, et l'eau qui se forme est éliminée par distillation. Après extraction du produit à la manière habituelle, le mélange d'hydrocarbures obtenu distille à 67 °C sous 32 mm Hg. Une chromatographie en phase gazeuse à 130 °C sur une colonne de 2.5 m contenant 20% de Carbowax 20M adsorbé sur du Chromosorb P indique la présence de 25% de *t*-butyl-3 isopropyl-1 cyclopentène (X*c*) à 10 min, alors que le pic du *t*-butyl-4 isopropyl-1 cyclopentène (XI*c*), représentant 9% du total, apparaît à 11.5 min. Les pics de *t*-butyl-3 isopropylidène cyclopentane (XII*c*) et *t*-butyl-4 diméthyl-1,2 cyclohexène (XIII*c*) apparaissent à 16 et 18 min et représentent, respectivement, 41 et 25% du total. Les hydrocarbures préparés dans la présente section étaient disponibles dans notre laboratoire, provenant d'un travail précédent (1). Il ne fut pas nécessaire de les séparer par chromatographie en phase gazeuse préparative.

4. Préparation des alcools tertiaires III et IV par l'intermédiaire d'époxydes

4.1. Procédé général; application au t-butyl-4 méthyl-1 cyclopentène (XIa)

La réaction de 138 mg (1 mmole) de *t*-butyl-4 méthyl-1 cyclopentène (XI*a*) avec 410 mg d'acide *m*-chloroperbenzoique (XIV) dans 15 ml de chlorure de méthylène pendant 1 h conduit, après extraction à la manière habituelle, à 127 mg (82% du rendement théorique) d'un mélange d'époxydes XVII*a* et XVIII*a*; par analyse par chromatographie en phase gazeuse à 55 °C à l'aide d'une colonne de 2.5 m contenant 15% de β,β'-oxydipropionitrile adsorbé sur du Chromosorb P, ces deux époxydes seraient respectivement présents dans la proportion de 94 à 6. Leur temps de rétention respectif serait de 10 et 6.5 min. La réduction de ce produit (127 mg, 0.82 mmole) par 100 mg d'hydrure double de lithium et d'aluminium dans le tétrahydrofuranne à reflux pendant 18 h conduit, après traitement habituel, à 118 mg (93% du rendement théorique) d'un mélange des alcools III*a* et IV*a* qui, par chromatographie en phase gazeuse dans les conditions décrites à la section 2.1, seraient présents dans le rapport de 95% du produit III*a* et 5% du produit IV*a*.

4.2. Epoxydations des autres hydrocarbures

De la même manière les hydrocarbures X*a*, X*b*, X*c*, XI*b*, XI*c* et XII*c* ont été traités par l'acide *m*-chloroperbenzoique (XIV) et ont fourni, après réduction des époxydes intermédiaires, les alcools tertiaires III et IV dans des proportions rapportées au Tableau IV.

For personal use only.

5. Oxydation permanganique des alcools III et IV

5.1. Procédé général; application au t-butyl-3 méthyl-1 cyclopentanol trans (IVa)

Un gramme de *t*-butyl-3 méthyl-1 cyclopentanol *trans* (IV*a*) est mis en présence de 4 g de permanganate de potassium dans 50 ml d'eau sous agitation constante à la température de la pièce pendant 3 jours. Le mélange réactionnel est alors extrait trois fois avec l'éther. La phase éthérée, séchée sur du sulfate de sodium, est concentrée au travers d'une colonne de Widmer, et 320 mg (32%) de l'alcool IV*a* de départ sont récupérés. La couche aqueuse est filtrée et extraite d'une façon continue avec l'éther pendant 4 jours; l'évaporation de l'éther conduit à une huile qui est dissoute dans de l'hexane; de cette solution se dépose 48 mg (6.4% du rendement théorique)[3] de *t*-butyl-3 méthyl-1 cyclopentanediol-1,3 *trans* (XXXI*a*) fondant à 107 °C.

Anal. Calc. pour $C_{10}H_{20}O_2$: C, 69.72; H, 11.70. Trouvé: C, 69.42; H, 11.40.

Un spectre infra-rouge en solution diluée dans le tétrachlorure de carbone montre une seule bande à 3 610 cm^{-1}.

5.2. t-Butyl-3 méthyl-1 cyclopentanediol-1,3 cis (XXXa)

De la même manière, 1 g de *t*-butyl-3 méthyl-1 cyclopentanol *cis* (III*a*) est oxydé et conduit à 63 mg (10% du rendement théorique)[3] de *t*-butyl-1 cyclopentanediol-1,3 *cis* (XXX*a*) fondant à 124 °C.

Anal. Calc. pour $C_{10}H_{20}O_2$: C, 69.72; H, 11.70. Trouvé: C, 69.37; H, 11.55.

Un spectre infra-rouge en solution diluée dans le tétrachlorure de carbone montre une bande hydroxyle libre à 3 610 cm^{-1} et d'une bande hydroxyle liée à 3 540 cm^{-1}.

5.3. t-Butyl-3 éthyl-1 cyclopentanediols-1,3 cis et trans (XXXb et XXXIb)

De la même manière, les alcools III*b* et IV*b* ont été transformés dans les diols XXX*b* et XXXI*b* correspondants, avec des rendements variant entre 5 et 10%. Les conditions réactionnelles étant les mêmes, les rendements et les caractéristiques de ces produits sont rapportés dans le Tableau V en regard des analyses obtenues pour les produits nouveaux.

REMERCIEMENTS

Les auteurs remercient le Conseil National de Recherches du Canada et la Province de Québec pour l'aide financière apportée sous forme d'octroi de recherche (C.N.R. A-1295) et de bourse de perfectionnement (P. B.); les auteurs remercient également la compagnie Dow Chemical du Canada pour avoir fourni un généreux échantillon de *t*-butyl-4 cyclohexanone, et la compagnie Fisher Scientific du Canada, qui a gracieusement mis à leur disposition un appareil Fisher Prep-Partitioner modèle 24.

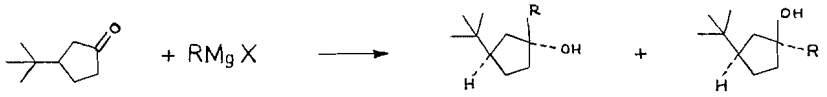
ÉTUDES CONFORMATIONNELLES EN SÉRIE CYCLOPENTANIQUE

III. L'ADDITION DE DÉRIVÉS ORGANOMAGNÉSIENS SUR LA *t*-BUTYL-3 CYCLOPENTANONE[1]

JEAN-CLAUDE RICHER ET PATRICE BÉLANGER
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 31 mars 1966

RÉSUMÉ



L'addition de dérivés organomagnésiens sur la *t*-butyl-3 cyclopentanone a été effectuée sous différentes conditions. L'influence sur la stéréochimie des produits obtenus de divers facteurs, tels que la nature du dérivé organomagnésien et du solvant, a été examinée. Les résultats obtenus sont discutés en fonction de facteurs stériques et électroniques.

INTRODUCTION

Dans le travail précédent (1), la stéréochimie relative des alcools tertiaires III et IV obtenus lors de l'addition de réactifs de Grignard (II) sur la *t*-butyl-3 cyclopentanone (I) a été établie; le but du présent travail était d'examiner l'influence de divers facteurs, tels que la nature du dérivé organomagnésien et du solvant, sur la stéréochimie et la nature des produits obtenus au cours de ces réactions. Le présent travail rapporte les résultats obtenus.

RÉSULTATS

L'addition de dérivés organomagnésiens (II) sur la *t*-butyl-3 cyclopentanone (I) conduit à des mélanges de *t*-butyl-3 alkyl-1 cyclopentanols *cis* (III) et *trans* (IV) (Schéma Réactionnel 1). Par définition, l'isomère *cis* est celui où les deux groupes alkyles sont du même côté du cycle.

I II III IV

SCHÉMA RÉACTIONNEL 1. *a*, R = Me; *b*, R = Et; *c*, R = *i*-Pr; *d*, R = H.

L'addition de méthylmagnésiens (II*a*) conduit à des mélanges d'alcools tertiaires où l'isomère *trans* IV*a* est en légère prédominance. Les résultats obtenus en faisant varier la nature du dérivé magnésien d'une part, et la nature du solvant d'autre part, sont résumés dans le Tableau I.

Les résultats obtenus lors de l'addition d'éthylmagnésiens (II*b*) sur la *t*-butyl-3 cyclopentanone (I) sont résumés dans le Tableau II. Il est à noter qu'avec ces magnésiens possédant un hydrogène en position β de l'atome de magnésium il y a possibilité de réduction (2) de la cétone I, qui donnerait lieu à la formation de *t*-butyl-3 cyclopentanols *cis* et *trans* (IV*d* et III*d*) d'après la mécanisme proposée dans le Schéma Réactionnel 2; la présence des alcools secondaires III*d* et IV*d* n'a toutefois été observée que dans le cas de l'addition du diéthylmagnésium (II*b* où X = CH_2CH_3) sur la cétone I. L'évaluation du degré de réduction est compilée dans le Tableau III.

[1]*Extrait de la thèse de doctorat soumise par M. Bélanger en vue de l'obtention du grade de Ph.D. en chimie Faculté des Sciences, Université de Montréal, Montréal, février 1966.*

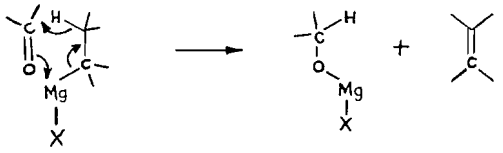


Schéma Réactionnel 2.

TABLEAU I

Pourcentage* de *t*-butyl-3 méthyl-1 cyclopentanol *trans* (IV*a*) formé par l'addition de méthylmagnésiens (II*a*)

	Solvant			
Magnésien	Éther	Tétrahydro-furanne	Anisole	Éther – méthyl-3 pentanol
CH_3MgBr	53.6	53.2	53.8	53.0
CH_3MgI	51.0	60.8	52.5	51.3
$(CH_3)_2Mg$	52.9	52.4	53.5	55.1

*Le pourcentage indiqué est le pourcentage de *t*-butyl-3 méthyl-1 cyclopentanol *trans* (IV*a*) et est relatif à la quantité totale d'isomère *cis* et *trans*. La valeur est la moyenne de trois mesures. Ces mesures ont été déterminées par chromatographie en phase gazeuse, en mesurant les surfaces sous les pics à l'aide d'un planimètre. En se basant sur les travaux de Powell et Whitting (21) et d'Eliel (22), il est permis de supposer que les deux épimères possèdent une conductivité thermique identique et que la surface sous les pics est une mesure directe du pourcentage relatif de ces deux épimères.

TABLEAU II

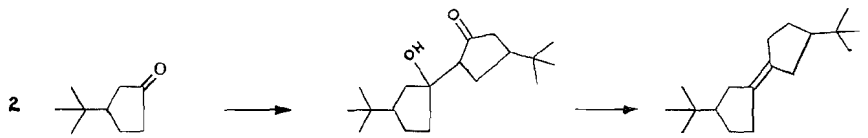
Pourcentage* de *t*-butyl-3 éthyl-1 cyclopentanol *trans* (IV*b*) formé par l'addition d'éthylmagnésiens (II*b*)

	Solvant			
Magnésien	Éther	Tétrahydro-furanne	Anisole	Éther – méthyl-3 pentanol
C_2H_5MgCl	55.2	55.9	55.1	56.0
C_2H_5MgBr	56.0	56.8	56.5	56.6
C_2H_5MgI	59.0	59.5	59.1	59.9
$(C_2H_5)_2Mg$	56.5	56.2	55.2	66.4

*Les remarques sous le Tableau I s'appliquent aussi au présent tableau. Il s'agit d'une mesure de l'isomère *trans* vis-à-vis de l'isomère *cis* sans tenir compte des autres produits pouvant être présents.

TABLEAU III

Réduction* de la *t*-butyl-3 cyclopentanone (XII) par le diéthylmagnésium



Conditions	% réduction	% *t*-butyl-3 cyclo-pentanol *cis* (IV*d*)
Éther	3	58
Tétrahydrofuranne	25	60
Anisole	17	61
Éther – $(C_2H_5)_2CH_3COMgX$	4	59
Éther – $(C_2H_5)_2CH_3COMgC_2H_5$	50	58

*Le pourcentage de réduction est le rapport des surfaces des pics de *t*-butyl-3 cyclo-pentanols *cis* (IV*d*) et *trans* (III*d*) sur la surface totale des pics des alcools secondaires et tertiaires. Il est impossible d'admettre que les conductivités thermiques des alcools secondaires et tertiaires soient identiques; cependant, si on suppose que ces conductivités thermiques sont du même ordre de grandeur, le pourcentage indiqué dans le Tableau III est une valeur donnant un ordre de grandeur de la réduction.

Le pourcentage de *t*-butyl-3 cyclopentanol *cis* (IV*d*) est une valeur déterminée en ne tenant compte que des deux alcools secondaires.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Comme il a été montré dans le travail précédent (1), l'addition de dérivés magnésiens portant un groupe isopropyle conduit à de faibles quantités d'alcools tertiaires III*c* et IV*c*. Ces produits sont accompagnés par des quantités variables d'une part d'alcools secondaires III*d* et IV*d*, provenant de la réduction de la cétone I, et d'autre part de produits qui ont des points d'ébullition très élevés et qui proviendraient selon toute probabilité d'une aldolisation (3–6) de la cétone de départ I suivant le Schéma Réactionnel 3. Dans le Tableau IV, les pourcentages de *t*-butyl-3 isopropyl-1 cyclopentanol *trans* formé par l'addition de différents organomagnésiens sur la cétone I sont rapportés; ces résultats ne tiennent compte que des alcools tertiaires III*c* et IV*c* présents dans le milieu réactionnel. Le Tableau V rapporte les résultats de réduction observés au cours de ces réactions, alors que le Tableau IV indique les pourcentages relatifs des divers produits formés au cours de ces réactions.

V VI VII

SCHÉMA RÉACTIONNEL 3.

TABLEAU IV

Pourcentage* du *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*) formé par l'addition d'isopropylmagnésiens (III*c*)

	Solvant			
Magnésien	Éther	Tétrahydro-furanne	Anisole	Éther – méthyl-3 pentanol
i-C_3H_7MgCl	62.3	64.8	64.5	69.7
i-C_3H_7MgBr	61.1	—	60.8	70.1
i-C_3H_7MgI	66.5	—	67.8	68.7
$(i\text{-}C_3H_7)_2Mg$	61.8	—	62.1	75.2

*Les remarques du Tableau I s'appliquent aussi pour ces résultats, qui ont été obtenus après les manipulations décrites dans les sections 3.1 et 3.2 de la Partie Expérimentale.

TABLEAU V

Réduction* lors de l'addition de dérivés isopropylmagnésiens (II*c*) sur la *t*-butyl-3 cyclopentanone (I)

	Solvant			
Magnésien	Éther	Tétrahydro-furanne	Anisole	Éther – méthyl-3 pentanol
i-C_3H_7MgCl	25, 60	35, 61	30, 57	30, 58
i-C_3H_7MgBr	24, 57	100, 59	37, 61	39, 63
i-C_3H_7MgI	27, 60	100, 59	52, 61	63, 63
$(i\text{-}C_3H_7)_2Mg$	41, 57	100, 57	78, 62	100, 63

*Le premier chiffre inscrit dans le Tableau V est le pourcentage des produits de réduction dans la fraction volatile tel que déterminé sous forme d'acétates après les manipulations décrites dans les sections 3.1 et 3.2 de la Partie Expérimentale.

Le second chiffre est le pourcentage de *t*-butyl-3 cyclopentanol *cis* (IV*d*) vis-à-vis son isomère *trans* (III*d*). Cette valeur est obtenue après avoir effectué les manipulations décrites dans les sections 3.1, 3.2 et 3.3 de la Partie Expérimentale.

Les remarques faites au Tableau I s'appliquent aussi ici.

TABLEAU VI

Produits* formés par l'addition d'isopropylmagnésiens (II*c*) sur la *t*-butyl-3 cyclopentanone (I)

Produits	Magnésiens		
	i-C_3H_7MgCl	*i*-C_3H_7MgBr	*i*-C_3H_7MgI
A	20.7	29.1	26.6
B	27.8	17.5	31.8
C	30.8	22.1	16.2
D	10.9	18.0	12.7
E	9.8	13.3	15.7

*A, (*t*-butyl-3 cyclopentylidène)-2 *t*-butyl-4 cyclopentanone (VII); B, mélange de *t*-butyl-3 cyclopentanone (I), de *t*-butyl-3 isopropyl-1 cyclopentanols *cis* (III*c*) et *trans* (IV*c*) et de *t*-butyl-3 cyclopentanols *cis* (IV*d*) et *trans* (III*d*); C, solide fondant à 90 °C; D, huile; E, solide fondant à 182 °C.

Les résultats obtenus ici ont été déterminés en suivant la technique décrite dans la section 3.4 de la Partie Expérimentale.

DISCUSSION

Jacques (7) a montré que l'augmentation de la grosseur d'un substituant alkyle en position 3 d'une cyclopentanone cause l'augmentation de l'effet Cotton. Cette augmentation est expliquée par l'accroissement de la taille du substituant, qui augmente la rigidé conformationnelle du cycle; cependant, contrairement à la *t*-butyl-4 cyclohexanone, la *t*-butyl-3 cyclopentanone n'existe pas dans une conformation hautement priviligiée à la température de la pièce. L'examen du modèle moléculaire de la *t*-butyl-3 cyclopentanone montre que dans la forme demi-chaise le groupe *t*-butyle doit se placer dans une position pseudo-équatoriale. Dans une telle conformation, les hydrogènes en α du carbonyle sont placés symétriquement de part et d'autre du plan formé par les carbones (1, 2, 5). Si la cétone I existe dans cette conformation, alors seule l'influence légère d'un groupe *t*-butyle en position 3 donnera une préférence à l'attaque du magnésien du côté opposé pour conduire à une majorité de l'alcool tertiaire *trans* IV. L'examen des résultats rapportés dans les Tableaux I, II et IV indique d'une façon non-ambiguë que l'attaque *trans* au groupe *t*-butyle est d'autant plus favorisée que le groupe alkyle est volumineux. Dans tous les cas sauf celui de l'addition de l'iodure de méthylmagnésium (II*a* où X = I) et de l'iodure d'éthylmagnésium (II*b* où X = I) dans le tétrahydrofuranne, il y a augmentation de l'attaque *trans* par rapport au groupe *t*-butyle lorsqu'on passe du groupe méthyle au groupe éthyle et finalement au groupe isopropyle.

Le dialkylmagnésium (II où X = R) s'additionne à une cétone comme le font les dérivés magnésiens ordinaires (II où X = halogènes). Houlihan (8) a trouvé que le comportement du diméthylmagnésium (II*a* où X = CH_3) est identique à celui du chlorure (II*a* où X = Cl) ou du bromure (II*a* où X = Br) de méthylmagnésium quant à la stéréochimie d'addition sur la *t*-butyl-4 cyclohexanone. Dans les Tableaux I, II et IV il est possible de se rendre compte que les résultats obtenus indiquent un comportement semblable à celui des chlorure et bromure d'alkylmagnésium si les pourcentages de *t*-butyl-3 alkyl-1 cyclopentanols *trans* sont considérés. Cependant, lorsque l'addition du dialkylmagnésium se fait en présence de méthyl-3 pentanol-3, House (9) a montré que la stéréochimie de l'addition peut être changée, et il en a été conclu que les résultats suggèrent que l'espèce réactionnelle obtenue par l'action du dialkylmagnésium sur le méthyl-3 pentanol-3 possède un plus grand volume stérique. L'examen des résultats rapportés dans les Tableaux I, II et IV nous permet de confirmer ces remarques pour l'addition du dialkylmagnésium sur la cétone I.

Des facteurs de même nature devraient influencer la stéréochimie de la réduction de la *t*-butyl-3 cyclopentanone (I) par les organomagnésiens; en effet, lors de la réduction, un groupe alkyl doit s'approcher du groupement carbonyle pour effectuer la réduction, et l'effet stérique faible mais décisif du groupe *t*-butyle en position 3 devrait influencer la réduction de la même manière qu'il influence la réaction d'addition conduisant aux alcools tertiaires. L'examen des résultats rapportés dans les Tableaux III et V indique clairement que les groupes alkyles provoquant la réduction s'approchent par la face *trans* (par rapport au groupe *t*-butyle) de la molécule et conduisent en légère prépondérance à la formation du *t*-butyl-3 cyclopentanol *cis* (IV*d*). Ces résultats sont comparables à ceux obtenus précédemment (10) lors de la réduction de la cétone I par l'isopropylate d'aluminium; il existe une analogie très marquée entre les deux intermédiaires qui se forment au cours de ces réactions de réduction. Dans les deux cas, il s'agit de mécanisme cyclique où se fait un déplacement d'hydrure.

L'examen des résultats rapportés dans les Tableaux I, II et IV rend visible l'effet stérique des halogènes; les résultats obtenus lors de l'addition du chlorure (II*b* où X = Cl), du bromure (II*b* où X = Br) et de l'iodure (II*b* où X = I) d'éthylmagnésium sur la *t*-butyl-3 cyclopentanone (I) sont 55.2, 56 et 59% de *t*-butyl-3 éthyl-1 cyclopentanol *trans* (IV). Il faut donc en conclure que plus l'halogène est volumineux, plus le dérivé magnésien est volumineux et plus l'attaque du côté le plus dégagé sera favorisée. D'ailleurs, un tel effet stérique des halogènes a déjà été remarqué par plusieurs chercheurs (11, 12). Dans le cas du chlorure (II*c* où X = Cl), du bromure (II*c* où X = Br) et de l'iodure (II*c* où X = I) d'isopropylmagnésium, il est fort probable que des résultats semblables auraient été obtenus si les *t*-butyl-3 cyclopentanols *cis* et *trans* (IV*d* et III*d*) n'avaient pas interféré au cours de l'analyse des produits normaux d'addition. En effet, il a fallu effectuer une réaction d'acétylation sur le mélange isolé, ce qui a pour effet de diminuer la précision des résultats; l'erreur devient alors plus importante et un effet ayant le même ordre de grandeur que l'erreur rend les résultats moins sûrs. Néanmoins, il est possible de constater l'effet stérique des halogènes si l'attaque du chlorure ou du bromure d'isopropylmagnésium est comparé à celle de l'iodure d'isopropylmagnésium. L'iode étant beaucoup plus volumineux que le chlore ou le brome, le dérivé magnésien de l'iode fournit un pourcentage de *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*) plus important que les dérivés magnésiens du chlore ou du brome. Le cas des halogénures de méthylmagnésium (I*a*) montre un accroissement inversé, ce qui semble indiquer que le bromure de méthylmagnésium (I*a* où X = Br) est plus volumineux que l'iodure de méthylmagnésium (I*a* où X = I). Cet accroissement va à l'inverse de l'ordre de grandeur. Cependant, il ne faut pas s'étonner d'un tel résultat puisque Houlihan (8), dans son étude des additions de dérivés organomagnésiens sur la *t*-butyl-4 cyclohexanone, a observé un phénomène semblable. L'explication d'un tel phénomène a été suggéré à la suite du travail de Kirrmann et ses collaborateurs (13), qui ont déterminé le nombre de molécules de solvant autour du bromure d'éthylmagnésium. En se servant de solvants de différentes basicités, ils ont noté que le nombre de molécules de solvant autour d'un dérivé magnésien varie en fonction de la basicité du solvant. Lorsque le solvant est fortement basique, il y a autour du magnésien une plus forte quantité de solvant, ce qui rend le dérivé magnésien plus volumineux. Dans un solvant faiblement basique, le nombre de molécules de solvant entourant le magnésium sera plus petit. Dans notre cas, ce n'est pas la basicité du solvant qui change mais celle du dérivé magnésien. L'iodure de méthylmagnésium étant moins acide que le bromure de méthylmagnésium, un effet semblable à celui observé par Kirrmann (13) doit se produire. Le bromure de méthylmagnésium, étant plus acide, sera

entouré d'une plus grande quantité de molécules de solvant, ce qui augmentera le volume effectif du bromure de méthylmagnésium et conduira aux résultats obtenus.

Outre l'effet stérique faible mais existant des halogènes, il y a un second effet qui est responsable des réactions secondaires de réduction ou d'énolisation. Cet effet électronique peut aussi jouer un rôle en ralentissant la vitesse d'addition d'un magnésien sur une cétone. L'acidité d'un dérivé magnésien dépend de l'électronégativité de l'halogène. Le chlore est plus électroaffinitaire que le brome, et aura tendance à faire paraître une charge positive sur le magnésium beaucoup plus facilement que le brome. Cette propriété de donner au magnésium des propriétés plus acides expliquerait pourquoi le chlorure d'alkylmagnésium n'existe que sous forme dimérique. Le magnésium est très acide et accepte facilement le doublet d'électrons du chlore, formant un dimère. Cette acidité le rend aussi plus apte à former un complexe avec le solvant, qui est une base. Ainsi, le chlorure de méthylmagnésium est un acide beaucoup plus fort que le bromure de méthylmagnésium, car le chlore est plus électroaffinitaire que le brome. Un tel effet serait la raison du ralentissement de la vitesse d'addition, car il est admis que la première étape pour une telle réaction consiste en une formation de complexes magnésiens–cétones. La stabilité d'un complexe magnésien–éther rend difficile la formation de l'important complexe magnésien–cétone, ce qui est l'étape déterminante de la réaction. Cet effet électronégatif causera un ralentissement de la vitesse de réaction dans le même ordre que l'acidité du magnésien ou de l'électronégativité de l'halogène. C'est ce que Anteunis (14) a observé lors de l'addition du bromure de méthylmagnésium, de l'iodure de méthylmagnésium ou du méthylmagnésium sur le benzophénone. La deuxième façon pour cet effet de se manifester est la variation du pourcentage des produits secondaires de la réaction d'addition de magnésiens sur une cétone. La nature des halogènes cause un changement dans le pourcentage de la réaction dite anormale, et Grignard (15) a noté que durant l'addition de dérivés magnésiens sur la pulégone le degré d'énolisation diminue avec augmentation du poids atomique de l'halogène. Kharasch (16) a aussi noté un tel effet. Il est à remarquer que l'augmentation du poids atomique va de pair avec la diminution de l'électronégativité, ce qui revient à dire que plus l'électronégativité est faible plus l'énolisation sera diminuée. L'énolisation est donc une mesure de l'électronégativité de l'halogène et, tel que montré précédemment, l'halogène a une grande influence sur l'acidité du magnésien. On sait que l'énolisation d'une cétone est d'autant plus favorisée que l'acidité du milieu est grande. Il en résulte que plus le magnésien est acide plus l'énolisation sera poussée. D'autre part, l'étude de Shine (17) montre que la réduction est faible lorsque l'énolisation est forte. Ce fait est aussi observé dans le cas de l'addition de magnésiens sur la cétone I. Cette augmentation dépend indirectement de l'électronégativité des halogènes. Ainsi, pour les dérivés de l'iodure d'alkylmagnésium, l'énolisation est très favorisée par la faible acidité du magnésien. La réduction devient prédominente, étant donné que la réaction normale est de beaucoup empêchée par des effets stériques importants.

Les changements de solvant dans la réaction d'addition de dérivés organomagnésiens ont généralement un effet marqué sur le cours de la réaction de Grignard. Ainsi, Lewis (18) avait remarqué que l'anisole favorise les réactions normales d'addition au dépens de réactions anormales de réduction, d'énolisation ou d'aldolisation. De plus, Bromberg (19) a pu effectuer des synthèse asymétriques en utilisant des solvants optiquement actifs, alors que Houlihan (8) a montré que le solvant possède une influence dans la répartition des pourcentages de *t*-butyl-4 méthyl-1 cyclohexanols *cis* et *trans*. L'examen des Tableaux I, II et IV montre que le solvant ne possède que peu ou pas d'influence

sur la stéréochimie de l'addition des magnésiens sur la cétone I. Ce résultat n'est pas surprenant, puisque les effets stériques du *t*-butyle sont relativement faibles et puisque l'addition de molécules de solvant ne semble pas provoquer des changements majeurs dans la grosseur des entitées réactives au cours des réactions d'addition de magnésiens sur la *t*-butyl-3 cyclopentanone (I). Il est à noter toutefois que les observations de Lewis (18), à savoir qu'une réaction de Grignard faite dans l'anisole conduit à une plus grande proportion de produits normaux, ne sont pas observés dans nos travaux; les résultats obtenus semblent même indiquer une tendance contraire. Il pourrait donc être suggérer que les observations de Lewis (18) ne sont pas générale et que la basicité d'un solvant ne joue un rôle vraiment important qu'au point de vue cinétique.

Les résultats obtenus au cours du présent travail montreraient donc d'une façon définitive que l'addition sur I de réactifs nucléophiles se fait généralement par le côté opposé au groupe *t*-butyle. Les facteurs qui auraient comme influence d'augmenter la grosseur effective des réactifs tendraient à favoriser encore plus cette stéréochimie. Ces résultats sont conformes au concept complètement stérique proposé récemment (20) pour expliquer les résultats d'addition sur des carbones du type sp^2 en série cyclique.

PARTIE EXPÉRIMENTALE[2]

1. Additions de dérivés méthylmagnésiens (IIa) sur la t-butyl-3 cyclopentanone (I)

1.1. Préparation du bromure de méthylmagnésium (IIa où X = Br) et détermination de sa concentration

Le bromure de méthylmagnésium (II*a* où X = Br) est préparé en chauffant à reflux pendant 1 h un mélange de 9.5 g de bromure de méthyle et 2.3 g de magnésium dans 150 ml d'éther. La solution éthérée est alors décantée, permettant l'obtention d'une solution claire de magnésien. La concentration de cette solution est alors déterminée en titrant la quantité de base formée lorsque le dérivé est hydrolysé par l'eau. Ainsi, 2 ml de la solution éthérée du dérivé magnésien sont hydrolysés par de l'eau, et il faut 10.6 ml d'acide chlorhydrique 0.1 *N* pour effectuer la neutralisation; la solution éthérée est donc 0.53 *M* en bromure de méthylmagnésium.

1.2. Addition du bromure de méthylmagnésium sur la t-butyl-3 cyclopentanone

Le dérivé magnésien (II*a* où X = Br) (1.8 ml, 1 mmole) est placé dans une éprouvette plongée dans de la glace, et 70 mg (0.5 mmole) de la cétone I dans 1.8 ml d'éther sont ajoutés lentement. L'éprouvette est placée dans un bain d'huile maintenu à 36 °C. Après 1 h, le mélange réactionnel est hydrolysé, et le résidu obtenu après le traitement habituel est analysé par chromatographie en phase gazeuse à 110 °C à l'aide d'une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P. Le résultat de cette chromatographie est décrit dans le Tableau I.

1.3. Addition du bromure de méthylmagnésium sur la t-butyl-3 cyclopentanone dans le tétrahydrofuranne

Le dérivé magnésien (II*a* où X = Br) (1.8 ml, 1 mmole) est placé dans une éprouvette et l'éther est évaporé sur le bain-marie. Le magnésien cristallise sur les parois de l'éprouvette, et 2 ml de tétrahydrofuranne sont alors ajoutés; la solution est placée sur le bain-marie pour permettre le dégagement des dernières traces d'éther. La solution est refroidie dans un bain de glace, et 70 mg (0.5 mmole) de I dans 2 ml de tétrahydrofuranne sont alors ajoutés. L'éprouvette est bouchée et placée dans un bain d'huile maintenu à 36 °C. Après 1 h, le mélange réactionnel est hydrolysé, et le résidu recueilli est analysé par chromatographie en phase gazeuse dans les conditions décrites dans la section 1.2. Les résultats obtenus sont rapportés dans le Tableau I.

1.4. Addition du bromure de méthylmagnésium sur la t-butyl-3 cyclopentanone dans l'anisole

Le dérivé magnésien (II*a* où X = Br) (1.8 ml, 1 mmole) est placé dans une éprouvette et l'éther est évaporé sur le bain-marie. Le magnésien cristallise sur les parois de l'éprouvette, et 2 ml d'anisole sont ajoutés. La solution est chauffée sur le bain-marie pour chasser les dernières traces d'éther, et puis est refroidie dans un bain de glace. La cétone I (70 mg, 0.5 mmole) dans 2 ml d'anisole est alors ajoutée. L'éprouvette est bouchée et placée sur un bain d'huile maintenu à 36 °C. Après 1 h, le mélange réactionnel est traité à la façon habituelle, et le résidu obtenu est analysé par chromatographie en phase gazeuse dans les conditions décrites dans la section 1.2. Les résultats obtenus sont rapportés dans le Tableau I.

1.5. Addition du bromure de méthylmagnésium sur la t-butyl-3 cyclopentanone dans l'éther contenant du méthyl-3 pentanol

Le dérivé magnésien (II*a* où X = Br) (1.8 ml, 1 mmole) est ajouté à un solution de méthyl-3 pentanol (115 mg, 1 mmole) dans 2 ml d'éther. A ce mélange, 1.8 ml (1 mmole) de bromure de méthylmagnésium

[2]*Les techniques expérimentales utilisées pour la réalisation du présent travail ont été décrites dans le travail précédent (1).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sont ajoutés. Finalement, 70 mg (1 mmole) de la cétone I dans 2 ml d'éther sont introduits dans le mélange refroidi dans un bain de glace. La solution est maintenue à 36 °C pendant 1 h, et puis hydrolysée. Après le traitement habituel le résidu obtenu est analysé par chromatographie en phase gazeuse dans les conditions décrites dans la section 1.2. Les résultats obtenus sont rapportés dans le Tableau I.

1.6. Préparation du diméthylmagnésium (IIa où X = CH_3) à partir de bromure de méthylmagnésium

Le diméthylmagnésium est préparé d'après les indications de Kirrmann (13) à partir de 100 ml de bromure de méthylmagnésium (53 mmoles) auxquels sont ajoutés 4.5 g (55 mmoles) de dioxanne et 100 ml d'éther. Le mélange réactionnel est laissé à la température de la pièce pour la nuit, et 80 ml d'une solution de magnésien dans l'éther peuvent alors être décantés et analysés. Un titrage acide du magnésien hydrolysé indique une concentration de 0.107 *M* en dérivé magnésien hydrolysable. Un titrage du bromure par la méthode standard indique la présence de 0.001 *M* de bromure. La solution éthérée contient donc 0.106 mole de diméthylmagnésium, ce qui fait un ordre de pureté de plus de 99%.

1.7. Addition du diméthylmagnésium sur la t-butyl-3 cyclopentanone

La technique expérimentale est la même que celle qui a été décrite auparavant, sauf qu'il faut utiliser 9.5 ml de magnésien (1 mmole) sur 70 mg (1 mmole) de cétone I.

2. Additions de dérivés éthylmagnésiens (IIb) sur la cétone I

Les techniques expérimentales utilisées dans ces cas sont les mêmes que celles décrites dans la section 1. Les produits obtenus ont été analysés par chromatographie en phase gazeuse à 135 °C sur une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P. Dans ces conditions, les temps relatifs de rétention des *t*-butyl-3 éthyl-1 cyclopentanols *trans* (IV*b*) et *cis* (III*b*) et des *t*-butyl-3 cyclopentanols *cis* (IV*d*) et *trans* (III*d*) sont, respectivement, de 48, 55, 58 et 60 min. La stéréochimie des produits d'addition est rapportée dans le Tableau II, alors que les pourcentages relatifs de *t*-butyl-3 cyclopentanols (III*d* et IV*d*), provenant de la réduction de I, sont rapportés dans le Tableau III.

3. Additions d'isopropylmagnésiens (IIc) sur la cétone I

3.1. Addition du chlorure d'isopropylmagnésium (IIc où X = Cl) sur la cétone I

A une solution de chlorure d'isopropylmagnésium préparé à partir de 0.9 g de magnésium et de 3 g de chlorure d'isopropyl, 2.8 g (0.02 mole) de I sont ajoutés lentement à 0 °C. Le mélange réactionnel est porté à reflux durant 15 h, et le complexe intermédiaire est alors détruit par addition de 50 ml d'une solution d'acide acétique à 10%. La couche éthérée est décantée et la phase aqueuse extraite avec de l'éther. Après extraction à la manière habituelle, 3.05 g (87% du rendement théorique) de produit sont obtenus. Une chromatographie en phase gazeuse de ce résidu à 160 °C à l'aide d'une colonne de 4 m contenant 10% d'Hyprose adsorbé sur du Chromosorb P montre la présence de trois pics et d'un épaulement: à 35 min la *t*-butyl-3 cyclopentanone (I) qui n'a pas réagi (27.6% du produit) est éluée; la *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*, 28.9% du produit) apparaît à 41 min; à 47 min un mélange formé de *t*-butyl-3 isopropyl-1 cyclopentanol *cis* (III*c*) et de *t*-butyl-3 cyclopentanols *cis* et *trans* (IV*d* et III*d*), formant au total 43.5% du produit, apparaissent sous forme de pic et d'un épaulement sur le chromatogramme.

3.2. Acétylation du mélange préparé dans la section 3.1

Un mélange formé de 100 mg du produit préparé à la section 3.1, de 1 ml de pyridine et de 1 ml d'anhydride acétique est laissé à la température de la pièce pour la nuit. Après traitement à la manière habituelle, un résidu est obtenu et analysé par chromatographie en phase gazeuse d'après les conditions décrites à la section 3.1. Les acétates de *t*-butyl-3 cyclopentanols *cis* et *trans*, qui interféraient dans le chromatogramme précédent, apparaissent maintenant ensemble à 33 min et forment 25.5% du total. A 35 min le pic de la *t*-butyl-3 cyclopentanone (I) qui n'a pas réagi apparaît; il représente 27.6% du total. Les *t*-butyl-3 isopropyl-1 cyclopentanols *trans* (IV*c*) et *cis* (III*c*) apparaissent alors, respectivement, à 41 et 47 min; ils représentent 27.9 et 19% du total. Il est à noter que l'acétylation ne semble pas provoquer de changements dans les pourcentages relatifs des divers constituants, puisque dans le mélange brut la cétone I qui n'a pas réagi représentait 27.6% du total et puisqu'après acétylation la quantité présente est encore de 27.6%; d'autre part, le *t*-butyl-3 isopropyl-1 cyclopentanol *trans* (IV*c*), qui formait 28.9% du total dans le produit brut, représente 27.9% du total dans le produit acétylé.

3.3 Déshydratation du mélange de la section 3.2 et saponification du produit

Afin de déterminer la quantité relative des *t*-butyl-3 cyclopentanols *cis* et *trans* (IV*d* et III*d*) présents dans les produits volatils, 150 mg du produit obtenu à la section 3.2 ont été traités par quelques cristaux d'iode sur un bain-marie pendant 15 min. Le mélange réactionnel est alors extrait à la manière habituelle et fournit un produit qui est traité par 1 ml d'une solution de méthanol–eau contenant une pastille d'hydroxyde de sodium. Le mélange réactionnel est laissé pendant 1 h sur le bain-marie et est ensuite extrait à l'éther. Le produit obtenu est alors chromatographié en phase gazeuse dans les conditions décrites à la section 3.1. Les *t*-butyl-3 cyclopentanols *cis* (IV*d*) et *trans* (III*d*) sont élués à 47 et 48.5 min; l'isomère *cis* prédomine dans le mélange avec un pourcentage de 60. La série de tests décrite dans les sections 3.1, 3.2 et 3.3 nous permet donc de déterminer la composition des produits volatiles obtenus par réaction entre la *t*-butyl-3 cyclopentanone (I) et les isopropylmagnésiens (II*c*). Les pourcentages relatifs de *t*-butyl-3 isopropyl-1 cyclopentanols *cis* (III*c*) et *trans* (IV*c*), tels que mesurés dans la section 3.2, sont rapportés dans le Tableau IV, alors que les pourcentages relatifs de *t*-butyl-3 cyclopentanols *cis* (IV*d*) et *trans* (III*d*), tels que mesurés dans la section 3.3, sont rapportés dans le Tableau V.

3.4. Chromatographie sur colonne

Le mélange brut (850 mg) obtenu à la section 3.1 est placé sur 100 g de silica gel. En éluant avec de l'éther de pétrole, 16 mg d'une huile jaune, qui n'a pas été étudiée, sont recueillis. Continuant l'élution à l'aide d'éther de pétrole, 134 mg de (*t*-butyl-3 cyclopentylidène)-2 *t*-butyl-4 cyclopentanone (VII) fondant à 124 °C après recristallisation de l'éther de pétrole sont recueillis. Son spectre infra-rouge montre la présence de bandes à 1 680 et 1 640 cm^{-1}, alors que le spectre ultraviolet montre une absorption à 258 mμ avec un ϵ de 11 500.

Anal. Calc. pour $C_{18}H_{30}O$: C, 82.38; H, 11.52. Trouvè: C, 82.74; H, 11.38.

La dinitro-2,4 phénylhydrazone de cette cétone, préparée à la manière habituelle, fond à 235 °C.

Anal. Calc. pour $C_{24}H_{34}O_4N_4$: C, 65.14; H, 7.74; N, 12.66. Trouvé: C, 65.42; H, 7.83; N, 12.36.

Continuant l'élution avec de l'éther de pétrole contenant 5% d'éther, 207 mg d'un mélange de plusieurs produits sont obtenus. Le spectre infra-rouge montre une bande à 3 400 cm^{-1} et une autre à 1 740 cm^{-1}. Une analyse par chromatographie en phase gazeuse dans les conditions décrites à la section 3.1 montre la présence de trois pics et d'un épaulement. Cette fraction représente les produits volatiles déjà étudiés dans les sections 3.1, 3.2 et 3.3.

En éluant avec de l'éther de pétrole contenant 10% d'éther, 251 mg d'un solide qui, après sublimation à 80 °C sous 1 mm Hg, fond à 90 °C sont recueillis. Son spectre infra-rouge montre une bande à 1 730 cm^{-1}, alors que le spectre de résonance magnétique nucléaire montre des pics à 0.85 et 0.92 p.p.m., fournissant une intégration dans le rapport de 1 à 3. Le produit ne fut pas examiné de plus près.

L'élution par de l'éther de pétrole contenant 15% d'éther conduit à l'obtention d'une huile (113 mg) qui ne fut pas examinée plus attentivement. Finalement, l'élution avec de l'éther anhydre fournit 102 mg d'un solide qui, après sublimation à 150 °C sous 1 mm Hg, fond à 182 °C. La structure de ce produit ne fut pas déterminée.

Utilisant la technique décrite dans cette section, les quantités relatives des divers produits obtenus par réaction d'isorpopylmagnésiens (IIc) sur la *t*-butyl-3 cyclopentanone (I) peuvent être déterminées; les résultats obtenus sont résumés dans le Tableau VI.

REMERCIEMENTS

Les auteurs remercient le Conseil National de Recherches du Canada et la Province de Québec pour l'aide financière apportée sous forme d'octroi de recherche (C.N.R. A-1295) et de bourse de perfectionnement (P. B.); les auteurs remercient également la compagnie Dow Chemical du Canada, qui a fourni le généreux échantillon de *t*-butyl-4 cyclohexanone utilisée pour la synthèse de la *t*-butyl-3 cyclopentanone.

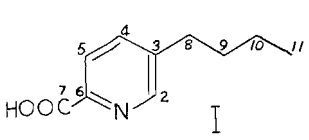
THE BIOSYNTHESIS OF FUSARIC ACID FROM ^{14}C-LABELLED ACETATE IN GIBBERELLA FUJIKUROI

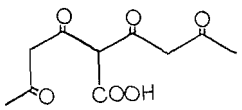
R. D. HILL,[1] A. M. UNRAU,[2] AND D. T. CANVIN[3]
Department of Plant Science, University of Manitoba, Winnipeg, Manitoba
Received April 21, 1966

ABSTRACT



Acetate-1-^{14}C and acetate-2-^{14}C were supplied to cultures of *Gibberella fujikuroi* (Saw.) Wr., and the radioactive fusaric acid consequently formed was isolated. Acetate-1-^{14}C contributed activity mainly to C-4, C-6, C-7, C-8, and C-10 of fusaric acid, whereas acetate-2-^{14}C contributed activity to C-2, C-3, C-5, C-9, and C-11 of fusaric acid. These results are consistent with the hypothesis that fusaric acid is formed from a polyacetate unit and aspartic acid or closely related metabolites.

It is well established that more than one route exists for the biological formation of the pyridine ring. Nicotinic acid is formed from tryptophan in mammals and in the fungus *Neurospora crassa* (1). In higher plants (2) and certain bacteria (3), however, experiments with isotopically labelled tryptophan have failed to show any transformation to nicotinic acid. Glycerol and succinate have been shown to be precursors of nicotinic acid in *Escherichia coli* (4, 5). Aspartate and glycerol are incorporated into nicotinic acid in *Mycobacterium tuberculosis* (6).



Nicotinic acid is a precursor of the pyridine ring of nicotine (7) and anabasine (8) and of the pyridone-ring compound ricinine (9, 10). Nicotine derived from acetate-2-^{14}C (11) or aspartate-3-^{14}C (12) was shown to have one-half of the activity of the pyridine ring at C-3. Acetate-2-^{14}C (13) labelled C-2 and C-3 of the pyridine ring of anabasine equally, with little activity on C-4 and C-6. Administration of acetate-2-^{14}C or succinate-2,3-^{14}C to *Ricinus communis* plants yielded ricinine labelled equally at C-2 and C-3 (15); succinate-1,4-^{14}C gave radioactive ricinine in which most of the activity was located on the nitrile carbon (16). Glycerol-1,3-^{14}C and glycerol-2-^{14}C were also incorporated into the pyridone ring (17, 18), the pattern of labelling strongly suggesting that the three-carbon chain of glycerol formed C-4, C-5, and C-6 of ricinine. The accumulated evidence thus suggests that, in higher plants, nicotinic acid is formed from a condensation of glycerol and succinate or closely related metabolites.

The structure of the wilt toxin, fusaric acid (I), suggests that the pyridine ring of this compound may not be derived from glycerol and succinate. Leete (19) has suggested that the molecule may be formed biologically from a branched chain derived from five acetate units (structure I*a*). Vining[4] has proposed a slightly different condensation involving a polyacetate unit and aspartic acid (structure I*b*). The two hypotheses differ only in the origin of C-2, C-3, C-4, and C-7 of fusaric acid. In Leete's scheme, C-7 and C-3 would be derived from the methyl group of acetate, with C-2 and C-4 originating from the carboxyl group. Vining's suggestion requires C-2 and C-3 to be formed from the methyl group of acetate, with C-7 and C-4 being formed primarily from the carboxyl group.

I

Ia

Ib

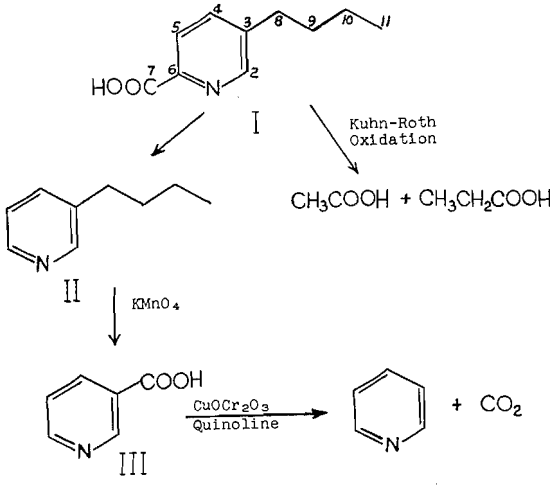
The incorporation of acetate-1-^{14}C, acetate-2-^{14}C, aspartate-1-^{14}C, and aspartate-4-^{14}C into fusaric acid by *Fusarium orthoceras* cultures has been demonstrated.[5] Aspartate contributed activity only to C-7 and the pyridine ring. Partial degradation of the labelled fusaric acid derived from acetate feedings suggested that the activity was probably distributed in a manner consistent with Vining's hypothesis.

The purpose of this investigation was to determine the complete distribution of label in fusaric acid derived from acetate-^{14}C in *G. fujikuroi* (Saw.) Wr. cultures. The incorporation data for acetate-1-^{14}C and acetate-2-^{14}C presented in Table I demonstrate that the methyl carbon and carboxyl carbon of acetate are equally efficient precursors of the carbon skeleton.

TABLE I

Incorporation of acetate-^{14}C into fusaric acid by *G. fujikuroi*

Compound supplied	Fusaric acid		Dilution of specific activity	Incorporation (%)
	Yield (g)	Specific activity (d.p.m.$\times 10^{-6}$/mmole)		
Acetate-1-^{14}C*	1.084	1.07	810	12.9
Acetate-2-^{14}C†	1.427	2.0	275	15.1



*5×10^7 d.p.m.; 8.5×10^8 d.p.m./mmole.
†1.06×10^8 d.p.m.; 5.5×10^8 d.p.m./mmole.

The radioactive fusaric acid was degraded as illustrated in Reaction Scheme 1. Chromic acid oxidation of fusaric acid (I) yielded a mixture of acetic and propionic acids which was separated by gas–liquid chromatography. A Schmidt reaction on the sodium salt of acetic acid gave carbon dioxide (C-10) and methylamine. The activity at C-11 was determined either by difference or by oxidation of the methylamine to yield carbon dioxide. The propionic acid was degraded by the Schmidt reaction to yield carbon dioxide (C-9). Decarboxylation of fusaric acid gave carbon dioxide (C-7) and 3-butylpyridine (II), which was oxidized with potassium permanganate to nicotinic acid (III). Decarboxylation of nicotinic acid with copper chromite in quinoline yielded carbon dioxide (C-7). Sequential degradation of the pyridine ring of nicotinic acid was accomplished by the method described by Friedman and Leete (13 14), with the exception that, in one case, the activity at C-4 was determined directly by a Schmidt reaction of the 2-methyl-3-phenylpropanoic acid obtained by permanganate oxidation of 2-methyl-3-phenylpropylamine.

The distribution of activity in fusaric acid from acetate-1-^{14}C is presented in Table II. The specific activity values reported are for undiluted material. It is apparent that the activity from acetate-1-^{14}C is concentrated on C-4, C-6, C-7, C-8, and C-10 of the molecule. The distribution of activity at three of the positions approaches the value expected if one-half of the carbon atoms of fusaric acid were derived from the carboxyl group of acetate. The low activity at C-10 may have resulted from contamination of the acetic

REACTION SCHEME 1.

acid by propionic acid in the gas chromatographic separation. This would also account for the presence of activity at C-11 in this degradation.

The distribution of activity in fusaric acid from acetate-2-^{14}C (Table III) is compatible with the data obtained for the acetate-1-^{14}C feeding experiment. The activity is found mainly in positions 2, 3, 5, 9, and 11 of the fusaric acid. The low activity at C-2 and C-3 of the pyridine ring and the presence of activity at C-4 and C-7 are consistent with the participation of a four-carbon Krebs cycle acid or its equivalent.[6]

TABLE II

Distribution of activity in the degradation products of fusaric acid synthesized from acetate-1-^{14}C by *G. fujikuroi*

Compound	Carbon No.	Specific activity (d.p.m. × 10^{-5}/mmole)	Distribution of activity (%)

[6]*For example, the equilibrium distribution of label in oxalacetate derived from acetate-2-^{14}C via the Krebs cycle is: C-1, 16.7%; C-2, 33.3%; C-3, 33.3%; and C-4, 16,7%. If C-7, C-2, C-3, and C-4 of fusaric acid are formed from a four-carbon dicarboxylic acid and contain 40% of the activity derived from acetate-2-^{14}C, then the percentage contribution of each carbon would be 6.65, 13.3, 13.3, and 6.65, respectively.*

‡‡Obtained from a Schmidt reaction on the sodium salt of 2-methyl-3-phenylpropanoic acid.

The evidence presented in this communication thus indicates that all the carbons of fusaric acid are derived from acetate or closely related metabolites. The pattern of labelling is consistent with the aspartate–polyacetate hypothesis[4] for fusaric acid formation, and is not consistent with the polyacetate hypothesis (19). The incorporation of ^{14}C-labelled aspartate into fusaric acid[5] and the incorporation of aspartate-1,4-^{14}C,^{15}N into nicotinic acid in *M. tuberculosis* (6) suggest that aspartate may be incorporated intact into fusaric acid.

EXPERIMENTAL

Conditions of Culture

Gibberella fujikuroi (Saw.) Wr., strain ETH M 82, was obtained from the Department of Special Botany, Swiss Federal Institute of Technology, Zurich, Switzerland. The fungus was maintained on malt agar or Difco potato-dextrose agar slants at 4 °C, with regular subculturing every 2 months.

Inoculum was prepared by transferring a suspension of the mycelium to 125 ml Erlenmeyer flasks containing sterile, water-saturated rice. After 5 days in the dark, the conidia were harvested by shaking the mixture with sterile, distilled water (60 ml). This spore suspension was transferred to a 250 ml Erlenmeyer flask and incubated on a shaker in the dark for 24 h. Ten milliliters of this inoculum was added to 250 ml of Czapek's medium in 1 l Erlenmeyer flasks, and the fungus was grown in the dark in shake culture.

Czapek's medium has the following composition: sucrose, 4%; sodium nitrate, 0.3%; monopotassium phosphate, 0.1%; magnesium sulfate, 0.05%; potassium chloride, 0.05%; ferrous sulfate, 0.001%; all in distilled water. The pH of the medium was adjusted to 5.5 before autoclaving.

Administration of Labelled Compounds

The fungus from shake cultures that were 3 days old was collected by low-speed centrifugation. The harvest from two culture flasks was resuspended in Czapek's medium (50 ml) and used to inoculate fresh medium (200 ml). Six flasks were normally used for each tracer experiment.

Aqueous solutions of sodium acetate-1-^{14}C or sodium acetate-2-^{14}C (Atomic Energy of Canada, Ltd.) were prepared and divided equally between the six flasks. After the flasks were shaken for 24 h in the dark, they were removed and the fusaric acid was extracted from the culture filtrate.

Assay of Radioactivity

Samples were counted in a Nuclear-Chicago model 725 liquid scintillation counter using, as solvents, either (*a*) toluene containing 0.4% 2,5-diphenyloxazole (PPO) and 0.005% 1,4-bis-2-(5-phenyloxazolyl)-benzene (POPOP); or (*b*) dioxane – ethyl cellosolve (5:1) containing 5% naphthalene, 0.4% PPO, and 0.01% POPOP. Sample activities were determined in duplicate, with a counting error of 5% or less in each determination.

Extraction and Isolation of the Fusaric Acid

Celite was added to the culture flasks and the slurry filtered. The filtrate was reduced to one-quarter of its volume on a rotary evaporator and filtered. The filtrate (ca. 400 ml) was adjusted to pH 4.0 and extracted with ethyl acetate (3 × 300 ml). The ethyl acetate fraction was evaporated to dryness, the residue dissolved in water (50 ml), and the pH adjusted to 8.0 with 2 *N* sodium hydroxide. After extraction with ether (25 ml), the aqueous phase was adjusted to pH 4.0 with dilute hydrochloric acid and extracted with ether for 36 h in a continuous liquid–liquid extractor. The ether extract was dried with anhydrous magnesium sulfate, filtered, and evaporated to dryness on a rotary evaporator. The residue was extracted with petroleum ether (5 × 100 ml) and the extract evaporated to dryness. The residue was crystallized three times from petroleum ether to give colorless needles of fusaric acid, m.p. 101–102 °C.

Degradation of the Fusaric Acid

Dilutions with non-radioactive intermediates were made whenever the amounts available were too small for subsequent degradation steps.

Kuhn–Roth Oxidation of Fusaric Acid

Fusaric acid (123 mg) in water (2 ml) was added to a refluxing solution of chromium trioxide (0.8 g) in 10% sulfuric acid (14 ml). Distillation was started immediately. The volume of the reaction mixture was maintained by addition of distilled water through a dropping funnel. The distillate (130 ml) was titrated to pH 8.0 with 0.03227 *N* sodium hydroxide solution (20.1 ml) and evaporated to dryness. The residue was dissolved in water (5 ml), acidified (pH < 1) with sulfuric acid, and extracted with ether (4 × 5 ml). The ether extract, containing acetic and propionic acids, was dried, filtered, and evaporated to ca. 0.5 ml in an air stream at room temperature.

The mixture of acetic and propionic acids was separated by gas chromatography, with a copper column (6 ft × 0.25 in. outside diameter) packed with 20% neopentyl glycol succinate on 60–80 mesh firebrick treated with 2% phosphoric acid. The column temperature was 128 °C and the helium flow rate was 50 ml/min. The pure acids were collected by bubbling the exit gas through distilled water, and the solutions were then titrated to pH 8.0 with 0.03227 *N* sodium hydroxide solution (4.56 ml for propionic acid; 3.32 ml for acetic acid). The solutions were each evaporated to dryness *in vacuo*, the residues dissolved in absolute ethanol (10 ml), and the solutions evaporated to dryness again. Treatment with absolute ethanol was repeated twice, followed by final treatment with absolute ether (10 ml) and evaporation to dryness to yield the dry sodium salts of acetic and propionic acids.

Schmidt Reaction on Sodium Acetate or Sodium Propionate

The flask containing the dry sodium salt of the acid (0.1–0.15 mmole) was cooled in an ice bath, 100% sulfuric acid (0.1 ml) was added, and the contents were dissolved by rotating the flask. Sodium azide (15 mg) was added and the flask was connected to a gas train containing a 5% potassium permanganate in 5% sulfuric acid scrubber (to remove sulfur dioxide). The flask was flushed for 2 min with carbon dioxide free nitrogen, and a carbon dioxide trap of ethanolamine or barium hydroxide was attached after the permanganate scrubber. The nitrogen flow was stopped and the reaction flask was heated on a water bath at 75–80 °C for 1 h. The system was flushed with nitrogen for 15 min, after which the carbon dioxide trap was removed and analyzed for carbon dioxide and radioactivity.

Degradation of Methylamine from Schmidt Reaction on Sodium Acetate

A solution of 3% potassium permanganate (5ml) was added to the residue from the Schmidt reaction, followed by the addition of a 40% sodium hydroxide solution (0.2 ml). The flask was connected to the gas train, containing a fresh carbon dioxide trap, and was heated for 15 min on a boiling water bath. The system was flushed with nitrogen, the water bath removed, and the reaction mixture acidified with sulfuric acid to release carbon dioxide. After the system was flushed with nitrogen for 15 min, the carbon dioxide trap was removed and the contents were analyzed for radioactivity and carbon dioxide.

3-n-Butylpyridine

A flask containing fusaric acid (2.95 g) was connected to a reflux condenser and flushed with carbon dioxide free nitrogen. A gas train containing a dilute sulfuric acid scrubber and a carbon dioxide trap was connected after the condenser. The nitrogen flow was stopped, and the reaction flask heated at 200 °C on an oil bath. After 5 h the oil bath was removed and the system flushed with nitrogen for 10 min. The carbon dioxide trap was removed and the contents were analyzed for carbon dioxide and radioactivity. The condenser was set for distillation and the flask contents were distilled under reduced pressure to give 3-*n*-butylpyridine (2.04 g, 94%).

Nicotinic Acid

3-*n*-Butylpyridine (2.04 g), mixed with water (50 ml), was reacted with potassium permanganate (4 g). The potassium permanganate was added in 0.5 g portions over a 4 h period to the stirred solution. The temperature of the reaction mixture was raised to 40 °C, and additional portions of permanganate (4 g) were added after 12 and 24 h. After 48 h the excess permanganate was decomposed by the addition of methanol. The manganese dioxide was filtered off and thoroughly washed with hot water. The combined filtrates were evaporated to dryness, the residue was redissolved in water (25 ml), and the pH of the solution was adjusted to 8.0 with dilute hydrochloric acid. A saturated aqueous solution of cupric acetate (50 ml)

was added, and the resultant precipitate of cupric nicotinate was filtered off and washed with water. The copper salt was suspended in water and decomposed with hydrogen sulfide. The mixture was filtered and the filtrate evaporated to dryness. The residue was crystallized from ethanol to yield nicotinic acid (862 mg, 47%).

Decarboxylation of Nicotinic Acid

Nicotinic acid (35 mg) was refluxed with quinoline (1 ml) and copper chromite (40 mg) for 20 min in a stream of nitrogen. The liberated carbon dioxide was passed through a solution of 2 *N* sulfuric acid (to remove pyridine vapors), and then trapped in ethanolamine – methyl cellosolve or barium hydroxide solution. The yield of carbon dioxide in the reaction was 91% of the theoretical yield.

Degradation of the Pyridine Ring

Sequential degradation of the pyridine ring was accomplished by previously described methods (36, 37).

ACKNOWLEDGMENTS

The authors are indebted, and express their appreciation, to Dr. L. C. Vining for access to some unpublished work concerned with the biosynthesis of fusaric acid by *Fusarium orthoceras* App. and Wr. Financial assistance from the National Research Council is also gratefully acknowledged.

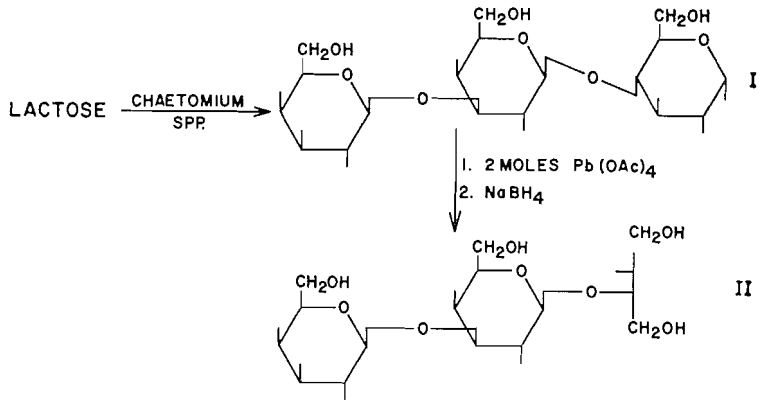
NOTES

A NEW GALACTOBIOSYL GLUCOSE FORMED FROM LACTOSE BY CHAETOMIUM GLOBOSUM[1]



P. A. J. Gorin, R. H. Haskins, and D. W. S. Westlake[2]

During the production of lactose from cheese whey, the crystal habit of lactose sometimes becomes adversely modified so that crystal recovery by centrifugation is affected. It appears that this occurrence is due to the presence of very small amounts of a galactobiosyl glucose arising from lactose.[3] It was therefore of interest to prepare new galactobiosyl glucoses of this type for comparison and for crystal habit modification studies. So far, *O*-β-D-galactopyranosyl-(1 → 6)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose (1–3) and *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose (4) have been prepared. The present publication describes the synthesis of *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose by *Chaetomium globosum* PRL 2200, *Chaetomium cochlioides* PRL 1907, and *Chaetomium funicola* PRL 2184.

These isolates were grown under rotary shake-culture conditions on a medium containing 5% lactose and 0.75% yeast extract. The culture filtrates were examined on paper chromatograms at intervals for the production of tri- and tetra-saccharides. Under these cultural conditions *C. globosum* produced two trisaccharide spots[4] (R_L 0.49 and 0.66), and *C. funicola* and *C. cochlioides* produced one trisaccharide spot (R_L 0.49). Small amounts of tetrasaccharide were also detected on some chromatograms.

The culture filtrate from *C. globosum* was fractionated by charcoal column chromatography to give *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose in 1% yield based on lactose. The other component crystallized in 3% yield as a hydrate of *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-α-D-glucose (I), which could be converted by sodium borohydride reduction into crystalline *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-D-sorbitol. Hydrolysis of the product gave galactose and a hexitol (paper chromatogram), thus indicating a glucose reducing end, which lead tetraacetate oxidation kinetics (5) showed was 1,4-linked. Oxidation with 2 moles of lead tetraacetate on a larger scale followed by sodium borohydride reduction gave *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 2)-D-erythritol (II), which consumed 3 moles of sodium periodate with release of 1 mole of acid, in accord with the structure formulated. The β-configurations of the glycosidic linkages in trisaccharide I were demonstrated by partial hydrolysis to two disaccharides. Since these were not readily separable by cellulose chromatography, they were converted into a mixture of *O*-β-galactosyl glycitols by successive lead tetraacetate oxidation and sodium borohydride reduction. The two products were separated and identified as 2-*O*-β-D-galactopyranosyl-D-lyxitol, arising from 3-*O*-β-D-galactopyranosyl-D-galactose, and 2-*O*-β-D-galactopyranosyl-D-erythritol, arising from lactose.

[1]*Issued as N.R.C. No. 9067.*
[2]*Present address: Department of Microbiology, Faculty of Science, University of Alberta, Edmonton, Alberta.*
[3]*J. M. Wood, personal communication.*
[4]*Rate on a paper chromatogram compared with lactose.*

The low yield of galactobiosyl glucoses from lactose did not promise effective β-galactopyranosyl disaccharide synthesis in a medium containing lactose and a sugar acceptor (6). In addition, *Chaetomium globosum* rapidly utilized as carbon sources such possible acceptors as xylose and arabitol. However, the system had some interest as a method of producing new disaccharides as reference compounds. 3-*O*-β-D-Galactopyranosyl-L-arabinose and 3-*O*-β-D-galactopyranosyl-D-ribose could be prepared, although these disaccharides were synthesized much better by *Sporobolomyces singularis* (6). Transfer of galactose to L-rhamnose gave rise to a mixture of two disaccharides, from which 3-*O*-β-D-galactopyranosyl-L-rhamnose was crystallized. The position of the glycosidic linkage was shown by lead tetraacetate oxidation kinetics. The other component, 2-*O*-β-D-galactopyranosyl-L-rhamnose, could be isolated in an unchanged form by oxidation of the mother liquor components with lead tetraacetate. Although syrupy, it could be reduced with sodium borohydride to give crystalline 2-*O*-β-D-galactopyranosyl-L-rhamnitol.

O-β-D-Galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-α-D-glucose (I) was formed from lactose by *C. cochlioides* and isolated by charcoal column chromatography in a somewhat lower yield than from *C. globosum*. However, contamination of the product with *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose was less pronounced.

The trisaccharide produced by *C. funicola* was isolated by charcoal column chromatography but could not be induced to crystallize. Lead tetraacetate oxidation kinetics indicated a 1,4-*O*-linked reducing end. Two galactobiosyl glucoses appeared to be present, since methylation of the derived galactobiosyl sorbitols followed by methanolysis gave methyl 2,3,4,6-tetra-*O*-methyl-α,β-galactoside, 1,2,3,5,6-penta-*O*-methyl sorbitol, and two methyl tri-*O*-methyl-α,β-galactosides (gas–liquid chromatography). The tri-*O*-methyl components appeared to correspond to the 2,4,6-isomer (62%) and the 2,3,4-isomer (38%) arising from trisaccharide I and *O*-β-D-galactopyranosyl-(1 → 6)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose, respectively.

EXPERIMENTAL

Production of Galactobiosyl Glucoses with Chaetomium spp.

Stock cultures of the isolates used in these studies were maintained on potato-dextrose agar (Difco) slants at 5°. The inoculum used for the production studies was grown in 250 ml Erlenmeyer flasks containing distilled water (50 ml), glucose (1 g), and yeast extract (0.375 g (Difco)). The production medium that was used

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

contained distilled water (100 ml), lactose (5 g), and yeast extract (0.75 g (Difco)) per 500 ml Erlenmeyer flask. All cultures were incubated at 25° on a Gump rotary shaker ($1\frac{1}{4}$ inch eccentricity, 110 r.p.m.). Cells were removed from cultures by filtration, under vacuum, with Whatman No. 5 filter paper.

Isolation of Galactobiosyl Glucose from C. globosum Culture Filtrate

The culture filtrate (500 ml) was fractionated on a charcoal G60 – Celite 545 column; 10% aqueous ethanol eluted lactose and 20% ethanol eluted the trisaccharide having R_L 0.66 (0.80 g) and the trisaccharide having R_L 0.49 (2.70 g) (paper chromatography in ethyl acetate – acetic acid – water (9:2:2 v/v/v) (solvent A)). The faster moving trisaccharide was recrystallized from aqueous methanol to give *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose, m.p. 227–229°, $[\alpha]_D$ +59 → +39° (constant value; *c*, 1.1 in H_2O). It gave a X-ray diffraction pattern identical with that of an authentic specimen (4).

The slower moving trisaccharide was recrystallized from aqueous methanol. The product (1.4 g) was recrystallized from aqueous dioxane to give hydrated *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-α-D-glucose (I), m.p. 197–200°, $[\alpha]_D$ +56 → +43° (constant value; *c*, 1.0 in H_2O).

Anal. Calcd. for $2C_{18}H_{32}O_{16}\cdot 3H_2O$: C, 40.68; H, 6.64; mol. wt. 531. Found: C, 40.9; H, 6.6; mol. wt. (in H_2O) 530.

Based on this formula the trisaccharide consumed 0.28, 0.65, and 1.44 moles of lead tetraacetate after 2, 5, and 15 min, respectively. These figures are consistent with a 1,4-*O*-linked reducing end (5).

Derivatives from O-β-D-Galactopyranosyl-(1 → 3)-O-β-D-galactopyranosyl-(1 → 4)-D-glucose (I)

The trisaccharide was reduced with sodium borohydride to give *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-D-sorbitol, which, after two recrystallizations from aqueous methanol, had m.p 202–203° and $[\alpha]_D$ +20° (*c*, 0.9 in H_2O).

Anal. Calcd. for $C_{18}H_{34}O_{16}$: C, 42.68; H, 6.76. Found: C, 42.5; H, 6.9.

This material gave galactose and a hexitol (paper chromatogram) on hydrolysis with *N* HCl at 100° for 18 h.

The trisaccharide (0.26 g) in water (2 ml) was oxidized by addition of 1% lead tetraacetate (2 moles) in acetic acid. After 18 h, oxalic acid (2 moles) in acetic acid was added, the precipitate filtered off, and the filtrate evaporated to dryness. The oxidized trisaccharide was reduced with sodium borohydride to give *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 2)-D-erythritol (II), which, after two recrystallizations from aqueous methanol, had m.p. 210–213° and $[\alpha]_D$ +18° (*c*, 1.0 in H_2O); yield 73 mg.

Anal. Calcd. for $C_{16}H_{30}O_{14}$: C, 43.04; H, 6.77. Found: C, 42.7; H, 6.9.

Oxidation with aqueous sodium periodate for 18 h resulted in the consumption of 3.0 moles of oxidant and the formation of 1.0 mole of acid. The oxidation product was reduced with sodium borohydride and the product hydrolyzed with *N* HCl at 100° for 24 h. Galactose and glycerol were detected on a paper chromatogram (sprays: *p*-anisidine hydrochloride and ammoniacal silver nitrate; solvent: *n*-butanol–ethanol–water (40:11:19 v/v/v)).

Partial Hydrolysis of O-β-D-Galactopyranosyl-(1 → 3)-O-β-D-galactopyranosyl-(1 → 4)-D-glucose (I)

Trisaccharide I (0.50 g) was partially hydrolyzed by treatment in *N* HCl (5 ml) at 80° for 45 min. The solution was neutralized (Ag_2CO_3), filtered, and evaporated to a syrup which contained some disaccharide in addition to unchanged trisaccharide, glucose, and galactose. The mixture was oxidized with 1.5 moles of lead tetraacetate (based on hexose) as described previously. The product was reduced with sodium borohydride and the mixture fractionated on a cellulose column with *n*-butanol saturated with water as eluent. 2-*O*-β-D-Galactopyranosyl-D-erythritol (56 mg) was eluted and had m.p. and mixed m.p. 182–184° (after crystallization from ethanol). The next fraction contained 2-*O*-β-D-galactopyranosyl-D-lyxitol (38 mg), which, after crystallization from ethanol, had m.p. and mixed m.p. 175–177°. The X-ray diffraction patterns of the above galactosyl polyols were identical with those of authentic specimens.

3-O-β-D-Galactopyranosyl-L-arabinose and 3-O-β-D-Galactopyranosyl-D-ribose

C. globosum, after 7 days growth on a medium (1 l) containing 5% lactose and 2.5% L-arabinose, gave a mixture of compounds which was fractionated on a charcoal column. Elution with 10% ethanol gave lactose and another disaccharide. The mixture was then fractionated on a cellulose column with *n*-butanol saturated with water as solvent. 3-*O*-β-D-Galactopyranosyl-L-arabinose (0.18 g) was isolated and, after recrystallization from methanol–ethanol, had m.p. 192–194° and $[\alpha]_D$ +80 → +65° (constant value; *c*, 1.0 in H_2O). It gave a X-ray diffraction pattern identical with that of an authentic specimen.

From a medium containing 5% lactose and 2.5% D-ribose, a disaccharide having R_{Gal} 0.92 in solvent A (0.57 g) was isolated by a similar procedure. This material consumed 0.63, 0.67, and 0.76 mole of lead tetraacetate after 2, 5, and 15 min, respectively. Reduction of the product with sodium borohydride followed by hydrolysis gave galactose and erythritol (paper chromatogram), consistent with a 3-*O*-β-D-galactopyranosyl-D-ribose structure.

2-O- and 3-O-β-D-Galactopyranosyl-L-rhamnose

C. globosum was grown for 7 days on a medium (1 l) containing 5% lactose and 2.5% L-rhamnose, and the resulting mixture was fractionated on a charcoal column. Elution with 10% ethanol gave lactose and then a

mixture of disaccharides (1.0 g) having R_{Gal} 1.09 (solvent A). Crystallization from ethanol gave 3-*O*-β-D-galactopyranosyl-α-L-rhamnose (0.40 g), m.p. 200–202°, $[\alpha]_D$ +2 → +15° (constant value; *c*, 1.2 in H_2O).

Anal. Calcd. for $C_{12}H_{22}O_{10}$: C, 44.17; H, 6.80. Found: C, 44.1; H, 6.8.

The disaccharide consumed 0.91, 0.94, and 0.98 mole of lead tetraacetate after 2, 5, and 15 min, respectively, consistent with a 3-*O*-link.

The mother liquor appeared to contain equal amounts of 2-*O*- and 3-*O*-β-D-galactopyranosyl-L-rhamnose, as shown by lead tetraacetate oxidation kinetics. A portion (0.24 g) was oxidized with 0.6 mole of lead tetraacetate for 30 min and the product fractionated on a cellulose column with *n*-butanol one-half saturated with water as solvent. The resulting 2-*O*-β-D-galactopyranosyl-L-rhamnose was syrupy, but 2-*O*-β-D-galactopyranosyl-L-rhamnitol, obtained on sodium borohydride reduction, was crystalline and had m.p. 101–103° (after crystallization from ethanol) and $[\alpha]_D$ +9° (*c*, 0.8 in H_2O).

Anal. Calcd. for $C_{12}H_{24}O_{10}$: C, 43.90; H, 7.37. Found: C, 43.8; H, 7.8.

Isolation of O-β-D-Galactopyranosyl-(1 → 3)-O-β-D-galactopyranosyl-(1 → 4)-D-glucose (I) from C. cochlioides Culture Filtrate

Isolation of I from the culture filtrate (2 l) was effected as described for the experiment with *C. globosum*. The product (1.82 g), on crystallization from aqueous methanol, had m.p. 195–199° and $[\alpha]_D$ +57 → +45° (constant value; *c*, 1.0 in H_2O). It gave a X-ray diffraction pattern different from that of the authentic specimen of I crystallized from aqueous dioxane. However, the product proved to be only a different crystalline form of I, since sodium borohydride reduction gave *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-galactopyranosyl-(1 → 4)-D-sorbitol. It had m.p. 201–203° and $[\alpha]_D$ +20° (*c*, 1.1 in H_2O), and gave a X-ray diffraction pattern identical with that of an authentic specimen.

Isolation and Identification of Galactobiosyl Glucoses from C. funicola Culture Filtrate

The culture filtrate (1 l) was fractionated on a charcoal column; 10% aqueous ethanol eluted lactose and 20% ethanol eluted galactobiosyl glucoses (1.1 g) having R_L 0.49. The trisaccharide mixture gave galactose and glucose on acid hydrolysis, and consumed 0.41, 0.80, and 1.24 moles of lead tetraacetate after 2, 5, and 15 min, respectively.

The trisaccharide mixture was reduced to give galactobiosyl sorbitols, which gave galactose and hexitol on hydrolysis (paper chromatograms). A sample (100 mg) of the galactobiosyl sorbitols was methylated by the sodium hydroxide – dimethyl sulfate method (7). Excess reagent was destroyed with heat, the solution neutralized and continuously extracted with chloroform, and the extracted material (120 mg) further methylated with silver oxide and methyl iodide under reflux (8). The fully methylated material, on hydrolysis with *N* H_2SO_4 at 100° for 18 h, gave tetra-*O*-methyl- and tri-*O*-methyl-galactoses on paper chromatograms (*p*-anisidine hydrochloride spray). Treatment with 3% methanolic hydrogen chloride under reflux for 4 h gave a mixture of 1,2,3,5,6-penta-*O*-methyl sorbitol and methyl 2,3,4,6-tetra-*O*-methyl- and methyl tri-*O*-methyl-α,β-galactosides. It was examined by gas–liquid chromatography with 2% neopentyl glycol succinate (9) on hexamethyldisilazane-treated Chromosorb W (80–100 mesh) in 8 ft × ¼ inch outside diameter copper tubing at 143°, with helium (30 p.s.i.) as carrier gas. The gas–liquid chromatographic unit was of conventional design and had thermal conductivity detectors. The following peaks were detected (retention times in parentheses): methyl 2,3,4,6-tetra-*O*-methyl-α,β-galactoside (10.0 and 10.5 min), 1,2,3,5,6-penta-*O*-methyl sorbitol (15.5 min), methyl 2,4,6-tri-*O*-methyl-α,β-galactoside (21.0 and 24.5 min), and methyl 2,3,4-tri-*O*-methyl-α,β-galactoside (40.5 min). The 2,3,4-*O*- and 2,4,6-*O*-isomers were present in a 19:31 ratio.

ESTIMATED MOLECULAR WEIGHT OF AMYLOSE FROM THE YEAST RHODOTORULA PENEAUS[1]

P. A. J. GORIN, J. F. T. SPENCER, AND S. L. MACKENZIE[2]

Starch and starch-like substances are produced by a number of bacteria and fungi. Members of the genus *Cryptococcus* are known to excrete polysaccharides which give a blue color with iodine – potassium iodide solution (1); this characteristic has been used in yeast taxonomy (2). In addition to starch-like material, a pentose-containing polysaccharide has been detected (3), its production being favored at pH values higher than 5. Abercrombie *et al.* (4) investigated the exocellular polysaccharide of *Cr. laurentii* grown at pH 7, and isolated a heteropolymer containing mannose, xylose, and glucuronic acid. A glucan containing 1,3-, 1,4-, 1,2-, and (or) 1,6-links was also isolated. Miyazaki (5) investigated in detail the structure of a capsular polysaccharide from *Cr. neoformans* which also contained mannose, xylose, and glucuronic acid.

Kooiman has found that cultures of *Cr. albidus* and *Cr. laurentii* contain a mixture of starch and heteropolymer (6). The starch from *Cr. albidus* was isolated by fractionation and assigned a molecular weight of 7 000 by the hypoiodite oxidation method. The reliability of this method for molecular weight determination, however, is questionable; in addition, the author pointed out that the polymer may have suffered degradation during the fractionation processes. These involved the use of aqueous alkali, which would degrade amylose unless care was taken to exclude oxygen (7).

Exocellular polysaccharides from *Rhodotorula macerans*, *R. peneaus*, and *R. infirmo-miniata* have now been found to contain starch-like material, as indicated by the iodine blue test. The neutral exocellular polysaccharide from *R. peneaus* was investigated in more detail and was found to be indistinguishable from amylose. The organism was grown on a defined medium (8), and after removal of cells by centrifugation the supernatant liquid was allowed to stand at 3° for a few days. Amylose settled out as a slime and was readily separable from the supernatant. This contained some amylose and an acidic heteropolymer which gave an aldobiouronic acid, mannose, and xylose on hydrolysis. The heteropolymer could readily be purified through an insoluble Cetavlon complex (4).

The isolated amylose gave only glucose on acid hydrolysis, and was hydrolyzed to maltose with β-amylase. The polymer consumed 1 mole of oxidant when treated with sodium periodate; reduction of the oxidized polysaccharide followed by hydrolysis gave erythritol, thus indicating 1,4-*O*-links. The polysaccharide further resembled amylose in that its acetate had a specific rotation close to that of amylose acetate.

Methylation of the yeast amylose followed by hydrolysis showed it was a straight-chain polymer. The *O*-methyl hexose product, from which 2,3,6-tri-*O*-methyl-D-glucose was isolated, was treated with methanolic hydrogen chloride and the resulting methyl glucosides were examined by gas–liquid chromatography. Methyl 2,3,6-tri-*O*-methyl-α,β-glucoside and a trace of methyl-di-*O*-methyl-glucosides resulting from demethylation or undermethylation were detected. The absence of methyl 2,3,4,6-tetra-*O*-methyl-α,β-glucoside (<0.2%) indicated, barring cyclic structures, a straight-chain amylose of more than 500 anhydroglucose units and the absence of amylopectin.

[2]*Postdoctorate Fellow, 1964–1966, Division of Biosciences, National Research Council of Canada, Ottawa, Canada.*

An estimate of the molecular weight was provided by ultracentrifugal and viscosity measurements. The weight-average molecular weight of the amylose in 0.15 *M* KOH was approximately 2×10^6, as determined by substitution of the observed viscosity and sedimentation coefficient into the Scheraga–Mandelkern equation (9, 10). The limiting viscosity of an amylose sample in aqueous potassium hydroxide is related linearly to the degree of polymerization (as determined by osmotic pressure measurements) of the derived acetate (11). If the observed viscosity of yeast amylose in 0.15 *M* KOH is adjusted to the expected value in *M* KOH, the degree of polymerization should be about 3 700, corresponding to a number-average molecular weight of about 7×10^5. The difference between the number- and weight-average molecular weights reflects the polydispersity of the amylose.

The molecular weight of isolated yeast amylose, which could have undergone fractionation during the 'retrogradation' process, is only accurate to 10–15%. On the other hand, it is evident that the yeast amylose molecule is of the same order of size as 'large' amyloses from plant sources. One example is potato amylose, which has a minimum number-average molecular weight of 1.1×10^6 (11).

EXPERIMENTAL

Cultural Conditions for Amylose Production

Rhodotorula peneaus, strain 48-206, was obtained from Dr. H. J. Phaff of the University of California, Davis, California. It was maintained on slants of malt extract agar.

For production of polysaccharides it was grown in shaken cultures in 500 ml Erlenmeyer flasks containing 100 ml of media. The medium contained a yeast–nitrogen base (Difco), 5% glucose, 0.2% Casamino acids, and 0.02% of a vitamin mixture (8). The liquid medium was inoculated from the slants, and incubated at 25° on a rotary shaker operated at 230 r.p.m. and having an eccentricity of 1 inch. After 3 or 4 days the pH of the solution was 2.0; then cells were removed by centrifugation and the supernatant liquid was allowed to stand at 3°. In 24–48 h the starch settled to the bottom of the container as a viscous slime, and the supernatant solution containing the acidic heteropolysaccharide could be decanted. Alternatively, under certain conditions the starch could be separated by centrifugation, appearing as a layer of slime immediately above the layer of packed cells. The acidic heteropolysaccharide could then be removed by decantation as before. From 3 l of medium was obtained 3.27 g of amylose. Increasing the concentration of glucose to 7.5% and 10% resulted in the production of 3.55 g and 0.71 g of starch, respectively. Hydrolysis with *N* H_2SO_4 at 100° gave only glucose, as shown by paper chromatography (solvent: *n*-butanol–ethanol–water (40:11:19 v/v/v); spray: *p*-anisidine hydrochloride).

Treatment of amylose with *N*,*N*-dimethylformamide containing acetic anhydride and pyridine gave an acetate having $[\alpha]_D^{25}$ $+159 \pm 3°$ (*c*, 0.2 in $CHCl_3$), which compares with $[\alpha]_D^{19}$ $+170°$ (*c*, 0.7 in $CHCl_3$) for the acetate of potato amylose (12).

Using the method of Bernfeld and Gürther (13), we dissolved amylose in 2 *N* NaOH and then added the alkaline solution to a β-amylase (Nutritional Biochemicals Corp.; 0.2 times the weight of amylose) solution buffered to pH 4.8. After 18 h the solution was deionized with Amberlite IR 120 and Dowex 1 (bicarbonate form) and evaporated to a syrup which was examined by paper chromatography (solvent: ethyl acetate – acetic acid – water (9:2:2 v/v/v); spray: *p*-anisidine hydrochloride). Spots corresponding to maltose and a trace of glucose were detected.

The soluble portion from the fermentation was concentrated to 500 ml and polysaccharide was precipitated by addition of methanol (2 l). Using 5%, 7.5%, and 10% glucose in the medium gave polysaccharide yields of 6.75 g, 6.73 g, and 5.73 g, respectively. These polysaccharides contained some amylose, since a blue color with iodine was obtained. Acid hydrolysis gave galactose, glucose, mannose, xylose, and an aldobiouronic acid having R_{lactose} 1.2 on paper chromatography in the ethyl acetate – acetic acid – water (9:2:2 v/v/v) solvent.

The water-soluble polysaccharide (1 g) obtained with a 5% glucose medium was dissolved in water (100 ml), and 1% Cetavlon in water (200 ml) was added. The precipitated complex (0.21 g) which separated on centrifugation was hydrolyzed to give mannose, xylose, and an aldobiouronic acid.

Periodate Oxidation of Amylose

After 3.5, 7, 24, 48, and 96 h the polymer respectively consumed 0.77, 0.92, 1.00, 1.08, and 1.15 moles of oxidant per anhydroglucose unit with the concomitant formation of 0.02, 0.05, 0.09, 0.12, and 0.19 mole of acid. The final product was precipitated by addition of 5 volumes of acetic acid, isolated, and reduced with sodium borohydride. Hydrolysis of the resulting polyalcohol with *N* H_2SO_4 at 100° gave erythritol, as shown by paper chromatography (spray: ammoniacal silver nitrate).

Methylation of Amylose

Amylose (0.10 g) was methylated by the Haworth procedure at room temperature (14), and after destruction of dimethyl sulfate and neutralization the solution was extracted continuously with chloroform; yield 0.12 g. The partly methylated amylose was further methylated during 7 days by the method of Kuhn (15). The product was methanolyzed for 18 h in 3% methanolic hydrogen chloride (10 ml); the solution was neutralized (Ag_2CO_3), filtered, and evaporated, and the partly degraded material was hydrolyzed for 18 h in 2 *N* sulfuric acid (5 ml) at 100°. The solution was neutralized ($BaCO_3$), filtered, and evaporated; examination by paper chromatography (solvent: *n*-butanol–ethanol–water (40:11:19 v/v/v); spray: *p*-anisidine hydrochloride) showed the presence of tri-*O*-methyl glucose and a barely detectable amount of di-*O*-methyl glucose. No tetra-*O*-methyl glucose was detected. A portion of the mixture was treated with 3% methanolic hydrogen chloride for 4 h and the resulting methyl glucosidic mixture was analyzed by gas–liquid chromatography.

The product was examined by gas–liquid chromatography with 2% neopentyl glycol succinate (16) on hexamethyldisilazane-treated Chromosorb W (80–100 mesh) in a 4 ft × $\frac{1}{4}$ inch outside diameter copper tube at 143°, with helium at 30 p.s.i. as the carrier gas. The gas–liquid chromatographic unit was of conventional design, with thermal conductivity detectors. Methyl 2,3,6-tri-*O*-methyl-α,β-glucoside was shown to be present, but even with heavy applications of the mixture no methyl 2,3,4,6-tetra-*O*-methyl-α,β-glucoside was detected.

The above aqueous hydrolysate of methylated starch crystallized from ether, and 2,3,6-tri-*O*-methyl-α-D-glucose, m.p. 117–119° and $[\alpha]_D$ +90 → +66° (constant value; *c*, 1.3 in H_2O), was isolated. It gave a X-ray diffraction pattern identical with that of an authentic specimen.

Molecular Weight of Amylose from Rhodotorula peneaus

Ultracentrifugal and viscosity measurements were combined in the Scheraga–Mandelkern equation (9, 10) to provide an estimate of the molecular weight.

The limiting viscosity number $\left(\lim_{c\to 0} \frac{\eta_{sp}}{c}\right)$ was determined as a 0.15 *M* KOH solution in oxygen-free water at 20° with a Cannon–Ubbelohde viscometer, and found to be 590 ml/g. This value alone indicates that the amylose chain is long (cf. ref. 17); a $[\eta]$ of 590 ml/g in 0.15 *M* KOH would correspond[3] to a $[\eta]$ of approximately 495 ml/g in *M* KOH and, hence (11), to a number-average degree of polymerization of approximately 3 700. This observation, however, is based on the assumption that amylose from *R. peneaus* behaves, in solution, in a manner similar to that of potato amylose.

A Spinco model E analytical ultracentrifuge was used to determine the sedimentation coefficient in 0.15 *M* KOH at 20°. Precautions were taken to exclude oxygen from the solution throughout the determination. The schlieren patterns that were obtained consisted of one peak in each case, indicating the absence of any amylopectin. However, the homogeneity of the amylose may only be apparent (18). Because of the concentration dependence of the sedimentation coefficient of most long polymers, S_{20} was determined at several concentrations and a graph of $1/S_{20}$ versus concentration was extrapolated to zero concentration. The resultant value of S_{20} (13.5×10^{-13} s) is somewhat higher than might be expected for even a large amylose molecule; this is due to the extreme concentration dependence of the sedimentation coefficient. However, the extrapolation based on S_{20} values at lower concentrations does appear to be valid.

The equation of Scheraga and Mandelkern as outlined by Greenwood and Thomson gave

$$M = \left(\frac{N\eta_0}{\beta(1 - \bar{v}\rho)}\right)^{\frac{3}{2}} (S^0)^{\frac{3}{2}} \left(\frac{[\eta]}{100}\right)^{\frac{1}{2}},$$

where η_0 is the solvent viscosity (0.010256 dyne s/cm²), *N* is Avogadro's No. (6.02×10^{23}), $\bar{v}$ is the partial specific volume of the solute (0.62 (10)), ρ is the solvent density (1.00589 g/cm³), S^0 is the sedimentation coefficient at infinite dilution (13.5×10^{-13} s), $[\eta]$ is the limiting viscosity number (590 ml/g), β is a constant (2.5×10^6 for a random-coil configuration), and *M* is the molecular weight.

It must be emphasized that this molecular weight is an estimate based on the assumption that the partial specific volume of amylose from *R. peneaus* is close to that of potato amylose. The molecular weight is therefore only accurate to 10–15%.

ALKALINE PERMANGANATE DECARBOXYLATION OF β-AMINO- AND β-HYDROXY-PROPIONIC ACID

A. M. UNRAU[1] AND MAY-LAY FAN[2]

In a previous communication (1), it was reported that the alkaline permanganate oxidation of β-hydroxypropionic acid gave a quantitative yield of carbon dioxide upon acidification. Furthermore, the remaining two-carbon fragment was acetate, and the correct analytical values were obtained in a Schmidt degradation (2); also, 2 equivalents of carbon dioxide was obtained by oxidation with persulfate. The possible oxidation of β-hydroxypropionic acid to malonic acid had, however, not been considered.[3] If malonate was indeed formed, then the degradative procedure developed for the sequential degradation of 2-deoxy-D-ribose (1) would obviously be of much reduced value in biosynthesis experiments involving ^{14}C-labelled metabolic intermediates. It was necessary, therefore, to establish the reaction sequence involved in the alkaline permanganate decarboxylation of β-hydroxypropionic acid. A simple approach to a solution of this problem entailed the decarboxylation of compounds appropriately labelled with ^{14}C.

β-Alanine-1-^{14}C was commercially available and was subsequently used in the preparation of β-hydroxypropionic acid-1-^{14}C. Decarboxylation of unlabelled β-alanine gave a fully quantitative yield of carbon dioxide (Table I). Since it was possible that this compound might also be oxidized to malonic acid before decarboxylation, it was necessary to degrade the appropriate ^{14}C-labelled compound.

Decarboxylation of carboxyl-labelled β-alanine (Table II) gave 85 to 90% $^{14}CO_2$ in four different experiments, thus indicating that a concerted elimination of the carboxyl carbon occurred by a mechanism probably involving a β-elimination in the semialdehyde intermediate.

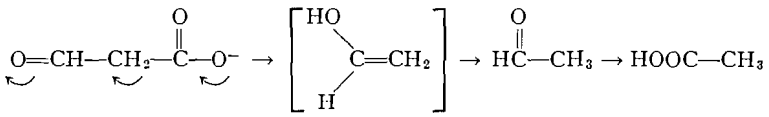
ALKALINE PERMANGANATE DECARBOXYLATION OF β-AMINO- AND β-HYDROXY-PROPIONIC ACID

A. M. UNRAU[1] AND MAY-LAY FAN[2]



In a previous communication (1), it was reported that the alkaline permanganate oxidation of β-hydroxypropionic acid gave a quantitative yield of carbon dioxide upon acidification. Furthermore, the remaining two-carbon fragment was acetate, and the correct analytical values were obtained in a Schmidt degradation (2); also, 2 equivalents of carbon dioxide was obtained by oxidation with persulfate. The possible oxidation of β-hydroxypropionic acid to malonic acid had, however, not been considered.[3] If malonate was indeed formed, then the degradative procedure developed for the sequential degradation of 2-deoxy-D-ribose (1) would obviously be of much reduced value in biosynthesis experiments involving ^{14}C-labelled metabolic intermediates. It was necessary, therefore, to establish the reaction sequence involved in the alkaline permanganate decarboxylation of β-hydroxypropionic acid. A simple approach to a solution of this problem entailed the decarboxylation of compounds appropriately labelled with ^{14}C.

β-Alanine-1-^{14}C was commercially available and was subsequently used in the preparation of β-hydroxypropionic acid-1-^{14}C. Decarboxylation of unlabelled β-alanine gave a fully quantitative yield of carbon dioxide (Table I). Since it was possible that this compound might also be oxidized to malonic acid before decarboxylation, it was necessary to degrade the appropriate ^{14}C-labelled compound.

Decarboxylation of carboxyl-labelled β-alanine (Table II) gave 85 to 90% $^{14}CO_2$ in four different experiments, thus indicating that a concerted elimination of the carboxyl carbon occurred by a mechanism probably involving a β-elimination in the semialdehyde intermediate.

[1]*Present address: Department of Chemistry, Simon Fraser University, Burnaby, British Columbia.*
[2]*Present address: Department of Plant Science, University of Manitoba, Winnipeg, Manitoba.*
[3]*R. Stewart, private discussions.*

Decarboxylation of β-hydroxypropionic acid-1-^{14}C gave similar results, in that, in four experiments, the ^{14}C-labelled carboxyl carbon was essentially eliminated quantitatively. This observation thus shows that the alkaline permanganate decarboxylation likely proceeds via a β-elimination mechanism at the intermediate semialdehyde stage, as illustrated below. The first reaction product, apart from carbon dioxide, would be acetaldehyde, which is then further oxidized to acetate. In previous experiments (1) involving

unlabelled starting compound, a Schmidt degradation of the residue from the permanganate decarboxylation gave the expected analytical values. When these experimental results are considered, the methods and reactions described earlier (1) for the sequential degradation of 2-deoxy-D-ribose are further established and verified.

EXPERIMENTAL

Synthesis of β-Hydroxypropionic Acid-1-^{14}C from β-Alanine-1-^{14}C

A concentrated aqueous solution of sodium nitrite (2 moles of $NaNO_2$ per mole of amino acid) was added slowly to an ice-chilled solution of β-alanine (117 mg unlabelled β-alanine and 6×10^5 d.p.m. β-alanine-1-^{14}C) in 50% aqueous acetic acid under a nitrogen atmosphere. The chilled mixture was stirred for 40–48 h, the solution concentrated under reduced pressure to a small volume, and the concentrate applied as a narrow band on sheets of Whatman No. 1 paper. Standard β-hydroxypropionic acid was used as a marginal marker. Chromatography was carried out with ethyl acetate – acetic acid – water (8:2:2 v/v/v) as the eluent and with a developing time of 16 h. The paper was dried in a stream of warm air until free of acetic acid. Two marginal guide strips were cut and sprayed with bromocresol green reagent. The β-hydroxypropionic acid in the remaining unsprayed central portion of the paper was eluted with water. The percentage yield of β-hydroxypropionic acid synthesized from β-alanine was found to be 34.4. This was determined by comparing the disintegrations per minute of the mixture before chromatography (8 825 d.p.m.) and the disintegrations per minute of the β-hydroxypropionic acid eluted from the paper chromatograms (3 040 d.p.m.).

Decarboxylation with Potassium Permanganate

Unlabelled β-Alanine

β-Alanine (10.25 mg) was dissolved in distilled water (5 ml) in a 50 ml distillation flask. The solution was made neutral, and then 3 ml alkaline permanganate solution (consisting of 0.1 *M* NaOH, 0.2 *M* $KMnO_4$, and 0.02 *M* $MnSO_4$) was added. The flask was fitted to an aeration train and the contents held at room temperature for about 45 min. Before the solution was acidified, the train was flushed with nitrogen for 10 to 15 min. The solution was then acidified (2 *N* H_2SO_4, 2 ml), and the CO_2 that was evolved was swept into a $Ba(OH)_2$ trap. The precipitate that formed ($BaCO_3$) was collected on tared porcelain planchets, dried, and weighed. The results are given in Table I.

TABLE I

Permanganate decarboxylation of β-alanine

Weight of β-alanine (mg)	Weight of $BaCO_3$ expected (mg)	Weight of $BaCO_3$ obtained (mg)

REACTION OF SODIUM *o*-NITROPHENOLATES WITH ETHYL 2-BROMO-2-CYANOACETATE

R. T. Coutts and K. W. Hindmarsh

We have reported earlier that the 2-(*o*-nitrophenoxy) esters required for the synthesis of benzoxazine hydroxamic acids were prepared by the interaction of ethyl 2-bromoesters and the sodium salts of various *o*-nitrophenols (1). We now report that, when ethyl 2-bromo-2-cyanoacetate is the ester employed, a different reaction occurs.

An attempt to prepare ethyl 2-(4,6-dibromo-2-nitrophenoxy)-2-cyanoacetate (I) from 2-bromo-2-cyanoacetate and the sodium salt of 4,6-dibromo-2-nitrophenol yielded a yellow product (product A) which, because of its infrared spectrum and its elemental analysis, was thought to be a solvated form (i.e. $C_{11}H_8Br_2N_2O_5 \cdot \frac{1}{2}EtOH$) of the required compound. An effort to remove the suspected ethanol of crystallization by heating the

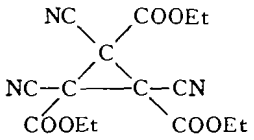
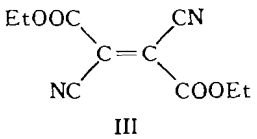
REACTION OF SODIUM *o*-NITROPHENOLATES WITH ETHYL 2-BROMO-2-CYANOACETATE



R. T. COUTTS AND K. W. HINDMARSH

We have reported earlier that the 2-(*o*-nitrophenoxy) esters required for the synthesis of benzoxazine hydroxamic acids were prepared by the interaction of ethyl 2-bromoesters and the sodium salts of various *o*-nitrophenols (1). We now report that, when ethyl 2-bromo-2-cyanoacetate is the ester employed, a different reaction occurs.



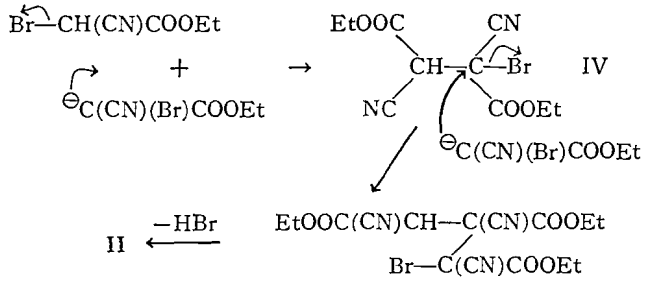
An attempt to prepare ethyl 2-(4,6-dibromo-2-nitrophenoxy)-2-cyanoacetate (I) from 2-bromo-2-cyanoacetate and the sodium salt of 4,6-dibromo-2-nitrophenol yielded a yellow product (product A) which, because of its infrared spectrum and its elemental analysis, was thought to be a solvated form (i.e. $C_{11}H_8Br_2N_2O_5 \cdot \frac{1}{2}EtOH$) of the required compound. An effort to remove the suspected ethanol of crystallization by heating the

I

II

III

product under vacuum, however, resulted in partial sublimation, and a nonvolatile, non-aromatic residue was obtained. Furthermore, reduction of product A with sodium borohydride and palladium–charcoal gave 2-amino-4,6-dibromophenol. Both of these results indicated that product A did not possess the anticipated structure, but rather appeared to be a mixture of 4,6-dibromo-2-nitrophenol and a nonvolatile second product.



Identification of the products obtained from the interaction of sodium *o*-nitrophenolate and ethyl 2-bromo-2-cyanoacetate established the structure of the nonvolatile portion. In this case, an instantaneous reaction occurred and a colorless solid (product B), m.p. 122–124°, separated initially from the concentrated filtrate, followed by precipitation of *o*-nitrophenol. A similar condensation involving the sodium salt of 4-methyl-2-nitrophenol also gave the same product, m.p. 122–124°. An infrared study showed that these two products and the nonvolatile, non-aromatic residue previously described were all identical.

Elemental analysis of product B indicated the empirical formula to be $C_5H_5NO_2$. It was therefore thought to be either triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate ($C_{15}H_{15}N_3O_6$) (II) or diethyl 1,2-dicyanoethylene-1,2-dicarboxylate ($C_{10}H_{10}N_2O_4$) (III), because both compounds can be prepared from ethyl 2-bromo-2-cyanoacetate under conditions which differ from those described in this note. The melting point of the former is reported as 122–123° (2); the latter has a melting point of 117–117.5° (3). On the basis of its melting point and because product B did not decolorize bromine water and did not have an infrared spectrum characteristic of a tetra-substituted alkene, it was concluded that product B was triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate. A molecular weight determination agreed with this conclusion.

Product A, therefore, was a mixture of 4,6-dibromo-2-nitrophenol and II. An infrared spectrum of a known mixture of both components was identical with that of product A.

The formation of triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate in these reactions is due presumably to the fact that ethyl 2-bromo-2-cyanoacetate is sufficiently acidic to permit the equilibrium shown in eq. [1]. The reaction sequence shown in eq. [2], therefore, is plausible. Alternatively,[1] dehydrobromination of the diethyl monobromodicyanosuccinate (IV) could occur, and II could then be formed from the resulting

[1] $$ArO^{\ominus}Na^{\oplus} + HC(CN)(Br)COOEt \leftrightharpoons ArOH + {}^{\ominus}C(CN)(Br)COOEt + Na^{\oplus}$$

[2] 

[1]*The authors thank Dr. R. A. Abramovitch for suggesting that another explanation of the formation of II could involve the intervention of a carbene intermediate.*

diethyl 1,2-dicyanoethylene-1,2-dicarboxylate by a mechanism similar to that described by Krapcho and Huyffer (2).

These results should be contrasted with the findings of Griffin and Peterson (4), who obtained a *cis* and *trans* mixture of 1,2,3-tricyanocyclopropane by reacting ethyl 2-bromo-2-cyanoacetate with potassium acetate in ethanol at room temperature. Triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate (II) was postulated as an intermediate in their reaction, but was not isolable. It hydrolyzed and decarboxylated spontaneously to give the previously mentioned products. In contrast, the present study has shown that, by replacing potassium acetate with sodium *o*-nitrophenolates, the tri-ester II is formed and the reaction proceeds no further.

EXPERIMENTAL

Reaction of Ethyl 2-Bromo-2-cyanoacetate with Sodium o-Nitrophenolates

Reaction with 4,6-Dibromo-2-nitrophenol

The sodium salt of 4,6-dibromo-2-nitrophenol (15.94 g) was suspended in acetone (100 ml). Ethyl 2-bromo-2-cyanoacetate (9.6 g) was added and the mixture was heated to boiling, allowed to stand for 45 min, and then filtered. The filtrate, when cooled to 0°, deposited a green-colored solid which was recrystallized from aqueous ethanol to give a greenish-yellow product (product A) (11.4 g), m.p. 101–104°. A further recrystallization did not alter this melting point. The infrared spectrum (KBr disk), recorded on a Unicam SP 200 spectrophotometer, showed absorption peaks at 1 760 (s) (ester carbonyl); 1 540 (m), 1 335 (m) (shoulder), or 1 280 (s) (NO_2) cm^{-1}.

Anal. Found: C, 33.43; H, 2.46; N, 6.92; Br, 37.27, 37.41. This analysis apparently indicated a formula of $C_{11}H_8Br_2N_2O_5 \cdot \frac{1}{2}EtOH$ (Calcd.: C, 33.42; H, 2.56; N, 6.50; Br, 37.15).

When product A was heated at 78° and 0.5 mm for 1 week, a bromine-free solid, m.p. 110–114°, remained. Recrystallization from aqueous alcohol raised the melting point to 122–124°. This melting point, a mixed melting point, and the infrared spectrum confirmed that this product was identical with the sample of triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate obtained as described below.

When product A (2 g) was reduced by means of sodium borohydride and palladium–charcoal, by the reported (5) method, 2-amino-4,6-dibromophenol (0.65 g), m.p. 97–98°, was isolated.

Reaction with o-Nitrophenol

To a solution of ethyl 2-bromo-2-cyanoacetate (9.6 g) in acetone (100 ml) was added the sodium salt of *o*-nitrophenol (8.1 g). An immediate reaction occurred. After 10 min, unreacted salt and sodium bromide were removed by filtration; when the filtrate was concentrated, an almost colorless solid, m.p. 102–106°, separated. After the filtrate had stood for 24 h, a second product was obtained.

The first product was recrystallized three times from ethanol to give triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate (II) (2.59 g), m.p. 122–124° (lit. (2) m.p. 122–123°). The infrared spectrum in KBr showed strong ester absorption at 1 762 cm^{-1}.

Anal. Calcd. for $C_{15}H_{15}N_3O_6$: C, 54.05; H, 4.54; N, 12.61; mol. wt. 333.5. Found: C, 53.83; H, 4.43; N, 12.52; mol. wt. (vapor pressure) 309.

The second product was recrystallized from aqueous ethanol to give a yellow solid (2.63 g), m.p. 46–47°, which was shown by means of melting point, mixed melting point, and infrared spectrum to be *o*-nitrophenol.

Reaction with 4-Methyl-2-nitrophenol

Ethyl 2-bromo-2-cyanoacetate (9.6 g) and the sodium salt of 4-methyl-2-nitrophenol (8.75 g), when treated as described in the reaction immediately above, gave triethyl 1,2,3-tricyanocyclopropane-1,2,3-tricarboxylate (1.82 g), m.p. 122–124°.

LA SYNTHÈSE DE QUELQUES NOUVELLES PYRIDAZINES BICYCLIQUES

L. ERICHOMOVITCH ET FRANCIS L. CHUBB

Depuis la découverte par Druey des propriétés pharmacologiques des phtalazines (1, 2), de nombreux chercheurs ont orienté leurs travaux vers des composés bicycliques similaires, l'un des cycles étant une pyridazine plus ou moins substituée, l'autre étant un hétérocycle (3–5). D'autre part, la généralisation par Huisgen des réactions de cycloaddition 1,3 dipolaire a permis une synthèse facile de certains esters de diacides carboxyliques hétérocycliques, lesquels sont de très utiles produits de départ dans la synthèse de pyridazines bicycliques. Jones (3) et d'autres chercheurs (4,5) ont déja rapporté la synthèse de pyridazines bicycliques par réaction de l'hydrazine sur des esters ou des anhydrides d'acides dicarboxyliques. Dans cette communication, nous nous proposons de décrire la synthèse de quelques nouveaux dérivés de pyridazine en partant de la réaction de l'hydrazine, soit avec le phényl-1 triazole-1,2,3 dicarboxylate de diméthyle (I), soit avec le phényl-3 isoxazole dicarboxylate de diméthyle (XII).

Le phényl-1 triazole-1,2,3 dicarboxylate de diméthyle préparé selon Michael (6) a été converti en dihydrazide II par action de l'hydrazine en milieu alcoolique. La cyclisation de II conduit à la dihydroxy-4,7 phényl-1 triazolo (4,5-*d*) pyridazine (III). Néanmoins, selon la méthode de préparation utilisée, deux modifications solides différentes mais interconvertibles ont été obtenues, lesquelles différent seulement par leur spectre infrarouge (pastilles de KBr).

La pyrolyse de II donne un solide A dont le spectre infrarouge montre des pics à 1 720 et 1 650 cm^{-1}. Le même composé A a été obtenu par acidification de la solution résultant du traitement de II par un large excès d'hydrazine à reflux. En chauffant le dihydrazide II avec une solution d'acide chlorhydrique 2 *N* pendant 4 h au bain-marie, on a obtenu un composé B montrant deux pics à 1 690 et 1 575 cm^{-1} à l'infrarouge. On peut convertir A en B par recristallisation dans eau–dioxane. Une solution de B dans NaOH, acidifiée par HCl, donne naissance au produit A. En solution, A et B montrent des spectres ultraviolets identiques (il est possible que A et B soient deux des formes tautomériques de III). (Voir le Schéma 1.)

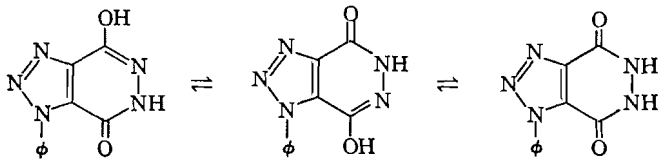

SCHÉMA 1.

La dihydroxypyridazine III, traitée par $POCl_3$, donne le composé dichloré IV ainsi que le composé monochloré V. Le spectre infrarouge de V montre un pic à 1 700 cm^{-1}, indiquant qu'il existe sous la forme cétonique. Aucune absorption dans la région OH n'a été observée. Pour ce dernier composé V nous n'avons pas encore déterminé la position exacte du chlore et du carbonyle. Il convient de noter que le même problème s'est presenté dans le cas des composés VIII, XI, XIII et XVII. En traitant le composé dichloré IV par deux molécules de méthoxide de sodium, on obtient le dérivé VI correspondant. L'action de deux molécules de diméthylaminoéthanolate de sodium sur le composé dichloré IV nous a conduit au

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dérivé disubstitué VII. Ce dernier, traité par HCl alcoolique, s'hydrolyse partiellement pour conduire au chlorhydrate du dérivé monosubstitué VIII.

Des tentatives de conversion du composé dichloré IV en composé diaminé ou dihydraziné correspondant, par action d'ammoniac ou d'hydrazine en autoclave, ont échoué. Cependant, IV a été converti en dimercaptan IX, qui à son tour a été méthylé en diméthylmercaptan X. Ce dernier traité par de l'hydrazine en excès a donné naissance au dérivé monohydrazino monométhylmercapto XI.

Toutes ces réactions sont résumées dans le Schéma 2.

Dans le cas des composés dérivés du phényl-3 isoxazole, nous avons suivi une procédure analogue à celle du phényl-1 triazole-1,2,3. Nous avons ainsi préparé les dérivés suivants (voir le Schéma 3): dihydroxy-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (XIV), diméthoxy-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (XVIII), dichloro-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (XVI), chloro-7(4) oxo-4(7) phényl-3 isoxazolo (4,5-*d*) pyridazine (XVII), diméthylmercapto-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (XX) et diméthylamino-éthoxy-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (XIX).

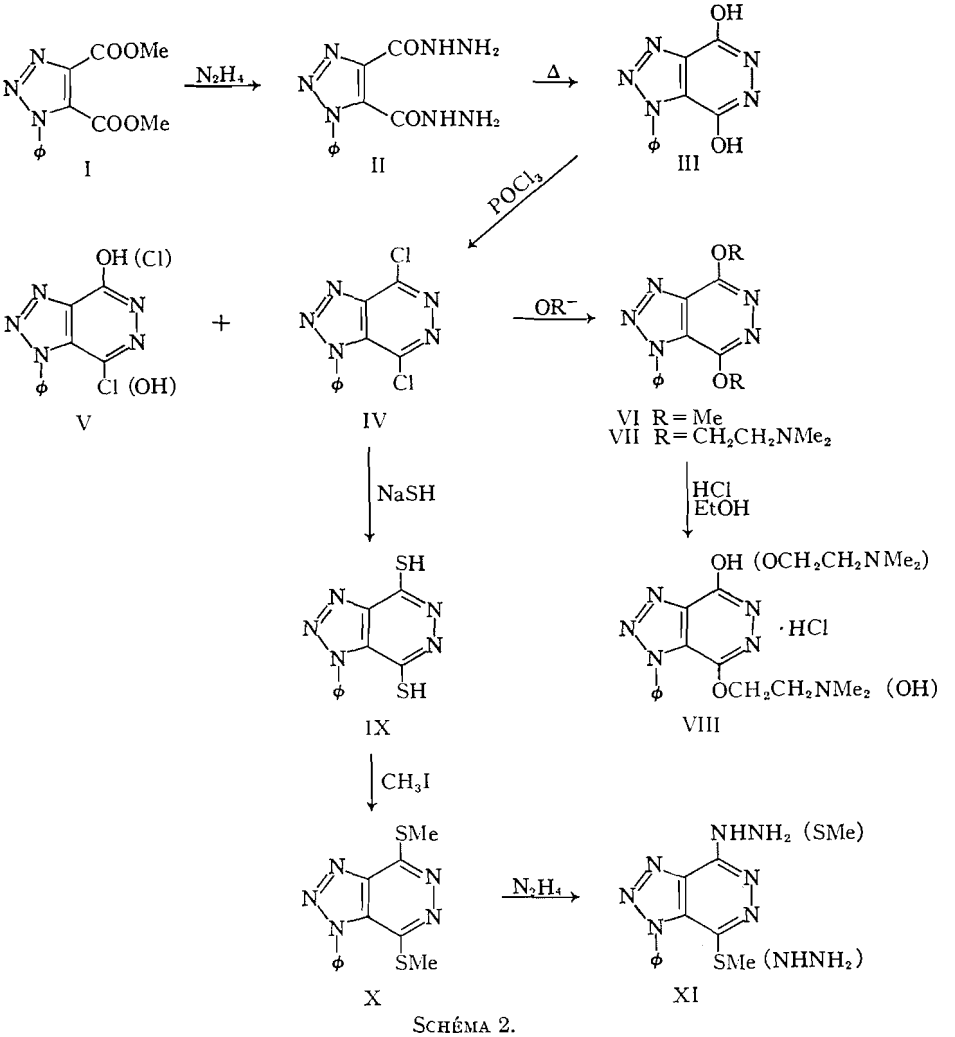

Schéma 2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

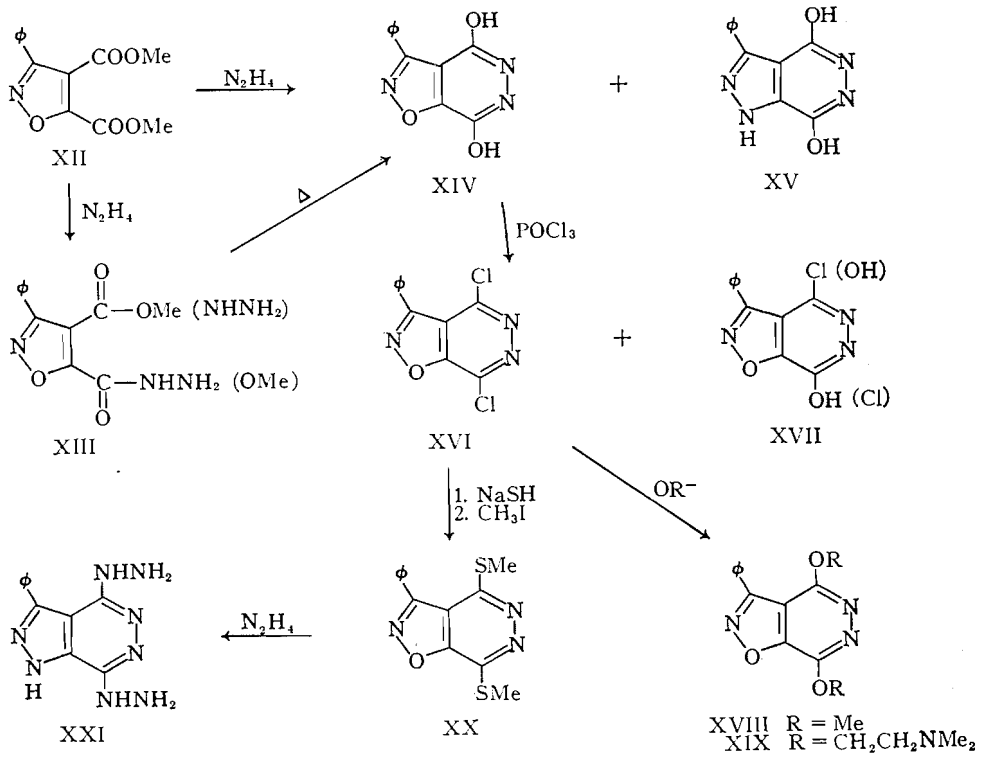

SCHÉMA 3.

Il faut, néanmoins, noter quelques différences. Lors de l'action de l'hydrazine sur l'ester méthylique du dicarboxy-4,5 phényl-3 isoxazole (XII), nous avons pu obtenir trois produits différents selon les conditions employées. L'action d'une molécule d'hydrazine sur 1 mole de diester XII conduit, avec un rendement de 40%, au monohydrazide XIII. L'action de deux molécules d'hydrazine sur le diester conduit au dérivé cyclique XIV (40%) plus un dérivé pyrazolique, la dihydroxy-4,7 phényl-3 pyrazolo (4,5-*d*) pyridazine (XV) (40%). La formation de ce dernier est facilement explicable par hydrazinolyse du dérivé XIV (7). Ici aussi, la pyrolyse du monohydrazide XIII conduit au produit cyclique XIV. Il est à noter que nous n'avons pu obtenir un dihydrazide comme dans le cas des dérivés du phényl-1 triazole-1,2,3 (II).

Autre différence qu'il convient de noter, au cours de la réaction de l'hydrazine sur le diméthylmercaptan XX, nous avons obtenu la dihydrazino-4,7 pyrazolo (4,5-*d*) pyridazine (XXI), un autre exemple de l'hydrazinolyse du cycle isoxazole.

PARTIE EXPÉRIMENTALE

Les microanalyses ont été faites par le Dr. Claude Daesslé, 5757 Decelles, Montréal. Les points de fusion ne sont pas corrigés. Les spectres infrarouges sont mesurés avec un appareil Perkin–Elmer modèle 237 dans du Nujol.

Dicarboxyhydrazide-4,5 phényl-1 triazole-1,2,3 (II)

L'ester diméthylique du dicarboxy-4,5 phényl-1 triazole-1,2,3 (6) (50 g) est mis en suspension dans 200 ml de méthanol et on y ajoute, en agitant, 32 g d'hydrate d'hydrazine à 85%. La réaction est exothermique. On chauffe ensuite la masse pendant 40 min au bain-marie, puis filtre et obtient 46 g (90%) de produit, p.f. 160°.

Anal. Calc. pour $C_{10}H_{22}N_7O_2$: C, 45.96; H, 4.24; N, 37.53. Trouvé: C, 45.77; H, 3.83; N, 38.15.

Dihydroxy-4,7 phényl-1 triazolo (4,5-d) pyridazine (III)

(*a*) Le dihydrazide II (10 g) est chauffé pendant 6 h à 240°. On obtient ainsi 8.7 g de produit brut qui, recristallisé dans eau–dioxane plus charbon, donne 6.8 g (75%) de solide, p.f. 310–312°. Infrarouge: 1 720 et 1 650 cm^{-1}.

Le dihydrazide II (5 g) est chauffé à reflux pendant 4 h avec 10 ml d'hydrazine. On laisse refroidir et dilue avec 100 ml d'eau. On acidifie ensuite avec HCl. On obtient ainsi 3.6 g (80%) de solide, p.f. 310–312° (recristallisé dans eau–dioxane). Infrarouge: 1 720 et 1 650 cm^{-1}.

(*b*) Le dihydrazide II (3 g) est chauffé pendant 4 h avec 25 ml d'HCl 2 *N*. On obtient ainsi 2.4 g (88%) de solide, p.f. 306–308°. Infrarouge: 1 690 et 1 575 cm^{-1}. Ce dernier produit, recristallisé dans eau–dioxane, donne un point de fusion de 310–312°. Infrarouge: 1 720 et 1 650 cm^{-1}.

Anal. Calc. pour $C_{10}H_7N_5O_2$: C, 52.40; H, 3.08; N, 30.56. Trouvé: C, 52.48; H, 3.39; N, 30.77.

Dichloro-4,7 phényl-1 triazolo (4,5-d) pyridazine (IV)

La dihydroxy-4,7 phényl-1 triazolo (4,5-*d*) pyridazine (III) (5 g) est chauffée pendant 6 h à reflux dans 50 ml de $POCl_3$. Le tout se dissout. On chasse ensuite $POCl_3$ sous vide et verse le résidu sur de la glace pilée. On neutralise avec NH_4OH 28%, filtre et recristallise le solide dans l'éthanol. On obtient 2.7 g (50%), p.f. 168–170°.

Anal. Calc. pour $C_{10}H_5N_5Cl_2$: C, 45.13; H, 1.89; N, 26.32; Cl, 26.64. Trouvé: C, 45.26; H, 2.03; N, 26.04; Cl, 26.86.

Chloro-4(7) oxo-7(4) phényl-1 dihydro-4,5(6,7) triazolo (4,5-d) pyridazine (V)

En évaporant à sec les eaux-mères alcooliques de recristallisation du composé dichloré IV, on a pu isoler 0.5 g (9%) de V.

Anal. Calc. pour $C_{10}H_6N_5OCl$: C, 48.49; H, 2.44; N, 28.28; Cl, 14.31. Trouvé: C, 48.29; H, 2.71; N, 28.57; Cl, 14.16.

Diméthoxy-4,7 phényl-1 triazolo (4,5-d) pyridazine (VI)

Le composé IV (2.65 g) est traité par du méthoxide de sodium (0.5 g de sodium dissout dans 50 ml méthanol) dans la bombe Parr à 120° pendant 6 h. On obtient 2.15 g (68%) de solide après lavage à l'eau bouillante pour éliminer NaCl. Le produit, recristallisé dans eau–dioxane, fond à 195–197°.

Anal. Calc. pour $C_{12}H_{11}N_5O_2$: C, 56.02; H, 4.31; N, 27.22. Trouvé: C, 55.77; H, 4.12; N, 27.17.

Bis diméthylaminoéthoxy-4,7 phényl-1 triazolo (4,5-d) pyridazine (VII)

A une solution de 1.80 g de diméthylaminoéthanol, 0.5 g de sodium et 20 ml de xylène, on ajoute 2.65 g de composé dichloré IV. La réaction est exothermique. On reflue pendant 4 h, filtre à chaud le NaCl formé puis chasse le xylène sous vide. Il reste 2.4 g de résine. On chromatographie ces 2.4 g sur une colonne d'alumine et on obtient 1 g d'huile (30%) en éluant avec une solution benzene–éther. Cette huile peu à peu cristallise et fond à 58–61°.

Anal. Calc. pour $C_{18}H_{25}N_7O_2$: C, 58.20; H, 6.78; N, 26.39. Trouvé: C, 57.73; H, 6.50; N, 26.36.

Une tentative de préparer le chlorhydrate de ce dernier produit nous a amené à un rendement quantitatif de chlorhydrate de diméthylaminoéthoxy-7(4) oxo-4(7) phényl-1 dihydro-4,5(6,7) triazolo (4,5-*d*) pyridazine (VIII), fondant à 257–258° (recristallisé dans alcool).

Anal. Calc. pour $C_{14}H_{17}N_6O_2Cl$: C, 49.92; H, 5.09; N, 24.95; Cl, 10.52. Trouvé: C, 49.91; H, 5.19; N, 24.90; Cl, 10.32.

Dimercapto-4,7 phényl-1 triazolo (4,5-d) pyridazine (IX)

Le composé dichloré IV (5 g) est agité avec 4 g de NaSH et 40 ml d'éthanol absolu pendant 4 h à température ordinaire. La réaction est exothermique. On étend d'eau, puis acidifie par 4 ml d'HCl concentré. Il se forme un précipité que l'on filtre. On obtient 3.5 g (70%) de composé IX, p.f. 195–198° (recristallisé dans alcool).

Anal. Calc. pour $C_{10}H_7N_5S_2$: C, 45.96; H, 2.70; N, 26.80. Trouvé: C, 46.32; H, 2.99; N, 26.86.

Diméthylmercapto-4,7 phényl-1 triazolo (4,5-d) pyridazine (X)

Les 3.5 g précédents (IX) sont dissouts dans 50 ml de NaOH 15%. On ajoute 5 ml de CH_3I et agite pendant 2 h à température ordinaire. On chasse le CH_3I sous vide et extrait au chloroforme. On chasse ce dernier et cristallise le solide dans du méthanol. On obtient 2.6 g (70%), p.f. 167–168°.

Anal. Calc. pour $C_{12}H_{11}N_5S_2$: C, 49.80; H, 3.83; N, 24.20; S, 22.16. Trouvé: C, 50.07; H, 3.88; N, 24.22; S, 22.38.

Hydrazino-4(7) méthylmercapto-7(4) phényl-1 triazolo (4,5-d) pyridazine (XI)

Le dérivé précédent (X) (1 g) est dissout dans 40 ml d'isopropanol auquel on ajoute 3 ml d'hydrazine 95%. On chauffe pendant 14 h à reflux. Au refroidissement un précipité volumineux se forme. On filtre et on obtient 6 g (66%) de solide, p.f. 210–211° (recristallisé dans isopropanol).

Anal. Calc. pour $C_{11}H_{11}N_2S$: C, 48.30; H, 4.05; N, 35.87; S, 11.73. Trouvé: C, 48.41; H, 3.89; N, 36.07; S, 11.87.

Ester méthylique du dicarboxy-4,5 phényl-3 isoxazole (XII)

A une solution éthérée comprenant un mélange de 40 g d'ester méthylique du dicarboxy-1,2 acétyléne et de 40 g de chlorure de l'acide benzhydroxamique, on ajoute, après avoir refroidi à −5°, 40 g de triéthylamine goutte à goutte en agitant fortement. On filtre le chlorhydrate de triéthylamine et lave ce dernier à l'éther. On sèche le filtrat éthéré sur sulfate de sodium et chasse l'éther. On obtient 53 g (72%) d'une huile qui cristallise, p.f. 62–63°.

Anal. Calc. pour $C_{13}H_{11}NO_5$: C, 59.76; H, 4.24; N, 5.36. Trouvé: C, 59.64; H, 4.24; N, 5.31.

Carboxyhydrazide-4(5) carbométhoxy-5(4) phényl-3 isoxazole (XIII)

Le diester XII (5 g) dissout dans 30 ml d'alcool absolu est chauffé pendant 2 h à reflux avec une solution de 1.2 g d'hydrate d'hydrazine 85% dans 10 ml d'alcool. La solution évaporée à sec, donne 2 g (40%) d'une huile qui cristallise, p.f. 100–101°.

Anal. Calc. pour $C_{12}H_{11}N_3O_4$: C, 55.36; H, 4.74; N, 15.75. Trouvé: C, 55.16; H, 4.24; N, 16.08.

Dihydroxy-4,7 phényl-3 isoxazolo (4,5-d) pyridazine (XIV)

Le diester XII (5 g) dissout dans 30 ml d'alcool absolu est chauffé pendant 45 min avec 3.6 g d'hydrate d'hydrazine 85%. On concentre la solution à moitié, puis refroidit et filtre. On traite le solide par de l'acide chlorhydrique 2 *N* pendant 1 h au bain-marie. On filtre à froid le solide et on obtient 2.5 g (50%), p.f. 280° (recristallisé dans eau–dioxane).

Anal. Calc. pour $C_{11}H_7N_3O_3$: C, 57.63; H, 3.07; N, 18.34. Trouvé: C, 57.73; H, 3.04; N, 18.19.

Dihydroxy-4,7 phényl-3 pyrazolo (4,5-d) pyridazine (XV)

Le filtrat éthanolique obtenu au cours de la préparation précédente du composé XIV est évaporé à sec. On obtient 2 g (40%) de solide, p.f. >300° (recristallisé dans eau–dioxane).

Anal. Calc. pour $C_{11}H_8N_4O_2$: C, 57.89; H, 3.53; N, 24.55. Trouvé: C, 57.53; H, 3.70; N, 24.88.

Dichloro-4,7 phényl-3 isoxazolo (4,5-d) pyridazine (XVI)

On chauffe à reflux 10 g de dérivé XIV dans 100 ml $POCl_3$ pendant 5 h. Puis on chasse le $POCl_3$ sous vide et traite le résidu par de la glace pilée. On neutralise la suspension aqueuse par de l'ammoniaque 28%. On filtre et recristallise dans l'alcool absolu, et on obtient 5 g (45%), p.f. 158–160°.

Anal. Calc. pour $C_{11}H_5N_3OCl_2$: C, 49.65; H, 1.89; N, 15.78; Cl, 26.64. Trouvé: C, 49.58; H, 1.88; N, 16.11; Cl, 27.07.

Chloro-4(7) oxo-7(4) phényl-3 dihydro-6,7(4,5) isoxazolo (4,5-d) pyridazine (XVII)

Des eaux-mères alcooliques du produit précédent (XVI) on a obtenu 2 g (20%) d'un produit fondant à 235°.

Anal. Calc. pour $C_{11}H_6O_2N_3Cl$: C, 53.34; H, 2.44; N, 16.96; Cl, 14.31. Trouvé: C, 53.29; H, 3.02; N, 16.37; Cl, 14.81.

Diméthoxy-4,7 phényl-3 isoxazolo (4,5-d) pyridazine (XVIII)

On chauffe pendant 6 h à 120° dans la bombe Parr un mélange de 2.65 g de produit dichloré XVI et de 0.5 g de sodium dissout dans 50 ml de méthanol. On obtient, après filtration, 2.5 g (90%) de fines aiguilles, p.f. 114–115° (recristallisé dans eau–dioxane).

Anal. Calc. pour $C_{13}H_{11}O_3N_3$: C, 60.69; H, 4.31; N, 16.33. Trouvé: C, 61.14; H, 4.65; N, 16.12.

Bis diméthylaminoéthoxy-4,7 phényl-3 isoxazolo (4,5-d) pyridazine (XIX)

On dissout 1.5 g de sodium dans un mélange de 5.4 g de diméthylaminoéthanol et de 60 ml de xylène. On y ajoute 7.95 g de composé dichloré XVI et on chauffe le tout à reflux pendant 4 h. On filtre le chlorure de sodium et chasse le xylène sous vide. On obtient 7 g (70%) d'huile qui se solidifie peu à peu, p.f. 52–56°. On a identifié ce produit par son dipicrate, p.f. 157–160° (recristallisé dans eau–dioxane).

Anal. Calc. pour $C_{31}H_{31}N_{11}O_{17}$: C, 44.86; H, 3.78; N, 18,57. Trouvé: C, 44.70; H, 3.89; N, 18.52.

Diméthylmercapto-4,7 phényl-3 isoxazolo (4,5-d) pyridazine (XX)

On agite à température ordinaire pendant 4 h un mélange de 5 g de produit dichloré XVI, 4 g de sulfhydrate de sodium et 40 ml d'alcool absolu. La réaction est exothermique. On dissout le tout dans une solution d'hydroxyde de sodium 10%, filtre et acidifie la solution. Il se forme un précipité que l'on filtre, dissout dans de l'hydroxyde de sodium 15% et agite pendant 2 h avec 5 ml d'iodure de méthyle. On chasse l'iodure de méthyle sous vide et extrait au chloroforme. On chasse le solvant et recristallise le solide obtenu dans du méthanol. On obtient ainsi 4.4 g (85%), p.f. 134–136°.

Anal. Calc. pour $C_{13}H_{11}N_3OS_2$: C, 53.95; H, 3.83; N, 14.52. Trouvé: C, 53.69; H, 4.14; N, 14.34.

Dihydrazino-4,7 phényl-3 pyrazolo (4,5-d) pyridazine (XXI)

La diméthylmercapto-4,7 phényl-3 isoxazolo (4,5-*d*) pyridazine (1 g) est chauffée à reflux pendant 12 h avec 6 ml d'hydrazine (95%) et 15 ml d'isopropanol. Le tout se dissout, puis reprécipite peu à peu. On obtient ainsi 0.6 g (70%), p.f. 265°.

Anal. Calc. pour $C_{11}H_{12}N_8$: C, 51.55; H, 4.71; N, 43.72. Trouvé: C, 51.33; H, 4.98; N, 43.02.

SYNTHESIS OF QUINAZOLONE HYDRAZIDES AS MONOAMINE OXIDASE INHIBITORS[1]

SURENDRA S. PARMAR AND R. C. ARORA

The specific inhibition of monoamine oxidase by the hydrazine derivative iproniazid, 1-isonicotinic acid-2-isopropyl hydrazine, was reported by Zeller *et al.* (1). Monoamine oxidase, an enzyme responsible for oxidative deamination of biologically active amines, is considered to play a role in the activity of the central nervous system, and the inhibitors of this enzyme have been shown to possess pronounced anticonvulsant properties (2). Furthermore, when 2,3-disubstituted quinazolones were investigated (3), 2-methyl-3-*o*-tolyl-4-quinazolone was found to be a potent anticonvulsant, and was superior to sodium phenobarbitone when used against pentylenetetrazole-induced seizures (4). In a continuation of our work on the synthesis of 2,3-disubstituted quinazolones (5), we have synthesized some hydrazides having a quinazolone moiety, with a view to obtaining compounds affecting the activity of the central nervous system. The present study describes the synthesis and the inhibition of the rat liver mitochondrial monoamine oxidase by such hydrazide derivatives. Structure–activity relationships have been examined briefly.

The quinazolone hydrazides have been synthesized according to the following scheme (X = H, Cl, Br, I, or NO_2).

EXPERIMENTAL[2]

Synthesis of Anthranilic Acids (I)

The various substituted anthranilic acids (I) were synthesized according to the methods reported earlier in the literature. The anthranilic acids used were 5-chloroanthranilic acid (6), 5-bromoanthranilic acid (7), 5-iodoanthranilic acid (8), and 5-nitroanthranilic acid (9); their melting points were found to be identical with those reported earlier.

A summary of this work was presented at the 23rd International Congress of Physiological Sciences, Tokyo, Japan, September 1965.*

[2]*Melting points were determined in a capillary tube and are corrected.*

Synthesis of Acetanthranils (II)

The acetanthranils (II) were synthesized by refluxing 1 mole of the appropriate anthranilic acid with 2 moles of acetic anhydride for 1 h. After the excess of acetic anhydride was distilled off, the acetanthranils, which separated out as a solid mass, were used without further purification. These acetanthranils have been reported earlier, except for that prepared from 5-nitroanthranilic acid (6-nitroacetanthranil, m.p. 217–219 °C, yield 40%).

Anal. Calcd. for $C_9H_6N_2O_4$: C, 52.42; H, 2.9; N, 13.59. Found: C, 52.0; H, 2.4; N, 13.9.

Synthesis of Quinazolones (III)

The quinazolones (III) were synthesized by heating equimolar proportions of the substituted acetanthranils and *p*-aminoethyl benzoate (benzocaine) as reported earlier (10). The quinazolones shown in Table I were characterized by their melting points and empirical compositions.

TABLE I

Substituted quinazolones (III)

X	Melting point (°C)	Yield (%)	Formula	Nitrogen (%) Calculated	Nitrogen (%) Found
H	174–175	60	$C_{18}H_{16}N_2O_3$	9.09	8.8
Cl	186–187	55	$C_{18}H_{15}ClN_2O_3$	8.1	8.6
Br	170	58	$C_{18}H_{15}BrN_2O_3$	7.25	7.18
I	196–197	58	$C_{18}H_{15}IN_2O_3$	6.45	6.9
NO_2	222	50	$C_{18}H_{15}N_3O_5$	11.19	11.15

Synthesis of Quinazolone Hydrazides (IV)

Quinazolone hydrazides (IV) were synthesized as described earlier (11) by refluxing 1 mole of quinazolone with 2 moles of hydrazine hydrate (99–100%) in absolute ethanol for 6 to 8 h. When the excess of alcohol was distilled off, the quinazolone hydrazides separated out as solid masses. These hydrazides were recrystallized from ethanol. The physical constants are given in Table II.

Determination of Monoamine Oxidase Activity

The monoamine oxidase activity of rat liver mitochondria was determined by the conventional Warburg manometric method (12) as described earlier (13). Mitochondria were isolated by differential centrifugation of rat liver homogenate in ice-cold 0.25 *M* sucrose (10% w/v) by the method (14) of Hogeboom *et al.* (15). The enzyme was assayed by measuring the oxygen consumption after the addition of tyramine.

TABLE II

Quinazolone hydrazides (IV) and their monoamine oxidase inhibition

X	Melting point (°C)	Yield (%)	Formula	Nitrogen (%) Calculated	Nitrogen (%) Found	% inhibition
H	114–116	60	$C_{16}H_{14}N_4O_2$	19.04	18.8	9.5 9.5 (11.33) 15.0
Cl	167–170	55	$C_{16}H_{13}ClN_4O_2$	17.04	17.27	59.3 61.5 (60.27) 60.0
Br	155–157	58	$C_{16}H_{13}BrN_4O_2$	15.37	15.7	52.5 52.8 (52.6) 52.5
I	179	50	$C_{16}H_{13}IN_4O_2$	13.4	13.54	73.7 76.3 (75.03) 75.1
NO_2	204–206	45	$C_{16}H_{13}N_5O_4$	20.6	20.1	52.0 48.0 (50.66) 52.0

NOTE: The percentage inhibition was calculated from the decrease in the oxygen uptake during 1 h. Washed rat liver mitochondria equivalent to 250 mg of fresh tissue were used in each Warburg vessel in a total volume of 3 ml containing 66 m*M* phosphate buffer (pH 7.4) and 10 m*M* tyramine (substrate). The inhibitors present in the side arm at a final concentration of 1×10^{-4} *M* were incubated with the enzyme preparation for 10 min before tyramine was added. The enzyme system was further incubated at 37 °C for 1 h in an atmosphere of oxygen. The figures in parentheses are averages.

RESULTS AND DISCUSSION

Oxygen uptake has been shown to reflect the true monoamine oxidase activity in washed mitochondrial preparations during oxidation of tyramine (16). The use of cyanide and semicarbazide, as suggested earlier (12), was therefore not necessary in the present investigation. The relative percentage of enzyme inhibition by the new hydrazides was estimated (see Table II) at a fixed concentration of 10^{-4} M of inhibitors.

It was found that a substituent at position 6 of the quinazolone ring markedly enhanced inhibition, a maximum effect being obtained with iodine as a substituent. However, 6-iodo-substituted quinazolone hydrazide, the most potent compound in the present series, was found to be a rather weak inhibitor as compared with other classical inhibitors. The relative electronegativity of the 6-substituents does not appear to be the factor affecting the inhibitory power of the various analogues. The parameter(s) controlling the structure–activity relationship is (are) not discernible. The active surface of the enzyme and the uptake sites of the mitochondria appear to require structural features other than the basic hydrazine moiety for optimum binding. It has already been shown that the presence of an iodine substituent on the ring of benzylamine substrates markedly enhances their affinity for the enzyme (17). Further studies on the determination of the nature of the inhibition produced by these compounds and the synthesis of other related structures carrying different substituents[3] may contribute to a better understanding of the chemical requirements of the active sites of the enzyme.

ACKNOWLEDGMENTS

α-NEROL AND α-GERANIOL

BERNARD M. MITZNER, VITO J. MANCINI, AND SEYMOUR LEMBERG

Neither α-nerol nor α-geraniol has been reported as occurring in nature. The two isomeric materials have not previously been prepared in a pure form synthetically, and their spectra have not been characterized.[1] In this note we report the preparation of pure α-nerol (I) (*cis*-2,6-dimethyl-1,6-octadiene-8-ol) and pure α-geraniol (II) (*trans*-2,6-dimethyl-1,6-octadiene-8-ol). (Their purity was ascertained by gas chromatography, with a nonpolar and a polar column.)

α-Myrcene (III) was hydrochlorinated to give α-neryl chloride (IV) and α-geranyl chloride (V) which, when treated with sodium acetate, gave the α-acetates VI and VII; hydrolysis with potassium hydroxide gave the alcohols I and II.

Proof of Structure

The infrared spectra of α-nerol and α-geraniol are shown in Fig. 1. The isopropenyl moiety is clearly visible at 11.25 μ (CH_2 out-of-plane deformation) and at 6.05 μ (C—C stretching). The allylic hydroxyl exhibits very strong absorption at 10 μ (C—O stretching); the trisubstituted double bond allylic to the hydroxyl exhibits very strong absorption at 5.95 μ (C—C stretching). The nuclear magnetic resonance spectra of the two isomeric alcohols are shown in Fig. 2. The terminal groups have a τ value of 5.33 (α-nerol) and 5.37 (α-geraniol). The significant allylic methylene groups have a τ value of about 8.31. The pertinent assignments are illustrated in Fig. 2.

A small sample of pure α-nerol was subjected to hydrogenation with 10% palladium on carbon at atmospheric pressure. The isopropenyl double bond was completely hydrogenated and dihydro-nerol (*cis*-2,6-dimethyl-6-octen-8-ol) was obtained. The same process was carried out with pure α-geraniol to give dihydro-geraniol (*trans*-2,6-dimethyl-6-octen-8-ol). The structures of the last two compounds are well characterized in the literature (3–5). When a mixture of nerol and geraniol along with their alpha isomers was subjected to gas chromatography on a Carbowax column, the order of elution was nerol, α-nerol, geraniol, and α-geraniol. It should be noted that, in systems where *cis* and *trans* double bonds are in position 6 (in the C-10 terpene series), the *cis* isomer is always eluted first. The molecular weight of the two alcohols is 154 ($C_{10}H_{18}O$). The cracking pattern of the molecular weight determination was carried out with a C.E.C. model 103 mass spectrometer. The pattern of α-nerol closely resembled that of nerol; those of the two geraniols were likewise similar.

[1]*The existence of α-nerol and (or) α-geraniol is suggested, or their presence in a mixture is postulated, in the papers listed in ref. 1.*

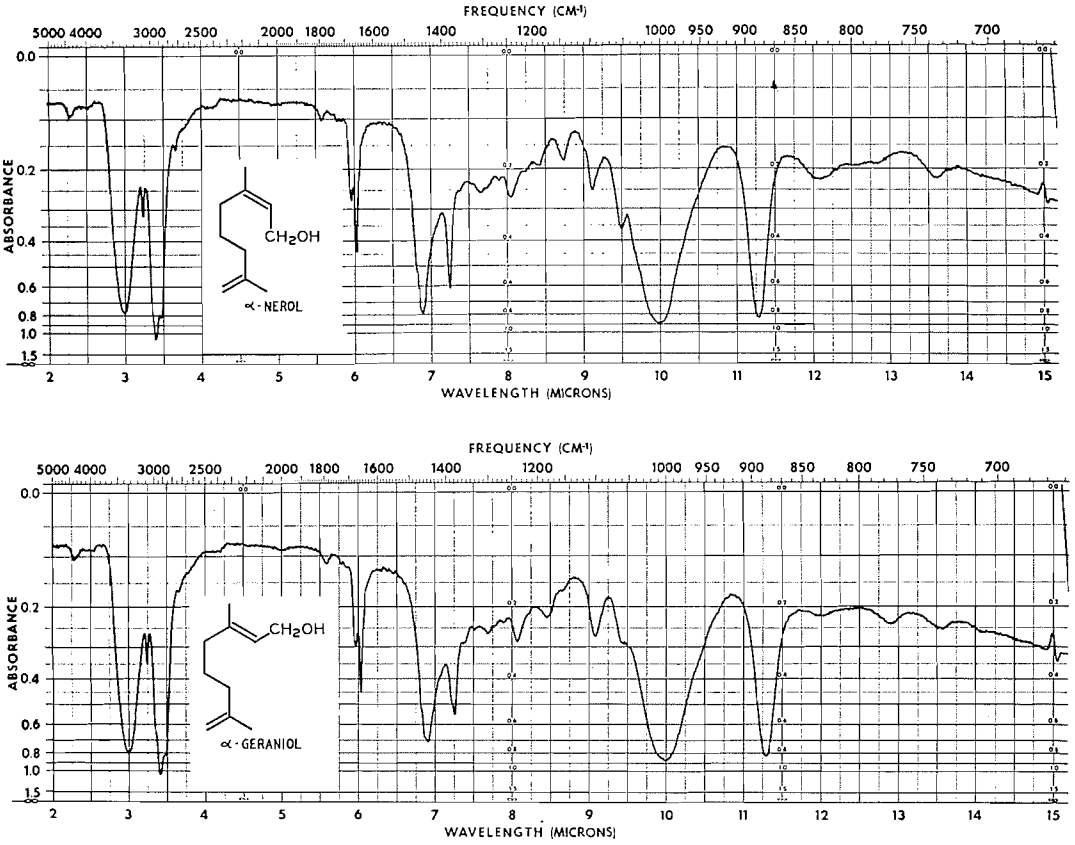

FIG. 1.

EXPERIMENTAL

α-Myrcene (50 g, 0.37 mole), prepared via the pyrolysis of myrcenyl acetate (2), was hydrochlorinated at ambient temperature and pressure with 2 mole % copper bronze as catalyst. Anhydrous hydrogen chloride (0.33 *M*) was added, and the resultant hydrochloride was washed with water until neutral, dried with magnesium sulfate, and reacted with 1 mole of sodium acetate and 0.5 mole of acetic anhydride at 75 °C for 6 h to yield 45 g of the ester mixture; this was washed with water until neutral. An aliquot of the mixture (35 g) was hydrolyzed by refluxing it in 20% ethanolic KOH; the resulting alcohols were washed until neutral. Approximately 20 g of a mixture consisting of α-nerol and α-geraniol was obtained. Preparative gas chromatography led to the isolation of pure α-nerol and pure α-geraniol. The following gas–liquid chromatographic parameters were employed: a 10 ft ($\frac{3}{8}$ inch outside diameter) × $\frac{5}{16}$ inch inside diameter copper column filled with 20% Carbowax 20M adsorbed on silane-treated Celite of 60–80 mesh, maintained at a temperature of 150 °C with a flow rate of 250 ml of helium/min; repeated injections of 0.1 ml of the alcohol mixture were employed.

DISCUSSION

There has been a great deal of controversy regarding the actual structure of nerol and geraniol for many years. Many workers, especially in the past, have ascribed the previously described alpha structure to nerol and geraniol. This present work has served to synthesize, isolate, and characterize the alpha compounds, thus aiding in definitively establishing the structure of nerol and geraniol as having an isopropylidene group.

Experimental work carried out in our laboratories over the last 7 years on the examination of various natural oils containing geraniol has failed to reveal a compound having the alpha structure reported in this paper.

to ethyl α-(*o*-nitrophenylthio)acetoacetate (I*a*). When, however, 4-chloro-2-nitrobenzenesulfenyl chloride was reacted with diethyl malonate, the expected product, diethyl α-(4-chloro-2-nitrophenylthio)malonate, was not produced (3). The major product in this case was bis(4-chloro-2-nitrophenyl) disulfide. *o*-Nitrobenzenesulfenyl chloride also reacts atypically with diethyl malonate, with malonic acid, and with ethylmalonic acid. The products identified by us were bis(*o*-nitrophenyl) disulfide and the *S*-*o*-nitrophenyl ester of *o*-nitrothiobenzenesulfonic acid; α-(*o*-nitrophenylthio)butyric acid was an additional product in the reaction with ethylmalonic acid which yielded none of the desired compound (I*e*).

IV

In contrast with these results, when malonamide was reacted at room temperature with *o*-nitrobenzenesulfenyl chloride in acetonitrile, an almost quantitative yield of α-(*o*-nitrophenylthio)malonamide (I*c*) was obtained. As expected, this compound is a weak acid and is insoluble in sodium bicarbonate solution but readily soluble in aqueous sodium hydroxide, giving an orange solution from which I*c* is reprecipitated when acid is added. When the aqueous sodium hydroxide solution was heated, ammonia was rapidly evolved, but no α-(*o*-nitrophenylthio)malonic acid (I*b*) was isolable. An obvious extension of the above successful condensation was the interaction of *o*-nitrobenzenesulfenyl chloride with barbituric acid. This reaction occurred readily, and 5-(*o*-nitrophenylthio)barbituric acid (I*d*) was isolated in excellent yield. It is a relatively strong acid which dissolves in sodium bicarbonate solution. Also, it is stable in hot concentrated sulfuric acid. After such a solution was heated at 80–100° for 6 h, the addition of water precipitated the unchanged acid, almost quantitatively.

Our attention was then directed towards the preparation of 4-(*o*-nitrophenylthio)-2-pyrazolin-5-ones (II), which were required for our reductive cyclization studies (4). The initial method chosen to prepare the 4-(*o*-nitrophenylthio)-2-pyrazolin-5-ones was by the interaction of hydrazine or phenylhydrazine with ethyl α-(*o*-nitrophenylthio)acetoacetate or ethyl α-(*o*-nitrophenylthio)benzoylacetate. The action of phenylhydrazine on ethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

α-(*o*-nitrophenylthio)acetoacetate gave the expected product (II*b*) in poor yield; however, when ethyl α-(*o*-nitrophenylthio)acetoacetate was treated with hydrazine hydrate, hydrolysis occurred and the only product isolated was the hydrazide of (*o*-nitrophenylthio)acetic acid. The action of phenylhydrazine on ethyl α-(*o*-nitrophenylthio)benzoylacetate was more complex; once again, the expected product (II*c*) was not obtained.

Instead, two red products were isolated in poor yields. The first contained sulfur and melted at 158°; the second product, m.p. 173°, was sulfur-free. Because neither product was the desired one, these compounds were not identified at this time. In view of these results, this synthetic approach was abandoned.

The fact that *o*-nitrobenzenesulfenyl chloride readily reacts with malonamide suggested that it might also condense with the active methylene group of the structurally related 2-pyrazolin-5-ones (III). Thus, *o*-nitrobenzenesulfenyl chloride was reacted in acetonitrile with 3-methyl-2-pyrazolin-5-one, with 3-methyl-1-phenyl-2-pyrazolin-5-one, and with 1,3-diphenyl-2-pyrazolin-5-one; in each case the reaction proceeded as expected, yielding the corresponding 4-(*o*-nitrophenylthio) derivatives (II*a*, II*b*, and II*c*, respectively).

The infrared spectra of the pyrazolones (II*a*–II*c*) in potassium bromide were of interest. They showed no carbonyl absorption, whereas absorption attributable to the hydroxyl group was present, which indicated that, in the solid state, the pyrazolones are better represented in the tautomeric form (IV). This conclusion is in agreement with the findings of Katritzky and Maine (5), who have studied in detail the tautomerism of pyrazolin-5-ones.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra (KBr disks) were recorded on a Unicam SP 200 spectrophotometer. Palladium–charcoal refers to 10% palladium on charcoal.

Ethyl 2-(*o*-nitrophenylthio)acetoacetate (1) and *o*-nitrobenzenesulfenyl chloride (6), which was obtained by the action of chlorine on bis(*o*-nitrophenyl) disulfide (7), were prepared by previously reported methods.

Reaction of o-Nitrobenzenesulfenyl Chloride with Ethylmalonic Acid

A solution of *o*-nitrobenzenesulfenyl chloride (3.0 g) and ethylmalonic acid (2.5 g) in acetonitrile (60 ml) was heated under reflux for 6 h; then the solution was concentrated to ca. 30 ml, from which, when it was allowed to stand, bis(*o*-nitrophenyl) disulfide (0.72 g), m.p. 195–200° (decomp.), precipitated and was filtered off. A yellow solid (0.82 g), m.p. 125–130°, slowly precipitated from the mother liquors over a period of 48 h. Crystallization of this solid from methanol gave the *S*-*o*-nitrophenyl ester of *o*-nitrothiobenzenesulfonic acid (0.54 g), m.p. 140–142° (lit. (8) m.p. 142–143°), the infrared spectrum of which was superimposable on that of an authentic sample. The mother liquors remaining were evaporated to dryness, and the resulting waxy solid was treated with 5% aqueous sodium hydroxide (50 ml). The solution was filtered and the filtrate, on acidification, gave α-(*o*-nitrophenylthio)butyric acid (0.39 g), m.p. 105–108°, as a yellow solid, the melting point of which was raised to 112–114° on crystallization from aqueous ethanol. Infrared spectrum: broad absorption from 2 100 to 3 400 with maxima at 2 970 (m) and 2 910 (m) (OH); 1 702 (s) (C=O); 1 520 (s), 1 338 (s), and 868 (m) (NO_2) cm^{-1}.

Anal. Calcd. for $C_{10}H_{11}NO_4S$: C, 49.78; H, 4.59; S, 13.29. Found: C, 49.75; H, 4.40; S, 12.66.

(o-Nitrophenylthio)malonamide (Ic)

Malonamide (1.0 g) was added to a solution of *o*-nitrobenzenesulfenyl chloride (1.9 g) in acetonitrile (60 ml), and the resulting suspension was stirred at room temperature for 24 h. The yellow solid which formed (2.48 g), m.p. 222–225° (decomp.), dissolved completely in aqueous sodium hydroxide or sodium carbonate to give an orange solution. The title compound was reprecipitated when hydrochloric acid was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

added. Infrared spectrum: broad absorption from 2 900 to 3 500 (s) with maxima at 3 400, 3 280, and 3 200 (amide NH_2); 1 665 (s) (C=O); 1 515 (s), 1 345 (s), and 865 (w) (NO_2) cm^{-1}.

Anal. Calcd. for $C_9H_9N_3O_4S$: C, 42.35; H, 3.55; N, 16.47; S, 12.56. Found: C, 42.16; H, 3.58; N, 16.08; S, 12.41.

Hydrolysis of (o-Nitrophenylthio)malonamide

The title compound (8 g) was dissolved in 10% aqueous sodium hydroxide (200 ml), and this solution was gently boiled until the evolution of ammonia ceased (90 min). The solution was cooled, acidified with hydrochloric acid, and extracted with ether. The dried ether solution, on evaporation, gave a brown oil (1.2 g) which was only partially soluble in sodium bicarbonate solution and was therefore not further investigated.

5-(o-Nitrophenylthio)barbituric Acid (Id)

Barbituric acid (2.56 g) was added to a solution of *o*-nitrobenzenesulfenyl chloride (3.8 g) in acetonitrile (100 ml), and the resulting suspension was stirred at room temperature for 30 h. The yellow solid (5.23 g), m.p. 243° (decomp.), was removed. This was the title compound. Crystallization from acetonitrile did not raise the melting point. Infrared spectrum: broad absorption from 2 100 to 3 350 (m) with maxima at 2 600, 2 680, 3 120, and 3 280 (cyclic ureide); 1 728 (s) (C=O); 1 525 (s), 1 375 or 1 345 (s), and 865 (w) (NO_2) cm^{-1}.

Anal. Calcd. for $C_{10}H_7N_3O_5S$: C, 42.70; H, 2.51; N, 14.95; S, 11.40. Found: C, 42.47; H, 2.58; N, 14.54; S, 11.06.

Crystallization from water gave the monohydrate as a yellow solid, m.p. 244–246° (decomp.).

Anal. Calcd. for $C_{10}H_7N_3O_5S \cdot H_2O$: C, 40.13; H, 3.03. Found: C, 40.38, 40.21; H, 3.14, 3.12.

The acid (I*d*) was soluble, with vigorous effervescence, in aqueous sodium bicarbonate, giving an orange solution, from which the acid was reprecipitated when hydrochloric acid was added. A suspension of the acid (I*d*) (2.2 g) in 80% sulfuric acid (250 ml) was heated on a boiling water bath for 6 h, during which time the acid dissolved completely. The orange solution was poured into water (500 ml); the resulting yellow crystalline precipitate (1.7 g) melted at 248° (decomp.). An infrared spectrum confirmed that I*d* had been recovered.

3-Methyl-4-(o-nitrophenylthio)-1-phenyl-2-pyrazolin-5-one (IIb)

Method a

When a solution of *o*-nitrobenzenesulfenyl chloride (3.0 g) in acetonitrile (20 ml) was added to a suspension of 3-methyl-1-phenyl-2-pyrazolin-5-one (3.0 g) in acetonitrile (20 ml), the latter dissolved and a yellow precipitate formed almost immediately. The mixture was heated under reflux for 4 h (during which time hydrochloric acid was evolved), cooled, and filtered to give the title compound (4.6 g) as a bright-yellow solid, m.p. 209–211° (decomp.) when crystallized from aqueous ethanol (lit. (9) m.p. 207°). Infrared spectrum: broad absorption from 2 000 to 3 200 with a broad maximum centered at 2 600 (m) (OH); 1 520 (s), 1 340 (s), and 855 (w) (NO_2) cm^{-1}; carbonyl absorption absent.

Anal. Calcd. for $C_{16}H_{13}N_3O_3S$: C, 58.70; H, 4.00; N, 12.84; S, 9.80. Found: C, 58.68; H, 4.20; N, 12.10; S, 10.21.

Method b

A solution of phenylhydrazine (2.1 g) and ethyl 2-(*o*-nitrophenylthio)acetoacetate (3.0 g) in acetonitrile (30 ml) was heated under reflux for 5 h. When the red solution was allowed to cool and stand, the title compound (1.35 g) precipitated out, m.p. 200–202°, raised to 208–210° (decomp.) when crystallized from ethanol. The infrared spectrum was identical with that of the product obtained by method *a*.

3-Methyl-4-(o-nitrophenylthio)-2-pyrazolin-5-one (IIa)

Method a

This pyrazolone was obtained by the method used in the preparation of II*b* (method *a*). The bright-yellow solid (91% yield) was dissolved in 10% sodium hydroxide solution, this solution was extracted with ether, and the ether extract was rejected. The aqueous layer was acidified with hydrochloric acid; the resulting yellow solid had m.p. 273–274° (decomp.) when crystallized from ethanol. Infrared spectrum: 3 390 (m) (NH); broad absorption from 3 300 to 2 000 with a maximum at 2 600 (w) (OH); 1 525 (s), 1 345 (s), and 855 (w) (NO_2) cm^{-1}; carbonyl absorption absent.

Anal. Calcd. for $C_{10}H_9N_3O_3S$: C, 47.81; H, 3.61; N, 16.72; S, 12.76. Found: C, 47.40; H, 3.60; N, 16.89; S, 13.09.

Method b

Hydrazine hydrate (2.1 g) was added to a solution of ethyl (*o*-nitrophenylthio)acetoacetate (4.0 g) in acetonitrile (25 ml), and the resulting deep-red solution was stirred for 2 h. The crystalline yellow precipitate (2.7 g), m.p. 163–165°, which formed was the hydrazine of (*o*-nitrophenylthio)acetic acid (lit. (10) m.p. 164°). The infrared spectrum was identical with that of an authentic sample.

Anal. Calcd. for $C_8H_9N_3O_3S$: C, 42.28; H, 3.99; N, 18.50. Found: C, 42.59; H, 3.76; N, 18.25.

For personal use only.

4-(o-Nitrophenylthio)-1,3-diphenyl-2-pyrazolin-5-one (IIc)

Using essentially the conditions described for the preparation of II*b* (method *a*), we obtained the title compound (8.9 g), initially as a brown oil which quickly solidified, from *o*-nitrobenzenesulfenyl chloride (4.6 g) and 1,3-diphenyl-2-pyrazolin-5-one (5.8 g). Crystallization from anhydrous benzene gave a yellow solid, m.p. 182–183° (decomp.) after preliminary softening around 110°. Infrared spectrum: broad absorption from 2 100 to 3 200 with maxima at 3 080 (w) and 2 260 (w) (OH); 1 525 (s), 1 340 (m), and 860 (w) (NO_2) cm^{-1}; carbonyl absorption absent.

Anal. Calcd. for $C_{21}H_{15}N_3O_3S$: C, 64.76; H, 3.88; N, 10.79; S, 8.23. Found: C, 64.46; H, 3.84; N, 10.64; S, 8.27.

ON THE FORMATION OF A PEROXY PHTHALAZINE COMPOUND BY THE AUTOXIDATION OF 1-METHYL-1,2-DIHYDROPHTHALAZINE

Arthur Hirsch and Demetrius G. Orphanos

It was recently shown (1) that autoxidation of 1-methyl-1,2-dihydrophthalazine (I), prepared by the reaction of phthalazine with methyllithium, yields a mixture of 1-methylphthalazine (III) and an organic peroxide. The isolation of III has been successful. However, the peroxy compound, although it was the main reaction product, could not be obtained in a pure state. Formation of an organic peroxide in the phthalazine series, as far as we are aware, has not been reported previously.

However, it has now been possible, by applying the chromatographic technique of Milas *et al.* (2), to isolate such a substance and to determine its structure.

The elemental analysis, molecular weight and active oxygen determinations, and infrared and nuclear magnetic resonance spectra of this compound were compatible with a structure such as II. Additional support for II was obtained by the fact that the organic peroxide, on reduction with Na_2SO_3, was quantitatively converted into the known 1-methylphthalazine (III) (1). The conversion of II into III could proceed by a mechanism involving the unstable intermediate IV (Reaction Scheme 1).

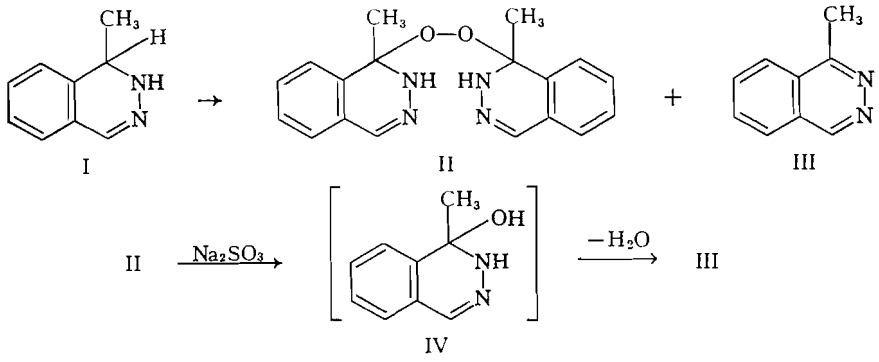
ON THE FORMATION OF A PEROXY PHTHALAZINE COMPOUND BY THE AUTOXIDATION OF 1-METHYL-1,2-DIHYDROPHTHALAZINE



Arthur Hirsch and Demetrius G. Orphanos

It was recently shown (1) that autoxidation of 1-methyl-1,2-dihydrophthalazine (I), prepared by the reaction of phthalazine with methyllithium, yields a mixture of 1-methylphthalazine (III) and an organic peroxide. The isolation of III has been successful. However, the peroxy compound, although it was the main reaction product, could not be obtained in a pure state. Formation of an organic peroxide in the phthalazine series, as far as we are aware, has not been reported previously.

However, it has now been possible, by applying the chromatographic technique of Milas *et al.* (2), to isolate such a substance and to determine its structure.

The elemental analysis, molecular weight and active oxygen determinations, and infrared and nuclear magnetic resonance spectra of this compound were compatible with a structure such as II. Additional support for II was obtained by the fact that the organic peroxide, on reduction with Na_2SO_3, was quantitatively converted into the known 1-methylphthalazine (III) (1). The conversion of II into III could proceed by a mechanism involving the unstable intermediate IV (Reaction Scheme 1).

REACTION SCHEME 1.

EXPERIMENTAL[1]

Preparation of Peroxide II

A solution of phthalazine (2 g) (3) in dry diethyl ether (150 ml) was cooled to 0°. Into it, under a blanket of nitrogen and with vigorous stirring, 12 ml of 6% methyllithium solution[2] was added dropwise during 15 min. Stirring was continued for an additional 15 min. The light orange colored reaction solution was poured onto crushed ice and stirred for a few minutes. The organic layer was separated, washed once with 15 ml of water, and dried over K_2CO_3. The ether was removed under reduced pressure and the oily residue subjected to a high vacuum for half an hour. The yellow oil thus obtained, being crude 1-methyl-1,2-dihydrophthalazine (I) (1), was dissolved in diethyl ether (50 ml) and stirred for 8 h at about 10°. The separated white solid was collected and dried. It melted at 96–98° and weighed 1.2 g. This crude peroxidic product was chromatographed on a column maintained at 0° and packed with cellulose powder impregnated with dimethylformamide. The peroxide was eluted with diethyl ether. In this manner a pure organic peroxide melting at 100–101° and weighing 0.98 g was obtained. When the column was washed out with methanol, a small amount of impure 1-methylphthalazine (III) was isolated.

Anal. Calcd. for $C_{18}H_{18}N_4O_2$: C, 67.06; H, 5.63; N, 17.38; active oxygen, 4.96; mol. wt. 322.37. Found: C, 67.23; H, 5.66; N, 17.54; active oxygen, 4.94; mol. wt. 328.

The active oxygen was determined iodometrically with potassium iodide in glacial acetic acid. The infrared spectrum showed a strong absorption at 3 125 cm^{-1} caused by NH, and a weak band at 828 cm^{-1} which may be attributed to the peroxy group. The integrated nuclear magnetic resonance spectrum, in deuteriochloroform with tetramethylsilane = 0 p.p.m., showed a multiplet centered at 7.96 (8H) p.p.m., and singlets at 9.43 (2H), 9.16 (2H), and 3.03 (6H) p.p.m. The spectrum, after addition of deuterium oxide, showed no signal at 9.16 p.p.m.

1-Methylphthalazine (III) from Peroxide II

A mixture of 1 g of peroxide II and 25 ml of a saturated solution of Na_2SO_3, maintained at 0° under a blanket of nitrogen, was stirred for 4 h. The resulting solution was extracted with diethyl ether (25 ml) to remove some yellow impurities, and then extracted with methylene chloride (100 ml). The latter extract was washed with water and dried over K_2CO_3. Removal of the solvent under reduced pressure, followed by a high vacuum, led to a yellowish oily material which, when scratched with a spatula, rapidly solidified. It melted at 68–70° and weighed 0.8 g. This slightly impure material was dissolved in methanol and passed through a short silica gel column packed on the top with a small amount of charcoal. The colorless solution, after removal of the methanol, gave pure 1-methylphthalazine, m.p. 71–72°, which had an infrared spectrum identical with that of an authentic sample (1).

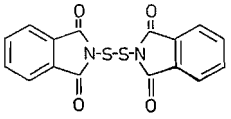
REACTIONS OF PHTHALIMIDE AND POTASSIUM PHTHALIMIDE WITH SULFUR MONOCHLORIDE



MALDA V. KALNINS

The reaction of amines and amides with sulfur monochloride (S_2Cl_2) in a variety of nonpolar solvents and in absolute ethanol has been reported to yield mixtures of *N,N'*-dithio and *N,N'*-polythio compounds (1–11). In a few instances, substances identified as *N,N'*-monothio derivatives of amines and amides have been isolated (2, 3, 12, 13). The unreactivity of imides, such as phthalimide, toward sulfur monochloride has been attributed to the decreased basicity of the nitrogen atom (2). However, potassium phthalimide has been reported to react with sulfur monochloride in light petroleum to give a compound which melted at 190° and decomposed when allowed to stand. On the basis of nitrogen and sulfur analyses, Naik assigned structure I to this product (2).

In our hands, reinvestigation of the reaction between potassium phthalimide and sulfur monochloride in petroleum ether did not provide a product, m.p. 190°, which Naik (2) described as *N,N'*-thiobisphthalimide (I). Instead, a higher melting compound (m.p. 228–230°) was formed, the elemental analyses of which suggested the empirical formula $C_{16}H_8N_2S_2O_4$. The infrared and nuclear magnetic resonance spectra[1] of the product (m.p. 228–230°) were consistent with structure II. Therefore, the compound reported by Naik (2) is not I but probably a mixture of II and phthalimide.

I

II

In addition, we have found that phthalimide itself reacts very readily with sulfur monochloride in *N,N*-dimethylformamide (DMF) at room temperature to give a colorless crystalline solid, m.p. 315–317°. The elemental analysis, molecular weight determination, infrared absorption spectrum, and nuclear magnetic resonance spectrum[1] of the compound were consistent with structure I. The structural assignment was supported by the fact that desulfurization of the reaction product with Raney nickel under anhydrous conditions provided phthalimide. The synthesis of I from potassium phthalimide and sulfur dichloride (SCl_2) in petroleum ether afforded additional support for the assigned structure. Compound I was also obtained from the reaction of sulfur monochloride and potassium phthalimide in DMF.

The reactions of phthalimide and its potassium salt with sulfur monochloride were explored in a variety of solvents. The results showed that sulfur monochloride converted phthalimide or its potassium salt into I only in DMF. Treatment of phthalimide with sulfur monochloride in as similar a solvent as *N,N*-dimethylacetamide, as well as in more basic solvents such as pyridine or trimethylamine, gave only II. The reaction of sulfur monochloride with potassium phthalimide in acetone or nitrobenzene also provided II. In view of these experimental observations, it appears that I is probably formed by the reaction of phthalimide with an adduct of sulfur monochloride and DMF.[2] It

[1]*The nuclear magnetic resonance spectrum was obtained in deuterated chloroform on a Varian model A-60 spectrometer by Dr. J. E. Lancaster at the American Cyanamid Company, Stamford, Connecticut.*

[2]*The existence of adducts of DMF with thionyl chloride, phosphorus oxychloride, and phosgene has been well established. For example, consult refs. 14–17.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

may be of interest to note that a quantitative study demonstrated that the conversion of 2 moles of phthalimide into 1 mole of I requires 2 moles of sulfur monochloride.

Thus, reinvestigation of the reaction between phthalimide (or potassium phthalimide) and sulfur monochloride in various solvents led to a convenient synthesis of either *N,N'*-thiobisphthalimide (I) or *N,N'*-dithiobisphthalimide (II). The type of product depends upon the choice of solvent.

EXPERIMENTAL

Melting points were determined using open-glass capillaries either in a Thomas–Hoover melting point apparatus or in an aluminium block, and are uncorrected. Microanalyses were provided by Galbraith Microanalytical Laboratory, Knoxville, Tennessee. Infrared spectra were recorded on a Perkin–Elmer Infracord spectrophotometer.

N,N'-Thiobisphthalimide (I)

(a) From Phthalimide and Sulfur Monochloride

Phthalimide (7.36 g, 0.05 mole) was dissolved in anhydrous DMF (40 ml, dried over Molecular Sieve type 4A), and to the resulting solution sulfur monochloride[3] (6.75 g, 0.05 mole) was added in several portions at 28° (anhydrous conditions). After 20 min a precipitate appeared. The yellow mixture was stirred for 20 h at 28° before collection of the colorless, crystalline solid by filtration. The dry product (7.46 g, 92% yield) melted at 280–288°. The infrared spectrum of the solid exhibited no $-NH_2$, $=NH$, —OH, or —COOH bands.

Recrystallization of the product from dry chloroform gave a sample of I, m.p. 315–317°; λ_{max}^{Nujol} 5.66, 8.07, 9.71, 11.50, and 14.00 μ.

Anal. Calcd. for $C_{16}H_8N_2SO_4$: C, 59.26; H, 2.49; N, 8.64; S, 9.89; mol. wt. 324. Found: C, 59.06; H, 2.46; N, 8.79; S, 10.03; mol. wt. 320.

The approximate solubility of I in DMF was found to be 1.87 g/100 ml at 28°. Product I exhibited no signs of decomposition in water or 6 *N* HCl at room temperature; however, I hydrolyzed readily in 5% sodium hydroxide at 28°.

Reactions performed at 50° resulted in a considerable decrease in the yield of I, but at temperatures above 90° no product (I) was isolated. The use of purified sulfur monochloride (18) in the reaction proved of no particular advantage.

(b) From Potassium Phthalimide and Sulfur Monochloride

To a mixture of potassium phthalimide (9.26 g, 0.05 mole) and dry DMF (40 ml), sulfur monochloride (6.75 g, 0.05 mole) was added dropwise at 28–32° (anhydrous conditions), with cooling. After the addition was completed, the reaction mixture was allowed to remain at 28° for 20 h (continuous stirring) before collection of the solid by filtration. Extraction of the crude, dry solid with hot chloroform and removal of the solvent gave a colorless product (7.0 g, 86% yield) which melted at 315°. The infrared spectrum of this solid was identical with that of the product obtained by method *a*.

(c) From Potassium Phthalimide and Sulfur Dichloride

To a suspension of potassium phthalimide (9.26 g, 0.05 mole) in dry petroleum ether (25 ml, b.p. 36–54°), sulfur dichloride (2.58 g, 0.025 mole) was added, and the mixture heated at reflux for 1 h. The solid was collected by filtration, washed with dry petroleum ether, and extracted with hot chloroform. Concentration of the extracts gave a colorless solid (6.5 g, 80% yield), which was shown by melting point and infrared spectral comparison to be identical with the product obtained by method *a*.

Similarly, I can be obtained in about 80% yield from the reaction of phthalimide with the calculated amount of sulfur dichloride in DMF.

N,N'-Dithiobisphthalimide (II)[4]

A stirred suspension of potassium phthalimide (9.26 g, 0.05 mole) and dry petroleum ether (25 ml, b.p. 36–60°) was treated with sulfur monochloride (6.75 g, 0.05 mole; dropwise addition), and the resulting mixture was refluxed for 1 h. The liquid was then decanted, and the residue washed thoroughly with fresh petroleum ether and filtered. Extraction of the solid with hot dry chloroform and subsequent removal of the solvent gave 4.6 g (51%) of large colorless needles, m.p. 190–210°. The infrared spectrum of this material indicated a weak —NH— absorption band, which disappeared upon recrystallization from chloroform. Two additional recrystallizations from the same solvent raised the melting point to 228–230°; λ_{max}^{Nujol} 5.73, 7.86, 8.01, 9.61, 11.50, and 13.95 μ.

Anal. Calcd. for $C_{16}H_8N_2S_2O_4$: C, 53.92; H, 2.26; N, 7.86; S, 17.99; mol. wt. 356. Found: C, 54.01; H, 2.22; N, 7.93; S, 18.05; mol. wt. 360.

[3]*Sulfur monochloride (Baker Chemical Co.) was assayed by gas–liquid chromatography. The analysis, performed by Mr. H. V. Lewry on a F & M Scientific Corporation model 500 instrument and a diethylene glycol succinate column at 50°, showed that the sample contained 98%* S_2Cl_2.

[4]*For comparison of the experimental conditions, consult ref. 2.*

Desulfurization of N,N-'Thiobisphthalimide (I)

A solution of I (0.5 g) in anhydrous DMF (90 ml) was treated with W-4 Raney nickel (19) (1.1 ml, 18 days old). The continuously stirred mixture was heated at 60–70° for 25 h (anhydrous conditions). At the end of the reaction period, the hot mixture was filtered through a sintered-glass funnel, the residue was washed once with a small amount of dry DMF, and the combined filtrate was concentrated *in vacuo* at 60–70°. The residual crystalline solid (0.4 g) was identified by melting point and infrared spectrum as phthalimide. A mixture melting point of the product with authentic phthalimide exhibited no depression.

THE DEHYDRATION OF AMIDES TO NITRILES WITH LITHIUM ALUMINIUM HYDRIDE

L. G. Humber and M. A. Davis

In connection with the synthesis of the benzo[1,2]cyclohepta[3,4,5-*d*,*e*]isoquinoline ring system (1), we required 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-methylamine (I) as an intermediate. Our initial attempts were directed to the lithium aluminium hydride reduction of the carbonitrile II, and to the lithium aluminium hydride – mercuric chloride reduction of the carboxamide III.

I R = CH_2NH_2
II R = C≡N
III R = $CONH_2$

IV R = CH_2NH_2
V R = C≡N
VI R = $CONH_2$

In the former case the carbonitrile was recovered essentially unchanged, and in the latter the product obtained from the reaction consisted of a mixture of carbonitrile II (67%) and amine I (19.8%). Reduction of carboxamide III with lithium aluminium hydride alone gave the carbonitrile II, in 92% yield, as the only isolable product. The

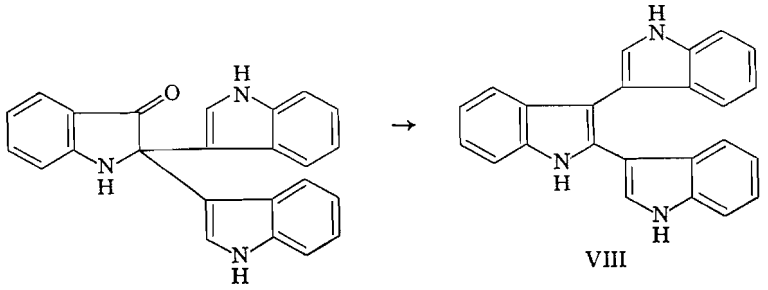
THE DEHYDRATION OF AMIDES TO NITRILES WITH LITHIUM ALUMINIUM HYDRIDE

L. G. HUMBER AND M. A. DAVIS

In connection with the synthesis of the benzo[1,2]cyclohepta[3,4,5-*d*,*e*]isoquinoline ring system (1), we required 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-methylamine (I) as an intermediate. Our initial attempts were directed to the lithium aluminium hydride reduction of the carbonitrile II, and to the lithium aluminium hydride – mercuric chloride reduction of the carboxamide III.

I R = CH_2NH_2
II R = C≡N
III R = $CONH_2$



IV R = CH_2NH_2
V R = C≡N
VI R = $CONH_2$

In the former case the carbonitrile was recovered essentially unchanged, and in the latter the product obtained from the reaction consisted of a mixture of carbonitrile II (67%) and amine I (19.8%). Reduction of carboxamide III with lithium aluminium hydride alone gave the carbonitrile II, in 92% yield, as the only isolable product. The

desired amine I has subsequently been obtained in high yields (1) either by the lithium aluminium hydride – aluminium chloride reduction, or by the Raney nickel catalyzed hydrogenation, of the carbonitrile II.

We have also treated 2,2-diphenylacetamide (VI) with lithium aluminium hydride – mercuric chloride, and the product consisted of 81% of carbonitrile V and 13% of amine IV.

The use of lithium aluminium hydride alone or in combination with mercuric chloride has not previously been observed to effect the dehydration of carboxamides to carbonitriles; however, in at least one instance, lithium aluminium hydride behaves as a Lewis acid, causing the skeletal rearrangement VII → VIII (2). The present observations may constitute another example of such behavior by lithium aluminium hydride; this suggests that, in some limited situations, this reagent may be of use in the preparation of nitriles.

VII VIII

EXPERIMENTAL

Treatment of 10,11-Dihydro-5H-dibenzo[a,d]-cycloheptene-5-carboxamide with Lithium Aluminium Hydride – Mercuric Chloride

10,11-Dihydro-5*H*-dibenzo[*a,d*]cycloheptene-5-carboxamide (III) (3) (10.0 g), lithium aluminium hydride (5.0 g), and mercuric chloride (500 mg) were mixed in tetrahydrofuran (250 ml) and refluxed for 16 h. Water (22.5 ml) was added and the mixture filtered. Treatment of the dried filtrate with ethereal hydrogen chloride yielded the hydrochloride of I, m.p. >295° (2.1 g, 19.8%). The analytical sample was crystallized from a methanol – ethyl acetate mixture.

Anal. Calcd. for $C_{16}H_{18}ClN$: C, 73.97; H, 6.98; Cl, 13.65; N, 5.39. Found: C, 73.81; H, 6.92; Cl, 13.66; N, 5.71.

The free base I had b.p. 127° at 0.15 mm, n_D^{23} 1.6122.

Anal. Calcd. for $C_{16}N_{17}N$: C, 86.05; H, 7.67; N, 6.27. Found: C, 86.08; H, 7.51; N, 6.16.

The filtrate from the preparation of the hydrochloride of I was evaporated and the residue crystallized from methanol to yield the carbonitrile II (6.2 g, 67%), $\nu_{max}^{CHCl_3}$ 2 245 cm^{-1}, m.p. 91–93° (lit. (4) m.p. 91–92°). When the carboxamide III (1.0 g) was refluxed with lithium aluminium hydride (1.0 g) alone in tetrahydrofuran (50 ml) for 16 h, the carbonitrile II (850 mg, 92%) was obtained along with traces of basic material.

Treatment of 2,2-Diphenylacetamide with Lithium Aluminium Hydride – Mercuric Chloride

2,2-Diphenylacetamide (1.0 g), lithium aluminium hydride (500 mg), and mercuric chloride (50 mg) were mixed in tetrahydrofuran (100 ml) and refluxed for 16 h. Water (4.5 ml) was added and the mixture filtered to yield, after drying (Na_2SO_4) and evaporation, a light-yellow oil that solidified when allowed to stand. It was dissolved in ether and treated with ethereal hydrogen chloride to yield the hydrochloride of IV (145 mg, 13%), m.p. 263–265° (lit. (5) m.p. 263°).

The filtrate from above was evaporated to yield an oil (750 mg, 81%), which was shown to be homogeneous by thin-layer chromatography. It was crystallized from acetonitrile to give V (500 mg), $\nu_{max}^{CHCl_3}$ 2 250 cm^{-1}, m.p. 74–75° (lit. (6) m.p. 72–73.5°) (undepressed when mixed with an authentic sample of V).

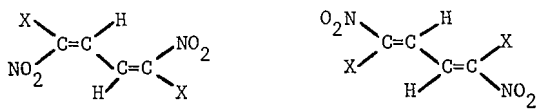
THE SYNTHESIS OF 1,4-DICHLORO-1,4-DINITRO-1,3-BUTADIENE



F. I. CARROLL, SANDRA C. KERBOW, AND MONROE E. WALL

1,4-Dichloro-1,4-dinitro-1,3-butadiene (IV, X = Cl) was first prepared by Reppe and his co-workers (1) in 1948 by the nitration of 1,4-dichloro-1,3-butadiene. The synthesis was improved by Braye (2), but under optimum conditions only a 7.7% yield of the dichlorodinitrodiene was obtained.

This note reports an entirely different synthesis of IV (X = Cl). 1,4-Dinitro-1,3-butadiene (II), prepared from DL- or *meso*-1,4-dinitro-2,3-butanediol (I) (3, 4), was chlorinated in acetic acid saturated with hydrogen chloride, to give a 98.5% yield of 1,2,3,4-tetrachloro-1,4-dinitrobutane (III, X = Cl). When the tetrachlorodinitrobutane was stirred with a suspension of Florisil in benzene for 4 h, a 99% yield of IV (X = Cl) was obtained. Attempts to dehydrochlorinate III (X = Cl) with pyridine or triethylamine yielded a dark mass from which only very small yields of IV (X = Cl) could be obtained. Lipina and Perekalin (5) have reported a similar synthesis of 1,4-dibromo-1,4-dinitro-1,3-butadiene (IV, X = Br), in which III (X = Br) was dehydrobrominated by heating it in alcohol. We found that IV (X = Br) was more conveniently prepared by bromination of II in chloroform or dioxane followed by dehydrobromination of the intermediate 1,2,3,4-tetrabromo-1,4-dinitrobutane (III, X = Br) with Florisil. When II was treated with iodine in chloroform a quantitative recovery of II was obtained.

IVa IVb

The structure of the 1,4-dichloro- and 1,4-dibromo-1,4-dinitro-1,3-butadienes is not known. However, the nuclear magnetic resonance spectra of both compounds show only one peak, indicating that they have the symmetrical structure IV*a* or IV*b*.

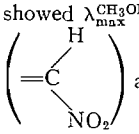
EXPERIMENTAL

The melting points were obtained on a Kofler hot stage and are corrected. The infrared spectra were obtained with a Perkin–Elmer model 221 spectrophotometer. The nuclear magnetic resonance spectra were obtained on a Varian A-60 spectrometer with samples dissolved in deuteriochloroform (the internal standard was tetramethylsilane). The ultraviolet spectra were obtained with a Bausch and Lomb model 505 spectrophotometer. The thin-layer chromatograms were obtained on columns of silica gel HF. The microanalyses were carried out by Micro-Tech Laboratories, Inc., Skokie, Illinois.

Preparation of meso-1,4-Dinitro-2,3-diacetoxybutane

A mixture of 36 g (0.2 mole) of *meso*-1,4-dinitro-2,3-butanediol (3), 44 g (0.56 mole) of acetyl chloride, and 70 ml of acetic acid was warmed gently until hydrogen chloride evolution ceased. The mixture was cooled and diluted with water until crystallization started. The crystals were collected, washed with water, and dried. Recrystallization from ethanol gave 43.4 g (82.4%) of *meso*-1,4-dinitro-2,3-diacetoxybutane, m.p. 94.5–96.5° (reported (4) m.p. 91.5–92°).

Anal. Calcd. for $C_8H_{12}N_2O_8$: C, 36.37; H, 4.58; N, 10.61. Found: C, 36.57; H, 4.48; N, 10.44.



Preparation of DL-*1,4-Dinitro-2,3-diacetoxybutane*

Acetylation of DL-1,4-dinitro-2,3-butanediol (3) in the same manner as described for the preparation of *meso*-1,4-dinitro-2,3-diacetoxybutane gave a 72.6% yield of DL-1,4-dinitro-2,3-diacetoxybutane, m.p. 94–95° (reported (4) m.p. 89.5–90°). A mixture of this acetate and *meso*-1,4-dinitro-2,3-diacetoxybutane melted at 79–95°.

Anal. Calcd. for $C_8H_{12}N_2O_8$: C, 36.37; H, 4.58; N, 10.61. Found: C, 36.58; H, 4.62; N, 10.78.

Preparation of 1,4-Dinitro-1,3-butadiene (II)[1]

According to the procedure reported by Noviko *et al.* (4), *meso*- or DL-1,4-dinitro-2,3-diacetoxybutane was refluxed with a catalytic amount of anhydrous potassium hydrogen carbonate in chloroform to give 70–85% of 1,4-dinitro-1,3-butadiene, m.p. 150–150.5° (reported (4) m.p. 146.5–147°). The ultraviolet spectrum showed $\lambda_{max}^{CH_3OH}$ 281 mμ (ϵ = 18 487). The nuclear magnetic resonance spectrum showed a singlet at δ 7.52

and a singlet at δ 7.55 p.p.m. (=CH—).[2]

Anal. Calcd. for $C_4H_4N_2O_4$: C, 33.33; H, 2.78. Found: C, 33.27; H, 2.70.

Preparation of 1,4-Dichloro-1,4-dinitro-1,3-butadiene (IV, X = Cl)

A stream of chlorine and hydrogen chloride was passed simultaneously through a solution of 9.98 g (0.0693 mole) of 1,4-dinitro-1,3-butadiene in 645 ml of acetic acid (distilled from potassium permanganate) heated to 56°. A thin-layer chromatogram (benzene) after $3\frac{3}{4}$ h indicated that all of the diene had reacted. After concentration by freeze-drying, 19.4 g (98.5%) of a white solid was obtained. The infrared spectrum (methylene chloride) showed peaks at 3 022, 2 970, and 2 915 (C—H), and at 1 580 and 1 348 cm^{-1} (NO_2). The crude 1,2,3,4-tetrachloro-1,4-dinitrobutane (III, X = Cl) was used, without further purification, for the preparation of 1,4-dichloro-1,4-dinitro-1,3-butadiene. When the chlorination was conducted at a higher temperature or higher concentration an oil was obtained. The infrared spectrum (methylene chloride) showed, in addition to the absorption mentioned above, weak peaks in the carbonyl region and a sharp peak at 1 600 cm^{-1}.

A mixture of 1,2,3,4-tetrachloro-1,4-dinitrobutane (19.4 g, 0.0680 mole), 1 500 ml of benzene, and 500 g of Florisil was stirred at room temperature for 4 h. The mixture was then placed on a chromatography column and eluted with benzene until a thin-layer chromatogram (benzene) indicated that all of the product had been eluted (3 l of benzene). Concentration of the benzene gave 15 g of a yellow solid. Recrystallization from carbon tetrachloride yielded 14.20 g (99%) of 1,4-dichloro-1,4-dinitro-1,3-butadiene, m.p. 124–125° (reported (2) m.p. 124–125°). The infrared spectrum (potassium bromide) showed absorption at 3 110 and 3 080 (=C—H), at 1 568 (C=C), and at 1 532 and 1 322 cm^{-1} (NO_2). The ultraviolet spectrum showed $\lambda_{max}^{CH_3OH}$ 330 mμ (ϵ = 12 928). The nuclear magnetic resonance spectrum showed only one resonance, a singlet at δ 8.03 p.p.m.

Anal. Calcd. for $C_4H_2N_2Cl_2O_4$: C, 22.54; H, 0.95; N, 13.16; Cl, 33.29. Found: C, 22.75; H, 0.87; N, 12.88; Cl, 33.25.

[1]*Subsequent work has shown that 1,4-dinitro-1,3-butadiene can be caused to explode forcefully when heated in a closed container or when detonated by a blasting cap; accordingly, due precaution should be taken when this and related compounds are handled.*

[2]NOTE ADDED IN PROOF: *A 100 Mc.p.s. nuclear magnetic resonance spectrum of II obtained in dimethyl sulfoxide showed 12 peaks. We thank Dr. Charles G. Moreland, North Carolina State University, for determining this spectrum.*

Preparation of 1,4-Dibromo-1,4-dinitro-1,3-butadiene (IV, X = Br)

A solution of 1.44 g (0.01 mole) of 1,4-dinitro-1,4-butadiene and 3.19 g (0.02 mole) of bromine in 150 ml of chloroform was refluxed for 2 h. A thin-layer chromatogram (benzene) indicated that all of the diene had reacted. The reaction mixture was concentrated to give 4.6 g (99.2%) of crude 1,2,3,4-tetrabromo-1,4-dinitrobutane (III, X = Br). The infrared spectrum (CH_2Cl_2) showed absorption at 3 025 and 2 968 (C—H) and at 1 577 and 1 347 cm^{-1} (NO_2). The crude product was used, without further purification, for the preparation of 1,4-dibromo-1,4-dinitro-1,3-butadiene. Similar results were obtained when the bromination was carried out in dioxane.

A mixture of 4.6 g (0.00992 mole) of 1,4-dinitro-1,2,3,4-tetrabromobutane, 160 ml of benzene, and 60 g of Florisil was stirred at room temperature overnight. The mixture was transferred to a chromatography column and eluted with benzene. Concentration of the benzene solution gave 2.91 g of a solid that showed only one spot on a thin-layer chromatogram (benzene–cyclohexane (1:1)). Recrystallization from carbon tetrachloride gave 2.5 g (84.6%) of 1,4-dibromo-1,4-dinitro-1,3-butadiene, m.p. 123.5–125.5° (reported (5) m.p. 125–126°). The infrared spectrum (potassium bromide) showed absorption at 3 068 (=CH), at 1 610 (C=C), and at 1 525 and 1 310 cm^{-1} (NO_2). The ultraviolet spectrum (CH_3OH) showed λ_{max} 339 mμ (ϵ = 10 023). The nuclear magnetic resonance spectrum showed only one resonance, that at δ 8.22.

Anal. Calcd. for $C_4H_2N_2O_4Br_2$: C, 15.90; H, 0.66; N, 9.27; Br, 52.98. Found: C, 16.17; H, 0.62; N, 9.07; Br, 52.77.

ELECTROLYTIC REDUCTION AND ELLINGHAM DIAGRAMS FOR OXY-ANION SYSTEMS

H. E. BARTLETT AND K. E. JOHNSON[1]

Department of Chemistry, Sir John Cass College, Jewry Street, London, England

Received April 28, 1966

ABSTRACT

Standard reversible decomposition voltages, E^0, for various decomposition reactions of K_2CO_3, Na_2CO_3, Li_2CO_3, $BaCO_3$, $CaCO_3$, $MgCO_3$, Na_2SO_4, $NaNO_3$, and KNO_3 are calculated from thermal data and the values obtained plotted against temperature. That reaction which has the lowest values of E^0 is considered to be the most likely to occur when the particular salt is electrolyzed. The results obtained indicate that in the case of the carbonates metal deposition is possible only for K_2CO_3 and Na_2CO_3 above 870 °K. In all other cases metal oxide and carbon (or CO at higher temperatures) are the favored cathode products. For Na_2SO_4, Na_2S and Na_2O are the favored cathode products and for the nitrates, nitrite and oxide or nitrogen evolution and oxide formation appear equally feasible thermodynamically.

Once the likely electrolytic decomposition products are known, a method is presented whereby the products formed by reduction of the oxy-anions by metals (and in the case of the carbonates, by carbon) may be predicted. This method involves drawing an appropriate redox line on an Ellingham diagram. Finally, a comparison is made between the thermodynamic predictions and the few experimental results available.

INTRODUCTION

Hamer and co-workers have published theoretical electromotive force (e.m.f.) series for chlorides, fluorides, and oxides at various temperatures (1–3). These series were obtained by calculating the reversible decomposition potentials of cells such as

$$M|MX|\tfrac{1}{2}X_2 \quad \text{or} \quad M|MO|\tfrac{1}{2}O_2 \quad (X = \text{halogen}).$$

This present work applies the same type of treatment to Na_2CO_3, K_2CO_3, Li_2CO_3, $CaCO_3$, $BaCO_3$, $MgCO_3$, Na_2SO_4, KNO_3, and $NaNO_3$ in an attempt to predict (*a*) their electrolytic reduction products at various temperatures, (*b*) their reversible decomposition potentials, and (*c*) which metals will reduce them.

A complementary approach to this work has been provided in the form of potential vs. pO^{2-} diagrams (analogous to potential vs. pH diagrams (4)) by Littlewood (5) and others (6, 7).

CARBONATES

Electrolytic Reduction of Carbonates

When a solid or liquid carbonate is electrolyzed, CO_2 and O_2 are evolved at the anode according to the equation

$$CO_3^{2-} = CO_2 + \tfrac{1}{2}O_2 + 2e,$$

[1]*To whom all communications should be sent. Present address: University of Saskatchewan, Regina, Sask.*

whereas at the cathode there are at least four possible processes:

(*a*) the formation of carbon and oxide

$$CO_3^{2-} + 4e = C\downarrow + 3O^{2-},$$

(*b*) the formation of carbon monoxide and oxide

$$CO_3^{2-} + 2e = CO + 2O^{2-},$$

(*c*) the deposition of metal

$$M^{n+} + ne = M\downarrow,$$

(*d*) the formation of carbide and oxide

$$2CO_3^{2-} + 10e = C_2^{2-} + 6O^{2-},$$

Combination of the anodic reaction with the various cathodic reductions gives eqs. [1] to [4].

[1] $$3M_2CO_3 = 3M_2O + C + 2CO_2 + O_2$$

[2] $$2M_2CO_3 = 2M_2O + CO + CO_2 + \tfrac{1}{2}O_2$$

[3] $$M_2CO_3 = 2M + CO_2 + \tfrac{1}{2}O_2$$

[4] $$7M_2CO_3 = M_2C_2 + 6M_2O + 5CO_2 + \tfrac{5}{2}O_2$$

Each equation may be represented by one of the cells 1*a* to 4*a*. The double vertical lines represent salt bridges with assumed liquid junction potentials equal to 0.

$$C|M_2O, M_2CO_3||M_2CO_3|CO_2, O_2, Pt \qquad (1a)$$

$$Pt, CO|M_2O, M_2CO_3||M_2CO_3|CO_2, O_2, Pt \qquad (2a)$$

$$M|M_2CO_3|CO_2, O_2, Pt \qquad (3a)$$

$$Pt|M_2O, M_2C_2, M_2CO_3||M_2CO_3|CO_2, O_2, Pt \qquad (4a)$$

The standard free energy of reaction, ΔG^0, was calculated for reactions [1] to [4] at various temperatures using the low temperature data of the National Bureau of Standards (8) and, where available, the high temperature data listed by Kelley (9). Where Kelley has no data, the estimates given in the JANAF tables (10) were used. The free energies of formation of Li_2CO_3 at high temperatures were calculated from enthalpy data given by Janz (11) and the free energies of formation of Li_2C_2 at various temperatures were estimated using methods suggested by Kubaschewski and Evans (12).

ΔG^0 was then converted to E^0, the standard reversible decomposition potential, by means of the relationship

$$\Delta G^0 = -nFE^0.$$

For the purposes of the calculations it was assumed that (i) all electrode processes were reversible; (ii) all components were in their standard states, i.e., all gases were ideal and at 1 atm partial pressure, any deposited metal was neither alloyed with the indicator electrode nor dissolved in the carbonate, and the carbonates, oxides, and carbides were all in the form of pure crystals or melts; (iii) the carbonates were thermally stable.

The thermal decomposition of the carbonates can be inhibited by keeping them under CO_2. However, this introduces the complication that the CO_2 itself can be reduced, either to carbon or to carbon monoxide as in eqs. [5] and [6].

(*e*) Reduction to carbon.

$$3CO_2 + 4e = 2CO_3^{2-} + C \qquad \text{at the cathode,}$$

$$CO_3^{2-} = CO_2 + \tfrac{1}{2}O_2 + 2e \qquad \text{at the anode.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Overall process

[5] $$CO_2 = C + O_2.$$

(*f*) Reduction to carbon monoxide.

$$2CO_2 + 2e = CO_3^{2-} + CO \qquad \text{at the cathode,}$$

$$CO_3^{2-} = CO_2 + \tfrac{1}{2}O_2 + 2e \qquad \text{at the anode.}$$

Overall process

[6] $$CO_2 = CO + \tfrac{1}{2}O_2.$$

Figures 1 to 6 show the variation of E^0 with temperature for the decomposition of potassium, sodium, lithium, barium, calcium, and magnesium carbonates according to eqs. [1] to [4]. On Fig. 2 the decomposition of CO_2 is also plotted.

From these graphs it is evident that in the case of K_2CO_3 (Fig. 1), the deposition of alkali metal is the favored electrode process at all temperatures, whereas with Na_2CO_3 (Fig. 2) carbon production is favored up to a temperature of about 870 °K after which alkali metal deposition is again preferred. With the other carbonates the favored processes are, at low temperatures, carbon, production and, at high temperatures, CO evolution. In all cases, however, direct reduction of CO_2 (eqs. [5] and [6]) would be favored but the low activity of CO_2 in carbonates should prevent significant contributions from this reaction.

Reduction of Carbonates with Metals and Carbon

Carbonates can be reduced with reactive metals or with carbon and, as in the case of electrolytic reduction, the products depend on both the carbonate cation and on the temperature at which the reduction takes place.

The easiest way to present the data is on an Ellingham diagram (13) as shown in Fig. 7. On the conventional Ellingham diagram the standard free energy of formation, ΔG^0, is plotted against temperature T, for oxidations such as

[7] $$2Fe + O_2 = 2FeO.$$

In the case of the carbonates there are several ways in which the carbonate can be reduced and each of these ways can be represented as a line on the Ellingham diagram. For instance the carbonate can be reduced to metal oxide and carbon. This redox process may be represented as

[8] $$M_2O + C + O_2 = M_2CO_3.$$

At higher temperatures carbon monoxide rather than carbon will be produced and the corresponding redox process would be

[9] $$2M_2O + 2CO + O_2 = 2M_2CO_3.$$

The temperature at which ΔG^0 for reaction [9] becomes numerically lower than ΔG^0 for reaction [8] will be given by the point at which line [8] intersects the $2C + O_2 = 2CO$ line on the Ellingham diagram. For K_2CO_3 and Na_2CO_3 above about 870 °K alkali metal is produced on reduction of the carbonate. Before the $2C + O_2 = 2CO$ line is crossed, alkali metal production may be represented as

[10] $$\tfrac{4}{3}M + \tfrac{2}{3}C + O_2 = \tfrac{2}{3}M_2CO_3,$$

and after crossing as

[11] $$2M + CO + O_2 = M_2CO_3.$$

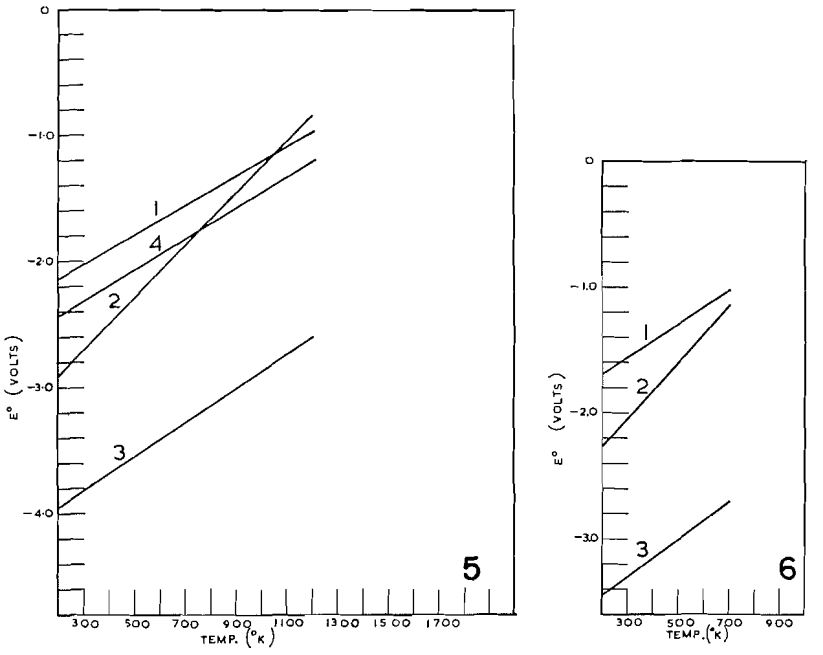

FIG. 5. Variation with temperature of the standard reversible decomposition voltage, E^0, of calcium carbonate. Line 1, CaO and C formed. Line 2, CaO and CO formed. Line 3, Ca deposited. Line 4, CaO and CaC_2 formed.

FIG. 6. Variation with temperature of the standard reversible decomposition voltage, E^0, of magnesium carbonate. Line 1, MgO and C formed. Line 2, MgO and CO formed. Line 3, Mg deposited.

In Fig. 7, of the reactions [8] to [11], the reaction which has the lowest value of ΔG^0 is plotted for each of the carbonates. The plain carbonate lines below the $2C + O_2 = 2CO$ line refer to the production of the metal oxide and carbon (reaction [8]), those above refer to the production of CO and oxide (reaction [9]). The dashed line below the $2C + O_2 = 2CO$ line refers to the metal and carbon deposition reactions (reaction [10]) and the dashed line above to the deposition of metal and evolution of CO (reaction [11]). Also on the diagram are the lines corresponding to the various carbon oxidations viz.

[12] $$C + O_2 = CO_2$$

[13] $$2CO + O_2 = 2CO_2$$

[14] $$2C + O_2 = 2CO$$

For the sake of clarity only a few of the metal oxidation lines are plotted. Data for plotting any others may be obtained either from Hamer (3) or from Richardson and Jeffes (14).

If a metal oxidation line lies below a carbonate redox line, that metal will reduce the carbonate. At a temperature of 700 °K, for instance, the sodium oxidation line lies below all the carbonate lines. Hence at this temperature sodium will reduce all the carbonates. For example sodium carbonate will be reduced thus:

	ΔG^0 at 700 °K (kcal mole^{-1} O_2)
$4Na + O_2 = 2Na_2O$	−153.1
$Na_2O + C + O_2 = Na_2CO_3$	−147.6

Subtracting

[15] $$4Na + Na_2CO_3 = 3Na_2O + C \qquad -5.5$$

For personal use only.

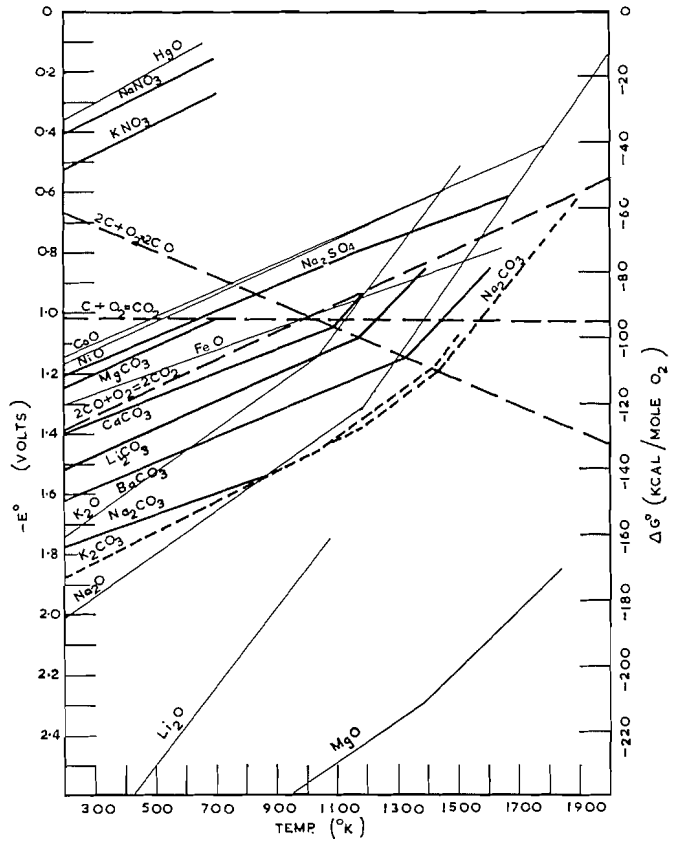

FIG. 7. Variation with temperature of the standard free energy of reaction (ΔG^0) and of the standard reversible decomposition voltage, E^0, for various oxy-anion systems and oxides (see text).

This gives the value for ΔG^0 for reaction [15] as -5.5 kcals mole^{-1} at 700 °K.

It is also possible to estimate the standard reversible decomposition potential of a carbonate by means of this diagram. As an example the overall decomposition reaction for K_2CO_3 is

$$K_2CO_3 = 2K + CO_2 + \tfrac{1}{2}O_2.$$

This can be split up as follows (where m is the number of moles of oxygen involved in a process):

	m	mE^0 (1 000 °K), V
$3 \times (\frac{2}{3}K_2CO_3 = \frac{4}{3}K + \frac{2}{3}C + O_2)$	3	$-3 \times 1.48 = -4.44$
$2 \times (C + O_2 = CO_2)$	2	$-2 \times 1.02 = -2.04$

Subtracting

$2 \times (K_2CO_3 = 2K + CO_2 + \frac{1}{2}O_2)$	1	-2.40

This value of -2.40 V is precisely that obtained from Fig. 1.

Comparison with Experiment

Most of the experimental work on the electrolysis of carbonates has been conducted on eutectics, one component of which is usually Li_2CO_3. With such eutectics several

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

workers (15–17) have identified carbon as one of the cathode products at temperatures between 500 °C and 600 °C. At a temperature of 700 °C there is apparently no deposit of carbon (18) but at such temperatures any carbon produced would react with CO_2 to produce CO.

There is only one report of the electrolytic production of sodium from molten sodium carbonate (19) but the now obsolete Deville process for the production of sodium relied upon the reduction of Na_2CO_3 with carbon at a temperature of 1 200 °C. Very similar to the Deville process is Curaudaus' process (20) for the reduction of K_2CO_3 to potassium with carbon. This process works for all alkali metals except lithium, in which case carbon monoxide and lithium oxide are the products. There are also reports of the production of sodium from sodium carbonate by reduction with aluminium and magnesium (19).

Although the thermodynamic treatment so far presented enables one to predict the products of reduction, it is difficult to relate the standard reversible decomposition voltage, E^0, to the actual decomposition voltage as measured experimentally. There are several reasons for this. Firstly all the electrode processes envisaged may not be reversible, secondly polarization effects are not considered, and thirdly the activities of the reduction products produced in the carbonate are unknown. However, the decomposition voltage of a ternary carbonate eutectic has been reported by Dubois (16) to be of the order of -1.8 to -2.5 V at 560 °C. Work in this laboratory (17) on the current–voltage behavior of $LiNaCO_3$ at 550 °C supports Dubois' results but a wave was observed at a potential of about -1.2 V versus a $Ag|Ag^+$ reference electrode. The standard reversible decomposition voltage of lithium carbonate at 550 °C is -1.65 V (Fig. 3), whereas that for CO_2 is -1.01 V (Fig. 2). The wave occurring at -1.2 V probably corresponds to the reduction of CO_2, whereas the lithium carbonate is not decomposed until a potential of about 2.0 V is applied across the cell.

Examination of Fig. 7 shows that the CoO and NiO lines are above those for all the carbonates and hence it is to be expected that cobalt and nickel would not reduce a $LiNaCO_3$ eutectic. This is in fact the case since it is possible to measure reversible $Co|Co^{2+}$ and $Ni|Ni^{2+}$ potentials in such a eutectic at 550 °C provided water is rigorously excluded from the system (17). However, an $Fe|Fe^{2+}$ potential is unstable and indeed the FeO line lies below the CO_2 lines in accord with iron being oxidized by CO_2 dissolved in the melt. For the same reason it would not be possible to measure a $Na|Na^+$ potential in molten sodium carbonate at any temperature below about 1 570 °K where the Na_2O line crosses the CO_2 line because the sodium would be oxidized. This is presumably one of the reasons for the low yields obtained from the Deville process (19). However, the K_2O line crosses the CO_2 line at a far lower temperature (1 200 °K) and hence it is to be expected that the reduction of K_2CO_3 would give higher yields.

SULFATES

Electrolytic Reduction of Sulfates

When a solid or liquid sulfate is electrolyzed, it is assumed that SO_3 and O_2 are evolved at the anode at temperatures below 1 200 °K. Above this temperature SO_2 and O_2 evolution is thermodynamically more favored. Hence all potentials below 1 000 °K are referred to a SO_3, $O_2|SO_4^{2-}$ electrode and those above to a SO_2, $O_2|SO_4^{2-}$ electrode. As with the carbonates it is assumed that all components are in their standard states.

Again there are a number of feasible cathode processes:

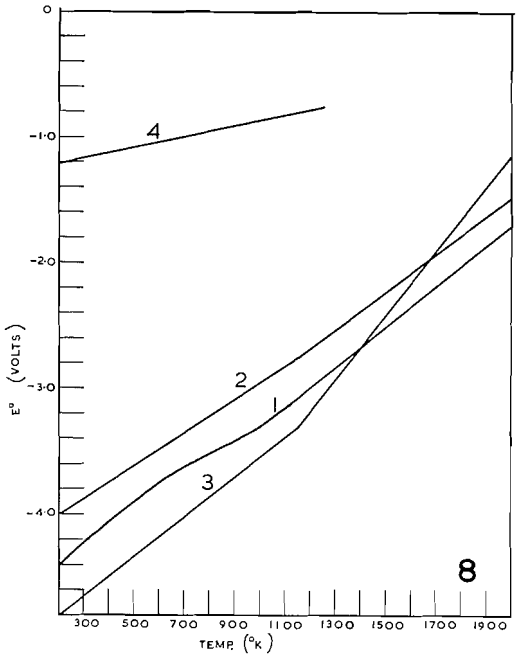
(*g*) the formation of sulfur and oxide

$$SO_4^{2-} + 6e = \tfrac{1}{2}S_2 + 4O^{2-},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*h*) the formation of sulfide and oxide

$$SO_4^{2-} + 8e = S^{2-} + 4O^{2-},$$



(*j*) the deposition of alkali metal.

It is also possible that sulfite is formed as an unstable intermediate which decomposes to sulfate and sulfide.

Each of the three cathode processes may be combined with the anode processes giving as overall cell reductions:

[16]	$4Na_2SO_4 = \frac{1}{2}S_2 + 4Na_2O + 3SO_3 + \frac{3}{2}O_2$	below 1 200 °K
and	$4Na_2SO_4 = \frac{1}{2}S_2 + 4Na_2O + 3SO_2 + 3O_2$	above 1 200 °K
[17]	$5Na_2SO_4 = Na_2S + 4Na_2O + 4SO_3 + 2O_2$	below 1 200 °K
and	$5Na_2SO_4 = Na_2S + 4Na_2O + 4SO_2 + 4O_2$	above 1 200 °K
[18]	$Na_2SO_4 = 2Na + SO_3 + \frac{1}{2}O_2$	below 1 200 °K
and	$Na_2SO_4 = 2Na + SO_2 + O_2$	above 1 200 °K.

ΔG^0 and E^0 are plotted against T for each of these reactions in Fig. 8. From this it can be seen that sulfide formation is favored up to a temperature of about 1 700 °K after which alkali metal evolution is favored.

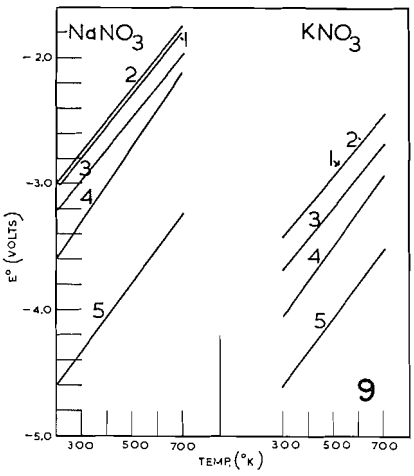


FIG. 8. Variation with temperature of the standard reversible decomposition voltage, E^0, of sodium sulfate. Line 1, Na_2O and sulfur produced. Line 2, Na_2S and Na_2O produced. Line 3, Na deposited. Line 4, SO_3 reduction.

FIG. 9. Variation with temperature of the standard reversible decomposition voltage, E^0, of sodium nitrate and potassium nitrate. Line 1, nitrite and oxide production. Line 2, nitrogen evolution and oxide production. Line 3, N_2O evolution and oxide production. Line 4, NO evolution and oxide production. Line 5, alkali metal deposition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It is also possible that any SO_3 that is formed by thermal decomposition of the sulfate may be reduced. This may first be reduced to sulfite which decomposes to sulfide and sulfate.

$$4SO_3 + 8e = 4SO_3^{2-}$$

$$4SO_3^{2-} = S^{2-} + 3SO_4^{2-}$$

Combination of these reactions with the anodic reaction yields as the overall cell reaction

[19] $$Na_2SO_4 = Na_2S + 2O_2.$$

This, too, is plotted on Fig. 8.

Reduction of Sodium Sulfate with Metals

At temperatures below 1 700 °K the favored electrolytic reduction products of sodium sulfate are sodium sulfide and sodium oxide (Fig. 8). Hence should a reactive metal M be added to sodium sulfate it would be reasonable to assume that sulfide and oxide would be formed. However, for the purposes of the thermodynamic calculations the sulfide may combine with the metal M or with the sodium in the melt. Hence there are two possible equations

[20] $$4M + Na_2SO_4 = 4MO + Na_2S$$

or

[21] $$4M + Na_2SO_4 = 3MO + MS + Na_2O.$$

Each of these reactions may be split up for plotting on an Ellingham diagram

$$4M + 2O_2 = 4MO$$

[22] $$Na_2S + 2O_2 = Na_2SO_4.$$

Subtracting

$$4M + Na_2SO_4 = Na_2S + 4MO$$

or

$$4M + \tfrac{1}{2}S_2 + \tfrac{3}{2}O_2 = 3MO + MS$$

[23] $$Na_2O + \tfrac{1}{2}S_2 + \tfrac{3}{2}O_2 = Na_2SO_4$$

Subtracting

$$4M + Na_2SO_4 = Na_2O + 3MO + MS.$$

In the first case the sulfate redox line (eq. [22]) may be plotted directly on an oxide Ellingham diagram (Fig. 7), but in the second (eq. [23]) a composite diagram has to be drawn incorporating both the sulfides and oxides. It has been found that reaction [20] is in general the thermodynamically more favored and hence the composite sulfide, oxide diagram is not presented.

Comparison with Experiment

The products of electrolytic reduction of a lithium sodium potassium sulfate eutectic at temperatures between 550 °C and 580 °C have been identified by Johnson and Laitinen (21) as sulfur, oxide, and sulfite, whereas Liu (22) reported the production of oxide and sulfide from a lithium potassium sulfate eutectic at 625 °C. The decomposition potential of these eutectics is of the order of −3 V compared with the standard reversible decomposition voltage of sodium sulfate which is about −3.1 V at 900 °K (Fig. 8). This indicates that it is the sulfate anion which is being reduced and not the SO_3 evolved thermally. However, the current–voltage curve of a sulfate eutectic exhibits a high residual current which may be caused by this SO_3 reduction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

From Fig. 7 it can be seen that iron reduces sodium sulfate melts but cobalt and nickel apparently do not. It has been shown experimentally that iron is in fact attacked in sulfate media and that cobalt is sufficiently noble for its standard electrode potential to be measured (21). On the other hand, nickel is slowly attacked in sulfate media. The thermodynamic treatment presented here offers no explanation for the different behavior of cobalt and nickel. It has been suggested that SO_3 corrodes the nickel (7) but should this be the case the cobalt would also be attacked. The explanation may lie in the different solubilities of the cobalt and nickel oxides and sulfides in the melt.

NITRATES

Electrolytic Reduction of Nitrates

When a solid or liquid alkali nitrate is electrolyzed it is assumed that NO_2 and O_2 are evolved at the anode. The feasible cathode processes are:

(*k*) formation of nitrite and oxide

$$NO_3^- + 2e = NO_2^- + O^{2-},$$

(*l*) evolution of nitrogen and formation of oxide

$$NO_3^- + 5e = \tfrac{1}{2}N_2 + 3O^{2-},$$

(*m*) evolution of N_2O and formation of oxide

$$2NO_3^- + 8e = N_2O + 5O^{2-},$$

(*n*) evolution of NO and formation of oxide

$$NO_3^- + 3e = NO + 2O^{2-},$$

(*o*) deposition of alkali metal

$$M^+ + e = M\downarrow.$$

Combination of each of these cathode reactions with the anode reaction gives equations

[24] $$3MNO_3 = MNO_2 + M_2O + 2NO_2 + O_2$$

[25] $$6MNO_3 = \tfrac{1}{2}N_2 + 3M_2O + 5NO_2 + \tfrac{5}{2}O_2$$

[26] $$10MNO_3 = N_2O + 5M_2O + 8NO_2 + 4O_2$$

[27] $$4MNO_3 = NO + 2M_2O + 3NO_2 + \tfrac{3}{2}O_2$$

[28] $$MNO_3 = M + NO_2 + \tfrac{1}{2}O_2.$$

The data for the calculation of E^0 were obtained from refs. 8–10. The data for the nitrites were estimated. ΔG^0 and E^0 are plotted against T for sodium and potassium nitrates (Fig. 9). From the diagram it can be seen that nitrite production (reaction [24]) and nitrogen evolution (reaction [25]) are almost equally thermodynamically favored with N_2O and NO production following fairly closely behind. Alkali metal production, however, appears to be out of the question.

Reduction of Nitrates with Metals

Either the nitrate to nitrite process (reaction [24]) or the nitrogen evolution reaction (reaction [25]) can be chosen as the redox line on the oxide Ellingham diagram. However, since the data for the nitrogen evolution is the more readily available, this line has been plotted on Fig. 7. This line may be represented as

$$\tfrac{1}{5}(2M_2O + 2N_2 + 5O_2 = 4MNO_3).$$

For personal use only.

Comparison with Experiment

An analysis of the cathodic reduction products of potassium and sodium nitrates is presented elsewhere (23).

From the position of the sodium and potassium nitrate redox lines on Fig. 7 it can be seen that these two melts are strongly oxidizing and hence most of the common structural metals will reduce these melts. However, the HgO line is above the nitrate redox lines and hence it is to be expected that mercury would not be oxidized in the melt. This is the case at comparatively low temperatures, since a dropping mercury electrode can be used in nitrate media at 250 °C (24). At higher temperatures the mercury is oxidized but this is probably by the oxygen evolved in the thermal dissociation of the nitrate ion.

HALIDE ALKOXIDES OF SAMARIUM

III. REACTIONS OF SAMARIUM ALKOXIDES WITH ACETYL CHLORIDE AND ACETYL BROMIDE

B. S. SANKHLA AND R. N. KAPOOR
Chemical Laboratories, University of Jodhpur, Jodhpur, India

Received February 8, 1966

ABSTRACT

The reactions of samarium *n*-butoxide, isopropoxide, and *tert*-butoxide with acyl halides in different stoichiometric ratios have been studied and products of the type $Sm(OR)_2X$, $Sm(OR)X_2.0.5CH_3COOR$ and $SmX_3.CH_3COOR$ (where R = $C_4H_9^n$, $C_3H_7^i$, or $C_4H_9^t$ and X = Cl or Br) have been isolated in quantitative yields. All these reactions are exothermic and the amount of heat liberated also increases with the increase in the concentration of acyl halide. These reactions have been further confirmed by the reactions with anhydrous samarium trichloride and the corresponding esters, which are also exothermic reactions. Attempts to sublime the dialkoxy monohalide derivatives of samarium were unsuccessful. The reaction of a dry current of hydrogen chloride gas on samarium isopropoxide has also been investigated.

INTRODUCTION

Considerable work has been carried out on the reactions of alkoxides of aluminium (1–2), titanium (3), zirconium (4), germanium (5), tin (6), vanadium (7), and niobium (8) with acyl halides (chloride and bromide). Mehrotra *et al.* (2) have studied the reactions of aluminium isopropoxide with acetyl chloride, which have been represented by the general equation:

$$Al(OPr^i)_3 + xCH_3COCl \rightarrow Al(OPr^i)_{3-x}Cl_x + xCH_3COOPr^i.$$

The reaction between aluminium *tert*-butoxide and acetyl chloride is complicated and leads to the formation of acetoxy derivatives of the type $AlCl_x(OAc)_y(OBu^t)_{3-x-y}$. They have also reported a novel method for the preparation of tetraacetate derivatives of silicon, titanium, and zirconium by the reaction of the corresponding chlorides with *tert*-butyl acetate (9):

$$MCl_4 + 4Bu^tOAc \rightarrow M(OAc)_4 + 4Bu^tCl.$$

In view of the interesting results obtained in the above experiments, it was considered worthwhile to carry out the reactions of samarium alkoxides (*n*-butoxide, isopropoxide, and *tert*-butoxide) with acyl halides (chloride and bromide) and also the reactions of samarium trichloride and corresponding esters.

The technique for these reactions consists of adding the requisite amount of acyl halide to a solution of alkoxide in benzene whereupon an exothermic reaction takes place. The products precipitate quickly, suggesting apparent completion of the reaction; however, the mixture was heated under reflux for 1 h to ensure completion. The reactions of samarium alkoxides with acyl halides (chloride and bromide) have been carried out in different molar ratios and can be represented by the following general equations:

$$Sm(OR)_3 + 1CH_3COX \rightarrow Sm(OR)_2X + CH_3COOR.$$

$$Sm(OR)_3 + 2CH_3COX \rightarrow Sm(OR)X_2.0.5CH_3COOR + 1.5CH_3COOR.$$

$$Sm(OR)_3 + 3CH_3COX \text{ or excess} \rightarrow SmX_3.CH_3COOR + 2CH_3COOR.$$

(Where R = $C_4H_9^n$, $C_3H_7^i$, or $C_4H_9^t$ and X = Cl or Br.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It was noteworthy that the halide alkoxides so formed exhibit an increasing tendency to add on the molecule of ester formed in the reaction itself. It may be that the replacement of the alkoxy group by a more electronegative halide radical would tend to decrease electron density around the samarium atom thereby increasing the tendency to accept donor bonds from organic ester molecules.

All these halide alkoxides are sparingly soluble in the alcohol of the parent alkoxide and are insoluble in benzene. Thus the molecular weight could not be determined.

To give support to the above reactions, the reactions of anhydrous samarium trichloride with excess of the corresponding ester were carried out. Products of the type $SmCl_3.CH_3COOR$ (where R = $C_4H_9^n$, $C_3H_7^i$, $C_4H_9^t$, $C_3H_7^n$, $C_4H_9^s$, $C_4H_9^i$, CH_3, and $C_5H_{11}^n$) were obtained.

For a complete comparative study, the reaction of samarium isopropoxide with anhydrous hydrogen chloride gas was also studied. The reaction was exothermic and the product (chlorine to samarium ratio 3:1) insoluble in benzene was obtained. When the mixture was cooled, the triisopropanol derivative crystallized from the solution. This shows that the product obtained as above is the same as that obtained by a reaction between anhydrous samarium trichloride and isopropanol.

$$Sm(OPr^i)_3 + 3HCl \rightarrow SmCl_3.3Pr^iOH$$

$$SmCl_3 + 3Pr^iOH \rightarrow SmCl_3.3Pr^iOH$$

EXPERIMENTAL

Apparatus

An all-glass apparatus fitted with interchangeable standard joints was employed and adequate precautions were taken to exclude moisture. Fractionations were carried out in a column packed with Raschig rings and fitted to a stillhead.

Materials

Samarium isopropoxide and normal butoxide were prepared by the sodium alkoxide method (10) and were analyzed before use. Samarium *tert*-butoxide was prepared from isopropoxide by alcohol interchange technique. Benzene (B.D.H.) was dried over sodium wire followed by a careful fractionation over a long column. Acetyl chloride (B.D.H./A.R) and acetyl bromide (B.D.H./A.R.) were distilled at 51–52 °C and 76 °C respectively before use. The organic esters were prepared (11), dried over anhydrous sodium sulfate, and purified by careful fractionation, and a middle fraction was taken.

Analytical Methods

Samarium was estimated gravimetrically as its sesquioxide (Sm_2O_3) by igniting the oxalate. Halogens were estimated as silver halide by gravimetry. The isopropoxy group was estimated by oxidation with normal potassium dichromate in 12.5% sulfuric acid (12).

Reactions

Reaction of Samarium Isopropoxide with Acetyl Chloride in Molar Ratio 1:1

When samarium isopropoxide (1.15 g) was allowed to react with acetyl chloride (0.280 g) in benzene, an exothermic reaction occurred. The contents were shaken well and then refluxed at low temperature for 1 h. The compound settled from the reaction mixture as soon as the acetyl chloride was added to the alkoxide solution. The excess of the solvent was then removed at room temperature and under reduced pressure. On drying, a white powdered compound was obtained. Yield 1.02 g.

Anal. Calcd. for $SmCl(OPr^i)_2$: Sm, 49.5; Cl, 11.7. Found: Sm, 49.1; Cl, 11.9.

Reaction of Samarium tert-Butoxide with Acetyl Bromide in Molar Ratio 1:Excess

When acetyl bromide (2.67 g) was admitted to a benzene solution of samarium *tert*-butoxide (1.23 g), an exothermic reaction occurred with the precipitation of a yellow solid. The reaction mixture was refluxed for 1 h. The excess solvent was then removed under reduced pressure at room temperature and finally a yellow powdered solid was obtained. Yield 1.24 g.

Anal. Calcd. for $SmBr_3.CH_3COOBu^t$: Sm, 29.7; Br, 47.4. Found: Sm, 30.2; Br, 47.0.

Other reactions of samarium alkoxides with acyl halides are summarized in Tables I, II, and III.

Reaction of Samarium Trichloride with tert-Butyl Acetate (Excess)

When samarium trichloride (1.23 g) was allowed to react with *tert*-butyl acetate (39.7 g), an exothermic reaction occurred. After the mixture was shaken for 15 min, a curdy precipitate appeared. The reactants

TABLE IV

Reactions of samarium trichloride with esters

Samarium trichloride (g)	Esters (g)	Product, its state and amount	Analysis				Remarks
			Found (%)		Calcd. (%)		
			Sm	Cl	Sm	Cl	
1.426	CH_3COOPr^i (39.7)	$SmCl_3.CH_3COOPr^i$ white powdered solid (1.48 g)	41.9	29.2	41.9	29.67	All these derivatives have a fruity odor. They are solids, insoluble in benzene and readily soluble in water
1.366	CH_3COOBu^n (46.2)	$SmCl_3.CH_3COOBu^n$ yellow crystalline solid (1.41 g)	40.1	28.7	40.3	28.57	
1.227	CH_3COOBu^t (39.7)	$SmCl_3.CH_3COOBu^t$ faint-yellow solid (1.26 g)	40.7	28.9	40.3	28.57	
1.337	CH_3COOPr^n (45.3)	$SmCl_3.CH_3COOPr^n$ faint-yellow solid (1.40 g)	43.0	29.0	41.9	29.67	
1.126	CH_3COOBu^s (41.2)	$SmCl_3.CH_3COOBu^s$ yellow crystalline solid (1.21 g)	40.9	28.7	40.3	28.57	
1.219	CH_3COOBu^i (35.6)	$SmCl_3.CH_3COOBu^i$ faint-yellow solid (1.25 g)	40.0	28.9	40.3	28.57	
1.429	CH_3COOMe (38.7)	$SmCl_3.CH_3COOMe$ faint-yellow solid (1.45 g)	43.7	33.1	44.1	33.1	
1.221	CH_3COOAm^n (38.4)	$SmCl_3.CH_3COOAm^n$ deep-yellow solid (1.25 g)	39.1	27.9	38.9	27.5	

were then refluxed and the excess ester removed under reduced pressure at room temperature; on drying, a white compound was obtained.

Anal. Calcd. for $SmCl_3.CH_3COOBu^t$: Sm, 40.3; Cl, 28.57. Found: Sm, 40.7; Cl, 28.9.

Other reactions of samarium trichloride with esters are given in Table IV.

Reaction of Samarium Isopropoxide and Anhydrous Hydrogen Chloride Gas in Benzene

Samarium isopropoxide (1.23 g) was dissolved in benzene (60.2 g) and a controlled current of dry hydrogen chloride gas was passed through the solution. The reaction was exothermic and immediately a faint-yellow solid separated from the solution. After completion of the reaction, indicated by the cooling of the reaction flask, the solution was filtered and the precipitate was dried under reduced pressure.

Anal. Calcd. for $SmCl_3.3Pr^iOH$: Sm, 34.4; Cl, 24.34; Pr^iOH, 41.2. Found: Sm, 34.7; Cl, 24.8; Pr^iOH, 41.9.

ACKNOWLEDGMENTS

The authors are thankful to Prof. R. C. Mehrotra, Head of Chemistry Department, and Dean, Faculty of Science, Rajasthan University, Jaipur, for his valuable suggestions and to Dr. S. N. Misra for his interest in the work. Thanks are also due to Prof. R. C. Kapoor, Head of Chemistry Department, and Dean, Faculty of Science, Jodhpur University, for laboratory facilities. One of us (B. S. S.) is thankful to Ministry of Education, Govt. of India, for a research fellowship, during the tenure of which this work was carried out.

HEATS OF POTASSIUM–LITHIUM ION EXCHANGE ON SULFONATED POLYSTYRENE RESINS

W. R. HEUMANN AND D. PATTERSON
Département de chimie, Université de Montréal, Montreal, Quebec

Received March 11, 1966

ABSTRACT

A Tian–Calvet microcalorimeter has been used at 25 °C to measure the heats of the exchange between K^+ and Li^+ as a function of the ionic composition of commercial Dowex 50W exchange resins of the following divinylbenzene contents: 1, 4, 8, and 16%. The heats, which are exothermic for the forward reaction, where K^+ replaces Li^+ on the resin, and endothermic for the reverse direction, increase with the degree of cross-linking. A sharp variation in the heat with ionic composition of the resin is observed for the forward exchange at low K^+, and for the reverse exchange at low Li^+ content. These results are consistent with a non-uniformity of the resin.

INTRODUCTION

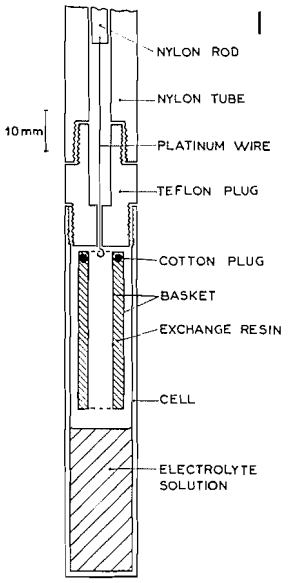
Only few calorimetric determinations have been made of heats of cation exchange (1–4) on sulfonated resins, or of their variation as a function of the ionic composition of the resin. In particular, results are lacking for the extreme ends of the composition range where the heat effects to be measured are relatively small. We have attempted to obtain data using a highly sensitive microcalorimetric method. The exchange between K^+ and Li^+ was studied since comparatively large heats could be expected, there being a considerable difference in selectivity of the ion exchanger toward the two cations.

EXPERIMENTAL

Materials

The ion exchangers were the commercial Dowex 50W resins of 30–50 mesh/in. size in the swollen state, and having degrees of cross-linking corresponding to 1, 4, 8, and 16% divinylbenzene content. They were purified by removing traces of heavy metals as described by Edge (5), then converted into either the potassium or the lithium form and washed with deionized distilled water. The resins are labelled according to their degree of cross-linking and the cationic form X1 K, X1 Li, X4 K, etc. Exchange capacities were determined as described by Kunin (6) by alkalimetric titrations of the hydrogen form after drying for 48 h at 120 °C.

Solutions of KCl and LiCl were prepared with reagent grade material and deionized water. Their concentrations were determined by titrating with standard $AgNO_3$ solution.



Apparatus

The calorimetric measurements were carried out using a Tian–Calvet microcalorimeter of the differential isothermal type which has been described elsewhere (7, 8). In our installation, a photo-pen recorder followed the light beam reflected from the galvanometer mirror. The instrument was calibrated electrically, and the heat absorbed or liberated by the reaction was found by measuring the area under the curve. This microcalorimeter is sensitive to a thermal effect of about 0.001 cal/h and is designed to follow thermal phenomena over extended periods of time.

The calorimetric cell is shown in Fig. 1. The cylindrical vessel containing the solution of the exchanging electrolyte was of stainless steel. The basket containing the ion exchanger consisted of two concentric cylinders of 100 mesh/in. platinum gauze, welded onto a supporting frame of platinum. The whole basket including the welding was of pure platinum to avoid any thermal effect by electrolytic corrosion. For the same reason, the inner wall of the stainless steel vessel was lined with a thin film of plastic, which was applied by vaporizing a solution in a volatile solvent. The basket was suspended by a platinum wire connected to a nylon rod. This rod, together with the surrounding nylon tube protruded through the top of the calorimeter and could be moved up and down. The opening in the Teflon plug leading the platinum wire was filled with silicone grease to avoid any thermal effect by either evaporation of water or friction due to movement of the wire.

Method

The ion exchanger sample was placed in the space between the two cylinders in the basket, dried 48 h at 120 °C to determine its anhydrous weight, then soaked in a chloride solution of its own cation having the same mean ion activity as the solution of the exchange electrolyte with which the ion exchanger was to react.

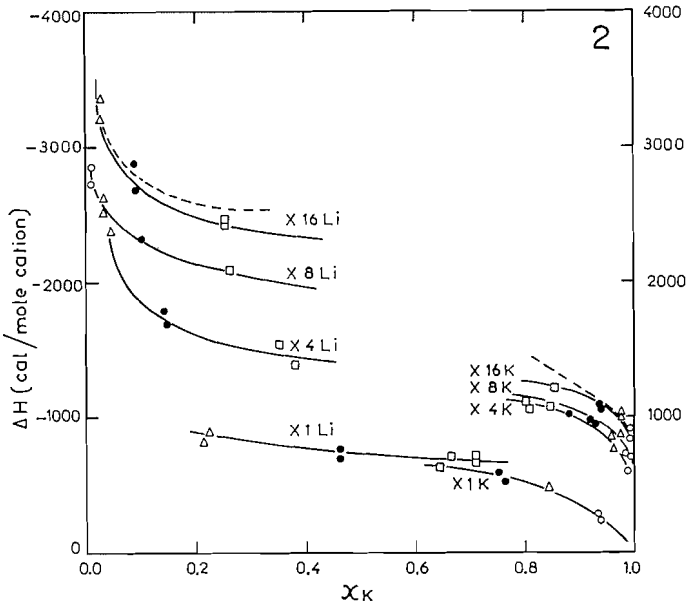


FIG. 1. Calorimetric cell assembly.

FIG. 2. Integral heats of exchange (ΔH) for Dowex 50W resins as a function of potassium mole fraction of resin cation at equilibrium, % divinylbenzene contents and original cationic forms of the resins as indicated. Left-hand scale for reaction on the resin for replacement of Li by K and the right-hand scale for replacement of K by Li. External solution molarities indicated by: ○, 0.01 M; △, 0.032 M; ●, 0.10 M; □, 0.32 M. The broken curves ($\Delta H'$) for the X16 Li and X16 K resins were obtained using the correction procedure of eq. [1].

This minimized heat effects by changes of concentration in the liquid phase during the reaction and by swelling or shrinking of the resin. The soaked sample was weighed again to determine the amount of solution retained. The basket was then suspended in the upper part of the cell as shown in Fig. 1, i.e. above 5 ml of the exchange electrolyte solution which had been placed into the cell in advance. The whole cell assembly was introduced into the calorimeter and allowed to reach thermal equilibrium overnight. All experiments were carried out at 25 ± 0.05 °C. To start the reaction, the basket was lowered until it reached the bottom to stay thus immersed during the experiment. Between 2 and 4 h were required to record the total heat effect. The larger effects obtained with the more highly cross-linked resins required more time, because the exchange reaction is slower in these resins. Stirring by moving the basket up and down then produced no further heat effect due to exchange, showing that equilibrium was attained. The basket with the exchanger was then transferred to a small column resembling the lower part of a buret, and the solution electrolyte was removed quantitatively by washing with water. The effluent was combined with the reacted solution from the cell to determine both the potassium and lithium content by flame photometry using a Zeiss PMQII spectrophotometer. From this analysis, the weight of the anhydrous exchanger and its exchange capacity, the amount of exchanged ions and the equilibrium ionic composition of the ion exchanger could be computed.

The washed exchanger in the basket was prepared for the next experiment by converting it into the desired pure cation form with the corresponding 2M chloride solution. The same sample could thus be used for a series of measurements.

Integral heats of exchange were obtained by starting each experiment with the resin in either the pure K^+ or pure Li^+ form. The extent of exchange in attaining equilibrium was varied by changing the molarity of the LiCl or KCl solutions used to effect the exchange. The effect of changing the ionic strength of the solutions on the heats of exchange will be shown below to be negligible to small.

RESULTS AND DISCUSSION

The experimental integral heats of exchange (ΔH), expressed per mole of exchanged cation, are shown in Fig. 2 as a function of the ionic composition of the resin at equilibrium, i.e. of the potassium fraction, x_K, of the resin phase ions. On the left of the figure are the negative ΔH values for reactions starting with the resin in the pure Li^+ form, and on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

right the positive ΔH values observed for the resin initially in the K^+ form. The ionic strengths of the exchange solutions are also indicated. The precision of the calorimetric results ranges from $\pm 2\%$ for the highest measured values to $\pm 10\%$ for the smallest. The accuracy is estimated to be also of this order.

Corrected values of the heat of exchange ($\Delta H'$) may be calculated bringing the pure or mixed resins and the solutions to standard states chosen to be equilibrium with pure water for the resins and infinite dilution for the solutions. Thus, for a reaction starting with the pure Li^+ resin (LiR) and KCl solution of molarity M and proceeding towards the mixed resin of composition x_K, we find

$$[1] \qquad \Delta H' = \Delta H - \{\varphi_{LiCl} M - \varphi_{KCl} M\} - \frac{}{x_K}\{\Delta H_{res}(LiR) - \Delta H_{res}(LiKR)\}.$$

Here the φ are the relative apparent molar heat contents of the indicated electrolyte solutions, values of which have been tabulated (9). The heat of mixing equal quantities of 1 M LiCl and KCl solutions is <20 cal/mole of salt (10); in the present calculation concerning much less concentrated solutions, the heat content of the mixed electrolyte has therefore been replaced with negligible error by the appropriate average of heat contents for the pure electrolytes. The ΔH_{res} are the heats, expressed per mole of resin cation, associated with swelling the pure LiR and the mixed resin as they pass to the standard state. A different, but sensitive, calorimeter was used to investigate these heats; in going from equilibrium with 1 M solutions to equilibrium with pure water no heats beyond experimental error could be found using the resins of different cross-linking in the pure forms (i.e. <20 cal/mole of cation). The concentrations of concern here are much less than 1 M, and hence the second correction term of eq. [1] can be omitted. $\Delta H'$ values are then found and are almost negligibly different from the ΔH values; they are shown in Fig. 2 for the two resins X16.

The main qualitative feature of the results is the rapid variation of the integral heats of exchange at the extremes of the range of ionic composition. (The differential heats would present a similar behavior.) Further points toward the middle of the composition range were obtained by using solutions at 1 M. They are not reproduced here because the corrections given by eq. [1] become rather large and may be uncertain. However, it seems clear that there is a relatively slow variation of the heats in the middle region. A decrease of the absolute value of the heat of exchange, $|\Delta H|$, with increasing uptake of the preferred K^+ ion, is in accord with (*a*) a non-uniformity of the resin arising from either local variations of cross-linking density (11) or of the nature of the exchange sites (12), or (*b*) ion-binding as in the Rice–Harris theory (13). In this theory, the decrease of selectivity, or of $|\Delta H|$ is due to the resin being able to hold cations in two states—an unbound state having no selectivity, and a bound state which accounts for the overall selectivity of the resin. Thus even for the uniform resin this model corresponds to two types of "sites" in the resin, leading to a decrease of $|\Delta H|$ with x_K as relatively more of the K^+ ions are found in the unbound state. Furthermore, the higher the degree of cross-linking the greater the fraction of ions in the bound state and the greater $|\Delta H|$ and its variation.

ΔH also changes owing to electrostatic effects and an increase of total ion-binding as x_K increases. These effects, however, have been shown in a number of examples (13) to be of lesser importance as far as selectivity is concerned. Neglecting them, simple calculations show that the ion-binding theory alone cannot give the S-shaped curves of Fig. 2 but only a "smooth" decrease of $|\Delta H|$. The shape of the curves suggests that the resin itself must be non-uniform as indicated by refs. 11 and 12.

THE THERMAL UNIMOLECULAR ISOMERIZATION OF 1,2-DICHLOROETHYLENE[1]

L. D. HAWTON AND G. P. SEMELUK
Chemistry Department, University of New Brunswick, Fredericton, New Brunswick

Received April 6, 1966

ABSTRACT

The thermal *cis–trans* isomerization of 1,2-dichloroethylene in a toluene carrier was found to follow first order kinetics at temperatures below 846 °K. Within the limits of detection, no decomposition was observed, but there was evidence of a surface contribution to the isomerization. The results, extrapolated to a surface to volume ratio of zero, give for the *cis* to *trans* conversion

$$k_1 = 5.7 \times 10^{12} \exp(-56\,000 \text{ cal}/RT)$$

and for the reverse action

$$k_{-1} = 4.8 \times 10^{12} \exp(-55\,300 \text{ cal}/RT).$$

It is concluded that previous investigations which did not use a radical scavenger most probably were observations of a mixture of radical chain, heterogeneous, and unimolecular contributions to the isomerization.

It has become increasingly evident in recent years that many of the *cis–trans* isomerizations originally classified as homogeneous unimolecular reactions were in fact radical-induced or heterogeneous processes. In particular, the low frequency factor – low activation energy isomerizations for which the (non adiabatic) singlet–triplet–singlet theory (1, 2) of the reaction path has been developed have become suspect. Implicit in many of the early studies is the assumption that "conditioning" the reaction vessel to obtain a reproducible reaction finally yields a homogeneous unimolecular reaction. A representative example is that of the isomerization of 1,2-dichloroethylene (3), in which it has been shown that the reproducibility achieved is very seldom better than 50% in the rate constants (4). Steel (5) has demonstrated that under these conditions the isomerization is a radical chain reaction, and that the best reproducibility in a static system is obtained by starting with a fresh "clean" surface for each reaction. A differential calorimetry study by Kapralova and Semenov (6) on the pyrolysis of 1,2-dichloroethane is probably pertinent in the understanding of these reactions. This investigation indicated that carbonizing the walls of the reactor did not completely eliminate radicals from the system, but only decreased their rate of production. At the same time, the heterogeneous contribution reached a limiting low value on a thoroughly conditioned surface.

Molera and Ariza (7) have reinvestigated the isomerization of dichloroethylene using essentially the same approach of conditioning the reactor through repeated runs in a painstaking attempt to achieve reproducibility. However, even for the "reproducible" reaction there was in the first five minutes of each experiment a significant deviation from a first order reaction. The reported rate constants are derived from the latter part of the reaction where first order behavior is observed. By choosing the lowest measured rate values at a number of temperatures they obtained an activation energy of 52.1 kcal/mole for the *cis* to *trans* conversion, and 51.6 kcal/mole for the reverse reaction. It would appear therefore that the mechanism in the early stages of the reaction differs in some way from that in the latter stages.

In view of the difficulties associated with the interpretation of data obtained under experimental conditions which allow a mixed mechanism to operate, we felt it would be

[1]*Abstracted from Part I of the Ph.D. thesis of L. D. Hawton, 1965.*

worthwhile to study the isomerization in a toluene carrier. The system we adopted differed from the conventional only in that the toluene pressure in the reactor was considerably higher than customary. These conditions should be unfavorable to the initiation of a radical chain conversion, and the higher pressure should decrease the proportion of the heterogeneous component. This approach has proven quite successful.

EXPERIMENTAL

The reduced pressure flow apparatus, attached at convenient points to a conventional high vacuum system, was similar to that employed by Szwarc (8) except that all sections carrying feed or effluent gases were wound with resistance wire and heated electrically to about 90 °C. The reservoir pressures of toluene and dichloroethylene were controlled by thermostating the reservoirs at the appropriate temperatures, and the flow of these gases and their ratio was controlled by means of capillary flow meters. The residence time within the reactors was determined by a capillary at the exit of the reactor, with the effluent being condensed and trapped just beyond the capillary in a modified Le Roy still so that the pressure in this section never exceeded 10^{-4} mm.

Two Vycor reactors were used in the study, one with an internal diameter of 5.15 cm and a volume of 201 ml for which $S/V = 0.88$ cm^{-1}, and one with an internal diameter of 1.08 cm and a volume of 199 ml for which $S/V = 3.7$ cm^{-1}. With these reactors it was possible to vary the surface to volume ratio by a factor of 4.2 but to have a nearly constant volume. The electrical resistance furnace which housed the reactors had two end "maintenance" heating coils and one control winding which extended the complete length of the furnace core. The current to the control winding was regulated by a phase-shift temperature control unit based on a design by Sturtevant (8). The control unit was actuated by a platinum resistance thermometer which constituted one arm of an electronic bridge circuit. The longitudinal temperature differences in the furnace were of the order of a few degrees, while during a run the variation at any one point within the furnace was $<0.5°$.

The duration of a "run" was typically 30 min. In this period all the effluent was collected at liquid air temperatures in the modified Le Roy still. After the completion of the run the contents of the Le Roy still were warmed and cooled repeatedly in the usual manner so that any HCl produced in the reaction would be released. This "HCl fraction" was then distilled onto a small amount of NaOH contained in a second detachable trap. The contents of this trap were subsequently dissolved in HNO_3 and the chloride concentration determined by the method of amperometric titration (9) with $AgNO_3$, which has a sensitivity of about 10^{-5} g ion.

The material remaining in the still after the "removal of HCl" was then subjected to the usual type of distillation from a Le Roy still to separate the dichloroethylene–toluene solution into a dichloroethylene-rich fraction and a toluene-rich fraction, the progress of the fractionation being followed with the help of a Consolidated Vacuum Corporation Pirani gauge. The dichloroethylene-rich portion was collected in a short narrow ampoule, sealed *in vacuo*, and set aside to await injection into the chromatograph. Although time consuming, this enrichment procedure was reliable and essentially quantitative, as indicated by control distillations of prepared mixtures of the isomers with toluene.

Baker Analyzed reagent grade toluene was fractionated, the middle third being retained. Gas chromatographic analysis showed it to contain <0.01 mole % impurities.

Eastman *cis*-1,2-dichloroethylene was subjected to two successive fractionations, the middle third portion of the first being used in the second fractionation. The middle third portion of the latter was then purified by preparative gas chromatography in a Perkin Elmer model 222 chromatograph equipped with a 10 ft long, 1 in. diameter, stainless steel column packed with 25% by weight of DC 710 silicone oil on 80–100 mesh Chromosorb W. This procedure lowered the *trans* isomer concentration from 4 mole % to less than 0.1 mole %, and reduced to a negligible concentration all other impurities. After purification, the *cis* isomer was stored over purified pyro-catechol, under a purified nitrogen atmosphere in hermetically sealed containers. When needed, the dichloroethylene was distilled from the catechol at low pressures.

Analyses were carried out on an F and M model 500 Linear Temperature Programmed gas chromatograph with the ampoules injected by an F and M model SI-4 injector, into a 10 ft column containing 25% by weight of tricresyl phosphate and 2% by weight of polyethylene glycol on 80–100 mesh Chromosorb W. When a hydrogen carrier inlet pressure of 30 p.s.i.g., a flow rate of 1.2 cc/s, and a column temperature of 115 °C were used, the *trans* isomer had a retention time of 3 min and the *cis* isomer 5 min 10s. Peak areas, which were used for quantitative analysis, were measured with a Keuffel and Esser model 4242 planimeter.

RESULTS AND DISCUSSION

A summary of experimental results appears in Tables I and II, with Arrhenius plots shown in Figs. 1 and 2. The data presented refer to a residence time of 4.8 s and a molar ratio of dichloroethylene to toluene of 3×10^{-2}, except for one experiment in which the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ratio was increased to 10^{-1} as a check on the reaction order with respect to dichloroethylene. The rate constants were calculated from the integrated form of the rate law for reversible first order reactions (9)

$$[1] \qquad k_1 + k_{-1} = \frac{1}{t} \ln \frac{x'_e}{x'_e + x},$$

where k_1 is the rate constant for the forward reaction (*cis* to *trans*), k_{-1} is the rate constant for the reverse reaction and x is the amount (in terms of partial pressure) of *cis* isomer converted to *trans* during the residence time t. The quantity x'_e is given by

$$[2] \qquad x'_e = \frac{K\alpha - \beta}{K + 1},$$

where $K = k_1/k_{-1}$ is the equilibrium constant for the isomerization, α is the initial pressure of *cis* isomer, and β is the initial pressure of the *trans* isomer. The equilibrium constant K was calculated from the appropriate thermodynamic functions which Pitzer and Hollenberg have derived from spectroscopic and other data (10). Since the *cis* isomer was almost exclusively used, the reverse rate constant k_{-1} reported here is actually the

TABLE I

"reflection" of the forward constant through this equilibrium constant, and therefore, contains the errors of both k_1 and K. However, a few check runs carried out by using 99.5 mole % *trans* isomer and the same method of calculation gave values of k_1 and k_{-1} not significantly different from those listed. The rate constants for the two reactors having different S/V values are listed in Table I along with the values extrapolated to $S/V = 0$, according to the procedure outlined below. Table II give the Arrhenius parameters for the

forward and reverse reactions obtained by the method of least squares. The Arrhenius plots of these data are shown in Figs. 1 and 2 in order to illustrate the remarkable reproducibility which can be achieved with this experimental approach. The results obtained were independent of the order with respect to temperature in which the runs were made, but the reactors may be considered "conditioned" since a toluene–dichloroethylene feed mixture had been previously passed through for a short time. Many of the runs listed in Table I are consecutive ones, and do not represent "best" values selected from different experimental sequences, which has been the questionable practice of some previous investigators.

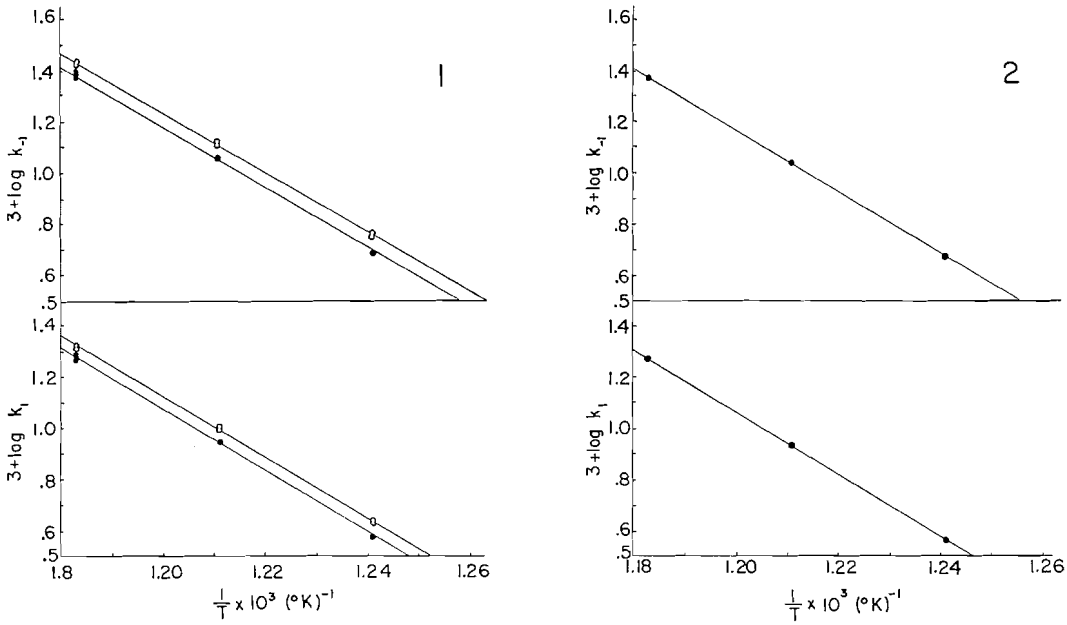

FIG. 1. Arrhenius plots of the data given in Table I: ○, $S/V = 3.7$ cm^{-1}; ●, $S/V = 0.88$ cm^{-1}.
FIG. 2. Arrhenius plots of the data given in Table I for $S/V = 0$ cm^{-1}.

Since it was obvious from the results obtained in the two reactors of different S/V values that there was a heterogeneous isomerization, the results were extrapolated to $S/V = 0$, according to the following considerations:

At the temperature and pressures used in this study, it is reasonable to assume that only a monolayer adsorption would be important, and that the extent of surface coverage would be very small. On this basis one would expect the total material adsorbed at a constant pressure to be proportional to the surface area. Since there are two unimolecular components in this reaction, the completely homogeneous and the purely heterogeneous, the rate equation can be expressed

$$[3] \qquad \text{Rate} = k_{obs}[cis]_g = k_{het}(cis)_s + k_{homo}[cis]_g,$$

where k_{obs} is the rate constant obtained directly from the experimental data, k_{het} and k_{homo} are the rate constants for the heterogeneous and homogeneous components respectively, $[cis]_g$ is the concentration or partial pressure of the *cis* isomer in the gas phase,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and $(cis)_s$ the quantity adsorbed on the surface. Further, because of monolayer adsorption, we may assume that the following relationship holds

[4] $$(cis)_s = b[cis]_g$$

where b is a proportionality factor. Putting this into [3] gives

[5] $$k_{obs} = bk_{het} + k_{homo}$$

and taking logarithms

[6] $$\ln k_{obs} = \ln \{k_{homo} + bk_{het}\}$$
$$= \ln k_{homo} + \ln \left\{1 + b\frac{k_{het}}{k_{homo}}\right\}.$$

Since the contribution from the heterogeneous reaction is small and decreases as S/V becomes smaller, this equation becomes

[7] $$\ln k_{obs} = \ln k_{homo} + b\frac{k_{het}}{k_{homo}}$$
$$= \ln k_{homo} + \frac{k_{het}}{k_{homo}} \cdot \frac{(cis)_s}{[cis]_g}.$$

Then, in any experiments which differ only in S/V values, but which have the same constant volume, the concentration of *cis* isomer in the gas phase is constant, and therefore the amount of *cis* isomer on the surface is proportional to the surface area of the reactor. Therefore a plot of $\ln k_{obs}$ versus surface area, or S/V (for reactors having equal volumes) will give a straight line as $S/V \rightarrow 0$. This extrapolation to $S/V = 0$ is readily recognized as being equivalent to an extrapolation to $(cis)_s = 0$. The value of k obtained from this extrapolation will be that for the purely homogeneous component.

The present study indicates that the effect of the heterogeneous component is to decrease both the observed activation energy and the pre-exponential factor of the rate constant. As a consequence of these observations, it is not surprising that the activation energies reported by Molera and Ariza are somewhat lower than those observed in this investigation. In fact, the activation energies which are noted in Table II are, to the best of our knowledge, the highest ever reported for this isomerization. It seems possible that the reaction observed by Molera and Ariza contained not only a homogeneous and heterogeneous component, but quite probably a radical-induced isomerization as well. This latter is indicated by the presence of both HCl and heavy products in their experiments. HCl was determined by the Volhard method, which is somewhat less sensitive than the amperometric titration method used in the present study. We estimate the extent of decomposition in our study to be <0.6 mole %. Neither HCl nor any other decomposition product was detected in any experiment.

Although the lower activation energies for the isomerizations reported by Molera and Ariza are readily explained as being due to contributions from heterogeneous and radical chain mechanisms, it is not entirely clear why their pre-exponential factors should be so high (10^{15} s^{-1}). Indeed, it is uncertain whether or not any significance should be attributed to them. If an explanation is sought, the clue may lie in the differences in pressure used in the two studies. Thus, our experiments were performed at pressures no greater than 4 cm Hg, while the static system studies used pressures as great as 35 cm. A classical explanation of high pre-exponented factors at such pressures has been advanced (11), which would imply that our investigations were carried out in the region of the transition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pressure where the rate of isomerization would be limited by the frequency of bimolecular collision. However, the evidence from other isomerization studies on similar molecules indicates that this is unlikely. Thus, the pre-exponential factor for the isomerization of *trans*-dideuteroethylene has been reported (12) as 3.3×10^{12} s^{-1} in substantially the same pressure region. Similarly, the isomerization of *cis*-butene-2 which has many more degrees of freedom, gives a "high pressure" pre-exponential factor in the range 6.1×10^{13} s^{-1} (13) to 10^{14} s^{-1} (14).

The results of our study suggest it may be possible to use the toluene carrier technique in isomerization investigations of other ethylenic derivatives in which radical chain contributions are suspected, especially those in which relatively reactive radicals may be formed. Although it is possible to isolate the homogeneous unimolecular isomerization reaction with this technique, it may not be readily adaptable to the testing of theories of unimolecular reactions. However, it could give a reliable estimate of the potential barrier to isomerization in the ground electronic state.

PHOTOLYSIS OF GROUP VI HYDRIDES

I. SOLID H_2S, H_2S_2, AND D_2S

ABSTRACT

The primary photochemical step occurring in solid H_2S, D_2S, or H_2S_2 was shown to be loss of a hydrogen or deuterium atom. Electron spin resonance spectra are assigned to HS, DS, and HS_2, which have not previously been detected in the solid phase, and behavior of these radicals on warming the samples is described. When H_2S and D_2S matrices were warmed from 77 to 125 °K, the HS and DS spectra collapsed into a doublet and singlet respectively. The hyperfine splitting in HS increased and both signals appeared at lower average g-values than when anisotropically broadened at 77 °K.

INTRODUCTION

Much attention has been devoted to the gas phase photochemistry of the Group VI hydrides as these compounds may readily be prepared and handled and, further, show simple effects of changing atomic number and size of the heavy atom. Photolysis of H_2S vapor ($\lambda > 2\,000$ Å) has been monitored by kinetic spectroscopy (1, 2) and undoubtedly the primary process is

[1] $$H_2S \rightarrow H + HS$$

Abstraction from the substrate and disproportionation of HS subsequently form H_2

[2] $$H + H_2S \rightarrow H_2 + HS$$

[3] $$HS + HS \rightarrow H_2 + S_2$$

The activation energy of reaction [2] is unknown. However, by comparison with results for mercaptans (3) the value is likely to be >5 kcal/mole, which would almost certainly preclude its occurrence at 77 °K. In addition to the intense absorption spectrum of ground state S_2, a weak band system at longer wavelengths was noted in the flash photolysis experiments. This persists for $\sim$100 μs and may be assigned to HS_2, since it is present strongly in flashed H_2S_2 (4). However, the exact course of processes forming HS_2 in flashed H_2S has not yet been determined.

Reaction [2] has been exploited in gas phase electron spin resonance (e.s.r.) studies of the radicals HS or DS, in which products of an electric discharge through H_2 or water vapor were mixed with H_2S or D_2S in specially designed spectrometer cavities. Electron spin resonance absorption was detected and assigned to HS (5, 6) and DS (5), each in the lowest rotational state, $^2\Pi_{3/2}(J = 3/2)$; e.s.r spectroscopy of molecules with smaller moments of inertia is complicated by the large array of rotational states and sub-levels populated in the gas phase. It is therefore convenient to study such species in the solid state, where rotation is restricted, although less information about the molecular parameters is obtained since the energy levels are 'broadened' by anisotropy. It is a further advantage that many radicals persist for long periods when trapped in solid matrices, particularly at low temperatures.

We have irradiated H_2S ($\lambda > 2\,200$ Å), both pure and in various matrices, in order to characterize the primary photolytic steps at 77 °K and to identify e.s.r. spectra of the radicals so formed. Earlier results from this laboratory (7) showed that sulfur atoms

and S_2, produced by photolysis of COS, polymerized rapidly to long chains of about 10^3 atoms. Emphasis in this investigation was therefore placed on the effects of different matrix materials on migration and subsequent reactions of the radicals. Acetylene, ethylene, and *trans*-2-butene were employed as reactive matrices, in an attempt to study some simple organic sulfide radicals. Additional experiments were performed with samples of H_2S_2 and D_2S, in order to accumulate further evidence concerning the photolytic steps of sulfur hydrides.

RESULTS

A pale yellow coloration formed during photolysis ($\lambda > 2\,200$ Å) in pure samples of H_2S, D_2S, and H_2S_2. No coloration or e.s.r. signals were observed in samples exposed to light filtered through Corex glass which transmits $\lambda > 2\,800$ Å. With the filter removed from the light path, all samples developed e.s.r. spectra (A, B, C, or D) during irradiation at 77 °K (Figs. 1–3), of which the principal features are listed in Table I. Substantially the same signals were present in irradiated H_2S (100%) and H_2S in inert matrices (20% in Xe or 1%, 20% in C_3F_8). In a sample of H_2S (1% in Xe) the spectrum B was enhanced slightly relative to spectrum A. Additional diffuse signals in the region of $g = 2.04$ appeared in samples of H_2S in 'reactive' matrices (1% in C_2H_2, C_2H_4, or *trans*-2-butene) but the spectra were very weak, even after prolonged periods of irradiation.

In an attempt to detect short-lived precursors of the observed radicals, some samples were irradiated in the microwave cavity. However, no differences were apparent in the relative intensities of spectral lines, and no new signals were detected. The spectra in irradiated samples persisted for several weeks on storing at 77 °K.

Significant changes occurred in the observed e.s.r. spectra of all samples, when the temperature was raised above 77 °K and the effect of different matrix materials on the fragments from H_2S was studied in detail. Interpretation in some experiments was handicapped by overlapping of lines when two or more radicals were present. When samples of irradiated H_2S (100%) were warmed to 125 °K, the spectrum illustrated in Fig. 4 was observed. Quite different behavior was noted in a sample of H_2S (20%) in a xenon matrix. On warming this sample to 100 °K, the outer lines of spectrum A decayed markedly, while the central line and spectrum B increased in relative intensity. A three-line spectrum without hyperfine structure remained at 110 °K, which degenerated

D_2S	100% (125 °K)	Single intense line Weak structure	2.002	DS ·(S)$_n$·	

into a single line at 120 °K, but reverted to the three lines on recooling to 77 °K. At ~140 °K, a broad weak signal appeared at lower fields, and the central spectrum decayed, suggesting that the temperature was near the melting point of the matrix (m.p. of Xe, 153 °K).

There was little alteration of the spectra on warming the D_2S sample to 110 °K. At 125 °K, however, we observed rather similar changes to those detected in H_2S. Spectrum B increased in relative intensity, while spectrum C apparently had collapsed into a single line at $g = 2.00$. On recooling to 77 °K, the original three-line spectrum (C) reappeared in place of the single line, while spectrum B was altered little. By 140 °K, the spectra had decayed almost completely. The spectrum from H_2S_2 gradually decayed as the temperature was raised, without significant changes in relative intensities of the lines.

DISCUSSION

Assignment of Electron Spin Resonance Spectra

The intense three-line spectra from H_2S (A) and D_2S (C) appear at the same average g-values, within uncertainty of measurement (Table I). A three-line spectrum is characteristic of randomly orientated molecules possessing anisotropic g-tensors. (8) The hyperfine structure (h.f.s.) of A is consistent with that of a radical containing a single proton, and therefore spectra A and C are assigned, respectively, to HS and DS. The magnetic moment of a deuteron is 31% of that of a proton, and therefore the three line h.f.s. due to D($I = 1$) in DS is much smaller than that due to H in HS, and was not resolved in these experiments, or in the gas-phase work (5). The average h.f.s. in HS is 7 G, which is comparable with the gas-phase value of 5.4 G (5). To a first approximation, the h.f.s. is in direct proportion to the spin carried in the 1s orbital of the proton (9). Since the nuclear splitting of free H is 505 G, we estimate that 1.5% of the spin in HS resides in the 1s orbital of H. The Λ splitting in the spectrum (190 G for HS in the gas phase) was not detected, and its absence is attributed to decoupling of orbital and spin angular momenta of HS in the field of neighboring molecules.

The e.s.r. spectrum observed after photolysis of H_2S_2 has a rather similar appearance to the spectrum assigned to sulfur chains (7), which has principal g-values of 2.002, 2.028, and 2.042. However, the central line of the spectrum reported here lies at $g = 2.025$, differing from the position of the $\cdot(S)_n\cdot$ line by an amount greater than experimental errors. Although h.f.s. was not observed, this spectrum is assigned to HS_2, which is known to form, together with HS, in flashed H_2S_2 vapor (3). Absence of h.f.s. is consistent with a crude model of HS_2 built from S_2 by adding H$\cdot$ to one of the two equivalent orthogonal non-bonding orbitals. The single electron in the other non-bonding orbital of such a model then has zero interaction with the proton. However, a similar model predicts zero h.f.s. in HS; the observed h.f.s. is presumably due to configurational interaction of a type similar to that responsible for the h.f.s. in hydrocarbon radicals. An additional weak signal (B) was present in irradiated H_2S and D_2S, which could correspond to the low-field component of either HS_2 or $\cdot(S)_n\cdot$, the other lines being obscured by the more intense HS or DS spectra. Unequivocal distinction between these carriers is impossible here, since the spectra are very weak. Sulfur polymers form in much greater yield than HS_2 when H_2S is photolyzed in the gas phase, supporting our assignment of this spectrum to $\cdot(S)_n\cdot$. During warm-up experiments, the overall intensity of the spectra decreased greatly, with a corresponding decrease in the precision with which line positions could be measured. However, there is little doubt that sulfur chains are responsible for the three-line spectrum that appeared, although the warm-up behavior was rather different from that of $\cdot(S)_n\cdot$ formed in photolyzed COS (7). The warm-up characteristics of HS, DS, and $\cdot(S)_n\cdot$ will be discussed as matrix effects.

Primary Photochemical Processes

Evidence presented thus far characterizes photolysis of H_2S or D_2S as loss of H or D, which must dimerize rapidly at 77 °K, since no resonance of the free atoms was detected. Although the HS and DS spectra did not decay during several weeks storage at 77 °K, sulfur polymers were present after very short periods of irradiation, which suggests that HS and DS are generated in at least two types of lattice size, from one of which rapid chemical or physical migration is possible, prior to disproportionation (reaction [3]). The products of this reaction bear ~42 kcal/mole of excess energy (10) which may induce local melting of the matrices facilitating polymerization of S_2.

It is not possible to distinguish directly between two types of scission that might occur in H_2S_2

[4] $$H_2S_2 \xrightarrow{h\nu} HS + HS$$

[5] $$H_2S_2 \xrightarrow{h\nu} HS_2 + H$$

since HS formed in [4] might rapidly be consumed in the reaction

[6] $$HS + H_2S_2 \rightarrow H_2S + HS_2$$

Experiments with H_2S showed that the disproportionation of HS radicals (reaction [3]) is rapid; therefore, if [4] is important, sulfur chains should be detected in photolyzed H_2S_2, together with HS_2. In the gas phase photolysis, HS was observed strongly, as well as HS_2, indicating that reaction [5] is, at best, moderately fast at room temperature. It appears that the primary step in the solid-phase photolysis of H_2S_2 is S—H cleavage, even though dissociation to 2HS is ~30 kcal/mole less endothermic (10).

Matrix Effects

Surrounding molecules interact with radicals in what may broadly be described as physical or chemical processes. Physical effects of warming matrices have been discussed by Ingram (11) and are divided into transport phenomena (alterations in the freedom of motion and rotation of the radicals) and changes in the intermolecular interaction parameters with temperature. An interesting example of these effects is presented by the HS and DS radicals. On warming the H_2S or D_2S matrices to 125 °K, the spectra degenerated respectively into a doublet and a single line at *g*-values much lower than the average values measured at 77 °K (Table I). When the samples were recooled to 77 °K, the original three-line spectra reappeared, showing that this was indeed a physical effect, and not a chemical one. The collapse of a three-line spectrum into a single line is typical of a radical starting to rotate in a lattice as the temperature is raised. In addition to the change in the average *g*-value, the h.f.s. in HS increased to 10 G at 125 °K, suggesting that the spin of the unpaired electron was increasingly resident in the 1s orbital of the H atom. Both these effects indicate that changes occur in the coupling of the angular momenta associated with the spin and orbitals of the HS, caused by alterations of the interactions with neighboring molecules. However, no differences in the h.f.s. were detected in different matrices at 77 °K. As intermolecular forces become less important, the molecular *g*-value of HS changes to a value of 0.8739, observed in the gas phase (6), i.e. the changes shown in Table I are much smaller than those on changing from the gas to the solid phase.

Further changes in e.s.r. spectra of the samples in inert lattices (H_2S, Xe, or C_3F_8) are classified as chemical, and seem to be associated with increased ease of radical migration through the matrix at temperatures above 77 °K. Thus HS and DS decay forming sulfur chains, presumably via reaction [3], and subsequent polymerization of S_2. Sulfur chains in these matrices decayed at lower temperatures than those reported for decay of $\cdot(S)_n\cdot$ in photolyzed COS (7), and this may be due to processes such as

[7] $$\cdot(S)\cdot_n + HS \rightarrow \cdot(S)_nSH$$

No attempt was made to analyze photolyzed mixtures for polysulfides.

The excess energy with which S_2 or Se_2 are formed in matrices apparently determines their rates of polymerization. We have studied several systems in which sulfur (7) or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

selenium (12) chain polymers were produced via these species and the intermediate was detected only in photolyzed COSe (12). The reaction

[8] $$COSe + Se(4^3P) \rightarrow CO + Se_2$$

is probably almost thermoneutral, and the Se_2 apparently remains trapped in the matrix. When S_2 or Se_2 were formed by exothermic processes, only chain polymers were detected by e.s.r. spectroscopy. It will be interesting to determine whether disproportionation of HSe or HTe leads to stable or labile Se_2 or Te_2.

Limited information can be derived from the experiments in which H_2S was irradiated in chemically reactive matrices (C_2H_2, C_2H_4, or *trans*-2-butene), since the new spectra are very weak. Each sample displayed the HS spectrum quite strongly, with diffuse underlying structure at *g*-values above 2.00. No spectra could be assigned to hydrocarbon radicals, which are known to react rapidly with H_2S at 195 °K (13). The high *g*-values of the observed weak lines indicate that the carriers had their spins largely associated with a sulfur atom, and not a carbon atom. However, the spectra detected in irradiated sulfides are quite different (14, 15). At 77 °K, HS reacts much more slowly with the hydrocarbons than at 195 °K, which is consistent with trapping of the radicals at lattice sites in the solid phase.

EXPERIMENTAL

The main features of our experimental techniques have been reported (7, 12). Electron spin resonance spectra were obtained as the first derivative of the resonance absorption using a Varian V4502 spectrometer, operating at a nominal frequency of 9.5 Gc/s and fitted with a dual cavity (V4532) and other Varian accessories, previously described (12). Spectra were calibrated with respect to the three lines of Fremy's salt (16).

Samples were prepared in conventional high-vacuum systems, care being taken to avoid interaction of H_2S_2 with mercury or metal surfaces. Pure compounds and mixtures were distilled into quartz sample tubes at 77 °K, degassed and sealed off under vacuum, before irradiation at 77 °K in a quartz Dewar. Most samples were photolyzed externally by a Hanovia medium-pressure mercury lamp, emitting discontinuous light ($\lambda > 2\,200$ E). Other samples were irradiated in the cavity of the spectrometer by the output of an Osram high-pressure mercury arc.

Spectra of photolyzed mixtures were first obtained at 77 °K, after which warm-up experiments were performed, in which the temperature of a sample in one cavity was raised above 77 °K, using a Varian (V4547), variable temperature device.

Materials

Hydrogen sulfide was prepared by the reaction of dilute sulfuric acid with 'Analar' sodium sulfide and distillation of the product at 140 °K. Mass spectral analysis showed that the H_2S obtained in this way contained less than 0.25% H_2O. H_2S_2 was prepared by the method described by Féher (17), and distilled carefully in a metal-free vacuum apparatus.

The Xe was Airco assayed reagent grade. Acetylene and perfluoropropane (Matheson) were purified by distillation on the vacuum line and exhibited satisfactory mass spectra. Ethylene and *trans*-2-butene (Phillips research grade) were used without further purification. D_2S was obtained from Merck, Sharp and Dohme of Canada Ltd. Care was taken to deal always with a large quantity of D_2S in order to minimize effects of equilibration with water absorbed on Pyrex surfaces.

CONCLUSION

The primary photolytic step in H_2S, D_2S, and H_2S_2 ($2\,800 > \lambda > 2\,200$ Å) is loss of a hydrogen atom. Electron spin resonance spectra were assigned to HS, DS, and HS_2. Sulfur chains are formed on warming mixtures containing HS or DS; these decay rapidly, possibly by reaction with HS or DS.

New spectra were observed weakly when H_2S was photolyzed in unsaturated hydrocarbon matrices, although reaction of HS with these compounds was slow at 77 °K. The radicals apparently have free spins associated with S rather than C atoms, and are different from those detected in irradiated sulfides.

EQUILIBRIUM CONSTANTS OF ZINC(II) AND COPPER(II) WITH HEMATOPORPHYRIN IX

D. A. Brisbin and R. J. Balahura
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received October 14, 1965

ABSTRACT

Equilibrium constants have been measured for the following displacement reactions between copper(II) and zinc(II) with hematoporphyrin IX.

$Zn^{++} + PH_2 \leftrightarrows ZnP + 2H^+$ in aqueous solution at pH 7

$Cu^{++} + PH_4^{++} \leftrightarrows CuP + 4H^+$ in glacial acetic acid solution.

Preliminary measurements have also been made for the reactions of Mn(II) and Co(II) with hematoporphyrin IX in glacial acetic acid solutions.

INTRODUCTION

Metalloporphyrins play an important role as iron complexes in the hemoproteins, as magnesium complexes in chlorophylls and as a cobalt complex in vitamin B_{12}.

The porphyrin nucleus is a tetradentate ligand which in coordination with metallic cations loses the two protons from the pyrrole nitrogen atoms, leaving two negative charges distributed about the inner ring.

Monovalent metallic complexes (Na_2P, Li_2P, etc.) are known to be of low thermodynamic stability, with the cations probably sitting one above and one below the plane of the nucleus. Divalent metallic ions such as Co(II), Ni(II), and Cu(II) form neutral square planar chelates. Mg(II), Cd(II), and Zn(II) are able to add on another ligand and form a pentacoordinate complex of a square pyramidal structure, whereas Fe(II), Co(II), and Mn(II) are able to add two extra ligand molecules and form distorted octahedral complexes.

Note is made of some of the excellent review articles which discuss the structure and properties of the porphyrin complexes (1–5) and of several pertinent books (6–9).

Since the pyrrole pigments occur in essentially aqueous environments in living cells, it would be preferable to obtain data on their formation and stability constants in this medium. Their low solubility in water has prevented much quantitative measurements in this medium, and what information is available is in essentially nonaqueous or aqueous detergent solutions.

Porphyrins, unlike many ligands, require a sizeable activation energy to incorporate metal ion, and the rate of incorporation depends on the type of solvent, the particular metal, and the porphyrin being used.

Studies of replacement and dissociation reactions of metalloporphyrins have provided many qualitative estimates of relative stabilities (10–13). However, for the stability constant,

$$K_s = \frac{[MP]}{[M^{++}][P^{=}]},$$

where [MP], [M^{++}], and [$P^{=}$] are the concentrations of the complex, metal ion, and dianionic porphyrin species respectively, the only published figure is $\log K_s = +29$,

estimated for the zinc chelate of mesoporphyrin dimethyl ester in 0.25% cetyltrimethylammonium bromide solution at room temperature (14). In the absence of acid pK data for mesoporphyrin the value of 32 for the pK_1 plus pK_2 of aetioporphyrin was used in the above estimation (15).

Our present work has been concerned with obtaining quantitative measurements for the equilibrium constants of Zn(II) and Cu(II) with hematoporphyrin IX by a spectrophotometric method. These constants can then be translated into semiquantitative stability constants.

The convention of Phillips (16) of expressing both acidity and basicity of the porphyrin nucleus in terms of the negative logarithm of the acid dissociation constant has been used here.

pK values are defined as

$$pK_1 = pH - \log [P^{=}]/[PH^{-}] \qquad pK_2 = pH - \log [PH^{-}]/[PH_2]$$

$$pK_3 = pH - \log [PH_2]/[PH_3^{+}] \qquad pK_4 = pH - \log [PH_3^{+}]/[PH_4^{++}]$$

where pK_1 and pK_2 refer to the acidic equilibria involved in dissociation of protons from the pyrrole nitrogen (—NH—) and pK_3 and pK_4 to the basic equilibria associated with the addition and loss of protons to the pyrrolenine nitrogens (=N—). The structure of hematoporphyrin IX is shown in Fig. 1.

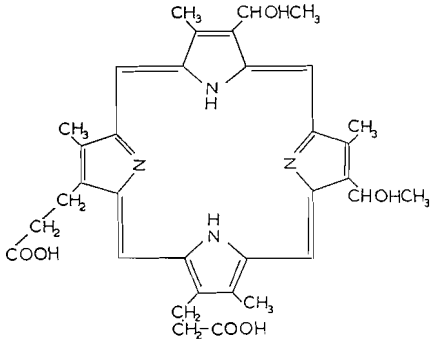

FIG. 1. Structure of hematoporphyrin IX.

Porphyrins behave as extremely weak acids. They are generally soluble in dilute acid ~ 0.1 N, and form the dication species PH_4^{++}. In general pK_3 and pK_4 differ by only 2–3 pK units, and the detection of the species PH_3^{+} is difficult, except in anionic detergent solutions.

The neutral species PH_2 is stable even in concentrated sodium hydroxide. A more alkaline medium such as sodium alkoxide is required to observe the dianion $P^{=}$ spectroscopically.

Where the porphyrin has β-substituted carboxylic acid side chains as in hematoporphyrin, there are additional pK values due to these. According to Phillips (8), the pK values of analogous pyrrole carboxylic acids are of the order of +4.8, and likely to correspond to the intrinsic pK values of similarly substituted porphyrin monocarboxylic acids. The intrinsic pK values of polycarboxylic acid porphyrins, however, would be altered by the electrostatic effect of other ionized carboxylate groups and the ionized ring nitrogens, and therefore the effective pK value will be pH dependent. The mean pK value should approach a limiting value in alkaline solutions where all carboxylic groups

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

are ionized. For a dicarboxylic acid porphyrin such as hematoporphyrin this value would be approximately +5.7.

METHOD

Spectrophotometric analysis in the 500–600 mμ region has been used to obtain the equilibrium constants for the following two displacement reactions

$$M^{++} + PH_2 \leftrightarrows MP + 2H^+$$

for Zn(II) and hematoporphyrin in aqueous solution at a pH of 7, and

$$M^{++} + PH_4^{++} \leftrightarrows MP + 4H^+$$

for Cu(II) and hematoporphyrin with glacial acetic acid as solvent.

Neutral hematoporphyrin PH_2 has a typical visible porphyrin spectrum of four bands in the region of 450–700 mμ (Fig. 2) where the intensity of band IV is > III is > II is > I, numbering from the red end of the spectrum.

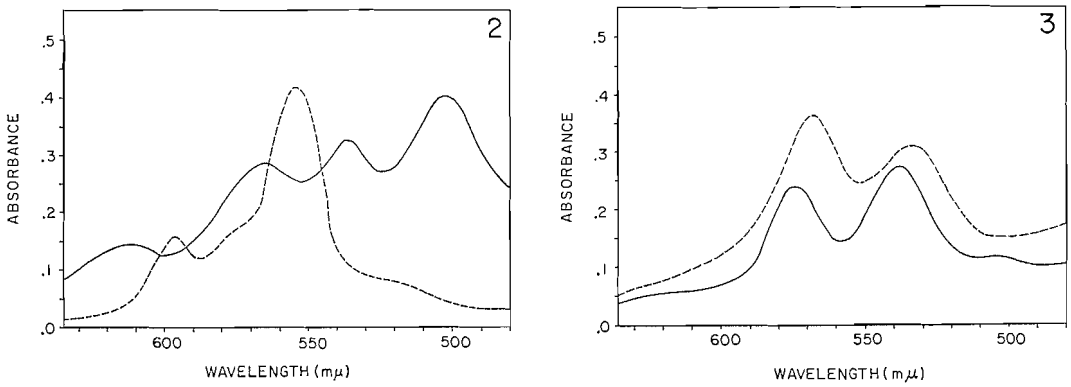

FIG. 2. Absorption spectra of hematoporphyrin IX, neutral species (PH_2), in aqueous solution, pH 7 (—) and hematoporphyrin IX, dication species (PH_4^{++}), in glacial acetic acid solution (--).

FIG. 3. Absorption spectra of Zn(II) hematoporphyrin in aqueous solution, pH 7 (—) and Cu(II) hematoporphyrin in glacial acetic acid solution (--).

The dication PH_4^{++} has a two-band spectrum (Fig. 2). When complexing occurred, the porphyrin spectrum (PH_2 or PH_4^{++}) was replaced by that of the metalloporphyrin 1:1 complex, showing two absorption peaks in the visible region known as the α and β peaks (Fig. 3). The α/β ratio of band intensities vary with the complexes. It is < 1 in ZnP and > 1 in CuP.

Since the average pK value of a porphyrin with two carboxyl side chains is considered to be about 5.7, it is probable that one if not both carboxyl groups are ionized at pH 7 and both are un-ionized in the glacial acetic acids solutions.

A series of solutions was prepared in which metal ion was complexed with porphyrin in 0.1 M sodium perchlorate at a fixed pH. The porphyrin concentrations were varied throughout the series while the metal ion concentration remained constant at a concentration in excess of any of the porphyrin concentrations used. The absorbance of each of the solutions was measured at 25 °C, at two wavelengths (one in the region of the α peak of the metalloporphyrin and one in the region of the β peak). Neither the metal ion or the background salt absorbs in the spectral region 500–600 mμ.

The extinction coefficients for the free porphyrin and the metalloporphyrins were found at the two wavelengths chosen. To obtain the extinction coefficients for the metalloporphyrins, porphyrin of a known concentration was complexed with metal ion of varying

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

but increasing concentrations. The absorbance of the solutions was seen to increase as the metal ion concentration increased until a maximum absorbance was reached when the metal ion concentration was 10^2 or more greater than the porphyrin. The extinction coefficient calculated for several initial concentrations of porphyrin gave the same results.

Beers-law plots of optical density versus concentration at the wavelengths used were linear.

K equilibrium constants at 25 °C could be calculated where

$$K_e(\mathrm{ZnP}) = \frac{[\mathrm{MP}][\mathrm{H}^+]^2}{[\mathrm{M}^{++}][\mathrm{PH}_2]} \quad \text{for zinc porphyrin}$$

and

$$K_e(\mathrm{CuP}) = \frac{[\mathrm{MP}][\mathrm{H}^+]^4}{[\mathrm{M}^{++}][\mathrm{PH}_4^{++}]} \quad \text{for copper porphyrin.}$$

The equations for the zinc system are developed as follows and those for the copper system are comparable.

$$[\mathrm{P}]_t = [\mathrm{PH}_2] + [\mathrm{MP}]$$

$$[\mathrm{M}]_t = [\mathrm{M}^{++}] + [\mathrm{MP}]$$

where $[\ ]_t$ represents total concentration.

$$A = A_{obs} = A_0' + A_0''$$

where $A_0' = \epsilon[\mathrm{PH}_2]$, $A_0'' = \epsilon_q[\mathrm{MP}]$, ϵ = extinction coefficient of PH_2 at the wavelength chosen, ϵ_q = extinction coefficient of metalloporphyrin (MP_q) where $q = 1$.

Since $[\mathrm{PH}_2] = A_0'/\epsilon$,

$$[1] \qquad K_e = \frac{\dfrac{A_0''}{\epsilon_q}[\mathrm{H}^+]^2}{[\mathrm{M}^{++}]\dfrac{A - A_0''}{\epsilon}} \quad \text{or} \quad K_e[\mathrm{M}^{++}]\frac{A - A_0''}{\epsilon} = \frac{A_0''}{\epsilon_q}[\mathrm{H}^+]^2.$$

$$[2] \qquad \mathrm{Log}\, K_e + \log\left([\mathrm{M}^{++}]\frac{A - A_0''}{\epsilon}\right) = \log\frac{A_0''}{\epsilon_q} + \log[\mathrm{H}^+]^2$$

When $[\mathrm{M}]_t$ is $\gg [\mathrm{PH}_2]$ then $[\mathrm{M}]_t \sim [\mathrm{M}^{++}]$. $[\mathrm{H}^+]$ is a constant.

$$[3] \qquad \mathrm{Log}\frac{K_e}{[\mathrm{H}^+]^2} + \log\left(\frac{[\mathrm{M}]_t A}{\epsilon} - \frac{[\mathrm{M}]_t A_0''}{\epsilon}\right) = \log\frac{A_0''}{\epsilon_q}$$

A_0'' is not known, but since $[\mathrm{P}]_t = [\mathrm{PH}_2] + [\mathrm{MP}]$ then

$$[\mathrm{P}]_t = \frac{A_0'}{\epsilon} + \frac{A_0''}{\epsilon_q}$$

and

$$[\mathrm{P}]_t = \frac{A - A_0''}{\epsilon} + \frac{A_0''}{\epsilon_q}.$$

A_0'' can be calculated for each value of porphyrin concentration and substituted back in [3].

A plot of $\log A_0''/\epsilon_q$ versus $\log(([\mathrm{M}]_t A/\epsilon) - ([\mathrm{M}]_t A_0''/\epsilon))$ should give a straight line of slope 1, the intercept of which is $\log K_e/[\mathrm{H}^+]^2$. K_e can then be calculated.

Where $[\mathrm{M}]_t$ is not $\gg [\mathrm{P}]_t$, $[\mathrm{M}^{++}]$ must be retained in eq. [1] and $[\mathrm{M}]_t - [\mathrm{MP}]$ substituted for it.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Equation [2] than becomes

$$\log K_e + \log \left(\left([M]_t - \frac{A_0''}{\epsilon_q} \right) \left(\frac{A - A_0''}{\epsilon} \right) \right) = \log \frac{A_0''}{\epsilon_q} + \log [H^+]^2 .$$

For purposes of comparison it is convenient to express K_e in terms of the familiar stability constant K_s, where $K_s = [MP]/([M^{++}][P^=])$. Since $K_1K_2 = ([P^=][H^+]^2)/[PH_2]$, then $K_e(ZnP) = K_sK_1K_2$ and $K_s = K_e/K_1K_2$.

For the copper porphyrin complex

$$[P]_t = [PH_4^{++}] + [MP]$$

and

$$[M]_t = [M^{++}] \text{ unbound} + [MP].$$

The copper ion not complexed with porphyrin may exist in more than one form in glacial acetic acid but this would in no way alter the calculations. It is simply referred to as $[M^{++}]$ unbound.

The intercept from the log plot would be $K_e/[H^+]^4$, and since

$$K_1 \cdot K_2 \cdot K_3 \cdot K_4 = \frac{[P^=][H^+]^4}{[PH_4^{++}]},$$

then

$$K_e(CuP) = K_s \cdot K_1 \cdot K_2 \cdot K_3 \cdot K_4 \text{ and } K_s = \frac{K_e}{K_1K_2K_3K_4}.$$

EXPERIMENTAL

All chemicals used were reagent grade. Spectrophotometric measurements were made on a Cary model 14 recording spectrophotometer, using 1 cm cells.

Recrystallized hematoporphyrin from Mann Research Laboratories (98% spectro assay) was used and standards were prepared by dissolving the reagent in a small amount of alcohol and making up to volume with doubly distilled water. When the standards were allowed to stand for periods of several weeks, there appeared to be no diminution in the absorption bands of the hematoporphyrin, nor increase in absorption in the regions where a monovinyl or divinyl group would absorb if dehydration of hematoporphyrin to protoporphyrin were occurring.

Complexing with zinc was done in aqueous solution using zinc acetate, and 0.1 *M* sodium perchlorate background. The pH was then adjusted to 7 with NaOH.

Because of the difficulty in complexing copper in aqueous medium, the method of Dorough *et al.* (17) was used. An aliquot of porphyrin, to which glacial acetic acid had been added, was boiled gently with copper(II) acetate until the spectrum of the copper porphyrin complex showed the absence of the free porphyrin absorption bands (about 5 min). The aliquot was then made up to a known volume with glacial acetic acid; the resulting solution was 75:1 (by volume) glacial acetic acid to water. The absorbances were measured at 25 °C. This method proved successful although it appears to contradict the statement of Fleischer *et al.* (18) that the diacid species is known to be unreactive to metalloporphyrin formation.

It was noted that an intermediary color of green appeared in the copper solutions. The green color disappeared on further heating, and the solutions became orange brown. The spectrum was not that of the metal complex, and could be the sitting-atop type of complex discussed by Fleischer and Wang (19). Preliminary experiments with Mn(II), Co(II), Ni(II), and Cd(II) as their acetates showed complexing in glacial acetic acid.

RESULTS

Extinction coefficients at 25 °C. (Deviation $\pm 0.05 \times 10^3$.)

At pH 7:

$\epsilon(PH_2) = 4.4 \times 10^3$ at 540 mμ.
$= 3.6 \times 10^3$ at 574 mμ.
$\epsilon_q(ZnP) = 7.6 \times 10^3$ at 540 mμ.
$= 6.5 \times 10^3$ at 574 mμ.

In glacial acetic acid:

$\epsilon(PH_4^{++}) = 6.4 \times 10^3$ at 568 mμ.
$= 3.2 \times 10^3$ at 534 mμ.
$\epsilon_q(CuP) = 11.1 \times 10^3$ at 568 mμ.
$= 9.7 \times 10^3$ at 534 mμ.

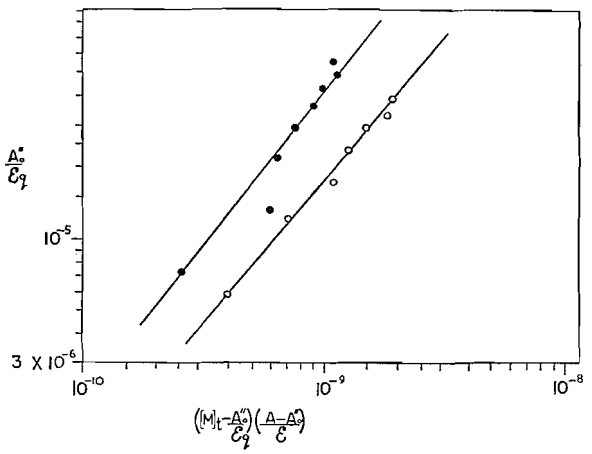

FIG. 4. Typical plots of $\log \frac{A_0''}{\epsilon_q}$ against $\log \left(([M]_t - \frac{A_0''}{\epsilon_q}) (\frac{A - A_0''}{\epsilon}) \right)$ for Zn(II) with hematoporphyrin (●) and Cu(II) with hematoporphyrin (○).

Tables I and II show typical absorbance data. Plots from such data are shown in Fig. 4.

NOTE: Slopes of the straight lines varied from 1.0 to 1.2. The lower slopes seemed to occur when the approximation $[M] \sim [M^{++}]$ was used. The more rigorous treatment of data produced slopes slightly greater than 1.

The average value obtained for $K_e/[H^+]^2$ for zinc hematoporphyrin was 1.3×10^7. Since $[H^+]$ was 10^{-7} moles/l, K_e is of the order of 1.3×10^{-7} at 25 °C.

If K_1 and K_2 were of the order of those for aetioporphyrin (i.e. 10^{-16} each), the K_s value will be large (of the order of 10^{+25}), since

$$K_s = \frac{K_e}{K_1 K_2}.$$

The average value obtained for $K_e/[H^+]^4$ for copper hematoporphyrin was 1.8×10^5. The H^+ concentration in the glacial acetic acid solution could not be determined with any meaning, but the over all acidity of the solution could be considered a constant, since the release of H^+ ions from the dication would be a negligible amount.

$$K_e = 1.8 \times 10^5 [H^+]^4 \text{ at } 25 \text{ °C}.$$

Since K_1, K_2, K_3, and K_4 are not known in glacial acetic acid, K_s cannot be estimated. It would no doubt be exceptionally large, however, since

$$K_s = \frac{K_e}{K_1 K_2 K_3 K_4}.$$

Until further work has been done with other metals in glacial acetic acid, it is too early to speculate on the orders of stability as compared with those deduced from replacement and dissociation reactions (9), where Pt(II) > Pd(II) > Ni(II) > Co(II) > Ag(II) > Cu(II) > Fe(II) > Zn(II) > Mg(II) > Cd(II) > Sn(II) > Li > Na > Ba > K > Ag.

Although the measurements in glacial acetic acid solution are only semiquantitative, they provide a means of comparison within a given medium.

THE CORRELATION OF ABSORPTION SPECTRA AND STRUCTURE OF PSEUDO-OCTAHEDRAL AND TRIGONAL BIPYRAMIDAL COPPER(II)–1,10-PHENANTHROLINE COMPLEXES IN ACETONE SOLUTIONS

G. H. FAYE

Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received March 17, 1966

ABSTRACT

By the use of elementary ligand field theory to interpret the absorption spectra of complexes formed in the copper(II)–1,10-phenanthrolene (Phen) system in an acetone medium, it has been shown that the mono-Phen complex is of approximately octahedral symmetry and the bis-Phen complex probably has a trigonal bipyramidal structure. At high Phen concentration, a tris-complex is formed that is probably trigonally distorted from octahedral symmetry. The results of the present work suggest that the "pentammine effect" observed in spectra of the copper(II)–ammonia complex is due to the formation of a trigonal bipyramidal complex.

INTRODUCTION

Copper(II) complexes of 1,10-phenanthroline, 2,2′-bipyridine, and their derivatives have been the subject of numerous investigations. However, the literature reveals that the structures of the species formed in solution have not been firmly established even though several studies (1–4, 7, 8) (mainly spectrophotometric) have been concerned, at least in part, with this matter; the difficulty seems to have been due to a lack of recognition of the existence of five-coordinate copper(II) species by some workers and (or) to the structural interpretations of incomplete d–d band absorption spectra by others.

Using crystal field considerations in a spectral study, Jorgensen (1) concluded that bis- and tris-phenanthroline (Phen) and bipyridine (Bip) copper(II) complexes are of approximately octahedral symmetry. Banks and Bystroff (2) measured the stability constants of the mono-, bis-, and tris-Phen complexes and assumed that all three have octahedral structures. These workers arrived at the conclusion, as did Jorgensen, that the bis-complex is of the *cis* configuration because the *trans* isomer is sterically unstable.

Using electrochemical techniques, James and Williams (3) studied the copper complexes formed with variously substituted Phens and Bips and implied that bis-complexes formed by the 3,4,5-substituted bases are planar and the tris-complexes are octahedral. With Phen substituted in the 2,9-positions, James and Williams found no evidence for a tris-complex and attributed this to steric hindrance.

From a spectrophotometric study, James, Parris, and Williams (4) concluded that unsubstituted Phens and Bips form distorted octahedral bis-complexes with copper(II), whereas Phen substituted in the 2,9-positions forms tetrahedral mono- and bis-complexes. James *et al.* made the unlikely supposition that the spectra of the octahedral and tetrahedral species were much alike.

Harris, Lockyer, and Waterman (5) and Barclay and Kennard (6) have shown that copper(II) forms a number of crystalline trigonal bipyramidal species with Phen and Bip under conditions that were apparently similar to those prevailing in certain of the studies cited above. However, these workers did not study the absorption spectra, thus a direct correlation of structure in solution with that of the solids containing five-coordinate copper has not been made.

From the foregoing it is apparent that further experimental work is required to elucidate the structure of the complexes formed by copper and relatively bulky bidentate nitrogenous bases of the Phen and Bip type.

Although ligand field theory in conjunction with a detailed examination of the absorption spectra in the near ultraviolet to near infrared region of the energy spectrum is capable of yielding a wealth of structural information about transition metal complexes, this approach seems not to have been used to full advantage in the studies discussed above. Therefore, the author has undertaken the present spectrophotometric investigation of the copper(II)–Phen system with the object of correlating the d–d absorption bands with the structure of the complexes formed in solution.

It will be shown that with unsubstituted Phen, copper(II) probably forms a pseudo-octahedral mono-complex, a trigonal bipyramidal bis-complex, and, at high ligand concentration, a tris-species, which based on a comparison with its bis-Bip analog probably has trigonal symmetry. Some speculations are made on the reason why an octahedral bis-complex does not form in detectable amounts. Also, arguments are presented which suggest that the so-called "pentammine effect" (9) observed in the spectra of the copper–ammonia system can be attributed to the formation of a trigonal bipyramidal complex.

EXPERIMENTAL

With the exception of acetonic solutions of Phen, the materials, apparatus, and experimental procedure were similar to those described previously in a spectrophotometric study (10) of halogenocopper(II) complexes in acetone media.

Extinction coefficients (ϵ) were calculated using total copper concentrations.

Preparation of $[Cu(Phen)_2ClO_4]ClO_4$ (I)

This compound was prepared at room temperature by mixing 10 ml of a 4×10^{-2} *M* solution of $Cu(ClO_4)_2$ in acetone with 16 ml of a 5×10^{-2} *M* solution of Phen in acetone. The finely divided turquoise solid (I), so produced, was allowed to settle for approximately 15 min and was then recovered by filtration, washed with acetone, and dried at approximately 100 °C. Approximately 95% of the copper was recovered as compound I.

Preparation of $[Cu(Phen)_2Cl]ClO_4$ (II) and $CuPhenCl_2$ (III)

Compounds II (dark green) and III (pale green) were prepared in the same manner as I, except that Phen was added to copper solutions containing 4×10^{-4} and 8×10^{-4} mole of HCl respectively (added as a mixture of 12 *M* hydrochloric acid and acetone). Compounds II and III accounted for 90–95% of the copper used for their preparation.

Table I gives the analytical data for the three solid compounds and the formula assigned to each on the basis of the analyses and the structural implications of their absorption spectra which are discussed later in the paper.

The absorption spectra of nitromethane solutions of compounds I, II, and III are shown in Fig. 2.

RESULTS AND DISCUSSION

The spectra in Fig. 1 indicate that as the ratio of the total concentration of Phen to Cu^{2+} is increased from 0 to 3, profound changes occur in the nature of the absorbing species in the acetone medium. Associated with these changes is the appearance of turquoise crystals (compound I) when the ratio is between 1 and 3. The spectrum and structure of I is discussed under "Crystalline Compounds".

Spectrum A, with band maximum at 12 500 cm^{-1}, is considered to be due to a mixture of the distorted octahedral species $[Cu(OH_2)_5ac]^{2+}$ and $[Cu(OH_2)_4(ac)_2]^{2+}$ (10). Friedman and Plane (11) have shown that such complexes are present in acetone solutions of copper perchlorate containing small amounts of water. Because the acetone used in the present work was not dried and because the extinction coefficient, ϵ, = 17 l/mole cm is similar to that for $[Cu(OH_2)_5ac]^{2+}$ (11), it is reasonable to assume that this is the predominant species in the solution and the one reacting with Phen.

Pseudo-Octahedral Mono-Phen Complex

Spectrum C with band maximum at 14 300 cm^{-1} is that of a solution in which $[Phen]/[Cu^{2+}] = 1$. At ratios between 1 and 2 the band maximum shifts to lower energy and the spectrum changes greatly, indicating formation of a new complex. It is highly probable that spectrum C is that of a pseudo-octahedral mono-complex, $[Cu(Phen)(OH_2)_{4-x}(ac)_x]^{2+}$, formed by the replacement of two solvent molecules in $[Cu(OH_2)_5ac]^{2+}$ by a Phen molecule. An increase of 1 800 cm^{-1} in $\Delta_{\sim oct}$ (where $\Delta_{\sim oct}$ symbolizes d-orbital splitting in an approximately octahedral field) on the replacement of two Cu—O bonds by two Cu—N bonds is to be expected from the known greater perturbing effect of N-bonding ligands and also possibly to increased distortion caused by the complexing of Phen. For example, $\Delta_{\sim oct}$ for $[Cu(NH_3)_2(OH_2)_4]^{2+}$ is approximately 14 800 cm^{-1}, whereas that for $[Cu(OH_2)_6]^{2+}$ is 12 500 (9). That the field produced by a Phen molecule is less than that produced by two ammonias may be due to its poorer donor properties and (or) to longer Cu—N bond lengths in the chelate complex.

The "smearing" of the broad absorption band into the lower energy region is indicative of considerable Jahn–Teller distortion and is also consistent with the mixed-ligand coordination sphere indicated above (12).

Trigonal Bipyramidal Bis-Phen Complex

When acetonic solutions of copper perchlorate and Phen are mixed so that the final total copper concentration is greater than approximately 10^{-4} *M* and the $[Phen]/[Cu^{2+}]$ is in the range 1.5 to 2.5, the resulting solution turns pale blue and after a few minutes finely divided turquoise crystals (compound I) are formed.

Spectrum D in Fig. 1 is that of a freshly prepared solution in which $[Phen]/[Cu^{2+}] = 2$ and in which a detectable amount of crystalline material had not formed at the completion of the scan. Two prominent bands with maxima at 13 900 and 11 000 cm^{-1} are evident; these can be accounted for by the presence of a single complex in which two well-separated d-orbital transitions are possible, or by two absorbing species each exhibiting a single band as expected for copper(II) in an approximately octahedral or tetrahedral field.

Jorgensen (1) observed two bands in the spectra of aqueous solutions of the copper(II) bis-complexes of bipyridine at 13 900 and 10 500 cm^{-1} and of Phen at 13 300 and 10 200 cm^{-1} and ascribed these bands to a tetragonally distorted octahedral complex with a *cis* arrangement of the bound aromatic diimines. To account for the large separation of the bands ($> 3\,000$ cm^{-1}) such a six-coordinate complex would have to be highly distorted. If the distortion tended toward a planar configuration, the band at highest

energy would certainly be found at a frequency greater than that of the pseudo-octahedral mono-Phen complex, for it is well known that the ligand field splitting parameter for planar symmetry (17.4*D*q) is much larger than that for octahedral symmetry (10*D*q).

James, Parris, and Williams (4) also studied the spectra of aqueous solutions of the copper(II) bis-complexes of variously substituted Phens and Bips and concluded that the two bands observed at approximately 13 500 and 11 000 cm^{-1} were due to a distorted octahedral species in the unsubstituted aromatic diimines, and to a distorted tetrahedral complex, at least in Phen substituted in the 2- and 9-positions.

The occurrence of two widely separated bands at unlikely energies for the distorted "tetrahedral" complex was reconciled with theory by James *et al.* by assuming that for steric reasons the Cu—N distance is less than in the octahedral complex; this gives rise to a ligand field of exceptionally high strength.

It has been shown above that the pseudo-octahedral mono-Phen complex has its band maximum at 14 300 cm^{-1}. Therefore it is reasonable to assume that a pseudo-octahedral bis-complex would exhibit a maximum at significantly higher energy because of the greater field produced by the second Phen molecule. However, spectrum D in Fig. 1 shows instead that the higher energy transition of the bis-complexes lies 400–700 cm^{-1} lower than in the spectrum of the mono-complex, and this strongly suggests that the band is not due to an octahedral complex, distorted or otherwise.

Consideration of a d-orbital energy level splitting scheme for a ligand field of trigonal bipyramidal symmetry (13) indicates that a d^9 ion should give rise to two absorption bands due to the transitions $d_{x^2-y^2}$, $d_{xy} \rightarrow d_{z^2}$ and d_{xz}, $d_{yz} \rightarrow d_{z^2}$; the former accounting for 7.89*D*q or $0.806\Delta_{trl\ bp}$ and the latter 9.70*D*q. Furthermore, the high energy transition should lie somewhat below that in a corresponding octahedral complex with similar ligands.

Spectrum D in Fig. 1 can be interpreted in terms of a d-orbital splitting scheme for a trigonal bipyramidal structure, considering electrostatic effects only. Thus, if the band maximum at 13 900 cm^{-1} is taken to be due to the d_{xz}, $d_{yz} \rightarrow d_{z^2}$ transition, then, theoretically, the $d_{x^2-y^2}$, $d_{xy} \rightarrow d_{z^2}$ transition should lie at $(7.89Dq/9.79Dq) \times 13\ 900 = 11\ 200$ cm^{-1}, a value with which the observed band maximum at 11 000 cm^{-1} is in excellent agreement. Therefore, it is concluded that the complex giving rise to spectrum D is essentially trigonal bipyramidal, and, as we will show later, may be formulated $[Cu(Phen)_2solv]^{2+}$, or $[Cu(Phen)ClO_4]^+$.

Spectrum D is qualitatively very similar to that found recently by Ciampolini and Nardi (14) for trigonal bipyramidal complexes formed by copper(II) and tris(2-diethylaminoethyl)amine. Thus it would seem that five-coordinate copper(II) complexes with nitrogen-bonding ligands are relatively common (15) and this suggests that the appropriate absorption spectra should be examined routinely for the presence of such species.

Tris-Phen Complex

Spectrum E in Fig. 1 is obtained from solutions in which $[Phen]/[Cu^{2+}] = 3$ or higher. The appearance of the widely separated bands with maxima at 14 800 and 7 000 cm^{-1} with each having ϵ_{max} values significantly lower than the bands in spectrum D indicates that major structural changes occur in the dissolved species as $[Phen]/[Cu^{2+}]$ is increased from 2 to 3 and over.

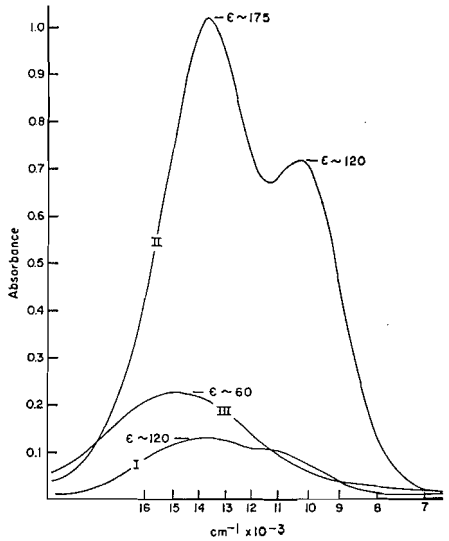

FIG. 2. Spectra of nitromethane solutions of compounds I, II, and III. Nature of absorbing solution (scanned in 5-cm cell): (I) 1.1×10^{-3} *M* solution of $[Cu(Phen)_2ClO_4]ClO_4$ in nitromethane; (II) 5.7×10^{-3} *M* solution of $[Cu(Phen)_2Cl]ClO_4$ in nitromethane; (III) $\sim 8 \times 10^{-4}$ *M* solution of $CuPhenCl_2$ in nitromethane.

Spectrum E in Fig. 2 is very similar to both the solid and solution spectrum of the tris-Bip copper(II) complex recently studied by Palmer and Piper (16). These workers concluded that their spectrum was due to a complex having trigonal symmetry. By analogy, it is probable that the copper-Phen complex giving rise to spectrum E is also of the same symmetry.

The unusually large splitting of the bands of the tris-complex earlier led this worker to consider the possibility of the coexistence of both an octahedral and a tetrahedral copper-Phen complex. If it is taken that the 14 800 cm^{-1} band in spectrum E is that of an octahedral tris-Phen complex, and the low energy band is that of a tetrahedral

bis-complex, then the band maximum of the latter can be predicted from ligand field theory ($\Delta_{tetr} \simeq 4\Delta_{oct}$) to lie at approximately 6 600 cm^{-1}, a value with which the observed frequency of approximately 7 000 cm^{-1} is in good agreement. Such agreement with theory would suggest that neither the hypothetical octahedral or tetrahedral complex is highly distorted.

It is of interest to note here that Jorgensen (1) found that the weak bands below 9 000 cm^{-1} in the spectra of the "tris-complexes" formed by copper(II) with Phen or Bip were not easily explained by ligand field theory.

When an acetone solution containing the tris-Phen complex and excess Phen is treated with Cl^-, compound II crystallizes (the nature of II is described below). The formation of the five-coordinate complex is indicative of the relatively low stability of the tris-species, a factor probably related to steric effects.

That a pseudo-octahedral bis-Phen copper(II) complex is not detected in the absence of excess Phen is considered to be due, at least in part, to the higher crystal field stabilization energy available in a d^9 ion in a trigonal bipyramidal environment than in a corresponding octahedral one, i.e. 7.07*D*q and 6*D*q respectively. Thus it is not difficult to imagine a transient *cis*-octahedral complex losing a solvent molecule and undergoing an energetically favorable rearrangement to the five-coordinate configuration.

Charge-Transfer Bands

Because of their intensity and energy, the bands at approximately 30 000 and 29 000 cm^{-1} in spectra C-1 to E-1 in Fig. 1 are considered to be of the charge-transfer type. That the intensity of the high energy band increases approximately linearly as $[Phen]/[Cu^{2+}]$ goes from 1 to 2 and the energy of the transitions remain essentially constant as the structure of the copper complexes changes radically strongly suggest that the charge-transfer processes take place within the ligand molecules.

Crystalline Compounds

Trigonal Bipyramidal Bis-Phen Complexes (I and II)

The spectra of nitromethane solutions of compounds I and II are shown in Fig. 2. It is evident that each contains two bands at energies similar to those of spectrum D in Fig. 1, and, therefore, it can be concluded that the dissolved species both have an approximately trigonal bipyramidal structure. This conclusion together with the analytical data indicates that the soluble complexes may be formulated as $[Cu(Phen)_2solv]^{2+}$ or $[Cu(Phen)_2ClO_4]^+$ and $[Cu(Phen)_2Cl]^+$.

Copper is probably also five coordinate in the corresponding solids $[Cu(Phen)_2ClO_4]ClO_4$ (I) and $[Cu(Phen)_2Cl]ClO_4$ (II); this is supported by the simliarity of the spectrum of a Nujol mull of compound I (see F in Fig. 1) to that of spectrum D in Fig. 1.

That a perchlorate is apparently coordinated directly to copper, at least in compound I, is of considerable interest because it is commonly held that there is little or no tendency for such coordination to metal cations to take place, especially in solution. Recently, however, evidence for the binding of perchlorate to transition metals has been presented (17–19).

Pseudo-Octahedral Mono-Phen Complex (III)

Spectrum III in Fig. 2 is that of a nitromethane solution of compound III. It is clear that there is only a single band with maximum at 14 500 cm^{-1} and this is indicative of a pseudo-octahedral environment for copper, as in the mono-Phen complex giving rise to spectrum C in Fig. 1. It is obvious from the analytical data that compound III may be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formulated as $CuPhenCl_2$. In the solid, copper is probably six coordinate with a Phen and two chlorines in a plane and with two chlorines perpendicular to the plane and shared by other coppers.

Some Speculations on the "Pentammine Effect"

Bjerrum, Ballhausen, and Jorgensen (9) studied the absorption spectra of copper(II)–ammonia complexes and observed what is known as the "pentammine effect". This effect refers to an "anomalous" change in the spectrum of aqueous solutions in which the $[NH_3]/[Cu^{2+}]$ ratio increases from 4 to 5. The octahedral tetrammine complex, $[Cu(NH_3)_4(OH_2)]^{2+}$, exhibits a symmetrical band with a maximum at approximately 17 000 cm^{-1}, whereas the pentammine complex (presumed to be $[Cu(NH_3)_5OH_2]^{2+}$) exhibits an absorption envelope of considerably greater intensity that contains two major components at approximately 15 400 and 11 800 cm^{-1} respectively.

The spectrum of the pentammine complex is thus very similar to that of the five-coordinate bis-Phen complex (D, in Fig. 1). Therefore, it is suggested that the pentammine complex has a trigonal bipyramidal structure and the pentammine spectral effect is a logical consequence of such geometry.

It is reported (9) that the spectrum of cupric nitrate in liquid ammonia is much like that of the pentammine complex, therefore it is probable that this system too contains the trigonal bipyramidal complex $[Cu(NH_3)_5]^{2+}$.

ACKNOWLEDGMENTS

The author wishes to express appreciation to Dr. P. G. Manning for helpful discussions during the course of this work.

Special thanks are due to George F. Morris, Analytical Chemistry Research Branch, Department of Agriculture, for the analysis of compounds I, II, and III.

INTERSYSTEM CROSSING OF THE ELECTRONICALLY EXCITED DIDEUTEROETHYLENE MOLECULES FORMED IN BENZENE PHOTOSENSITIZATION[1]

ABSTRACT

Experimental evidence is presented for a rapidly occurring intersystem crossing of the electronically excited dideuteroethylene molecules initially formed in the benzene-photosensitized reaction at 2 537 Å and 25 °C to another excited state which is responsible for the internal H-atom scrambling. The mechanism is entirely analogous to that previously postulated for the photoexcited states sensitized by $Hg(^3P_1)$ atoms but the rate constants for intersystem crossing and molecular decomposition are drastically decreased as a result of the smaller amount of energy available for the excitation.

INTRODUCTION

Electronically excited states of olefins are formed when olefin molecules absorb ultraviolet light either directly or indirectly from photosensitizers. The chemical behavior of the photoexcited states depends both on the amount of energy transferred and on the nature of the sensitizer employed. With ethylene the following reactions are observed: (i) *cis–trans* isomerization (in the reaction of *cis-* and *trans*-1,2-dideuteroethylene), (ii) internal H-atom scrambling (formation of 1,1- from 1,2-dideuteroethylene), (iii) molecular decomposition into H_2 and acetylene, and (iv) decomposition into H-atoms and vinyl radicals.

Studies of these chemical processes present an interesting opportunity to gain insight into the nature and behavior of the excited states involved. Direct photolysis and mercury-photosensitized reactions of ethylene have been investigated in considerable detail (1). In the present article we report the results of a study of the benzene-photosensitized isomerization of dideuteroethylene at room temperature.

LOW-LYING ENERGY LEVELS OF ETHYLENE

Benzene photosensitization of olefins is believed to occur through a triplet–triplet energy transfer (2, 3). Inasmuch as the transfer occurs from the lowest triplet state of benzene, the available energy is around 3.6 eV (4–6). The chemical processes likely to be energetically favorable will depend on the energy levels of the species involved. Unfortunately, there are still large uncertainties about the energy levels of ethylene, especially of the most stable configuration of the first triplet state. A very tentative energy diagram is given in Fig. 1. This is based on the low-lying electronic states according to Mulliken (7): N (ground state), T (the first triplet state, at 4.6 eV), T_R (the Rydberg triplet state, at 6.4 eV), R (The Rydberg singlet state, at 7.1 eV), and V (singlet excited

[1]*Issued as N.R.C. No. 9099.*
[2]*Department of Applied Physics, Tokyo Institute of Technology, Tokyo, Japan.*
[3]*Visiting Scientist, Applied Chemistry Division, National Research Council, Ottawa.*

state, at 7.6 eV). The excitation energies correspond to the spectroscopically observed vertical transitions (8–11). The T and V, and T_R and R states have the same electronic configurations (....$(\pi_x + \pi_x)$ $(\pi_x - \pi_x)$ and .... $(\pi_x + \pi_x)$ (3s), respectively) but different spin interactions.

From the point of view of the occurrence of the *cis–trans* isomerization it is important to know how the potential energy depends on the angle of twist (θ) around the CC bond. The stability of the Rydberg states appears to depend little on θ (11, 12). There is still a considerable divergence of views regarding the behavior of the first triplet state in this respect (13–16). The curve for the T state in Fig. 1 has been traced approximately in the following manner. The location of an imaginary averaged "center-of-gravity" state (17) between T and V is placed at 5.4 eV, i.e. $(3 \times 4.6 + 1 \times 7.6)/4$. At a 90° angle of twist, the electronic configurations (and the energy level) of this imaginary state and of the ground state would be the same. The common energy level is not known but it can be approximately assumed to be a half of the vertical level of the imaginary state, i.e. 2.7 eV. It is also assumed that the imaginary state, the T state, and the V state all show parallel dependence on the angle of twist.

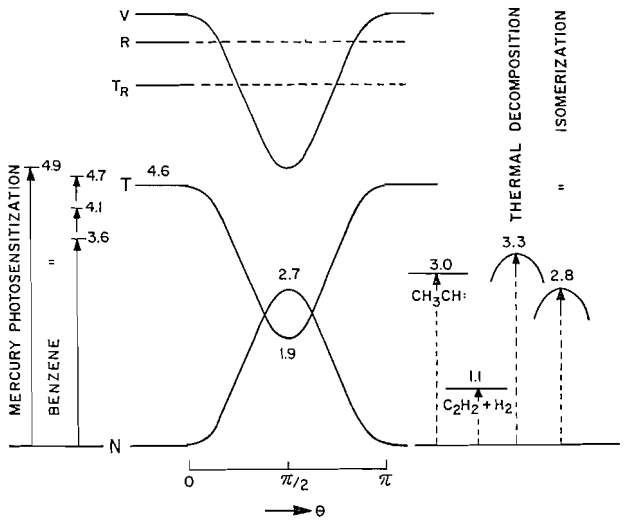

FIG. 1. Schematic diagram of the energy levels (in eV) of the low-lying electronic states of ethylene.

The lowest value of the T state is approximately placed in this manner at 1.9 eV, i.e. 2.7 − (5.4 − 4.6). This is not necessarily too low a value in view of the lack of *cis–trans* isomerization in Na photosensitization (18) (available energy 2.1 eV), since energy transfer in this process is most probably to the planar form of the triplet, although there could be some deviation from the rigorously vertical transition if an intermediate complex of finite lifetime is formed. The value of 2.7 eV for the 90°-twisted ("perpendicular") ground state should equal the activation energy of the thermal *cis–trans* isomerization if a spin multiplicity change is not involved. It agrees with the experimental value of 2.8 eV obtained by Douglas *et al.* (19), which these authors identify with the energy of the perpendicular form of the ground state of ethylene. They have also estimated the energy level of the perpendicular form of the T state and their value of 2.2 eV is only slightly higher than the value of 1.9 eV in Fig 1.

Ethylidene biradical has been postulated as an intermediate in the mercury-photosensitized reaction of ethylene (20). Its energy level above the ground state of ethylene has been estimated from the bond dissociation energies and the heat of hydrogenation at around 3.0 eV (21). The thermal decomposition of ethylene, with the activation energy of at least 3.3 eV (22), might therefore occur via an intermediate formation of ethylidene.

RESULTS AND DISCUSSION

Inspection of the diagram in Fig. 1 shows that in the benzene photosensitization of ethylene *cis–trans* isomerization, internal H-atom scrambling, and molecular decomposition into H_2 and acetylene should be energetically possible. Decomposition into H and vinyl would be quite endothermic and therefore unlikely. All the four processes occur in mercury photosensitization (20), although the fourth is of very minor importance at room temperature.

Several experiments were carried out at 25° in a mercury-free system using the 2 537 Å radiation from a low-pressure mercury arc. Figure 2 shows, as an example, the infrared spectra of 5 cm of *cis*-dideuteroethylene after irradiation for various periods of time in the absence and presence of 2.7 cm of benzene. The absorption peak at 842 cm^{-1} is assigned to *cis*, at 725 and 987 cm^{-1} to *trans*, and at 750 and 943 cm^{-1} to *asym*-dideuteroethylene (24). It is seen that *cis–trans* isomerization occurs readily but H-atom scrambling (formation of the *asym* isomer) is at best only a very minor process. Analogous behavior is shown by the corresponding infrared spectra of *trans*- and of *asym*-dideuteroethylene, which are not reproduced here for lack of space. The former readily isomerizes to the *cis* isomer but very little if at all to the *asym* isomer; the latter shows no or a very small tendency to isomerize. The lack of scrambling in the three isomers is in sharp contrast to the mercury-photosensitized reactions where, at these pressures, the scrambling and decomposition are almost the same (23). Furthermore, again in contrast to the mercury photosensitization, no evidence was found (by gas chromatography) for any decomposition of ethylene.

The lack of H-atom scrambling in ethylene in the benzene photosensitization may appear surprising. However, the corresponding process in mercury photosensitization is pressure dependent (23) with the maximum yield at about 65 mm, in agreement with the postulated (20) rapid intersystem crossing (reaction [2]) of the originally formed excited state (E*) to another excited state (E**) which is capable of decomposing:

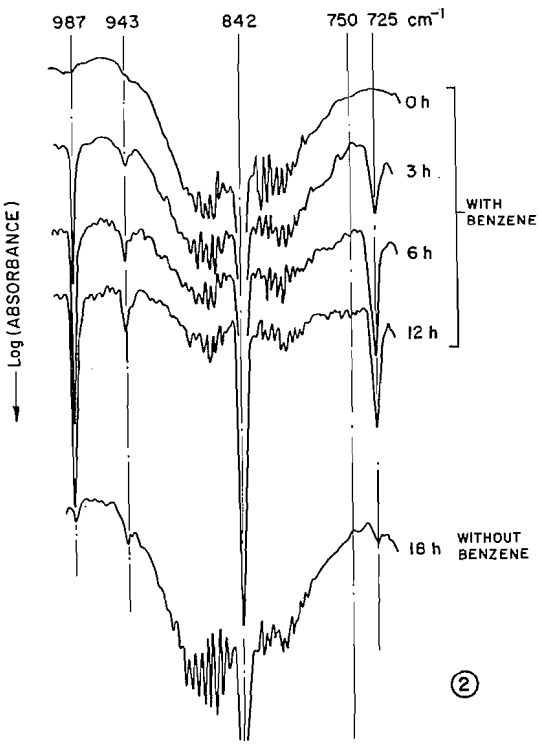
[1] $$E + Hg^* \rightarrow E^* + Hg$$

[2] $$E^* \rightarrow E^{**}$$

[3] $$E^* + M \rightarrow E + M$$

[4] $$E^{**} \rightarrow C_2H_2 + H_2$$

[5] $$E^{**} + M \rightarrow E + M.$$



The observed kinetics require the internal scrambling of H atoms to occur in reaction [5]. At small conversions the quantum yield of the *asym*-dideuteroethylene (ϕ_{asym}), formed, for example, from the *cis* isomer, is given by

[6] $$\phi_{asym} = \frac{\alpha[M]}{\left(1 + \frac{k_3}{k_2}[M]\right)\left(\frac{k_4}{k_5} + [M]\right)}$$

with α representing the fraction of E** molecules (presumably ethylidene (20)) which are stabilized into the *asym*-dideuteroethylene. Inasmuch as the above two-state mechanism is also applicable to the benzene photosensitization, it can be seen that the ϕ_{asym}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

maximum would be observed at a lower pressure if k_4 is smaller. If decomposition does not occur at all ($k_4 = 0$), eq. [6] reduces to a very simple form and the maximum value of ϕ_{asym} will be equal to α and will be reached at a negligibly small pressure. Under such conditions, therefore, at a pressure approaching zero, ϕ_{asym} may be expected to be close to the statistical factor of 1/3 and to approach ϕ_{trans} (if the original reactant is the *cis* isomer). As the pressure is increased ϕ_{asym} would continuously decrease.

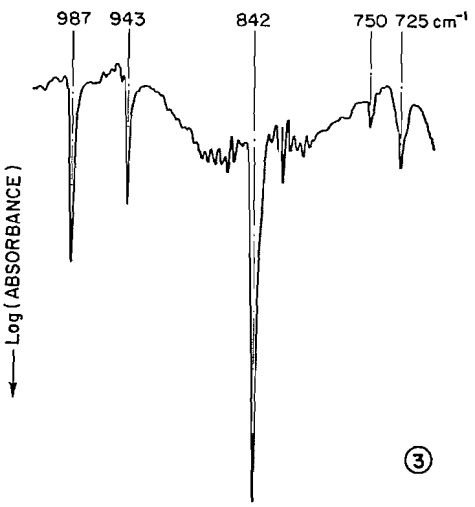


FIG. 2. Benzene-photosensitized isomerization of *cis*-dideuteroethylene. Infrared spectra of the product ethylene after various irradiation times. Initial pressures: 5 cm *cis*-dideuteroethylene, 2.7 cm benzene.
FIG. 3. Benzene-photosensitized isomerization of *cis*-dideuteroethylene at low pressure. Infrared spectrum after 12 h irradiation. Initial pressures: 2 mm *cis*-dideuteroethylene, 1.1 mm benzene.

In agreement with these predictions we find that at lower pressures H-atom scrambling does indeed become important. As shown in Fig. 3, after 12 h irradiation of 1.1 mm benzene and 2 mm *cis*-dideuteroethylene considerable isomerization is observed, with ϕ_{asym} beginning to approach ϕ_{trans}. In this experiment a longer absorption path (larger reaction vessel) was used so that both the ratio of the reactants and the light absorption were approximately the same as in the comparable experiment in Fig. 2.

These results show that more than one excited state must be involved in the process and that the initially formed excited molecules undergo intersystem crossing to another excited state in which internal H-atom scrambling occurs. If only one excited state were involved, either H-atom scrambling would not occur at all or the ratio ϕ_{asym}/ϕ_{trans} would remain the same at all pressures.

Scrambling of hydrogen atoms and ethylene decomposition have also been observed without the sensitizer (benzene) but to a very minor extent, as shown in Fig. 2 and similarly in the analogous experiments with the *trans*- and *asym*-dideuteroethylene. Since a low-pressure mercury arc was used in these experiments, the small amount of reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

observed may be due to one of the following two possibilities: (*a*) contamination by a trace of mercury in the reagents, in spite of the precautions taken, or (*b*) direct light absorption by ethylene at 2 537 Å, which is well known to be very small (25). Two experiments were carried out in the absence of benzene with a Cd resonance lamp and with a medium-pressure mercury lamp through a mercury filter (2 cm thick, containing a drop of mercury and 70 mm hydrogen). With these light sources essentially no *cis–trans* isomerization and no decomposition were observed. These results support the first of the two possibilities mentioned above.

To determine the unimolecular rate constant (k_2) for the intersystem crossing reaction [2] we have carried out a number of experiments at two lower pressures, close to 3 mm and 0.3 mm, respectively, in a 1 100 ml reaction flask. In these experiments a medium-pressure mercury lamp (Hanovia 637A) was used to avoid any mercury photosensitization. The incident light was passed through a Corning 9–54 filter and a chlorine filter. Because of the emission characteristics of the lamp and the absorption properties of benzene vapor (26), most light absorption occurred at 2 537 Å and probably only to a considerably smaller extent at 2 482 Å. The initial excitation of benzene is therefore closely analogous to that in the earlier experiments with the use of the low-pressure mercury lamp. The results are summarized in Table I. It is seen that irradiation of *cis*-1,2-dideuteroethylene alone (run 2) does not lead to isomerization. In the presence of benzene, on the other hand, isomerization occurs and after prolonged irradiation (run 10) the statistical composition of about one third of each of the three isomers is obtained.

TABLE I

Benzene-photosensitized isomerization of *cis*-1,2-dideuteroethylene and of 1,1-dideuteroethylene at 25 °C

Run	Pressure (mm)			Exposure (h)	Product ethylene (%)			k_2 (s^{-1})
	Benzene	Ethylene	Total		*cis*	*trans*	*asym*	
I. *cis*-1,2-Dideuteroethylene as the reactant

6	0.12	0.20	0.32	65.5	46.3	27.6	26.0	
II. 1,1-Dideuteroethylene as the reactant								
12	0.95	2.00	2.95	4.5	4.1	4.4	91.5	
		Initial reactant			—	—	100	

At negligibly small conversions, an expression for the intersystem crossing rate constant (k_2) based on the two-state mechanism (reactions [1]–[5]) can be readily obtained. At finite conversions the relationship is more complex, but it does simplify considerably when decomposition (reaction [4]) is negligible. It was found that even at these lower pressures extremely little or no decomposition occurs, so that the following simplified expression holds

$$[7] \qquad k_2 = k_3[\mathrm{M}] \log_{10}\left(\frac{3x-1}{3x_1-1}\right) \Big/ \log_{10}\left(\frac{0.5+(3y-1)/(3x-1)}{0.5+(3y_1-1)/(3x_1-1)}\right).$$

The quantities x and y represent, respectively, the fractions of the *asymmetric* and the *trans* isomer in the ethylene after the reaction and the subscript i indicates the corresponding fractions initially present in the reactant *cis* isomer. It is assumed that k_3 is equal to the collision frequency in reaction [3] and this is calculated using a collision diameter of 4.95×10^{-8} cm, as was done previously by Setser *et al.* (23). The values of k_2 obtained from eq. [7] are given in the last column of Table I for the experiments at 3 mm. In spite of the low precision of the infrared analyses, the values are mutually consistent. The results at 0.3 mm show the expected behavior. However, it can be readily seen that the values of k_2, although of right magnitude, are strongly affected by small analytical inaccuracies since ϕ_{asym} is very close to ϕ_{trans}. These values are therefore not included in the table. It can be seen further (Table I, run 12) that 1,1-dideuteroethylene also isomerizes readily in the benzene-photosensitized reaction, giving equal amounts of the *cis* and *trans* isomer within the analytical accuracy. Equation [7] is not applicable in this case and k_2 could not be evaluated.

The mean value of k_2 obtained in the present work is 7.6×10^7 s^{-1}. The corresponding value obtained by Setser *et al.* (23) in the mercury-photosensitized isomerization is $(k_2)_{Hg} = 3.1 \times 10^9$ s^{-1}, which is about 41 times larger than the present value, $(k_2)_B$.This difference must be ascribed to a smaller amount of energy available in the benzene photosensitization. The ratio (ρ) of the two values of k_2 based on the classical theory of Kassell is

$$[8] \qquad \rho = \frac{(k_2)_{Hg}}{(k_2)_B} = \left(\frac{(1 - \epsilon_0/\epsilon)_{Hg}}{(1 - \epsilon_0/\epsilon)_B}\right)^{s-1},$$

where ϵ represents the actual vibrational excitation energy of the electronically excited ethylene molecules E* and ϵ_0 the minimum vibrational excitation energy required for the intersystem crossing step (reaction [2]). With 12 normal vibrational modes in ethylene, the number of "effective" oscillators (s) is likely to be between 6 and 8. The values of ϵ and ϵ_0 are not known but, for a tentative evaluation of ρ, certain values can be assumed on the basis of the energy level diagram in Fig. 1. Assuming that the zero vibrational level of E* is 1.9 eV (44 kcal) and the minimum energy required for reaction [2] to correspond to the level of ethylidene (69 kcal), then ϵ_0 = 25 kcal. In the case of mercury photosensitization ϵ is then 68 kcal (112 − 44), whereas in the benzene photosensitization ϵ is 39 kcal if the transfer occurs from the lowest triplet. Transfer from the lowest triplet cannot be vertical, but some deviation from a vertical transition cannot be ruled out since it is possible that a transient complex of finite lifetime is formed between ethylene and the benzene triplet. With these assumptions $\rho = (1.76)^{s-1}$, which for $s = 8$ gives $\rho = 52$. With Kassell's expression for k_2 ($k_2 = A[1 - \epsilon_0/\epsilon]^{s-1}$) a value of about 1×10^{11} s^{-1} is obtained for A. This is probably rather low, although there may be an appreciable loss of entropy in the transition state if the intersystem crossing indeed represents the formation of a triplet ethylidene from the ethylene triplet, as tentatively postulated (20). However, it is clear that any calculations of this type can have little quantitative significance at the present time. Not only is the position of the energy levels in doubt, but it is also not certain whether energy transfer to ethylene does occur from the first triplet of benzene as is usually assumed. Such an energy transfer would have to depart considerably from a vertical transition. Alternatively, the second or third triplet of benzene (placed tentatively by Parisier (27) on theoretical grounds at 4.1 and 4.7 eV, respectively, as shown in Fig. 1) may be the energy donors or even an isomeric form of benzene. This aspect of the process will require separate studies.

Investigations of the photosensitized isomerization of dideuteroethylene with other sensitizers of known lower triplet energies would be of interest from this point of view and also from the point of view of the chemical behavior of the excited triplet of ethylene. The latter has been of primary interest in present work.

In conclusion it may be mentioned briefly that a very small amount of hydrogen and of some other products appears to be formed at prolonged irradiations, especially at very low pressures. It was difficult to carry out reliable analysis, but hydrogen appeared to contain only very little deuterium and probably results mainly from some decomposition of benzene. A trace of acetylene found in the experiments at 0.3 mm pressure could come from reaction [4], but its yield is extremely small. A conservative estimate of k_4 from the equation

$$k_4 = \tfrac{1}{3}k_5[\mathrm{M}] \Big/ \left(\frac{\phi_{asym}}{\phi_{\mathrm{decomp}}}\right)_1$$

gives a value which is at least three orders of magnitude smaller than the corresponding value of 3.5×10^8 s^{-1} found by Setser *et al.* (23) in mercury photosensitization. Evidently, the molecular detachment of hydrogen (reaction [4]) is strongly dependent on the amount of vibrational energy in E**.

EXPERIMENTAL

This investigation has been carried out at two places, at the Tokyo Institute of Technology in Tokyo (TIT) and at the National Research Council in Ottawa (NRC).

Materials

At TIT, *trans*-dideuteroethylene was synthesized (28). Special care was taken to prevent contamination by mercury.

At NRC, the three dideuteroethylenes were purchased from the Merck, Sharp and Dohme of Canada, Ltd., and were used as supplied.

Apparatus

The apparatus used was practically the same as described previously (19). At NRC, the glass system was treated with NO_2 gas before use and the storage vessel for ethylene was packed with silver foil to eliminate any traces of mercury which might be present. Experiments with the medium-pressure lamp at NRC were carried out in the presence of mercury vapor.

The 2 537 Å radiation was obtained from a low-pressure mercury lamp and was passed through a 7–54 Corning glass filter at NRC and through a UV-25 Toshiba Denki glass filter at TIT. The Cd lamp used at NRC was supplied by Phillips Electronic Co. Ltd. The medium-pressure mercury lamp used at TIT was supplied by Wako Denki Co. Ltd. and at NRC, by the Engelhard Hanovia, Inc. Infrared spectra shown in the figures were obtained on a Perkin–Elmer model 21 double-beam spectrometer.

ACKNOWLEDGMENTS

The authors are grateful to L. C. Doyle for assistance with several of the experiments and to the Analytical Section of the Division of Applied Chemistry at NRC, especially to R. Ironside, for the infrared analyses.

We also thank Professor K. Kozima for the infrared analyses and Dr. S. Ikeda for his helpful advice in the preparation of dideuteroethylene.

MEAN MOLAL ACTIVITY COEFFICIENT RATIOS OF MIXED Na^+–K^+ SOLUTIONS OF *p*-TOLUENE AND POLYSTYRENE SULFONATES

DONALD S. GAMBLE,[1] JACOB A. MARINSKY,[2] AND JOEL P. GUPTILL
Department of Chemistry, State University of New York at Buffalo, New York

Received March 15, 1966

ABSTRACT

A zeolite ion exchange technique for measuring mean molal activity coefficient ratios of mixed electrolytes has been further developed. The work was confined to systems of the type

(Zeolite Type 4A – Na^+ – K^+)

The 4A Zeolite has been calibrated for this kind of system by fitting the function

$$Q(X_{Na}) = \ln(\gamma_{Na}/\gamma_K) - (2.303 \log a_w \Delta \bar{V})/18.016$$

to a fifth degree polynomial, in the range $0.1 \leqslant X_{Na} \leqslant 0.7$.

Selectivity coefficient measurements with calibrated zeolite have been used to calculate ratios of mean molal activity coefficients for mixed Na^+–K^+ salts of model compounds. The model compounds were: *p*-toluene sulfonate, polystyrene sulfonate (mean molecular weight 400 000), and polystyrene sulfonate (mean molecular weight 30 000 to 40 000). The agreement between these measurements of activity coefficient ratios, and those calculated by Myers and Boyd for Dowex resins, ranges from excellent to fair.

INTRODUCTION

Numerous attempts have been made to interpret the ion-exchange phenomenon by employing for the exchanger phase activity coefficients of model compounds, selected for this purpose on the basis of their close resemblance to the repeating monomer unit of the cross-linked ion-exchange resin under consideration. For example, Gregor and Bregman (1) in 1951 attempted to predict ion-exchange selectivity coefficients of copolymers of divinylbenzene and sulfonated polystyrene by substituting the solution activity coefficients of the appropriate toluene sulfonates. Bregman (2) later predicted, with some success, equilibria for K^+–Li^+ and K^+–Na^+ systems by this approach. Bonner, Holland, and Smith (3) in their attempt to interpret selectivity reversal in the H^+–Na^+ ion-exchange reaction, made isopiestic measurements of solutions containing 80% *p*-toluene sulfonate and 20% 2,5-dimethylbenzene sulfonate with the counterions, Na^+ and H^+, present in varying proportions. They computed the activity coefficient ratio of these ions as a function of ion composition and total molality and on the basis of their results concluded that polystyrene divinylbenzene sulfonate ion-exchange resins are composed of at least two kinds of sulfonate groups. Recently available for application of this manner of approach to the elucidation of ion-exchange selectivity, are the mean molal activity coefficients that have been computed for various methane and ethane sulfonates from isopiestic measurements of the pure electrolytes (4).

The above technique for the analysis of the ion-exchange phenomenon suffers from the fact that the contribution of the polyelectrolyte environment of the resin to the thermodynamic characteristics of the counterions in the exchanger phase cannot be analyzed. A first approach to overcome this deficiency has been made by Bonner and Overton, who have reported isopiestic measurements on a wide molecular weight range of polystyrene

[1]*Union Carbide Fellow, 1963–1964. This paper is based on a dissertation submitted by D. S. Gamble in partial fulfillment of the requirements of the degree of Doctor of Philosophy. [2]*Requests for reprints to be addressed to this author.*

sulfonates (5). Although no attempt was made by them to apply these measurements to selectivity coefficient predictions, we believe that such use of their measurements is desirable. In earlier studies by Marinsky *et al.* (6–8), a polyelectrolyte model was employed with some success to analyze ion-exchange behavior, and justifies this prognosis. In fact, because of this estimate, the ultimate objective of the present research program was to compare directly the thermodynamic parameters of the linear sulfonated polystyrene polyelectrolyte and the cross-linked sulfonated polystyrene cation-exchange resin at similar counterion concentrations.

For this purpose, an ion-exchange method for measuring activity coefficient ratios of mixed electrolytes was employed. The synthetic A-type zeolite, (9, 10) because of its special properties of rigidity and high resistance to electrolyte incursion, maintains essentially invariant its composition-based free energy. As a consequence, once these free energy parameters have been determined experimentally for a pair of counterions over a complete composition range in the zeolite, they may be employed to probe the mixed electrolyte behavior of systems containing these counterions. The effect of variables such as the nature of the by-ion, the relative composition of counterions, and the total ionic strength on mixed electrolyte properties are thus susceptible to study by this technique.

We have, in this investigation, employed the zeolite calibration that was obtained in a separate study of the K^+–Na^+ ion pair (11) to elucidate the thermodynamic behavior of Na–K polystyrene sulfonate and Na–K paratoluene sulfonate mixtures, respectively. This calibration was based on selectivity measurements at one ionic strength for the exchange reaction

$$\bar{K}_z^+ + Na_{(aq)}^+ \rightleftarrows \bar{Na}_z^+ + K_{(aq)}^+$$

in the mixed NaCl–KCl system. The thermodynamic properties of this mixed electrolyte system have been carefully evaluated by Robinson (12, 13) and could be used with complete confidence for characterization of the zeolite. The utility of the calibration over an extensive composition range of K^+ and Na^+ in the zeolite was then demonstrated by the ability to predict within the limits of experimental error the selectivity behavior of this system at other ionic strengths and at various composition ratios of the counterions (11).

THEORETICAL BASIS OF EXPERIMENTAL METHOD

The 4-A Zeolite has been rather extensively studied and the following characteristic properties have been demonstrated for this material. (*a*) The structure is well defined (14, 15) and no perceptible contraction, swelling, or structural changes occur when it is equilibrated at 25 °C with electrolyte at any concentration. (*b*) Electrolyte sorption at 25 °C, under controlled conditions, is either absent or can be limited to insignificant proportions. Barrer and Walker (16) have shown that the rate of sorption is extremely slow at 25 °C. In our laboratory we have observed, over the period of equilibration used in our studies of the KCl – NaCl – 4-A Zeolite system (11), that the sorption of Cl^- ion at 25 °C is measurable only at external concentrations exceeding 0.5 *m* and then only when the Na^+ ion content of the zeolite is at least 2.5-fold greater than its K^+ ion content. (*c*) The H_2O content of the zeolite is an insensitive function of the water activity (a_w) of the external solution. Water sorption measurements by Breck *et al.* (10) show that above an a_w value of 0.16 additional entry of water is essentially excluded because of the rigid structure.

Bukata and Marinsky (17) concluded from these facts that the properties of the zeolite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

interior should depend only on the two cations used and the ion composition and were able to verify this assumption experimentally. In the equation

$$[1] \qquad \log K_K^{Na} = \log (\bar{\gamma}_K/\gamma_{Na}) + \pi(V_K - V_{Na})/2.303RT + 2 \log (\gamma^{\pm}_{NaCl}/\gamma^{\pm}_{KCl})$$

for the Na^+–K^+ system, K_K^{Na} is the experimentally determined selectivity coefficient, $\bar{\gamma}$ is the activity coefficient of the ion in the zeolite phase, $\gamma^{\pm}$ is the mean molal activity coefficient of the electrolyte in the external solution phase, π is the difference in osmotic pressure between the interior of the zeolite and the external solution, V represents the partial molar volume of the ions at infinite dilution and the bar placed above a symbol is used to differentiate the zeolite phase from the aqueous phase. The function

$$\log (\bar{\gamma}_K/\bar{\gamma}_{Na}) = g(X_{Na})$$

is assumed to be independent of the anion composition and water activity of the external solution. Bukata and Marinsky also assumed a zeolite water activity constant at $\bar{a}_w = 0.16$, so that with $(\bar{V}_K - \bar{V}_{Na}) = 10.2\ cm^3/mole$ from the literature (18),

$$[2] \qquad \begin{aligned} \pi(\bar{V}_K - \bar{V}_{Na})/2.303RT &= (\log a_w - \log \bar{a}_w)(\bar{V}_K - \bar{V}_{Na})/18.016 \\ &\approx 0.566 \log a_w + 0.450. \end{aligned}$$

With conversion to natural logarithms, this gives

$$\ln K_K^{Na} = \ln (\gamma_K/\gamma_{Na}) + 1.04 + 0.566 \ln a_w + 2 \ln (\gamma^{\pm}_{Na}/\gamma^{\pm}_K)$$

where the terms outside the square brackets on the right hand side characterize the external solution. It is not necessary to calculate

$$- \log \bar{a}_w(\bar{V}_K - \bar{V}_{Na})/18.016$$

as was the practice in earlier work. Any error arising from small deviations from constancy of this term can be avoided by defining the function

$$[3] \qquad \begin{aligned} Q(\bar{X}_{Na}) &= \ln (\gamma_K/\gamma_{Na}) - (2.303 \log \bar{a}_w(\bar{V}_K - \bar{V}_{Na})/18.016 \\ &= \ln K_K^{Na} - 0.566 \ln a_w - 2 \ln (\gamma^{\pm}_{Na}/\gamma^{\pm}_K). \end{aligned}$$

This calibration function is calculated only from experimental selectivity coefficients and from external solution properties. It is only necessary that

$$- \log \bar{a}_w(\bar{V}_K - \bar{V}_{Na})/18.016$$

be approximately constant. The quantity $RT(Q - 1.04)$ may therefore be regarded as the excess free energy of the Na^+–K^+ ion-exchange reaction, and according to the above is a function only of $\bar{X}_{Na}$. The calibration of the zeolite therefore consists of experimentally determining the function $Q = Q(\bar{X}_{Na})$. The calibrated zeolite may then be used to measure

$$2 \ln (\gamma^{\pm}_{Na}/\gamma^{\pm}_K)$$

for any Na^+–K^+ solution for which the assumptions of Bukata and Marinsky are valid. The ratio of mean molal activity coefficients in the external solution is thus calculated from the equation

$$[4] \qquad \log (\gamma^{\pm}_{Na}/\gamma^{\pm}_K) = (1/4.606)\ (\ln K^{Na}_K - Q - 1.304 \log a_w) = f(m, X_{Na}).$$

EXPERIMENTAL

Chemicals

Baker Analyzed and Fisher Certified Reagent grade acetic acid, sodium hydroxide, potassium hydroxide, potassium acetate, potassium chloride, and sodium chloride were used as received.

The zeolite (Linde Molecular Sieve, type 4-A), supplied by the Linde Corporation of Tonawanda, New York, was prepared for use in 100 g portions. Each portion was hydrated and sieved, the residue retained by a 100 mesh screen being discarded. The screened zeolite product was then equilibrated 2 or 3 times for as long as 12 h with 1.85 *M* sodium acetate adjusted to a pH of 6.5 with acetic acid, thereby assuring the conversion of any hydrolyzed material to the sodium form. Fines were then removed by decantation after sedimentation several times in 0.2 *M* NaCl. The zeolite product was then washed with deionized water until the complete removal of Cl^- ion. An alternate final treatment of the zeolite consisted of washing with 0.2 *M* NaCl to assure removal of traces of acetate ion. Analysis of the sodium content of zeolite samples prepared by both methods were identical within experimental error limits and demonstrated conclusively that zeolite hydrolysis during the final wash with water was insignificant. In addition, selectivity measurements were reproducible from one batch to the other.

Fisher Certified Reagent *p*-toluene sulfonic acid (m.p. 104.1° to 105.1° C) was converted to the potassium salt with 1 *M* KOH. Insoluble material was removed by filtration. After concentration of the filtrate two crystallizations were effected by cooling the approximately 4 *m* solutions to 1 °C. A third set of crystals, recovered in the same way, was dissolved and decolorized with activated charcoal; it was then filtered and recrystallized before being combined with the earlier crystal product. The total sample was dissolved, decolorized, and recrystallized by evaporation at room temperature. Separate samples of sodium polystyrene sulfonate, mean molecular weight 400 000 and 30 000 – 40 000, respectively, were supplied by Dow Chemical Company, Midland, Michigan, in powder form.

Conversion of the low molecular weight polymer to the K^+ salt form was accomplished by passing a solution of the Na^+ salt (100 g dissolved in 600 g of H_2O) through an ion-exchange (Dowex 50-X8) column. A small fraction separated during the conversion to the K^+ salt was discarded. A flame test detected no Na^+ in the final polymer solution. Solutions of the higher molecular weight polymer were too viscous for the ion-exchange column operation. However, the polymer is insoluble in concentrated potassium acetate and in ethanol. The K^+ salt of the polymer was therefore prepared by repeated salting out from aqueous solution with concentrated potassium acetate. Excess potassium acetate was finally washed out of the solid polymer with ethanol.

Carrier free 2.6 y ^{22}Na was purchased from the Nuclear Science and Engineering Corporation, Pittsburgh, Pennsylvania, in half mCi amounts and was diluted to 1 ml prior to use.

Analytical Procedures

Paratoluene sulfonate solutions were quantitatively converted by ion exchange to the free acid, which was then titrated with standard NaOH. Solid samples of polystyrene sulfonate were analyzed the same way, after being dried to constant weight over P_2O_5.

The zeolite was analyzed for H_2O content by ignition at 800 °C until constant weight was attained. The precision of the dry weights after 48 h was $\pm 0.05\%$ or better. The ion exchange capacity of the zeolite was measured by an isotope dilution technique involving ^{22}Na and γ-ray counting. Typical results for 3 samples are given in Table I. Breck *et al.* (10) have reported that $96\% \pm 4\%$ of the theoretical amount of Na^+ is found in this zeolite. This corresponds to an ion-exchange capacity of $6.758 \pm 4\%$ meq/g of dry Na^+-form zeolite, a value approximately 0.7% higher than is measured. This deviation is almost within the experimental error of the tracer method. All calculations were made using the average capacity value given in Table I.

Selectivity Coefficient Measurements

Portions of zeolite, and of K^+ salt solutions containing ^{22}Na radiotracer, were weighed into polyethylene bottles. Equilibrium was established by shaking and thermostatting at 25.0 °C during two to four weeks, depending on viscosity. Solutions from the equilibrated mixtures were centrifuged free of zeolite, and weighed into cellulose nitrate test tubes for γ-ray counting. The counting was done with a NaI crystal well detector. Three aliquots of each stock solution were counted, to serve as standards.

Counting Procedure

Four 10 min counts were made on each experimental sample, and a total of twelve 10 min counts were made on each standard. The precision attained was usually within the statistical error of counting.

Isopiestic Measurements

A few isopiestic measurements were made with K^+ polystyrene sulfonate solutions at high water activities. The solutions and isopiestic standards were put into jars which were sealed with rubber gaskets and placed in the constant temperature chamber at 25.0 ± 0.02 °C. Two samples approached equilibrium from opposite directions in the same jar. No special provisions were made to promote heat and mass transfer. Instead, the isopiestic jars were simply left undisturbed for about eight weeks.

RESULTS

(1) Selectivity Coefficients

The total radioactivity of an exchange sample (solution + zeolite) is given by

$$A_T = (C_0/t_0 - C_B/t_B)W_s/W_0 \text{ counts/min}$$

while that taken up by the zeolite is

$$A_z = [(C_0/t_0 - C_B/t_B)1/W_0 - (C_A/t_A - C_B/t_B)1/W_{AK}]W_s \text{ counts/min.}$$

The mole fraction of Na^+ in the zeolite is calculated from

[5] $$\bar{X}_{Na} = 1 - (C_A/t_A - C_B/t_B)W_0/(C_0/t_0 - C_B/t_B)W_{AK}.$$

The Na^+ ion concentration of the external solution is then

[6] $$m_{Na} = Z(W_z/W_w)(1 - \bar{X}_{Na})$$

[7] $$X_{Na} = (ZW_z/mW_w)(1 - \bar{X}_{Na}).$$

The aliquots of stock solution that are weighed out as standards contain only the pure K^+ salt, apart from the trace ^{22}Na. After equilibration of these solutions there is significant substitution of Na^+ for K^+ ion. Consequently at a given total molality, the value of W_{AK} must be modified to correct for the loss in solution weight that results from the ion exchange reaction since the selectivity coefficient is so sensitive to error. The following equation has been employed for this purpose:

[8] $$W_{AK} = (1 + mM_K/10^3)W_A^1/\{1 + m[X_{Na}(M_{Na} - M_K) + M_K]/10^3\}$$

The zeolite phase concentrations are given by

$$\bar{c}_{Na} = Z\bar{X}_{Na}$$

$$\bar{c}_K = Z(1 - \bar{X}_{Na}).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

By using these and $m_K = m - m_{Na}$, the equation with which the selectivity coefficient is related to the experimental measurements is obtained:

$$[9] \qquad K_K^{Na} = \bar{X}_{Na}[mW_w/ZW_z - (1 - X_{Na})]/(1 - X_{Na})^2$$

In these equations C/t represents the observed counts per minute, W the weight in grams of the various samples, M the atomic weight of K^+ or Na^+ and Z the ion-exchange capacity in meq per dry gram of zeolite. The subscripts 0, s, B, A, AK, z, and w identify the operation or the sample subjected to the specified measurement, as follows:

0 = aliquot of initial equilibrating sample (standard)
s = total initial equilibrating sample
B = background measurement
A, AK = aliquot of equilibrated sample
z = zeolite
w = water.

An iterative calculation, employing eqs. [5], [7], [8], is necessary before the calculation of K_K^{Na} from eq. [9] is begun. The iteration is started by using $W_{AK} \simeq W_A$[1] to get the zeroth order approximation of X_{Na}. The calculation converges very rapidly so that very little if any change occurs within four significant figures after the first iteration.

An error in C_0 can seriously affect the shape of a K_K^{Na} vs. $\bar{X}_{Na}$ plot. Since a plot of $(C_A - C_B)$ per unit mass against (W_z/W_w) should extrapolate to $(C_0 - C_B)$ per unit mass at $(W_z/W_w) = 0$, such errors were easily found and corrected. The only requirement for this test was the increased precision which derived from the greater number of measurements. This test was made for all of the K_K^{Na} vs. $\bar{X}_{Na}$ data and is illustrated in Fig. 1 for several sets of experiments. The sample plot for 0.4960 m polystyrene sulfonate does not extrapolate to the measure value of the $(C_0 - C_B)/2.000$ g. The extrapolation value gives better agreement with another series of 0.4960 m experiments. Such correction of

C_0 was needed only in some of the *p*-toluene sulfonate results since repeated measurements of the standards were not made in this earlier phase of the program.

The selectivity coefficient calculations were duly programmed in Fortran II for the I.B.M. 1620 computer. This program used eqs. [5–8] and eq. [9] to calculate $\bar{X}_{Na}$, m_{Na}, and K_K^{Na}. Four iterations were used. The data are summarized in Tables II and III.

Figures 2 and 3 illustrate the typical shapes of the K_K^{Na} vs. $\bar{X}_{Na}$ curves. All show maxima for $0.3 < \bar{X}_{Na} < 0.4$, at $X_{Na} \approx 0.35$. For the polystyrene sulfonate solutions the value of the maximum increases with total concentration. In the *p*-toluene sulfonate system, the 2.168 *m*, 3.179 *m*, and 3.766 *m* curves are within experimental error of each other, somewhat above the 1 *m* curves. Below $\bar{X}_{Na} = 0.1$, the curves are generally ill defined. Mixing and separation problems caused by high viscosity may have contributed to the scatter in

[3]*More extensive tables of selectivity coefficients have been placed in The Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada, and photocopies may be obtained upon request to the Depository.*

Fig. 3. Solid circles indicate points calculated from plots similar to those presented in Fig. 2.

(2) Calibration of the Zeolite

Robinson and Stokes (19) have published the mean molal activity coefficients and H_2O activities of mixed NaCl–KCl solutions, over a complete range of X_{Na} and over a considerable range of concentration. These data are ideally suited for calibration of the zeolite.

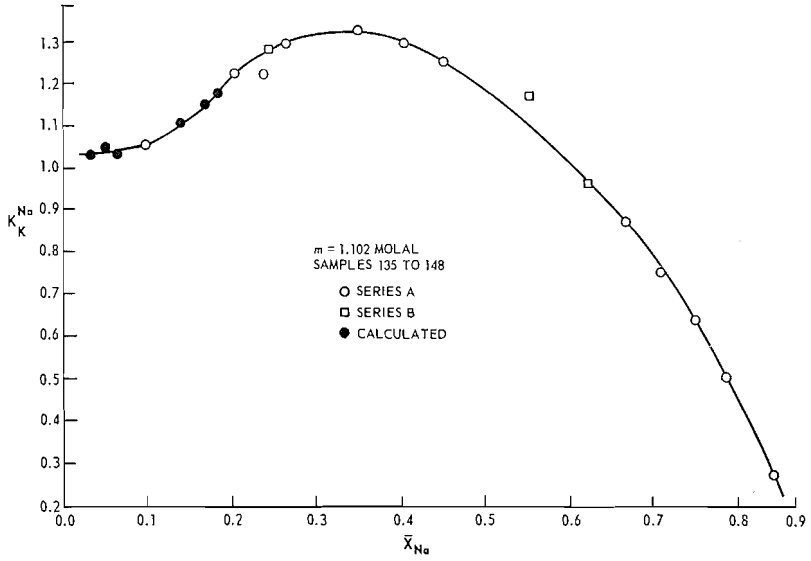

FIG. 2. Selectivity behavior of *p*-toluene sulfonate.

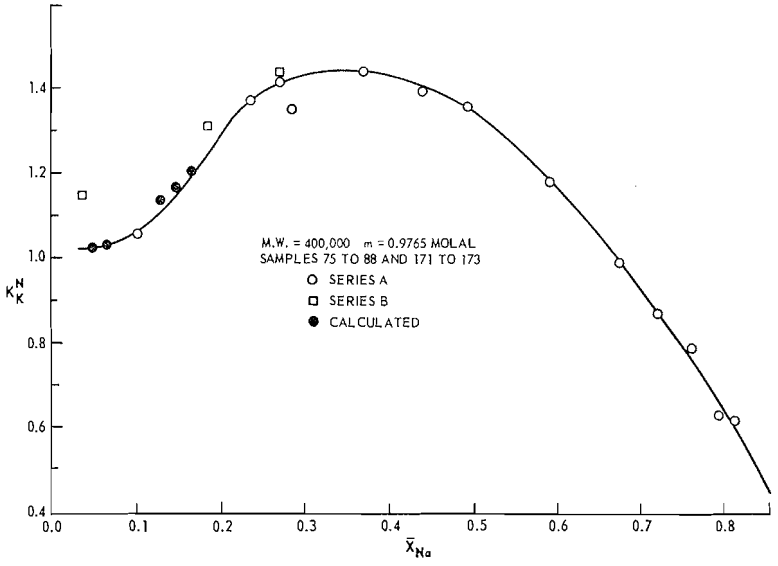

FIG. 3. Selectivity behavior of polystyrene sulfonate.

For personal use only.

By using eq. [3], $Q = Q(X_{Na})$ has been calculated for 99 sets of K_K^{Na} measurements with NaCl–KCl solutions. These have been fitted by least squares to the polynomial,

$$[10] \qquad Q = \sum_{n=0}^{5} C_n \bar{X}_{Na}{}^n$$

within the range $0.1 \leqslant \bar{X}_{Na} \leqslant 0.7$. Both the calculation of Q and the least squares fit were accomplished with the I.B.M. 1620. The pertinent polynomial coefficients for the equation representing the zeolite calibration curve are:

$$\begin{aligned} \sigma &= 0.0225 \\ C_0 &= -0.4360 \\ C_1 &= +5.075 \\ C_2 &= -10.21 \\ C_3 &= +3.314 \\ C_4 &= +7.694 \\ C_5 &= -7.071 \end{aligned}$$

The calibration curve in Fig. 4 has the same general shape as the selectivity coefficient curves, with a maximum at $\bar{X}_{Na} = 0.34$. The fourth degree polynomial had a standard deviation almost as small, but did not give quite as good a fit at the extreme ends of the curve.

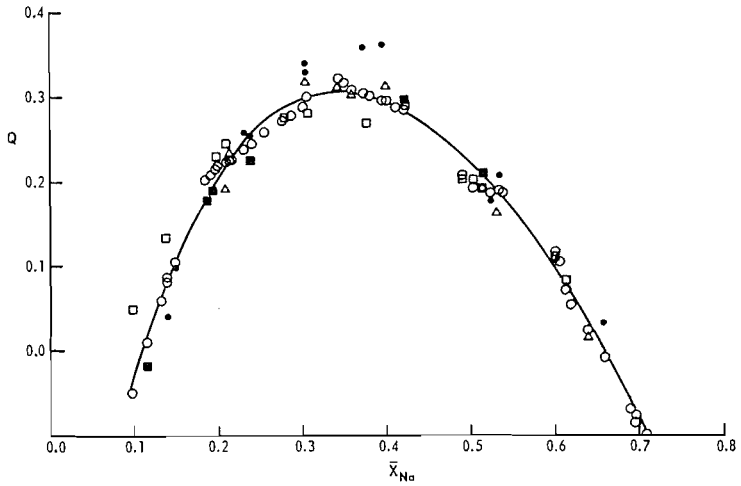

FIG. 4. Calibration of Zeolite 4-A.

(3) Solution Activity Coefficient Ratios

Equations [4], [10], and [7] were used to calculate log $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ as a function of X_{Na} for each of the ten solutions studied. Water activities were taken from data published by Robinson and Stokes (19). The water activity values used for the polystyrene sulfonate solutions were taken from Fig. 5 which contains our data for the K^+ polystyrene sulfonate and the data published for the Na^+ salt by Bonner and Overton (5). In all cases a_w was assumed to be a linear function of X_{Na}. This is justified, since neglecting the a_w term completely in eq. [4] causes an error of only 1% to 3% in log $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$. In addition, this linear approximation causes negligible error in the NaCl–KCl computations. The solutions were fitted to straight lines by least squares.

For personal use only.

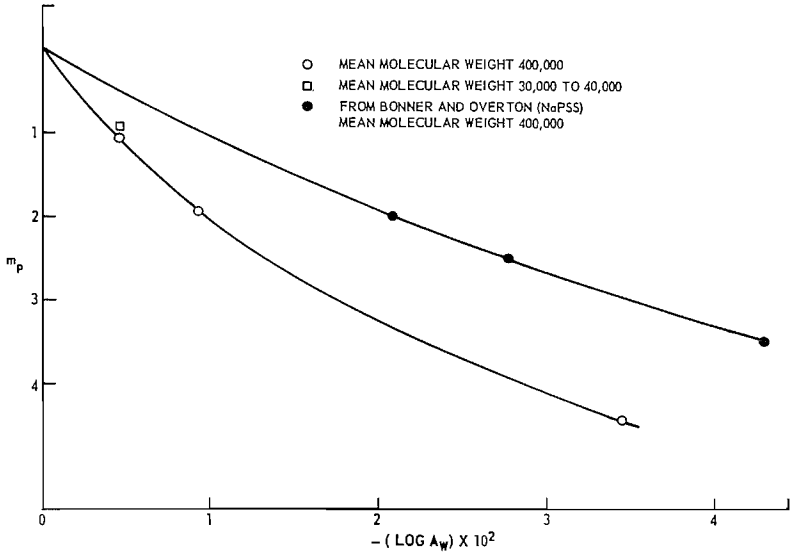

FIG. 5. Water activities of potassium polystyrene sulfonate.

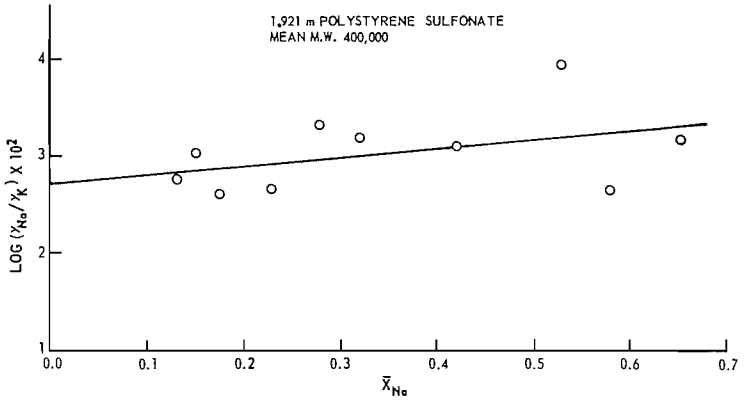

FIG. 6. Activity coefficient ratio.

A sample plot of log $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ versus X_{Na} for the 1.921 *m* polystyrene sulfonate system is presented in Fig. 6. The variation of $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ with mole fraction of Na in the zeolite is summarized briefly in Table IV.

(4) Experimental Errors

The experimental errors are classified according to their effects on the calculation of K_K^{Na}. In eq. [9], let

$$y = (C_A/t_A - C_B/t_B)W_0(C_0/t_0/ - C_B/t_B)W_A$$

$$u = mW_w/ZW_z$$

This gives

$$\bar{X}_{Na} = 1 - y$$
$$K_K^{Na} = (1 - y)(u - y)/y^2.$$

				0.656	0.972

Therefore, a positive error in y gives a negative error both in $\bar{X}_{Na}$ and in K_K^{Na}, with the error in K_K^{Na} being magnified. A positive error in u makes a positive error in K_K^{Na} of similar magnitude.

The error in y is less than $\pm 0.5\%$. The measurements of m and Z are the most important sources of error in u. Together they give u an error of at least $\pm 1\%$. The selectivity coefficient computer program was used to examine the effects of the errors in y and u on K_K^{Na}. These indicate that the error in K_K^{Na} is $\pm 3\%$, and that the shape of the K_K^{Na} vs. $\bar{X}_{Na}$ curve is quite uncertain for $\bar{X}_{Na} \leqslant 0.1$. From this and from the σ of the Q curve, $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ is estimated to have $\sigma = \pm 8\%$, or $\rho = \pm 5.4\%$.

DISCUSSION

The objective of this program was blunted by propagation of errors. The intended calculation of Harned–Cook constants to describe the functional dependence of $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ on X_{Na} in the monomer and the polyelectrolyte is not possible because of the scatter of the data points. As a result a quantitative comparison of the thermodynamic parameters for the monomer, the linear polyelectrolyte and the cross-linked ion-exchange resin (16) cannot be made. In fact, the behavior of the three systems is so similar that a qualitative comparison is difficult as well.

Resin phase single ion activity coefficient ratios calculated by Myers and Boyd (20) for Dowex 50 are given in Table V for this purpose. These authors reported a possible

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

TABLE V

Resin phase activity coefficient ratios calculated by Myers and Boyd (20) for Dowex 50

% DVB*	$\bar{X}_{Na}$	$(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ ±8 to ±14%	Resin phase total molality
2	1.0	1.34	1.95
2	0.5	1.26	1.97
2	0.0	1.19	2.00
4	1.0	1.48	3.30
4	0.5	1.38	3.36
4	0.0	1.30	3.40
8	1.0	1.71	5.81
8	0.5	1.57	5.90
8	0.0	1.44	5.99

*%DVB here means "nominal mole % divinylbenzene".

experimental error of 8% to 14% in their measurements. The error in $(\gamma^{\pm}_{Na}/\gamma^{\pm}_{K})$ was assumed to be similar since other terms made small contributions to the total error, and much better agreement than this between calculated and measured selectivity coefficients was obtained by them.

There is excellent agreement between the calculations of Myers and Boyd for 2% crosslinked Dowex 50, which has a resin phase molality of 2, and the present measurements for 2.168 *m* *p*-toluene sulfonate solution. The agreement with the 1.921 *m* and 2.379 *m* polystyrene sulfonate is not as good, but is within experimental error.

The results with the polymer appear to be consistently low. There is fair agreement between the 3.179 *m* and 3.766 *m* *p*-toluene sulfonate measurements and the calculations of Myers and Boyd for 4% crosslinked resin, in which the total exchanger phase molalities are 3.3 to 3.4.

Although the experimental program failed in its primary objective in this investigation the selectivity method for quantitative analysis of the type attempted herein is undoubtedly useful for other systems such as the Ag–Na polystyrene sulfonate where interaction effects are considerable. A recent investigation by this method of the nitrates and acetates of K and Na has proved fruitful and a report of this study is being prepared for publication (11).

ON THE PRESSURE DEPENDENCE OF REACTION RATES

H. S. GOLINKIN, W. G. LAIDLAW, AND J. B. HYNE
Department of Chemistry, University of Calgary, Calgary, Alberta
Received March 8, 1966

ABSTRACT

The functional dependence of the rate constant for benzyl chloride solvolysis on pressure is investigated with a view to obtaining reliable values of the activation parameters. It is concluded that a second order polynomial is the best description of this system, reproducing the experimental data with a greater degree of precision than the other published functions. A method for determining the precision of the derivatives of the logarithmic rate is presented, and the pressure dependence of the activation volume is demonstrated. Various systems from the literature are analyzed to demonstrate the general applicability of the quadratic function.

INTRODUCTION

The pressure dependence of reaction rate has long been used to obtain the pseudo-thermodynamic parameter of activation, ΔV^*, the volume change on activation. The sign and numerical value of this parameter are clearly related to such important mechanistic phenomena as bond extension and solvent electrostriction during the activation process. Accordingly, considerable attention has been directed toward obtaining meaningful ΔV^* values for a number of solvolytic and displacement reactions in an attempt to further elucidate the mechanisms of these processes. The major problems faced in such determinations are twofold: firstly the determination of rate constants (k) as a function of pressure of sufficient precision to permit extraction of ΔV^* values with associated error limits that are small compared with the numerical magnitude of ΔV^* itself; and secondly the establishment of the *functional dependence* of the rate constant on pressure.

These problems are similar to those that for many years characterized the difficulties attendant upon the determination of activation enthalpy, ΔH^*. Here, the corresponding problems were those of accurate rate determinations as a function of temperature and the establishment of the functional dependence of rate constant on temperature. It was not until the postwar period that rate data of sufficient accuracy became available to permit detailed testing of various functional dependencies of rate on temperature. Such work led to the recognition of the reality of the ΔCp^* activation parameter, implying the nonlinear dependence of $\ln k$ on $1/T$, or alternatively, the temperature dependence of ΔH^* (1). Many of the analytical problems associated with the rate/pressure dependency are remarkably similar to those previously encountered in the rate/temperature relationship, as will be seen in subsequent sections of this paper.

Crucial to the whole problem of both rate/temperature and rate/pressure dependency is the determination of sufficiently accurate rate data. Although there inevitably will be continued scepticism as to whether the rate data obtained are, in fact, of sufficient accuracy to permit the refined analysis necessary to test various functional dependencies, it seems to us that at some stage a start must be made to obtain an objective technique for comparing the various functional forms. We believe that the rate data on the solvolysis of benzyl chloride in ethanol–water mixtures as a function of pressure analyzed in this paper are of sufficient accuracy. The *in situ* conductimetric technique used to follow the rate of the reaction as a function of pressure is very similar to the methods used to

obtain highly accurate rate/temperature data. We have also applied our analytical methods to a number of other sets of rate/pressure data available in the literature. Although the precision of these data may well not be sufficient to justify the refined level of analysis applied, the form of analysis used in a number of the cases cited has been the basis of protracted argument in the literature (2, pp. 98–99; 3; 4). The application of our analytical comparison to these cases therefore serves to highlight the crucial factors involved in the formulation of the rate/pressure dependency.

BENZYL CHLORIDE SOLVOLYSIS (RATE DATA)

The rate of solvolysis of benzyl chloride in various water–ethanol mixtures has been studied as a function of pressure up to 4 000 atm at 50.25 °C (5). The rate data as a function of pressure and solvent composition is reproduced in Table I. The most crucial aspect of this data as far as the purpose of this paper is concerned is the confidence that can be placed in the error limits claimed for each rate constant. The *in situ* conductimetric technique used eliminates many of the sampling and timing errors that are characteristic of aliquot sampling techniques.

TABLE I

Rate constants and activation parameters for the solvolysis of benzyl chloride in aqueous ethanol at 50.25 °C

Pressure (atm)	$10^5 \times k$ (s^{-1}) for mole fraction ethanol				
	0.000	0.100	0.200	0.300	0.400
1	23.1 ±0.4	6.690±0.007	1.93±0.01	0.80±0.01	0.459±0.007
341	24.42±0.02	8.47 ±0.01	2.46±0.01	1.06±0.01	
681	30.0 ±0.2	10.25 ±0.02	3.02±0.07	1.29±0.01	0.68 ±0.03
1 362	39.3 ±0.3	13.68 ±0.01	4.64±0.01	2.04±0.03	1.041±0.002
2 723		21. ±2.	7.7 ±0.2	3.00±0.02	1.81 ±0.02
4 084					2.6 ±0.2
ΔV_0^* (ml/mole)	−8. ±1.	−17. ±1.	−20.3±0.2	−22.9±0.2	−17.9±0.9
$10^3 \times (\partial \Delta V^*/\partial p)_T$ (ml/atm mole)	−4. ±1.	+4. ±1.	+4.9±0.3	+7.3±0.1	+3.2±0.6

The considerable variation in the percentage size of the uncertainty claimed for each rate results from the concommitant variation in the experimental difficulties encountered as solvent and pressure are varied. The uncertainty tends to be larger at higher pressures where rates are faster and pressure control more difficult.[1] Similarly in more aqueous media the rates are also faster, resulting in a shorter reaction period available for study after pressure and temperature equilibration in the pressure vessel has been attained. The combination of all of these factors results in considerable variation of the uncertainty limits associated with each rate reported. Because of the crucial nature of the rate accuracy factor in such a study, however, it would be completely unjustifiable to report a single averaged uncertainty for all of the rate values.

The actual uncertainties reported in Table I are obtained from a minimum of two independent rate determinations and in many cases from three or four independent determinations.

[1]*The automatic pressure-regulating device used in this study (5) enabled the pressure to be controlled to ±14 atm (200 psig).*

ANALYTICAL FUNCTIONS AND THEIR SIGNIFICANCE

Theoretical Considerations

No strictly theoretical, analytical function describing the pressure dependence of reaction rate is available. The usual differential form of the dependence used is that given by Evans and Polanyi (6),

$$[1] \qquad \Delta V^* = -RT(\partial \ln k/\partial p)_T,$$

but the question immediately arises as to whether ΔV^* is pressure independent or not. Precisely the same question arises for the temperature dependence of rate where ΔH^* can be written

$$[2] \qquad \Delta H^* = -RT(\partial \ln k/\partial \left(\frac{1}{T}\right)_p).$$

If the pseudo-thermodynamic ΔH^* parameter has the same form as the real thermodynamic ΔH, then it is not temperature independent, since there is a non-zero value of ΔC_p^*. In an exactly similar manner ΔV^* may be expected to be pressure dependent according to eq. [3]

$$[3] \qquad (\partial \Delta V^*/\partial p)_T = -V_0^* \kappa^* \exp(-\kappa^* p) + V_0^g \kappa^g \exp(-\kappa^g p),$$

where the first term on the right-hand side refers to the transition state with V_0^* being the partial molal volume of the transition state at some reference pressure and κ the compressibility; the second term on the right-hand side applies similarly to the initial state. Equation [3] is unusable as an anlytical function for treating experimental rate data, since the partial molal isothermal compressibilities (κ's) cannot be determined in reacting systems.

While, therefore, there is good reason to believe that the functional dependence of rate on pressure is at least of second order with respect to pressure (just as the dependence of rate on temperature is second order in temperature), there is no theoretically derive-able form of the functional dependence which has practical utility.

Two further factors must be considered as possible contributors to the pressure dependence of rate: concentration effects and viscosity effects. In solvolytic reactions of the benzyl chloride type considered here the reaction is between the molecular species of the solvent environment and the dissolved substrate. Accordingly, if the volume of the initial and transition states is considered to be the volume of the substrate *plus* its immediate solvation shell in both states the effect of pressure on "concentration" is included in the volume of the two states as so defined. The viscosity effect would not be expected to become a major contributor until the viscosity of the system increased to a point where the diffusion rate of the reacting species was significantly reduced. This requires very high pressures as has been shown by Hamann (7) where for bimolecular reactions the rate dependence on pressure actually changes sign from positive to negative at very high pressures. Again, however, in solvolyses reactions, diffusion together of the reacting species is not an important factor, since the reacting substrate is always in immediate contact with the reactant solvent.

The Functions

In the absence of a strictly based theoretical functional form of practical utility for expressing the dependence of rate on pressure, four basic semiempirical functions have been employed. It is the purpose of this paper to examine these relations between rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

and pressure from the standpoint of their utility and ability to reproduce the experimentally observed dependencies and not from the theoretical viewpoint. However, comments will be made when appropriate about the physical significance of the relationships. The first of these relationships assumes that the dependence of the logarithm of the rate constant on pressure is linear (8) (eqs. [4] and [5]). This treatment regards the activation volume as being pressure independent, and consequently neglects a possible additional activation parameter $-(\partial \Delta V^*/\partial p)_T$. The second type of function is a power series in p, usually of second order (9), which allows for the pressure dependence of the activation volume (eqs. [6] and [7]). Benson and Berson (4) have used a modified form of the Tait equation (10) to calculate both the volume of activation and the change in compressibility (eq. [8]).

Whalley has plotted the average slope of any increment of the ln k vs. p curve against the average pressure of that increment[2] (11; 2, p. 100). Extrapolation to an average pressure of zero gives an intercept which can be taken as equalling $(\partial \ln k/\partial p)_{T,p} = 0$. Such a function is given in eq. [9] in which linearity of the incremental function is assumed.

In this study we considered each of these functions in turn, using the forms shown in eqs. [4] through [9]. Here k_0 is the rate constant at atmospheric pressure, and k_{n+1} and k_n are rate constants at adjacent pressures. Equation [5] is identical to eq. [4] except that, in the former, the curve is forced to pass through the experimental ln k_0. Equations [6] and [7] also differ only in the forced intercept treatment.

$$\ln k = A + Bp \qquad [4]$$

$$\ln k = \ln k_0 + Bp \qquad [5]$$

$$\ln k = A + Bp + Cp^2 \qquad [6]$$

$$\ln k = \ln k_0 + Bp + Cp^2 \qquad [7]$$

$$\ln(k/k_0)/p = A + Bp^{0.523} \qquad [8]$$

$$\ln(k_{n+1}/k_n)/(p_{n+1} - p_n) = A + B(p_{n+1} + p_n)/2 \qquad [9]$$

TEST OF BENZYL CHLORIDE SYSTEM

Using our experimental data (5) for the solvolysis of benzyl chloride in water and in mixtures of ethanol and water (Table I), we calculated the various constants of eqs. [4] through [9] by the method of least squares using an IBM 1620 computer. A representative set of these constants is presented in Table II. From these we obtained the values of the activation volume which are presented in Table III. The value at atmospheric pressure is reported for those functions which take account of the pressure dependence of ΔV^*.

Our interest lies in the variation of ΔV^* with solvent composition. This dependence is shown in Fig. 1. The values of ΔV^* obtained from functions [6] and [7] are identical for all solvents except pure water, and the difference at this one point is probably within the experimental error. It appears that utilization of the experimental intercept introduces no significant error. The values from functions [4] and [5], which also differ only with regard to the forced intercept treatment, do not agree so well. However, the differences are less than 2 ml/mole. It may be noted that the ΔV^*'s from function [9] agree

[2]*Note that refs. 11 and 2, p. 100 contain an error in the statement of the method of extracting the pressure dependence of ln k. The corrected version, as used here, is given in ref. 12.*

†The values reported for functions [6], [7], [8], and [9] are those evaluated at atmospheric pressure.

well with those from [6] and [7]. This is not surprising since all three allow for the pressure dependence of ΔV^*, i.e. $(\partial \Delta V^*/\partial p)_T \neq 0$. For this study we consequently can restrict further consideration to eqs. [4], [6], [8], and [9].

It is readily apparent that the general shapes of the curves in Fig. 1 are similar (viz. they all show a minimum in the region between 0.2 and 0.3 mole fraction alcohol). It can therefore be concluded, from a qualitative viewpoint, that the different functions give similar results. However, from a quantitative viewpoint, there are striking differences. The depth of the minimum, as measured with respect to pure water, ranges from 2 ml/mole for the linear analysis to 26 ml/mole for the Benson–Berson equation (4). Evidently for our interest, namely the effect of solvent composition on ΔV^*, it is necessary to ascertain which analysis is the most reliable. As the measure of reliability we chose to use the ability of the functions to reproduce the experimental data.

After the constants of eqs. [4], [6], and [8] were obtained, the value of $\ln k$ at each of the experimental pressures was calculated, giving $\ln k_{\text{calcd}}$. We then used the deviation, Δ (eq. [10])

$$\Delta = \ln k_{\text{obs}} - \ln k_{\text{calcd}}, \qquad [10]$$

as a measure of the functional reproducibility (the subscript "obs" refers to the experimental value). For the Benson–Berson equation (eq. [8]) the experimental value of $\ln k_0$ was used in these calculations.

Equation [9] has two unknowns, k_{n+1} and k_n, prohibiting the determination of $\ln k_{\text{calcd}}$. Therefore only the values of $\ln(k_{n+1}/k_n)_{\text{calcd}}$ can be calculated and compared with the observed value. In this case the deviation is given by eq. [11].

$$\Delta = \ln (k_{n+1}/k_n)_{\text{obs}} - \ln (k_{n+1}/k_n)_{\text{calcd}} \qquad [11]$$

The Δ values for the four equations are shown in Fig. 2 as a function of pressure for each of the solvents.

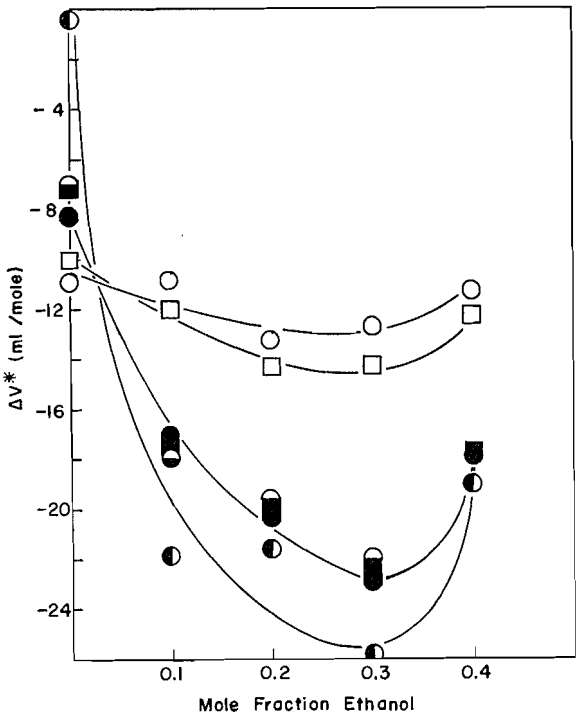

FIG. 1. The variation of ΔV^* with solvent composition: (○) eq. [2]; (□) eq. [3]; (●) eq. [4]; (■) eq. [5]; (◐) eq. [6]; (◒) eq. [7].

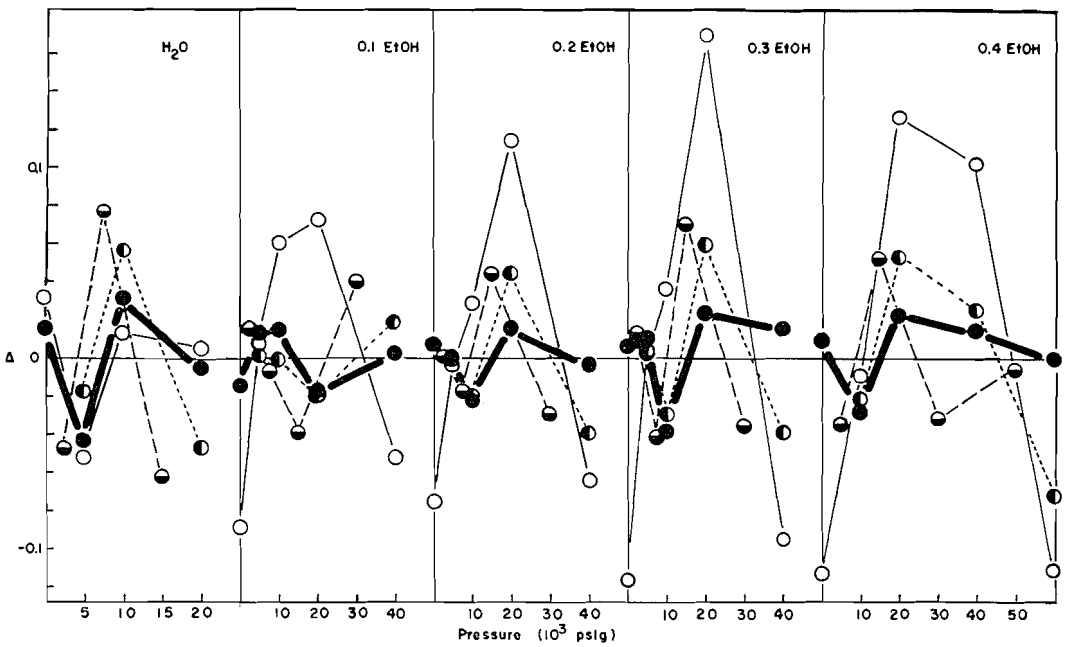

FIG. 2. Variation of the deviation of ln k with pressure for each solvent: (○) linear analysis (eq. [2]); (●) quadratic analysis (eq. [4]); (◐) Benson–Berson analysis (eq. [6]); (◒) incremental slope analysis (eq. [7]).

The most noticeable feature in Fig. 2 is the systematic error present in the linear analysis (eq. [4]). Only for pure water does the linear relationship appear to give a random error. The fact that systematic errors appear in this function suggests that it is not a reliable representative function of the present data. The second order polynomial. the Benson–Berson equation, and the incremental slope analysis (eqs. [6], [8], and [9]) all appear to give random scatter about zero. The only exception is in the Benson–Berson equation for 0.4 mole fraction ethanol. A further comparison of the four functions is shown in Table IV where the standard deviations are reported.

In accord with the above suggestion, function [4] gives a relatively large standard deviation, whereas eqs. [8] and [9] have values about twice that of eq. [6]. From the data presented in Fig. 2 and Table IV, it is evident that the quadratic function (eq. [6]) best represents our data. It must be emphasized that although we conclude the most reliable function for our data to be a second order polynomial, it need not be generally applicable to all reactions. However, by analogy, we would consider it to be generally applicable to ionic unimolecular decompositions.

TABLE IV

Standard deviation of each function

Function	Number of points	Standard deviation	Relative values
[4]	24	0.0814	4.24
[6]	24	0.0192	1.00
[8]	19	0.0374	1.94
[9]	19	0.0420	2.19

Physical Significance

We have, so far, indicated the empirical merits of various methods of handling kinetic pressure data. An analysis of the physical significance of each would be useful.

The first order polynomial (eq. [4]) ignores the fact that the transition state and substrate may have different isothermal compressibilities. Consequently, the inadequacy of this function in giving a good fit for our data is not unexpected (although Burris and Laidler (8) have found that a linear plot is satisfactory for some S_N2 reactions of ionic species). The use of a second order polynomial recognizes that $(\partial \Delta V^*/\partial p)_T \neq 0$, but requires that $(\partial^2 \Delta V^*/\partial p^2)_T = 0$.[3]

The question arises as to whether our data are precise enough to allow a meaningful calculation of $(\partial \Delta V^*/\partial p)_T$. It is readily seen that (see eqs. [6] and [1])

$$[12] \qquad (\partial \Delta V^*/\partial p)_T = -2RTC.$$

For the systems considered in this paper the percent deviation of this derivative (see *Precision Analysis*) lies between 2 and 41%. The actual values of the derivatives and their deviations are presented in Table I.

A good fit of the Benson–Berson equation (eq. [8]) is perhaps not to be expected. Benson and Berson point out that the exact pressure dependence of the rate constant reflects the change in activity coefficient as well as the change in volume during the

[3] *It is true, of course, that $(\partial^2 \Delta V^*/\partial p^2)_T$ is not generally zero. The compressibility of a real substance is known to be pressure dependent (13) so that $(\partial^2 V/\partial p^2)_T \neq 0$. It would be fortuitous indeed if two states had the same value for this derivative, especially when the polarities of the two differed markedly. Since the polarity of the initial state in the present reaction is practically negligible when compared with that of the transition state, it is not to be expected that the two states have the same value for $(\partial^2 V/\partial p^2)_T$. Hence the difference in the values of this derivative cannot be zero, i.e. $(\partial^2 \Delta V^*/\partial p^2)_T \neq 0$.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

activation process (4). For ionic reactions in water the authors demonstrated that the term due to the activity coefficients is negligibly small, but may become important in solvents of lower dielectric constant. For nonionic reactions, for which this term is zero, these authors used the Tait equation (10) to represent the compressibilities of both the initial and transition states of the reaction (4). This led to the development of eq. [8]. Since this function was developed for nonionic reactions, it appears fortuitous that it gives reasonable results when applied to the analysis of our data for an ionogenic reaction. However, the activity coefficient contribution to $(\partial \ln k/\partial p)_T$ can be shown to be negligible for the systems considered here.

The incremental slope analysis (eq. [9]) was seen to give ΔV_0^* values which coincide with the second order polynomial (Fig. 1). As stated previously, this is because they both allow for the same pressure dependence of ΔV^*. That this is true can be shown by taking the limit of infinitesimal increments and integrating eq. [9] at constant temperature. Thus there is no "a priori" advantage to using one of these methods over the other. However, eq. [6] reproduces the experimental data better than eq. [9] within a factor of two (Table IV). It may be noted that eq. [6] is a strictly analytical function, whereas eq. [9] becomes an analytical function only when the increments become infinitesimal. Therefore, it is not surprising that the two functions do not give identical results. It should also be noted that the incremental slope analysis may suffer from excessive amplification of the effect of the experimental uncertainties in the rate determinations when rate and pressure intervals used become small. Each k and p in the $\ln (k_{n+1}/k_n)$ and $(p_{n+1} - p_n)$ terms has an experimental error associated with it which is independent of the value of the difference between the logarithmic rates and pressures used in each term. Accordingly, as the rate and pressure intervals used become smaller the value of the experimental uncertainties in k and p approach the value of the differences, and increasing scatter of points in the plot of $\ln (k_{n+1}/k_n)/(p_{n+1} - p_n)$ versus $(p_{n+1} + p_n)/2$ is to be expected. This situation is analogous to that which results if one attempts to evaluate enthalpies of activation from two rate determinations at temperatures that are relatively close together. A similar argument was used by Benson and Berson (4) when they neglected the low pressure rates in their study of Walling and Peisach's data for isoprene dimerization (3) because of large scatter. For these reasons, and because eq. [6] is more convenient in that it lends itself to a precision analysis of the type described below, we prefer the quadratic function to the incremental slope analysis.

Precision Analysis

The functional dependence of the rate of benzyl chloride solvolysis on pressure having been established, the next step is to establish the precision of the derivatives. Since we have shown that eq. [6] is the desirable function it is necessary to determine the maximum deviations of the constants. It is convenient to determine these deviations by differentiation (14). By use of the least square functional forms of A, B, and C (eq. [6]), the deviations are given by [13] where f, g, and h are the least square functions for A, B, and C respectively.

$$\begin{aligned} dA &= \sum_i \left(\frac{\partial f}{\partial k_i}\right)_{p_j} dk_i + \sum_j \left(\frac{\partial f}{\partial p_j}\right)_{k_i} dp_j \\ dB &= \sum_i \left(\frac{\partial g}{\partial k_i}\right)_{p_j} dk_i + \sum_j \left(\frac{\partial g}{\partial p_j}\right)_{k_i} dp_j \\ dC &= \sum_i \left(\frac{\partial h}{\partial k_i}\right)_{p_j} dk_i + \sum_j \left(\frac{\partial h}{\partial p_j}\right)_{k_i} dp_j \end{aligned} \qquad [13]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

These equations were solved for dA, dB, and dC on an IBM 1620 computer using the average deviation of the rate constants for the dk_i's and the pressure fluctuation limits for the dp_j's. The signs of the dp_j and dk_i were taken to be positive in all cases.

The percent deviation in ΔV_0^* is given by $100\,dB/B$, whereas that for $(\partial \Delta V^*/\partial p)_T = 100\,dC/C$. For the experimental data under consideration in this paper the former has values between 0.9 and 15%, whereas the values for the latter are between 2 and 41%. The actual values for each solvent can be found in Table I.

APPLICATION TO OTHER SYSTEMS

The relative reliability of various functional representations of the data for the pressure dependence of a unimolecular ionogenic reaction having been determined, the applicability of these functions to other reaction types is of interest.[4]

The six reactions studied were (A) bromoacetate with thiosulfate in water (8), (B) methoxide with ethyl bromide in methanol (7), (C) *t*-butyldimethyl sulfonium iodide hydrolysis (15), (D) hydroxide with bromopentammine cobaltic ion in water (8), (E) urea formation in water (16), and (F) isoprene dimerization (3). The ability of each function to reproduce the experimental rate data as a function of pressure for each reaction, together with the values of the activation volumes and the standard deviations, are shown in Fig. 3.

It can be seen that of the six reactions considered, only two (A and C) do not show a systematic error in the linear analysis. Such a situation would be expected for truly linear pressure dependencies. In reaction A all of the analyses give approximately the same value for ΔV^* as well as consistently small values for the standard deviation. In reaction C the Benson–Berson and Whalley analyses give systematic errors.

Reactions B, D, and E are much better represented by the quadratic than the linear analysis (Fig. 3). Since B was designed to demonstrate a viscosity inhibition of a bimolecular reaction in solution (7), it is not surprising that the pressure dependence is nonlinear. The fact that the Benson–Berson and Whalley treatments give rather large standard deviations is somewhat surprising, as is the fact that the Benson–Berson analysis gives a standard deviation only half as large as the quadratic analysis for reaction D. It would seem that this analysis is suited to a wider variety of systems than suggested by the original authors (4). Reaction E has identical values of the standard deviation for the quadratic and Benson–Berson analyses, but a large difference in the ΔV^* values from the two methods. Unfortunately there is no way of distinguishing between their reliability.

A great deal of attention has been given to the pressure dependence of reaction F as evidence by the papers of Walling and Peisach (3), Benson and Berson (4), and rebuttals by both groups of workers (9, 17). Benson and Berson disregarded the low pressure rate constants in analyzing the data for this reaction because of much scatter of the points (*vide supra*) (4), and obtained an activation volume some 50% more negative than the original authors (3). In this study, all of the rate constants were used, and it can be seen that, execpt for the linear analysis, the activation volumes are all very similar (Fig. 3F). A glance at Fig. 3F indicates that if any of the points were to be omitted, those between 3 500 and 5 500 kg/cm^2 should be the likely candidates. The value of -30.4 ml/mole obtained from the quadratic analysis lies midway between those calculated by the two sets of authors (-24.3 (3) and -36.5 (4) ml/mole).

CONCLUSION

In summary it can be concluded that: (1) A quadratic polynomial is generally the best representation of the pressure dependence of a logarithmic rate constant regardless of the reaction type; (2) it appears *necessary* and *sufficient* to allow for the non-zero pressure dependence of activation volumes, and *this dependence is measurable*; and (3) differentiation of the appropriate function gives rise to a precise measurement of activation parameters.

XXXIV. A FLOW REACTOR FOR MEASUREMENT OF FAST THERMAL REACTIONS[1]

I. P. FISHER,[2] J. B. HOMER,[3] B. ROBERTS,[4] AND F. P. LOSSING
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received April 21, 1966

ABSTRACT

A new type of flow reactor for use with a mass spectrometer has been constructed, in which many of the disadvantages of flow systems for rate measurements have been overcome. Rate constants for unimolecular decompositions can be measured in the range 50 – 5 000 s^{-1}, with helium carrier gas pressures of 10–50 mm and residence times of 10^{-3} to 10^{-1} s. Measurements of the rate of thermal decomposition of trioxane are in good agreement with the rates predicted from literature data obtained at much lower temperatures.

INTRODUCTION

The ability of a mass spectrometer to follow partial pressure changes in gaseous mixtures provides in principle a means for measuring rate constants of gas-phase reactions, as well as for identifying and measuring the concentrations of free radical and other transient species. Earlier work in this field has recently been reviewed in some detail (1, 2). For measurements on fast homogeneous reactions, the reactors have usually taken the form of a heated tubular furnace, through which a gas stream consisting of the reactant, or the reactant diluted with an inert carrier gas, is passed at considerable velocity. The effluent gas is sampled through a pinhole leak leading directly to the ionization chamber of a mass spectrometer. Fast pumping must be provided at the ionization chamber to maintain it at a reasonably low pressure, and to reduce interference by secondary processes.

Attempts to make precise measurements of the rate constants of thermal decomposition reactions at elevated temperatures by means of such reactors, however, have had only limited success. One important difficulty lies in the uncertainty in the residence time – temperature relationship. Before reaching a steady temperature, the gas stream entering the reactor passes through a region of rising temperature, the length of which is not negligible compared with the total reactor length. The extent of reaction occurring in this part of the reactor is dependent on the flow rate and gas temperature and cannot be evaluated precisely. Although earlier measurements of the thermal decomposition of di-*t*-butyl peroxide using such a reactor (3) appeared to be consistent with experiments at lower temperatures, the activation energy for the thermal decomposition of dimethyl mercury at higher temperatures was in poor agreement with the literature data, probably as a result of uncertainties in the temperature profile at elevated temperatures. A further difficulty arose when the temperature in this reactor was varied, for the flow of gas through the leak was strongly dependent on the gas temperature. A correction to the observed peak heights to allow for this effect was required. This correction was large and difficult to assess accurately.

An improved reactor has now been constructed which obviates many of the difficulties previously encountered. Its function is to duplicate exactly the region of temperature rise and the temperature of the gas at the leak, while the length of the intermediate region of constant temperature is extended by known amounts. The effects of the indeterminate regions can thereby be cancelled out.

EXPERIMENTAL METHODS AND RESULTS

Construction of the Reactor

A cross-sectional view of the reactor assembly is shown in Fig. 1. The reactor itself is a fused-silica tube of internal diameter 7.1 mm, on whose outer surface has been ground a spiral groove of 100 turns, forming a seat for the furnace winding. The winding is of tantalum wire (0.015 in. diameter) which is tapped at equal intervals so as to give 15 identical sections each occupying 5.05 turns. At the upstream end are two preheating sections each consisting of 10.05 turns. The overall length of the furnace winding is 6.1 cm. Leads to the 17 sections are taken out through a pinwheel kovar seal. The current to the 17 sections is controlled by 17 autotransformers each capable of supplying a maximum of 6 V.

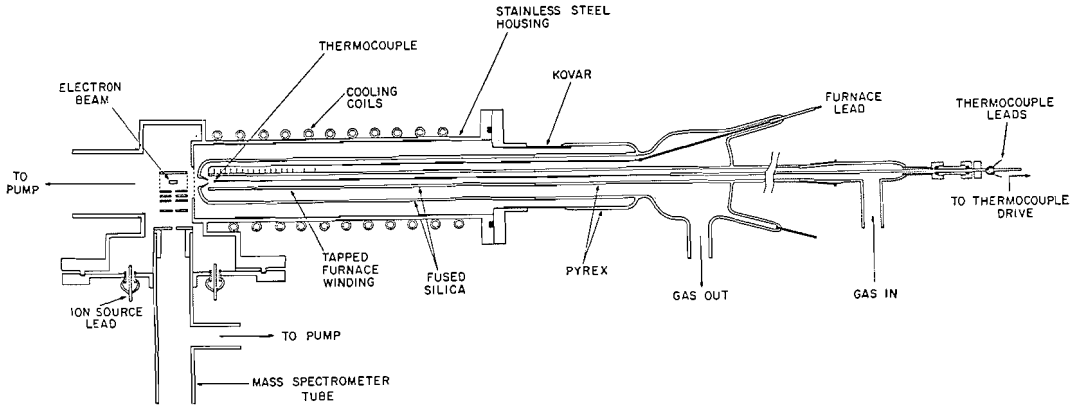

FIG. 1. Reactor assembly.

The temperature of the gas stream is measured by a 0.001 in. diameter platinum – platinum–rhodium thermocouple supported axially by a thin-walled fused-silica capillary probe. The bare junction projects 2 mm from the end of the probe. The probe is joined to a thin-walled metal tube which passes through a double O-ring seal to a rack and pinion driven by a synchronous motor. The temperature profile in the reactor can be traced on a strip-chart recorder from the preheating zone to within 1 mm of the leak.

The gas pressure in the reactor is measured by two mercury manometers, one at the inlet to the reactor and one at the outlet. At the highest pressures and flow rates the pressure drop through the reactor becomes as large as 8% of the pressure. The residence times are calculated using the mean pressure.

The reactor tube is enclosed by an outer fused-silica sheath into which is sealed a thin-walled cone which projects 2 mm into the end of the reactor tube. At the tip of the cone, which is blown out to a wall thickness of about 0.015 mm, is a hole 0.026 mm in diameter formed by an electric spark. This leak admits a small fraction of the gas stream to the ionization chamber. The reactor is surrounded by a stainless-steel vacuum housing provided with copper coils for cooling by water circulation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

By calibration with mixtures of known composition it has been established that the peak height for a component gas is proportional to its partial pressure in the helium mixture, provided that the total pressure and the gas temperature at the leak is constant. The proportionality constant (sensitivity coefficient) decreases with increasing temperature, and increases slightly with increasing helium pressure.

For greater speed of pumping in the ionization chamber, the side walls of the chamber are made of fine tungsten screen.

Operation of the Reactor

The desired gas temperature profiles and the transformer settings for these profiles are shown in Fig. 2. These are four superimposed profiles whose "temperature rise" zones are activated by sections 4, 5, 7, and 10 of the furnace winding. Each profile consists of three distinct parts: a preheating zone A maintained at a constant temperature at which thermal decomposition of the reactant is negligibly slow, a zone B of rapid temperature rise, and a zone C held at the constant temperature at which the rate of decomposition is to be measured. The length of zone C can be varied by moving zone B along the reactor. Since the tapped sections of the furnace are identical, it is possible to duplicate the profile of zone B at several positions along the reactor. The exactness of duplication can be tested by comparing plots such as those in Fig. 2. It follows that the amount of reaction occurring in zone B is the same for any position of the zone, so that the amount of reactant remaining at the onset of zone C is constant. The amount of reaction in zone C, as a function of its length, can be measured from the change in partial pressure of the reactant (or products) at the leak. It may be noted that whereas the sharpness of zone B is affected by the pressure and flow rate, the distance between corresponding positions of the profiles was found to be invariant.

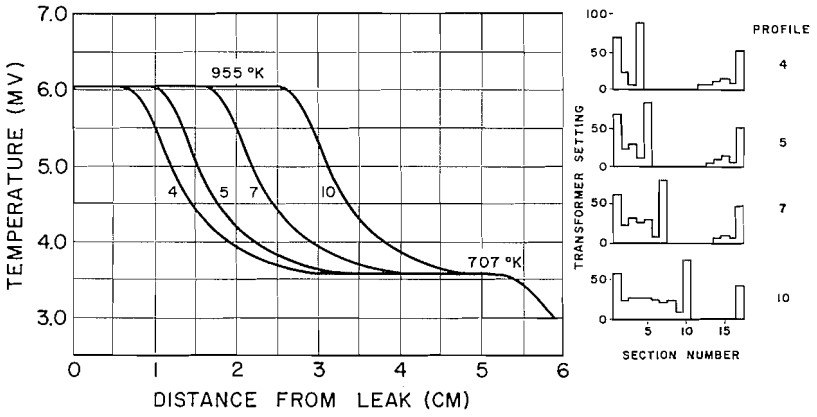

FIG. 2. Temperature profiles. The small figures at the right show the autotransformer settings required to produce the four temperature profiles. A large power input is required in the section which produces the temperature rise. A much lower setting is sufficient to maintain the temperature at a constant level. For example, in profile 10 the center of section 10 of the heater corresponds to a distance from the leak of 2.9 cm.

The transformer settings for the desired profiles are set up prior to the main experiment with a helium stream of the required pressure and velocity. Since the settings are found to be slightly dependent on the prior conditioning of the reactor, presumably as a result of reaction between the furnace winding and the reactant gas on the downstream side of the leak, it is preferable to determine the settings with the reactant present in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

stream. The profile is scanned repeatedly with the thermocouple probe and the transformer settings are adjusted until the deviations from the required profile are within $\pm 1°$. These settings are noted, and the next profile is set up. Although 2–3 h are required initially to obtain settings for four profiles at new temperature and flow conditions, a profile can be reproduced at a later time to within a few degrees from the same transformer settings. Only minor adjustments are then required to bring the profile within the $\pm 1°$ tolerance.

Measurement of First-Order Kinetic Rates

The first-order rate constant is defined by the equation $k = (2.303/t)(\log c_0 - \log c)$, where t is the time for reaction, and c_0 and c are the initial and final concentrations of the reactant. In the present apparatus, t is the average residence time, and is directly proportional to the length of zone C. The proportionality constant is the linear flow rate v calculated on the basis of plug flow through the reactor. (The assumption of plug flow will introduce an error into the absolute time scale which may be as great as a factor of 2, but which is nearly temperature independent.) If c_0 is allotted to the peak height measured with profile 4, a plot of log (peak height) against the length of zone C (taking profile 4 as a starting point) should be a straight line of slope $-k/2.303v$. Such a linearity is obtained (examples are shown in Fig. 3). For first-order reactions the sensitivity coefficient relating c to the peak height does not enter into the calculation of the rate, since it is a constant at a given temperature.

Measurement of the Gas Temperature

There is some question as to whether a thermocouple gives an accurate measurement of the temperature of a flowing gas. There is reason to believe, however, that in the present apparatus the true temperature of the gas is not significantly different from that registered by the thermocouple.

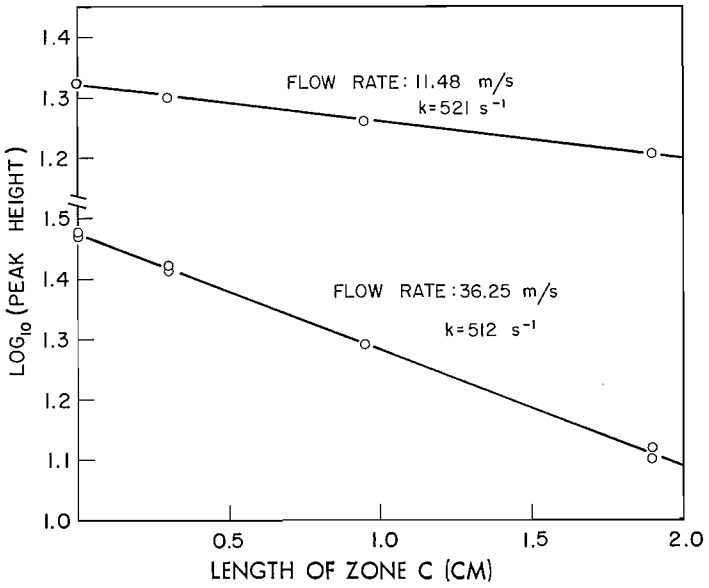

FIG. 3. Plots of $\log_{10}$ (peak height) against length of zone C, showing that the experimental rate constant is independent of the flow rate.

The bulk flow of gas down this reactor is not very large; a calculation shows Reynold's number to have a maximum of about 30. This is at least 50 times lower than that corresponding to the onset of turbulence. This is not to say that the flow is strictly laminar, since cross diffusion and disturbances from geometrical factors must surely take place. Calculations show that helium can indeed be heated as quickly as the thermocouple indicates. Calculations also show that the thermocouple leads are small enough to reduce the effect of conduction down them to negligible proportions after immersion of less than 1 cm into the hot zone. Experimentally, the presence of the thermocouple does not materially affect the gas temperature, for it can be moved in and out of the hot zone without producing a change in the partial pressure of the decomposing compound at the leak.

An experiment was performed in which benzene, which did not decompose at the temperature employed, was added to the helium stream passing through the hot reactor. The peak height was found to be independent of the length of zone C. Since the sensitivity coefficient changes detectably for a gas temperature change of $\pm 2°$ (as a result of the change in the viscosity of helium) the constant peak height for benzene provided an independent measurement of the constancy of the real temperature of the gas as a function of the length of zone C. This experiment shows that the correspondence between the temperature indicated by the thermocouple and the real temperature of the gas is not significantly affected by the temperature of the wall. Moreover, the linearity of the plot of log (peak height) against distance (Fig. 3) gives further evidence that the gas and thermocouple temperatures correspond. Let us consider the various temperatures in a cross-sectional plane containing the thermocouple as it moves into the hot zone. As it passes from zone A to zone B, the wall temperature is higher than the gas temperature, and the thermocouple indicates a temperature somewhere between. Further into the hot zone these three temperatures begin to converge, and after a certain distance will reach a common value. If this distance were longer than the combined lengths of zone B and zone C in profile 4, then the main gas temperature of zone C would increase (even though the thermocouple temperature remained constant) as it was stretched to profiles 5, 7, and 10. The plot of log (peak height) against distance would therefore be concave downwards. This trend has never been observed despite greatly varied conditions. It must be concluded that not only is the temperature in the extension of zone C uniform, but it is effectively equal to the temperature of the thermocouple.

Further evidence for the absence of serious systematic errors is provided by measurement of rate constants at the same temperature and helium pressure, but at flow rates differing by a factor greater than 3. The resultant slopes, corresponding to the first-order rates of decomposition, are given in Fig. 3. For these experiments the transformer settings required for the temperature profiles were quite different. The agreement of the rate constants is satisfactory, indicating that despite differences in wall temperature in the two experiments the measured temperatures were those of the gas.

Experimental Tests

As a test for the operation of the reactor, the thermal decomposition of *sym*-trioxane was investigated over the temperature range 748–977 °K, at helium carrier gas pressures from 5–50 Torr. In this temperature range the values of k ranged from $10 - 3\,600$ s^{-1}, and were dependent on the total pressure. These results have been described elsewhere (4). Extrapolation of the data to infinite pressure gave values for k_∞ in good agreement

with the accepted Arrhenius parameters for this reaction, derived from data at lower temperatures where k was of the order of 10^{-2}–10^{-4} s^{-1}. This result appears to confirm the main assumptions in the operation of this reactor. The magnitude of the absolute error in the rate measurements is difficult to estimate, however. Extrapolation of rate data over such a large temperature interval is almost certain to involve an appreciable error. Moreover, the extrapolation of rate constants from 50 Torr to infinite pressure introduces an additional uncertainty. Further confirmation of the performance using a unimolecular decomposition reaction which is not in the fall-off region at helium pressures of 50 Torr, and whose rate parameters are accurately known, would be desirable. Reactions which meet these specifications and which have a suitable activation energy, 35–55 kcal/mole, are extremely limited in number.

FREE RADICALS BY MASS SPECTROMETRY

XXXV. THE HEAT OF FORMATION OF ALLYL RADICAL FROM BIALLYL PYROLYSIS[1]

J. B. HOMER[2] AND F. P. LOSSING

Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received April 14, 1966

ABSTRACT

The thermal decomposition of biallyl has been investigated from 977 – 1 070 °K at helium carrier gas pressures of 10–50 Torr. Under these conditions the rate of central C—C bond fission to give two allyl radicals can be measured without interference from secondary reactions. The reaction at the pressures employed is first order with respect to biallyl, but between first and second order in the total pressure. The temperature dependence of the rate constants, extrapolated to infinite pressure, and corrected to 298 °K, gives an activation energy of 45.7 kcal/mole for the reaction, corresponding to ΔH_f(allyl) = 33.0 kcal/mole.

INTRODUCTION

The resonance energy of methyl-substituted allyl radical has recently been determined by Benson *et al.* (1) from the difference in the activation energies for the abstraction by I atoms of H atoms from 1-butene (E) and from propane (E'). The allylic resonance energy, defined as the difference in dissociation energy between a C—H bond conjugated with a double bond and the corresponding bond in a saturated paraffin, was obtained from the relationship $(E' - E) + (E_b - E_b')$. $(E_b - E_b')$ is the difference in activation energy for the back reactions, that is, the attack of HI on methyl allyl radicals and on isopropyl radicals. This term was assumed to be zero within ± 0.5 kcal/mole, and the possible error from all causes, including the assumption that D(*sec*-C—H) in *n*-butane was the same as that in propane, was estimated to be ± 1 kcal/mole. The value they obtained for the allylic resonance energy, 12.6 kcal/mole, is quite significantly lower than earlier experimental values for the allyl radical of around 21 kcal/mole from pyrolytic studies (2) and calculated values of 17–18 kcal/mole (3). This difference, and a comparison of their value with recent kinetic measurements (4), has been discussed by Benson *et al.* (1), who conclude that the current evidence favors a value of about 13 kcal/mole rather than the higher value. On this basis, and assuming the allylic resonance energy to be the same in allyl as in methyl allyl radical, then D(allyl—H) in propylene = $D(n\text{-}C_3H_7\text{—H}) - 13$. Since $D(n\text{-}C_3H_7\text{—H})$ is probably 98 kcal/mole with an uncertainty of about ± 2 kcal/mole, one obtains D(allyl—H) = $(98 \pm 2) - (13 \pm 1) = 85 \pm 3$ kcal/mole. From standard thermochemical data, this leads to ΔH_f(allyl) = 37.8 ± 3 kcal/mole.

Although the assumptions made in arriving at this value appear to be inherently reasonable, it would appear advantageous to try to obtain ΔH_f(allyl) by a more direct route. A measurement of the activation energy for the primary rupture of the allylic C—C bond in 1,5-hexadiene, or the C—X bond in allyl halides, would appear to be the method involving the minimum of assumptions. The thermal decomposition of 1,5-hexadiene is to be preferred for two reasons; the heat of formation of 1,5-hexadiene is known with greater accuracy than that of allyl halides (5), and secondly, since two allyl radicals are formed in the decomposition,

[1] $$CH_2{=}CHCH_2{-}CH_2CH{=}CH_2 \rightarrow 2CH_2{-}CH{=}CH_2,$$

[1] *National Research Council Contribution No. 9177.*
[2] *National Research Council Postdoctorate Fellow, 1963-1965.*

the errors in the measurement of the activation energy and in ΔH_f(1,5-hexadiene) are halved in the subsequent calculation of ΔH_f(allyl). This reaction was investigated by Ruzicka and Bryce (6) at a pressure of 70 Torr. Under these conditions interference by recombination, abstraction, and other secondary reactions made the overall reaction extremely complicated. For instance, Ruzicka and Bryce found an apparent activation energy of 31.3 ± 1 kcal/mole. This is evidently much too low to be allotted to the primary step. At low partial pressures, in a stream of helium, however, the decomposition of 1,5-hexadiene is a simple C—C bond fission with production of two allyl radicals (7), and secondary reactions become unimportant.

In the present work, the thermal decomposition of 1,5-hexadiene has been investigated in the temperature range 977 – 1 070 °K with a new type of flow reactor coupled to a mass spectrometer. Under the reaction conditions employed the rate of the primary C—C fission can be measured without interference from secondary reactions, and consequently with no assumptions as to the mechanism.

EXPERIMENTAL

A description of the flow reactor and a check of its performance using the thermal decomposition of trioxane has been published (8, 9). The extent of reaction could be monitored either by following the decrease in height of a 1,5-hexadiene peak or by the increase of the mass-41 peak of allyl radical using low energy electrons. For greatest accuracy the mass-67 peak of 1,5-hexadiene was employed, since it has a much greater intensity than the parent ion at mass 82. To confirm that the mass-67 peak was truly representative of the 1,5-hexadiene concentration. the mass spectrum of the compound was measured as a function of the length of the hot zone of the reaction (i.e. as a function of the extent of decomposition). The ratio of the peaks at masses 82 and 67 remained unaltered. No interfering reactions could be detected provided that the partial pressure of hexadiene was low enough. At the higher partial pressures (5×10^{-3} Torr) recombination of allyl radicals was observed, and manifested itself in nonlinear first-order plots of log (peak height) against distance. This effect is shown in Fig. 1. Partial pressures of the order of 5×10^{-4} Torr were therefore used in the determination of the rate of decomposition.

The rates were measured at four pressures of helium carrier gas: 10, 15, 25, and 50 Torr. Higher helium pressures, although most desirable for kinetic reasons, could not be employed since not enough power

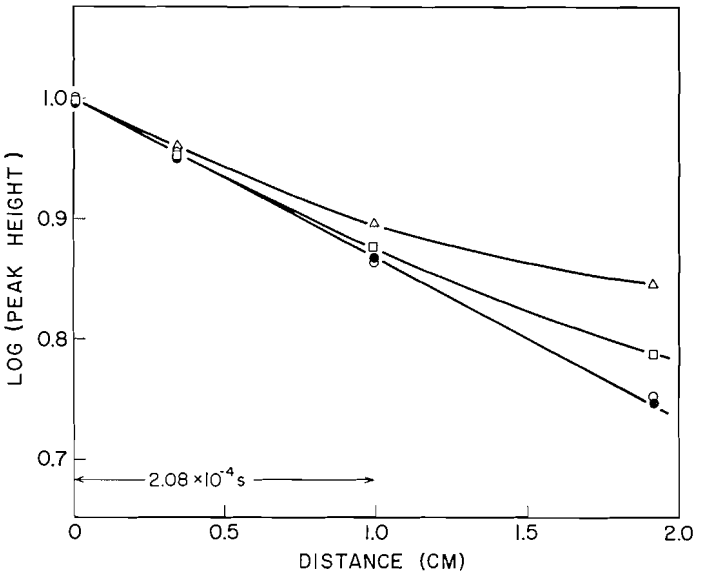

FIG. 1. Plots showing the divergence of biallyl decomposition from first-order dependence with increasing partial pressure of biallyl, and the consequent increase in the concentration of allyl radicals. The re-formation of biallyl by allyl recombination at the residence time employed becomes significant at biallyl pressures above 2×10^{-3} Torr. (△) 17.1; (□) 6.05; (○) 1.63; (●) 0.32×10^{-3} Torr.

could be applied to raise the gas temperature sufficiently rapidly to permit proper matching of the temperature profiles.

RESULTS

Table I gives the first-order rate constants that were determined, and the ranges of pressure, gas flow rates, and temperatures studied.

TABLE I

First-order rate constants

Temperature (°K)	Helium pressure (Torr)	Flow rate (m/s)	k (s^{-1})

	15.3	12.67	219
	10.5	11.55	178

The Evaluation of the Activation Energy

For each temperature examined the rate constants are seen to decrease with decreasing pressure of helium. This indicates that while the rate of decomposition is first order with respect to 1,5-hexadiene, it is in an intermediate region between zero and first order with respect to the helium pressure. In this fall-off region the activation energy will also be a function of the helium pressure. It is therefore necessary to extrapolate the experimental rate constants as a function of helium pressure, and to evaluate the rate constants at infinite pressure (k_∞) for each temperature. An Arrhenius plot using these k_∞ values can then be used to determine the activation energy. For these results, extrapolations of $1/k$ against $1/P$ plots to infinite pressure can introduce a large source of error in evaluating k_∞, since the degree of curvature is not known above 50 Torr. Previous experience with Kassel integrals would suggest that the curve dips rather strongly as it approaches the $1/P = 0$ axis. The exact curvature cannot be predicted theoretically without assigning a number of parameters, and the pressure range experimentally examined is not wide enough to evaluate these. For the present work, in which a correct evaluation of E is more important than a correct evaluation of the pre-exponential factor, it is sufficient to provide a *consistent* method of extrapolation at the different temperatures. An examination of experimental curves determined by other workers and of theoretical curves predicted by unimolecular rate theory reveals that the shape of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

these curves is virtually independent of temperature over a small temperature range. On this basis the rate data in Table I were superimposed on the same plot by varying the attenuation and origin of the $1/k$ axis. This provides the closest possible fit to an identical extrapolating curve for the results at the various temperatures. This plot is shown in Fig. 2. The fit of the experimental points for different temperatures is extremely good, indicating that extrapolation will give a nearly consistent set of k_∞ values.

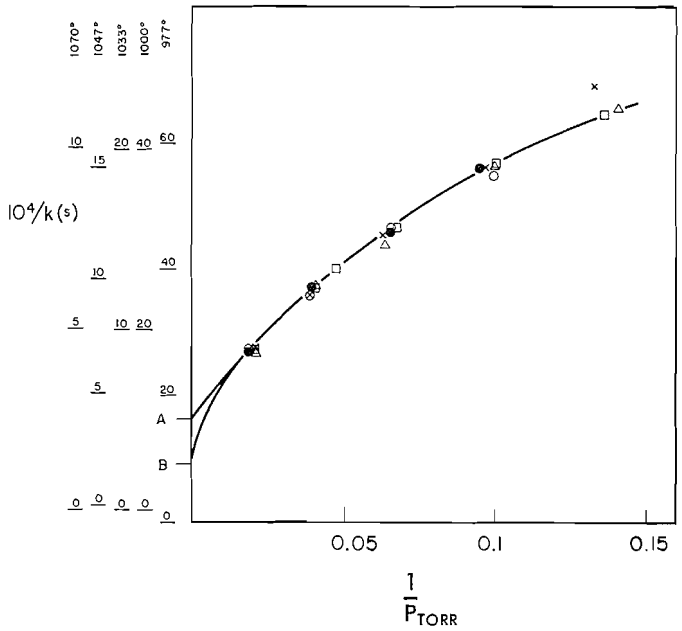

FIG. 2. Composite plot for extrapolation of rate data to infinite pressure. By varying the attenuation and origin of the $1/k$ axis, all the data can be fitted to a single curve. (×) 1 070°; (△) 1 047°; (□) 1 033°; (○) 1 000°; (●) 977°.

With reference to other theoretical and experimental curves, and taking into account the low efficiency of helium as a third body, two limits have been set on the extrapolation. The two limits are marked A and B in Fig. 2. The resultant double set of k_∞ values derived from these limits are shown as two Arrhenius plots in Fig. 3. The rate equations for these two lines are:

$$\text{(A)} \quad \log k_\infty = 12.31 - 42600/2.303RT$$
$$\text{(B)} \quad \log k_\infty = 13.26 - 45600/2.303RT.$$

Taking an average of these limiting cases, we can evaluate the activation energy for 1,5-hexadiene dissociation at 1 000 °K as $E_{1000} = 44.1$ kcal/mole. The experimental limits indicate an error of ± 1.5 kcal/mole in this result. In view of experimental uncertainties and the long extrapolation to k_∞, however, the true limit of error, although significantly larger, cannot be realistically estimated. The results are therefore given without an error limit.

Determination of ΔH_f Allyl

The heat of formation of allyl radical is given by the expression

$$\Delta H_f(\text{allyl}) = \tfrac{1}{2}(D(\text{allyl—allyl}) + \Delta H_f(\text{1,5-hexadiene})).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

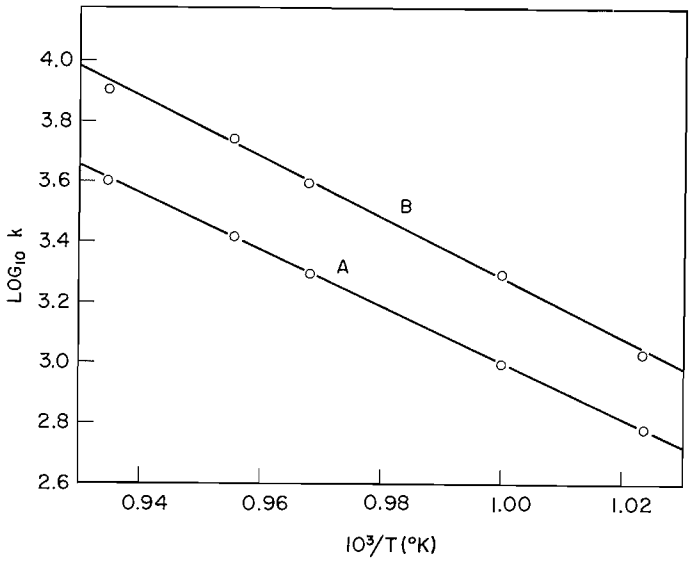

FIG. 3. Arrhenius plots obtained from the limiting values A and B of the extrapolation in Fig. 2.

To obtain ΔH_f(allyl) at 298° it is, of course, necessary to use values of D(allyl—allyl) and ΔH_f(1,5-hexadiene) corresponding to this temperature. The latter quantity is known to be 20.25 kcal/mole, calculated from its heat of hydrogenation at 298° (5). This value is in good agreement with 20.42 kcal/mole calculated from additivity rules (10). On the assumption that the recombination of allyl radicals requires zero activation energy, D_{1000}(allyl—allyl) can be taken as 44.1 kcal/mole, the experimental activation energy found for 1,5-hexadiene dissociation. It is then necessary to compute the difference $(D_{298} - D_{1000})$. This cannot be done directly since the necessary data for allyl radical are not known, but an approximate value can be obtained by considering the changes in enthalpy with temperature in the closely related hypothetical reactions:

[2] 1,5-hexadiene → propylene + allene

[3] 1-hexene → propylene + propylene.

For these reactions, a calculation (see Appendix) from standard thermochemical data (11) gives $\Delta H_{298} - \Delta H_{1000} = +1.64$ and $+1.65$ kcal/mole, respectively. There seems no reason why the change in enthalpy with temperature of reaction [1] should be appreciably different from that of reactions [2] and [3]. On this assumption, D_{298}(allyl—allyl) is 44.1 + 1.6 = 45.7 kcal/mole. From this value and ΔH_f(1,5-hexadiene) one obtains ΔH_f(allyl) = 33.0 kcal/mole at 298 °K. From ΔH_f(propylene) = 4.88 kcal/mole and $\Delta H_f°$(H) = 52.1 kcal/mole this leads to D(allyl—H) in propylene = 80.2 kcal/mole. If $D(n\text{-}C_3H_7\text{—H})$ is taken to be 98 kcal/mole, the resonance energy of allyl radical as defined above is given as 17.8 kcal/mole.

DISCUSSION

The value of ΔH_f(allyl) = 33 kcal/mole derived from the present results lies between the "low" value of 30 kcal/mole from pyrolytic studies (2, 12) and the recent "high" value of 38 kcal/mole derived from the iodine-catalyzed isomerization of 1-butene (1). It is close to a value of 34.0 ± 2.8 kcal/mole obtained recently from the thermal decomposition of sulfones (13). Although our value appears to differ from that of Benson *et al.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by 5 kcal/mole, part of the difference may arise from the fact that the two results cannot be compared directly without making certain assumptions. The results of Benson *et al.* give a direct[3] measurement of the difference

$$D(CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}H\text{—}H) - D(CH_2{=}\underset{\displaystyle CH_3}{\underset{|}{C}}HCH\text{—}H) = 13 \pm 1 \text{ kcal/mole.}$$

It is possible that this difference is less than the difference

$$D(CH_3CH_2CH_2\text{—}H) - D(CH_2{=}CHCH_2\text{—}H).$$

That is, the stabilization brought about by CH_3 substitution in the *n*-propyl radical could be greater than the stabilization brought about by substitution in the allyl radical, in which the unpaired electron is already extensively delocalized. Since $D(n\text{-}C_3H_7\text{—}H) - D(sec\text{-}C_4H_9\text{—}H)$ is probably 3–4 kcal/mole, one could perhaps allow for an extra 2 kcal/mole for the resonance energy of allyl itself over that of methyl allyl, giving 15 kcal/mole as an upper limit. To convert this to a value for ΔH_f(allyl) brings in the further uncertainty in $D(n\text{-}C_3H_7\text{—}H) = 98$ kcal/mole, which is probably ± 2 kcal/mole. On this basis one could arrive at D(allyl—H) $= 83 \pm 2$ kcal/mole and ΔH_f(allyl) $= 36 \pm 2$ kcal/mole as the lower limits consistent with the results of Benson *et al.*

It should be pointed out that there is no experimental evidence for or against a slight dependence of allylic resonance energy on substitutional effects. This question cannot be settled at present by reference to the analogous benzyl radical, since its resonance energy is similarly subject to an uncertainty of about 5 kcal/mole. As summarized by Skinner (14), there has been recent kinetic support for a low value, $D(PhCH_2\text{—}H) = 80 \pm 2$ kcal/mole, and a high value, 84.6 ± 2 kcal/mole.

The magnitude of systematic error in the present result is difficult to evaluate. The susceptibility of kinetic measurements in flow systems to large errors is well known (15). On the other hand the present reactor has been designed to eliminate the main sources of these errors. Calibration experiments on the thermal decomposition of trioxane at slightly lower temperatures, for example, gave A and E values in good agreement with those obtained by conventional experiments (8). The pre-exponential factor found here for biallyl decomposition is probably less accurate than the measurement of E as a result of the method of extrapolation described above. Nevertheless it appears that if these data are correct, A must be not much greater than 10^{13} s^{-1}. From a consideration of the high recombination efficiencies of alkyl radicals like CH_3 and C_2H_5, and the estimated entropy changes for central bond fissions in radical dimers, it has been calculated that $\log (A_{forward}/A_{reverse})$ for such reactions should be about 4, and that A_f is therefore about 10^{17} (15–17). This is interpreted in terms of an extremely loose transition state, without strong orientational effects. Owing to the configurational requirements for attainment of the electron delocalization energy in allyl radical, formation of the transition state in 1,5-hexadiene decomposition may involve a smaller change in entropy than that involved in the formation of the transition state in ethane decomposition. The combination rate and A_f for allyl may therefore be correspondingly smaller. The total entropy change for reaction [1] cannot be calculated with certainty, since it depends strongly on the assumed properties of allyl radical. On the assumption that the entropy of allyl is nearly the same as that of propylene, ΔS for reaction [1] would be about

[3]*The necessary assumptions are outlined above in the introductory paragraph.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the same as that for the dissociation of ethane, and $\log A_f/A_r = 4.1$ (at 298 °K). If, on the other hand, the structural properties of allyl are nearly the same as those of allene, ΔS is much smaller, and $\log A_f/A_r = 1.7$. Both these numbers would imply that the efficiency of allyl recombination is very much lower than that of methyl recombination. There appears to be no experimental evidence on this point. It would seem therefore that one cannot decide a priori whether or not $A \sim 10^{13}$ for reaction [1] is smaller than might reasonably be expected for this reaction.

APPENDIX

From values given in ref. 11, ΔH_f(1,4-pentadiene) decreases from 25.20 at 298° to 20.40 kcal/mole at 1 000°. The incremental change of —CH_2— from pentane to hexane changes from −4.96 to −6.06 kcal/mole, so that ΔH_f(1,5-hexadiene) changes from 20.24 (comparing well with the experimental value of 20.25) to 14.34 kcal/mole. Also $\Delta H_{f298} - \Delta H_{f1000}$ for propylene is +4.85 and for allene is +2.69 kcal/mole. $\Delta H_{298} - \Delta H_{1000}$ for 1,5-hexadiene → propylene + allene is $(4.85 + 2.69 - (20.24 - 14.39)) = +1.64$ kcal/mole. $\Delta H_{f298} - \Delta H_{f1000}$ for 1-hexene is 8.05 kcal/mole, so that $\Delta H_{298} - \Delta H_{1000}$ for the reaction 1-hexene → propylene + propylene is $[(2 \times 4.85) - 8.05] = +1.65$ kcal/mole.

NOTES

THE RADIATION-INDUCED ADDITION OF HBr TO OLEFINS IN THE LIQUID PHASE

R. C. RUMFELDT[1] AND D. A. ARMSTRONG

The occurrence of a free-radical-catalyzed chain addition reaction between HBr and the lower molecular weight olefins, ethylene and propylene, is well established. In 1942 Vaughan, Rust, and Evans (1) produced initiating radicals by the direct photolysis of HBr, and also by the photolysis of sensitizers which had been incorporated in HBr–olefin reaction mixtures. In all instances the chain length of the resulting reaction was shown to be several thousand. More recently (2, 3) it has been found that an addition reaction of similar chain length can be initiated by the action of ionizing radiation on HBr–ethylene mixtures, and this has led to the development of an industrial process for the ^{60}Co-catalyzed production of ethyl bromide (3). The purpose of the present communication is to report the results of a kinetic study of this radiation-induced reaction in the liquid phase at -79 °C. A number of experiments have also been conducted with propylene.

EXPERIMENTAL

Propylene, ethylene, and HBr were purified and stored in a suitable vacuum line (2). Mixtures of HBr and olefin in the required proportions were synthesized in this vacuum line and condensed directly into the irradiation cells. The latter consisted of round-bottomed tubes 24 cm long and of 8 mm bore. They were closed at the top end by a stopcock or break-seal. Samples were kept frozen at liquid nitrogen temperature until a few minutes before irradiation. They were then liquefied, rendered homogeneous, and placed in position in a small dewar filled with a dry ice – ethanol slurry. The liquefied samples normally had a volume of about 1 ml. After the sample had stood for a period long enough to ensure temperature equilibration the dewar was positioned in the ^{60}Co source compartment and the irradiation was started. Dose rates were determined by ferrous sulfate dosimetry with corrections for differences in the electron density of the samples and the dosimetry solution. By the use of two sources of different strength and by alteration of the source to sample distances several different dose rates were obtained.

The rate of the HBr–C_2H_4 addition reaction was followed as in the earlier study (2*a*). It has already been established that ethyl bromide is by far the major product of this reaction (2, 3), and no further gas chromatographic analyses were conducted in the present work. The rate of the γ-ray-induced addition of HBr to propylene was followed by absorbing the residual HBr in water and titrating it with a standard solution of silver nitrate. In a number of the propylene experiments the liquid irradiation product was extracted in ether solution and analyzed on a gas chromatographic column with tri-*m*-cresyl phosphate as stationary phase.

RESULTS AND DISCUSSION

Liquid mixtures of propylene and HBr undergo a spontaneous thermal addition reaction (4), the major product of which is isopropyl bromide with traces of hexyl and other higher molecular weight bromides. This type of reaction is catalyzed by Friedel–Crafts catalysts (5) and in ionizing solvents it has been postulated (6) to involve carbonium ion intermediates. In the present work the γ-ray-induced addition reaction was studied in solutions containing only HBr and propylene in a mole ratio of 1:2.66. In the absence of radiation the rate of the thermal reaction in these mixtures was found to be 0.1% of the HBr per minute (cf. the earlier work of ref. 4). The radiation-induced addition was much faster than this. In fact essentially complete addition was observed after ~ 100 s of irradiation at a dose rate of 2×10^{19} eV/l s. An average G value of about

[1]*Department of Chemistry, University of Windsor, Windsor, Ontario.*

10^5 over the period of irradiation is thus required, and the chain character of the radiation-induced addition to propylene is established. As in the photo-initiated reactions (1) *n*-propyl bromide was by far the major product. The yield of isopropyl bromide was of the order of 1% (or less) of the *n*-propyl bromide. These observations are consistent with a free-radical mechanism for this liquid phase radiation-induced reaction. The small yield of isopropyl bromide indicates that, if it occurs at all, the ionic chain reaction sequence[2]

$$i\text{-}C_3H_7^+ + HBr \rightarrow i\text{-}C_3H_7BrH^+$$
$$i\text{-}C_3H_7BrH^+ + C_3H_6 \rightarrow i\text{-}C_3H_7Br + C_3H_7^+$$

is relatively slow under the present conditions.

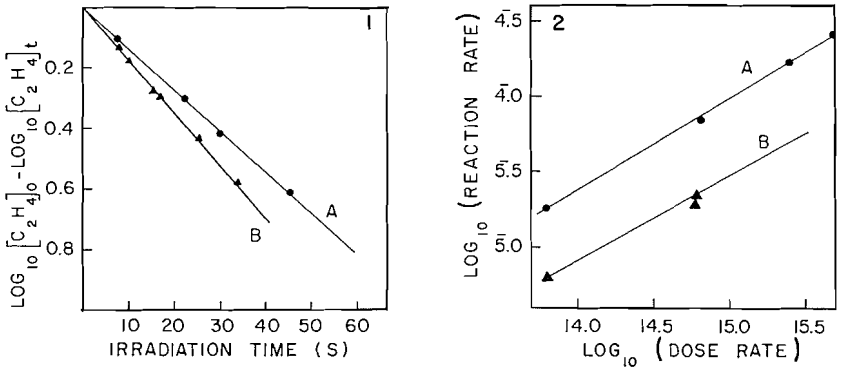

FIG. 1. First-order log plots for the consumption of ethylene in the radiation-induced addition of HBr. Line A: $[C_2H_4]_0 = 1.8$ moles/l. Line B: $[C_2H_4]_0 = 6.0$ moles/l.

FIG. 2. Logarithmic plots of reaction rate versus dose rate for the radiation-induced addition of HBr to C_2H_4. The units are: reaction rate in mole/ml s and dose rate in eV/ml s. Line A: $[C_2H_4]_0 \simeq 6 \times 10^{-3}$ mole/ml. Line B: $[C_2H_4]_0 \simeq 1.8 \times 10^{-3}$ mole/ml.

At dose rates lower than 2×10^{19} eV/l s the addition to propylene was complicated by an induction period. For this reason kinetic studies were confined to the ethylene–HBr reaction, which showed no evidence of any such behavior. The major product of this reaction is ethyl bromide (2, 3) and the thermal rate at −79 °C quite negligible (0.01%/min for a HBr:ethylene mole ratio of 5:1; see also ref. 4). The results of the kinetic studies for HBr–ethylene mixtures of mole ratios in the range 5:1 to 20:1 are presented in Table I. As shown in Fig. 1 the reaction is first order in ethylene. The slopes of the log–log plots of reaction rate versus dose rate in Fig. 2 indicate a dose rate exponent lying between 0.5 and 0.6 for dose rates in the range 6.4×10^{16} to 5.7×10^{18}. These observations can be satisfactorily accommodated by a free-radical mechanism involving the reactions (all reactions are numbered as in ref. 2*b*)

[1] $\quad HBr \overset{R}{\rightsquigarrow} H + Br$

[3*a*] $\quad H + HBr \rightarrow H_2 + Br$

[13], [16] $\quad Br + C_2H_4 \underset{k_{16}}{\overset{k_{13}}{\rightleftharpoons}} C_2H_4Br$

[14*a*] $\quad C_2H_4Br + HBr \xrightarrow{k_{14a}} C_2H_5Br + Br$

[18] $\quad Br + Br(+ M) \xrightarrow{k_{18}} Br_2(+ M).$

[2]*Because of its large relative stability, the isopropyl carbonium ion should be formed in this system by proton transfer to propylene from the* $C_3H_6^+$ *or* H_2Br^+ *ions produced by the ionizing radiation (see ref. 8). Ionic intermediates of this type have been postulated as leading to cationic polymerization reactions in irradiated liquid olefins (see refs. 9, 10). In some systems large chain lengths are observed.*

For personal use only.

where the concentration of third body M is such that reaction [18] will be second order and its rate constant of the order of 10^{10} l/mole s (7). If reaction [16] is neglected as seems reasonable at −79 °C and with the high concentrations of HBr being employed, the rate expression takes the form required by the present data, viz.

$$d[C_2H_5Br]/dt = k_{13}[C_2H_4]\sqrt{(R/k_{18})}.$$

The quantity R is equal to the rate of formation of initiating radicals. Assuming a radical yield of 12 per 100 eV in liquid HBr[3] one arrives at the values of $k_{13}/\sqrt{k_{18}}$ given in Table I. Taking k_{18} as $\simeq 10^{10}$ l/mole s, one can show that k_{13} must be 10^6–10^7 l/mole s under the conditions stated above.

TABLE I

Kinetic data for the C_2H_4–HBr addition reaction

$[C_2H_4]$ (moles/l)	Dose rate (eV/l s)	Initial reaction rate (moles/l s)	$k_{13}/\sqrt{k_{18}}$ (l/mole s)$^{1/2}$
1.80	5.80×10^{17}	2.29×10^{-2}	37.4
1.80	5.80×10^{17}	1.94×10^{-2}	31.6
1.80	6.41×10^{16}	6.44×10^{-3}	31.7
6.13	5.70×10^{18}	2.69×10^{-1}	41.0
6.32	2.27×10^{18}	1.94×10^{-1}	45.5
6.46	5.80×10^{17}	6.48×10^{-2}	29.4
6.46	5.80×10^{17}	6.19×10^{-2}	28.2
5.62	6.41×10^{16}	2.41×10^{-2}	38.0
		Mean value	35±6

In further experiments the ethylene reaction was found to be completely inhibited by the addition of 0.1 mole % nitric oxide. The same concentration of nitric oxide reduced the rate of the propylene addition reaction to a level which was, within experimental error, the same as the rate of the thermal reaction. From experiments in the absence of radiation the latter reaction was shown to be insensitive to the presence of nitric oxide. If the free-radical mechanism is correct an inhibitory effect by nitric oxide is certainly to be expected in view of the small activation energy which would be anticipated for reaction [20]:

[20] $$NO + Br(+ M) \rightarrow NOBr(+ M) \quad .$$

Thus the results of the present study are all consistent with a free-radical mechanism for the radiation-induced addition of HBr to ethylene and propylene in the liquid phase.

MULTICOMPONENT DIFFUSION IN THE ^{85}Kr–SO_2–Kr SYSTEM

ANIL SARAN AND YASHWANT SINGH

Curtiss and Hirschfelder (1) have shown that the multicomponent diffusion coefficient D_{ij} can be written to a first approximation as

$$[1] \qquad D_{ij} = \frac{1}{M_j}\left(\sum_k x_k M_k\right)\frac{K^{ji} - K^{ii}}{|K|},$$

where $K_{ii} = 0$ and

$$K_{ij} = \frac{x_i}{(\mathfrak{D}_{ij})_1} + \frac{M_j}{M_i}\sum_{k\neq i}\frac{x_k}{(\mathfrak{D}_{ik})_1}, \quad i \neq j.$$

$|K|$ is the determinant of K_{ij} and K^{ji} are the minors. If, however, one component 'i' is present in trace quantity, then its diffusion coefficient $D_{i\to\text{mix}}$ is given by (2)

$$[2] \qquad \frac{1}{(D_{i\to\text{mix}})_1} = \sum_{j\neq i}\frac{x_j}{(\mathfrak{D}_{ij})_1},$$

where x_j is the mole fraction of the jth component and $\mathfrak{D}_{ij}$ is the usual binary diffusion coefficient. For a three-component system eq. [2] becomes

$$[3] \qquad \frac{1}{(D_{1\to 23})_1} = \frac{x_2}{(\mathfrak{D}_{12})_1} + \frac{x_3}{(\mathfrak{D}_{13})_1},$$

and hence to a first approximation:

$$[4] \qquad \frac{1}{D_{\text{expt}}} = x_3\left(\frac{1}{\mathfrak{D}_{13}} - \frac{1}{\mathfrak{D}_{12}}\right) + \frac{1}{\mathfrak{D}_{12}}, \quad (\text{since } x_1 \simeq 0).$$

The plot of $1/D_{\text{expt}}$ vs. x_3 will be a straight line whose intercepts on the ordinate at $x_3 = 0$ and $x_3 = 1$ give the values of $\mathfrak{D}_{12}$ and $\mathfrak{D}_{13}$. Applying the mass correction, we get the usual $\mathfrak{D}_{22}$ and $\mathfrak{D}_{23}$ values.

Several experiments (3–6) confirm that eq. [4] holds quite accurately. However, Watts (7) in a recent paper on the multicomponent diffusion of ^{133}Xe in binary mixtures of Xe with other inert gases has observed a departure from eq. [4]. In the present investigation we have measured the diffusion coefficient of radioactive ^{85}Kr in binary mixtures of normal krypton and SO_2 to test further the validity of eq. [4].

EXPERIMENTAL RESULTS

The apparatus employed in the present investigation is a two-chamber apparatus of the Ney and Armistead (8) type. The apparatus and the experimental procedures have been fully described by Srivastava and Paul (3). Pure dry SO_2 gas was prepared by a method

MULTICOMPONENT DIFFUSION IN THE ^{85}Kr–SO_2–Kr SYSTEM

ANIL SARAN AND YASHWANT SINGH

Curtiss and Hirschfelder (1) have shown that the multicomponent diffusion coefficient D_{ij} can be written to a first approximation as

$$[1] \qquad D_{ij} = \frac{1}{M_j}\left(\sum_k x_k M_k\right)\frac{K^{ji} - K^{ii}}{|K|},$$

where $K_{ii} = 0$ and

$$K_{ij} = \frac{x_i}{(\mathfrak{D}_{ij})_1} + \frac{M_j}{M_i}\sum_{k\neq i}\frac{x_k}{(\mathfrak{D}_{ik})_1}, \quad i \neq j.$$

$|K|$ is the determinant of K_{ij} and K^{ji} are the minors. If, however, one component 'i' is present in trace quantity, then its diffusion coefficient $D_{i\to\text{mix}}$ is given by (2)

$$[2] \qquad \frac{1}{(D_{i\to\text{mix}})_1} = \sum_{j\neq i}\frac{x_j}{(\mathfrak{D}_{ij})_1},$$

where x_j is the mole fraction of the jth component and $\mathfrak{D}_{ij}$ is the usual binary diffusion coefficient. For a three-component system eq. [2] becomes

$$[3] \qquad \frac{1}{(D_{1\to 23})_1} = \frac{x_2}{(\mathfrak{D}_{12})_1} + \frac{x_3}{(\mathfrak{D}_{13})_1},$$

and hence to a first approximation:

$$[4] \qquad \frac{1}{D_{\text{expt}}} = x_3\left(\frac{1}{\mathfrak{D}_{13}} - \frac{1}{\mathfrak{D}_{12}}\right) + \frac{1}{\mathfrak{D}_{12}}, \quad (\text{since } x_1 \simeq 0).$$

The plot of $1/D_{\text{expt}}$ vs. x_3 will be a straight line whose intercepts on the ordinate at $x_3 = 0$ and $x_3 = 1$ give the values of $\mathfrak{D}_{12}$ and $\mathfrak{D}_{13}$. Applying the mass correction, we get the usual $\mathfrak{D}_{22}$ and $\mathfrak{D}_{23}$ values.

Several experiments (3–6) confirm that eq. [4] holds quite accurately. However, Watts (7) in a recent paper on the multicomponent diffusion of ^{133}Xe in binary mixtures of Xe with other inert gases has observed a departure from eq. [4]. In the present investigation we have measured the diffusion coefficient of radioactive ^{85}Kr in binary mixtures of normal krypton and SO_2 to test further the validity of eq. [4].

EXPERIMENTAL RESULTS

The apparatus employed in the present investigation is a two-chamber apparatus of the Ney and Armistead (8) type. The apparatus and the experimental procedures have been fully described by Srivastava and Paul (3). Pure dry SO_2 gas was prepared by a method

described in detail by Srivastava and Saran (9). The thermostatic bath temperature was maintained constant at 30 °C within ±0.05 °C by a Sunvic electronic relay. The analysis was done by a scintillation counter.

TABLE I

Composition of SO_2	Pressure in mm Hg	D_{expt} (cm^2/s)	D_{calcd} (cm^2/s)		
			a^*	b^*	c^*
0.0000	30.70	0.1018	0.1018	0.1008	0.1008
0.2556	32.88	0.0970	0.0972	0.0966	0.0955
0.4959	25.53	0.0932	0.0932	0.0929	0.0909
0.7343	22.19	0.0894	0.0896	0.0896	0.0868
1.0000	30.54	0.0859	0.0859	0.0861	0.0827

*(*a*) Utilizing the experimental values of D_{expt} at $x = 0$ and $x = 1$ and using eq. [4]; (*b*) utilizing the unlike force parameters for the Kr–SO_2 system from observed binary diffusion coefficients (9) and eq. [4]; (*c*) utilizing the force parameters for SO_2 from viscosity (10) and the combination rules for polar–nonpolar interaction and eq. [4].

The experimental values of the diffusion coefficient for various concentrations of SO_2 are given in Table I. The D_{expt} values recorded in column 3 were obtained by reduction to atmospheric pressure. We believe that our data are correct within ±1%.

DISCUSSION

The values of D_{calcd} in column 4 have been obtained by using the D_{expt} values for 0 and 100% SO_2 and eq. [4] to calculate the composition dependence of D_{expt}. It can be seen that the agreement between the two sets is quite satisfactory. The values of D_{calcd} in column 5 have been obtained by utilizing the unlike interaction parameters for the Kr–SO_2 system from observed binary diffusion coefficients (9) and applying the mass correction. The agreement with the observed values is quite satisfactory. Column 6 gives the values of D_{calcd} obtained by utilizing the force constants of SO_2 from viscosity (10) in the combining rules for unlike force parameters and applying the mass correction. The calculated values of diffusion coefficients are somewhat smaller than the observed values. This is due to the smaller values of the binary diffusion coefficient obtained from the force constants of SO_2 from viscosity. The possible sources of discrepancy between the values of binary diffusion coefficients obtained from viscosity and those observed have been discussed elsewhere (9). After application of the mass correction, the values of $\mathfrak{D}_{13}$ and $\mathfrak{D}_{12}$ from Table I become 0.0862 and 0.102 respectively. These values compare quite well with the values $\mathfrak{D}_{23} = 0.0864$ at 30 °C (9) and $\mathfrak{D}_{22} = 0.1035$ at 31.5 °C (3).

SOLVENT EFFECTS ON THE ULTRAVIOLET SPECTRA OF N,N-DIMETHYLFORMAMIDE

MAHMOOD F. MAYAHI, A. H. AL-TAIAR, S. A. AL-BALDAWI, AND H. A. HUSSAIN

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In recent years, many papers have appeared dealing with the chemical reaction and structures of amides. The structure of N,N-dimethylformamide (DMF) has been established by infrared and nuclear magnetic resonance spectroscopy (1–4). The infrared and nuclear magnetic resonance spectra of adducts of N,N-dialkylamides strongly support coordination at the oxygen atom (1, 5–7).

Our interest in the DMF structure was initiated by the interesting conductivity curves we obtained in work on hydrogen-bonded organic compounds in benzene (8, 9) and DMF. These curves could not be understood without a knowledge of the structure and reaction sites of DMF with the organic compounds. We report here the study of the ultraviolet spectra of DMF in hydrogen bonding and in non-H-bonding solvents. Table I shows the characteristics of the ultraviolet absorption peaks in *n*-hexane, cyclohexane, dioxane, acetonitrile, chloroform, ethyl alcohol, and water, at various concentrations of DMF. The ultraviolet absorption band in DMF is that of the carbonyl group, the $n-\pi^*$ transition. Normally, amides absorb around 214 mμ in water (10). However, Table I shows that the absorption peak shifts to shorter wavelengths as the concentration is decreased. This result might have been expected, since in our work on the absorption of the non-bonding electrons in triethylamine, ethyl acetate, and in polyvinyl acetate (11, 12), the same effect was observed and explained.

TABLE I

Ultraviolet spectra of DMF in various solvents

Solvent	Concentration (mole/l) $\times 10^2$	λ_{max} (mμ)	Optical density
n-Hexane	11.04	225	3.0
	0.088	212	2.03
	0.0071	205	0.426
Cyclohexane	12.38	227	3.0
	0.099	214	1.835
	0.008	206	0.354
Dioxane	0.740	225	2.95
	0.059	215	1.227
	0.0095	213	0.278
	0.0047	213	0.140
CH_3CN	5.93	240	1.423
$CHCl_3$	7.00	242	1.096
	1.93	240	0.632
	0.71	240	0.219
	0.385	240	0.193
Ethyl alcohol	1.14	227	3.0
	0.091	213	1.92
	0.0073	207	0.321
Water	1.118	225	3.0
	0.089	212	2.150
	0.0450	208	1.741
	0.0224	203	1.293

The n–π^* absorption band of the C=O group of acetone is at 279 mμ in hexane (10), and because of the strong electron-withdrawing inductive effect of the N atom in DMF, this band is shifted to 205 mμ in hexane (Table I). In addition the inductive effect of nitrogen makes the non-bonding electrons on the oxygen less prone to excitation and therefore less sensitive to solvent changes. This point can be appreciated if a comparison is made between the effect of solvents on the ultraviolet spectra of acetone and DMF. The n–π^* absorption bands of acetone in various solvents are at the following positions: hexane 279 mμ, chloroform 277 mμ, ethanol 272 mμ, water 264.5 mμ (10). This shows a blue shift depending on the hydrogen-bonding ability of the solvent, and the shift is 14.5 mμ (1 900 cm^{-1}) in changing from hexane to water, whereas for DMF the shift is only 5 mμ (1 200 cm^{-1}) in changing from hexane to water. Another striking difference between the n–π^* absorption band of acetone and of DMF is that $\nu_{C=O}$ of acetone is progressively shifted to higher frequencies in the solvents mentioned above, whereas $\nu_{C=O}$ of DMF is shifted to lower frequencies in $CHCl_3$ and in ethanol relative to hexane. This is similar to our results on triethylamine and ethyl acetate (11, 12).

The solvent effect on the ultraviolet absorption spectra has been treated theoretically by Bayliss (13) and McRae (14). Rao and Balazveramanien used the McRae equation for the n–π^* transition of C=O, N=N, NO_2, and C=S groups and found in nonpolar solvents and in polar non-H-bonding solvents that plots of ν_{max} vs. $(D-1)/(D+2)$ were "fairly linear" (15). Similar plots were made for triethylamine in a number of nonpolar and H-bonding solvents, but, in those cases, ν_{max} values were obtained for infinitely dilute solutions. Good straight lines were found for triethylamine, one line for the nonpolar solvents with a negative slope and another line for the H-bonding solvents with a positive slope (11). That the solvents are separated into two distinct series according to their H-bonding capabilities to the solute is in accord with the predictions made by McRae (14).

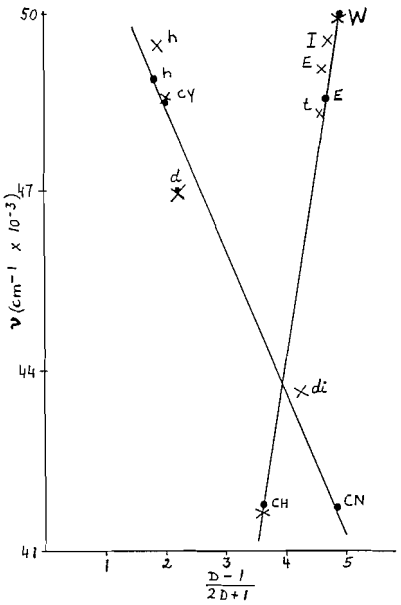

FIG. 1. ν (cm^{-1} × 10^{-3}) vs. $(D-1)/(2D+1)$ for DMF (●) and triethylamine (×), in the solvents: *n*-hexane (h), cyclohexane (cy), dioxane (d), acetonitrile (CN), chloroform (CH), dichloromethane (di), *t*-butyl alcohol (t), ethyl alcohol (E), isopropyl alcohol (I), and water (W) at 20 °C.

For DMF, ν_{max} vs. $(D-1)/(2D+1)$ is used (Fig. 1) (10, 13), where ν_{max} is that of infinitely dilute solutions obtained by graphical extrapolation of the values given in Table I. The use of $(D-1)/(2D+1)$ instead of $(D-1)/(D+2)$ gives less scatter of points, especially for the line involving the nonpolar solvents and CH_3CN. The data for triethylamine from ref. 11 are recalculated and included in Fig. 1. The point representing DMF in dioxane does not fall on the line for non-H-bonding solvents; this was also found by Rao and Balazveramanien (15) and McRae (14). The deviation was explained by McRae, who argued that the dioxane molecule has two nonadjacent dipolar groups whose moments cancel, so that the effective reaction field is probably greater than is indicated by the macroscopic properties.

PRODUCTION OF HYDRATED ELECTRONS

David C. Walker

Recent radiation chemical studies[1] have shown that ionization of liquid water leads to the formation of hydrated electrons (e_{aq}^-), rather than hydrogen atoms, as the principal reactive chemical species. In certain photochemical electron-transfer processes, in which the reducing species was formerly identified, but mistakenly, as a hydrogen atom, the characteristic absorption spectrum of e_{aq}^- has now been observed (2). A hydrated electron is barely distinguishable chemically from a hydrogen atom, its conjugate acid, but is converted to it by reaction [1] only very slowly, if at all (3).

[1] $$e_{aq}^- + H_2O \rightarrow H + OH_{aq}^-;\ k_1 \leqslant 16\ \text{mole}^{-1}\ \text{s}^{-1}$$

We have investigated three types of reaction in which e_{aq}^- could have been mistaken for H atoms as the precursors of molecular H_2. These are (i) the reaction between an alkali metal and water, (ii) the cathode reaction in the electrolytic decomposition of water, and (iii) the reduction of water by a cation having an oxidation potential > 0.413 V, such as U^{3+}.

PRODUCTION OF HYDRATED ELECTRONS

David C. Walker

Recent radiation chemical studies[1] have shown that ionization of liquid water leads to the formation of hydrated electrons (e_{aq}^-), rather than hydrogen atoms, as the principal reactive chemical species. In certain photochemical electron-transfer processes, in which the reducing species was formerly identified, but mistakenly, as a hydrogen atom, the characteristic absorption spectrum of e_{aq}^- has now been observed (2). A hydrated electron is barely distinguishable chemically from a hydrogen atom, its conjugate acid, but is converted to it by reaction [1] only very slowly, if at all (3).

[1] $$e_{aq}^- + H_2O \rightarrow H + OH_{aq}^-;\ k_1 \leqslant 16\ \text{mole}^{-1}\ \text{s}^{-1}$$

We have investigated three types of reaction in which e_{aq}^- could have been mistaken for H atoms as the precursors of molecular H_2. These are (i) the reaction between an alkali metal and water, (ii) the cathode reaction in the electrolytic decomposition of water, and (iii) the reduction of water by a cation having an oxidation potential > 0.413 V, such as U^{3+}.

[1]*For review of evidence, see Hart (1).*

For personal use only.

A distinction between e_{aq}^- and H atoms was made by kinetic competition studies based on the known rates of reactions [2] to [5].[2]

[2] $e_{aq}^- + N_2O \rightarrow N_2 + O^-(\rightarrow OH)$; $k_2 = 9 \times 10^9$ mole^{-1} s^{-1}

[3] $H + N_2O \rightarrow N_2 + OH$; $k_3 < 3 \times 10^5$ mole^{-1} s^{-1}

[4] $e_{aq}^- + CH_3OH \rightarrow ?$; $k_4 < 10^4$ mole^{-1} s^{-1}

[5] $H + CH_3OH \rightarrow H_2 + CH_2OH$; $k_5 = 2 \times 10^6$ mole^{-1} s^{-1}

It is evident from these rate constants that if both methanol and N_2O are present as scavengers for the precursors of molecular H_2 and if $[CH_3OH]/[N_2O] \approx 10$, that N_2 will be formed only if e_{aq}^- is a reactive intermediate. The technique employed was to add N_2O to the water in sufficient concentration to reduce the yield of H_2 significantly, with a concomitant production of N_2, for each of the reactions (i), (ii), and (iii); then to repeat this experiment with an excess of CH_3OH and note whether the yields of N_2 and H_2 were affected.

[6] $e_{aq}^- + e_{aq}^- \rightarrow H_2 + 2OH_{aq}^-$; $2k_6 = 4.5 \times 10^9$ mole^{-1} s^{-1}

[7] $H + H \rightarrow H_2$; $2k_7 = 6 \times 10^9$ mole^{-1} s^{-1}

Since in all three systems H_2 was shown to be formed in a bimolecular reaction ([6] or [7]) at the metal–water interface, it was necessary to control the rate of generation of reactive intermediates so that the N_2O could compete successfully by reaction [2] or [3]. In (i) we used very dilute sodium amalgams so that the reaction time was several hours, and N_2O at atmospheric pressure reduced the H_2 yield to $\sim 10\%$ of its value without scavenger (5). For (ii) it was necessary to use very low current densities in an electrolysis cell having a large and smooth platinum cathode. At ~ 50 μA cm^{-2} the H_2 yield was reduced to $\sim 35\%$ of its value in the absence of N_2O. Unfortunately there was no control of the rate of H_2 generation when solid lumps of uranium trichloride were added to the solution, and since the H_2 yield was reduced to only $\sim 80\%$ of its former value, this is less sensitive than (i) and (ii) but qualitatively equally valid. (We are currently repeating (iii), and are using dipositive europium salts since the oxidation potential of the Eu^{2+}/Eu^{3+} couple is much less than that of U^{3+}/U^{4+}.) Highly purified water was used, and it was thoroughly deaerated before the other reagents were added. Samples of the results are given in Tables I, II, and III.

TABLE I

Effect of [Na], [N_2O], pH, and [CH_3OH] on N_2 and H_2 yields (reaction (i))

[Na] in Hg (M)	Weight of amalgam (g)	pH	[N_2O] (M)	[CH_3OH] (M)	N_2 (μmoles)	H_2 (μmoles)
2.5×10^{-4}	~190	~7	0	0	0	1.7
2.5×10^{-2}	~190	~7	7.1×10^{-3}	0	1.4	0.3
1.4×10^{-2}	~30	~7	7.6×10^{-3}	0	6.6	8.2
1.4×10^{-2}	~30	~7	1.5×10^{-2}	0	11.7	3.3
1.4×10^{-2}	~30	2	8.5×10^{-3}	0	0.3	14.6
1.6×10^{-3}	~40	~7	2.1×10^{-2}	0	2.0	0.2
1.6×10^{-3}	~40	~7	2.1×10^{-2}	0.1	2.1	0.1
1.6×10^{-3}	~40	~13	2.1×10^{-2}	0.1	2.3	0.1

Since the addition of methanol does not affect the N_2 and H_2 yields, it is evident that in all three reactions H atoms are not reaction intermediates. Furthermore, the results are entirely consistent with the postulate that hydrated electrons are the precursors of H_2.

[2] *All rate constants quoted in this paper are taken from Anbar and Neta (4).*

For personal use only.

TABLE II

Ratio of N_2/H_2 yields at the cathode in the electrolytic decomposition of 0.25 M Na_2SO_4 solution (reaction (ii))

Current density (μA cm^{-2})	[N_2O] (M)	CH_3OH (M)	pH	N_2/H_2 ratio*
64	0	0	~7	<0.004
80	1.9×10^{-2}	0	~7	0.40
47	1.9×10^{-2}	0	~7	1.67
47	1.9×10^{-2}	0.1	~7	1.75
47	1.9×10^{-2}	0	1.3	<0.008
47	1.9×10^{-2}	0.1	1.3	<0.001

*To minimize polarization effects, a sample of gas was extracted during steady electrolysis; hence only gas ratios are reported.

TABLE III

Effect of [N_2O] and [CH_3OH] on the yields of N_2 and H_2 by reaction of UCl_3 with 25 ml water (reaction (iii))

[U^{4+}] formed (mM)	[N_2O] (M)	CH_3OH (M)	N_2 (μmoles)	H_2 (μmoles)	N_2/H_2
1.4	0	0	<0.05	17.2	~0
0.52	1.8×10^{-2}	0	1.25	5.2	0.24
0.80	1.8×10^{-2}	0.1	2.08	8.0	0.26

This is corroborated by the effect of pH on the gas yields. Since e_{aq}^- and H can be interconverted, it follows that the species reacting in neutral water is the same as that expected at high pH values whereas, in acidic solution, e_{aq}^- would be converted to H atoms, and reaction [3] cannot compete with the formation of H_2 by reaction [7] because $k_7 > 10^4 k_3$ (contrast $k_6 \approx k_2$).

[8] $$H + OH_{aq}^- \rightarrow e_{aq}^-; \quad k_8 = 2 \times 10^7 \text{ mole}^{-1} \text{ s}^{-1}$$

[9] $$e_{aq}^- + H_{aq}^+ \rightarrow H \quad ; \quad k_9 = 2.3 \times 10^{10} \text{ mole}^{-1} \text{ s}^{-1}$$

Our results on process (i) are endorsed by the findings of Hughes and Roach (6) and since we failed to find a polarographic half-wave potential corresponding to the reduction of N_2O at a dropping-Hg electrode, the possibility that electrons at the metal surface were reacting with N_2O before they became solvated can probably be discounted. The absence of O_2 in the products and the correspondence between the diminution of H_2 and formation of N_2 are explained by the consumption of an additional e_{aq}^- at the metal–water interface by the OH radical produced in reaction [2] (5).

It is proposed that reactions [10], [11], and [12] represent the relevant primary steps.

[10] $$Na \xrightarrow{H_2O} Na_{aq}^+ + e_{aq}^-$$
(rather than $Na + H_2O \rightarrow Na_{aq}^+ + OH_{aq}^- + H$)

[11] $$e_{(cathode)}^- \xrightarrow{H_2O} e_{aq}^-$$
(rather than $e_{(cathode)}^- + H_{aq}^+ \rightarrow H$)

[12] $$U^{3+} \xrightarrow{H_2O} U_{aq}^{4+} + e_{aq}^-$$
(rather than $U^{3+} + H_2O \rightarrow U_{aq}^{4+} + OH_{aq}^- + H$)

Perhaps, in general, hydrated electrons are the reaction intermediates when water at natural pH is reduced to H_2 in reactions involving electron transfer processes.

THE IMPORTANCE OF INDUCTIVE EFFECTS IN α-SILYL AND α-GERMYL KETONES

KEITH YATES AND FRANCO AGOLINI

The unusual spectroscopic properties of α-silyl ketones (1) have been attributed to p–π–d–π interactions involving the vacant 3d orbitals of silicon (1, 2). The α-triphenylgermyl ketones which have been previously prepared (1, 3) have spectral characteristics similar to those of the α-silyl ketones, i.e. abnormally low carbonyl stretching frequency and unusually long wavelength ultraviolet absorption resulting in yellow color. We have now prepared the first α-trimethylgermyl ketone to be reported, trimethylbenzoylgermane, by the following route using standard procedures (1).

$$Ph_4Ge + 3GeCl_4 \xrightarrow[350°]{\text{sealed tube}} 4Cl_3GePh \xrightarrow{MeMgI} Me_3GePh \xrightarrow[EtBr]{Br_2} Me_3GeBr \xrightarrow{PhCH_2MgCl}$$

$$Me_3GeCH_2Ph \xrightarrow{NBS} Me_3GeCBr_2Ph \xrightarrow{MeCOOAg} Me_3GeCOPh$$

The product (b.p. 53.5–54° (0.28 mm), $n_D^{24.5} = 1.5364$) is also yellow, with λ_{max} at 252 mμ ($\epsilon = 10\,700$) and 412 mμ ($\epsilon = 120$) in ethanol, and has an unusually low carbonyl frequency at 1 629 cm^{-1} in CCl_4. These properties are very similar to those of the previously reported triphenylbenzoylgermanes, and p–π–d–π interactions involving germanium 4d orbitals could also be responsible for the shifted $n \rightarrow \pi^*$ and carbonyl stretching bands (1). However, it has been pointed out (3; Orgel, quoted in ref. 4; 5) that inductive effects could be responsible for the spectral shifts observed when an α carbon is replaced by either silicon or germanium. Until now there has been neither experimental evidence nor theoretical calculations to indicate which effect, if either, predominates. We now present evidence to show that insofar as the electronic ground states are concerned the inductive effect of silicon or germanium predominates over any possible d-orbital interaction. We have measured the base strengths of the ketones R_3XCOPh (X = C, Si, Ge; R = Me, Ph) by two different methods and find that in each series the α-silyl or α-germyl ketone is more strongly basic than its carbon analogue. The pK values were determined in aqueous sulfuric acids by the standard spectrophotometric technique (6), except that in some cases

decomposition of the ketone in the highest acid concentrations made zero-time extrapolation procedures necessary. Relative base strengths were determined by measuring the effect of the ketone on the ν_{OH} bands of hydrogen bond donors such as phenol or methanol in dilute solution (0.005 M) in CCl_4, the shift $\Delta\nu$ produced being taken as a measure of the base strength of the ketone. The results given in Table I show that the order of base strength in each series is $R_3SiCOPh \geqslant R_3GeCOPh > R_3CCOPh$. Thus replacement of an α carbon by silicon or germanium increases the availability of electrons on the carbonyl oxygen. This is consistent with an increased contribution of II arising

from a strong inductive effect[1] of silicon or germanium on the X—C bond and explains why α-silyl and α-germyl ketones have carbonyl absorption at some 50–70 cm^{-1} lower frequency than the corresponding carbon compounds. Any important contributions from III or IV, involving d-orbital interaction, would reduce the availability of electrons on

I II III IV

oxygen in lowering the CO bond order. It should be emphasized that these considerations do not necessarily extend to the electronically excited states of these molecules. The above conclusions are supported by the results of molecular orbital calculations on the model compounds H_3XCOPh (X = C, Si, Ge). Simple Hückel molecular orbital calculations using the recently obtained heteroatom parameters of Curtis and Allred (7) for Si and Ge result in very small π-bond orders for the X–C bond, 0.097 for C—Si and 0.067 for C—Ge, and π-bond orders for the carbonyl group which are practically identical for X = C (0.781), X = Si (0.783), X = Ge (0.782). We find that only by including *both* σ- and π-type orbitals in an extended Hückel treatment (8) can we arrive at electron densities and bond orders (F. Agolini, I. G. Csizmadia, S. Klemenko, and K. Yates, unpublished results) consistent with the experimentally observed decrease in carbonyl stretching frequency and increase in basicity when α-carbon is replaced by silicon or germanium. The results of these calculations will be presented in a future paper dealing with the unusual electronic transitions of these ketones.

[1]*It is worth noting that the electronegativity differences* $(X_C - X_{Si})$ *and* $(X_C - X_{Ge})$ *are greater than the* $(X_{Cl} - X_C)$ *differences on either the Pauling or Mulliken scale.*

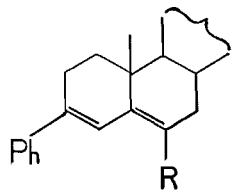
ELECTROPHILIC REACTIONS OF STEROIDAL AND OTHER α-PHENYL DIENES[1]

MAURICE DOUEK[2] AND GEORGE JUST
Department of Chemistry, McGill University, Montreal, Quebec



Received May 17, 1966

ABSTRACT

3-Phenylcholesta-3,5-diene (I) is shown to undergo electrophilic substitution reactions exclusively at the 6 position with formaldehyde – perchloric acid, acetic anhydride – aluminium chloride, and the Vilsmeier reagent.

In the case of formaldehyde, the final product is "dimer" II. The reaction is specific for formaldehyde and can be used to detect trace amounts of formaldehyde in, for example, commercial acetic acid and acetic anhydride.

In connection with an extension of the work on the photolysis of conjugated diene systems in various solvents (1–4), we investigated the photolysis of conjugated α-phenyl dienes in ethyl acetate – acetic acid containing 1% perchloric acid. Upon addition of perchloric acid to an ethyl acetate – acetic acid solution of 3-phenylcholesta-3,4-diene (I) at 45°, the colorless solution turned, in rapid succession, yellow, pink, red, and deep purple and a flocculent precipitate appeared. It was shown by thin-layer chromatography (t.l.c.) that a product (II) with an R_f value close to that of the starting material was formed.

I R=H
Ia R=D
Ib R=$COCH_3$
Ic R=CHO
Id R=CH_2OH

This product could be separated from the starting material I (I being the only other important fraction) either by column chromatography on alumina or simply by two careful crystallizations from hexane. Variations of the reaction conditions showed that the yield of product II was directly proportional to the amount of acetic acid used and was not increased by a prolonged reaction time. Since attempts to drive the reaction to completion by filtering the flocculent precipitate failed, it was concluded that this reaction did not produce an equilibrium mixture. Products of a similar nature were shown to be formed when 3-*p*-ethoxyphenylcholesta-3,5-diene (III), 3-phenylandrosta-3,5-diene-17β-ol acetate

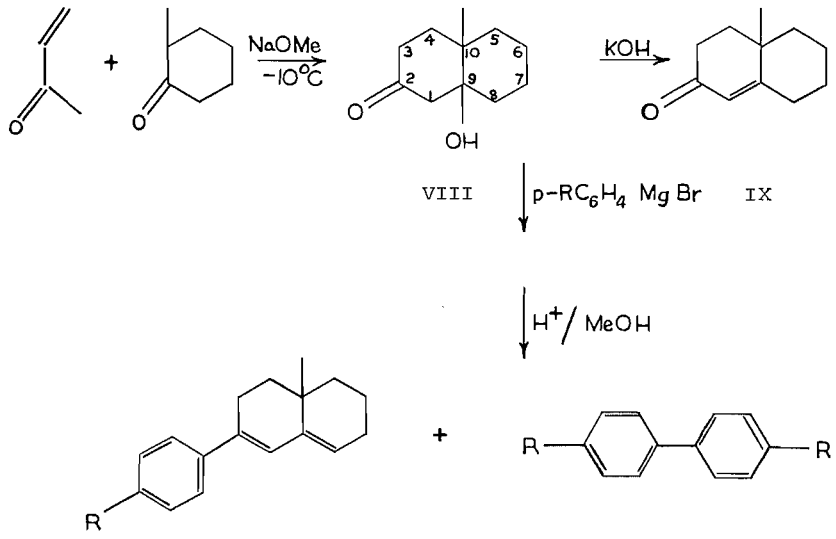
(IV), 3-phenylandrosta-3,5-diene-17-one (V), and 3-phenylandrosta-3,5-diene (VI) were used, thus proving that the reaction was general for conjugated α-phenyl dienes of this type.



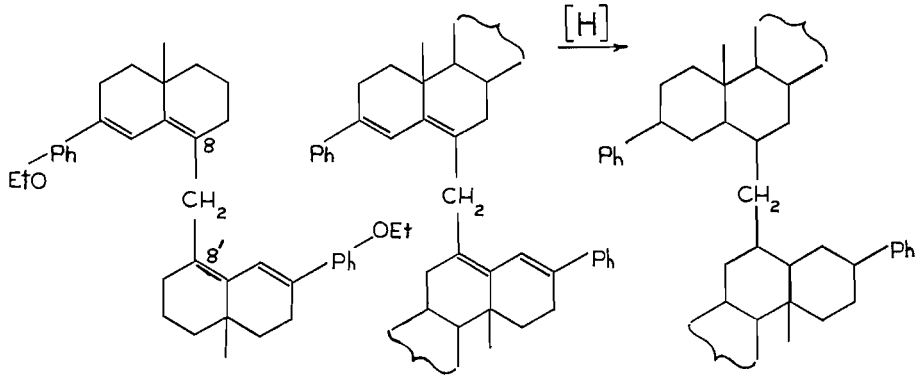
Product II, m.p. 228–229°, was shown by analysis to be a hydrocarbon. An osmometric molecular weight determination gave a molecular weight of 860 (the molecular weight of the starting material was 445). The strong ultraviolet absorption of I at 282 mμ was shifted in product II to 292 mμ, and its intensity was increased by 25%. This fact was interpreted as evidence for the retention of the unsaturated system present in I. This was confirmed by a quantitative hydrogenation in the presence of 10% palladium on charcoal, since 4 moles of hydrogen were absorbed to yield compound VII. Absorption in the 6.8–7.3 p.p.m. region in the nuclear magnetic resonance (n.m.r.) spectrum of VII proved that the phenyl rings were not affected by the hydrogenation. The n.m.r. spectrum of II showed a complex multiplet in the 7–7.4 p.p.m. region and a singlet at 6.93 p.p.m. These were respectively assigned to the five hydrogens on the benzene ring and to the two hydrogens in the 4 and 4′ positions; in addition, a singlet at 3.15 p.p.m. was interpreted as belonging to two doubly allylic protons. Since no other peaks were found in the olefinic region, it was concluded that the 6 and 6′ positions were substituted. The lowest whole number ratio of the integrated areas of the complex multiplet at 7–7.5 p.p.m., the singlet at 6.93 p.p.m., and the singlet at 3.15 p.p.m. was 5:1:1. This ratio was taken as strong evidence for a symmetrical dimer. Finally, a broad absorption centered at 2.45 p.p.m. was assigned to protons allylic to the double bonds. It was impossible to integrate this area since it overlapped with the steroid envelope. The infrared spectrum was quite similar to that of 3-phenylcholesta-3,5-diene (I). All attempts to obtain a mass spectrum of "dimer" II failed, extensive pyrolysis occurring at the high temperatures necessary to produce an appreciable vapor pressure.

Since the evidence obtained by spectral data in the steroidal models was insufficient to deduce the structure of product II, a more suitable model compound had to be found. Conjugated α-phenyl dienes in the decalin series were chosen, since it was felt that the change in the geometry of the compound would not be too large, that the vapor pressure of the resulting dimer would be high enough to take a mass spectrum, and that a fairly exact integration of the n.m.r. signals caused by all protons of the dimer would be possible.

Condensation of methyl vinyl ketone with 2-methylcyclohexanone, as described by Marshall and Fanta (5), gave a good yield of *cis*-10-methyl-2-decalon-9-ol (VIII). Dehydration of VIII with potassium hydroxide gave 10-methyl-1(9)-octalone-2 (IX). Grignard reaction of VIII or IX with phenylmagnesium bromide, followed by dehydration with 10% methanolic hydrochloric acid, gave a mixture of two compounds. All attempts to separate this mixture by column chromatography, by t.l.c., or by crystallization failed. However, vapor-phase chromatography showed that one component of the mixture was biphenyl, and comparison of the n.m.r. spectrum of the crude mixture with that of 3-phenylcholesta-3,5-diene (I) indicated that the other compound was 10-methyl-2-phenyl-$\Delta^{2,9}$-hexalin.

Since it was felt that ether X*b* would be easier to separate from bi-*p*-ethoxyphenyl (XI*b*), *p*-ethoxyphenylmagnesium bromide was added to VIII. After dehydration, a mixture containing X*b* and XI*b* was obtained. Chromatography gave 52% of α-phenyl diene X*b*.

Reaction of X*b* in acetic acid–ethyl acetate containing 1.5% perchloric acid at 50° gave a compound XII analogous to those obtained from the steroidal dienes. The infrared spectra of XII and the starting material X*b* were again quite similar. It absorbed in the ultraviolet at 296 mμ (ϵ 63 500), and its n.m.r. spectrum showed an A_2B_2 quartet at

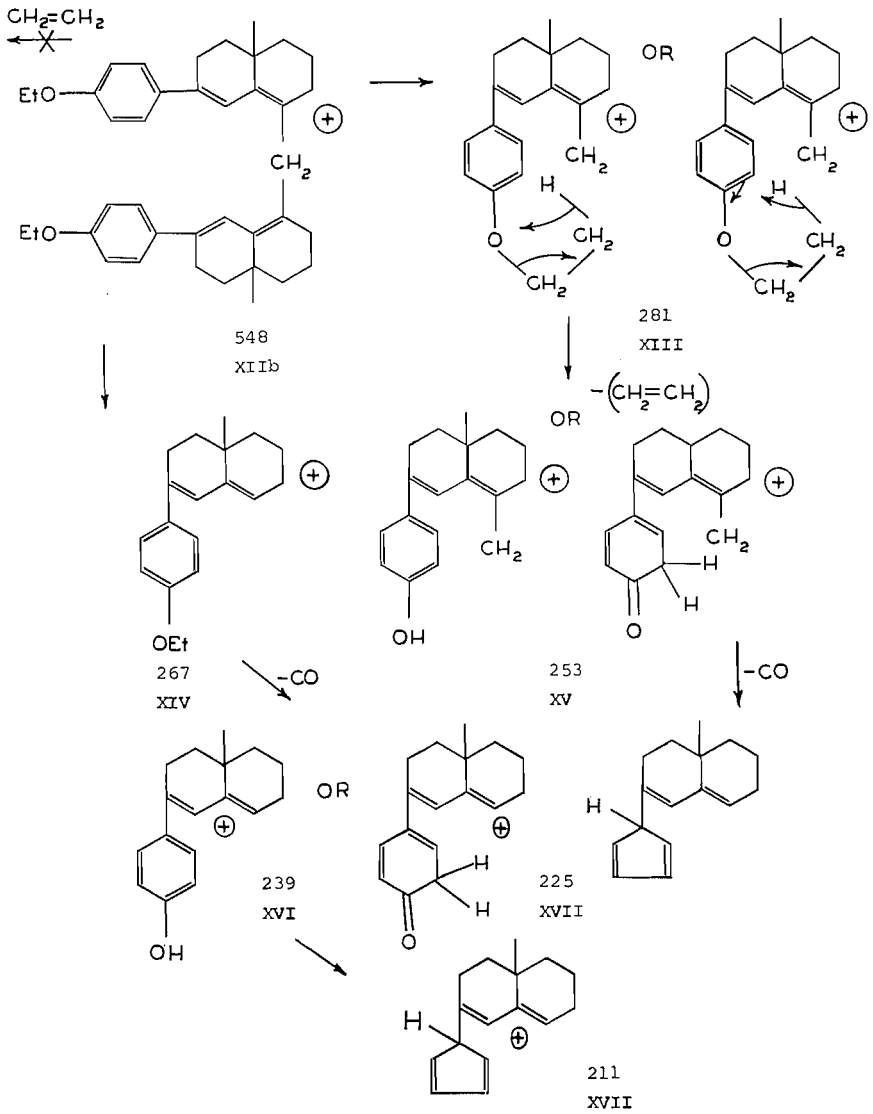


Xa R=H
Xb R=OEt

XIa R=H
XIb R=OEt

6.99 p.p.m. characteristic of the aromatic protons, a singlet at 6.87 p.p.m. caused by the 1 and 1′ protons, a quartet centered at 3.94 p.p.m. for the CH_3—CH_2—O protons, and a singlet at 3.12 p.p.m. assigned to the doubly allylic protons.

In the mass spectrum, the molecular ion peak had a mass of 548, and the elemental analysis derived for it gave an empirical formula of $C_{39}H_{48}O_2$. The elemental analysis and the molecular weight of the product were interpreted as evidence for the inclusion of a methylene group in addition to "dimerization" of the starting material.



XII II VII

On the basis of structure XII, the signal at 3.12 p.p.m. in the n.m.r. spectrum can be attributed to the doubly allylic protons on the carbon between the 8 and 8′ positions. Substitution in these positions would be expected to cause a bathochromic shift in the ultraviolet spectrum. Finally, a fragmentation pattern based on structure XII may be used to explain a number of the peaks in the mass spectrum (Scheme 1).

Since the yield of "dimer" was directly proportional to the amount of acetic acid, it was felt that the source of the included methylene was probably an impurity in the acetic

For personal use only.

SCHEME 1. Probable fragmentation pattern of product XII.

acid. Indeed, it soon was discovered that upon addition of a drop of aqueous formaldehyde the reaction went to completion, giving an almost quantitative yield of "dimer". Moreover, "dimer" formation, which previously had been impossible in solvents other than acetic acid, became possible when a small amount of formaldehyde and perchloric acid was added. Thus, the reaction was found to proceed in chloroform, ethyl acetate, benzene, and acetone. The reaction, however, seemed to be specific for formaldehyde, since attempts to use other aldehydes, such as benzaldehyde, *p*-nitrobenzaldehyde, and chloroacetaldehyde, were unsuccessful.

The specificity of this reaction provides a convenient method of estimating trace amounts of formaldehyde in the presence of other aldehydes. If one uses a steroidal compound, such as 3-phenylcholesta-3,5-diene (I), the determination[3] can become quite accurate, since the

[3]*This method is closely analogous to the chromotropic test (6).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

formaldehyde is trapped in a molecule of high molecular weight which absorbs strongly in the ultraviolet. From the average yield of "dimer", it can be concluded that the commerical acetic acid used in these experiments contains about 15 p.p.m. of formaldehyde.[4] It is interesting to note that approximately the same amount of formaldehyde was found in acetic anhydride decomposed with water. Propionic acid was also found to contain a small amount of formaldehyde. Even acetic acid which had been purified by refluxing with 5% potassium permanganate and distilled at reduced pressure still contained some formaldehyde. Formaldehyde-free acetic acid could be obtained by refluxing the acetic acid with 5% potassium permanganate, 10% water, and 1% sulfuric acid. This suggests that the aldehyde exists in acetic acid mainly in the form of diacetoxymethane.

We next studied the reactivity of α-phenyl dienes with other electrophilic reagents. The "dimerization" reaction was carried out in deuterated acetic acid with 3-phenylcholesta-3,5-diene (I) as starting material. The n.m.r. spectrum of the unreacted I showed that the C-6 proton was completely replaced by deuterium, to give 3-phenylcholesta-3,5-diene-6*d* (I*a*). In contrast, no incorporation of deuterium in the 4 position or in the aromatic ring had occurred. The signal caused by the C-4 hydrogen in the deuterated starting material was found to be much sharper than in the undeuterated starting material, thus showing that there was long-range coupling between the C-4 and C-6 protons in I. In the infrared spectrum, in addition to a band at 2 235 cm^{-1} assigned to the olefinic C—D stretching, a broad band between 2 085 cm^{-1} and 2 190 cm^{-1} suggested that some replacement of the protons by deuterium in the allylic positions had occurred. The n.m.r. spectrum of the "dimer ' showed practically no change. In the infrared spectrum, a broad band at 2 100 cm^{-1} was interpreted as being caused by allylic deuteration.

The Friedel–Crafts acylation was then investigated. Addition of 3-phenylcholesta-3,5-diene (I) to carbon tetrachloride containing acetic anhydride in the presence of anhydrous aluminium chloride gave, after chromatography on alumina, a product which was identified as 6-acetyl-3-phenylcholesta-3,5-diene (I*b*).

The Vilsmeier reaction was also studied. Formylation of 3-phenylcholesta-3,5-diene (I) with the complex prepared from phosphorus oxychloride and *N*-methylformanilide gave a high yield of a product identified as 6-formyl-3-phenylcholesta-3,5-diene (I*c*). Lithium aluminium hydride reduction of I*c* gave, in a quantitative yield, 6-hydroxymethyl-3-phenylcholesta-3,5-diene-6-yl methane (I*d*). Addition of a drop of perchloric acid to an equimolar chloroform solution of I and I*d* gave a product which was identical with II.

EXPERIMENTAL

The melting points were determined on a Gallenkamp melting point apparatus in open capillaries, and are corrected. The analyses were carried out by Dr. C. Daesslé, Montreal, and by Schwarzkopf Microanalytical Laboratory, New York. The infrared spectra were determined on a Perkin–Elmer 337 grating spectrophotometer, with 1 mm sodium chloride cells. The ultraviolet absorption spectra were measured by means of a Beckman recording spectrophotometer, model DK1. The nuclear magnetic resonance spectra were recorded on a Varian A60 instrument at 60 Mc.p.s., and carbon tetrachloride was used as solvent (tetramethylsilane = 0 p.p.m.). The optical rotations were measured on a Carl Zeiss automatic polarimeter at 25°, in an 0.5 dm tube and with chloroform as solvent. The mass spectra were taken by Morgan and Schaffer Corp., Montreal, on a Hitachi Perkin–Elmer RMU60 mass spectrometer. Woelm alumina was used for column chromatography, and silica gel for t.l.c. The glacial acetic acid used was Anachemia A.C.S. reagent grade.

Preparation of Phenyl Dienes

Bromobenzene (0.030 mole) in 30 ml of anhydrous ether was added slowly (1 h) to 0.041 mole of magnesium turnings, activated by a crystal of iodine and under a nitrogen atmosphere. The mixture was then stirred for 1 h.

To this Grignard solution, the corresponding Δ^4-3-ketone (0.020 mole) was added as a solid, followed by 50 ml of anhydrous ether. The reaction mixture was stirred under reflux for 1.5 h. Excess Grignard reagent

[4] *This value is to be compared with that of Peterson and Joslyn (7), who have estimated the amount of formaldehyde in a sample of Baker and Adamson reagent-grade glacial acetic acid to be 1–3 p.p.m.*

was destroyed by the careful addition of 50 ml of methanol. A solution of 10 ml of concentrated HCl, diluted with water in a 1:1 ratio, was then added and the mixture was refluxed for 1 h to ensure complete dehydration of the reaction product.

In the case of the steroidal 3-phenyl dienes, a large excess of water was added and the product was isolated by filtration, washed with water, and crystallized from methanol – methylene chloride.

In the case of 10-methyl-2-phenyl-$\Delta^{2,9}$-hexalin (X*a*), all attempts to isolate, on a preparative scale, this phenyl diene from biphenyl failed.

Preparation of p-Ethoxyphenyl Dienes

Exactly the same procedure as that described for the phenyl dienes was used, except that bromobenzene was replaced by *p*-bromophenetole. In the case of 10-methyl-2-*p*-ethoxyphenyl-$\Delta^{2,9}$-hexalin (X*b*), after dehydration of the reaction product, water was added and the mixture was extracted several times with ether. The combined ether extracts were washed with a saturated solution of sodium bicarbonate until acid free, and once with brine. The ether solution was dried with magnesium sulfate and the solvent evaporated. The residue was chromatographed on alumina (activity I). Elution with hexane–benzene (3:1) gave 1.5 g of X*b* which could be purified further by crystallization from methanol.

Bi-(3-phenylcholesta-3,5-diene-6-yl) methane (II) (General Procedure for the Preparation of the Steroidal "Dimers")

3-Phenylcholesta-3,5-diene (I) (500 mg) was dissolved in 100 ml of hot ethyl acetate, and 400 ml of glacial acetic acid was added. The temperature of the stirred solution was then adjusted to 45 °C, and 7.5 ml of 70% perchloric acid was added dropwise. A flocculent precipitate appeared after approximately 12 min. The solution was kept at 45 °C for 0.5 h, and then 500 ml of water was added. The precipitate formed by the addition of water was filtered off and washed 3 times with 50 ml of water and then once with 5 ml of methanol. Column chromatography of the precipitate on alumina (activity I) and elution with hexane gave first I and then II. Alternatively, two careful crystallizations from hexane yielded 180–200 mg of colorless beads of "dimer" II, m.p. 224–225°. Recrystallization raised the melting point to 228–229°; λ_{max}^{hexane} 296 mμ (ϵ 52 300), $[\alpha]_D^{25}$ −110°.

Anal. Calcd. for $C_{67}H_{96}$: C, 89.26; H, 10.73; mol. wt. 901.5. Found: C, 89.04; H, 11.09; mol. wt. (osmometry) 860.

The above procedure was used to prepare all the "dimers" in the steroid series.

Effect of Formaldehyde and Solvent on "Dimer" Formation

To 10 mg samples of I dissolved in 10 ml of the solvents hexane, carbon tetrachloride, ethyl acetate, chloroform, and acetone, 0.1 ml of 70% perchloric acid and 0.1 ml of an aqueous solution of formaldehyde (40%) were added. The solutions were stirred at 45° for 1.5 h. In ethyl acetate, chloroform, and acetone "dimer" formation was complete (as shown by t.l.c.), whereas in hexane and carbon tetrachloride starting material was recovered unchanged.

Catalytic Hydrogenation of II

To 75 mg of 10% palladium on charcoal in 75 ml of benzene, 65 mg of "dimer" II was added at 24 °C. The mixture was stirred until the uptake of hydrogen had stopped (about 3 h). The benzene solution was then filtered and the catalyst washed 3 times with 20 ml of benzene. The combined filtrates were then evaporated to give a crystalline material. Recrystallization from hexane gave bi-(3-phenylcholestane-6-yl) methane (VII), m.p. 251–252°, $[\alpha]_D$ +13.8°. A signal at 6.8–7.3 p.p.m. in the n.m.r. spectrum proved that the aromatic system was not affected by the hydrogenation.

Anal. Calcd. for $C_{67}H_{104}$: C, 88.48; H, 11.52. Found: C, 87.77; H, 12.24.

A duplicate hydrogenation was carried out. The hydrogen uptake corresponded to 110% and 91.2% of the value required for complete saturation of the four double bonds of II.

6-Acetylcholesta-3,5-diene (Ib)

A carbon tetrachloride solution (5 ml) of cholesta-3,5-diene (I) (500 mg) was added dropwise to a mixture of 25 ml of carbon tetrachloride, 1.5 g of finely powdered anhydrous aluminium chloride, and 1 ml of acetic anhydride. The resulting dark-brown reaction mixture was left at room temperature for 15–20 min, and 200 ml of water was then added. The carbon tetrachloride layer, which was now straw yellow, was diluted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

500 ml of ether. The organic layer was separated from the aqueous phase, and washed with bicarbonate solution until neutral and then with water. The solution was dried over magnesium sulfate, evaporated, and chromatographed on alumina (activity II–III). Elution with hexane gave 83 mg of I. Further elution with hexane–ether (19:1) gave 218 mg of 6-acetylcholesta-3,5-diene (I*b*). Two crystallizations from methanol gave light-yellow crystals, $[\alpha]_D$ −123°, m.p. 108–109°, λ_{max}^{hexane} 303 mμ (ε 18 400), ν_{CCl_4} 1 680 cm^{-1}; δ_{CCl_4} complex multiplet between 7.1 and 7.6 p.p.m. for the five aromatic protons, a singlet at 6.99 p.p.m. for the C-4 proton, and a sharp singlet at 2.18 p.p.m. for the CH_3—C protons.

Anal. Calcd. for $C_{35}H_{50}O$: C, 86.36; H, 10.35; O, 3.29. Found: C, 86.33; H, 10.33; O, 3.52.

Di(10-methyl-2-p-ethoxyphenyl-Δ^{2,9}-hexalin-8-yl) methane (XII)

10-Methyl-2-*p*-ethoxyphenyl-Δ^{2,9}-hexalin (X*b*) (700 mg) was dissolved in 100 ml of ethyl acetate, and 400 ml of acetic acid was added, followed by 7.5 ml of 70% perchloric acid. The solution was stirred for 1 h at 50°, and then 500 ml of water was added. The mixture was extracted with four 250 ml portions of ether; the ether extracts were washed with saturated sodium bicarbonate until acid free and then with brine. After the combined extracts were dried and the solvent evaporated, the residue was chromatographed on alumina (activity I). Elution with hexane–benzene (3:1) gave 200 mg of X*b*. Further elution with pure benzene gave 130 mg of XII. Crystallization from hexane gave pure XII, m.p. 163–163.5°, $\lambda_{max}^{cyclohexane}$ 295 mμ (ε 63 500).

6-Formyl-3-phenylcholesta-3,5-diene (Ic)

To 1.5 g of 3-phenylcholesta-3,5-diene dissolved in 5 ml of *o*-dichlorobenzene, 1 ml of *N*-methylformanilide mixed with 0.5 ml of $POCl_3$ was added and the reaction mixture was stirred at 90–95 °C for 2 h (8). To the cooled mixture, 20 g of sodium acetate in 25 ml of water was added, and the solution evaporated to dryness. The residue was washed with one portion of water (10 ml), one portion of 6 *N* HCl, and then water again (200 ml). The residue was crystallized once from methanol – methylene chloride. The resulting brown crystals were chromatographed on 30 g alumina (activity II–III). Elution with 300 ml of hexane gave 200 mg of starting material I. Further elution with 100 ml of hexane–ether (1:3) gave 953 mg of I*c*. Crystallization from methanol–ether gave pure light-yellow crystals of 6-formyl-3-phenylcholesta-3,5-diene (I*c*), $[\alpha]_D$ −115°, m.p. 125–126°, λ_{max}^{hexane} 315 mμ (ε 27 000), ν_{CCl_4} 1 660 cm^{-1}. In the n.m.r., a singlet at 10.62 p.p.m. was assigned to the aldehydic proton; a broad signal between 7.18 and 7.66 p.p.m. could clearly be resolved into two signals: a signal at 7.56 p.p.m. for the C-4 proton and an overlapping complex multiplet arising from the five aromatic protons.

Anal. Calcd. for $C_{34}H_{48}O$: C, 86.38; H, 10.24; O, 3.38. Found: C, 86.40; H, 10.20; O, 3.54.

6-Hydroxymethyl-3-phenylcholesta-3,5-diene (Id)

Lithium aluminium hydride (500 mg) was added to 6-formyl-3-phenylcholesta-3,5-diene (I*c*) (650 mg) dissolved in 50 ml of anhydrous ether. The light-yellow solution became colorless immediately. The reaction mixture was stirred for 0.5 h at room temperature, the excess hydride was carefully decomposed with methanol, and a small amount of 10% aqueous sodium hydroxide was added. The resulting gelatinous precipitate was filtered off and washed thoroughly with ether. The combined filtrates were then dried over magnesium sulfate and evaporated. Crystallization of the resulting oil from hexane gave 6-hydroxymethyl-3-phenylcholesta-3,5-diene (I*d*), $[\alpha]_D$ −162°, m.p. 120.5–121°, $\lambda_{max}^{methanol}$ 288 mμ (ε 26 400); δ_{CCl_4} a complex multiplet between 7 and 7.5 p.p.m. for the five aromatic protons, a singlet at 6.78 p.p.m. for the C-4 proton, and a broad band at 4.12 p.p.m. for the —CH_2—O protons. The hydroxy proton signal was hidden under the steroid envelope.

Anal. Calcd. for $C_{34}H_{50}$: C, 86.01; H, 10.62. Found: C, 86.10; H, 10.21.

Synthesis of "Dimer" II from Alcohol Id

6-Hydroxymethyl-3-phenylcholesta-3,5-diene (I*d*) (10 mg) and 3-phenylcholesta-3,5-diene (I) (10 mg) were dissolved in 10 ml of chloroform, and 1 drop of perchloric acid was added. The mixture was swirled on a warm steam bath for a few minutes, and then 50 ml of 10% aqueous sodium bicarbonate was added, followed by 50 ml of ether. The organic layer was separated, washed with water, dried, and evaporated. Crystallization of the residue from hexane gave a compound whose melting point was not depressed on admixture with "dimer" II and which was further identified by t.l.c. and its ultraviolet spectrum.

ACKNOWLEDGMENTS

We thank Mr. K. Valentin for taking the n.m.r. spectra, and Mr. Kastner of Ayerst Laboratories, Montreal, for the quantitative hydrogenation.

THE ADDITION OF CARBOXYLIC ACIDS TO ACETYLENIC COMPOUNDS

J. DiPietro and W. J. Roberts
Summit Research Laboratories, Celanese Corporation of America, Summit, New Jersey
Received April 4, 1966

ABSTRACT

The free radical induced addition of acetic acid and its derivatives to olefins has been reported recently. As an extension of this reaction, the addition of acetic acid to acetylenic compounds was investigated.

Adipic acid was found to be the major product of the reaction of excess acetic acid and acetylene at 110–120 °C under pressure in the presence of organic peroxides. A second oily acidic product with a molecular weight of about 300, not yet identified, was found to the extent of about 2 parts by weight to every 3 parts of adipic acid.

Octen-3-oic acid and its anhydride were synthesized from hexyne-1 and excess acetic acid in the presence of organic peroxides. Acetic anhydride was substituted for acetic acid, with the net advantage that acetylene was more soluble in the solvent. The general scope of the reaction was expanded to include other transfer agents, such as acetone, formic acid, and propionic acid.

INTRODUCTION

Free-radical addition reactions to compounds containing a double bond have been known for some time (1, 2). Recently (3), it was reported that malonic esters, acetoacetic esters, and related compounds can be added by a free radical induced reaction to α-olefins.

$$RCH{=}CH_2 + CH_2(CO_2C_2H_5)_2 \xrightarrow[\Delta]{\text{Peroxide}} RCH_2CH_2CH(CO_2C_2H_5)_2$$

The first example of the addition of acetic acid to an olefin was the peroxide-induced reaction with ethylene, which gives a mixture of homologous acids ($CH_3(CH_2)_{2n}\cdot COOH$) (4). In 1962 Allen *et al.* reported the radical-induced addition of acetic acid and its derivatives to olefins (5). Apart from these examples, few radical addition reactions of carboxylic acids or their derivatives have been reported.

Our interest in this general type of reaction was to extend its scope to acetylenic compounds, and to suggest new synthetic routes for dicarboxylic acids in general.

EXPERIMENTAL

Addition of Acetic Acid to Hexyne-1

A 5 l, three-necked flask was charged with 3 kg of glacial acetic acid and 5.0 cc of di-*t*-butyl peroxide. The solution was heated to reflux (118 °C), and 50 g (0.70 mole) of hexyne-1, 120 cc of glacial acetic acid, and 2.0 cc of di-*t*-butyl peroxide were added. The reaction was refluxed for 24 h, and then was fractionally distilled in a 12 inch helix-packed column to yield 24% of octen-3-oic acid, b.p. 84–87 °C at 0.7–1.0 mm.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.60; H, 9.86. Found: C, 67.00; H, 9.87.

The infrared spectrum was consistent with the suggested structure. The sample shows carbonyl absorption at 5.83 μ, broad OH absorption at 3.0–3.8 μ, CH stretching at 7.75 μ, and *trans* unsaturation at 10.34 μ. The first three absorptions are characteristic of monocarboxylic acids, and the latter one is typical of double bond unsaturation. The material was quantitatively hydrogenated to yield *N*-octanoic acid, thus suggesting the absence of 3-ethynylhexanoic acid from the reaction products.

In addition to octen-3-oic acid, a 15% yield of octen-3-oic anhydride was obtained, b.p. 135–140 °C at 0.4–0.5 mm, with normal anhydride infrared absorptions at 5.51 μ and 5.66 μ.

Addition of Acetic Acid to Acetylene

The apparatus used for the free-radical addition of acetic acid to acetylene is diagrammatically shown in Fig. 1. The procedure by which adipic acid was ultimately synthesized was as follows. A 36 inch × 4 inch Aminco rocking bomb was charged with 1.8 kg of glacial acetic acid and 3.3 g (0.02 mole) of di-*t*-butyl peroxide. The bomb was then closed and purged with nitrogen, the pressure was checked, and the system was vented to atmospheric pressure. With the rocker on, the bomb was heated to 110 °C. Acetylene (4.5–5.5 g) was then added, the time of addition ranging from 1 to 1½ h. The pressure in the bomb at the end of the

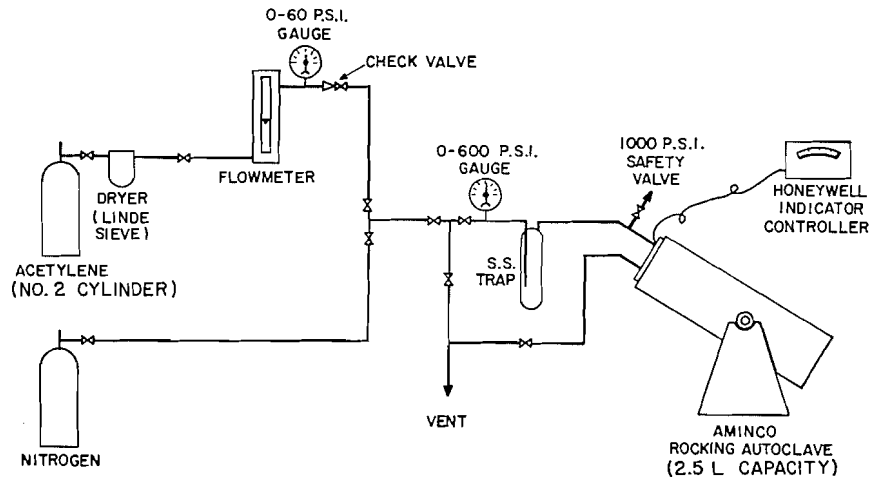

FIG. 1. Apparatus used when acetic acid was added to acetylene. All lines are $\frac{1}{4}$ inch 316 S.S. tubing. The flowmeter is a Matheson, model 620 BBV, instrument.

addition was 27–30 p.s.i.g., and the gauge reading of the rotameter through which the acetylene tank was connected was 16–18 p.s.i.g. The reaction mixture was rocked and allowed to heat up to 120 ± 5 °C for a period of 18 h, after which it was cooled down to room temperature and the gases were passed through a series of silver nitrate traps to obtain a quantitative estimate of the amount of unreacted acetylene. The liquid portion of the reaction was heated under a nitrogen atmosphere until most of the acetic acid was distilled off. The concentrated liquid was then heated until crystals appeared to form. Cold water was added to separate the water-white adipic acid from an oily product. The latter possessed a molecular weight of about 300, with a carboxyl content of 36% (by weight); an infrared spectrum did not show any unsaturation. Several runs were made to justify the validity of the reaction in question (Table I). Proof for the presence of adipic acid was obtained from the infrared spectrum, melting point determination, vapor-phase gas chromatography of the dimethyl ester, elemental analysis, determination of the neutralization equivalent, and condensation with hexamethylenediamine to m.p. 260 °C. The data given in Table I indicate a high degree of reproducibility among the various runs (e.g. runs 1, 3, and 4), and also that not all the acetylene charged is converted into products at the first pass.

TABLE I

Run	Acetylene (g) Charged	Acetylene (g) Recovered	Adipic acid recovered (g)	Oil (g)
1	4.34	2.02	3.0	2.1
2	2.87	1.34	1.9	1.4
3	4.34	2.11	3.1	2.0
4	4.34	2.16	3.1	1.9

Addition of Acetic Anhydride to Acetylene

Gaseous acetylene was slowly metered into 500 cc of anhydrous acetic anhydride kept at −50 °C. The rate of addition was 100 cc/min (0.232 g/min). The solubility of acetylene in cold acetic anhydride is much higher than it is in cold acetic acid. To a 5 l, three-necked flask containing 1.9 kg of acetic anhydride and 7.0 cc of di-*t*-butyl peroxide kept at 120 °C was added, by means of a funnel, the acetic anhydride – acetylene solution over a period of 1 h. The reaction was heated for 18 h at 120 °C; then the excess acetic anhydride was stripped off by distillation and the residue was allowed to crystallize. The analysis of the sample indicates that the product is adipic acid. The percentage conversion of acetylene into adipic acid was of the order of 25–30.

DISCUSSION

The initial study was made with acetic acid because it is an excellent transfer agent and has a high degree of purity. The relatively low explosive hazards of di-*t*-butyl peroxide made it possible to use it as a free-radical initiator at atmospheric pressure. Hexyne-1,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

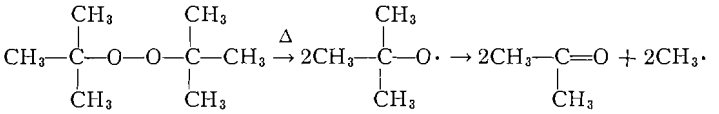
which contains a triple bond, was the first such compound used in this free-radical type of addition.

The major products of the reaction of *t*-butoxy radicals in the presence of two potential hydrogen donors (acetic acid and hexyne-1) are determined by the competition shown in eqs. [1]–[3].

[1] $$(CH_3)_3CO\cdot \xrightarrow{K_d} CH_3COCH_3 + CH_3\cdot$$

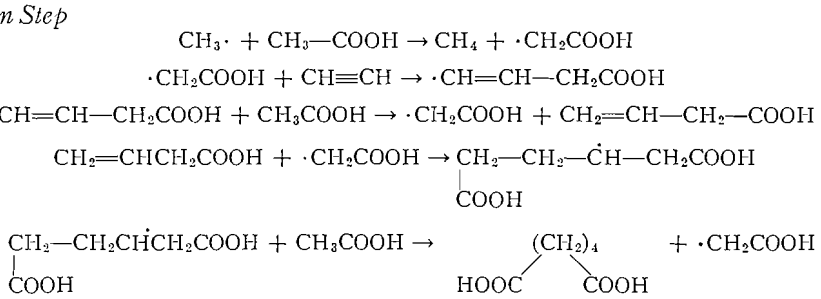
[2] $$(CH_3)_3CO\cdot + CH_3COOH \xrightarrow{K_{a_1}} (CH_3)_3COH + \cdot CH_2COOH$$

[3] $$(CH_3)_3CO\cdot + CH_3(CH_2)_3C{\equiv}CH \xrightarrow{K_{a_2}} (CH_3)_3COH + CH_3(CH_2)_3C{\equiv}C\cdot$$



The rate constant K_{a_1}/K_{a_2} may be measured directly from the relative rates of disappearance of acetic acid and hexyne-1, or indirectly by determining K_{a_1}/K_d and K_{a_2}/K_d from the ratios of *t*-butyl alcohol to acetone obtained in separate experiments in the presence of acetic acid and hexyne-1 alone. It was found by gas chromatographic techniques that reaction [1] is the predominant one, and that reaction [3] does not occur to an appreciable extent because of the low concentration of the acetylenic compound in the reaction. It is indeed a necessary requirement that the reactants be highly diluted, to obtain the products herein described. Had reactions [2] and [3] occurred to any significant extent, the gas chromatographic analysis of the reaction product should have indicated the presence of *t*-butyl alcohol, which was proven to be absent in all cases.

These data seem to indicate that the addition of acetic acid to a compound containing a triple bond can occur in a manner analogous to that observed for compounds having a double bond.



A typical reaction run for the free-radical addition of acetic acid to acetylene gave the following results. From 4.34 g of gaseous acetylene charged to the reactor, 3.0 g of adipic acid and 2.1 g of an oily, gummy material were isolated. Unreacted acetylene has been shown to be present by passage of the gaseous material remaining after the reaction into aqueous silver nitrate and by gas chromatography.

A mechanistic path for the reaction under study suggests a chain reaction with a requirement for a low level of initiator.

Initiation Step

Propagation Step

Possible Termination Step

$$\cdot CH_2COOH + CH_3\cdot \rightarrow CH_3CH_2COOH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A close look at the proposed mechanism shows that the methyl free-radical appears to be the crucial species for initiating the propagation step. It also appears that other peroxide initiators could be employed in producing the necessary methyl free-radical; even saturated hydrocarbons, when subjected to pyrolysis, could yield the desired methyl free-radicals.

This proposed mechanism requires a high dilution of reactants, to minimize the dimerization of the methyl free-radical with itself. It is indeed a necessary prerequisite, for the synthesis of adipic acid by this route, that the molar ratio of the solvent (acetic acid) to acetylene be kept at 50 or higher.

Whether the reaction proceeds in a stepwise manner through the formation of vinyl acetic acid, or by a simultaneous free-radical addition of 2 moles of acetic acid to acetylene still has to be determined. It is of interest to point out that vinyl acetic acid, when added to a large excess of boiling acetic acid in the presence of di-*t*-butyl peroxide, yields adipic acid, presumably because the molecule has a terminal vinyl group and thus is more reactive towards radical addition.

The catalytic effect of copper salts on the reactions of peroxides with a variety of hydrogen-donor substrates has been described by Kharasch and Fono (6). In view of this, we carried out several experiments with selected metal salts (e.g. nickel oxide and zinc carbonate) and di-*t*-butyl peroxide, to ascertain whether the half-life of the initiator, as well as its thermal stability, could be affected advantageously. We were unable to observe any change in the yield or rate of reaction.

ACKNOWLEDGMENT

The authors express their gratitude to Dr. C. L. Smart for his interest in this work.

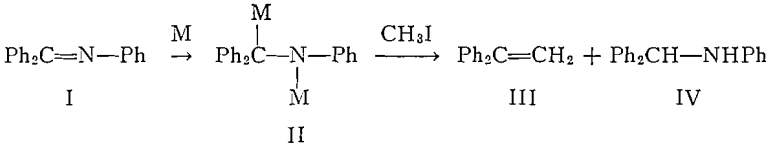
THE REACTIONS OF THE DISODIUM ADDUCT OF BENZOPHENONE ANIL[1]



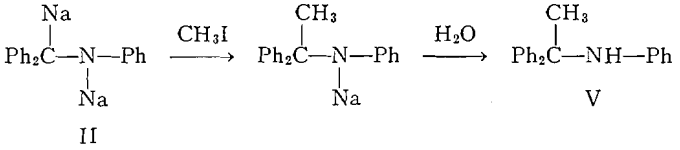
JAMES G. SMITH AND C. DOREEN VEACH
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received May 11, 1966

ABSTRACT

The disodium adduct of benzophenone anil has been treated with a variety of reagents, and the products have been isolated and identified. With alkyl halides, ethylene oxide, and diethyl sulfate, alkylation occurs at the carbon atom. With tri- and tetra-methylene dibromide, nitrogen alkylation also occurs, thereby producing substituted pyrrolidine and piperidine derivatives. Benzaldehyde abstracts the alkali metal from the adduct whereas esters react to form the *N*-acyl derivatives.

INTRODUCTION

Solutions of benzophenone anil (I) in ether solvents react with alkali metals to form a complex (II) containing two atoms of alkali metal per mole of anil (1, 2). The chemical behavior of this adduct has been examined in the past (2–4), but conflicting results have been reported. In the original study by Schlenk and Bergmann (2), benzophenone anil was the only product formed when the adduct was treated with methyl iodide or with several other reagents. On the other hand, Mikhailov (3) reported the formation of 1,1-diphenylethylene (III) and *N*-benzhydrylaniline (IV) upon treatment of II with methyl iodide.



In our hands, the adduct II behaved in a manner quite different from that reported in these earlier studies. Generally speaking, the chemical behavior of the benzophenone anil adduct resembles that recently reported for the benzophenone ketyls (5–8).

Adduct Preparation

The reaction of benzophenone anil and sodium proceeds very rapidly in tetrahydrofuran. This is not surprising in view of the well-known efficacy of such solvents in the preparation of organometallic compounds. However, it is surprising that the adduct forms in diethyl ether with equal ease, especially since much longer reaction times have been employed elsewhere (2).

Reaction with Alkyl Halides

The disodium adduct II in tetrahydrofuran reacts smoothly with 1 equivalent of methyl iodide to produce the *C*-methyl derivative, *N*,1,1-triphenylethylamine (V). This behavior of the adduct was initially thought to be due to the use of tetrahydrofuran as solvent

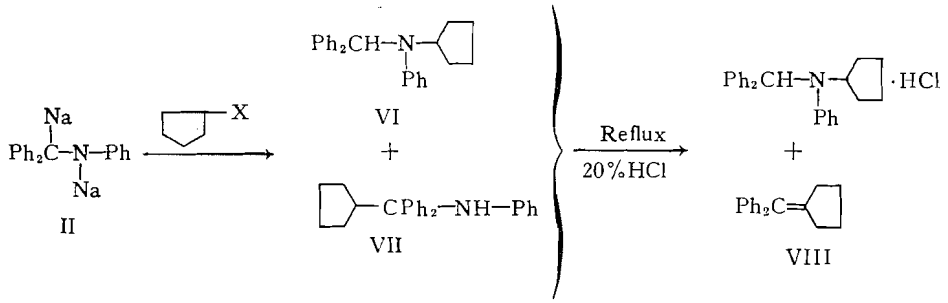
[1]*Contribution No. 142 from the Exploratory Research Laboratory.*

rather than the diethyl ether used in the earlier investigations (2, 3). However, a repetition of the experiment with diethyl ether produced the same product accompanied by *N*-benzhydrylaniline, thus establishing that the same reaction is occurring but to a lesser extent.

The structure V of the reaction product is consistent with its nuclear magnetic resonance (n.m.r.) spectrum, and additional proof has been obtained by decomposition in 20% hydrochloric acid to 1,1-diphenylethylene and aniline.

$$\underset{\text{V}}{Ph_2C(CH_3)-NHPh} \xrightarrow[20\%\ HCl]{\text{Reflux}} Ph_2C{=}CH_2 + PhNH_2\cdot HCl$$

A similar decomposition of *N*,1,1,2-tetraphenylethylamine to *N*,1,1-triphenylethylene has been reported (9).



$$PhCH_2{-}CPh_2{-}NH{-}Ph \rightarrow Ph_2C{=}CHPh + PhNH_2\cdot HCl$$

This decomposition provides an explanation for Mikhailov's earlier observation (3) of the formation of 1,1-diphenylethylene from methyl halides and the alkali metal adducts of benzophenone anil. During his separation of the individual constituents of the crude reaction mixture, Mikhailov employed refluxing 20% hydrochloric acid. This undoubtedly resulted in decomposition of the initial reaction product to the observed unsaturated hydrocarbon. In the present experiments, the crude reaction product has also been examined by precipitating with hydrogen chloride the amines from the ether solution as their hydrochloride salts and examining the ether-soluble portion. Only small yields of 1,1-diphenylethylene have been observed.

The scope of this reaction has been investigated with a number of alkyl halides, and the results are summarized in Table I. Certain obvious trends are evident. The reaction is slow with bulky halides, such as *t*-butyl chloride, with a consequently reduced yield and the formation of *N*-benzhydrylaniline on hydrolysis. Inert halides, such as vinyl chloride, do not react whereas reactive halides, such as allyl or benzyl chloride, react rapidly, even at −60°.

The yield of product is lower with alkyl iodides than with alkyl bromides or chlorides. An investigation of the reaction products by thin-layer chromatography reveals the presence of unidentified by-products which increase in quantity when an alkyl iodide is used.

In the case of the simple alkyl halides, the products formed by nitrogen alkylation of the benzophenone anil adduct have not been isolated. However, with cyclopentyl halides, the amount of nitrogen alkylation is quite large and comparable to the carbon-alkylated product. The nitrogen-alkylated derivative VI may be isolated by decomposing the carbon-alkylated compound VII to cyclopentylidene diphenylmethane (VIII) with hydrochloric acid, leaving the nitrogen-alkylated product as the hydrochloride salt.

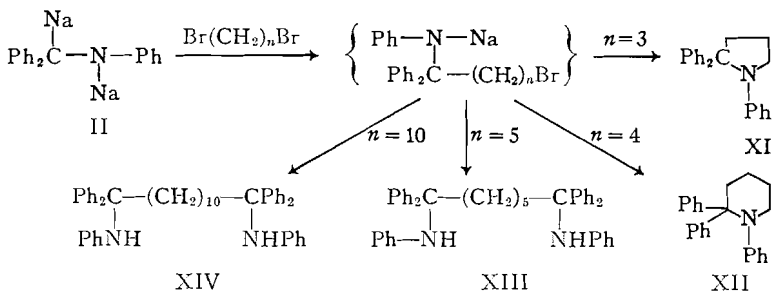
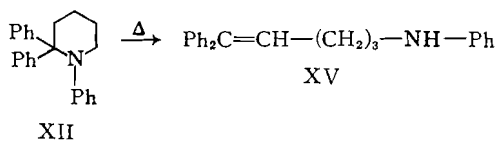
§Diethyl ether as reaction solvent.



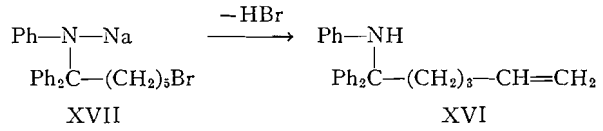
Attempts to synthesize an authentic sample of the tertiary amine VI from *N*-cyclopentylaniline and benzhydryl chloride were unsuccessful.

The reaction of the disodium adduct of benzophenone anil with 2 equivalents of methyl iodide produces a product whose n.m.r. spectrum is compatable with that expected for the dialkylated derivative, *N*-methyl-*N*,1,1-triphenylethylamine (IX). In addition to IX, a small amount of the nitrogen-alkylated derivative, *N*-methyl-*N*-benzhydrylaniline (X), can be isolated.



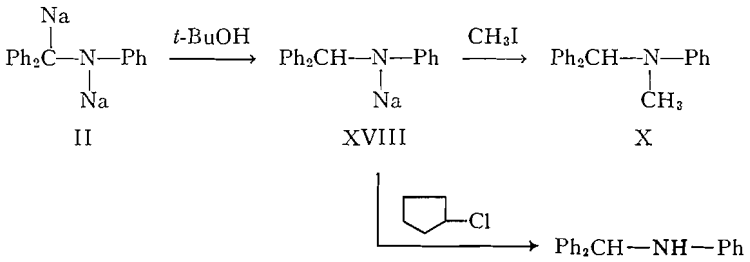
The dialkylated product IX is sufficiently stable that it can be distilled. However, attempts to purify it further by means of its hydrochloride, or by chromatography, result in it being decomposed to *N*-methylaniline and 1,1-diphenylethylene. Indeed, so facile is this decomposition that it can be effected by an equivalent amount of formic acid and the reaction followed by observation of the n.m.r. spectrum.

With polymethylene dibromides the sodium adduct of benzophenone anil reacts in two ways. Carbon alkylation presumably occurs first, and then, if the chain length of the pendant bromoalkyl group is of the proper length to bring the remaining bromo group into close proximity with the nitrogen atom, nitrogen alkylation occurs to form the heterocyclic derivative (XI or XII). However, if the chain length is too long, nitrogen alkylation is not favored and dimeric products result from the carbon alkylation of a second molecule of adduct to form the diamines (XIII or XIV).



Distillation of 1,2,2-triphenylpiperidine (XII) effected its decomposition to an isomer which, on the basis of its n.m.r. spectrum, is believed to be *N*,1,1-triphenyl-5-aminopentene-1 (XV).

An additional product has also been isolated from the reaction leading to XIII. In this case, the material has been assigned the structure *N*,1,1-triphenyl-1-aminohexene-5

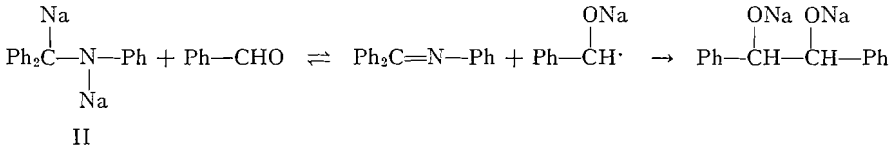


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(XVI) on the basis of its n.m.r. spectrum. Its formation probably occurs by dehydrohalogenation of the intermediate XVII in a competitive side reaction.

XVII XVI

A successful attempt has been made to take advantage of the selective reactivity of the two anionic sites in the disodium adduct of benzophenone anil by treating it first with 1 equivalent of an acid to form the amide ion XVIII, and then alkylating it with methyl iodide to produce *N*-methyl-*N*-benzhydrylaniline (X).

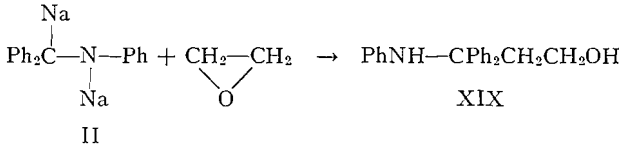


II XVIII X

An attempt to apply this to the synthesis of *N*-cyclopentyl-*N*-benzhydrylaniline by treating XVIII with cyclopentyl chloride failed; only *N*-benzhydrylaniline was produced. It is not clear why the dianion of the disodium adduct of benzophenone anil is capable of nitrogen alkylation with cyclopentyl chloride whereas the monoanion XVIII is not.

Reaction with Benzaldehyde

The reaction of the sodium adduct with aldehydes has been studied with benzaldehyde, an aldehyde free of enolizable (acidic) protons. The products which have been isolated are benzophenone anil and *dd,ll*-hydrobenzoin. In addition, the presence of *meso*-hydrobenzoin has been demonstrated spectroscopically.

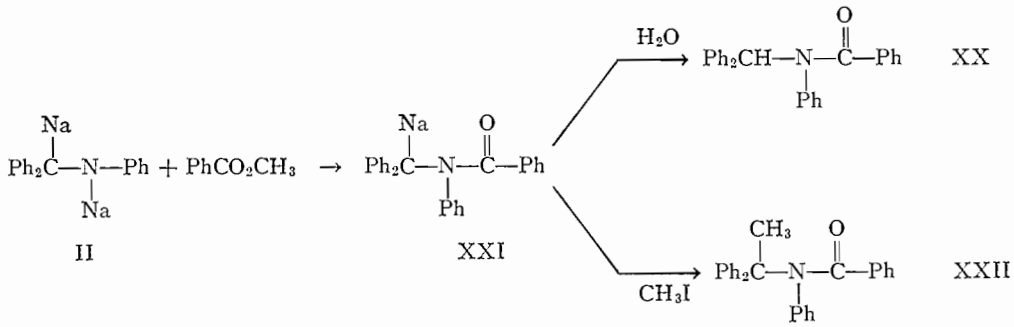


Evidently, a transfer of the sodium from the benzophenone anil to the carbonyl group of the aldehyde occurs with regeneration of the starting material. Dimerization of the radical ion formed from the benzaldehyde produces the two diastereomeric hydrobenzoins. Similar transfers of alkali metal to carbonyl groups have been reported (6, 10).

II

Reactions with Ethylene Oxide

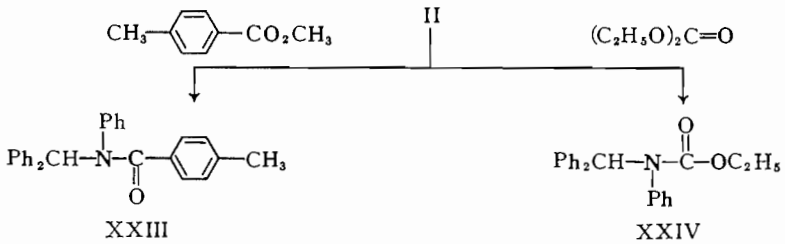
Treatment of the sodium adduct with 1 equivalent of ethylene oxide effected alkylation at the carbon atom to produce *N*,1,1-triphenyl-3-hydroxypropylamine (XIX).



II XIX

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Alkylation at the carbon atom is not surprising, since the anionic carbon should be more basic than the anionic nitrogen and should react faster.



Reaction with Esters

Treatment of the disodium adduct of benzophenone anil with methyl benzoate produces *N*-benzhydrylbenzamide (XX) on hydrolysis of the initially formed reaction product XXI. That XXI is initially formed is shown by treating the intermediate with methyl iodide to produce *N*-phenyl-*N*-(1,1-diphenylethyl)benzamide (XXII).

The structure XX has been established by comparison with an authentic sample. In the infrared spectra, the amide carbonyl band appears at 1 625 cm^{-1} for XX and at 1 640 cm^{-1} for XXII. In the n.m.r. spectrum of XX, the benzylic proton is shifted downfield and becomes obscured by the aromatic proton band.

Similarly, methyl *p*-toluate and diethyl carbonate react with the disodium adduct II to produce the corresponding *N*-acyl derivatives XXIII and XXIV. In the latter case, the carbamate structure is indicated by the position of the carbonyl band in the infrared spectrum (1 690 cm^{-1}) and by the presence of an ethyl group (from the diethyl carbonate) in the n.m.r. spectrum.

EXPERIMENTAL

Melting points are uncorrected and were determined in an open capillary with a Gallenkamp melting point apparatus. Infrared spectra were recorded on a Perkin–Elmer 221 with prism-grating interchange, using Nujol mulls of the compounds. Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer, using deuterated chloroform solutions, with tetramethylsilane as an internal reference. The chemical shifts reported are in parts per million downfield from the tetramethylsilane.

Benzophenone anil was prepared from benzophenone and aniline, with aniline hydrochloride as catalyst (12). The product, after two recrystallizations from 95% ethanol, melted at 113.5–115°. It was dried under vacuum at 45° and stored in a dry box. All operations connected with the preparation and reaction of the alkali metal complexes were performed in an atmosphere of purified and dried nitrogen.

Tetrahydrofuran and diethyl ether were purified by refluxing for at least 8 h over lithium aluminium hydride and distilling onto a fresh batch of hydride for storage. When needed, the solvent was refluxed for 2 h and the required amount permitted to distill into the reaction vessel, a modified Schlenk tube (13). The tube was transferred to a dry box, where the benzophenone anil and the sodium metal (freshly cut) were weighed and added. After the tube was sealed, it was removed from the dry box and agitated in a horizontal shaker until the reaction was complete.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

To study the rate of adduct formation, aliquot samples of the deep reddish purple solution were withdrawn periodically and quenched in 1:1 ethanol–water, and the alkaline mixture was titrated with 0.1 *N* standard hydrochloric acid to determine the extent of reaction. Preparative conditions were standardized at 50 ± 5 g of solvent/0.01 mole of benzophenone anil, a 100% excess of sodium, and a reaction time of 4 h, which was sufficient to ensure completion of the reaction in both tetrahydrofuran and diethyl ether.

Thin-layer chromatography was carried out using silica gel G adsorbent 0.25 mm thick, with a 10 cm rise of the solvent front. Developing solvents varied and are specified in the experimental details. The detecting spray was a 1% solution of *p*-nitrobenzenediazonium tetrafluoroborate (14) in water.

Reaction with Alkyl Halides

The solution of the adduct was transferred from the excess sodium to an oven-dried, nitrogen-filled flask equipped with a Teflon-coated magnetic stirrer bar. The solution was then cooled with a dry ice and methanol mixture and stirred, and an equivalent amount of alkyl halide was introduced by a pipette or syringe. Stirring was continued for an hour at dry-ice temperatures and then the reaction was permitted to warm to room temperature spontaneously. The final solution, generally a deep reddish brown color, was treated with 15 ml of water to destroy any remaining adduct. Extraction with ether, followed by washing, drying, and evaporating the ether extract, served to isolate the crude reaction product as an oil or gummy solid.

From this point on, the procedures differed depending on the nature of the product or the information desired. The purification procedures and additional comments together with the analytical and n.m.r. data are given below. Unless otherwise specified, each experiment was carried out with the disodium adduct prepared from 0.01 mole of benzophenone anil.

Reaction with Methyl Iodide

The reaction with methyl iodide was repeated several times because of the conflicting literature reports on the nature of the products. The roughly quantitative evaluation of the reaction products that was employed resembled that used by Mikhailov (3) but under milder conditions. The crude reaction product was dissolved in 50 ml of diethyl ether and treated with hydrogen chloride. The amine salt which precipitated out was filtered off, dried, and weighed, and the ether filtrate was evaporated and the residue weighed (1,1-diphenylethylene). The amine salt was then suspended in a mixture of 25 ml of water and 25 ml of benzene. Any aniline hydrochloride that was present dissolved in the water layer, from which it was subsequently isolated by the addition of base and ether extraction. The hydrochloride of *N*,1,1-triphenylethylamine dissociated and the free amine dissolved in the benzene layer, from which it was isolated by evaporation. The yields so obtained were 2–13% aniline, 7–19% 1,1-diphenylethylene, and 71–90% *N*,1,1-triphenylethylamine.

The identity of the isolated 1,1-diphenylethylene was confirmed by distillation and by comparison of the infrared spectrum with that of an authentic sample. The identity of the aniline was confirmed by preparing the benzenesulfonamide derivative.

The crude *N*,1,1-triphenylethylamine was obtained as a gum, and the presence of *N*-benzhydrylaniline was suspected. Small amounts could be detected by thin-layer chromatography with cyclohexane containing 17% acetic acid as developing solvent: *N*-benzhydrylaniline, R_f 0.60; *N*,1,1-triphenylethylamine, R_f 0.43. However, the amount was too small to show a benzylic proton peak in the n.m.r. spectrum of the crude amine.

The crude reaction product was purified by recrystallization from methanol (10 ml/g). The hydrochloride decomposes above 170°, forming two layers in the melting point capillary. Nuclear magnetic resonance: CH_3 singlet at 2.0 (3.0 H), NH singlet at 4.2 (1.0 H), aromatic H's complex band at 6.2–7.6 (15.8 H).

A repetition of the above experiment with diethyl ether as the solvent for adduct formation and for reaction with methyl iodide led to the formation of substantial amounts of *N*-benzhydrylaniline. The crude reaction product, isolated as previously described, contained 32% of *N*-benzhydrylaniline,[2] as determined by the relative areas of the appropriate n.m.r. peaks: the benzyl proton at 5.4 caused by *N*-benzhydrylaniline and the methyl protons at 2.0 caused by *N*,1,1-triphenylethylamine.

Reaction with Ethyl Iodide

The crude reaction product was dissolved in 50 ml of diethyl ether and precipitated as the hydrochloride with hydrogen chloride. The dry salt (2.535 g, 81% yield) was neutralized with aqueous sodium hydroxide, extracted with ether, concentrated, and distilled, b.p. 165–172° at 2 mm, 1.745 g (61% yield). This material crystallized and was purified for analysis by recrystallization from methanol (6 ml/g). Nuclear magnetic resonance: CH_3 triplet at 0.74 (3.0 H), CH_2 quartet at 2.53 (1.9 H), NH singlet at 4.24 (1.0 H), aromatic H's complex band at 6.2–7.6 (14.7 H).

Reaction with Propyl Halides

The crude reaction product was purified by recrystallization from methanol (6 ml/g). Nuclear magnetic resonance: CH_3CH_2 broad band at 0.7–1.5 (4.9 H) with the methyl appearing as a distorted triplet at 0.8, CH_2 triplet at 2.51 (2.0 H), NH singlet at 4.4 (1.0 H), aromatic H's complex band at 6.2–7.8 (15.0 H).

[2]*Reference 3 reports 25–33% N-benzhydrylaniline formed under similar reaction conditions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Identical experiments were carried out with propyl chloride, propyl bromide, and propyl iodide. The yield was obtained by dissolving the crude product in 10 ml of hot methanol, cooling, seeding, and allowing to crystallize for 2 days (see Table I).

The crude reaction product was also examined by thin-layer chromatography with cyclohexane containing 17% acetic acid as developing solvent. Besides the spot caused by the product (R_f 0.59), two additional spots appeared: R_f 0.63 and 0.72. These were readily seen in the product derived from propyl iodide, but not in that derived from propyl chloride. The product from propyl bromide showed an intermediate amount.

Reaction with Isopropyl Chloride

The crude product was purified by recrystallization from methanol (10 ml/g). Nuclear magnetic resonance: CH_3 doublet at 0.82 (6.0 H), CH multiplet at 2.8 (1.0 H), NH singlet at 4.3 (0.8 H), aromatic H's complex band at 6.2–7.7 (14.4 H).

Reaction with t-Butyl Chloride

The crude reaction product was chromatographed on 70 g of Woelm grade I acidic alumina using, as eluting solvents, 350 ml of hexane and then four 150 ml portions of hexane containing methylene chloride in concentrations of 5%, 10%, 25%, and 50% (v/v), respectively. Fifty milliliters of eluent was collected per fraction, and the fractions were examined by thin-layer chromatography with cyclohexane containing 17% acetic acid as developing solvent. The first two fractions contained 0.111 g of unidentified material, the next three fractions contained 0.683 g (22%) of the product *N*,1,1-triphenyl-2,2-dimethylpropylamine (R_f 0.68), and the remaining fractions (total weight 1.58 g) were mixtures of benzophenone anil (R_f 0.42), *N*-benzhydrylaniline (R_f 0.57), and product.

The product was purified by recrystallization from methanol (40 ml/g). Nuclear magnetic resonance: CH_3 singlet at 1.0 (9.0 H), NH singlet at 4.8 (0.9 H), aromatic H's complex band at 5.9–7.9 (15.2 H).

Reaction with Allyl Chloride

The crude product, *N*,1,1-triphenyl-1-aminobutene-3, was purified by recrystallization from methanol (6 ml/g). Nuclear magnetic resonance: CH_2 doublet at 3.2 (2.0 H), $-CH=CH_2$ multiplet at 4.7–5.5 (3.2 H), NH singlet at 4.4 (0.8 H), aromatic H's complex band at 6.1–7.7 (15.3 H).

Reaction with Benzyl Chloride

The crude product, *N*,1,1,2-tetraphenylethylamine, was purified by recrystallization from *n*-butanol (5 ml/g). Nuclear magnetic resonance: CH_2 singlet at 3.75 (2.1 H), NH singlet at 4.48 (0.91 H), aromatic H's complex band at 6.1–7.6 (20.0 H).

Reaction with Vinyl Chloride

No color change of the sodium adduct was noted over an 18 h period. The crude product was a viscous oil whose infrared spectrum was identical with that of *N*-benzhydrylaniline.

Reaction with Cyclopentyl Chloride

The crude reaction product was examined by thin-layer chromatography with cyclohexane containing 17% acetic acid as developing solvent. Two products were detected: R_f 0.57–0.59 and 0.67–0.68.

The crude product (5.24 g) from 0.02 mole of adduct was boiled with 30 ml of 20% hydrochloric acid for 2 h. The final mixture was treated with 30 ml of ether and filtered. The insoluble solid, which amounted to 3.21 g (44% yield), was the hydrochloride of *N*-cyclopentyl-*N*-benzhydrylaniline, m.p. 180–184°. Purification was effected by dissolving in 15 ml of warm methanol and adding 70 ml of ether to precipitate the salt. Two such treatments raised the melting point to 190–193°. Nuclear magnetic resonance: cyclopentyl protons broad band at 1.65 (8.9 H), benzyl proton at 5.8 (0.87 H), aromatic H's complex band at 6.4–7.5 (15.0 H).

Anal. Calcd. for $C_{24}H_{26}NCl$: C, 79.2; H, 7.22; N, 3.85. Found: C, 78.7; H, 6.95; N, 3.78.

The ether layer in the filtrate from the amine hydrochloride was separated, washed, and evaporated, and the residue was distilled, b.p. 155–170° at 3 mm, to give 1.421 g of a partially crystalline liquid. A 0.50 g sample of this was recrystallized from 2 ml of methanol to give 0.20 g of cyclopentylidene diphenylmethane, m.p. 61–63°; the mixed melting point with an authentic sample was undepressed. The crude distillate was analyzed by vapor-phase chromatography, using a 7 ft long $\frac{1}{4}$ inch outside diameter column packed with 30% Apiezon on Chromosorb W heated at 248°, and using helium as carrier gas. The material was found to consist of 70% of cyclopentylidene diphenylmethane (representing a 21% yield) and 28% of an unknown material (relative retention time 1.53).

The authentic sample of cyclopentylidene diphenylmethane, m.p. 61–63°, was prepared from methyl cyclopentanecarboxylate and excess phenylmagnesium bromide followed by dehydration of the alcohol (without isolation) in refluxing acetic anhydride (15, 16). Nuclear magnetic resonance: CH_2 multiplet at 1.6 (4.0 H), CH_2 multiplet at 2.4 (4.0 H), aromatic H's singlet at 7.2 (9.8 H).

Decomposition of N,1,1-Triphenylethylamine

N,1,1-Triphenylethylamine (2.06 g, 0.076 mole) was refluxed with 10 ml of 20% hydrochloric acid for 1 h. The acid solution was extracted with 10 ml of benzene, washed twice with 5 ml of water, and dried over sodium sulfate. The dried solution was filtered and evaporated to give 1.075 g of a liquid residue. This was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

distilled under vacuum, b.p. 76–82° at 2 mm, to yield 0.965 g (71%) of 1,1-diphenylethylene, whose infrared spectrum was identical with that of an authentic sample.

The aqueous acid phase and washings were combined, made alkaline, and extracted with ether. After the ether layer was washed, dried over sodium sulfate, and evaporated, a residue of 0.441 g of aniline (62%) was obtained. Its identity was established by preparing the benzenesulfonamide, m.p. 109–110°, undepressed on admixture with an authentic sample.

Reaction with 2 Equivalents of Methyl Iodide

The disodium adduct was treated with 0.02 mole of methyl iodide at −60°. Within 2 h the solution had decolorized, and thin-layer chromatography with 7:2:2 benzene – tetrahydrofuran – 98% formic acid as solvent showed the presence of four products: R_f 0.13, 0.26, 0.45, and 0.85. The first (R_f 0.13) and last (R_f 0.85), *N*-methylaniline and 1,1-diphenylethylene, respectively, were by far the largest; the other two were relatively small. One of these (R_f 0.39) is *N*-methyl-*N*-benzhydrylaniline (see below), and the other (R_f 0.26) is unknown.

The product was isolated by an ether extraction; after evaporation of the solvent, the residue (2.43 g) was distilled. Two fractions were collected: 0.746 g, b.p. 50–140° at 2 mm, and 1.225 g, b.p. 175–180° at 2 mm; 0.121 g was left as a residue. Thin-layer chromatography showed the first fraction to contain only *N*-methylaniline and 1,1-diphenylethylene, whereas the second contained these as the major components as well as the by-products, R_f 0.26 and 0.39.

The n.m.r. spectrum of this second fraction (CH_3 singlet at 1.79 (2.7 H), CH_3 singlet at 2.71 (3.0 H), aromatic H's complex band at 6.6–7.6 (16.8 H)) strongly indicated that the material was primarily *N*-methyl-*N*,1,1-triphenylethylamine. A small peak in the n.m.r. spectrum at 5.4 (equivalent to 0.2 H) was caused by an impurity, 1,1-diphenylethylene; this, in turn, affected the integration of the aromatic protons, giving too high a value. The addition of formic acid to the solution of the amine in the n.m.r. sample tube caused a marked change in the spectrum over a 24 h period. The peaks caused by the methyl groups decreased in intensity, the peak caused by the 1,1-diphenylethylene impurity grew larger, and a new peak appeared at 3.2 caused by *N*-methylaniline (in formic acid – deuterated chloroform).

N-Methyl-*N*,1,1-triphenylethylamine (0.547 g, 0.0019 mole) was dissolved in 25 ml of ether and treated with hydrogen chloride. A gum separated which crystallized when allowed to stand for 16 h. This was filtered off and weighed (0.275 g). The ether layer was evaporated to give 0.321 g (94% yield) of 1,1-diphenylethylene, whose identity was established by its infrared spectrum. The solid which was filtered off was treated with 5 ml of water containing 1 drop of concentrated hydrochloric acid and 5 ml of ether. The ether layer was separated, washed once with water, evaporated, and dried at 40° under vacuum.

The residue from the evaporation was dissolved in 5 ml of ether and treated with hydrogen chloride. A gummy solid (0.037 g) separated out and was dissolved in 1 ml of methanol; the solution was treated with 10 ml of ether, and a solid (0.020 g, m.p. 150–152.5°) precipitated out. The mixed melting point of the solid with *N*-methyl-*N*-benzhydrylaniline hydrochloride was 153–155° and its infrared spectrum was identical with that of an authentic sample.

The aqueous acid layer was made basic, extracted with ether, and evaporated to give 0.156 g (88% yield) of *N*-methylaniline, identified by comparison of its infrared spectrum with that of an authentic sample.

Reaction with 1,4-Dibromobutane

The adduct from 0.02 mole of benzophenone anil was treated with 2.38 ml (0.02 mole) of 1,4-dibromobutane at −60°. The crude orange product, isolated as previously described, amounted to 6.25 g. This was dissolved in 40 ml of *n*-hexane, and chromatographed on 60 g of Woelm grade I basic alumina packed in a 16 × 430 mm column, with 100 ml of *n*-hexane and then 100 ml of hexane – 10% benzene as eluting solvent. The color remained on the column and was not further investigated, and 5.22 g of a semisolid was recovered. This was dissolved in 60 ml of hot methanol and cooled to approximately 30 °C, and the warm solution was decanted from the gums which separated. Cooling the decantate to 10° overnight gave 2.77 g (44% yield), m.p. 74.5–77°, of 1,2,2-triphenylpiperidine.

The gum (1.35 g) crystallized when allowed to stand, and melted at 74–76.5°; the mixed melting point with the above product was 74–76.5°. The combined yield was 65%. Nuclear magnetic resonance: CH_2 broad band at 1.6 (3.95 H), CH_2 complex triplet at 2.5 (1.9 H), CH_2 complex triplet at 3.75 (1.9 H), aromatic H's complex band at 6.5–7.6 (15.0 H). The spectrum was unchanged after the solution was shaken with D_2O, indicating the absence of an amine proton.

Anal. Calcd. for $C_{23}H_{23}N$: C, 88.1; H, 7.41; N, 4.47. Found: C, 88.1; H, 7.16; N, 4.52.

At one point, an attempt was made to purify the crude product by vacuum distillation. The main fraction, b.p. 210–220° at 1 mm, was a yellow mobile liquid (the original crude material was a gum) and had an R_f (1:1 cyclohexane–chloroform) of 0.45, whereas the original material had an R_f of 0.70. Evidently some change had occurred, perhaps caused by trace amounts of acid remaining in the crude product.

This material (1.501 g) was dissolved in 25 ml of diethyl ether and treated with hydrogen chloride. The solid which precipitated (1.326 g, m.p. 175–180°) was dissolved in 10 ml of methanol; 35 ml of diethyl ether was added to give 1.115 g, m.p. 180–183°. An analytical sample was recrystallized from methanol, m.p. 182–184°. Nuclear magnetic resonance of the free amine: CH_2 quartet at 1.65, CH_2 quintet at 2.06 (combined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

areas 4.0 H), CH_2 triplet at 2.96 (1.95 H), NH singlet at 3.34 (1.0 H), CH triplet at 6.00 (0.85 H), aromatic H's complex band at 6.4–7.4 (15.5 H).

Anal. Calcd. for $C_{23}H_{24}ClN$: C, 78.9; H, 6.92; N, 4.00. Found: C, 78.8; H, 6.71; N, 3.96.

The structure appears to be *N*,1,1-triphenyl-5-aminopentene-1.

Reaction with 1,3-Dibromopropane

The reaction of the sodium adduct and 1,3-dibromopropane was quite rapid at −60 °C. The crude product (3.265 g) was crystalline and was readily purified by recrystallization from methanol (20 ml) to give 2.24 g (75% yield) of 1,2,2-triphenylpyrrolidine, m.p. 112–114°. The analytical sample, after two additional crystallizations, had m.p. 115–116.5°. Nuclear magnetic resonance: CH_2 quintet at 1.74 (1.8 H), CH_2 triplet at 2.60 (1.85 H), CH_2 triplet at 3.70 (1.85 H), aromatic H's complex band at 6.0–7.6 (15.0 H).

Anal. Calcd. for $C_{22}H_{21}N$: C, 88.2; H, 7.08; N, 4.68. Found: C, 88.6; H, 7.06; N, 4.66.

Reaction with 1,5-Dibromopentane

The crude reaction product (3.35 g) was dissolved in 15 ml of hot *n*-propanol and allowed to stand for 24 h at room temperature. The product, *N,N'*,1,1,7,7-hexaphenylheptanediamine-1,7, separated slowly, 1.513 g (51% yield), m.p. 141–145°. Two recrystallizations from *n*-propanol gave an analytical sample, m.p. 154–156°. Nuclear magnetic resonance: CH_2 broad band at 1.1 (6.0 H), CH_2 broad band at 2.4 (3.8 H), NH very broad band at 4.2 (1.7 H), aromatic H's complex band at 6.2–7.7 (30.0 H).

Anal. Calcd. for $C_{43}H_{42}N_2$: C, 88.0; H, 7.23; N, 4.78; mol. wt. 589. Found: C, 88.3; H, 6.95; N, 4.87; mol. wt. 590.

The filtrate from the crude product was concentrated under vacuum, and the residue (1.53 g) was dissolved in 20 ml of hexane and placed on a 16 × 430 mm column of Woelm grade I basic alumina. Elution was carried out with 150 ml of hexane, 100 ml of hexane – 10% benzene, 100 ml of hexane – 25% benzene, 100 ml of hexane – 50% benzene, and finally 100 ml of benzene – 50% methylene chloride. The eluate was collected in 50 ml fractions. Fractions 1, 2, and 3 contained no material, and the remaining fractions contained 1.24 g. Examination of these by thin-layer chromatography with benzene – tetrahydrofuran – 98% formic acid (70:15:15) as developing solvent showed that fractions 4–7 (1.01 g) contained an unknown material and that fraction 9 (0.131 g) was the hexaphenylheptanediamine. The unknown material was combined and recrystallized from 25 ml of methanol, with cooling to 10°, to give 0.637 g of a solid, m.p. 55–58°. This was recrystallized again for an analytical sample, m.p. 58–59°.

Anal. Calcd. for $C_{24}H_{25}N$: C, 88.0; H, 7.71; N, 4.28. Found: C, 87.8; H, 7.72; N, 4.41.

On the basis of its n.m.r. spectrum, the structure was considered to be *N*,1,1-triphenyl-1-aminohexene-5. The spectra showed a broad CH_2 band at 1.3 (2.0 H), a CH_2 quartet at 1.9 (2.2 H), a complex triplet at 2.5 (2.0 H), an NH band at 4.35 (0.85 H), two major peaks with complex fine structure at 4.7 and 4.9 caused by the vinyl group, a complex multiplet at 5.5 (total area 2.8 H), and a complex series of peaks at 6.1–7.4 (15.5 H) caused by the aromatic protons.

Reaction with 1,10-Dibromodecane

The crude reaction product from 0.01 mole of the sodium adduct in tetrahydrofuran and 1.5 g (0.005 mole) of 1,10-dibromodecane (3.751 g) was recrystallized from 25 ml of methanol and 13 ml of benzene. The recrystallized product amounted to 3.114 g (94% yield), m.p. 152–155°, of *N,N'*,1,1,12,12-hexaphenyldodecanediamine-1,12 having an orange color. Attempts to remove this color by recrystallization from *n*-butanol in the presence of Norit failed. Purification was finally effected by placing a solution of 1.65 g of the product in 30 ml of 1:1 hexane–benzene on a 16 × 450 mm column of 60 g of Woelm grade I basic alumina. Elution with 300 ml of the solvent removed 1.47 g of an almost colorless material, m.p. 147–152°; the color remained on the column. Two recrystallizations from *n*-butanol (20 ml/g) raised the melting point to 155–156.5°. Nuclear magnetic resonance: CH_2 broad band at 1.07 (8.0 H), CH_2 broad band at 2.48 (1.9 H), NH broad band at 4.26 (0.8 H), aromatic H's complex band at 6.2–7.7 (15.0 H).

Anal. Calcd. for $C_{48}H_{52}N_2$: C, 87.7; H, 7.99; N, 4.26; mol. wt. 657. Found: C, 88.0; H, 8.09; N, 4.15; mol. wt. 660.

Reaction with Benzaldehyde

The crude reaction product (3.41 g) was recrystallized from 20 ml of ethanol to give 0.987 g of benzophenone anil, m.p. 107–110°. A recrystallized sample of this, m.p. 110–113°, showed no depression on admixture with an authentic sample.

The filtrate from the recovered benzophenone anil was evaporated and the residue chromatographed on 70 g of Woelm grade I basic alumina packed into a 16 × 430 mm column. Elution with 250 ml of 1:1 benzene–hexane removed 1.36 g of a solid which, on recrystallization from 10 ml of hexane, gave 0.967 g, m.p. 77–80°. Investigation of this material by thin-layer chromatography with benzene as developer showed that it consisted of benzophenone anil (R_f 0.60) and *N*-benzhydrylaniline (R_f 0.73); n.m.r. analysis established that it was a mixture of 1 part of the former and 2 parts of the latter.

It was necessary to use methylene chloride plus 5% methanol and finally acetone plus 5% methanol to remove anything more from the alumina column. These eluents gave 0.701 g of a solid which, on recrystallization from 10 ml of benzene, gave 0.395 g of *dd,ll*-hydrobenzoin, m.p. 113–120°, undepressed on admixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with an authentic sample. Comparison of the infrared spectrum of the isolated material with that of an authentic sample confirmed its identity.

The solvent in the benzene filtrate from the recrystallization was evaporated and the residue was recrystallized from water to give 0.176 g of a solid, m.p. 80–85°. An examination of the infrared spectrum of this material showed it to be a mixture of *dd,ll*-hydrobenzoin and *meso*-hydrobenzoin.

The authentic sample of *meso*-hydrobenzoin was prepared by sodium borohydride reduction of benzoin in 80% dioxane. It was recrystallized from water and had m.p. 134–136.5°.

dd,ll-Hydrobenzoin was prepared by acetolysis of α-stilbene dibromide by the procedure of Breuer and Zincke (17). Two recrystallizations from 80% water – 20% ethanol gave material having m.p. 117–120°.

The total yields of isolated compounds were 50% benzophenone anil and 25% *N*-benzhydrylaniline (based on the original benzophenone anil), and 65% of the diastereomeric hydrobenzoins (based on the benzaldehyde used).

Reaction with Ethylene Oxide

The crude reaction product from 0.01 mole of adduct and 0.01 mole of ethylene oxide amounted to 3.12 g. This was crystallized from 15 ml of petroleum ether (b.p. 30–60°) to give 2.17 g (72% yield) of an orange solid, m.p. 118–122°. Recrystallization from 25 ml of hexane and 10 ml of benzene with 2 g Norit and a hot filtration sufficed to remove the color and give an analytical sample, m.p. 122–125°. Nuclear magnetic resonance: CH_2 triplet at 2.67 (1.85 H), CH_2 triplet at 3.51 (2.0 H) superimposed on a broad NHOH band at 3.3–3.7, aromatic H's complex band at 6.2–7.6 (14.5 H). The peak areas were determined after the NHOH band was eliminated with D_2O. The difference between the peak areas of the 3.5 triplet plus the NHOH band before and after D_2O treatment established that the broad NHOH band corresponded to 1.9 H.

Anal. Calcd. for $C_{21}H_{21}NO$: C, 83.1; H, 6.99; N, 4.62. Found: C, 83.6; H, 6.96; N, 4.57.

Reaction with Methyl Benzoate

The crude reaction product from 0.01 mole of sodium adduct and 0.01 mole of methyl benzoate was recrystallized from 10 ml of methanol to give 2.50 g (69% yield) of *N*-benzhydrylbenzanilide, m.p. 108–110°; the mixed melting point with an authentic sample was undepressed, and the infrared spectra of the material and of an authentic sample were identical.

The authentic sample was prepared by refluxing *N*-benzhydrylaniline and an equivalent amount of benzoyl chloride in pyridine for 16 h. The crude product was crystallized from hexane, and recrystallized once from hexane and once from methanol, m.p. 108–109°. Nuclear magnetic resonance: aromatic H's only in a complex band at 6.5–7.5 (the benzylic proton is shifted into the aromatic region).

Anal. Calcd. for $C_{26}H_{21}NO$: C, 85.9; H, 5.83; N, 3.85. Found: C, 85.7; H, 5.70; N, 3.80.

Reaction with Methyl p-Toluate

The crude product was purified by one crystallization from methanol and two recrystallizations from hexane to give 1.562 g of *N*-phenyl-*N*-benzhydryl-*p*-toluamide, m.p. 112.5–114° (41% yield). Nuclear magnetic resonance: CH_3 singlet at 2.15 (3.0 H), aromatic H's complex band at 6.5–7.5 (20.0 H), indicating that the 19 aromatic protons and the 1 benzyl proton are in the same region.

Anal. Calcd. for $C_{27}H_{23}NO$: C, 85.9; H, 6.15; N, 3.71. Found: C, 85.6; H, 5.98; N, 3.58.

Reaction with Diethyl Carbonate

Diethyl carbonate (0.01 mole) produced 3.15 g of a crude product which was chromatographed on 60 g of Woelm basic alumina grade I. Fifty milliliter fractions were collected and the solvents used were 100 ml of hexane, 100 ml of hexane – 10% benzene, 50 ml of hexane – 25% benzene, and 100 ml of hexane – 50% benzene.

This treatment removed 1.82 g of material from the column. Additional eluting solvent containing methylene chloride removed the remaining material, but no products could be isolated from it.

The 1.82 g was covered with petroleum ether (b.p. 30–60°). After the mixture had stood overnight at 10°, the solution was decanted from the ethyl *N*-benzhydrylphenylcarbamate, which amounted to 1.53 g (46% yield), m.p. 54–58°. Two recrystallizations from 20 ml of petroleum ether (b.p. 30–60°), with cooling to 10°, gave 1.03 g of the carbamate, m.p. 60–62°. Nuclear magnetic resonance: CH_3 triplet at 1.1 (3.3 H), CH_2 quartet at 4.1 (2.0 H), CH singlet at 6.7 (1.0 H), aromatic H's complex band at 6.8–7.4 (15.0 H).

Anal. Calcd. for $C_{22}H_{21}NO_2$: C, 79.7; H, 6.35; N, 4.23. Found: C, 80.0; H, 6.01; N, 4.24.

Reaction with Diethyl Sulfate

The crude product obtained when the sodium adduct was treated with 0.01 mole of freshly distilled diethyl sulfate amounted to 2.98 g. One recrystallization from 10 ml of petroleum ether (b.p. 30–60°) gave 1.78 g (62% yield) of *N*,1,1-triphenylpropylamine, m.p. 67–70.5°.

Stepwise Reaction with Methyl Benzoate and Methyl Iodide

The sodium adduct (0.01 mole) was allowed to react with 0.01 mole of methyl benzoate for 1 h at −60° and for 4 h at room temperature. The solution was then cooled again to −60° and 0.01 mole of methyl iodide added; after the solution had warmed to room temperature, it was allowed to stand overnight.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The crude product, isolated by ether extraction, amounted to 3.47 g and was crystallized from 30 ml of *n*-hexane to give 2.39 g (63% yield) of the benzamide of *N*,1,1-triphenylethylamine, m.p. 142–144°. One recrystallization from *n*-butanol and one from isopropanol raised the melting point to 146.5–149°. Nuclear magnetic resonance: CH_3 singlet at 2.0 (2.9 H), aromatic H's complex band at 6.7–7.6 (20.0 H), very similar in structure to that of *N*-benzhydrylbenzanilide.

Anal. Calcd. for $C_{27}H_{23}NO$: C, 85.9; H, 6.15; N, 3.71. Found: C, 85.9; H, 6.13; N, 3.70.

Preparation of N-Methyl-N-benzhydrylaniline[3]

A solution of 15.0 g (0.074 mole) of benzhydryl chloride and 17.4 g (0.162 mole) of *N*-methylaniline in 50 ml of benzene was stirred at room temperature for 16 h, during which time a precipitate formed. The solution was examined by thin-layer chromatography with 7:2:2 benzene – tetrahydrofuran – 98% formic acid as solvent to follow the progress of the reaction: *N*-methylaniline, R_f 0.12; product, R_f 0.59; by-products of unknown constitution, R_f 0.30, 0.42, and 0.74.

The solution was washed with 10% potassium hydroxide, the benzene stripped off, and the residue distilled, collecting the main fraction, b.p. 185–205° at 4 mm, 8.50 g. This was dissolved in 100 ml of diethyl ether, and hydrogen chloride was passed briefly through the solution. The resulting precipitate amounted to 2.4 g, m.p. 152–203° (decomp.).

The filtrate from this first salt was again treated with hydrogen chloride to give 4.63 g of a second crop, m.p. 159–160°. This was dissolved in 15 ml of chloroform, the solution was filtered to remove a small amount of insoluble material, and 25 ml of ether was added. The product amounted to 4.40 g, m.p. 160–161°. Nuclear magnetic resonance: CH_3 singlet at 3.33 (2.90 H), CH singlet at 6.44 (1.02 H), aromatic H's in two broad bands at 6.9–8.7 (15.0 H); for the free amine: CH_3 singlet at 2.73 (2.95 H), CH singlet at 6.15 (0.92 H), aromatic H's complex band at 6.5–7.5 (15.0 H).

Anal. Calcd. for $C_{20}H_{20}NCl$: C, 77.5; H, 6.52; N, 4.52. Found: C, 77.1; H, 6.59; N, 4.35.

Stepwise Reaction with t-Butyl Alcohol and Methyl Iodide

The disodium adduct was treated at −60° with 0.94 ml (0.01 mole) of *t*-butyl alcohol. After the dark-green solution was allowed to warm to room temperature for 2 h, the solution was recooled and 0.62 ml (0.01 mole) of methyl iodide added. When warmed to room temperature, the solution changed from a dark-green color through a royal blue to a clear pale yellow. After 16 h, the solution was treated with water, and the reaction product isolated by ether extraction.

The gummy residue remaining after evaporation of the ether was dissolved in 50 ml of diethyl ether, and hydrogen chloride was bubbled through to precipitate the hydrochloride of *N*-methyl-*N*-benzhydrylaniline, 2.80 g, m.p. 146–149°. This salt was dissolved in 10 ml of methanol and the solution treated with 25 ml of ether. The solid which precipitated amounted to 2.0 g (65% yield), m.p. 160–161°, undepressed on admixture with an authentic sample. Its infrared spectrum was identical with that of the authentic sample.

Stepwise Reaction with t-Butyl Alcohol and Cyclopentyl Chloride

The above experiment was repeated with 0.01 mole of cyclopentyl chloride instead of the methyl iodide. The crude reaction product gave 2.77 g (92% yield) of the hydrochloride of *N*-benzhydrylaniline, m.p. 196–198°. Dissolution in 40 ml of methanol followed by crystallization from 60 ml of ether gave 2.17 g (72% yield) of the salt, m.p. 198–200°, undepressed on admixture with an authentic sample. Its infrared spectrum was identical with that of the authentic sample.

ACKNOWLEDGMENTS

The authors are indebted to Mr. H. Mak (Dow Chemical of Canada, Limited) for his assistance in recording and interpreting the n.m.r. spectra, and to Mr. L. E. Swim (The Dow Chemical Company, Midland, Michigan) for the microanalyses.

TREIBS' 119° GLYCOL; TRANSANNULAR ATTACK AT THE TERTIARY CARBON OF A SECONDARY–TERTIARY EPOXIDE[1]

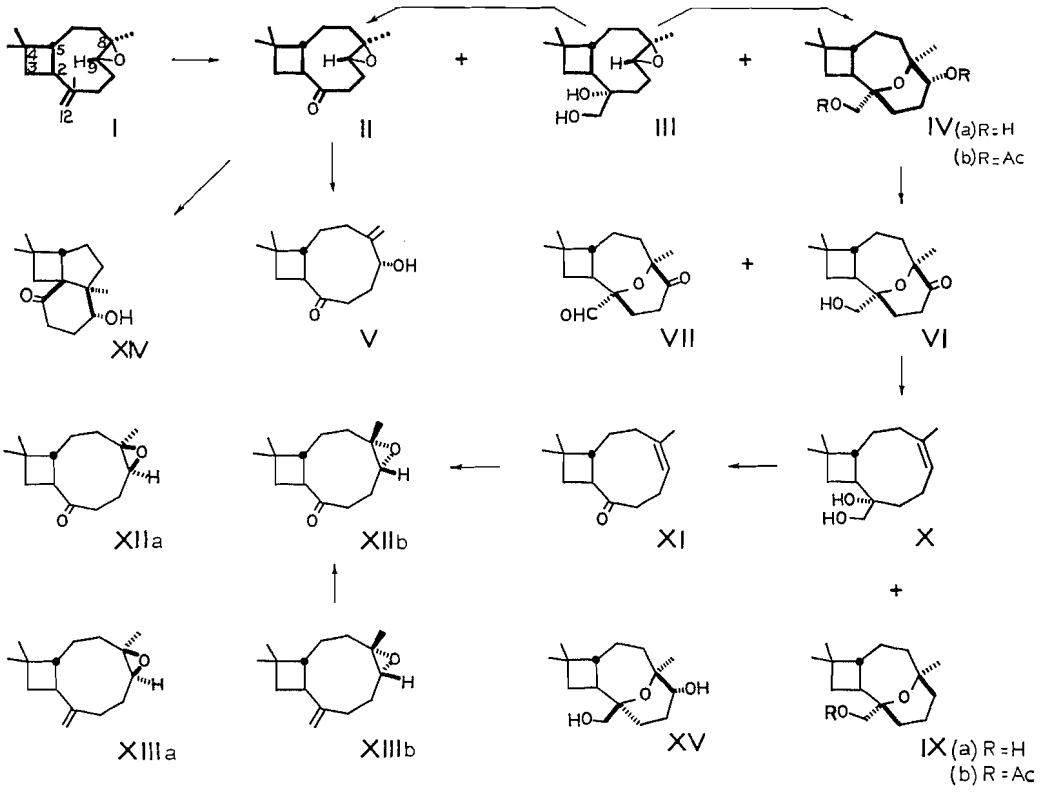
E. W. WARNHOFF AND V. SRINIVASAN
Department of Chemistry, University of Western Ontario, London, Ontario
Received May 10, 1966

ABSTRACT

The glycol, $C_{15}H_{26}O_3$, of m.p. 119° formed in the oxidation of caryophyllene oxide (I) has been found to have the structure and stereochemistry IV*a* formed by intramolecular transannular displacement at the tertiary carbon of the secondary–tertiary oxide in III. A rationalization of this mode of attack is offered. The glycol IV*a* has been transformed into the known keto epoxide XII*b* obtained from isocaryophyllene.

From the oxidation of caryophyllene oxide (I) with permanganate in acetone, Treibs (1) isolated three compounds: the keto oxide II (69%); a glycol, $C_{15}H_{26}O_3$, m.p. 141°, $[\alpha]_D$ −72° (7%); and a second glycol, $C_{15}H_{26}O_3$, m.p. 119°, $[\alpha]_D$ −1° (1.7%). Šorm *et al.* later repeated the reaction and isolated the same three substances (2).[2] These authors found that the glycol of m.p. 141–142° was cleaved by lead tetraacetate to the keto oxide II, but that the glycol of m.p. 119° was recovered unchanged from this reagent in benzene solution at 40°. From these observations it was concluded that the two glycols were "*cis* and *trans* isomerides" of the expected 1,2-diol. However, there seem to be no known examples of 1,2-diols not oxidized by lead tetraacetate (4), and therefore the 119° glycol was reexamined.

In our hands, the permanganate oxidation of I gave the same result reported earlier, but the poor yield of 119° glycol made it desirable to explore other methods of preparation. Hydroxylation of caryophyllene oxide with osmium tetroxide gave a crude product from which the 119° glycol could be crystallized in the much improved yield of 41%. The presence of the 142° glycol in the mother liquors from the crystallization could not be detected by nuclear magnetic resonance (n.m.r.) spectroscopy or optical rotation. Although this reaction was a suitable preparation of the 119° glycol, the cost of osmium tetroxide encouraged investigation of its use as a catalyst rather than a stoichiometric reactant. Oxidation of I with the hydrogen peroxide – osmium tetroxide – *t*-butyl alcohol reagent of Milas and Sussman (5) gave 25% of a diol fraction containing mainly the 119° glycol, and, surprisingly, 59% of the keto oxide II. This example of carbon–carbon bond cleavage by an oxide of osmium[3] provides, in our experience, a more convenient synthesis of the keto oxide than the permanganate oxidation of I. The glycol yield based on osmium tetroxide was much better in the catalytic than in the stoichiometric reaction, and therefore the catalytic method was adopted for larger scale reactions. It was fortunate that the 119° compound, the major constituent of the glycol fraction, could be separated by crystallization, because its chromatographic behavior was identical with that of hydroxylic



[1]*Presented in part at the 49th annual conference of the Chemical Institute of Canada, Saskatoon, Saskatchewan, June 1966.*

[2]*A fourth compound isolated, V, $C_{14}H_{22}O_2$, m.p. 110°, has since been shown (3, p. 1669) to arise by isomerization of the keto oxide II on alumina, as suspected by the Czech workers.*

[3]*Although Milas and Sussman (5) found that the hydrogen peroxide – osmium tetroxide – t-butyl alcohol reagent at low temperature gave only 1,2-diols, Criegee (6) has reported carbon–carbon bond rupture to be the normal reaction of the hydrogen peroxide – osmium tetroxide – ether reagent. As he suggested, the carbon–carbon bond scission is probably a consequence of reoxidation of the osmium(VI) in the initially formed cyclic ester to osmium(VIII) before solvolysis of the ester takes place.*

contaminants. The 142° glycol, although it also exhibits the same chromatographic behavior as the 119° glycol, could not be detected in the n.m.r. spectrum of the residue from the crystallization mother liquors.

The infrared spectrum of the 119° compound showed the presence of hydroxyl absorption and the absence of carbonyl absorption. The n.m.r. spectrum contained peaks from three unsplit methyl groups: a singlet at 1.02 p.p.m. from the *gem*-dimethyl group and a

singlet at 1.20 p.p.m. from a methyl group on a carbon atom bearing oxygen; there were no vinyl protons. The appearance of the spectrum in the 2.4–4 p.p.m. region (five protons) was concentration dependent, and in the more dilute solutions coupling of the hydroxyl protons could be observed (Fig. 1). Addition of deuterium oxide removed the peaks from two hydroxyl protons, and thereby simplified the pattern from the remaining three protons. These spectral changes could be interpreted as manifestations of a primary and a secondary alcohol function. The doublet (two protons, J = 6.5 c.p.s.) at 3.20 p.p.m., which collapses to a singlet on deuteration, would be the methylene group of the primary alcohol; the triplet from the hydroxyl proton coupled to the adjacent methylene group can be seen at 2.67 p.p.m. (J = 6.5 c.p.s.). The doublet of the secondary hydroxyl group coupled to the adjacent methine hydrogen appears at 2.47 p.p.m. (one proton, J = 8 c.p.s.), where it overlaps one peak of the hydroxyl triplet; the methine hydrogen is a broad lump at 3.55 p.p.m. Since there are no other protons at low field, the third (ethereal) oxygen atom must be bonded to two tertiary carbon atoms. Acetylation of the 119° glycol produced the expected shifts of the α-protons (7). In the liquid diacetate the methylene group of the primary alcohol was shifted downfield by 0.65 p.p.m. to 3.85 p.p.m., and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the methine proton of the secondary alcohol was moved downfield by 1.41 p.p.m. to 4.96 p.p.m. At this point, the logical formulation for the 119° glycol was the oxygen-bridged non-vicinal diol IV*a*, which would arise by intramolecular transannular attack of the tertiary hydroxyl group on the epoxide ring in the 1,2-diol precursor III. Structure IV*a* was confirmed by relating the 119° glycol to a known isocaryophyllene derivative in the following manner.

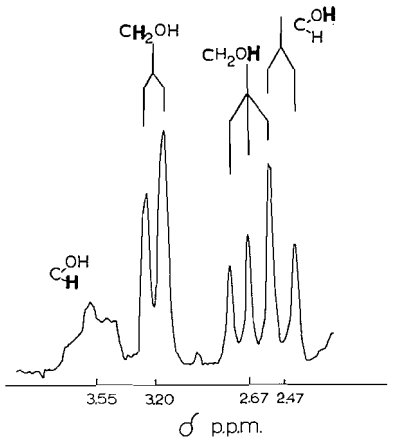


FIG. 1. The n.m.r. spectrum of Treibs' 119° glycol in the 2.4–4 p.p.m. region in deuteriochloroform solution.

Oxidation of the 119° glycol by the chromic acid – pyridine reagent produced a hydroxy ketone VI accompanied by a small amount of a keto aldehyde VII. Various attempts at reductive cleavage of the α-alkoxy group of ketone VI, including the use of zinc (or magnesium) – acetic acid or anhydride (8, 9), calcium – liquid ammonia (10), and potassium–*sec*-butylamine (11), gave starting material or acylated starting material, or else merely reduced the carbonyl group. Therefore, advantage was taken of the elimination that usually occurs in the Wolff–Kishner reduction of α-substituted ketones, including α-alkoxy ketones (9, 12), a particularly close analogy being the ketone VIII (13). Application of this reaction to the hydroxy ketone VI gave both the normal reduction product IX*a* (48%) and the reductive elimination product X (36%). The crystalline elimination product was a *vic*-diol, since it was oxidized by sodium metaperiodate to a liquid ketone XI. Proof of the structure of XI, as well as proof that the double bond had the *cis* configuration, was obtained by epoxidation of the double bond with monoperphthalic acid. From the reaction product was crystallized a keto epoxide XII*b*, m.p. 75–76°, $[\alpha]_D$ −13.8°, which was identical with a sample prepared from *cis*-caryophyllene via epoxidation to isocaryophyllene oxide-*b* (XIII*b*) and subsequent permanganate oxidation. The infrared and n.m.r. spectra (Table I) of the intermediates in the conversion of the 119° glycol into the *cis*-keto oxide XII*b* are all consistent with the structures proposed.

Provided that the oxirane ring is opened with inversion, the stereochemistry of the 119° glycol will be controlled by the hydroxyl configuration at C-1 in the 1,2-diol precursor. Of the two possibilities, Dreiding models show that stereoisomer IV*a* with the α-oriented oxygen bridge is free of angle strain,[4] whereas stereoisomer XV with the "β-oxygen bridge" has considerable angle strain[4] (four-carbon chain bridging the *trans*-2,6-positions

[4]*The discussion is restricted to angle strain over and above that present in the four-membered ring of all of these compounds.*

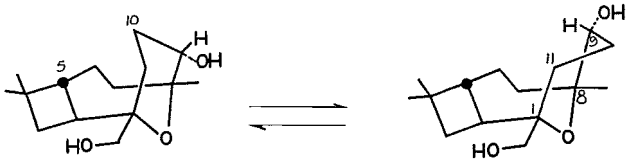
TABLE I

Nuclear magnetic resonance absorption of caryophyllene derivatives*



Compound	C-4 *gem*-dimethyl	C-8 methyl	C-9 H	C-12 H_2	Other peaks
Caryophyllene keto oxide II	1.03 s	1.29 s	?	—	—
142° glycol III	0.97 s	1.33 s	?	3.69 b s (2H)	2.38 b m (OH)
119° glycol IV*a*	1.02 s	1.20 s	3.55 m	3.20 s or d (2H)	2.89 b m (2H, OH)
119° glycol diacetate IV*b*	1.03 s	1.09 s	4.96 dd ($J \sim 3, 8$)	3.85 s (2H)	2.05 s (6H, $OOCCH_3$)
Hydroxy ketone VI	1.00 s	1.28 s	—	3.40 s (2H)	?
2,4-Dinitrophenylhydrazone of VI	0.96 s, 1.02 s	1.42 s	—	3.37 s (2H)	—
Keto aldehyde VII	1.01 s	1.32 s	—	9.52 s (1H)	—
Normal Wolff–Kishner product IX*a*	1.02 s	1.14 s	—	3.22 s (2H)	2.43 s (1H, OH)
Normal Wolff–Kishner acetate IX*b*	1.02 s	1.14 s	—	3.82 s (2H)	2.04 s (3H, $OOCCH_3$)
Unsaturated diol X	0.96 s	1.66 d ($J \sim 1$)	5.35 b m	3.60 d ($J \sim 1$)	2.58 b s (2H, OH)
Unsaturated ketone XI	1.00 s, 1.05 s	1.67 d ($J \sim 0.5$)	5.27 b m	—	—
Isocaryophyllene keto oxide XII*b*	1.01 s, 1.10 s	1.25 s	?	—	—

*Chemical shifts are given in parts per million from tetramethylsilane (= 0) for deuteriochloroform solutions. The symbol ? means that the peak position is not given because the assignment would be uncertain; s = singlet; d = doublet, b = broad, m = multiplet, and dd = doublet of doublets.

VIII

of a tetrahydropyran ring) and would not be expected to form readily. Furthermore, the failure of the keto alcohol VI to undergo reductive cleavage of the α-alkoxy group is in better agreement with an unstrained structure. Therefore, the 119° glycol is assigned the α-oxygen-bridged stereostructure IV*a* (IVA $\rightleftharpoons$ IVB).[5] This stereochemistry is consistent with, and supported by, some further experiments.

IVA IVB

[5]*The tetrahydropyran ring might prefer either a chair or a deformed boat conformation. In the more rigid chair form IVA, there is a very unfavorable interaction of the hydrogens on C-5 and C-10; in the distorted boat form IVB, this interaction is reduced, but the substituents on adjacent atoms C-8, C-9 and C-1, C-11 are more nearly eclipsed. Alleviation of these interactions in the ketone VI may account for the more rapid oxidation of the secondary relative to the primary hydroxyl group of IVa.*

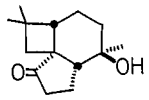
When the 142° diol from the permanganate oxidation was refluxed with methanolic sodium hydroxide, it was converted cleanly into the 119° glycol IV*a* with no detectable (n.m.r., thin-layer chromatography) amount of any other product. The stereostructure of the 142° glycol is therefore III, with the same configuration at C-1 as IV*a*. However, the formation of IV*a* from III in basic methanol solution is much slower than the formation of IV*a* in the basic permanganate oxidation of I, and it is presumably some manganese ester of III which is undergoing cyclization to IV*a* in this reaction. The conversion of III into IV*a* almost quantitatively was also catalyzed by dilute sulfuric acid in a rapid reaction, and, hence, the transannular cyclization of III is appreciably faster than pinacol rearrangement of the 1,2-diol or opening of the strained *trans*-epoxide to an allylic alcohol as in the isomerization of II to V (3).

Since the products from the oxidation of I could contain, at most, only traces of the other possible 1,2-diol or its derivatives, the attack of permanganate ion or osmium tetroxide apparently occurs only from the α-side of the exocyclic double bond. An inspection of a Stuart–Briegleb model of I shows that this is a reasonable restriction.



The intramolecular attack of the C-1 hydroxyl group of III exclusively at the *tertiary* carbon of the secondary–tertiary epoxide in basic solution is remarkable but can be rationalized. The product XVI of attack at the secondary carbon atom with inversion would be strained[4] (*trans* fusion of a ring across the 2,5-positions of a tetrahydrofuran ring), and the consequent increase in activation energy for its formation presumably overrides the usual preference for attack at the less-substituted oxide carbon atom in basic solution. The same explanation can be invoked to rationalize a long-known, closely related reaction in the chemistry of caryophyllene: the attack of the enolate anion of the keto oxide II at the *tertiary* carbon atom of the same oxide system to give XIV in over 90% yield (14, 15). Again, the compounds XVII (*trans* 6,5 fusion) and XVIII (*trans* 4,6 fusion) resulting from attack at the secondary carbon atom with inversion would be more strained[4] than the observed product XIV.

XVI

XVII

XVIII

The above rationalization does not take into account the following possible complication. The steric factors, which normally compel base-catalyzed *intermolecular* attack at the least substituted carbon atom of an oxirane ring (16), might be negligible in the case of the *intramolecular* reaction. If this is so, displacement at a tertiary carbon atom might become as facile as that at a secondary carbon atom. A test of this possibility can be provided by the 1,2-diols from the two isocaryophyllene oxides, provided that oxidation of XIII*a* and XIII*b* occurs from the α-side of the exocyclic double bond in these molecules too. The 1,2-glycol from isocaryophyllene oxide-*a* (XIII*a*) could give a strain-free[4] cyclic ether from attack of the C-1 hydroxyl group at either the secondary or tertiary oxirane carbon atom, and the proportion of products formed may be interpreted as a measure of the preference for secondary over tertiary displacement. On the other hand, the 1,2-glycol from isocaryophyllene oxide-*b* (XIII*b*) cannot give a strain-free[4] cyclic ether by attack of the C-1 hydroxyl group at either oxirane carbon atom, and therefore this reaction would not be expected to take place. These experiments are in progress.

EXPERIMENTAL

General

Melting points were taken on a Reichert microscope hot stage and are corrected. Optical rotations were measured with chloroform solutions, unless otherwise specified, in a 1 dm tube on a Rudolph model 80 polarimeter. Infrared spectra were recorded on a Beckman IR-5 or IR-5A spectrophotometer. The ultraviolet spectrum was taken on a Cary model 14 spectrophotometer. Nuclear magnetic resonance spectra were determined with deuteriochloroform solutions (20–30 mg/0.1 ml) on a Varian A-60 or DP-60 spectrometer. The spectra taken on the DP-60 instrument were calibrated by the audio side-band technique. Camag DF-5 silica gel with calcium sulfate binder was used for thin-layer chromatography (t.l.c.). Reported R_f values are taken from one plate on which all compounds were present, and which was developed in petroleum ether – ethyl acetate (40:60). The separations on this comparison plate are not necessarily the best obtained. Solutions in organic solvents were dried by washing them with saturated sodium chloride solution and then allowing them to stand with anhydrous magnesium sulfate. Petroleum ether refers to the fraction boiling at 60–80°. Microanalyses were carried out by Dr. A. Bernhardt, Mülheim, Germany.

Permanganate Oxidation of Caryophyllene Oxide (I)

The procedure of Treibs was followed (1). To a vigorously stirred solution of 12.3 g (56 mmoles) of caryophyllene oxide and 3.5 ml of water in 130 ml of acetone was added, in portions and with cooling, 26 g of powdered potassium permanganate over a period of 24 h. The reaction mixture was filtered through a sintered-glass funnel, and the colorless filtrate was evaporated to leave 8.5 g of oily product. Thin-layer chromatographic examination of the crude product revealed a spot corresponding to the keto epoxide II, a spot corresponding to both the 119° glycol IV*a* and the 142° glycol III, and a spot at the origin. The crude product was chromatographed on 240 g of Woelm neutral alumina (activity IV). Elution with petroleum ether gave 5.96 g (48%) of the keto epoxide II, m.p. 62–63°, $[\alpha]_D^{22}$ −148° (*c*, 1.95), R_f 0.85 (lit. (14) m.p. 62–63°, $[\alpha]_D$ −134° (chloroform)). Elution with benzene–chloroform (50:50) gave 0.64 g (4.5%) of the mixture of glycols. Recrystallization from benzene – petroleum ether gave a first crop of 220 mg of III which, after further recrystallization from the same solvent pair, had m.p. 138–139° and R_f 0.38 (lit. (1) m.p. 141°, $[\alpha]_D$ −72° (alcohol)). From the mother liquors of the first recrystallization above was obtained a second crop consisting of 118 mg of IV*a* which, after further recrystallization from benzene – petroleum ether, had m.p. 118–119°, $[\alpha]_D^{20}$ −7.2° (*c*, 1.91), $[\alpha]_D^{21}$ −5.3° (*c*, 2.21), $[\alpha]_D^{22}$ −10.4° (*c*, 2.12 in 95% ethanol), and R_f 0.40 (lit. (1) m.p. 119°, $[\alpha]_D$ −1.00° (alcohol)).

Continued elution of the chromatographic column with methanol – acetic acid gave 0.38 g of an oil. Trituration of this oil with chloroform gave 58 mg of white crystals, m.p. 181–182°, whose t.l.c. behavior corresponded to that of the spot remaining at the origin in the crude oxidation product.

A solution of 100 mg (0.39 mmole) of the 119° glycol IV*a* in 5 ml of methanol was treated with 160 mg (0.75 mmole) of sodium metaperiodate in 2 ml of water. After 8 h the clear solution was diluted with water and extracted with ether. Evaporation of the dried ether extract left 87 mg of recovered IV*a*, m.p. 117–118.5°, undepressed on admixture with starting material. The infrared spectrum of the product was identical with that of the 119° glycol and had no trace of carbonyl absorption.

Osmium Tetroxide Oxidation of Caryophyllene Oxide (I)

To a solution of 773 mg (3.04 mmoles) of osmium tetroxide in 1 ml of pyridine and 4 ml of ether was added 660 mg (3.00 mmoles) of pure caryophyllene oxide. The reaction mixture became warm and turned brown. Several days later, when brown crystals had appeared, the reaction mixture was diluted with ether and saturated with hydrogen sulfide. The black precipitate of osmium sulfide which precipitated was removed by filtration through Celite. The yellow filtrate was diluted further with ether, washed with dilute sulfuric acid and dilute potassium bicarbonate solutions, and dried. Evaporation of the solvent left 500 mg of white solid. Two recrystallizations from chloroform – petroleum ether gave 316 mg (41%) of colorless prisms of glycol IV*a*, m.p. 116–117.5°, undepressed on admixture with a sample, m.p. 117–118.5°, from the permanganate oxidation of I.

A second crop of 117 mg of crystals which was obtained from the mother liquors melted over a much wider range, <80–117°, although it gave a single spot corresponding to IV*a* on t.l.c. comparison. These facts together with the optical rotation, $[\alpha]_D^{21}$ −8.05° (*c*, 2.15), and the n.m.r. spectrum of this material show it to be almost pure 119° glycol IV*a* containing no noticeable amount of 142° glycol III. It is estimated that 3–5% of III could easily have been detected in the n.m.r. spectrum. The n.m.r. spectrum of the mother liquors from the second crop of crystals showed that they were also mainly 119° glycol IV*a* containing no detectable amount of 142° glycol III.

Oxidation of Caryophyllene Oxide with the Milas Reagent

The hydrogen peroxide – *t*-butyl alcohol reagent was prepared as described (5) and was assumed to contain 6.32% of peroxide. To 30 ml of the reagent was added a solution of 60 mg of osmium tetroxide in 2 ml of *t*-butyl alcohol, and the mixture was cooled to 0° in an ice–salt bath. Then 3.130 g (14.2 mmoles) of caryophyllene oxide was added in small portions during 5 min. The reaction mixture turned reddish brown and finally became a clear light-yellow after 30 min. It was then stored in a refrigerator at 4° for 96 h, whereupon it was diluted with ether. The organic solution was washed with 40 ml of 10% aqueous ferrous sulfate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solution to destroy excess peroxide, then with water, and finally dried. Removal of the solvent under reduced pressure left 3.13 g of crude product. Thin-layer chromatography in pure ethyl acetate gave two main spots, one corresponding to authentic keto oxide II and the other corresponding to the 119° and 142° glycol mixture. The crude product was chromatographed on 90 g of Woelm neutral alumina (activity IV) packed in petroleum ether (b.p. 60–80°). Petroleum ether eluted 1.87 g (59%) of keto epoxide II (single t.l.c. spot) which, on recrystallization from petroleum ether, gave long prisms, m.p. 62–63°, $\nu_{max}^{CS_2}$ 1 695 cm^{-1} (C=O). Further elution with benzene–chloroform (50:50) gave 990 mg of glycol fraction. Three recrystallizations from chloroform – petroleum ether gave 600 mg (16%) of glycol IV*a*, m.p. 117–117.5°, $[\alpha]_D^{20}$ −9.5° (*c*, 2.39), $[\alpha]_D^{22}$ −2.27° (*c*, 2.29 in 95% ethanol). The n.m.r. spectrum of the residue from the recrystallization mother liquors did not reveal any peaks from the 142° glycol III.

119° Glycol Diacetate IVb

A solution of 100 mg (0.39 mmole) of IV*a* in 2 ml of pyridine and 1 ml of acetic anhydride was allowed to stand at room temperature for 24 h. The reaction mixture was diluted with water and extracted with ether. The ethereal extracts were washed with dilute sulfuric acid and aqueous sodium bicarbonate, and dried. Evaporation of ether left 131 mg (98%) of colorless glass, $[\alpha]_D^{22}$ +8.8° (*c*, 2.09), $\nu_{max}^{CS_2}$ 1 740 cm^{-1} (ester C=O). A sample was evaporatively distilled at 75–80° and 0.01 mm for analysis.

Anal. Calcd. for $C_{19}H_{30}O_5$ (338.41): C, 67.43; H, 8.92. Found: C, 67.37; H, 8.96.

Chromic Acid – Pyridine Oxidation of 119° Glycol IVa

Chromium trioxide (3.2 g, 32 mmoles) was added to 35 ml of pyridine. To this slurry of the orange complex was added at room temperature a solution of 4.25 g (16.7 mmoles) of the 119° glycol IV*a* in 45 ml of pyridine. The color changed immediately to dark brown. After 24 h the reaction mixture was diluted with methylene chloride and filtered through a short column of Woelm neutral alumina (activity IV) to remove chromium salts. The eluate was evaporated under reduced pressure to leave 3.85 g of crude product. Thin-layer chromatography in ethyl acetate – petroleum ether (85:15) gave two intense spots and two very faint spots after charring. The crude product was chromatographed on a column of 160 g of silica gel (British Drug Houses) packed in chloroform. Elution with ether–chloroform (3:97) gave 175 mg (4%) of colorless crystalline keto aldehyde VII which was not quite free of VI. Four recrystallizations from petroleum ether gave colorless crystals, m.p. 84–86°, $[\alpha]_D$ +65° (*c*, 1.05), R_f 0.90, ν_{max} 2 700 cm^{-1} (CHO) and 1 724 cm^{-1} (broad, —CH=O, 6-ring C=O).

Anal. Calcd. for $C_{15}H_{22}O_3$ (250.32): C, 72.00; H, 8.85. Found: C, 72.30; H, 8.58.

Further elution of the column with the same solvent gave 2.70 g (67%) of colorless viscous liquid VI, $[\alpha]_D^{19}$ +76° (*c*, 2.96), R_f 0.80, $\nu_{max}^{CS_2}$ 3 484 cm^{-1} (OH) and 1 724 cm^{-1} (6-ring C=O). A sample was evaporatively distilled at 55–65° and 0.05 mm for analysis.

Anal. Calcd. for $C_{15}H_{24}O_3$ (252.34): C, 71.39; H, 9.59. Found: C, 71.11; H, 9.36.

The 2,4-dinitrophenyhydrazone was prepared and recrystallized from ethyl acetate – petroleum ether at −60° to give small yellow crystals, m.p. 80–82°.

Anal. Calcd. for $C_{21}H_{28}O_6N_4$ (432.47): C, 58.31; H, 6.52. Found: C, 57.73; H, 6.46.

Oxidation of IV*a* with chromium trioxide in acetic acid was more complex and gave acidic as well as neutral products; therefore it was not investigated further.

Attempted Reductive Cleavage of Hydroxy Ketone VI

The following reactions were carried out with the purpose of cleaving reductively the α-alkoxy group of the ketone VI: (*a*) 225 mg of VI, 5.5 ml acetic anhydride, and 5.25 g of zinc dust were refluxed for 6 h; (*b*) 160 mg of VI, 15 ml of acetic anhydride, and 4 g of zinc dust were refluxed for 48 h; (*c*) 180 mg of VI, 15 ml of propionic anhydride, and 4 g of zinc dust were refluxed for 36 h; (*d*) 185 mg of VI, 1.5 ml of glacial acetic acid, 25 ml of acetic anhydride, and 1 g of magnesium were refluxed for 18 h; (*e*) 210 mg of VI in 10 ml of toluene was added to 200 mg of calcium in 30 ml of liquid ammonia; and (*f*) 125 mg of VI in 25 ml of *sec*-butylamine was treated with 150 mg of potassium. Infrared spectra and t.l.c. examination indicated that, except for reaction *f*, the product of each reaction was starting material VI, or starting material with the primary alcohol acylated, or else the epimeric glycols of structure IV*a*.

Wolff–Kishner Reduction of Hydroxy Ketone VI

To a solution of 885 mg (3.50 mmoles) of hydroxy ketone VI in 30 ml of triethylene glycol were added 10 ml of hydrazine hydrate (85%) and 4.5 g of potassium hydroxide pellets. The mixture was refluxed in an oil bath at 130–135° for 3.7 h, after which the excess hydrazine hydrate was distilled out. The temperature of the oil bath was then raised to 230° and maintained at that temperature for 3 h. The cooled reaction mixture was diluted with water and extracted with ether. The combined ether extracts were washed with water and dried. Evaporation of the solvent left 818 mg of crude product. Thin-layer chromatography in ethyl acetate – petroleum ether (50:50) revealed two intense spots and one faint low-R_f spot. The crude product was chromatographed on 25 g of Woelm neutral alumina (activity IV) packed in petroleum ether. Elution with petroleum ether gave 400 mg (48%) of the normal reduction product IX*a* as a colorless liquid, $[\alpha]_D^{26}$ −19° (*c*, 2.00), R_f 0.85, $\nu_{max}^{CCl_4}$ 3 559 cm^{-1} (OH). A sample was evaporatively distilled at 50–60° and 0.01 mm for analysis.

Anal. Calcd. for $C_{15}H_{26}O_2$ (238.37): C, 75.58; H, 11.00. Found: C, 75.16; H, 10.96.

Further elution of the column with benzene – petroleum ether (75:25) gave 300 mg (36%) of solid reductive elimination product X. Five recrystallizations from petroleum ether gave small colorless needles, m.p. 91–92°, $[\alpha]_D^{24}$ −0.47° (*c*, 1.75), R_f 0.65, $\nu_{max}^{CCl_4}$ 3 390 cm^{-1} (OH) and 850 cm^{-1} (C=CH). Material of m.p. 92–93° could also be obtained by two sublimations of the crude product.

Anal. Calcd. for $C_{15}H_{26}O_2$ (238.37): C, 75.58; H, 11.00. Found: C, 76.02; H, 10.79.

Acetylation of Normal Reduction Product IXa

A solution of 250 mg (1.05 mmoles) of IX*a* in 2 ml of pyridine and 1.5 ml of acetic anhydride was refluxed for 1 h, cooled, and diluted with water. The product was removed by extraction with ether. The ether extracts were washed with dilute sulfuric acid and water. The dried ethereal solution was evaporated at reduced pressure to leave 280 mg (95%) of colorless liquid IX*b*, $[\alpha]_D^{20}$ −12.4° (*c*, 1.90), R_f 0.90, $\nu_{max}^{CCl_4}$ 1 751 cm^{-1} (ester C=O). A sample was evaporatively distilled at 60–65° and 0.05 mm for analysis.

Anal. Calcd. for $C_{17}H_{28}O_3$ (280.39): C, 72.82; H, 10.06. Found: C, 72.32; H, 9.84.

Periodate Cleavage of Reductive Elimination Product X

To a solution of 250 mg (1.05 mmoles) of the 1,2-diol X in 7 ml of methanol was added a solution of 500 mg (2.33 mmoles) of sodium metaperiodate in 5 ml of water. An exothermic reaction occurred, and a voluminous white suspension appeared almost immediately. The reaction mixture was left at room temperature for 9 h, after which it was diluted with water and extracted with ether. The water-washed and dried ethereal solution was evaporated at reduced pressure to yield 200 mg (92%) of a colorless liquid which was chromatographed on 6 g of Woelm neutral alumina (activity IV) packed in petroleum ether. Elution with the same solvent gave 151 mg of colorless liquid XI, $[\alpha]_D^{22}$ −77° (*c*, 2.26), λ_{max}^{EtOH} 235 mμ (ε 440),[6] $\nu_{max}^{CCl_4}$ 1 695 cm^{-1} (9-ring C=O) and 837 cm^{-1} (C=CH), R_f 0.90. During sulfuric acid charring of XI a characteristic mauve color appeared before carbonization. A sample was evaporatively distilled at 65–70° and 0.05 mm for analysis.

Anal. Calcd. for $C_{14}H_{22}O$ (206.32): C, 81.50; H, 10.75. Found: C, 81.37; H, 10.69.

Epoxidation of Unsaturated Ketone XI

To a solution of 103 mg (0.50 mmole) of XI in 5 ml of ether cooled to 0° was added 40 ml of a solution of monoperphthalic acid in ether (equivalent to 0.50 mmole of peracid). The reaction mixture was kept in the refrigerator for 60 h, after which it gave a negative starch–iodide test. Then the precipitated phthalic acid was removed by filtration. The filtrate was washed with sodium bicarbonate solution and with water. The dried ethereal solution was evaporated at reduced pressure to leave 95 mg of a mixture of the *cis* keto oxides XII*a* and XII*b*, which solidified when chilled. Two recrystallizations from petroleum ether gave 42 mg of colorless prisms of XII*b*, m.p. 75–76°, $[\alpha]_D^{15}$ −13.8° (*c*, 1.78 in methanol), R_f 0.80, $\nu_{max}^{CCl_4}$ 1 695 cm^{-1} (9-ring C=O). The mixed melting point with the authentic sample of isocaryophyllene keto epoxide-*b*, m.p. 77.5–78°, prepared as described below was undepressed. The infrared spectra of the two samples were identical.

Anal. Calcd. for $C_{14}H_{22}O_2$ (222.32): C, 75.63; H, 9.97. Found: C, 75.17; H, 10.01.

Isocaryophyllene (cis-Caryophyllene) (with V. Dave)

The procedure of Schreiner and Kremers (17) was followed in part. A solution of 22 g of combined caryophyllene fractions ($[\alpha]_D$ −9 to −9.5°) in 60 ml of petroleum ether (b.p. 35–60°) was stirred at room temperature with 25 ml of a saturated aqueous solution of sodium nitrite. To this suspension was added slowly 25 ml of glacial acetic acid. The reaction mixture became blue and then light green. After 25 min the solution was chilled and kept below 0° overnight. The reaction mixture was allowed to come to room temperature and was filtered to remove some crystalline material. The filtrate was diluted with water and extracted with ether. The dark-green ethereal solution was washed with several portions of 10% aqueous potassium hydroxide and with water. The ether was removed from the dried solution by distillation to leave 19 g of green oil. This residue was steam-distilled until the oily droplets in the distillate began to be denser than water. Extraction of the steam-distillate with ether yielded 9.89 g of yellow oil after removal of the ether. Fractional distillation through a 1 m Nester and Faust spinning spiral column gave four fractions totalling 4.8 g (22%) of colorless isocaryophyllene, b.p. 116° at 8.5 mm, $[\alpha]_D^{25.5}$ −22.2° (neat) (lit. (18) b.p. 125.5° at 14.5 mm, $[\alpha]_D^{19}$ −26.1° (neat)); ν_{max}^{neat} 3 060 cm^{-1} (vinyl H), 1 635 cm^{-1} (C=C), 885 cm^{-1} (C=CH$_2$), and 836 cm^{-1} (C=CH). Repetition of the isomerization process on this material did not change the optical rotation. The isocaryophyllene was 96.5% pure by vapor-phase chromatography, and the 3.5% of impurity was not caryophyllene or α- or β-humulene. On a 2 m × ¼ inch column of Chromosorb P (coated with silver nitrate – Carbowax 20M, 10% of each) at 162°, the compounds had the following retention times: isocaryophyllene, 8.0 min; impurity, 5.5 min; and caryophyllene, 8.8 min.

Authentic Isocaryophyllene Keto Epoxide-b (XIIb)

The procedure of Ramage and Whitehead (19) was followed. A solution of 4.03 g (19.7 mmoles) of isocaryophyllene in 25 ml of ether was cooled to 0° and treated with 65 ml (20 mmoles) of an ethereal solution of monoperphthalic acid. The reaction mixture was kept at 4° for 48 h, after which it was filtered to remove precipitated phthalic acid. The filtrate was washed successively with aqueous sodium bicarbonate and water

[6]*This chromophore is apparently an example of a σ-coupled p-electron system (20).*

For personal use only.

before it was dried. Evaporation of the ether left 3.72 g of a residue which partially crystallized. Trituration of the crude product with cold petroleum ether and filtration left 1.10 g of crystalline material which was recrystallized once from petroleum ether to yield colorless crystals of isocaryophyllene oxide-*a* (XIII*a*), m.p. 73–75°, $[\alpha]_D^{20}$ −7.3° (*c*, 3.30 in methanol), R_f 0.90 (lit. (19) m.p. 77°, $[\alpha]_D$ −5° (methanol)).

The oily mother liquor, after separation of the crystalline isocaryophyllene oxide-*a*, contained mainly isocaryophyllene oxide-*b* (XIII*b*), and it was oxidized directly. To a solution of 1.31 g of the material and 1 ml of water in 25 ml of acetone was added 4.0 g of powdered potassium permanganate. The reaction was worked up as described for the oxidation of caryophyllene oxide above. The crude oily product (1.05 g) was chromatographed on 35 g of Woelm neutral alumina (activity IV) and yielded 80 mg[7] of isocaryophyllene keto epoxide-*b* (XII*b*), which had m.p. 77.5–78° and $[\alpha]_D^{20}$ −13.1° (*c*, 1.91 in methanol) (lit. (19) m.p. 78–79°, $[\alpha]_D$ −13° (methanol)) after two recrystallizations from petroleum ether.

Isomerization of 142° Glycol III

Basic Catalysis

A solution of 80 mg of III, m.p. 138–139°, and 250 mg of potassium hydroxide in 5 ml of methanol was refluxed for 168 h. Dilution with water and extraction with ether yielded 65 mg of a white solid, m.p. 114–117°, whose n.m.r. spectrum and t.l.c. behavior were identical with those of the 119° glycol IV*a*. Recrystallization from chloroform – petroleum ether raised the melting point to 116–117°, undepressed on admixture with authentic 119° glycol IV*a*.

When the isomerization was allowed to proceed for only 19 h, the reaction was incomplete and the product was a mixture of III and IV*a* (n.m.r. spectrum).

Acid Catalysis

A solution of 14 mg of III, m.p. 138–139°, and 2 ml of 5% aqueous sulfuric acid in 3 ml of acetone was refluxed for 2 h. Dilution with water and extraction with ether yielded 12 mg of colorless solid, m.p. 110–113°. Thin-layer chromatographic examination revealed only traces of two less-polar impurities besides the main III–IV*a* spot. Recrystallization from petroleum ether raised the melting point to 117–118°, undepressed on admixture with authentic 119° glycol IV*a*. Thin-layer chromatographic examination of the recrystallized product gave a single spot corresponding to III–IV*a*.

The melting point of a control mixture of III and IV*a* was depressed.

STUDIES ON CHITAN (β-(1 → 4)-LINKED 2-ACETAMIDO-2-DEOXY-D-GLUCAN) FIBERS OF THE DIATOM THALASSIOSIRA FLUVIATILIS HUSTEDT.

II. PROTON MAGNETIC RESONANCE, INFRARED, AND X-RAY STUDIES[1]

MICHAEL FALK, D. G. SMITH, J. MCLACHLAN, AND A. G. MCINNES
Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia

Received December 7, 1965

ABSTRACT

The extracellular fibers attached to the diatom *Thalassiosira fluviatilis* have been shown to be pure β-(1 → 4)-linked 2-acetamido-2-deoxy-D-glucan. This polysaccharide was given the systematic trivial name chitan to distinguish it from chitin, which is not a chemically distinct species and which has a radically different X-ray diffraction pattern and infrared spectrum. Proton magnetic resonance studies on the acid hydrolysis of chitan have established that the hydrolysis occurred in three distinct steps: (*a*) the degradation of the polysaccharide to smaller polymeric units, (*b*) the production of *N*-acetylglucosamine from the latter, and (*c*) the conversion of *N*-acetylglucosamine into glucosamine and acetic acid. X-ray and infrared studies have shown that chitan has a different macrostructure from that of arthropod chitin. Chitan is completely crystalline and can be converted irreversibly into a form indistinguishable from that of chitin by treatment with hot aqueous lithium thiocyanate. Boiling chitan in water converts it into a second crystalline modification, possibly a hydrate, which can be reconverted into the starting material by drying *in vacuo*. The exceptionally sharp infrared spectrum of chitan allows a more unequivocal assignment of a number of bands common to chitan and chitin, and provides information about the nature of the bands at 1 626 and 1 656 cm^{-1} in the spectrum of chitin. The correlation of the bands in the region of 840 to 890 cm^{-1} with the configuration at the anomeric center of glycopyranose derivatives is discussed.

INTRODUCTION

The biological importance of chitin, which is widely distributed among invertebrates and most fungi, is reflected in the large number of publications on this material since it was discovered by Braconnot in 1811 (1). Work on chitin falls into three broad categories. Firstly, there are investigations on the isolation, composition, and structure of chitin. Secondly, there are those dealing with its physical properties and macrostructure as determined largely by infrared and X-ray diffraction techniques. Finally, there are studies of the biochemical and biological role of chitin. Previous work has been reviewed (2–4).

We have previously described the isolation of fibers from *Thalassiosira fluviatilis* (5) and other diatoms (6) which we claimed were composed of *pure, homogeneously crystalline* β-(1 → 4)-linked 2-acetamido-2-deoxy-D-glucan. The polysaccharide was given the trivial name chitan to conform with modern nomenclature, and to distinguish it from chitin. Since most carbohydrate chemists seem to regard the above structure as being synonymous with chitin, an explanation for our choice of name is necessary. A critical survey of the literature offers no experimental justification for assuming, as some workers have (3, 4, 7), that chitin has the above composition. Indeed, all relevant studies on this material have actually established that it is a mixture of polysaccharides which contain variable amounts of *N*-acetylglucosamine and glucosamine (2, 8, 9). It is interesting to note that, although the presence of the latter is attributed to chemical degradation with a strong acid and (or) base, Giles (9) has found that even the use of enzymatic procedures to remove the protein associated with chitin gives a product which has been calculated to have 12.5% glucosamine. A striking feature of all preparations of chitin, moreover, is the

[1]*Issued as N.R.C. No. 9096.*

deviation of the elemental analyses from the theoretical values (2, 9). Some workers have drawn attention to these facts (2, 9), and have suggested that "native" chitin may always contain considerable amounts of glucosamine. In fact, Richards (10) goes so far as to question whether chitin can really be considered a "natural" chemical entity since it may be a degradation product of the various complexes in which it exists. Furthermore, any structure for chitin based on X-ray or infrared studies should be accepted with considerable reservation (see the section on macrostructure). Consequently, we feel that the name chitin should be reserved as a group name for those polysaccharides which contain glucosamine in addition to *N*-acetylglucosamine. The polysaccharide which we have isolated has a uniform composition, and its X-ray diffraction pattern and infrared spectrum are radically different from those of chitin. Consequently, we felt that this well-defined substance required a specific well-defined name, and for the sake of brevity the trivial name chitan was selected in addition to the somewhat lengthy systematic name.

In this communication we report the results of chemical, infrared, X-ray diffraction, and proton magnetic resonance (p.m.r.) studies which establish the composition and structure of chitan, and provide information on its macrostructure and the nature of the difference between this polysaccharide and arthropod chitin. Attempts to prepare oriented samples (fibers and films) suitable for future X-ray crystallographic and polarized infrared studies have been undertaken. Such studies should allow a more complete elucidation of the macrostructure of chitan.

EXPERIMENTAL

Materials

The methods used for the production and isolation of chitan fibres have been described in detail elsewhere (5). For elemental analysis the fibers were dried at 100° for 48 h under reduced pressure.

Anal. Calcd. for $(C_8H_{13}O_5N)_n$: C, 47.29; H, 6.45; N, 6.89. Found: C, 47.43; H, 6.40; N, 6.84.

Crustacean chitin was purchased from Brickman Co., Montreal. 2-Acetamido-2-deoxy-D-mannose (*N*-acetylmannosamine) had been synthesized previously in this laboratory (11). 2-Acetamido-2-deoxy-D-glucose (*N*-acetylglucosamine) was prepared from D-glucosamine hydrochloride (12).

Hydrolysis of Chitan at 40°

Chitan (50 mg) was weighed into a p.m.r. sample tube and triturated with 10.2 *N* HCl in D_2O (0.50 ml). A homogeneous solution was obtained when the mixture was warmed to 35°. The sample tube was capped with a "caplug", which supported a sealed capillary tube containing the external standard tetramethylsilane in $CDCl_3$, and was subsequently transferred to the probe of a Varian A60 nuclear magnetic resonance spectrometer equipped with a V-6057 variable-temperature accessory. Controlled hydrolysis of the chitan sample was carried out at 40°, and the progress of the reaction was followed by scanning the p.m.r. spectrum periodically. After an interval of 60 h glucosamine hydrochloride crystallized from the solution. This caused the p.m.r. spectrum to broaden, and prevented further quantitative measurements. After several days at 40° the mixture was taken to dryness under reduced pressure. The crystalline residue was dissolved in a minimum amount of distilled water, and ethanol and ether were added to induce crystallization. The p.m.r. and infrared spectra of the crystalline product (yield ≈70%) and an authentic sample of glucosamine hydrochloride were identical, and the former compound had $[\alpha]_D^{25}$ +72.0°, which is in excellent agreement with the reported values (13). Assignments of the signals for the products of hydrolysis of chitan were made by comparing the p.m.r. spectra with those obtained for authentic mixtures of *N*-acetylglucosamine, glucosamine, and acetic acid.

Hydrolysis of Chitan at 80°

The general procedure used in these experiments was the same as that described for the experiments at 40°. However, 8.2 *N* HCl in D_2O was used for the hydrolysis, and under these conditions no precipitation of glucosamine hydrochloride occurred as the reaction progressed. The hydrolysis of chitan was carried out in a sealed p.m.r. sample tube, and the reaction solution contained sodium 3-trimethylsilyl-1-propane sulfonate as an internal standard.

Hydrolysis of Chitin at 40° and 80°

The hydrolysis experiments described above for chitan were repeated for crustacean chitin under identical experimental conditions.

Specific Rotations of Chitan and Chitin

Chitan had $[\alpha]_D^{20}$ −19° (*c*, 1.07 in 10 *N* HCl) and crustacean chitin had $[\alpha]_D^{20}$ −21° (*c*, 1.03 in 10 *N* HCl). Both of these rotations were determined 30 min after the addition of the acid. Chitan immediately formed a gel in the presence of acid and had to be heated at 40° for a longer period (≈4 min) than chitin (≈0.5 min) before it dissolved. Considerable degradation of the polysaccharide had undoubtedly occurred during preparation of the solutions, and the rotations are only reported for the purpose of comparison. The change in $[\alpha]_D$ with time reached a plateau after approximately 100 h, at which time both solutions had $[\alpha]_D^{20}$ +56°. It was not possible to follow the hydrolysis to completion (glucosamine hydrochloride has $[\alpha]_D^{20}$ +72° in 10.2 *N* HCl) because the solution became highly colored and material precipitated.

Formation of Chitosan from Chitan

Chitan mats were treated with a boiling 50% potassium hydroxide solution for 1 h. The precipitated chitosan was removed from the solution, subsequently washed with dilute hydrochloric acid, distilled water, and acetone, and finally dried over phosphorus pentoxide under reduced pressure.

Infrared Technique

The chitan was studied in the form of unoriented fibrous mats prepared as described previously (5). The thickness of the mats was about 2.5 μ (calculated from their diameter (3.8 cm), their weight (4 mg), and the density of chitin (1.6 g/cm³)). The mats possessed sufficient mechanical strength to withstand boiling in water and various chemical treatments without disintegration. After the various chemical manipulations the mats were washed thoroughly with water and acetone and finally air-dried. More thorough drying in vacuum over phosphorus pentoxide had no further effect on the spectrum. The hydrogen–deuterium exchange was studied by immersing a mat in D_2O at various temperatures for various periods of time. The mats were then washed with acetone and air-dried.

Crustacean chitin, chitosan, *N*-acetylglucosamine, and *N*-acetylmannosamine were studied with potassium bromide pellets and Nujol mulls. The last two compounds were also studied as vitreous films prepared by the evaporation of drops of aqueous solution on silver chloride plates.

The infrared spectra were recorded from 4 000 to 250 cm^{-1} on a Perkin–Elmer model 521 spectrophotometer equipped with a frequency marker. The calibration of the instrument was accurate to 1 cm^{-1} below 2 000 cm^{-1} and to 2 cm^{-1} above 2 000 cm^{-1}. All frequencies reported are the average of at least three recordings.

X-ray Diffraction Technique

Measurements on chitan and lithium thiocyanate treated chitan were carried out on mats of fibers stacked to a thickness of 40 μ, whereas crustacean chitin was studied as a powder sprinkled to about the same thickness on a thin film of Mylar. Front-reflection patterns were obtained with CuK_α or CoK_α radiations, using a Laue camera with a rotating specimen holder (specimen to film distance, 3.75 cm). Thin aluminium foils were used for calibration.

RESULTS AND DISCUSSION

Structure of Chitan

In contrast to the chemical and (or) enzymatic procedures used in the preparation of chitin, the purification of chitan fibers was accomplished by a simple solvent wash followed by drying them *in vacuo*. The elemental analysis of these fibers then conformed to the molecular formula for poly-*N*-acetylglucosamine, namely $(C_8H_{13}O_5N)_n$.

Proton magnetic resonance studies on the acid hydrolysis of chitan, with an internal standard, enabled the number of hydrogen atoms directly attached to the carbon of each type in the repeating unit to be determined, and at the same time provided useful information on the mechanism of hydrolysis. It was necessary to carry out the hydrolysis in deuterium oxide, because the intense side bands of the signal from the hydroxyl protons of water obscured the p.m.r. spectrum of chitan.

The signals in the spectrum of chitan (Fig. 1A) could be assigned to the anomeric hydrogen on C-1 (τ 4.80) of each repeating unit, the four hydrogens in the pyranose ring together with those of the two methylene hydrogens at C-6 (τ 5.70), and the three methyl hydrogens of the *N*-acetyl group at C-2 (τ 7.10). Slight hydrolysis of chitan had also given rise to smaller signals for the methyl hydrogens of acetic acid (τ 7.47) and the α-anomeric hydrogens of *N*-acetylglucosamine (τ 4.25). The signal for the β-anomeric hydrogen of the latter was hidden under the envelope at τ 4.80, and that for the anomeric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydrogens of glucosamine, which should have one-third the intensity of the signal at τ 7.47, was too weak to be observed. Figure 1B effectively illustrates the conversion of chitan into glucosamine and *N*-acetylglucosamine. The signals for the α-anomeric hydrogens of *N*-acetylglucosamine and glucosamine were doublets centered at τ 4.25 (spacing 2.4 c.p.s.) and τ 4.04 (spacing 3.6 c.p.s.), whereas the corresponding doublets for the β-anomers occurred at higher field and were centered at τ 4.65 (spacing 7.6 c.p.s.) and τ 4.49 (spacing 8.0 c.p.s.). These assignments were based on the spectra of the pure compounds and the hydrolysis products of an authentic sample of *N*-acetylglucosamine (see Fig. 1C). The pyranose ring and methylene hydrogens (on C-6) of glucosamine and its *N*-acetyl derivative appeared at higher field with an average τ value of 5.72, and the methyl hydrogens of the *N*-acetyl group and acetic acid could be assigned to the sharp singlets at τ 7.10 and τ 7.48. No signals were obtained for any hydroxyl protons because of exchange with deuterium oxide. It should be noted that the p.m.r. evidence established that *N*-acetylglucosamine, glucosamine, and acetic acid were the *only* products of hydrolysis, and the use of an internal standard established that 1 mole of acetic acid was produced per $C_8H_{13}O_5N$ repeating unit. Glucosamine hydrochloride could also be isolated in an excellent yield after the hydrolysis reaction was complete. Results obtained for the hydrolysis of crustacean chitin under the same experimental conditions were identical with those reported above, except that the yield of acetic acid was significantly lower than the theoretical amount.

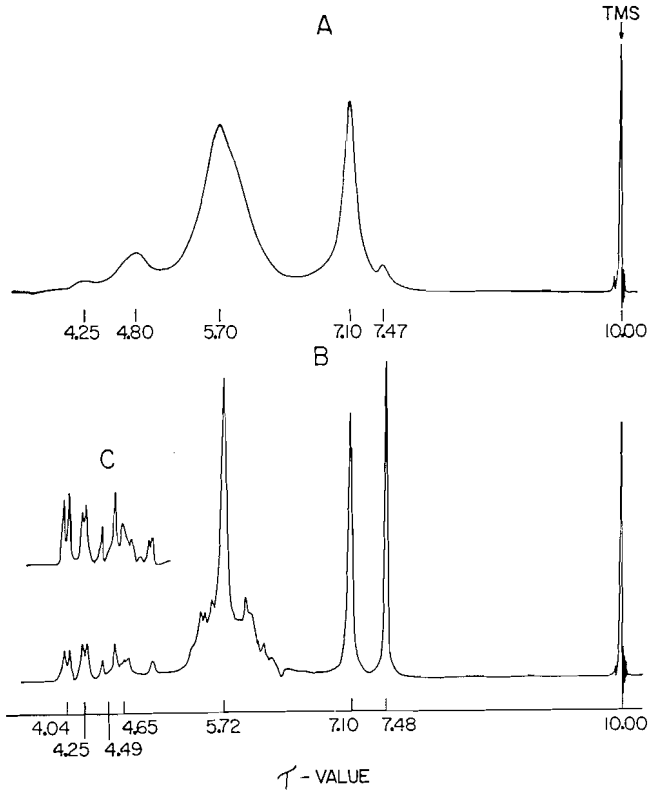

FIG. 1. The p.m.r. spectra of chitan after 1.7 h (A) and 32 h (B) in 10.2 *N* HCl at 40°. A section of the spectrum from the hydrolysis products (ca. 4 h at 50°) of an authentic sample of *N*-acetylglucosamine is shown in the insert (C). TMS = tetramethysilane.

The breadth of the signal for the anomeric hydrogen in chitan (τ 4.80; see Fig. 1A) obscured the spin–spin coupling with the neighboring hydrogen on C-2, and did not permit the configuration at the anomeric position to be derived from the magnitude of the coupling constant (14). Nevertheless, the data in the literature (15, 16) and experience in this laboratory suggest that under comparable experimental conditions the chemical shifts of anomeric hydrogens in oligosaccharides and polysaccharides containing a glycopyranose repeating unit occur within approximately ± 0.2 p.p.m. of the corresponding α- or β-anomeric hydrogens of the free glycopyranoses. In contrast, the chemical shifts of the α- and β-anomeric hydrogens differ by 0.4 to 1.0 p.p.m. Also, equatorial anomeric hydrogens usually occur at lower field than the corresponding axial hydrogens (17). The signals for the axial anomeric hydrogens of β-glucosamine and β-*N*-acetylglucosamine occur at higher field (τ 4.49 and τ 4.65) than those for the corresponding α-anomers. It can be concluded that the signal for the anomeric hydrogen of chitan at τ 4.80 indicates an axial orientation for this hydrogen, and therefore a β-configuration at the anomeric center of each repeating unit. Chitin is known to have a β-configuration at the anomeric center of each repeating unit. The identity of the chemical shifts for the anomeric hydrogens of crustacean chitin and chitan therefore provides supporting evidence for a β-configuration in the latter. The optical rotation data for chitan and crustacean chitin are also indicative of a β-D-configuration in these compounds (3, p. 379). These data establish that chitan is β-linked 2-acetamido-2-deoxy-D-glucan.

The only structural feature of chitan which has still to be considered is the type of linkage between the *N*-acetylglucosamine residues. It was found experimentally, however, that the p.m.r. spectra of chitan and crustacean chitin were superposable except for differences in the intensity of the signals for the methyl hydrogens of the *N*-acetyl groups. The identity of the chemical shifts for the hydrogens in the two polysaccharides provides strong evidence that they have the same type of linkage. It should be remembered that slight degradation and deacetylation of chitan had occurred before its p.m.r. spectrum was recorded (see Fig. 1A). In other words, chitan had been degraded by dissolving it in concentrated hydrochloric acid. Further evidence that the linkage in chitan is the same as in chitin was obtained by infrared studies. When chitan was treated with strong base it was converted into a material which gave a characteristic van Wisselingh iodine color test for chitosan (8), and an infrared spectrum identical with that reported (18) for the latter. Moreover, hot aqueous lithium thiocyanate converted chitan into a material giving an infrared spectrum indistinguishable from that of crustacean chitin (see the section on macrostructure). Chitosan and chitin are considered to be β-(1 $\rightarrow$ 4)-linked (3, p. 380; 19), although we believe that the type of linkage has not been elucidated unambiguously. Since the experimental conditions for the conversion of chitan into chitin and chitosan could not result in changes in the anomeric configuration or type of linkage, and keeping in mind our reservations on the validity of the proof for the type of linkage, we have assigned the structure β-(1 $\rightarrow$ 4)-linked 2-acetamido-2-deoxy-D-glucan to chitan.

Chitan remained unchanged when heated to a temperature of 300°. It has a molecular weight of approximately 3×10^7, as calculated from the average length of 80 μ for the microfibers (5) and an assumed value of 10 Å for the length of the repeating unit in the polysaccharide as compared with 10.4 Å for cellulose. Chitan will therefore contain approximately 8×10^4 repeating units if the polymer chain is fully extended. Chitan does not dissolve in any organic solvents.

Mechanism of Hydrolysis of Chitan

Some information on the mechanism of hydrolysis of chitan can be deduced from the data in Fig. 2. The rate of production of *N*-acetylglucosamine was the same as the rate of disappearance of polymer over the initial reaction period of 4.5 h. At this time, the *N*-acetylglucosamine concentration was at a maximum, and thereafter showed a gradual decrease with time because the rate of hydrolysis to glucosamine and acetic acid exceeded the rate of formation from chitan. A maximum concentration of *N*-acetylglucosamine was

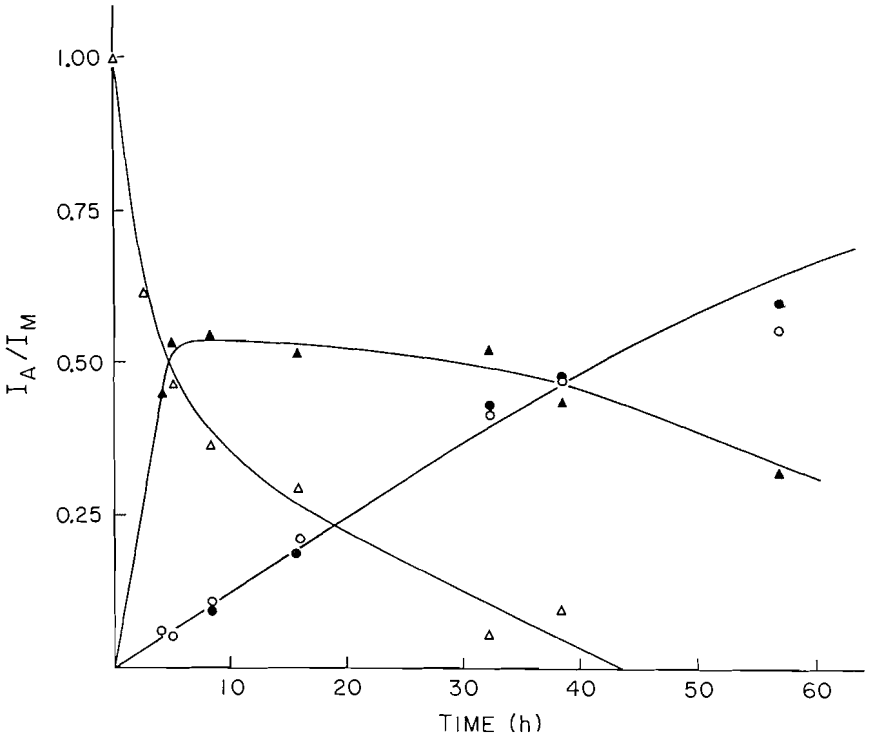

FIG. 2. Rate curves, calculated from the p.m.r. data, for the hydrolysis of chitan $((C_8H_{13}O_5N)_n)$ in 10.2 *N* HCl at 40°, showing the disappearance of chitan (△) and the formation of *N*-acetylglucosamine (▲), glucosamine (●), and acetic acid (○). The curves are a plot of I_A/I_M against time, where I_A represents the total anomeric hydrogen for each carbohydrate (or the methyl hydrogens of acetic acid), and I_M the total methyl hydrogens present in the acetic acid and *N*-acetyl groups.

obtained when 50% of the polymer was hydrolyzed. The rates of production of acetic acid and glucosamine, on the other hand, were the same within experimental error, and initially were considerably less than the rate of appearance of *N*-acetylglucosamine. It can be concluded, therefore, that most of the acetic acid was produced by the hydrolysis of *N*-acetylglucosamine, rather than by direct hydrolysis of the *N*-acetyl groups in the polymer. The data also established that good yields of *N*-acetylglucosamine cannot be obtained by controlled acid hydrolysis of chitan (or chitin).

It was observed experimentally that the p.m.r. signals for chitan sharpened appreciably after a short reaction time, and that this change in the spectrum was accompanied by a decrease in the viscosity of the reaction solution. The latter effect was undoubtedly due to the polymer chain being hydrolyzed indiscriminately along the chain length, with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

production of smaller polymeric units, and it is reasonable to conclude that the *N*-acetylglucosamine units which were being produced during hydrolysis were not being removed by preferential hydrolysis at the end of the polymer chain. These results are in agreement with those obtained by other workers, who followed the hydrolysis of chitin by a colorimetric procedure (20). The direct observation of the p.m.r. spectrum not only offers the advantage of following the reaction with more precision, but also enables all of the components in the system to be observed and analyzed simultaneously.

Macrostructure of Chitan

Comparison of Chitan and Crustacean Chitin

The infrared spectrum of chitan is shown in Fig. 3, and its X-ray diffraction pattern in Fig. 4. Chitan has extremely sharp infrared absorption bands and X-ray diffraction rings.

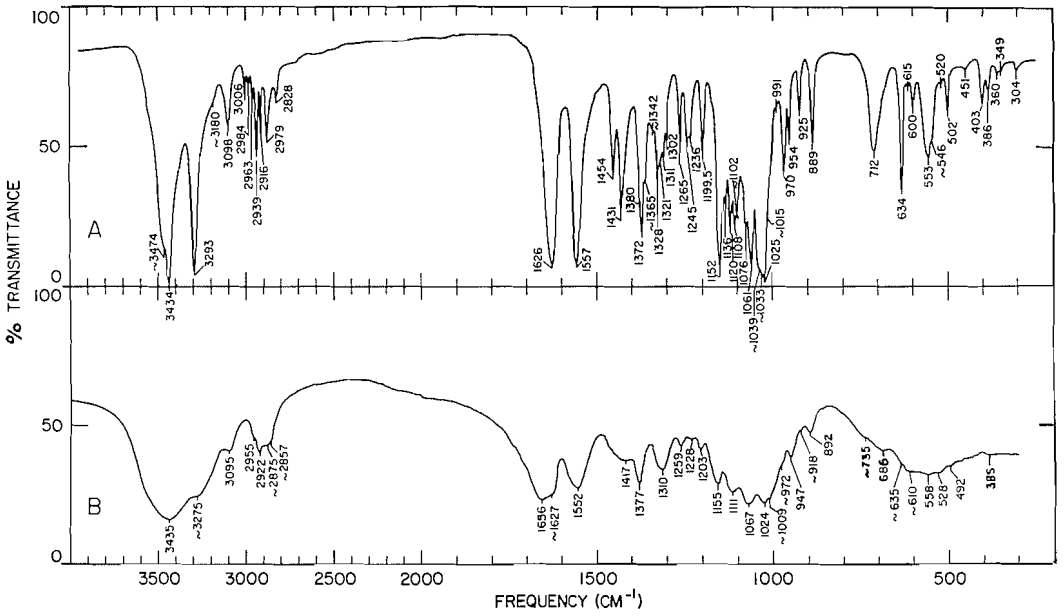

FIG. 3. The infrared absorption spectrum of chitan (A) and chitin (B).

Such sharpness is rare in polymers of biological origin and is characteristic of pure, crystalline compounds. In contrast, the far more diffuse infrared spectra and X-ray diffraction patterns of chitin point to a much less highly ordered macrostructure. The differences in the frequencies and intensities of the infrared bands (Fig. 3) and in the positions and intensities of the X-ray diffraction rings (Table I) show that chitan must have a macrostructure different from that of crustacean chitin.

It should be noted that the infrared spectrum of chitin reflects mainly the macrostructure of the fully *N*-acetylated regions, because the spectral contributions of a small number of glucosamine residues are lost in the presence of broad and intense bands caused by the bulk of the polysaccharide. The X-ray diffraction pattern of chitin, on the other hand, is obtained exclusively from the more highly ordered regions of the polysaccharide, which need not be representative of the bulk of the sample. Because of these limitations, previous conclusions about the macrostructure of chitin derived from X-ray diffraction and infrared studies (21–27) are suspect, and in any case are not relevant to chitan.

FIG. 4. The X-ray diffraction pattern of chitan obtained with CoK_{α} radiation.

It is possible to transform chitan into a form with an infrared spectrum and X-ray diffraction pattern indistinguishable from those of crustacean chitin. Such a transformation occurred when chitan mats were immersed in hot aqueous lithium thiocyanate (50%). The transformation was completed within a few seconds and was irreversible. Longer immersion of the mats in hot or cold aqueous lithium thiocyanate, immersion of the lithium thiocyanate treated mats in hot or cold water or organic solvents, and drying *in vacuo* at temperatures up to 200° caused no further spectral changes. A similar transformation also occurred when chitan was immersed in hot aqueous solutions of strong acids and alkalis, though more slowly than in lithium thiocyanate solutions. Immersion of chitan in hot concentrated aqueous solutions of lithium iodide, lithium perchlorate, urea, and other strong denaturing agents had no effect on chitan. It appears, therefore, that the transformation may involve some deacetylation in addition to a complete destruc-

tion of the macrostructure of chitan. Acids and alkalis are known to cause deacetylation, and aqueous lithium thiocyanate, which has a pH of about 9, may have a similar effect.

The conclusion that chitan, but not chitin, is completely crystalline is supported by hydrogen–deuterium exchange experiments. When mats of chitan were immersed in deuterium oxide at 21°, only about 25% of the hydroxyl protons and 6% of those in the NH groups were exchanged after 1 month. The lithium thiocyanate treated mats exchanged many times faster. Analogous experiments with cellulose (28) have established that the rate of deuterium exchange is much faster for amorphous than for crystalline samples.

OH Stretching Bands

The infrared spectrum of chitan shows two absorption bands at 3 474 and 3 434 cm^{-1} caused by the OH stretching vibrations of the two hydroxyl groups in each *N*-acetylglucosamine residue. Deuterium exchange caused a slow diminution of both bands at about the same rate, with the concomitant appearance of the bands of the two corresponding OD vibrations at 2 565 and 2 545 cm^{-1}. The absence of absorption above 3 500 cm^{-1} in chitan shows that there are no "free" hydroxyl groups, i.e. that all of the hydroxyl groups in chitan are involved in hydrogen bonds.

The sharpness of the OH stretching bands is particularly remarkable. The half-widths of the OH bands (about 20 cm^{-1}) and of the corresponding OD bands (about 10 cm^{-1}) are smaller by an order of magnitude than those of OH bands in the spectra of most biopolymers. Indeed, *these may be the sharpest such bands ever observed for hydrogen-bonded OH groups at room temperature.* The sharpness of the OH absorption bands shows that each type of hydroxyl group in chitan, in contrast to chitin, has an identical environment.

Amide Group Bands

Amide groups in chitan give sharp infrared bands at 3 293, 1 557, and 712 cm^{-1} which are due to the NH stretching vibration, the amide II vibration (largely the in-plane NH bending), and the amide V vibration (largely the out-of-plane NH bending). The behavior of chitan is similar to that of other hydrogen-bonded secondary amides such as proteins and polypeptides (29), which exhibit slow rates of isotope exchange of the NH protons in the presence of deuterium oxide at room temperature. For example, only 6% of these protons in chitan are replaced by deuterium after 1 month at 21°, although there is a marked temperature dependence which results in the exchange of almost 40% of the NH protons in 2 h at 100°. The diminution of the NH bands is accompanied by the appearance of the corresponding ND vibrations at 2 462 – 2 428 (doublet), 1 479, and 522 cm^{-1}. Doublet formation in the ND stretching region is probably due to Fermi resonance. These frequencies are characteristic of hydrogen-bonded NH groups in polyamides and polypeptides (30, 31), and clearly establish the absence of free NH groups. Frequencies similar to those discussed above are observed in the spectrum of chitin, although the bands are much broader.

One of the most distinctive features of the infrared spectrum of chitan is the single, sharp, intense band at 1 626 cm^{-1}, which is due to the amide I vibration (largely C=O stretching). The sharpness of the band indicates immediately that the amide groups in this polysaccharide are in an equivalent environment. Crystalline *N*-acetylglucosamine also exhibits a single absorption band at 1 626 cm^{-1}, and so does its 2-epimer *N*-acetylmannosamine at 1 623 cm^{-1}. It seems probable, therefore, that this band position is characteristic of monomeric or polymeric 2-amino-2-deoxy-glycopyranoside units *in the crystalline state*. The position of the amide I band in this class of compounds appears to be insensitive to the configuration at C-2 of the hexosamine residue, and suggests that the factors influencing this mode of vibration are largely confined to the amide group itself. A recent X-ray study (32) indicates that the plane of the amide group in crystalline *N*-acetylglucosamine is perpendicular to the plane of the pyranose ring of the hexose residue, and that a network of hydrogen bonds exists between the NH and C=O groups in neighboring molecules. An analogous *interchain* system of hydrogen bonds is likely to be present in chitan. Certainly, the characteristic vibrations associated with the amide groups in the latter are consistent with the presence of a hydrogen-bonded secondary amide (30, 31, 33), and the presence of a system of C=O · · · HN hydrogen bonds in a plane perpendicular to the plane of the pyranose ring is supported by a consideration of the molecular models.

The Chitin Bands at 1 626 and 1 656 cm^{-1}

In contrast to the spectrum of chitan, which has only one band in the C=O stretching (amide I) region, that of chitin contains bands at 1 626 and 1 656 cm^{-1} which have been the source of some disagreement. The band at higher frequency has previously (22–24) been attributed to the amide I vibration. On the other hand, the band at 1 626 cm^{-1} has been assigned to a C=N stretching vibration (22), an overtone or combination mode (23), an amide C=O group hydrogen-bonded to an OH group (21), or the C=O group of a rotational isomer of the aminoacetyl group (22), or has been completely ignored (25). The present evidence strongly indicates that these two bands are in fact both due to amide I vibrations, but correspond to two different classes of amide groups. This conclusion is supported by the following observations. (*a*) Chitan has only one band, that at 1 626 cm^{-1}, and crystalline *N*-acetylglucosamine and *N*-acetylmannosamine also have a single amide I band at very nearly the same frequency. (*b*) Treatment of chitan with lithium thiocyanate

and with other reagents causes a simultaneous appearance of the new band at 1 656 cm^{-1}, and a decrease in the intensity at 1 626 cm^{-1}. (*c*) Reprecipitation of chitin from hydrochloric acid causes an intensification of the band at 1 656 cm^{-1}, with a corresponding decrease at 1 626 cm^{-1}. (*d*) The band at 1 626 cm^{-1} has been observed to disappear more rapidly than does the band at 1 656 cm^{-1} on progressive deacetylation and during nitration (21). (*e*) The two bands differ in their relative intensities and dichroism in different preparations of chitin (10, 21–24, 34).

It has been suggested that the band at 1 656 cm^{-1} in chitin may be due to water of hydration (34). However, we have found that prolonged drying at 110° under vacuum has no effect whatsoever on the intensity of this band in samples of crustacean chitin or of lithium thiocyanate treated chitan. The reported diminution of this band upon partial deuteration of chitin (34) was reproduced in our laboratory, but may correspond to the usual decrease in the frequency of an amide I band upon deuteration (31, 33). There was certainly no appearance of the corresponding bands of HDO near 1 450 cm^{-1} and of D_2O near 1 200 cm^{-1} as deuteration proceeded. Thus the band at 1 656 cm^{-1} cannot be due to water of hydration.

The amide I vibrations of neighboring amide groups within a unit cell are often strongly coupled, in which case the coupled vibrations may be removed as much as 20 cm^{-1} from the frequency of the uncoupled vibrations (35–37). It is thus possible that the band at 1 626 cm^{-1} in chitan (as well as the band at 1 626 cm^{-1} in chitin, at 1 626 cm^{-1} in crystalline *N*-acetylglucosamine, and at 1 623 cm^{-1} in crystalline *N*-acetylmannosamine) may represent one of two coupled vibrations of the unit cell, the other vibration being infrared inactive. The band at 1 656 cm^{-1} in chitin may represent the uncoupled vibration in the vicinity of "missing" *N*-acetyl groups or in the noncrystalline or less-regular regions of the sample. This would certainly explain the variation of the ratio of intensities of the 1 656 and 1 626 cm^{-1} bands in chitin and the absence of the 1 656 cm^{-1} band in chitan.

We have also observed that *N*-acetylglucosamine and *N*-acetylmannosamine in the vitreous form have a single broad amide I band at about 1 640 cm^{-1}, some 14 to 17 cm^{-1} higher than the corresponding sharp band in the spectra of the crystalline form of these compounds. The 1 640 cm^{-1} band is probably due to uncoupled amide I vibrations in these compounds. The magnitude of the coupling constants observed in our compounds (30 cm^{-1} for chitin, 14 cm^{-1} for *N*-acetylglucosamine, and 17 cm^{-1} for *N*-acetylmannosamine) agrees with the values calculated for the amide I vibrations in polyglycine (18 cm^{-1} (38)), nylon (11 cm^{-1} (37)), and horsehair keratin (13 cm^{-1} (37)).

Whether the above explanation of the nature of the two amide I bands in chitin is correct, the two bands do appear to correspond to two distinct classes of amide groups in chitin, originating in distinct structural regions which may differ in their degree of order and which need not both contribute to the X-ray diffraction pattern of chitin.

The 840–890 cm^{-1} Region

It has been claimed that the frequency of the deformation mode of an anomeric axial (891 ± 7 cm^{-1}) or equatorial (844 ± 8 cm^{-1}) CH can be used to characterize the configuration at the anomeric center of the glycopyranose residues (39–42). Since chitan absorbs at 889 cm^{-1}, this empirical correlation would indicate that the sugar residues in this polysaccharide have a β-configuration at the anomeric center. However, during deuterium exchange studies on chitan it was observed that progressive substitution of the hydrogen atoms of the hydroxyl groups by deuterium resulted in the gradual disappearance of the band at 889 cm^{-1}, with the simultaneous appearance of a band at 843 cm^{-1}. Similar results were also obtained on deuteration of chitin. Since the isotope exchange does not

involve a change in the macrostructure of chitan, it is clear that one or both of the modes of vibration associated with the two bands must contain a contribution from the motion of the hydroxyl groups at C-3 or C-6 in the repeating unit of the polysaccharide. It should be noted that the band at 893 cm^{-1}, on deuteration, actually moved to a position claimed to be characteristic of an α- rather than a β-configuration at the anomeric center. A vibrational mode which is sensitive to change at other sites in the molecule does not, in our opinion, constitute reliable evidence for assigning the configuration at C-1 in a glycopyranose unit. Consequently, the above empirical correlation should be used only if both anomers are analyzed, and even then the evidence for configuration should be accepted with reservation in the absence of other supporting evidence.

Effect of Boiling on Chitan

When chitan is immersed in water at 100° for several hours or at 90° for several days, it is transformed into a material having an infrared spectrum different from those of chitan and chitin. The sharp absorption bands in the spectrum are still characteristic of a crystalline rather than an amorphous material. The spectrum of the boiled material differs from that of chitan by having an additional band in the OH stretching region at 3 400 cm^{-1} (possibly the antisymmetric stretching vibration of water molecules), two bands in the carbonyl stretching region at 1 645 and 1 664 cm^{-1}, and two bands in the NH stretching region at 3 295 and 3 337 cm^{-1}, as well as by the doubling of some other bands present in the spectrum of chitan. On prolonged heating at 110° and 10^{-3} Torr, the material reverts to the original chitan structure. Consequently, the new material is probably a hydrate.

State of Chitin in Nature

The methods employed in the past for the isolation of arthropod chitin have generally included boiling with aqueous acids and alkalis (10, 21–25, 34, 43, 44). The present results indicate that even much less drastic treatment, such as boiling in pure water, may produce extensive changes. The macrostructure of chitin, as previously isolated (21–27), may therefore be an artifact formed in the process of isolation. In particular, the so-called α-, β-, and γ-types of chitin, isolated from some organisms and reported to have different X-ray diffraction patterns and infrared spectra (34, 43, 44), may be unrelated to the native state of chitin in these organisms. Certainly, until samples of chitin are isolated and purified by milder (e.g. enzymatic) procedures, the state of chitin in arthropods and elsewhere in nature must be considered to be uncertain. It is very likely that crystalline chitan may be present in many other organisms in addition to the two genera of diatoms (5, 6) in which it has so far been found.

ACKNOWLEDGMENTS

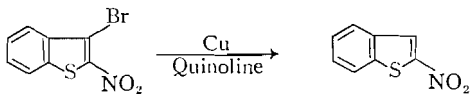
A STUDY OF THE SUBSTITUTION REACTIONS OF BENZO[*b*]THIOPHENE AND ITS DERIVATIVES

GERRIT VAN ZYL, C. J. BREDEWEG, R. H. RYNBRANDT, AND D. C. NECKERS
Department of Chemistry, Hope College, Holland, Michigan

Received April 13, 1966

ABSTRACT

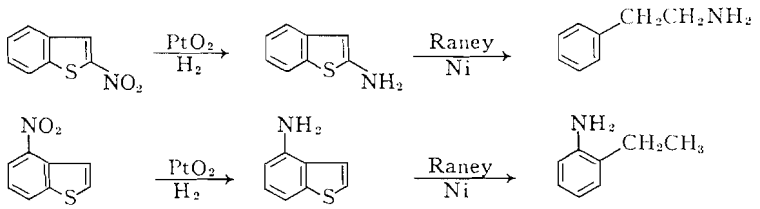


The nitration, halogenation, and amination reactions of benzo[*b*]thiophene and some of its derivatives are reported. Several new benzo[*b*]thiophenes have been prepared and directional influences of groups in the thiophene portion of the nucleus confirmed.

In a continuation of our interest in substitution reactions of benzo[*b*]thiophene and its derivatives, we have reinvestigated the isomer distribution in the nitration and halogenation of benzo[*b*]thiophene. It was of interest to study the orientation effects in reactions of electrophilic reagents with benzo[*b*]thiophene derivatives which were substituted on the thiophene portion of the benzo[*b*]thiophene ring system.

RESULTS AND DISCUSSION

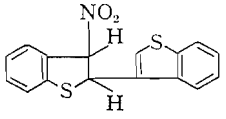
Nitration of Benzo[b]thiophene



The nitration of benzo[*b*]thiophene (1–8) has been reported to give 3-nitrobenzo[*b*]-thiophene. No other mononitro derivatives have been isolated. Recently, an infrared study (8) suggested that the nitration reaction mixture contained about 61% 3-nitrobenzo[*b*]thiophene and 16% 5-nitrobenzo[*b*]thiophene. The 2-nitro derivative was also assumed to be present in the nitration mixture (9, 10). Since 2-nitrobenzo[*b*]thiophene has not been characterized previously, its synthesis was necessary to establish its presence in the nitration mixture. 2-Nitrobenzo[*b*]thiophene was prepared by an unambiguous synthesis involving a copper–quinoline dehalogenation (11) of 3-bromo-2-nitrobenzo[*b*]-thiophene (eq. [1]).

[1] 

The nitration of benzo[*b*]thiophene with fuming nitric acid – acetic acid mixtures at 60–70° results in the formation of mononitrated benzo[*b*]thiophene (85% yield). The mixture was shown to contain 2-, 3-, and 4-nitrobenzo[*b*]thiophene. Infrared analysis of the reaction mixture indicated that the products included 10–15% 2-nitrobenzo[*b*]thiophene, 60–65% 3-nitrobenzo[*b*]thiophene, and 20–30% of other components, mainly 4-nitrobenzo[*b*]thiophene.



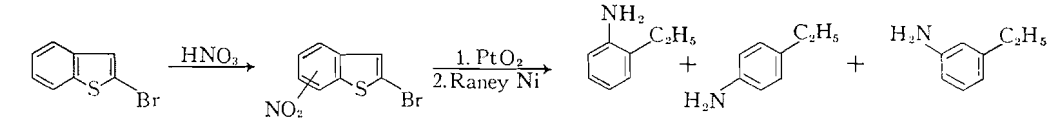
The presence of 4- and 2-nitrobenzo[*b*]thiophene in the nitration mixture was confirmed by chemical degradation. Thus, the nitration mixture was catalytically reduced over platinum oxide, followed by Raney nickel desulfurization, to give a mixture of aromatic amines including 2-phenylethylamine and *o*-aminoethylbenzene (eq. [2]).

Although 3-nitrobenzo[*b*]thiophene is also known to be in the nitration mixture, none of the corresponding degradation product, α-phenylethylamine, was observed. The reduction product of 3-nitrobenzo[*b*]thiophene, 3-aminobenzo[*b*]thiophene, reportedly

[2] 

cannot be distilled (2, 12), and is too unstable to be isolated in the pure form (3, 13, 14). No evidence was obtained for the presence of 5-nitrobenzo[*b*]thiophene or other isomers in the nitration mixture.

Optimum yields of the 3-nitrobenzo[*b*]thiophene were obtained when the nitration of benzo[*b*]thiophene was carried out above room temperature. At lower temperatures the formation of I, an unstable intermediate observed earlier by Komppa (3), was competitive with 3-nitrobenzo[*b*]thiophene formation.



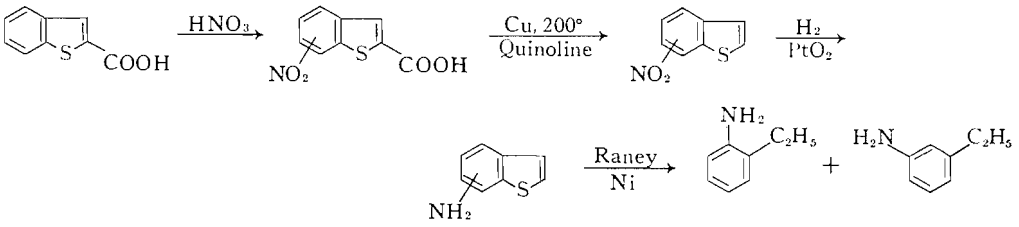
I

3-Nitrobenzo[*b*]thiophene undergoes no further nitration with fuming nitric acid and glacial acetic acid at 105°. Therefore, the possibility of the presence of dinitro products in the nitration mixture is doubtful. This is substantiated by the fact that no residue remained after the distillation of the mononitro products from the reaction mixture of nitric acid and benzo[*b*]thiophene at 60–70°.

Nitration of 2- and 3-Bromobenzo[b]thiophene

Although the nitration of 3-bromobenzo[*b*]thiophene occurs with preferential attack at the 2 position of the thiophene nucleus,[1] the nitration of 2-bromobenzo[*b*]thiophene yields several products. Vapor-phase chromatographic analysis, after dehalogenation, reduction, and desulfurization, confirmed the presence of *o*-aminoethylbenzene, *p*-aminoethylbenzene, and *m*-aminoethylbenzene. These products result from 4-nitro-2-bromobenzo[*b*]thiophene, 6-nitro-2-bromobenzo[*b*]thiophene, and 5(or 7)-nitro-2-bromobenzo[*b*]thiophene, respectively. Although no α-aminoethylbenzene was found, this does not prove that 3-nitro-2-bromobenzo[*b*]thiophene was not formed, because of the possible instability of the intermediate amino derivative mentioned previously (eq. [3]).

[3] 



From the nitration mixture of 2-bromobenzo[*b*]thiophene, three distinct mononitro-2-bromobenzo[*b*]thiophenes were isolated. After debromination of the nitration mixture (11) one of the isolated compounds had a melting point corresponding to that of 4-nitrobenzo[*b*]thiophene. This fact further supports the postulate that 4-nitro-2-bromobenzo[*b*]thiophene was one of the original nitration products.

[1]*Reference 3 reports the 3-bromo-2-nitro derivative, but the 3-bromo derivative, which is a liquid, is incorrectly listed as a solid melting at 146–156°.*

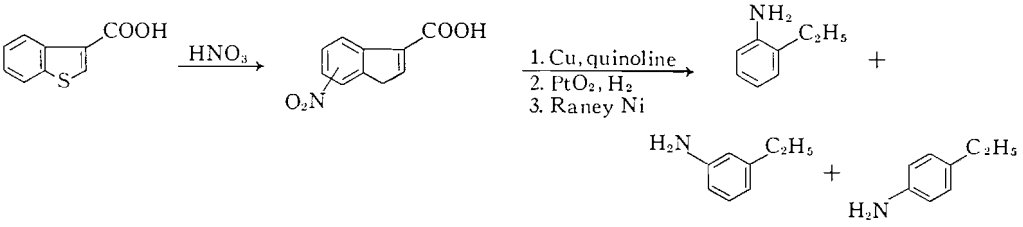
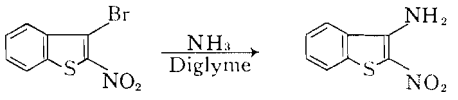
For personal use only.



Nitration of 2- and 3-Benzo[b]thiophenecarboxylic Acids

Nitration of benzo[*b*]thiophene-2-carboxylic acid also produced a mixture of products. Structural elucidation was effected by decarboxylation to the corresponding nitrobenzo-[*b*]thiophenes followed by reduction and desulfurization as previously described (eq. [4]).

[4] 



The *o*- and *m*-aminoethylbenzenes which were obtained correspond to 4-nitrobenzo[*b*]-thiophene-2-carboxylic acid and either 5- or 7- (or a mixture of both) nitrobenzo[*b*]thiophene-2-carboxylic acid. No *p*-aminoethylbenzene was found. Again, the 3-nitrobenzo-[*b*]thiophene-2-carboxylic acid cannot be eliminated, because of the unstable intermediate, 3-aminobenzo[*b*]thiophene.

Nitration of benzo[*b*]thiophene-3-carboxylic acid also led to a mixture of mononitro derivatives. By the decarboxylation, reduction, and desulfurization technique previously outlined, *o*-aminoethylbenzene was obtained as the major product. Minor quantities of *m*- and *p*-aminoethylbenzene, corresponding to 4-nitro-, 5- or 7-nitro-, and 6-nitrobenzo[*b*]thiophene-3-carboxylic acid, were also obtained (eq. [5]).

[5] 

Preparation of Amino Derivatives of 2-Nitrobenzo[b]thiophene

Heating 3-bromo-2-nitrobenzo[*b*]thiophene in diglyme with anhydrous ammonia gives 3-amino-2-nitrobenzo[*b*]thiophene by a simple aromatic nucleophilic substitution reaction (eq. [6]).

[6] 

3-Amino-2-nitrobenzo[*b*]thiophene was shown by its infrared spectrum to exist only in the tautomeric amino form. Recent reports indicate that 2-aminobenzo[*b*]thiophene also exists in the amino form (15). In addition to the known aminobenzo[*b*]thiophenes (16), 3-diethylamino and 3-phenylamino derivatives were also prepared by heating 3-bromo-2-nitrobenzo[*b*]thiophene with diethylamine and aniline, respectively.

Halogenation of Benzo[b]thiophene

Although the chlorination (3, 17, 18), bromination (3, 4, 19–22), and iodination (23–25) of benzo[*b*]thiophene have been reported, no isomer distributions are known. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the chlorination and bromination of benzo[*b*]thiophene, we observed the formation of small quantities of 2-substituted and disubstituted products. Substitution in the 3 position is predominant. In the iodination of benzo[*b*]thiophene, no evidence for any 2-substitution or disubstitution products was obtained. Table I lists the isomer distributions obtained upon halogenation of benzo[*b*]thiophene.

TABLE I

Halogenation distribution products of benzo[*b*]thiophene

Halogen	2-Substitution (%)	3-Substitution (%)	2,3-Disubstitution (%)
Chlorine	3	69	28
Bromine	3	87	10
Iodine	0	100	0

EXPERIMENTAL[2]

Preparation of Mononitrobenzo[b]thiophenes

To a heated (60–70°) solution of 50 ml acetic acid and 12 ml fuming nitric acid was added dropwise, with stirring, 15 g (0.11 mole) benzo[*b*]thiophene which had been diluted with an equal volume of acetic acid. After the addition of the nitric acid solution was complete, the reaction mixture was stirred for an additional 2 h at 60–70° and then poured into ice water. The oily layer was extracted with chloroform, neutralized with an aqueous solution of sodium bicarbonate, and dried over anhydrous magnesium sulfate. An 85% yield of yellow mononitrobenzo[*b*]thiophenes was obtained upon distillation at 105–110° and 0.1 mm.

Preparation of Aminobenzo[b]thiophenes

A solution of 17 g (0.09 mole) of the mononitration mixture in 150 ml of acetone was reduced with 0.2 g of platinum oxide as catalyst in a Parr hydrogenation apparatus for 1 h at 50 p.s.i. hydrogen pressure. The reaction mixture was filtered and concentrated under vacuum. Vacuum distillation of the residue gave a mixture of aminobenzo[*b*]thiophenes; yield 11.9 g (81%), b.p. 110–115° at 0.2 mm.

Preparation of Aminoethylbenzenes

A mixture of 12 g (0.08 mole) of the aminobenzo[*b*]thiophenes, 800 ml of methanol, and 150 g of Raney nickel was refluxed for 0.5 h. After the Raney nickel was removed by filtration, the resulting filtrate was distilled *in vacuo* to give a mixture of aminoethylbenzenes; b.p. 49–53° at 0.1 mm. The aminoethylbenzenes were shown to consist of a mixture of 2-phenylethylamine and *o*-aminoethylbenzene in a ratio of about 2:1, as determined by vapor-phase chromatography with a 2 m Carbowax column.

Preparation of Mononitro-2-bromobenzo[b]thiophenes

A mixture of 5 ml of fuming nitric acid and 5 ml of acetic acid was added dropwise to a cooled (5–10°) solution of 5 g (0.02 mole) of 2-bromobenzo[*b*]thiophene in 20 ml of acetic anhydride. The reaction mixture was stirred for 2 h at room temperature and the resulting yellow solution poured into an ice–water mixture. After the yellow precipitate was washed with water and sodium carbonate solutions, 6 g of solid yellow product was obtained. From column chromatography with activated alumina, three mononitro-2-bromobenzo[*b*]thiophenes were obtained. They possessed the following melting points: 124.5–125°, 148°, and 164.0–164.5°.

Anal. Calcd. for $C_8H_4NO_2BrS$: C, 37.27; H, 1.56; S, 12.43; N, 5.43; Br, 30.97. Found:

Melting point	C	H	S	N	Br
124.5–125°	37.63	1.78	12.05	5.32	31.13
148°	37.17	1.71	12.05	5.17	30.69
164.0–164.5°	37.33	1.75	12.60	5.31	31.03

Debromination of the Nitration Products of 2-Bromo[b]thiophene

A mixture of 10 g of the nitration product of 2-bromo-[*b*]thiophene, 3.3 g of copper bronze powder, and 55 ml of quinoline was heated to 135° under a nitrogen atmosphere for 30 min. After the reaction mixture was cooled, dilute hydrochloric acid and benzene were added. The benzene layer was evaporated and the residue distilled at 0.1 mm. The resulting solid yellow material was chromatographed on activated alumina. A fraction melting at 85–86° was obtained (lit. (7, 26, 27) m.p. 84–85° and 88° for 4-nitrobenzo[*b*]thiophene).

[2]*All melting points are uncorrected. Analyses were performed by Schwarzkopf Microanalytical Laboratory. Infrared spectra were obtained with a Perkin–Elmer model 137 Infracord. Vapor-phase chromatographic analyses were performed with a Burrell model K-2 chromatograph equipped with thermal conductivity detectors.*

For personal use only.

Preparation of Aminoethylbenzenes from Mononitro-2-bromobenzo[b]thiophenes

Reduction and desulfurization of the mononitration products of 2-bromobenzo[*b*]thiophene were carried out under conditions similar to those used for the mononitration products of benzo[*b*]thiophene. Vapor-phase chromatographic analysis of the products indicated the presence of *o*-aminoethylbenzene, *p*-aminoethylbenzene, and *m*-aminoethylbenzene by comparison of their retention times with those of known samples. No α-aminoethylbenzene was observed.

Nitration of 3-Bromobenzo[b]thiophene

A solution of 23 ml of fuming nitric acid and 23 ml of acetic acid was added dropwise, with stirring, to a cooled (5–10°) mixture of 20 g (0.095 mole) of 3-bromobenzo[*b*]thiophene and 80 ml of acetic anhydride. The reaction mixture was stirred for 1 h and poured onto ice. The yellow solid was recrystallized from ethanol and sublimed, m.p. 164–165° (4).

When a mixture of 3-bromo-2-nitrobenzo[*b*]thiophene and 20% sodium hydroxide was refluxed, 3-hydroxy-2-nitrobenzo[*b*]thiophene was obtained, m.p. 104–105° (decomp.) (lit. (28) m.p. 104–105° (decomp.)).

Preparation of 2-Nitrobenzo[b]thiophene

A mixture of 6 g (0.02 mole) of 3-bromo-2-nitrobenzo[*b*]thiophene, 1.8 g of copper bronze powder, and 30 ml of quinoline was vigorously stirred under a nitrogen atmosphere, gradually heated to 150°, and maintained at that temperature for 45 min. The reaction mixture was then cooled, made acidic with dilute hydrochloric acid, and extracted with benzene. After the benzene was removed, the residue was distilled at 105° and 0.1 mm. After recrystallization from methanol and sublimation, the yellow crystals melted at 117°; yield 25%.

Anal. Calcd. for $C_8H_5NO_2S$: C, 53.62; H, 2.81; S, 17.89; N, 7.82. Found: C, 53.83; H, 2.98; S, 17.93; N, 7.85.

Preparation of Mononitrobenzo[b]thiophene-2-carboxylic Acids

To a cold (0–5°) solution of 10 g (0.055 mole) of benzo[*b*]thiophene-2-carboxylic acid (19, 29) in 75 ml of acetic anhydride was added 10 ml of fuming nitric acid in 10 ml of acetic acid. After the solution was stirred for 30 min at 0°, it was allowed to warm to room temperature; the stirring was continued for an additional 2½ h. The mixture was poured into ice water, filtered, and washed. A 68% yield of a yellow mixture of mononitrocarboxylic acids, m.p. 230–240°, was obtained.

Anal. Calcd. for $C_9H_5NSO_4$: N, 6.28; S, 14.35. Found: N, 6.56; S, 14.35.

Decarboxylation of the Mixture of Mononitrobenzo[b]thiophene-2-carboxylic Acids

A mixture of 10 g (0.045 mole) of the mononitrobenzo[*b*]thiophene-2-carboxylic acids (30, 31) was decarboxylated with 2.5 g of copper bronze powder and 50 ml of quinoline by heating it at 190° for 30 min in a nitrogen atmosphere. At the end of this period, the reaction mixture was poured into a mixture of 250 g of ice and 50 ml of concentrated hydrochloric acid. The resulting yellow precipitate was filtered off, dried, and distilled *in vacuo* to give 4 g (50% yield) of mononitrobenzo[*b*]thiophenes, b.p. 105–110° at 0.1 mm, m.p. 50–70°.

Anal. Calcd. for $C_8H_5NSO_2$: N, 7.82; S, 17.90. Found: N, 7.89; S, 17.80.

Reduction and Desulfurization of the Mixture of the Decarboxylation Products from the Mononitrobenzo[b]thiophene-2-carboxylic Acids

The reduction and desulfurization procedure for the mononitrobenzo[*b*]thiophenes was the same as that described earlier.

Nitration of Benzo[b]thiophene-3-carboxylic Acid

The nitration procedure for benzo[*b*]thiophene-3-carboxylic acid was the same as that used for benzo[*b*]-thiophene-2-carboxylic acid (32). A 75% overall yield of a mixture of mononitrobenzo[*b*]thiophene-3-carboxylic acids, m.p. 192–225°, was obtained.

Anal. Calcd. for $C_9H_5NSO_4$: N, 6.28; S, 14.35. Found: N, 6.38; S, 13.93.

Decarboxylation of the Nitration Products of Benzo[b]thiophene-2-carboxylic Acid

A 62% yield of a mixture of mononitrobenzo[*b*]thiophenes was obtained by a decarboxylation procedure analogous to that used for the nitration mixture of benzo[*b*]thiophene-2-carboxylic acid.

Anal. Calcd. for $C_8H_5NSO_2$: N, 7.82; S, 17.90. Found: N, 7.91; S, 18.00.

Reduction and Desulfurization of the Decarboxylation Products from the Mononitrobenzo[b]thiophene-3-carboxylic Acids

Catalytic reduction and Raney nickel desulfurization were carried out by the previously described techniques. A 60% yield of aminobenzo[*b*]thiophenes was obtained, b.p. 120–123° at 0.5–0.3 mm. A 52% yield of aminoethylbenzene resulted after desulfurization, b.p. 48–52° at 0.1 mm. The aminoethylbenzenes consisted of mostly *o*- and minor amounts of *m*- and *p*-aminoethylbenzenes.

Gas Chromatographic Analysis

A 2½ m glass column packed with 20% Carbowax 4000 on Chromosorb W was used in all cases. Identifications were made by comparison of peaks with those of authentic compounds under the same experimental conditions (150° and a helium flow rate of 90 ml/min). The compounds used for comparison, α-phenylethylamine, 2-phenylethylamine, *o*-aminoethylbenzene, and *p*-aminoethylbenzene, were commercially available. *m*-Aminoethylbenzene was prepared from *m*-nitroacetophenone.

3-Amino-2-nitrobenzo[b]thiophene

A mixture of 10 g (0.039 mole) of 3-bromo-2-nitrobenzo[*b*]thiophene and 100–150 ml of diglyme was heated to 120°, and dry ammonia was passed into the solution for 3 h. After the solution was added to ice water, the crude solid was filtered off and dried. The crude material, which melted near 200°, was chromatographed on grade 3 activated alumina, yielding yellowish-orange crystals, m.p. 218.0–218.5°.

Anal. Calcd. for $C_8H_6N_2O_2S$: C, 49.47; H, 3.11; N, 14.43; S, 16.51. Found: C, 49.53; H, 3.17; N, 14.70; S, 16.24.

3-Phenylamino-2-nitrobenzo[b]thiophene

A mixture of 1 g (3.9 mmoles) of 2-nitro-3-bromobenzo[*b*]thiophene and 1.8 g (19.4 mmoles) of aniline was heated for 15 min at 100°. Dilute hydrochloric acid was added and the resulting mixture was extracted with benzene. After the benzene was evaporated, the residue was recrystallized from a mixture of chloroform and ethanol, to give a quantitative yield of bright-orange needles, m.p. 210–211°.

Anal. Calcd. for $C_{14}H_{10}N_2O_2S$: C, 62.21; H, 3.73; S, 11.86; N, 10.35. Found: C, 62.11; H, 3.56; S, 11.90; N, 10.50.

3-Diethylamino-2-nitrobenzo[b]thiophene

The procedure was the same as that used for the preparation of 3-phenylamino-2-nitrobenzo[*b*]thiophene, except that diethylamine was used instead of aniline; yield quantitative, m.p. 54°.

Halogenation of Benzo[b]thiophene

Benzo[*b*]thiophene was chlorinated, brominated, and iodinated according to the procedures of Schlesinger and Mowry (17), Szmuszkovicz and Modest (21), and Gaertner (24), respectively. Vapor-phase chromatographic analysis of the reaction products was accomplished on a 7 ft column packed with 20% Carbowax 4000 on Chromosorb W. The retention times of the various halobenzo[*b*]thiophenes were determined with authentic samples, and these times were compared with those of the various components found in the halogenation mixture.

Preparation of 2-Chlorobenzo[b]thiophene

An ethereal solution of *n*-butyllithium was prepared by the gradual addition, with stirring, of 20.0 g (0.2 mole) of *n*-butyl chloride in 40 ml of anhydrous ether to 3.7 g (0.5 mole) of lithium ribbon suspended in 100 ml of anhydrous ether. One milliliter of *n*-butyl bromide was added as catalyst and the mixture was allowed to reflux for 1 h. The solution was then cooled to 0–5°, and 13.5 g (0.10 mole) of benzo[*b*]thiophene in 30 ml of ether was added with stirring. The mixture was kept at 0° for 1 h. Into the above solution was bubbled 7.1 g (0.10 mole) of chlorine gas, during which time the temperature was maintained between −30° and −20°. The ether solution was washed with 200 ml of water and dried, and the solvent was removed *in vacuo*. Distillation gave 5 g (30% conversion, 48% yield) of 2-chlorobenzo[*b*]thiophene, b.p. 60–70° at 0.1 mm, m.p. 34°.

Anal. Calcd. for C_8H_5SCl: C, 57.0; H, 2.97; S, 19.0; Cl, 21.0. Found: C, 56.7; H, 3.16; S, 18.2; Cl, 20.8.

The picrate melted at 97°. The 1-dioxide was prepared by hydrogen peroxide oxidation, m.p. 141–142° (lit. (17) m.p. 142–143°).

THE WATER-SOLUBLE POLYSACCHARIDES OF DERMATOPHYTES

V. GALACTOMANNANS II FROM TRICHOPHYTON GRANULOSUM, TRICHOPHYTON INTERDIGITALE, MICROSPORUM QUINCKEANUM, TRICHOPHYTON RUBRUM, AND TRICHOPHYTON SCHÖNLEINII[1]

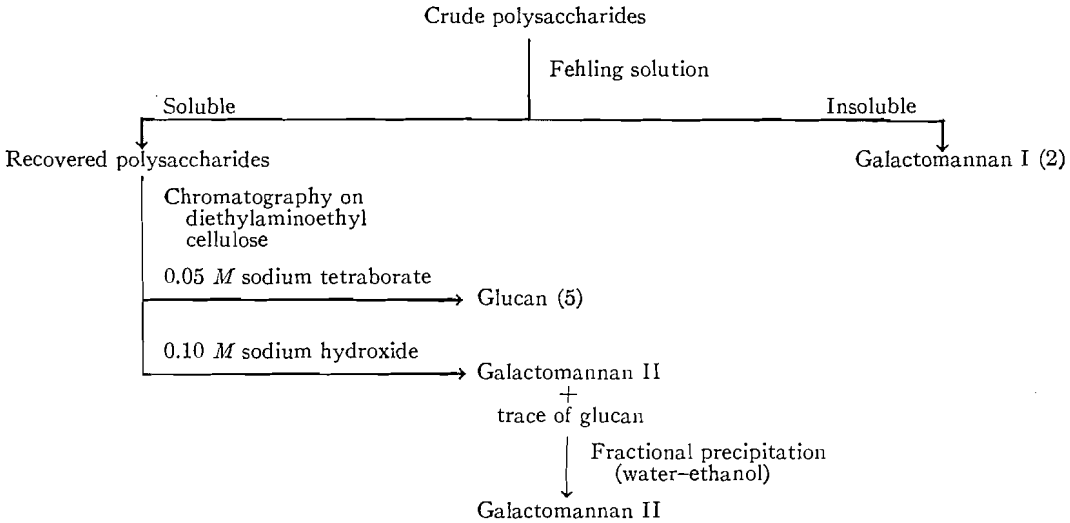
ABSTRACT

Polysaccharides obtained from each of the organisms designated in the title have been resolved into three groups: galactomannans I, galactomannans II, and glucans. The five galactomannans II were homogeneous under conditions of electrophoresis, and had positive specific rotations. Methylation and hydrolysis of the five galactomannans II yielded varying amounts of the following: 2,3,5,6-tetra-*O*-methyl-D-galactose, 2,3,4,6-tetra-*O*-methyl-D-mannose, 2,3,4-tri-*O*-methyl-D-mannose, 3,4,6-tri-*O*-methyl-D-mannose, 3,5-di-*O*-methyl-D-mannose, and 3,4-di-*O*-methyl-D-mannose. The galactomannans II were therefore very similar to each other in their gross structural features. The unbranched portions of the polysaccharides were formed by $1 \rightarrow 2$ and $1 \rightarrow 6$ linked α-D-mannopyranose units, with the former predominating. Branch points were formed through substitutions at the C-2 and C-6 positions of D-mannofuranose and D-mannopyranose, and branches were terminated by D-galactofuranose and D-mannopyranose units. The presence of $1 \rightarrow 2$ linked α-D-mannopyranose units in the linear portions of the galactomannans II constitutes a major structural difference between this group of polysaccharides and the galactomannans I. The two groups of galactomannans differ serologically.

It was reported earlier that each of five dermatophytes had a similar pattern of water-soluble polysaccharides, specifically, two galactomannans and a glucan (1). The previous paper in this series described the properties and gross structural features of one group of the galactomannans (called galactomannan I) (2).



The present paper describes the separation of the three groups of polysaccharides and reports the properties and gross structural features of the second group of galactomannans (called galactomannan II) from *Trichophyton granulosum* Sabouraud, 1909, *Trichophyton interdigitale* Priestley, 1917, *Microsporum quinckeanum* (Zopf) Guiart and Grigorakis, 1928, *Trichophyton rubrum* (Castellani) Sabouraud, 1911, and *Trichophyton schönleinii* (Lebert) Langeron and Milochevitch, 1930.

Crude polysaccharides were extracted from powdered cells of the organisms in yields of 5–10% as described previously for *T. granulosum* (3). The procedure was designed to yield polysaccharide preparations which were free of lipid and protein. The aim of this continuing program is to relate structures to serological properties in the polysaccharides from dermatophytes. The presence of any contaminating lipid or protein, bound or free, could interfere in the serological tests and cause difficulties in interpreting the results of structural studies.

The crude polysaccharides were resolved into two galactomannans and a glucan by the procedure shown in Reaction Scheme 1. Addition of Fehling solution to aqueous solutions of the crude polysaccharides precipitated galactomannans I as insoluble copper complexes (2). The polysaccharides which were soluble in Fehling solution were recovered and

[1]*Issued as N.R.C. No. 9108.*

resolved, by chromatography on diethylaminoethyl cellulose (4), into glucans and the second group of galactomannans (galactomannans II). The latter still contained traces of glucan, but fractional precipitation from aqueous solutions by addition of ethanol yielded homogeneous samples of galactomannans II. The properties and structures of the five glucans are described in the next paper in this series (5).

REACTION SCHEME 1. Separation of the polysaccharides of dermatophytes.

Table I shows the yields and some of the properties of the galactomannans II. This group of polysaccharides formed roughly the same proportion of the crude polysaccharides in each organism. The specific rotations were positive and, except for the galactomannan II of *M. quinckeanum*, were lower than the specific rotations of the galactomannans I (2). The amounts of D-galactose in galactomannans II (23–33%) were higher than in the galactomannans I (0–13%). The results of periodate oxidation were not included because the galactomannans II showed extensive overoxidation, probably because of the malondialdehyde structure resulting from periodate oxidation of terminal D-galactofuranose units. Extrapolated values could not be used because it was impossible to decide which portion of the curve (oxidant consumption plotted against time) should be extrapolated. The galactomannans II were indistinguishable by electrophoresis, having the same mobility in borate buffer.

The galactomannans II were methylated fully and then hydrolyzed to yield mixtures of D-mannose and D-galactose methyl ethers. These mixtures were analyzed by a combination of paper electrophoresis and gas–liquid and thin-layer chromatography, and the

TABLE I

Yields and properties of galactomannans II from dermatophytes

results are shown in Table II. The ratio of tetra- to tri- to di-*O*-methyl sugars was obtained by integration of the peaks on gas–liquid chromatograms and was checked by preparative thin-layer chromatography. The relative amounts of the two tetra-*O*-methyl sugars were determined by both gas–liquid and thin-layer chromatography. The amounts of 2,3,4- and 3,4,6-tri-*O*-methyl-D-mannoses in the tri-*O*-methyl fraction were determined by preparative paper electrophoresis. The di-*O*-methyl-D-mannoses were analyzed by gas–liquid chromatography. Except for the four minor di-*O*-methyl-D-mannoses, each compound was characterized by isolation of a crystalline derivative.

The results in Table II showed that the five galactomannans II were very similar in structure. Each one contained branch points formed primarily through substitutions at

2,3,5,6-Tetra-*O*-methyl-D-galactose	27.3	27.9	23.0	24.0	29.0
2,3,4,6-Tetra-*O*-methyl-D-mannose	7.4	2.1	6.7	2.7	7.5
2,3,4-Tri-*O*-methyl-D-mannose	17.6	22.0	15.6	19.2	14.9
3,4,6-Tri-*O*-methyl-D-mannose	24.4	25.7	35.6	29.3	26.6
3,5-Di-*O*-methyl-D-mannose	10.4	11.0	9.2	6.0	10.4
3,4-Di-*O*-methyl-D-mannose	6.8	7.1	5.5	13.3	7.0
Four di-*O*-methyl-D-mannoses*	6.1	4.2	5.3	5.5	4.7

*Each of these four di-*O*-methyl-D-mannoses amounted to less than 2% of the total mixture of *O*-methyl sugars. The amount were too small to permit identification.

the C-2 and C-6 positions of D-mannofuranose and D-mannopyranose units, giving rise to the 3,5- and 3,4-di-*O*-methyl-D-mannoses, respectively. Most of these branch points occurred at the D-mannofuranose units in each galactomannan II, except in that from *T. schönleinii*. The presence of 3,4,6- and 2,3,4-tri-*O*-methyl-D-mannoses showed that the unbranched portions of the polysaccharides were formed by $1 \rightarrow 2$ and $1 \rightarrow 6$ linkages, with the former predominating. D-Mannopyranose and D-galactofuranose units formed the nonreducing terminal units of the galactomannans II, as shown by the presence of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,5,6-tetra-*O*-methyl-D-galactose. The latter compound was the only derivative of D-galactose found in the hydrolysis products from the methylated galactomannans II, and showed that this sugar was present in the polysaccharide exclusively as furanosidic nonreducing end groups.

The simplest general structure that can be proposed for the galactomannans II is shown in Fig. 1. The basic chain consists of $1 \rightarrow 6$ and $1 \rightarrow 2$ linked α-D-mannopyranose units. The sequence of these linkages cannot be determined from the present evidence, but $1 \rightarrow 2$ linkages predominate in the unbranched portions of the polysaccharides and some of them must therefore occur consecutively. Similarly, the length and distribution of the side chains must remain unknown at this stage of the work.

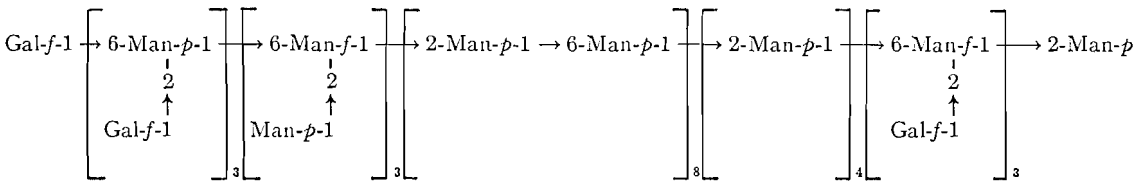

FIG. 1. General structure for galactomannans II.

For personal use only.

Like the galactomannans I (2, 3), the galactomannans II appear to be unique among naturally occurring polysaccharides. The two groups of galactomannans resemble each other in having D-galactofuranoside nonreducing end groups, but the quantity of these units is higher in the galactomannans II. Both groups of galactomannans also contain $1 \rightarrow 6$ linked α-D-mannopyranose units but in different amounts. However, in the galactomannans II, $1 \rightarrow 2$ linked α-D-mannopyranose units predominate in the linear portions of the polysaccharide, and no such units occurred in galactomannans I. This constitutes a major structural difference between the two groups and demonstrates that two different galactomannans were present. Because of this basic structural difference it would be impossible for one galactomannan to be converted into the other by inadvertent chemical modification (e.g. removal of the acid-labile D-galactofuranoside units) during extraction or fractionation.

Preliminary tests have shown that the two groups of galactomannans have different serological properties, undoubtedly because of the major structural difference described above. There are only slight differences between the galactomannans within each group, as revealed by the studies of gross structure reported here and in the previous part (2) of this series. If the galactomannans within a group prove to have different serological properties, then further studies on the length of side chains and sequence of linkages may be required to explain the serological differences on a structural basis.

EXPERIMENTAL

Paper chromatograms were run by the descending method with the following solvent systems (v/v): (A) pyridine – ethyl acetate – water (1:2.5:2.5) (upper phase), and (B) butanone saturated with water. Whatman 3 MM paper was used for paper electrophoresis (6) in 0.1 *M* sodium tetraborate at a potential gradient of 25 V/cm for 1.5 h. A Tiselius-type, Spinco model H apparatus was used for moving-boundary electrophoresis in 0.05 *M* borate buffer (7). A Pye argon chromatograph and an F and M model 500 chromatograph were used for gas–liquid chromatography (8); the column packings were (*a*) 10% Carbowax 6000 on Chromosorb W, 100–120 mesh, and (*b*) 15% polyphenyl ether on Gas Chrom A, 100–120 mesh. Thin-layer chromatograms were on silica gel G with benzene–acetone (1:1) as developing solvent (9). Preparative thin-layer chromatography was carried out as previously described (2). Sugars on paper chromatograms, electrophoretograms, and thin-layer templates were detected by the *p*-anisidine hydrochloride spray reagent (10). Solvents were evaporated at 35–40 °C under reduced pressure; melting points are corrected; specific rotations are equilibrium values unless otherwise specified.

Isolation of Crude Polysaccharides

The growth and harvesting of the organisms and the extraction of mixtures of crude polysaccharides have been described in earlier papers in this series (1, 3).

Separation of Polysaccharides

The polysaccharides from each organism were resolved into two galactomannans and a glucan according to the scheme shown in Reaction Scheme 1. The first step, precipitation of galactomannans I as their insoluble copper complexes, was described in detail in part IV of this series (2). The water washings from the precipitates were combined with the individual supernatants, and the cooled solutions were acidified with concentrated hydrochloric acid at such a rate that the temperature never rose above 10 °C. The clear solutions were diluted with methanol until precipitation was complete. The precipitates were allowed to settle and the supernatants were decanted and discarded. The precipitates were then redissolved in the minimum amount of water and the solutions were deionized by passage through columns of Rexyn-101 (H^+) and Duolite-A4 (OH^-) ion-exchange resins. The deionized solutions were concentrated to thin syrups, to which ethanol was then added until precipitation was complete. The precipitates were centrifuged, washed successively with ethanol and ether, and air-dried to yield the polysaccharides soluble in Fehling solution (Reaction Scheme 1).

The recovered polysaccharides were chromatographed on diethylaminoethyl cellulose (4) (6 g per run on a 29 × 9 cm column containing 240 g of diethylaminoethyl cellulose). The sample was applied to the column as a 10% solution in 0.01 *M* sodium tetraborate, and the column was washed with a further 1 l of the same buffer; the eluate gave a negative anthrone test for carbohydrate. The buffer was then changed to 0.05 *M* sodium tetraborate, which displaced a polysaccharide (fraction 1). Elution with the same buffer was continued until the eluate gave a negative anthrone test (ca. 2.5 l), and the eluent was then changed to 0.1 *M* sodium hydroxide. Approximately 3.5 l of the latter was required to elute all of the second polysaccharide fraction (fraction 2).

The solution containing fraction 1 was passed over Rexyn-101 (H^+) ion-exchange resin and evaporated to dryness. Boric acid was removed from the residue by repeated addition and evaporation of methanol. The polysaccharide residue was then dissolved in the minimum volume of water and the solution was poured into a 10-fold volume of ethanol. The precipitated polysaccharide was then dried by solvent exchange with ethanol and ether. Samples (5 mg) of this fraction from each organism were hydrolyzed by *N* hydrochloric acid at 100 °C in sealed tubes for 10 h. D-Glucose was the only sugar detectable in the hydrolysates by paper chromatography (solvent A) or paper electrophoresis. The glucans behaved as homogeneous polysaccharides on moving-boundary electrophoresis, each with the same mobility ($\mu = 3.1 \times 10^{-5}$ cm^2 V^{-1} s^{-1}). Part VI of this series (5) describes other properties of the glucans and the investigation of their structures.

The solution containing fraction 2 from the diethylaminoethyl cellulose chromatography was neutralized by passage over Rexyn-101 (H^+) ion-exchange resin and evaporated to a thin syrup. Ethanol was added until precipitation was complete; the precipitated polysaccharides were centrifuged and dried by solvent exchange with ethanol and ether. Small samples of this fraction from each organism were hydrolyzed as described above for the glucans. Paper chromatography (solvent A) showed the presence of D-galactose, D-mannose, and small amounts of D-glucose.

The polysaccharides from fraction 2 were fractionally precipitated from aqueous solution by the stepwise addition of ethanol (11). A typical fractionation was as follows. The polysaccharide (6 g) was stirred in water (600 ml) and the solution was then centrifuged to remove a small, insoluble fraction (0.36 g). The addition of ethanol to the clarified aqueous solution yielded precipitates at the following ethanol concentrations: 50% (0.80 g), 60% (0.98 g), 65% (0.90 g), 70% (2.1 g), and 85% (0.31 g); recovery, 5.45 g (91%). The fraction that was insoluble in water and the one precipitated by 50% ethanol yielded D-glucose and smaller amounts of D-galactose and D-mannose on hydrolysis. The fractions precipitated by higher concentrations of ethanol (60–85%) yielded only D-galactose and D-mannose on hydrolysis, and were combined to give the galactomannans II.

Properties of Galactomannans II

The yields, based on the percentage of crude polysaccharides, and specific rotations of the galactomannans II are given in Table I. Samples (ca. 5 mg) of each galactomannan II were hydrolyzed by *N* hydrochloric acid (1 ml) in sealed tubes at 100 °C for 10 h. Sugars in the hydrolysates were separated by paper chromatography (solvent A) and their relative amounts, shown in Table I, were determined by the phenol – sulfuric acid method (12). The enantiomorphic forms of the sugars were established by isolation of crystalline derivatives of their *O*-methyl ethers as described below.

Galactomannans II were oxidized by periodate as described previously for the galactomannans I (2). Periodate was determined spectrophotometrically (13), and formic acid was determined by titration at the end of the oxidation. The following data indicated that extensive overoxidation occurred.

	Periodate consumed[2]					Formic acid produced[2]
Galactomannan II	2 h	10 h	18 h	24 h	48 h	
T. granulosum	0.72	1.33	1.42	1.51	—	0.41
T. interdigitale	1.34	1.52	1.68	1.80	1.92	1.04
M. quinckeanum	1.22	1.36	1.46	1.52	1.68	0.68
T. rubrum	1.15	1.34	1.45	1.52	1.76	0.68
T. schönleinii	1.19	1.37	1.54	1.66	1.91	0.63

Each galactomannan II gave a single, sharp symmetrical peak on moving-boundary electrophoresis in 0.05 *M* sodium tetraborate (electrophoretic mobility = 8.1×10^{-5} cm^2 V^{-1} s^{-1}). The galactomannans II also gave identical infrared spectra.

Methylation of Galactomannans II

Samples of the galactomannans II were methylated, first by the Haworth procedure (14) and then by the method of Falconer and Adams (15). Recoveries and methoxyl contents were as follows (calcd. methoxyl, 45.6%).

Galactomannan II	Original sample (g)	Recovered from methylation (g)	Methoxyl (%)
T. granulosum	0.50	0.28	45.2
T. interdigitale	2.60	1.48	42.8
M. quinckeanum	2.00	1.12	44.4
T. rubrum	2.00	1.30	45.5
T. schönleinii	1.97	1.30	43.3

These methylated galactomannans II showed no hydroxyl absorption in the infrared and had degrees of polymerization of 45–50, as determined by osmometry in chloroform solution with a Mechrolab vapor-pressure osmometer.

[2]*In moles per mole anhydrohexose.*

Hydrolysis Products from Methylated Galactomannans II

(i) Quantitative Estimation

The methylated galactomannans II were each hydrolyzed by sulfuric acid under conditions least likely to cause degradation or demethylation (16). A small portion (ca. 50 mg) of each mixture of hydrolysis products was boiled under reflux in 2% methanolic hydrogen chloride (2 ml) for 6 h. The methanolysates were neutralized by Duolite-A4 ion-exchange resin and then examined by gas–liquid chromatography (columns *a* and *b*). The following products were detected (with retention volumes relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside): column *a* (175 °C)—methyl tetra-*O*-methyl hexosides (1.00, 1.26); methyl tri-*O*-methyl mannosides (2.32, 2.82); methyl di-*O*-methyl mannosides (3.61, 5.33, 7.58, 9.32, 10.9, 13.7); column *b* (175 °C)—methyl 2,3,5,6-tetra-*O*-methyl-α,β-D-galactosides (0.94); methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside (1.00); methyl tri-*O*-methyl mannosides (1.29, 1.50); methyl di-*O*-methyl mannosides (1.79, 2.11). Quantitative results were obtained by triangulation of the peaks on the gas–liquid chromatograms; the separation on column *a* provided the relative amounts of the methyl di-*O*-methyl mannosides, in which there were two major components: those with retention volumes of 7.58 and 13.7. Each of the other methyl di-*O*-methyl-D-mannosides amounted to less than 2% of the total mixture of methylated sugars. The separation on column *b* gave the ratio of di- to tri- to tetra-*O*-methyl-D-mannose methyl glycosides, and also permitted estimation of the methyl tetra-*O*-methyl-D-galactosides. Preparative thin-layer chromatography of the hydrolysates gave the same separation as column *b* and provided (by weight) the following check on the quantitative results for one of the mixtures; the others gave similar results.

	mole %	
Compound	Thin-layer chromatography	Gas–liquid chromatography
2,3,5,6-Tetra-*O*-methyl-D-galactose	29.7	28.3
2,3,4,6-Tetra-*O*-methyl-D-mannose	7.8	7.2
Tri-*O*-methyl-D-mannoses	40.5	42.5
Di-*O*-methyl-D-mannoses	22.2	22.0

The tri-*O*-methyl fraction contained two compounds which were not separable by paper or thin-layer chromatography or by gas–liquid chromatography of their methyl glycosides. However, the relative amounts of 2,3,4- and 3,4,6-tri-*O*-methyl-D-mannoses in the tri-*O*-methyl fractions were determined by the amounts recovered from preparative paper electrophoresis as described below. The quantitative results are summarized in Table II.

(ii) Isolation and Identification

The methylated sugars in each of the five mixtures were isolated and characterized by the same procedure. The mixtures of *O*-methyl sugars from hydrolysis of the methylated galactomannans II were resolved by preparative thin-layer chromatography to give the following fractions, in order of greatest mobility.

Fraction I.—The syrupy product gave a single spot on paper chromatography (solvent B) and a grey color with the spray reagent. Oxidation by bromine water yielded a syrupy lactone, which was converted into an amide in methanol saturated with ammonia. The amide crystallized spontaneously after evaporation of the solvent and was recrystallized from butanone to yield 2,3,5,6-tetra-*O*-methyl-D-galactonamide (17), m.p. 155–156 °C, $[\alpha]_D^{25}$ +6° (*c*, 3 in water).

Fraction II.—The syrupy product gave a single spot on paper chromatography (solvent B) and a red color with the spray reagent. A portion (ca. 5 mg) of the compound was boiled under reflux for 18 h in methanol containing Rexyn-101 (H^+) ion-exchange resin. The product had the same mobility on gas–liquid chromatography (column *b*) as methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside. The rest of fraction II was converted into its anilide, which was recrystallized from ethyl acetate – light petroleum to yield *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-mannosylamine (18), m.p. 145–146 °C.

Fraction III.—The syrup gave one spot on paper chromatography (solvent B) and its methanolysate gave a single peak on gas–liquid chromatography (columns *a* and *b*). Paper electrophoresis showed the presence of two compounds, one migrating and one non-migrating, which were separated by preparative paper electrophoresis. The sections of the electrophoretograms containing the two compounds were eluted with water; the eluates were deionized (Rexyn-101 and Duolite-A4) and evaporated to dryness to yield the migrating (fraction III*a*) and non-migrating (fraction III*b*) components. The amounts recovered from each of the five mixtures provided the ratios of the two tri-*O*-methyl-D-mannoses.

Fraction III*a* crystallized spontaneously; recrystallization from ether–hexane (2:1) yielded 3,4,6-tri-*O*-methyl-D-mannose (19), m.p. 104–106 °C, $[\alpha]_D^{25}$ +35° (*c*, 2.17 in methanol).

Fraction III*b* was oxidized by bromine water and the product was esterified by 2% methanolic hydrogen chloride. The methyl ester was converted into the amide by methanol saturated with ammonia, and the amide was recrystallized from butanone to yield 2,3,4-tri-*O*-methyl-D-mannonamide (20), m.p. 142–144 °C.

Fraction IV.—Gas–liquid chromatography of the methyl glycosides of this fraction showed the presence of six components, two of which were present in larger amounts than the other four (see Table II). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

two major components were isolated by preparative paper chromatography in solvent A, which yielded fraction IV*a*, R_G 0.88, and fraction IV*b*, R_G 0.77. The latter fraction showed a streak on the chromatogram probably caused by the other minor components, which were not resolved; the streak was not collected.

Fraction IV*a* gave a brown color on the chromatograms with the *p*-anisidine hydrochloride spray. On paper electrophoresis it gave a single spot of the same mobility (M_G 0.42) as authentic 3,4-di-*O*-methyl-D-mannose. After methanolysis fraction IV*a* gave a single peak on gas–liquid chromatography, with the same retention volume as methyl 3,4-di-*O*-methyl-α-D-mannoside. Oxidation of fraction IV*a* with 4 moles of periodate at room temperature for 10 h gave a product which had the same mobility and color reactions on paper chromatograms as 2,3-di-*O*-methyl-L-arabinose. The syrupy product crystallized when seeded with an authentic sample of 3,4-di-*O*-methyl-D-mannose (21). Recrystallized from ethyl acetate, it had m.p. 71–73 °C, unchanged on admixture with an authentic sample.

Fraction IV*b* crystallized spontaneously; recrystallization from ethyl acetate yielded 3,5-di-*O*-methyl-D-mannose (22), m.p. 126–127 °C, unchanged on admixture with an authentic sample.

Serological Tests

Antisera produced in rabbits to autoclaved mycelial suspensions of each of these dermatophytes were used for analysis of these polysaccharides. By immunodiffusion and immunoelectrophoretic analyses, galactomannans I and galactomannans II were shown to be serologically distinct polysaccharides.

ABSTRACT

Polysaccharides obtained from each of the organisms designated in the title have been resolved into three groups: galactomannans I, galactomannans II, and glucans. The five glucans were homogeneous under conditions of electrophoresis, and had identical electrophoretic mobilities and infrared spectra. Methylation and hydrolysis of the glucans yielded varying amounts of the following: 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,3,4-tri-*O*-methyl-D-glucose, 2,4,6-tri-*O*-methyl-D-glucose, and 2,4-di-*O*-methyl-D-glucose. The glucans were therefore branched polysaccharides, with branches formed by substitution at the C-3 and C-6 positions of D-glucopyranose units and terminated by D-glucopyranose units. The linear portions of the glucans contained $1 \rightarrow 6$ and $1 \rightarrow 3$ linkages but in varying amounts. These differences and some variation in the degrees of branching constituted the only dissimilarities detectable in the glucans by these structural studies.

Previous papers in this series have described the separation of three groups of polysaccharides from five dermatophytes: two galactomannans and a glucan (1,2). Structural studies on the galactomannans I have been reported (3,4), and the galactomannans II were described in part V of this series (2). The present paper describes the properties and gross structural features of the glucans from *Trichophyton granulosum* Sabouraud, 1909, *Trichophyton interdigitale* Priestley, 1917, *Microsporum quinckeanum* (Zopf) Guiart and Grigorakis, 1928, *Trichophyton rubrum* (Castellani) Sabouraud, 1911, and *Trichophyton schönleinii* (Lebert) Langeron and Milochevitch, 1930. A study of the glucan from *M. quinckeanum* was reported previously (1), and the results are included in the present paper to provide a full comparison of the glucans from the five organisms.

Mixtures of the three polysaccharides were extracted from powdered cells of the organisms as described previously (5), and separated into two galactomannans and glucans as reported in part V of this series (2).

Table I shows the yields and some of the properties of the glucans. The glucans were obtained in only 3–7% yields as compared with 30% for the galactomannans I (4) and 25% for the galactomannans II (2), and therefore constituted the smallest of the three groups of polysaccharides in the crude mixture. The specific rotations of the glucans showed considerable variation, the glucan from *T. granulosum* being singularly different in showing a positive value. The glucans showed no tendency to overoxidation by periodate; the values given for periodate consumption and formic acid production were constant over the period 24–42 h. The glucans were indistinguishable by electrophoresis; each one had the same mobility in borate buffer ($\mu = 3.1 \times 10^{-5}$ cm^2 V^{-1} s^{-1}).

TABLE I

Yields and properties of glucans from dermatophytes

Organism	Yield*	$[\alpha]_D$ (in water)	Periodate consumed†	Formic acid produced†
T. granulosum	6.5	+43°	1.54	0.72
T. interdigitale	5.0	−16°	1.46	0.76
M. quinckeanum	6.8	±0°	1.53	0.70
T. rubrum	2.8	−37°	1.12	0.52
T. schönleinii	4.0	−27°	1.50	0.67

*Percentage of crude polysaccharides.
†In moles per mole anhydroglucose unit.

The glucans were methylated fully and then hydrolyzed to yield mixtures of *O*-methyl-D-glucoses. These mixtures were analyzed by gas–liquid and paper chromatography to give the results shown in Table II. The ratio of tetra- to tri- to di-*O*-methyl-D-glucoses was determined by preparative paper chromatography; the relative amounts of the two isomers in the tri-*O*-methyl fraction were determined by gas–liquid chromatography of their methyl glucosides. Each of the *O*-methyl-D-glucoses was characterized by isolation of a crystalline derivative. The results showed that each glucan contained each of the structural features shown below and differed only in the relative amounts of them.

Thus, the glucans were branched polysaccharides, the branches occurring at the 3 and 6 positions of a D-glucopyranose unit (IV) and giving rise to the 2,4-di-*O*-methyl-D-glucose after methylation and hydrolysis. The branches were terminated by D-glucopyranose units (I), as shown by the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose. The linear portions of the glucans contained $1 \rightarrow 6$ (II) and $1 \rightarrow 3$ (III) linkages, as represented by 2,3,4- and 2,4,6-tri-*O*-methyl-D-glucose, respectively. However, the relative amounts of $1 \rightarrow 6$ and $1 \rightarrow 3$ linkages in the linear portions varied from one glucan to another. The ratios of $1 \rightarrow 6$ to $1 \rightarrow 3$ linkages in the different glucans were as follows: *T. granulosum*, 1:0.72; *T. interdigitale*, 1:0.91; *M. quinckeanum*, 1:0.38; *T. rubrum*, 1:4.1; *T. schönleinii*, 1:1.32. These differences and some variation in the degree of branching, as represented by the amount of 2,4-di-*O*-methyl-D-glucose, constituted the only dissimilarities detectable in the glucans by the methods used.

TABLE II

Hydrolysis products of methylated glucans

	mole %				
	T. granulosum	*T. interdigitale*	*M. quinckeanum*	*T. rubrum*	*T. schönleinii*
2,3,4,6-Tetra-*O*-methyl-D-glucose	21.0	12.2	10.2	16.8	15.8
2,3,4-Tri-*O*-methyl-D-glucose	34.9	40.5	57.7	13.1	30.1
2,4,6-Tri-*O*-methyl-D-glucose	25.1	37.2	22.2	53.4	39.7
2,4-Di-*O*-methyl-D-glucose	19.0	10.2	8.1	16.7	14.4

The observed values for periodate oxidation of the original glucan (Table I) were all higher by about 0.5 mole than the values calculated from the methylation data. This is difficult to explain; any degradation that might have occurred under the alkaline conditions of methylation would be expected to cleave the periodate-resistant $1 \rightarrow 3$ linked units in preference to those joined by $1 \rightarrow 6$ glycosidic bonds (6). Such a degradation would therefore give a product for which the calculated periodate consumption was higher than the observed values.

The structural units I–IV could be joined together in a number of ways, and variations in the sequence of linkages could occur in the different glucans. There may also be some variation in the relative amounts of α- and β-glucosidic bonds, as shown by the specific rotations of the glucans (Table I). From those values it would appear that the glucans from *T. granulosum* and *M. quinckeanum* contained a higher proportion of α-linkages than the other three glucans. The five glucans gave identical infrared spectra, but the bands in the range 960–730 cm^{-1}, reported to be indicative of anomeric configuration (7), were not resolved.

The glucans from these five dermatophytes differ from most glucans that have been isolated from other microorganisms. They are distinguished by their specific rotations from the highly dextrorotary bacterial dextrans (8) and from *pullulan*, a glucan from the yeast-like fungus *Pullularia pullulans* (9, 10). However, a β-glucan has also been isolated from cultures of *Pullularia pullulans* and shown to contain $1 \rightarrow 6$ and $1 \rightarrow 3$ linkages in a highly branched structure (11) similar to those of the glucans from dermatophytes. Glucans from species of *Agrobacteria* contain a preponderance of β-$1 \rightarrow 2$ linkages (12), and an intracellular glucan from *Brucella suis* was shown to have β-$1 \rightarrow 4$ or β-$1 \rightarrow 2$ linkages but no $1 \rightarrow 6$ glycosidic bonds (13). A glucan from the fungus *Polyporus betulinus* contained mainly $1 \rightarrow 3$ linkages, but small amounts of other linkages could not be excluded (14).

The glucans from dermatophytes resemble the glucans isolated from the yeasts *Saccharomyces cerevisiae* (15, 16) and *Candida albicans* (17), a glucan produced by the fungus *Claviceps purpurea* (18), and a glucan from another unidentified fungus (19), in containing $1 \rightarrow 3$ and $1 \rightarrow 6$ linkages. Differences occur only in the relative amounts of these two linkages and in the degrees of branching in the polysaccharides. The glucans from *Claviceps purpurea* (18) and from the unidentified fungus (19) were shown to have a basic chain of $1 \rightarrow 3$ linked D-glucopyranose units, with single unit branches of D-glucopyranose attached by $1 \rightarrow 6$ linkages. Further work is required to determine whether a similar arrangement of $1 \rightarrow 3$ and $1 \rightarrow 6$ linkages occurs in the glucans from dermatophytes.

EXPERIMENTAL

Paper chromatograms were run by the descending method with the following solvent systems (v/v): (A) pyridine – ethyl acetate – water (1:2.5:2.5) (upper phase), and (B) butanone saturated with water. Sugars were detected on chromatograms by the *p*-anisidine hydrochloride spray reagent (20). Whatman 3 MM paper was used for paper electrophoreses, which were run in 0.1 *M* sodium tetraborate at 750 V (potential gradient, 25 V/cm) and 25–40 mA for 1.5 h (21). A Pye argon chromatograph was used for gas–liquid chromatography (22); the column packing was 10% of neopentyl glycol sebacate on Gas Chrom Z (100–120 mesh), the column temperature was 165 °C, and the flow rate was 100 ml argon/min. Solvents were evaporated at 35–40 °C under reduced pressure; melting points are corrected; specific rotations are equilibrium values unless otherwise specified. R_G values represent movement relative to 2,3,4,6-tetra-*O*-methyl-D-glucose on paper chromatograms.

Isolation and Properties of Glucans

The organisms were cultured and polysaccharides were extracted from the dried mycelia as reported previously (5). The separation of the glucans from the two galactomannans was described in the preceding paper (2). Yields, based on crude polysaccharides, and specific rotations of the glucans are shown in Table

I. A Tiselius-type, Spinco model H apparatus was used for moving-boundary electrophoresis of the glucans in 0.05 *M* sodium tetraborate (23); each glucan gave a single, sharp symmetrical peak of mobility = 3.1 $\times 10^{-5}$ cm^2 V^{-1} s^{-1}. Hydrolysis of these glucans yielded D-glucose exclusively, as shown by paper chromatography (solvent A) and paper electrophoresis.

Periodate Oxidations

Samples (11–12 mg) of each glucan were dissolved in 0.015 *M* sodium periodate (10 ml) and stored in the dark at room temperature. At intervals aliquots (0.1 ml) were removed and diluted to 25 ml with water, and periodate was determined spectrophotometrically (24). Periodate consumptions reached the values given in Table I after 24 h and were unchanged after 42 h. The amount of formic acid was determined by titration of the remaining oxidation solutions to a phenolphthalein end point after destruction of the excess periodate by the addition of 2 drops of butan-1,3-diol.

Methylation

Glucans from the five dermatophytes were dissolved in water and reduced by potassium borohydride (50 mg) to protect them from alkaline degradation (6). The reduced glucans were then methylated, first by dimethyl sulfate and 40% sodium hydroxide (25), then by dimethyl sulfate and solid sodium hydroxide in tetrahydrofuran (26). Recoveries and methoxyl contents were as follows (calcd. methoxyl, 45.6%).

Organism	Glucan	Methylated glucan	Methoxyl (%)
T. granulosum	100 mg	83.7 mg	43.3
T. interdigitale	1.1 g	0.48 mg	41.8
M. quinckeanum (1)	3.5 g	1.8 g	44.3
T. rubrum	400 mg	175.5 mg	44.8
T. schönleinii	801 mg	240 mg	42.9

The methylated glucans showed only traces of hydroxyl absorption in the infrared.

Hydrolysis Products from Methylated Glucans

The methylated glucans were hydrolyzed by sulfuric acid under the conditions reported as causing minimum degradation and demethylation (27). Paper chromatography (solvent B) of the hydrolysate showed the presence of the following products: 2,3,4,6-tetra-*O*-methyl-D-glucose (R_G 1.00), 2,3,4-tri-*O*-methyl-D-glucose (R_G 0.70), 2,4,6-tri-*O*-methyl-D-glucose (R_G 0.60), 2,4-di-*O*-methyl-D-glucose (R_G 0.23). Small portions (ca. 5 mg) of each hydrolysate were boiled under reflux for 6 h with 2% methanolic hydrogen chloride (1 ml). Acid was removed by silver carbonate and the methyl glucosides in the solution were examined by gas–liquid chromatography to give the relative amounts of the two tri-*O*-methyl isomers. Complete analysis of the mixture could not be obtained with the open injection system because some of the methyl di-*O*-methyl glucosides were either preferentially adsorbed or destroyed. The closed injection apparatus used in the earlier investigation of the glucan from *M. quinckeanum* (1) was not available at this time.

The rest of the hydrolysates were resolved by preparative paper chromatography in solvent B; the amounts recovered gave the mole percentage compositions shown in Table II. The compounds were identified as follows.

2,3,4,6-Tetra-O-methyl-D-glucose

The compound crystallized and was recrystallized from *n*-hexane to yield 2,3,4,6-tetra-*O*-methyl-D-glucose (28), m.p. 93–94 °C, $[\alpha]_D^{24}$ +83° (*c*, 1 in water).

2,3,4-Tri-O-methyl-D-glucose

The syrupy product yielded a crystalline anilide that was recrystallized from ether to give *N*-phenyl-2,3,4-tri-*O*-methyl-D-glucosylamine (29), m.p. 144–145 °C, $[\alpha]_D^{24}$ +70° (*c*, 1 in ethanol).

2,4,6-Tri-O-methyl-D-glucose

This product crystallized spontaneously and was recrystallized from ether to yield 2,4,6-tri-*O*-methyl-D-glucose (30), m.p. 121–122 °C, $[\alpha]_D^{25}$ +71° (*c*, 1 in water).

2,4-Di-O-methyl-D-glucose

The syrupy product was boiled under reflux for 6 h with 2% methanolic hydrogen chloride. The resulting mixture of methyl 2,4-di-*O*-methyl-α,β-glucosides crystallized when seeded with a crystal of methyl 2,4-di-*O*-methyl-α-D-glucoside obtained previously (1). Recrystallization from ether yielded methyl 2,4-di-*O*-methyl-α-D-glucoside (31), m.p. 79–80 °C, $[\alpha]_D^{24}$ +160° (*c*, 0.3 in acetone).

SUBSTITUTIONS ÉLECTROPHILES EN SÉRIE NAPHTALÈNIQUE

III. SUR LE DI-*t*-BUTYL-2,7 NAPHTALÈNE[1]

LUCIEN ERICHOMOVITCH, MARCEL MÉNARD[2] ET FRANCIS L. CHUBB
Frank W. Horner Ltée, Montréal, Québec

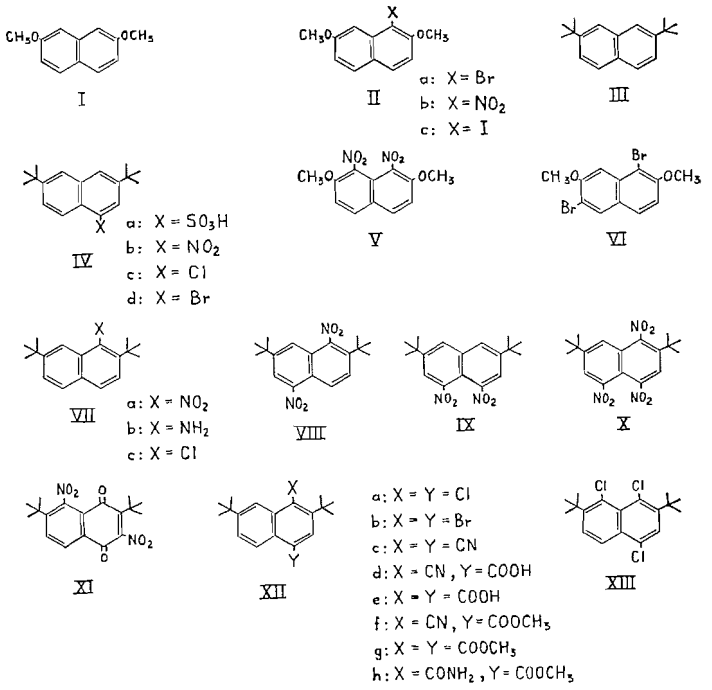
Reçu le 16 mai 1966

RÉSUMÉ

Les produits de réaction entre le di-*t*-butyl-2,7 naphtalène d'une part et l'acide nitrique, le brome, le chlorure de sulfuryle ou le chlorure d'iode d'autre part ont été examinés. La structure des produits obtenus a été établie grâce à la résonance magnétique nucléaire.

INTRODUCTION

Dans des travaux précédents (1, 2), il a été démontré que les réactions de monosubstitution sur le diméthoxy-2,7 naphtalène (I) conduisent aux dérivés du type II, alors que la sulfonation du di-*t*-butyl-2,7 naphtalène (III), qui est stériquement plus empêché, conduit au produit IV*a*. Un autre effet stérique a été noté au cours de ces travaux; en effet, alors que la dinitration du diméthoxy-2,7 naphtalène (I) conduit au dinitro-1,8 diméthoxy-2,7 naphtalène (V), la réaction de dibromuration pour sa part conduit au dibromo-1,6 diméthoxy-2,7 naphtalène (VI). Il s'avérait donc intéressant d'examiner la nature des produits de monosubstitution sur le di-*t*-butyl-2,7 naphtalène (III) et l'effet des substituants déjà présents sur les réactions de di- et de tri-substitution dans la série du di-*t*-butyl-2,7 naphtalène. Les résultats rapportés dans le présent travail auront donc trait aux réactions de nitration, chloruration, bromuration et iodation du di-*t*-butyl-2,7 naphtalène. De plus, certains dérivés des produits originaux de substitution seront aussi décrits.



RÉSULTATS

La mononitration de l'hydrocarbure III conduit à deux isomères, l'un nitré en position 1 (VII*a*) et l'autre nitré en position 4 (IV*b*). Les proportions relatives de chacun, telles que déterminées par résonance magnétique nucléaire sur l'huile du mélange réactionnel, seraient de 56% de produit VII*a* et 44% du produit IV*b*; une détermination par infrarouge utilisant les bandes à 837 et 826 cm^{-1} pour les nitro-1 (VII*a*) et nitro-4 (IV*b*) di-*t*-butyl-2,7 naphtalène, respectivement, conduisent à des conclusions semblables. Une nitration plus poussée du di-*t*-butyl-2,7 naphtalène (III) conduit à un mélange contenant les dinitro-1,5 (VIII), dinitro-4,5 (IX) et trinitro-1,4,5 (X) di-*t*-butyl-2,7 naphtalènes aux côtés de la dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4 (XI); en plus de ces produits, la chromatographie sur couche mince permet de détecter cinq autres produits qui sont présents en faible quantité et qui n'ont pas été isolés. Il est à noter que la nitration du nitro-4 di-*t*-butyl-2,7 naphtalène (IV*b*) conduit exclusivement aux dinitro-1,5 (VIII) et dinitro-4,5 (IX) di-*t*-butyl-2,7 naphtalènes, alors que la nitration du nitro-1 di-*t*-butyl-2,7

[1]*Les résultats rapportés dans cette communication sont extraits, en partie, du mémoire soumis par Yvon Pépin à la Faculté des Sciences de l'Université de Montréal, Montréal, en vue de l'obtention du grade de Maître ès Sciences (mars 1966).*

[2]*Adresse actuelle: Laboratoires Bristol du Canada, Candiac, Québec.*

naphtalène (VII*a*) conduit principalement au dinitro-1,5 di-*t*-butyl-2.7 naphtalène (VIII) et à la quinone dinitrée XI. La chromatographie sur couche mince permet dans chacun des cas de distinguer la présence des isomères à l'état de traces. Pour fins de comparaison, le nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*) a été réduit par l'étain et l'acide chlorhydrique en amino-1 di-*t*-butyl-2,7 naphtalène (VII*b*).

Lors de la chloruration du di-*t*-butyl-2,7 naphtalène (III) par 1 mole de chlorure de sulfuryle, un seul produit à savoir le chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*) a pu être isolé de l'huile provenant du mélange réactionnel. La dichloruration conduit aussi à un seul produit à savoir le dichloro-1,4 di-*t*-butyl-2,7 naphtalène (XII*a*); la réaction est toutefois assez délicate en ce sens que l'on est toujours en présence d'un mélange de monochloro-1 et de trichloro-1,4,8 di-*t*-butyl-2,7 naphtalène et qu'il est assez difficile d'arrêter la réaction au moment opportun. Quant à la trichloruration elle conduit au trichloro-1,4,8 di-*t*-butyl-2,7 naphtalène (XIII). D'autres produits seraient présents dans le mélange réactionnel mais n'ont pu être isolés.

Un essai d'iodation du di-*t*-butyl-2,7 naphtalène (III) par ICl ne conduit qu'au chloro-4 di-*t*-butyl-2,7 naphtalène (IV*c*). La chloruration de ce dérivé conduit au dichloro-1,4 di-*t*-butyl-2,7 naphtalène (XII*a*) obtenu précédemment.

La réaction du di-*t*-butyl-2,7 naphtalène (III) avec 1 mole de brome conduit exclusivement au bromo-4 di-*t*-butyl-2,7 naphtalène (IV*d*). Si des conditions réactionnelles plus énergiques sont utilisées, le dibromo-1,4 di-*t*-butyl-2,7 naphtalène (XII*b*) est isolé. La réaction de ce dérivé dibromé avec le cyanure cuivreux dans la diméthylformamide selon la méthode de Friedman et Schecter (3) conduit au dicyano-1,4 di-*t*-butyl-2,7 naphtalène (XII*c*), qui peut être hydrolysé par l'acide sulfurique pour conduire à un mélange d'acide cyano-1 di-*t*-butyl-2,7 naphtalène carboxylique-4 (XII*d*), d'acide di-*t*-butyl-2,7 naphtalène dicarboxylique-1,4 (XII*e*) et de leurs dérivés.

hydrogènes a aussi été utilisée; en effet, grâce à la méthode empirique de Wells et Alcorn (4), il est possible de prévoir quelles devraient être les positions d'absorption pour les différents hydrogènes aromatiques de ces molécules. Ces prédictions ainsi que les valeurs expérimentales observées sont résumées dans le Tableau II. La concordance entre les valeurs calculées et les valeurs expérimentales dans le cas des nitro-4 (IV*b*), dinitro-1,5 (IX) et trinitro-1,4,5 (X) di-*t*-butyl-2,7 naphtalènes est à la fois surprenante et convaincante. Cette méthode empirique échoue toutefois si elle est appliquée à l'isomère (VII*a*); l'explication plausible pour cette anomalie serait que, dans le nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*), le groupe nitro ne se trouve pas, comme dans les autres dérivés nitrés, dans le plan de la molécule à cause du groupe *t*-butyle en position 2. Il y aurait alors inhibition stérique de la résonance et l'effet du groupe nitro sur les hydrogènes aromatiques s'en trouverait pour autant diminué spécialement pour l'hydrogène en position 8, qui est maintenant retrouvé vers les champs élevés contrairement aux calculs qui le placent vers les champs les plus bas (Tableau II). Le déplacement de l'hydrogène en position 8 est aussi observé (2) dans le cas du nitro-1 diméthoxy-2,7 naphtalène (II*b*), et Wells et Alcorn (4) rapportent le même effet pour différents nitro-1 naphtalènes ayant un substituant alkyle en position 2. La réduction du groupe nitro en amine (composé VII*b*) ramène la bande due à l'hydrogène 8 vers les bas champs. Cependant, l'effet de déplacement de l'ensemble des pics disparaît aussi (Tableau II).

La structure du chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*) a été attribuée en se basant sur le fait que, dans le spectre de résonance magnétique nucléaire (r.m.n.) de ce composé, un système AB, avec constantes de couplage de 9 c.p.s., se retrouve superposé aux bandes attendues pour le système ABX des hydrogènes en position 5, 6 et 8. De même, dans le spectre r.m.n. du chloro-4 di-*t*-butyl-2,7 naphtalène (IV*c*), un système AB (J = 2 c.p.s.) est superposé aux bandes attendues pour le système ABX des hydrogènes en positions 5, 6 et 8. La structure du dichloro-1,4 di-*t*-butyl-2,7 naphtalène (XII*a*) est déduite du fait que les chloro-1 (VII*c*) et chloro-4 (IV*c*) di-*t*-butyl-2,7 naphtalènes conduisent au même dérivé dichloré; de plus, la présence dans le spectre r.m.n. de ce composé d'un pic sous forme de singulet suggère la présence de deux atomes de chlore attachés au même noyau. La présence dans le spectre r.m.n. du trichloro di-*t*-butyl-2,7 naphtalène (XIII) d'un singulet superposé aux bandes d'un système AB (J = 9 c.p.s.) n'est compatible qu'avec la présence des trois atomes de chlore dans les positions 1, 4 et 8. Les structures des bromo-4 (IV*d*) et dibromo-1,4 (XII*b*) di-*t*-butyl-2,7 naphtalènes ont été attribuées principalement à cause de la similitude très grande des spectres infrarouges de ces produits avec ceux des dérivés chlorés correspondants (IV*c* et XII*a*). Le

spectre r.m.n. du dibromo-1,4 di-*t*-butyl-2,7 naphtalène (XII*b*) est en accord avec la structure proposée. Les spectres r.m.n. du dicyano-1,4 di-*t*-butyl-2,7 naphtalène (XII*c*) et ses dérivés (XII*d* et XII*e*) obtenus à partir du dibromo-1,4 di-*t*-butyl-2,7 naphtalène (XII*b*) sont aussi en parfait accord avec les structures proposées.

2. Sur le mécanisme de formation des différents composés

Le premier fait important à noter est qu'alors que la chloruration de l'hydrocarbure III par SO_2Cl_2 ne conduit qu'au chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*) et que la nitration de III conduit aussi à des quantités importantes de nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*), les réactions de bromuration, sulfonation et chloruration par ICl ne conduisent qu'aux produits substitués en position 4 (IV*d*, IV*a* et IV*c*). Ces résultats indiqueraient que les intéractions stériques qui se développent entre certains réactifs et le groupe *t*-butyle peuvent déplacer le point d'attaque de la réaction de la position 1 vers la position 4 au fur et à mesure de l'augmentation de la grosseur du réactif.

Il est connu depuis longtemps (5) que la nitration du nitro-1 naphtalène conduit aux dinitro-1,8 et dinitro-1,5 naphtalènes. Par conséquent, la nitration du nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*) devrait conduire aux dinitro-1,5 (VIII) et dinitro-1,8 di-*t*-butyl-2,7 naphtalènes, alors que le nitro-4 di-*t*-butyl-2,7 naphtalène (IV*b*) devrait fournir les dinitro-1,5 (VIII) et dinitro-4,5 (IX) di-*t*-butyl-2,7 naphtalènes. Les résultats obtenus confirment ces prédictions en ce qui a trait à la formation des dinitro-1,5 (VIII) et dinitro-4,5 (IX) di-*t*-butyl-2,7 naphtalènes; toutefois, le dinitro-1,8 di-*t*-butyl-2,7 naphtalène ne semble pas se former, alors qu'une quantité appréciable de dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4 (XI) est isolée du mélange réactionnel de la nitration du nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*). L'examen de ces résultats expérimentaux suggère que la quinone XI se forme à partir du nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*) et non pas à partir du nitro-4 di-*t*-butyl-2,7 naphtalène (IV*b*).

La formation de trinitro-1,4,5 di-*t*-butyl-2,7 naphtalène (X) indique que l'introduction d'un deuxième groupe nitro en position α d'un groupement *t*-butyle s'avère très difficile.

Le chlore offrant un encombrement stérique plus petit que celui d'un groupe nitro, l'approche de l'halogène vers la position 1 serait facilitée. Il n'est donc pas surprenant d'obtenir en prédominance la substitution en position 1 du chlore au cours de la monochloruration par le chlorure de sulfuryle.

Lors de la réaction de ICl avec l'hydrocarbure III les conditions sont telles que l'iodation du noyau aromatique s'effectuerait mais l'iode dans le complex intermédiaire serait aussitôt substitué par un atome de chlore pour donner le chloro-4 di-*t*-butyl-2,7 naphtalène. Ce genre de réaction a déjà été observé à plusieurs reprises par Andrews et Keefer (6). Ces résultats pourraient aussi être rapprochés à ceux rapportés par Lambourne et Robertson (7); ces auteurs ont notés que, lorsque le centre réactionnel est adjacent à une position portant un substituant volumineux, des réactions de chloruration plutôt que d'iodation sont observées. L'iode réagissant en premier, la réaction serait orientée de la même manière que la réaction de bromuration à savoir vers la position 4, qui est stériquement moins encombrée que la position 1, et le dérivé chloré provenant du remplacement de l'iode par un atome de chlore aurait donc la structure du chloro-4 di-*t*-butyl-2,7 naphtalène (IV*c*). Cette explication permettrait de justifier ce qui aurait pu apparaître comme une anomalie à savoir que la réaction de chloruration de III par le chlorure de sulfuryle conduit à un dérivé chloré en position 1 (VII*c*), alors que la réaction de chloruration par ICl conduit au chloro-4 di-*t*-butyl-2,7 naphtalène (IV*c*).

Il est toutefois surprenant que la dichloruration se produise sur le même noyau

aromatique. Il est bien connu en effet que les halogènes désactivent le noyau sur lequel ils sont substitués et devraient orienter un deuxième substituant sur le noyau adjacent. Les effets mésomériques des groupes *t*-butyles étant très faibles et leur encombrement stérique grand, les positions 3, 6 et 8 du chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*) peuvent être considérées comme défavorisées par opposition aux positions 4 et 5. Le fait que le deuxième atome de chlore s'introduise en position 4 pourrait être expliqué en admettant que l'effet inductif du chlore en position 1 est faible comparé à son effet mésomérique. La position 4 serait alors relativement peu désactivée mais serait quand même fortement polarisée par le chlore en position 1, qui favoriserait ainsi une disubstitution dans les positions 1 et 4. Il est intéressant de noter ici qu'une deuxième substitution sur un noyau portant déjà un atome de brome a été notée (8) dans la dibromuration du diméthoxy-1,7 naphtalène. De plus, dans des travaux antérieurs certains auteurs (9) ont supposé que les réactions de substitutions sur des halogéno-1 naphtalènes conduiraient aux naphtalènes substitués dans les positions 1 et 4. Il est probable que d'autres résultats seront nécessaires pour expliquer complètement cette réactivité.

La monobromuration donnant exclusivement l'isomère en position 4 peut être expliquée par le fait que le brome est beaucoup plus volumineux que le chlore et l'approche vers la position 1 est alors plus difficile et le brome est alors orienté vers la position 4. Si des conditions énergiques sont utilisées pour effectuer la réaction, il est alors possible d'introduire un deuxième atome de brome en position 1. La disubstitution sur le même noyau pourrait être expliquée par les mêmes raisons invoquées précédemment pour la dichloruration. Les expériences effectuées avec le diméthoxy-2,7 naphtalène ont montré que deux bromes ne peuvent s'accommoder en positions péri à savoir 1, 8 et 4, 5. Il ne reste donc alors que les positions 3 et 6 de disponibles pour une réaction de trisubstitution. Ces positions étant des positions β et encombrées, il n'est pas surprenant qu'aucun tribromo ne se soit formé même dans les conditions de réaction poussées.

Parmi les effets stériques dus aux groupes *t*-butyles qui ont été notés dans le présent travail, il convient de mentionner la stabilité relativement grande de groupes cyano vis-à-vis les réactions d'hydrolyse. En effet, dans les conditions où l'hydrolyse d'un des deux groupes cyano s'effectue complètement, des quantités considérables de produits qui n'ont pas été hydrolysés sont présentes; il est suggéré que le groupe cyano en position 1, qui est soumis à l'encombrement stérique du groupe *t*-butyle, est celui qui résiste le mieux à l'hydrolyse.

Il est donc évident que les groupes *t*-butyles dans les positions 2 et 7 influençent d'une façon prépondérante sur le cours des réactions de substitution sur ce noyau aromatique et provoquent aussi un ralentissement des vitesses de réaction des groupes attachés en position α.

PARTIE EXPÉRIMENTALE

Les spectres infra-rouges ont été mesurés à l'aide d'un spectrophotomètre Beckman, modèle IR-8, à double réseau. Les spectres ultra-violets ont été mesurés dans l'éthanol 95% à l'aide d'un appareil Bausch & Lomb Spectronic 505. Les spectres r.m.n. ont été déterminés à l'aide d'un spectromètre, modèle A-60, de la compagnie Varian. Les déplacements chimiques (δ) sont exprimés en parties par million et le tétraméthylsilane est utilisé comme référence interne. Les points de fusion ont été mesurés sur un "Hot Stage Apparatus" de la compagnie Reichert (Autriche). Les analyses élémentaires ont été effectuées par le Docteur Claude Daesslé, Montréal.

1. Nitrations

1.1. Mononitration du di-t-butyl-2,7 naphtalène

Un mélange de 3 g (12.5 mmoles) d'hydrocarbure III dans 200 ml d'acide acétique et 100 ml d'acide nitrique concentré est agité à la température de la pièce pendant 2 h. Après extraction à l'éther et cristallisation dans l'éthanol, 1.87 g (53% du rendement théorique) de produit mononitré sont obtenus. Par

cristallisation fractionnée dans l'éthanol, il est possible d'isoler le nitro-4 di-*t*-butyl-2,7 naphtalène (IV*b*), p.f. 68–69°C, et le nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*), p.f. 81–82 °C.

1.2. Dinitration du di-t-butyl-2,7 naphtalène

Un mélange de 1 g (4.2 mmoles) d'hydrocarbure III dans 30 ml d'acide acétique et 20 ml d'acide nitrique concentré est agité sur un bain-marie pendant 1 h. Le mélange est alors refroidi et extrait à l'éther. Par cristallisation de l'huile résiduelle dans l'éthanol, les dinitro-4,5 di-*t*-butyl-2,7 naphtalène (IX), p.f. 216–218 °C, dinitro-1,5 di-*t*-butyl-2,7 naphtalène (VIII), p.f. 76–78 °C, et dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4 (XI), p.f. 225 °C, sont obtenus avec des rendements respectifs de 11%, 12% et 14% du rendement théorique.

1.3. Trinitration du di-t-butyl-2,7 naphtalène

Un mélange de 3 g (12.5 mmoles) d'hydrocarbure III dans 20 ml d'acide acétique et 30 ml d'acide nitrique fumant est chauffé sur un bain-marie pendant 30 min. Après refroidissement le mélange est extrait à l'éther; par recristallisation de l'huile résiduelle par de l'éthanol, 250 mg (6% du rendement théorique) de trinitro-1,4,5 di-*t*-butyl-2,7 naphtalène (X), p.f. 260 °C, et 500 mg (11% du rendement théorique) de dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4 (XI), p.f. 225 °C, sont obtenus.

1.4. Nitration du nitro-1 di-t-butyl-2,7 naphtalène (VIIa)

Un mélange de 1 g (3.5 mmoles) de produit nitré VII*a* dans 50 ml d'acide acétique et 50 ml d'acide nitrique concentré est chauffé pendant 15 min sur un bain-marie. Le mélange est alors refroidi et extrait à l'éther; par cristallisation de l'huile obtenue à l'aide d'éthanol, 286 mg (22% du rendement théorique) de dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4 (XI), p.f. 225 °C, et 106 mg (9% du rendement théorique) de dinitro-1,5 di-*t*-butyl-2,7 naphtalène (VIII), p.f. 76–78 °C, sont obtenus.

1.5. Nitration du nitro-4 di-t-butyl-2,7 naphtalène (IVb)

Un mélange de 500 mg (1.75 mmoles) de dérivé nitré IV*b* dans 10 ml d'acide acétique et 10 ml d'acide nitrique concentré est chauffé sur un bain-marie pendant 1 h. L'extraction à l'éther conduit à 450 mg (75% du rendement théorique) de produits dinitrés. Le spectre infra-rouge de ce produit brut ne révèle la présence d'aucune bande due à la dinitro-3,8 di-*t*-butyl-2,7 naphtoquinone-1,4; cependant, la présence des deux isomères dinitrés en proportion relative d'environ 50:50 est observée. La recristallisation de ce produit brut dans l'éthanol conduit à 153 mg (25% du rendement théorique) de dinitro-4,5 di-*t*-butyl-2,7 naphtalène (IX), p.f. 216–218 °C, et 110 mg (18% du rendement théorique) de dinitro-1,5 di-*t*-butyl-2,7 naphtalène (VIII), p.f. 76–78 °C.

1.6. Amino-1 di-t-butyl-2,7 naphtalène (VIIb)

A 1.0 g (3.5 mmoles) de nitro-1 di-*t*-butyl-2,7 naphtalène (VII*a*) dans 10 ml d'éthanol et 2 g d'étain en poudre, 20 ml d'acide chlorhydrique 20% sont ajoutés. Le mélange est alors chauffé pendant 10 min sur un bain-marie tout en maintenant une agitation. Après extraction des produits à l'éther et lavage avec de la soude 10%, 500 mg (50% du rendement théorique) d'amine VII*b*, p.f. 118–122 °C, sont isolés.

TABLEAU III

Analyse des produits nouveaux

	Point de fusion (°C)	C (%)		H (%)		Autre (%)

2. Chlorurations

2.1. Chloro-1 di-t-butyl-2,7 naphtalène (VIIc)

Un mélange de 3 g (12.5 mmoles) d'hydrocarbure III dans 10 ml de chloroforme et 3.1 ml de chlorure de sulfuryle est laissé dans la glace pendant 2 h. Pour décomposer l'excès de chlorure de sulfuryl 25 ml d'éther et 10 ml d'eau sont alors ajoutés. L'extraction à l'éther et l'évaporation des solvants conduit à 3 g d'une huile qui, après recristallisation dans l'éthanol, donne 1.52 g (45% du rendement théorique) de chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*), p.f. 80–81 °C.

2.2. Chloro-4 di-t-butyl-2,7 naphtalène (IVc)

A 5 g (21 mmoles) d'hydrocarbure III dans 150 ml d'acide acétique, une solution contenant 3 équivalents de ICl (préparée à partir de 15 g de dichloroamine-*T* et 18.75 g d'iodure de sodium) dans 250 ml d'acide acétique est ajoutée. Le mélange est maintenu à la température de 55 °C pendant 2 h; après dilution avec 1 l d'eau le produit est extrait à l'éther. La recristallisation des produits dans l'éthanol conduit premièrement à la *p*-toluène sulfonamide, p.f. 137 °C, et puis à 2.41 g (42% du rendement théorique) de chloro-4 di-*t*-butyl-2,7 naphtalène (IV*c*), p.f. 63–65 °C.

2.3. Dichloro-1,4 di-t-butyl-2,7 naphtalène (XIIa)

Un mélange de 3 g (12.5 mmoles) d'hydrocarbure III dans 10 ml de chloroforme et 2.05 ml de chlorure de sulfuryle est laissé à la température de la pièce pendant 4 h. L'extraction des produits à l'éther conduit à une huile qui, après cristallisation dans l'éthanol, donne 750 mg (20% du rendement théorique) de dichloro-1,4 di-*t*-butyl-2,7 naphtalène (XII*a*), p.f. 88–89 °C. Du chloro-1 di-*t*-butyl-2,7 naphtalène (VII*c*, 900 mg) est aussi recueilli.

2.4. Trichloro-1,4,8 di-t-butyl-2,7 naphtalène (XIII)

A 3 g (12.5 mmoles) d'hydrocarbure III dans 10 ml de chloroforme, 9 ml de chlorure de sulfuryle sont ajoutés lentement. Après l'addition, le mélange est chauffé à reflux pendant 10 min, puis refroidi et extrait à l'éther. L'huile ainsi obtenue est cristallisée dans l'éthanol et conduit à 730 mg (19% du rendement théorique) de trichloro-1,4,8 di-*t*-butyl-2,7 naphtalène (XIII), p.f. 105–109 °C.

3. Bromurations

3.1. Bromo-4 di-t-butyl-2,7 naphtalène (IVd)

A 5 g (21 mmoles) d'hydrocarbure III dans 200 ml de chloroforme, 1.4 ml (21 mmoles) de brome dans 50 ml de chloroforme sont ajoutés. Le mélange est agité à reflux pendant 7 h et puis refroidi. L'extraction des produits et la cristallisation de l'huile résiduelle dans l'éthanol conduit à 3.07 g (45% du rendement théorique) de bromo-4 di-*t*-butyl-2,7 naphtalène (IV*c*), p.f. 69–70 °C. Le reste est du produit qui n'a pas réagi.

3.2. Dibromo-1,4 di-t-butyl-2,7 naphtalène (XIIb)

Bromuration dans l'acide acétique.—A une solution de 2 g (8.3 mmoles) d'hydrocarbure III dans 100 ml d'acide acétique, 3 ml (45 mmoles) de brome dissous dans 50 ml d'acide acétique sont ajoutés. Le mélange est agité sur un bain-marie pendant 2 h, puis refroidi et extrait à l'éther. L'excès de brome est détruit par du thiosulfate de sodium, et l'huile obtenue après extraction à la manière habituelle conduit à 1.62 g (50% du rendement théorique) de dibromo-1,4 di-*t*-butyl-2,7 naphtalène (XII*b*), p.f. 90–91 °C.

Bromuration dans le tétrachlorure de carbone.—Un mélange de 25 g d'hydrocarbure III dans 400 ml de tétrachlorure de carbone est traité par 15 ml de brome et chauffé à 80 °C pendant 4 h. Le mélange réactionnel est laissé à la température de la pièce pour la nuit et le produit alors extrait à la manière habituelle. La cristallisation à l'aide d'éthanol de l'huile obtenue conduit à 12 g (30% du rendement théorique) de dibromo-1,4 di-*t*-butyl-2,7-naphtalène, p.f. 90–92 °C; l'huile résiduelle distillée à 174 °C et 0.5 mm Hg montre un spectre infra-rouge identique à celui du solide précédent.

3.3 Essai de tribromuration du di-t-butyl-2,7 naphtalène

Un mélange de 3 g (12.5 mmoles) de di-*t*-butyl-2,7 naphtalène et de 6 ml (110 mmoles) de brome dans 50 ml d'acide acétique est chauffé sur un bain-marie pendant 5 h. Après extraction à la manière habituelle, un spectre infra-rouge du produit brut de la réaction a été déterminé et s'avérait en tous points semblable à celui du dibromo-1,4 di-*t*-butyl-2,7 naphtalène. La cristallisation du produit brut dans l'éthanol redonne du dibromo-1,4 di-*t*-butyl-2,7 naphtalène.

4. Dérivés du dibromo-1,4 di-t-butyl-2,7 naphtalène

4.1. Préparation du dicyano-1,4 di-t-butyl-2,7 naphtalène (XIIc)

Le dibromo-1,4 di-*t*-butyl-2,7 naphtalène (XII*b*, 200 g) est traité par du cyanure cuivreux dans la diméthylformamide selon la méthode de Friedman et Schecter (3) et fournit 93 g (76% du rendement théorique) de dicyano-1,4 di-*t*-butyl-2,7 naphtalène (XII*c*), p.f. 147–148 °C, après cristallisation dans l'éthanol.

4.2. Préparation de l'acide cyano-1 di-t-butyl-2,7 naphtalène carboxylique-4 (XIId)

Par l'action d'un mélange d'acide sulfurique 70% et d'acide acétique glacial sur le dicyano-1,4 di-*t*-butyl-2,7 naphtalène à l'ébullition pendant 6 h, un solide de point de fusion entre 220 et 290 °C est obtenu par cristallisation dans l'éthanol du produit brut de la réaction. La recristallisation de ce solide dans un excès

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

d'acide acétique glacial bouillant fournit l'acide cyano-1 di-*t*-butyl-2,7 naphtalène carboxylique-4 (XII*d*), p.f. 234–236 °C. Le solide qui ne s'est pas dissous dans l'acide acétique bouillant fond entre 305 et 320 °C. Après plusieurs recristallisations de ce solide dans l'éthanol, l'acide di-*t*-butyl-2,7 naphtalène dicarboxylique-1,4 (XII*e*), p.f. 322–325 °C, est obtenu.

4.3. Préparation du cyano-1 méthoxycarbonyle-4 di-t-butyl-2,7 naphtalène (XIIf)

A 3 g du nitrile acide XII*d* obtenu dans la section précédente, une solution éthérée de diazométhane en excès est ajoutée. Après évaporation de l'éther, 2.5 g de l'ester attendu XII*f* sont obtenus sous forme de solide blanc, p.f. 147–150 °C.

4.4. Préparation du diméthoxycarbonyle-1,4 di-t-butyl-2,7 naphtalène (XIIg)

Une solution éthérée contenant 3 g du produit fondant entre 305 et 320 °C obtenu dans la section 4.2 est traitée par une solution éthérée de diazométhane. L'évaporation de l'éther conduit à une huile qui laisse précipiter 0.4 g d'un solide, p.f. 256–258 °C, dont l'analyse correspondrait à celle du méthoxy-carbonyl-4 di-*t*-butyl-2,7 naphtalène carboxamide-1 (XII*h*). L'huile résiduelle, qui distille sans décomposition à 250 °C et 0.1 mm Hg, fournit 1.5 g de diméthoxycarbonyle-1,4 di-*t*-butyl-2,7 naphtalène (XII*g*), dont le spectre infra-rouge est exempt des pics dûs au groupe NH.

REMERCIEMENT

Les auteurs remercient sincèrement le Conseil National de Recherches pour l'aide financière apportée sous forme d'octroi (A-1295).

THE THERMAL REVERSIBILITY OF THE MICHAEL REACTION

V. THE EFFECT OF THE STRUCTURE OF CERTAIN THIOL ADDUCTS ON CLEAVAGE

C. F. H. ALLEN

Received October 22, 1965

ABSTRACT

A large number of Michael adducts have been prepared from β-morpholinoethanethiol and α,β-unsaturated compounds bearing a variety of functional groups. The extent of cleavage of 23 of these under reversal conditions has been determined quantitatively. The relation between structure and amount of cleavage has been discussed. A few heterocyclic thiols were also employed, to extend the generality of the reactions. With the latter, the thiol-cleaved product was separated and identified, to show that the cleavage was normal.

It has been noted earlier that an arrangement of functional groups in the order of their activation of the Michael reaction would be useful (1). In our previous paper (2), morpholinoethanethiol adducts of α,β-unsaturated ketones (chalcones) having substituents in the ortho, meta, and para positions of both aromatic rings were described. Furthermore, the extent of their cleavage (reversibility of the Michael reaction) in hot water was determined. Adducts Nos. 1–4 (Table I) (2) illustrate similar reactivity in the present work. It was noted that related Michael adducts lacking an aryl group in the beta position were cleaved slightly or not at all under the same conditions, but were converted, in varying degrees, into their components in aqueous alkaline solution. To compare adducts with and without beta substituents, a study was made of a considerable number of such adducts lacking β-aryl groups. The addend, β-morpholinoethanethiol, was always the same so that the reversal would depend upon only the structure of the acceptor molecule (2); thus the functional groups in the latter were varied. The α,β-unsaturated compounds included those bearing open-chain (COAr, $COCH_3$) and cyclic ketonic, acidic ($CONH_2$, COOH), and neutral (CN, NO_2, $COOC_2H_5$) groups as well as two sulfones and three vinylpyridines. The degrees of cleavage of the substances investigated are shown in Table I. The adducts of heterocyclic mercaptans (Table II) underwent a similar reversal. In some of these instances, the reaction was not observed analytically, but instead, the resulting mercaptan was isolated and identified.

DISCUSSION OF RESULTS

Study suggests that the reversal reactions reached equilibrium rapidly at reflux, thus minimizing the dependency of the comparisons on rates. The data determined after 1 h of reflux (Table I) appear to represent equilibrium. The comparison of substituent effects was made under these conditions.[1] Previously, few quantitative data have been available on the position of the equilibrium (3).

[1]*A referee has suggested that: "It would be risky to equate relative yields after a fixed reaction period with relative reactivities. Discussion of substituent effects must relate to potential-energy variations, but it is entirely possible that two reactions could have the same energy of activation, thus leading to rate differences which have nothing to do with electronic effects of substituents. In the absence of a demonstration that all the reported reversals have similar entropies of activation, a correlation of relative yields with substituent effects may or may not be valid; some reservations should be expressed concerning the correlation."*

In general, activation of the α-hydrogen atom appears to activate the adduct towards reversal, as expected by electronic theory. Thus, the cleavage may largely be predicted. The order of cleavage indicated is ketone > nitrile > amide > acid. Esters are not included within this order because of their probable hydrolysis to carboxylic acids (cf. Nos. 12 and 15). However, the adduct of methyl vinyl ketone was observed to reverse upon attempted distillation, whereas the adducts of acrylonitrile and methyl acrylate were unchanged upon distillation. These orders support that of Connor's generalization: ketones > esters > nitriles (1). The activating influence of a β-phenyl group is evident from a comparison of the ketones (Nos. 5 and 6). The adduct of a phenyl ketone (No. 7) appears to be more reactive than that of a methyl ketone (No. 6). An electron-repelling group in the para position (No. 8) measurably decreases the activity. On this basis, the relative reactivities of ketones is expected to be $-COC_6H_4NO_2$-4 > $-COC_6H_5$ > $-COCH_3$ = $-COC_6H_4OCH_3$-4. The adduct of acrylic acid (No. 15) is practically stable, whereas the derivative bearing a strong electron-attracting alpha substituent (No. 16) shows activation towards cleavage. Cleavage is particularly large because of activation by two carbonyl groups, as in the adducts of methylenemalonic esters (Nos. 9–11). A β-phenyl effect is also evident (No. 10). The cleavage reactivity of adducts of conjugated sulfones (Nos. 18 and 19) suggests significant α-hydrogen activity. The adducts of the heterocyclic unsaturated compounds (Nos. 21–23) indicate that the adduct from 4-vinylpyridine is more reactive than that from 2-vinylpyridine. The forming of a quaternary ammonium salt is expected to increase the reactivity.

EXPERIMENTAL

Adduct Formation

Mercaptans have been used to a limited extent in Michael additions (4–6); they add to α,β-unsaturated ketones without a catalyst more readily than to esters (7). In this work the procedure was varied depending upon the components. β-Morpholinoethanethiol was added to the second component, even to acrylic acid, simply by refluxing in alcohol; the amine moiety probably functioned as a catalyst (method A). Similarly, heterocyclic mercaptans were added to 2- and 4-vinylpyridine. The addition failed, however, with methyl cinnamate, methyl crotonate, and cinnamonitrile. A similar failure has been noted when nitromethane and an amine catalyst were used (8). 5-Mercapto-1-phenyltetrazole and 2-mercapto-5-phenyl-1,3,4-oxadiazole were added to conjugated ketones effectively in acetic acid (method B). In a few instances, when sodium acetate and refluxing in acetic acid were used (method C), appropriate Mannich bases served as the source of vinyl ketones. The addition of 2-mercaptobenzoxazole was catalyzed by sodium methoxide (method D).

Dimethyl malonate (9), dimethyl benzalmalonate (10), diethyl methylenemalonate (11), β-dimethylaminopropiophenone hydrochloride (12), maleimide (13), ethyl vinyl sulfone (14), and phenyl vinyl sulfone (15) were prepared as described in the literature. Diethyl benzalmalonate and dimethyl p-methoxybenzalmalonate were preferably prepared by the use of a continuous reactor (16). The latter ester solidified after distillation, b.p. 130–135° at 0.03 mm, m.p. 59–60° after crystallization from ethanol (66% yield).

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.4; H, 5.6. Found: C, 62.4; H, 5.7.

Method A

Equimolar amounts of the acceptor component and β-morpholinoethanethiol in absolute ethyl alcohol were refluxed for 1 h and the solvent was removed under reduced pressure. Volatile products were fractionated through a 10 cm column filled with glass helices. Nonvolatile products, whether oils or solids, were dissolved in ether, and converted into salts with hydrogen chloride. Perchlorates were prepared by treating the hydrochlorides in methanol with sodium perchlorate.

Method B

Equimolar amounts of the acceptor molecule and β-morpholinoethanethiol in acetic acid were refluxed for 1 h, unless the acceptor had a low boiling point (methyl vinyl ketone, methyl acrylate); in these instances the reaction mixture was maintained at 70–80° for 30 min and then boiled for 10 min. Most of the solvent was removed under reduced pressure. When the residue was allowed to stand overnight, the crude product crystallized.

Method C

(*i*) A suspension of 0.2 mole of either component (42.6 g of β-dimethylaminopropiophenone hydrochloride or 54.8 g of the corresponding p-methoxypropiophenone hydrochloride), 29.5 g of β-morpholinoethanethiol, and 19.5 g of dry potassium acetate in 500 ml of xylene was refluxed for 1 h, during which time the solids

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

became a fine powder. The reflux condenser was removed and the mixture was boiled to remove the dimethylamine. After filtration of the precipitated potassium chloride, the solvent was removed under reduced pressure, leaving a brown oil. Addition of hydrogen chloride to a solution of this oil in ether gave the hydrochloride, which crystallized after being allowed to stand for 1 h. β-Dimethylamino-*p*-methoxypropiophenone hydrochloride was made by the usual procedure and used without purification.

(*ii*) A mixture of 0.04 mole of β-dimethylamino-α-(*p*-nitrophenyl)propionic acid (17), 6.9 g of β-morpholinoethanethiol, 4.1 g of potassium acetate, and 100 ml of acetic acid was maintained at 80° for 15 min, and then boiled for 10 min. Hydrogen chloride was passed through the cooled mixture, and sufficient ether was then added to precipitate the hydrochloride as an oil. After the oil had been decanted, addition of a small amount of ether–alcohol caused crystallization. The product was collected and recrystallized, after filtration of any salt present.

(*iii*) 5-Mercapto-1-phenyltetrazole formed adducts (Table IIB) on treatment of the hydrochlorides of β-dimethylaminopropiophenone, β-dimethylamino-*p*-methoxypropiophenone, and β-dimethylaminomethylcyclohexanone (18) in the following manner. Equimolar amounts of the Mannich base and potassium acetate in acetic acid were boiled for 15 min and then poured into 15 volumes of ice water. The product crystallized when allowed to stand overnight.

Method D

Sufficient sodium methoxide was added to a solution of 11.8 g (0.1 mole) of divinyl sulfone and 30.2 g (0.2 mole) of 2-mercaptobenzoxazole in 300 ml of hot ethanol to make the solution basic. The adduct began to separate as the mixture was refluxed for 1 h. The reaction mixture was then concentrated and the product was collected.

Cleavage of Adducts

Iodometric Estimation of Thiols

About 1 meq of adduct was placed in the alkaline solution, at the temperature and for the time indicated (Table I). An equivalent of hydrochloric acid was added, to render the solution approximately neutral, followed by 60 ml of acetic acid. Five milliliters of 0.25% starch indicator was then added, and the mixture was titrated with 0.1 *N* iodine solution to a blue end point. The results are shown in Table I.

Identification of Thiols

One gram (0.004 mole) of β-(1-phenyltetrazolyl-5-thio)propiophenone was dissolved in 10 ml of methanol, and a solution of 0.5 g of potassium hydroxide in 5 ml of water was added. The mixture was diluted with 15 ml of water and stirred for 10 min at room temperature. After removal of the methanol under reduced pressure, the mixture was acidified with hydrochloric acid. The precipitated 5-mercapto-1-phenyltetrazole (0.62 g, 87%) was collected; the melting point was 155°, and the mixture melting point was not depressed. Satisfactory elemental and infrared analyses of the compound, after it had been recrystallized from xylene, were obtained. Related adducts obtained from 3-hexene-2,5-dione, β-dimethylaminomethylcyclohexanone, and 2-cyclohexanone (Table IIB) gave a similar result. An analogous treatment of 1 g (0.0029 mole) of 2-(5-phenyl-1,3,4-oxadiazolyl-2-thio)-1,1-dicarbethoxyethane in 200 ml of methanol, with 1 g of potassium carbonate in 200 ml of water, yielded 0.4 g (79%) of 2-mercapto-5-phenyl-1,3,4-oxadiazole, m.p. 215–217°; the mixture melting point was not depressed.

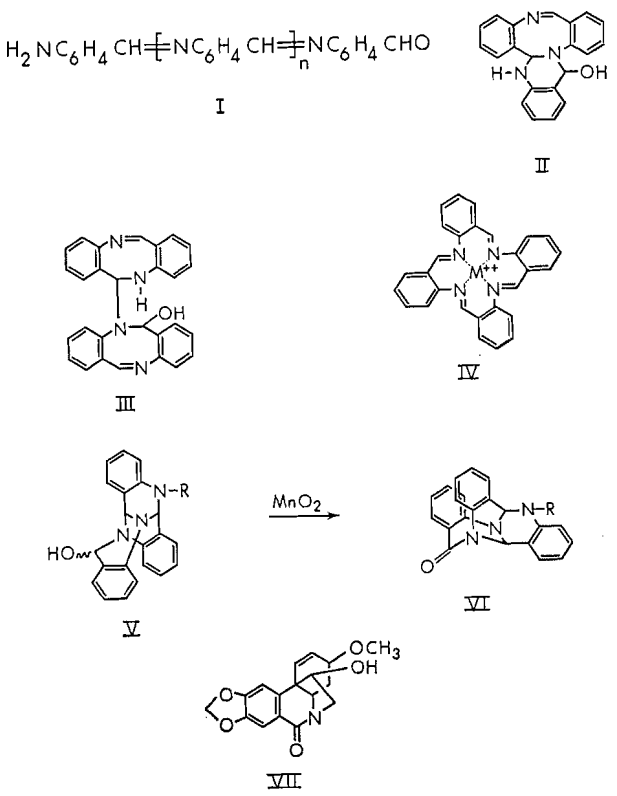
THE STRUCTURES OF TWO SELF-CONDENSATION PRODUCTS FROM *o*-AMINOBENZALDEHYDE

S. G. McGeachin
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received July 13, 1965



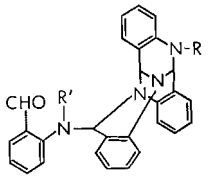
ABSTRACT

The nature of two self-condensation products of *o*-aminobenzaldehyde (one a bisanhydro trimer and the other a trisanhydro tetramer) formed under different conditions of acid catalysis has been reexamined Spectroscopic evidence is presented to support the assignment of structures V (R = H) and VIII (R = R′ = H) to these.

There exists considerable literature on self-condensation products formed from *o*-aminobenzaldehyde (1 and references therein). The number and nature of these were considerably clarified by the work of Seidel (1), who isolated and characterized a bisanhydro trimer and trisanhydro tetramer of the parent compound. Chemical evidence was interpreted in terms of simple linear Schiff base formation among three or four molecules of *o*-aminobenzaldehyde to give structures I ($n = 1$) and I ($n = 2$). These were later amended to the cyclic formulae II and III (2). Melson and Busch (3) have described self-condensation products formed in the presence of certain metal ions. These are the macrocyclic tetramer IV and an analogous trimer in which the nitrogen atoms are coordinated around the cation in a planar array. The two condensation products described by Seidel have now been reexamined and new structures assigned on the basis of evidence detailed below.

According to Seidel's method the first of these was most conveniently prepared by weakly acidifying an aqueous solution of *o*-aminobenzaldehyde, from which it precipitated in a crystalline form. Its formulation as a bisanhydro trimer followed from a correct elemental analysis for $C_{21}H_{17}N_3O$. The infrared spectrum, with bands at 3 560 and 3 390 cm^{-1}, indicated the presence of a hydroxyl and at least one NH group. That there was only one NH group was shown by the preparation of an *O,N*-diacetyl derivative which possessed no further NH band in the infrared spectrum. The nature of the remaining 15 hydrogens was apparent from the nuclear magnetic resonance (n.m.r.) spectrum of a deuterated sample, which exhibited complex 12-proton absorption between τ 2.58 and 3.50, assigned to the aromatic hydrogens, and three closely spaced one-proton singlets between τ 4.43 and 4.60, assigned to hydrogens of the type (Ar, Y_2)C*H* (Y = N or O). The ultraviolet spectrum, with maxima at 241 mμ (ϵ 14 600) and 285 mμ (ϵ 2 300), resembled that of *N*-ethyl-*o*-toluidine, which has maxima at 244 mμ (ϵ 7 200) and 291 mμ (ϵ 2 450) (4). These data indicated that the three units of *o*-aminobenzaldehyde must be joined by bonds formed between the aldehyde and amino functions only, and that no aldimine groups (—CH=N—) were present in the product. It follows that, of the three original aldehyde carbons, one must carry the hydroxyl function and be linked to nitrogen, and the other two must each be bonded to two nitrogens. If the reasonable assumption is made that no aldehyde carbon is linked to the nitrogen of the same unit, this allows only one structure for the trimer, namely V (R = H).

When stirred with methanol containing a catalytic amount of *p*-toluenesulfonic acid, the trimer gave an *O*-methyl ether consistent with its formulation as a carbinolamine.



Reaction of the monoacetylbisanhydro trimer V (R = $COCH_3$) with manganese dioxide yielded a dehydro derivative (VI, R = $COCH_3$), $C_{23}H_{17}N_3O_2$, in which the hydroxyl had been oxidized to a carbonyl function, $\nu_{max}^{CCl_4}$ 1 714 cm^{-1}. Examination of a molecular model indicated that this compound belongs to the rare class of lactams in which steric requirements prevent overlap of the nitrogen lone-pair electrons with the carbonyl π bond. This results in their behaving more as aminoketones than as lactams. The position of the carbonyl band in the infrared spectrum is one consequence of this. The shift to higher frequencies than would be normal even for an aromatic ketone is probably caused by the inductive effect of the directly attached but unconjugated nitrogen atom. In the ultraviolet spectrum the band at longest wavelength, λ_{max} 333 mμ, lies between that of *o*-dimethylaminoacetophenone at 350 mμ and that of *o*-dimethylaminobenzamide at 315 mμ (5). In keeping with its behavior as a ketone, the lactam was reduced by sodium borohydride to the starting alcohol. Another example of such a "lactam" is oxohaemanthidine (VII), which has ν_{max}^{Nujol} 1 695 cm^{-1} (6).

The second self-condensation product was obtained, according to Seidel's method, through the action of 50% sulfuric or hydrochloric acids on *o*-aminobenzaldehyde or on the bisanhydro trimer. This led to the formation of red crystalline salts, from which the free base was liberated by treatment with water. Analysis of this substance and a molecular weight determination on its monoacetyl derivative confirmed its formulation as a trisanhydro tetramer, $C_{28}H_{22}N_4O$. The most important observations from the infrared spectrum were two NH bands at 3 380 and 3 310 cm^{-1}, and a carbonyl band at 1 665 cm^{-1}. The nature of the carbonyl function as a formyl group was apparent from the presence in the n.m.r. spectrum of a one-proton singlet at τ 0.10, and from the preparation of an oxime of the monoacetyl derivative which underwent ready dehydration to

a nitrile. In the n.m.r. spectrum of the tetramer there also appeared resonances for the two hydrogens attached to nitrogen, one a broad band centered at τ 5.1, and the other a doublet (J = 5 c.p.s.) at τ 0.93 coupled to one of three one-proton resonances in the τ 4.3–4.7 region, all three ascribed, as in the trimer, to the system (Ar, Y_2)C*H*. A multiplet of weight 16 between τ 1.90 and 3.50 was also present for the aromatic hydrogens. It was apparent that the bonds joining the four units were once more between amino and formyl groups. By virtue of the presence of a formyl group one unit must be linked to the rest of the molecule by one or two bonds from its nitrogen atom. The former possibility requires that the molecule as a whole have two separate NH groups, whereas the latter requires either this or the presence of one NH_2 function. The very different positions of the NH resonances in the n.m.r. spectrum, the fact that the low-field NH exchanged much more slowly with deuterium, and its coupling to an aliphatic CH favored the presence of two separate NH groups. Under a variety of conditions, however, only a monoacetyl derivative of the tetramer could be obtained. A convincing answer came from nitrosation of this monoacetyl compound. This yielded an *N*-nitroso compound which had no NH absorption in its infrared spectrum. The absence in its ultraviolet spectrum of the long-wavelength band at 369 mμ characteristic of the *o*-aminobenzaldehyde chromophore suggested that the nitroso group was bonded to the nitrogen of this unit, which therefore was attached to the rest of the molecule by only one bond. The disappearance of this band or its appearance at shorter wavelengths on attachment of an electron-withdrawing substituent to the nitrogen is to be expected (7), and can be observed, for example, in *N*-acetyl-*o*-aminobenzaldehyde, which has its longest wavelength band at 330 mμ. The attachment of one of the four units by only a single bond from its nitrogen to the aldehyde carbon of a second, and the requirement that the aldehyde carbons of the remaining three units be linked each to two nitrogens permits, with the same assumption used in deriving the structure of the trimer, only one structure (VIII, R = R′ = H) for the tetramer. The *N*-acetyl compound and its nitroso derivative are therefore VIII (R = $COCH_3$, R′ = H) and VIII (R = $COCH_3$, R′ = NO), respectively. Since, in the latter, the relationship of nitroso to aldehyde functions is critical for the deduction of structure, it was desirable to confirm this chemically. Reduction

VIII

IX

of the nitroso group with zinc in acetic acid gave a substance, $C_{30}H_{23}ON_5$, which possessed no NH bands and no carbonyl band (other than that of the *N*-acetyl group) in the infrared spectrum. Its n.m.r. spectrum was similar to that of the parent nitroso compound, but in place of the signal assigned to the formyl proton at τ 0.10 there was a new one-proton doublet at τ 1.88 (J = 0.8 c.p.s.). The formula and spectra indicated that it was the desired indazole derivative IX. The lowest field signal at τ 1.88 in the n.m.r. spectrum is assigned to the C-3 hydrogen of the indazole ring and is in reasonable agreement with that reported for C-3 of indazole itself at τ 1.94 (doublet, J = 0.8 c.p.s.) (8).

Although the ring systems of both the trimer and tetramer remain unaltered during

the mild chemical transformations described above, the inherent lability in protonic solvents is seen on treatment with cupric nitrate in refluxing ethanol. Under these conditions they give the macrocyclic tetramer IV (M = Cu) that was obtained directly from *o*-aminobenzaldehyde by Melson and Busch (3).

EXPERIMENTAL

General

Melting points were taken on a Kofler melting point apparatus and are uncorrected. Infrared, ultraviolet, and n.m.r data were obtained on Perkin–Elmer model 337, Perkin–Elmer model 202, and Varian Associates model A-60 spectrometers, respectively.

Bisanhydro Trimer (V, R = H)

Freshly prepared *o*-aminobenzaldehyde (9) (4.5 g) was dissolved in water (700 ml) at 50°. The solution was placed under a nitrogen atmosphere, cooled to 25°, and acidified with a solution of concentrated hydrochloric acid (6 ml) in water (50 ml). The mixture was seeded with the bisanhydro trimer and allowed to stand for 1 h until precipitation was complete. The product was collected, washed with 2% aqueous sodium bicarbonate solution, and dried. Crystallization from acetone–methanol gave the bisanhydro trimer (3.1 g). The analytical sample formed prisms when recrystallized from the same solvents, and had m.p. 233–237°.

Anal. Calcd. for $C_{21}H_{17}N_3O$: C, 77.04; H, 5.23; N, 12.84. Found: C, 76.85; H, 5.51; N, 13.09.[1]

Ultraviolet spectrum: λ_{max}^{MeOH} 241 mμ (ε 14 600), 285 mμ (ε 2 300), with a shoulder at 304 mμ (ε 1 400). Infrared spectrum: $\nu_{max}^{CH_2Cl}$ 3 560 (OH), 3 390 (NH) cm^{-1}; ν_{max}^{Nujol} 3 300 (broad, NH and OH) cm^{-1}. Nuclear magnetic resonance spectrum of a deuterated sample in CD_3SOCD_3: τ 2.58–3.50 (12H, complex), τ 4.43 (1H, singlet), τ 4.45 (1H, singlet), τ 4.60 (1H, singlet).

N-Acetylbisanhydro Trimer (V, R = $COCH_3$)

The bisanhydro trimer (100 mg) was stirred with acetic anhydride (0.5 ml) at room temperature for 4 h. The monoacetyl derivative was collected by filtration and purified by crystallization from acetone. The analytical sample formed prisms when recrystallized from acetone, m.p. 227–229°.

Anal. Calcd. for $C_{23}H_{19}N_3O_2$: C, 74.78; H, 5.18; N, 11.38. Found: C, 75.05; H, 4.97; N, 11.36.

Infrared spectrum: $\nu_{max}^{CH_2Cl}$ 3 550 (OH), 1 660 ($NCOCH_3$) cm^{-1}; ν_{max}^{Nujol} 3 200 (broad), 1 660 cm^{-1}. Nuclear magnetic resonance spectrum on a deuterated sample in CD_3SOCD_3: τ 2.25–3.25 (12H, complex), τ 3.42 (1H, singlet), τ 4.40 (1H, singlet), τ 4.44 (1H, singlet), τ 7.40 (3H, singlet).

O,N-Diacetylbisanhydro Trimer

The bisanhydro trimer (100 mg) was acetylated in 1:1 pyridine – acetic anhydride (0.5 ml) for 12 h at room temperature. Addition of a few drops of water gave the diacetyl derivative in a crystalline form. The analytical sample formed needles when crystallized from dichloromethane–methanol, and had m.p. 222–225°.

Anal. Calcd. for $C_{25}H_{21}N_3O_3$: C, 72.98; H, 5.14; N, 10.21. Found: C, 72.86; H, 5.12; N, 10.03.

Infrared spectrum: $\nu_{max}^{CH_2Cl_2}$ 1 740 ($OCOCH_3$), 1 660 ($NCOCH_3$) cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2.50–3.33 (14H, complex), τ 4.43 (1H, singlet), τ 7.48 (3H, singlet), τ 7.70 (3H, singlet).

O-Methylbisanhydro Trimer

The bisanhydro trimer (150 mg) was suspended in a solution of *p*-toluenesulfonic acid (10 mg) in methanol (5 ml), and the mixture stirred for 3 days at room temperature. After dilution with benzene it was washed with dilute aqueous sodium bicarbonate and water, and dried. Removal of the solvent and crystallization from dichloromethane–ether gave the product (105 mg). The analytical sample formed prisms when recrystallized from the same solvents, and had m.p. 228–230°.

Anal. Calcd. for $C_{22}H_{19}ON_3$: C, 77.39; H, 5.61. Found: C, 77.15; H, 5.77.

The Lactam (VI, R = $COCH_3$)

A solution of the monoacetylbisanhydro trimer (89 mg) in dichloromethane (50 ml) was stirred at room temperature with manganese dioxide (3 g) for 4 h. After filtration through Celite the solution was evaporated to dryness *in vacuo* and the residue crystallized from dichloromethane–ether to yield the lactam (40 mg). The analytical sample separated from the same solvent mixture as prisms, m.p. 229–231°.

Anal. Calcd. for $C_{23}H_{17}N_3O_2$: C, 75.19; H, 4.66; N, 11.44. Found: C, 74.93; H, 4.90; N, 11.65.

Ultraviolet spectrum: λ_{max}^{MeOH} 210 mμ (ε 34 900), 238 mμ (ε 25 900), 333 mμ (ε 2 800). Infrared spectrum: $\nu_{max}^{CCl_4}$ 1 714 (lactam C=O), 1 678 ($NCOCH_3$) cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 1.88 (1H, multiplet belonging to an aromatic hydrogen ortho to the lactam carbonyl), τ 2.25–3.00 (12H, complex), τ 4.11 (1H, singlet), τ 7.46 (3H, singlet).

A sample of the lactam (30 mg) was dissolved in dioxane (1 ml) and water (0.2 ml), and reduced with sodium borohydride (11.5 mg) for 15 min at room temperature. The solution was poured onto ice and

[1]*Analyses are by Galbraith Laboratories, Inc., P.O. Box 4187, Knoxville, Tennessee 37921, and by Miss D. Roberts, Chemistry Department, University of Alberta, Edmonton.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the product (19 mg) collected and dried. On examination by thin-layer chromatography (alone and admixed with monoacetylbisanhydro trimer) it showed one spot. It was crystallized once from acetone, and was found to be identical with the monoacetyl compound by comparison of their infrared spectra and melting points.

Trisanhydro Tetramer (VIII, R = R′ = H)

A mixture of *o*-aminobenzaldehyde (2.5 g) and 1:1 sulfuric acid – water (10 ml) was stirred until solution was complete (ca. 0.5 h). Water (10 ml) was added and the solution was allowed to stand for 1 day until crystallization of the salt was complete. This was filtered off, washed with anhydrous ethanol, and dried, yield 2.05 g. It was converted quantitatively (as shown by thin-layer chromatography) into the trisanhydro tetramer by shaking it with water and chloroform. The free base was isolated from the chloroform solution and was crystallized once from chloroform–methanol. An analytical sample was obtained from the same solvent mixture, and had m.p. 235–236.5°.

Anal. Calcd. for $C_{28}H_{22}N_4O$: C, 78.12; H, 5.15; N, 13.02. Found: C, 77.92; H, 5.02; N, 12.83.

Ultraviolet spectrum: λ_{max}^{MeOH} 210 mμ (ε 44 000), 237 mμ (ε 32 700), 267 mμ (ε 11 000), 286 mμ (ε 2 700), 369 mμ (ε 6 900). Infrared spectrum: $\nu_{max}^{CH_2Cl_2}$ 3 380 (NH), 3 310 (NH), 2 740 (aldehyde CH stretch), 1 665 (CHO) cm^{-1}; ν_{max}^{Nujol} 3 370, 3 555, 3 315 (NH), 1 665 (CHO) cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.10 (1H, singlet), τ 0.93 (1H, doublet, J = 5 c.p.s.), τ 1.90–3.50 (16H, complex), τ 4.26 (1H, doublet, J = 5 c.p.s.), τ 4.33 (1H, singlet), τ 4.66 (1H, singlet), τ 5.1 (1H, broad band). Deuteration removed the doublet at τ 0.93 and the band at τ 5.1 from the spectrum, and collapsed the doublet at τ 4.26 to a singlet.

Similar results were obtained by using the bisanhydro trimer in place of *o*-aminobenzaldehyde.

Acetyltrisanhydro Tetramer (VIII, R = $COCH_3$, R′ = H)

The trisanhydro tetramer (730 mg) was acetylated overnight in 1:1 acetic anhydride – pyridine (2 ml) at room temperature. Addition of a little water precipitated a crystalline product which, after one recrystallization from dichloromethane–methanol, gave the pure acetyl derivative. The analytical sample formed plates, m.p. 255–259°, when crystallized from the above solvent mixture.

Anal. Calcd. for $C_{30}H_{24}N_4O_2$: C, 76.25; H, 5.12; N, 11.86; mol. wt. 472. Found: C, 75.93; H, 5.11; N, 11.57; mol. wt. 469 (osmometric).

Infrared spectrum: $\nu_{max}^{CCl_4}$ 3 300 (NH), 1 668 ($NCOCH_3$) cm^{-1}; ν_{max}^{Nujol} 3 325, 1 675 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.05 (1H, singlet), τ 0.92 (1H, doublet, J = 5 c.p.s.), τ 2.0–3.25 (17H, complex), τ 4.20 (1H, doublet, J = 5 c.p.s.), τ 4.25 (1H, singlet), τ 7.5 (3H, singlet). Deuteration removed the doublet at τ 0.92, and collapsed that at τ 4.20 to a singlet.

An oxime was obtained by reaction of *N*-acetyltrisanhydro tetramer (150 mg) with hydroxylamine hydrochloride (145 mg) in pyridine (1 ml) for 12 h at room temperature. The analytical sample formed prisms, m.p. 248–250°, when crystallized from dichloromethane–ether.

Anal. Calcd. for $C_{30}H_{25}O_2N_5$: C, 73.90; H, 5.17; N, 14.37. Found: C, 73.76; H, 5.30; N, 14.20.

A sample of the oxime (115 mg) was dehydrated with toluenesulfonyl chloride (50 mg) in dry pyridine (1 ml) at 0° for 24 h. The solution was poured onto ice, and the product was collected by filtration and crystallized from dichloromethane–methanol to give the corresponding nitrile (107 mg). The analytical sample formed colorless prisms, m.p. 232–234°, when recrystallized from these solvents.

Anal. Calcd. for $C_{30}H_{23}ON_5$: C, 76.74; H, 4.94; N, 14.92. Found: C, 76.28; H, 5.08; N, 15.02.

Infrared spectrum: $\nu_{max}^{CH_2Cl_2}$ 3 420 (NH), 2 225 (CN), 1 675 ($NCOCH_3$) cm^{-1}.

N-Acetyl-N′-nitrosotrisanhydro Tetramer (VIII, R = $COCH_3$, R′ = NO)

Dry nitrosyl chloride was passed slowly during 4 min into a well-stirred ice-cold solution of acetyltrisanhydro tetramer (244 mg) in pyridine (6 ml). The solution was kept at 0–5° for a further 30 min, and then poured onto ice to give the product. This was purified by crystallization from dichloromethane–benzene, giving 205 mg of the *N*-nitroso derivative. The analytical sample formed prisms when recrystallized from benzene, m.p. 192–195°.

Anal. Calcd. for $C_{30}H_{23}N_5O_3$: C, 71.86; H, 4.62; N, 13.96 Found: C, 71.95; H, 4.86; N, 14.24.

Ultraviolet spectrum: λ_{max}^{EtOH} 209 mμ (ε 61 800), with shoulders at 240 mμ (ε 28 600), 275 mμ (ε 6 000), and 283 mμ (ε 5 300). Infrared spectrum: $\nu_{max}^{CCl_4}$ 1 704 (CHO), 1 675 ($NCOCH_3$). Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.10 (1H, singlet), τ 1.65–3.40 (18H, complex), τ 4.57 (1H, singlet), τ 7.50 (3H, singlet).

The Indazole (IX)

A mixture of zinc dust (460 mg) and *N*-acetyl-*N′*-nitrosotrisanhydro tetramer (210 mg) was added to a solution of anhydrous sodium acetate (750 mg) in glacial acetic acid (6 ml). The mixture was stirred for 0.5 h and poured onto ice; the crude product was filtered off and dried. It was purified by filtration through a column of grade III alumina (10 g) followed by crystallization from acetone to yield 155 mg of product. The analytical sample formed needles, m.p. 255–257°, when recrystallized from acetone.

Anal. Calcd. for $C_{30}H_{23}ON_5$: C, 76.74; H, 4.94; N, 14.92. Found: C, 76.22; H, 4.94; N, 14.97.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Ultraviolet spectrum: λ_{max}^{EtOH} 207 mμ (ε 61 500), 282 mμ (ε 5 800), 287 mμ (ε 5 750), and 300 mμ (ε 3 650), with shoulders centered at 245 mμ (ε 16 000) and 292 mμ (ε 5 000). Nuclear magnetic resonance spectrum (100 mCi in $CDCl_3$): τ 1.88 (1H, doublet, J = 0.8 c.p.s.), τ 2.1–3.4 (18H, complex), τ 3.27 (1H, singlet), τ 7.44 (3H, singlet).

Macrocyclic Tetramer (IV, M = Cu)

A solution of cupric nitrate trihydrate (53 mg) in ethanol (1 ml) was added to a refluxing suspension of trisanhydro tetramer (93 mg) in ethanol (2 ml). After 6 h at reflux temperature the solution was cooled and crystalline (IV, M = Cu) nitrate (121 mg, 93%) collected. The product was identical in its solid-state infrared spectrum with that obtained directly from *o*-aminobenzaldehyde by the method of Melson and Busch (3).

By using an equivalent amount of the bisanhydro trimer the same product was obtained in an 85% yield.

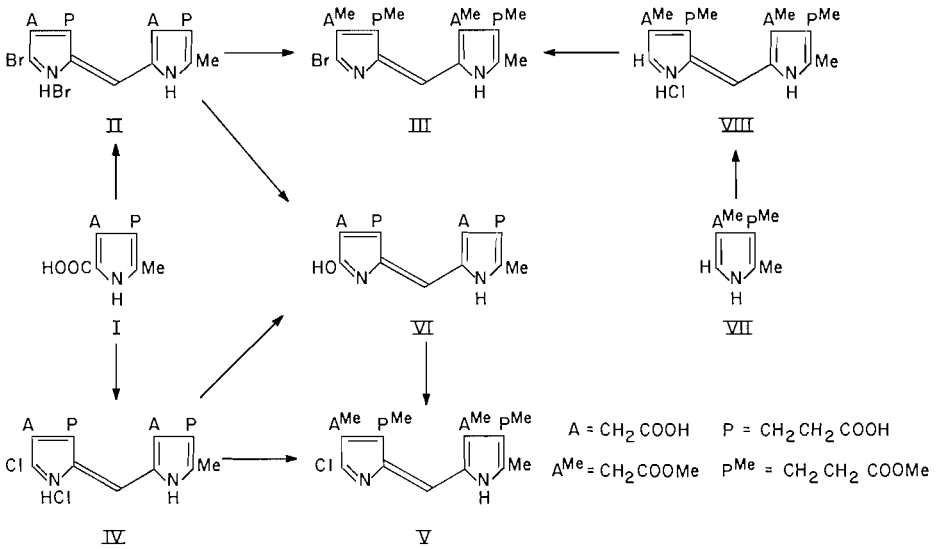
ABSTRACT

Like the known II, the 5-halo-dipyrrylmethenes IV, X, and XI were obtained conventionally by halogenating the pyrroles I and IX. The 5-free dipyrrylmethene VIII, a new type of intermediate in such halogenations, was obtained from the pyrrole ester VII. The four 5-halo-dipyrrylmethenes were hydrolyzed to the 5-hydroxy derivatives VI and XIII, and these were reconverted into 5-chloro-dipyrrylmethenes.

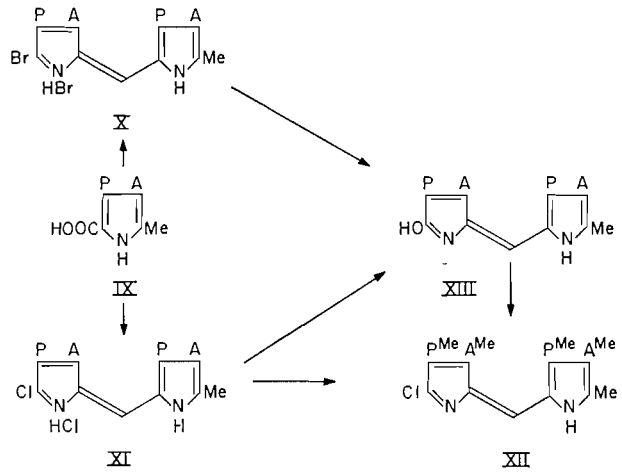
INTRODUCTION



We have tried to obtain the dipyrrylmethene II (CH_2Br for CH_3) and its isomers as intermediates for the syntheses of polypyrranes related to porphobilinogen. They were attractive because, in their analogues, the bromomethyl group condensed with pyrroles (1, pp. 106 and 619; 2), and reduction converted the stable 5-bromo-dipyrrylmethenes into the labile 5-free dipyrrylmethanes (3, 4). Such bromomethyl-dipyrrylmethenes are often obtained by brominating either 5-methyl-dipyrrylmethenes or 2-methyl-pyrroles. However, these methods frequently fail, as in the case of XIV*b* (5), which has only recently been obtained as its ester by brominating 5-*t*-butoxycarbonyl-2,4-dimethyl-pyrrole-3-propionic acid methyl ester (6).

Having failed to halogenate the methyl groups in II or III, we prepared IV, X, and XI to study their halogenation. These were obtained, like II, from the pyrroles I and IX with bromine or sulfuryl chloride. For better characterization, they were esterified and then converted into the free bases III, V, and XII. The hydrochlorides IV and XI dissolved in water, but rapidly precipitated again as the rather unstable free bases, in which the halogen content tended to be low (lower still after recrystallization, the recovery being poor). The free base derived from XIV*a* is reportedly too unstable to be isolated (7).

The investigation of routes to the 5-halomethyl-dipyrrylmethenes was diverted when it was found that 2 moles of VII reacted with 1 mole of sulfuryl chloride to give the 5-free dipyrrylmethene VIII (43%). This was further identified as the free base and by conversion into the authentic 5-bromo-dipyrrylmethene III. It is thus clearly distinguished from another conceivable (cf. ref. 8) product, the ester of 5,5′-dimethyl-dipyrrylmethene-3,3′-diacetic acid 4,4′-dipropionic acid. The occurrence of this 5-free dipyrrylmethene cannot be reconciled with previous assumptions about the course of such halogenations: that the pyrrole is first halogenated in the 5-position and then in the 2-methyl group, and that the 2-halomethyl group (whether arising directly (1, p. 62) or indirectly (8)) then forms the bridge. However, the 5-free dipyrrylmethene would be a possible intermediate if anionotropy (cf. ref. 9, p. 588) made the 5-halo-2-methyl-pyrrole equivalent to the 5-free 2-halomethyl-pyrrole.



Another diversion occurred when the analysis of the hydrochloride XI showed that the ring halogen was unexpectedly labile, both chlorine atoms being determined as chloride

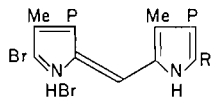
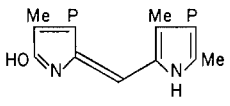
by adding mercuric nitrate and titrating the excess of mercury ion (10).[6] This observation was followed up, for we had had an interest in the likely product: the 5-hydroxy-dipyrrylmethene XIII. These 5-hydroxy-dipyrrylmethenes may have unexploited synthetic possibilities, because the nucleus is stable, the 5-position is blocked, and the reactivity at the 5′-position is similar to that of pyrroles (1, pp. 125, 136, 668, 670, 706, and 710). Other substituents may have the same effect as hydroxy (11). The 5-hydroxy-dipyrrylmethenes would then be attractive as intermediates if the hydroxy groups could be replaced by halogen and thus by hydrogen. However, there was no clear evidence that the replacement by halogen was possible (5, 12).



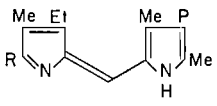
As well as being prepared directly from pyrroles, 5-methoxy- and 5-hydroxy-dipyrrylmethenes have been obtained from 5-bromo-dipyrrylmethenes by refluxing them with methanolic potash (5) or with potassium or silver acetate in acetic acid (13), or by heating them with alkali above 150° (1, p. 135). However, XV, the 5-hydroxy-dipyrrylmethene most closely related to VI, had been obtained from XIV*a* in only a 15% yield (5, 13).

[6]*We owe this observation to Mr. H. Séguin.*

By using mercuric nitrate at room temperature, the 5-chloro-dipyrrylmethene XI was rapidly converted into the 5-hydroxy-dipyrrylmethene XIII, but this method failed with the 5-bromo-dipyrrylmethene X. However, the 5-halo-dipyrrylmethenes II, IV, X, and XI were converted into the corresponding 5-hydroxy-dipyrrylmethenes VI and XIII by Dowex 3 (a weakly basic resin) in boiling 50% ethanol, the chloro derivatives giving more consistent yields (50–60%). This method too is not general, for we did not obtain XV (5, 13) from XIV*a* by using either mercuric nitrate or Dowex 3.



It is difficult to rationalize these and analogous preparations of 5-hydroxy-dipyrrylmethenes. The rates of reaction (2) and the yields have been influenced strongly by the other substituents (13) and by the purity of the materials (14), and 5-hydroxy-dipyrrylmethenes may be oxidized further to tetrapyrroles (13). The variable stability of the 5-halo-dipyrrylmethenes may be important, for X lost nearly all of its halogen when treated with mercuric nitrate but, unlike XI, did not yield XIII. Earlier methods suggest that base catalysis is involved, but sodium hydroxide removed the halogen from IV and XI slowly and incompletely, and the recovery was poor. It was also possible that acid catalysis might be effective, as with the 4-chloroquinazolines (15), because the halogen in the free base of the methyl ester derived from XIV*a* was easily replaced by aniline though not by methylamine or ammonia (5). Apparently, the halogen in 5-bromo-5′-carbethoxy-4,4′-dimethyl-dipyrrylmethene-3,3′-dipropionic acid is more readily hydrolyzed in acidic than in alkaline media, but the report (16) is confused, and this behavior might be conditioned by the 5′-carbethoxy group. The above hydrolysis with mercuric nitrate suggests electrophilic catalysis (cf. ref. 9, p. 357), but there was no evidence of such when XVI*a* was hydrolyzed to XVI*b* with silver acetate rather than with potassium acetate (17).

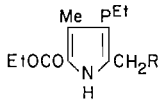


XIV

a, R = Me

b, R = CH_2Br

XV

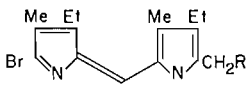


XVI

a, R = Br (Hydrobromide)

b, R = OH

c, R = OMe



XVII

a, R = Br

b, R = N_3

P^{Et} = CH_2CH_2COOEt

XVIII

a, R = Br (Hydrobromide)

b, R = N_3 (Hydrozoate)

The hydroxyl groups in VI and XIII were replaced with chlorine by methanolic hydrogen chloride at room temperature, the products being isolated as the methyl esters V and XII (30%). This was surprising because the hydroxy groups in the dipyrrylmethenes studied earlier (13, 17) were unchanged under these conditions; there the initial products were the hydrochlorides of 5-hydroxy-dipyrrylmethenes, which readily lost hydrogen chloride to give the 5-hydroxy-dipyrrylmethenes. It is unlikely that these hydrochlorides were actually very easily hydrolyzed 5-chloro-dipyrrylmethenes, for 5-chloro-4,3′,5′-trimethyl-3,4′-diethyl-dipyrrylmethene is not that easily hydrolyzed (18). A reaction

related to the above is the conversion of XVI*c* into XVI*b* by methanolic hydrogen chloride (17).

Attempts were made to improve the synthesis of uroporphyrin 1, which had been obtained in a 5.9% yield from II at 118° (19). At 135° the yield from II was 3%, and at 118° the yields from X and from IV were, respectively, 5.3% and <0.1%. In a preliminary experiment modelled on a synthesis of coproporphyrin 1 (20), no porphyrin was obtained from VIII with 6% potassium methoxide in methanol at 180°.[7]

Few meaningful comparisons have been made between 5-chloro- and 5-bromo-dipyrrylmethenes, although the differences are significant. We obtained better yields of 5-hydroxydipyrrylmethenes from the former, whereas the latter have given better yields of porphyrins (cf. ref. 18). Apparently, the labilities of the halogens are not very different, but the 5-bromo-dipyrrylmethenes are more prone to other changes (but less so as esters).

As one projected use of compounds such as II (CH_2Br for CH_3) involved replacing the side-chain halogen with an amino group, we treated XVII*a* and XVIII*a* with sodium azide to obtain XVII*b* and XVIII*b*.

EXPERIMENTAL

5'-Methyl-dipyrrylmethene-4,3'-diacetic Acid-3,4'-dipropionic Acid Tetramethyl Ester Hydrochloride (VIII)

Methyl cryptopyrrole dicarboxylate (VII, 238 mg, 2 moles (21)) in 10 ml of chloroform was treated with 0.04 ml (1 mole) of sulfuryl chloride in 2 ml of chloroform. After 20 h at 20°, the solvent was evaporated *in vacuo* and the crystalline residue recrystallized from chloroform–ether. For analysis, the product (110 mg, 43%, m.p. 156–158°) was recrystallized as red prisms, m.p. 164–165°.

Anal. Calcd. for $C_{24}H_{31}O_8N_2Cl$: C, 56.41; H, 6.12; N, 5.48; Cl, 6.94. Found: C, 56.59; H, 6.00; N, 5.60; Cl (total or ionic (10)), 7.00.

To obtain the *free base*, 100 mg was dissolved in 3 ml of methanol and neutralized with ammonia, and the solution cooled. The product which separated was recrystallized from methanol as yellow needles (55 mg), m.p. 125–127°.

Anal. Found: Cl, 0.00.

5-Bromo-5'-methyl-dipyrrylmethene-4,3'-diacetic Acid-3,4'-dipropionic Acid Tetramethyl Ester (III)

(*a*) 5-Bromo-5'-methyl-dipyrrylmethene-4,3'-diacetic acid-3,4'-dipropionic acid hydrobromide (II, 350 mg (19)) was dissolved in methanol (5 ml) containing acetyl bromide (0.25 ml), and the solution was kept for 24 h at 20°. The solvent was removed *in vacuo* and the residue dissolved in chloroform. The solution was washed with aqueous sodium bicarbonate, and dried (sodium sulfate), and the solvent was evaporated. The residue was recrystallized from methanol as yellow needles (310 mg, 92%), m.p. 127–128°, with solid-phase changes at about 122°.

Anal. Calcd. for $C_{24}H_{29}O_8N_2Br$: C, 52.08; H, 5.28; Br, 14.44. Found: C, 52.35; H, 5.25; Br, 14.97.

A solution of this ester in methanol – acetyl bromide quickly set as a mass of brown prismatic needles of the *hydrobromide*, m.p. 158–163°.

Anal. Calcd. for $C_{24}H_{30}O_8N_2Br_2$: C, 45.44; H, 4.77; Br, 25.20. Found: C, 45.20; H, 4.72; Br, 24.95.

(*b*) 5'-Methyl-dipyrrylmethene-4,3'-diacetic acid-3,4'-dipropionic acid tetramethyl ester hydrochloride (VIII, 100 mg) was suspended in 2 ml of acetic acid, treated with 0.03 ml of bromine in 0.1 ml of acetic acid, and allowed to stand for 3 h at 20°. The solvent was removed *in vacuo*, the residue left overnight in 5 ml of methanol containing 0.25 ml of acetyl bromide, and the product (free base) isolated as in method *a* above to give orange-yellow needles (80 mg, 74%), m.p. 126–127°.

Anal. Found: Br, 14.47.

The products from methods *a* and *b* gave identical X-ray powder photographs and their mixed melting point was undepressed.

5-Bromo-5'-methyl-dipyrrylmethene-3,4'-diacetic Acid-4,3'-dipropionic Acid Hydrobromide (X)

5-Carboxy-hemopyrrole-dicarboxylic acid (IX, 500 mg (22)) was suspended in 3 ml of acetic acid at 50–60°, and 0.16 ml of bromine in 1 ml of acetic acid was added. After 20 min at this temperature, scratching induced crystallization, and the mixture was then left for 16 h in a partially evacuated vacuum desiccator over NaOH. The orange-brown rods (285 mg, 50%, m.p. 190–191° (decomp.)) were washed with acetic acid and then with ether. For analysis, it was recrystallized three times from acetic acid containing some formic acid, m.p. 197–198°.

Anal. Calcd. for $C_{20}H_{22}N_2O_8Br_2$: C, 41.54; H, 3.84; N, 4.85; Br, 27.64. Found: C, 41.26; H, 3.95; N, 4.91; Br, 27.65.

[7]*This was carried out by Dr. B. Gregorovich.*

5-Chloro-5'-methyl-dipyrrylmethene-3,4'-diacetic Acid-4,3'-dipropionic Acid Hydrochloride (XI)

Sulfuryl chloride (0.09 ml) was added to a suspension of 5-carboxy-hemopyrrole-dicarboxylic acid (IX, 245 mg) in 5 ml of acetic acid at 50–60°. After the evolution of gas ceased (about 10 min) the solution was left overnight in a partially evacuated vacuum desiccator over NaOH. The crystalline product (140 mg, 58%, m.p. 175° (decomp.)) was separated and washed with acetic acid and then with ether. For analysis, it was recrystallized from methanol–ether as red-brown prisms, m.p. 179–180° (decomp.), λ_{max} 481 mμ (in methanol).

Anal. Calcd. for $C_{20}H_{22}O_8N_2Cl_2$: C, 49.09; H, 4.53; N, 5.73; Cl, 14.49. Found: C, 49.17; H. 4.69; N, 5.63; Cl, 14.29.

To obtain the *free base*, 100 mg of the hydrochloride was dissolved in 2 ml of water to give a clear solution. After a few seconds the base separated as yellow-brown needles (60 mg), m.p. 191–193° (decomp.) (block preheated to 180°), λ_{max} 462 mμ (in methanol).

Anal. Calcd. for $C_{20}H_{21}O_8N_2Cl$: Cl, 7.83. Found: Cl, 7.31.

The Methyl Ester of the Free Base (XII)

(A) This was prepared from 100 mg of XI and 5 ml of 5% HCl in methanol by the same method as III, except that it was crystallized from ether–*n*-hexane instead of from methanol. It formed yellow prismatic rods (85 mg, 82%), m.p. 101°. For analysis it was recrystallized in the same way, m.p. 103–104°.

Anal. Calcd. for $C_{24}H_{29}N_2O_8Cl$: C, 56.63; H, 5.74; N, 5.50; Cl, 6.97. Found: C, 56.83; H, 5.59; N, 5.66; Cl, 6.80.

(B) 5-Hydroxy-5'-methyl-dipyrrylmethene-3,4'-diacetic acid-4,3'-dipropionic acid (XIII), prepared by methods *a*, *b*, and *c* below, was used. In each case 100 mg of the hydroxy-dipyrrylmethene was dissolved in 10 ml of 10% methanolic hydrogen chloride, and the solution was allowed to stand for 48 h at 20°. The solvent was removed *in vacuo* at 20°. The solution of the residue in chloroform was washed with aqueous sodium bicarbonate, dried, and evaporated. The resulting residue was extracted with 20 ml of ether. The ether was evaporated, leaving the product, which was crystallized from ether–*n*-hexane as yellow prisms (35 mg, 30%), m.p. 100–101°, mixed melting point with the product from method A above 100–101°. The X-ray powder photographs of the products from methods A and B (using XIII prepared by method *b* below from XI and Dowex 3) were identical.

The material insoluble in ether was recrystallized from chloroform–*n*-hexane to give a yellow product (15 mg) which was halogen free, m.p. 220° ("urobilirubin"? (cf. ref. 13)).

5-Chloro-5'-methyl-dipyrrylmethene-4,3'-diacetic Acid-3,4'-dipropionic Acid Hydrochloride (IV)

This was prepared in the same way as its isomer (above), except that 5-carboxy-cryptopyrrole-dicarboxylic acid (I (23)) was used. The crystalline product (200 mg, 81%), m.p. 179–180° (decomp.), was recrystallized for analysis from methanol–ether as orange-brown prisms, m.p. 180–181° (decomp.).

Anal. Calcd. for $C_{20}H_{22}O_8N_2Cl_2$: C, 49.09; H, 4.53; N, 5.73; Cl, 14.49. Found: C, 49.29; H, 4.52; N, 5.66; Cl, 14.45.

The *free base*, like its isomer above, was formed by dissolving the hydrochloride in water, from which the base separated as brown needles (68 mg), m.p. 195–200° (decomp.) (block preheated to 180°).

Anal. Calcd. for $C_{20}H_{21}O_8N_2Cl$: Cl, 7.83. Found: Cl, 7.29.

The Methyl Ester of the Free Base (V)

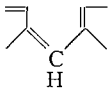
(A) This was prepared from 100 mg of IV and 5 ml of 5% HCl in methanol by the same method as III, except that it was crystallized from ether–*n*-hexane instead of from methanol. It formed orange-yellow prismatic needles (87 mg, 84%), m.p. 117–118°. Recrystallized for analysis, it formed yellow needles, m.p. 119–120°.

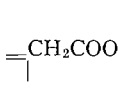
Anal. Calcd. for $C_{24}H_{29}O_8N_2Cl$: C, 56.63; H, 5.74; N, 5.50; Cl, 6.97. Found: C, 56.51; H, 5.69; N, 5.59; Cl, 6.82.

(B) 5-Hydroxy-5'-methyl-dipyrrylmethene-4,3'-diacetic acid-3,4'-dipropionic acid (VI), prepared by methods *a* and *b* below, was used. In each case 100 mg of the hydroxy-dipyrrylmethene was converted into the crude 5-chloro-dipyrrylmethene in the same manner as the isomeric XIII was converted into XII (see above). After the chloroform was evaporated the black crude product was extracted several times with ether. When the extract was evaporated a brown crystalline product remained which was recrystallized three times from ether–*n*-hexane as yellow needles (35 mg, 30%), m.p. 118–119°, undepressed on admixture with the product from method A above. Of the two products here, that of the sequence IV → VI → V was analyzed.

Anal. Found: C, 56.91; H, 6.17; N, 5.33; Cl, 6.82.

The nuclear magnetic resonance spectra of the product from method A and the two products from method B above showed the same chemical shifts.





The Behavior of the 5-Chloro-dipyrrylmethenes IV and XI with Sodium Hydroxide

The dipyrrylmethene XI (100 mg) was allowed to stand at 20° for 1 h in 2 ml of 10% sodium hydroxide, and the product (60 mg containing 6.33% Cl) was then precipitated with acetic acid. This product (60 mg) was twice recycled in the same way, allowing the solution to stand for 3 h (45 mg recovered, 3.42% Cl) and then overnight (20 mg recovered, 0.1% Cl).

When IV was given the same three treatments, the final product contained 0.3% Cl.

TABLE I

Chemical shifts of dipyrrylmethenes (p.p.m., τ scale)

				OCH_3	CH_2CH_2COO		Solvent
V	3.12	—	6.38, 6.51	6.30, 6.33	7.25	7.67	$CDCl_3$ + tetramethysilane
XII	3.18	—	6.40, 6.52	6.31, 6.33	7.29	7.69	$CDCl_3$ + tetramethylsilane
VI	3.92	—	6.62, 6.78	—	7.52	7.85	D_2O/Na + CH_3CN
XIII	3.85	—	6.53, 6.72	—	7.55	7.80	D_2O/Na + CH_3CN
VIII (HCl)	2.55		6.28, 6.22, 6.18		7.30, 7.75		$CDCl_3$
VIII (base)	3.10	2.72	6.27, 6.35		7.33	7.63	$CDCl_3$

5-Hydroxy-5'-methyl-dipyrrylmethene-3,4'-diacetic Acid-4,3'-dipropionic Acid (XIII)

(a) With mercuric nitrate.—The corresponding 5-chloro-dipyrrylmethene hydrochloride (XI, 100 mg) was dissolved in 10 ml of 80% ethanol and the pH adjusted to 9–10 with 5% sodium hydroxide, giving a clear solution. The pH was then brought to 3.6 with 0.1% nitric acid, and 20 ml of mercuric nitrate solution (10) was added. The dark solution was concentrated and the crystalline product (40 mg, 45%) separated. It was extracted into methanol (thimble) and the solution was concentrated, filtered while hot, and cooled. The product (30 mg) formed yellow prisms, m.p. 230° (decomp.) (block preheated to 210°).

Anal. Calcd. for $C_{20}H_{22}O_9N_2$: C, 55.30; H, 5.11; N, 6.45; Cl, 0.00. Found: C, 55.18; H, 5.29; N, 6.60; Cl, 0.00.

(b) With Dowex 3 and aqueous ethanol.—The 5-chloro-dipyrrylmethene hydrochloride (XI, 500 mg) was dissolved in 50 ml of 50% ethanol, and 2.5 g (dry weight) of Dowex 3 was added. The mixture was refluxed on the steam bath for 30 min with occasional shaking. The resin was filtered off and washed well with water, and the combined filtrate and washings were evaporated in a rotary evaporator to give the yellow crystalline product (266 mg, 60%). It was recrystallized from methanol (thimble) or from hot water as yellow prisms, m.p. 231–232° (decomp.) (block preheated to 210°) alone or admixed with the product from method *a* above.

Anal. Found: C, 55.57; H, 5.28; N, 6.23; Cl, 0.00.

(*c*) The 5-bromo-dipyrrylmethene hydrobromide (X, 500 mg) was heated with Dowex 3 and 50% ethanol as under method *b* above. When the very-dark filtered solutions and washings were evaporated a brown residue (250 mg) remained. This was extracted with methanol (from a thimble, above a second thimble containing Darco), and the methanol concentrated. The product (100 mg, 27%) separated as yellow prisms, m.p. 230° (decomp.) (block preheated to 210°) alone or admixed with the product from method *a* above.

Anal. Found: Br, 0.00.

The Dowex 3 had been washed well with water. Some lots of the resin adsorb the products, and the apparent yields are low. In this case, the products were extracted from the resin by leaving it overnight in dilute ammonia. The resin was then washed with water as long as the washings were yellow. The extracts (500 ml) were evaporated in a rotary evaporator, the residue was dissolved in a little water, and the product was precipitated with acetic acid.

The products obtained by methods *a*, *b*, and *c* above, λ_{max} 421 mμ (in water), showed the same chemical shifts in their nuclear magnetic resonance spectra and were converted into the same 5-chloro-dipyrrylmethene methyl ester (XII, see above).

5-Hydroxy-5'-methyl-dipyrrylmethene-4,3'-diacetic Acid-3,4'-dipropionic Acid (VI)

(*a*) The 5-chloro-dipyrrylmethene hydrochloride (IV, 500 mg) was refluxed in 50% ethanol with Dowex 3 in the same manner as its isomer (above), and a crude brown product (270 mg) was isolated. It was recrystallized from methanol as yellow-brown prisms (250 mg, 56%), m.p. 238° (decomp.) (block preheated to 220°). For analysis it was again recrystallized as yellow prisms, m.p. 238–240° (decomp.).

Anal. Calcd. for $C_{20}H_{22}O_9N_2$: C, 55.30; H, 5.11; N, 6.45; Cl, 0.00. Found: C, 55.25; H, 5.38; N, 6.60; Cl, 0.00.

(*b*) The 5-bromo-dipyrrylmethene hydrobromide (II, 500 mg) was treated as in method *a*. The crude brown product (220 mg) was extracted with methanol (thimble, above a second thimble containing Darco), and the extract concentrated. The product (200 mg, 53%) separated as brownish-yellow prisms, m.p. 236–238° (decomp.) (block preheated to 220°) alone or admixed with the product from method *a* above.

Anal. Found: Br, 0.00.

The products obtained by methods *a* and *b* above, λ_{max} 419 mμ (in water), showed the same chemical shifts in their nuclear magnetic resonance spectra, and were converted into the same 5-chloro-dipyrrylmethene methyl ester (V, see above).

Uroporphyrin 1 Octamethyl Ester

(*a*) 5-Bromo-5'-methyl-dipyrrylmethene-3,4'-diacetic acid-4,3'-dipropionic acid hydrobromide (X) was heated with methylsuccinic acid at 118°, and the product was isolated in the same way as was that from the isomeric dipyrrylmethene II (19), 5.3%, m.p. 282–285°, raised to 284–285° (lit. (19) m.p. 285–286°) after several recrystallizations.

Anal. Calcd. for $C_{48}H_{54}O_{16}N_4$: C, 61.14; H, 5.77; N, 5.94; OMe, 26.33. Found: C, 61.06; H, 5.68; N, 5.90; OMe, 26.18.

This uroporphyrin methyl ester was degraded to coproporphyrin 1 methyl ester, m.p. 251–254° (lit. (19) m.p. 251–252°).

(*b*) 5-Chloro-5'-methyl-dipyrrylmethene-4,3'-diacetic acid-3,4'-dipropionic acid hydrochloride (IV, 250 mg) was heated with 1 g of methylsuccinic acid at 118° and the melt worked up as above. The product (0.13 mg, 0.06% (estimated spectroscopically)) did not crystallize.

2-Azidomethyl-4-methyl-5-carboxy-pyrrole-3-propionic Acid Diethyl Ester (XVIIb)

Powdered sodium azide (1 g) was warmed in 240 ml of dimethylformamide (distilled over P_2O_5) until it dissolved. A solution of 5 g of 2-bromomethyl-4-methyl-5-carboxy-pyrrole-3-propionic acid diethyl ester (XVII*a* (24)) in 10 ml of warm dimethylformamide was added. The solution was heated on the steam bath for 2 h and the solvent then removed at 50° in a rotary evaporator. The residue was washed with

water (2 × 10 ml), and then extracted with 60 ml of chloroform. The chloroform solution was washed with water (3 × 10 ml), and dried with sodium sulfate; then the solvent was evaporated. This residue was dissolved in 10 ml of warm chloroform, and 45 ml of pentane was added. The product (3.38 g) separated slowly as stable colorless needles, m.p. 110–110.5°.

Anal. Calcd. for $C_{14}H_{20}O_4N_4$: C, 54.53; H, 6.54; N, 18.17. Found: C, 54.64; H, 6.44; N, 18.20.

5-Bromo-5′-azidomethyl-4,3′-dimethyl-3,4′-diethyl-dipyrrylmethene Hydrazoate (XVIIIb)

The hydrobromide of 5-bromo-5′-bromomethyl-4,3′-dimethyl-3,4′-diethyl-dipyrrylmethene (XVIII*a*, 480 mg (4)) and 140 mg of sodium azide were refluxed in 20 ml of acetone and 5 ml of water for 1 h. The solvent was evaporated *in vacuo* and the residue, after being washed with water, crystallized from 85% acetone. This product (300 mg), m.p. 125–126°, was recrystallized three times to give brown rods, m.p. 129–130° (decomp.).

Anal. Calcd. for $C_{16}H_{21}N_8Br$: C, 47.41; H, 5.22; N, 27.65; Br, 19.72. Found: C, 47.52; H, 5.16; N, 27.42; Br, 19.60.

The *free base*, though crystalline, was quite unstable.

ACKNOWLEDGMENTS

We are indebted to Dr. Maria Przybylska for the X-ray powder photographs, and to Mr. H. Séguin for the microanalyses.

A NOVEL SYNTHESIS OF SOME MIXED ARYLMETHYL–ALKYL ETHERS

K. G. RUTHERFORD, O. A. MAMER, J. M. PROKIPCAK, AND R. A. JOBIN

During an investigation into the synthesis of optically active trityl systems, it was found that triphenylcarbinol could be converted into its methyl ether in an excellent yield by treatment with iodine in methanol. Although the reaction appeared to be an obvious one, a survey showed that such a procedure had not as yet been recorded in the literature. It became of interest, then, to study this ether-forming reaction with other arylcarbinols which have become available in our laboratory.

Table I indicates the mixed ethers synthesized by this procedure. Although iodine was shown to be a catalyst by titration with standard sodium thiosulfate, the best results were obtained when it was used in approximately equimolar amounts. The arylcarbinol was dissolved in a mixture of acetone and aliphatic alcohol, iodine was added, and the reaction mixture was stirred at room temperature for periods of up to 2 h.

TABLE I

Properties of the mixed ethers

Ether	Melting point (°C)		Boiling point (°C)		Yield (%)
	Reported	Observed	Reported	Observed	
$(R)_3COCH_3$ (I)	80–82 (1)	81.5–82.5			90
$(R)_3COC_2H_5$ (II)	84.5 (2)	82.5–83.5			80

¶$n_D^{18.5}$ 1.5150.

It is apparent from the table that ether formation coincides quite favorably with what would be expected from the structure of the arylcarbinol and the ease of carbonium ion formation. Thus methyl ethers I, VI, VII, VIII, XI, XII, and XIII are obtained in good yields from the corresponding arylcarbinols. Again, those arylcarbinols which were nitro substituted did not undergo reactions under the conditions employed.

A definite trend towards a decrease in the yield of ether formation is observed from methyl, ethyl, *n*-propyl, and *i*-propyl alcohols. This effect could well be a manifestation of

the progressive decrease in the dielectric constant (32.63, 24.3, 20.1, and 18.3, respectively, (10)), although *i*-propyl alcohol presents a formidable steric effect as well. No *t*-butyl ether could be made from the reaction of *t*-butyl alcohol and the arylcarbinols employed. Undoubtedly, iodine-catalyzed dehydration of *t*-butyl alcohol was a competing reaction. A very unfavorable steric effect is also operative in this case.

The mechanism of the reaction is probably best represented by the sequence of reactions shown in eqs. [1]–[4].

[1] $$R{-}OH + I_2 \rightleftharpoons R{-}\overset{\displaystyle I}{\underset{|}{O}}{-}H^+ + I^-$$

[2] $$R{-}\overset{\displaystyle I}{\underset{|}{O}}{-}H^+ \rightleftharpoons R^+ + HOI$$

[3] $$R^+ + R'OH \rightarrow R{-}O{-}R' + H^+$$

[4] $$HOI + HI \rightleftharpoons H_2O + I_2$$

This mechanism is essentially the same as that proposed by Dhar and his co-workers (11) for the iodine-catalyzed dehydration of alcohols, and accounts for the trends in the yields of methyl ether formation previously discussed as well as for the catalytic activity of iodine. Further support for the carbonium ion nature of the reaction (eq. [2]) was found when 4-methoxybenzyl alcohol was reacted with anisole in the presence of iodine. Bis-(4-methoxyphenyl)-methane was isolated in 82% yield (eq. [5]). To our knowledge, this is the first recorded example of an iodine-catalyzed Friedel–Crafts reaction.

[5] 

All of the ethers prepared by this method were well characterized by infrared spectrometry, elemental analysis, and (in all cases where possible) mixed melting point determinations with authentic samples which were prepared according to known procedures.

EXPERIMENTAL

All melting points were determined on the Fisher–Johns melting point apparatus and are uncorrected. Analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside 77, New York.

Triphenylcarbinol was obtained from commerical sources. Phenyl-*p*-tolyl-1-naphthylcarbinol was obtained by the reaction of 1-naphthylmagnesium bromide with 4-methylbenzophenone. The appropriate carbinols were obtained by the reduction of the appropriate ketones with sodium borohydride. This reagent does not reduce the nitro groups.

Authentic samples of the mixed ethers were prepared by the well-known reaction of arylmethyl chlorides with aliphatic alcohols in the presence of pyridine.

The general procedure for the synthesis of the mixed ethers by the iodine-catalyzed method involved dissolution of the arylcarbinol in an excess of the aliphatic alcohol. Iodine was added and the reaction mixture was stirred for approximately 2 h, whereupon it was poured onto a mixture of crushed ice and sodium thiosulfate solution. The product was isolated by crystallization or distillation. The preparation of the methyl ethers of triphenylcarbinol and 4-methoxybenzyl alcohol is given below.

Methyl Ether of Triphenylcarbinol

A solution of 10 g (0.0385 mole) of triphenylcarbinol, 10 g (0.039 mole) of iodine, and 50 ml of methanol was stirred at room temperature for 2 h. The reaction mixture was poured slowly, with stirring, into a cold solution of sodium thiosulfate (50 g $Na_2S_2O_3$ in 500 ml water). The methyl ether was recovered by filtration. Recrystallization from ethanol gave 9.5 g (90%) of the methyl ether, m.p. 81.5–82.5°.

Methyl Ether of 4-Methoxybenzyl Alcohol

A solution of 10 g (0.082 mole) of 4-methoxybenzyl alcohol, 15 g (0.059 mole) of iodine, 50 ml of methanol, and 50 ml of acetone was stirred at room temperature for 18 h, after which it was poured slowly into a solution of 50 g of sodium thiosulfate in 500 ml of water. The resultant mixture was extracted twice with 50 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

portions of methylene chloride. These extracts were combined, dried over anhydrous sodium sulfate, and subjected to fractional distillation. The fraction boiling in the range of 223–225° at 745 mm was collected (reported (9) b.p. 225.5° at 758 mm). A yield of 8.1 g (80%), η_D^{20} 1.5150, was obtained.

Bis-(4-methoxyphenyl)-methane

A mixture of anisole (5.4 g, 0.05 mole), 4-methoxybenzyl alcohol (6.9 g, 0.05 mole), and iodine (12.7 g, 0.05 mole) was dissolved in 40 ml acetone, whereupon the temperature rose quickly to 45°. The mixture was allowed to stand, with stirring, for 30 min and then was poured into a solution of excess sodium thiosulfate and ice water. The mixture was extracted twice with 50 ml portions of ether. The ether extracts were dried over anhydrous potassium carbonate, treated with Norit, and evaporated *in vacuo* to an oil which crystallized when allowed to stand (9.4 g, 82%), m.p. 35–41°. The product was dissolved in hot ethanol and the solution was cooled to give white crystals of bis-(4-methoxyphenyl)-methane, m.p. 44–46° (recorded (12) m.p. 46–47°). The infrared spectrum showed the following bands: aromatic ring skeletal vibrations at 1 613, 1 585, 1 506, and 1 464 cm^{-1}, multiple CO stretching bands in the region of 1 300 to 1 030 cm^{-1}, methoxyl CH stretching at 2 830 cm^{-1}, and aromatic CH "out of plane" bending overtones at 1 875 and 1 775 cm^{-1}, which corresponds to 1,4-disubstitution on the benzene nucleus.

The structure of the product was confirmed by oxidation with chromic oxide in acetic acid to 4,4′-dimethoxybenzophenone, m.p. 144–145° (recorded (13) m.p. 143.5–145°).

For personal use only.

reaction of cyclohexene oxide with sulfuryl chloride and pyridine or with thionyl chloride and pyridine produces the 1,2-dichlorocyclohexanes in satisfactory yield, with the *cis* isomer predominating. Depending on the conditions, the proportion of the *cis* isomer can be increased to greater than 99.5%. This is therefore a convenient route to a *cis* dichloride. The application of the conditions worked out in the present study to other epoxides[1] indicates that the reaction is a general one and proceeds with inversion of configuration at both termini of the epoxide.

Table I summarizes the results of a number of experiments performed in the absence of a solvent, using various quantities and modes of addition of the reagents at different temperatures. These results indicate that, with sulfuryl chloride, higher yields of dichloride are obtained with an excess of the halide, but the stereospecificity is greater when equivalent amounts of the three reactants are used. Equivalent amounts of oxide and sulfuryl chloride with an excess of pyridine (run 5) led to a poor yield of dichloride, which consisted mainly of the *trans* isomer. The proportions of the *cis* and *trans* isomers are not temperature dependent. However, the reaction is more difficult to control at the lower temperatures and the yields are not as good. Replacing sulfuryl chloride with thionyl chloride had no significant effect on the yield or the stereospecificity (runs 3 and 13) when equal amounts of the reactants were used. Excess thionyl chloride caused a reduction in the yield but not in the stereospecificity (runs 9 and 13).

TABLE I

The neat reaction of cyclohexene oxide with thionyl chloride and pyridine and with sulfuryl chloride and pyridine

§This run was performed in the presence of 10.2 mmoles of added pyridine hydrochloride.
‖The reaction mixture spontaneously warmed to 75°.
¶Halide added to the oxide and pyridine.
**A violent evolution of gas occurred as the reaction mixture was being brought to room temperature.
††$SOCl_2$.

The data summarized in Table II show that there is a dramatic improvement in the stereospecificity when the reaction is mediated by a solvent. Chloroform is more effective than carbon tetrachloride (runs 15 and 17) and, in chloroform, sulfuryl chloride is more effective than thionyl chloride (runs 18 and 19). The optimum conditions for the reaction appear to be those of run 18.

The reaction of iodobenzene dichloride with olefins may yield either a *cis* (4) or a *trans* (5) dichloride depending on the structure of the substrate. With cyclohexene this reagent produced the highest stereospecificity of any chlorinating agent which we have used, the product containing *no detectable amount of the cis isomer*. Table IV shows this result together with the results obtained from the action of other chlorinating agents on cyclohexene.

EXPERIMENTAL

Preparation of Reagents

Commercial *pyridine* was purified by refluxing over sodium hydroxide (1 g/10 ml) and distillation, the fraction boiling at 115.0–115.5° being retained.

Commercial *sulfuryl chloride* was purified by distillation, the fraction boiling at 68.5–69.2° being retained.

Thionyl chloride was purified by distillation, the fraction boiling at 78.6–79.1° being retained.

Cyclohexene oxide was prepared by reacting cyclohexene bromohydrin with 20% sodium hydroxide (6), and was purified by distillation, the fraction boiling at 131.5–132.5° being retained.

Iodobenzene dichloride was prepared by the addition of chlorine to iodobenzene (7).

Cyclohexene chlorohydrin was prepared by reacting cyclohexene with aqueous *N*-chlorosuccinimide (8), and was purified by distillation, b.p. 67.0–68.0° at 5 mm.

Analytical Procedure

The dichlorides were analyzed by gas chromatography on a 6 ft column packed with 15% butanediol succinate on Embacel. The instrument used was a Beckman GC2 gas chromatograph operated at 130° and 30 p.s.i. of helium. The appearance times were: *trans*, 10.3 min; *cis*, 22.2 min. The ratios were determined by the triangulation method (9).

General Procedure

(a) Without Solvent

A solution of cyclohexene oxide (15.8 g, 0.161 mole) in pyridine (25.45 g, 0.322 mole) was added during a 40 min period to sulfuryl chloride (43.1 g, 0.322 mole) at 75° (gentle reflux). A gas was evolved and the mixture darkened. After a further 1.5 h at 75°, water was cautiously added and the organic layer was extracted with ether. The ether extract was washed with 10% sodium carbonate and water, and was then dried over anhydrous magnesium sulfate. Concentration gave 18.5 g of a brown oil which consisted of 88.4% of *cis*-1,2-dichlorocyclohexane and 11.6% of *trans*-1,2-dichlorocylohexane. The *cis* dichloride was freed from the *trans* isomer by preparative gas chromatography (Fisher preparative partitioner) and was then distilled at 75.0–75.3° and 3–4 mm.

Anal. Calcd. for $C_6H_{10}Cl_2$: C, 47.08; H, 6.59. Found: C, 46.92; H, 6.31.

The infrared spectrum of the *cis* isomer (10% in carbon disulfide) showed a single peak at 13.6 μ; the *trans* compound showed a doublet in this region, at 13.5 μ and 13.6 μ.

(b) In Chloroform

Sulfuryl chloride (1.51 g, 11.2 mmoles) was added during 5 min to a refluxing solution of cyclohexene oxide (1.0 g, 10.2 mmoles) and pyridine (0.81 g, 10.2 mmoles) in chloroform (10 ml). There was no darkening during the addition. The reaction mixture was refluxed for 16 h and was then diluted with water (15 ml) and ether (35 ml). The organic layer was dried over anhydrous magnesium sulfate and concentrated to give 1.08 g of material which was chromatographed on neutral alumina (activity III). Elution with petroleum ether gave 0.68 g (45%) of the dichlorocyclohexanes which contained 99.0% of the *cis* isomer.

REARRANGEMENT STUDIES WITH ^{14}C
XXVIII. SOLVOLYSES OF 1-^{14}C-1-PROPYL *p*-TOLUENESULFONATE

C. C. LEE AND JAMES E. KRUGER[1]

In the deamination of isotopically labeled 1-propylamine, published data (1, 2) have suggested the possible occurrence of 1,3-hydride shifts in accounting for the isotope position rearrangements observed in the resulting 1-propanol. More recent studies (3–5), however, have demonstrated that such rearrangements arose from some involvement of protonated cyclopropanes rather than 1,3-hydride shifts. It is of interest to investigate the possible isotopic rearrangements that may accompany solvolyses of 1-^{14}C-1-propyl *p*-toluenesulfonate (I) so as to assess the role, if any, of protonated cyclopropanes in such reactions.

1-^{14}C-1-Propanol was purchased commercially or prepared by the lithium aluminium hydride reduction of 1-^{14}C-propionic acid obtained from the reaction of ethylmagnesium bromide with ^{14}C-carbon dioxide. The alcohol was converted into the *p*-toluenesulfonate I, which was then subjected to solvolysis in acetic acid at 110 °C for 42 h or in refluxing formic acid for 18 h. The product, 1-propyl acetate or formate, was separated from minor amounts of 2-propyl acetate (less than 1%) or formate (1–2%) by preparative vapor-phase chromatography. After alkaline hydrolysis of these esters, the resulting 1-propanol was oxidized to propionic acid which was, in turn, degraded to acetic acid and methylamine as previously described (1, 3, 4). The propionic acid, acetic acid, and methylamine were converted into the appropriate solid derivatives, which were purified by repeated crystallizations until their specific activities were constant. The activity of the acetic acid served as a measure of the rearrangement of the ^{14}C-label from C-1 to C-2 and C-3, and the activity of the methylamine indicated the rearrangement to C-3. The results are summarized in Table I.

TABLE I

Rearrangements in the solvolyses of 1-^{14}C-1-propyl *p*-toluenesulfonate (I)

*Measured by a liquid scintillation counter.
†Assayed as the *p*-bromophenacyl ester.
‡Assayed as the *N*-methyl *p*-toluenesulfonamide.
§The starting material I was prepared from commercially obtained 1-^{14}C-1-propanol, a control degradation of which gave CH_3COOH containing an appreciable amount of activity.
‖The starting material I was prepared from 1-^{14}C-1-propanol synthesized in this laboratory; a controlled degradation gave CHC_3COOH with negligible activity.

In the first acetolysis run (expt. 1, Table I), the specific activities of the compounds assayed were such that the degradation product, the solid *p*-bromophenacyl ester of acetic acid, showed an actually observed net activity, for samples weighing about 15 mg, of only about 10 c.p.m., whereas the background activity was of the order of 15–20 c.p.m.

The reliability of the apparent rearrangement of 0.3% from this experiment was thus questionable. In expt. 2, starting material of much higher specific activity was employed, and the results indicated an essentially negligible isotopic rearrangement in the 1-propyl acetate from the acetolysis of I.

In the formolysis studies, a preliminary run with I of relatively lower specific activity suggested the possible presence of rearranged ^{14}C on both C-2 and C-3. Further experiments with starting materials of higher specific activities were carried out. In expt. 3, I was prepared from commercially obtained 1-^{14}C-1-propanol, the degradation of which, however, gave a sample of acetic acid containing an appreciable amount of radioactivity (about 0.2–0.3%). The formolysis product from expt. 3 was therefore degraded only to acetic acid, and not to methylamine. For expt. 4, 1-^{14}C-1-propanol of very high specific activity was synthesized in the laboratory. Its degradation to essentially inactive acetic acid showed that all of the ^{14}C-label was located on C-1. The alcohol was then converted into I and subjected to formolysis. The results from this experiment indicated a total of 0.83% ^{14}C-rearrangement from C-1 to C-2 and C-3 in the 1-propyl formate. From the activity on C-3, it was deduced that 0.15% and 0.68% of the rearranged ^{14}C were located on C-2 and on C-3, respectively. Although the magnitudes of these rearrangements were small, the reliability of these values was good (because of the high activities involved). The difference between the specific activities of the solid derivatives of acetic acid and methylamine was beyond experimental error. It can therefore be concluded that the formolysis of I gave 1-propyl formate showing a small amount of isotopic rearrangement, the rearranged ^{14}C being located on both C-2 and C-3, with the amount of ^{14}C on C-3 greater than that on C-2.

The absence of isotopic rearrangement in the acetolysis and the observation of only minor amounts of rearrangement in the formolysis showed the expected similarity with the solvolyses of 1-^{14}C-ethyl *p*-toluenesulfonate, which gave no detectable isotopic scrambling (6). These findings, coupled with the low yields of the 2-propyl products (which have also been reported by Huisgen and Ruchardt (7) for acetolysis), may be regarded as being consistent with a direct displacement as the major reaction pathway in the solvolyses of I. Alternatively, the results could also be interpreted in a manner similar to that discussed by Streitwieser (8) for the acetolysis and formolysis of optically active 1-*d*-1-butyl *p*-bromobenzenesulfonate. According to this view (8), solvolyses of even primary substrates in solvents of low nucleophilic character, such as acetic and formic acids, are not necessarily direct displacements of the S_N2 type. The structure usually regarded as the transition in an S_N2 displacement, a "covalently solvated carbonium ion", may be considered as the initial *intermediate*. For a primary central carbon with its low steric requirements and relative inability to delocalize a positive charge, the major reaction path would lead to an inverted product, the same as in a direct displacement. In the 1-propyl system, 1,2-hydride shifts in the solvated carbonium ion would account for the small amount of the 2-propyl product. The isotopic rearrangements observed in the formolysis could be interpreted as arising from some involvement of edge-protonated cyclopropanes. The initially formed protonated cyclopropane, II*a*, would give rise to the isotopically rearranged 3-^{14}C-1-propyl formate and the unrearranged 1-^{14}C-1-propyl formate. Subsequent equilibration of the three equivalent edge-protonated cyclopropanes (II*a* $\rightleftarrows$ II*b* $\rightleftarrows$ II*c*) would result in the distribution of the rearranged ^{14}C over all three carbon positions. In the formolysis of I, more formate was derivated from the initially formed edge-protonated cyclopropane, thus accounting for a greater amount of the rearranged ^{14}C on C-3 than on C-2.

In the deamination of 1-propylamine (3–5), the decomposition of the alkyldiazonium ion gave stable nitrogen and a highly energetic or vibrationally excited "hot" carbonium ion. In contrast to solvolyses, more 1,2-hydride shifts as well as a greater involvement of protonated cyclopropanes were noted. More 1,2-hydride shifts in the deamination of 1-^{14}C-ethylamine (9) than in the solvolyses of 1-^{14}C-ethyl *p*-toluenesulfonate (6) have also been observed. In the deamination of 1-propylamine, that portion of the reaction which proceeds via protonated cyclopropane apparently results from a more complete equilibration of II*a*–II*c*, giving rise to a rearranged 1-propanol with an isotopic distribution approaching that expected for a complete equivalence of all three carbon positions (3–5).

EXPERIMENTAL

1-^{14}C-1-Propyl p-Toluenesulfonate (I)

1-^{14}C-1-Propanol was prepared by the lithium aluminium hydride reduction of 1-^{14}C-propionic acid obtained from the reaction of ethylmagnesium bromide with carbon dioxide generated from sodium carbonate containing 10 mCi of ^{14}C. Treatment of the alcohol with *p*-toluenesulfonyl chloride in pyridine gave I, b.p. 136–140 °C at 2 mm (lit. (7) b.p. 102–109 °C at 0.01 mm).

Anal. Calcd. for $C_{10}H_{14}O_3S$: C, 56.05; H, 6.58; S, 14.96. Found: C, 56.05; H, 6.65; S, 14.93.

Acetolysis

A solution of 16.95 g (0.079 mole) of I in 75 ml of glacial acetic acid containing 8.75 g of potassium acetate was heated under reflux, with stirring, in a bath at 110 °C for 42 h. The material was poured into a 500 ml flask containing 150 ml of ice water; the resulting mixture was distilled, the fraction boiling between 80 and 99 °C being collected. The distillate was saturated with potassium carbonate and the upper organic layer was separated. After the organic material was dried over anhydrous magnesium sulfate, it was redistilled. Analytical vapor-phase chromatography showed that the major product was 1-propyl acetate, the amount of 2-propyl acetate being less than 1%. Final purification was effected by preparative vapor-phase chromatography with a column packed with 20% didecyl phthalate on Chromosorb P. The recovery of 1-propyl acetate was 5.12 g (63%).

Formolysis

A solution of 13.80 g (0.064 mole) of I in 55 ml of formic acid (reagent grade, 98–100% HCOOH, redistilled) was gently refluxed for 18 h. The material was poured into 150 ml of ice water and then extracted with four 30 ml portions of ether. The extract was carefully treated with solid potassium carbonate, washed with a small amount of water, and dried over anhydrous magnesium sulfate. After removal of the ether, the residue was fractionated, the fraction boiling between 65 and 83 °C being collected. Analytical vapor-phase chromatography showed that the major product was 1-propyl formate, the amount of 2-propyl formate being about 1–2%. Final purification was effected by preparative vapor-phase chromatography with a column packed with 20% Carbowax 20M on Chromosorb P. The recovery of 1-propyl formate was 1.30 g (23%).

Degradation

Samples of 1-propyl acetate or formate were hydrolyzed by refluxing them in 10% sodium hydroxide for 3 h. The resulting mixture was steam-distilled to give an aqueous solution of 1-propanol, which was used directly for oxidation to propionic acid (1, 3, 4). Where necessary, some inactive 1-propanol was added as carrier before the oxidation. The propionic acid was, in turn, degraded to acetic acid and methylamine by previously described methods (1, 3, 4).

POLYFLUORINATED AROMATIC ESTERS
PREPARATION AND CARBONYL STRETCHING FREQUENCIES

ROBERT FILLER, JAMES F. WHITE, ANDREW J. KACMAREK, AND IRVINE J. SOLOMON

As part of studies currently in progress on the chemistry of highly fluorinated aromatic compounds, we have prepared a number of esters and have examined their infrared spectra with reference to the influence of pentafluorophenyl substitution on the carbonyl frequency. The role of perfluoroalkyl groups in shifting the ester carbonyl band to higher frequencies has been discussed previously (1–4).

In this note we report the preparation and infrared spectral data for phenyl benzoates in which a pentafluorophenyl group is located in the acid and (or) phenolic portions of the ester, as well as data for several other esters containing the C_6F_5 group. The results are summarized in Table I.

TABLE I
Carbonyl frequencies of pentafluorophenyl esters

Compound	$\nu_{C=O}$ (cm^{-1})
$C_6H_5CO_2C_6H_5$	1 740
$C_6F_5CO_2C_6H_5$	1 770
$C_6H_5CO_2C_6F_5$	1 765
$C_6F_5CO_2C_6F_5$	1 780
$C_6F_5CO_2CH_2CH_3$	1 741
$C_6F_5CO_2CH_2CF_3$	1 760, 1 765
$CF_3CO_2C_6F_5$	1 787

The data may be rationalized in terms of both the inductive and mesomeric effects. If we consider the canonical structures *a–d*, we see that, when R = alkyl, electron release causes the relative contribution of structure *d* to be much more significant than when R = C_6H_5, thereby enhancing the single-bond character of the $\rangle C{=}O$ group (lower frequency). Thus, methyl benzoate exhibits carbonyl absorption at 1 724 cm^{-1} (5), whereas in phenyl benzoate the band shifts to 1 740 cm^{-1}. Comparison of ethyl pentafluorobenzoate with phenyl pentafluorobenzoate provides a second example.

When the phenyl group is replaced by the C_6F_5 group in the acid portion of the ester,

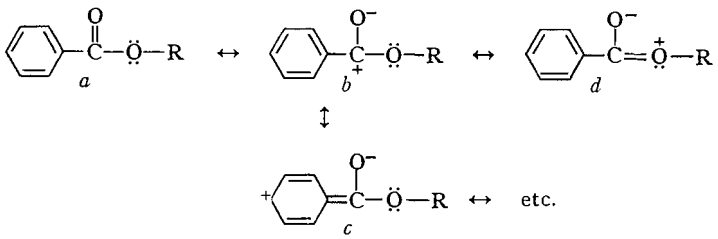
POLYFLUORINATED AROMATIC ESTERS
PREPARATION AND CARBONYL STRETCHING FREQUENCIES

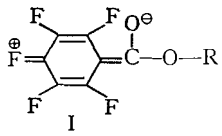
ROBERT FILLER, JAMES F. WHITE, ANDREW J. KACMAREK, AND IRVINE J. SOLOMON

As part of studies currently in progress on the chemistry of highly fluorinated aromatic compounds, we have prepared a number of esters and have examined their infrared spectra with reference to the influence of pentafluorophenyl substitution on the carbonyl frequency. The role of perfluoroalkyl groups in shifting the ester carbonyl band to higher frequencies has been discussed previously (1–4).



In this note we report the preparation and infrared spectral data for phenyl benzoates in which a pentafluorophenyl group is located in the acid and (or) phenolic portions of the ester, as well as data for several other esters containing the C_6F_5 group. The results are summarized in Table I.

TABLE I
Carbonyl frequencies of pentafluorophenyl esters



Compound	$\nu_{C=O}$ (cm^{-1})
$C_6H_5CO_2C_6H_5$	1 740
$C_6F_5CO_2C_6H_5$	1 770
$C_6H_5CO_2C_6F_5$	1 765
$C_6F_5CO_2C_6F_5$	1 780
$C_6F_5CO_2CH_2CH_3$	1 741
$C_6F_5CO_2CH_2CF_3$	1 760, 1 765
$CF_3CO_2C_6F_5$	1 787

The data may be rationalized in terms of both the inductive and mesomeric effects. If we consider the canonical structures *a–d*, we see that, when R = alkyl, electron release causes the relative contribution of structure *d* to be much more significant than when R = C_6H_5, thereby enhancing the single-bond character of the $\rangle C{=}O$ group (lower frequency). Thus, methyl benzoate exhibits carbonyl absorption at 1 724 cm^{-1} (5), whereas in phenyl benzoate the band shifts to 1 740 cm^{-1}. Comparison of ethyl pentafluorobenzoate with phenyl pentafluorobenzoate provides a second example.

When the phenyl group is replaced by the C_6F_5 group in the acid portion of the ester,

the strong electron-attracting inductive effect serves to diminish the contributions of structures *b*, *c*, and *d*, thus enhancing the double-bond character of the carbonyl group relative to that of the C_6H_5-substituted ester. However, the mesomeric effect operates in the opposite direction and increases contributions of type *c*, as indicated in structure I (and its ortho analogues).

I

In other recent experiments, we have demonstrated that the inductive effect is considerably stronger than the mesomeric effect in the C_6F_5 group. Therefore, the observed increase in the carbonyl stretching frequency is to be expected. When R = C_6F_5, structure *d* is strongly destabilized by the inductive effect. This is substantiated by the pronounced shift to higher frequency of pentafluorophenyl benzoate (1 765 cm^{-1}) compared with phenyl benzoate (1 740 cm^{-1}). Pentafluorophenyl pentafluorobenzoate, the first stable, completely fluorinated ester, reflects the influence of the C_6F_5 group at both ends of the molecule (1 780 cm^{-1}), but the effect is somewhat less than additive.

EXPERIMENTAL

Infrared Spectra

All compounds were measured as 5% solutions in carbon tetrachloride. The spectra were obtained on two instruments, a Beckman IR-8 grating spectrometer and a Perkin–Elmer 21 double-beam spectrometer equipped with sodium chloride optics.

Phenyl Pentafluorobenzoate

Pentafluorobenzoyl chloride (4.58 g) and phenol (1.88 g) were heated under reflux for 1.5 h in a 25 ml flask, with occasional shaking. After the flask was cooled, its contents were dissolved in ether, washed successively with water, 5% sodium carbonate solution, and again with water, and dried over anhydrous sodium sulfate; then the ether was removed. The residue was crystallized from hot methanol to give 1.4 g (24.6%) of ester, m.p. 66–67°.

Anal. Calcd. for $C_{13}H_5O_2F_5$: C, 54.13; H, 1.73. Found: C, 54.01; H, 1.95.

Pentafluorophenyl Benzoate[1]

Pentafluorophenol (3.68 g) and benzoyl chloride (2.8 g) were heated under reflux for 1.5 h. The contents of the flask were dissolved in ether and worked up as described above to give 1.0 g (17.5%) of ester, m.p. 73.0–73.5°.

Anal. Calcd. for $C_{13}H_5O_2F_5$: C, 54.13; H, 1.73. Found: C, 54.01; H, 1.87.

Pentafluorophenyl Pentafluorobenzoate

A mixture of 10.57 g of pentafluorobenzoyl chloride and 7.86 g of pentafluorophenol was heated under reflux for 3 days to give 16.0 g (99%) of pentafluorophenyl pentafluorobenzoate, b.p. 67–69° at 10^{-5} mm, m.p. 36.5–37.5°.

Anal. Calcd. for $C_{13}O_2F_{10}$: C, 41.30; F, 50.25; mol. wt. 378. Found: C, 41.34; F, 50.31; mol. wt. (osmometry in benzene) 371, 374.

[1]*Birchall and Haszeldine (6) reported m.p. 74–75° and* $\nu_{C=O}$ *(mull) 1 773* cm^{-1}.

Ethyl Pentafluorobenzoate

Pentafluorobenzoyl chloride (8.0 g, 0.035 mole) was added during 30 min to 1.7 g (0.037 mole) of absolute ethanol in a three-necked flask fitted with a dropping funnel, a reflux condenser, and a magnetic stirrer. The mixture was heated under reflux during the addition, and heating was continued for an additional 3 h at 70–80°. The solution was cooled, poured into 3 ml of water, and then washed with two 3 ml portions of a saturated sodium bicarbonate solution and two 3 ml portions of water. After the solution was dried over anhydrous sodium sulfate, distillation gave 4.5 g (54%) of ethyl pentafluorobenzoate, b.p. 93–94° at 10 mm.

Trifluoroethyl Pentafluorobenzoate

To a mixture of 5.0 g (0.022 mole) of pentafluorobenzoyl chloride and 2.2 g (0.022 mole) of trifluoroethanol was added, in small portions, 1.0 g of powdered anhydrous aluminium chloride. The mixture was heated under reflux overnight, cooled, poured into 6 *N* hydrochloric acid, and extracted with ether. The ether extracts were combined, washed with a 2% solution of sodium bicarbonate until neutral to litmus, and then washed with water. After the solution was dried over anhydrous sodium sulfate, the ether was removed and the product distilled to give 5.0 g (78%) of trifluoroethyl pentafluorobenzoate, b.p. 184–186° at 750 mm, 52–54° at 13 mm.

Anal. Calcd. for $C_9H_2O_2F_8$: C, 36.75; H, 0.69. Found: C, 37.45; H, 0.87.

Pentafluorophenyl Trifluoroacetate

Pentafluorophenol and trifluoroacetyl chloride reacted at −28° (carbon tetrachloride – dry ice) during 2.5 h. After the mixture was warmed to room temperature, it was dissolved in ether and washed thoroughly with water. The ether layer was dried over anhydrous sodium sulfate. Distillation gave two main fractions, b.p. 65–86° at 10 mm and 85–100° at 10 mm, both of which exhibited a single peak in the carbonyl region at 1 787 cm^{-1}.

method of converting a protected β-activated aspartate into the corresponding *N*-alkyl-L-asparagine derivative by treatment with the appropriate amine. The protecting groups of the activated ester were chosen in such a way that all of them could be eliminated in the final step.

For the synthesis of the protected amino acid intermediate N^2-carbobenzoxy-*N*-methyl-L-asparagine benzyl ester (II, R = CH_3), α-benzyl β-*p*-nitrophenyl *N*-carbobenzoxy-L-aspartate (I) (9) was treated with aqueous methylamine in dioxane (Reaction Scheme 1).

I II III

REACTION SCHEME 1.

Similarly, the *p*-nitrophenyl ester was allowed to react with higher alkyl amines (Table I). Some of the characteristic stretching bands in the infrared spectra of these protected *N*-alkyl-L-asparagines were located at 3 325 – 3 315 cm^{-1} (secondary NH), 1 755 – 1 744 cm^{-1} (ester carbonyl), 1 695 – 1 690 cm^{-1} (carbobenzoxy carbonyl), and 1 646 cm^{-1} (*N*-alkylamido carbonyl) (10).

In this study, the protecting groups were removed from the N^2-carbobenzoxy-*N*-alkyl-L-asparagine benzyl esters by catalytic hydrogenation in aqueous methanol to yield the *N*-alkyl-L-asparagines (Table II). The infrared spectra of these amino acids exhibited a pattern of strong absorption bands very similar to that already reported for *N*-ethyl-L-asparagine (3 330 – 3 280 cm^{-1}, 1 645 cm^{-1}, 1 610 – 1 585 cm^{-1}, and 1 570 – 1 550 cm^{-1}) (6). The *N*-alkyl-L-asparagines were subjected to paper chromatcgraphy in two solvent systems: phenol saturated with water, and *n*-butanol – acetic acid – water (4:1:5 v/v/v). The elution behavior of these amino acids during ion-exchange chromatography by the method of Spackman *et al.* (11) was also investigated. Increasing the hydrophobicity of the *N*-alkyl-L-asparagines by lengthening the alkyl chain resulted in an increase in the retention time. Pertinent details and physical properties of the individual *N*-alkyl-L-asparagines are listed in Table II.

EXPERIMENTAL[2]

Preparation of N^2-Carbobenzoxy-N-alkyl-L-asparagine Benzyl Ester (II)

Ester I (8.4 mmoles) was dissolved in 50 ml of dioxane at room temperature. The appropriate primary alkylamine (9.2 mmoles in 10 ml of water) was added over a period of 1 h. Stirring was continued for 24 h and the solvent was evaporated to dryness under reduced pressure. The residue was crystallized from a minimum amount of hot ethanol. After two or three recrystallizations the melting point remained unchanged. Pertinent data for the protected *N*-alkyl-L-asparagines are summarized in Table I.

Preparation of N-Alkyl-L-asparagine (III)

N^2-Carbobenzoxy-*N*-alkyl-L-asparagine benzyl ester (5.0 mmoles) was dissolved in 40 ml of methanol at 40°. To the clear solution, 10 ml of water and 0.2 g of 10% palladium on charcoal, suspended in 10 ml of methanol, were added. This mixture was hydrogenated for 3 h at 40°. The catalyst was removed by filtration, and the filtrate and aqueous washings were taken to dryness under reduced pressure. *N*-Butyl- and *N*-amyl-L-asparagines were extracted from the catalyst by additional washings with methanol. The *N*-alkyl-L-asparagine was dissolved in a small amount of water (or aqueous methanol), and alcohol or acetone was added until the solution turned turbid. After two recrystallizations the melting point remained constant. The yields were consistently high.

[2]*All melting points were determined with a Thomas–Hoover capillary melting point apparatus and are uncorrected. The infrared spectra were measured in pressed disks of potassium bromide at a concentration of 0.3% for the protected asparagines and 0.23% for the free asparagines. The optical rotations were determined with a Carl Zeiss photoelectric precision polarimeter (0.005°), code 550300. The elementary analyses were carried out by Galbraith Laboratories, Knoxville, Tennessee.*

Elution of N-Alkyl-L-asparagines from Ion-Exchange Resin

The *N*-alkyl-L-asparagines were chromatographed on the Beckman–Spinco model 120C amino acid analyzer, using Beckman custom research resin PA-28 packed in a 56 × 0.9 cm column. Color values ($H \times W/\mu$mole = C value) are the constants per micromole of ninhydrin-positive compound. The time from the start of all chromatograms to the change to pH 4.25 buffer was 165.0 min, and to temperature change from 30° to 55° 100.0 min. The flow rate of buffer for the experiments was set at 50.0 ml/h, and of ninhydrin reagent 25.0 ml/h; the total flow rate was found to be 7.5 ± 0.8 ml/h. The calculated developing time of the ninhydrin color was 10.5 min. The elution times are reported in minutes. On our instrument, aspartic acid, glycine, and leucine were eluted at 81, 166, and 259 min, respectively, and the buffer (pH 4.25) front appeared at 229 min. The C values and elution times for each *N*-alkyl-L-asparagine are recorded in the last two columns of Table II. The numbers in parentheses indicate the number of determinations.

NOTE SUR LE CLIVAGE DE L'OZONIDE PRIMAIRE DU STYRÈNE

S. Fliszár

D'après les vues de Criegee (1), et si nous postulons les deux modes de réaction *a* et *b*, les produits engendrés par le clivage de l'ozonide primaire[1] du styrène[2] seraient ceux représentés par le schéma suivant.

Des ozonolyses du styrène effectuées dans du CCl_4 révèlent les quantités appréciables de Ph—CHO et de HCHO formés (Tableau I). On note également que la proportion des composés à O actif (ozonides et peroxydes) engendrés est, dans chaque cas, inférieure à celle de l'oléfine consommée; puisque, à la suite du clivage de l'ozonide primaire, il se

[1]*Nous adoptons cette représentation schématique uniquement dans le but de faciliter l'exposé de nos résultats expérimentaux et non pas avec l'intention d'aborder ainsi le fond des problèmes très complexes (dont la revue de Bailey (2) résume l'ampleur) se rattachant à la structure de l'ozonide primaire et au mécanisme de son clivage.*

[2]*Un travail étendu portant sur le clivage de nombreuses oléfines asymétriques (et, notamment, des styrènes substitués) sera présenté ultérieurement.*

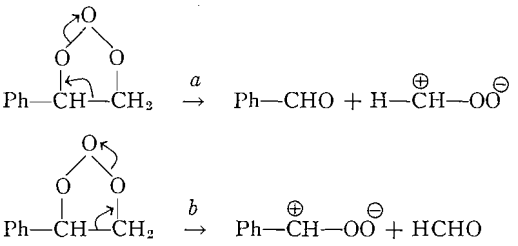
NOTE SUR LE CLIVAGE DE L'OZONIDE PRIMAIRE DU STYRÈNE

S. Fliszár



D'après les vues de Criegee (1), et si nous postulons les deux modes de réaction *a* et *b*, les produits engendrés par le clivage de l'ozonide primaire[1] du styrène[2] seraient ceux représentés par le schéma suivant.

Des ozonolyses du styrène effectuées dans du CCl_4 révèlent les quantités appréciables de Ph—CHO et de HCHO formés (Tableau I). On note également que la proportion des composés à O actif (ozonides et peroxydes) engendrés est, dans chaque cas, inférieure à celle de l'oléfine consommée; puisque, à la suite du clivage de l'ozonide primaire, il se

[1]*Nous adoptons cette représentation schématique uniquement dans le but de faciliter l'exposé de nos résultats expérimentaux et non pas avec l'intention d'aborder ainsi le fond des problèmes très complexes (dont la revue de Bailey (2) résume l'ampleur) se rattachant à la structure de l'ozonide primaire et au mécanisme de son clivage.*

[2]*Un travail étendu portant sur le clivage de nombreuses oléfines asymétriques (et, notamment, des styrènes substitués) sera présenté ultérieurement.*

For personal use only.

forme 1 mole de composés à O actif par mole de styrène ozoné, on reconnait ainsi la réduction d'une partie de zwitterion, tout comme cela avait été montré dans le cas du stilbène (3) et du diphényl-1,4 butène-2 (4).

En vue de déterminer dans quelles proportions les voies de clivage *a* et *b* sont suivies, nous avons avantage à effectuer les ozonolyses en présence de CH_3OH (Tableau II). Dans des conditions expérimentales adéquates, les zwitterions sont alors quantitativement transformés en méthoxyhydroperoxydes stables, qui n'engendrent pas des molécules d'aldéhyde et ne consomment pas les molécules d'aldéhyde ayant pris naissance par le clivage de l'ozonide primaire. Nous nous sommes encore assuré que dans nos conditions

TABLEAU I

Ozonation de 20 ml de solution de styrène dans du CCl_4 à 25 (±0.1) °C

[Styrène] (*M*)	Débit O_3	Styrène consommé	Oxygène actif	Ph—CHO formé	HCHO formé
0.25	0.170	1.49	1.26	0.36	0.09
0.25	0.163	3.24	2.44	0.61	0.26
0.50	0.037	3.58	3.18	0.68	0.55
0.50	0.135	5.72	4.58	0.86	0.76
0.50	0.143	9.17	7.02	1.21	1.50

NOTONS: Débit O_3, millimoles/minute; les quantités de styrène consommé, d'oxygène actif, de Ph—CHO et de HCHO formés sont indiquées en millimoles.

expérimentales ([styrène] = 0.2 *M*, $[CH_3OH]$ = 1.0 *M*, température 15–35 °C, débit O_3 0.084–0.114 mmole/min) il n'y a pas de réduction appréciable de $Ph—\overset{\oplus}{C}H—OO^{\ominus}$ en Ph—CHO, en effectuant des ozonolyses de *trans*-stilbène dans les mêmes conditions; ces expériences ont montré qu'il se forme 1.0 mole d'hydroperoxyde et 1.0 mole de Ph—CHO par mole de stilbène consommé.[3] Finalement, les résultats du Tableau II indiquent bien que les quantités d'hydroperoxyde formé sont égales aux quantités d'oléfine consommée, aux erreurs expérimentales près.

Dès lors pouvons-nous considérer l'aldéhyde benzoïque[4] observé comme étant celui formé lors du clivage de l'ozonide primaire selon la voie *a* et n'ayant pas pu être utilisé par les zwitterions qui ont réagi avec le méthanol. Par conséquent, les rendements[5] en Ph—CHO (rapportés à l'oléfine consommée) expriment également le pourcentage de clivage de l'ozonide primaire selon la voie *a*.

[3]*Ces résultats étant en tous points comparables à ceux déjà publiés, nous renvoyons à cette étude (3) pour plus de détails.*

[4]*Nous n'avons malheureusement pas pu doser le formaldéhyde engendré lors des expériences faites en présence de méthanol. Toutefois, bien que n'étant pas entraîné par le courant gazeux (comme cela avait été le cas lors des expériences effectuées dans le* CCl_4*), et en raison de sa rapide conversion en hémiacétal, cet aldéhyde ne gêne pas les dosages spectrographiques de l'aldéhyde benzoïque; en effet, une solution 0.1 M de* HCHO *dans du* CCl_4*, en présence de* CH_3OH *1.0 M, ne présente pas de bande dans la région des fréquences du groupement carbonyle.*

[5]*Ces rendements ont été calculés en divisant "*PhCHO *formé" par la moyenne entre "styrène consommé" et "hydroperoxyde formé".*

	0.112	2.47	2.45	0.99	40.4
	0.114	3.10	3.06	1.25	40.5
35±0.1	0.110	1.24	1.22	0.51	41.4
	0.084	2.36	2.25	0.96	41.7
	0.085	3.30	3.20	1.34	41.2

NOTONS: Débit O_3, millimoles/minute. Les quantités de styrène, d'hydroperoxyde et de benzaldéhyde s'entendent en millimoles.

L'analyse statistique des résultats du Tableau II ne permet pas de conclure à une variation significative de ce pourcentage avec la température entre 15 et 35 °C. Ainsi retiendrons-nous, avec une limite de confiance de 95%, que l'ozonation de 1 mole de styrène dans les conditions décrites conduit à la formation de 0.408 (±0.007) mole de Ph—CHO, ce calcul tenant compte de l'ensemble des résultats de ce tableau.

Cette production d'aldéhyde benzoïque, tout en confirmant les vues généralement admises (selon lesquelles le clivage du styrène par l'ozone se ferait préférentiellement selon le mécanisme engendrant l'aldéhyde formique (voie *b*)), fait cependant ressortir la contribution importante (40.8%) du clivage aboutissant à la formation de benzaldéhyde (voie *a*).

PARTIE EXPÉRIMENTALE

La technique d'ozonation et le dosage de l'ozone et des hydroperoxydes ont été décrits précédemment (5), ainsi que la méthode de dosage de l'oxygène actif (4).

L'aldéhyde benzoïque a été dosé par voie spectrographique infrarouge, d'après les mesures des densités optiques de la bande de vibration du groupement carbonyle vers 1 705 – 1 708 cm^{-1}; les courbes de calibration ont été établies au moyen de solutions de benzaldéhyde dans le CCl_4, ou dans du CCl_4 en présence de CH_3OH 1.0 *M*, ce dernier solvant étant utilisé lors des mesures faites sur des systèmes ozonés en présence de méthanol.

L'aldéhyde formique engendré lors des ozonations du styrène dans le CCl_4 est entraîné par le gaz d'ozonation et receuilli par de l'eau à 0 °C contenue dans un flacon laveur placé sur le circuit du gaz. Un balayage de la solution ozonée par un courant de N_2 sec (pendant 15 min) permet de receuillir pratiquement quantitativement le HCHO dans l'eau. Le dosage est ensuite effectué selon Signer (6) par iodométrie.

Le styrène a été dosé par chromatographie en phase gazeuse, au moyen d'un appareil F & M, modèle 810, avec détecteur à flamme ionisante, comprenant une colonne d'Hyprose 10% de 2.5 m, température du four 100 °C. Les solutions ozonées ont été diluées dans du CCl_4 dans la proportion de 1:25 (ou de 1:50 pour des solutions dont la concentration en styrène est supérieure à 0.2 *M*) et injectées en raison de 5.0 µl. Les intensités des pics chromatographiques du styrène, mesurées à l'aide d'un planimètre, ont été comparées à une courbe de calibration établie dans les mêmes conditions expérimentales avec des solutions de styrène de concentrations connues (0.05–0.2 *M*), ce qui permet de déterminer les concentrations en styrène des solutions ozonées. Chaque analyse a été faite 3–5 fois, avec une reproductibilité illustrée par l'exemple suivant, se rapportant à 5 mesures faites sur une solution 0.1 *M* de styrène dans les conditions décrites; surfaces mesurées: 12.35, 12.49, 12.80, 12.32 et 12.50 cm^2.

THE THERMAL DECOMPOSITION OF ETHANE

PART II. THE UNIMOLECULAR DECOMPOSITION OF THE ETHANE MOLECULE AND THE ETHYL RADICAL

M. C. LIN AND M. H. BACK

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 5, 1966

ABSTRACT

The rate of the elementary dissociation of ethane into two methyl radicals has been measured in its pressure-dependent region at temperatures from 913–999 °K and at pressures from 1–200 mm. The high-pressure first-order rate constant obtained by extrapolation was in agreement with that obtained at lower temperatures,

$$k_1^{\infty} = 1.0 \times 10^{16}\, e^{-86000/RT}\, s^{-1}.$$

Comparison with calculated Kassel curves showed that the best fit of the data was obtained with the Kassel parameter $s = 12 \pm 1$. The high-pressure first-order rate constant for the decomposition of the ethyl radical was obtained by extrapolation of the data reported in Part I, assuming the rate constant for combination of ethyl radicals is independent of temperature.

$$k_3^{\infty} = 3.8 \times 10^{13}\, e^{-38000/RT}\, s^{-1}.$$

From the measured constant for the dissociation of ethane, the rate constant for the combination of methyl radicals was calculated and compared with the values measured in a lower temperature region. Differences in the values of the rate constants and in the shapes of the unimolecular falloff curves are discussed.

INTRODUCTION

In Part I of this study (1) the rates of initiation and termination in the decomposition of ethane were measured and the following mechanism, previously proposed (2, 3), was confirmed.

[1] $C_2H_6 \rightarrow 2CH_3$

[2] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[3] $C_2H_5 \rightarrow C_2H_4 + H$

[4] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[5*a*] $C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$

[5*b*] $\rightarrow C_2H_4 + C_2H_6$

There was some indication in the temperature range reported in Part I that pressure dependence of reaction [1] was observed at low pressures. We now report more extensive results on this pressure dependence over the temperature range 913–999 °K and at pressures from 1–200 mm.

Measurements of the rate of combination of methyl radicals at temperatures in the neighborhood of 500 °K (4, 5) have indicated that pressure dependence begins to occur at pressures below about 10 mm of acetone. Measurements at 1 273 °K have shown a

linear dependence on pressure in the range 3–15 mm of helium and a negative temperature coefficient of 1.5 kcal/mole (6). Between these temperature regions the results relating to the combination of methyl radicals are obtained by indirect kinetic evidence and are somewhat conflicting (7). The measurement of the rate of the reverse reaction, the dissociation of ethane, which is conveniently measured in the intermediate temperature region, should allow a more exact interpretation of the effect of temperature on the rate of stabilization of the energy-rich ethane molecule.

EXPERIMENTAL

The apparatus and procedure have been described in Part I. Initial pressures of ethane in the range 5–20 mm were determined by expansion of a small volume of ethane into the reaction vessel. The pressure readings were calibrated at each temperature with carbon dioxide. For initial pressures less than 5 mm a smaller calibrated volume was used and the resulting pressure in the reaction vessel was calculated from the ideal gas law. The measured pressure before expansion was always greater than 50 mm.

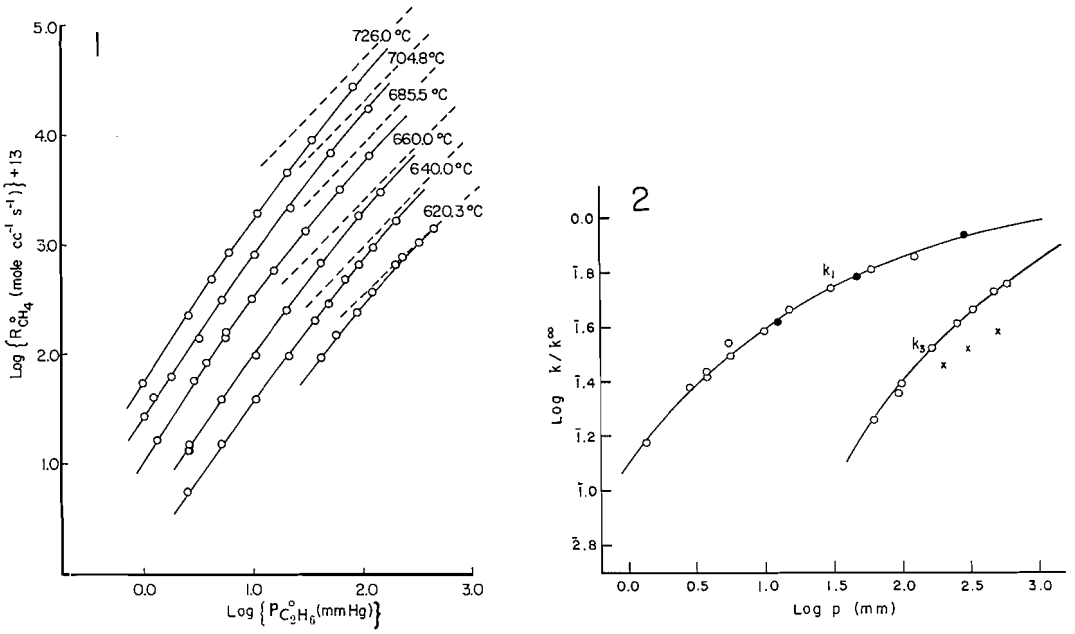
RESULTS

Ethane

Initial rates of methane formation in the temperature region 893–999 °K and at pressures from 1–200 mm are shown as a function of initial pressure of ethane in a double logarithmic plot in Fig. 1. Initial rates were obtained by extrapolation to zero time by methods described in Part III. The dotted lines were calculated using the equation for the first-order rate constants for methane production reported in Part I.

$$k_1^{\infty} = 1.00 \times 10^{16}\, e^{-86000/RT}\ s^{-1}$$

The effect of addition of carbon dioxide on the first-order rate coefficients at 958 °K is shown in Fig. 2. The results indicate that carbon dioxide is equally as effective as ethane in the intermolecular transfer of energy. The fact that the first-order coefficient is increased



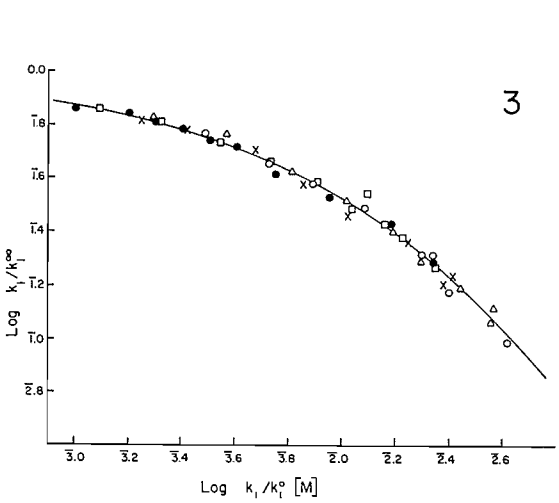


FIG. 1. Double logarithmic plot of the initial rate of methane formation against the ethane pressure.
FIG. 2. Effect of addition of carbon dioxide on the first-order rate coefficients k_1 and k_3 at 958 °K. Abscissa refers to total pressure. (○) Pure ethane; (●) 3.8 mm $C_2H_6 + CO_2$; (×) 100 mm $C_2H_6 + CO_2$.

by addition of inert gas is strong evidence that the dissociation reaction is pressure-dependent in this region of pressure. If the decrease in the rate of methane production were due to incomplete scavenging of methyl radicals by ethane, inert gas would not increase the rate of production of methane.

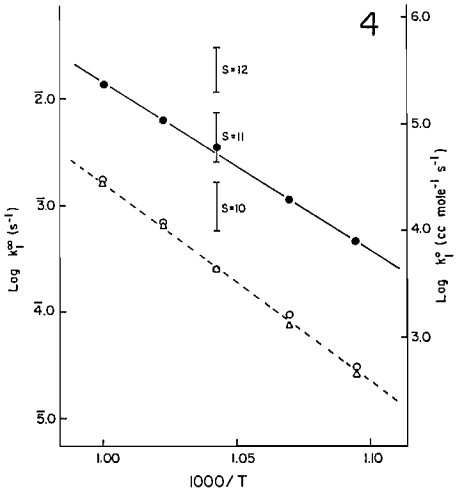

FIG. 3. Application of Powell's method of extrapolation to k_1. (○) 726.0 °C; (△) 704.8 °C; (□) 685.5 °C; (×) 660.0 °C; (●) 640.0 °C.

FIG. 4. Arrhenius plot of k_1^∞ and k_1^0. (-) Calculated from $k_1^\infty = 1.00 \times 10^{16}\ e^{-86000/RT}\ s^{-1}$; (○, ●) Powell extrapolation with $s' = 6$; (△) Lindemann–Hinshelwood extrapolation; (I) calculated from eq. [1].

The extrapolation of the first-order rate coefficient as expressed by Kassel's integral to obtain the first- and second-order rate constants was done using the approximation suggested by Powell (8). A discussion of the relation of the parameter s' used by Powell to the Kassel parameter s is given in the Appendix. Figure 3 shows the results at each temperature fitted to Powell's curve with parameter $s' = 6$. The first-order rate constants obtained in this way were in exact agreement with those obtained in the high-pressure region at lower temperatures. The first- and second-order rate constants are shown in an Arrhenius plot in Fig. 4. The Lindemann–Hinshelwood method of extrapolation gave very similar first-order rate constants and is a reasonably reliable method when the extrapolation is not long.

The second-order rate constants obtained by extrapolation could be represented by

$$k_1^0 = 1.82 \times 10^{21}\ e^{-(72500\pm1500)/RT}\ \text{cc mole}^{-1}\ s^{-1}.$$

The data are shown in Fig. 4 along with the range of values calculated for $\sigma = 4 \pm 1$ Å at 958 °K from the equation (9),

$$[1] \qquad k^0 = \lambda Z\left(\frac{E^\infty}{RT}\right)^{s-1}\frac{1}{(s-1)!}e^{-E^\infty/RT},$$

for various values of s, assuming the collision efficiency $\lambda = 1$. The best fit of the extrapolated and calculated values is obtained with $\sigma = 3.3$ Å and $s = 11$.

This value for the collision diameter was consequently used to evaluate Kassel curves for each temperature. The values of A and E were those obtained in the high-pressure region. Calculations were made using an IBM-650 computer.[1] The calculated curves are

[1]*The authors thank Dr. D. F. Swinehart, University of Oregon, for supplying the program for the Kassel integrals, and Mr. James Muirhead-Gould for suitable modifications.*

For personal use only.

shown in Fig. 5 with the experimental points superimposed. The best fit of the experimental points was obtained with $s = 13$. The data of Dexter and Trenwith (10) are in reasonable agreement with this value of s, although these authors preferred a higher value of 15 or 16.

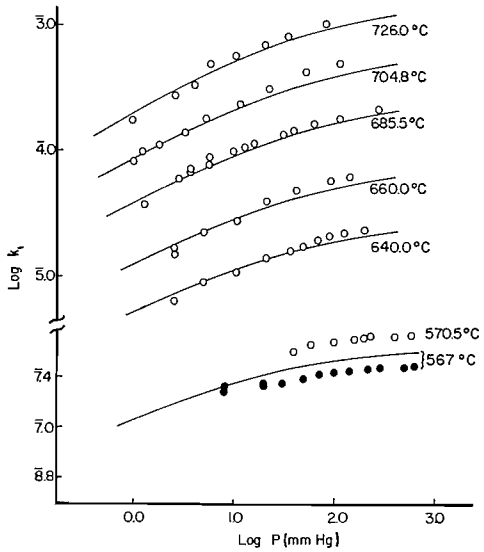

FIG. 5. Comparison of experimental results with calculated Kassel curves. Solid lines are curves calculated with $s = 13$. (○) Present results; (●) Dexter and Trenwith.

The values of the parameter s obtained from eq. [1] and from the direct comparison of the Kassel curves with k_1 are in satisfactory agreement in view of the uncertainties involved in the extrapolation to k_1^0 and in the application of the Kassel theory to reactions with high-frequency factors (11).

Recently Setser and Rabinovitch (12) evaluated theoretical curves for $\log k_1/k_1^\infty$ vs. $\log P$ at 873 and 1 273 °K based on the theory proposed by Marcus and Rice (13, 14). The expressions used for k_1^∞ were

$$k_1^\infty(873\ ^\circ\text{K}) = 1.0 \times 10^{17}\, e^{-85300/RT}\ s^{-1}$$

$$k_1^\infty(1\ 273\ ^\circ\text{K}) = 1.3 \times 10^{17}\, e^{-85300/RT}\ s^{-1}.$$

Their calculated curves are shown in Fig. 6 along with the present results at 958 °K. The difference between the calculated and the experimental results indicates that the model of the activated complex described by Setser and Rabinovitch is too "loose".

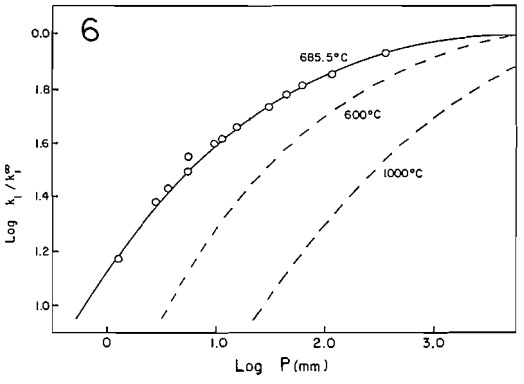
The activation energy was determined at several pressures and is compared in Table I with the activation energy evaluated from the series of Kassel curves with $s = 13$.

Ethyl Radical



The rate constant for decomposition of the ethyl radical, k_3, was measured over the temperature range 823–913 °K and the pressure range 50–600 mm and was given in Part I. The rate constant was found to be pressure-dependent over the whole range and the order of the decomposition with respect to ethane varied from 0.38 to 0.59. The effect of addition of CO_2 on the first-order rate coefficient is shown in Fig. 2. In this case CO_2 appears to be less efficient than ethane in the deactivation of the energy-rich ethyl radical. It may be that ethane is unusually effective in the deactivation of a radical where chemical interaction may occur, whereas in the case of a molecule ethane and CO_2 are equally effective.

Powell's method of extrapolation was again applied and in Fig. 7 the experimental points are compared with the theoretical curve for parameter $s' = 3$. The values of k_3^∞ and k_3^0 thus obtained could be represented by the expressions

$$k_3^\infty = 3.8 \times 10^{13}\, e^{-38000/RT}\ s^{-1}$$

$$k_3^0 = 1.8 \times 10^{18}\, e^{-32400/RT}\ cc\ mole^{-1}\ s^{-1}$$

with an error of about ±2 kcal/mole in the activation energies, assuming the rate constant for the combination of ethyl radicals is 2.0×10^{13} cc mole^{-1} s^{-1} (15) for all temperatures studied.[2] The high-pressure rate constant is in reasonable agreement with that found by Bywater and Steacie (16), $k_3 = 1.4 \times 10^{14}\, e^{-39500/RT}\ s^{-1}$, and calculated by Benson (17), $k_3 = 2.4 \times 10^{13}\, e^{-40000/RT}\ s^{-1}$. Kerr and Trotman-Dickenson (18) recently obtained an

FIG. 7. Application of Powell's method of extrapolation to k_3. (○) 640.0 °C; (△) 620.3 °C; (●) 599.7 °C; (▲) 584.7 °C; (□) 570.5 °C; (×) 549.7 °C.

activation energy of 32.0 kcal/mole for the decomposition of the ethyl radical from a study of the photolysis of propionaldehyde. The pressure of reactant was low, about 45 mm, and comparison with the present values would suggest that in their experiments the decomposition was in the pressure-dependent region.

[2] *If* $k_{3a} = 1.5 \times 10^{14}\, e^{-2000/RT}$ *cc mole*$^{-1}$ *s*$^{-1}$ *(15), then* $k_3^\infty = 1.0 \times 10^{14}\, e^{-39000/RT}\ s^{-1}$.

The range of pressure over which k_3 was measured was not wide enough to allow a meaningful comparison with calculated Kassel curves. The parameter s of Kassel's theory may, however, be estimated from eq. [1] for the second-order rate constant. At 873 °K, using a value for $\sigma = 3.3$ Å, the closest approximation to the extrapolated values was obtained with $s = 6$ and was given by the following expression:

$$k_3^0 = 1.4 \times 10^{17}\, e^{-31800/RT} \text{ cc mole}^{-1}\text{ s}^{-1}.$$

The frequency factor would be increased by the use of a larger collision diameter. This result is consistent with that of Purnell and Quinn (19), who found, from a study of the thermal decomposition of butane, that a value of $s = 7$ gave the best fit to their data.

DISCUSSION

Comparison of Dissociation and Combination Rate Constants

For comparison with the rate constant for methyl radical combination, k_{-1} was calculated from the measured k_1 and the equilibrium constant.

$$C_2H_6 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2CH_3$$

$$K_1 = k_1/k_{-1} = (\exp(\Delta S_1^0/R))\,(\exp(-\Delta H_1^0/RT))$$

Recent calculations of S^0 for methyl radicals (20) were used to determine ΔS_1^0. There is some doubt about the exact relation between the measured activation energy, the dissociation energy of the bond broken, and the enthalpy change of the reaction at any temperature. In Part I we related the activation energy for the dissociation of ethane to the dissociation energy, D, as follows (21),

$$D + RT \geqslant E_1 \geqslant D,$$

and under our experimental conditions where $Nh\nu/RT \approx 1$, we took

$$D = E_1 - \tfrac{1}{2}RT = 85.0 \pm 0.5 \text{ kcal/mole}.$$

Since

$$\Delta H_1^0 = \Delta E_1^0 + RT,$$

$$\Delta H_1^0 = D + \tfrac{3}{2}RT = 85.0 + \tfrac{3}{2}RT.$$

Values of $(\Delta H_1^0)_T$ calculated in this way are given under column A in Table II. Use of the more exact relation

$$(\Delta H_1^0)_T = (\Delta H_1^0)_{T=0} + \int_0^T (\Delta C_p^0)\, dT$$

or

$$E_1 - E_{-1} + RT = D + \int_0^T (\Delta C_p^0)\, dT$$

leads to very similar values for $(\Delta H_1^0)_T$ which are shown in column B in Table II. Values for ΔC_p^0 were taken from JANAF (22). In column C ΔH_1^0 has been calculated from this equation using a value of $\Delta H_1^0(CH_3) = 34.0$ kcal/mole at 298 °K recently obtained (23, 24). It may be pointed out that the classical correction to the enthalpy based on the assumption that the vibrational degrees of freedom are not appreciably excited (25) is not valid at the temperatures considered here even for a molecule as small as ethane.

In Fig. 8 the values of k_{-1} thus obtained from the present measurements of k_1 are compared with k_{-1} measured at 520 °K (5) relative to abstraction from acetone. The latter

constant has been calculated relative to the value of 2.2×10^{13} cc mole^{-1} s^{-1} for the methyl combination constant in the pressure-independent region (26). The measurements of Dodd and Steacie give the most extensive data in the pressure-dependent region and hence were chosen for comparison.

(a) The Magnitude of k_1 and k_{-1}

From the quantities in Table II the present measurements of k_1 give a value of $k_{-1} = 1.1 \times 10^{12}$ cc mole^{-1} s^{-1} at 500 °K. The difference in the combination rate constants from the two types of measurements is much greater than can be accounted for by the estimated errors for each method and indicates a fundamental error in one of the four quantities, k_{-1}, k_1, ΔS_1^0, or ΔH_1^0. The most reliable of these four quantities is probably the entropy change of the reaction. The constants describing the structure of the methyl radical are well established and the estimated error in the calculation of S^0 for CH_3 was ± 0.5 e.u. (entropy unit) (20). Taking $A_{-1} = 2.2 \times 10^{13}$ cc mole^{-1} s^{-1} at 298 °K, the observed ratio of frequency factors corresponds to an entropy change of 12.2 e.u. (standard state: 1 mole cc^{-1}) or 5.7 e.u. less than the calculated value. It seems very unlikely that the calculated standard entropy of a methyl radical is too large by 2.9 e.u.

An error in k_1 might arise in several ways. First, k_1 might be low by a factor of 20

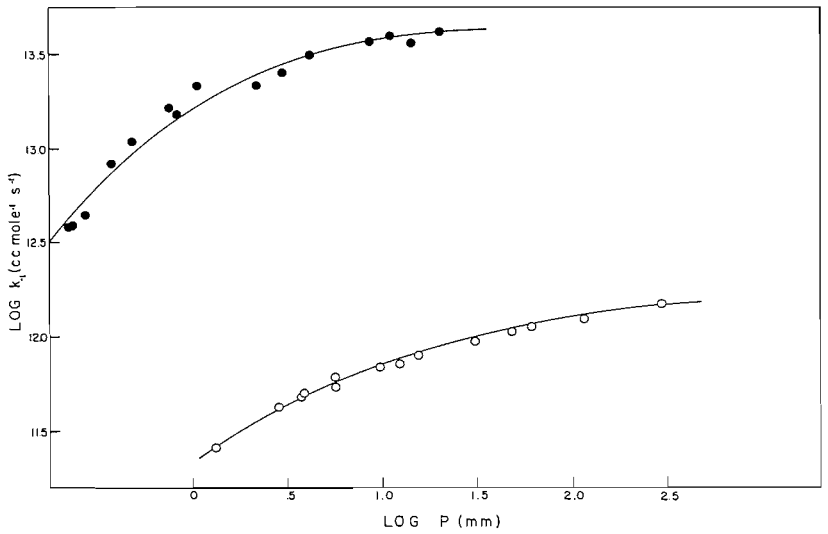

FIG. 8. Comparison of k_{-1} measured at different temperatures. (●) Dodd and Steacie; (○) present results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

throughout the whole temperature range. This would raise A_1 to satisfy the entropy requirements, $\log A_1/A_{-1} = \Delta S_1^0/2.3R$, and maintain E_1 at a value which agrees with the enthalpy change. The two most recent measurements of k_1 (3, 27) are in excellent agreement with the present values and at 828 °K are within 20%. These values of k_1 were all obtained by the measurement of the initial rate of production of methane from the pyrolysis of ethane, although the methods of analysis were different. This indicates that the measurement itself is reliable and an error of a factor of 20 in the rate constant would have to arise from a basic fault in the mechanism.

Secondly, a slight temperature-dependent error in the present results might give rise to a low activation energy and hence a low frequency factor. In fact the measurements of k_1 by Quinn (3) give a frequency factor of 2.8×10^{17} s^{-1}, which is in good agreement with the calculated entropy change. However, the activation energy of 91.7 kcal/mole thus obtained leads to a value of $\Delta H_f^0(CH_3) = 37.1$ kcal/mole at 0 °K and $D(CH_3—H) = 104.7$ kcal/mole at 0 °K or 105.6 kcal/mole at 298 °K. This is outside the error currently attributed to this quantity. The most recent measurement of $\Delta H_f^0(CH_3)$ of 34.1 kcal/mole at 298 °K (24), which is probably an upper limit, leads to $E_1 = 88.0$ kcal/mole at about 858 °K. With the values of k_1 from three independent measurements (3, 27) this activation energy gives a frequency factor of 3×10^{16} s^{-1}, which is still much below the predicted value.

To sum up, mutual consistency with the present measured k_1 and the currently accepted values of ΔS_1^0, ΔH_1^0, and k_{-1} is not attained within the estimated errors. It is not clear from the evidence where the error is most likely to occur.

(b) The Pressure Dependence of k_{-1}

The comparison of the pressure dependence of k_{-1} between the two systems involves two effects, both of which are imperfectly understood. Firstly, the efficiency of ethane and acetone in the deactivation of the excited ethane molecule is not the same. The results of Dodd and Steacie (5) suggest that ethane is much less efficient than acetone in this process. For two different third bodies of efficiencies λ and λ' it can be shown that

$$\lambda\omega = \lambda'\omega',$$

where ω is the collision frequency, defined as $z[X]$, and where [X] is the concentration of third body. This difference means that at the same temperature, pressure dependence of k_{-1} would be observed at a higher pressure in a system containing ethane than in one containing acetone. The effect in various systems has been discussed by Wieder and Marcus (28).

Secondly, the effect of increasing temperature on the lifetime of the activated molecule acts to shift the pressure-dependent region to higher pressures for any given system. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pressure at which the first-order rate coefficient for a unimolecular reaction has declined to a certain fraction of its high pressure value is related to the temperature by the parameter s as follows (29)

$$\log p_1/p_2 = (s - \tfrac{1}{2}) \log T_1/T_2, \qquad [2]$$

where s refers to the parameter as defined by Kassel. Table III shows some values for s obtained for three ratios of k/k^∞ by two methods, (*a*) by comparison of the present results with those for the combination of methyl radicals and (*b*) using the largest temperature difference available in the present work. The value of s is very much smaller than that obtained by fitting the curves to the Kassel integral and the discrepancy is well outside the errors of the estimation. This emphasizes the weakness of the simple theories in dealing with changes in the lifetime of the activated molecule with changing temperature.

This result might be accounted for if the value of the parameter s increases with temperature. As s increases the pressure at which falloff is observed is decreased. This effect would tend to counteract the effect described by eq. [2] which shifts the falloff curve to higher pressures as the temperature is increased. The result would be a smaller pressure change and hence a smaller value of s than obtained by curve-fitting at a given temperature. In fact, different values of s were obtained at 520 and 958 °K, as is easily seen from the shape of the two curves in Fig. 8. At 520 °K the best value of s was about 9, whereas in the temperature region of the pyrolysis of ethane the value was 12 ± 1. The different shape of the curves also accounts for the trend to lower values of s at lower fractional declines.

Recent calculations of the decline in the first-order rate coefficient for methane and fluoroform (30) indicated that the parameter s increased with temperature and approached the total number of vibrational degrees of freedom in the molecules. This effect has been explained as the relaxation of quantum restrictions with rise of temperature (31). The trend has been demonstrated by the measurements of the rates of decomposition of molecules with large amounts of excess energy, which lead to the conclusion that under such conditions intramolecular energy transfer is very rapid and involves virtually all the normal modes of vibration in the molecule (32).

NOTE ADDED IN PROOF: A similar though larger discrepancy between dissociation and combination rate constants has been reported by Tsang (33). The rate constants measured were as follows:

$$\text{hexamethylethane} \rightarrow 2t\text{-}C_4H_9 \qquad k = 10^{16.3}\, e^{-68500/RT}\ s^{-1}$$

$$\text{2,2,3-trimethylbutane} \rightarrow t\text{-}C_4H_9 + i\text{-}C_3H_7 \qquad k = 10^{16.2}\, e^{-73000/RT}\ s^{-1}$$

$$\text{neopentane} \rightarrow t\text{-}C_4H_9 + CH_3 \qquad k = 10^{16.1}\, e^{-78200/RT}\ s^{-1}.$$

The frequency factors were a factor of 10^3 lower than calculated from the combination rate constants. The heat of formation of the methyl radical derived from these results was $\Delta H_f(CH_3)_{298} = 31.6$ kcal/mole.

APPENDIX

The fractional decline in the first-order rate coefficient was expressed by Kassel as

$$\frac{k}{k^\infty} = \frac{1}{(s-1)!}\int_0^\infty \frac{x^{s-1}\,e^{-x}\,dx}{1+\frac{k^\pm}{Z[M]}\left(\frac{x}{b+x}\right)^{s-1}},$$

where $x = (\epsilon - \epsilon^*)/kT$, $b = \epsilon^*/kT$, $k^\infty = k^\pm e^{-\epsilon^*/kT}$.

To obtain an expression convenient for extrapolation to k^∞ and k^0, Powell made the assumption that

$$\frac{x}{b+x} \approx \frac{x}{b} \quad \text{or} \quad \frac{\epsilon-\epsilon^*}{\epsilon} \approx \frac{\epsilon-\epsilon^*}{\epsilon^*}.$$

This implies that few molecules contain energy much in excess of the critical energy for dissociation. Replacing $(s-1)$ by s', he then obtained the expression (8)

$$\frac{k}{k^\infty} = \int_0^\infty \frac{e^{-x}\,dx}{\frac{(s')!}{x^{s'}}+\frac{1}{m}},$$

where $$m = \frac{k^0[M]}{k^\infty} \text{ and } k^0 = Z\left(\frac{\epsilon^*}{kT}\right)^{s'}\frac{1}{(s')!}e^{-\epsilon^*/kT}.$$

Powell's assumption is not strictly obeyed in any dissociation and it is not surprising that different values of $(s-1)$ and s' may be obtained by fitting experimental values of k/k^∞ to calculated Kassel curves and to calculated Powell curves. Only the parameter obtained by fitting to the Kassel curves has the physical significance intended in the development of the theory. The extrapolation to k^∞ and k^0 by the simplified expression is strictly reliable only insofar as the approximation is valid. The extrapolations to k_1^∞ and k_3^∞ are, however, in reasonable agreement with previous measurements. The extrapolated values of k_1^0 and k_3^0 are in accord with the predictions of the theory, but are not necessarily exact.

THE THERMAL DECOMPOSITION OF ETHANE

PART III. SECONDARY REACTIONS

M. C. LIN AND M. H. BACK
Chemistry Department, University of Ottawa, Ottawa, Canada

Received May 5, 1966

ABSTRACT

The kinetics of the secondary reactions producing methane, butane, and butene-1 in the pyrolysis of ethane have been investigated over the temperature range 550–726 °C and at pressures from 600–10 mm. The rate of secondary methane production was second order in ethylene at high pressures but was first order in ethylene at low pressures and high temperatures. In the latter region it is concluded that isomerization of the *n*-butyl radical to *sec*-butyl with subsequent decomposition to $CH_3 + C_3H_6$ was the main source of methane. The rate of butane formation increased with time at low temperatures and decreased with time at high temperatures. It is shown that the decrease in rate was mainly due to the thermal dissociation of butane. The main source of butene-1 was probably decomposition of the *n*-butyl radical.

INTRODUCTION

Because ethylene is much more reactive than ethane, secondary reactions occur at an early stage in the pyrolysis of ethane. These secondary reactions produce mainly methane, propylene (1), butane, butene, butadiene, and acetylene. Most of the secondary products probably arise from addition of radicals to ethylene with subsequent decomposition of or abstraction by the radicals so formed. The purpose of the present study was firstly to distinguish the primary products from the secondary products and to separate the primary and secondary rates of formation of those products, mainly methane and butane, which are produced by both mechanisms, and secondly, to evaluate the mechanisms for formation of the secondary products.

EXPERIMENTAL

The apparatus and procedure have been described in Part I (2). The additional products, butene-1, butadiene, and acetylene, were analyzed by vapor phase chromatography on the column described for the analysis of butane in Part I. The yields were measured over the temperature range 550–726 °C and at pressures from 600–10 mm. In the experiments in which acetylene was measured the distillation procedure described in Part I was not followed in order to avoid losses of acetylene. The present method of separation of the products was not sufficient to obtain a quantitative measure of the yield of propylene.

RESULTS AND DISCUSSION

The effect of added ethylene on the rates of formation of hydrogen, methane, butane, butene, and butadiene at 570 °C is shown in Fig. 1. The rates were obtained with a constant ethane pressure and a constant reaction time of 100 s. This shows that methane and butane are both primary and secondary products, whereas butene and butadiene are secondary products only. The mechanism for the formation of each product will be discussed separately.

(a) Inhibition of the Rate of Hydrogen Production

The decrease in the rate of production of hydrogen with reaction time may be satisfactorily explained by the addition of reactions [−3] and [−4] to the mechanism proposed in Part I.

[1] $$C_2H_6 \rightarrow 2CH_3$$

[2] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[3] $$C_2H_5 \rightarrow C_2H_4 + H$$

[4] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[5a] $C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$

[5b] $\rightarrow C_2H_4 + C_2H_6$

[−3] $H + C_2H_4 \rightarrow C_2H_5$

[−4] $C_2H_5 + H_2 \rightarrow C_2H_6 + H$

On the assumption that $[C_2H_4] = [H_2]$ and $[C_2H_5]$ and [H] are independent of reaction time, the yield of hydrogen is given as

$$[1] \qquad [H_2] = \frac{a}{b}(1 - e^{-bt})$$

where $a = k_3[C_2H_5]$ and $b = k_{-3}[H]$. If t^3 and higher terms are neglected, eq. [1] leads to

$$[2] \qquad [H_2]/t = R_{H_2} = a - \frac{ab}{2}t.$$

The rate of hydrogen production will thus be a linear function of time in the early stages of decomposition. Typical plots of R_{H_2} against t are shown in Fig. 2 and from the linear

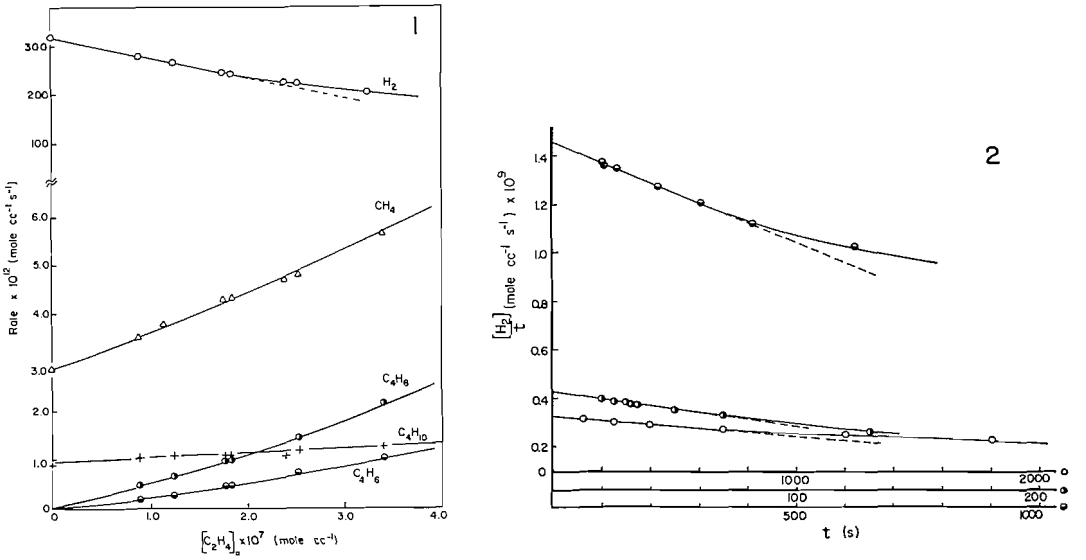

FIG. 1. Effect of added ethylene on the rates of formation of hydrogen, methane, butane, butene, and butadiene at 570 °C.
FIG. 2. Rate of hydrogen production against time.

portion values of a and b for each temperature and pressure were obtained. From eq. [1] the yield of hydrogen was then calculated beyond the short time interval over which a and b were obtained. These calculated yields agreed with the experimental yields up to 30% conversion. Since a and b were obtained assuming $[C_2H_5]$ and [H] were independent of time, it may be concluded that the decrease in the rate of hydrogen production is mainly the result of the back reactions [−3] and [−4] and not to a reduction in the steady-state radical concentration.

From eq. [2] the slope $ab/2 = \frac{1}{2}k_3k_{-3}[C_2H_5][H]$. Inserting the steady-state concentration of $[C_2H_5]$ and [H] yields

$$ab/2 = k_1(k_3)^3/2K_3k_4k_5.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Double-logarithmic plots of $ab/2$ against pressure of ethane, given in Fig. 3, showed a marked pressure dependence, as would be expected from the dependence on pressure of k_3 observed in Part I. At 570 °C and 400 mm the order of $ab/2$ was 1.32. Under the same conditions the order of k_3 was 0.45, whereas the other rate constants were pressure-independent. The temperature coefficient of $ab/2$ was found to be 139 kcal/mole at both 400 and 200 mm. Using the relevant values from Table I we calculated $E_{ab} = 138.7$ kcal/mole.

(b) Secondary Production of Methane

Two processes were found to be responsible for the secondary production of methane. At high pressures the secondary rate of production was proportional to the square of the ethylene concentration, whereas at low pressures this rate was linear with ethylene concentration. The first process was observed by Quinn (1) and he proposed a mechanism involving the isomerization of *n*-hexyl radicals.

[6] $C_2H_5 + C_2H_4 \rightleftharpoons n\text{-}C_4H_9$

[7] $n\text{-}C_4H_9 + C_2H_4 \rightleftharpoons n\text{-}C_6H_{13}$

[8] $n\text{-}C_6H_{13} \rightleftharpoons sec\text{-}C_6H_{13}$

[9] $sec\text{-}C_6H_{13} \rightarrow n\text{-}C_3H_7 + C_3H_6$

[10] $n\text{-}C_3H_7 \rightleftharpoons CH_3 + C_2H_4$

This mechanism accounted for the fact that no C_5 products were observed and that the yields of propylene and secondary methane were almost equal (1). It also explained the dependence of the secondary yield of methane on the square of the ethylene concentration.

TABLE I

Summary of values used and obtained in this work

Reaction	E (kcal/mole)	A (s^{-1} or cc $mole^{-1}$ s^{-1})	ΔH^0 (kcal/mole)	ΔS^{0*} (e.u.)	Reference
1	86.0	1.0×10^{16}			(2)
3	32.7 (p=200–400 mm)		38.6	1.7	(2)

*Note: standard state 1 mole/cc.

It can be shown that the equilibrium [6] is probably established under the present experimental conditions. In other words, the dissociation of the *n*-butyl radical into ethylene and ethyl radical is faster than the dissociation into butene and a hydrogen atom or the reaction with ethane or ethylene. Similar considerations show that reactions [7] and [−7] are also probably at equilibrium. To obtain a simple expression for the concentration of $sec\text{-}C_6H_{13}$ radicals, Quinn (1) assumed that $k_{-8} \gg k_9$. If the activation energy for reaction [−8] is comparable to that for hydrogen-atom abstraction from paraffins by large alkyl radicals, about 15 kcal/mole (3), while the activation energy for the decomposition of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sec-C_6H_{13} radical is in the range 25 kcal/mole (4), then this assumption is quite reasonable, provided only that A_9/A_{-8} is not greater than 10^3.

Thus $[sec\text{-}C_6H_{13}] = K_6K_7K_8\,[C_2H_5][C_2H_4]^2$. The rate of formation of methane is thus given by the expression:

$$d[CH_4]/dt = 2k_1[C_2H_6] + k_9\,K_6K_7K_8\,[C_2H_5]\,[C_2H_4]^2.$$

In the early stages of the decomposition while the concentration of the ethyl radical is constant

$$[CH_4] = ct + d\int_0^t [C_2H_4]^2\,dt = ct + d\overline{[C_2H_4]^2}t,$$

where $c = 2k_1[C_2H_6]$ and $d = k_9\,K_6K_7K_8\,[C_2H_5]$. From eq. [1] for the concentration of ethylene as a function of time,

$$[CH_4] = ct + d\int_0^t [\frac{a}{b}(1 - e^{-bt})]^2\,dt.$$

Integrating and dividing by t yields

$$[3] \qquad [CH_4]/t = c + \frac{a^2d}{b^3}\frac{1}{t}[bt - (1 - e^{-bt}) - \tfrac{1}{2}(1 - e^{-bt})^2]$$

$$= c + \frac{a^2d}{b^3}f(t).$$

When t is small eq. [3] becomes

$$[CH_4]/t = c + \frac{a^2d}{3}t^2.$$

The rate of methane production may thus be plotted against $\overline{[C_2H_4]^2}$ obtained graphically, against $f(t)$ using the values of b obtained from the hydrogen rates, and against t^2. Examples of these three methods are shown in Figs. 4, 5, and 6 respectively. The initial rates, c, obtained from the intercepts by these three methods agreed within 2%. In the temperature range 550–660 °C the initial rates of methane production were obtained by the t^2 plots. At temperatures higher than 685 °C, however, the rate of methane formation is approximately a linear function of time. This is the result of the rapid decomposition of ethane itself which compensates for the increase in rate due to the secondary reactions. Consequently, in this region initial rates were obtained by extrapolation of the rate against time.

The slopes of these plots together with values of a and b obtained from the hydrogen rates yield values for the quantity d.

$$d = k_9K_6K_7K_8(k_1/k_5)^{1/2}\,[C_2H_6]^{1/2}$$

A plot of logarithm of d against logarithm of the ethane pressure is shown in Fig. 7, which includes the results obtained by Quinn (1). At high pressures the order is fairly close to 1/2 as predicted, but at low pressures it becomes negative and a change in mechanism must therefore occur.

The two high-pressure values of d at 640 and 620 °C give a temperature coefficient of 27 kcal/mole. If the heat change in reactions [6] and [7] are taken equal to those of the following reactions (5),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

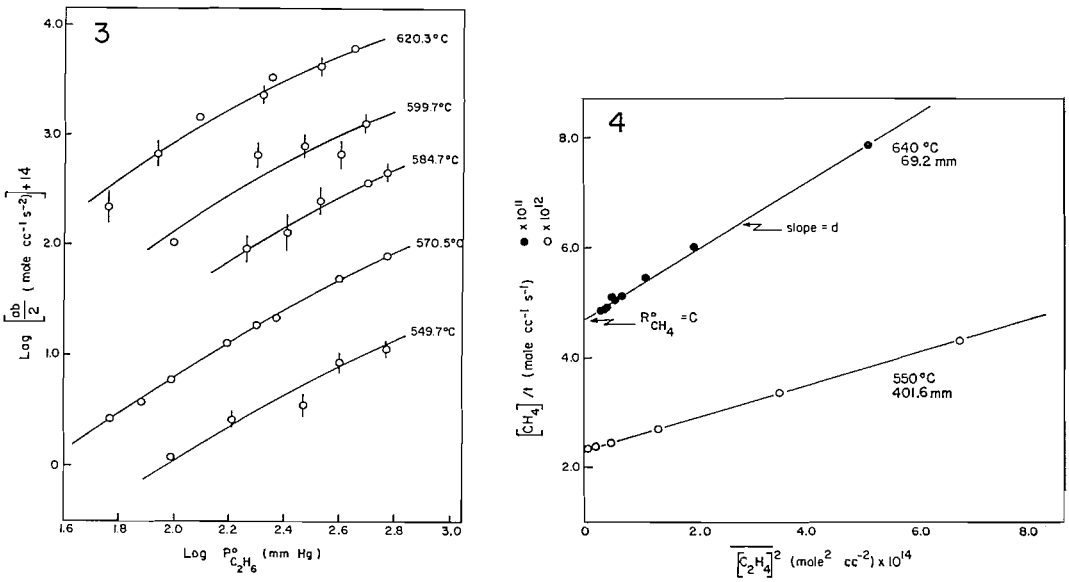

FIG. 3. Double-logarithmic plots of $ab/2$ against pressure.
FIG. 4. Rate of methane production as a function of $\overline{[C_2H_4]^2}$.

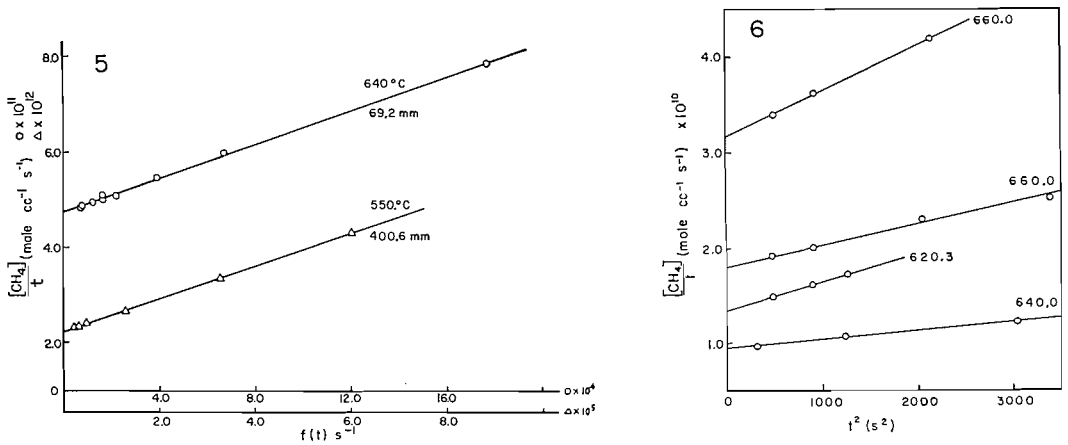

FIG. 5. Rate of methane production against $f(t)$.
FIG. 6. Rate of methane production as a function of t^2. From top to bottom, pressures and temperatures were: 145.2 mm, 660.0 °C; 91.1 mm, 660.0 °C; 448.3 mm, 620.3 °C; 123.3 mm, 640.0 °C.

[6′] $$C_2H_6 + C_2H_4 \rightleftharpoons n\text{-}C_4H_{10}$$

[7′] $$n\text{-}C_4H_{10} + C_2H_4 \rightleftharpoons n\text{-}C_6H_{14},$$

then $\Delta H_6^0 = \Delta H_7^0 = -22$ kcal/mole. If the entropy changes for reactions [6] and [7] are also equal to those for reactions [6′] and [7′] respectively, then at 640 °C $\Delta S_6^0 = -10.0$ e.u. (entropy units) and $\Delta S_7^0 = -10.6$ e.u. (5) (standard state 1 mole/cc). Using the relevant values from Table I and the data at 640 °C gives

$$E_9 = 26 \text{ kcal/mole and } A_9 = 3.2 \times 10^{13} \text{ s}^{-1}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

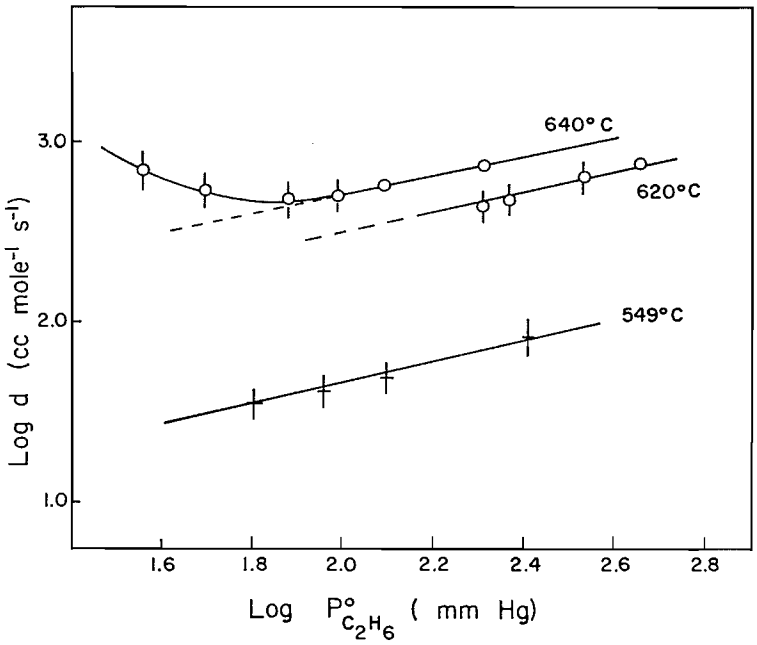

FIG. 7. Plot of log d against log of the ethane pressure. (O) This experiment; (+) Quinn.

At high temperatures and low pressures the rate of methane production increased linearly with $[C_2H_4]$ and may be expressed as

$$\mathrm{d}\,[CH_4]/\mathrm{d}t = c + d'\,[C_2H_4].$$

The same three methods of plotting the rates were again used and are shown in Figs. 8 and 9. The function $g(t) = [bt + e^{-bt} - 1]/t$ is that obtained by substitution of eq. [1] for the concentration of ethylene. The extrapolated rate was the same from all three plots and values of d' were in good agreement.

The change in the order of the rate of secondary methane formation indicates that the mechanism suggested by Quinn is no longer effective under these conditions of temperature and pressure. As the pressure is lowered the isomerization of the *n*-butyl radical to *sec*-butyl may compete with its addition to ethylene. Although *n*-butyl radicals do not decompose to yield methyl radicals (6), *sec*-butyl radicals may rapidly decompose to give propylene and a methyl radical (7, 8). The rate of production of methane thus formed would be proportional to the concentration of ethylene. The mechanism may then be represented by reactions [1]–[5] and the following.

[6] $\quad C_2H_5 + C_2H_4 \rightleftharpoons n\text{-}C_4H_9$

[11] $\quad n\text{-}C_4H_9 \rightarrow sec\text{-}C_4H_9$

[12] $\quad sec\text{-}C_4H_9 \rightarrow CH_3 + C_3H_6$

It may be argued that the decomposition may occur essentially in one step without the separate formation of a *sec*-butyl radical (4). However, the appearance of small amounts of *cis*- and *trans*-butene-2 at high conversions would suggest that *sec*-butyl radicals are formed in the system and hence would favor the mechanism as written.

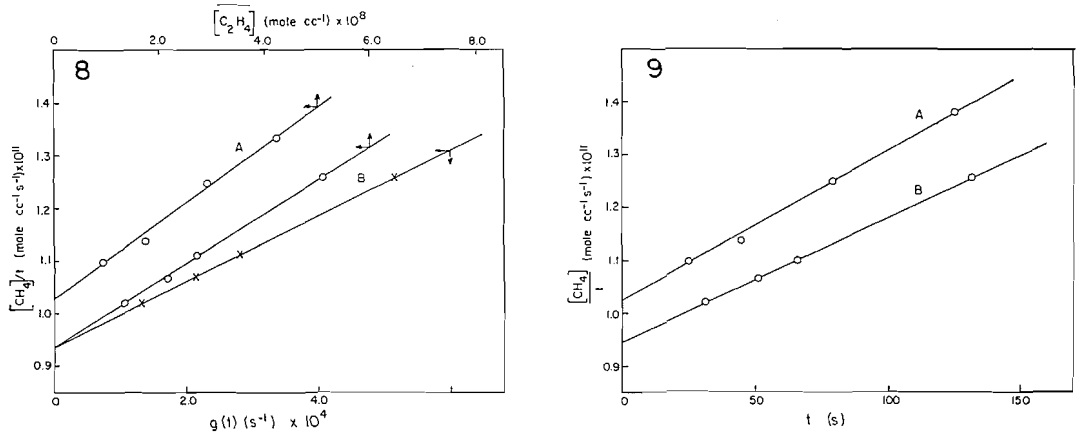

FIG. 8. Rate of methane formation as a function of $\overline{[C_2H_4]}$ and of $g(t)$. (A) 660 °C, 10.7 mm; (B) 640 °C, 20.7 mm.
FIG. 9. Rate of methane formation as a function of time. (A) 660 °C, 10.7 mm; (B) 640 °C, 20.7 mm.

The rate of formation of methane is now given as

$$d[CH_4]/dt = 2k_1 [C_2H_6] + k_{11}K_6 [C_2H_5] [C_2H_4].$$

Hence,
$$d' = k_{11}K_6 [C_2H_5] = k_{11}K_6(k_1/k_5)^{1/2} [C_2H_6]^{1/2}.$$

Since at these pressures and temperatures k_1 is no longer a first-order rate constant the ratio $d'/(k_1/k_5)^{1/2} [C_2H_6]^{1/2}$ was evaluated at 640 and 660 °C using the values of k_1 from Part II. The temperature coefficient of this ratio was 19 kcal/mole, from which values of E_{11} and A_{11} were calculated and are shown in Table I. The formation of propylene from *n*-butyl radicals was not observed, in a slightly different reaction system (6), at temperatures up to 450 °C, and it is not surprising that the activation energy for this process is rather large It may be pointed out that the present system is more favorable for the observation of isomerization since the equilibrium [6] is probably established and the decomposition into C_2H_5 and C_2H_4 is not a competing reaction.

(c) Secondary Reactions Producing Butane

At temperatures below 585 °C the rate of butane production increased with reaction time, whereas at higher temperatures the rate decreased as the reactions proceeded. Typical plots of the rate against time are shown in Fig. 10. The increase in production of butane may be ascribed to the abstraction reaction of a *n*-butyl radical

[13] $$n\text{-}C_4H_9 + C_2H_6 \rightarrow n\text{-}C_4H_{10} + C_2H_5,$$

whereas the decrease in yield may be caused by attack of radicals, mainly the ethyl radical, or thermal dissociation:

[14] $$R + C_4H_{10} \rightarrow RH + C_4H_9$$

[−5*a*] $$C_4H_{10} \rightarrow 2C_2H_5$$

The rate of butane production is thus given by

$$d[C_4H_{10}]/dt = k_{5a}[C_2H_5]^2 + k_{13}[n\text{-}C_4H_9][C_2H_6] - (k_{14}[R] + k_{-5a})[C_4H_{10}].$$

If one assumes equilibrium between *n*-butyl radicals, ethyl radicals, and ethylene as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

discussed earlier, $k_{13}[n\text{-}C_4H_9] = k_{13}K_6[C_2H_5][C_2H_4]$. Substituting eq. [1] for the concentration of ethylene and integrating at short reaction times yields

$$[4] \qquad [C_4H_{10}]/t = R^0_{C_4H_{10}} + \frac{k_3k_{13}K_6[C_2H_5]^2[C_2H_6] - R^0_{C_4H_{10}}(k_{14}[R] + k_{-5a})}{2}\,t.$$

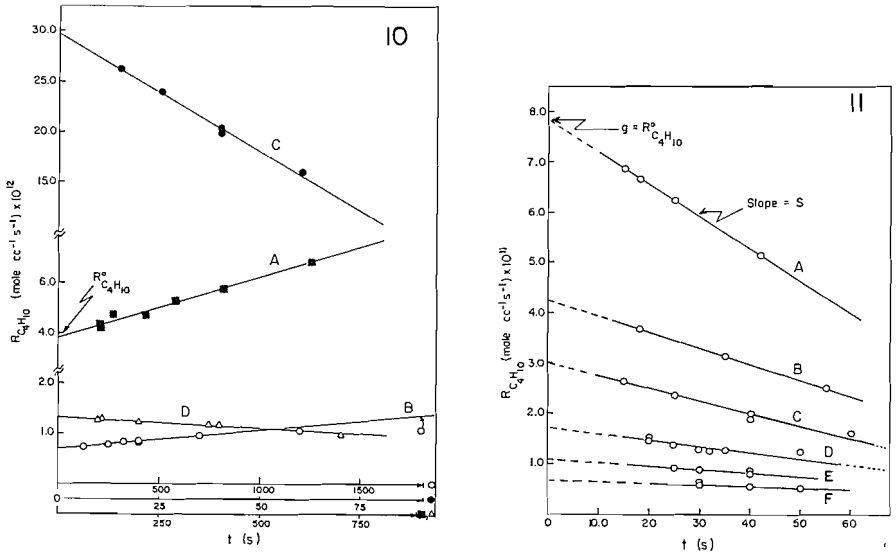

FIG. 10. Rate of butane production as a function of time. (A) 570.5 °C, 590.5 mm; (B) 549.7 °C, 401.5 mm; (C) 640.0 °C, 91.2 mm; (D) 584.7 °C, 100.0 mm.
FIG. 11. Rate of butane production as a function of time at 640 °C.

At 640 °C the rates of butane production decrease linearly with time at all pressures, as shown in Fig. 11. The ratios of slope to intercept for each pressure, given by the expression

$$[5] \qquad \frac{\text{slope}}{\text{intercept}} = \frac{k_3k_{13}K_6[C_2H_6]}{2k_{5a}} - \frac{(k_{14}[R] + k_{-5a})}{2},$$

are independent of pressure over the range 200–36 mm. The only term in [5] which is independent of pressure is k_{-5a} and it is concluded that at this temperature the unimolecular decomposition of butane is responsible for the decrease in the rate of butane formation. The ratio of slope to intercept therefore equals $\frac{1}{2}k_{-5a}$.

At 640 °C the value obtained is $(1.53 \pm 0.05) \times 10^{-2}$ s^{-1}. Assuming an activation energy for dissociation of butane of 80.0 kcal/mole (9) leads to

$$[6] \qquad k_{-5a} = (2.2 \pm 0.1) \times 10^{17}\, e^{-80000/RT}\ s^{-1}.$$

At 570 °C where the rate increased as the reaction proceeded, the first term in eq. [5] must be contributing to the butane yield and the ratio of slope to intercept should be dependent on the pressure. Since k_3 is roughly proportional to the square root of the ethane pressure in this region (2) the ratio should be approximately proportional to $[C_2H_6]^{3/2}$. This relation was obeyed at 570 °C and the value of the intercept, $(k_{14}[R] + k_{-5a})$, was 3.8×10^{-4} s^{-1}. This is close to the value of k_{-5a} at this temperature calculated from equation [6] and indicates that the dissociation of butane may still be an important factor in lowering the yield of butane even at 570 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

If therefore for the term $(k_{14}[R] + k_{-5a})$ the calculated value of k_{-5a} from equation [6] is used the ratio $k_{13}K_6/k_{5a}^{1/2}$ may be calculated from the ratio of slope to intercept of plots of $R_{C_4H_{10}}$ against t. Making the substitution $k_3[C_2H_5] = R^0_{H_2}$, we obtain

$$\frac{\text{slope}}{\text{intercept}} = \frac{k_{13}K_6[C_2H_6]R^0_{H_2}}{2k_{5a}^{1/2}(R^0_{C_4H_{10}})^{1/2}} - \frac{k_{-5a}}{2}.$$

An Arrhenius plot of the ratio $k_{13}K_6/k_{5a}^{1/2}$ gives a temperature coefficient of -7 ± 4 kcal/mole, which leads to $E_{13} = 15 \pm 4$ kcal/mole, and $A_{13} = 5 \times 10^{11}$ cc mole^{-1} s^{-1}. This is a reasonable value for a hydrogen abstraction reaction by larger alkyl radicals.

(d) Production of Butene-1, Butadiene, and Acetylene

These products were produced by secondary reactions only. Butene-1 was the first secondary product observed, and butadiene and acetylene became important at higher temperatures. Being very reactive, these unsaturated products themselves disappear rapidly and the kinetics becomes complex even in the early stages of decomposition. It is difficult therefore to draw definite conclusions regarding their origins.

Typical yields of secondary products as a function of time are shown in Figs. 12 and 13. The following reactions are proposed to account for the main features of the rates of formation.

[15] $H + C_2H_4 \rightarrow H_2 + C_2H_3$

[16] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

[17] $C_2H_3 + C_2H_4 \rightarrow C_4H_7$

[18] $C_2H_3 + C_2H_5 \rightarrow C_4H_8$

[19] $n\text{-}C_4H_9 \rightarrow C_4H_8 + H$

[20] $C_4H_7 \rightarrow C_4H_6 + H$

[21] $C_2H_3 + C_2H_3 \rightarrow C_4H_6$

[22] $C_2H_3 \rightarrow C_2H_2 + H$

Steady-state treatment yields

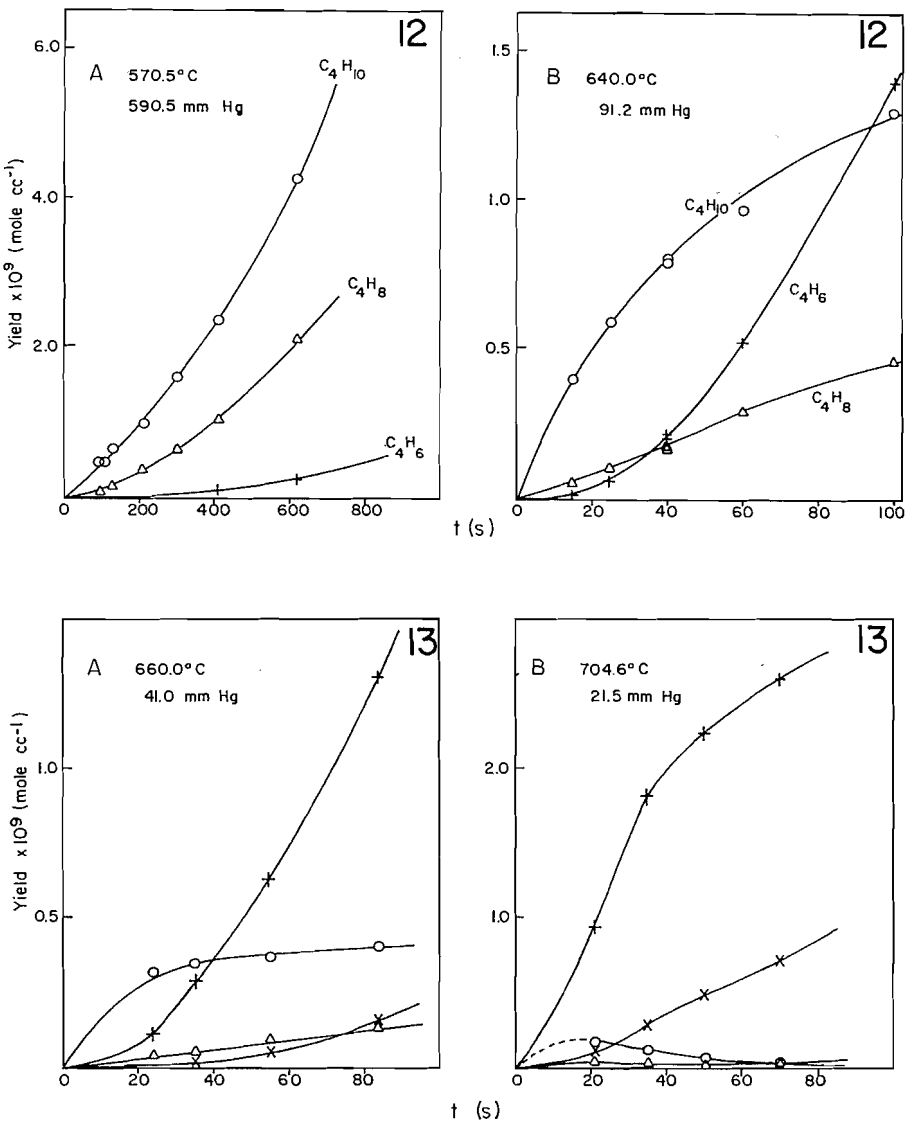
$$R_{C_4H_8} = k_{19}[n\text{-}C_4H_9] + k_{18}[C_2H_3][C_2H_5]$$

$$R_{C_4H_6} = k_{17}[C_2H_3][C_2H_4] + k_{21}[C_2H_3]^2$$

$$R_{C_2H_2} = k_{22}[C_2H_3].$$

Substituting the steady-state concentrations of n-C_4H_9 and C_2H_3 radicals yields

$$d[C_4H_8]/dt = k_{19}K_6[C_2H_5][C_2H_4] + \frac{k_{18}(k_{15}[H] + k_{16}[C_2H_5])[C_2H_4]}{k_{-16}[C_2H_6] + k_{17}[C_2H_4] + k_{18}[C_2H_5] + k_{22}},$$



which may be written as

$$d[C_4H_8]/dt = (n + p)[C_2H_4].$$

The rate will be a linear function of $[C_2H_4]$ if $n \gg p$ or if the term $k_{17}[C_2H_4]$ is small compared with the other terms in the denominator of p. Plots of $R_{C_4H_8} = [C_4H_8]/t$ against $\overline{[C_2H_4]}$, the average ethylene concentration, at 550 °C are shown in Fig. 14 where linearity is observed only at short reaction times. Since the rate decreases at higher conversions, the reaction

$$C_4H_7 + C_2H_6 \rightarrow C_4H_8 + C_2H_5,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

FIGS. 12 and 13. Yields of secondary products as a function of time. (○) Butane; (△) butene-1; (+) butadiene; (×) acetylene.

which gives an increasing rate of butene production with increasing ethylene concentration, is probably not important at these temperatures. At lower temperatures where the rate of butene does increase with time this reaction may occur.

In the linear portion of the plot of $R_{C_4H_8}$ against $\overline{[C_2H_4]}$ it may be assumed that the term $k_{17}[C_2H_4]$ is unimportant and the following expression may thus be obtained,

$$\left(\frac{R_{C_4H_8}}{[C_2H_4]}\right)_0 \Big/ (R^0_{C_4H_{10}})^{1/2} = \frac{k_{19}K_6}{k_{5a}^{1/2}} + \frac{k_{18}(k_{15}[H] + k_{16}[C_2H_5])}{k_{5a}^{1/2}(k_{-16}[C_2H_6] + k_{18}[C_2H_5] + k_{22}[C_2H_5])}.$$

T (°C)	P (mm)	$\left(\frac{R_{C_4H_8}}{\overline{[C_2H_4]}}\right)_0 \Big/ (R^0_{C_4H_{10}})^{1/2}$ (cc mole^{-1} s^{-1})$^{1/2}$
549.7	401.6	4.4±0.3
550.7	590.5	5.2±0.5
	400.0	5.1±0.3
	199.0	4.9±0.5
	96.3	5.2±0.3
584.7	341.8	6.9±0.3
	168.1	7.1±0.2
599.7	402.1	8.4±0.6
	298.9	8.3±0.3
	203.1	9.2±0.7
	99.9	5.3±1.5
620.3	335.1	10.4±0.3
	209.8	10.7±0.3

It may be shown that the predominant term in the denominator of the second ratio is $k_{-16}[C_2H_6]$ and hence this ratio should be dependent on pressure. The left-hand side was,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

however, independent of pressure over the range 100–590 mm as given in Table II. Thus it may be concluded that

$$\left(\frac{R_{C_4H_8}}{[C_2H_4]}\right)_0 \Big/ (R^0_{C_4H_{10}})^{1/2} = \frac{k_{19}K_6}{k_{5a}^{1/2}}.$$

The temperature coefficient of this ratio was 18 ± 4 kcal/mole, from which values for E_{19} and A_{19} were calculated and are given in Table I. The main conclusion is that reaction [19] is more important than reaction [18] in the formation of butene-1. The decrease in butene production at higher conversions may be due to its unimolecular decomposition or to radical-addition reactions.

At 640 °C the rate of butadiene production was found to be proportional to $\overline{[C_2H_4]^2}$. The measurements of the rates of butadiene and acetylene, however, were not sufficiently extensive to suggest a mechanism for their formation.

The authors wish to thank the National Research Council and the American Petroleum Fund for grants in support of this work. One of us (M. C. L.) thanks the Ontario Research Foundation for a fellowship.

REACTIONS OF ALKOXY RADICALS

I. HYDROGEN ATOM ABSTRACTION FROM SUBSTITUTED TOLUENES[1]

B. R. KENNEDY[2] AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received June 2, 1966

ABSTRACT

The relative rates of hydrogen atom abstraction from ten substituted toluenes by *t*-butoxy radicals in carbon tetrachloride at 40 °C have been measured and the data fitted to the Hammett equation. A much better correlation is obtained with the σ^+ constants than with the σ constants of the substituents. In this respect, therefore, the reaction is similar to the majority of hydrogen atom abstraction reactions by radicals of moderate and high electron affinity. That is, the polar properties of the substituents are much more important than their stabilizing effect on the benzyl radical formed in the reaction.

The cumyloxy radical has a similar reactivity to the *t*-butoxy radical. The *p*-nitrocumyloxy radical appears to be slightly more reactive and also slightly more susceptible to the polar effects of substituents than are *t*-butoxy or cumyloxy radicals.

The relative rates of hydrogen atom abstraction from compounds of the type XC_6H_4YH by free radicals can frequently be correlated by means of the Hammett $\rho\sigma$ relationship. Data for a wide variety of such relations were summarized in a recent paper from this laboratory (1). It was shown that with few exceptions, notably hydrogen abstraction by *t*-butoxy radicals from substituted toluenes (2, 3), a better correlation was usually obtained with σ^+ constants rather than with σ constants.[3] Further support for this generalization has been provided by Russell and Williamson (5) who specifically pointed out that for the *t*-butoxy radical the proper substituents had not been examined to distinguish clearly between a σ- and a σ^+-correlation. With this point in mind we decided to reinvestigate this reaction with particular attention to those substituents having significantly different σ and σ^+ constants. While this work was in progress a similar study by Gilliom and Ward appeared (6). However, we feel that our results and conclusions differ sufficiently from theirs to warrant the present communication.

EXPERIMENTAL

Reagents

Toluene, *m*-xylene, *p*-xylene, ethylbenzene, and cumene were Phillips Research Grade materials. *m*-Chlorotoluene, *p*-chlorotoluene, *m*-nitrotoluene, *p*-nitrotoluene, and *p*-methoxytoluene were obtained from Eastman. These compounds were used as supplied, their purity being checked by gas–liquid chromatography (g.l.c.). Toluene-α-d_3 was obtained from Merck, Sharp & Dohme; it contained over 95% trideuterotoluene. We are grateful to the Benzol Products Company for a generous sample of *p*-methoxybenzyl chloride.

p-Phenoxytoluene was prepared by the method of Russell and Williamson (5). *p*-Cyanotoluene was prepared by the dehydration of *p*-tolualdehyde oxime with acetic anhydride (cf. ref. 7). *t*-Butyl hypochlorite was prepared as described by Teeter and Bell (8). Cumyl hypochlorite and *p*-nitrocumyl hypochlorite were prepared from the corresponding alcohols by the method of Zavitsas and Seltzer (9). The *p*-nitrocumyl alcohol was prepared from cumene by nitration (10) followed by oxidation of the purified *p*-nitrocumene by the method of Kwart and Francis (11). The complete esterification of the three alcohols to their hypochlorites was checked by infrared spectroscopy. Baker and Adamson Reagent Grade carbon tetrachloride was used as the solvent throughout this work.

[1]*Issued as N.R.C. No. 9120.*
[2]*National Research Council Postdoctorate Fellow 1965–1966.*
[3]*The suggestion that such free radical reactions might be correlated with σ^+ constants was first put forward by G. A. Russell (4).*

Chlorination Procedure

Relative reactivities were determined by competitive experiments in sealed, degassed ampoules. Solutions of the reactants were made by weight. The initial concentrations were 0.1 *M* in hypochlorite and 0.5 *M* in each of two toluenes. Excess hydrocarbon was used to prevent polychlorination (3) while the relatively dilute solutions ensured that any solvent effects caused by changing the reactants were held to a minimum. The ampoules were placed in a water bath at 40 °C and were irradiated with a 100 W tungsten filament lamp for not less than 4 h. All experiments were performed in duplicate.

Analytical Procedures

After irradiation the reaction solutions were generally analyzed for benzyl chlorides by g.l.c. on Chromosorb-supported columns containing di-isodecyl phthalate or diethyleneglycol succinate polyester. Relative reactivities were calculated from the relative yields of benzyl chlorides. The reactivities of *m*- and *p*-xylene, *m*- and *p*-chlorotoluene, and *p*-cyanotoluene were all measured directly against toluene. The reactivities of *m*- and *p*-nitrotoluene were measured against *p*-cyanotoluene. The reactivity of *p*-phenoxytoluene relative to diphenylmethane was determined by hydrocarbon consumption using benzonitrile as an internal standard. (Reactivity of diphenylmethane to toluene under these conditions = 3.46 per benzylic hydrogen (12), cf. a value of 4.70 given by Walling and Jacknow (3).) The reactivity of *p*-methoxytoluene was determined by nuclear magnetic resonance spectroscopy (13) since its chloride is too reactive for analysis by g.l.c. That is, the relative concentrations of benzyl chloride and *p*-methoxybenzyl chloride were determined by integrating the area of the peaks corresponding to their benzylic hydrogens on a Varian Associates model A-60 nuclear magnetic resonance spectrometer. Most of the CCl_4 was removed at low temperature under vacuum before analysis. This procedure gave satisfactory results with *t*-butyl hypochlorite but the spectra of the chlorides from the cumyl hypochlorite and the *p*-nitrocumyl hypochlorite reactions were not sufficiently well resolved for analysis.

The reactivities of the benzylic hydrogens of ethylbenzene and cumene were determined in competitive experiments with toluene by measuring the total concentration of benzylic chlorine by solvolysis and the concentration of benzyl chloride (compared to an internal standard) by g.l.c. The benzylic chlorine was determined by the following procedure. An aliquot of the irradiated solution (1.0 ml) was cooled to $-45° \pm 5$ °C and all the CCl_4 was removed under high vacuum (1 h). The residue was diluted with 25 ml ethanol and hydrolyzed with 0.5 *M* aqueous NaOH (10 ml) under reflux for 2 h. The solution was then acidified and the chloride ion concentration determined by potentiometric titration with *N*/100 silver nitrate.

All the relative reactivities given in this paper represent the average of not less than four analyses on duplicate experiments. All were reproducible to better than ±10%.

RESULTS

The relative reactivities obtained in this work for the reaction of substituted toluenes with *t*-butoxy radicals at 40 °C are compared in Table I with the data of Walling and Jacknow (3) and Gilliom and Ward (6). The agreement between the three sets of data is fairly good except for *p*-phenoxytoluene and *p*-chlorotoluene. In the latter case, no significant variation in the measured reactivity was found over a fourfold change in the ratio [*p*-chlorotoluene]/[toluene] and over a twofold change in the total extent of reaction. It is possible that the differences in reactivity are connected with a solvent effect. The much higher reactivity of *p*-phenoxytoluene found in the present work (compared with the value reported by Gilliom and Ward) has an important bearing on the choice between a correlation of the reaction with σ or σ^+ constants since there are relatively few substituents that can be employed in free radical reactions to draw this distinction.[4] The different reactivities are probably due to the different analytical methods employed. Thus, Gilliom and Ward compared *p*-phenoxytoluene with cyclohexane by selective solvolysis of the benzyl chloride and comparison of this with the total chloride. By this method, chlorination of the *p*-phenoxytoluene in either ring would give an apparently low reactivity.[5] In contrast, our analysis for hydrocarbon consumption will give somewhat

[4]*Substituents such as* OH *and* NH_2 *are unsuitable because they react rapidly with alkoxy radicals and the resultant phenoxy and anilino radicals do not continue the reaction chain. The p-dimethylamino group, which has a very large difference between its* σ *and* σ^+ *constants, was also unsuitable as the toluene was found to react directly with* CCl_4 *(cf. refs. 14 and 15).*

[5]*In this connection it is interesting to note that we have found diphenyl ether to be an unsatisfactory solvent for kinetic studies of chlorination with t-butylhypochlorite, since the ether appears to undergo a slow direct reaction with the hypochlorite. Anbar and Ginsberg (16) have reported that phenols and other reactive aromatics undergo electrophilic substitution with hypochlorites to give aryl chlorides.*

too high a reactivity if ring chlorination is significant. However, this difficulty does not arise in the method used in this work for measuring the reactivity of *p*-methoxytoluene (see Experimental). The high reactivity of this compound lends support to a high reactivity for *p*-phenoxytoluene.

The reactivity of some substituted toluenes towards *t*-butoxy radicals, cumyloxy radicals, and *p*-nitrocumyloxy radicals are compared in Table II. The deuterium isotope effects for hydrogen abstraction from toluene and toluene-α-d_3, which are also recorded in this table were calculated from competitive experiments with toluene-α-d_3 and *p*-xylene. Brook and Glazebrook (17) have reported a very rough value in the range 3.3–6.1 for this isotope effect with *t*-butoxy radicals at 135 °C (cf. also ref. 18).

TABLE II

Relative reactivities of substituted toluenes toward *t*-alkoxy radicals at 40 °C

DISCUSSION

The present data on the relative reactivities of substituted toluenes towards *t*-butoxy radicals were fitted to the Hammett equation.[6] The following correlations were obtained:

[1] $$\log k/k_0 = -0.86\sigma + 0.08;\ s, 0.259;\ r, 0.972$$

[2] $$\log k/k_0 = -0.68\sigma^+ - 0.02;\ s, 0.012;\ r, 0.999.$$

The differences in the standard deviations (s) and correlation coefficients (r) for the σ and σ^+ equations leave little doubt that the substituent effect is best represented by σ^+ constants. The reaction of *t*-butoxy radicals with substituted toluenes in CCl_4 is therefore

[6]*The σ constants are from ref. 19, σ^+ constants from ref. 20 except for the p-phenoxy substituent for which the σ^+ constant was taken from ref. 5.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

similar to the majority of hydrogen atom abstraction reactions which involve radicals of moderate to high electron affinity (1, 5). If the transition state is represented by the following extreme resonance forms (4) then the correlation with σ^+ constants implies

$$\underset{\text{I}}{XC_6H_4CH_2{:}H\cdot OBu^t} \leftrightarrow \underset{\text{II}}{XC_6H_4\overset{+}{C}H_2\cdot H\,\dot{:}\,\bar{O}Bu^t} \leftrightarrow \underset{\text{III}}{XC_6H_4CH_2\cdot H{:}OBu^t}$$

that structure II makes a very important contribution to the transition state (1, 4, 5). This conclusion differs from that of Gilliom and Ward whose data give a slightly better fit with σ than with σ^+ constants.[7] It seems unlikely that this difference could be due to a solvent effect, although it would appear that carbon tetrachloride is a more satisfactory solvent than benzene for *t*-butyl hypochlorite chlorinations as CCl_4 does not enter into the chain reaction even with quite reactive alkyl radicals (21). The kinetics for the hypochlorite–toluene reaction are more complex in benzene than in CCl_4 which implies that benzene may enter into the reaction (22).

None of the values found for the toluenes studied in this work deviate substantially from the line defined by eq. [2]. This implies that in no case is the reactivity significantly affected by the stability of the resultant benzyl radical (cf. ref. 23) even though the two methylbenzyl radicals and the *p*-cyanobenzyl radical are stabilized by over 1 kcal/mole relative to the benzyl radical.[8] Gilliom and Ward (6) (cf. also ref. 25) reported that *p*-phenyltoluene showed a large positive deviation from both their σ and σ^+ Hammett equations. This is attributed to the radical-stabilizing ability of the *p*-phenyl group.[9] However, their relative reactivity for *p*-phenyl toluene of 1.64 deviates by only +0.12 log units from our Hammett relationship defined by eq. [2]. Although the *m*-chloro group does not stabilize the benzyl radical (24) our result with *m*-chlorotoluene deviates from eq. [2] by +0.06 log units. The deviation of the *p*-phenyltoluene is therefore hardly significant.[10] That is, in the transition state of this reaction radical stabilization by substituents (structure III) does not play a very important role compared with their polar effects (structure II).

The relative reactivities listed in Table II suggest that *t*-butoxy and cumyloxy radicals are equally sensitive to polar effects. The *p*-nitrocumyloxy radical may be slightly more sensitive but the difference is small since the inductive effect of the *p*-nitro group must be considerably attenuated at the radical center. Cumyloxy also has a similar reactivity to *t*-butoxy in its abstraction of other benzylic hydrogens. For example, the reactivities (per α-hydrogen relative to toluene) of ethylbenzene and cumene were 4.25 and 7.4 respectively, for cumyloxy and 3.7 and 6.4, respectively, for *t*-butoxy.[11] The significantly

[7] *That is, Gilliom and Ward report*

$$\log k/k_0 = -0.750\sigma - 0.007;\ s,\ 0.047;\ r,\ 0.984.$$
$$\log k/k_0 = -0.599\sigma^+ - 0.066;\ s,\ 0.092;\ r,\ 0.953.$$

[8] *Hodgkins and Megarity's (24) ultraviolet measurements on substituted benzyl radicals give the following stabilities (in kcal/mole relative to the unsubstituted radical): p-CN 1.55; p-CH_2 1.23; m-CH_3 1.17; p-Cl 0.28; and m-Cl 0.0.*

[9] *The p-C_6H_5 group stabilizes the benzyl radical by 2.15 kcal/mole (24).*

[10] *Deviations from the Hammett equation are generally attributed to any factor that will conveniently rationalize the results, for example, experimental error or special interactions between solvent and substituent. However, the electronic contribution of a substituent cannot really be represented by a single constant since the resonance contribution will vary from one reaction to another depending on the electron demand at the reaction center. This is particularly the case for the p-phenyl substituent since the magnitude of the angle between the two phenyl nuclei is strongly dependent on electron demand (26). In view of the potential variation in the electronic contribution of a substituent, the general success of the σ^+ treatment in correlating hydrogen atom abstractions by electrophilic radicals is really quite surprising.*

[11] *For t-butoxy, Walling and Jacknow (3) give 3.18 and 6.84, respectively, and Johnston and Williams (25) give 3.9 and 9.3, respectively (at 110 °C).*

For personal use only.

smaller deuterium isotope effect obtained with the *p*-nitrocumyloxy radical suggests that it is probably rather more reactive than the *t*-butoxy and cumyloxy radicals. A similar increase in reactivity for radicals containing electron-attracting groups has been observed previously in the reaction of substituted polystyryl peroxy radicals with 2,6-di-*t*-butyl-4-methylphenol (27).

SOME STUDIES OF SLOW ROTATIONS AROUND BONDS IN AMIDES

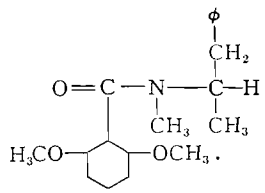
T. H. SIDDALL III

Savannah River Laboratory, E. I. du Pont de Nemours and Co., Aiken, South Carolina

AND

R. H. GARNER

Department of Chemistry, University of Alabama, University, Alabama



Received May 19, 1966

ABSTRACT

Studies were made of the relative rates of rotation around the benzene-to-carbonyl, carbonyl-to-nitrogen, and nitrogen-to-benzene bonds in some α-naphthamides, *o*-substituted benzamides, and related compounds. In general bulky substituents on the nitrogen atom tend to increase the rate of rotation around the carbonyl-to-nitrogen bond, but to decrease the rate around the benzene-to-carbonyl bond. Naphthanilides with *o*-substitution in the benzene ring have a rapid rate of rotation around the naphthalene-to-carbonyl bond compared with other naphthamides. Relative rates of rotation can be rationalized on the basis of combined steric and electronic effects.

INTRODUCTION

In preliminary work (T. H. Siddall III and R. H. Garner, submitted to Tetrahedron Letters) it was established that rotation is slow around the ring-carbonyl bond in the benzamide,

This paper reports the further exploration of the factors that affect the rotation around this bond and the carbonyl-to-nitrogen (amide) bond in various benzamides and related compounds, and compares qualitatively the rate of rotation around the ring-carbonyl bond with the rate around other bonds within the same molecule.

EXPERIMENTAL

The amides in this paper were prepared and purified by techniques described previously (1). All proton magnetic resonance spectra were taken on a Varian A-60 spectrometer equipped with a variable temperature insert.

RESULTS

Results are given in Table I (some additional information is included in the figures). The symbol $\langle \nu_a - \nu_b \rangle$ denotes the chemical shift in p.p.m. between non-equivalent methylene protons with AB patterns. The symbol $\langle \nu_1 - \nu_9 \rangle$ is the distance between the first and ninth signals (because of overlap this is actually the first and seventh) of the ABC_3 pattern for the non-equivalent methylene protons of ethyl groups. Where two amide isomers exist, the signals for the more abundant (major) isomer have been set in italics. Coupling constants are given in c.p.s. With only a few exceptions, $J_{AB} = 14$ c.p.s. for both the AB and ABC_3 patterns (ABX_3 approximation). Except where specifically noted, $CDCl_3$ was the solvent. The only other solvent employed was *sym*-tetrachloroethane. The concentration was 250 mg/ml for all solutions. Relative abundance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of isomers is expressed as a ratio (such as 1.3:1 for compound VI). Tetramethylsilane was used as a reference.

DISCUSSION

Rotation around Amide Bond

The effects of slow rotation around the carbonyl-to-nitrogen (amide) bond is observable in all compounds except VIII, for which rotation around this bond may be rapid, even at −40°. For the 2-substituted benzamides, coalescence of amide signals in general occurs at about the same or a slightly higher temperature than it does in acetamides (2; 3; also, unpublished work from this laboratory) and at a somewhat higher (as much as 50°) temperature than for benzamides not substituted in the ring. For the 2,6-dimethoxy benzamides (IX and X), coalescence occurs above 100 °C, in the same range as for formamides.

TABLE I (*Continued*)

	Amide				Data and observations		
No.	R	R_1	R_2	R	R_1	R_2	Interpretation
(V)		Benzyl	Methyl		See Fig. 2 for data at −40° —CH_2— non-equivalent in both isomers up to −10°. At 0° major has coalesced; minor still just resolved into two signals	(Signals for major isomer in italics here and for all entries that follow.)	Two amide isomers 1.4:1 at 25°, 1.3:1 at −20° (probably not at equilibrium). Amide coalescence well under way at 60°. Rotation around ϕ—CO much, much more rapid than around amide bond. Rotation around ϕ—CO more rapid in major amide isomer than it is in minor
(VI)		Benzyl	Methyl		—CH_2— is two sets at −30°: 4.85 (equivalent), *4.26* (AB pattern, blurred, $(\nu_a-\nu_b) \sim 0.1$); coalesces at 20° at 4.18 —CH_2— is two sets at 40°: 4.19, *4.80*	*3.10*, 2.60 at −30° 3.06, *2.68*	Two amide isomers 1.3:1 at 40°, but decreases below 1:1 at low temperatures (probably not at equilibrium at −30°). Rotation around ϕ—CO (4.26 at −30°) slower than in V (4.25 at −40°)
(VII)		Benzyl	2-Propyl	—CH_3 at *2.39*, 2.28 at −40° *2.37*, 2.27 at −30° 2.37, 2.26 at −20° 2.38, 2.23 at −20°	—CH_2— is *4.71*, 4.28 at −40°, −30°, −20°: *4.71* non-equivalent, $(\nu_a-\nu_b) = 0.2$, $J_{AB} = 16$; 4.28 equivalent. —CH_2— is *4.67* (singlet), 4.26 at 20°	CH_3— two broad doublets: 1.29, 1.09; one doublet: *0.098* at −20°, −30°, −40°. Coalesce to two doublets: 1.23, *0.99*, at 20°. Methine two sets: *3.80*, other mixed with —CH_2—	Two amide isomers 3:1 (signals for major isomer in italics). Major —CH_2—, minor βCH_3— non-equivalent at low temperature. Rotation around amide bond about same rate as in III; around ϕ-to-CO bond rotation is very much ($\geqslant$10?) faster
(VIII)		Benzyl	*t*-Butyl	—CH_3 at 2.35 at −40°	One signal: 4.48 at −40°, all blurred at 40 °C	One signal: 1.51 at −40°	No evident isomerism. Rotation rapid around all bonds
(IX)		Ethyl		At 40° —O—CH_3 at 3.79, *3.76*, *3.57*	At 40° two non-equivalent —CH_2—: *3.84*, $(\nu_1-\nu_9) = 1.21$; 3.7, $(\nu_1-\nu_9) = 0.41$. Two CH_3—: *1.17* 0.96	At 40° CH_3— at 2.36, *2.28*	Two amide isomers 2.4:1 in $CDCl_3$ at 40°. Two amide isomers 1.3:1 in *sym*-$C_2H_2Cl_4$, coalescence begins at about 90° and is complete at about 140 °C. Coalescence *not* in two separable stages

TABLE I (*Concluded*)

No.	Amide R	Amide R_1	Amide R_2	Data and observations R	Data and observations R_1	Data and observations R_2	Interpretation
(X)		Benzyl			See Fig. 4 for data in $CDCl_3$ at 60° —CH_2— two AB patterns: $(\nu_a-\nu_b)$ = 1.72 (−20°), *1.45 (60)*, 0.29 (−20°); partly coalesced (60°)		Amide isomers 2.9:1 in $CDCl_3$ at 60°; in *sym*-$C_2H_2Cl_4$ ratio is 1.8:1. Otherwise spectrum qualitatively same as in $CDCl_3$. Behavior with temperature is complex. Single sets of signals at 145°, but —CH_2— one broad hump. Rotation rates are: ϕ—N (minor) > amide bond > ϕ—CO (major)
(XI)		Ethyl		At 40° —CH_3 at 2.40 (note assignment with —CH_3 of R_2 may be interchanged)	At 40° two non-equivalent —CH_2—: *3.81*, $(\nu_1-\nu_9)$ = 0.95; ~3.4 (mixed with high field half of *3.81* set); $(\nu_1-\nu_9)$ much less than 0.95. CH_3—: *1.20*, 0.93	At 40° CH_3— at 2.33, *2.21* (see note under R)	Two amide isomers 3.2:1 at 40°; 2.3:1 at 0°. High field CH_3— (R_1) broad at −25°, −50° (third signal set?). In *sym*-$C_2H_2Cl_4$ isomer ratio is 1.2 at 40°. —CH_2— broad quartet at 145°; other signals are sharp, single sets. Rotation around amide bond more rapid than around ϕ—N.
(XII)		Methyl		At −20° —CH_3 at 2.57, *2.46*	At −20° —CH_3 at *3.53*, 3.17		Amide isomers 10:1 at −20°. Essentially same spectrum at −40°. No indication of additional isomerism
(XIII)				At 35° —CH_3 at *2.40*, 2.15	At 35° one non-equivalent set: ~3.7, overlaps a quartet *3.48* for —CH_2— CH_3— at 1.23, *0.97*	CH_3— at 35°: 2.46, *2.50*, ring-H two AB patterns with overlap, coupled to CH_3—, ~0.6 c.p.s.	Two amide isomers 2.0:1. No evidence for further isomerism even at −20°
(XIV)		Ethyl			See Fig. 3 for data in $CDCl_3$ at −40° and 25°	CH_3— at *2.47* broad at −10°, two definite signals but blurred at −20°. No additional signals even at ~−70°	Two amide isomers; equilibrium at 25° is 1.3:1 in $CDCl_3$, 1.3:1 at 60 °C in *sym*-$C_2H_2Cl_4$, 2:1 at 100°. Amide coalescence starts between 100–130°, but is not complete at 145°. ϕ—CO coalescence at −10 to 0°; rotation much, much faster than around amide bond
(XV)		Methyl			At 25° 3.39, *2.94* At −60° 3.47, *3.01* (broad)	At 25° CH_3— at *2.42*, 2.03 At −60° CH_3— at 2.54, 2.45, *2.07* (very broad) At −40° CH_3 at 2.47, just not quite two peaks At −45° CH_3 at 2.50, 2.44, *2.06*	Two amide isomers; equilibrium at 25° is 1.1:1 in $CDCl_3$, 1.7:1 at 100° in *sym*-$C_2H_2Cl_4$. Coalescence starts >100 °C, is not complete at 145°. ϕ—CO coalescence at −40 °C. Rotation many factors of 10 faster around ϕ—CO than around amide bond

*Aryl group to carbonyl bond.

It seems reasonable to conclude that the slower rotation around the amide bond (higher coalescence temperature) with increasing ortho substitution in the benzene ring attached to the carbonyl group reflects two effects. First, because of "steric inhibition of resonance", substitution decreases the effect of cross conjugation of the benzene ring with the carbonyl group (4) and thereby increases the double-bond character of the amide bond. Second, substitution on the benzene ring tends to lock the substituents on the nitrogen atom into a plane with the carbonyl group. This effect has already been noted for mesitamides (5).

This steric effect is evidently quite pronounced in favorable situations, even for cases with substitution on only one side of the ring. Essentially pure amide isomers were crystallized from ether for XV and from ethanol for XIV. On dissolution in $CDCl_3$ at 25° the equilibration of isomers was measured by observing the growth and decay of the separate signals. Both the N-methyl signals (3.39 grows in, while *2.94* decays) and the ring-methyl signals (2.03 grows in, while *2.42* decays) were utilized to monitor the equilibration for XV (see Fig. 3) while the ring-methyl signals only were used for XIV (1.98

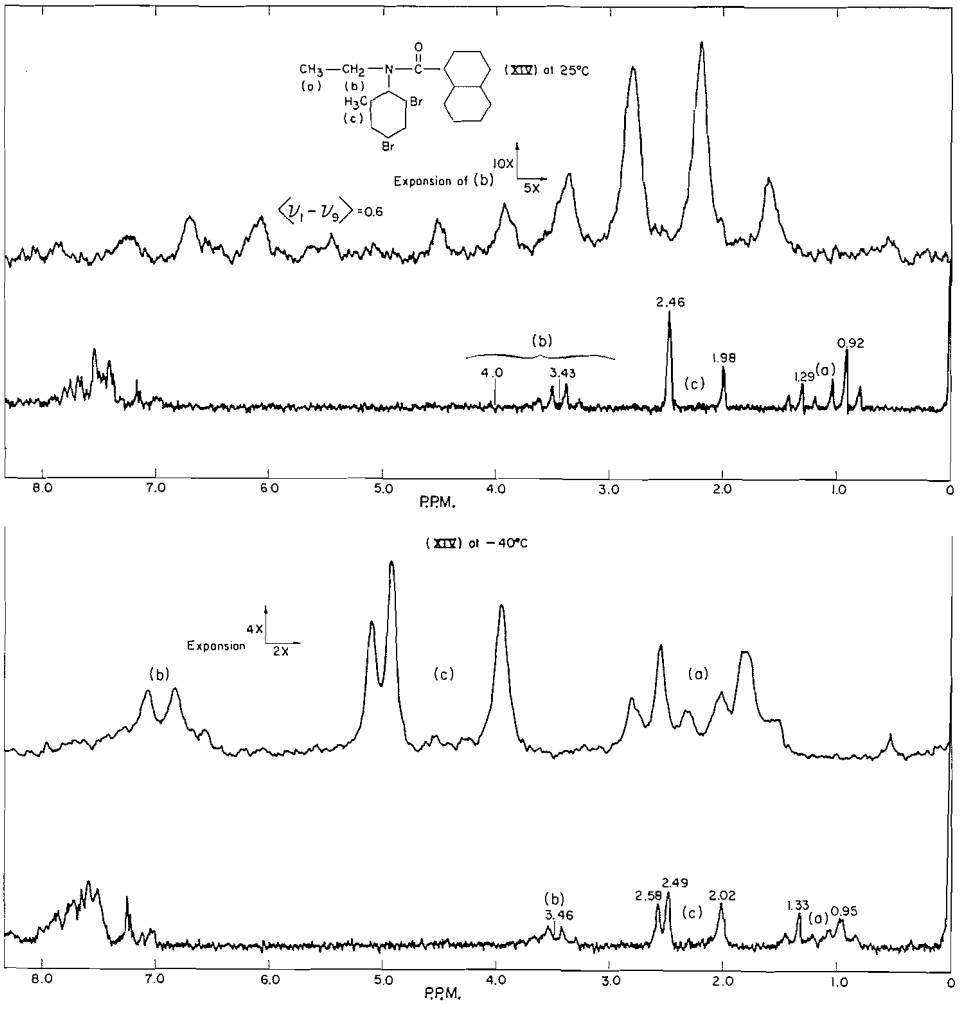

FIG. 3. Proton magnetic resonance spectrograms for compound XIV.

grows in, while *2.46* decays). The half-life of the forward reaction (major isomer to minor isomer) for XV is 70 min, whereas for the reverse reaction it is 60 min. For XIV the corresponding values are 22 min and 17 min. These half-lives lie in the same range as those obtained in this laboratory for N-ethyl-N-2,6-dimethylformanilide (6) and by Mannschreck (5) for N-methyl-N-benzyl mesitamide. The rotation around the amide bond in XIV is more rapid than in XV, as might be expected on the basis of steric factors.

Rotation around Benzene-to-Nitrogen Bond

Rotation around the benzene-to-nitrogen bond (IX through XV) occurs at about the same rate as rotation around the amide bond. However, since separate coalescence could not be clearly observed, it is not possible to make a more definite statement.

Rotation around the Ring-Carbonyl Bond

Appropriate comparisons between compounds I through VII show that increased size of substituents on nitrogen slows rotation around the ring-carbonyl bond. This effect could be predicted on the basis that the activated state for rotation around this bond would presumably place this benzene ring in the amide plane. As the amide plane becomes more crowded by larger substituents, the activated state for rotation at the benzene-to-carbonyl bond is pushed to a higher energy. However, with VIII, apparently the entire 360° of rotation has become crowded; there is no evidence for slow rotation around either the amide bond or the benzene-to-carbonyl bond.

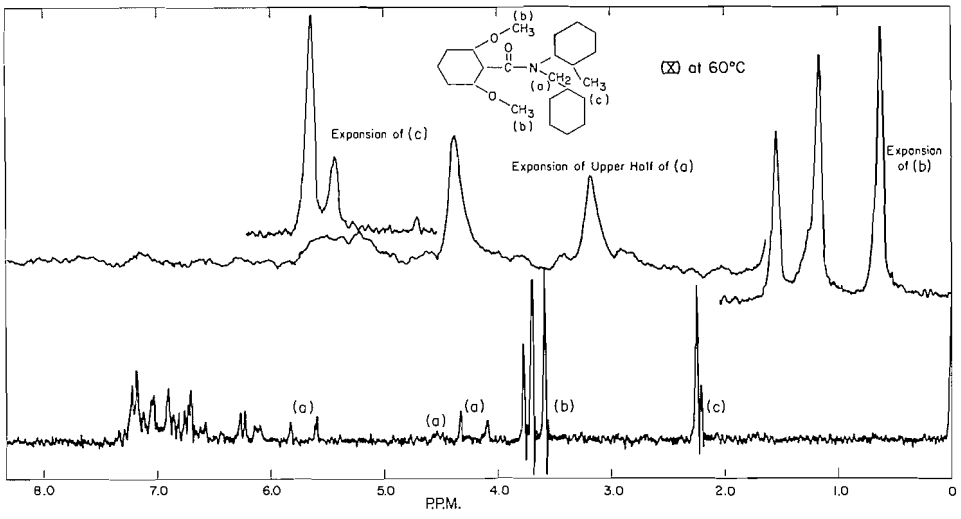

FIG. 4. Proton magnetic resonance spectrogram for compound X.

The spectra of XI, XIV, and XV show part of a third set of signals and, therefore, evidence for slow rotation around the ring-carbonyl bond.[1] However, this effect occurs only at much lower temperature than it does for I through VII.

[1]*Ortho substitution in both positions slows the half-life for rotation around the nitrogen-to-benzene bond to the order of 100 h even at 100 °C (7). However, for epimers to exist, as demonstrated by more than two sets of signals, rotation at the other asymmetry center (the ring-carbonyl bond) must also be slow.*

Interaction between Rotation Modes

There are several cases where it was possible to see clearly separate stages of coalescence for the two or three rotational modes and therefore to make qualitative assignments of relative rotation rates. For V, rotation around the ring-carbonyl bond was more rapid in the major than in the minor amide isomer. Even though the slow exchange chemical shift ($\langle \nu_a - \nu_b \rangle$) is greater for the geminal protons of the major isomer (see Fig. 2), the AB pattern for the major isomer coalesces at a lower temperature.

The spectrograms of compound X also permit considerable, detailed interpretation of relative rotation rates, as shown in Table I. Unfortunately the $\langle \nu_a - \nu_b \rangle$ for the major amide isomer for this compound is so much greater than other shifts associated with other rotational combinations that even qualitative comparison involving this particular rotation are difficult. However, after very close study of the spectrograms, assignment of the relative rotation rates is ring—N (minor) > ring—N (major) $\sim$ amide bond > ring—CO (major). Since only one signal is observable for the methoxy protons of the minor isomer, no assignment of relative rotation rate for the ring-carbonyl bond in the minor isomer can be made. More quantitative information can probably be obtained by changing substituents and (or) solvent.

THE IONIZATION BEHAVIOR OF AMIDES IN CONCENTRATED SULFURIC ACIDS

III. INDICATOR ACTIVITY COEFFICIENT VARIATION

LINDA M. SWEETING[1] AND KEITH YATES
Department of Chemistry, University of Toronto, Toronto, Ontario

Received May 10, 1966

ABSTRACT

Activity coefficient data for ten substituted benzamides and two benzamide salts have been obtained from solubility measurements in 0–70% sulfuric acid. The ionic activity coefficients have been referred to a standard ion, the tetraethylammonium ion. The variations of activity coefficient with acid concentration are discussed and compared with available data for anilines and anilinium ions. Estimates have been made of the relative importance of the various terms contributing to the total acidity function for sulfuric acid. Up to 40% acid the order of importance of these terms is $f_{H^+} > f_{AH^+} > C_{H^+} > f_A$ and in more concentrated acids becomes $f_{H^+} \gg f_{AH^+} \gg f_A > C_{H^+}$.

Hammett-type acidity functions such as H_0 (1, 2), which is based on the ionization of a set of primary aniline indicators $B + H^+ \rightleftharpoons BH^+$ and is defined by

$$[1] \qquad H_0 = -\log a_{H^+} f_B / f_{BH^+} = pK_{BH^+} - \log C_{BH^+}/C_B,$$

have recently been shown to be more sensitive to variations in indicator structure than was at one time supposed. Although Hammett (3) originally pointed out that different acidity scales would be required for positive, neutral, and negatively charged indicator bases, it has recently been demonstrated that several different scales can be established even for neutral Brönsted bases which are structurally different (4–6). These have been shown to depend particularly on the nature of the site protonated in the equilibrium $In + H^+ \rightleftharpoons InH^+$. The acidity function determined using a set of primary amide indicators (6), and defined in an analogous way,

$$[2] \qquad H_A = -\log a_{H^+} f_A / f_{AH^+} = pK_{AH^+} - \log C_{AH^+}/C_A$$

is quite different from that based on primary amines. This is not unexpected, since amides have been shown to be protonated on the carbonyl oxygen (7) and are therefore oxonium type bases.

From eqs. [1] and [2], the dependence of the measured acidity of an aqueous mineral acid solution on indicator structure may be correlated with the variation in the activity coefficients of the species involved in the protonation equilibria. If it is assumed that a_{H^+} is a function only of the acid concentration, then

$$[3] \qquad H_0 - H_A = \log f_{BH^+} f_A / f_B f_{AH^+}.$$

Further, such differences in activity coefficient behavior may be related qualitatively to the hydration requirements of the base and conjugate acid forms (6, 8).

Boyd (9) has recently measured the activity coefficients of indicators of several types and has found that within a particular group of bases such as substituted anilines there are quite large variations in the individual values of $\log f$ for both neutral bases and conjugate acids, although the ratio $\log f_{BH^+}/f_B$ must have a similar medium dependence

[1]*Present address: Department of Chemistry, University of California, Los Angeles, California 90024.*

for each indicator. We have now investigated the activity coefficient behavior of several amides to determine the extent to which H_A is dependent on f_A and f_{AH^+} and to compare the relative importance of the amide and aniline activity coefficient terms in eq. [3]. Although it is generally assumed that differences such as that in eq. [3] in the measured acidity of a medium towards different types of base are essentially due to the conjugate acid terms, the relative importance of the log f_{InH^+} and log f_{In} terms has never been established, although Boyd's results show that variation in the log f_B terms is by no means negligible.

DETERMINATION OF ACTIVITY COEFFICIENTS

Activity coefficients were determined from the solubilities of the indicators in sulfuric acid – water solutions, essentially as described by Boyd (9). For any two saturated solutions the activities of a solute i in equilibrium with pure solid i are equal, hence

$$a_i(1) = f_i(1)C_i(1) = f_i(2)C_i(2) = a_i(2).$$

Therefore if the reference state ($f = 1$) is taken to be a dilute solution of the indicator in pure water (w), the activity coefficient in any sulfuric acid solution (a) is given by

$$f_i(a) = C_i(w)/C_i(a).$$

For a 1:1 electrolyte, the mean ionic activity coefficient is similarly

$$f_\pm(a) = C_\pm(w)/C_\pm(a),$$

where $f_\pm^2 = f_+f_-$. Since the cation and anion terms are inseparable, the single ion activity coefficients can only be estimated indirectly. If the electrolyte is highly dissociated in the medium used, it is possible to estimate the cation activity coefficient behavior by comparing two cations which have a common anion, since

$$f_\pm^2(BA)/f_\pm^2(CA) = f_{B^+}f_{A^-}/f_{C^+}f_{A^-} \cong f_{B^+}/f_{C^+}$$

if the ionic activity coefficients are reasonably independent of each other. In solvents of such high dielectric constant as sulfuric acid – water mixtures, the assumption of separability of the cation and anion activity coefficients is quite reasonable for comparisons of dilute solutions of cations of similar charge and size, since their interactions with the anion should be similar and tend to cancel (10). Following Boyd's example we have chosen the 1,1,2,3,3-pentacyanopropenide ion (PCP^-) as counter ion since this is a large charge-delocalized anion which is not protonated over the entire acid range used and would not be expected to interact specifically with other species in the medium. Similarly we have used the tetraethylammonium ion (TEA^+) as standard cation, so that all our cationic activity coefficients are referred back to this standard ion, i.e.

$$f_{AH^+}f_{PCP^-}/f_{TEA^+}f_{PCP^-} = f_{AH^+}/f_{TEA^+} = f^*_{AH^+}$$

Thus our results can be compared directly with Boyd's log $f^*_{BH^+}$ values for the anilinium ions.

The range of acid solutions over which log f_A and log f_{AH^+} values can be measured is limited experimentally by the protonation equilibria of these bases. The compounds studied must remain essentially unprotonated or protonated (depending on whether f_A or f_{AH^+} is being measured) over the particular range of acid investigated. Therefore only the weaker bases can be used to study f_A over a reasonable range, and only the stronger bases to study f_{AH^+}. A particular difficulty with the amides arises because these are considerably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

weaker bases than the corresponding anilines, and no amide is available whose cation will remain unhydrolyzed in dilute aqueous acids. Therefore estimates of $\log f_{AH^+}$ are particularly difficult to obtain. The method by which this can be circumvented will be described in a later section.

EXPERIMENTAL

Preparation of Amides and Salts

The substituted benzamides were either obtained commercially, or prepared from the corresponding benzoic acids as described previously (6) and were recrystallized from aqueous ethanol to constant melting point.

Tetraethylammonium and pyridinium pentacyanopropenides were prepared by the method of Middleton *et al.* (11) and recrystallized from water. Melting points were 222–223.5 °C for TEA^+PCP^- and 165.5–167 °C for Py^+PCP^-.

The pentacyanopropenide salts of benzamide and *p*-methoxybenzamide were prepared by mixing equivalent amounts of the amide and pyridinium pentacyanopropenide dissolved in the minimum volumes of warm sulfuric acid and cooling to 0 °C. The amidonium pentacyanopropenides precipitated as yellow needles, which, however, could not be completely dried of the concentrated sulfuric acid required to ensure complete protonation of the amide before mixing. These needles were filtered off and washed with further sulfuric acid before being used to make up saturated solutions in the sulfuric acids of interest. Attempts to prepare pure pentacyanopropenide salts of the other more strongly basic amides were unsuccessful. Since preparation requires precipitation of the least soluble of four salts, the amide salts are subject to contamination by pyridinium and bisulfate salts. This could be detected by comparing the ratio of optical densities at the amide conjugate acid and PCP^- maxima (412 mμ). If the ratio D_{amide}/D_{412} was independent of the concentration of acid used to prepare the salt, it was assumed that only AH^+PCP^- had been precipitated, and in the cases of all the benzamide and some of the *p*-methoxybenzamide solutions the total ultraviolet absorption corresponded to that expected for AH^+ and PCP^- absorption. Contamination by bisulfate ion (which is transparent in the region of the spectrum investigated) resulted in too high a D_{amide}/D_{412} ratio, and contamination by pyridinium ion resulted in a low ratio and a peak at 250 mμ. If was not considered worthwhile to prepare salts of the weakly basic nitro- and dinitro-substituted amides since their range of usefulness would be too limited by hydrolysis even in moderately concentrated acids.

Preparation of Solutions

Sulfuric acid – water solutions were prepared by diluting CIL reagent grade acid ($\geqslant 98$ %) and concentrations determined by titrating weighed samples with standard sodium hydroxide.

Saturated solutions of both amides and salts were obtained by shaking mixtures of the solid with the appropriate acid solution for about 15–20 h in a water bath at 25 ± 0.5 °C. Samples were taken during this time and analyzed spectrophotometrically until the concentration of solute no longer increased. In a few cases the concentration began to decrease slowly after prolonged exposure to the sulfuric acid, presumably due to hydrolysis. In these cases log *D* was extrapolated to zero time to obtain corrected values for the solubility.

Samples of the saturated solutions were obtained by filtering carefully through fine glass wool into temperature-equilibrated flasks. A 1.0 ml aliquot was then withdrawn by means of a calibrated Hamilton syringe with Chaney adaptor and diluted to a known volume with water. Concentrations were then determined from the ultraviolet absorbance at the amide maximum for the neutral amides and at the pentacyanopropenide maximum for the salts.

Simple corrections were applied to take account of protonation in the case of the f_A determinations and hydrolysis in the case of the f_{AH^+} determinations, but in most solutions studied protonation or hydrolysis was less than 10%.

RESULTS AND DISCUSSION

Activity Coefficients of Neutral Amides

The bases investigated were all substituted benzamides, since these were predominantly used as indicators in establishing the H_A acidity scale (6). The solubility data and calculated activity coefficients ($\log f_A$ values) are listed in Table I. The results show generally that the neutral amide is "salted in" by the acid, except at the lower acid concentrations in a few cases. A plot of typical $\log f_A$ behavior with increasing acid concentration is shown in Fig. 1 for compounds containing different numbers of nitro substituents. This indicates that log *f* values for amides are generally more negative and decrease more rapidly with acid concentration than those for the corresponding aniline type bases. The $\log f_B$ values for 2,4-dichloro-6-nitroaniline and 2,4-dinitroaniline are shown for comparison (9). Like

the aniline indicators, the amides give increasingly negative log f values as the number of nitro groups is increased. This is presumably due to strong hydrogen-bond interactions between these groups and the acidic solvent. The only direct comparison which can be made between log f_A and log f_B values for two bases with identical substituents is shown in Fig. 2, where log f_A for 2,4-dinitrobenzamide is plotted against log f_B for 2,4-dinitroaniline. Since the two compounds were studied in different acid solutions, interpolated values have been used. The remarkable straight line obtained shows that the two types of base respond qualitatively in the same way to changes in the medium, but the less than unit slope shows that the amino group is more sensitive than the amido group to decreases in the water content of the medium (i.e. anilines are "salted in" less rapidly with increasing acid than amides).

Activity Coefficients of Salts

Solubility and activity coefficient data for benzamidonium, *p*-methoxybenzamidonium, and tetraethylammonium pentacyanopropenides are listed in Table II. For the latter

compound Boyd's original data have been supplemented and in some cases corrected. The data for the *p*-methoxybenzamidonium salt is limited because of the coprecipitation problem discussed earlier, and only the data for benzamidonium pentacyanopropenide is suitable for estimation of $\log f_{AH^+}$ values. Calculation of $\log f_{AH^+}/f_{TEA^+}$ for this compound is complicated by the fact that benzamides are much weaker bases than anilines. Therefore the benzamidonium ion is completely hydrolyzed in dilute aqueous solution and the usual standard state for the activity coefficients is experimentally inaccessible. A convenient first reference state can be defined as the lowest acid concentration in which the salt can be studied without serious interference from hydrolysis. These values are designated as $\log f^0_{AH^+}$. To obtain a set of values for $\log f_{AH^+}$ based on the same standard state as the $\log f_{BH^+}$ values for anilines, the following procedure was used. As a first approximation, all activity coefficients for the benzamidonium ion up to and including the above reference acid (52.8% sulfuric acid) were assumed to be the same as those for the anilinium ion itself. This first approximation is designated as $\log f^1_{AH^+}$ in Table III. Since according to

eq. [3] the experimentally observed difference between the H_0 and H_A functions must be accounted for entirely by the activity coefficient ratio

$$F = \log f_{BH^+} f_A / f_B f_{AH^+}$$

the function $(H_0 - H_A - F)$ was calculated for all concentrations up to 65% sulfuric acid, using the data for the 2,4-dinitro compounds for the neutral base activity coefficients and the unsubstituted compounds for the conjugate acids. (Since the first approximate values for the $\log f_{AH^+}$ were used, this function is designated in Table III as $(H_0 - H_A - F)^1$.) Ideally all the bases and conjugate acids for such a calculation should have the same substituents but it is experimentally impossible to study both the base and conjugate acid of any one compound in the same range of acid concentrations. However, it was hoped that by choosing each pair of bases or conjugate acids with the same substituents any large effect of substituents on the individual activity coefficients would cancel.

Since activity coefficients are usually a smooth function of the water activity, $(H_0 - H_A - F)^1$ was plotted against $\log a_{H_2O}$ as shown in Fig. 3. The figure consists of two linear portions: from dilute aqueous solution up to the first reference state (52.8% acid) the function has a slope of 1.44 (correlation coefficient 0.996) and for all acids above the first reference state it is essentially constant with a value of -0.66 ± 0.01. Since the function plotted should be constant over the whole range and hence independent of the water activity this value represents a constant difference in activity coefficient between that of the first reference state and that of dilute aqueous solution. The first part of the curve gives the correction for the error made in the 0–50% range by assuming $f_{AH^+} = f_{BH^+}$ below the reference state concentration. Smoothing all these values by least squares and adding them to $\log f_{AH^+}/f_{TEA}$ gives $\log f_{AH^+}/f_{TEA^+}$ values for the whole acid range, now based on dilute aqueous solution as standard state (Table IV). Using these values the function $H_0 - H_A - \log f_{BH^+} f_A / f_B f_{AH^+}$ now has the value 0.00 ± 0.01 over the range 0–65% acid and the estimated values of $\log f_{AH^+}/f_{TEA^+}$ are a smooth function of the acid concentration over the entire range as shown in Fig. 4. The corresponding curve for anilinium ion is included for comparison. This shows that the benzamidonium ion is "salted

out" more rapidly than anilinium ion, especially above 40% acid. Thus the amide ions are appreciably more sensitive to decreasing water content of the medium than the corresponding anilinium ions.

Analysis of Acidity Function Variation

We are now in a position to assess the relative importance of the various terms which contribute to the total acidity of aqueous sulfuric acids towards these organic bases. The H_A function can be expressed as

$$[4] \qquad -H_A = \log f_{H^+} + \log C_{H^+} + \log f_A - \log f_{AH^+}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Values of log C_{H^+} can be calculated by assuming that the first dissociation of H_2SO_4 is essentially complete in the range 0–70% acid, and by using the known value of K_2. An estimate of log f_A can be made from the data in Table I either by averaging log f_A values for all the amides studied or by choosing one amide as representative. The latter seems preferable since a smoother function of concentration is obtained. Since the log f_A curve for 2,4-dinitrobenzamide occupies a central position when all the data in Table I is plotted against % H_2SO_4, its behavior was chosen as typical. No direct estimates can be made of the ionic terms in eq. [4] since the log $f^*_{AH^+}$ values are all related to the standard ion TEA^+. However, if the equation is rewritten as

$$-H_A = \log f_{H^+}/f_{TEA^+} + \log C_{H^+} + \log f_A - \log f_{AH^+}/f_{TEA^+},$$

values of log $f^*_{AH^+}$ for benzamidonium ion can be used to calculate values of log f_{H^+}/f_{TEA^+}. Since there is no possibility of obtaining single ion activity coefficients such as f_{TEA^+}, only the relative importance of the various contributions to H_A can be estimated. These are plotted in Fig. 5 as a function of acid concentration. Since there is reason to believe that the tetraethylammonium ion would not show large activity coefficient variation with medium (9, 12) it is unlikely that the positions of these curves would be changed greatly even if the correct values were accessible. It is reasonable to expect that TEA^+ would be "salted in" over most of the range studied, so that the curves for log f_{H^+}/f_{TEA^+} and log a_{AH^+}/f_{TEA^+} should probably be shifted upwards. It is also unlikely that substitution of log f_A or log $f^*_{AH^+}$ data for other compounds would change the relative positions of these two curves greatly.

It can be seen from Fig. 5 that except for the very dilute acid range where all values of f approach unity the most important single contribution to the acidity function is the f_{H^+} term. In the 5–40% range the order of importance is

$$f_{H^+} > f_{AH^+} \geqslant C_{H^+} > f_A$$

and in the more concentrated region it is

$$f_{H^+} \gg f_{AH^+} \gg f_A > C_{H^+}.$$

Although the f_{H^+} term is clearly the most important, it is clear that the variation of log f_{AH^+} has a powerful moderating effect on the magnitude of the acidity function. Although it is frequently assumed that activity coefficient variations of the neutral indicators are of little importance, it can be seen that log f_A contributes approximately half as much as log f_{AH^+} to the overall logarithmic acidity scale. The least important term (except for very dilute solutions) is that involving the stoichiometric hydronium ion concentration. The major influence of increasing the acid concentration results from the corresponding decrease in the water activity. As the available water is drastically reduced, the free energies of the ionic species are greatly increased, due to their inability to achieve sufficient solvation through hydrogen bonding. This is most pronounced for the hydronium ion which can form three very strong hydrogen bonds to other water molecules (13).

A similar treatment of the H_0 function can be made using Boyd's data for the anilines (9). The results are qualitatively similar to those in Fig. 5. The reason for the marked differences in acidity of aqueous mineral acids towards anilines (H_0) and amides (H_A) is twofold. Firstly, the AH^+ species is "salted out" to a greater extent than BH^+, especially in the more concentrated acids. This leads to the conclusion that amide conjugate acids are more strongly hydrated than the corresponding anilinium ions. Secondly, and equally important, is the fact that neutral amides are "salted in" to a greater extent than neutral

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

anilines. Thus the free amides are less strongly hydrated than the corresponding anilines. Therefore differences in hydration of both the neutral and cationic species contribute almost equally to the greater overall hydration changes (6, 8) produced when amides are protonated as compared with the protonation of anilines.

SOLVENT SHIFTS IN CHARGE-TRANSFER SPECTRA. INFLUENCE OF DONOR STRENGTH

H. M. ROSENBERG, E. EIMUTIS, AND D. HALE
Air Force Materials Laboratory, Research and Technology Division, Wright-Patterson Air Force Base, Ohio
Received June 6, 1966

ABSTRACT

The charge-transfer transition energies for a series of methylbenzene–tetracyanoethylene complexes in four solvents are reported. The charge-transfer transition energies are found to decrease with increasing solvent refractive index. The magnitude of the decrease appears to be a function of donor strength. It is inferred that the excited state dipole moment decreases with increasing donor strength for these complexes.

A number of authors have attempted to account for the influence of solvent on electron donor-acceptor complex spectra (1). Thus, solvent shifts have been attributed to dielectric constant of solvent (1*a*, *b*, *f*), solvent interaction with donor and acceptor species (1*c*), *Z*-value of solvent (1*d*, *f*), and specific solvent interaction (1*e*). None of these hypotheses provide a satisfactory description of experimentally observed solvent shifts. In a previous study of aromatic hydrocarbon – tetracyanoethylene (TCNE) complexes (2), we found that the charge-transfer absorption bands vary monotonically with index of refraction of solvent, the transition energy decreasing with increasing index of refraction. Support for this relationship was found in published data for other π-complexes (3). Voigt has recently confirmed these observations (4). We interpreted these results by postulating an interaction between the induced solvent dipole and the excited state of the complex (2, 3).

The magnitude of the solvent shifts observed in our first study appeared to depend on the donor. This paper reports the results of a detailed investigation of this effect for methylbenzene-TCNE complexes.

RESULTS AND DISCUSSION

Consistent with our previous observations (2, 3), the transition energies of the complexes decrease with increasing solvent refractive index. The decrease in the transition energies in going from acetonitrile to chloroform is shown in the last column of Table I. The energy changes appear to be a function of donor ionization potential, being greatest for the benzene–TCNE complex and least for the hexamethylbenzene–TCNE complex. The same trend is exhibited for the solvent shifts between any pair of solvents in Table I. The gas-to-solution frequency shifts for methylbenzene–TCNE complexes are reported by Voigt (4). These shifts are consistent with our data.

A number of theoretical relationships have been derived for correlating electronic spectral shifts with solvent properties (5). Experimental support for the Bilot and Kawski equation (5*c*) was advanced in a recent study (6). For molecules of similar size this treatment yields the following approximation:

$$[1] \qquad \frac{\Delta E(\mathrm{I})}{\Delta E(\mathrm{II})} = \frac{\mu_e^2(\mathrm{I}) - \mu_g^2(\mathrm{I})}{\mu_e^2(\mathrm{II}) - \mu_g^2(\mathrm{II})}$$

where ΔE is the energy difference for an electronic transition in two nonpolar solvents; μ_e and μ_g are excited and ground state dipole moments respectively; I and II identify different complexes. The literature μ_g values for methylbenzene–TCNE complexes show

‡Solvent index of refraction at 20°.

a maximum value of 1.35 D for the hexamethylbenzene–TCNE complex (7) compared with $\mu_e \approx 11$ D for the hexamethylbenzene - tetrachlorophthalic anhydride complex (8). Therefore:

$$[2] \qquad \frac{\Delta E(\mathrm{I})}{\Delta E(\mathrm{II})} \approx \frac{\mu_e^2(\mathrm{I})}{\mu_e^2(\mathrm{II})}$$

Application of eqs. [1] and [2] requires that the charge-transfer transition energy for a given complex show a linear dependence on $(n^2 - 1)/(2n^2 + 1)$ for the choice of solvents, where n is solvent refractive index.

Voigt has reported charge-transfer transition data for several methylbenzene–TCNE complexes in two sets of solvents which satisfy the above condition (4). From the ratio of the slopes obtained from the plot of charge-transfer energy vs. $(n^2 - 1)/(2n^2 + 1)$, (ref. 4) and assuming μ_e value of 12.0 D for the benzene–TCNE complex, we calculated from eq. [2] the μ_e values shown in Table II. These computed data have no absolute significance but show relative values based on an arbitrary choice of μ_e for the benzene–TCNE complex. The maximum value of μ_e is 15.3 D, based on an interplanar distance of 3.2 Å. The actual value is reduced by resonance and inductive effects. It is noteworthy that the calculated values for μ_e show a decreasing trend with decreasing ionization potential of donor.

According to Mulliken (9) the wave functions for the ground and excited states of a complex can be represented as follows:

$$[3] \qquad \psi_N \approx a\psi_0(\mathrm{D, A}) + b\psi_1(\mathrm{D^+ - A^-})$$

$$[4] \qquad \psi_E \approx a^*\psi_1(\mathrm{D^+ - A^-}) - b^*\psi_0(\mathrm{D, A})$$

where $a^2 \gg b^2$; $a^{*2} \gg b^{*2}$; neglecting overlap, $a^* \approx a$; $b^* \approx b$.

Briegleb has shown that the excited state dipole moment can be expressed as follows:

$$[5] \qquad \mu_e = \mu_1(a^{*2} + a^*b^*S) \approx a^{*2}\mu_1$$

where μ_1 is the dipole moment of the dative form of the complex (10).

Since the interplanar distances in π-complexes are generally similar, the dipole moments of the dative forms, which represent a complete electron transfer, can be considered constant. The excited state dipole moments are therefore proportional to a^*. It is reasonable to assume that the ground state resonance contribution of the dative canonical form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

will vary directly with donor strength, i.e. b increases and a decreases with donor strength. This premise is supported by μ_g data for π-complexes with methyl benzene donors (10). Since $a^* \approx a$ and $b^* \approx b$, a^* and b^* should exhibit the same dependence on donor strength.[1] It is therefore predicted that as donor strength of a complex increases, μ_g should increase and μ_e decrease. The computed values presented in Table II are consistent with these deductions, and the ΔE_π data shown in Table I are also in good qualitative agreement. Quantitative μ_e comparisons, through use of eq. [2], cannot be made for these data since polar solvents were used in obtaining these measurements.

‡Assumed value (arbitrary).

EXPERIMENTAL

All solvents were spectroquality grade reagents and all donors were the highest purity commerically available hydrocarbons and were used without further purification. The TCNE was sublimed twice *in vacuo*. Solutions were prepared to give charge-transfer bands having optical densities of 0.4 to 0.5, using excess donor. Spectra were measured on a Cary model 11 spectrophotometer in tared 1 cm quartz cells, with pure solvent as reference. Where there was evidence for overlapping double bands, spectra were resolved according to the method of Voigt and Reid (10). Data for charge-transfer transition energies at the absorption maxima are given in Table I together with donor photoionization potentials (taken from ref. 11).

HIGH RESISTANCE ANODIC OXIDE FILMS ON ALUMINIUM

A. C. HARKNESS

AND

L. YOUNG
Electrical Engineering Department, University of British Columbia, Vancouver, British Columbia

Received October 25, 1965

ABSTRACT

The thicknesses of oxide films formed in aqueous borate solutions were obtained by the spectrophotometric method after developing the interference colors by evaporating a very thin film of gold or bismuth onto the oxide. The refractive index of the stripped films was determined by the Becke immersion method as 1.57 to 1.58 at 5 900 Å wavelength. The dielectric constant was estimated as 9.8 ± 0.5. Experimental data on the steady state ionic current density, I, through the oxide as a function of the field strength, E, in the oxide could be represented by $I = I_0 \exp -(W - qaE)/kT$ where $I_0 = 2.24 \times 10^7$ A cm^{-2}, $W = 1.3 \pm 0.15$ eV, $q = 3e$, $a = 2.95 \pm 0.15$ Å.

INTRODUCTION

The aim of this work was to investigate, as a contribution to the comparative study of the various film-forming metals, the dielectric and ionic conduction properties of the films formed on aluminium in dilute aqueous borate solutions. The anodic behavior of aluminium is far more sensitive to the nature of the electrolyte than is that of tantalum, and it is probable that different results would have been obtained with other electrolytes which give high resistance films. The present films are, of course, quite different from the low resistance films which are produced in sulfuric acid and some other electrolytes.

The high resistance films have been reported by Franklin (1) to resemble the low resistance films in having a cell (or honeycomb) structure, though without pores. It is not clear how general this result is, and an earlier report (2) of cell structure in high resistance films shows that it is not invariably present. If it is present, the thickness determinations presumably refer to a mean value, and the associated differences in the solubility of the film material in Altenpohl's reagent (chromic plus phosphoric acid) at different places in the cells introduces a further complication. The present films were formed to comparatively small thicknesses at which they are reported to be amorphous; crystalline oxide is reported (3) to appear only at greater thicknesses (apart from any hydrated oxide present before anodization).

Several investigations have been made of the kinetics of formation, and several other investigations have been concerned with determining the "angstroms per volt" at a single current density. The first work was by Güntherschulze and Betz (4) who used the capacity to determine the thickness. The dielectric constant was taken as the mean of 7.04 and 7.85 obtained from thickness calibrations by weight gain determinations, and by measurement of electrical resistance changes, respectively. The current efficiencies reported were quite low as was to be expected from the purity of the available metal. These measurements were of interest in establishing that the dependence of I on E could be represented by

$$I = A \exp BE \qquad [1]$$

where I = ionic current density and E = field strength in the oxide. Charlesby (5) obtained data by several methods and based his field strengths on the value of Güntherschulze and Betz at $I = 10\ \mu A\ cm^{-2}$. Bernard and Cook (6) used substantially non-aqueous solutions and estimated thickness by weighing, capacity, and Faraday's Law methods. They found $(\partial E/\partial \log I)_T$ to be constant, in accordance with eq. [1]. Dignam, Goad, and Sole (7) have presented evidence to show that with Bernard and Cook's electrolyte the behavior of aluminium is better described by an equation of the form proposed by Young (8, p. 99) for tantalum.

Among the determinations of thickness and other properties, reference is made to the work of Hennig (9) using an interference method (Köster double prism) and to the work of Van Geel and Schelen (10) who found the dielectric constant to be 8.7 with various methods of determining the thickness.

EXPERIMENTAL PROCEDURES

The specimens were cut from 99.99% purity sheet by a die in the shape of a rectangle with a small tab at one end. A wire lead was spot welded to the tab. Several methods of surface preparation were tried. Finally, the specimens were etched in a 10% sodium hydroxide solution, chemically polished in a bath of concentrated orthophosphoric, sulfuric, and nitric acids in the volume ratio 70:25:5 at 85° for 5 min, and then formed to 200 V. The wire lead and the tab were covered with Picien wax. The exposed specimen of about 2 cm^2 in area was then etched in 1:1 hydrofluoric acid and reformed to 200 V. The etching and forming procedure was repeated several times with the final etching being done just before use. This method tended to give a more constant rate of voltage rise during formation at constant current density than did the other methods tried. The electrolyte was a 20 g/l recrystallized orthoboric acid solution which was adjusted to a pH of 7 with concentrated ammonium hydroxide. The measurement of pH was done on a small portion of the electrolyte to avoid contamination of the main body of the electrolyte by chloride ions.

The films were formed at constant current using an automatic electronic control which terminated the formation at the required potential with respect to a reference electrode and which indicated the time to traverse the successive 1 or 10 V intervals during formation. A specimen was inserted into the cell with care being taken to avoid touching the large concentric cylinder of platinized platinum which served as the cathode during formation and as the counter electrode for capacity measurements. The cell was immersed in a constant temperature bath. During formation the electrolyte was stirred to avoid heating effects. The specimen was formed to 10 V at 10 mA cm^{-2} and the capacity measured. The specimen was then formed to a higher voltage at the current density of the experiment and the capacity measured again. A different specimen was used for each formation voltage.

The films, as formed, showed only very faint interference colors. This is evidently due to the comparatively low refractive index of the oxide which causes the Fresnel coefficient for the oxide/air interface, r_1, to be small compared with that for the oxide/metal interface, r_2. The colors, as was shown by Güntherschulze and Betz, may be rendered quite intense by laying down by evaporation a very thin, invisible layer of metal. This process evidently increases the magnitude of r_1. A layer of bismuth was used in the first experiments, but in the later work gold was used instead since it was found to give sharper and more reproducible minima in the specular reflectivity. There was no significant difference between the wavelength of the minimum obtained with gold and that obtained with bismuth. Tests made with varying small amounts of the two metals showed no significant variation, so that the process was considered to be sufficiently controlled for the present purpose. The scatter is greater than for tantalum or niobium which do not require such treatment to enhance their colors and which are less sensitive to impurities in the solution. The peaks were moderately sharp from 2 700 Å to 4 000 Å. The measurements could be carried to 2 700 Å before interference from the intrinsic absorption of the oxide.

RESULTS AND DISCUSSION

The function $[Q\Delta(1/C)]^{1/2}$, where Q is the charge to form an increment of thickness starting with a film formed to 10 V at 10 mA cm^{-2} and $\Delta(1/C)$ is the change in the reciprocal of the capacity at 1 kc/s, gives a measure of the increments of thickness of the film (8, p. 78). This measure is in terms of ρ/ϵ, the ratio of the density of the film to its dielectric constant, and is independent of the knowledge of the surface area. This assumes 100% current efficiency, an assumption which we justify later.

Figure 1 shows a plot of grouped averages for many specimens of $[Q\Delta(1/C)]^{1/2}$ plotted against the wavelengths of minimum reflectivity. Each point covers a wavelength range of 400 to 900 Å and includes from 4 to 12 specimens. Specimens formed at 0 and 25 °C

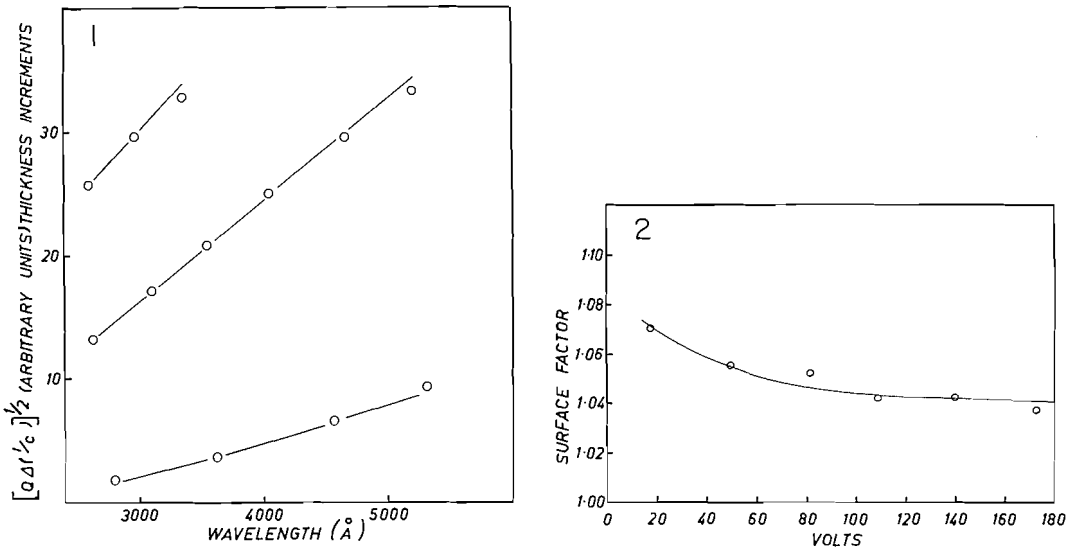

FIG. 1. Grouped averages of thickness increments from charge and capacity data vs. wavelength of minimum reflectivity of films.

FIG. 2. Grouped averages of the ratio of effective to apparent area calculated from charge and capacity data vs. formation voltage.

with current densities from 0.1 to 10 mA cm^{-2} were included. The units of $[Q\Delta(1/C)]^{1/2}$ are arbitrary in that time was measured in counts (120 s^{-1}) and capacities in microfarads.

The increment in thickness at a wavelength λ between consecutive orders of interference is $\lambda/2n \cos\theta$, if the refractive index, n, is constant, and where θ = angle of refraction. The refractive index of films isolated by using a bromine and methanol mixture to dissolve the metal was found by the Becke immersion method to be 1.57 to 1.58. The standard reference liquids were calibrated using an Abbé refractometer. Using a monochromator, the anomalous decrease in n at 4 360 Å reported by Hennig (9) was not detectable. The above value for n agrees with Hennig's value at the same wavelength but not with that of Van Geel and Schelen (10). The variation between the values reported by different authors is so large that it appears to be beyond experimental error; very probably the films formed under different conditions are different in structure.

Taking $n = 1.58$ at 3 600 Å, which is justified by the low dispersion of the oxide in this region shown by Hennig's results and confirmed by the present results, we obtain a value of $\rho/\epsilon = 0.306$. Taking a round number value of $\rho = 3.0$ g cm^{-3} (which is within about 5% of values reported by Van Geel and Schelen and by Bernard and Cook) we obtain $\epsilon = 9.8$ with about $\pm 5\%$ uncertainty. With these values the ordinate of Fig. 1 may be converted to cm by multiplying by 6.52×10^{-7}.

The function $[Q/\Delta(1/C)]^{1/2}$ measures the effective area (8, p. 78). Data averaged in groups of the ratio of effective to apparent area are shown in Fig. 3. These indicate that the effective area is only a few percent greater than the apparent area. The larger ratios found by Plumb (11) are for abraded surfaces. The fact that the plotted quantity is only slightly greater than unity shows that the current efficiency must have been close to 100%.

The field strengths estimated with the thickness obtained from the capacity and the charge passed, respectively, using the apparent area, showed a tendency to increase and to decrease respectively with increasing thickness. However, when the area-independent function, $[Q\Delta(1/C)]^{1/2}$, was used to obtain the thickness the field strengths were substantially independent of thickness. Some results for experiments at 0 °C are shown in Fig. 3.

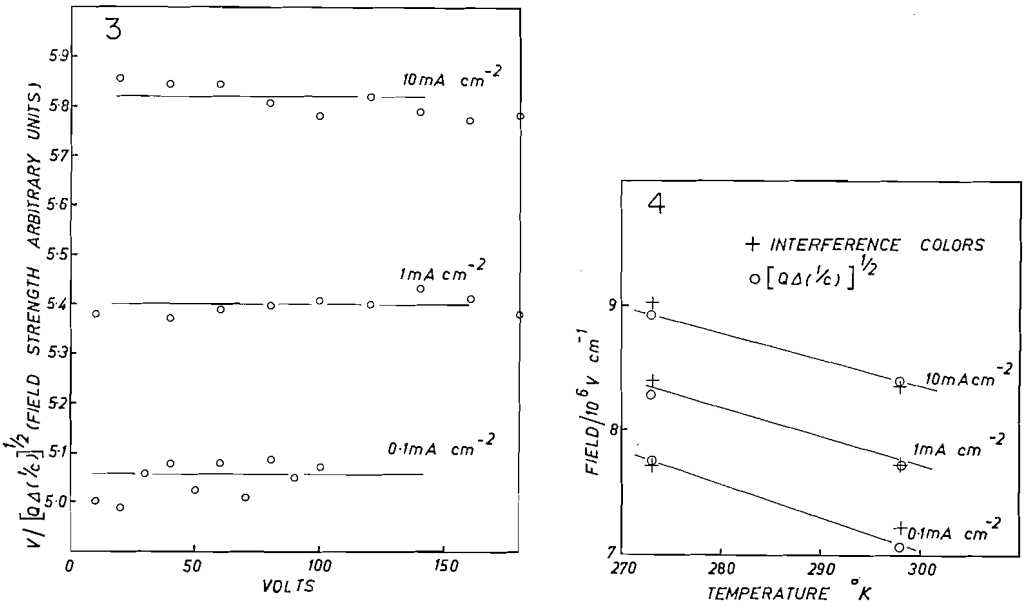

FIG. 3. Field strengths using $[Q\Delta(1/C)]^{1/2}$ for film thickness vs. formation voltage. Various current densities at 0 °C.

FIG. 4. Field strengths from $[Q\Delta(1/C)]^{1/2}$ and interference colors as a function of formation temperature. Colors made to agree with $[Q\Delta(1/C)]^{1/2}$ at 25 °C and 1 mA cm^{-2}.

(Field strengths in V cm^{-1} can be obtained by multiplying by 1.53×10^6.) The scatter was similar at 25 °C, but at 40 °C the results were more scattered and for films formed at temperatures above 40 °C the capacity changed markedly and continuously with the time—evidently due to hydrolysis.

Field strengths were also estimated by using estimates of the thickness obtained from the wavelengths of interference, taking a plot of wavelengths of interference vs. voltage for films formed at 1 mA cm^{-2} at 25 °C as a reference chart. The field was taken as the slope of plots of voltage vs. thickness.

Mean values of the field using $[Q\Delta(1/C)]^{1/2}$ excluding data from very small and from very large increments of thickness are shown in Fig. 4, together with fields estimated from the colors. Values at 40 °C were excluded since, as already stated, they were less reliable.

The straight lines shown in Fig. 4 correspond to

$$I = I_0 \exp - (W - qaE)/kT \qquad [2]$$

with $I_0 = 2.24 \times 10^7$ A cm^{-2}, $W = 1.3$ eV, and $a = 2.95$ Å, taking q as the valence charge $3e$. The uncertainties were estimated as ± 0.15 eV in W, ± 0.15 Å in a, and a corresponding error in I_0. These are the accuracies with which the constants are required to fit the results; the parameters are not independently determined to these accuracies.

The experimental data are consistent with the theoretical form, eq. [2], but the available temperature range was too small to detect whether the second order deviations which occur with tantalum and niobium also occur with aluminium. At 150 V and 25 °C in 30 wt. % ammonium pentaborate solution in ethylene glycol the data of Bernard and Cook derived from weight gain (with $\rho = 3.17 \pm 0.03$ g cm^{-3}), capacity (with $\epsilon = 8.4 \pm 0.2$), and Faraday's laws (with effective area taken as 1.03 times the apparent area from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

comparison with chemically polished specimens) yield effective activation distances (defined by $a = BkT/q$ with $q = 3e$) of 4.1, 4.6, and 3.8 Å respectively. From weight gain and capacity, respectively, Bernard and Cook found $qa/kT = 4.8 \times 10^{-6}$ and 4.4×10^{-6} cm V^{-1} and the value of A in eq. [1] to be 10^{-22} and 10^{-20} A cm^{-2}.

In the present work from $A = I_0 \exp -(W/kT)$ we found the value of A at 25° to be $10^{-14.6}$ A cm^{-2}. It is easier to judge the significance of these results if the corresponding field strengths are calculated; the results are shown in Table I.

TABLE I

Field strength as a function of I

I (mA cm^{-2})	E (V $cm^{-1} \times 10^{-6}$)		
	Bernard and Cook (from weight gain)	Bernard and Cook (from capacity)	This work

1	9.11	9.10	7.77
0.1	8.64	8.57	7.10

The present data are about 15% lower which is evidently greater then experimental error. The fields are basically calibrated from the refractive index. Davies, Domeij, Pringle, and Brown (12) are therefore incorrect in suggesting the difference could be caused by the current efficiency being low. Their low current efficiencies were not obtained under comparable experimental conditions. It is noteworthy that, allowing for the different densities used, if we calculate the capacity to be expected for a film formed to a given voltage, the lower value of $\epsilon = 8.4 \pm 0.2$ found by Bernard and Cook as compared with the present value (9.8 ± 0.5) results in a compensation. These authors found that the capacity of films formed to a given voltage at a given current density in dilute aqueous solution of boric acid and in their non-aqueous solution were the same. This is found in analogous experiments with tantalum (13) though the films may differ markedly in optical thickness and in the charge required for their formation, so that it seems possible that there is a similar effect with aluminium. Randall, Bernard, and Wilkinson (14) have emphasized that the properties of anodic films depend on electrolyte composition even with dilute solutions and have found a similar inverse relation between dielectric constant and ionic resistivity for such dilute solutions.

Some of the results from the present work were quoted previously (8, p. 220).

ELECTROPHILIC CATALYSIS IN SOLVOLYTIC REACTIONS

IX. INDUCTOMERIC EFFECT[1]

R. ANANTARAMAN AND M. R. NAIR[2]
Chemistry Department, University of Kerala, Trivandrum, India

Received March 16, 1966

ABSTRACT

The rates of solvolysis of 1-(*p*-alkylphenyl)ethyl chlorides (Alk = Me, Et, *i*-Pr, and *t*-Bu) in the presence and absence of mercuric chloride have been measured in aqueous acetone and ethanol solvents. In all cases, the Baker–Nathan order is followed. For all normal reactions and for the catalyzed reactions in 90% aqueous acetone and 90% aqueous ethanol there is an increase in the heats and entropies of activation as the series is ascended, while for the catalyzed reaction in 75% and 80% aqueous acetone, there is a decrease. It is suggested that in the more aqueous acetone solvents the catalyst calls into play an inductomeric effect. The effect of added chloride ions on the rate of hydrolysis has been studied and the results are discussed.

In a previous paper on the kinetics of mercuric chloride catalyzed hydrolysis of 1-phenylalkyl chlorides (Alk = Me, Et, *i*-Pr, and *t*-Bu), to understand the trend in the rates it was found necessary to postulate that the electrophilic catalyst brought into play an inductomeric mode of electron release from the alkyl groups (1). We have now studied the corresponding 1-(*p*-alkylphenyl)ethyl system from this standpoint.

RESULTS AND DISCUSSION

The first-order rate constants for the normal and catalyzed hydrolysis in aqueous acetone solvents and for the solvolysis in 90% aqueous ethanol, together with the values for the heats and entropies of activation, are given in Table I. Data for 1-phenylethyl chloride and *t*-butyl chloride are included for purposes of comparison. Considering first the data in 80% aqueous acetone, it can be seen that the rates for both reactions follow the Baker–Nathan order (2). The values for the ratios of rates of 1-*p*-tolylethyl chloride and *p*-*t*-butyl-α-chloro-α-methyltoluene at 25° for the normal and catalyzed hydrolysis are 2.75 and 2.43, respectively. Theoretically, however, the ratio for the catalyzed reaction should be larger than that for the normal reaction since the catalytic efficiency should increase with the ease of heterolysis of the C—Cl bond. This implies that in the catalyzed reaction, some factor has been introduced which favors the hydrolysis, the magnitude of which increases in the order Me < Et < *i*-Pr < *t*-Bu. An examination of the heats and entropies of activation also support this conclusion. The values for the normal reaction show the usual trend, which is similar to that found for the hydrolysis of *p*-alkylbenzhydryl chlorides (3). Provided both the normal and catalyzed reactions follow the S_N1 mechanism, as is the case here, the heat of activation for the catalyzed reaction for all four alkyl chlorides should be lower than that for the corresponding normal reaction while the trend in their values should be the same, i.e., the heats of activation should increase as the series is ascended; the entropy of activation values should be lower for the catalyzed reaction in all cases. 1-Phenylethyl chloride and *t*-butyl chloride are examples which obey this rule. The reason for expecting a decrease in the entropy of activation on passing from the normal to the catalyzed reaction is that the transition state for the latter will be more polar and so will be more highly solvated. With 1-*p*-tolylethyl chloride, while the heat of

*For 80% v/v acetone–water, RCl = 0.050 M.

activation is lower than that for the normal reaction, the entropy factor remains practically constant. A likely explanation appears to be that the larger fractional charges in the transition state of the catalyzed reaction are effectively delocalized by C—H hyperconjugation. This would naturally reduce solvation and so will lead to a higher entropy value. As the series is ascended, in marked contrast to the trend noted for the normal hydrolysis, the heats of activation progressively decrease. It is suggested that this could be understood on the basis that the catalyst induces an inductomeric mode of electron release from the *p*-alkyl groups, the magnitude of which should obviously increase as the series is ascended. Consistent with this interpretation is the observed trend in the values of the entropy of activation. Again, in contrast to the normal reaction, where there is a slight increase in entropy as the series is ascended, the entropy values decrease markedly; the only exception is 1-*p*-tolylethyl chloride, as noted above. Now, the magnitude of C—H hyperconjugation should decrease, and that of the inductomeric effect increase along the series. The net result would be to accentuate the normal loss in entropy of activation which would be expected to occur on passing from the normal to the catalyzed reaction.

In 90% aqueous acetone also the Baker–Nathan order is observed for the normal and catalyzed reactions. The heats and entropies of activation have been determined only for 1-*p*-tolylethyl chloride and *p*-*t*-butyl-α-chloro-α-methyltoluene. Their trend for the normal reaction is quite similar to that in 80% aqueous acetone and so does not call for comment. However, the trend in the catalyzed reaction is similar to that in the normal reaction and opposite to that for the catalyzed reaction in 80% aqueous acetone. A simple explanation for the higher heat of activation noted for *p*-*t*-butyl-α-chloro-α-methyltoluene is that the solvent polarity is too low to call into play an appreciable inductomeric effect. However, this explanation alone is not adequate to account for the trend in the entropy values. For 1-*p*-tolylethyl chloride, the entropy of activation, as in 80% aqueous acetone, is essentially the same for both the normal and catalyzed reactions and C—H hyperconjugative effect can account for this observation. But in contrast to the position in 80% aqueous acetone, the entropy values for *p*-*t*-butyl-α-chloro-α-methyltoluene are also similar for both reactions. We suggest that this may be due to the operation of C—C hyperconjugation, the effect of which will increase the entropy of activation, and thus compensate the drop in entropy which should normally occur on passing from the normal to the catalyzed reaction. In the normal hydrolysis of *p*-alkylphenyldimethylcarbinyl chlorides, the heats and entropies of activation are practically the same for all four alkyl chlorides (Alk = Me, Et, *i*-Pr, and *t*-Bu). Brown has explained this by assuming an interplay of C—H and C—C hyperconjugation (4). In view of the different trends noted in the heats and entropies of activation in 80% and 90% aqueous acetone, data were also obtained in 75% aqueous acetone. The trends are quite similar to that in 80% aqueous acetone, thus supporting the above conclusion that the different behavior in 90% aqueous acetone is due to its low solvent polarity.

Since rates of mercuric chloride catalyzed solvolysis of alkyl chlorides are rather anomalous in aqueous ethanol (5), and aqueous alcohols generally (6), the kinetics of 1-*p*-tolylethyl chloride and *p*-*t*-butyl-α-chloro-α-methyltoluene were examined in 90% aqueous ethanol. In agreement with previous findings (5), the catalytic efficiency for both alkyl chlorides is much lower than in the aqueous acetone solvents. The rates follow the Baker–Nathan order for both the normal and catalyzed reactions. The trend in the heats and entropies of activation for the catalyzed reaction is quite similar to that for the normal reaction in this solvent, and the values are higher than for the catalyzed reaction in 90% aqueous acetone. This is to be expected because of the low catalytic efficiency, since not

only will there be no inductomeric effect, but even the reduction in the heats and entropies of activation normally associated with the catalyzed reaction will be largely absent.

The peculiar tendency of mercuric chloride to induce a mass-law effect in the hydrolytic reactions of alkyl chlorides (provided the structure of the alkyl chloride is sufficiently favorable) has been established (7) and given a probable theoretical basis (8). To determine whether the hyperconjugative effect can cause detectable difference in the stability of the carbonium ions derived from the four alkyl chlorides—such differences would obviously show themselves in the magnitude of the mass-law effect (9)—the effect of added chloride ions on their rates of catalyzed hydrolysis in 90% aqueous acetone was studied (Table II).

A probable explanation for the results is as follows. Chloride ions reduce the rate of the catalyzed reaction in two ways, by inactivating the catalyst through complex formation, and by inducing a mass-law effect in suitable cases. The first effect is the sole cause with such substrates as benzyl (10) and *p*-chlorobenzyl chloride (11). *t*-Butyl chloride also does not show a mass-law effect presumably because of the low stability of the carbonium ion (12). So the smaller rate reductions for *t*-butyl chloride must mean that with the other alkyl chlorides part of the observed rate reductions must be due to a mass-law effect. At all chloride ion concentrations the rate reductions with the other five alkyl chlorides are closely similar, which must mean that the hyperconjugative effect, if present, is not great enough to affect the mass-law effect. This is understandable, since the hyperconjugative effect, like any other electronic effect, will have a polarizability component, and so its effect should be larger in the transition state of the hydrolytic reaction because of the presence of the powerful electrophilic catalyst. The mass-law effect, on the other hand, will depend on the stability of the carbonium ion and the differences on this account should be much smaller since only the polarization component of the hyperconjugative effect will be differentially involved.

EXPERIMENTAL

Materials

The nuclear-substituted alcohols were prepared by the Meerwein–Pondorff reduction of the corresponding ketones, and were purified through their acid phthalates. They were converted into the chlorides by reaction with thionyl chloride.

The physical constants of three alkyl chlorides are given in Table III. Data for the others have been given earlier (5).

Kinetic work

Details of purification of solvents, preparation of solvent mixtures, and technique of rate measurements have been given (5). It was noted that in the catalyzed hydrolysis of the nuclear-substituted alkyl chlorides, the rate coefficients steadily decreased during the course of the reaction. To obtain the initial rate, therefore, log k was plotted against log $(a - x)$ (13) and the best straight line was obtained by the method of least squares. As a check on the accuracy of the measurements, the initial rates were also evaluated graphically. The agreement between the two values was always good. An illustrative kinetic run is given in Table IV. All runs for the catalyzed reaction were conducted in triplicate and the others in duplicate. The average deviation of the rate in the replicate runs is: for about two-thirds <1%; for the rest between 1 and 2%. For the catalyzed reaction in 80% and 90% aqueous acetone, measurements at four temperatures were carried out, the range being 15°. The errors quoted for the heats and entropies of activation are probable errors obtained from least square calculations (14) rounded off to the values shown in Table I.

EFFECT OF THERMIONIC EMISSION ON ELECTROCHEMICAL MEASUREMENTS AT HIGH TEMPERATURES[1]

S. G. WHITEWAY AND C. R. MASSON
Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia
Received May 9, 1966

ABSTRACT

In the measurement of electromotive forces at temperatures over 1 000° spurious contact potentials, which may be asymmetric, are sometimes encountered. As an example of these, contact potentials between solid oxides and electrically grounded portions of their environment were measured at temperatures between 1 000° and 1 450°. Their variation with temperature, gaseous environment, and impedance of the measuring circuit is presented and interpreted in terms of thermionic emission.

INTRODUCTION

Electrochemical measurements at high temperatures (> 1 000°) are subject to errors not encountered at lower temperatures. An example is the presence of "asymmetry potentials" (1, 2) in electrochemical cells. This effect is most troublesome when the internal resistance of the cell is high and it becomes necessary to use a potentiometer of high impedance for the measurements. If one side of the circuit is grounded, contact potentials (2) can develop between parts of the cell and grounded parts of the high temperature environment. These may not be the same for each side of the cell so that the difference can appear as an asymmetry contribution to the electromotive force even if a non-grounded instrument is used for the measurements.

An analogous effect influences measurements of electrical conductivity if the conductivity of the gaseous environment is high in comparison with that of the test specimen (3, 4). Loup and Anthony (5) have concluded that gaseous conduction may be initiated by thermal emission of electrons from heated surfaces, leading to ionization of the gas phase.

Although contact potentials exist even at low temperatures they are normally difficult to measure because of the extremely high source impedances involved (6). It seemed likely that their ready detection at high temperatures was due also to thermionic emission.

EXPERIMENTAL

Ceramic test pieces of size about 1.5 × 0.5 × 0.5 cm were suspended by two platinum leads inside an impervious alumina tube heated by a platinum–rhodium element. The leads were wound in grooves cut near the ends of the piece and were secured by twisting. Most of the experiments were performed with magnesia (Norton Co. optical grade), but ZrO_2 – 15 mole % CaO (made by pressing and sintering the powders) and FeO (made by melting a stoichiometric mixture of Fe and Fe_2O_3 under argon) were also used.

A grounded cylinder of Pt – 20% Rh, normally placed within the alumina tube, shielded the specimen from the electrical field of the furnace and also served as a reference point for potentials. Electrical leads outside of the furnace were also protected by grounded shields. Various arrangements involving test piece, shield, and auxiliary probe were employed, as shown schematically in Fig. 1 and described more fully below. Temperatures were recorded with a Pt – 13% Rh thermocouple placed outside the furnace tube.

Potentials were normally measured with a Leeds and Northrup recording potentiometer of sensitivity 5×10^9 Ω/V. Resistances for small applied voltages (up to 1.5 V) were determined by measuring the current with a galvanometer of sensitivity 1.75×10^{-11} A/mm deflection at 1 m. Resistances at a much higher voltage (135 V) were measured with an AVO meter.

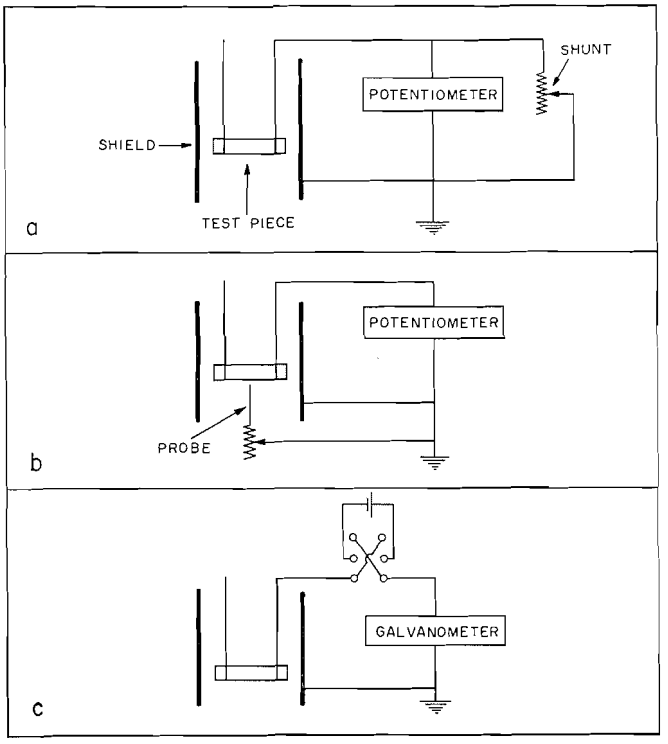

FIG. 1. Typical measuring circuits.

EXPERIMENTAL RESULTS AND DISCUSSION

Effect of Temperature and Impedance of Measuring Circuit

Typical data for the potential on MgO in air are shown in Fig. 2. The potential was measured between one end and the shield (Fig. 1*a*) while being shunted with resistances of 10, 20, 50, 90 and ∞ MΩ. In the last case the effective impedance of the measuring circuit would be that of the potentiometer itself, 1 000 MΩ.

The potential exhibited a maximum with temperature, V_{max}, which decreased as the input impedance of the measuring circuit was lowered. At the same time the position of V_{max} shifted to higher temperatures with decreasing impedance. It is apparent that the potential of the magnesia with respect to the shield increased with decreasing temperature but that below a certain temperature the potential decreased because of the current drawn by the measuring circuit. Potentials tended toward zero at temperatures of 1 400° rather than continued decreasing to negative values.

Negative potentials which became more positive with increasing temperature were encountered when a platinum wire probe, connected to ground, was placed a few millimeters from the MgO test piece (Fig. 1*b*). This arrangement was chosen to simulate the effect of a thermocouple in the vicinity of the test piece. The results are shown in Fig. 3. As the probe was isolated more and more from the shield by resistances of 10, 20, 90, and ∞ (open circuit between probe and ground) MΩ, the MgO tended to assume the potential it had in the absence of the probe.

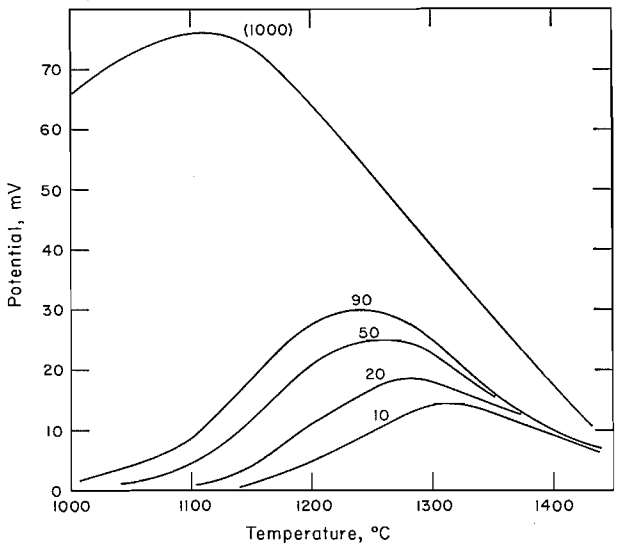

FIG. 2. Temperature variation of potential on MgO in air, with respect to shield, for various circuit impedances. Number beside each curve is impedance in megohms.

Relationship of Potential to Thermionic Emissivity

The above experiments indicated that the magnitude and sign of the potential, and its variation with temperature, depended on the material which constituted the nearest "ground", and it is likely that differences in the work functions of the two surfaces were responsible for the potential difference. Since the work function is related to the emission current by the Richardson–Dushman equation

$$[1] \qquad j = BT^2 \, e^{-\phi/kT}$$

(j = current density, B a constant, T the absolute temperature, ϕ the work function, and k the Boltzmann constant), measurements of the ratio of emission currents from test piece and shield should be related to the potential.

When direct current voltages between 0 and 1.5 V were applied first in one direction and then in the other between one end of the test piece and the shield, emission currents could be measured with the galvanometer (Fig. 1*c*). The potential for zero current agreed with potentials obtained with the recording potentiometer. The calculated resistances for electron flow from and to the test piece were equal near this equilibrium potential, but differed at higher applied potentials: the resistance to electron flow was greater in the direction: test piece to shield. Currents were non-ohmic but were not saturation currents within this voltage range.

Resistances at an applied voltage high enough to ensure that currents were saturation currents were measured with an AVO meter at 135 V. Resistances were measured, in both directions, between each end of the test piece and the shield, as well as across the test piece itself. In all experiments the shield was at ground potential. The results are given in Table I and are for an MgO test piece in air. Shown also are the equilibrium potentials between each end of the test piece and the shield, as measured with the recording potentiometer.

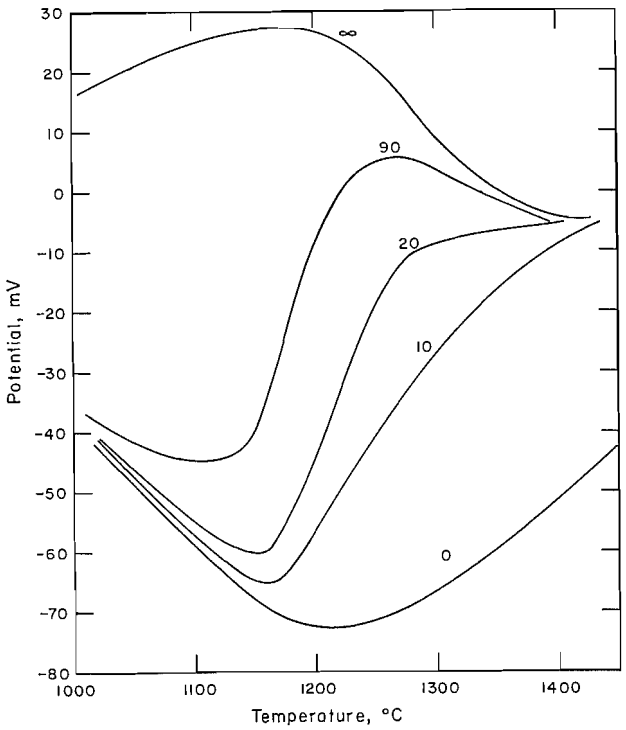

FIG. 3. Temperature variation of potential on MgO in air, with respect to shield–probe combination. Probe isolated from ground by resistances, in megohms, shown beside curves.

It may be noted that none of the resistances in Table I are simple. For example, the path for electron flow from end 1 to shield is shunted by the path consisting of the test piece in series with end 2 to shield. Ignoring these effects, the ratio "resistance test piece to shield / resistance shield to test piece", R_2/R_1, was calculated for each end. This ratio is a measure of the electron-emitting power of the shield compared with the test piece, and it is evident that as the ratio increases the equilibrium potential of the test piece becomes more negative.

From eq. [1] it may be shown that the ratio of resistances is related to the difference in emissivities of the two surfaces by

$$[2] \qquad \log_{10} R_2/R_1 = C + \frac{\phi_2 - \phi_1}{kT},$$

where the constant C involves the respective areas. If the contact potential between shield and test piece is proportional to $(\phi_2 - \phi_1)$, a plot of $\log_{10} R_2/R_1$ against potential / absolute temperature should be linear. As shown in Fig. 4 this is approximately true, although the relationship appears to break down at the lower temperatures where the potential is difficult to measure.

It is concluded that the sign of the potential assumed by the test piece is negative if it can emit fewer electrons/cm^2 than the reference surface, positive if it can emit more, and that the magnitude of the potential is a function of the ratio of the two emissivities. The equilibrium potential is established when the two surfaces are in thermionic equilibrium and no current flows between them. This equilibrium potential cannot be measured

1 400	−63.0	0.465	0.036	12.9	−54.0	0.557	0.046	12.1	0.445	0.505

*Resistances, in megohms, are quoted in the direction of electron flow, i.e. for R_2 the negative side of the applied voltage was connected to the test piece.

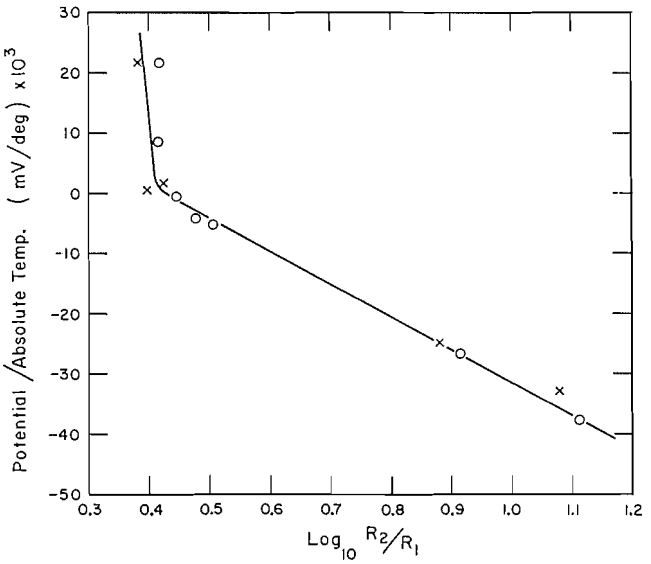

FIG. 4. Potential / absolute temperature vs. log resistance ratio. MgO in air. (○) End 1, (×) end 2.

exactly by a device which draws current, and at low temperatures may not be detected at all. At higher temperatures the potential tends to zero and it is likely that thermal ionization of the gaseous environment dissipates the electron double layers responsible for the equilibrium potential difference.

Asymmetry Potentials

From Table I it can be seen that an asymmetry potential existed across the piece itself, amounting to 9 mV at 1 400°. This behavior was characteristic of MgO and presumably was related to local differences in emissivities in the system. The asymmetry was neither predictable nor reproducible, although the end of the test piece which was more positive tended to remain that way during an experiment.

It might be expected that such a potential difference could only be maintained if the specimen itself had sufficient resistance compared to the resistance of the path: test piece to shield. In line with this, asymmetry potentials were smaller or absent when ZrO_2–CaO or FeO was used in place of MgO, although the contact potentials themselves were similar. The specific conductivities of these materials are much higher than for MgO.

Effect of Atmosphere

Potentials between magnesia and shield were similar in argon, helium, and air. When air was replaced by hydrogen the potential generally became negative, but was very erratic. It is possible that this was due partly to enhanced emissivity of the platinum, since hydrogen reduces the work function of platinum (6) by about 2 eV. Other possible effects of hydrogen in creating anion vacancies and excess electrons in the magnesia have been discussed elsewhere (2).

A further serious effect of atmosphere on the measurement of electromotive forces at high temperatures may be due to the short-circuiting effect of the ionized environment. This is the effect which also renders conductivity measurements difficult, and may be minimized by the use of a gas of high molecular weight, such as argon, which has a low mobility. Mitoff (4) has devised a guard circuit to prevent such short-circuiting.

TETRASUBSTITUTED-CYCLOPENTADIENONE AND -*p*-BENZOQUINONE COMPLEXES OF RHODIUM(I)

S. McVey and P. M. Maitlis[1]
Chemistry Department, McMaster University, Hamilton, Ontario
Received June 20, 1966

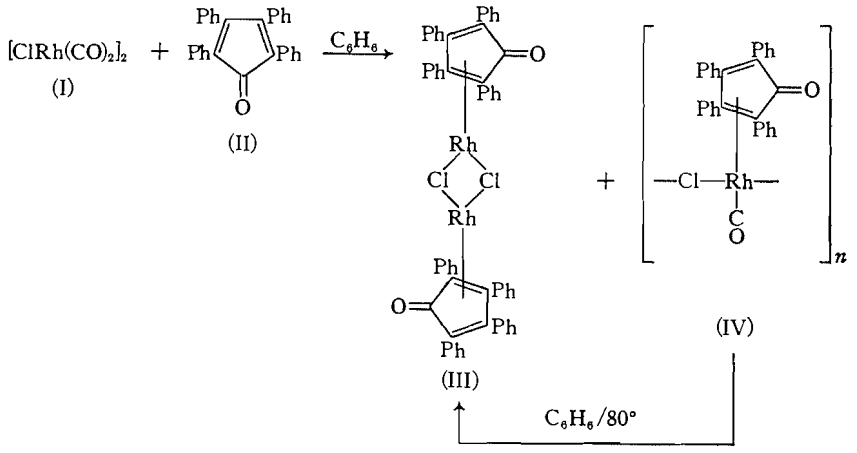
ABSTRACT

The preparation of tetraphenylcyclopentadienone rhodium chloride, tetraphenylcyclopentadienone rhodium carbonyl chloride, duroquinone rhodium chloride, and 2,3,5,6-tetraethyl-*p*-benzoquinone rhodium chloride from rhodium dicarbonyl chloride dimer and the appropriate organic ligand are described. The properties of these complexes and some of their reactions are discussed.

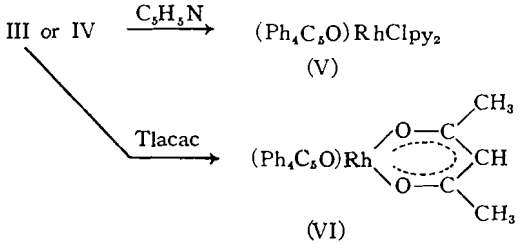
During our investigation of the reactions of acetylenes with rhodium dicarbonyl chloride dimer (I), we obtained some new organo-rhodium(I) complexes (1). We here present details of the chemistry of some of these compounds.

As briefly reported (1), the main product obtained from the reaction of diphenylacetylene with I was 2,3,4,5-tetraphenylcyclopentadienone rhodium chloride dimer (III).[2] This we also synthesized directly from tetraphenylcyclopentadienone (tetracyclone) (II) and I. The yield of III was highest (65%) when the reaction was carried out in refluxing benzene; at 50° in benzene only 30% of III and at 25° in benzene 25% of III were obtained. The other product, obtained from the two latter reactions in 57% and 71% yield respectively, was identified as tetracyclone rhodium carbonyl chloride (IV).

The infrared spectrum of IV showed the presence of a terminal metal carbonyl at 2 062 cm^{-1}; this together with the reactions described below and the extreme insolubility of the compound lead us to formulate it as a chlorine-bridged polymer (IV).



On heating, IV readily lost carbon monoxide and III was formed. The further reactions of III and IV with chlorine-bridge-splitting reagents are shown in the chart. Pyridine reacted with either III or IV to give bis-pyridine tetracyclone rhodium chloride (V), whereas thallous acetylacetonate (Tlacac) reacted with both to give the same rhodium acetylacetonate complex (VI). Triphenylphosphine, in contrast, gave the expected monomeric adduct (VII) from III, but this was not formed when IV was reacted with only 1 mole of triphenylphosphine. Instead disproportionation occurred and the products obtained were tetracyclone (II), the complex (III), and bis(triphenylphosphine)rhodium carbonyl chloride (VIII). This curious result must be due to the extremely strong tendency for the formation of VIII, which has already been commented on by Wilkinson *et al.* (3) and others (4) and has been used in the decarbonylation of aldehydes and similar molecules.



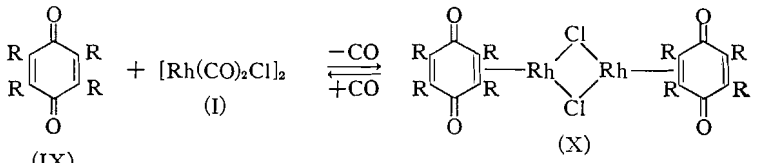
One other result of interest is that if tetracyclone is assumed to occupy two coordination positions, then the complexes (III), (VI), and (VII) are four-coordinate (and presumably square planar) while the bis-pyridine adduct (V) is five-coordinate. This may be due to the relative sizes of the various ligands.

2,3,5,6-Tetramethyl-*p*-benzoquinone (duroquinone) (IX, R=Me) reacted slowly in benzene with rhodium dicarbonyl chloride dimer (I) to give duroquinone rhodium chloride

[1]*Author to whom any correspondence should be addressed.*

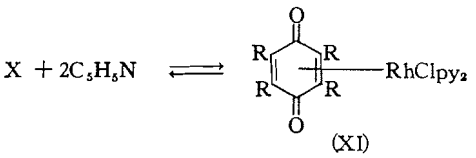
[2]*The exact structure for a cyclopentadienone metal complex is still the subject of considerable dispute (2a; 2b and references therein). The most reasonable structure, based on X-ray structure determinations, appears to be one where the five-membered ring is linked to the metal by two partial σ-bonds and one π-bond. However, for simplicity of representation here, and since the detailed structure of III is not known, we have chosen to represent it as shown.*

$$III + Ph_3P \rightarrow (Ph_4C_5O)RhClPPh_3$$



(VII)

$$\tfrac{1}{n}IV + PPh_3 \rightarrow III + II + (Ph_3P)_2RhCOCl$$



(VIII)

dimer (X, R=Me) in 83% yield. The compound (X, R=Me) was characterized by analysis, infrared, and ^1H nuclear magnetic resonance (n.m.r.) spectra and by the reversal of the reaction leading to its formation when it was treated with carbon monoxide. A rather unstable bis-pyridine adduct (XI, R=Me) was also obtained.

Duroquinone rhodium chloride has already been described by Schrauzer and Dewhirst (5), who prepared it from rhodium trichloride and duroquinone in ethanol. Their reaction, which we have verified, gave a product similar to the one described above. However, the compound from rhodium trichloride in ethanol is virtually insoluble in all but complexing solvents and must be formulated as a halogen-bridged linear polymer, as the authors

(IX) (I) (X)

(XI)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

suggest. In contrast, X (R=Me) is quite readily soluble in organic solvents and molecular weight determinations show it to be dimeric in solution. This type of behavior, while unusual, is not without precedent, thus tetramethylcyclobutadiene nickel chloride has been shown to exist in the crystal (containing benzene of solvation) as a chlorine-bridged dimer (6). However, Criegee and Schroeder (7) report that in bromoform solution a molecular weight corresponding to $[(Me_4C_4)NiCl_2]_{10}$ is obtained. No doubt other examples of this type of behavior also exist.

2,3,5,6-Tetraethyl-*p*-benzoquinone (IX, R=Et) also reacted with I to give the complex (X, R=Et), which was again dimeric in solution. However, while the ^1H n.m.r. spectrum of IX (R=Et) showed the typical A_3B_2 spectrum expected for a molecule with equivalent ethyl groups, that of X (R=Et) was quite unusual. The methyl protons appeared as a triplet centered at 8.75 τ, but in the methylene region, instead of the expected quartet, a nonet centered at 7.90 τ with intensities 1:2.3:3.3:4.6:4.6:4.3:3.0:1.5:1 was observed. The total integrated intensities of the methyl and methylene protons remain as 3:2. This suggests that when IX (R=Et) is complexed to a metal, the methylene carbons are no longer free to rotate and hence the methylene protons become non-equivalent. Examination of a molecular model shows that this is indeed the case. This effect is increased if the carbonyl groups are also somewhat bent away from the metal, as was suggested by Schrauzer and Dewhirst (5) for the duroquinone complexes to account for the split carbonyl stretching frequency in the infrared. The n.m.r. spectrum of X (R=Me) was normal.

Tetraethyl-*p*-benzoquine and rhodium dicarbonyl chloride dimer were obtained when X (R=Et) was treated with carbon monoxide. The complex (X, R=Et) gave a bis-pyridine adduct (XI, R=Et) more unstable than XI (R=Me) and for which good analyses could not be obtained.

EXPERIMENTAL

Reaction of Rhodium Dicarbonyl Chloride with Diphenylacetylene

Rhodium dicarbonyl chloride dimer (I) (0.5 g, 1.25 mmole) and diphenylacetylene (1.35 g, 7.5 mmole) were refluxed in 20 ml of benzene for 24 h. A dark-brown solid (0.11 g, 12%), decomposing at 340°, was filtered off; this was insoluble in common organic solvents; it showed a strong infrared maximum at 2 015 cm^{-1} (terminal CO).[3]

Anal. Calcd. for $(C_{15}H_{10}ClORh)_n$: C, 52.2; H, 2.9; Rh, 29.9. Found: C, 51.8; H, 3.0; Rh, 31.4.

Chromatography of the filtrate on Florisil in benzene gave hexaphenyl benzene (0.12 g, 9%) and a red solid which eluted with methylene chloride – ethanol (9:1). Recrystallization from cyclohexane gave tetraphenylcyclopentadienone rhodium chloride (III) (0.63 g, 47%), m.p. 316–318°. The complex showed ν_{CO} at 1 621 cm^{-1} (KBr) and 1 647 cm^{-1}($CHCl_3$ solution).

Anal. Calcd. for $C_{58}H_{40}Cl_2O_2Rh_2$: C, 66.6; H, 3.8; Cl, 6.9; Rh, 19.7; mol. wt., 1 044. Found: C, 65.7; H, 4.8; Cl, 6.7; Rh 18.6; mol. wt., 1 085.

Reaction of Rhodium Dicarbonyl Chloride with Tetracyclone

Tetracyclone (II) (1.05 g, 3 mmole) and rhodium dicarbonyl chloride dimer (I) (0.5 g, 1.25 mmole) were heated at 50° in 30 ml of benzene for 42 h. A crystalline yellow solid (IV) (0.85 g, 57%), m.p. 328–330° (decomp.), was filtered off. This was purified by washing with benzene. The complex showed ν_{CO} at 2 062, 1 666 (sh), and 1 642 cm^{-1} (KBr).

Anal. Calcd. for $(C_{30}H_{20}ClO_2Rh)_n$: C, 65.0; H, 3.7; Cl, 6.4; Rh, 18.6. Found: C, 64.8; H, 3.8; Cl, 6.7; Rh, 19.2.

The filtrate was reduced to small bulk and chromatographed on Florisil to give, in addition to unchanged tetracyclone, a dark-red crystalline solid eluted with methylene chloride – ethanol (9:1). Recrystallization from cyclohexane gave tetracyclone rhodium chloride (III) (0.42 g, 30%), mixed melting point with the compound described above 316–318°.

Tetracyclone rhodium carbonyl chloride was smoothly converted to tetracyclone rhodium chloride in refluxing benzene or xylene.

[3]*Further details on this interesting compound will be published shortly.*

Bis-Pyridine Tetracyclone Rhodium Chloride (V)

A suspension of tetracyclone rhodium carbonyl chloride (IV) (0.15 g) in 25 ml of methylene chloride was treated with 2 ml of pyridine for 2 h at 25°. Filtration, removal of the solvent, and the addition of petrol gave bis-pyridine tetracyclone rhodium chloride (V) (0.175 g, 90%), m.p. 286–288°. Mixed melting point with the compound obtained under identical conditions from tetracyclone rhodium chloride 282–284°. The infrared spectrum showed ν_{CO} at 1 623, 1 603 cm^{-1} (KBr), and 1 621 cm^{-1} ($CHCl_3$ solution).

Anal. Calcd. for $C_{39}H_{30}ClN_2ORh$: C, 68.8; H, 4.4; N, 4.1; mol. wt., 680. Found: C, 68.6; H, 4.6; N, 4.1; mol. wt., 730.

Tetracyclone Rhodium Acetylacetonate (VI)

Tetracyclone rhodium carbonyl chloride (IV) (0.15 g) was suspended in 20 ml of benzene and a solution of thallous acetylacetonate (0.11 g) in 10 ml of hot benzene was added. The mixture was stirred overnight to give a red precipitate which was filtered off and extracted with methylene chloride. Removal of the methylene chloride followed by recrystallization of the residue from methylene chloride and petroleum ether gave tetracyclone rhodium acetylacetonate (VI) (0.14 g, 88%), m.p. 269–271° (softening at 257°). Mixed melting point with the product obtained under the same conditions from tetracyclone rhodium chloride 255–270° (decomp.). The n.m.r. spectrum ($CDCl_3$) showed, in addition to phenyl absorption, two singlets at 8.1 τ and 8.62 τ with relative intensities 1:5.5. The infrared spectrum shows ν_{CO} at 1 650 cm^{-1} (KBr) and 1 637 cm^{-1} ($CHCl_3$ solution).

Anal. Calcd. for $C_{34}H_{27}RhO_3$: C, 69.7; H, 4.6; mol. wt., 586. Found: C, 70.2; H, 5.4; mol. wt., 611.

Triphenylphosphine Tetracyclone Rhodium Chloride (VII)

Tetracyclone rhodium chloride (0.1 g) was dissolved in 20 ml of hot benzene, and triphenylphosphine (0.094 g) in 5 ml of benzene was added. The mixture was filtered after stirring for 30 min, and the solvent removed to give a dark red solid. Recrystallization from methylene chloride and petroleum ether gave triphenylphosphine tetracyclone rhodium chloride (VII) as red needles (0.125 g, 83%), m.p. 260–262° (effervescence). The infrared spectrum showed ν_{CO} at 1 645 cm^{-1} (KBr) and 1 642 cm^{-1} ($CHCl_3$ solution).

Anal. Calcd. for $C_{47}H_{35}ClOPRh$: C, 71.9; H, 4.5; mol. wt., 784. Found: C, 71.7; H, 4.3; mol. wt., 748.

Reaction of Tetracyclone Rhodium Carbonyl Chloride with Triphenylphosphine

Tetracyclone rhodium carbonyl chloride (IV) (0.1 g) suspended in 10 ml of benzene was treated with triphenylphosphine (47 mg, exactly 1 molar equivalent) in 2 ml of benzene and the mixture was stirred at 20° for 15 min. Filtration and removal of the solvent gave a red oil. Upon addition of methylene chloride yellow needles of bis(triphenylphosphine)rhodium carbonyl chloride (30 mg, 24%) were obtained, m.p. 282°; mixed melting point with an authentic sample 290–294°. The infrared spectrum was identical with that of the authentic sample.

The solvent was removed from the filtrate and the resultant brown residue was recrystallized from methylene chloride and petroleum ether to yield tetracyclone rhodium chloride (III) (24 mg, 25%), m.p. 291–295°, mixed m.p. 316–320°. Removal of the solvent from the mother liquor gave a small amount of impure purple solid whose infrared spectrum was identical with that of tetracyclone.

Duroquinone Rhodium Chloride (X, R=Me)

Rhodium dicarbonyl chloride (0.5 g, 1.25 mmole) and duroquinone (0.47 g, 2.5 mmole) were refluxed in 25 ml of benzene for 4 days. Removal of the solvent to small bulk gave a red crystalline solid (0.65 g, 83%). Recrystallization from benzene gave duroquinone rhodium chloride dimer (X, R=Me), m.p. > 300° (decomp. from 200°). The n.m.r. spectrum ($CDCl_3$) showed one methyl resonance at 8.36 τ. The infrared spectrum showed ν_{CO} at 1 608 cm^{-1} (KBr) and 1 658 cm^{-1} (CH_2Cl_2 solution).

Anal. Calcd. for $C_{20}H_{24}Cl_2O_4Rh_2$: C, 39.7; H, 4.0; mol. wt., 605. Found: C, 39.7; H, 3.9; mol. wt., 582.

2,3,5,6-Tetraethyl-p-Benzoquinone Rhodium Chloride (X, R=Et)

2,3,5,6-Tetraethyl-*p*-benzoquinone (0.55 g, 2.5 mmole) (1) and rhodium dicarbonyl chloride (0.5 g, 1.25 mmole) were refluxed in 20 ml of benzene for 4 days. The mixture was worked up as described above to yield the complex (X, R=Et) (0.6 g, 65%), m.p. 224–225° after recrystallization from benzene. The infrared spectrum showed ν_{CO} at 1 610 cm^{-1} (KBr) and 1 656 cm^{-1} (CH_2Cl_2 solution).

Anal. Calcd. for $C_{28}H_{40}Cl_2O_4Rh_2$: C, 46.9; H, 5.6; mol. wt., 717. Found: C, 46.8; H, 5.5; mol. wt., 678.

Treatment of methylene chloride solutions of either X (R=Me) or X (R=Et) with carbon monoxide for 30 min at 25° yielded quantitative amounts of the respective *p*-benzoquinone (IX, R=Me or Et) and rhodium dicarbonyl chloride dimer.

Bis-Pyridine Duroquinone Rhodium Chloride (XI, R=Me)

Duroquinone rhodium chloride dimer (X, R=Me) (0.1 g) was dissolved in methylene chloride (10 ml) and pyridine (2 ml) was added. After 5 min the solvent was removed to small bulk and petroleum ether added to give an orange crystalline solid. Recrystallization from methylene chloride and petroleum ether containing a few drops of pyridine gave XI (R=Me) as orange needles (0.11 g, 87%), m.p. > 300° (softens at 187°). The n.m.r. spectrum ($CDCl_3$) showed in addition to phenyl resonances a singlet at 8.62 τ. The infrared spectrum showed ν_{CO} at 1 939 and 1 600 cm^{-1} (KBr).

Anal. Calcd. for $C_{20}H_{22}ClN_2O_2Rh$: C, 52.1; H, 4.8; N, 6.0. Found: C, 51.1; H, 4.9; N, 6.5.

THE INFRARED SPECTRUM AND THERMAL DECOMPOSITION OF HYDRAZINE PERCHLORATE HEMIHYDRATE[1]

P. W. M. JACOBS[2] AND A. RUSSELL-JONES[3]
Department of Chemistry, Imperial College, London, England

Received April 28, 1966

ABSTRACT

The infrared spectrum of hydrazine perchlorate hemihydrate (HPH) has been determined and an assignment of the absorption bands made. *In vacuo*, HPH will partially dehydrate even at room temperature; when heated the remainder of the half-mole of water is lost at 61 °C. The dehydrated salt melts at 138 °C and decomposition ensues. The kinetics of decomposition may be followed in the temperature range 180–280 °C. The activation energy is 36.3 kcal/mole. At low temperatures the decomposition is represented by the chemical equation

$$2N_2H_5ClO_4.\tfrac{1}{2}H_2O = 0.8NH_4ClO_4 + 0.7O_2 + 1.6N_2 + 0.6Cl_2 + 4.4H_2O,$$

but when the temperature is high enough the rate of decomposition of the ammonium perchlorate formed becomes appreciable also. Possible reaction mechanisms are discussed.

There have been no previous investigations of either the infrared spectrum or the decomposition kinetics of hydrazine perchlorate hemihydrate (HPH). This is remarkable because it is a substance of both chemical and technological interest. As the fourth member of the series nitronium perchlorate, hydroxylamine perchlorate, ammonium perchlorate, hydrazine perchlorate it contains the smallest excess of oxidant. Because of its greater hydrogen content it would be expected to be more unstable than ammonium perchlorate and thus to be a potentially useful, but possibly dangerous, additive to solid rocket propellants. The anhydrous salt (HP) is more sensitive to impact than pentaerythritol tetranitrate and is also highly friction-sensitive, being said to explode violently on gentle rubbing in a porcelain mortar (1). The burning of HP has been studied by Shidlovskii *et al.* (1), and by Levy *et al.* (2). The heat of formation of HP was found to be $\Delta H_{298} = -42.9 \pm 0.2$ kcal/mole (1), in good agreement with a previous value of -42 kcal/mole obtained by Medard (3). From measurements of the vaporization rate Levy *et al.* (2) deduced an enthalpy of vaporization for the equilibrium

$$N_2H_5ClO_4\ (l) = N_2H_4\ (g) + HClO_4\ (g)$$

of 59.2 kcal/mole.

HPH was found (2) to burn in a reasonably stable manner in the presence of small amounts of fuel (e.g. stabilized formaldehyde polymers) even at atmospheric pressure, the burning rate being some 15 times greater than the extrapolated rate at 1 atm for ammonium perchlorate (AP). The measured flame temperature (2) was $2\,275 \pm 50$ °K, indicative of thermodynamic equilibrium which corresponded closely to the stoichiometric equation

$$N_2H_5ClO_4 = N_2 + HCl + 2H_2O + O_2.$$

The burning rate of HP mixed with manganese dioxide or cuprous chloride is a factor of 2–3 times faster than similar mixtures with AP (1). Mixtures of AP and HP containing 30–60% of the latter will burn steadily, if ignited, at room temperature and pressure (1).

Ammonium perchlorate decomposes by first dissociating into ammonia and perchloric

acid (4). At low temperatures ($< \sim 300$ °C) decomposition is incomplete and, if sublimation is suppressed, a residue of AP, representing about 70% of the original material, remains. At higher temperatures this residue itself decomposes through the evaporation of ammonia and perchloric acid into the gas phase and the oxidation of the former by radicals from the pyrolysis of the latter. Catalysts, such as copper chromite, promote the reaction by substituting heterogeneous reactions for these gas-phase reactions (4). In view of the chemical similarity between ammonia and hydrazine it was interesting to see if a similar mode of reaction applied for hydrazine perchlorate.

EXPERIMENTAL

Because of its instability and shock sensitivity the main batches of HPH used were prepared at the Explosives Research and Development Establishment at Waltham Abbey. We had previously prepared small amounts of the material using essentially the same method, which was the neutralization of 60% aqueous perchloric acid with hydrazine. The recrystallized powder was pressed into pellets of mass 40 mg at Waltham Abbey. The normal precautions used in the storage and handling of unstable materials were observed. Storage in a desiccator is not recommended, since the dehydrated salt is considerably more sensitive than the hydrate.

Two methods were used to study the kinetics of the thermal decomposition of HPH. Pellets were dropped *in vacuo* into a reaction vessel (pyrex glass or silica) surrounded by an electronically controlled electric furnace and the ensuing pressure changes at constant volume were measured either with a glass spiral gauge or with a recording mercury manometer. In the latter, the surface of the mercury in the limb connected to the reaction vessel was protected from attack by chlorine by a layer of silicone oil. Alternatively the reaction was followed thermogravimetrically at 1 atm pressure with a Stanton automatic recording thermobalance.

At first an attempt was made to record the infrared spectrum of HPH by the KBr disc method but the measured spectrum corresponded to that of a mixture of potassium perchlorate and hydrazine bromide. Accordingly, mulls in Nujol, hexachlorobutadiene, and Fluorolube were employed. Among them these three provided sufficient peak-free zones for a complete spectrum to be determined. A Perkin–Elmer model 21 with a fluorite prism was used for the 4 000 – 2 000 cm^{-1} region and a Perkin–Elmer model 137 with a sodium chloride prism from 2 000 – 650 cm^{-1}.

RESULTS

Infrared Spectrum

The complete spectrum is shown in Fig. 1. The band due to N—H and O—H stretching frequencies is very broad and complex, the general shape being similar to that found by Decius and Pearson (5) for hydrazine hydrochloride. There is a well-defined pair of peaks between 6 and 7 μ and a second broad absorption band between 8 and 10 μ, with another sharp peak at 960 cm^{-1} and a broad band of low intensity at 765 cm^{-1}.

Kinetics

The kinetics of thermal decomposition was followed by pressure measurements in the temperature range 196 to 280 °C with an initial pressure of 10^{-6} Torr. The rate of decomposition in a silica vessel was significantly greater than that in one made of pyrex glass.

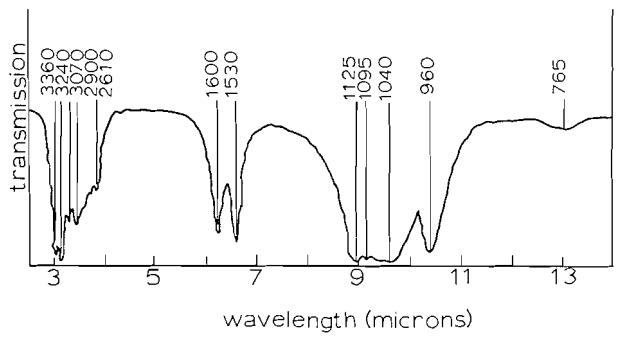

FIG. 1. Infrared spectrum of hydrazine perchlorate hemihydrate. The frequencies of the principal absorption peaks are given in cm^{-1}.

The evolution of the water of crystallization was clearly marked either on the recorder trace or by a sudden deflection of the light spot reflected from the mirror on the spiral gauge and this was taken as zero time for the decomposition. After this very rapid evolution of water the pressure–time curve followed a deceleratory course until the reaction was virtually complete. A typical plot of α (the fraction decomposed in time t) against t is shown in Fig. 2. As these $\alpha(t)$ curves did not appear to fit any of the usual kinetic equations, rate constants were determined as the initial slopes of the $\alpha(t)$ plots. These are plotted in the form log k vs. T^{-1}, with k in min^{-1}, in Fig. 3. This figure shows (*a*) the reproducibility achieved with two separate preparations of HPH and (*b*) the faster rate of reaction in silica vessels. The activation energies in silica and in pyrex vessels were found to be 36.4 and 36.6 kcal/mole respectively.

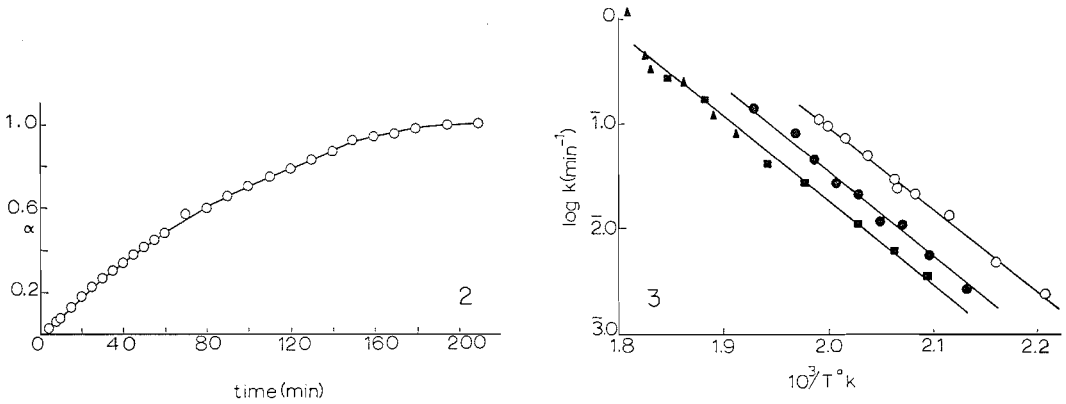

FIG. 2. Thermal decomposition of HPH in a silica vessel at 215 °C. The fractional decomposition α is plotted as a function of time.

FIG. 3. Logarithm of the initial rate of decomposition of HPH as a function of reciprocal temperature. Pressure measurements: pyrex vessel, batch I (▲); pyrex vessel, batch II (■); silica vessel (●); thermogravimetry (○).

Analysis of gaseous products was carried out by doing runs with a liquid nitrogen trap in the system. When reaction was complete, the permanent gas pressure was measured. The permanent gases were then pumped off and the system re-isolated. The liquid nitrogen was then replaced by a series of coolants, the equilibrium pressure being measured after each replacement. The quantity of gas released could then be calculated from the effective volume of the system at each trap temperature. The trap temperatures (78 °K, 90 °K, 147.5 °K, 156 °K, 175.4 °K, 195.2 °K, 250.8 °K, and 297 °K) were chosen so as to provide a separation of all likely products, but the only temperatures at which gases were evolved were 195.2 °K (chlorine) and 297 °K (water). At first both the chlorine and water balances were low: these were traced, respectively, to attack of Apiezon grease by chlorine and partial dehydration of the HPH during the pre-run room-temperature outgassing. As a check of this a pellet of HPH was outgassed for 60 h under hard vacuum. The pellet lost 6.05% of its weight, compared with 6.35% expected for complete dehydration.

The reaction was also studied in the temperature range 180 to 229 °C by thermogravimetry. The kinetics were again deceleratory throughout and did not conform to any of the usual rate equations. Rate constants were therefore again determined from initial slopes. A point of inflection was observed in the weight-loss curve at $\alpha = 0.33$. The infrared spectrum of the solid residue at this stage of the reaction contained none of the strong peaks characteristic of HPH: the spectrum did, however, conform to that of ammonium perchlorate. X-ray powder photographs of HPH, AP, and the residue were therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

taken. That for pure HPH proved difficult to analyze since it was evident that the structure was one of low symmetry (6, 7). It was clear from a comparison of the powder photographs, however, that the residue at $\alpha = 0.33$ was not HPH but ammonium perchlorate, in confirmation of the infrared spectra.

The weight loss data and the gas analyses lead to the following chemical equation for the decomposition of HPH.

[1] $$2N_2H_5ClO_4.\tfrac{1}{2}H_2O = 0.8NH_4ClO_4 + 0.7O_2 + 1.6N_2 + 0.6Cl_2 + 4.4H_2O$$

The activation energy for the decomposition, as determined by thermogravimetry, is 35.8 kcal/mole, in good agreement with that found by pressure measurements.

DISCUSSION

Infrared Spectrum

Interpretation of this spectrum is facilitated by a comparison of the spectra of related compounds for which data are available. In Table I such a comparison is effected with spectra for $KClO_4$ (8–10), $NaClO_4.H_2O$ (8), NH_4ClO_4 (8), NH_4NO_3 (11), and N_2H_5Cl (5). The HPH spectrum can be divided conveniently into four regions.

(i) 4 000 to 2 000 cm^{-1}

Neglecting intermolecular coupling we should expect to find a maximum of six peaks in this region. The first band at 3 360 cm^{-1} is clearly due to the $(O—H)_s$ vibration though it may also include some contribution from the highest $(N—H)_s$ vibration which occurs at 3 261 cm^{-1} in hydrazine chloride. In AP and in ammonium nitrate the $(N—H)_s$ vibrations are all degenerate under T_d symmetry and give rise to bands at 3 330 and 3 260 cm^{-1} respectively. Because of the lack of symmetry in $(N_2H_5^+)$, a maximum of five peaks from the $(N—H)_s$ vibrations is expected. Four of these are clearly resolved. With better resolution one might see more than six peaks and thus would indicate intermolecular coupling, possibly through hydrogen bonding to the O atoms of the ClO_4^- ions.

(ii) 2 000 to 1 300 cm^{-1}

In this region we expect to find the $(O—H)_d$ frequency (1 630 cm^{-1} in $NaClO_4.\frac{1}{2}H_2O$) and $(H—N—H)_d$ frequencies. The degenerate asymmetric deformation of the NH_4^+ ion gives rise to absorption peaks at 1 420 and 1 435 cm^{-1} respectively in NH_4ClO_4 and NH_4NO_3. In N_2H_5Cl three $(H—N—H)_d$ peaks are observed at 1 500, 1 584, and 1 638 cm^{-1}. The 1 530 cm^{-1} peak in HPH is therefore due to this vibration also, whereas the 1 600 cm^{-1} peak is presumably due to both $(O—H)_d$ and $(H—N—H)_d$. In N_2H_5Cl two $(H—N—N)_b$ frequencies are detected at 1 246 and 1 417 cm^{-1} but these were not resolved in HPH.

(iii) 1 200 to 900 cm^{-1}

This is the most complicated region of the spectrum since the group-bending frequencies of the NH_3^+ group (1 101 and 1 124 cm^{-1} in N_2H_5Cl) are overlapped by the asymmetric stretching frequency of the ClO_4^- ion (1 135 cm^{-1} in NH_4ClO_4). We resolve three peaks at 1 125, 1 095, and 1 040 cm^{-1}. The first of these at 1 125 cm^{-1} is due to unresolved components from $(ClO_4^-)_s$ and $(NH_3^+)_b$, the second at 1 095 cm^{-1} arises from $(NH_3^+)_b$, and the third component at 1 040 cm^{-1} is due (9) to a combination of the asymmetric and symmetric deformations of the ClO_4^- ion. The frequency of the former is 624–628 cm^{-1} and thus beyond the range of our measurements, whereas the latter is of course observed only in Raman spectroscopy (461 cm^{-1} in $KClO_4$). Well resolved from this group of peaks is one at 960 cm^{-1} due to the $(N—N)_s$ vibration.

*Two very small bands reported by Miller and Wilkins at 2 030 cm^{-1} in $NaClO_4.\frac{1}{2}H_2O$ and at 1 990 cm^{-1} in $KClO_4$ have been omitted.
†Raman spectrum.
‡Phase IV; only NH_4^+ frequencies shown.
§Beyond the range of our determination.
‖Not resolved in $NaClO_4.\frac{1}{2}H_2O$.

(iv) Below 900 cm^{-1}

The only peak observed is one at 795 cm^{-1}, which is due to a vibrational mode of the $N_2H_5^+$ ion since it correlates well with the 763 cm^{-1} peak in N_2H_5Cl.

Mechanism of Decomposition

The first step in the decomposition of HPH is dehydration which occurs partially during outgassing at room temperature and is completed at a temperature of 61 °C. The anhydrous HP then melts at 138 °C. The vapor pressure of HP has been calculated by Levy *et al.* (2) from measurements of the rate of sublimation. They give values of 1.16 $\times$ 10^{-4} Torr at 180 °C and 33.4 $\times$ 10^{-4} Torr at 235 °C. The heat of vaporization for the dissociative equilibrium

$$N_2H_5^+ClO_4^- \text{ (l)} = N_2H_4 \text{ (g)} + HClO_4 \text{ (g)} \quad [2]$$

found from these vapor pressure measurements is $\Delta H_v = 59.2$ kcal/mole (2), in agreement with the value of 60.4 kcal/mole calculated from thermodynamic data. We first examine the available evidence to try and decide if reaction occurs in the melt or in the gas phase (including heterogeneous reactions on the walls of the reaction vessel).

If the mechanism of decomposition of HP involved the decomposition of hydrazine and perchloric acid in the gas phase with the vaporization step rate determining, then the experimental activation energy E would be 30 kcal/mole ($\frac{1}{2}\Delta H_v$). Similarly, if the gas-phase reaction were a bimolecular one between hydrazine and perchloric acid with vaporization rate determining, then E would be 60 kcal/mole. If the vapor is in equilibrium with the melt and the decomposition of one of the vapor species is rate determining (rate = $k'p_{N_2H_4}$ or rate = $k'p_{HClO_4}$), then the experimental activation energy E would be $E' + 30$ kcal/mole where E' is the activation energy corresponding to the rate constant k'. Since $E = 36.3$ kcal/mole, this is a theoretically possible situation, whereas a mechanism in which vaporization is rate determining is excluded ($E \neq \frac{1}{2}\Delta H_v$ or ΔH_v). Further evidence that vaporization is not rate determining comes from a comparison of the kinetics obtained from pressure measurements and from weight loss. The pressure measurements give the true reaction rate of the slowest step which leads to an increase in pressure and it is impossible to say from these alone whether the vaporization step or the subsequent gas-phase reactions are rate determining. Weight-loss measurements give the loss of material from the sample whether by reaction or vaporization. If the ambient pressure over the sample is increased by introducing an inert gas, then the rate of vaporization will be reduced. Thus, if vaporization were rate determining, the reaction rate determined from weight loss measurements under 1 atm pressure would be much lower than that found by pressure measurements at low pressures. In fact (Fig. 3) the rate is practically the same. (The rate determined by weight loss is actually higher than that found by pressure measurements, but the discrepancy is only of the same order as occurs on changing from a pyrex to a quartz reaction vessel and we do not therefore regard it as very significant.) For the above reasons we conclude that vaporization is not rate determining. One would like to support this conclusion quantitatively using the measured vaporization rates of Levy *et al.* (2), but unfortunately we do not know the surface area A of our molten HP. The order of magnitude of A may be 1 cm^2. If we assume a surface area of 1.5 cm^2 then the initial vaporization rate is faster than the initial reaction rate at all temperatures at which measurements were carried out. If we choose $A = 0.6$ cm^2 then the initial vaporization rate is faster than the initial reaction rate in a pyrex vessel at all temperatures, but marginally slower than the rate in quartz at the top two temperatures.

Another hypothesis which is consistent with the above facts is that the rate-determining

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

reaction occurs in the melt. The vaporization experiments of Levy *et al.* (2) were carried out in the temperature range 180–235 °C, which covers about the lower two thirds of our temperature range. Run durations varied from 315 to 37 min and it is clear from our kinetic experiments (e.g. Fig. 1) that substantial decomposition would have occurred during times of this order of magnitude. In fact, Levy *et al.* (2) analyzed both condensate and residue: they recovered 97–99% of their original charge and both condensate and residue contained 95–100% HP. This means that when the hydrazine and perchloric acid evaporate from the melt directly on to a cold finger, substantially no decomposition occurs. The above considerations thus show that reaction occurs not in the melt but in the gas phase (or on the reaction-vessel walls) after evaporation and that it is the rate of these chemical processes rather than the evaporation process which is rate determining in the temperature range of our experiments.

Although the chemical processes after evaporation cannot be established in complete detail certain general features of the reaction are clear. The homogeneous thermal decomposition of perchloric acid is not involved. Between 357 and 439 °C the reaction is first order (12) with a rate constant k given by

$$k = 5.8 \times 10^{13} \exp(-45100/RT)\ \mathrm{s}^{-1}. \qquad [3]$$

The extrapolated rate in our temperature range is two orders of magnitude lower than the rate of decomposition of HP. Below 350 °C, however, Levy's results (12) show a considerable scatter and a sensitiveness to the nature and pretreatment of the reaction vessel, both of which indicate the onset of a heterogeneous reaction. Superimposing a plot of our rate constants for the decomposition of HP on to Levy's data (12) shows that they lie between the rather wide limits indicated by his results. Of the nine points within our temperature range six lie below our lines, one is between the pyrex and quartz lines, and the other two lie above the quartz line. Thus we conclude that in the decomposition of HP, perchloric acid becomes adsorbed on the walls of the reaction vessel adjacent to the melt and that partial but not complete decomposition of $HClO_4$ ensues. The stoichiometric equation for this reaction is

$$HClO_4 = \tfrac{1}{2}Cl_2 + 1\tfrac{3}{4}O_2 + \tfrac{1}{2}H_2O. \qquad [4]$$

The mechanism of the heterogeneous reaction has not been established, but the primary step in the homogeneous reaction is the splitting of the HO—ClO_3 bond, which requires $\sim$ 45 kcal/mole, followed by decomposition of ClO_3. In this (or a likely alternative) route O atoms will be produced. Recombination of O atoms on the walls will occur and we may thus safely presume the presence of oxygen molecules, and possibly O atoms, from the decomposing perchloric acid.

The homogeneous decomposition of hydrazine may be safely excluded as a possible contributory feature. It has been studied (13) in the range 630–780 °C using toluene carrier gas to react with the NH_2 radicals produced by N—N bond fission, which requires 60 kcal/mole. The heterogeneous thermal decomposition occurs on silica between 270 and 310 °C (14). The stoichiometric equation for the reaction is

$$3N_2H_4 = 4NH_3 + N_2, \qquad [5]$$

but because it is first order (15) and does not involve free radicals[4] the mechanism probably involves the formation of an activated complex by one N_2H_4 molecule approaching two adsorbed N_2H_4 molecules (12). The activation energy of this reaction [5] is in doubt but is

[4]*Decomposition of hydrazine in the presence of para hydrogen (16) does not cause any para–ortho conversion; neither does randomization of nitrogen isotopes occur in the decomposition of* $H_2{}^{15}N{}^{14}NH_2$ *(17).*

variously estimated to be 18 kcal/mole (12) and 9.3 or 15.7 kcal/mole (15). Ammonia produced on the walls from this reaction will react with adsorbed but unreacted perchloric acid to produce the deposit of ammonium perchlorate observed at the bottom of the reaction tube.

The remaining reaction is the oxidation of hydrazine by oxygen from the perchloric acid. The chief uncertainty about the whole process is whether this involves O atoms or O_2 molecules. The vapor-phase reaction between hydrazine and molecular oxygen has been investigated by Bowen and Birley (18) who found the reaction approximately first order with respect to each component and with an activation energy of 38 kcal/mole falling to 20.5 kcal/mole at 'higher temperatures'. (The temperature range investigated was 100–160 °C.) Winning (19) investigated the same reaction between room temperature and 100 °C and found it to be second order and heterogeneous with an activation energy of 6.4 kcal/mole. The reaction of hydrazine with O atoms does not appear to have been studied, but there is substantial evidence that hydrogen abstraction from hydrazine is substantially easier (by several orders of magnitude) than from ammonia. Schiavello and Volpi (20) found that whereas the reaction of H atoms with ammonia proceeds only with difficulty at 150 °C, that with hydrazine goes at a measurable velocity in the range 25–150 °C. Estimated bimolecular rate constants at 150 °C are 3.5×10^{10} mole^{-1} cm^3 s^{-1} for $H + N_2H_4$ and 10^7 mole^{-1} cm^3 s^{-1} for $H + NH_3$. Similarly Gray and Thynne (21) found that at 150 °C CH_3 radicals will abstract H atoms from N_2H_4 450 times faster than from ammonia. Bimolecular rate constants for $O + NH_3$ are known from the work of Wong and Potter (22), but it is impossible to estimate the possible contribution of this reaction since the concentrations of O and NH_3 during the reaction are unknown. The main products, as would be expected, are water and nitric oxide (22) and because of the absence of NO in the products from the decomposition of HP, we conclude that this reaction does not occur either because it is much slower than the comparable reaction with hydrazine or because of the more rapid combination reaction

[6] $$O + O + M = O_2 + M.$$

Hydrazine is sufficiently reactive to be oxidized by molecular oxygen (18, 19) even if the O-atom concentration is negligible. The reaction probably occurs both heterogeneously on the walls and homogeneously in the gas phase.

The overall stoichiometry of the decomposition of HP in the temperature range 180–280 °C is thus satisfied by the following mechanism:

[2] $$N_2H_5^+ClO_4^- (l) = N_2H_4 (g) + HClO_4 (g)$$

[4] $$0.6HClO_4 = 0.3Cl_2 + 0.3H_2O + 1.05O_2$$

[7] $$0.7N_2H_4 + 0.7O_2 = 0.7N_2 + 1.4H_2O$$

[5] $$0.3N_2H_4 = 0.1N_2 + 0.4NH_3$$

[8] $$0.4NH_3 + 0.4HClO_4 = 0.4NH_4^+ClO_4^-.$$

Reactions [4], [5], [8], and probably [7] are heterogeneous. The oxygen produced in [4] will be initially present in part as O atoms. It is uncertain whether reaction [7] involves oxygen molecules or O atoms or both, since this depends on the relative speeds of the reactions $O + O + M = O_2 + M$ and $O + N_2H_4 =$ products.

ACKNOWLEDGMENTS

We are indebted to Dr. J. Powling for his support and encouragement of this research and to members of the staff of the Explosives Research and Development Establishment for undertaking the preparation and pelleting of the hydrazine perchlorate hemihydrate.

ON THE POSSIBLE CONTRIBUTION OF A MOLECULAR MECHANISM TO THE PHOTODECOMPOSITION OF NITROGEN DIOXIDE[1]

K. F. PRESTON AND R. J. CVETANOVIĆ

INTRODUCTION

Experimental investigations (1) of the photolysis of NO_2 have been mainly confined to the wavelength (λ) region 3 000 Å – 4 500 Å. The importance of [1]

[1] $$NO_2 + h\nu \rightarrow NO + O(^3P)$$

as a primary process in this wavelength region, suggested by the appearance of diffuseness in the absorption spectrum of NO_2 at 3 980 Å, has been established by several workers (1). The results of a recent investigation by Pitts, Jr., Sharp, and Chan (2) imply that even at wavelengths longer than the threshold for $O(^3P)$ production, photodecomposition of NO_2 takes place entirely by way of an oxygen atom route, and that the contribution from reactions of excited molecules (NO_2^*) of the form

[1*a*] $$NO_2^* + NO_2 \rightarrow 2NO + O_2$$

is negligible. In a search for suitable sources of excited oxygen atoms, we have had occasion to study the photolysis of NO_2 at wavelengths in the region beyond the second onset of diffuseness in the absorption spectrum (2 490 Å), which we (3) believe corresponds to the predissociation

[1*b*] $$NO_2 + h\nu \rightarrow NO + O(^1D).$$

The photooxidation of butene-1 by nitrogen dioxide[2] exhibits distinct behavior not only at wavelengths at which reaction [1*b*] is energetically possible ($< 2\,490$ Å) but also at and in the neighborhood of 2 537 Å. In view of these observations we have thought it necessary to determine the extent of O-atom exchange during the photolysis of mixtures of NO_2 and O_2^{36} at 2 537 Å and at other wavelengths. This method, which is similar to that of Pitts, Jr. *et al.* (2), is based on the underlying assumption that only free oxygen atoms are capable of exchange with O_2^{36} while other potential intermediates (such as, for example, NO_2^*) are not. The exchange reaction is therefore used as a test for the involvement of free oxygen atoms in the photolysis of NO_2.

EXPERIMENTAL

The isotopic composition of the oxygen remaining after the photolysis at 27 ± 2 °C of mixtures of NO_2 and O_2^{36} at 2 288 Å, 2 537 Å, 3 660 Å, 4 047 Å, and at $\lambda > 4\,200$ Å was determined by mass spectrometry. Corrections ($< 10\%$) for the formation of small amounts of O_2^{34} in the mass spectrometer by exchange reactions between O_2^{32} and O_2^{36} were taken from a plot of ΔO_2^{34} against $[O_2^{32}] \times [O_2^{36}]$ obtained by analysis of synthetic mixtures of the 32 and 36 isotopes of oxygen.

A 325 cc cylindrical quartz vessel was used for photolyses at 2 288 Å and a 180 cc cylindrical quartz vessel for photolyses at all other wavelengths. Initial pressures of NO_2 were in the range 3–10 mm Hg; the total initial pressure was usually 11 mm Hg and never exceeded 30 mm Hg. Exposure times varied from a few minutes for runs at 3 660 Å to a maximum of 3 h for some runs at 2 537 Å, but photolysis of NO_2 was never allowed to proceed to more than 15% of complete decomposition. (Extents of decomposition were estimated from the atom % ^{18}O in initial and final oxygen.) The isotopic composition of the O_2^{36} at the

[1]*Issued as N.R.C. No. 9151.*
[2]*K. F. Preston and R. J. Cvetanović. To be published.*

end of a 4 h dark run with initial pressures, $NO_2 = O_2^{36} = 8$ mmHg, NO = 1 mm Hg, was identical within experimental error to the starting composition (the parenthetical values): O_2^{34} 1.31 (1.30), O_2^{35} 0.65 (0.65), O_2^{36} 98.04 (98.05). The dark exchange among the molecules NO, NO_2, and O_2^{36} was therefore negligible.

The following lamps and filter combinations were used: cadmium lamp and chlorine filter (3) for 2 288 Å; low-pressure Hg-resonance lamp with 4 cm Cl_2 (600 mm Hg), 3 cm $NiSO_4.6H_2O$ at 200 g/l H_2O and Corning C.S. 9-54 for 2 537 Å; Hanovia medium-pressure Hg lamp (673A-10) with Corning C.S. 0-52 and C.S. 7-39 for 3 660 Å; Hanovia medium-pressure Hg lamp with C.S. 7-51 and C.S. 3-74 for 4 047 Å; Hanovia medium-pressure Hg lamp with C.S. 3-73 for $\lambda > 4\,200$ Å. In all cases the transmission characteristics of the filter combinations were checked with an ultraviolet spectrophotometer to ensure that only light of the desired wavelength range was obtained from the lamps.

Full details of the apparatus and experimental procedure have been given elsewhere (3).

RESULTS AND DISCUSSION

The ratio of the yields of O_2^{32} and O_2^{34} (R_{32}/R_{34}) resulting from the photolysis of mixtures of NO_2 and O_2^{36} was determined as a function of the concentration ratio $[NO_2]/[O_2^{36}]$ for several wavelengths. The results are plotted in Fig. 1, where the abscissae refer to average ratios of $[NO_2]$ to $[O_2^{36}]$ during the course of a run. Apart from the results for $\lambda > 4\,200$ Å, the experimental data for all wavelengths are consistent with the following simple mechanism:

[1] $$NO_2 + h\nu \rightarrow NO + {}^{16}O$$

[2] $${}^{16}O + NO_2 \rightarrow NO + O_2^{32}$$

[3] $${}^{16}O + O_2^{36} \rightarrow O_2^{34} + {}^{18}O$$

[4] $${}^{18}O + NO_2 \xrightarrow{(a)} NO + O_2^{34}$$
$$\xrightarrow{(b)} N^{18}O + O_2^{32}$$
$$\xrightarrow{(c)} N^{16}O^{18}O + {}^{16}O$$

Formation and subsequent reactions of ozone have been ignored since stabilization of the intermediate O_3* for [3] is negligible compared with decomposition at the pressures used here (4). For similar reasons (5, 6) we have chosen to neglect reactions of NO_3* other than unimolecular decomposition.

For stationary concentrations of ^{16}O and ^{18}O the reaction scheme predicts:

$$R_{32}/R_{34} = \frac{k_{4b}}{(k_4 + k_{4a})} + \frac{k_2 k_4}{k_3(k_4 + k_{4a})} \times \frac{[NO_2]}{[O_2^{36}]},$$

and Fig. 1 shows that such a linear relation is obeyed at all wavelengths shorter than 4 200 Å. The fact that all the data for $\lambda < 4\,200$ Å fit the *same* relationship suggests very strongly that the oxygen atom mechanism is operative at all wavelengths and accounts for the entire extent of decomposition. (An alternative possibility that a molecular path may exist and account for precisely the same fraction of photodecomposition at all wavelengths is unlikely.) This confirms the earlier work of Pitts, Jr., Sharp, and Chan (2). On the other hand, for light of wavelength > 4 200 Å (principally 4 358 Å) there is evidently some production of oxygen molecules without the intermediate participation of oxygen atoms, suggesting the importance of reactions of type [1*a*]. No attempt was made to measure the quantum yield of O_2 production at 4 358 Å, although Pitts, Jr., *et al.* (2) found it to be very small. They believed that the small quantum yields which they observed for photolysis by "monochromatic" 4 358 Å light were actually due to traces of 4 047 Å light transmitted by their filter combination. Such an explanation cannot

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

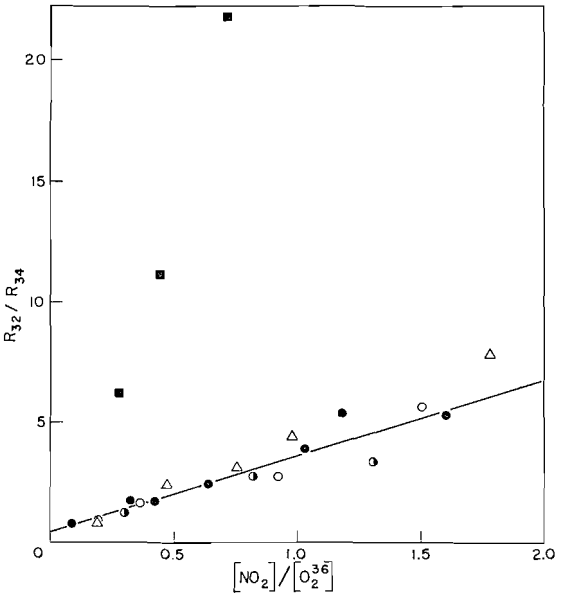

FIG. 1. Plot of R_{32}/R_{34} against $[NO_2]/[O_2^{36}]$ (27 ± 2 °C): (△) 2 288 Å, (●) 2 537 Å, (○) 3 660 Å, (◑) 4 047 Å, (■) > 4 200 Å.

account, however, for the large differences observed in this work between the extents of scrambling at 4 047 Å and 4 358 Å. It is possible, of course, that some photolysis and some or all of the scrambling for $\lambda > 4\,200$ Å was caused by extraneous 4 047 Å light, but we conclude that absorption at 4 358 Å does result in some (although admittedly (2) very small) decomposition and that it occurs at least in part by way of a molecular mechanism.

The results of Fig. 1 show that the overall mechanism for photolysis at 2 537 Å is essentially the same as at 4 047 Å and 3 660 Å, where an O-atom mechanism holds. Reactions of type [1*a*] do not then contribute to the photodecomposition at 2 537 Å. However, in principle, NO_2^* may still be an important intermediate, provided it participates in an indirect production of oxygen atoms, for example by

$$[1c] \qquad NO_2^* + NO_2 \rightarrow [N_2O_3 + O(^3P)] \rightarrow NO_2 + NO + O(^3P).$$

The implication of these results on the photooxidation of butene-1 by NO_2 at 2 537 Å will be discussed elsewhere.[2] A reaction analagous to [1*c*] has been proposed by Ford and Jaffe (5) to explain oxygen atom formation in the photolysis of NO_2 at 4 047 Å. (Reaction [1*a*] rather than [1*c*] is evidently necessary to explain the present results at $\lambda > 4\,200$ Å.)

A least-squares treatment of the data in Fig. 1 for 2 537 Å, 3 660 Å, and 4 047 Å gives a value for $k_2k_4/k_3(k_4 + k_{4a})$ of 3.1 ± 0.3. Klein and Herron (6) have measured k_3 at 37 °C and have determined k_2 as a function of temperature. From their value of k_2/k_3 and their estimate (6) of the contributions of *a*, *b*, and *c* to [4] we calculate $k_2k_4/k_3(k_4 + k_{4a}) = 4.5$ at 37 °C, in fair agreement with our value.

The fit of the 2 288 Å data to the straight line in Fig. 1 is somewhat surprising. We (3) have shown that $O(^1D)$ atoms participate in the photolysis of NO_2 at 2 288 Å, and have estimated that approximately 40% of the atoms generated in the primary step are in the excited state. One might expect the ratio of the rate constants k_2/k_3 for $O(^1D)$ (denoted in this case by k_2^*/k_3^*) to be closer to unity than the value of k_2/k_3 for $O(^3P)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(4.0 derived from this work) and, in consequence, the values of R_{32}/R_{34} for 2 288 Å to be smaller than those observed at longer wavelengths. Consideration of a revised mechanism including reactions of $O(^1D)$ atoms shows, however, that the values of R_{32}/R_{34} for 2 288 Å will deviate by less than 10% from the values at longer wavelengths provided $6 > k_2^*/k_3^* > 3$. This inequality is very much dependent on the value assumed for the percentage of atoms generated in the ^1D state, which is not known precisely (3). Thus, for 10% $O(^1D)$, deviations from the straight line in Fig. 1 will be $< 10\%$ provided $k_2^*/k_3^* > 1.5$. It is possible that some deactivation of $O(^1D)$ by O_2[36] occurs without exchange and this will tend to reduce the predicted lower limit for k_2^*/k_3^*. For 40% $O(^1D)$ generation and equal rates of quenching of $O(^1D)$ by O_2[36] with and without exchange it can be shown that $3 > k_2^*/k_3^* > 1.4$.

ACKNOWLEDGMENT

We wish to express our thanks to Dr. R. Pottie and Mr. R. Sander for carrying out the mass spectrometric analyses.

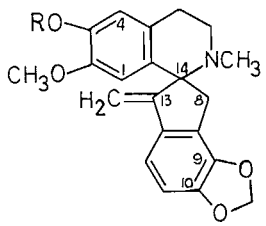
AND

RICHARD H. F. MANSKE
Research Laboratories, Dominion Rubber Company Limited, Guelph, Ontario



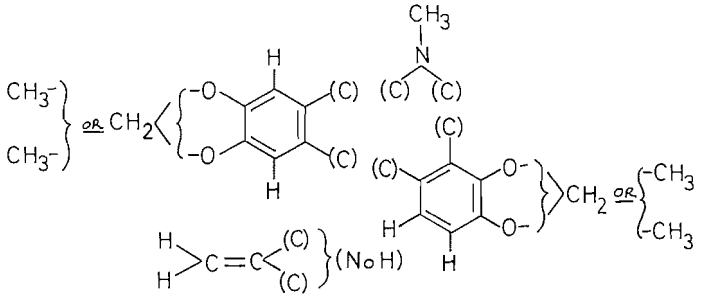
Received June 15, 1966

ABSTRACT

A combination of physical and chemical techniques has led unequivocally to the demonstration that ochotensimine and ochotensine have structures I and II, respectively.

Ochotensine and ochotensimine were isolated from *Corydalis ochotensis* Turcz. more than 25 years ago (1). Ochotensimine, $C_{22}H_{23}NO_4$, was shown to be the *O*-methyl ether of the phenolic ochotensine, and it was possible to convert ochotensimine methiodide into a crystalline degradation product under Emde conditions; however, other common degradative methods for determining structure gave no useful results when applied to these alkaloids.

When we examined these alkaloids again after a considerable lapse of time, we found that they were particularly susceptible to an attack by spectroscopic techniques. The nuclear magnetic resonance (n.m.r.) spectra were particularly useful, and it was mainly on the basis of an examination of these that we proposed structures I and II for ochotensimine and ochotensine, respectively (2). Our proposals have recently been completely confirmed by an X-ray crystallographic study of ochotensine methiodide (3). We now report in detail on the chemical and spectroscopic results we used to elucidate the structures of these alkaloids.



I R = Me (ochotensimine)
II R = H (ochotensine)

Ochotensimine is an optically active base which could not be induced to crystallize. The source of the alkaloid led us to anticipate that its structure would be based on a benzylisoquinoline skeleton, and the infrared and ultraviolet spectra did not contradict this, although in the latter case, because of the high intensity of the peaks, we suspected

that either the usual benzenoid chromophores had been modified or an additional chromophore was superimposed on the usual spectrum. However, the mass spectrum did not show a close correspondence with that of any class of benzylisoquinoline alkaloids studied previously (4); the spectrum was, in fact, almost devoid of positive information regarding structure since it showed the molecular ion to be the strongest peak by far, and showed few other peaks of significant intensity (see Experimental). The 60 MHz n.m.r. spectrum, on the other hand, gave a wealth of information; when this was amplified by results obtained at 100 MHz we were able to make a working hypothesis for the structure of the alkaloid. The two *O*-methyl groups and the *N*-methyl group were immediately recognized from the singlets with τ values of 6.17, 6.38, and 7.87, and the methylenedioxy protons appeared unsplit at τ 4.03. The general features of the substitution around the two aromatic rings followed from the observation that a two-proton AB quartet at τ 3.04 (J = 8.0 Hz, with an internal chemical shift of 19 Hz at 60 MHz) and two one-proton singlets at τ 3.47 and 3.70 required one ring to be tetra-substituted with two ortho-related hydrogens and the other to be tetra-substituted with two para-related hydrogens.

The appearance of two one-proton singlets at τ 4.37 and 5.10 was at first puzzling, since it suggested that there were two protons, uncoupled to any others, on two independent ethylenic systems. This appeared to be completely incompatible with the other evidence. However, the dilemma was resolved when it was found that these peaks did not appear in the spectrum of the product of the catalytic hydrogenation of ochotensimine (*vide infra*), which exhibited instead the methyl signal of a $CH_3CH\langle$ grouping at τ 9.05 (J = 7.2 Hz). The signals in ochotensimine must therefore arise from a $H_2C{=}C\langle$ grouping in which J_{gem} is zero (5), and furthermore, the two protons must be situated in rather different environments within the molecule and be too distant from other protons to couple with them.

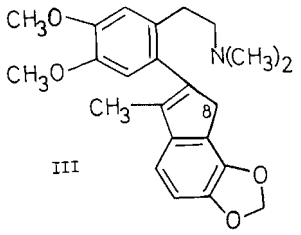
The data reported so far showed that ochotensimine has the following partial structure.

From the molecular formula it was clear that four of the bracketed carbon atoms in the partial structure corresponded to sites that had been represented more than once and that two more rings had to be incorporated into the skeleton. If the presence of the structural feature $ArCH_2CH_2N\langle$ (common to most benzylisoquinoline alkaloids) could be assumed, then structure I possessed the only skeleton that satisfied all the data, although there were, however, still several ways in which the oxygen functions could be distributed.

We recognized that, if this were the correct structure, the C-8 methylene protons should appear as a clean AB quartet near τ 7. However, all six remaining protons gave rise to a complex pattern in this region, and it was only when the 100 MHz spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was examined that the presence of the quartet could be established conclusively. It appeared at τ 6.80 (J = 18.0 Hz, with an internal chemical shift of 50 Hz); the A and B components could be decoupled by double irradiation, and it was clear that neither proton was coupled to any other outside the AB group. The proposal was thus placed on firm ground as far as ring C was concerned. The four protons still unaccounted for were presumably part of a complex multiplet arising from the postulated $ArCH_2CH_2N<$ grouping. It was necessary to carry out a rational degradation to prove that this structural feature was, in fact, present and so establish unequivocally that ochotensimine has the skeleton shown in structure I.



In the presence of palladium on charcoal catalyst, ochotensimine consumed 1 equivalent of hydrogen and formed the dihydro derivative referred to above. This was clearly the *C*-methyl compound produced by reduction of the $>C{=}CH_2$ grouping in I, and the difference in base strength between ochotensimine (pK_a 6.7) and dihydroochotensimine (pK_a 7.4) was of the magnitude anticipated for a molecule with the double bond and the basic center related as in I. Dihydroochotensimine had the predicted ultraviolet spectrum, with peaks of considerably lower intensity than ochotensimine. It was not possible to obtain crystalline dihydroochotensimine, and several hydrogenation experiments with different batches of catalyst gave products which were not completely identical with that already described. These bases formed methiodides that did not crystallize well, and led to poor and unreproducible microanalytical results. However, as far as we can ascertain, all samples were equally suitable for the degradation that is described next.

Hofmann degradation of dihydroochotensimine methiodide with potassium hydroxide in aqueous ethanol gave rise to an optically inactive base, $C_{23}H_{27}NO_4$, identical with the product previously obtained by reduction of ochotensimine methiodide with sodium amalgam (1). We now found that reduction of ochotensimine methiodide by hydrogenation in the presence of pre-reduced platinum oxide or by treatment with sodium borohydride also gave this product in an excellent yield.

Spectroscopic data clearly indicated that the Hofmann product had structure III (with the same reservations as before concerning the positions of the oxygen functions). The *C*-methyl signal in the n.m.r. spectrum had the appearance of a closely spaced triplet at τ 8.07, the cyclic CH_2 produced a multiplet (probably an incompletely resolved quartet) at τ 6.42, and there was no evidence for the presence of a vinyl proton. This compound is the expected Hofmann product of dihydroochotensimine methiodide; it should be recalled that, if any of the Δ^8 isomer of III were formed, it would be expected to rearrange to III under the conditions of the reaction (6). The formation of III by the reduction of ochotensimine methiodide can be accounted for by assuming that the C—N bond, which is both benzylic and allylic, is extremely susceptible to hydrogenolysis when the nitrogen is quaternized. The methyleneindane so formed would then rapidly isomerize to the methylindene III, which is resistant to further reduction; alternatively, 1,4 hydrogenation would lead directly to III.

The methiodide of III underwent a further Hofmann degradation and yielded the expected nitrogen-free styrene. Spectroscopic data for this compound supported the proposed structure, the most important evidence coming from the n.m.r. spectrum, which was almost superimposable on that of styrene in the vinyl region, but very slightly shifted to higher field. Catalytic hydrogenation readily converted the sytrene into a dihydro derivative in which the vinyl side chain had been transformed into an ethyl group attached directly to an aromatic ring (a triplet at τ 8.87 and a quartet at τ 7.48 with J = 7.8 Hz in the n.m.r. spectrum). This evidence establishes unequivocally that ochotensimine has the postulated $ArCH_2CH_2N<$ grouping; since the presence of this feature was the only

III

assumption made initially, it follows that the alkaloid has the skeleton depicted in structure I. However, as has been pointed out already, the oxygen functions can still be distributed in a number of ways. Presumptive evidence for this distribution has been obtained by a chemical degradation but, in agreement with previous experience (1), it was impossible to carry out a rational degradative sequence that would establish this point unambiguously. We have subjected ochotensimine and several of its transformation products to a variety of oxidative degradations; however, with one exception, either the conditions were too mild to affect the compounds or they were so severe that they apparently degraded the molecule indiscriminately at several sites and led to intractable mixtures or tars. The tetra-substituted double bond of III and its transformation products was particularly inert to chemical attack.

As has been described previously (1), the Hofmann degradation of ochotensimine methiodide led to an amorphous product. However, we now found that treatment of this product with permanganate gave a low yield of metahemipinic acid. This is good evidence that ochotensimine has ring A substituted as in I, but it is not conclusive since it is based on the assumption that ochotensimine, by analogy with other benzylisoquinoline alkaloids, is 2,3 disubstituted. Furthermore, even if this is so, ring D may be 9,10 or 11,12 disubstituted.

We did little work with ochotensine itself, but we succeeded in converting it into a crystalline methiodide which proved to be suitable for the X-ray crystallographic investigation (3) that led to the elucidation of the structures of both ochotensine and, as a corollary, ochotensimine. Information which we obtained from this methiodide led us to suspect at an early stage that ochotensine had structure II rather than the isomeric 2-hydroxy-3-methoxy structure; the ultraviolet spectrum of ochotensine methiodide showed λ_{max} 290 mμ which, on addition of aqueous alkali, shifted to a longer wavelength and underwent a complex sequence of changes with time; these changes were not reversed by neutralization of the sample. This suggested that the following type of cleavage was occurring.

Since the X-ray crystallographic investigation has confirmed completely the deductions based on other evidence, even those made very tentatively, the attempts to obtain unequivocal proof of structure for ochotensine and ochotensimine by degradative methods have been discontinued. However, it may be noted that, since these alkaloids have a unique skeleton (at least for the present), the biosynthetic pathways leading to them are obviously of great interest, and suitable rational degradations will have to be found before this feature can be studied adequately.

EXPERIMENTAL

Melting points were determined on a micro hot stage apparatus. Nuclear magnetic resonance spectra of samples in deuteriochloroform solution were obtained on a Varian A60 spectrometer, unless otherwise indicated.[1] A Beckman IR8 spectrometer was used to record infrared spectra, and samples were dissolved in chloroform unless otherwise indicated. A Bausch and Lomb Spectronic 505 spectrometer was used to record ultraviolet spectra, and a Hilger polarimeter was used to obtain optical rotations. In the mass spectra, the *m/e* value of a peak and its intensity (as a percentage of that of the base peak) are recorded if the intensity is 10% or greater and the *m/e* value is above 50.[2]

Ochotensine and Ochotensimine

The isolation of these alkaloids has been described previously (1). Ochotensimine, which formed a hydriodide, m.p. 190°, and a perchlorate, m.p. 172°, had pK_a 6.7 (by potentiometric titration with *p*-toluenesulfonic acid in 50% aqueous ethanol). Spectroscopic data: infrared 6.14 (sh), 6.20 (m) μ; ultraviolet λ_{max}^{MeOH} 226 (ϵ 25 700), 287 (ϵ 13 100) mμ; n.m.r. τ 3.04 (2 H; AB quartet, J = 8.0 Hz, with an internal chemical shift of 19 Hz), 3.47 (1 H), 3.70 (1 H), 4.03 (2 H), 4.37 (1 H), 5.10 (1 H), 6.17 (3 H), 6.38 (3 H), 6.65 to 7.3 (6 H; complex), 7.87 (3 H); at 100 MHz, the 4.03 peak is broadened and a peak at 6.80 (2 H; AB quartet, J = 18.0 Hz, with an internal chemical shift of 50 Hz; confirmed by decoupling) becomes apparent; mass spectrum 366 (24%), 365 (base), 364 (40%), 363 (14%), 350 (18%), 337 (10%), 336 (18%), 334 (10%), 205 (10%), 148 (16%), 85 (50%), 83 (24%).

Ochotensine, which is remarkably insoluble in most solvents, showed the following spectroscopic features: infrared (KBr pellet) 6.06 (sh), 6.23 (s) μ; mass spectrum 352 (24%), 351 (base), 350 (50%), 349 (48%), 348 (22%), 336 (24%), 334 (16%), 323 (10%), 322 (24%), 321 (12%), 320 (26%), 308 (10%), 306 (14%), 305 (14%), 191 (16%), 190 (18%), 189 (16%), 176 (16%), 148 (34%), 103 (16%), 102 (16%), 99 (16%), 94 (22%), 83 (14%), 78 (14%), 77 (16%), 76 (14%), 65 (12%), 63 (14%).

Ochotensine in dimethylformamide was allowed to react with excess methyl iodide at room temperature for 4 days. Evaporation of the solvent yielded a residue which, after repeated recrystallizations from methanol, formed crystals, m.p. 215° (the melting point was not well defined and depended on the rate at which the sample was heated).

Anal. Calcd. for $C_{22}H_{24}NO_4I$: C, 53.56; H, 4.87; N, 2.84; I, 25.74. Found: C, 53.69; H, 5.06; N, 2.94; I, 25.28.

The ultraviolet spectrum, λ_{max}^{MeOH} 290 mμ (ϵ 18 100) shifted to λ_{max} 360, 265, and 250 mμ on the addition of 2 drops of 5 *N* aqueous NaOH; the spectrum continued to change with time and the addition of hydrochloric acid did not regenerate the original chromophore.

Dihydroochotensimine

Ochotensimine (75 mg, 0.20 mmole) in 10 ml of 95% ethanol was hydrogenated at atmospheric pressure and room temperature in the presence of 30% palladium on charcoal (30 mg). After 20 h, 0.18 mmole hydrogen had been consumed, and dihydroochotensimine (74 mg) was isolated in the usual manner. This material, $[\alpha]_{Hg}^{22}$ +112° (*c*, 0.7 in $CHCl_3$), pK_a 7.4 (by potentiometric titration with *p*-toluenesulfonic acid in 50% aqueous ethanol), could not be induced to crystallize. With methyl iodide at room temperature it formed a methiodide (yield 70–80%) which, after several recrystallizations, formed white crystals, m.p. 169–175°.

Anal. Calcd. for $C_{23}H_{28}NO_4I$: C, 54.23; H, 5.50; N, 2.75. Found: C, 53.13, 53.61; H, 5.41, 5.02; N, 3.24, 2.71.

Spectroscopic data for dihydroochotensimine: infrared 6.20 (m) μ; ultraviolet λ_{max}^{MeOH} 223 (shoulder) (ϵ 12 400), 282 (ϵ 5 900) mμ; n.m.r. τ 3.45 (2 H; complex), 3.63 (1 H), 3.88 (1 H), 4.13 (2 H), 6.32 (3 H), 6.63 (3 H), 6.4 to 7.5 (7 H; complex), 7.65 (3 H), 9.05 (3 H; doublet, J = 7.2 Hz); mass spectrum 368 (25%), 367 (base), 366 (28%), 352 (28%), 339 (18%), 338 (76%), 337 (32%), 336 (50%), 322 (12%), 218 (18%), 206 (12%), 204 (16%), 163 (18%), 162 (54%), 149 (12%).

First Hofmann Degradation

A solution of dihydroochotensimine methiodide (133 mg) in 20 ml of 50% ethanol containing 0.6 g potassium hydroxide was refluxed for 21 h. The crude product (72 mg) was isolated in the usual way and recrystallized from a mixture of acetone and hexane. It formed crystals, m.p. 91–92°, $[\alpha]_D$ 0°, which were identical with the Emde product reported previously (1). Spectroscopic data: ultraviolet λ_{max}^{MeOH} 278 (ϵ 12 700), 316 (inflection) (ϵ 4 800) mμ; n.m.r. τ 3.17 (3 H), 3.34 (1 H), 4.02 (2 H), 6.10 (3 H), 6.18 (3 H), 6.42 (2 H; complex, width 8 Hz), 7.3 to 7.6 (4 H; complex), 7.84 (6 H), 8.07 (3 H; 1:2:1 triplet, J = 2.0 Hz).

The same product was conveniently prepared by hydrogenation of ochotensimine methiodide (400 mg) in 15 ml of 95% ethanol in the presence of pre-reduced platinum oxide (30 mg) for 44 h at room temperature and atmospheric pressure. The solid obtained after the solvent had been evaporated was treated with 4%

[1]*We are grateful to Professor R. U. Lemieux, University of Alberta, Edmonton, for the spectrum obtained at 100 MHz.*

[2]*We are grateful to Professor D. B. MacLean, McMaster University, Hamilton, for obtaining these spectra for us. A Hitachi Perkin–Elmer RMU-6A spectrometer was used.*

aqueous sodium carbonate and the resulting product was extracted with chloroform. The crude residue (258 mg), after evaporation of the chloroform, yielded, on recrystallization, a product identical with that described above. Alternatively, a suspension of ochotensimine methiodide in methanol was converted into the same product in a quantitative yield by treatment with excess sodium borohydride.

With methyl iodide at room temperature overnight, the base formed a methiodide which melted at 157–160°, resolidified at 175°, and remelted at 233–236°.

Anal. Calcd. for $C_{24}H_{30}NO_4I$: C, 55.07; H, 5.73; N, 2.67. Found: C, 54.88; H, 5.81; N, 2.70.

Second Hofmann Degradation

The methiodide (200 mg) just described was dissolved in 30 ml of 50% ethanol containing 1.0 g potassium hydroxide. The solution was refluxed for 2 h and the crude product (102 mg) was isolated in the usual way. Recrystallization of the product from a mixture of acetone and hexane yielded crystals, m.p. 142–144°.

Anal. Calcd. for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99. Found: C, 75.17; H, 5.74.

Spectroscopic data: infrared 6.25 (m) μ; ultraviolet λ_{max}^{MeOH} 266 (ϵ 14 400), 274 (inflection) (ϵ 14 000), 300 (broad shoulder) (ϵ 10 000) mμ; n.m.r. τ 2.86 (1 H), 3.17 (2 H), 3.30 (1 H), 4.03 (2 H), 6.07 (3 H), 6.14 (3 H), 6.44 (2 H; 1:3:3:1 quartet, J = 2.0 Hz), 8.10 (3 H; 1:2:1 triplet, J = 2.0 Hz); in addition, the signals from the three vinylic protons (ABC) of a styrene can be recognized and analyzed approximately: τ 3.35 (A), 4.39 (B), 4.89 (C); $J_{AB(trans)}$ = 18.0 Hz, $J_{AC(cis)}$ = 11.0 Hz, $J_{BC(gem)}$ = 1.5 Hz.

Dihydro Derivative

The above material (145 mg, 0.43 mmole) in 10 ml of 95% ethanol containing 3 ml chloroform was hydrogenated at atmospheric pressure and room temperature in the presence of pre-reduced platinum oxide (30 mg). After 3 h, 0.44 mmole hydrogen had been consumed and the product was isolated as crystals, m.p. 110.5–112°.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.53; H, 6.55. Found: C, 74.67; H, 6.68.

Spectroscopic data: infrared 6.25 (m) μ; ultraviolet λ_{max}^{MeOH} 277 (ϵ 16 100), 289 (shoulder) (ϵ 13 700), 310 (inflection) (ϵ 5 800) mμ; n.m.r. τ 3.13 (3 H), 3.27 (1 H), 4.00 (2 H), 6.07 (3 H), 6.14 (3 H), 6.42 (2 H; 1:3:3:1 quartet, J = 2.0 Hz), 7.48 (2 H; 1:3:3:1 quartet, J = 7.8 Hz), 8.07 (3 H, 1:2:1 triplet, J = 2.0 Hz), 8.87 (3 H; 1:2:1 triplet, J = 7.8 Hz).

Metahemipinic Acid

Ochotensimine methiodide suspended in methanol was treated with slightly more than 1 equivalent of potassium hydroxide. Warming caused a brown resinous mass to separate, and precipitation was completed by the addition of water. A solution of this amorphous residue in acetone was treated with saturated aqueous potassium permanganate until the color of the solution was retained for 1 h. The mixture was filtered, the filtrate was diluted with water, and the acetone was removed by distillation. The cold aqueous solution was then oxidized with further potassium permanganate solution until a permanent color was produced. Excess calcium chloride was added (to remove any oxalic acid) and the mixture was filtered again. Acidification of the filtrate and extraction with ether yielded a partly crystalline acid which was treated with excess ethylamine and then sublimed *in vacuo*. The resulting colorless stout prisms (yield ca. 5%) melted sharply at 232° either alone or on admixture with *N*-ethylmetahemipinimide.

AZAINDOLES

I. PREPARATION OF 7-AZAINDOLES BY THERMAL INDOLIZATION OF 2-PYRIDYLHYDRAZONES

A. H. Kelly and J. Parrick[1]

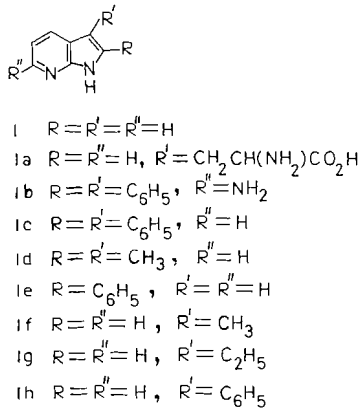
Department of Chemistry and Metallurgy, Rutherford College of Technology, Newcastle-upon-Tyne, England

Received May 6, 1966

ABSTRACT

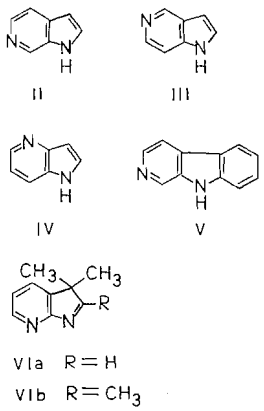
The preparation of 2-pyridylhydrazones and their thermal indolization to 2- and 3-monosubstituted and 2,3-disubstituted 7-azaindoles, and to 3,3-disubstituted and 2,3,3-trisubstituted 7-azaindolenines are described. Attempts to cause thermal indolization of two 2-(5-nitropyridyl)hydrazones were unsuccessful.

Azaindoles of the types I, II, III, and IV are of chemical interest because they contain the π-electron deficient pyridine nucleus fused to the π-electron excessive pyrrole nucleus (1), and their relationship to indole adds biochemical interest. In the cases of I and II additional similarities to purine are apparent. The biological activity of azaindoles might be expected to be similar to that of the corresponding indoles and purines but with potentially useful differences. The possible use of azaindoles as purine antimetabolites has stimulated other investigations (2), and some evidence of noteworthy biological activity of 7-azatryptophan (I*a*) is available (3). Neither the parent heterocycles nor simple derivatives of azaindoles seem to occur in nature, but the presence of the β-carboline nucleus V in certain alkaloids is well known (4).



Several investigations of azaindoles (I, II, III, and IV) have been reported by Clemo (5), Herz (6), Möller (7), and Robison (8), and currently by Albert (9) and Badger (2). Numerous 2,3-dihydroazaindole derivatives have been reported by Yakhontov and Rubtsov (10), and Ficken and Kendall (11) have prepared some azaindolenines (e.g. VI*b*). The methods employed in the preparations of azaindoles have been predominantly adaptations of standard indole syntheses and involve the formation of the pyrrole ring on the pyridine ring. For example, preparations based on the Madelung (9, 12), Fischer (8*b*, 11, 13), and Reissert (14) indole syntheses have been reported (the recent successful application of the last method (14) is in contrast to the earlier reports of failures when this technique was applied to azaindole syntheses (2, 6)). An interesting method involving photochemical ring contraction to give azaindoles has been developed (7). Synthetic approaches involving the formation of a pyridine ring on an existing pyrrole nucleus have met with only modest success (15).

7-Azaindoles have received more attention than the other azaindoles, and the parent heterocycle I is available in a good yield by a modification of the Madelung synthesis (12) and by reaction of 3-pyridylacetylene with sodamide (16), or, less readily, through the photochemical route (7*b*). The base occurs in coal tar (17) and as a pyrolysis product of nicotine (18). The 2-, 3-, 4-, 5-, and 6-methyl-7-azaindoles have been prepared by the Madelung technique (5*a*, 9, 19), and 6-amino-2,3-diphenyl-7-azaindole (I*b*) was obtained in a high yield from 2,6-diaminopyridine and benzoin in the presence of the diaminopyridine hydrochloride (20).



Probably the most useful method for the preparation of indoles is the Fischer synthesis

[1]*Present address: Department of Chemistry, Brunel College, Acton, London, W.3, England.*

(21). However, adaptations of this technique to the synthesis of azaindoles while using the usual acid catalysts have met with only limited success: 2,3-diphenyl-7-azaindole (I*c*) (8*a*) and 6,7,8,9-tetrahydro-α-carboline (VII*b*) (8*a*, 13) were obtained in a moderate yield, and the technique has been used for the preparation of azaindolenines (VI*b*) (11).

VIIa $n=3$
VIIb $n=4$

VIIIa $n=1$
VIIIb $n=2$

The purely thermal indolization technique reported by Fitzpatrick and Hiser (22) appeared to offer advantages for the synthesis of azaindoles from pyridylhydrazones, since this method avoids the deactivation caused by quaternization of the pyridyl nitrogen atom. A brief study of the thermal indolization of pyridylhydrazones as part of a more general investigation of thermal indolization (23) gave encouraging results, and the application of this method to the synthesis of 7-azaindoles has been investigated in more detail.

2-Pyridylhydrazine was prepared from 2-chloropyridine (24) and then quickly converted into the 2-pyridylhydrazones of acetone, ethyl methyl ketone, isopropyl methyl ketone, acetophenone, cyclopentanone, α-indanone, α-tetralone, propionaldehyde, butyraldehyde, isobutyraldehyde, phenylacetaldehyde, pyruvic acid, and ethyl pyruvate by the usual techniques. Refluxing a solution of these 2-pyridylhydrazones in a high-boiling solvent gave the corresponding 7-azaindole in most cases (Table II). (Unless indicated in this table an inert atmosphere was not necessary to obtain the yields quoted.)

TABLE I

2-Pyridylhydrazone of:	Melting point	Formula	Calculated (%) C	H	N	Found (%) C	H	N
Cyclopentanone	91–92°	$C_{10}H_{13}N_3$	68.6	7.43		68.2	7.54	
α-Indanone	87–88°	$C_{14}H_{13}N_3$			18.8			18.5
α-Tetralone	112–114°	$C_{15}H_{15}N_3$			17.7			17.7
Propionaldehyde	54–55.5°	$C_8H_{11}N_3$	64.4	7.38		64.4	7.59	
Butyraldehyde	42–43°	$C_9H_{13}N_3$	66.3	7.97		66.5	7.99	
Phenylacetaldehyde	79–80°	$C_{12}H_{11}N_3$			19.9			19.6

NOTE: The 2-pyridylhydrazones of ethyl methyl ketone, isopropyl methyl ketone, and isobutyraldehyde were obtained only as oils and were not analyzed; those of acetone, acetophenone, pyruvic acid, and ethyl pyruvate had melting points in agreement with the literature values (25).

‡Crystallized from ethanol.
§Crystallized from acetone.
‖Obtained as an oil, b.p. 90–110° at 0.5 mm.
NOTE: Liquid 3-ethyl-7-azaindole (I*g*) yielded a picrate by reaction with ethanolic picric acid. Recrystallization from ethanol gave yellow needles, m.p. 221–222.5°.
Anal. Calcd. for $C_{15}H_{11}N_5O_7$: C, 48.0; H, 3.47. Found: C, 47.8; H, 3.57.

Several attempts were made to cause indolization of acetone 2-pyridylhydrazone under a variety of conditions; in no case was an azaindole isolated, but the pyridylhydrazone was recovered in some experiments. This result is in marked contrast to the fairly ready thermal indolization of acetone phenylhydrazone (22). All attempts to obtain an azaindole from the 2-pyridylhydrazones of pyruvic acid and ethyl pyruvate were unsuccessful.

2-(5-Nitropyridyl)hydrazine, prepared from 2-chloro-5-nitropyridine, gave the nitropyridylhydrazones on reaction with cyclohexanone and ethyl methyl ketone. Again, all attempts to cause indolization failed, though extensive decomposition did occur. In this connection it is interesting that cyclohexanone *p*-nitrophenylhydrazone gives only a poor yield of 6-nitro-1,2,3,4-tetrahydrocarbazole by a purely thermal technique (23) but gives a high yield when both an elevated temperature and an acidic medium are used (24).

These results are in agreement with the idea that protonation of the hydrazino nitrogen atom is not essential in the Fischer indole synthesis but may be necessary for success when indolization is difficult (21). However, when pyridylhydrazones are used, the acidic reaction medium deactivates the nucleus for the electrophilic cyclization stage of the reaction, thus making the purely thermal method particularly useful in this series, though not successful, in the examples examined, where the pyridyl nucleus contains an electron-withdrawing nitro substituent, nor when enehydrazine formation is difficult (as is presumably the case for acetone 2-pyridylhydrazone).

EXPERIMENTAL

2-Pyridylhydrazones

Equimolecular quantities of 2-pyridylhydrazine (25) and the aldehyde or ketone were warmed on a water bath for 30 min, and then benzene was added and the water removed by azeotropic distillation. The hydrazones (Table I) were obtained in a crystalline form (except those from ethyl methyl ketone, isopropyl methyl ketone, and isobutyraldehyde) either directly or after distillation under reduced pressure.

Indolization Procedure

In a typical experiment the hydrazone (3 g) was dissolved in a suitable solvent (30 ml) and the mixture boiled under reflux. After the mixture was cooled, it was poured into ice water and the oil crystallized. Recrystallization (charcoal) gave colorless crystals (Table II). (Analytical samples were sublimed under reduced pressure.)

2-(5-Nitropyridyl)hydrazine

Hydrazine hydrate (98%, 4 g) was added to 2-chloro-5-nitropyridine (3.2 g) (26) dissolved in ethanol (100 ml) and the mixture refluxed gently for 8 h. After the mixture was cooled, the solid was filtered off and crystallized from a large volume of ethanol as yellow prisms (2.1 g), m.p. 199–200° (27).

2-(5-Nitropyridyl)hydrazones

The aforementioned hydrazine and a small excess of the ketone were mixed in ethanol and then heated on a boiling water bath for 1 h.

Ethyl methyl ketone 2-(5-nitropyridyl)hydrazone was crystallized from a small volume of ethanol as yellow needles, m.p. 92–93°.

Anal. Calcd. for $C_9H_{12}N_4O_2$: C, 52.0; H, 5.78. Found: C, 52.3; H, 5.53.

Cyclohexanone 2-(5-nitropyridyl)hydrazone was crystallized from ethanol as yellow needles, m.p. 114–116°.

Anal. Calcd. for $C_{11}H_{14}N_4O_2$: C, 55.5; H, 5.99. Found: C, 55.2; H, 6.17.

ACKNOWLEDGMENT

We are grateful to the Newcastle-upon-Tyne Education Committee for the award of a research studentship to A. H. K.

THE ESSENTIAL OIL OF ILLICIUM ANISATUM LINN.

W. B. Cook and A. S. Howard
Department of Chemistry, Montana State University, Bozeman, Montana

Received June 13, 1966

ABSTRACT

The oil of the Japanese star anise tree, *Illicium anisatum* Linn., was analyzed by gas–liquid chromatography. The major constituents were found to be cineole (18.1%), linalool (10.1%), methyleugenol (9.8%), α-terpenyl acetate (6.8%), safrole (6.6%), and a sesquiterpene hydrocarbon of unknown constitution (7.2%). The composition of this oil differs widely from that of the commercially used star anise oil obtained from *Illicium verum* Hooker. The most striking difference between the two oils is found in the anethole content, which constitutes 88% of the commercial oil but only 1.2% of the oil here investigated.

INTRODUCTION

The Japanese star anise tree, *Illicium anisatum* Linn. (botanical synonym *Illicium religiosum* Sieb. and Zucc. (1)) is commercially cultivated for the fruit, which is used in the preparation of incense sticks and mixed with the fruit of the Chinese star anise tree as a spice in cooking (2, p. 378). It has long been known, however, that the fruit has poisonous properties, and the structure of the active principle, anisatin, has recently been elucidated by Yamada *et al.* (3). In connection with other investigations on this plant, we recently separated the steam-volatile oil and here report its composition.

The oil of *Illicium anisatum* has not been used much commercially (2, p. 378), but that of the botanically closely related Chinese star anise tree, *Illicium verum* Hooker, is widely used. It has been known for many years (2, p. 373) that the major constituent of the Chinese oil is *trans*-anethole (approximately 90%). Recently, Porsch *et al.* (4) analyzed the oil by gas chromatographic techniques and identified a further 17 compounds, most of which were monoterpene hydrocarbons. The general characteristics of the Japanese oil have been reported (5, 6) and a few compounds identified (7), but no detailed investigation appears to have been performed. It was with this object in mind that the present study was undertaken.

EXPERIMENTAL

Apparatus

Analytical gas chromatograms were carried out on an F & M Biomedical gas chromatograph, model 400, equipped with a flame ionization detector and a Disc integrator. Preparative gas chromatography was performed on an Aerograph model A-700 "Autoprep".

Infrared spectra were recorded with a Beckman IR-4 infrared spectrophotometer. The samples were mounted as liquid films between salt plates or in a 0.025 mm path length mercury amalgam cell. In the cases of some of the minor constituents, the samples were measured as carbon tetrachloride solutions in a 0.1 mm path length cavity cell. Nuclear magnetic resonance spectra were measured in carbon tetrachloride or deuteriochloroform solutions on a Varian model A-60 analytical nuclear magnetic resonance spectrometer.

Analytical gas chromatography was performed with 180 cm by 0.4 cm internal diameter glass columns. The solid support in each case was 100–120 mesh Gas Chrom Q, and the following liquid phases were used: Carbowax 20 M, SE 30, S.A.I.B., and F.F.A.P., each 16% (w/w); Hyprose SP 80, 4.5% (w/w); and β,β′-oxidipropionitrile, 20% (w/w). For the preparative work, a 10 ft × $\frac{3}{8}$ inch aluminium column packed with 20% (w/w) Carbowax 20 M on 60–80 mesh potassium hydroxide washed Chromosorb W and a 20 ft × $\frac{1}{4}$ inch copper column containing 20% (w/w) β,β′-oxidipropionitrile on 60–80 mesh acid-washed Chromosorb W were used. Samples were collected by passing the effluent gas through a U-tube suspended in a liquid air bath or by bubbling it through a solvent, usually pentane, cooled in an acetone – dry ice bath.

Isolation of the Oil

The dried seeds and husks (1 kg), obtained from the Applications Development Corporation, Washington, D.C., were ground to a powder and steam-distilled in the normal manner. The distillate, saturated with sodium chloride and extracted with ether, yielded, after it was dried over sodium sulfate and the solvent

removed, 4.5 g (0.45%) of a harsh-smelling yellow oil. This was separated into neutral (96%) and acidic (4%) fractions by extraction of an ethereal solution with 5% sodium carbonate.

Oils obtained separately from the seeds and husks showed only minor quantitative differences in some of the constituents.

Percentage Composition

This was calculated from the areas under the peaks, measured with a Disc integrator, in temperature-programmed runs using the Carbowax column and an Aerograph 200 equipped with a thermal conductivity detector. The results are the average of five runs. When compounds were not resolved under these conditions, the relative amounts of these particular compounds were obtained using different conditions or columns.

Preliminary Fractionation

The oil (1.00 g) was dissolved in pentane and adsorbed onto a column of silicic acid (15 g) deactivated with Carbowax 20 M (2% w/w), and the hydrocarbon fraction (230 mg) was eluted with pentane (120 ml). Further development with ethyl acetate (100 ml) and methanol (70 ml) eluted the oxygenated compounds (762 mg). Collection of the ethyl acetate eluent in smaller fractions allowed the partial separation of the esters and ethers from the alcohols.

Separation into Individual Compounds

This was performed by means of preparative gas–liquid chromatography under optimum conditions of temperature, gas flow rate, and amount of material injected.

Hydrocarbons

Initially, these were divided into monoterpene and sesquiterpene fractions on the Carbowax 20 M column. Separation into individual compounds was done on either of the preparative columns. The β,β'-oxidipropionitrile column was particularly useful in the separation of the monoterpenes.

Oxygenated Compounds

These were separated on the Carbowax column.

Identification of Compounds

In all cases, the purity of the isolated materials was checked on at least two of the analytical columns, and unless otherwise specified, all identifications are based on the comparison of the infrared spectrum of the isolated compound with that of an authentic specimen. In the cases where identifications are based on the retention times, at least three analytical columns were used.

The Acid Fraction

This was analyzed on the 16% F.F.A.P. column at 152 °C. The compounds were identified by comparison of their retention times with those of authentic acids.

RESULTS AND DISCUSSION

Originally, the separation of the oil into hydrocarbons and oxygenated compounds was performed according to the procedure of Kugler and Kovats (8). However, under these conditions, considerable losses of materials, in particular the monoterpene hydrocarbons, resulted, and it was necessary to increase the amount of impregnated Carbowax 20 M to 2% (w/w). Under these conditions, a clean separation was obtained and no significant loss of material or isomerization was observed.

Analysis of the acidic fraction of the oil indicated that only simple aliphatic acids were present. Straight-chain acids from C_2 to C_6 inclusive and isobutyric and isovaleric acids were identified.

The complex composition of the neutral fraction is illustrated in Fig. 1, and Table I provides a summary of the percentages of the individual components. A comparison between these results and those of Porsch *et al.* (4) for the oil of *Illicium verum* reveals that very considerable differences exist. The most striking of these is in the anethole content, which is 1.2% in the present case and 88% in the Chinese oil. This clearly indicates why the Japanese oil is not an acceptable substitute for the Chinese variety. Other aromatic ethers (peaks 23, 24, 27, and 29) constitute approximately 21% of the Japanese oil, and it is interesting to note that they all contain the allyl rather than the propenyl side chain found in anethole (1-methoxy-4-propenylbenzene). The major differences in composition between the two oils are summarized in Table II.

14*a*	Sesquiterpene hydrocarbon	1.3			

*Peak numbers are those shown in Fig. 1. Where the peaks contain more than one compound, this is indicated by the letters *a* and *b*.
†Identified by means of relative retention times and thin-layer chromatography according to Attaway *et al.* (9).
‡Identified by interpretation of their infrared and nuclear magnetic resonance spectra. No authentic specimens were available.

TABLE II

Main differences in the composition of Japanese and Chinese star anise oils

Compound	% content	
	Japanese oil	Chinese oil
Cineole	18.1	0.5
Linalool	10.1	1.0
α-Terpenyl acetate	6.8	Nil
trans-Anethole	1.2	88.0
Safrole	6.6	Nil
Methyleugenol	9.8	Nil

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

As can be seen from Table I, sesquiterpene hydrocarbons (peaks 10, 11, 13, 14*a*, 15, 18*a*, and 20) make up approximately 15% of the oil, and small samples of all of these compounds have been isolated in a pure state. On the basis of the information available at present, it appears that these compounds are not the bisabolenes and cadinenes reported to be present in the oil of *Illicium verum* (4), and it seems probable that at least some of them are new compounds. The constitutions of these compounds will be the subject of a later publication.

ACKNOWLEDGMENTS

Support of this work by a grant from the Geschickter Fund for Medical Research is gratefully acknowledged. In addition, the National Science Foundation is to be thanked for grant No. GP-3632 to cover the purchase of the Aerograph model A-700 "Auotprep". Finally, the authors are indebted to Messrs. Fritzsche Brothers, Inc., Hercules Powder Co., The Glidden Company, and Givaudan Corporation for the supply of numerous terpene samples.

THIAZOLOISOQUINOLINES

I. THE SYNTHESIS OF THIAZOLO[4,5-*c*]ISOQUINOLINE[1]

CATHERINE E. HALL[2] AND ALFRED TAURINS
Department of Chemistry, McGill University, Montreal, Quebec

Received May 13, 1966

ABSTRACT

Thiazolo[4,5-*c*]isoquinoline (I), a new heterocyclic ring system, has been synthesized from 3-aminoisoquinoline (II) in four steps by reaction with potassium thiocyanate and bromine to give 3-amino-4-thiocyanoisoquinoline (VII), cyclization with hydrochloric acid to yield 2-aminothiazolo[4,5-*c*]isoquinoline (VIII), Sandmeyer reaction to give 2-chlorothiazolo-[4,5-*c*]isoquinoline (IX), and finally reduction with hydrogen iodide and red phosphorus to yield I. The attempted preparation of I via 3-amino-4-bromoisoquinoline was unsuccessful. Various 2-substituted derivatives of I were prepared by nucleophilic displacement of the chlorine atom in 2-chlorothiazolo[4,5-*c*]isoquinoline. The nuclear magnetic resonance and ultraviolet spectra of I and some of its derivatives were studied.

INTRODUCTION

Although all four isomers of thiazolopyridines (1–8) and many of the isomers of thiazoloquinolines (9–16) are known, thiazoloisoquinolines, of which eight isomers are possible, have remained an unknown class of heteroaromatic compounds, even in the form of derivatives. However, some thiazoloisoquinolinium compounds are known (17, 18). The synthesis of various isomers of thiazoloisoquinolines was undertaken to study the chemical, physical, and spectral properties of this new class of compounds. The first isomer chosen was thiazolo[4,5-*c*]isoquinoline (I).

RESULTS AND DISCUSSION

The preparation of thiazolopyridines and thiazoloquinolines is usually accomplished by reaction of the appropriate *o*-aminoarylthiol with carboxylic acids or their derivatives, such as the acid chlorides or the anhydrides (2, 5, 8, 10–12). The cyclization of *o*-thiocyanoarylamines to yield 2-aminothiazolo compounds has also been used (1, 13, 14). The former method was first chosen for the synthesis of thiazolo[4,5-*c*]isoquinoline (I), but difficulties were encountered in the attempted preparation of the intermediate 3-aminoisoquinoline-4-thiol (III).

The preparation of III was attempted with 3-amino-4-bromoisoquinoline as an intermediate. The method of Johnson and Nasutavicus (19) was used to prepare 3-aminoisoquinoline (II) from 2-cyanobenzyl cyanide. Bromination of II with bromine in carbon tetrachloride gave a 73% yield of 3-amino-4-bromoisoquinoline (IV). The bromine atom was proven to be in the 4-position in IV by infrared and nuclear magnetic resonance (n.m.r.) spectral evidence. In the infrared, a strong band at 750 cm^{-1}, indicative of an *o*-disubstituted benzene ring, showed that the bromine atom was in the heterocyclic ring. Since the resulting compound was different from the known 3-amino-1-bromoisoquinoline (19), it must be 3-amino-4-bromoisoquinoline. Comparison of the n.m.r. spectrum of IV

with that of 3-aminoisoquinoline confirmed this assignment (Figs. 1A and 1B). 3-Aminoisoquinoline (II) shows a singlet at 1.15 τ for proton 1, a complex multiplet at 2.16 to 2.95 τ for the four protons on the carboxylic ring (H-5, H-6, H-7, and H-8), a singlet at 3.31 τ for the proton ortho to the amino group (H-4), and a broad singlet at 5.65 τ for the amino group protons. 3-Amino-4-bromoisoquinoline (IV) has a singlet at 1.38 τ for proton 1, a multiplet at 2.18 to 3.00 τ for the carboxylic ring protons, and a broad singlet at 5.00 τ for the amino group protons. Loss of the singlet at 3.31 τ, corresponding to proton 4 in II, proves that the bromine atom must be in the 4-position in IV.

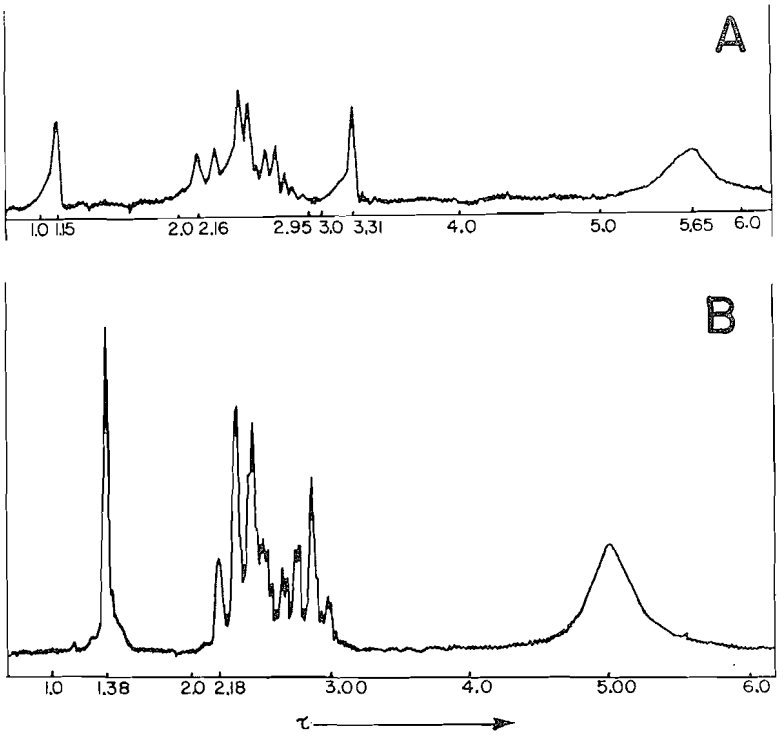

FIG. 1. The n.m.r. spectra (in $DCCl_3$) of (A) 3-aminoisoquinoline and (B) 3-amino-4-bromoisoquinoline.

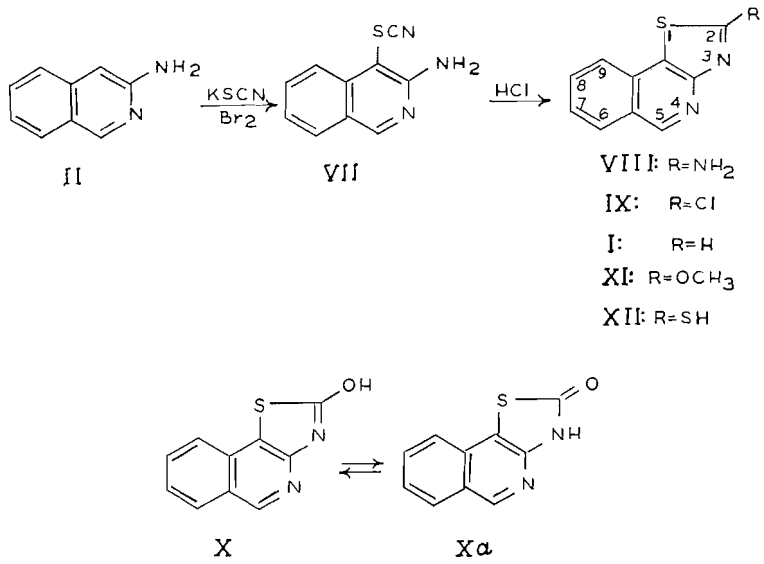
Acetylation of 3-amino-4-bromoisoquinoline with acetic anhydride in the presence of pyridine gave a mixture of 3-monoacetamido-4-bromoisoquinoline (V) and 3-*N*,*N*-diacetylamino-4-bromoisoquinoline (VI). The infrared spectrum of V showed a strong band at 1 663 cm^{-1} (C=O stretching) and a medium-intensity band at 3 240 cm^{-1} (N—H stretching). Its n.m.r. spectrum (in a $CDCl_3$ and $(CD_3)_2SO$ mixture) exhibited a singlet at 1.04 τ for H-1, a multiplet at 1.88 to 2.61 τ for the four aromatic protons of the benzenoid ring plus the proton on the acetamido nitrogen, and a singlet at 7.60 τ for the methyl protons. After exchange with deuterium oxide, one proton was lost from the aromatic region (1.88 to 2.61 τ), thus confirming that the amide proton absorbed in this region.



The attempted reaction of 3-acetamido-4-bromoisoquinoline (V) with thiourea to obtain 3-acetamidoisoquinoline-4-thiol was unsuccessful.

The infrared spectrum of 3-*N*,*N*-diacetylamino-4-bromoisoquinoline (VI) had a strong doublet at 1 705 and 1 725 cm^{-1} in the solid state (KBr pellet), but only a single strong

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

band at 1 725 cm^{-1} in either carbon tetrachloride or carbon disulfide solution. The n.m.r. spectrum of VI (in $CDCl_3$) exhibited a singlet at 0.94 τ for H-1, a complex multiplet at 1.80 to 2.43 τ for the four remaining aromatic protons, and a sharp singlet at 7.78 τ for the six methyl protons.

The synthesis of thiazolo[4,5-*c*]isoquinoline (I) was successfully accomplished via 3-amino-4-thiocyanoisoquinoline (VIII) (Reaction Scheme 1). The latter was obtained by the reaction of 3-aminoisoquinoline with potassium thiocyanate and bromine (20). The structure of VII was proven by infrared and n.m.r. spectroscopy. Thus, its infrared spectrum showed a strong band at 753 cm^{-1} characteristic of an *o*-disubstituted benzene ring, as well as a band at 2 143 cm^{-1} for the thiocyano group (21) and bands at 3 433 and 3 270 cm^{-1} for the amino group. In the n.m.r. spectrum of 3-amino-4-thiocyanoisoquinoline (VII) (in chloroform-*d* solution), a singlet at 1.29 τ was assigned to proton 1, a complex multiplet at 2.03 to 2.96 τ to the four benzenoid ring protons, and a broad singlet at 4.65 τ to the amino group protons.

REACTION SCHEME 1.

The cyclization of the thiocyano and amino groups in compound VII was achieved by refluxing VII in aqueous ethanolic hydrochloric acid. The resulting 2-aminothiazolo-[4,5-*c*]isoquinoline (VIII) was obtained in a 73% yield. Diazotization of VIII followed by reaction with cuprous chloride gave 2-chlorothiazolo[4,5-*c*]isoquinoline (IX). Reduction of IX with hydriodic acid and red phosphorus produced the parent compound of this series, thiazolo[4,5-*c*]isoquinoline (I). The n.m.r. spectrum of I (Fig. 2) exhibits a doublet at 0.87 and 0.92 τ with an area corresponding to two protons (assigned to H-2 and H-5), and a complex ABCD pattern of bands at 1.93 to 2.64 τ with an area corresponding to four protons of the benzenoid ring. It is not possible to state definitely whether H-2 absorbs at lower field than H-5, or vice versa. It was noted that, in the n.m.r. spectrum of I recorded in an acetone solution, the band for one of these protons moves downfield more than the other (two peaks at 0.44 and 0.60 τ).

The preparation of other 2-substituted derivatives of thiazolo[4,5-*c*]isoquinoline was accomplished by displacement of the chlorine atom of IX with various nucleophilic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

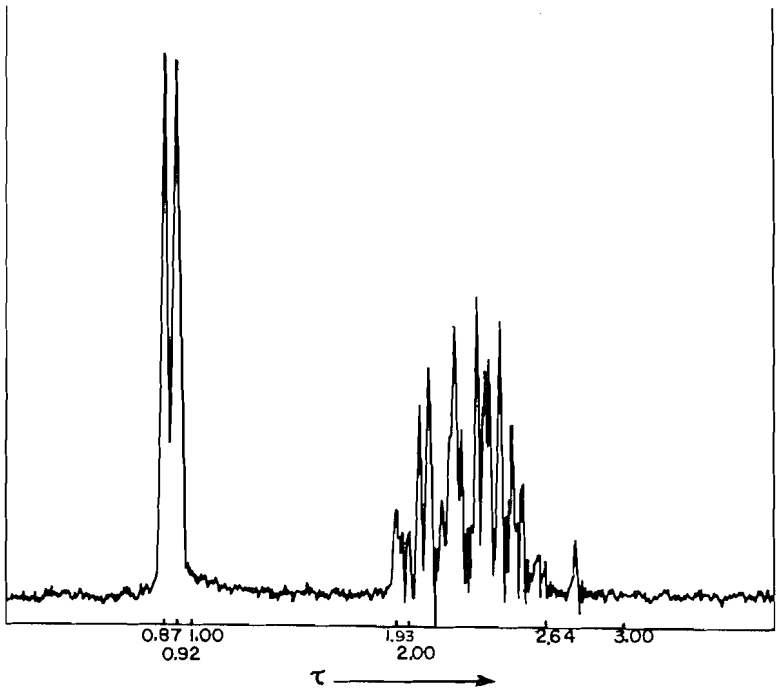


FIG. 2. The n.m.r. spectrum of thiazolo[4,5-*c*]isoquinoline (in $DCCl_3$).

reagents. For example, reaction of IX with sodium hydroxide gave the 2-hydroxy derivative X, and reaction of IX with sodium methoxide gave the 2-methoxy derivative XI. Reaction of IX with thiourea yielded the 2-mercapto derivative XII. The 2-hydroxythiazolo[4,5-*c*]isoquinoline (X) was shown, by infrared and other evidence (which will be the subject of a future publication in this series), to exist mainly in the lactam form X*a* rather than the hydroxy form. By analogy, 2-mercaptothiazolo[4,5-*c*]isoquinoline (XII) also probably exists as the thiolactam.

The chemical shifts of the protons of I and some of its derivatives are summarized in Table I. In all the compounds studied, the proton on the carbon atom adjacent to the heterocyclic nitrogen atom absorbs at lower field than the benzenoid protons. This is in agreement with the observations of other workers (22).

TABLE I

Proton chemical shifts of thiazolo[4,5-*c*]isoquinoline and some 2-substituted derivatives

Compound	Solvent	Chemical shift (τ)			
		H-2	H-5	H-6, H-7, H-8, H-9	Other
Thiazolo[4,5-*c*]-isoquinoline	$CDCl_3$	0.87 or 0.92	0.87 or 0.92	1.93 to 2.64	—
Thiazolo[4,5-*c*]-isoquinoline	Acetone	0.44 or 0.60	0.44 or 0.60	1.48 to 2.37	—
Derivatives					
2-Chloro	$CDCl_3$	—	0.73	1.81 to 2.38	—
2-Chloro	CH_3SOCH_3	—	0.50	1.46 to 2.22	—
2-Amino	CH_3SOCH_3	—	0.83	1.73 to 2.46	NH_2*
2-Hydroxy	CD_3SOCD_3	—	1.05	1.95 to 2.64	−2.58 (NH)
2-Methoxy	$CDCl_3$	—	0.78	1.80 to 2.59	5.62 (OCH_3)

*Superimposed upon the H-5, H-6, H-7, and H-8 bands.

The ultraviolet spectra of thiazolo[4,5-*c*]isoquinoline and its 2-substituted derivatives (Table II) generally show three groups of absorption bands, which are classified as the α-, *p*-, and β-bands (23). All the bands of I occur at longer wavelengths than do the corresponding bands of isoquinoline (α-band, 319 mμ and 308 mμ; *p*-band, 268 mμ; β-band, 220 mμ (24)). Annealing the thiazole ring to benzene, quinoline, and naphthalene similarly results in a bathochromic displacement of the bands from those of the parent compounds (25, 26). Electron-donating substituents, such as chlorine, give rise to bathochromic displacements of all the bands of the parent compound (I), as expected.

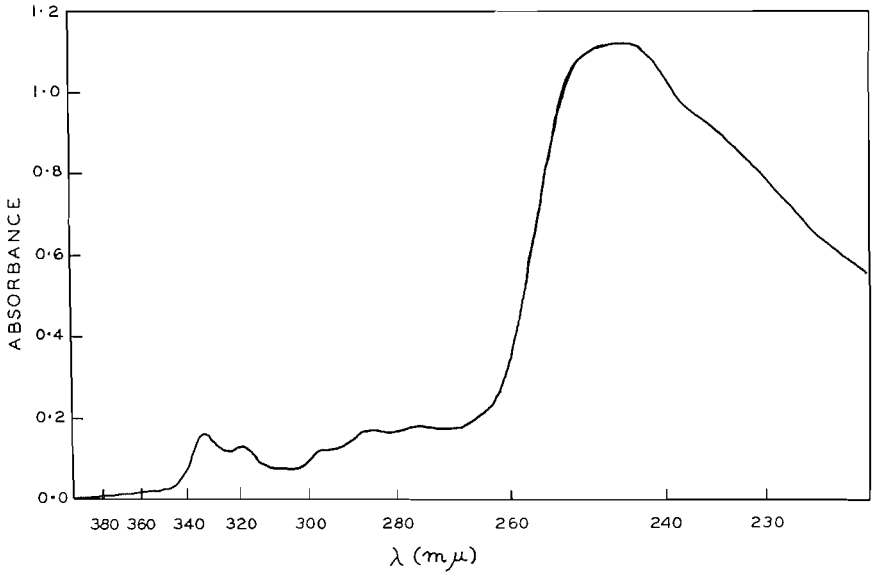

FIG. 3. The ultraviolet spectrum of thiazolo[4,5-*c*]isoquinoline (in ethanol).

EXPERIMENTAL

Melting points were determined on a Gallenkamp melting point apparatus and are corrected. Infrared spectra were recorded on a Perkin–Elmer model 421 grating spectrophotometer in KBr disks. Ultraviolet spectra were obtained on a Perkin–Elmer model 350 spectrophotometer with absolute ethanol as solvent. Nuclear magnetic resonance spectra were determined on Varian high-resolution n.m.r. spectrometers, model HR-60 or model A60. Solvents used for the n.m.r. work were chloroform-*d*, dimethyl sulfoxide, and dimethyl sulfoxide-d_6; tetramethylsilane was used as an internal reference. Elemental analyses were carried out by Dr. C. Daesslé, Montreal, and by A. Bernhardt, Mülheim, Germany.

Preparation of 3-Amino-4-bromoisoquinoline (IV)

3-Aminoisoquinoline (2.90 g, 0.02 mole) was dissolved in 100 ml of glacial acetic acid in a 500 ml three-necked flask equipped with an air condenser, a dropping funnel, and a mechanical stirrer. To this stirred solution was added dropwise, over 45 min, 210 ml of 0.1 *M* bromine solution in carbon tetrachloride.

The reaction mixture was stirred for an additional 5 min and then poured into 500 ml of a sodium acetate solution. The organic layer was separated and the aqueous layer extracted once with carbon tetrachloride. The organic extract was dried over sodium sulfate and filtered, and the solvent was evaporated, leaving 4.46 g of a black solid. Crystallization from hexane gave 3.25 g (73% yield) of 3-amino-4-bromoisoquinoline (IV) as yellow needles, m.p. 120.5–122°.

Anal. Calcd. for $C_9H_7BrN_2$: C, 48.46; H, 3.16; Br, 35.83; N, 12.55. Found: C, 48.24; H, 3.01; Br, 35.71; N, 12.61.

Acetylation of 3-Amino-4-bromoisoquinoline

3-Amino-4-bromoisoquinoline (2.32 g, 0.01 mole) was dissolved in a mixture of 32 ml of acetic anhydride and 16 ml of pyridine, and the resulting solution was heated at 90–95° for 4 h. It was cooled to room temperature and poured into an excess of dilute ammonium hydroxide solution, whereupon a crystalline substance

*Because of very low solubility, log ϵ could not be calculated.

precipitated. This was filtered off to yield 1.33 g (43% yield) of tan needles, m.p. 105–108°. Recrystallization from hexane gave colorless needles of the diacetyl derivative VI, m.p. 107–108.5°.

Anal. Calcd. for $C_{13}H_{11}BrN_2O_2$: C, 50.83; H, 3.61; N, 9.12. Found: C, 50.57, 50.73; H, 3.15, 3.33; N, 9.48, 9.41.

Evaporation of most of the filtrate from the crude reaction product above yielded 1.22 g (46% yield) of the monoacetyl derivative V as colorless needles, m.p. 166–168° (crystallized from ethanol).

Anal. Calcd. for $C_{11}H_9BrN_2O$: C, 49.83; H, 3.42; N, 10.57. Found: C, 49.83, 49.74; H, 3.11, 3.35; N, 10.80, 10.60.

Attempted Reaction of 3-Acetamido-4-bromoisoquinoline (V) with Thiourea

3-Acetamido-4-bromoisoquinoline (0.50 g, 0.0019 mole) was refluxed with 0.17 g (0.0022 mole) of thiourea in 15 ml of absolute ethanol for 7 h. Evaporation of the solvent and recrystallization of the residue from ethanol gave colorless needles, m.p. 165–168°, the infrared spectrum of which was identical with that of the starting 3-acetamido-4-bromoisoquinoline.

Preparation of 3-Amino-4-thiocyanoisoquinoline (VII)

3-Aminoisoquinoline (12.9 g, 0.09 mole) and potassium thiocyanate (34.8 g, 0.36 mole) were dissolved in 165 ml of 95% acetic acid in a 500 ml three-necked flask equipped with a mechanical stirrer, a reflux condenser, and a dropping funnel. The resulting solution was cooled to −5 to −10°, and bromine (5.10 ml, 0.09 mole) in 25 ml of 95% acetic acid was added dropwise to the stirred solution over a period of 35 min. After the reaction mixture was stirred for a further 15 min, it was poured into 1 500 ml of water. The resulting precipitate was filtered off and recrystallized from ethanol to give 11.74 g (65% yield) of 3-amino-4-thiocyanoisoquinoline as yellow needles, m.p. 158.5–160.5°. Two more recrystallizations from ethanol gave pale-yellow needles, m.p. 163–164°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88. Found: C, 59.84; H, 3.67; N, 20.77.

When the original reaction mixture was allowed to stand overnight at room temperature, no cyclization of 3-amino-4-thiocyanoisoquinoline to 2-aminothiazolo[4,5-*c*]isoquinoline (VIII) was observed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Preparation of 2-Aminothiazolo[4,5-c]isoquinoline (VIII)

3-Amino-4-thiocyanoisoquinoline (11.8 g, 0.06 mole) was dissolved in 900 ml of boiling ethanol, and 510 ml of 15% hydrochloric acid was added. The resulting solution was refluxed for 6 h. It was cooled to room temperature, diluted with 1 500 ml of water, and basified with solid sodium carbonate. The resulting precipitate was filtered off, dried, and washed with benzene to yield 8.57 g (73% yield) of yellow needles. Recrystallization from a large volume of benzene gave VIII as colorless needles, m.p. 240–242°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88. Found: C, 59.87; H, 3.54; N, 20.76.

The acetyl derivative of VIII was prepared by refluxing VIII (1.00 g, 0.005 mole) in a mixture of 16 ml of acetic anhydride and 8 ml of pyridine for 5 h. The starting material did not appear to dissolve, but a new insoluble product was formed. Filtration of the cooled reaction mixture gave 0.85 g (75% yield) of tan needles, m.p. 326.7°. Recrystallization from absolute ethanol gave pale-tan needles of the monoacetyl derivative of VIII, m.p. 327–328°.

Anal. Calcd. for $C_{12}H_9N_3OS$: C, 59.24; H, 3.73; N, 17.27; S, 13.18. Found: C, 59.34; H, 3.51; N, 17.53; S, 13.03.

Preparation of 2-Chlorothiazolo[4,5-c]isoquinoline (IX)

Cuprous chloride was prepared in the usual manner from 1.32 g of sodium chloride, 6.00 g of hydrated cupric sulfate, 1.08 g of sodium bisulfite, and 0.72 g of sodium hydroxide, and was dissolved in 10 ml of concentrated hydrochloric acid.

2-Aminothiazolo[4,5-*c*]isoquinoline (2.40 g, 0.012 mole) was dissolved in a mixture of 80 ml of 85% phosphoric acid and 20 ml of 70% nitric acid, and then cooled to 0–5°. Sodium nitrite (0.88 g, 0.013 mole) in 8 ml of water was added over a 15 min period to the cooled stirred solution. The reaction mixture was stirred for another 20 min at 0–5°. The cold diazonium solution was then added over 20 min, with stirring, to the cuprous chloride solution at 0–5°. A vigorous reaction occurred during the addition. The reaction mixture was stirred for 1 h longer at room temperature. It was then basified with 10% sodium hydroxide solution, with cooling, and the basic mixture extracted with three 200 ml portions of ether. The organic extract was dried over sodium sulfate and the solvent evaporated, leaving 1.53 g of an oily brown solid. Extraction of this solid with boiling hexane gave 1.20 g (45% yield) of pale-yellow 2-chlorothiazolo[4,5-*c*]isoquinoline (IX), m.p. 114–117°. Recrystallization from hexane followed by vacuum sublimation gave colorless crystals of IX, m.p. 116.5–118°.

Anal. Calcd. for $C_{10}H_5ClN_2S$: C, 54.42; H, 2.28; Cl, 16.07; N, 12.70. Found: C, 54.36; H, 2.13; Cl, 15.97; N, 12.59.

Preparation of Thiazolo[4,5-c]isoquinoline (I)

2-Chlorothiazolo[4,5-*c*]isoquinoline (0.51 g, 2.3 mmoles) was dissolved in a mixture of 8 ml of 47% hydriodic acid, 4 ml of water, and 4 ml of acetic acid, and 0.28 g of red phosphorus was added. The resulting mixture was refluxed for 3½ h. It was cooled to room temperature, diluted with 250 ml of water, and filtered. The filtrate was basified with solid sodium carbonate and extracted with two 200 ml portions of ether. After the extract was dried over sodium sulfate, the ether was evaporated, leaving 0.39 g (91% yield) of a tan solid. Chromatography of 0.21 g of this material on 10 g of alumina (Woelm, activity 1) with benzene–ether (1:1) as eluent gave 0.18 g of a colorless solid. Recrystallization from hexane gave colorless needles of thiazolo-[4,5-*c*]isoquinoline (I), m.p. 117–118°.

Anal. Calcd. for $C_{10}H_6N_2S$: C, 64.49; H, 3.25; N, 15.05. Found: C, 64.68; H, 3.50; N, 15.08.

2-Hydroxy[4,5-c]isoquinoline (X)

2-Chlorothiazolo[4,5-*c*]isoquinoline (0.16 g, 0.7 mmole) was refluxed in 30 ml of 0.1 *N* sodium hydroxide solution for 5 h. The resulting solution was filtered while hot, cooled to room temperature, and acidified with dilute acetic acid. The flocculent precipitate was filtered off, washed with water, and dried to give 0.11 g (79% yield) of a tan solid, m.p. 285–285.5°. Recrystallization from ethanol–water gave pale-yellow needles of 2-hydroxythiazolo[4,5-*c*]isoquinoline (X), m.p. 286.7°.

Anal. Calcd. for $C_{10}H_6N_2OS$: C, 59.38; H, 2.99; N, 13.85; S, 15.86. Found: C, 59.34; H, 3.20; N, 13.87; S, 15.79.

2-Methoxy[4,5-c]isoquinoline (XI)

2-Chlorothiazolo[4,5-*c*]isoquinoline (0.20 g, 0.9 mmole) was dissolved in 15 ml of absolute methanol, and a solution of 0.05 g (1.2 mmoles) of sodium in 5 ml of absolute methanol was added. After the mixture was stirred at room temperature for 1 h, the clear-yellow solution was neutralized with dilute acetic acid, diluted with water, and dried to give 0.15 g (79% yield) of 2-methoxythiazolo[4,5-*c*]isoquinoline, m.p. 147–148.5°. Recrystallization from methanol gave pale-yellow needles, m.p. 149.5–150.5°.

Anal. Calcd. for $C_{11}H_8N_2OS$: C, 61.09; H, 3.73; N, 12.96; S, 14.83. Found: C, 61.04; H, 3.51; N, 13.11; S, 14.76.

Thiazolo[4,5-c]isoquinoline-2-thiol (XII)

A solution of 2-chlorothiazolo[4,5-*c*]isoquinoline (0.20 g, 0.9 mmole) and thiourea (0.10 g, 1.3 mmoles) in 10 ml of ethanol was refluxed for 1 h. The reaction mixture was cooled to room temperature and filtered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The crystalline precipitate was dissolved in 40 ml of 1 *N* sodium hydroxide solution and filtered. Acidification of the filtrate with acetic acid gave a flocculent precipitate, which was filtered off, washed with water, and dried to give 0.14 g (70% yield) of pale-yellow thiazolo[4,5-*c*]isoquinoline-2-thiol, m.p. 323–326°. After this compound was dissolved in sodium hydroxide again and reprecipitated with acetic acid, the melting point was 324–326°.

Anal. Calcd. for $C_{10}H_6N_2S_2$: C, 55.03; H, 2.77; N, 12.84. Found: C, 55.05; H, 2.75; N, 12.80.

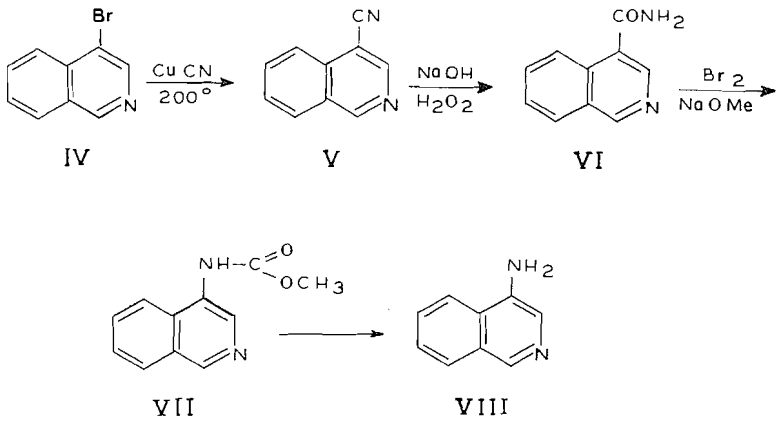
THIAZOLOISOQUINOLINES

II. THE SYNTHESIS OF THIAZOLO[5,4-*c*]ISOQUINOLINE[1,2]

CATHERINE E. HALL[3] AND ALFRED TAURINS
Department of Chemistry, McGill University, Montreal, Quebec

Received May 13, 1966

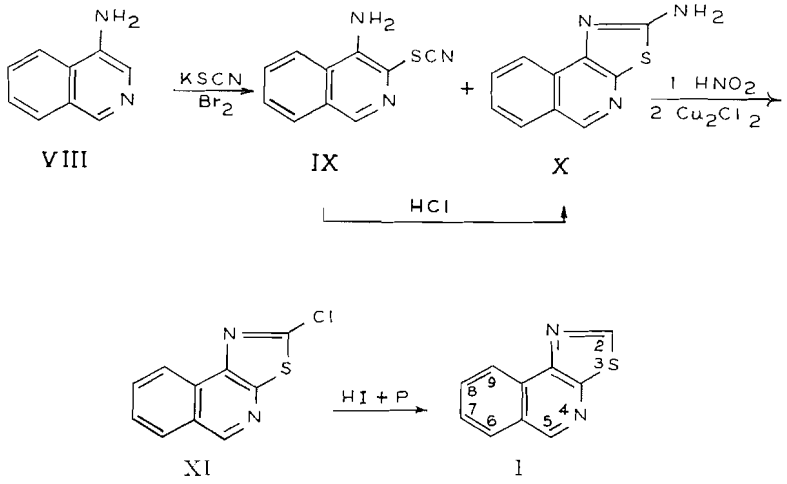
ABSTRACT



Thiazolo[5,4-*c*]isoquinoline (I) has been synthesized by cyclization of 4-amino-3-thiocyanoisoquinoline (IX) to 2-aminothiazolo[5,4-*c*]isoquinoline (X), which was converted into I via the 2-chloro derivative XI. Some 2-substituted derivatives of I were obtained by displacement of the chlorine atom in XI. The attempted preparation of 3-chloro-4-nitroisoquinoline as an intermediate in the synthesis of I was unsuccessful. Nuclear magnetic resonance and ultraviolet spectra of I and its derivatives were investigated.

In a continuation of our work on the synthesis of thiazoloisoquinolines, the preparation of thiazolo[5,4-*c*]isoquinoline (I) was undertaken. It was planned to arrive at I by cyclization (with formic acid) of 4-aminoisoquinoline-3-thiol, which could be prepared from 3-chloro-4-nitroisoquinoline (II) via 4-nitroisoquinoline-3-thiol. It was hoped that nitration of 3-chloroisoquinoline would yield the required 3-chloro-4-nitroisoquinoline. The starting material, 3-chloroisoquinoline, was prepared from homophthalimide (1) by way of 1,3-dichloroisoquinoline (2, 3). Nitration of 3-chloroisoquinoline with potassium nitrate in sulfuric acid gave a mononitro derivative which, from its nuclear magnetic resonance (n.m.r.) spectrum ($CDCl_3$), was established to be 3-chloro-5-nitroisoquinoline (III) rather than the desired 3-chloro-4-nitroisoquinoline (II). The singlet at 0.96 τ is attributed to proton 1, the multiplet at 1.43 to 1.54 τ to H-4 plus H-6, the doublet centered at 1.79 τ (J = 6.9 c.p.s.) to H-8, and the triplet centered at 2.37 τ (J = 6.9 c.p.s.) to H-7. The low-field absorption of H-4, caused by the diamagnetic anisotropy of the 5-nitro group, eliminates any position other than C-5 for the nitro group. In 5-nitroisoquinoline, H-4 was found to absorb in the region 1.1 to 1.4 τ, whereas in 3-chloroisoquinoline it appeared in the region 2.2 to 2.5 τ.

The infrared spectrum of III exhibited bands at 1 326 and 1 514 cm^{-1} (NO_2 group), 880 cm^{-1} (2,4,5-trisubstituted pyridine ring), and 686 and 760 cm^{-1} (1,2,3-trisubstituted benzene ring).



Since 3-chloro-4-nitroisoquinoline did not appear to be prepared as easily as originally envisaged, the synthesis of thiazolo[5,4-*c*]isoquinoline (I) via 4-aminoisoquinoline-3-thiol was abandoned in favor of the method involving 4-amino-3-thiocyanoisoquinoline (IX) as an intermediate (4). The synthesis of IX required 4-aminoisoquinoline (VIII) as a precursor; this compound was prepared as shown in Reaction Scheme 1. The conversion of isoquinoline into isoquinoline-4-carboxamide (VI) via the 4-bromo (IV) and 4-cyano (V) derivatives followed known procedures (5–7). The Hofmann rearrangement of VI with bromine and sodium hydroxide was unsuccessful and led to only resinous products. However, the use of bromine and sodium methoxide in methanol gave methyl isoquinoline-4-carbamate (VII), which was subsequently hydrolyzed to VIII with 93% sulfuric acid.

[1]*This work received financial assistance from the National Research Council of Canada, Ottawa. Taken from a portion of the Ph.D. Thesis of C. E. Hall.*

[3]*Holder of a National Research Council studentship, 1962–1963 and 1963–1964.*

REACTION SCHEME 1.

The conversion of 4-aminoisoquinoline (VIII) into thiazolo[5,4-*c*]isoquinoline (I) is shown in Reaction Scheme 2. Thiocyanation of VIII produced a mixture of 4-amino-3-thiocyanoisoquinoline (IX) (33% yield) and 2-aminothiazolo[5,4-*c*]isoquinoline (X) (21% yield). 4-Amino-3-thiocyanoisoquinoline (IX) was characterized by its infrared spectrum, which showed thiocyano absorption at 2 143 cm^{-1} (8), as well as bands at 755 cm^{-1} for an *o*-disubstituted benzene ring and 3 460, 3 315, and 3 210 cm^{-1} for a primary amino group. The n.m.r. spectrum of IX (in a $CDCl_3$ and $(CH_3)_2SO$ mixture) had a singlet at 1.50 τ for H-1, a multiplet at 1.66 to 2.42 τ for the carbocyclic ring protons, and a broad singlet at 3.98 τ for the amino group protons. The presence of the singlet at 1.50 τ for H-1 excluded the possibility that the thiocyano group could be in the 1-position.

REACTION SCHEME 2.

The infrared spectrum of 2-aminothiazolo[5,4-*c*]isoquinoline (X) no longer showed thiocyano absorption at 2 143 cm^{-1}; however, a primary amino group was indicated by bands at 3 050, 3 215, and 1 662 cm^{-1}. A band at 747 cm^{-1} showed the presence of an *o*-disubstituted benzene ring.

4-Amino-3-thiocyanoisoquinoline (IX) could be converted into 2-aminothiazolo[5,4-*c*]-isoquinoline (X) by refluxing it in aqueous–ethanolic hydrogen chloride. It is significant that X was formed in the original thiocyanation reaction, whereas none of the cyclized 2-aminothiazolo[4,5-*c*]isoquinoline was formed in the thiocyanation of 3-aminoisoquinoline even after the reaction mixture was allowed to stand overnight at room temperature (9). This is attributed to a decreased electron density about the amino nitrogen in the intermediate 3-amino-4-thiocyanoisoquinoline in the latter case, which inhibits the nucleophilic attack of this nitrogen on the carbon of the thiocyano group.

Diazotization of 2-aminothiazolo[5,4-*c*]isoquinoline (X) followed by reaction with cuprous chloride gave 2-chlorothiazolo[5,4-*c*]isoquinoline (XI). Reduction of XI with hydriodic acid and red phosphorus gave the unsubstituted thiazolo[5,4-*c*]isoquinoline (I), a new heteroaromatic parent compound.

Several other 2-substituted derivatives of I were prepared by reaction of the 2-chloro derivative XI with various nucleophiles. For example, reaction with sodium hydroxide gave the 2-hydroxy derivative XII, and reaction with sodium methoxide gave the 2-methoxy compound XIII. Reaction with thiourea produced the 2-mercapto derivative XIV. The 2-hydroxy derivative XII was shown, by infrared and other evidence (which will be presented in a future paper), to exist predominantly in the lactam form. By analogy, the 2-mercapto derivative XIV probably exists mainly as the thiolactam.

The chemical shifts in the proton magnetic resonance spectra of thiazolo[5,4-*c*]isoquinoline (I) and some of its 2-substituted derivatives are presented in Table I. The n.m.r. spectrum of the parent compound I (in $CDCl_3$) (Fig. 1) shows two singlets at 0.80 and 0.83 τ integrating for two protons, an octet centered at 1.27 τ integrating for one proton, and a multiplet at 1.80 to 2.47 τ integrating for three protons. The singlets at 0.80 and 0.83 τ are assigned to the protons on the carbon atoms adjacent to the heterocyclic nitrogen atoms (H-2 and H-5), the octet to H-9 of the carbocyclic ring, and the multiplet to the three remaining aromatic protons (H-6, H-7, and H-8). The difference in chemical shift between protons H-2 and H-5 is very small in deuteriochloroform, although this difference is increased somewhat in acetone. However, it was not ascertained which proton absorbed at lower field. A similar result was observed for the corresponding protons of the isomeric thiazolo[4,5-*c*]isoquinoline (9).

The four benzenoid protons of thiazolo[5,4-*c*]isoquinoline (I) exhibit an ABCX pattern in contrast to the corresponding protons of thiazolo[4,5-*c*]isoquinoline, which show an ABCD pattern (9). The X part of the spectrum of I and its derivatives occurs at lower field than the ABC part and is assigned to H-9. The 9-position of I is comparable to the 10-position of benzo[*f*]quinoline, in which H-10 absorbs at much lower field than the other aromatic protons (10). This deshielding was attributed to the field effect of the "angularly opposite" hetero atom (10).

The ultraviolet spectra of thiazolo[5,4-*c*]isoquinoline (I) (Fig. 2) and its 2-substituted derivatives (Table II) generally show three groups of absorption bands, which are classified as the α-, p-, and β-bands (11). All three bands of I occur at shorter wavelengths than do the corresponding bands of thiazolo[4,5-*c*]isoquinoline (9). This is especially notable in the short-wavelength β-band, and it may be attributed to the overall greater length of conjugation in thiazolo[4,5-*c*]isoquinoline. Both electron-donating and electron-withdrawing substituents in the 2-position of thiazolo[5,4-*c*]isoquinoline give bathochromic displacements of the bands as expected.

The work on the synthesis and properties of other thiazoloisoquinolines is being continued.

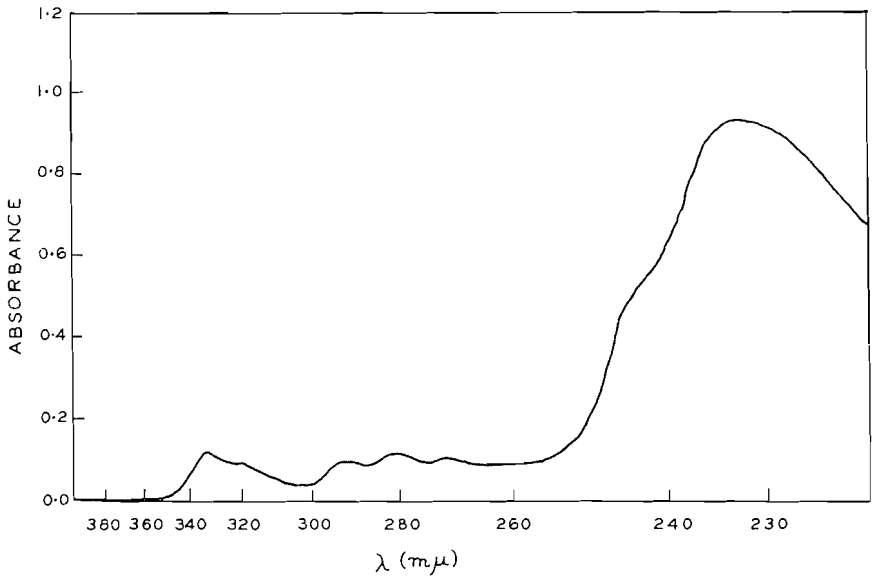

FIG. 2. The ultraviolet spectrum of thiazolo[5,4-*c*]isoquinoline (in ethanol).

EXPERIMENTAL

Melting points were determined on a Gallenkamp melting point apparatus and are corrected. Infrared spectra were recorded on a Perkin–Elmer model 421 grating spectrophotometer as KBr disks. Ultraviolet spectra were obtained on a Perkin–Elmer model 350 spectrophotometer with absolute ethanol as solvent. Nuclear magnetic resonance spectra were determined on Varian high-resolution n.m.r. spectrometers, model HR-60 or model A60. Solvents used were chloroform-*d*, dimethyl sulfoxide, and dimethyl sulfoxide-d_6. Tetramethylsilane was used as an internal standard. Elemental analyses were carried out by A. Bernhardt, Mülheim, Germany.

Nitration of 3-Chloroisoquinoline

3-Chloroisoquinoline (0.25 g, 1.5 mmoles) was dissolved in 4.0 ml of concentrated sulfuric acid, and potassium nitrate (0.19 g, 1.9 mmoles) in 3.0 ml of concentrated sulfuric acid was added dropwise to the stirred solution. The reaction mixture was stirred for 1 h at room temperature. It was then poured onto ice and basified with concentrated ammonium hydroxide solution, with cooling. Filtration yielded 0.30 g of a crude yellow product. Crystallization from hexane–benzene gave 0.23 g (74% yield) of 3-chloro-5-nitroisoquinoline (III) as pale-yellow needles, m.p. 162–164°. A second recrystallization raised the melting point to 163–165°.

Anal. Calcd. for $C_9H_5ClN_2O_2$: C, 51.81; H, 2.42; N, 13.43. Found: C, 51.75; H, 2.30; N, 13.22.

Hofmann Reaction of Isoquinoline-4-carboxamide (VI)

(a) In Sodium Hydroxide

Bromine (0.97 g, 0.006 mole) was added dropwise to 8 ml of a cooled (0–5°) stirred 10% sodium hydroxide solution. Isoquinoline-4-carboxamide (0.83 g, 0.005 mole) was added all at once to this cool, vigorously stirred solution. The reaction mixture was stirred for a further 15 min at this temperature, and was then heated to 55–70° and kept there for 25 min. During this time a black resinous material precipitated.

The reaction mixture was cooled to room temperature, and the resinous material was separated and dissolved in dilute sulfuric acid. The acid solution was filtered and the filtrate basified with solid sodium carbonate. The resulting flocculent precipitate was insoluble in boiling benzene, and thus was not the desired 4-aminoisoquinoline (10).

(b) In Methanol

Sodium methoxide was prepared by adding 19.5 g (0.85 mole) of sodium to 800 ml of absolute methanol in a 2 l three-necked flask equipped with a reflux condenser, a mechanical stirrer, and a dropping funnel. Isoquinoline-4-carboxamide (67.0 g, 0.39 mole) in 800 ml of absolute methanol was added all at once. Bromine (65.6 g, 0.41 mole) was then added dropwise to the stirred solution over a period of 13 min. The resulting solution was refluxed on the steam bath for 20 min.

The reaction mixture was cooled to room temperature and made just acidic with acetic acid, whereupon a small amount of a white solid precipitated. This was filtered off and dried *in vacuo* over calcium chloride to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

give 25.6 g of methyl isoquinoline-4-carbamate (VII), m.p. 201–206°. Evaporation of the filtrate left a brown residue which was washed with water, filtered, and dried to give another 36.3 g of a tan-colored product. The total yield of crude methyl isoquinoline-4-carbamate was thus 61.9 g (79% yield). Recrystallization from ethanol gave colorless needles, m.p. 205–206°.

Anal. Calcd. for $C_{11}H_{10}N_2O_2$: C, 65.33; H, 4.98; N, 13.86. Found: C, 65.31; H, 5.11; N, 13.81.

Preparation of 4-Aminoisoquinoline (VIII)

Methyl isoquinoline-4-carbamate (VII) (66.3 g, 0.32 mole) and water (15 ml) were placed in a 1 l round-bottomed flask, and 365 ml of concentrated sulfuric acid was added. The resulting dark mixture was heated at 110° for 21 h. It was cooled to room temperature and poured into an equal volume of water, with cooling. The resulting mixture was carefully basified with concentrated ammonium hydroxide solution and extracted with three 800 ml portions of benzene. The benzene extract was dried over sodium sulfate and filtered, and the solvent was evaporated, leaving a viscous brown oil which later solidified. Crystallization from benzene gave 18.1 g (39% yield) of tan-colored crystals of 4-aminoisoquinoline, m.p. 101–106°. Sublimation gave colorless needles, m.p. 104.5–106.5° (lit. (10) m.p. 108°).

Thiocyanation of 4-Aminoisoquinoline

4-Aminoisoquinoline (VIII) (17 g, 0.12 mole) and potassium thiocyanate (45.9 g, 0.47 mole) were dissolved in 245 ml of 95% acetic acid in a 500 ml three-necked flask equipped with a reflux condenser, a mechanical stirrer, and a dropping funnel. Bromine (6.8 ml, 0.12 mole) in 35 ml of 95% acetic acid was added to this stirred solution at −5 to −10° over a period of 40 min. The reaction mixture was stirred for a further 20 min at this temperature and then poured into 2 100 ml of water.

The resulting precipitate was filtered off to give an orange solid. Extraction of this solid with boiling benzene gave 2.70 g of yellow needles, the infrared spectrum of which showed thiocyano absorption at 2 143 cm^{-1}. The benzene-insoluble material was crystallized from ethanol to give a mixture of yellow needles and brown amorphous material. The infrared spectrum of the yellow needles showed strong thiocyano absorption at 2 060 cm^{-1}, and that of the brown amorphous material was identical with the spectrum of 2-aminothiazolo-[5,4-*c*]isoquinoline (X) prepared as described below. The mixture was washed with sodium carbonate solution, then dissolved in 15% hydrochloric acid, and reprecipitated with solid sodium carbonate. The resulting yellow solid (5.15 g, 21% yield) showed an infrared spectrum identical with that of authentic 2-aminothiazolo-[5,4-*c*]isoquinoline.

The filtrate from the original acetic acid reaction mixture was basified with solid sodium carbonate, and the resulting precipitate was filtered off and dried *in vacuo*. Crystallization from benzene gave 5.13 g of pale-yellow needles, m.p. 148–149°. The infrared spectrum of this compound was identical with that of the benzene-soluble material obtained above. This was 4-amino-3-thiocyanoisoquinoline (IX), and the total yield was 7.83 g (33% yield).

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88. Found: C, 59.68; H, 3.33; N, 20.75.

Preparation of 2-Aminothiazolo[5,4-c]isoquinoline (X)

4-Amino-3-thiocyanoisoquinoline (IX) (7.83 g, 0.039 mole) was refluxed for 2 h in a mixture of 315 ml of 15% hydrochloric acid and 315 ml of ethanol. The reaction mixture was cooled to room temperature and basified with solid sodium carbonate. The resulting yellow solid was filtered off, washed with water, and dried to give 6.48 g (83% yield) of 2-aminothiazolo[5,4-*c*]isoquinoline (X). Recrystallization from benzene gave yellow needles, m.p. 292–294°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88. Found: C, 59.57; H, 3.43; N, 20.87.

The monoacetyl derivative of X was prepared by refluxing 0.25 g (1.2 mmoles) of X in a mixture of 5 ml of acetic anhydride and 2 ml of pyridine for 70 min. The reaction mixture was cooled and filtered to give 0.30 g (100% yield) of a tan solid, which was purified by dissolving it in hot glacial acetic acid, filtering, and diluting the filtrate with water, whereupon colorless needles precipitated, m.p. 361–362°.

Anal. Calcd. for $C_{12}H_9N_3OS$: C, 59.24; H, 3.73; N, 17.27; S, 13.18. Found: C, 59.60; H, 3.48; N, 17.23; S, 13.08.

Preparation of 2-Chlorothiazolo[5,4-c]isoquinoline (XI)

Cuprous chloride was prepared in the usual way from 2.64 g of sodium chloride, 10.00 g of hydrated cupric sulfate, 2.16 g of sodium bisulfite, and 1.44 g of sodium hydroxide, and was dissolved in 40 ml of concentrated hydrochloric acid.

2-Aminothiazolo[5,4-*c*]isoquinoline (X) (4.80 g, 0.024 mole) was dissolved in 160 ml of 85% phosphoric acid, and 40 ml of 70% nitric acid was added. The resulting solution was cooled to 0–5°, and sodium nitrite (1.76 g, 0.026 mole) in 16 ml of water was added, with stirring, over a period of 10 min. The reaction mixture was stirred for another 10 min at this temperature, and then it was added over 20 min to the stirred solution of cuprous chloride in hydrochloric acid at 0–5°.

The reaction mixture was stirred for 1 h at room temperature. It was then basified with 20% sodium hydroxide solution, with cooling. The basic mixture was extracted with three 500 ml portions of ether. The ether extract was washed once with water, dried over sodium sulfate, and filtered; then the ether was evaporated, leaving a tan-colored solid. This was extracted with 250 ml of boiling hexane and the hexane evaporated,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

leaving 3.56 g (67% yield) of a crude yellow solid, m.p. 89–92°. Vacuum sublimation gave colorless 2-chlorothiazolo[5,4-*c*]isoquinoline, m.p. 91.5–93°.

Anal. Calcd. for $C_{10}H_5ClN_2S$: C, 54.42; H, 2.28; Cl, 16.07; N, 12.70. Found: C, 54.31; H, 2.19; Cl, 16.45; N, 12.57.

Preparation of Thiazolo[5,4-c]isoquinoline (I)

2-Chlorothiazolo[5,4-*c*]isoquinoline (1 g, 4.5 mmoles) was dissolved in a mixture of 16 ml of 47% hydriodic acid, 8 ml of glacial acetic acid, and 8 ml of water; then 0.56 g of red phosphorus was added. The resulting mixture was refluxed for 3½ h. It was filtered while hot, cooled to room temperature, diluted with 125 ml of water, and filtered again. The filtrate was basified with solid sodium carbonate, and the resulting flocculent precipitate (0.48 g, 57% yield) was filtered off, washed with water, and dried. The crude product was chromatographed on 20 g of alumina (Woelm, activity 2–3) and eluted with benzene to give 0.33 g of a colorless product, m.p. 96–98°. Recrystallization from hexane gave fine white needles of thiazolo[5,4-*c*]isoquinoline (I), m.p. 97–98°.

Anal. Calcd. for $C_{10}H_6N_2S$: C, 64.49; H, 3.25; N, 15.05. Found: C, 64.56; H, 3.13; N, 14.92.

2-Hydroxythiazolo[5,4-c]isoquinoline (XII)

2-Chlorothiazolo[5,4-*c*]isoquinoline (1 g, 4.5 mmoles) was refluxed in 75 ml of 0.5 *N* sodium hydroxide for 3 h. The reaction mixture was filtered while hot, cooled to room temperature, and acidified with dilute acetic acid. The resulting flocculent precipitate was filtered off, washed with water, and dried to give 0.61 g (67% yield) of 2-hydroxythiazolo[5,4-*c*]isoquinoline (XII), m.p. 309–311°. Recrystallization from ethanol–water gave fine yellow needles, m.p. 310–311°.

Anal. Calcd. for $C_{10}H_6N_2OS$: C, 59.38; H, 2.99; N, 13.85; S, 15.86. Found: C, 59.21; H, 3.05; N, 13.77; S, 15.89.

2-Methoxythiazolo[5,4-c]isoquinoline (XIII)

2-Chlorothiazolo[5,4-*c*]isoquinoline (1 g, 4.5 mmoles) was dissolved in 70 ml of absolute methanol, and 0.25 g (6.2 mmoles) of sodium in 25 ml of absolute methanol was added. After the reaction mixture was stirred magnetically at room temperature for 1½ h, it was neutralized with dilute acetic acid and cooled with several ice cubes. The resulting flocculent yellow precipitate was filtered off and dried to give 0.80 g (82% yield) of 2-methoxythiazolo[5,4-*c*]isoquinoline (XIII), m.p. 101–103°. Recrystallization from methanol followed by vacuum sublimation gave pale-yellow needles, m.p. 105.5–106.5°.

Anal. Calcd. for $C_{11}H_8N_2OS$: C, 61.09; H, 3.73; N, 12.96; S, 14.83. Found: C, 61.24; H, 3.73; N, 12.98; S, 14.74.

Thiazolo[5,4-c]isoquinoline-2-thiol (XIV)

2-Chlorothiazolo[5,4-*c*]isoquinoline (0.20 g, 0.9 mmole) and thiourea (0.10 g, 13 mmoles) were refluxed in 10 ml of ethanol for 3 h. The reaction mixture was cooled and filtered to give 0.10 g of an orange solid. This solid was dissolved in 1 *N* sodium hydroxide solution, the mixture was filtered, and the filtrate was acidified with acetic acid. The resulting precipitate was filtered off and dried to give 0.08 g (42% yield) of pale-yellow thiazolo[5,4-*c*]isoquinoline-2-thiol (XIV), m.p. 299–300.5°.

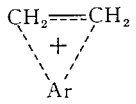
SOLVOLYSES OF 2-(2,4-DIMETHOXYPHENYL)-1,1-d_2-ETHYL AND 2-(3,5-DIMETHOXYPHENYL)-1,1-d_2-ETHYL *p*-BROMOBENZENESULFONATES; ION-PAIR RETURNS IN SOLVOLYSES OF 2-ARYLETHYL SYSTEMS

C. C. LEE AND L. NOSZKÓ[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan



Received July 5, 1966

ABSTRACT

Acetolysis and formolysis of 2-(2,4-dimethoxyphenyl)-1,1-d_2-ethyl and 2-(3,5-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonates were allowed to proceed for about two half-lives, and the corresponding acetate and formate products as well as the unsolvolyzed sulfonate esters were recovered and analyzed by nuclear magnetic resonance. In the 2,4-dimethoxy substituted system, both acetolysis and formolysis gave products showing practically equal distributions of the deuterium in the C-1 and C-2 positions of the ethyl chain. For the 3,5-dimethoxy substituted system, deuterium isotope position rearrangements from C-1 to C-2 in the products were found to be 14 and 26%, respectively, for acetolysis and formolysis. These results provide more quantitative verifications of earlier conclusions, based on kinetic data, regarding the extents of involvement of bridged ions as reaction intermediates. The unsolvolyzed sulfonate ester recovered from the acetolysis of either the 2,4- or 3,5-dimethoxy substituted system showed a significant amount of deuterium rearrangement from C-1 to C-2, indicating the occurrence of ion-pair returns. On the other hand, such rearrangements were negligibly small in the sulfonates recovered after partial formolysis. By utilizing data on isotopic rearrangements in the recovered sulfonates obtained from the present work or from the literature, values of k_a/k_t, the ratio of the total reaction rate to the titrimetric rate, were calculated for a number of 2-arylethyl systems. Implications of the present results on a general mechanism for the solvolyses of 2-arylethyl arenesulfonates are also discussed.

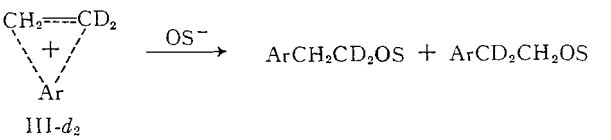
INTRODUCTION

From considerations of relative rates and entropies of activation, Winstein and Heck (1) concluded that the chief contributor to the rate of both acetolysis and formolysis of 2-(2,4-dimethoxyphenyl)-ethyl *p*-bromobenzenesulfonate (I-OBs) is the anchimerically assisted rate constant (k_Δ), whereas for 2-(3,5-dimethoxyphenyl)-ethyl *p*-bromobenzenesulfonate (II-OBs), acetolysis is chiefly anchimerically unassisted (k_s) and both k_s and k_Δ contribute to the formolysis of II-OBs. The anchimerically assisted process involves a nonclassical, bridged ion, such as the ethylene-2,4-dimethoxyphenonium ion, as an intermediate (1). Such bridged ions may be generalized for 2-arylethyl systems, as shown by III, which may be termed an ethylenearonium ion. These qualitative conclusions

III

derived from kinetic data can be verified more quantitatively by isotope position rearrangement studies. In the present work, 2-(2,4-dimethoxyphenyl)-1,1-d_2-ethyl and 2-(3,5-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonates (I-OBs-1-d_2 and II-OBs-1-d_2, respectively) were subjected to acetolysis and formolysis, and the deuterium distributions in the ethyl chain of the resulting products were determined to ascertain the extents of involvement of III.

The solvolyses of I-OBs-1-d_2 and II-OBs-1-d_2 were interrupted before completion and



[1]*Visiting scientist, 1964–1965. Present address: Central Research Institute for Chemistry, Hungarian Academy of Sciences, Budapest, Hungary.*

the deuterium distributions in the recovered *p*-bromobenzenesulfonates gave indications of the extents of return from ion-pairs to covalent bonding. The return processes for optically active systems which proceed via symmetrical bridged ions, such as in the solvolyses of *threo*-3-phenyl-2-butyl and *threo*-3-anisyl-2-butyl arenesulfonates (2, 3), have been measured by a comparison of the polarimetric rate constant (k_α) and the titrimetric rate constant (k_t). Recently, Smith and Showalter (4) have utilized data on isotopic rearrangements to calculate an equivalent of k_α/k_t for the acetolysis of *erythro*-3-phenyl-2-butyl *p*-toluenesulfonate. In studies with 2-arylethyl systems, it is impossible to evaluate k_α because of the lack of optical activity. The method of Smith and Showalter (4), however, can be employed. This treatment is applied to the present results on returns as well as to other 2-arylethyl systems for which isotopic rearrangement data on returns are available from the literature.

RESULTS AND DISCUSSION

I-OBs-1-d_2 and II-OBs-1-d_2 were prepared from the corresponding deuterated alcohols, which were obtained, respectively, from the lithium aluminium deuteride reduction of 2,4-dimethoxyphenylacetic acid (IV) and 3,5-dimethoxyphenylacetic acid (V). As indicated by Winstein and Heck (1), IV was prepared from 2,4-dimethoxybenzaldehyde by the azlactone method (5) and V was obtained from 3,5-dimethoxybenzoic acid by way of the corresponding benzyl alcohol, benzyl chloride, and nitrile. Acetolysis and formolysis of I-OBs-1-d_2 and II-OBs-1-d_2 were interrupted after the reactions had proceeded for about two half-lives (see Experimental). The resulting acetates and formates (I-OAc-*x*-d_2, II-OAc-*x*-d_2, I-OCHO-*x*-d_2, and II-OCHO-*x*-d_2) as well as the recovered unsolvolyzed sulfonates (I-OBs-*x*-d_2 and II-OBs-*x*-d_2) were examined by nuclear magnetic resonance (n.m.r.). The pertinent parts of typical sets of spectra are shown in Figs. 1 and 2. Integration of a number of such sets of spectra gave the averaged deuterium distributions in the C-1 and C-2 positions of the ethyl chain of the various compounds analyzed. The results are given in Table I.

The reaction of III-d_2 from I-OBs-1-d_2 or II-OBs-1-d_2 could give rise to products with an equal amount of deuterium at the C-1 and C-2 positions (eq. [1]). This prediction is fully

[1] 

III-d_2

met in both the acetolysis and formolysis of I-OBs-1-d_2, confirming the earlier conclusion based on kinetic data (1). The small excess over 50% of deuterium at C-2 (Table I) for I-OAc-*x*-d_2 and I-OCHO-*x*-d_2 may be attributable to an isotope effect, the reaction with III-d_2 being slightly more favorable at the carbon position containing hydrogen than at the one containing deuterium.

The isotope position rearrangements of deuterium in the products from the acetolysis and formolysis of II-OBs-1-d_2 indicate the partial involvement of III, again confirming the conclusion (1) that k_s competes favorably with k_Δ in this system. Winstein and Heck (1) have pointed out that a *m*-methoxy group on a participating phenyl group may give rise to either a small retardation or a small acceleration of the rate, depending on the relative influence of the inductive and resonance effects. In the formolysis of II-OBs, it was noted that the two *m*-methoxy groups in the 2-phenylethyl system decreased the rate by a factor

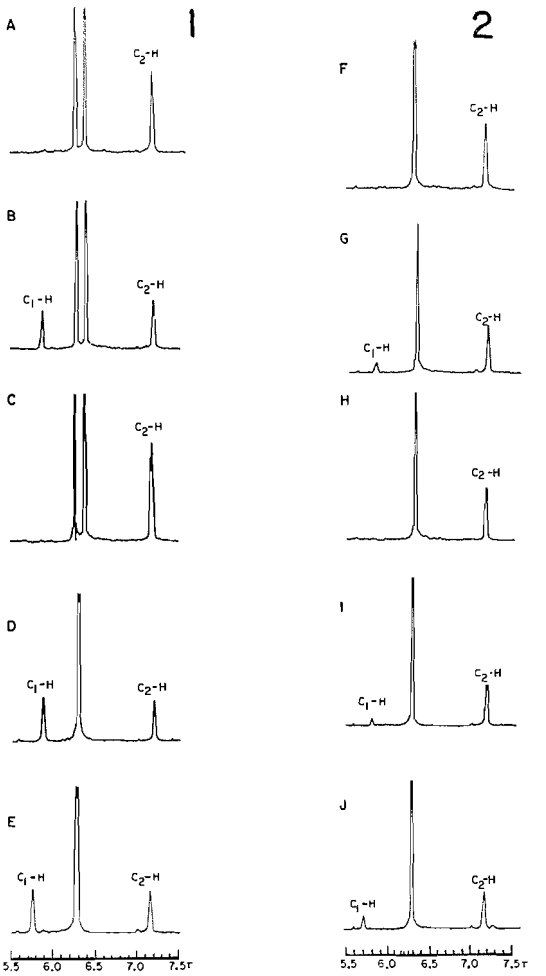

FIG. 1. Pertinent parts of the n.m.r. spectra obtained on the HA-100 spectrometer: A, 2-(2,4-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonate (I-OBs-1-d_2); B, I-OBs-x-d_2 recovered from acetolysis after 70.6% reaction; C, I-OBs-x-d_2 recovered from formolysis after 77.6% reaction; D, I-OAc-x-d_2 product from acetolysis; E, I-OCHO-x-d_2 product from formolysis. The undesignated peaks shown are caused by methoxyl hydrogens.

FIG. 2. Pertinent parts of the n.m.r. spectra obtained on the HA-100 spectrometer: F, 2-(3,5-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonate (II-OBs-1-d_2); G, II-OBs-x-d_2 recovered from acetolysis after 74.7% reaction; H, II-OBs-x-d_2 recovered from formolysis after 71.2% reaction; I, II-OAc-x-d_2 product from acetolysis; J, II-OCHO-x-d_2 product from formolysis. The undesignated peaks shown are caused by methoxyl hydrogens.

of 3 and that, when the $\Delta S^{\ddagger}$ values are considered, the formolysis rate for II-OBs "is not so predominantly composed of k_Δ as in the case of the parent $C_6H_5CH_2CH_2OBs$ system" (1). This statement is borne out more quantitatively by a comparison of the present results with known data from ^{14}C-labeled 2-phenylethyl *p*-toluenesulfonate (VI-OTs); the formolysis of II-OBs-1-d_2 gave 26% isotopically rearranged II-OCHO-2-d_2 (Table I) whereas the formolysis of VI-OTs-1-^{14}C resulted in 45% isotope position rearrangement to VI-OCHO-2-^{14}C (6).

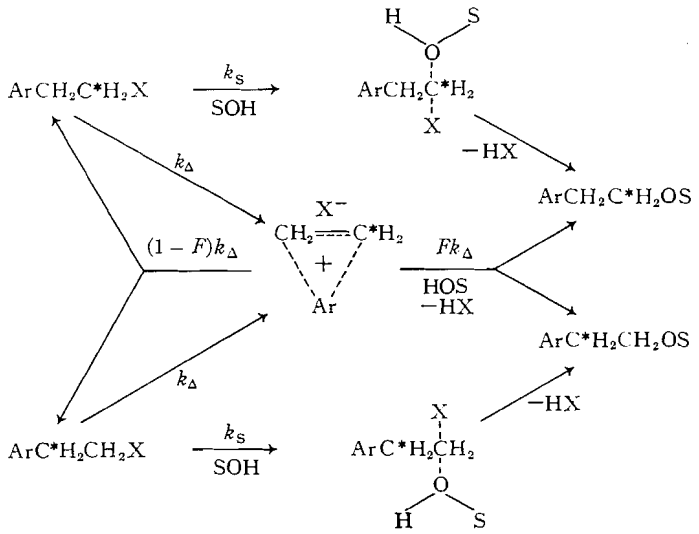
Ion-pair returns involving III-d_2 and its counter ion will result in the location of some deuterium at the C-2 position of the recovered sulfonate (eq. [2]). The data in Table I

[2]  $\rightarrow$ $ArCH_2CD_2OBs + ArCD_2CH_2OBs$

show that such returns are significant in the acetolyses of both I-OBs-1-d_2 and II-OBs-1-d_2, but are negligible in the formolyses. Similar studies on the solvolyses of other 2-arylethyl systems labeled with ^{14}C, including 2-(*p*-anisyl)-1-^{14}C-ethyl, 2-(α-naphthyl)-1-^{14}C-ethyl, and 2-(β-napthyl)-1-^{14}C-ethyl *p*-toluenesulfonates (VII-OTs-1-^{14}C, VIII-OTs-1-^{14}C, and IX-OTs-1-^{14}C, respectively) (7–9), also resulted in significant returns for acetolysis and negligible returns for formolysis. The fact that acetic acid is an optimum medium for ion-pair returns has been discussed in the early formulation of the theory on such processes (10). Returns from ionic intermediates to covalent starting material have also been studied in the solvolyses of 2-phenyl-1-^{14}C-ethyl *p*-toluenesulfonate (VI-OTs-1-^{14}C) (11, 12). In this case, significant returns were observed for formolysis. By investigating the formolysis of VI-OTs-1-^{14}C in the presence of added sodium ^{35}S-*p*-toluenesulfonate, it was shown that the major contributor to the return processes may be intermolecular external return involving exchangeable *p*-toluenesulfonate anion, rather than intramolecular internal return from intimate ion-pairs (12).



Following the mechanistic schemes given by Jenny and Winstein (7) and by Clayton and Lee (12), the processes occurring during the solvolyses of 2-arylethyl arenesulfonates are shown in Reaction Scheme 1, with the asterisk designating the isotopic label, either ^{14}C or D.

As pointed out earlier, the ionization rate constant (k_Δ) for optically active systems which proceed via symmetrical bridged ions can be followed polarimetrically as k_α. Because of the return processes, k_α is greater than the titrimetric rate constant (k_t) (2, 3). According to the scheme shown in Reaction Scheme 1, one can define k_α as the total reaction rate constant (eq. [3]) whereas the titrimetric rate constant is given by eq. [4]. Again, if returns occur ($F < 1$), k_α will be greater than k_t. Values for the k_α so defined can

[3] $$k_\alpha = k_\Delta + k_s$$

[4] $$k_t = Fk_\Delta + k_s$$

REACTION SCHEME 1.

be calculated according to the method of Smith and Showalter (4). For example, in the present studies, the acetolysis of I-OBs-1-d_2 was interrupted after 3 h at 60.6 °C when the reaction was 70.6% complete ($k_t = 1.13 \times 10^{-4}$ s^{-1}). The recovered sulfonate (I-OBs-x-d_2) showed 40% isotope position rearrangement of the deuterium label, which indicated that $2 \times 40 = 80\%$ of the recovered sulfonate has been involved in the return processes. Since the amount of sulfonate remaining was $100 - 70.6 = 29.4\%$, $(80/100) \times 29.4 = 23.5\%$ of the reactant would have been involved in returns. The total involved would be the sum of the percentage solvolyzed and the percentage return, namely, $70.6 + 23.4 = 94.0\%$. The total reaction rate constant would thus be $k_\alpha = (2.303/(3 \times 3\,600))(\log 100/(100 - 94.0)) = 2.5 \times 10^{-4}$ s^{-1}. These calculations can be summarized by eqs. [5]–[7].

[5] % return = 2(% rearrangement in recovered sulfonate/100) × (100 − % solvolyzed)

[6] % total involved = % solvolyzed + % return

[7] $k_\alpha = (2.303/\text{time})(\log 100/(100 - \%\text{ total involved}))$

In this way, k_α as well as k_α/k_t can be evaluated for the acetolysis of I-OBs-1-d_2, II-OBs-1-d_2, VII-OTs-1-^{14}C, VIII-OTs-1-^{14}C, and IX-OTs-1-^{14}C. These data are summarized in Table II.

It can be seen from Table II that, for the three acetolyses of VII-OTs-1-^{14}C which were interrupted at different stages of completion, the calculated values of k_α and k_α/k_t were quite constant. Also, as expected, k_α/k_t decreased markedly when the acetolyses of VII-OTs-1-^{14}C were carried out in the presence of lithium perchlorate. The latter salt is believed to prevent return from solvent-separated ion-pairs, but does not prevent returns from intimate ion-pairs (3, 7). According to eqs. [3] and [4], $k_\alpha/k_t = (k_\Delta + k_s)/(Fk_\Delta + k_s)$. In systems to which k_s does not contribute significantly, such as in the solvolyses of I-OBs-1-d_2 and VII-OTs-1-^{14}C, k_α/k_t would be equal to $1/F$. For the acetolysis of VII-OTs-1-^{14}C, the calculated k_α/k_t of about 3.9 is in reasonably good agreement with the value of 3.77 for $1/F$ reported by Jenny and Winstein (7).

For personal use only.

For the 2-phenylethyl system, in the earlier work on ion-pair returns during the solvolyses of VI-OTs-1-^{14}C (11), kinetic measurements were not made in conjunction with isotopic rearrangement studies. From the later investigation on the formolysis of VI-OTs-1-^{14}C (12), both kinetic data and isotope position rearrangements in the recovered sulfonate are available. In this case, however, intermolecular external return involving exchangeable *p*-toluenesulfonate anion may be chiefly responsible for the rearrangements observed in the recovered sulfonate (12). In such an event, the rate for that portion of the reaction proceeding via the bridged ion should be dependent upon the *p*-toluenesulfonate anion concentration, as given in eq. [8] (13), where k_1, k_2, and k_3 are, respectively, the rate constants for ionization, for return from the carbonium ion to the starting material, and for product formation from the carbonium ion.

$$\text{Rate} = \frac{k_1[\text{ArOTs}]}{(k_2/k_3)[\text{OTs}^-] + 1} \qquad [8]$$

However, if $(k_2/k_3)[\text{OTs}^-]$ is small compared with 1, first-order kinetics would still be observed. Apparently, this condition may have been met in the formolysis of VI-OTs-1-^{14}C, because the extent of return was not large and no significant downward drift in the rate was detectable during a kinetic run (12). It is thus possible to apply the first-order kinetic treatments, as given by eqs. [5]–[7], to calculate k_α for the formolysis of VI-OTs-1-^{14}C.

Summarized in Table III are the results from the formolysis of 0.350 *M* VI-OTs-1-^{14}C at 74 °C carried out with no added salt (12). The k_α values calculated from the data obtained after the reaction was interrupted at various stages of completion may be regarded as satisfactorily constant, the average being 3.4×10^{-5} s^{-1}. Since k_t, under the same conditions, has been found to be 3.0×10^{-5} s^{-1} (12), k_α/k_t is about 1.1. This average value of k_α/k_t gave at least a correct indication of the order of magnitude for the return processes; the factor *F*, which is the fraction of the bridged ion proceeding to products, has been evaluated as 0.91 (12).

TABLE III

Calculated k_α for the formolysis of 0.350 *M* 2-phenyl-1-^{14}C-ethyl p-toluenesulfonate (VI-OTs-1-^{14}C) at 74 ± 0.2 °C with no added salt*

†Isotope position rearrangement from C-1 to C-2 in the recovered *p*-toluenesulfonate.

Recently, Brown and his co-workers (14) have emphatically questioned the existence of nonclassical, bridged phenonium ions as intermediates, and special attention was directed to the 3-phenyl-2-butyl and 2-phenylethyl systems. As an alternative to nonclassical ions, these workers have suggested rapidly equilibrating classical ions. On the other hand, Cram (15) has strongly stated the case for phenonium ions. The existence of bridged ions has not been questioned in systems in which anchimeric rate enhancements have definitely been

established, such as in the solvolyses of I-OBs and VII-OTs. Moreover, the recent direct observation of the n.m.r. spectrum of the carbonium ions derived from the 3-phenyl-2-butyl system under highly acidic conditions at low temperatures favored the bridged-ion formulation (16). The present results on deuterium scrambling in the products of the solvolyses of I-OBs-1-d_2 and II-OBs-1-d_2 also further strengthen the already known correlation that the extents of isotope position rearrangement generally are closely related to the extents of involvement of bridged ions predicted from structural, kinetic, or stereochemical considerations. The phenomena of returns from ionic intermediates to covalent starting materials are also adequately explained by bridged ions. Finally, for the 2-phenylethyl system, Jensen and Ouellette (17) have reported significant rate enhancements for the solvolyses of 2-phenylethylmercuric perchlorate in acetic acid and in formic acid. It is of interest to point out that preliminary work in this laboratory on the acetolysis and formolysis of 2-phenyl-1-^{14}C-ethylmercuric perchlorate gave products in which the ^{14}C-label was almost equally distributed in the C-1 and C-2 positions.[2] From all of these considerations, it appears quite reasonable to conclude that, for 2-arylethyl systems, the nonclassical ethylenearonium ion III may be utilized confidently to correlate the existing experimental data.

EXPERIMENTAL

2-(2,4-Dimethoxyphenyl)-1,1-d_2-ethyl and 2-(3,5-Dimethoxyphenyl)-1,1-d_2-ethyl p-Bromobenzenesulfonates (I-OBs-1-d_2 and II-OBs-1-d_2)

2,4-Dimethoxyphenylacetic acid or 3,5-dimethoxyphenylacetic acid was reduced to the corresponding alcohol as described by Winstein and Heck (1), except that lithium aluminium deuteride instead of lithium aluminium hydride was used as the reducing agent. These alcohols were treated with *p*-bromobenzenesulfonyl chloride in pyridine, again by the procedure of Winstein and Heck (1), to give the desired sulfonate esters. 2-(2,4-Dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonate (I-OBs-1-d_2), m.p. 73° C (lit. (1) m.p. 72–73 °C), was obtained in a 48% yield, and the yield of 2-(3,5-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonate (II-OBs-1-d_2), m.p. 76 °C (lit. (1) m.p. 76.5–77.5 °C), was 43%. Deuterium analyses[3] showed the presence of 1.92 and 1.90 deuterium atoms per molecule in I-OBs-1-d_2 and II-OBs-1-d_2, respectively.

Acetolysis of I-OBs-1-d_2

A solution of 6.0 g (0.015 mole) of I-OBs-1-d_2 in 500 ml of reagent-grade glacial acetic acid was heated in a water bath at 60.6 °C for 3 h (70.6% solvolyzed). The mixture was poured into 2 l of ice water and then extracted with two 500 ml portions of ether. The extract was washed three times with cold water, twice with cold, diluted sodium carbonate solution, and finally once more with cold water. After the solution was dried over anhydrous magnesium sulfate, the ether was removed *in vacuo* at room temperature. The residue was triturated in 6 ml of a 1:2 solution of ether – petroleum ether (b.p. 40–60 °C) and then allowed to remain in the refrigerator for 2 days. The crystalline unsolvolyzed sulfonate ester was collected by filtration and recrystallized from ether – petroleum ether. The recovery was 1.4 g (79% based on 70.6% solvolyzed).

The filtrate obtained after the removal of the unsolvolyzed sulfonate was evaporated to an oil which, on vacuum distillation, gave 1.6 g (67% based on 70.6% solvolyzed) of 2-(2,4-dimethoxyphenyl)-*x*-d_2-ethyl acetate (I-OAc-*x*-d_2), b.p. 144° at 2 mm. The corresponding protio acetate isolated from a similar run boiled at 142 °C and 2 mm.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.22; H, 7.21.

Acetolysis of II-OBs-1-d_2

A solution of 6.0 g (0.015 mole) of II-OBs-1-d_2 in 500 ml of reagent-grade glacial acetic acid was heated in a thermostated oil bath at 100.0 °C for 37 h (74.7% solvolyzed). The reaction mixture was worked up in the same manner as described for the acetolysis of I-OBs-1-d_2. The recovery of unsolvolyzed sulfonate ester was 1.2 g (79% based on 74.9% solvolyzed). The yield of acetate product (II-OAc-*x*-d_2), b.p. 148–150 °C at 2 mm, was 1.3 g (52% based on 74.7% solvolyzed). The corresponding protio acetate obtained from a similar run boiled at 146 °C and 1.5 mm.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.20; H, 7.14.

Formolysis of I-OBs-1-d_2

A solution of 6.0 g (0.015 mole) of I-OBs-1-d_2 in 500 ml of reagent-grade 98–100% formic acid was kept at 25.0 °C in a water bath for 1 h (77.6% solvolyzed). The reaction mixture was worked up as described for the acetolyses. The recovery of unsolvolyzed sulfonate was nearly quantitative (1.3 g), and the yield of formate product (II-OCHO-x-d_2), b.p. 138 °C at 1.5 mm, was 1.5 g (60% based on 77.6% solvolyzed). The corresponding protio formate obtained in an analogous experiment boiled at 140° and 2 mm.

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71. Found: C, 62.58; H, 6.78.

Formolysis of II-OBs-1-d_2

A solution of 6.0 g (0.015 mole) of II-OBs-1-d_2 in 500 ml of reagent-grade 98–100% formic acid was heated in a water bath at 60.0 °C for 50 h (71.2% solvolyzed). The reaction mixture was worked up in the same way as described above. The recovery of unsolvolyzed sulfonate was again essentially quantitative (1.7 g). Some technical difficulty was experienced in the isolation of the formate product, and the yield of purified formate (II-OCHO-x-d_2), b.p. 150–152° at 3.5 mm, was only 0.5 g (22% based on 71.2% solvolyzed). The corresponding protio formate boiled at 152 °C and 3.5 mm.

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71. Found: C, 62.93; H, 6.85.

Nuclear Magnetic Resonance Analyses

The n.m.r. analyses of the various compounds were carried out in deuteriochloroform solution with Varian Associates HR-100 and HA-100 spectrometers by Mr. G. W. Bigam of the Department of Chemistry, University of Alberta, Edmonton, Alberta, and by Mr. M. Mazurek of the Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan.

SECONDARY KINETIC ISOTOPE EFFECTS IN THE SOLVOLYSES OF 2-(2,4-DIMETHOXYPHENYL)-1,1-d_2-ETHYL AND 2-(3,5-DIMETHOXYPHENYL)-1,1-d_2-ETHYL *p*-BROMOBENZENESULFONATES

C. C. LEE AND L. NOSZKÓ[1]

Received July 5, 1966

ABSTRACT

The secondary α-deuterium kinetic isotope effects in the acetolyses and formolyses of 2-(2,4-dimethoxyphenyl)-ethyl and 2-(3,5-dimethoxyphenyl)-ethyl *p*-bromobenzenesulfonates (I-OBs and II-OBs, respectively) and their corresponding 1,1-dideuterio analogues (I-OBs-1-d_2 and II-OBs-1-d_2) were determined. The observed k_H/k_D values are compared with similar data from the literature for 2-phenylethyl and 2-*p*-anisylethyl *p*-toluenesulfonates (III-OTs and IV-OTs, respectively). In the formolyses of III-OTs, IV-OTs, and I-OBs, which proceed either chiefly or exclusively by way of bridged ions as intermediates, the isotope effects appear to increase slightly with increasing bridged-ion stability. For I-OBs and I-OBs-1-d_2, acetolyses gave smaller k_H/k_D values than formolyses because of deuterium scrambling caused by ion-pair returns during the acetolysis. Acetolyses and formolyses of II-OBs and II-OBs-1-d_2 gave lower isotope effects than the corresponding reactions with I-OBs and I-OBs-1-d_2. The magnitudes of the observed isotope effects in relation to transition-state structures are discussed.

INTRODUCTION

The possibility of utilizing kinetic isotope effects to probe the structures of the rate-determining transition states in the solvolyses of 2-arylethyl systems has been suggested (1–3). In conjunction with the studies on isotope position rearrangements in the acetolyses and formolyses of 2-(2,4-dimethoxyphenyl)-1,1-d_2-ethyl and 2-(3,5-dimethoxyphenyl)-1,1-d_2-ethyl *p*-bromobenzenesulfonates (I-OBs-1-d_2 and II-OBs-1-d_2, respectively) (4), it is of interest to determine also the secondary kinetic isotope effects of α-deuterium substitution in these solvolytic reactions.

RESULTS AND DISCUSSION

The kinetic isotope effects, as measured by k_H/k_D, the ratio of the rate constants for the protio and the corresponding 1,1-dideuterio analogues, for the acetolyses and formolyses of I-OBs, I-OBs-1-d_2, II-OBs, and II-OBs-1-d_2 are summarized in Table I. For comparison, similar data from the literature for the solvolyses of 2-phenyl-1,1-d_2-ethyl and 2-*p*-anisyl-1,1-d_2-ethyl *p*-toluenesulfonates (III-OTs-1-d_2 and IV-OTs-1-d_2, respectively) are also given in Table I.

The influence of aryl participation on the kinetic isotope effects in the solvolyses of III-OTs-1-d_2 and IV-OTs-1-d_2 has been discussed (1–3) in terms of Streitwieser's proposal that such isotope effects arise mainly out of the change in hydridization from sp^3 to sp^2 at the α-carbon during ionization (5). Although other factors, including inductive (6, 7) and steric (8) effects, may play some role in the interpretation of isotope effects, the present results can be explained adequately by the suggestions advanced by Streitwieser (3, 5). According to this theory (3, 5), the secondary α-deuterium kinetic isotope effect can be ascribed largely to the decrease in a bending force constant from a starting tetrahedral C—H bending vibration to the generally lower frequency out-of-plane bending

motion in the transition state leading to the carbonium ion. It is also postulated that the out-of-plane C—H vibration in the transition state can be impeded by the proximity of the leaving or the entering group; the closer these groups are to the developing carbonium ion, the stiffer the out-of-plane C—H bending motion and the lesser the isotope effect. For an isolated carbonium ion, k_H/k_D has been calculated to be about 1.4 per α-deuterium atom (5). In limiting S_N1 solvolyses, the observed k_H/k_D is about 1.15 per α-deuterium atom, and the decrease from 1.4 may be attributed largely to the influence of the nearby leaving group. For direct S_N2 displacements, the presence of both entering and leaving groups in the transition state causes the virtual disappearance of the isotope effect. It is also predicted that anchimerically assisted solvolyses should show values of k_H/k_D less than 1.15 per α-deuterium atom, since the participating neighboring group may be counted as an entering group (3).

The formolyses of I-OBs (4, 9) and IV-OTs (10) are exclusively anchimerically assisted (k_Δ), and the chief contributor to the formolysis of III-OTs is also k_Δ (9, 11). These three reactions all show k_H/k_D values of less than 1.15 per α-deuterium atom (Table I). There is also a trend towards a higher isotope effect as the 2-aryl group is changed in the order of phenyl, *p*-anisyl, and 2,4-dimethoxyphenyl (k_H/k_D per α-deuterium atom about 1.09, 1.10, and 1.12, respectively). The findings suggest that the proximity of the participating aryl group is progressively farther from C-1 in the transition states for the formolysis of III-OTs, IV-OTs, and I-OBs. According to Hammond's hypothesis (12), the transition state in a carbonium ion reaction should resemble the intermediate ion more than the tetrahedral reactant. As developed by Streitwieser (3, pp. 66–68), this hypothesis, when applied to solvolytic reactions, also suggests that the more stable the intermediate carbonium ion, the farther away is the transition state from the intermediate along the reaction coordinate. Thus, in reactions involving bridged ions as intermediates, if the bridged ion is more stable, the bridging would be less developed in the transition state. In a 2-arylethyl system with the symmetrical bridged ion V as intermediate, the transition state could be written as VI (2). As the aryl group is changed in the order of phenyl,

V

VI

p-anisyl, and 2,4-dimethoxyphenyl, the stability of the corresponding bridged ion will also increase in that order. Thus, in the transition state, the distance between Ar and C-1, and hence the isotope effect, will increase in the order of increasing bridged-ion stability. Such arguments have been presented by Streitwieser (3, pp. 171–175) to explain the slightly higher k_H/k_D values for the formolyses of IV-OTs and IV-OTs-1-d_2 as compared with those for the formolyses of III-OTs and III-OTs-1-d_2. The present data on isotope effects in the formolyses of I-OBs and I-OBs-1-d_2 fit into this pattern, and thus further strengthen the applicability of such interpretations of α-deuterium kinetic isotope effects.

As in the formolysis, the acetolysis of I-OBs is exclusively anchimerically assisted via a bridged ion as intermediate (4, 9). One might then expect that both the acetolyses and formolyses of I-OBs and I-OBs-1-d_2 would give similar isotope effects. However, from Table I, it can be seen that the observed k_H/k_D value for the acetolyses of this system (about 1.14) is much lower than that for the formolyses (about 1.24). This decrease most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

likely arises from the occurrence of ion-pair returns. Such returns, highly significant in the acetolysis of I-OBs-1-d_2 but negligible in the formolysis, cause a "scrambling" of the deuterium from C-1 to C-2 in the reactant, the *p*-bromobenzenesulfonate ester (4). Since deuteration at C-2 gave no isotope effect in the solvolyses of analogous systems (III-OTs and IV-OTs) (1, 2), scrambling of deuterium to C-2 through ion-pair returns would cause a decrease in the k_H/k_D value, as is observed for the acetolyses of I-OBs and I-OBs-1-d_2. It is of interest to note that, when the acetolyses of IV-OTs and IV-OTs-1-d_2 were carried out in the presence of lithium perchlorate to suppress ion-pair returns, the difference in k_H/k_D for acetolysis and formolysis almost disappeared (2) (see Table I). Similarly, identical α-deuterium isotope effects for the 2,2-diphenylethyl system were observed for formolysis and for acetolysis in the presence of lithium perchlorate (2).

The solvolyses of II-OBs and II-OBs-1-d_2 show smaller isotope effects than the corresponding reactions with I-OBs and I-OBs-1-d_2 (Table I). This is to be expected, because k_s competes significantly with k_Δ in the solvolyses of II-OBs (4, 9). The acetolysis of III-OTs is largely due to k_s (9, 13), and the α-deuterium isotope effect is very small (1). Isotopic rearrangements of the C-1 label to C-2 in the solvolysis products have been found to be 14 and 5.5%, respectively, for the acetolyses of II-OBs-1-d_2 (4) and III-OTs-1-^{14}C (13), suggesting a greater extent of involvement of bridged ion V in the II-OBs system. Also, ion-pair returns are quite significant in the acetolysis of II-OBs-1-d_2 (4). When all this information is considered collectively, it is not surprising to note that the observed k_H/k_D value for the acetolyses of the II-OBs system appears to be slightly higher than that for the acetolyses of III-OTs and III-OTs-1-d_2, and is much lower than the α-deuterium isotope effects for the cases where involvement of the bridged ion V predominates.

The formolysis of II-OBs-1-d_2 gave 26% isotopic rearrangement in the product as compared with 14% of such rearrangement in its acetolysis, and there is no significant ion-pair returns in the formolysis (4). One would therefore expect a higher α-deuterium isotope effect for the formolyses than for the acetolyses; this is observed (Table I). The observed k_H/k_D value for the formolyses of II-OBs and II-OBs-1-d_2 ranged from 1.14 to 1.19. This range encompasses the k_H/k_D value for the formolyses of III-OTs and III-OTs-1-d_2 (1). From isotopic rearrangement data (4, 13), it can be estimated that the extents of involvement of bridged ion V in the formolyses of II-OBs and III-OTs are, respectively, 52 and 89%. Thus, the k_s contribution is greater in the formolysis of II-OBs than in that of III-OTs. If the k_s process involving the reaction with solvent were regarded as an S_N2 direct displacement with no isotope effect, one would expect that, in the formolyses, the k_H/k_D value would be smaller for the II-OBs system than for the III-OTs system; apparently this is not the case. A possible explanation of this observation may be as follows. Solvolyses of primary systems in nucleophilic solvents, such as alcohols, may be "pure" S_N2 or direct displacements with no α-deuterium kinetic isotope effects. However, solvolyses in highly ionizing solvents, such as formic acid, may proceed through a solvated carbonium ion as an *intermediate*, even for a primary system such as 1-butyl *p*-bromobenzenesulfonate (14). The k_s process in the formolysis of II-OBs or III-OTs could be regarded as proceeding via a solvated carbonium ion intermediate. In the transition state leading to such an intermediate, the separation between the entering solvent and C-1, and possibly also between the leaving group and C-1, would be greater than the corresponding separations in the transition states for solvolyses in more nucleophilic solvents, such as acetic acid or alcohols. Hence, in the formolyses of II-OBs and III-OTs, even the k_s process will give rise to some α-deuterium isotope effect, and the overall magnitude of k_H/k_D will not be very sensitive to variations in the relative contributions of k_s and k_Δ.

Finally, it may be pointed out that, in the present work, each system investigated was studied at two different temperatures (Table I). Because the temperature ranges employed were not large, extensive treatment of the limited data with regard to the effects of varying temperatures may not be justified. It is, however, of interest to note that, except for the acetolyses of II-OBs and II-OBs-1-d_2, which proceed largely by nucleophilic solvolysis with a relatively low isotope effect, the other reactions (acetolyses and formolyses of I-OBs and I-OBs-1-d_2 and formolyses of II-OBs and II-OBs-1-d_2) all appear to give a somewhat lower k_H/k_D value at a higher temperature. A similar trend of a slight decrease in the secondary α-deuterium kinetic isotope effect with increasing temperature has also been observed previously in this laboratory for the solvolyses of *exo*- and *endo*-norbornyl and 2-(Δ^3-cyclopentenyl)ethyl arenesulfonates (15–17).

EXPERIMENTAL

Preparations of the Sulfonate Esters

2-(2,4-Dimethoxyphenyl)-ethyl and 2-(3,5-dimethoxyphenyl)-ethyl *p*-bromobenzenesulfonates (I-OBs and II-OBs, respectively) were prepared by the methods outlined by Winstein and Heck (9). The syntheses of the corresponding 1,1-dideuterio analogues (I-OBs-1-d_2 and II-OBs-1-d_2) have been described in the preceding paper (4).

Kinetic Studies

The corresponding protio and dideuterio compounds (I-OBs and I-OBs-1-d_2 or II-OBs and II-OBs-1-d_2) were solvolyzed simultaneously at each temperature. About 0.03 *M* solutions of the appropriate compounds in either reagent-grade glacial acetic acid or reagent-grade 98–100% formic acid were heated in a water or an oil bath thermostated at the desired temperature, which remained constant within ±0.02 °C. The reaction rates were followed titrimetrically by known procedures (9, 16, 17). The specific rate constants were obtained from least-squares plots as described earlier (16).

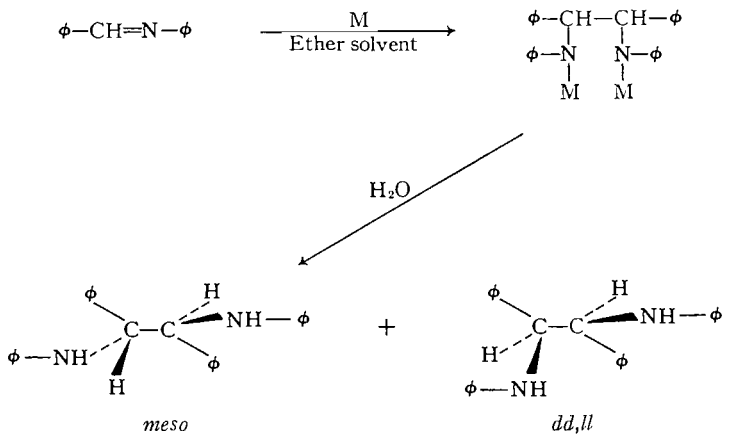
THE REDUCTIVE DIMERIZATION OF *N*-BENZYLIDENE ANILINE[1]

JAMES G. SMITH AND C. DOREEN VEACH
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received May 3, 1966

ABSTRACT



The formation of alkali metal adducts of *N*-benzylidene aniline in several inert solvents is studied by protonolysis of the adducts and analysis of the reaction products, the diastereomeric *N,N'*,1,2-tetraphenylethylenediamines. With sodium and potassium metal in polar solvents, the product is predominantly the *dd,ll* diamine. With lithium metal or with solvents of low polarity, the product contains approximately equal quantities of the two diastereomers.

It is demonstrated that the initially formed diastereomeric mixture generally contains appreciable amounts of the *meso* isomer. In polar solvents with sodium, isomerization to the stable *dd,ll* diastereomer occurs. However, with lithium or with sodium in nonpolar solvents, the isomerization does not occur. The reasons for the preponderance of the *dd,ll*-disodio compound in the equilibrating systems are discussed.

INTRODUCTION

Under certain conditions the reduction of *N*-benzylidene aniline proceeds with dimerization to give a diastereomeric mixture of *N,N'*,1,2-tetraphenylethylenediamines. This reaction occurs with alkali metals (1, 2), magnesium – magnesium iodide (3, 4), and aluminium amalgam (5, 6) as reducing agents. It has been reported (6) that the reduction product is approximately a 50:50 mixture of the two diastereomeric diamines.

A recent study in this laboratory (7) involved the preparation of the alkali metal adducts of *N*-benzylidene aniline (1, 2) (Reaction Scheme 1). Protonolysis of these adducts produced a diastereomeric mixture of diamines which was predominantly the *dd,ll*-*N,N'*,1,2-tetraphenylethylenediamine. This observation prompted a more detailed examination of the formation and protonolysis of these adducts by taking advantage of the facile analysis provided by the nuclear magnetic resonance spectra of the crude reaction product. A similar study has recently been described by Eisch (8). However, the conclusions reached here concerning the processes involved in the reductive dimerization differ somewhat from those of Eisch.

RESULTS AND DISCUSSION

Initially, the influence of different alkali metals and solvents on the ratio of the diastereomeric diamines was investigated. Since the sodium adduct is appreciably more soluble than either the lithium or potassium adduct, the effect of concentration on the diastereomeric ratio was examined. The diastereomeric ratio remained constant within the concentration range studied (0.1–0.3 *m*) with the exception of one experiment, in which the adduct precipitated from solution. Wherever possible, solutions of the adducts have been selected for quenching and subsequent analysis; the notable exception is the potassium adduct, which appears to be quite insoluble.

Table I presents the results obtained with various metals and solvents. Broadly speaking, the product compositions fall into two groups, the one consisting of approximately equal parts of the two diastereomeric diamines, and the other consisting of mainly the *dd,ll* diastereomer. The agreement with Eisch's results is fair; the differences are possibly due to the somewhat different conditions of preparation.

TABLE I

Effect of alkali metal and solvent on the diastereomeric ratio*

‡Reaction precipitated.
§Reaction incomplete.

The reason for these two widely divergent groups of compositions becomes apparent when the composition is examined as a function of time (Table II). The adduct formation in an ether solvent (7, 9) is very rapid, and generally complete in 1 or 2 h. In the more polar solvents, a simultaneous isomerization of the originally formed diastereomeric mixture occurs to produce predominantly the *dd,ll* diastereomer. This does not occur in the less-polar solvent diethyl ether even after 5 days of reaction. In dioxane, the isomerization reaction is slow but readily observable, whereas in tetrahydrofuran the reaction is quite rapid.

The data of Table II also show that at lower temperatures in tetrahydrofuran the rate of isomerization is slowed appreciably. The initially formed composition is close to that formed in dioxane. The rate of isomerization at higher temperatures has been studied, but only a slight shift of the diastereomeric composition occurs. Some cleavage of the bond connecting the benzylic carbons is observed, with the formation of *N*-benzylaniline, if the reaction time is extended for unusually long periods of time (greater than 5 days).

When isomerization occurs, it proceeds only in the direction of an increased *dd,ll* content of the product (Table III). Thus, preparation of the sodium adduct at 0 °C produces a product containing 30% *meso*-*N,N'*-disodio-*N,N'*,1,2-tetraphenylethylenediamine. Permitting the solution to warm to 25 °C effects isomerization to an 8% *meso* content; cooling this solution to 0 °C has no effect on the composition.

Addition of tetrahydrofuran to an ether solution of the sodium adduct causes the composition to be enriched in the *dd,ll* diastereomer. On the other hand, addition of ether to a tetrahydrofuran solution of the adduct does not change the composition.

Eisch has suggested (8) that the radical–ion, initially generated by an electron transfer from the alkali metal to *N*-benzylidene aniline, dimerizes either on the surface of the metal or, if it becomes solvated, in solution. In the former case, the protonolysis product consists of approximately equal amounts of the two diastereomeric *N,N'*,1,2-tetraphenylethylenediamines; in the latter case, the product is predominantly *dd,ll*.

The product composition is indeed affected by the solvent and metal used, as may be seen by comparing the initial compositions of the sodium–dioxane, sodium–ether, and lithium–tetrahydrofuran systems (Table II). However, the isomerization observed in polar solvents is at least an equally important factor. In these instances, the observed product composition is established largely after dimerization has occurred and not before. Dimerization of the radical–ion on the surface of the metal or in solution may affect the composition of the initially formed material, but the data on the initial compositions are insufficient to establish this.

The isomerization is probably effected[2] by the amide ion derived from the alkali metal

[2]*A referee has drawn our attention to the possibility that isomerization may occur through a reversion of the dimeric reduction product to its monomeric radical–ion followed by recoupling to the isomerized dimer. The present experimental data do not distinguish between this possibility and the one discussed above.*

adduct acting as its own isomerizing agent. Attempts have been made (Table IV) to prepare the *meso*-*N*,*N*′-disodio compound by treating the *meso*-*N*,*N*′,1,2-tetraphenylethylenediamine with sodium hydride. However, isomerization occurs too rapidly and is accompanied by some cleavage of the bond joining the benzylic carbon atoms, with the formation of *N*-benzylaniline.

TABLE IV

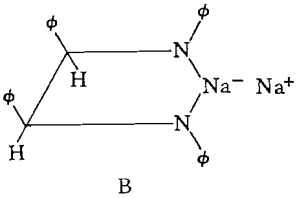
*17% *N*-benzylaniline formed.
†In the absence of isomerization, the final composition should be 54% *meso*.
‡7% *N*-benzylaniline formed.



In a second attempt to prepare high concentrations of the *meso*-*N*,*N*′-disodio compound the *meso*-*N*,*N*′,1,2-tetraphenylethylenediamine was treated with an equivalent amount of preformed *N*,*N*′-disodio compound. An exchange would be expected to occur between the existing sodium compound and the amine to convert the added *meso* diamine into its corresponding *meso*-*N*,*N*′-disodio compound. As this occurs, the newly formed *N*,*N*′-disodio derivative is isomerized to the *dd*,*ll*-disodio derivative. As a consequence, the overall composition of the system becomes richer in the *dd*,*ll* diastereomer.

The final composition is not the 8% *meso* observed in the preparation of the adduct itself, but then the system contains only half the amount of sodium necessary for all the amine groups. An appreciably greater degree of isomerization occurs if the excess sodium metal from the adduct preparation is allowed to remain in the reaction mixture. In this case, the amine groups of the *meso* diamine probably react to some extent with the sodium, thereby bringing the system to a closer resemblance with the *N*,*N*′-disodio compound itself.

An explanation for the greater stability of the *dd*,*ll* diastereomer in polar solvents may lie in the ability of the compound to adopt conformation A or B, in which one sodium

A

B

atom is solvated by the ether solvent and the other is coordinated intramolecularly to the two nitrogen atoms. It will be noted that conformation A arises from the *dd*,*ll* isomer and conformation B from the *meso* isomer. The greater steric interaction of the phenyl groups in B as compared with A would be expected to shift any equilibrium between the two in the direction of A. In a somewhat similar suggestion, Eisch (8) proposes that the radical-ions cluster in a specific manner before the benzylic carbon bond is formed.

In contrast to the behavior of the *N*,*N*′-disodio compound, the addition of either *meso*- or *dd*,*ll*-*N*,*N*′,1,2-tetraphenylethylenediamine to a solution of the *N*,*N*′-dilithio compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

does not result in any significant isomerization of the added diamines (Table V). The small changes in composition observed in these systems are due to cleavage of the bond connecting the benzylic carbons of the diamines and (or) their *N,N'*-dilithio analogues, with the formation of *N*-benzylaniline. No indication of an equilibrium between the two diastereomeric *N,N'*-dilithio compounds was observed.

TABLE V

Sodium adduct (1 equivalent) prepared in the same solution	30‡	29

*All experiments were conducted in tetrahydrofuran.
†9% *N*-benzylaniline present.
‡Calculated by averaging the composition of lithium adduct (53% *meso*) and the sodium adduct (7% *meso*).

Somewhat more surprising is the observation that the lithium adduct is unaffected by the presence of sodium metal or even by the preparation of the sodium adduct in a solution of the lithium adduct. There must be very little, if any, exchange of the lithium bonded to the nitrogen with either elemental sodium or sodium bonded to nitrogen. If such an exchange occurred, then the new *N,N'*-disodio compound thereby formed should isomerize to its equilibrium composition. It is possible to rationalize these observations by assuming that the N—Li bond has a high degree of covalent character so that the system contains a very low concentration of the corresponding amide ion. As a consequence, both isomerization and exchange of sodium for lithium would be very slow.

Eisch demonstrated (8) that, if the dimerization of *N*-benzylidene aniline is effected by the transfer of lithium from preformed lithium–biphenyl adduct (i.e. a homogeneous system), the protonolysis product contains appreciably more *dd,ll* diamine than if the lithium metal alone is used (i.e. a heterogeneous system). Although Eisch cites this as evidence for the dimerization of the radical-ion in solution to yield a *dd,ll*-rich product, it seems equally possible that the strong base lithium–biphenyl is isomerizing the *N,N'*-dilithio-*N,N'*,1,2-tetraphenylethylenediamine during the experiment.

In summary, the nitrogen–lithium bond of the *N,N'*-dilithio-*N,N'*1,2-tetraphenylethylenediamines behaves as a covalent bond, showing little tendency to form the amide ion and thus isomerize. The sodium–nitrogen bond of the corresponding *N,N'*-disodio compound possesses a much greater degree of ionic character as long as relatively polar solvents such as tetrahydrofuran are used. When less-polar solvents such as dioxane and diethyl ether are employed, the concentration of amide ion is reduced so that the isomerization of the initially formed *N,N'*-disodio compounds is slowed or halted.

The inability of diethyl ether to shift the equilibrium composition in tetrahydrofuran from its predominantly *dd,ll* composition indicates the exceptional stability of the *dd,ll*-amide ion once it is formed. The ether must not only displace the solvating tetrahydrofuran but also break the intramolecular coordination of the two nitrogen atoms to the sodium. This it does not appear to be able to do.

EXPERIMENTAL

The preparation of the alkali metal adducts has been described previously (7). Reference samples of *meso-* and *dd,ll-N,N'*,1,2-tetraphenylethylenediamine were prepared by reductive dimerization of *N*-benzylidene aniline with aluminium amalgam in wet ether (6) followed by separation of the individual components by means of their complexes with dimethylformamide (10). The reduction product, after isolation, was analyzed by means of its nuclear magnetic resonance spectrum taken on a Varian A-60 spectrometer in a manner similar to that described by Eisch (8).

Time Studies (Table II)

The time studies were carried out in a flask equipped with a mechanical stirrer and a stopcock at the bottom for withdrawing samples. Solutions were prepared in a dry box from freshly distilled solvents and *N*-benzylidene aniline. These were transferred from the dry box in a sealed separatory funnel and introduced into the reaction vessel under nitrogen. The metal was freshly cut in the dry box and transferred in a sealed test tube equipped with a standard taper joint. The metal was introduced into the reaction vessel by connecting the transfer tube to a side neck and gently tapping the tube to cause the metal to drop into the stirred solution. Color changes indicative of adduct formation were obvious within 2–3 min.

Weighed samples were withdrawn, quenched in 1:1 ethanol–water, and titrated with standard acid to determine the extent of reaction. The titrated samples were then extracted and analyzed as previously described (8).

In the case of the run at 0 °C, the entire reaction vessel was immersed in a Dewar flask filled with ice and water. Reactions at −15° and 40° were carried out in jacketed flasks through which methanol–water or water at the desired temperature was circulated.

In the experiments of Table IV, the adduct was first prepared in a modified Schlenk tube and then transferred to a second tube to which the second alkali metal was added. In the case of the experiments of Table V, the prepared adduct was transferred to a flask containing the second reagent, *dd,ll-* or *meso-N,N'*,1,2-tetraphenylethylenediamine.

ACKNOWLEDGMENTS

We are indebted to Dr. J. S. McIntyre of this laboratory for suggesting the analytical procedure, and to Dr. McIntyre and Mr. H. Mak for the determination of the nuclear magnetic resonance spectra.

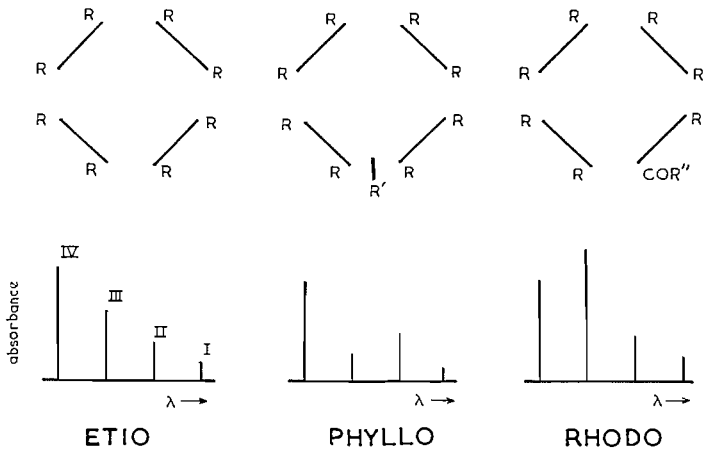
A COMMENT ON THE INADEQUACY OF THE CORRELATION BETWEEN PHYLLO-TYPE SPECTRUM AND *meso*-SUBSTITUTION IN THE PORPHYRIN SERIES

R. Bonnett, I. A. D. Gale, and G. F. Stephenson
Chemistry Department, Queen Mary College, London, E.1, England



Received June 21, 1966

ABSTRACT

The empirical correlation between *meso*-substitution and the phyllo-type spectrum in the porphyrin series is shown to be much less general than had previously been supposed. The variation of the spectrum with the electronic nature of the substituent is discussed.

It became apparent at an early stage in our study of the nitration (1) of octa-substituted porphyrins that deductions from visible and nuclear magnetic resonance spectra were in conflict. Thus, although the nuclear magnetic resonance spectrum of nitrooctaethylporphyrin clearly corresponded to a *meso*-substituted structure, the visible spectrum was of an etio type, whereas, on the basis of the correlation proposed by Stern and Wenderlein (2), a phyllo-type spectrum (Fig. 1) would have been expected. Indeed, Stern and Molvig (3) had applied this correlation to reject, incorrectly as it now emerges (1, 4), the *meso*-nitro structure for nitroetioporphyrin I. It thus became desirable to reconsider the correlation between *meso*-substitution and the phyllo-type spectrum.

The general correlation, which was proposed in 1936, and which has in recent years (5, 6) received a certain amount of theoretical interpretation, is summarized in Fig. 1. It is well documented (2, 7, 8)[1] for both the etio- and rhodo-type assignments, where it operates effectively in the sense that all porphyrins of the stated substitution pattern are expected

R
R
R

to have the spectral type shown. When the phyllo-type correlation was suggested, however, Stern and his colleagues had catalogued only five examples (examples 1–5 in Table I) which demonstrated the effect of a *meso*-substituent in the absence of a "rhodofying" group, and, of these, two (examples 2 and 3, both possessing the isocyclic ring) did not possess typical phyllo-type spectra in that band I was more intense than band II. Thus, the correlation in the phyllo case appears to have been based rather inadequately. Later work has shown that phyllo-type spectra may be observed in the absence of *meso*-substitution (e.g. porphyrin (6), noted by Stern (2)) and, more significantly, has provided many examples of *meso*-substituted porphyrins which do not possess phyllo-type spectra.

Some relevant spectra are summarized in Tables I and II. The original measurements and correlations refer to dioxane solutions (Table I), but in recent years spectra have frequently been recorded in chloroform (Table II). As examples in the tables suggest, solvent dependence in this case is significant but not marked; in a borderline case, there may be a change in spectral type in going from one solvent to another. This happens with α-chlorooctaethylporphyrin, which has an intermediate etio–phyllo type spectrum ($\epsilon_{III} = \epsilon_{II}$) in dioxane but has a phyllo-type spectrum in chloroform. However, inspection of the extinction coefficients shows that the numerical change from one solvent to another is rather small.

The following points emerge from a consideration of Tables I and II.

(*i*) The phyllo-type spectrum is often associated with mono *meso*-alkylated porphyrins. Some authors (18, 19) have, indeed, restricted the correlation in this way, but as examples

*See Table I.
†Extinction ratios.

7 and 16 show, even in this form there are exceptions, and many of the spectra are only marginally of the phyllo type (e.g. examples 6 and 13). Such exceptions have become significant in the structural work (13, 14) on porphyrins derived from the *Chlorobium* chlorophylls 660, in which the spectra (in ether) of various δ-phylloporphyrin homologues have been shown to have $\epsilon_{II} \simeq \epsilon_{III}$.

(*ii*) Many of the compounds, especially the *meso*-alkyl- and *meso*-halo-porphyrins, nevertheless show the development of phyllo character, although this does not necessarily extend as far as the phyllo-type spectrum. This can be demonstrated by observing in a given solvent the effect of introducing a *meso*-substituent into a porphyrin, e.g. by comparing in each case the extinction coefficient of band III with that of band II, the latter being rather insensitive to substituent changes (5, 8). Thus, the ratio (R) of ($\epsilon_{IIIp}/\epsilon_{IIp}$) to ($\epsilon_{IIIm}/\epsilon_{IIm}$), where p and m refer to the parent porphyrin and the *meso*-substituted porphyrin, respectively, is greater than unity in all but 1 (example 15) of the 14 instances where the comparison has been made (Tables I and II). The unusual nature of the spectrum of α-cyanoetioporphyrin I (example 15) has been remarked upon by Johnson and Oldfield (16); it is presumably associated with a combination of features (large negative spectroscopic moment (5) and low steric requirement) found with this substituent.

(*iii*) More bulky groups which are mesomerically electron withdrawing (e.g. NO_2 (examples 10, 11, 10*a*, and 11*a*)) appear to give spectra which are clearly of the etio type[2] (even though R is greater than unity, as indicated above). This may be rationalized in terms of the composition of the rhodo and phyllo effects *attributable to a single substituent*. The composition of such effects caused by two different substituents (as in chloroporphyrin e_6 trimethyl ester; etio-type spectrum in dioxane (9)) has numerous examples.

(*iv*) A *meso*-hydroxy substituent gives a spectrum of an unclassified type in which "band I" dominates the visible spectrum. Tautomeric forms (17) of such compounds may well be important, since in the acyl derivatives (e.g. example 18 → example 19) the spectrum returns to an etio type with pronounced phyllo character. In *meso*-aminoporphyrins this effect is much less marked (4).

[2]*Johnson and Oldfield discuss this point (4) and give several additional examples (in chloroform) (16).*

For personal use only.

(*v*) The introduction of the maximum number of *meso*-substituents is not associated with the development of a phyllo-type spectrum. Thus, Eisner (20) has noted that the spectrum of $\alpha,\beta,\gamma,\delta$-tetramethylporphyrin (in chlorobenzene) is of an unclassified type. This point is further illustrated (Table III) by the chloro derivatives. The phyllo character of the spectrum increases somewhat on proceeding from α-chlorooctaethylporphyrin to the α,γ-dichloro derivative; however, the $\alpha,\beta,\gamma,\delta$-tetrachloro compound has a spectrum of an unclassified type in which the bands have suffered a considerable bathochromic shift. The extent of the shift suggests that it is not merely due to the electronic effect of the substituents; possibly, this is a further example (21) where departure from coplanarity (caused by peripheral overcrowding (15)) results in a bathochromic shift because the diminution of the ground-state stabilization reduces the energy gap between the ground and excited states.

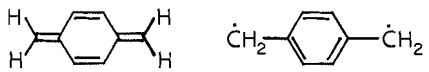
QUINODIMETHANE CHEMISTRY

THE GENERATION AND TRAPPING OF QUINODIMETHANES FROM SUBSTITUTED AROMATIC HYDROCARBONS WITH HIGH-POTENTIAL QUINONES



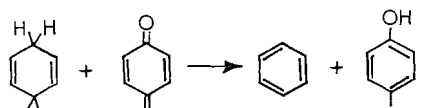
J. W. Lown and A. S. K. Aidoo
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 17, 1966

ABSTRACT

9,10-Dimethylanthracene and 9,10-dimethyl-9,10-dihydroanthracene react with 2 and 3 moles, respectively, of tetrachloro-1,2-benzoquinone to give the same 1:1 adduct of 9,10-anthraquinodimethane with the quinone, the structure of which was proved by ozonolysis. A lower limit for the rate of adduct formation in 1,2-dichlorobenzene at 80° is 4.22×10^{-2} l mole^{-1} s^{-1}. 7,12-Dimethylbenzanthraquinodimethane was generated in a similar way and the structure of the 1:1 adduct proved by ozonolysis and by mass spectrometry. The reaction of 9,10-anthraquinodimethane with a *p*-quinone gave a 1:2 adduct. 9-Methylanthracene reacts with high-potential quinones by hydride abstraction at the methyl group with the formation of an ether.

Quinodimethanes or *p*-xylylenes are of considerable interest both from the theoretical and experimental standpoints. The first evidence of their existence was obtained from the pyrolysis of *p*-xylene (1, 2), and subsequent investigations of the pyrolysis of related compounds proved that analogues of *p*-xylylene can be produced by similar techniques (2–5). More recently, *p*-xylylenes have been produced as reactive intermediates by the reaction of magnesium with 4-methoxymethylbenzyl chloride (6) and the decomposition of trimethyl-4-methylbenzyl ammonium hydroxide (7–10). Errede and Landrum (11) discovered that solutions of *p*-xylylene are relatively stable at low temperatures. That *p*-xylylene exists in the quinodimethane form I rather than as a diradical II is shown by its spectra and its diamagnetism. It is extremely reactive and polymerizes readily, but controlled polymerization leads to compounds of low molecular weight, including [2,2]-paracyclophane.

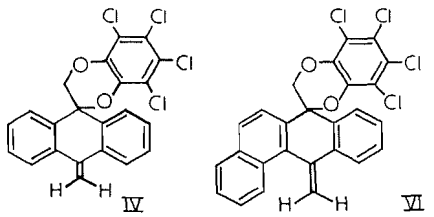


I II

Recently, a novel method has been introduced by Millar and Wilson (12, 13) and Stille and Foster (14), namely, the dehydration of the appropriate tertiary diols in high-boiling solvents such as diethyl phthalate. In this way, quinodimethanes derived from the anthracene and phenanthrene series have been generated and trapped by dienophiles, such as maleic anhydride, benzoquinone, and dimethyl acetylene dicarboxylate.

An interest in the homogeneous dehydrogenation of hydroaromatic compounds with high-potential quinones (15) led us to investigate the dehydrogenation of aromatic hydrocarbons as a method of generating quinodimethanes.

The driving force for the hydrogen transfer reaction, represented schematically below,



III

is provided by the gain in resonance energy of both reactants (15). Molecular orbital calculations predict that the resonance energy of *p*-xylylenes is comparable with that of the benzenoid precursor (16) (e.g. *p*-xylylene itself has a resonance energy of 38 kcal/mole compared with ca. 36 kcal/mole for *p*-xylene). Therefore, the dehydrogenation of a dimethyl aromatic hydrocarbon to a quinodimethane is energetically feasible. The generating reactant also acts as a dienophile, and therefore will trap the quinodimethane. Since the reaction is homogeneous, unlike the various methods described above, order-of-magnitude estimates may be made of the rate of the reaction between the quinodimethane and the dienophile, as shown below. By using different quinones, information is obtained on the steric requirements of the subsequent reactions.

9,10-Anthraquinodimethane

Previous attempts to prepare anthraquinodimethane by the pyrolysis of 9,10-dimethylanthracene were unsuccessful (2). Dehydration of 9,10-dimethyl-9,10-dihydroxy-9,10-dihydroanthracene in boiling diethyl phthalate in the presence of a dienophile gave 1:1 or 1:2 adducts (13, 17). We have observed that *cis*-9,10-dimethyl-9,10-dihydroanthracene (18) reacts readily with 3 moles of tetrachloro-1,2-benzoquinone and that the reaction is not confined to a simple dehydrogenation to 9,10-dimethylanthracene. The product mixture was complex, but by repeated chromatography in benzene on alumina a colorless crystalline compound, $C_{22}H_{12}Cl_4O_2$, could be isolated in a pure form in a 16.2% yield. The low yield reflects the difficulty of separation from other components of high molecular weight (estimated ca. 880), presumably arising from rapid polymerization of the anthraquinodimethane, as has often been observed in other methods of generating this type of intermediate (1, 2, 13, 14).

The nuclear magnetic resonance (n.m.r.) spectrum of the compound exhibited singlets which were each equivalent to two protons in the regions characteristic (19) of olefinic protons and protons of the type —CH_2—O—, respectively. There was also a complex band arising from eight aromatic protons. The infrared spectrum contained no bands attributable to carbonyl stretching, but exhibited a very strong band at 1 422 cm^{-1} characteristic of a tetrachlorobenzodioxin (20). The ultraviolet spectrum was compatible with the presence of a 1,1-diphenylethylene chromophor. This evidence leads to the formulation IV as the structure of this compound, and its formation is attributed to the addition of 1 mole of tetrachloro-1,2-benzoquinone to the carbon–carbon double bond at the 9 position of the anthraquinodimethane intermediate.

IV VI

The structure was confirmed by ozonolysis, which gave formaldehyde (isolated as the dimedone derivative) and a yellow solid V, $C_{21}H_{10}Cl_4O_3$, the n.m.r. spectrum of which resembles that of IV except for the absence of the olefinic band. The infrared spectrum of V shows a strong carbonyl absorption, as expected.

9,10-Dimethylanthracene similarly reacts with 2 moles of tetrachloro-1,2-benzoquinone to give IV as the main isolable product. The deep-red color of the quinone allows measurement of the reaction rates by a simple spectrokinetic procedure, the details of which have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

been presented elsewhere (21). It was thus shown that *cis*- and *trans*-9,10-dimethyl-9,10-dihydroanthracene undergo rapid, triply consecutive, second-order reactions with 3 moles of the quinone, with a relatively slow initial step. The reaction of 9,10-dimethylanthracene and tetrachloro-1,2-benzoquinone, which was bimolecular, consecutive second order with a fast second step (i.e. Diels–Alder reaction of the quinodimethane with the quinone), was 30–60 times faster than the reaction of the dihydrodimethylanthracenes.

On the basis of the evidence of the isolated product and the rate data, the following two series of reactions can be postulated.

Scheme 1

$$RH_4 + Q \xrightarrow{k_1} RH_2 + QH_2$$

$$RH_2 + Q \xrightarrow{k_2} RH_2Q$$

$$RH_2Q + Q \xrightarrow{k_3} QH_2 + RQ$$

k_2 and $k_3 \gg k_1$

Scheme 2

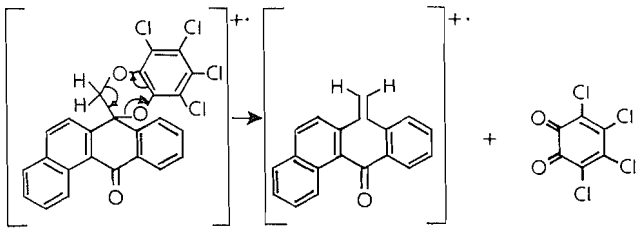
$$RH_4 + Q \xrightarrow{k_1} RH_2 + QH_2$$

$$RH_2 + Q \xrightarrow{k_2} R + QH_2$$

$$R + Q \xrightarrow{k_3} RQ$$

k_2 and $k_3 \gg k_1$

RH_4 represents 9,10-dihydro-9,10-dimethylanthracene, RH_2 represents 9,10-dimethylanthracene, R represents 9,10-anthraquinodimethane, and RQ represents the isolated product IV. Scheme 1 implies the formation of an intermediate Diels–Alder addition compound (RH_2Q) of 9,10-dimethylanthracene and tetrachloro-1,2-benzoquinone, which is then attacked at the CH_3 groups by a further molecule of quinone with the formation of IV. Scheme 2 represents the simpler mechanism, in which 9,10-dimethylanthracene is dehydrogenated directly to the 9,10-anthraquinodimethane (R), which undergoes Diels–Alder addition with the quinone to yield IV. Scheme 1 is rendered unlikely by the following observation. 9,10-Dimethyl-9,10-dihydro-9,10-ethanoanthracene-11,12-dicarboxylic anhydride (i.e. the Diels–Alder addition compound of 9,10-dimethylanthracene and maleic anhydride), in which the CH_3 groups are in an environment similar to that in the hypothetical intermediate RH_2Q, is completely inert to the action of tetrachloro-1,2-benzoquinone in 1,2-dichlorobenzene at 101° for 44 h. Since the rate data obtained are consistent only when k_3 is much greater than k_1, scheme 1 is rejected; the results are therefore interpreted in terms of scheme 2 involving the intermediacy of 9,10-anthraquinodimethane (see Experimental). Therefore, a lower limit for the reaction rate of 9,10-anthraquinodimethane with tetrachloro-1,2-benzoquinone in 1,2-dichlorobenzene at 80° is 4.22×10^{-2} l mole^{-1} s^{-1}.



The reaction of anthraquinodimethane, generated *in situ* by refluxing 9,10-dimethyl-9,10-dihydroxy-9,10-dihydroanthracene in ethyl phthalate, with tetrachloro-1,2-benzoquinone led only to tars. This result is not unexpected since the chloroquinone is sensitive to water and can undergo a variety of side reactions.

7,12-Benzanthraquinodimethane

7,12-Dimethylbenzanthracene reacted readily with tetrachloro-1,2-benzoquinone in benzene, and the main product was a colorless crystalline solid, $C_{26}H_{14}O_2Cl_4$, the spectral properties of which confirmed a 1:1 adduct of benzanthracenequinodimethane and tetrachloro-1,2-benzoquinone. Considerations of steric hindrance predict an orientation for the quinone at the double bond remote from the fused benzo ring corresponding to VI. This assignment is supported by the n.m.r. spectrum, which shows the olefinic protons to be non-equivalent owing to the different effects of the ring current from the angular benzene ring, in contrast to the equivalent protons shown by IV. Treatment with ozone

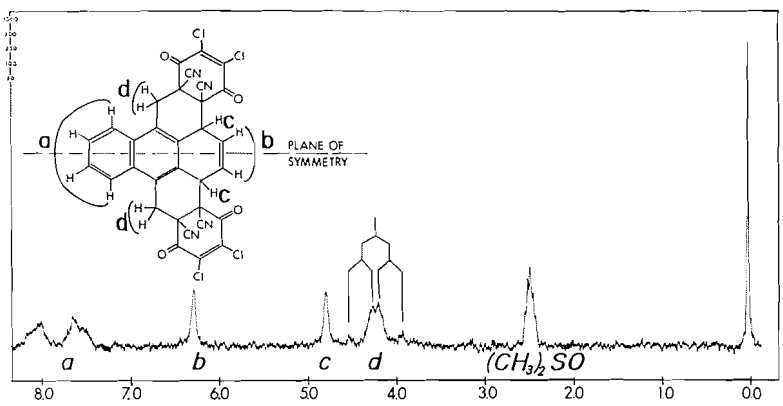
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

followed by decomposition of the ozonide with steam gave a yellow solid, the n.m.r. spectrum of which showed the absence of vinyl protons; the infrared spectrum showed a new carbonyl. Mass spectrometry showed a molecular ion peak measuring 499.9543, compared with 499.9540 calculated for $C_{25}H_{12}O_3Cl_4$. A strong peak in the spectrum at *m/e* 256 was expected and is due to the following fragmentation.

This interpretation is based on the very recent analogy provided by the mass spectrum of an adduct of tetrachloro-1,2-benzoquinone and abietic acid (22).

Reactions with Other Quinones

It was anticipated that the reaction of anthraquinodimethane with a *p*-quinone would give rise to different adducts owing to the different geometrical requirements of the dienophile. 9,10-Dimethylanthracene reacts very readily with 2,3-dichloro-5,6-dicyanobenzoquinone, and a bright-yellow solid, $C_{32}H_{12}N_4Cl_4O_4$, was isolated from the reaction mixture. The infrared spectrum exhibited bands characteristic of C≡N and enedione groupings. The n.m.r. spectrum (Fig. 1) was compatible with structure VIII, i.e. a



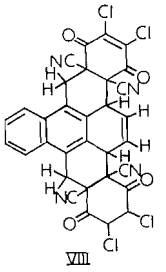


FIG. 1.

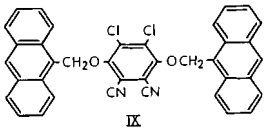

4,5-benzpyrene skeleton. The structure is analogous to similar 1:2 adducts obtained by Millar and Wilson by the reaction of anthraquinodimethane, generated by the dehydration of 9,10-dimethyl-9,10-dihydroxy-9,10-dihydroanthracene, with various dienophiles (12, 13). The simplicity of the n.m.r. spectrum supports the proposed 4,5-benzpyrene structure, which has a plane of symmetry, if the quinone rings are *cis* to one another and if both are *cis*-fused at the carbons bearing the nitrile groups (as expected) or, less likely, symmetrically *trans*-fused. The orientation of the 2,3-dichloro-5,6-dicyanobenzoquinone moieties

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is based, by analogy, on the studies of Ansell (23), in which the powerfully electron-attracting nitrile groups so enhance the dienophilic character of the double bond to which they are attached that addition takes place exclusively at this bond. Attempts to prove this point by the base-catalyzed elimination of hydrocyanic acid were unsuccessful owing to the general lability of the substance towards the action of strong bases.

VIII

IX

The reactivity of the 9-methyl group in anthracene derivatives towards hydride abstraction is not confined to 9,10-disubstituted compounds. 9-Methylanthracene reacted readily with 2,3-dichloro-5,6-dicyanobenzoquinone and gave a yellow solid, $C_{38}H_{22}Cl_2N_2O_2$, the infrared spectrum of which showed bands characteristic of ether and nitrile linkages. The material is assigned structure IX by analogy with a similar ether obtained by the reaction of 2,2-dimethylindane with the same quinone (20), and the structure was proved by cleavage of the ether linkage with hydriodic acid and reduction of the resulting 9-iodomethyleneanthracene with lithium aluminium hydride to 9-methylanthracene.

The scope of the above method of generating *p*- and *o*-quinodimethanes in other systems, particularly the phenanthrene and acepleiadylene series, is being investigated.

EXPERIMENTAL

Melting points were taken on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 421 spectrophotometer. Only the principal, sharply defined peaks are reported. Nuclear magnetic resonance spectra were recorded on a Varian A-60 analytical spectrometer operating at a fixed radiofrequency of 60 Mc.p.s. The spectra were measured on an approximately 15% (w/v) solution in an appropriate solvent, with tetramethylsilane as a standard. Line positions are reported in parts per million from the reference. Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were obtained on an AEI-MS-9 high-resolution mass spectrometer. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalyses Ltd., Montreal, Quebec, and by Miss D. Roberts, Microanalytical Laboratory, Chemistry Department, University of Alberta, Edmonton, Alberta.

Reaction of 9,10-Dimethylanthracene with Tetrachloro-1,2-benzoquinone

A mixture of 4.506 g (0.022 mole) of 9,10-dimethylanthracene and 10.822 g (0.044 mole) of tetrachloro-1,2-benzoquinone in 100 ml of sodium-dried benzene was refluxed under nitrogen for 2 days, cooled, diluted with 150 ml of *n*-hexane, and filtered to remove hydroquinone. The filtrate was concentrated *in vacuo* to ca. 40 ml and passed down a column of grade I alumina to remove hydroquinone and unreacted quinone. Elution with 1:1 benzene–*n*-hexane and evaporation of the solvents gave a pale-yellow crystalline solid (2.3 g) as the first fraction. Careful chromatography of this fraction on alumina in 1:2 benzene–*n*-hexane gave, as the main component, a colorless crystalline solid (1.75 g, 18% yield), which was purified by recrystallization from ethyl acetate, m.p. 240° (decomp.).

Anal. Calcd. for $C_{22}H_{13}Cl_4O_2$ (450.12): C, 58.6; H, 2.9; Cl, 31.50. Found: C, 58.4; H, 3.2; Cl, 31.9; mol. wt. (ebullioscopic in benzene) 444.4.

Infrared spectrum: ν_{max} ($CHCl_3$) 1 422 cm^{-1} (s) (characteristic (20) of a six-membered tetrachlorobenzodioxan structure); no absorption in the region expected for OH or C=O. Nuclear magnetic resonance spectrum ($CDCl_3$): 5.80 (2H, singlet, vinyl protons), 3.94 (2H, singlet, $—CH_2—O$), 7.44 (8H, complex aromatic absorption). Absorption spectrum (cyclohexane): λ_{max} 302 mμ (log ε 3.48), 253 mμ (sh) (log ε 4.20), 230 mμ (sh) (log ε 4.59).

Subsequent fractions of the chromatogram consisted of mixtures of minor, higher molecular weight, colored products which could not be separated.

For personal use only.

Reaction between cis-9,10-Dimethyl-9,10-dihydroanthracene and Tetrachloro-1,2-benzoquinone

A mixture of 1.032 g (0.0048 mole) of *cis*-9,10-dimethyl-9,10-dihydroanthracene (obtained by the reduction of 9,10-dimethylanthracene with sodium and ethanol (18) and 3.786 g (0.0154 mole) of tetrachloro-1,2-benzoquinone in 30 ml of dry benzene was refluxed for 12 h, then cooled, diluted with 100 ml *n*-hexane, and filtered. The filtrate was concentrated to ca. 40 ml and passed down a column of grade I alumina. Elution with 1:1 benzene–*n*-hexane and evaporation of the eluate gave a yellow solid (0.52 g), shown by thin-layer chromatography to be a mixture. Careful re-chromatography of this fraction on alumina in 1:2 benzene–*n*-hexane gave, as the main component, a colorless crystalline solid, which was purified by recrystallization from ethyl acetate (0.35 g, 16.2% yield), m.p. 240°, mixed m.p. with the pure product isolated from the previous reaction 240°. The spectral properties of the two samples were identical.

Again, subsequent fractions of both chromatograms proved to be complex mixtures of high molecular weight components, and no attempt was made to separate them.

Ozonolysis of the Adduct of Anthraquinodimethane and Tetrachloro-1,2-benzoquinone

A slow stream of dry ozone (from a Welsbach T-23 ozonator) was passed successively through a solution of 223 mg (0.0005 mole) of the adduct dissolved in 80 ml ethyl acetate in a 250 ml Dreschel bottle and a second bottle containing 50 ml of water, until ozone was detected in the effluent with moist starch – potassium iodide paper. The two liquids were combined and subjected to steam-distillation; a yellow solid separated in the flask. The steam-distillate was made neutral to phenolphthalein, and a solution of 3 g of 5,5-dimethyl-1,3-cyclohexanedione in 50 ml of 50% ethanol added. After 60 min the precipitate of formaldehyde dimedone was collected, washed with 5 ml of 20% aqueous ethanol, and dried (0.102 g, 0.7 mole).

The yellow solid was collected, dried, and purified by recrystallization from acetonitrile (0.180 g, 80% yield), m.p. 270°.

Anal. Calcd. for $C_{21}H_{10}O_3Cl_4$: C, 55.79; H, 2.23; Cl, 31.36. Found: C, 55.81; H, 2.48; Cl, 31.05.

Infrared spectrum: ν_{max} (KBr disk) 1 422 cm^{-1} (s) (characteristic of a six-membered tetrachlorobenzodioxin structure (20)), 1 672 cm^{-1} (C=O stretching). Nuclear magnetic resonance spectrum ($CDCl_3$): 4.06 (2H, singlet, $—CH_2O—$), 7.45 (8H, complex aromatic absorption); no vinyl absorption was present. Absorption spectrum (CH_3CN): λ_{max} 3.05 mμ (sh) (log ε 3.42), 264 mμ (log ε 4.68), 230 mμ (sh) (log ε 4.38).

Reaction of 7,12-Dimethylbenzanthracene and Tetrachloro-1,2-benzoquinone

A solution of 1 g (0.0032 mole) of 7,12-dimethylbenzanthracene and 2.06 g (0.0084 mole) of tetrachloro-1,2-benzoquinone in 20 ml of dry benzene was refluxed for 3 days, then cooled, and chromatographed on grade I alumina. The column was developed and eluted with 1:1 benzene–*n*-hexane. Evaporation of the first fraction gave a pale-yellow crystalline solid, which gave a single spot on thin-layer chromatography in a variety of solvents and was recrystallized from 1:1 benzene–*n*-hexane, m.p. 247° (decomp.) (0.375 g, 19% yield). Subsequent chromatographic fractions gave a yellow material, which was shown by thin-layer chromatography to be a complex mixture of minor products which were not investigated further.

Anal. Calcd. for $C_{26}H_{14}O_2Cl_4$: C, 62.43; H, 2.82; Cl, 28.77. Found: C, 62.57; H, 2.70; Cl, 28.90.

Infrared spectrum: ν_{max} ($CHCl_3$) 1 422 cm^{-1} (s) (characteristic of a six-membered tetrachlorobenzodioxan structure (20)). Nuclear magnetic resonance spectrum ($CDCl_3$): 4.10 (2H, singlet, $—CH_2—O$), 5.93 and 6.12 (1H, each narrow doublets, $J_{ab} < 1$ c.p.s., vinyl protons), 7.30–8.00 (10H, complex aromatic absorption). Absorption spectrum (cyclohexane): λ_{max} 302 mμ (log ε 4.07), 290 mμ (sh) (log ε 3.98), 232 mμ (log ε 4.86).

Ozonolysis of the Adduct of Benzanthraquinodimethane and Tetrachloro-1,2-benzoquinone

A solution of 47 mg (0.000095 mole) of the adduct in 70 ml of ethyl acetate was subjected to ozonolysis under conditions similar to those described for the anthraquinodimethane adduct. Decomposition of the ozonide with steam gave a yellow crystalline solid (27 mg, 51% yield), m.p. 253°. The mass spectrum showed a parent peak with an isotopic pattern typical of four chlorine atoms, measured as 499.9543 (calcd. for $C_{25}H_{12}O_3Cl_4$: 499.9540). A strong peak at *m/e* 256 was caused by the retro-Diels–Alder fragmentation typical of this type of adduct, as described in the Discussion.

Infrared spectrum: ν_{max} (KBr disk) 1 422 cm^{-1} (s) (characteristic of a six-membered tetrachlorobenzodioxin structure (20), 1 670 cm^{-1} (C=O). Nuclear magnetic resonance spectrum ($CDCl_3$): 4.16 (2H, singlet, $—CH_2—O—$), 7.3–8.1 (10H, complex aromatic absorption); no vinyl absorption was present. Absorption spectrum (CH_3CN): λ_{max} 292 mμ (log ε 3.55), 258 mμ (sh) (log ε 3.59), 232 mμ (sh) (log ε 3.99).

Reaction of 9,10-Dimethylanthracene with 2,3-Dichloro-5,6-dicyanobenzoquinone

A solution of 2.027 g (0.0099 mole) of 9,10-dimethylanthracene in 75 ml of warm benzene was added to a solution of 6.79 g (0.03 mole) of 2,3-dichloro-5,6-dicyanobenzoquinone in 225 ml of warm benzene, with shaking. There was an immediate darkening of the solution caused by charge transfer complexing; then a copious yellow precipitate separated. The mixture was refluxed for 7 h and cooled, and the solid was collected. Extraction of the solid with hot acetone left the insoluble brown hydroquinone, and evaporation of the extract gave adduct VIII as a bright-yellow crystalline solid (1.86 g, 28.2% yield), m.p. 217° (decomp.).

Anal. Calcd. for $C_{32}H_{12}O_4N_4Cl_4$ (658.38): C, 58.38; H, 1.85; N, 8.51; Cl, 21.54. Found: C, 58.44; H, 2.30; N, 8.36; Cl, 21.74; mol. wt. (by mass spectrometry) 656 (^{35}Cl).

Infrared spectrum: ν_{max} (Nujol mull) 1 726 cm^{-1} (br) (enedione C=O), 2 245 cm^{-1} (m) (C≡N). Nuclear magnetic resonance spectrum ($(CD_3)_2SO$): 4.82 (2H, singlet, 'angular' protons), 6.32 (2H, singlet, vinyl protons), 7.50–8.30 (4H, A_2B_2 aromatic protons), AB quartet, J = 16 c.p.s., centers of gravity at 4.17 and 4.37 (CH_2 protons). (See Fig. 1.) Absorption spectrum (CH_3CN): λ_{max} 375 mμ (log ε 3.19), 278 mμ (log ε 4.31), 260 mμ (sh) (log ε 4.25), 234 mμ (log ε 4.75).

Reaction of 9-Methylanthracene with 2,3-Dichloro-5,6-dicyanobenzoquinone

A solution of 2.4 g (0.0106 mole) of 2,3-dichloro-5,6-dicyanobenzoquinone in 45 ml of dry benzene was added to a solution of 1 g (0.0052 mole) of 9-methylanthracene in 5 ml of dry benzene. The solution darkened, and after it was refluxed for 10 min a light-yellow precipitate separated. The mixture was refluxed for 2 h and cooled, and the solid was collected by filtration. The major product was insoluble in chloroform, methanol, acetonitrile, dimethyl sulfoxide, and benzene, and was purified by Sohxlet extraction from it of impurities with methanol, leaving a bright-yellow solid (1.1 g, 34.6% yield), m.p. 215° (decomp.).

Anal. Calcd. for $C_{38}H_{22}Cl_2N_2O_2$ (609.482): C, 74.87; H, 3.61; Cl, 11.66; N, 4.61. Found: C, 74.74; H, 3.88; Cl, 11.98; N, 4.42; mol. wt. (by mass spectrometry) 608 (^{35}Cl).

Infrared spectrum: ν_{max} (KBr disk) 1 425 cm^{-1} (s) (C—O—C linkage (20)), 2 216 cm^{-1} (C≡N).

Adduct IX (0.227 g, 0.00036 mole) was refluxed with a mixture of 5 ml of 57% hydriodic acid and 3 ml of water for 8 h. White crystals of 9-iodomethyleneanthracene (45 mg), m.p. 65–66°, which had sublimed into the condenser were removed and dried *in vacuo*. The substance, without further purification, was dissolved in 10 ml of dry ether, treated with a solution of 85 mg of lithium aluminium hydride, and stirred for 4 h. The mixture was cooled, unreacted hydride decomposed with water, and the organic layer removed. Evaporation of the ether gave yellow crystals of 9-methylanthracene, m.p. 74–75°, mixed m.p. with authentic 9-methylanthracene 74–75°. The n.m.r. spectrum in $CDCl_3$ was identical with that of an authentic sample of the hydrocarbon.

Control Reaction of 9,10-Dimethyl-9,10-dihydro-9,10-ethanoanthracene-11,12-dicarboxylic Anhydride with Tetrachloro-1,2-benzoquinone

A mixture of 1.18 g (0.0039 mole) of 9,10-dimethyl-9,10-dihydro-9,10-ethanoanthracene-11,12-dicarboxylic anhydride and 1.65 g (0.0068 mole) of the quinone in 45 ml of dry 1,2-dichlorobenzene was heated in a constant-temperature bath at 101° for 44 h. The mixture was concentrated to a small volume and cooled, and the white crystalline solid was collected and washed with benzene, yielding the unchanged adduct (1.09 g, 92% recovery), m.p. 330°, mixed m.p. with an authentic sample 330° (lit. (25) m.p. 333–335°).

Kinetic Experiments

Materials

Pure 1,2-dichlorobenzene was distilled from sodium and had b.p. 177–178° at 750 mm, n_D^{22} 1.5518 (24). Commercial samples of tetrachloro-1,2-benzoquinone and 2,3-dichloro-5,6-dicyanobenzoquinone were purified by sublimation and by recrystallization from benzene–*n*-hexane, respectively, the benzene of crystallization being removed in a vacuum desiccator.

Reaction Rates

The rates were determined by following spectrophotometrically the disappearance of the colored quinone. The E_0 values were determined by graphical extrapolation. The experimental method used and detailed treatment of the rate data have been described previously (21).

Kinetic Equations Employed

Let a mole l^{-1} = the initial concentration of quinone; let b mole l^{-1} = the initial concentration of hydrocarbon; let x mole l^{-1} = the amount of quinone consumed at time t; let the initial extinction of the quinone at 5 600 Å be E_0; let the extinction of the quinone at 5 600 Å at time t be E. The meaning of the symbols RH_2, RH_2, and R used below is explained in the Discussion.

Bimolecular, Consecutive, Second-Order Reaction with Fast Second Step

$$\underset{(b-x)}{RH_2} + \underset{(a-x)}{Q} \xrightarrow{k} \underset{x}{R} + \underset{x}{QH_2}; \quad \underset{x}{R} + \underset{x}{Q} \xrightarrow{k_2} \underset{(a-x)}{RQ}$$

The overall rate expression when $k_2 \gg k$ is

$$dx/dt = k(b - x)(a - 2x).$$

Integration leads to

$$k = \frac{1}{(2b - a)t} \ln \left(\frac{a}{b} \cdot \frac{b - x}{a - 2x} \right).$$

$E_0 = \lambda a$; $E = \lambda(a - 2x)$; therefore, $E + E_0 = 2\lambda(a - x)$, where λ is a proportionality constant.

When $(b - x) = a\left(\frac{b}{a} - 1\right) + (a - x)$ is substituted,

$$k = \frac{1}{(2b - a)t} \ln \left[\frac{a}{b} \cdot \frac{E_0\left(\frac{b}{a} - 1\right) + \frac{E_0 + E}{2}}{E}\right]$$

$$k = \frac{1}{(2b - a)t} \ln\left[\frac{a}{b} \cdot \frac{E_0\left(\frac{2b}{a} - 1\right) + E}{2E}\right].$$

If $a = b$, then

$$k = \frac{1}{at} \ln\left[\frac{E_0 + E}{2E}\right].$$

Triply Consecutive, Second Order Reaction with Slow Initial Step

$$RH_4 + Q \xrightarrow{k_1} RH_2 + QH_2$$
$$RH_2 + Q \xrightarrow{k_2} R + QH_2$$
$$R + Q \xrightarrow{k_3} RQ$$

The overall rate expression when k_2 and $k_3 \gg k_1$ is $dx/dt = k_1(b - x)(a - 3x)$.
Integration leads to $(b > a)$

$$k = \frac{1}{(3b - a)t} \ln\left[\frac{a}{b} \cdot \frac{b - x}{a - 3x}\right].$$

$E_0 = \lambda a$; $E = \lambda(a - 3x)$; $(b - x) = a\left(\frac{b}{a} - 1\right) + (a - x)$; $(a - x) = 2E_0 + E/3\lambda$. Therefore,

$$k = \frac{1}{(3b - a)t} \ln\left[\frac{a}{b} \cdot \frac{E_0\left(\frac{b}{a} - 1\right) + \frac{2E_0 + E}{3}}{E}\right]$$

$$k = \frac{1}{(3b - a)t} \ln\left[\frac{a}{b} \cdot \frac{E + E_0\left(\frac{3b}{a} - 1\right)}{3E}\right].$$

Summary of Rate Constants

The units for the following rates are liters per mole per second. The initial concentration of hydrocarbon and quinone in 1,2-dichlorobenzene was 0.0100 *M*.

cis-9,10-Dihydro-9,10-dimethylanthracene

$T°$	76.4	77.0	79.4	82.0	88.1	90.6

STEROIDS AND STEROIDASES

III. DICYCLOHEXYLCARBODIIMIDE – DIMETHYL SULFOXIDE OXIDATIONS OF ALCOHOLS AND THIOLS[1]

J. BRYAN JONES AND DONALD C. WIGFIELD

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario

Received July 4, 1966

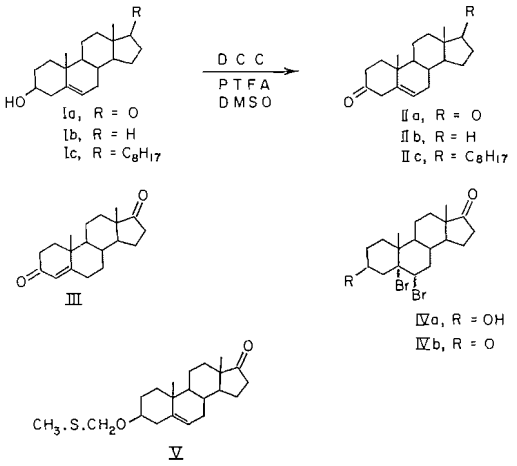
ABSTRACT

A survey of methods for the preparation of acid- and base-labile steroid Δ^5-3-ketones showed that oxidation of the appropriate Δ^5-3β-alcohols with dicyclohexylcarbodiimide – dimethyl sulfoxide (Moffatt reagent) was the most satisfactory, giving yields of 60–70% of the required ketones with little or no isomerization to the corresponding Δ^4-3-ketones. From the oxidation of 3β-hydroxyandrost-5-en-17-one, the product of a Pummerer rearrangement, 3β-(methylthiomethoxy)-androst-5-en-17-one, was isolated. The Moffatt reagent also was convenient for the oxidation of thiols to the corresponding disulfides.

In connection with studies related to the mechanism of action and specificity of the Δ^5-3-ketosteroid isomerase of *Pseudomonas testosteroni*, it became necessary to prepare several Δ^5-3-ketosteroids in a high state of purity. In the past, this has presented some difficulty because of the ease with which these compounds isomerize to the corresponding Δ^4-3-ketosteroids in the presence of traces of acid or base or when heat was applied. The problem is particularly acute for androst-5-ene-3,17-dione (II*a*), which is the substrate normally used in assaying the isomerases derived from both bacterial and mammalian sources (1).

Before 1963, the routes followed in the preparation of II*a* were those of Djerassi and his co-workers (2), using chromium trioxide oxidation of the 3β-alcohol I*a*, and of Butenandt and Schmidt-Thomé (3), in which the double bond of I*a* was protected by reaction with bromine before oxidation of the 3β-hydroxyl group. The physical properties reported in the literature for II*a* prepared by these methods were not consistent, and it was decided to investigate both routes to establish the optimum conditions for the preparation of the pure Δ^5-3-keto substrates.

Application of the chromic acid method (2) to 3β-hydroxyandrost-5-en-17-one (I*a*) gave a product whose melting point and specific rotation were identical with those reported previously (2, 4). However, thin-layer chromatographic analysis showed it to be a mixture of the starting alcohol, the required Δ^5-3-ketone II*a*, and some of the product of the subsequent acid-catalyzed isomerization, androst-4-ene-3,17-dione (III). Isolation of a pure sample of II*a* from the mixture could not be achieved.



The alternative method, involving addition of bromine to I*a*, followed by chromic acid oxidation of the dibromide IV*a* and subsequent debromination of IV*b* with zinc, proved to be rather tedious, but by using a modification (5) of the original (3) method, low yields of thin-layer chromatographically pure II*a* were obtained. The difficulties encountered in this method were due mainly to the instability of the intermediate dibromoketone IV*b*, which rapidly underwent considerable photolytic decomposition (cf. ref. 6).

Fortunately, the elegant procedure reported in 1963 by Pfitzner and Moffatt (7) with DCC,[2] PTFA, and DMSO enabled the oxidation of the 3β-alcohols I to be carried out

[1]*For part II, see J. B. Jones, V. Vlasinich, and J. D. Leman, Can. J. Biochem., 44, 1183 (1966).*

[2]*The following abbreviations have been used: DCC, N,N'-dicyclohexylcarbodiimide; DMSO, dimethyl sulfoxide; PTFA, pyridinium trifluoroacetate; t.l.c., thin-layer chromatography.*

under mild neutral conditions, thereby obviating most of the problems associated with the preparation of Δ^5-3-ketosteroids. By the application of slightly modified conditions for the Moffat oxidation, good yields (~70%) of androst-5-ene-3,17-dione (II*a*), androst-5-en-3-one (II*b*), and cholest-5-en-3-one (II*c*) have been obtained from the 3β-alcohols I*a*, I*b*, and I*c*, respectively.

During a survey carried out to determine the molar proportion of DCC required for optimum yields of the Δ^5-3-ketones, an oxidation was attempted with equimolar proportions of the alcohol I*a*, DCC, and PTFA. Under these conditions, only a 5% yield of the β,γ-unsaturated ketone II*a* was produced together with 5% of 3β-(methylthiomethoxy)-androst-5-en-17-one. Structure V was assigned to the latter compound on the basis of its acid hydrolysis to I*a* and its spectral data.[3] The formation of methylthiomethoxy compounds as by-products of the Moffatt oxidation of several other alcohols has now been reported (7–11).

The data currently available (7–12) indicate that the methylthiomethoxy compounds are formed by Pummerer rearrangement (13) of intermediates such as VI. Formation of a methylthiomethoxy derivative from this type of intermediate can occur either by rearrangement through an ion pair such as VII (path A, Diagram 1) or intramolecularly as shown in path B, Diagram 1.[4] From the data of Johnson (14) and Parham (15) and their collaborators and by analogy with the cleavage–recombination mechanisms proposed for the Stevens and Wittig reactions (16), to which the Pummerer rearrangement seems closely related, it would appear that path A is the more probable. *N*-Trifluoroacetyl-*N*,*N*′-dicyclohexylurea (IX), which arises by rearrangement of the first-formed isourea VIII (7, 17), could be isolated from all oxidations in which DCC and PTFA were used. Its structure was confirmed by comparison with an authentic sample obtained by reaction of DCC with trifluoroacetic acid.

DCC–PTFA–DMSO mixtures were also effective in oxidizing thiols to disulfides. Treatment of benzylthiol (α-toluenethiol, XI*a*) with the reagent gave dibenzyl disulfide (XII*a*) in a quantitative yield. Since the coupling of thiol residues to form disulfide bridges plays such an important role in determining the tertiary structure of proteins, the possible application of this mild reagent for the oxidation of the thiol side chains of

[3]*Details of the proof of structure have been given in a preliminary communication (8).*

[4]*The two pathways may be differentiated formally by considering whether rearrangement occurs by migration of the* OR *group with (path A) or without (path B) the electrons of the* S—OR *bond.*

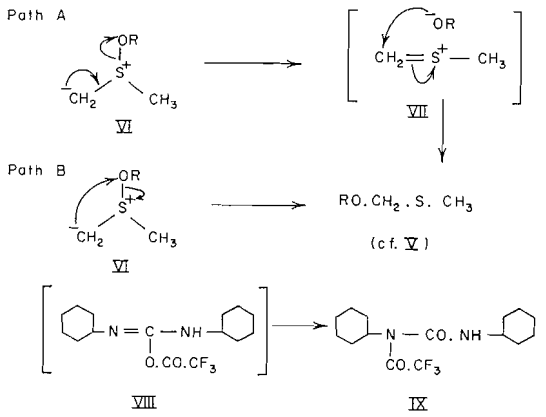

DIAGRAM 1.

cysteine derivatives was considered. The model compound selected, methyl *N*-acetyl-L-cysteinate (XI*b*), was prepared from *N*-acetyl-L-cysteine with anhydrous methanolic hydrogen chloride. On treatment with the Moffatt reagent it gave dimethyl *N*,*N*′-diacetyl-L-cystinate (XII*b*) in a high yield with little or no racemization.

The oxidation of the biologically important dithiol 6,8-dimercaptooctanoamide (XIII) to 6,8-dithiooctanoamide (XIV, lipoamide) was also investigated. Even though the reaction proceeded smoothly, the Moffatt reagent cannot be recommended for this particular oxidation, because isolation of the required lipoamide XIV from the dicyclohexylurea by-products proved to be extremely tedious and the final yields of pure material were very low.

While this communication was in preparation, Pfitzner and Moffatt (7) reported that thiols were not oxidized by the DCC–DMSO reagent. One of the mercaptans studied, *p*-chlorobenzylthiol, closely resembled the compound, benzylthiol, for which facile oxidation occurred in our hands. In view of these conflicting data, oxidation of the other mercaptan, octan-1-thiol (XI*c*), investigated by Moffatt and his co-workers was repeated. The reaction was found to proceed normally, and a 66% yield of dioctyl disulfide (XII*c*) was obtained.

The analytical method normally used for monitoring oxidations with the DCC–DMSO reagent, viz. t.l.c., was not wholly satisfactory for the above sulfur compounds since, surprisingly, some of the thiols and their corresponding disulfides, of which octan-1-thiol and dioctyl disulfide are examples, were found to have coincidental R_F values on chromatograms developed with the commonly used solvent systems.[5] Acidic spray reagents were not suitable for the t.l.c. detection of thiol–disulfide mixtures, but exposure of the plates to iodine vapor proved to be a convenient nonselective method for the detection of all the sulfur compounds studied. The disulfides could be distinguished from their thiol precursors by selective visualization of the latter with a sodium nitroprusside spray reagent. In all the reactions carried out, analysis by a combination of infrared and proton magnetic resonance spectroscopy enabled the mercaptans and their oxidation products to be identified unambiguously.

Since treatment of thiols with DMSO alone, usually for an extended period or at an elevated temperature, is known (18) to give the corresponding disulfides in a good yield,

[5]*The use of the usually reliable t.l.c. analytical methods alone for following their reactions undoubtedly misled Pfitzner and Moffatt (7) into concluding that thiols were not oxidized by the DCC–DMSO reagent.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

control experiments in which DCC and PTFA were omitted were carried out for each of the above thiols. In no case was a disulfide product detected, and the starting mercaptans were recovered unchanged.

These results, together with those of Wallace and his co-workers (18, 19), who showed that oxidation of thiols by DMSO alone proceeded via ionic intermediates with the formation of dimethyl sulfide,[6] suggest that the initial stages of thiol oxidation by DCC–DMSO are similar to those established for alcohols (12), as indicated in Diagram 2.

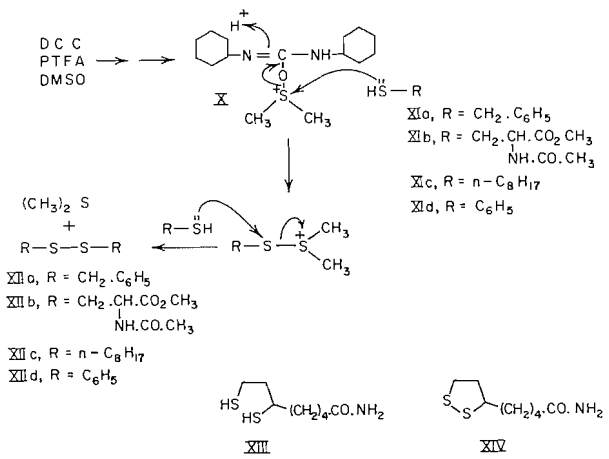

DIAGRAM 2.

The results of the studies carried out on the mechanism by which the Moffatt reagent effects oxidation (7, 9, 12) are in accord with the formation of the intermediate X. In an attempt to obtain further evidence for its existence, various mixtures of DCC, PTFA, and DMSO were examined by infrared and proton magnetic resonance spectroscopy. Solutions of DCC in DMSO possessed the spectra to be expected from a physical mixture of the unreacted components, but on addition of PTFA protonation of the DCC occurred immediately, as evidenced by the disappearance of the diimide infrared absorption at 2 114 cm^{-1}. However, no infrared or proton magnetic resonance peaks which could be ascribed to X were observed.

For the oxidation of thiophenol (XI*d*) to phenyl disulfide (XII*d*), it was not necessary to use the Moffatt reagent, since treatment with DMSO alone at room temperature (18) gave the disulfide in a quantitative yield.

EXPERIMENTAL

Melting points were determined on a Fisher–Johns block and are corrected. Infrared spectra were obtained on a Beckman IR.8 or a Perkin–Elmer 237-B spectrophotometer, and proton magnetic resonance spectra in deuteriochloroform, with tetramethylsilane as the internal standard, on a Varian A-60 instrument. Thin-layer and preparative layer chromatography were performed on silica gel G to which 3% of General Electric phosphor No. 118-2-7 had been added to facilitate the detection of ultraviolet-absorbing compounds. When the latter technique was not suitable, the compounds were visualized with the appropriate spray reagent (100% (w/v) aqueous toluene-*p*-sulfonic acid or concentrated sulfuric acid) or with iodine vapor. Selective detection of compounds containing a free thiol group was achieved with a sodium nitroprusside spray (20). Solvents for chromatography were redistilled, and the DMSO used (Fisher reagent grade) was stored over molecular sieves. All compounds were purified until t.l.c. and, where appropriate, gas–liquid chromatography showed no impurities. Gas–liquid chromatograms were obtained on an F and M 400 biomedical unit equipped with 3% SE-30 and 1% QF-1, on silanized Chromosorb G, columns.

[6]*During the oxidations, with DCC–PTFA–DMSO, of all the thiols surveyed a strong odor of dimethyl sulfide became apparent as each reaction proceeded.*

Pyridinium Trifluoroacetate

Pyridinium trifluoroacetate, m.p. 78°, was obtained in a quantitative yield by the reaction of pyridine with trifluoroacetic acid in dry ether (21).

Androst-5-en-3β-ol (Ib)

A solution of 3β-hydroxyandrost-5-en-17-one (9 g), potassium hydroxide (13 g), and 85% hydrazine hydrate (22 ml) in diethylene glycol (130 ml) was refluxed for 3 h. The bath temperature was then raised gradually to 200° and maintained at this level until nitrogen evolution ceased (4.5 h). The mixture was cooled and poured into water (600 ml), and the precipitate was filtered off and washed with water until the washings were neutral. The residue (7.1 g) was recrystallized from aqueous methanol to give androst-5-en-3β-ol as prisms (5.3 g), m.p. 133.5–134.5°, $[\alpha]_D^{22}$ −74° (*c*, 1 in dioxane), $\nu_{max}^{CHCl_3}$ 3 597 cm^{-1} (lit. (22) m.p. 136.5–137°, $[\alpha]_D$ −75° (dioxane)).

Androst-5-en-3-one (IIb)[7]

Androst-5-en-3β-ol (1.1 g, 4 mmoles), DCC (2.47 g, 12 mmoles), and PTFA (0.39 g, 2 mmoles) were dissolved in DMSO (10 ml) and benzene (10 ml), and the mixture was heated at 50° for 2 h. Ethyl acetate (40 ml) was added and the precipitated dicyclohexylurea, m.p. 236–237° after recrystallization from ethanol, ν_{max}^{DMSO} 1 660 cm^{-1}, was removed by filtration. The solution was extracted with 0.1 *M* phosphate buffer (2 × 10 ml, pH 7.2) and then with water (2 × 10 ml). The dried ($MgSO_4$) solution was rotary evaporated and the residue was recrystallized[8] from methanol (10 ml) to give androst-5-en-3-one as plates (0.74 g), m.p. 129–131°,[8] $[\alpha]_D^{20}$ −32° (*c*, 0.7 in methanol), $\nu_{max}^{CHCl_3}$ 1 712 cm^{-1}.

Anal. Calcd. for $C_{19}H_{28}O$ (272.4): C, 83.77; H, 10.36. Found: C, 83.97; H, 10.54.

Androst-5-ene-3,17-dione (IIa) and Cholest-5-en-3-one (IIc)

Androst-5-ene-3,17-dione (plates from methanol, m.p. 150–155°,[8] $[\alpha]_D^{21}$ 50° (*c*, 1.2 in chloroform), $\nu_{max}^{CHCl_3}$ 1 736 and 1 715 cm^{-1}) and cholest-5-en-3-one (prisms from methanol, m.p. 120–122°, $[\alpha]_D^{21}$ −3.5° (*c*, 0.8 in chloroform), $\nu_{max}^{CHCl_3}$ 1 712 cm^{-1}) were prepared by the method described above (60–70% yields) from the 3β-alcohols I*a* and I*c*, respectively.

Attempted Oxidation of 3β-Hydroxyandrost-5-en-17-one (Ia) with 1 Mole of DCC; Isolation of 3β-(Methylthiomethoxy)-androst-5-en-17-one (V) and N-Trifluoroacetyl-N,N′-dicyclohexylurea (IX)

A solution of 3β-hydroxyandrost-5-en-17-one (5 g, 17.4 mmoles), DCC (3.6 g, 17.4 mmoles), and PTFA (3.36 g, 17.4 mmoles) in DMSO (100 ml) was heated at 50° for 2 h. The mixture was then poured into water (1 l) and extracted with *n*-pentane (5 × 100 ml), and the combined pentane solutions were washed with water (3 × 100 ml) and dried ($MgSO_4$). Rotary evaporation yielded a solid (1.6 g), which was shown by t.l.c. to contain several compounds, including some unchanged starting material I*a*. (A further 4.5 g of the starting alcohol was recovered from the original aqueous mixture by ether extraction.) After repeated chromatography of the pentane-derived mixture on Florisil, using benzene with increasing proportions of ether as the elution solvents, *N*-trifluoroacetyl-*N*,*N*′-dicyclohexylurea (230 mg) and 3β-(methylthiomethoxy)-androst-5-en-17-one (192 mg) were isolated. The latter was recrystallized from hexane as needles, m.p. 171.5–172°, $\nu_{max}^{CHCl_3}$ 1 733 and 1 047 cm^{-1}; proton magnetic resonance δ 0.88 and 1.04 (3 H, singlets, C_{18}—CH_3 and C_{19}—CH_3), 2.17 (3 H, singlet, CH_3—S), 3.5 (1 H, multiplet, C_3—α-H), 4.67 (2 H, singlet, S—CH_2—O), and 5.4 p.p.m. (1 H, multiplet, C_5—H).

Anal. Calcd. for $C_{21}H_{32}O_2S$ (348.6): C, 72.34; H, 9.26; S, 9.20. Found: C, 72.03; H, 9.31; S, 9.39; mol. wt. (mass spectrum) 348.

The trifluoroacetylurea IX gave needles, m.p. 139°, when crystallized from hexane; $\nu_{max}^{CHCl_3}$ 3 425, 1 724, and 1 695 cm^{-1}; proton magnetic resonance δ 3.8 (22 H, multiplet, cyclohexyl protons) and 6.5 p.p.m. (1 H, multiplet, N—H). The material was identical in all respects with an authentic sample prepared from DCC (1 mole) and trifluoroacetic acid (1 mole) in refluxing pyridine.

Anal. Calcd. for $C_{15}H_{23}F_3N_2O_2$ (320.4): C, 56.26; H, 7.23; F, 17.79; N, 8.74. Found: C, 56.31; H, 7.44; F, 17.93; N, 8.77.

Acid Hydrolysis of 3β-(Methylthiomethoxy)-androst-5-en-17-one (V)

3-β-(Methylthiomethoxy)-androst-5-en-17-one (25 mg) dissolved in methanol (8 ml) and concentrated hydrochloric acid (2 ml) was kept overnight at 20°. The mixture was then poured into water (200 ml) and extracted with ether (2 × 50 ml), and the ethereal extracts were washed, first with saturated aqueous sodium bicarbonate (2 × 20 ml) and then with water (20 ml), and dried ($MgSO_4$). Rotary evaporation yielded

[7]*All glassware used in the preparation and purification of the Δ⁵-3-ketosteroids was washed with dilute aqueous potassium hydroxide during the final stages of the normal cleaning cycle. This was necessary because the traces of acid absorbed on the surfaces of glassware not treated in this way were sufficient to effect partial isomerizations of the desired β,γ-unsaturated ketones.*

[8]*Isomerization also occurred when heat was applied, and during all operations, especially recrystallization, the temperature was not allowed to exceed 50° for any extended period. Accordingly, melting point determinations of Δ⁵-3-ketones were carried out with the temperature increasing at 6°/min. Isomerization of Δ⁵-3-ketones during melting point determinations has been reported previously (7).*

3β-hydroxyandrost-5-en-17-one (17 mg) which, on recrystallization from hexane, gave prisms, m.p. 150–151°, identical in all respects with an authentic sample.

Oxidation of Benzyl Mercaptan (XIa) to Dibenzyl Disulfide (XIIa)

Benzyl mercaptan (1 g, 8.1 mmoles), DCC (5 g, 24.3 mmoles), and PTFA (1.6 g, 8.1 mmoles) were dissolved in DMSO (40 ml), and the mixture was heated at 50° for 6 h. Water (400 ml) was then added and the precipitate extracted with ether (3 × 50 ml). The ether solution was filtered to remove undissolved dicyclohexylurea, then washed with water (3 × 25 ml), and dried ($MgSO_4$). Evaporation yielded a white solid, from which the desired product was extracted with petroleum ether (b.p. 40–60°). Final purification was achieved by preparative layer chromatography, with benzene – petroleum ether (b.p. 40–60°) (1:3) as the developing solvent, followed by recrystallization from petroleum ether (b.p. 40–60°) to give dibenzyl disulfide as rhombs (0.95 g), m.p. 68–70° (lit. (18) m.p. 69–70°), proton magnetic resonance δ 3.57 (4 H, singlet, $(—CH_2—S—)_2$) and 7.23 p.p.m. (10 H, singlet, C_6H_5). Benzyl mercaptan was recovered unchanged when a control experiment without DCC was carried out under identical conditions.

Oxidation of Octan-1-thiol (XIc) to Dioctyl Disulfide (XIIc)

A solution of octan-1-thiol (2 g, 13.6 mmoles), DCC (9.6 g, 41.2 mmoles), and PTFA (1.4 g, 7.2 mmoles) in DMSO (50 ml) was kept at 25° for 24 h. Anhydrous ether (250 ml) was then added followed by oxalic acid (3.7 g, 42 mmoles) in methanol (25 ml). After the gas evolution had ceased the mixture was diluted with water (250 ml) and the precipitated *N,N'*-dicyclohexylurea filtered off. The ether layer was separated, washed with water (3 × 30 ml), dried ($MgSO_4$), and rotary evaporated. *n*-Hexane (20 ml) was added to the residue and the mixture was filtered to remove *N*-trifluoroacetyl-*N,N'*-dicyclohexylurea. Evaporation of the hexane solution followed by distillation gave dioctyl disulfide (1.3 g), b.p. 140° at 0.5 mm (lit. (23) b.p. 160–163° at 1.5 mm), proton magnetic resonance δ 2.63 p.p.m. (4 H, triplet, J = 7 c.p.s., $(—CH_2—S—)_2$). No oxidation occurred when a solution of octan-1-thiol alone in DMSO was kept for 24 h at room temperature.

Methyl N-Acetyl-L-cysteinate (XIb)

N-Acetyl-L-cysteine (15.1 g) in methanol (150 ml) was saturated with hydrogen chloride at 0°. The solution was refluxed for 20 min and was then concentrated to 75 ml under reduced pressure (nitrogen bleed). Solid sodium bicarbonate was added to neutralize the remaining acid and the mixture was again evaporated to dryness under reduced pressure (nitrogen bleed). The residue was extracted with methylene chloride (6 × 30 ml), and the combined extracts were dried ($MgSO_4$) and evaporated to a crystallizing oil (15.2 g). Recrystallization from isopropyl ether, followed by washing of the crystals with cold *n*-hexane to facilitate solvent evaporation, gave methyl *N*-acetyl-L-cysteinate as feathery needles (8.7 g), m.p. 79–80°, $[\alpha]_D^{22}$ −24° (*c*, 1 in methanol); $\nu_{max}^{CHCl_3}$ 3 436, 2 398, 1 745, and 1 678 cm^{-1}; proton magnetic resonance δ 1.62 (1 H, triplet, J = 9 c.p.s., S—H), 2.05 (3 H, singlet, —CO—CH_3), 2.95 (2 H, multiplet, —CH_2—S), 3.77 (3 H, singlet, O—CH_3), 4.90 (1 H, multiplet, α-CH), and 7.35 p.p.m. (1 H, multiplet, —CO—NH—).

Anal. Calcd. for $C_8H_{11}NO_3S$ (177.2): C, 40.68; H, 6.26; N, 7.91; S, 18.08. Found: C, 40.61; H, 6.18; N, 7.84; S, 18.23.

Oxidation of Methyl N-Acetyl-L-cysteinate to Methyl N-Acetyl-L-cystinate (XIIb)

A solution of methyl *N*-acetyl-L-cysteinate (1 g, 5.7 mmoles), DCC (3.5 g, 17.1 mmoles), and PTFA (1.1 g, 5.7 mmoles) in DMSO (20 ml) was heated at 50° for 2 h, after which time the precipitated dicyclohexylurea was filtered off. Methylene chloride (75 ml) was added to the filtrate, and the mixture was washed with water (4 × 20 ml), dried ($MgSO_4$), and rotary evaporated. The resulting syrup was washed with boiling *n*-hexane to remove unchanged DCC and *N*-trifluoroacetyl-*N,N'*-dicyclohexylurea, and the residue (0.9 g) was recrystallized from isopropyl ether – acetone to remove most of the dicyclohexylurea impurity. Subsequent recrystallization from ethyl acetate gave methyl *N*-acetyl-L-cystinate as needles (508 mg), m.p. 129–130° (lit. (24) m.p. 128–129°), $[\alpha]_D^{20}$ −121° (*c*, 1 in methanol); $\nu_{max}^{CHCl_3}$ 3 448, 1 730, and 1 678 cm^{-1}; proton magnetic resonance δ 2.07 (3 H, singlet, —CO—CH_3), 3.22 (2 H, doublet, J = 6 c.p.s., —CH_2—S), 3.78 (3 H, singlet, O—CH_3), 4.90 (1 H, multiplet, α-CH), and 7.05 p.p.m. (1 H, multiplet, CO—NH—).

Anal. Calcd. for $C_{12}H_{20}N_2O_6S_2$ (352.4) (sample dried at 100° *in vacuo* to remove ethyl acetate of crystallization): C, 40.90; H, 5.72; N, 7.95; S, 18.20. Found: C, 41.14; H, 5.91; N, 7.81; S, 18.36.

Methyl *N*-acetyl-L-cysteinate was recovered unchanged from a control experiment in which DCC was omitted.

Oxidation of Thiophenol (XId) to Diphenyl Disulfide (XIId)

Thiophenol (560 mg) in DMSO (20 ml) was heated at 50° for 17 h. The mixture was poured into water (250 ml) and extracted with ether (3 × 50 ml), and the ether extracts were washed with water (2 × 25 ml) and dried ($MgSO_4$). Rotary evaporation gave a solid (500 mg) which, on recrystallization from petroleum ether (b.p. 40–60°), yielded diphenyl disulfide as rhombs (420 mg), m.p. 58–59° (lit. (18) m.p. 60°), proton magnetic resonance δ 7.1–7.6 p.p.m. (multiplets, C_6H_5). In a control experiment carried out under identical conditions, but with benzene replacing DMSO as solvent, the thiophenol was recovered unchanged.

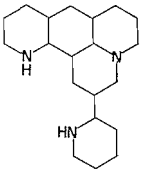
ORMOSIA ALKALOIDS

III. CHEMISTRY OF ORMOSANINE AND ORMOJANINE; DEHYDROGENATION TO 3,6,8-TRIALKYLATED QUINOLINES[1]

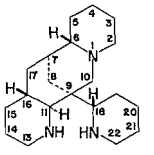
Z. VALENTA, P. DESLONGCHAMPS, M. H. RASHID, R. H. WIGHTMAN, AND J. S. WILSON
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received July 8, 1966



ABSTRACT

Degradations of ormosanine, $C_{20}H_{35}N_3$, are described which are in agreement with structure II (8) for this alkaloid. Nuclear magnetic resonance study of *N*-acetyl and *N*-nitroso derivatives has been used to clarify the environment of the secondary nitrogen atoms. Chemical and spectroscopic evidence leads to the formulation XV*b* for the related alkaloid ormojanine, $C_{20}H_{31}N_3$.



Both alkaloids were found to give 3-*n*-pentyl-6,8-dipropylquinoline together with the corresponding 3-*n*-butyl derivative in a catalytic dehydrogenation. The possible mechanism of formation of these dehydrogenation products is discussed and their synthesis is described.

The presence of a large number of alkaloids in *Ormosia jamaicensis* (1, 2), *O. panamensis* (3), and *O. dasycarpa* (4) has recently been reported. Three of the alkaloids were identified with lupin alkaloids of known structure: augustifoline (1, 2, 5, 6), epihydroxylupanine (2, 5), and (−)-sparteine (4). It thus became of great interest to investigate the C_{20}-alkaloids of unknown structure which are also present in the *Ormosia* plants (2, 3) and which could be expected to be formed by an interesting variation of the lupin alkaloid biogenesis.

In a preliminary communication (7), we proposed formula I as a representation of our physical and chemical data obtained for ormosanine, $C_{20}H_{35}N_3$, m.p. 179–181°, an alkaloid of *Ormosia jamaicensis*, and an unsaturated version of I for ormojanine, $C_{20}H_{31}N_3$, m.p. 124–126°, another alkaloid from the same plant. Recently, Karle and Karle reported an X-ray crystallographic investigation of jamine, the homo-derivative of ormosanine, on the basis of which ormosanine was assigned structure II (8). Using structure II, Wildman and his co-workers then explained their degradative and correlative work with alkaloids from *O. panamensis* (9, 10).

I

II

We now wish to describe our own degradative results (which are in agreement with the formulation II for ormosanine), to develop the structure of ormojanine, and to report an unusual dehydrogenative rearrangement which had been the cause of the incorrect placement of two C—C bonds in our previous structural proposal.[2]

[1]*For part II in this series, see P. Deslongchamps, J. S. Wilson, and Z. Valenta, Tetrahedron Letters, 3893 (1964).*

[2]*The stereochemistry of Ormosia alkaloids is discussed in the following communication (11).*

Ormosanine

The alkaloid $C_{20}H_{35}N_3$, which was isolated from the plant in its racemic form (9), was found to have three features common to lupin alkaloids: it contains no *C*-methyl groups and no *N*-alkyl groups, and its molecular composition fits the general formulation $(C_5N)_x + C_5$. No double bonds are present in the alkaloid, which must therefore be pentacyclic.
