Treatment with acetic anhydride in pyridine converted the alkaloid into *N*-acetyl-ormosanine, $C_{22}H_{37}N_3O$, m.p. 202–204°, and *N*,*N*′-diacetylormosanine, $C_{24}H_{39}N_3O_2$, m.p. 164–166°; *N*,*N*′-dinitroso-ormosanine, $C_{20}H_{35}N_5O_2$, m.p. 171–173°, was formed in a reaction with sodium nitrite and hydrochloric acid. Since the diacetyl and dinitroso derivatives are basic and their infrared spectra contain no NH signals, the alkaloid contains one tertiary and two secondary basic nitrogens. This is confirmed by two reactions in which a bridging of the two secondary nitrogen atoms is achieved. Treatment of ormosanine with formic acid and formaldehyde yielded homo-ormosanine, $C_{21}H_{35}N_3$, m.p. 148–149°,[3] in which the grouping N—CH_2—N had been created, whereas a treatment with phosgene and triethylamine in benzene gave the corresponding urea, homoxy-ormosanine, $C_{21}H_{33}N_3O$, m.p. 178–180°. These two derivatives could not be acetylated or nitrosated. The infrared spectrum of homoxy-ormosanine contained an amide maximum at 1 640 cm^{-1}, showing that the two secondary nitrogens in ormosanine must be separated by at least three carbon atoms.

The nuclear magnetic resonance study of the above derivatives provided an interesting method for the elucidation of the structural environment of the nitrogen atoms. Although the spectrum of ormosanine contains no absorption below 6.8 τ, both dinitroso- and diacetyl-ormosanine contain six deshielded hydrogen atoms with signals below 6.8 τ. These signals, furthermore, can be divided into two groups: a multiplet corresponding to two hydrogens appearing below 5.5 τ, and a multiplet corresponding to four hydrogens appearing between 5.9 and and 6.65 τ in both spectra.[4,5] It is reasonable to assume that these signals correspond to methine and methylene groups, respectively. Since the spectrum of monoacetylormosanine shows one methine hydrogen (5.66 τ) and two methylene hydrogens (6.50–6.80 τ), it can be concluded that two groupings III are contained in the structure of ormosanine.

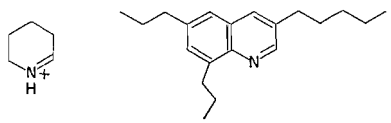
III

IV

V: R = Br
VI: R = OAc
VII: R = OH

[3]*Wildman and his co-workers found homo-ormosanine to be identical with the alkaloid jamine (9).*

[4]*The nitroso derivative is particularly well resolved; the method should be of general use for the nuclear magnetic resonance study of secondary bases.*



[5]*It should be noted that, in contrast, only two hydrogen atoms are deshielded (5.65 τ) in the spectrum of the cyclic urea, homoxy-ormosanine. Clearly, some neighboring hydrogen atoms must lie in the shielding region of the carbonyl group within the rigid cyclic framework of this derivative.*

The spectra of ormosanine and all the above derivatives contain a two-hydrogen singlet in the 7.5 τ region. This is best explained by the presence, in ormosanine, of a methylene group connected to the tertiary nitrogen atom and to a quaternary carbon (C_{10} in structure II).[6] The remaining features of the tertiary nitrogen environment were revealed by the von Braun degradation of homoxy-ormosanine. The crystalline cyanobromo adduct, $C_{22}H_{33}N_4BrO$, m.p. 184–186°, showed a cyanamide (2 200 cm^{-1}) and a urea peak (1 648 cm^{-1}) in its infrared spectrum. The nuclear magnetic resonance spectrum contained, in addition to the two hydrogens deshielded by the urea function (5.6 τ), a total of five deshielded hydrogen atoms in a partially resolved multiplet (6.1–6.9 τ). This assignment could be confirmed by further transformations of the cyanobromo adduct. Treatment with potassium acetate gave the oily cyanoacetate, $C_{24}H_{36}N_4O_3$, showing infrared peaks at 2 225 (cyanamide), 1 740 (acetate), and 1 647 cm^{-1} (urea), which was converted on mild hydrolysis into the crystalline cyanoalcohol, $C_{22}H_{34}N_4O_2$, m.p. 225–227°. The nuclear magnetic resonance spectra of both these compounds again showed a total of seven hydrogen atoms absorbing below 7.0 τ. Thus, the tertiary nitrogen in ormosanine must be joined to two methylene groups and one methine group.

A more detailed study of the unshielded region showed a two-hydrogen signal, with the appearance of a narrow triplet at 6.62 τ for the bromide, at 6.39 τ for the alcohol, and at 5.97 τ for the acetate. Furthermore, oxidation of the cyanobromo compound with pyridine-*N*-oxide gave an aldehyde which again contained the aldehydic hydrogen atom as a triplet (0.21 τ). The above evidence can thus be summarized by partial formulae IV, V, VI, and VII representing the transformations of the tertiary nitrogen.

The sharp singlet in the spectra of ormosanine and its acetyl and nitroso derivatives corresponding to the methylene at C* in formula IV (C_{10} in formula II) is not present in the spectra of the cyanamides. This can most likely be attributed to the change from an A_2 to an AB pattern. The A part of this pattern can, in fact, be discerned clearly in the deshielded region of the cyanobromo adduct (6.22 τ; doublet, J_{AB} = 12 c.p.s.).

It now remained to perform degradations which would reveal the skeleton of ormosanine. Several interesting products were obtained in the dehydrogenation of ormosanine with palladium on charcoal at 275° in a sealed tube. The presence of pyridine and β-picoline in the volatile basic fraction could be established by vapor-phase chromatography. Mass spectroscopy provided additional information about this fragmentation. The most prominent peak in the mass spectrum of ormosanine at *m/e* 84 is best explained by the ion VIII, and the presence of an α-monosubstituted piperidine in ormosanine is thus strongly indicated.

VIII IX

An even more diagnostic product was obtained from the nonvolatile fraction of the above dehydrogenation. A high-boiling quinoline could be obtained in a relatively pure form as a result of its unusual solubility properties. It is so weakly basic that only sulfuric acid stronger than 40% (by weight) would extract it efficiently from ether. After chromatography, the weakly basic fraction was converted into the picrate, and recrystallized from ether to a constant melting point (108–110°). Surprisingly, the liberated free base

[6] *Unfortunately, we had originally not considered this feature as sufficiently diagnostic, and it was therefore not incorporated into our first ormosanine formulation (structure I).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

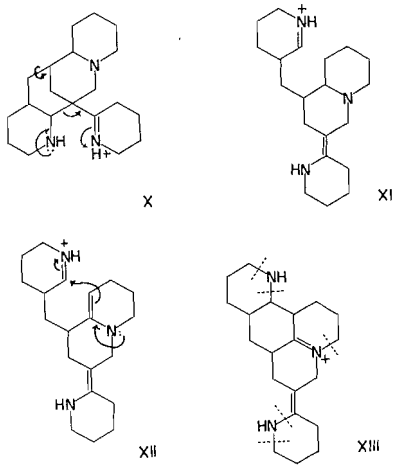
was found by vapor-phase chromatography to be a mixture of two compounds in which the higher boiling one predominated. Their separation was finally achieved by a nine-funnel countercurrent distribution between ether and sulfuric acid.

The structural elucidation of these two compounds proved relatively simple. The ultraviolet spectrum, with maxima at 237 (ϵ 31 600), 298 (ϵ 3 900), 310 (ϵ 3 700), and 322 mμ (ϵ 3 400) (λ_{max} in HCl at 248 and 322.5 mμ), indicated a substituted quinoline. The nuclear magnetic resonance spectra of both compounds contained the following diagnostic peaks: a doublet at 1.48 τ (1 H, J = 2 c.p.s.), a doublet at 2.42 τ (1 H, J = 2 c.p.s.), a sharp singlet at 2.85 τ (2 H's), a triplet at 6.88 τ (2 H's, J = 6 c.p.s.), a triplet at 7.32 τ (4 H's, J = 6 c.p.s.), and a triplet at 9.0 τ (9 H's, J = 6 c.p.s.). A multiplet centered at 8.6 τ was different in the two compounds.



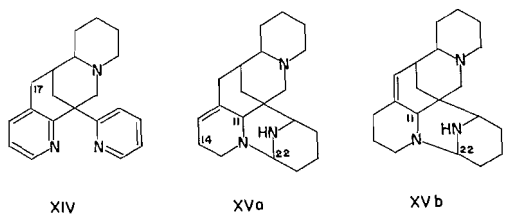
Integration of the nuclear magnetic resonance spectra, together with mass spectroscopy, showed the two quinolines to have the composition $C_{20}H_{29}N$ and $C_{19}H_{27}N$, respectively. A comparison of the aromatic region with that of model methylquinolines showed that the two quinolines must be 3,6,8-trisubstituted. Differently substituted quinolines gave distinctly different absorption patterns. In particular, only hydrogen atoms at C_5 and C_7 of the quinoline nucleus have a precisely identical τ value. Since the compounds only contain three methyl groups, the chains must be unbranched, and since no methyl group resonates below 9 τ, all chains must be longer than ethyl.

Because of the presence, in ormosanine, of an α-monosubstituted piperidine ring (*vide supra*), the higher boiling component should be an *n*-pentyl-dipropylquinoline. The three possible compounds were therefore synthesized in an unambiguous way from *p*-propyl- and *p*-*n*-pentyl-aniline,[7] and the degradation product was found to be identical in all respects with 3-*n*-pentyl-6,8-dipropylquinoline (IX). Furthermore, the lower boiling product was identified with authentic 3-*n*-butyl-6,8-dipropylquinoline, which was synthesized in a similar way. To our knowledge, 3,6,8-trialkylated quinolines have not been described previously.

Quinoline IX contains all 20 carbons of ormosanine. Although its formation can be explained easily on the basis of structure I for ormosanine and was, in fact, our key evidence for the formulation I, the crystallographically determined structure II does not contain the skeleton of IX. The question now arises whether formula II can be correct and, if so, how quinoline IX is formed from ormosanine. Two facts strongly favor formula II. Firstly, the above-mentioned nuclear magnetic resonance singlet corresponding to a methylene group joined to the tertiary nitrogen is only in accord with formula II. Secondly, and more significantly, several stereoisomers of ormosanine can be prepared, all of which are capable of forming the corresponding homoxy derivatives.[8] Whereas formula II allows this variety, it is clear from model inspection that, at best, two stereoisomers of formula I would be capable of forming a bridged compound of a sufficiently high stability.

It therefore follows that our faith in the stability of the ormosanine skeleton under the dehydrogenation conditions (7) was not justified, and that the molecule undergoes a deep-seated rearrangement in a relatively high yield (5–10% of quinoline). This can be illustrated by the scheme II → X → XI → XII → XIII, in which the exact sequence of steps and the precise oxidation level of all intermediates is, of course, not implied. The hypothetical intermediate XIII can be transformed into IX by the breakage of five C—N bonds (dotted lines in formula XIII) and a further dehydrogenation. Although the individual steps in this sequence are unexceptional, the total yield of the transformation is remarkable.

[7]*Synthetic details and physical properties of the synthetic compounds are given in the Experimental.*
[8]*These isomers are described in the following communication (11).*



Ormojanine

The alkaloid $C_{20}H_{31}N_3$ contains two more unsaturated centers than ormosanine and is optically active (2). It can be reduced to dihydro-ormojanine, $C_{20}H_{33}N_3$, m.p. 127–129°, on careful hydrogenation of its hydrochloride with platinum, and to tetrahydro-ormojanine, $C_{20}H_{35}N_3$, m.p. 107–109°, on prolonged hydrogenation.

The following dehydrogenation results leave no doubt that tetrahydro-ormojanine and ormosanine have the same skeletal structure. Dehydrogenation of tetrahydro-ormojanine at 275° also yielded the quinoline IX, again accompanied by the corresponding *n*-butyl derivative. Even more significantly, a dehydrogenation of dihydro-ormojanine at 200° with palladium on charcoal gave a high yield of a crystalline pyridine, $C_{20}H_{23}N_3$, m.p. 130–132°. Its ultraviolet spectrum (inflection 256 mμ, λ_{max} 262 mμ (ϵ 5 600) and 268 mμ (ϵ 5 300), inflection 278 mμ) shows the presence of two pyridine rings in the molecule, and the position of the absorption maxima together with the number of aromatic hydrogen atoms in the nuclear magnetic resonance spectrum clearly indicates one α-monosubstituted and one α,β-disubstituted pyridine ring.

This dehydrogenation product must possess structure XIV for the following reasons. Wildman reported that the dehydrogenation of ormosanine at 250° (10) gave a dehydro-ormosanine, for which he proposed structure XIV. We now find that this dehydrogenation product of racemic ormosanine is identical in ultraviolet, infrared, and nuclear magnetic resonance spectra with our product from optically active ormojanine. With the structure of ormosanine known (II), the dipyridine must undoubtedly be XIV, provided no rearrangement occurs during the dehydrogenation. This possibility is eliminated by our finding that the dipyridine can be reduced back to tetrahydro-ormojanine.[9] It is thus established that tetrahydro-ormojanine is a stereoisomer of ormosanine (II).

Nuclear magnetic resonance spectroscopy provides important information about the nature of the two unsaturated centers in ormojanine. The spectrum of the alkaloid

[9]*The reduction and stereochemistry of XIV are discussed in the following communication (11).*

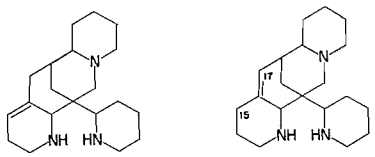
contains, in the region below 7.0 τ, a doublet at 4.65 τ (1 H, J = 6 c.p.s.), a broad singlet at 6.46 τ (1 H), and a sharp singlet at 6.84 τ (1 H). Of these three peaks, only the doublet remains in the spectrum of dihydro-ormojanine (4.68 τ), and the spectrum of tetrahydro-ormojanine contains no signals below 7.0 τ.

Ormojanine forms an oily *N*-monoacetyl derivative, $C_{22}H_{34}N_3O$, and an *N*-mononitroso derivative, $C_{20}H_{30}N_4O$, m.p. 178–181°. Thus, in contrast to ormosanine, only one secondary nitrogen atom is present in the molecule. Both these derivatives show the doublet at approximately 4.6 τ and a sharp singlet in the 6.6–6.8 τ region in their nuclear magnetic resonance spectra. However, the broad singlet found at 6.46 τ in the spectrum of ormojanine appears at 4.71 τ in the spectrum of the mononitroso derivative, which also shows an additional broad singlet at 5.27 τ (1 H).[10]

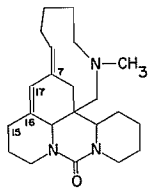
These findings only agree with formula XV*a* or XV*b* for ormojanine.[11] The shape and position of the sharp singlet at 6.84 τ indicate its correspondence to the hydrogen atom at C_{11}, placed between a double bond, a nitrogen atom, and a quaternary carbon atom. C_{11} cannot be alpha to the secondary nitrogen atom, since the signal does not shift significantly on nitrosation or acetylation. The hydrogen atom corresponding to the broad singlet at 6.46 τ in ormojanine can be assigned with confidence to C_{22} because of its low-field position and the fact that its signal shifts downfield on nitrosation and acetylation. The nuclear magnetic resonance study does not allow an unambiguous decision between XV*a* and XV*b*. The fact that the vinylic hydrogen appears as a doublet in the spectrum of ormojanine (4.65 τ) and all its derivatives favors formula XV*b*, but model inspection shows clearly that one of the hydrogen atoms at C_{14} in structure XV*a* forms a dihedral angle close to 90° with the vinylic hydrogen and need therefore not give any observable splitting.

On the basis of the above formulation, dihydro-ormojanine has structure XVI*a* or XVI*b* and tetrahydro-ormojanine, as stated above, a structure stereoisomeric with II. In agreement with this assignment, the corresponding bridged compounds, homodihydro-ormojanine, $C_{21}H_{33}N_3$, homoxydihydro-ormojanine, $C_{21}H_{31}N_3O$, m.p. 173–174° (infrared maximum at 1 645 cm^{-1}), homotetrahydro-ormojanine, $C_{21}H_{35}N_3$, m.p. 100–101°, and homoxytetrahydro-ormojanine, $C_{21}H_{33}N_3O$, m.p. 203–205° (infrared maximum at 1 640 cm^{-1}), could be prepared from the two reduction products under appropriate conditions.



The following degradation gives support for the formulation of ormojanine as XV*b* and of dihydro-ormojanine as XVI*b*. The urea derivative of XVI, homoxydihydro-ormojanine, was subjected to a Hofmann degradation, achieved by a dry distillation of the corresponding metho-hydroxide. The resulting product, m.p. 135–138°, obtained in a good yield, was found to be a conjugated diene. Its ultraviolet spectrum, with maxima at 225 mμ (ϵ 11 600) and 253 mμ (ϵ 11 700) in a neutral solution and at 243 mμ (ϵ 16 600) in acid, indicates a transoid arrangement of the two double bonds and a probable interaction of the electron pair on the basic nitrogen atom with the conjugated π-electron system. This and the nuclear magnetic resonance spectrum, showing one vinylic hydrogen at 3.85 τ (singlet) and one at 4.79 τ (triplet), are best explained by formula XVII for the Hofmann diene.[12]

It is clear that formula XVI*b* for dihydro-ormojanine provides a more satisfactory explanation for the formation of diene XVII in a good yield. Although XVII could, in

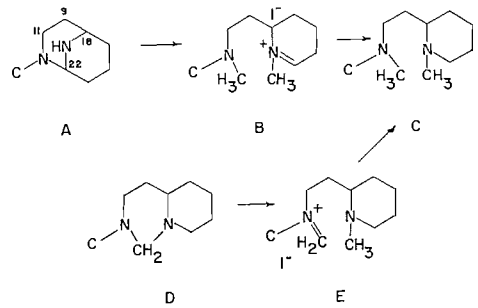


[10] *A similar situation is found in the spectrum of the acetyl derivative; the signals, however, are not as well resolved.*

[11] *The presence of an* N—C—N *linkage in unsaturated Ormosia alkaloids was postulated for the first time in our first publication of this series (7); Wilson (12) later correctly concluded that this linkage is also present in the alkaloid panamine.*

[12] *An alternative formulation, with double bonds at* C_{15}—C_{16} *and* C_{17}—C_7, *appears less likely on the basis of our evidence.*

XVIa XVIb



XVII

principle, be formed from XVIa via a non-conjugated diene, the necessary base-catalyzed double-bond migration does not appear to be probable under the experimental conditions used.

Our preference for formulae XV*b* and XVI*b* is somewhat tempered by the finding that the reduction of XVI with platinum and deuterium gas in acetic acid-OD, followed by a dehydrogenation of the product with palladium, gave deuterated compound XIV containing no deuterium at C_{17} or at any of the aromatic carbon atoms (nuclear magnetic resonance spectroscopy; see Experimental). This negative result, however, is not convincing, since a palladium-catalyzed hydrogen exchange at C_{17}, taking place during or after the formation of the pyridine ring, can readily be visualized.[13]

Further chemical evidence relevant to the environment of the secondary nitrogen atom in ormojanine is depicted in Scheme I, in which only partial formulae are used for the sake of brevity. Treatment of ormojanine (A) with methyl iodide in benzene gave the salt B, which could be reduced with sodium borohydride to *N*,*N*-dimethyldihydro-ormojanine (C), m.p. 120–122°. In another series, homodihydro-ormojanine (D), prepared by treatment of dihydro-ormojanine with formaldehyde and formic acid (see above), was converted, on treatment with methyl iodide in benzene, into the salt E, which could be reduced with sodium borohydride to a compound identical in all respects with *N*,*N*-dimethyldihydro-ormojanine (C).

In summary, dehydrogenation experiments have shown that tetrahydro-ormojanine is

SCHEME 1.

[13]*The two structural possibilities for ormojanine, XVa and XVb, are discussed by P. Deslongchamps in his Ph.D. thesis, University of New Brunswick, 1964; Wilson (13) recently concluded that our evidence leads to XVb as the most probable structure for ormojanine, but unfortunately did not support this conclusion with additional experimental evidence. It is hoped that a rigorous proof for the position of the double bond in ormojanine will be obtained by synthesis.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a stereoisomer of ormosanine (II). Our chemical and spectroscopic evidence has revealed the nature of the two additional unsaturations in ormojanine, which can be represented by formula XV. Of the two possible positions of the double bond (XV*a* and XV*b*), that in XV*b* is favored by our evidence. The configuration of all the asymmetric centers in ormojanine and related alkaloids is reported in the following communication (11).

EXPERIMENTAL

Nuclear magnetic resonance spectra were recorded in $CDCl_3$ on a Varian HR-60 spectrometer, and chemical shifts are reported in parts per million relative to an internal tetramethylsilane reference. Infrared spectra were obtained with Perkin–Elmer model 21 and 137B Infracord instruments, and ultraviolet spectra were recorded on a Beckman DK-2 instrument and mass spectra on a Hitachi Perkin–Elmer RMU-6D instrument. All melting points are uncorrected.

Extraction of Ormosanine and Ormojanine

Ground beans of *Ormosia jamaicensis* Urb. (5 kg) were extracted for 24 h with petroleum ether (b.p. 65–110°) in a Soxhlet apparatus and the extract was discarded. The ground material was then subjected for 60 h to a Soxhlet extraction with methanol; the solvent was then evaporated, the residue dissolved in water (3 l), and the solution acidified to pH 2 with hydrochloric acid. Exhaustive extraction with chloroform removed acidic and neutral material. The aqueous solution was then neutralized with potassium carbonate and made alkaline (pH 10) with concentrated ammonium hydroxide. A continuous ether extraction (70 h) of the aqueous solution yielded, after drying and removal of the ether, fraction A, 117.0 g of a viscous oil. Extraction of the aqueous solution with five portions of chloroform, drying, and evaporation of the solvent yielded fraction B, 26.8 g of an amorphous residue. Examination by paper chromatography and thin-layer chromatography (t.l.c.) revealed at least seven different compounds (three major constituents) in fraction A and five compounds (two comparable to components of fraction A) in fraction B.

The ether-soluble bases (fraction A) were crystallized from acetone to yield crude ormosanine, m.p. 165–178° (5.8 g, 0.12% of the original ground material). An extensive study of various purification methods showed that the mother liquors of fraction A could best be purified by a countercurrent separation. Distribution of 70 g of evaporated mother liquors between McIlvain's buffer (pH 7.8) and ether (2 l of each phase in each funnel) in 15 funnels yielded crude crystalline ormojanine, m.p. 115–125° (9 g, 0.18% of the original ground material) from funnels 12–15 (crystallized from acetone) and a small amount of crystalline ormosanine from funnels 8–10. A redistribution of the mother liquors from the crystallization of ormojanine with buffer (pH 8) yielded additional crystalline ormojanine.

Ormosanine (2, 3) was recrystallized from acetone and melted at 179–181°.

Anal. Calcd. for $C_{20}H_{35}N_3$: C, 75.65; H, 11.11; N, 13.24; 2 active H's, 0.628. Found: C, 75.35; H, 11.00; N, 13.29; active H, 0.475; no oxygen, O—CH_3, N—CH_3, C—CH_3.

Mass spectrum: 317 (molecular ion), 84 (largest peak).

Ormojanine (2) was recrystallized from acetone (or ethyl acetate) and melted at 124–126°.

Anal. Calcd. for $C_{20}H_{31}N_3$: C, 76.62; H, 9.97; N, 13.40; 1 active H, 0.319. Found: C, 75.65; H, 10.00; N, 13.40; active H, 0.444; no oxygen, O—CH_3, N—CH_3, C—CH_3.

Mass spectrum: 313 (molecular ion).

Acetylation of Ormosanine

(*a*) Ormosanine (105 mg) was acetylated for 8 h in 2 ml of dry pyridine with 2 ml of acetic anhydride at room temperature. Evaporation *in vacuo* followed by a separation into basic and nonbasic material by a distribution between aqueous hydrochloric acid and ether yielded 128 mg of a basic residue. Paper chromatography, with *n*-butanol – concentrated hydrochloric acid – water (100:20:36 by volume) (3) on Whatman No. 1 filter paper, showed two compounds with R_f 0.65 and 0.90. Crystallization from ethyl acetate gave pure acetylormosanine, m.p. 202–204°, R_f 0.65.

Anal. Calcd. for $C_{22}H_{37}N_3O$: C, 73.49; H, 10.38; N, 11.69; O, 4.45. Found: C, 73.55; H, 10.32; N, 12.66; O, 3.72.

(*b*) Acetylation of ormosanine (400 mg) for 16 h in 8 ml of dry pyridine and 8 ml of acetic anhydride, followed by a work-up as under method *a*, gave pure *N,N'*-diacetylormosanine, m.p. 164–166°, R_f 0.90 (420 mg).

Anal. Calcd. for $C_{24}H_{39}N_3O_2$: C, 71.79; H, 9.79; N, 10.47; O, 7.97. Found: C, 72.00; H, 9.91; N, 10.33; O, 7.71.

N,N'-Dinitroso-ormosanine

An aqueous solution of sodium nitrite (145 mg in 2 ml) was added during a period of 30 min to a solution of ormosanine (226 mg) in 3 ml of 1 *N* hydrochloric acid at 0°. After standing for 1 h at room temperature and 5 min at 60°, the solution was diluted with water (30 ml), extracted with ether to remove impurities, basified with sodium hydroxide, and extracted with ether. The basic ether extract (265 mg) was shown by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

paper chromatography to consist of one major and four minor products. Elution with benzene from basic alumina gave *N,N'*-dinitroso-ormosanine (170 mg), which, after crystallization from ether or methanol, melted at 171–173°.

Anal. Calcd. for $C_{20}H_{35}N_5O_2$: C, 63.96; H, 8.86; N, 18.65; O, 8.52. Found: C, 64.01; H, 8.85; N, 18.17; O, 8.30.

Homo-ormosanine

A solution of ormosanine (120 mg) in formic acid (5 ml, 90%) and formaldehyde (3 ml, 40% in water) was boiled for 3 h; additional formic acid (2.5 ml) and formaldehyde (1.5 ml) were added and reflux was continued for 12 h. The reaction mixture was then diluted with water (50 ml), non-basic impurities were removed by extraction with ether, and the aqueous solution was basified with sodium hydroxide and extracted with ether. The basic ether extract (130 mg) was crystallized from acetone to give pure homo-ormosanine, m.p. 148–149° (R_f comparable to that of ormosanine).

Anal. Calcd. for $C_{21}H_{35}N_3$: C, 76.55; H, 10.71; N, 12.75. Found: C, 76.84; H, 10.61; N, 12.66; no oxygen.

Homoxy-ormosanine

Phosgene was bubbled for 1 h into a stirred solution of ormosanine (500 mg) and triethylamine (10 ml) in dry benzene (65 ml) at 0°. The viscous orange-colored solution was then allowed to stand at room temperature for 3 h, and then washed with dilute aqueous hydrochloric acid and with water. The combined aqueous layers were washed with benzene, then basified with sodium hydroxide, and extracted with ether. The basic extract (524 mg) was homoxy-ormosanine, recrystallized from petroleum ether (b.p. 50–70°) to m.p. 178–180°.

Anal. Calcd. for $C_{21}H_{33}N_3O$: C, 73.43; H, 9.69; N, 12.23; O, 4.66. Found: C, 73.98; H, 10.18; N, 11.60; O, 5.06.

von Braun Degradation of Homoxy-ormosanine

A solution of homoxy-ormosanine (450 mg) in dry benzene (25 ml) was added over a period of 4 h to a refluxing solution of cyanogen bromide (1.5 g) in dry benzene (75 ml). The solution was refluxed for an additional 16 h, and then washed with dilute aqueous hydrochloric acid and water. The benzene layer, on evaporation, gave 517 mg of a neutral residue which crystallized from ethyl acetate to give the pure cyanobromo adduct, m.p. 184–186°.

Anal. Calcd. for $C_{22}H_{33}N_4BrO$: C, 58.79; H, 7.40; N, 12.47; O, 3.56; Br, 17.78. Found: C, 58.74; H, 7.47; N, 12.55; O, 3.78; Br, 17.58.

Treatment of the cyanobromo compound (60 mg) with pyridine-*N*-oxide (1.0 g) in boiling acetonitrile (25 ml) for 24 h, followed by addition of triethylamine (15 ml) and a 5 h reflux, yielded 60 mg of a neutral material which was chromatographed twice on acid-washed alumina (Shawinigan). Chloroform–ether (4:1) eluted the crude oily cyanoaldehyde (15 mg), infrared maxima (carbon tetrachloride) at 2 730 (aldehyde), 2 210 (cyanamide), 1 742 (aldehyde), and 1 650 cm^{-1} (urea); nuclear magnetic resonance maximum at 0.21 (aldehyde, triplet).

Cyanoacetate

A solution of the cyanobromo compound (100 mg) and potassium acetate (400 mg) in 95% ethanol (60 ml) was refluxed for 24 h, then evaporated to a small volume, and diluted with water (75 ml). After acidification with hydrochloric acid, the aqueous solution was extracted with ether. The oily ether extract (80 mg) was chromatographed on basic alumina (Merck). Chloroform eluted the homogeneous oily cyanoacetate.

Cyanoalcohol

A solution of the cyanoacetate (80 mg) and potassium carbonate (200 mg) in methanol (10 ml) and water (5 ml) was allowed to stand at room temperature for 45 min. The methanol was then removed *in vacuo* and the resulting solution was diluted to 75 ml with water. After acidification with hydrochloric acid, the aqueous phase was extracted with chloroform to give 72 mg of the crude cyanoalcohol, which crystallized from ethyl acetate and melted at 225–227°.

Dehydrogenation of Ormosanine

Ormosanine (4 × 0.5 g) was intimately mixed with a palladium catalyst (4 × 0.7 g; 10% palladium on charcoal, L. Light and Co.) and heated in four sealed Carius tubes at 275° for 9 h. After these were opened (strong smell of ammonia), the contents were washed out with ether, and the tubes were crushed and extracted in a Soxhlet apparatus with ether for 24 h. Most of the ether was then carefully evaporated from the combined ether extracts through a Vigreux column, and the residue was distilled at 85° under reduced pressure. Volatile amines were condensed in a dry ice – acetone trap; treatment of the volatile fraction with ethanolic picric acid gave a picrate, m.p. 155–165° (230 mg). Decomposition of the picrate gave a basic fraction containing at least five compounds (shown by vapor-phase chromatography (v.p.c.)). The major component showed a retention time identical with that of pyridine, and one of the minor components was comparable with β-picoline.

The nonvolatile residue (725 mg of brown oil) was shown to contain two major components and at least 23 additional compounds by v.p.c. The residue was dissolved in ether (30 ml) and shaken in a five-funnel countercurrent system between five portions of ether, three portions of sulfuric acid (20% by weight), and two portions of water. All layers had a volume of 30 ml and all ether layers were shaken with five aqueous layers. The combined ether layers contained 211 mg of material. The combined aqueous layers were neutralized with potassium carbonate, basified with sodium hydroxide, and extracted with ether to give 420 mg of a brown oil, which, according to ultraviolet analysis, contained mainly pyridines.

The weakly basic, ether-soluble fraction (211 mg) was chromatographed on basic alumina (18 g, Merck); petroleum ether (b.p. 40–60°) – benzene (9:1) eluted a colorless oil (106 mg) which readily formed a crystalline picrate. The salt (82 mg) was recrystallized 15 times from ether, the last five melting points remaining constant at 108–110°. The liberated free base (basic alumina, Woelm) was subjected to a v.p.c. analysis (25% silicone SE-30 on Chromosorb W; 12 ft × $\frac{1}{8}$ in. outside diameter column; 280°; N_2, 40 ml/min), which showed the presence of two compounds with the peak area ratio of 1.65:1 and retention times of 14 min 37 s and 11 min 57 s, respectively.

The quinoline mixture (30 mg) was subjected to a nine-funnel countercurrent distribution with ether (50 ml) and sulfuric acid (50 ml, 23.5% by volume) in each funnel, sulfuric acid being the moving phase. The first four funnels contained 5 mg of pure (v.p.c.) 3-*n*-pentyl-6,8-dipropylquinoline, picrate m.p. 115–116°, and the last funnel contained pure (v.p.c.) 3-*n*-butyl-6,8-dipropylquinoline, picrate m.p. 110–112°. The structure of these two compounds was established by comparing their identity with synthetic specimens (see below).

Synthesis of 3-n-Pentyl-6,8-dipropylquinoline (IX)

4-n-Propylaniline

Aniline (9.3 g, distilled from zinc dust) and fused zinc chloride (9.54 g) (14) in *n*-propanol (7.21 g) were placed into a Carius tube, which was sealed under nitrogen, and then heated to 240° for 9 h. After the tube was cooled and opened (caution, high pressure), the contents (a reddish paste) were washed with water to remove unreacted zinc chloride and with ether to remove non-primary amines. The resulting crystalline zinc salt was dissolved in concentrated sodium hydroxide and the solution was extracted with ether. Evaporation of the ether gave a residue (4 g) which, on distillation at atmospheric pressure, gave pure 4-*n*-propylaniline, b.p. 224–230°; nuclear magnetic resonance maxima at 3.20 (2 meta H's, doublet, J = 7 c.p.s.), 3.67 (2 ortho H's, doublet, J = 7 c.p.s.), 6.70 (NH_2, singlet), 7.58 (2 benzylic H's, triplet, J = 7 c.p.s.), 8.55 (—CH_2—, multiplet), and 9.10 τ (—CH_3, triplet, J = 6 c.p.s.).

No alkylation of aniline was observed when the reaction was carried out at 200°, whereas heating to 270° produced equal amounts of *n*-propyl- and isopropyl-aniline.

N-Allyl-4-propylaniline

4-Propylaniline (7.36 g) and allyl chloride (20.9 g) (15) were heated under reflux for 13 h in a nitrogen atmosphere, then basified with aqueous sodium hydroxide (5 *N*, 100 ml), and extracted with ether. The separation of starting material and its *N*-allyl and *N*,*N*-diallyl derivatives was effected by distillation at atmospheric pressure. *N*-Allyl-4-propylaniline was obtained in a 45% yield, b.p. 248–254°; infrared maximum (chloroform) at 3 400 cm^{-1} (NH); ultraviolet maxima (ethanol) at 253 (ϵ 10 500) and 303 mμ (ϵ 1 600); nuclear magnetic resonance absorption for 3 olefinic protons.

2-Allyl-4-propylaniline

N-Allyl-4-propylaniline (3.58 g) was heated under reflux with anhydrous zinc chloride (2.78 g) in xylene (10 ml) for 15 h (15). The reaction mixture was treated with a 5 *N* sodium hydroxide solution and extracted with ether; then the ether extract was distilled to give the desired product (1.6 g), b.p. 125–130° at 14 mm.

2,4-Dipropylaniline

2-Allyl-4-propylaniline (1.6 g) was hydrogenated in glacial acetic acid (25 ml) and concentrated hydrochloric acid (1 ml) in the presence of platinum oxide (200 mg) at atmospheric pressure and room temperature for 4 h. The mixture was filtered and evaporated to dryness; then the residue was dissolved in 5 *N* sodium hydroxide solution and extracted with ether. Evaporation of the ether gave a quantitative yield of 2,4-dipropylaniline; nuclear magnetic resonance maxima at 3.34 (H's at C_3 and C_5, multiplet), 3.63 (1 H at C_6, doublet, J = 8 c.p.s.), 6.78 (NH_2, singlet), 7.62 (4 benzylic H's, triplet, J = 7 c.p.s.), 8.52 (4 methylene H's, multiplet), and 9.05 τ (6 methyl H's, triplet, J = 6 c.p.s.).

n-Pentylmalonic Acid Diethyl Ester

Sodium (14 g), cut in thin slices, was gradually added to 350 ml of absolute ethanol in a flame-dried flask protected from moisture (16). Diethyl malonate (100 g) was then added slowly through a dropping funnel. Under vigorous stirring, *n*-pentyl bromide (90 g) was then added during a 30 min period. The mixture was then refluxed until the solution was neutral to litmus (about 2 h). Ethanol was then evaporated, water added, and the separated organic layer distilled under reduced pressure. The desired product was obtained in a 90% yield, b.p. 130–133° at 14 mm.

2,4-Dihydroxy-3-n-pentyl-6,8-dipropylquinoline

To a refluxing solution (255°) of diethyl *n*-pentylmalonate (12 g) in diphenyl ether (150 ml) (17) was added dropwise, over a period of 4 h, a solution of 2,4-dipropylaniline (1.88 g) in diphenyl ether (100 ml) under

nitrogen. The solution was refluxed for an additional hour, cooled, and extracted with four 100 ml portions of dilute sodium hydroxide. The combined aqueous layers were acidified with hydrochloric acid and extracted with ether. Evaporation of the ether gave the desired dihydroxyquinoline (1.6 g), which crystallized after sublimation, m.p. 160–162°; ultraviolet maxima (ethanol) at 234 (ε 53 700), 278 (ε 10 000), 290 (sh), 322 (ε 7 200), and 330 mμ (sh).

A faster addition of the dipropylaniline in the above condensation resulted in an extensive formation of the corresponding diamide (two molecules of aniline reacting with one molecule of malonate).

2,4-Dichloro-3-n-pentyl-6,8-dipropylquinoline

A mixture of 2,4-dihydroxy-3-*n*-pentyl-6,8-dipropylquinoline (150 mg), phosphorus pentachloride (680 mg), and phosphorus oxychloride (0.5 ml) was heated to 100° for 4 h in a flask protected from moisture. The cooled reaction mixture was decomposed with water, and the solution was basified with sodium carbonate and extracted with ether. Evaporation of the ether yielded 142 mg of product, which, on the basis of t.l.c. on alumina with petroleum ether as eluent, consisted of two compounds, showing R_f values of 0.9 and 0.2, respectively. A clean separation was achieved on a column of basic alumina (Woelm); the desired oily dichloroquinoline (R_f 0.9) was obtained in a 20% yield; ultraviolet maxima (ethanol) at 245 (ε 44 600), 280–305 (broad, ε 3 200), 315 (ε 2 800), and 330 mμ (ε 2 200); nuclear magnetic resonance maxima in the aromatic region at 2.30 (1 H, singlet) and 2.70 τ (1 H, singlet); no infrared absorption in the 3 400 – 3 600 cm^{-1} region.

The second compound (R_f 0.2) proved to be the corresponding chloro-hydroxyquinoline and could be recycled to give an additional amount of the dichloroquinoline.

The dichlorination could not be achieved in the absence of phosphorus pentachloride.

3-n-Pentyl-6,8-dipropylquinoline (IX)

The dichloroquinoline (98 mg) was hydrogenated in the presence of 15% palladium on charcoal (100 mg) and potassium hydroxide (200 mg) in ethanol (15 ml) for 15 h at room temperature and normal pressure. After filtration, the ethanol was evaporated and the residue distributed between ether and 5 *N* sodium hydroxide solution. Evaporation of the ether gave 80 mg of the desired quinoline, which formed a picrate, m.p. 115–116°, in methanol. Mass spectrum: 283 (molecular ion), 268, 255 (largest peaks).

The higher boiling quinoline obtained in the dehydrogenation of ormosanine proved to be identical with this compound in picrate melting point, mixed melting point, mass spectrum, infrared spectrum, ultraviolet spectrum, and v.p.c. retention time.

Synthesis of 3-n-Butyl-6,8-dipropylquinoline

This compound was prepared by a method identical with that used for the synthesis of IX, only using diethyl *n*-butylmalonate (16) for the condensation with 2,4-dipropylaniline.

The oily quinoline gave a picrate, m.p. 110–112°. The lower boiling quinoline obtained in the dehydrogenation of ormosanine proved to be identical with this compound in picrate melting point, mixed melting point, infrared spectrum, ultraviolet spectrum, and v.p.c. retention time.

Synthesis of 6-n-Pentyl-3,8-dipropylquinoline

Only minor variations from the synthesis of IX were necessary. The required starting material, 4-*n*-pentylaniline, was prepared by a reaction of aniline (7.0 g) with amyl alcohol (8.0 g) and zinc chloride (7.2 g) in a sealed Carius tube at 240° for 9 h. Distillation at atmospheric pressure gave the desired aniline in a 20% yield, b.p. 255–265°. This was then refluxed with 5 moles of allyl chloride for 15 h, and the resulting *N*-allyl-4-*n*-pentylaniline, after purification by fractional distillation (5.92 g), was heated under reflux with zinc chloride (4.0 g) in xylene (25 ml) for 10 h. Vacuum distillation of the product gave 2.7 g of 2-allyl-4-*n*-pentylaniline, which was hydrogenated to 4-*n*-pentyl-2-propylaniline with platinum oxide (300 mg) in glacial acetic acid (25 ml) and hydrochloric acid (2 ml).

Diethyl propylmalonate, b.p. 100–105° at 14 mm, needed for the condensation reaction, was prepared in an 85% yield by a reflux of propyl bromide with an equivalent amount of the sodium salt of diethyl malonate in dry ethanol (see above).

Condensation of 4-*n*-pentyl-2-propylaniline (700 mg) with diethyl propylmalonate (3.45 g) in 170 ml of diphenyl ether gave the dihydroxyquinoline (600 mg), which, on treatment with phosphorus pentachloride (1.1 g) and phosphorus oxychloride (2 ml), followed by chromatography on basic alumina, yielded the pure 2,4-dichloro-6-*n*-pentyl-3,8-dipropylquinoline (178 mg). Its hydrogenolysis with 15% palladium on charcoal (200 mg) and potassium hydroxide (400 mg) in ethanol (20 ml) then gave the required 6-*n*-pentyl-3,8-dipropylquinoline (163 mg), picrate m.p. 103–104°. Mass spectrum: 283 (molecular ion), 268, 255 (largest peaks).

The compound was found to be distinctly different from IX in picrate melting point, nuclear magnetic resonance spectrum (8–9 τ), and infrared and mass spectra. Ultraviolet spectra and v.p.c. retention times were identical.

Synthesis of 6-n-Butyl-3,8-dipropylquinoline

The required starting material, 4-*n*-butylaniline, was prepared by a reaction of aniline with butyl alcohol and zinc chloride as described above. The previously described steps, including condensation with diethyl propylmalonate, then gave the quinoline, picrate m.p. 130–131°.

For personal use only.

The lower boiling quinoline from ormosanine was distinctly different from this compound in picrate melting point and infrared spectrum. Ultraviolet spectra and v.p.c. retention times were identical.

Synthesis of 8-n-Pentyl-3,6-dipropylquinoline

The required starting material, 2-*n*-pentyl-4-propylaniline, was not attainable by the above *N*-allylation–rearrangement sequence. 4-Propylaniline (5.08 g; preparation, see above) was therefore heated directly with amyl alcohol (3.98 g) and fused zinc chloride (5.12 g) in a sealed Carius tube to 240° for 11 h. The resulting solid was dissolved in 10 *N* sodium hydroxide solution, which was extracted with ether. Vapor-phase chromatographic analysis (10% D.C. on Chromosorb W; 210°; N_2, 60 ml/min) of the ether extract showed the presence of over 20 compounds, with the two major components being starting material and what was later found to be the required product. A series of three fractional distillations produced v.p.c. pure 2-*n*-pentyl-4-propylaniline (610 mg), which, after condensation with diethyl propylmalonate, chlorination, and reduction as described above, gave the desired 8-*n*-pentyl-3,6-dipropylquinoline, picrate m.p. 130–132°. Mass spectrum: 283 (molecular ion), 254, 240, 227 (largest peaks).

The compound was found to be distinctly different from IX in picrate melting point, nuclear magnetic resonance, infrared, and mass spectra, and v.p.c. (IX is 13 s slower in a 4 min run).

Dihydro-ormojanine

Ormojanine (2.362 g) was dissolved in ethanol (50 ml) and treated with an excess of gaseous hydrochloric acid. The solution was then evaporated to dryness, and the hydrochloride was dissolved in 50 ml of ethanol and hydrogenated in the presence of platinum oxide (400 mg) at room temperature and normal pressure. The hydrogenation was stopped when 1 mole of hydrogen was absorbed, and the solution was filtered and evaporated. The residue was distributed between ether and a 2 *N* sodium hydroxide solution, the ether evaporated, and the solid residue crystallized from acetone to give pure dihydro-ormojanine, m.p. 127–129° (1.856 g).

Anal. Calcd. for $C_{20}H_{33}N_3$: C, 76.13; H, 10.55; N, 13.32. Found: C, 75.89; H, 10.71; N, 13.72.

Tetrahydro-ormojanine

Hydrogenation of ormojanine in ethanol in the presence of platinum oxide at room temperature and normal pressure for 2 days gave an almost quantitative yield of tetrahydro-ormojanine, m.p. 107–109° (crystallized from acetone).

Anal. Calcd. for $C_{20}H_{35}N_3$: C, 75.65; H, 11.11; N, 13.24. Found: C, 76.03; H, 11.07; N, 13.02.

Dehydrogenation of Ormojanine Derivatives

(*a*) Treatment of tetrahydro-ormojanine (2.0 g) with palladium on charcoal (15%, 3.0 g) at 275° for 18 h (sealed Carius tubes), followed by isolation and purification procedures similar to those described for the dehydrogenation of ormosanine (see above), resulted in the isolation of 3-pentyl- and 3-butyl-6,8-dipropyl-quinolines.

(*b*) Dihydro-ormojanine (4 × 1.025 g) was mixed with palladium on charcoal (15%, 4 × 1.15 g) and benzene (4 × 4.5 ml) and sealed under nitrogen in four Carius tubes. The tubes were heated to 200° for 12 h, cooled, opened, and washed with ether. After filtration, the ether solution was evaporated to give 1.53 g of a residue. Elution with 1% to 25% ether in benzene from basic alumina (Woelm, activity 1, 150 g) gave pure dipyridine XIV, m.p. 130–132° (700 mg).

Anal. Calcd. for $C_{20}H_{23}N_3$: C, 78.69; H, 7.61; N, 13.70. Found: C, 78.87; H, 7.93; N, 13.24.

Infrared maxima (chloroform) at 2 800 (s), 2 750 (s), 1 590 (s), 1 580 (s); nuclear magnetic resonance maxima (carbon tetrachloride) in the aromatic region at 1.53 and 1.89 τ (2 alpha H's, multiplets) and 2.50–3.20 τ (3 beta H's and 2 gamma H's, multiplet).

Dipyridine XIV was found to be identical in ultraviolet, infrared, and nuclear magnetic resonance spectra with (racemic) dipyridine, m.p. 146–147° and 154°, prepared from ormosanine according to Wildman *et al.* (10).

A further purification (countercurrent distribution) of later fractions of the above chromatogram gave a small amount (8 mg) of a t.l.c. pure material which, on the basis of its ultraviolet spectrum (inflection 262, maximum at 268 (ϵ 3 400), inflection 275 mμ) and the absence of NH absorption in the infrared spectrum, is very likely a C_{15} compound corresponding to XIV, but with the monosubstituted pyridine ring removed. Molecular weight (found by Mechrolab 301 osmometer): 235. Calcd. for $C_{15}H_{20}N_2$: 228.

N-Acetylormojanine

Ormojanine (165 mg) was acetylated with acetic anhydride (1.5 ml) in pyridine (1.5 ml). Evaporation of the solvents was followed by a distribution of the residue between ether and aqueous hydrochloric acid. Basification of the aqueous layer and extraction with ether gave 173 mg of the oily *N*-acetyl derivative, which appeared homogeneous by t.l.c. and paper chromatography.

Anal. Calcd. for $C_{22}H_{33}N_3O$: C, 73.90; H, 9.86; N, 11.75. Found: C, 73.51; H, 9.76; N, 11.82.

Infrared maximum (chloroform) at 1 630 cm^{-1} (s).

N-Nitroso-ormojanine

A solution of sodium nitrite (150 mg) in 1 ml of water was added during 30 min to a solution of ormojanine (200 mg) in 1 *N* hydrochloric acid (3 ml) at 0°. After standing for 1 h, the solution was heated to 100° for

5 min, cooled, diluted with water (75 ml), and extracted with ether. The ether extract (180 mg) crystallized from ether. Recrystallization gave the pure nitroso compound, m.p. 178–181°.

Anal. Calcd. for $C_{20}H_{30}N_4O$: C, 70.13; H, 8.83; N, 16.36. Found: C, 70.05; H, 8.92; N, 15.42.

Homoxydihydro-ormojanine

A solution of ethyl chloroformate (1 ml) in dry benzene (5 ml) was added dropwise to a well-stirred solution of dihydro-ormojanine (166 mg) in dry benzene (5 ml) containing triethylamine (1 ml). The mixture was stirred for 5 h at room temperature. Additional amounts of triethylamine (1 ml) and ethyl chloroformate (0.5 ml) in benzene were added after 2 h. The precipitated triethylamine hydrochloride was then filtered off, the filtrate evaporated to dryness, and the residue distributed between ether and 2 *N* hydrochloric acid. The aqueous layer was basified with sodium carbonate and extracted with ether. Evaporation of the ether gave 182 mg of a residue which, after recrystallization from petroleum ether, melted at 173–174°.

Anal. Calcd. for $C_{21}H_{31}N_3O$: C, 73.96; H, 9.16; N, 12.32; O, 4.69. Found: C, 73.30; H, 9.20; N, 13.09; O, 4.59.

Infrared maximum (KBr) at 1 645 cm^{-1}; nuclear magnetic resonance maxima below 7 τ at 4.49 (1 H, doublet, J = 5 c.p.s.), 5.20–5.81 (2 H's, multiplet), and 6.51 τ (1 H, singlet).

Homotetrahydro-ormojanine

Tetrahydro-ormojanine (143 mg) was boiled under reflux with formic acid (90%, 10 ml) and formaldehyde (40%, 6 ml) for 3 h. Additional formic acid (5 ml) and formaldehyde (3 ml) were then added and the solution was boiled for a further 7 h. Dilution with water (75 ml) and work-up in the usual manner gave 196 mg of a basic material, which, after recrystallization from acetone, melted at 100–101°.

Anal. Calcd. for $C_{21}H_{35}N_3$: C, 76.55; H, 10.71; N, 12.75. Found: C, 76.55; H, 10.54; N, 12.54.

The nuclear magnetic resonance spectrum contains an AB quadruplet for 2 protons centered at 6.69 τ (δ_{AB} = 17 c.p.s.; J_{AB} = 9 c.p.s.).

Homoxytetrahydro-ormojanine

The compound was prepared by the same method as that used for homoxydihydro-ormojanine (see above), using 334 mg of tetrahydro-ormojanine, 3 ml of ethyl chloroformate, 4 ml of triethylamine, and 30 ml of dry benzene. The basic extract (377 mg) crystallized from ether; recrystallization from ether gave pure homoxytetrahydro-ormojanine, m.p. 203–205°.

Anal. Calcd. for $C_{21}H_{33}N_3O$: C, 73.43; H, 9.69; N, 12.23; O, 4.66. Found: C, 73.64; H, 9.73; N, 11.87; O, 4.96.

Mass spectrum: 343 (molecular ion); infrared maximum (chloroform) at 1 640 cm^{-1}.

Hofmann Degradation of Homoxydihydro-ormojanine

Homoxydihydro-ormojanine (2.10 g) was converted into the methiodide by a reflux in benzene solution (10 ml) with methyl iodide (10 ml) for 3 days. The supernatant liquid was then decanted from the semi-crystalline precipitate, which was washed repeatedly with dry ether. The precipitated methiodide, which could be crystallized from water, was converted into the corresponding quaternary hydroxide on a column of basic Amberlite IRA-300 in methanol. After evaporation of the methanol, the residue was sublimed at 180–185° and 0.1 mm Hg.

The sublimate (1.56 g, amorphous solid) was subjected to an 11-funnel countercurrent distribution, using ether and McIlvain's buffer (pH 6.1) with the aqueous solution as a moving phase. The material in funnels 2–5 was recrystallized from ether – petroleum ether to give pure diene XVII, m.p. 135–138° (0.74 g).

Anal. Calcd. for $C_{22}H_{33}N_3O$: C, 74.43; H, 9.37; N, 11.84; O, 4.51; one N—CH_3, 4.22. Found: C, 74.43; H, 9.42; N, 11.85; O, 4.54; N—CH_3, 4.50.

Diagnostic nuclear magnetic resonance maxima at 3.85 (1 H, singlet), 4.79 (1 H, triplet, J = 7 c.p.s.), and 7.74 τ (N—CH_3, singlet).

Dehydrogenation of Deuterated Dihydro-ormojanine

Dihydro-ormojanine (620 mg) was reduced with deuterium gas in the presence of platinum oxide (1 g) in CH_3COOD (25 g) for 2 weeks at room temperature and normal pressure. The mixture was filtered, the filtrate evaporated to dryness, and the residue distributed between ether and a 5 *N* sodium hydroxide solution. The ether residue was crystallized from acetone to give deuterated dihydro-ormojanine, m.p. 107–109°. The infrared spectrum (carbon tetrachloride) shows strong deuterium absorption bands at 2 170 (sharp) and 2 000 cm^{-1} (broad).

The deuterated compound (245 mg) was mixed with palladium on charcoal (10%, 270 mg) and heated in a 10 ml test tube in a Wood's metal bath to 250° for 20 min. After cooling, the tube contents were washed exhaustively with benzene, and the solution was filtered and evaporated to dryness. Distribution between ether and aqueous acid and base in the usual manner gave 174 mg of a basic material which was chromatographed on neutral alumina (Woelm, activity 3, 10 g). Elution with benzene – petroleum ether (3:1) gave fractions containing pure deuterated dipyridine XIV, m.p. 130–132°. Deuterium analysis showed the presence of 2.3 deuterium atoms per molecule. The presence of deuterium is confirmed by weak infrared bands (chloroform) at 2 170 and 2 000 cm^{-1}. However, a quantitative comparison of the nuclear magnetic resonance spectra of deuterated XIV and of XIV prepared by dehydrogenation of dihydro-ormojanine (see above)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

showed that the deuterium atoms are definitely not located on the pyridine rings (identical 1.45–3.20 τ region) or on C_{17} (identical 6.80–7.30 τ region). All these hydrogens are clearly visible in both spectra. It can reasonably be concluded that the deuterium atoms were incorporated in a position alpha to the tertiary nitrogen atom (C_2, C_6, and (or) C_{10}).[14]

Formation of N,N-Dimethyldihydro-ormojanine

(*a*) Ormojanine (370 mg) was methylated with methyl iodide (2 ml) in dry benzene for 20 h at room temperature. The supernatant liquid was then decanted from the precipitated salt, which was washed repeatedly with fresh dry benzene. The dried salt was dissolved in methanol (50 ml) and reduced with sodium borohydride (470 mg) at reflux temperature for 1 h. Most of the solvent was then evaporated and the residue was distributed between ether and a 2 *N* sodium hydroxide solution. The ether extract (350 mg) crystallized from acetone to give pure *N,N*-dimethyldihydro-ormojanine, m.p. 120–122°.

Anal. Calcd. for $C_{22}H_{37}N_3$: C, 77.03; H, 10.75; N, 12.25; two N—CH_3 groups, 8.80. Found: C, 76.88; H, 10.62; N, 12.09; N—CH_3, 7.50.

Diagnostic nuclear magnetic resonance maxima at 4.40 (1 H, doublet, J = 6 c.p.s.), 6.66 (1 H, singlet), 7.38 (N—CH_3, singlet), and 7.79 τ (N—CH_3, singlet).

The above quaternary iodide could be converted into an unstable enamine by percolation through basic Amberlite IRA-300 in methanol. The enamine could be crystallized from acetone and showed a moderately strong absorption at 1 645 cm^{-1} in the infrared spectrum (KBr).

(*b*) Dihydro-ormojanine (77 mg) was boiled under reflux in formic acid (88%, 1 ml) and formaldehyde (37%, 2 ml); additional amounts of formic acid (2 ml) and formaldehyde (4 ml) were added in two portions at 3 h intervals, with the total reflux time being 9 h. The mixture was then diluted with water (25 ml) and extracted with ether. The aqueous layer was basified with sodium hydroxide and extracted with ether. The oily ether extract (74 mg) proved homogeneous on t.l.c. and was identified as homodihydro-ormojanine (D) by spectroscopy. The infrared spectrum (carbon tetrachloride) showed the absence of an NH group, and the nuclear magnetic resonance spectrum showed absorption typical for the N—CH_2—N grouping (AB quadruplet centered at 6.62 τ, δ_{AB} = 20 c.p.s., J_{AB} = 7 c.p.s.).

The homo derivative was boiled under reflux with methyl iodide (1 ml) in dry benzene (3 ml) for 3 h. After evaporation of the benzene, the resulting salt was dissolved in methanol (10 ml) and reduced with sodium borohydride (50 mg) at reflux for 1 h. Purification in the usual manner, followed by crystallization from acetone, gave 30 mg of a product identical in all respects with *N,N*-dimethyldihydro-ormojanine (see above).

ORMOSIA ALKALOIDS

IV. STEREOCHEMISTRY OF ORMOJANINE; STRUCTURE AND STEREOCHEMISTRY OF PIPTANTHINE, DASYCARPINE, AND ORMOSININE[1]

P. DESLONGCHAMPS, Z. VALENTA, AND J. S. WILSON

Received July 8, 1966

ABSTRACT

By using the known structure and stereochemistry of the alkaloid ormosanine, $C_{20}H_{35}N_3$ (I), as reference, the structure and stereochemistry of the isomeric compounds piptanthine (II), tetrahydro-ormojanine (XIV), isotetrahydro-ormojanine (XIII), and dasycarpine (XX) have been elucidated by isomerization and reduction experiments. Three additional $C_{20}H_{35}N_3$ bases possessing the ormosanine skeleton have been prepared by the reduction of pyridine VII. Thus, of the 15 possible stereoisomers of ormosanine, 7 are now known.

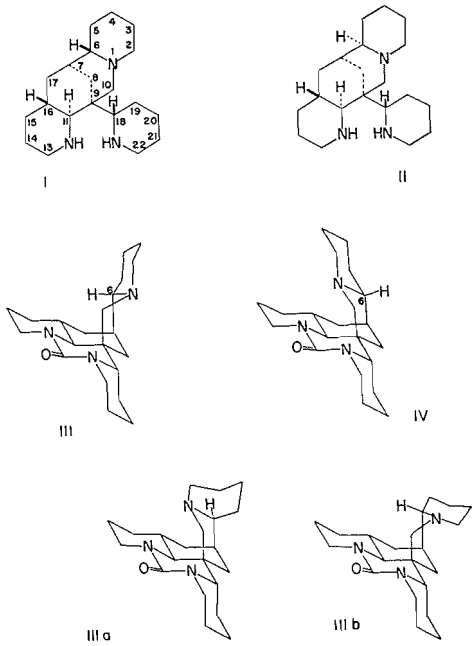
The study leads to the stereo-formula XIX for the alkaloid ormojanine, $C_{20}H_{31}N_3$. The alkaloid ormosinine has been found to be a dimer of panamine.

Stereochemical aspects of the catalytic and chemical reductions of the double bonds and pyridine rings contained in the described compounds are discussed. A possible biogenetic intermediate is proposed which explains the presence of both antipodal series of *Ormosia* alkaloids in nature.

The isolation of a number of alkaloids with the empirical formula $C_{20}H_{35}N_3$ has been reported; these are ormosanine from *Ormosia jamaicensis* (1), piptanthine from *Piptanthus nanus* (2), and dasycarpine from *Ormosia dasycarpa* (3). Recently, the structure and stereochemistry of ormosanine were found by X-ray crystallography to be as represented in I (4).[2] It appeared to be an interesting challenge to use the known structure and configuration of ormosanine as a point of departure and to establish the structure and stereochemistry of all the isomeric bases by correlative experiments and configurational arguments. Our interest in this problem was enhanced by the fact that we obtained two additional $C_{20}H_{35}N_3$ bases, tetrahydro-ormojanine and isotetrahydro-ormojanine, in reduction experiments on ormojanine, $C_{20}H_{31}N_3$, another constituent of *O. jamaicensis*.

Disregarding absolute configuration[2] and taking account of the fact that the two asymmetric centers C_7 and C_9 are configurationally interdependent, one arrives at 16 possible compounds containing the ormosanine skeleton. It now remains to establish whether tetrahydro-ormojanine, isotetrahydro-ormojanine, piptanthine, and dasycarpine all possess the same skeleton as ormosanine and, if so, to select for each of these compounds the correct configuration out of the 15 remaining stereochemical possibilities.

Piptanthine



The solution in the case of the alkaloid piptanthine proved to be remarkably easy. We have been able to show (5) that a prolonged treatment of ormosanine with platinum in acetic acid in a hydrogen atmosphere at room temperature converted it into piptanthine.[3] On the basis of this isomerization, the structure and stereochemistry of piptanthine must be II for the following reasons.

Homoxy-ormosanine (III), the urea derivative of ormosanine (8), was found to undergo the same catalytic isomerization to homoxypiptanthine (IV). Consequently, C_6 must be

[1]*For part III in this series, see ref. 8.*

[2]*The absolute configuration of ormosanine and related compounds is unknown, and none is implied in any of the formulae in this communication.*

[3]*Since natural ormosanine is racemic (6), the catalytically produced piptanthine is also racemic. Piptanthine from P. nanus is levorotatory ($[\alpha]_D$ −24.3°) (7).*

considered the most likely reaction center, since this process, which probably proceeds via dehydrogenation–hydrogenation, can be expected to be sufficiently rapid only in the vicinity of the basic nitrogen atom. The configurational assignments at C_6 are confirmed by infrared spectroscopy. A potassium bromide pellet spectrum of homoxy-ormosanine shows bands in the 2 800 cm^{-1} region characteristic of the *trans*-diaxial arrangement of the tertiary nitrogen electron pair and at least two α-hydrogen atoms (9), in agreement with conformation III (4). A spectrum of homoxy-ormosanine in chloroform, on the other hand, shows no bands in this region and indicates that the compound assumes conformation III*a* or III*b* in solution. In contrast, the infrared spectrum of homoxypiptanthine shows the diagnostic bands both in solid state and in solution, in agreement with the stable all-chair all-*trans* conformation IV (5).

This difference in spectroscopic behavior and the selectivity and efficiency of this essentially irreversible isomerization process can only be explained by the configuration II for piptanthine. It should be added parenthetically that a direct proof for the platinum-catalyzed exchange of hydrogen atoms situated alpha to the tertiary nitrogen atom in *Ormosia* alkaloids is also available. During our investigation of the alkaloid ormojanine, dihydro-ormojanine (VI) was reduced with deuterium gas and platinum in CH_3COOD and the product was dehydrogenated with palladium on charcoal to the pyridine VII (8). A nuclear magnetic resonance study of the resulting pyridine showed a complete absence of deuterium in the aromatic rings and at C_{17}, whereas analysis indicated the presence of 2.3 deuterium atoms in the molecule (8). Since the deuteration was done under very mild conditions (normal pressure and room temperature), it appears reasonable to assume that the incorporated deuterium atoms must be situated alpha to the tertiary nitrogen atom (C_2, C_6, and (or) C_{10}).

It is also interesting to note that the deep-seated rearrangement taking place during the catalytic dehydrogenation of ormosanine and tetrahydro-ormojanine to 3-pentyl-6,8-dipropylquinoline requires the removal of the C_6-hydrogen atom as one of the initial steps (8).

Tetrahydro-ormojanine and Isotetrahydro-ormojanine

As reported in the accompanying communication (8), the gross structure of the alkaloid ormojanine, $C_{20}H_{31}N_3$, a constituent of *O. jamaicensis*, can be represented by formula V.[4] The following three compounds were obtained by the reduction of ormojanine. A short catalytic reduction yielded dihydro-ormojanine (VI), whereas a longer hydrogenation saturated the double bond and gave pure tetrahydro-ormojanine (8, 10). A reduction of dihydro-ormojanine (VI) with lithium in boiling ethylene diamine (17) also saturated the double bond and gave an isomeric $C_{20}H_{35}N_3$ compound, isotetrahydro-ormojanine, in a good yield. The two isomeric reduction products were found to be distinctly different from ormosanine (I) and piptanthine (II) in their physical and chemical properties.

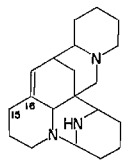
Dehydrogenation experiments showed clearly that ormosanine and ormojanine possess the same skeleton (8). Dehydrogenation of ormosanine and of tetrahydro-ormojanine at 280° with palladium on charcoal yielded 3-*n*-pentyl-6,8-dipropylquinoline (8, 10), whereas both ormosanine and dihydro-ormojanine gave the pyridine VII on dehydrogenation with the same catalyst at a lower temperature (8, 11). It should be noted that the hydrogen atom at C_6 in pyridine VII is assigned a configuration *cis* to the C_7—C_9 bridge, requiring an isomerization at C_6 during the dehydrogenation of ormosanine (5). This configuration follows from the presence of strong bands in the 2 800 cm^{-1} region of the infrared spectrum of pyridine VII both in solid state and in solution, in complete analogy to the spectral properties of piptanthine (see above), and is proved by the reduction study described below.

The question now arises whether ormojanine and its reduction products have the ormosanine or the piptanthine configuration at C_6. Several lines of evidence clearly show that the C_6-hydrogen atom is *cis* to the C_7—C_9 bridge (analogous to II and VII) in ormojanine and all its derivatives.

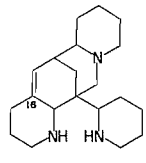
(*a*) Ormojanine and all its reduction products show infrared bands in the 2 800 cm^{-1} region analogous to those of piptanthine (II) and pyridine VII.

(*b*) Neither tetrahydro-ormojanine nor isotetrahydro-ormojanine change under conditions used for the ormosanine–piptanthine isomerization.

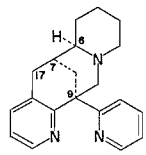
(*c*) Isomerization of dasycarpine to isotetrahydro-ormojanine (see below) proves that the C_6-hydrogen atom in the latter is *cis* to the C_7—C_9 bridge.



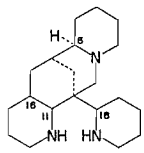
(*d*) Catalytic reduction of dihydro-ormojanine gives only one compound, tetrahydro-ormojanine.



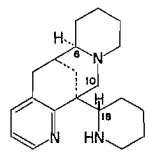
(*e*) The absence of an isomerization at C_6 during the catalytic reduction of ormojanine to dihydro-ormojanine is proved by the following evidence. *N*,*N*-Dimethyldihydro-ormojanine has been prepared from dihydro-ormojanine in three steps (8, 10). The identical dimethyl compound has also been prepared from ormojanine itself in a sequence in which no catalytic reduction was involved (8, 10).



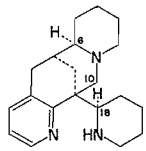
If tetrahydro-ormojanine, isotetrahydro-ormojanine, and piptanthine (II) have the same relative configuration at C_6, C_7, and C_9, they must obviously differ at some or all of the asymmetric centers C_{11}, C_{16}, and C_{18}. In other words, with the structure of piptanthine determined as II, tetrahydro-ormojanine and isotetrahydro-ormojanine must be two of the seven remaining possible compounds represented by formula VIII. Since the pyridine VII possesses the same configuration at C_6, C_7, and C_9 as the three compounds in question, it is clear that a detailed study of its reduction could provide a complete solution to the problem.



This opportunity was exploited in the following way. Pyridine VII was first reduced under mild catalytic conditions, which saturated only the monosubstituted pyridine ring.



[4] *An alternative position of the double bond at* C_{15}—C_{16} *in ormojanine is not rigorously excluded by our evidence.*



V

VI

VII

VIII

IX

X

Clearly, this reduction could be expected to give two compounds, IX and X, differing only in the configuration at C_{18}. In fact, the reduction product gave only one spot in thin-layer chromatography and was also reported (11) to appear homogeneous in vapor-phase chromatography. We have found, however, that acetylation of the reduction product gave two acetyl derivatives which could be separated chromatographically. To facilitate a reconversion into the secondary amines, the procedure was repeated with the corresponding carbobenzyloxy derivatives, which were separated by column chromatography and individually hydrogenolyzed to pure IX and pure X. The two secondary amines have the same R_f value in thin-layer chromatography, but show distinct differences in their infrared and nuclear magnetic resonance spectra. Most significantly, the two hydrogen atoms at C_{10} appear as a singlet (A_2) at 8.2 τ in the spectrum of one of the isomers and as a quadruplet (AB) centered at 8.11 τ (δ_{AB} = 19 c.p.s., J_{AB} = 10 c.p.s.) in the spectrum of the other isomer.

It must now be established which of these isomers is IX and which is X. To simplify the discussion, the results of the subsequent reduction experiments are anticipated; these demonstrate unambiguously that the isomer showing a singlet corresponding to the C_{10}-methylene group is X, and that the other isomer (quadruplet corresponding to C_{10}-methylene) is IX.

Pyridine IX was reduced catalytically with platinum in acetic acid at high pressure. Since the resulting mixture of completely saturated bases did not appear to be sufficiently stable for an extended experimentation, it was immediately treated with phosgene and thus converted into the corresponding cyclic urea derivatives. Purification by chromatography yielded two crystalline ureas, A_1 and A_2. Reduction of pyridine IX with sodium and isoamyl alcohol, followed by a treatment with phosgene and chromatography, also yielded A_1 and A_2.

Similarly, a high-pressure hydrogenation of pyridine X, followed by a treatment with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

phosgene and chromatography, yielded two crystalline ureas, B_1 and B_2, whereas the chemical reduction of X with sodium and isoamyl alcohol resulted, after treatment with phosgene, in two ureas, B_1 and B_3.

These transformations can be summarized by the following scheme.

$$A_1, A_2 \xleftarrow[2.\ COCl_2]{1.\ H_2/Pt} IX \xrightarrow[2.\ COCl_2]{1.\ Na/alcohol} A_1, A_2$$

$$B_1, B_2 \xleftarrow[2.\ COCl_2]{1.\ H_2/Pt} X \xrightarrow[2.\ COCl_2]{1.\ Na/alcohol} B_1, B_3$$

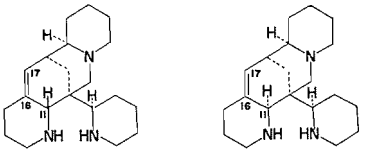
The five homoxy derivatives (ureas) obtained in this way are all pure, stable compounds with the expected molecular ion in their mass spectra (*m/e* 343) and showing distinct differences in thin-layer chromatography and infrared and nuclear magnetic resonance spectroscopy. Furthermore, their spectra show the complete absence of olefinic or aromatic hydrogen atoms. They must therefore be the homoxy derivatives of five of the eight possible $C_{20}H_{35}N_3$ isomers depicted by the general formula VIII.

Comparison with known compounds has shown that A_1 is identical with homoxy-piptanthine (IV) and that B_3 is identical with homoxytetrahydro-ormojanine. Since the complete stereochemistry of piptanthine is known, it is clear that these findings rigorously differentiate between the two monopyridines IX and X. Furthermore, ormojanine and its reduction products must clearly have a configuration at C_{18} opposite to that of piptanthine.

Just as significantly, however, the homoxy derivatives of ormosanine, dasycarpine, and isotetrahydro-ormojanine were found not to be identical with any one of the remaining reduction products, A_2, B_1, and B_2. The absence of homoxy-ormosanine (III) was to be expected and confirms our assignment of a configuration at C_6 in pyridine VII opposite to that of ormosanine (I) (5). Homoxy-dasycarpine cannot be expected to be present among the hydrogenation products on the basis of experiments described below.

The absence of the urea of isotetrahydro-ormojanine among the reduction products of X was, however, unexpected. It must be remembered that isotetrahydro-ormojanine is produced by the chemical reduction of dihydro-ormojanine (VI), whereas tetrahydro-ormojanine results from a catalytic reduction of VI. Since we now know that ormojanine possesses the more stable configuration at C_6 and since, furthermore, there is no evidence in our work of any isomerizations under the conditions of a chemical reduction, it must be assumed that the two tetrahydro isomers differ only in the configuration at the reduced center C_{16}.[5] It follows, therefore, that isotetrahydro-ormojanine must correspond to the missing fourth possible reduction product of X (B_4).

This postulate gives rise to a paradoxical situation. Since isotetrahydro-ormojanine is formed in a high yield in the chemical reduction of VI, it should be more stable than tetrahydro-ormojanine. How is it possible, then, that the less-stable compound, tetrahydro-ormojanine, is formed in the chemical reduction of pyridine X and that the more stable compound, isotetrahydro-ormojanine, is not obtained from X at all?



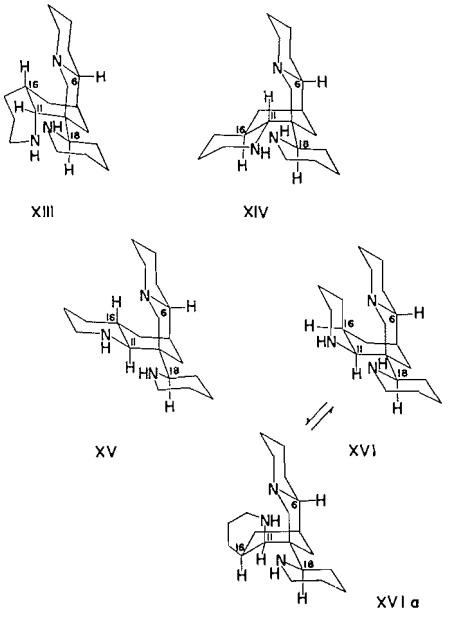
Actually, there is one, and only one, satisfactory solution to this dilemma. First of all, as stated above, the results of the hydrogenation of pyridines IX and X clearly show that the ormojanine series has a configuration at C_{18} opposite to that of ormosanine (I) and piptanthine (II). Dihydro-ormojanine (VI) can therefore definitely be represented by one of two complete stereo-formulae, XI and XII, differing in the configuration at C_{11}.

[5]*That isotetrahydro-ormojanine has a configuration at* C_6 *identical with that of X also follows clearly from our work on dasycarpine (see below).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Scheme 1 now shows the tetrahydro compounds to be expected from the two possibilities. Clearly, XI would, on reduction, give rise to XIII and XIV, whereas XII would be reduced to XV and XVI.

Should XI be the correct representation of dihydro-ormojanine, then XIII must be the formula for isotetrahydro-ormojanine and XIV for tetrahydro-ormojanine for the following reasons. Clearly, a catalytic reduction of the C_{16}—C_{17} double bond in XI should proceed from the less-hindered side. In this case, the two rings containing the tertiary nitrogen



XI XII

atom completely screen the upper side of the molecule, and the catalytic addition of hydrogen, which is found to be completely stereospecific, must therefore take place from the bottom. Thus, tetrahydro-ormojanine would be XIV. On the other hand, the chemical reduction of the C_{16}—C_{17} double bond in XI would be expected to give the more stable compound, and an inspection of models shows that XIII could well be more stable than XIV. This leads to formula XIII for isotetrahydro-ormojanine.

Similar considerations apply if XII were the structure of dihydro-ormojanine. Again, the catalytic reduction would be expected to proceed from the side opposite to the two rings containing the tertiary nitrogen; tetrahydro-ormojanine would therefore be XVI. Furthermore, XV is clearly more stable than XVI; isotetrahydro-ormojanine would thus have structure XV.

The decision between these two possibilities is now quite simple. It can be seen that the

XIII XIV XV XVI XVIa

For personal use only.

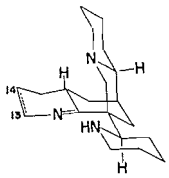
configuration at the important centers C_6, C_{11}, and C_{16} in formula XV is identical with that of piptanthine (II).[6] Since piptanthine is produced both by a catalytic and a chemical reduction of pyridine IX (see above), it can be expected that compound XV would be formed by both reductions, or at the very least one of the reductions, of pyridine X. Since B_3 is identical with homoxytetrahydro-ormojanine, structure XV must therefore definitely correspond to one of the two remaining reduction products of pyridine X, B_1 or B_2. However, neither B_1 nor B_2 are identical with homoxyisotetrahydro-ormojanine (see above); *isotetrahydro-ormojanine must therefore have structure XIII, tetrahydro-ormojanine structure XIV, and dihydro-ormojanine structure XI.*[7] Mechanistic considerations (see below), furthermore, clearly indicate that formula XV must correspond to reduction product B_1 and formula XVI to reduction product B_2.

It still remains to be explained, however, why the chemical reduction of pyridine X gives no isotetrahydro-ormojanine (XIII). It can be seen immediately that this and all other reported facts find a ready explanation when the reasonable assumption is made that the reduction of the pyridine ring with sodium and alcohol is a multistage process in which the tetrahydro-pyridines XVII and XVIII (or the corresponding dihydro-pyridines with an additional double bond at C_{13}—C_{14}) are intermediates.[8] The reduction of XVII can give XIII and XV, but if XV is the more stable compound of the two, only XV and no isotetrahydro-ormojanine (XIII) will be produced. Similarly, the reduction of XVIII can give XIV and XVI; only tetrahydro-ormojanine (XIV) will be produced if it is more stable than compound XVI.

The apparent paradox is thus seen to arise because, in the chemical reduction of dihydro-ormojanine, the stability of isotetrahydro-ormojanine is compared with that of tetrahydro-ormojanine, whereas in the chemical reduction of pyridine X, it is compared with that of isomer XV. In the first case, isotetrahydro-ormojanine is the more stable compound; in the second case, it is the less-stable one.

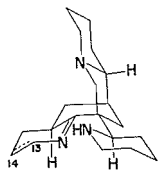
The above analysis thus explains all the known experimental facts satisfactorily and provides a unique solution of the stereochemistry of the ormojanine reduction products. *Based on the previously deduced gross structure V, ormojanine itself can then be represented by the complete formula XIX.* The opposite configuration at C_{22} in this structure is sterically impossible.

It is interesting to note that, on the basis of the hydrogenation study described above, the synthesis of pyridine VII will represent the total synthesis of one natural product, piptanthine, and four alkaloid reduction products, including tetrahydro-ormojanine. Stereochemically, the synthesis thus simplifies to the preparation of two possible diastereoisomers (VII and its epimer at C_6), which are furthermore connected by the described isomerization at C_6.



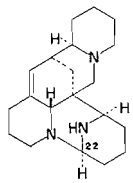
Dasycarpine

After the stereochemical relationships in the ormojanine series had been clarified, the structure and stereochemistry of dasycarpine, $C_{20}H_{35}N_3$, an alkaloid of *Ormosia dasycarpa* (3), were solved in the following simple way. A sample of dasycarpine was subjected to a

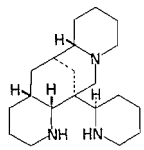


[6]*The two compounds only differ in their configuration at* C_{18}, *and this difference would not be expected to affect significantly the following arguments.*

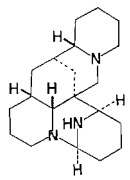
[7]*Another argument, independent of the piptanthine series, leads to the same conclusion. The assignment of formula XV to isotetrahydro-ormojanine and of XVI to tetrahydro-ormojanine cannot be correct, since it requires that compound XVI not be formed in the catalytic reduction of pyridine X, although an addition of two* α*-hydrogen atoms during this hydrogenation would be expected to be particularly favorable.*



[8]*It is known that the reduction of pyridines with sodium and alcohol proceeds via 1,4-dihydropyridines (12), and it can be expected that an enamine–imine isomerization will precede further reduction.*



XVII

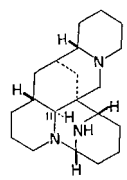


XVIII

XIX

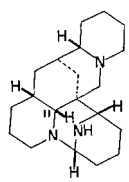
XX

XXI



prolonged treatment with platinum in acetic acid in a hydrogen atmosphere at room temperature under conditions identical with those necessary for the ormosanine–piptanthine isomerization. The resulting product was found to be isotetrahydro-ormojanine. *Dasycarpine is therefore epimeric with isotetrahydro-ormojanine at* C_6 *and can be represented by the stereo-formula XX.*

An oily alkaloid isolated from *O. jamaicensis* has been found to give dasycarpine in a mild hydrogenation. This compound is probably identical with ormosajine, $C_{20}H_{33}N_3$, which has been isolated and hydrogenated to dasycarpine by Hassall and Wilson (13, 14). Since the presence of an N—C—N linkage in this alkaloid is indicated by spectroscopy, it can be assigned the structure and stereochemistry XXI.



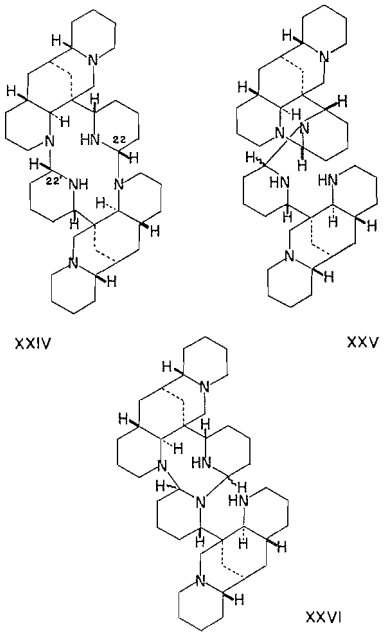
Panamine and Ormosinine

These two alkaloids of *Ormosia panamensis* have been studied under the assumption that they both have the composition $C_{20}H_{33}N_3$ (6, 15).

On the basis of the fact that panamine is converted into ormosanine by a reduction with sodium borohydride (6), and to ormosanine (6) and piptanthine (5) by catalytic hydrogenation, structure XXII was proposed for panamine (15). A recent X-ray analysis (16) confirmed the correctness of this proposal. Thus, panamine is a simple oxidative derivative of ormosanine.

XXII

XXIII



It was furthermore proposed that the alkaloid ormosinine can be represented by formula XXIII (15). The conversion of ormosinine into some derivatives of panamine (6), which requires an epimerization at C_{11} on the basis of this structural assignment, was explained by rather involved isomerization mechanisms (15).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

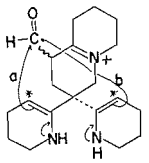
Our own interest in ormosinine was based on the following considerations. Should XXIII be the correct representation of this alkaloid, then one of its hydrogenation products would clearly be a C_{18}-epimer of dasycarpine and should, after isomerization at C_6, fit into our pyridine reduction series A. We have, however, found that vigorous hydrogenation of ormosinine produces, in addition to ormosanine and piptanthine, two reduction products, neither of which gives A_2 on conversion into the corresponding urea derivatives.

All published data and the above hydrogenation can readily be explained by the fact that *ormosinine is not an isomer but a dimer of panamine.* This follows from the following new findings. (*a*) Sublimation of ormosinine in a high vacuum gave pure panamine. (*b*) A molecular weight determination with a Mechrolab osmometer gave a value of 640 for ormosinine.

The identity of the mass spectra of panamine and ormosinine (6) and the conversion of ormosinine into panamine derivatives (6) can thus be explained in a very simple way.

SCHEME 2.

The only remaining question is the exact nature of the dimer. There are several ways in which two molecules of panamine (in the open imine form) can dimerize, and the available evidence does not lead to a unique solution. The structural possibilities are given in Scheme 2.[9] On the basis of steric considerations and a study of urea formation (see Experimental), we consider formula XXIV as the most probable structure of ormosinine.



Biogenesis

One of the unusual aspects of *Ormosia* alkaloid stereochemistry is the fact that the natural alkaloid ormosanine is racemic (6). Furthermore, our work has shown (5) that piptanthine from *Piptanthus nanus* and panamine from *Ormosia panamensis* belong to antipodal series.[10]

[9] *Additional structures with an opposite configuration at* C_{22} *and (or)* $C_{22'}$ *in XXIV are also sterically possible.*

[10] *Piptanthine form P. nanus is levorotatory (7), whereas piptanthine formed by the reduction and isomerization of panamine is dextrorotatory (5, 6).*

XXVII

It is interesting to note that the existence of both antipodal series in this class of alkaloids can be explained in a particularly simple manner by the postulate of a biogenetic intermediate of the type XXVII, formed by the condensation of four lysine units (10, 15). The enol of aldehyde XXVII has a plane of symmetry, and the two corresponding enantiomeric aldehydes can condense with the appropriate C*-atom (arrows *a* or *b* in formula XXVII) to give the two antipodal pentacyclic derivatives.

EXPERIMENTAL

Nuclear magnetic resonance spectra were recorded in $CDCl_3$ on a Varian HR-60 spectrometer, and chemical shifts are reported in parts per million relative to an internal tetramethylsilane reference. Infrared spectra were obtained with Perkin–Elmer model 21 and 137B Infracord instruments, and ultraviolet spectra were recorded on a Beckman DK-2 instrument and mass spectra on a Hitachi Perkin–Elmer RMU-6D instrument. All melting points are uncorrected.

Isomerization of Ormosanine

Ormosanine (35 mg) was stirred in a hydrogen atmosphere in acetic acid (10 ml) in the presence of platinum oxide (100 mg) at room temperature and normal pressure for 1 day. The catalyst was removed by filtration and the solution evaporated. Distribution between ether and 1 *N* hydrochloric acid, followed by basification of the aqueous layer with ammonia and its extraction with ether gave 29 mg of a basic material. To convert it into the corresponding urea, the residue was dissolved in dry benzene, one drop of triethylamine was added, and phosgene gas was bubbled through the solution for 1 min. The solution was then extracted with 1 *N* hydrochloric acid, and the aqueous layer was basified with ammonia and extracted with ether. The resulting mixture of two homoxy-derivatives (thin-layer chromatography (t.l.c.)) was purified by preparative t.l.c., using alumina and ether–benzene (1:4).

The faster moving fraction (11 mg) crystallized from petroleum ether and was found to be identical with homoxypiptanthine (IV) (2)[11] in t.l.c. and infrared and nuclear magnetic resonance spectra.

The slower moving fraction (8 mg) was homoxy-ormosanine (III) (8) on the basis of melting point, t.l.c., and infrared spectrum.

The same catalytic isomerization was performed, starting with homoxy-ormosanine (52 mg). Preparative t.l.c. again gave pure homoxypiptanthine (7 mg) and homoxy-ormosanine (27 mg).

Chemical Reduction of Dihydro-ormojanine

Dihydro-ormojanine (200 mg) (8) and ethylene diamine (40 ml) were heated to 90 °C in a purified nitrogen atmosphere in a dried apparatus protected with a mercury seal. Lithium wire (2.5 g) was then added in small portions to the stirred solution over a period of 45 min, the temperature being maintained at 90–100° (17). The mixture was then refluxed for 1 h and allowed to stand at room temperature for 15 h. After a careful addition of water under ice cooling, the mixture was acidified with concentrated hydrochloric acid and extracted with ether. The aqueous layer was basified with sodium hydroxide and extracted with ether to give 110 mg of a basic material. Crystallization from acetone gave pure isotetrahydro-ormojanine, m.p. 135–136°. The mass spectrum shows the expected molecular ion peak at *m/e* 317. Infrared maximum (CCl_4) at 3 300 cm^{-1} (NH, sharp).

Treatment of isotetrahydro-ormojanine with phosgene in the usual manner gave the homoxy derivative, showing a molecular ion peak at *m/e* 343 in its mass spectrum and an amide maximum at 1 610 cm^{-1} in its infrared spectrum ($CHCl_3$).

Isotetrahydro-ormojanine was found to be distinctly different from tetrahydro-ormojanine (8), ormosanine (1), and piptanthine (2) in melting point and infrared and nuclear magnetic resonance spectra.

Catalytic Reduction of Pyridine VII

Pyridine VII (1.08 g), prepared by the dehydrogenation of dihydro-ormojanine (8), was hydrogenated in the presence of platinum oxide (100 g) in acetic acid (70 ml) for 20 h at room temperature and normal pressure. The solution was filtered and evaporated, and the residue was distributed between aqueous ammonia and ether. The dried ether extract (1.10 g) showed only one spot in t.l.c. Maxima in the nuclear magnetic

[11] *We thank the Czech workers for a sample of piptanthine from P. nanus.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

resonance spectrum (CCl_4) at 1.83 (1 H, multiplet) and 2.80–3.40 τ (2 H's, multiplet) together with the ultraviolet spectrum (inflection 263, λ_{max} 268 (ϵ 3 400), inflection 275 mμ) clearly show that only one (α,β-substituted) pyridine ring is present in the product. Purification and characterization of this product as a mixture of pyridines IX and X is described below.

N-Acetyl Derivatives of Pyridines IX and X

The above mixture (68 mg) was acetylated with acetic anhydride (5 ml) in pyridine (5 ml) for 15 h at room temperature. The usual work-up gave 65 mg of a basic material which showed two spots in t.l.c. on alumina with benzene–ether (1:1) as eluent. Preparative t.l.c. gave one compound (R_f 0.6) as an oil (26 mg).

Anal. Calcd. for $C_{22}H_{31}N_3O$: C, 74.74; H, 8.88; O, 4.53; N, 11.88. Found: C, 74.12; H, 8.73; O, 4.42; N, 10.89.

Nuclear magnetic resonance maxima at 1.73 (1 H, multiplet), 2.70–3.20 (2 H's, multiplet), and 7.80 τ (*N*-acetyl, singlet).

The second acetyl derivative (R_f 0.4) weighed 31 mg and, after crystallization from ether, melted at 195–197°.

Anal. Found: C, 74.26; H, 8.60; O, 4.39; N, 10.99.

Nuclear magnetic resonance maxima at 1.70 (1 H, multiplet), 2.70–3.20 (2 H's, multiplet), and 7.65 and 7.70 τ (*N*-acetyl, two singlets).

N-Carbobenzyloxy Derivatives of Pyridines IX and X

The above mixture of pyridines IX and X (1.10 g) was dissolved in methylene chloride (175 ml), and the solution was mixed with water (50 ml) and magnesium oxide (280 mg). Benzyl chloroformate (3.6 g) in methylene chloride (75 ml) was added to the stirred mixture over a period of 90 min at ice-bath temperature. The stirring was continued for an additional hour, the mixture was acidified with dilute hydrochloric acid, and the organic layer was extracted exhaustively with 2 *N* hydrochloric acid. The combined aqueous layers were basified with ammonia and extracted with ether to give 1.54 g of a basic material. Thin-layer chromatography on alumina with ether indicated two compounds different from the starting material.

These were separated by column chromatography on neutral alumina (Woelm, activity 2, 80 g), taking 100 ml fractions and analyzing them by t.l.c. Elution with benzene – petroleum ether (1:2 (2.5 l) and 1:1 (500 ml)) gave pure *N*-carbobenzyloxy IX (630 mg), elution with benzene – petroleum ether (3:1, 800 ml) gave a mixture of the two isomers (120 mg), and elution with ether (500 ml) gave pure *N*-carbobenzyloxy X (790 mg). The two compounds, which could not be induced to crystallize, were found to be homogeneous by t.l.c. and showed the expected ultraviolet (λ_{max} 268 mμ), infrared (maxima at 1 680 and 1 580 cm^{-1}), and nuclear magnetic resonance spectra (a multiplet at 1.7 τ for 1 H, a multiplet at 2.8–3.3 τ for 7 H's, and a broad singlet at 5.0 τ for the benzylic CH_2).

Pyridines IX and X

N-Carbobenzyloxy IX (200 mg) was hydrogenolyzed in acetic acid (95%, 10 ml) with palladium on charcoal (10%, 40 mg) in a hydrogen atmosphere for 12 h. The usual work-up gave 140 mg of pure oily pyridine IX, homogeneous in t.l.c. Infrared maxima (CCl_4) at 3 300 (NH) and 1 560 cm^{-1} (broad); nuclear magnetic resonance maxima (CCl_4) at 1.81 (1 H, multiplet), 2.8–3.3 (2 H's, multiplet), and 8.11 τ (C_{10}-methylene, quadruplet).

N-Carbobenzyloxy X (156 mg) was hydrogenolyzed in the same manner to give 108 mg of pure oily pyridine X. Infrared maxima (CCl_4) at 3 300 (NH) and 1 560 cm^{-1} (broad); nuclear magnetic resonance maxima at 1.83 (1 H, multiplet), 2.8–3.3 (2 H's, multiplet), and 8.20 τ (C_{10}-methylene, singlet).

The pyridines IX and X show identical R_f values in all t.l.c. systems tried; their separation was therefore found to be possible only through the above derivatives.

Catalytic Reduction of IX

Pyridine IX (75 mg) was hydrogenated in acetic acid (10 ml) with platinum oxide (110 mg) at 100° and 2 200 p.s.i. for 12 h. The usual work-up gave 58 mg of a basic material. Since a preliminary study indicated that the product slowly decomposed on chromatography, it was immediately treated with phosgene and triethylamine in benzene (see above). The product (50 mg) was shown to be a mixture of two homoxy derivatives by t.l.c.

Separation was achieved by preparative t.l.c., using alumina and benzene–ether (1:1). The faster moving fraction was further purified by a second preparative t.l.c. under the same conditions, and the resulting crystalline product, A_1 (12 mg), m.p. 153–155°, was found to be identical in infrared spectrum and t.l.c. with homoxypiptanthine (2).

The second compound, A_2 (8 mg), crystallized from petroleum ether and melted at 164–165°. Its mass spectrum (molecular ion peak at *m/e* 343) confirms its composition. Its infrared spectrum contains the urea maximum at 1 620 cm^{-1} ($CHCl_3$); the fingerprint region, furthermore, shows that A_2 is not identical with the homoxy derivative of any of the known $C_{20}H_{35}N_3$ *Ormosia* isomers.

Chemical Reduction of IX

To a solution of pyridine IX (200 mg) in boiling isoamyl alcohol (30 ml) was added sodium (2.0 g) in small pieces during 90 min. The cooled solution was extracted with 1 *N* hydrochloric acid, and the aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

layer was washed with ether, basified, and extracted with ether. The residue was treated with phosgene in the usual way to give 156 mg of two homoxy derivatives (t.l.c.).

The faster moving fraction was obtained in a pure state (39 mg) by column chromatography with benzene on neutral alumina (Woelm, grade 2, 7.5 g) and identified as homoxypiptanthine, A_1.

The second compound could not be obtained in a pure state by column chromatography. The preparative t.l.c. method gave the pure product (10 mg), identical in all respects with A_2 (see above).

Catalytic Reduction of X

Pyridine X (76 mg) was hydrogenated in acetic acid (10 ml) with platinum oxide (20 mg) at 115° and 2 500 p.s.i. for 3 days. The usual work-up gave 40 mg of a basic material, which was immediately treated with phosgene as above. The product (40 mg), containing two compounds (t.l.c.), was subjected to preparative t.l.c. on alumina, with benzene–ether (1:1) as eluent.

The faster moving fraction, B_2 (15 mg), crystallized from petroleum ether and melted at 224–225°. Its mass spectrum shows the expected molecular ion peak at *m/e* 343; the infrared spectrum ($CHCl_3$) shows the urea peak at 1 610 cm^{-1}.

The second fraction, B_1 (11 mg), crystallized from petroleum ether and melted at 158–159°. Its mass spectrum shows the expected molecular ion peak at *m/e* 343, and its infrared spectrum ($CHCl_3$) contains the urea peak at 1 610 cm^{-1}.

The physical properties of B_1 and B_2 (melting point and infrared, nuclear magnetic resonance, and mass spectra) clearly show the non-identity of these compounds with the homoxy derivatives of ormosanine, piptanthine, tetrahydro-ormojanine, and isotetrahydro-ormojanine.

Chemical Reduction of X

Sodium (1.2 g) was added in small pieces during 90 min to a boiling solution of pyridine X (108 mg) in isoamyl alcohol (15 ml). The usual work-up (see above) gave 100 mg of a basic material, which was subjected to an additional reduction with sodium (1.2 g) in isoamyl alcohol (15 ml). The resulting basic material (70 mg) was subjected to preparative t.l.c. on silica, using 4% dimethylamine in petroleum ether as eluent.

The faster moving fraction (10 mg) was treated with phosgene as described above, and the resulting homoxy derivative was purified by preparative t.l.c. on alumina with benzene–ether (1:1). The pure product (7 mg) melted at 158–159° and was found to be identical with B_1, produced by the catalytic reduction of pyridine X.

The second fraction (7 mg) was also treated with phosgene and the product purified by preparative t.l.c. on alumina with benzene–ether (1:1). The resulting pure compound (4 mg) crystallized from petroleum ether and melted at 203–205°. This compound, B_3, was found to be identical in all respects (melting point, t.l.c., and infrared and mass spectra) with homoxytetrahydro-ormojanine (8).

Isomerization of Dasycarpine

(*a*) Dasycarpine (34 mg) (3)[12] was stirred in a hydrogen atmosphere in acetic acid (10 ml) in the presence of platinum oxide (100 mg) at room temperature and normal pressure for 3 weeks. The usual work-up gave 34 mg of a basic material, which was treated with phosgene as described above. Thin-layer chromatographic analysis of the product on alumina with ether – petroleum ether (1:1) as eluent showed the presence of two compounds with R_f values of 0.4 and 0.5, respectively.

Preparative t.l.c. on alumina with ether – petroleum ether (7:3) as eluent achieved a complete separation. The faster moving compound was found to be identical in all respects with homoxyisotetrahydro-ormojanine (see above). The slower moving compound was homoxydasycarpine (3). The two compounds were isolated in approximately equal quantities.

Although homoxyisotetrahydro-ormojanine shows a strong band at 2 750 cm^{-1} in the infrared spectrum ($CHCl_3$), this band is completely absent from the spectrum of homoxydasycarpine. This is analogous to the piptanthine–ormosanine pair.

(*b*) Mother liquors from the crystallization of ormosanine and ormojanine from *O. jamaicensis* (8) were subjected to a nine-funnel countercurrent distribution, using ether and McIlvaine's buffer (pH 7.3), with the buffer as a moving phase. Fraction 7 (1.95 g from 13.5 g of the original mixture) contained a foam which was homogeneous in t.l.c. and showed an R_f value of 0.4 on alumina with 4% methanol in benzene. Sublimation in a high vacuum gave a colorless oil; nuclear magnetic resonance maximum at 6.50 τ (1 H, broad singlet). This compound is probably identical with the alkaloid ormosajine (13, 14).

The oily sublimed alkaloid (215 mg) was hydrogenated for 16 h in 2% aqueous hydrochloric acid (40 ml) in the presence of platinum oxide (400 mg) at room temperature and normal pressure. The usual work-up gave 200 mg of a basic material which, on the basis of t.l.c. analysis (3% diethylamine in petroleum ether on silica), consisted of approximately equal amounts of two products with R_f values of 0.4 and 0.3, respectively.

Preparative t.l.c. with the above system achieved a complete separation. The component, R_f 0.3, was found to be identical with dasycarpine (3), and the second component, R_f 0.4, was isotetrahydro-ormojanine.

[12]*We thank Drs. Clarke and Grundon for this sample.*

For personal use only.

Ormosinine

The alkaloids ormosinine, m.p. 219–220°, and panamine were isolated from *O. panamensis* by the procedure reported by Lloyd and Horning (18). Ormosinine shows a strong sharp NH maximum at 3 300 cm^{-1} in the infrared spectrum (CCl_4) and a broad singlet at 6.56 τ characteristic of the N—CH—N grouping in the nuclear magnetic resonance spectrum.

A molecular weight determination with Mechrolab osmometer model 301 in carbon tetrachloride (four independent measurements) gave a value of 640 ∓ 30 for ormosinine.

Sublimation of ormosinine at 250° and 0.4 mm gave a quantitative yield of panamine (sublimate), identified by infrared and nuclear magnetic resonance spectra.

Thin-layer chromatographic analysis of crystalline ormosinine on silica with 7% diethylamine in petroleum ether (double elution) revealed the presence of two components, R_f 0.5 and 0.45, respectively. It is not yet certain whether crystalline ormosinine consists of two different dimers or whether a partial conversion takes place during chromatography.

Vigorous hydrogenation of ormosinine in acetic acid with platinum oxide at 40° and 1 850 p.s.i. for 20 h gave, in addition to starting material, four reduction products. After the conversion of the mixture into the corresponding homoxy derivatives, homoxy-ormosanine and homoxypiptanthine were isolated from the mixture by column chromatography on alumina. The two remaining compounds were separated by preparative t.l.c. on alumina, with ether as eluent. One of them crystallized from petroleum ether and melted at 245°, and the second one remained oily. Both compounds are almost certainly dimeric, since their mass spectra show fragments with *m/e* above 400.

Homoxy-ormosinine

Ormosinine (130 mg) was treated in the usual way with phosgene in dry benzene (15 ml) and triethylamine (0.5 ml). The usual extraction gave a quantitative yield of a basic material. The infrared spectrum of the product in chloroform showed a carbonyl absorption at 1 720 and a double maximum at 1 630 cm^{-1}. Although it has so far not been possible to achieve a separation, it appears possible that the maxima at 1 630 cm^{-1} indicate the presence of ureas formed after a partial opening of the dimer, and the maximum at 1 720 cm^{-1} corresponds to the homoxy derivative of XXIV, in which the geometry of the relevant orbitals would not allow the usual amide resonance.

Hydrogenation of Panamine

Panamine (18) (1.4 g) was hydrogenated in 4% hydrochloric acid (50 ml) in the presence of platinum oxide (550 mg) at room temperature and normal pressure for 16 h. The resulting basic material, obtained in a quantitative yield, was converted into the homoxy derivative on treatment with phosgene and triethylamine in benzene (see above). Separation of a portion of this product by t.l.c. on alumina with ether – petroleum ether (1:1) gave pure homoxy-ormosanine and pure homoxypiptanthine.

The original hydrogenation mixture could, without conversion into ureas, be separated by preparative t.l.c. on silica with 5% diethylamine in petroleum ether. The two components were identified as ormosanine and piptanthine.

ACKNOWLEDGMENT

The authors are grateful to the National Research Council, Ottawa, for the financial support of this work.

ISOTOPE EFFECT STUDIES ON ELIMINATION REACTIONS

V. THE MECHANISM OF THE CARBONYL ELIMINATION REACTION OF 9-FLUORENYL NITRATE WITH ACETATE ION[1]

P. J. SMITH[2] AND A. N. BOURNS

Department of Chemistry, Hamilton College, McMaster University, Hamilton, Ontario

Received June 30, 1966

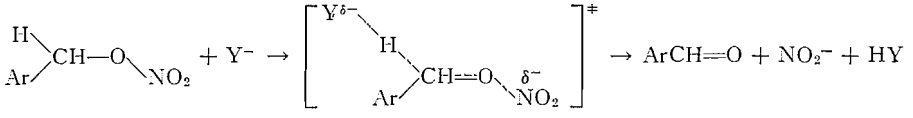
ABSTRACT

The carbonyl elimination reaction ($E_{CO}2$) of 9-fluorenyl nitrate with acetate ion in anhydrous ethanol was found to be second order and to give at 30° primary nitrogen-15 and deuterium isotope effects of 1.0091 ± 0.0007 and 4.3 ± 0.2, respectively. The ester showed no deuterium exchange with solvent under the reaction conditions. A change in solvent to 85 volume % ethanol–water increased the nitrogen isotope effect to 1.0131 ± 0.0007 without changing the deuterium effect. These results exclude any form of two-stage carbanion intermediate mechanism, but are in accord with a concerted process.

INTRODUCTION

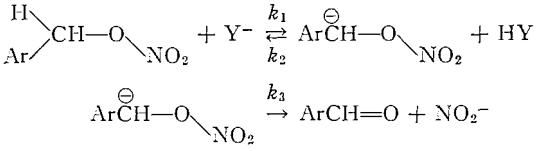
Nitrate esters of benzyl alcohol and its ring-substituted derivatives show competing reactions of substitution and elimination when treated with a strong base (1, 2).

Substitution (S_N2):



[1] $$ArCH_2ONO_2 + Y^- \rightarrow ArCH_2Y + NO_3^-$$

Carbonyl elimination ($E_{CO}2$):



[2] $$ArCH_2ONO_2 + Y^- \rightarrow ArCH{=}O + NO_2^- + HY$$

By analogy with other second-order elimination processes, two mechanisms have been considered for the latter.

Concerted mechanism:

[3] 

Two-step mechanism:

[4] 

In a previous investigation (3) in our laboratory, the combination of a test for deuterium exchange and the determination of the nitrogen isotope effect successfully distinguished between the two mechanisms for the reaction of benzyl nitrate with ethoxide ion in anhydrous ethanol. It was found that ester recovered from a reaction carried part way to completion in ethanol-O-*d* contained a barely detectable amount of the tracer. This virtual absence of exchange can be accommodated by the two-step mechanism only if the formation of the intermediate were to be rate determining ($k_3 \gg k_2[HY]$), a condition which is excluded by the observation of a primary nitrogen isotope effect of

[1] *For Part IV in this series, see A. N. Bourns and P. J. Smith, Proc. Chem. Soc., 366 (1964).*

[2] *Holder of a National Research Council studentship, 1963–1964.*

2% ($k^{14}/k^{15} = 1.020$). These results, however, as well as a deuterium isotope effect, k^H/k^D, of 5.0, are in accord with the concerted mechanism.

For base-promoted β-elimination reactions forming a carbon–carbon double bond, the concerted mechanism (E2) has been found to have broad generality and to be supplanted by a two-step process (E1*cb*) only in very infrequently encountered cases where the reactant has structural features which give exceptional stability to an intermediate carbanion (4, 5). In the carbonyl elimination of nitrate esters, however, reaction by the latter pathway might be expected to be more favorable because of the strong acidifying effect of the electron-withdrawing nitrate group. It was with the objective of exploring this possibility that the study has now been extended to 9-fluorenyl nitrate, which has previously been shown to undergo carbonyl elimination to give fluorenone in a high yield on treatment with methanolic potassium hydroxide (6) or with benzylamine, morpholine, or pyridine in acetonitrile (7, 8). A rough indication of the relative acidity of fluorenyl and benzyl nitrates is found from a comparison of the acid dissociation constants of the corresponding parent hydrocarbons. The pK_a of fluorene has been estimated variously as 25 (9) and 31 (10), whereas that of toluene is at least 37 (11) and is probably very much higher (10). It seems inherently reasonable, therefore, that the two esters might react by different mechanisms.

Unfortunately, the reaction of fluorenyl nitrate with alkoxide ion was found to be too rapid for a deuterium exchange test and nitrogen isotope effect measurements at ester concentrations suitable for such experiments. Also, the use of an amine as base seemed to be unsuitable because of possible contamination of the nitrogen from the nitrite ion by nitrogen from the amine in the isotope effect studies. A satisfactory base, however, was found in acetate ion in anhydrous and aqueous ethanol. In the anhydrous solvent, the carbonyl elimination reaction gives nitrite ion in about a 90% yield and is in competition with an S_N2 reaction giving nitrate ion. In aqueous ethanol, the carbonyl elimination accounts for less than 70% of the total reaction, and nitrate ion is formed by solvolysis as well as by a displacement with acetate ion. Despite these complications, it is possible, by using the methods described in the previous paper (3), to determine both the nitrogen and deuterium isotope effects associated with the elimination process. Measurements were made in both aqueous and anhydrous ethanol, since it was hoped that the influence of the medium on the magnitude of the isotope effects might provide further insight into the mechanism of the process.

RESULTS

Kinetics of the Reaction of Fluorenyl Nitrate with Acetate Ion in Anhydrous and Aqueous Ethanol

The kinetics of the reaction were studied under pseudo first order conditions with a large excess of acetate ion. The total reaction rate (carbonyl elimination and substitution) was followed spectrophotometrically and the fraction of each was determined by measuring the yields of nitrite and nitrate ions. In anhydrous ethanol, nitrate ion was formed only by S_N2 displacement with acetate ion. In 85% ethanol, however, solvolysis was significant and accounted for approximately one-third of the nitrate ion produced (10% of the total reaction rate).

The results of these kinetic experiments are shown in Table I. It is seen that in anhydrous ethanol the second-order rate constant ($k_2 = k_1/[\mathrm{MOAc}]$, where k_1 is the pseudo first order constant and [MOAc] is the concentration of acetate salt) decreases significantly with increasing concentration of the acetate salt. Furthermore, a comparison of the results of expts. 5 and 6 shows that this effect is found even when the ionic strength

For personal use only.

of the medium is kept constant by addition of lithium perchlorate. A similar situation has been observed by Berliner (12) in the bromination of naphthalene and fluorene in aqueous acetic acid, and it has been attributed to a primary salt effect, which is different for acetate and perchlorate salts. Although this may be the origin of the trend in rate constants found in the present study, an alternative explanation is an increased dissociation at higher dilutions of ion pairs (and triplets and higher aggregates) to the more reactive dissociated acetate ion. It is also noteworthy that the second-order rate constants for reaction in both anhydrous and aqueous ethanol are higher the lower the concentration of fluorenyl nitrate (compare expts. 7 and 8, and 9 and 10). The reason for this is not clear, although it may only be a medium effect.

TABLE I

Kinetic results for the reaction of 9-fluorenyl nitrate with acetate ion

Expt. No.	Temperature (°C)	[Ester] (M)	[KOAc] (M)	[$LiClO_4$] (M)	% E_{CO2} reaction	$k_2 \times 10^4$ (l mole^{-1} s^{-1}) Total	$k_2 \times 10^4$ (l mole^{-1} s^{-1}) E_{CO2}

*LiOAc was used in place of KOAc.

Finally, the rates in both solvents were found to be reduced only very slightly by addition of acetic acid. This establishes that it is acetate ion and not ethoxide or hydroxide ion which is acting as the base in the elimination reaction.

Deuterium Isotope Effects

The deuterium isotope effects for reaction with potassium acetate in anhydrous ethanol and 85 volume % ethanol–water at 30° were determined by separately measuring the rate constants for the reaction of 9-fluorenyl nitrate and 9-fluorenyl-9-*d* nitrate by the method described in the previous section. In every case, the reactions with labelled and unlabelled compounds were run in parallel. The results are shown in Table II.

Deuterium Exchange Tests

Deuterium exchange tests were carried out in anhydrous C_2H_5OD at 40° and in 85% C_2H_5OD – 15% D_2O at 30°. Reactant recovered after approximately one half-life was found to have no isotopic enrichment within the limits of detection, which were less than 0.04 atom %.

Kinetic Nitrogen Isotope Effects

The nitrogen isotope effect for the carbonyl elimination reaction in each of three solvents (anhydrous ethanol, 92 volume % ethanol–water, and 85 volume % ethanol–water) was obtained by comparing the $^{14}N/^{15}N$ ratio of fluorenyl nitrate of natural isotopic abundance with that of nitrite ion formed in the reaction of the ester carried to some known extent of completion. Selective reduction of the nitrite ion to ammonia accomplished the separation of the nitrogen of this ion from that of the nitrate ion formed in the simultaneous S_N1 and S_N2 displacement reactions (3). The ammonia was then converted into nitrogen gas, which was analyzed by mass spectrometry. The isotopic abundance for the reactant was obtained by analysis of the nitrogen gas similarly formed from nitrite plus nitrate ion produced in a reaction which had been allowed to proceed to completion. Different preparations of ester were used for measurements in anhydrous and aqueous ethanol, and isotopic analyses were performed on each. The results given in Table III show an isotope effect, k^{14}/k^{15}, of 1.009 in anhydrous ethanol, increasing to 1.013 in 85% aqueous ethanol. These values may be compared with 1.020 found previously (3) for the reaction of benzyl nitrate with ethoxide ion.

Test for Nitrogen Isotopic Exchange Between NO_2^- and NO_3^-

Since fluorenol–fluorenone is a good oxidation system, it was necessary to establish that there is no isotopic exchange between nitrite and nitrate ions under the reaction conditions and in the subsequent work-up. A solution containing ^{15}N-enriched sodium nitrate, isotopically normal sodium nitrite, potassium acetate, acetic acid, fluorenone, and fluorenol in absolute ethanol was maintained at 30° for 1 h. Nitrite and nitrate ions were separated by the method used in the isotope effect studies, and the nitrogen isotopic abundance of the recovered nitrate was compared with that of the original material. From the results shown in Table IV, it is concluded that there is no significant isotopic exchange between the two ions.

DISCUSSION

The absence of detectable deuterium exchange with the solvent, ROD, coupled with a primary nitrogen isotope effect of 0.9% or more, excludes reaction by way of a carbanion intermediate which is hydrogen bonded at the 9-position by a molecule of solvent (eq. [5]). If $k_2 \gg k_{-1}$, there would be no isotope effect, whereas any other relationship of these rate constants would result in some incorporation of deuterium in the unreacted ester. One is not jusified, however, on the basis of these observations alone, in concluding

[5] 

that the fluorenyl nitrate reaction is a concerted process, since there is a modification of the two-step mechanism which could give rise to a primary nitrogen isotope effect without requiring hydrogen exchange with the solvent. This is a reaction via a carbanion which is specifically hydrogen bonded to the acetic acid molecule formed by abstraction of a proton by acetate ion (eq. [6]). If this intermediate were to lose nitrite ion very much

[6] 

faster than it exchanges the hydrogen-bonded acetic acid molecule for a molecule of solvent ($k_2 \gg k_s$), there would be no observable deuterium exchange. Furthermore, if the rate of decomposition of the intermediate to product were not much greater than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

its rate of return to reactants, so as to make the O—N bond rupture step at least partially rate determining, there would be an isotope effect associated with the leaving group.

Such a specifically hydrogen-bonded species has been invoked by Cram (13) to account for the very low or reverse hydrogen isotope effects which have been observed in certain hydrogen exchange reactions. It can be seen that, if this species were formed in a pre-equilibrium step ($k_2 \gg k_{-1}$), the hydrogen isotope effect would be given by $K^H/K^D \cdot k_2^H/k_2^D$, where the K's are equilibrium constants for the first step of eq. [6]. Both of these isotopic ratios would be small; indeed, that for the equilibrium step might even be less than unity, since the vibrational stretching frequency of the O—H bond is greater than that of the original C—H bond (13).

Such a pre-equilibrium formation of the specifically hydrogen-bonded carbanion is precluded in the fluorenyl nitrate reaction by the observation of a deuterium isotope effect, k^H/k^D, of 4.25 at 30°. On the other hand, a rate-determining formation of this intermediate ($k_{-1} \ll k_2$) is also precluded by the observation of the primary nitrogen isotope effect. It should be noted, however, that both isotope effects are small in comparison with those found in the reaction of benzyl nitrate with ethoxide ion (3); in absolute ethanol, the nitrogen effect is 0.9% compared with 2.0% for the latter reaction, and k^H/k^D is 4.25 compared with 5.94.[3] It is possible, therefore, that these smaller effects might arise in a reaction proceeding by the mechanism of eq. [6] in the particular circumstance that the rate constants k_{-1} and k_2 are approximately equal, that is, that the C—H and O—N bond rupture processes are both partially rate determining. However, in this region of approximate equality of the rates for return of the intermediate to reactant and decomposition to product, the isotope effects would be very dependent upon the actual value of the k_{-1}/k_2 ratio, which in turn would be expected to depend upon the medium in which the reaction is carried out. Consequently, the proposed mechanism predicts that *both* the nitrogen and the hydrogen isotope effects should be very sensitive to changes in the solvent.

It can be seen from Table II that the nitrogen isotope effect increases by almost 50% in going from absolute ethanol to 85% aqueous ethanol as solvent. In terms of the mechanism of eq. [6], this would mean an increase in the k_{-1}/k_2 ratio, and therefore a much closer approach to a pre-equilibrium formation of the carbanion intermediate. This, however, would be expected to cause a large decrease in the hydrogen isotope effect (*vide supra*), which is not observed. As shown in Table III, the k^H/k^D ratio is the same within experimental error in the two solvents. Therefore, it is concluded that the reaction of fluorenyl nitrate with acetate ion does not proceed by way of any type of carbanion intermediate and, like the reaction of benzyl nitrate with ethoxide ion, is a concerted process.

That the leaving group isotope effect should be so sensitive to the change in solvent whereas the hydrogen isotope effect remains constant is surprising and requires comment. The nitrogen isotope effect is a measure of the extent to which the composite force constant of the O—N bond is decreased in going from the initial to the transition state (14), and the larger value of the effect in the more ionizing solvent is possibly a consequence of a greater solvation of the incipient nitrite ion tending to weaken this bond. Compensating factors must be responsible for the insensitivity of the hydrogen isotope effect to a change in the medium. There will be a smaller electron density associated with the

[3]*The previously reported effect of 5.04 for benzyl nitrate was for a reaction at 60° (3). A value of 5.94 has been found by the present authors at 30°.*

For personal use only.

three-center system, C---H---O, of the transition state in aqueous ethanol, because of both the smaller base strength of the acetate ion (15) and the greater transfer of charge to nitrogen. This will result in lower bending frequencies associated with the proton being transferred and an increased hydrogen isotope effect (16). The symmetrical stretching frequency of the three-center system also will be solvent dependent, probably in the direction of a higher value in the more aqueous solvent, since the relatively large decrease in the base strength of the acetate ion might be expected to result in a more unsymmetrical transition state, C---H--O (17). This would tend to decrease the hydrogen isotope effect (18–20,). It should be pointed out, however, that our understanding of the relative importance of the different factors which determine the magnitude of hydrogen isotope effects, particularly in multicenter systems such as β-eliminations, is very incomplete (21), and the situation is undoubtedly much more complicated than has been indicated.

EXPERIMENTAL

Materials

9-Fluorenyl Nitrate

This compound was prepared by the action of silver nitrate on 9-bromofluorene in acetonitrile (6) and was recrystallized from petroleum ether (b.p. 30–60°), m.p. 89–90° (lit. m.p. 88–89° (8)).

9-Fluorenyl-9-^{2}H Nitrate

The deuterated compound was prepared by the following reaction sequence: (*a*) reduction of 9-fluorenone to 9-fluorenol-9-^{2}H with lithium aluminium deuteride; (*b*) conversion of the alcohol into 9-bromofluorene-9-^{2}H by means of acetyl bromide; and (*c*) reaction of the bromo compound with silver nitrate. The overall yield of 9-fluorenyl-9-^{2}H nitrate was 60%. The product, recrystallized from petroleum ether, had a melting point of 88.5–89.5° and was at least 99% deuterated in the 9-position, as shown by nuclear magnetic resonance analysis.

9-Fluorenol-9-^{2}H

9-Fluorenone (7.9 g, 0.044 mole) was treated for 8 h with lithium aluminium deuteride (0.92 g, 0.022 mole) in 300 ml of diethyl ether which had been dried by distillation from lithium aluminium hydride. The complex was decomposed by addition of water, the precipitated salts were removed by filtration, and the product was isolated from the ether solution. Recrystallization from benzene gave 7.5 g of 9-fluorenol-9-^{2}H (94% yield), m.p. 157–157.5° (lit. m.p. 156° (22)).

9-Bromofluorene-9-^{2}H

Acetyl bromide (8.3 g, 0.067 mole) was added all at once to 9-fluorenol-9-^{2}H (7.5 g, 0.041 mole) and the flask stoppered. A vigorous reaction set in, and in a short time the mixture solidified. The reaction was completed by warming the mixture on a steam bath, and acetic acid and excess reagents were removed under reduced pressure. The residue was recrystallized from petroleum ether (b.p. 30–60°), giving 8.3 g (83% yield) of 9-bromofluorene, m.p. 102–102.8° (lit. m.p. 102–103° (23)).

Kinetic Measurements

The total reaction rate was followed spectrophotometrically by measuring the optical density of the reaction solutions at 380 mμ, the λ_{max} of the elimination product fluorenone. Since a large excess of acetate ion was used, the concurrent reactions of carbonyl elimination, S_N2 displacement, and solvolysis all follow first-order kinetics, and the rate constant for the nitrite ion forming elimination is given by the product of the rate constant for the disappearance of fluorenyl nitrate and the mole fraction of nitrite ion.

A solution of 9-fluorenyl nitrate (0.005–0.024 *M*) and potassium or lithium acetate (0.09–0.42 *M*) in anhydrous or aqueous ethanol, prepared by mixing temperature-equilibrated solutions of each reactant, was maintained in a constant-temperature bath at $\pm$0.02°. At suitable time intervals 5 ml samples were removed and immediately diluted to 50 ml with ethanol. The optical density of these solutions was measured on either a Beckman model D.U. or a Perkin–Elmer Hitachi spectrophotometer. Also, several times during the reaction 10 ml samples of the reaction solution were withdrawn and added to 15 ml of ether and 15 ml of water. The aqueous layer was separated and washed twice with 5 ml portions of ether. The combined ether layers were extracted 3 times with 5 ml portions of water, and the combined aqueous solutions were analyzed for nitrite and nitrate ions by the method of differential reduction to ammonia described previously (3). As expected, the ratio of nitrite and nitrate ion concentrations remained constant throughout the reaction.

The pseudo first order rate constants for the disappearance of fluorenyl nitrate were determined by plotting log ($OD_\infty - OD_t$) against time for the equation $kt = 2.303 \log ((OD_\infty - OD_0)/(OD_\infty - OD_t))$, where OD_0, OD_∞, and OD_t are the optical densities at time zero, infinity, and t, respectively. The best

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fit of the data was obtained by the method of least squares. These constants were converted into second-order constants by dividing by the concentration of the acetate salt, and the second-order constants were multiplied by $[NO_2^-]/([NO_2^-] + [NO_3^-])$ to give the second-order constants for the carbonyl elimination reaction.

Somewhat less precise rate constants were evaluated from the actual amounts of nitrite and nitrate ions formed at different reaction times. The agreement between these and the constants obtained by the method described in the preceding paragraph was within 3%.

Deuterium Exchange Tests

A solution of potassium acetate in anhydrous C_2H_5OD, prepared by the action of deuterium oxide on sodium ethoxide (3), or 85% C_2H_5OD – 15% D_2O was added to a solution of 9-fluorenyl nitrate in the corresponding solvent, and the reaction[4] was allowed to proceed for approximately one half-life. The reaction was quenched by cooling to 0°, and the solution was then added to an ice-cold mixture of 100 ml of ether and 100 ml of water. The ether layer was separated and the water layer washed thoroughly with fresh ether. The combined ether extracts were washed 5 times with 50 ml portions of water, and the ether solution was dried and concentrated to yield a crude solid nitrate ester. This solid was dissolved in 15 ml of ethanol and extracted 4 times with 25 ml portions of petroleum ether (b.p. 30–60°), with a little water present to cause separation of the layers. The petroleum ether was concentrated to 10 ml and fluorenyl nitrate allowed to crystallize. The ester was recrystallized 5 times from petroleum ether. This elaborate procedure was required to remove fluorenone and to ensure no contamination by the deuterated solvent.

Deuterium analyses were carried out by combustion of the recovered fluorenyl nitrate diluted with some unlabelled ester and measuring the deuterium content of the resulting water by either infrared spectroscopy (24) or by the falling-drop method.[5]

Nitrogen Isotope Effects

The procedure was essentially that previously described (3) for the reaction of benzyl nitrate, with the exception that acetate ion replaced ethoxide, sodium bicarbonate was not used to neutralize base, and separation of the organic compounds from inorganic ions was achieved by partition between diethyl ether – water rather than petroleum ether – water.

The kinetic isotope effect was calculated by using the expression

$$\frac{k^{14}}{k^{15}} = \frac{\ln\left(1 - \frac{f(1-p)}{1-fp}\right)}{\ln\left(1 - \frac{rf(1-p)}{1-fp}\right)},$$

where f is the mole fraction of the ester which has undergone reaction, p is the fraction of the total reaction which is substitution, and r is $(^{14}N/^{15}N)_{reactant}/(^{14}N/^{15}N)_{NO_2^-}$ (25). This is a modification of an expression derived by Stevens and Attree (26), and takes into account the fact that the reactant is being consumed by reactions other than that whose isotope effect is being measured.

ARYLATION DES QUINONES PAR LES SELS DE DIAZONIUM

VIII. SUR LES 3-ARYL-1,2-NAPHTOQUINONES

JACQUES ASSELIN, PAUL BRASSARD ET PHILIBERT L'ECUYER
Département de Chimie, Université Laval, Québec, Québec

Reçu le 12 mai 1966

RÉSUMÉ

Les 3-aryl-1,2-naphtoquinones se sont avérées les seuls produits de la réaction des sels de benzènediazonium avec la 1,2-naphtoquinone. Ces résultats sont différents des données antérieures. Nous avons recherché le meilleur milieu réactionnel pour effectuer la substitution et nous avons discuté la portée des résultats sur le mécanisme de la réaction.

ABSTRACT

The arylation of 1,2-naphthoquinone by benzenediazonium salts, in contrast to previously published results, gave only 3-aryl-1,2-naphthoquinones with poor to fair yields. The best reaction medium has been sought and the implications of the results with regard to the reaction mechanism are discussed.

La réaction des quinones avec les sels de diazonium aromatiques présente encore certains problèmes. En particulier, les mécanismes radicalaires proposés (1, 2) pour la réaction de Meerwein ne lui semblent pas appropriés. En effet, au cours de travaux sur les quinones (3 et la présente communication), nous avons observé que, contrairement à ce qui se produit dans la réaction de Meerwein avec d'autres composés carbonylés α,β-insaturés, l'addition de sels cuivriques au milieu réactionnel n'améliore pas le rendement de la réaction. Nous avons constaté également que les réactions des sels de benzènediazonium avec la chloroquinone, la toluquinone ou la 1,2-naphtoquinone, de même que les réactions des sels de benzènediazonium substitués en position ortho, ainsi que d'autres peu réactifs, avec la benzoquinone même donnent lieu à la formation d'un intermédiaire dans le mélange réactionnel. Cet intermédiaire, qui apparaît d'abord sous la forme d'un solide ou d'un liquide visqueux, dégage lentement de l'azote pour devenir éventuellement cristallin.

Nous avons déjà souligné (3) que la nature de l'anion du sel de diazonium n'influe pas sur le cours de la réaction avec les quinones, alors qu'un chlorure ou un bromure est nécessaire à la réaction de Meerwein. De plus, Bergmann et Weizman (4) ont démontré que la stabilité des sels de diazonium constitue le plus important des facteurs qui influencent le cours de la réaction. Nous avons au contraire observé que la nature de la quinone joue aussi un rôle considérable. Ainsi, dans des conditions identiques, la réaction du chlorure de benzènediazonium avec la benzoquinone est complète en 30 min; avec la chloroquinone le dégagement gazeux ne cesse qu'au bout de 24 h, tandis qu'avec la toluquinone la réaction dure plusieurs jours.

Toutes ces données expérimentales semblent favoriser un mécanisme différent de celui de la réaction de Meerwein. Elles permettent en outre d'en formuler un (7, 8) qui rend compte de toutes ces divergences (Schéma 1).

Nous avons pensé que la présence d'un substituant sur le noyau de la quinone pourrait influencer la direction de la substitution, mais nos expériences sur l'arylation de quelques quinones substituées (5 et résultats inédits) n'ont pas donné les résultats significatifs escomptés. Celles-ci ont montré que la substitution est peu sensible aux effets directeurs d'un substituant et qu'elle donne naissance à tous les isomères bisubstitués possibles.

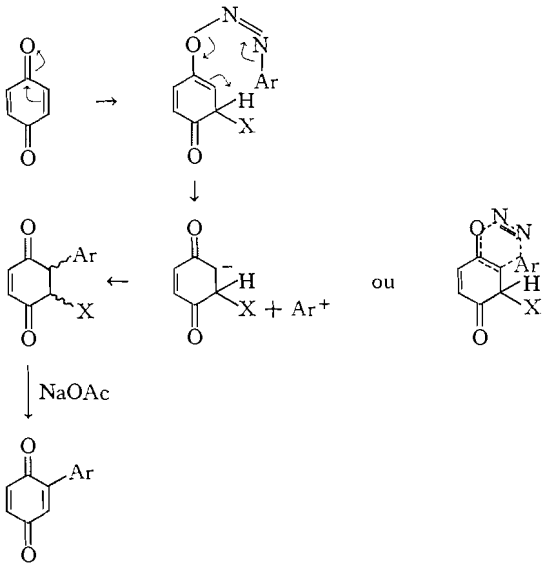

SCHÉMA 1.

Il est par contre bien établi que la 1,2-naphtoquinone subit la substitution électrophile (nitration) en position 3 et la substitution nucléophile (réaction de Thiele) en position 4. Un mécanisme radicalaire devrait conduire à la substitution en position 3.

Kvalnes (6) avait déjà trouvé que la substitution de la 1,2-naphtoquinone à l'aide du sel de *p*-carboxybenzènediazonium dans l'acide acétique en solution aqueuse n'aboutissait qu'à un dérivé bisubstitué. Toutefois, une étude de cette réaction avec d'autres sels de diazonium dans divers milieux réactionnels et à différentes températures nous a donné les produits monosubstitués en position 3. Nous n'avons pu déceler que des traces de produits bisubstitués. Ici encore, la présence de sels cuivriques dans le milieu réactionnel n'affecte pas le rendement mais elle permet, cependant, d'obtenir un produit plus facile à purifier. Les solutions d'acétone à 65% en volume, à 0°, et d'acide formique à 55% en volume, à 20°, dans l'eau se sont avérées les meilleurs solvants.

Les réactions représentées au Schéma 2 nous ont permis d'établir les structures des naphtoquinones ainsi obtenues.

PARTIE EXPÉRIMENTALE

Arylation de la 1,2-naphtoquinone

Le sel de diazonium se prépare de la façon habituelle par addition lente d'une solution de nitrite de sodium (1.6 g) dans de l'eau (10 ml) à un mélange de l'amine (0.02 mole), de 5.0 ml d'acide chlorhydrique concentré et de 25 ml d'eau. On ajoute goutte à goutte la solution ainsi obtenue à un mélange, maintenu entre 20 et 25°, de 3.2 g (0.02 mole) de 1,2-naphtoquinone, de 4.9 g (0.06 mole) d'acétate de sodium, de 0.5 g de chlorure cuivrique, de 80 ml d'acide formique et de 25 ml d'eau. On agite ensuite à la température ambiante jusqu'à ce que l'évolution d'azote soit complète (environ 12 h); puis on refroidit, on filtre et on triture le résidu avec un peu de méthanol glacé. La purification par chromatographie (gel de silice–benzène) n'améliore pas sensiblement le rendement.

3-o-Chlorophényl-1,2-naphtoquinone (I)

La substance cristallise en feuillets jaune-orangé (5%) dans l'éthanol à 70%, p.f. 171–172°; $\lambda_{max}^{CHCl_3}$ 5.87, 5.96, 6.02, 6.26 μ.

Anal. Calc. pour $C_{16}H_9O_2Cl$: C, 71.52; H, 3.38; Cl, 13.20. Trouvé: C, 71.63; H, 3.51; Cl, 13.11.

3-m-Chlorophényl-1,2-naphtoquinone (II)

Cristallisée dans l'acide acétique à 75% puis dans le benzène, la substance est obtenu en aiguilles rouges (17%), p.f. 197–198°; $\lambda_{max}^{CHCl_3}$ 5.88, 5.96, 6.02, 6.27 μ.

Anal. Calc. pour $C_{16}H_9O_2Cl$: C, 71.52; H, 3.38. Trouvé: C, 71.76; H, 3.46.

3-p-Chlorophényl-1,2-naphtoquinone (III)

La substance cristallise dans l'acide acétique à 75% en fines aiguilles rouges (37%), p.f. 214.5–215.0°; $\lambda_{max}^{CHCl_3}$ 5.88, 5.96, 6.27 μ.

Anal. Calc. pour $C_{16}H_9O_2Cl$: C, 71.52; H, 3.38; Cl, 13.20. Trouvé: C, 71.30; H, 3.40; Cl, 13.34.

TABLEAU I

2-Hydroxy-3-aryl-1,4-naphtoquinones

Groupe substituant	$\lambda_{max}^{CHCl_3}$ (μ)	Point de fusion et point de fusion mélangé	Point de fusion (littérature)
3-*o*-Chlorophényle	3.94, 5.99, 6.24	195–196°	194–195.5° (9)
3-*m*-Chlorophényle*	3.94, 5.99, 6.23	151.5–152.5°	203–204° (9)
3-*p*-Chlorophényle	3.93, 6.00, 6.24	190.5–191.5°	187.4–188° (9)

*Anal. Calc. pour $C_{16}H_9O_3Cl$: C, 67.50; H, 3.19; Cl, 12.45. Trouvé: C, 67.59; H, 3.16; Cl, 12.65.

Les 2-Hydroxy-3-aryl-1,4-naphtoquinones

On ajoute 0.5 g de 3-aryl-1,2-naphtoquinone à un mélange d'anhydride acétique (10 ml) et de 5 gouttes d'acide perchlorique à 70%, et la température est élevée lentement jusqu'à dissolution complète; puis on refroidit et verse dans de l'eau. Le triacétate brut est ensuite décomposé par chauffage à reflux dans un mélange de méthanol (10 ml) et d'acide chlorhydrique concentré (0.3 ml) pendant 1 h. On évapore à sec sous vide, on ajoute 30 ml d'eau, on porte le pH à 8 par addition d'une solution d'hydroxyde de sodium à 5% et l'on fait passer un courant d'air dans la solution pendant 1 h. Les 2-hydroxy-3-aryl-1,4-naphtoquinones (60–70%) obtenues après acidification sont identiques aux substances (point de fusion mélangé et spectres infrarouges) préparées d'après Fieser et Leffler et leurs collaborateurs (9) (Tableau I). La 2-hydroxy-3-(*m*-chlorophényl)-1,4-naphtoquinone obtenue par cette méthode diffère toutefois sensiblement par son point de fusion de la substance déjà décrite.

REMERCIEMENTS

Nous remercions le Ministère de l'Education de la Province de Québec pour une bourse de perfectionnement accordée à l'un de nous (J. A.), ainsi que le Conseil National de Recherches du Canada pour l'octroi de subventions qui ont permis la réalisation de ce travail.

DEUTERIUM ISOTOPE EFFECT ON THE RACEMIZATION OF A HIGHLY HINDERED BIPHENYL DERIVATIVE[1]

C. HEITNER AND K. T. LEFFEK

Suggestions that certain kinetic secondary deuterium isotope effects were manifestations of the steric differences between the normal and deuterated molecules (1, 2) have led to a search for such isotope effects which are unambiguously steric in origin. Recently, Mislow *et al.* (3, 4) found rate ratios (k_H/k_D) between 0.86 and 0.88 for 9,10-dihydro-4,5-dimethyl-d_6-phenanthrene under various conditions of solvent and temperature; almost simultaneously, the results of Melander and Carter (5, 6) on 2,2′-dibromo-4,4′-dicarboxybiphenyl-6,6′-d_2 appeared, for which they observed an 18% inverse isotope effect ($k_H/k_D = 0.82$) in several solvents. These rate changes are in the direction predicted by the greater steric requirements of carbon–hydrogen relative to carbon–deuterium bonds.

Mislow *et al.* concluded (4) that steric isotope effects would appear only in severely crowded situations, in contrast to Bartell's hypothesis (2) that steric factors contribute to many, if not all, isotopic rate changes.

In the present work, the rate of racemization of optically active *o*-(2-dimethyl-d_6-aminophenyl)-phenyltrimethyl-d_9-ammonium *d*-camphor-10-sulfonate (I) has been measured and compared with that of the normal compound. The cation is an ortho-substituted biphenyl more highly hindered than those previously studied.

I

RESULTS AND DISCUSSION

The rate constants and rate ratios for compound I are presented in Table I. The rate constants for the normal compound, together with those of Leffler and Graham (7), give a good straight-line plot for $\log_{10} k/T$ versus $1/T$, which yields $\Delta H^{\ddagger} = 27.46$ kcal (standard error = 0.06) and $\Delta S^{\ddagger} = -5.04$ cal mole^{-1} degree^{-1} (standard error = 0.05).

The rate constants for the normal and deuterated molecules are not significantly different in the two solvents, water and dimethyl sulfoxide, or at temperatures of 100 and 120 °C in water. Although there may be a small normal isotope effect in water at 120 °C, the rate difference is no bigger than twice the standard deviation.

In view of the isotope effects already observed in biphenyl systems, it is unlikely that

*Standard error.

the rate ratio of unity found for compound I means that the normal and deuterated molecules are identical. Melander and Carter (6), following Bartell (2), successfully accounted for their results in terms of the isotopic difference in the mean-square amplitude of the vibration between carbon–hydrogen and carbon–deuterium. If this is present in 2,2′-dibromo-4,4′-dicarboxybiphenyl-6,6′-d_2, it must also exist in compound I, although the isotopic difference may be slightly smaller in this case, since the inductive effect of the positive charge on the nitrogen should tend to weaken both the carbon–hydrogen and the carbon–deuterium bonds relative to an uncharged molecule. However, bond weakening is not extensive under the reaction conditions, because no isotope exchange was observed (see Experimental).

Qualitatively, the results may be rationalized in two ways: either the non-bonded interactions during racemization are so great that they are not significantly changed by deuteration, or a second effect occurs in the molecule with deuteration which compensates for the change in the mean-square amplitude. Although a discussion of such a second effect can only be speculatory, it is of interest to note the data of Mislow *et al.* (3, 4), which show opposing changes in the activation parameters ($(\Delta H_H^{\ddagger} - \Delta H_D^{\ddagger}) = 0.24$ kcal mole^{-1} and $(\Delta S_H^{\ddagger} - \Delta S_D^{\ddagger}) = 0.53$ cal mole^{-1} degree^{-1}) for 9,10-dihydro-4,5-dimethyl-d_6-phenanthrene in benzene. The results in Table I cannot be used to derive analogous figures for compound I, but if reasonable values are chosen (e.g. $(\Delta H_H^{\ddagger} - \Delta H_D^{\ddagger}) = 0.17$ kcal mole^{-1} and $(\Delta S_H^{\ddagger} - \Delta S_D^{\ddagger}) = 0.46$ cal mole^{-1} degree^{-1}) the rate ratios (k_H/k_D) at 100 °C and 120 °C would be 1.00 and 1.01, respectively. Hence, our results are not as inconsistent with those of Mislow *et al.* as they appear to be at first sight. The latter workers, understandably, did not attempt to explain the isotope effect on the entropy of activation. Further, it should be noted that Melander and Carter *assumed* their isotope effect to be on the enthalpy of activation, the proof being beyond the limits of their experiments.

It appears probable that secondary deuterium isotope effects in biphenyl systems may be more complicated than simply steric effects. The present results are useful in that they help to demonstrate this point, and also the limitations of Mislow's conclusion (4) "that steric hydrogen isotope effects are plainly operative only under special conditions of severe overcrowding", since Melander and Carter's system (6), which is not severely crowded, shows a large rate change per deuterium, whereas compound I, which is more severely crowded, shows none.

EXPERIMENTAL

Materials

2,2′-Diaminobiphenyl

2,2′-Dinitrobiphenyl (m.p. 125–126.5 °C), prepared in an 89% yield from *o*-chloronitrobenzene by the method of Kornblum and Kendall (8), was reduced with hydrogen catalytically (9) to yield 2,2′-diaminobiphenyl (m.p. 78–80 °C) in an 86% yield after recrystallization from ethanol.

For personal use only.

Methyl-d_6 Sulfate

Methyl-d_3 iodide was prepared by the method of Cotton *et al.* (10). The deuterium content was monitored by mass spectrometric analysis and was always 98% or greater.

Methyl-d_6 sulfate was prepared by mixing methyl-d_3 iodide with dry silver sulfate, whereupon the methyl-d_3 iodide refluxed spontaneously for 1½ h. Extraction with ether and distillation gave methyl-d_6 sulfate in a 74% yield.

dl-o-(2-Dimethyl-d_6-aminophenyl)phenyltrimethyl-d_9-ammonium Iodide

Methylation of the 2,2′-diaminobiphenyl with methyl-d_6 sulfate according to the procedure of Shaw and Turner (11) gave 2,2′-bisdimethyl-d_6-aminobiphenyl (m.p. 71–72 °C) in a 93% yield. This was then quaternized with methyl-d_3 iodide by the method of Leffler and Graham (7). The product melted at 185–186 °C and the yield was 93% with respect to the biphenyl when carried out on a scale of 0.005 mole.

d-o-(2-Dimethyl-d_6-aminophenyl)phenyltrimethyl-d_9-ammonium d-Camphor-10-sulfonate

This compound was prepared by the method of Shaw and Turner (11), m.p. 190–191 °C (uncorrected), $[\alpha]^{25}_{5461}$ +59.2° (in water).

The protium compound was prepared in the same manner, m.p. 189–190 °C (uncorrected), $[\alpha]^{25}_{5461}$ +59.5° (in water).

Kinetic Method

The kinetic runs were carried out at a concentration of 0.02 *M*, since at higher concentrations than this the first-order rate constant is not independent of the initial concentration (7).

Solution samples were sealed under nitrogen in tubes and, after they were preheated, were placed in a constant-temperature bath. After temperature equilibrium had been reached, 3 tubes were withdrawn to mark the kinetic zero, and thereafter 10 or 11 tubes were withdrawn at regular intervals. Three samples were left in the bath for 10 half-lives to give the optical rotation for the complete reaction.

The optical activity of each sample was measured with a Bendix–Ericsson ETL-NPL automatic polarimeter, type 143A, which gives an electric current directly proportional to the optical rotation. This current was passed through a resistance and the potential across it measured with a Croydon potentiometer, type P3. The system was calibrated with sucrose of a known specific rotation. The average of 20 readings was taken as the rotation for each sample. The rate constant was calculated by the method of least squares from the equation

$$2kt = 2.303 \log_{10}\left(\frac{\alpha_0 - \alpha_\infty}{\alpha_t - \alpha_\infty}\right),$$

where k is the first-order rate constant, t is the time, and α_0, α_t, and α_∞ are the optical rotations at the kinetic zero, time t, and after 10 half-lives, respectively. An illustrative run is shown in Table II.

TABLE II

Racemization of *d-o-*(2-dimethyl-d_6-aminophenyl)-trimethyl-d_9-ammonium *d*-camphor-10-sulfonate in water at 100.0 °C*

Time (s) × 10^{-2}	Optical rotation × 10^2	Time (s) × 10^{-2}	Optical rotation × 10^2
0	5.018°†	72.21	3.110°
12.00	4.592°	84.00	2.894°
24.00	4.230°	96.00	2.696°
36.00	3.890°	108.00	2.562°
48.00	3.615°	120.00	2.416°
60.01	3.342°	∞	1.402°†

*Run 28, concentration ca. 0.02 *M*, cell length 1 cm.
†Mean of three separate samples.
NOTE: From a least-squares calculation, $k_1 = 5.26 \times 10^{-5}$ s (standard error = 0.04×10^{-5} s).

Usually two runs, identical except for the isotopic composition of the substrate molecule, were carried out simultaneously. After one such pair of runs, the solvent was removed and a nuclear magnetic resonance spectrum, in deuterium oxide solution, was obtained for both the normal and deuterated compound. The normal compound showed two peaks at 6.38 τ and 7.42 τ for the $\overset{+}{N}(CH_3)_3$ and the $N(CH_3)_2$ hydrogens, respectively (12). The spectrum for the deuterated compound was identical except for the absence of the above peaks. Thus, the deuterated compound was at least 98% isotopically pure, and also no exchange took place with the solvent water under the reaction conditions.

A STUDY OF THE MANNICH REACTION WITH PROPARGYL ALCOHOL

R. L. SALVADOR AND D. SIMON

Although 1-alkynes are known to partake in the Mannich reaction, the seeming inertness of propargyl alcohol in undergoing this condensation prompted us to investigate the mechanism of this reaction. During this investigation we applied these theoretical aspects to the synthesis of a group of aminobutynols of the type $R_2N—CH_2—C\equiv C—CH_2OH$. The sequence of events in the Mannich reaction has been subject to many debates, two explanations being offered. One possible course is an aldol condensation of the active hydrogen component I with formaldehyde, followed by reaction of the acetylenic alcohol II with a secondary amine to produce the Mannich base III.

$$\underset{\text{I}}{R'—C\equiv C—H} + HCOH \rightarrow \underset{\text{II}}{R'—C\equiv C—CH_2OH} + R_2NH \rightarrow \underset{\text{III}}{R'—C\equiv C—CH_2—NR_2}$$

The alternative is the formation of the methylol derivative of the amine IV, followed by its reaction with the active hydrogen compound (1).

$$HCHO + HNO_2 \rightarrow \underset{\text{IV}}{HO—CH_2—NR_2} + \underset{\text{I}}{R'—C\equiv C—H} \rightarrow \underset{\text{III}}{R'—C\equiv C—CH_2—NR_2}$$

Since the acetylenic compound, in our case, was propargyl alcohol, it seemed probable that the second type of reaction was followed. Formation of the hydroxymethyl derivative of the acetylenic compound would lead to the production of 2-butyne-1,4-diol, with the probability of amination of both ends of the chain. The high yields of the expected products, however, precluded this line of reasoning. Also, attempts to isolate 2-butyne-1,4-diol were unsuccessful. Although the Mannich reaction proceeds well for 3-alkyl- and

A STUDY OF THE MANNICH REACTION WITH PROPARGYL ALCOHOL

R. L. SALVADOR AND D. SIMON

Although 1-alkynes are known to partake in the Mannich reaction, the seeming inertness of propargyl alcohol in undergoing this condensation prompted us to investigate the mechanism of this reaction. During this investigation we applied these theoretical aspects to the synthesis of a group of aminobutynols of the type $R_2N—CH_2—C\equiv C—CH_2OH$. The sequence of events in the Mannich reaction has been subject to many debates, two explanations being offered. One possible course is an aldol condensation of the active hydrogen component I with formaldehyde, followed by reaction of the acetylenic alcohol II with a secondary amine to produce the Mannich base III.

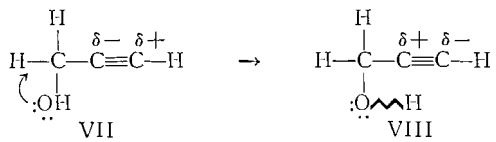
$$\underset{\text{I}}{R'—C\equiv C—H} + HCOH \rightarrow \underset{\text{II}}{R'—C\equiv C—CH_2OH} + R_2NH \rightarrow \underset{\text{III}}{R'—C\equiv C—CH_2—NR_2}$$

The alternative is the formation of the methylol derivative of the amine IV, followed by its reaction with the active hydrogen compound (1).

$$HCHO + HNO_2 \rightarrow \underset{\text{IV}}{HO—CH_2—NR_2} + \underset{\text{I}}{R'—C\equiv C—H} \rightarrow \underset{\text{III}}{R'—C\equiv C—CH_2—NR_2}$$

Since the acetylenic compound, in our case, was propargyl alcohol, it seemed probable that the second type of reaction was followed. Formation of the hydroxymethyl derivative of the acetylenic compound would lead to the production of 2-butyne-1,4-diol, with the probability of amination of both ends of the chain. The high yields of the expected products, however, precluded this line of reasoning. Also, attempts to isolate 2-butyne-1,4-diol were unsuccessful. Although the Mannich reaction proceeds well for 3-alkyl- and

3-aryl-1-alkynes (2) and for some hydroxy-1-alkynes (3), the method is not available if the hydroxy group of the latter is propargylic.



Although McLeod and Robinson (4) and Fernandez *et al.* (5) have shown that ethers of the type $R_2N—CH_2—O—R$ are formed under conditions similar to those of the Mannich reaction, and although it has been shown that propargyl alcohol reacts with amine and formaldehyde preferentially at the hydroxylic group rather than the acetylenic C—H, under the conditions described in this paper we were unable to isolate these ethers from the reaction mixture even without the copper catalyst, the bis-aminomethane $R_2N—CH_2—NR_2$ being the main product isolated. We must therefore conclude that the preferential reaction cited above does not obtain under these conditions. The limitation imposed upon the reaction with propargylic alcohols was overcome by esterifying (3) or etherifying (6) the hydroxyl function.

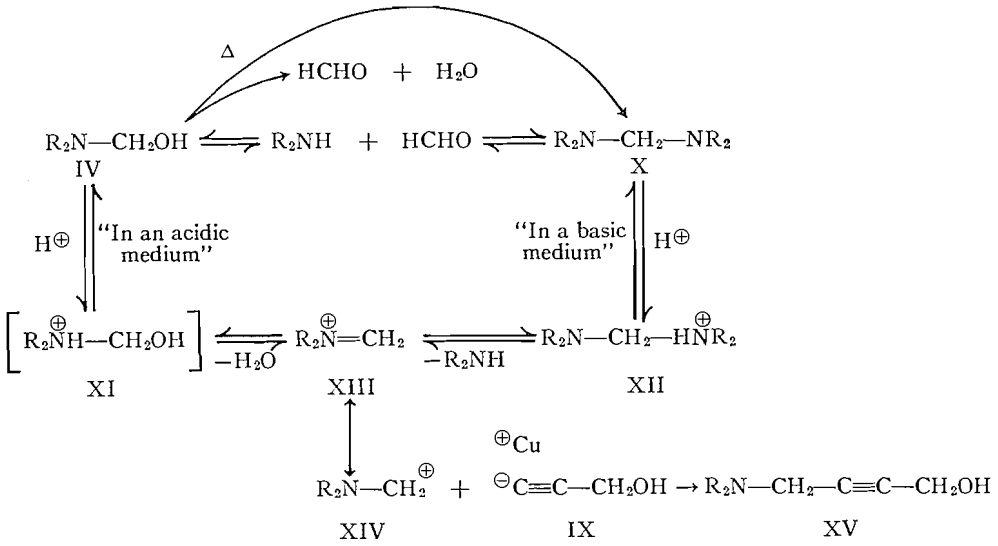
We have circumvented these steps by the use of cupric sulfate as a catalyst, following, to a limited extent, a German patent (7). The process was greatly modified. The elucidation of this process threw light upon the mechanism of the Mannich reaction. It is well understood that 1-alkynes may be envisioned as possessing two polarization forms V and VI, in which form VI accounts for the "acidity" of the acetylenic hydrogen. A hydroxy group propargylic to the acetylenic function prevents formation of the "acidic" polariza-

V VI

tion form VI by virtue of an electron shift involving an unbound electron pair on the oxygen atom. This phenomenon probably accounts for the well-known acidity of the hydrogen on a propargylic hydroxyl function. The electron shift would, incidentally, reverse the polarization pattern of the molecule and preclude the existence of an active acetylenic hydrogen (VII to VIII). However, since the Mannich reaction depends

VII VIII

precisely upon the presence of such a labile hydrogen, the condensation does not take place. The sharp and strong band at 2 118 cm^{-1} in the infrared absorption spectrum of propargyl alcohol shows that the acetylenic bond is strongly polarized, but the absence of condensation implies that it exists mainly as form VIII, which can account for both the acidity of the hydroxyl hydrogen and the lack of acidity of the acetylenic hydrogen. The formation of the copper salt IX (8) would produce, however, a labile center, or in essence a carbanion, which would react with the aminomethylol formed between the secondary amine and formaldehyde. The identical copper salt was produced by the reaction of cupric sulfate



IX

and propargyl alcohol alone in a basic medium, even at room temperature. In this case, reduction of the cupric ion is probably effected by the acetylene itself. Since the reaction was carried out in an aqueous medium, insoluble reaction products could be isolated and identified. An oily layer was immediately produced during the preparation of 4-piperidino-2-butyne-1-ol. Upon distillation of this layer, a vigorous evolution of formaldehyde was noted, and the distillate was identified as bis-piperidinomethane (1). The amine and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formaldehyde were not introduced in a 2:1 ratio, however, and the initial product was identified as piperidinomethanol. This product was identified by its infrared spectrum, which was identical with that of the piperidinomethanol produced by the method of Henry (9). Attempts to prepare 4-piperidino-2-butyne-1-ol from piperidinomethanol and propargyl alcohol in the presence of cupric ion in a basic medium resulted in inferior yields, whereas the preparation from the bis-piperidinomethane gave yields similar to those of the whole reaction itself (some yield was obtained even in the cold). It was therefore concluded that the principal species involved in this reaction, when run in a slightly basic medium, is the bis-piperidinomethane formed from the aminomethylol under the influence of heat, and the following mechanism is proposed for the reaction. Although the existence of these intermediates has been postulated by Wagner (10) and reviewed by Helman and Opitz (1), and although the properties of the stable species have been studied in some detail, we have isolated and identified the above-mentioned intermediates from the reaction itself.

It must be understood that the different species IV and X have different stabilities. Whereas IV is unstable in an acidic medium, rapidly reverting to the amine salt and formaldehyde, X will actually form a stable salt. Thus, the pathways of the reaction in acidic and basic media are somewhat different. The reaction in a slightly acid medium contributes to two species at differing rates. The reversible reaction involving IV to regenerate the amine and formaldehyde predominates. However, the formation of the carbenium species XIII by way of the unstable methylol salt XI is also accomplished, but at a much slower rate, as evidenced by the long reaction time in this medium. In a slightly basic medium, X is formed in the reaction, and also by the thermal decomposition of IV. This bis-aminomethane rapidly forms the carbenium species XIII through the intermediate salt XII. It is postulated that the carbenium ion XIV, stabilized by resonance with XIII, is the reactive species in both reactions (1). The carbanion IX formed from cupric sulfate and the 1-alkyne would then enter into reaction with XIV to produce the desired Mannich base XV. A similar series of events was noted during the synthesis of the diisopropyl analogue. By following the changes in the pH values during the preparation of the reaction, it was noted that the introduction of formalin, even when carefully

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

neutralized, brought about an abrupt drop in pH. The resultant solutions were strongly resistant to subsequent change in pH by the addition of excess amine until the amount of amine calculated to produce the bis-aminomethane was introduced. This strongly indicates a parallel course for all the reactions in the series, even those whose bis-aminomethanes are soluble in water.

The effect of pH on the yield in the reaction was studied. The diethyl analogue was prepared several times at varying initial pH values. It was established that at a pH greater than 8, the reaction, as evidenced by the precipitation of metallic copper, was complete after 55 min. At a pH less than 7 the reaction required at least 5½ h, and at pH 3 no reaction occurred. At a pH greater than 9 the yield decreased. It was decided to run all future reactions at pH 8.4.

TABLE I

Effect of pH on the yield of 4-diethylamino-2-butyne-1-ol

Initial pH	Yield (%)	Time of run	Remarks
9.0	62	55 min	Metallic copper precipitates
8.4	80	"	Some precipitation of metallic copper
7.9	80	5½ h	Some copper propargylate remains
6.0	80	"	Some copper propargylate remains
5.0	77	"	Copper propargylate slow to form
4.5	75	"	Copper propargylate slow to form
3.8	65	"	Copper propargylate slow to form
3.0	0	"	Copper propargylate does not form
7.0	0	"	No copper ion present

It should be noted, therefore, that the reaction should be run in a medium which is acidic enough to form and stabilize the postulated carbenium ion but not acidic enough to prevent the formation of the acetylide.

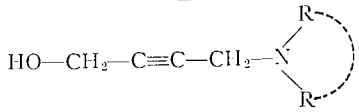
EXPERIMENTAL

The melting points were measured by the capillary method in an electrothermal apparatus and are uncorrected. Carbon–hydrogen analyses were determined by Dr. C. Daesslé, 5757 Decelles Avenue, Montreal. Amine nitrogen was determined by direct titration in acetic acid, using a Radiometer pH meter with a standard glass electrode and a sleeve-type calomel electrode filled with saturated potassium chloride in anhydrous acetic acid. The hydrochloride salt (compound 6, Table II) was determined by the mercuric acetate – acetic acid method of Pifer and Wollish (11) with the same titrating apparatus.

4-Dimethylamino-2-butyne-1-ol

Dimethylamine (1.2 moles) was dissolved in 80 ml of water and the solution was brought to pH 9 by the addition of a solution of 50% sulfuric acid. One and six-tenth moles of 40% formalin solution was added to the mixture followed by 1 mole of propargyl alcohol. A solution of 5 g of anhydrous cupric sulfate in 50 ml of water was admixed with the contents of the reaction vessel, and the pH adjusted to 8.4 by the addition of excess dimethylamine solution.

The reaction mixture was heated at 80° under reflux (dry ice condenser), with stirring, until the greenish precipitate, which gradually turned yellow, showing the formation of copper propargylate, was succeeded by the deposition of metallic copper (55 min). The mixture was cooled and poured into 300 ml of cold concentrated aqueous ammonia. The combined aqueous solutions were then extracted for 9 h with ether in a liquid–liquid extractor. The ether extract was separated and dried over anhydrous magnesium sulfate, and the solvent was evaporated. The residue was distilled *in vacuo* to yield 91.5 g (81%) of the aminobutynol, b.p. 76–78° at 1.5 mm, n_D^{23} 1.4765, $d_4^{22.5}$ 0.941 (reported (12) b.p. 101° at 1.5 mm, $n_D^{27.5}$ 1.4732).



4-Diethylamino-2-butyne-1-ol

This substance was prepared by the general procedure described above, except that the reflux condenser was replaced by a regular Allihn water condenser. A 1 mole run, based on propargyl alcohol, gave 112.8 g (80%) of the desired aminoalcohol, b.p. 92–93° at 2 mm, $n_D^{21.7}$ 1.4784, $d_4^{21.7}$ 0.975 (reported (7) b.p. 105° at 2 mm).

4-Diisopropylamino-2-butyne-1-ol

This aminoalcohol was prepared by the general method described above. Sufficient triethylamine was added to bring the pH to 8 and to aid in the solubilization of the insoluble bis-aminomethane. The reaction was heated at 80° for 72 h. A 1 mole run based on propargyl alcohol gave 147.5 g (87.5%) of the product, $n_D^{21.7}$ 1.4811, $d_4^{21.5}$ 0.931.

4-Pyrrolidino-2-butyne-1-ol

This compound was prepared by the general method described for the dimethyl analogue. A 1 mole run, based on propargyl alcohol, gave 117 g (84%) of the desired aminobutynol, b.p. 106–107° at 1.5 mm, $n_D^{21.7}$ 1.5039, $d_4^{26.5}$ 1.013 (reported (13) b.p. 101–102° at 0.4 mm, n_D^{22} 1.5092).

4-Piperidino-2-butyne-1-ol

This substance was prepared in 50% dioxane–water by the general method described above. A 1 mole run, based on propargyl alcohol, gave 122.4 g (80%) of the product, b.p. 112–113° at 1.5 mm, $n_D^{24.7}$ 1.5095, $d_4^{26.5}$ 1.030 (reported (13) b.p. 112–113° at 0.9 mm).

4-Morpholino-2-butyne-1-ol

This aminoalcohol was prepared by the general method. A 1 mole run, based on propargyl alcohol, gave 124 g (80%) of the desired product, b.p. 104–106° at 0.1 mm, $n_D^{21.7}$ 1.5095 (supercooled liquid), m.p. 51.5–52.5° (reported (14) b.p. 104–106° at 0.1 mm, n_D^{25} 1.5087).

CONVERSION OF NEOABIETIC ACID INTO MANOOL

Ernest Wenkert, J. R. Mahajan, M. Nussim, and F. Schenker

As a consequence of our recent total synthesis of abietoid resin acids (1), various intermediates became available for possible conversion into other diterpenic natural products. Thus, for example, the synthetic ketoester I*a* (2, 3), also a product of the ozonolysis of methyl neoabietate (2–4), appeared to be a likely candidate for transformation into manool (II) and sclareol (III), especially since the more readily accessible sclareol degradation product IV had already been converted into sclareol (5) and the latter had previously

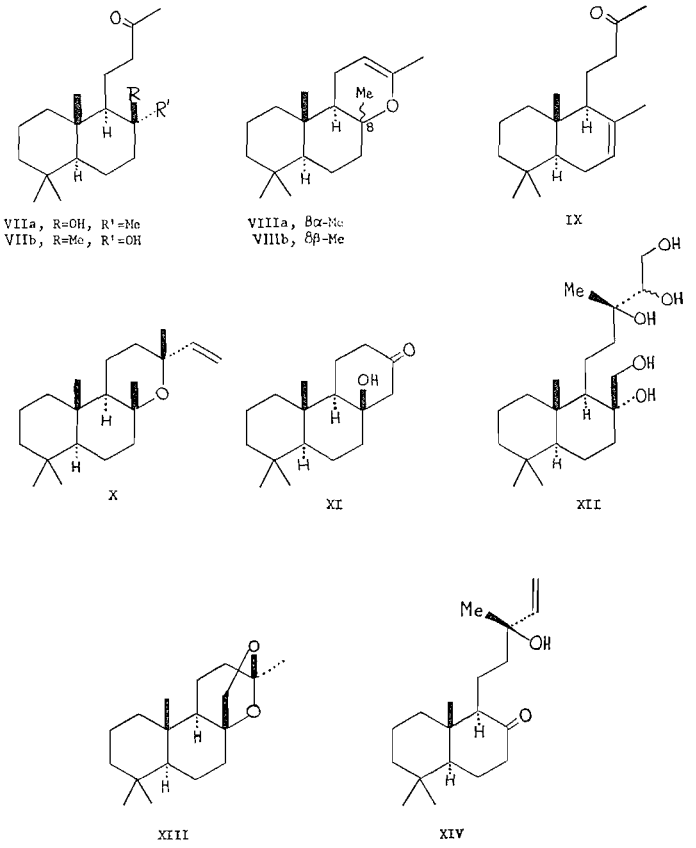
CONVERSION OF NEOABIETIC ACID INTO MANOOL

Ernest Wenkert, J. R. Mahajan, M. Nussim, and F. Schenker

As a consequence of our recent total synthesis of abietoid resin acids (1), various intermediates became available for possible conversion into other diterpenic natural products. Thus, for example, the synthetic ketoester I*a* (2, 3), also a product of the ozonolysis of methyl neoabietate (2–4), appeared to be a likely candidate for transformation into manool (II) and sclareol (III), especially since the more readily accessible sclareol degradation product IV had already been converted into sclareol (5) and the latter had previously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

been transformed into manool (6). The present communication describes the transformation of I*a* into IV.



Ethylene glycol ketalation of I*a*, lithium aluminium hydride reduction of the ketal ester, and Sarett oxidation of the resultant ketal alcohol yielded the crystalline aldehyde V. The absence of any olefinic hydrogen signal in the proton magnetic resonance spectrum of the aldehyde indicated the tetra-substituted nature of its double bond. Wolff–Kishner reduction of the aldehyde, followed by acid-catalyzed deketalation, yielded the unsaturated ketone I*b*, a known product of the oxidative degradation of manool (II) (7–9). Although racemic I*b* has been converted into *d,l*-IV, only optically active ketone IV has been transformed into natural sclareol (III) (5), thus leaving the total synthesis of the natural product unfinished. As a consequence, the I*b*–IV transformation was repeated in the optically active series.

Ozonolysis of the ketone I*b* produced the ketoacid VI*a*, whose exposure to methyllithium yielded ketol VII*a* and enol ether VIII*a*. The latter was an 8-epimer of VIII*b* obtained by oxidation of sclareol (III) (*vide infra*) and dehydration of the intermediate ketol VII*b*. Acid-induced isomerization of either epimer VIII yielded a mixture of olefinic ketones IV and IX, only the former of which had been noted previously (5). This completed a formal total synthesis of sclareol (III), manool (II), and manoyl oxide (X) (10).

Both the present and related projects have depended on the availability of large quantities of tricyclic ketone I*b*. Although it has been prepared previously by oxidation of manool (II) (7, 8, 10–12), base treatment of the resultant diketone VI*b*, and acid-catalyzed dehydration of the intermediate ketol XI, the first step of the three-reaction sequence has been inefficient. As a consequence of a search for an improved procedure the oxidation of manool by osmium tetroxide – periodate (13) was investigated. Since initial experiments indicated the formation of mixtures of products, some of which could have arisen only from acid-induced chemical changes, a qualitative study of the pH dependence of the oxidation was undertaken.

t-Butanolic solutions of manool were adjusted to various pH values while being exposed to periodic acid in the presence of a trace quantity of osmium tetroxide. At high alkalinity the product was exclusively the pentol XII. This may have been the consequence of low

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solubility of the product in the reaction medium. At pH 1 the oxidation yielded the diketone VI*b* along with the ketal XIII and a $C_{18}H_{30}O_4$ product whose structure was not investigated. In the pH range 6–8 the desired diketone VI*b* was the exclusive product. In a few experiments in which early nonhomogeneity of the reaction medium developed, hydroxyketone XIV appeared as a by-product. This product has not previously been obtained from oxidations of manool.

EXPERIMENTAL

All melting points are uncorrected. Unless otherwise stated, the optical rotations were carried out on chloroform solutions. A Beckman pH meter was used for the pH determinations.

Aldehyde V

A mixture of 1.26 g of the ketoester I*a*, 60 mg of *p*-toluenesulfonic acid, 5 ml of ethylene glycol, and 50 ml of benzene was refluxed for 18 h in the presence of a water separator. The mixture was cooled, washed with 10% sodium carbonate solution and with water, and evaporated. A solution of the residual (1.45 g), oily ketal ester in 30 ml of ether was added dropwise, with stirring, to a suspension of 0.5 g of lithium aluminium hydride in 20 ml of ether, and the mixture was refluxed for 3 h. After the usual work-up the mixture yielded 1.23 g of crude, gummy ketal alcohol. A solution of the latter in 13 ml of pyridine was added to a slurry of 1.2 g of chromic acid in 12 ml of pyridine, and the mixture was stirred at room temperature for 45 min. It then was extracted with ether and the extract washed successively with 10% sodium carbonate solution, water, 5% hydrochloric acid solution, and water once more. The extract was dried over sodium sulfate and evaporated to give 1.1 g of a pale-yellow, thick oil which became partly crystalline when allowed to stand. Several crystallizations from methanol yielded colorless needles of the ketal aldehyde V, m.p. 110–110.5°; $[\alpha]_D$ +90.0° (*c*, 1.5); μ (KBr) CH 3.67 (w), C=O 5.82 (s); δ C—CH_3 singlets at 1.02 and 1.04 p.p.m., ketal methylene broad singlet at 3.94 p.p.m., aldehyde CH singlet at 9.12 p.p.m.

Anal. Calcd. for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27. Found: C, 75.10; H, 9.38.

Ketone Ib

A mixture of 0.74 g of crude ketal aldehyde, 8 ml of 95% hydrazine, and 32 ml of diethylene glycol was heated for 2 h at a bath temperature of 125–135°. After the addition of 4.0 g of potassium hydroxide pellets, heating (170–180°) was continued for 8 h. The usual work-up gave 0.64 g of a pale-yellow oil; chromatography of this oil on 10 g of alumina and elution with hexane yielded 0.38 g of an oil showing one spot on thin-layer chromatography. A solution of the product and 1.6 ml of sulfuric acid in 30 ml of methanol was refluxed for 30 min and then worked up in the usual manner. Chromatography of the resultant oil (0.29 g) on 8 g of alumina and elution with 20:1 hexane–ether yielded 205 mg of a solid. Several crystallizations from hexane yielded the enone *Ib*, m.p. and mixed m.p. 61.5–62.5°; its infrared spectrum was identical with that of an authentic sample.

Ketoacid VIa

An excess of ozone was bubbled for 20 min through a solution of 0.56 g of ketone *Ib* in 10 ml of glacial acetic acid and 15 ml of ethyl acetate cooled in an ice–salt bath. After the addition of 0.6 ml of 30% hydrogen peroxide and 5 ml of water, the mixture was left to stand at room temperature for 2 h and then heated at 60–70° for 5 min. Work-up gave 0.60 g of an acidic fraction and negligible amounts of neutral material. Chromatography of the former on silica gel and elution with 3:2 benzene–ether gave 0.48 g of a solid, m.p. 83–88°. Crystallization from hexane yielded ketoacid VI*a*, m.p. 90–92°; μ (KBr) OH 3.0–3.3 (m), 3.6–3.8 (m), C=O 5.85 (s, broad).

Anal. Calcd. for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84. Found: C, 72.10; H, 9.79.

Ketones IV and IX

An ethereal solution of methyllithium (from 0.5 g of lithium) was poured through a glass-wool plug into a solution of 0.25 g of crude acid VI*a* in 15 ml of ether, and the mixture was refluxed for 3.5 h. The cooled mixture was poured onto ice and worked up in the usual manner. A hexane solution of the neutral product (0.23 g of a pale-yellow, viscous liquid) was treated with charcoal and filtered through 1.5 g of alumina. The hexane filtrate contained 106 mg of a semisolid mixture, and a subsequent ether eluate was composed of 102 mg of VII*a* (μ (KBr) OH 2.84 (m), C=O 5.87 (s)), m.p. 102–106° (softening at 95°). Despite crystallization from hexane and chromatographies over alumina the solid ketol could not be purified further. Chromatography of VII*a* and the earlier semisolid fraction (154 mg) on 5 g of alumina and elution with hexane yielded 86 mg of a colorless liquid which could be induced to crystallize. Unfortunately this substance, VIII*a*, m.p. 63–65° (μ (neat liquid) no OH, C=C 5.91 (m)), was as sensitive as its ketol precursor and could not be purified further. A solution of 85 mg of the enol ether and 1 ml of 5 *N* hydrochloric acid in 5 ml of 95% alcohol was kept at 70° under nitrogen for 2 h. The usual work-up gave 75 mg of a ketone mixture. Its gas-phase chromatography (20% polyester LAC 446 on WAW column, 225–300°, F. and M. model 500 apparatus) yielded IV as the major component (retention time 18 min; μ (neat) C=O 5.82 (s); δ C—CH_3 singlets at 0.83, 0.88, and 0.94 p.p.m., olefinic C—CH_3 singlet at 1.55 p.p.m., $COCH_3$ singlet at 2.13 p.p.m.) and IX as the minor component (retention time 22.8 min; μ (neat) C=O 5.80 (s); δ C—CH_3 singlets at 0.78, 0.86, and 0.87 p.p.m., olefinic C—CH_3 broad singlet at 1.67 p.p.m., $COCH_3$ singlet at 2.13 p.p.m., olefinic CH multiplet at 5.43 p.p.m.).

A 1% solution (2 ml) of osmium tetroxide in *t*-butanol was added to a solution of 200 mg of sclareol (III) in 50 ml of *t*-butanol. After the addition of a 0.5 *M* aqueous solution of periodic acid (8 ml) and enough 0.5 *M* sodium hydroxide solution to bring the mixture to pH 8, it was stirred at room temperature for 10 h. Some sodium sulfite and water were added and the mixture was extracted with ether. The extract was washed with water, dried over sodium sulfate, and evaporated to give 161 mg of a grey liquid. Gas-phase chromatographic analysis (see above) indicated a single peak, retention time 10.7 min, μ (neat) no OH, C=C 5.92 (m); hence it was VIII*b*. Acid-catalyzed isomerization of the latter in a manner identical with the isomerization of VIII*a* (see above) yielded also a mixture of IV and IX, identified and separated by gas-phase chromatography. As in the above case, IV was the major product, but much less so.

Osmium Tetroxide – Periodate Oxidations of Manool

A solution of osmium tetroxide (20 mg) in *t*-butanol (2 ml) was added to a solution of manool (200 mg) in *t*-butanol (50 ml). After the addition of a 0.5 *M* aqueous solution of periodic acid (15 ml) and a 0.5 *N* sodium hydroxide solution (100 ml) the mixture was stirred for 45 min. Within 5–10 min a fine precipitate appeared. The mixture was extracted with chloroform, and the extract was washed with saturated brine solution and dried over sodium sulfate. Evaporation of the solvent, chromatography of the residue (235 mg) on silica gel (8 g), and elution with chloroform–methanol (20:1) yielded a solid (196 mg) which, on crystallization from chloroform – ethyl acetate, gave pentol XII, m.p. 186–187° (lit. (10) m.p. 184–185°); $[\alpha]_D$ −9° (*c*, 0.80 in pyridine).

A solution of osmium tetroxide (50 mg) in *t*-butanol (5 ml) was added to a solution of manool (500 mg) in *t*-butanol (250 ml). After the addition of a 0.5 *M* aqueous solution of periodic acid (30 ml) and a 0.1 *N*

solution (225 ml) of sulfuric acid the clear mixture was left to stand for 22 h. It then was extracted with ether and worked up as above. Chromatography of the residue (505 mg) on silica gel (15 g) and elution with pentane–ether (50:1) gave a solid (177 mg) which, on crystallization from hexane, gave ketal XIII, m.p. 119–121° (lit. (12) m.p. 115–116°); $[\alpha]_D$ +26° (*c*, 0.52) (lit. (12) $[\alpha]_D$ +31° (*c*, 1.08)); its infrared and proton magnetic resonance spectra were identical with those reported (12).

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86. Found: C, 77.92; H, 10.80.

Elution with pentane–ether (9:1) gave the diketone VI*b* (195 mg) as an oil, $[\alpha]_D$ −10.3° (*c*, 2.08) (lit. (10) $[\alpha]_D$ +36° (*c*, 1.0)); μ (neat) C=O 5.85 (s); δ C—CH_3 singlets at 0.71, 0.84, and 0.97 p.p.m., $COCH_3$ singlet at 2.08 p.p.m.

Anal. Calcd. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67. Found: C, 77.37; H, 10.44.

Elution with pentane–ether (4:1) gave a solid (52 mg) whose crystallization from acetone–hexane yielded crystals, m.p. 173–175°; $[\alpha]_D$ +40.5° (*c*, 0.83); μ (KBr) OH 2.76 (w), 2.91 (m); δ C—CH_3 singlets at 0.77, 0.81, 1.02, and 1.24 p.p.m., hydroxymethine broad singlet at 5.01 p.p.m., molecular ion *m/e* 310.

Anal. Calcd. for $C_{18}H_{30}O_4$: C, 69.64; H, 9.74. Found: C, 69.61, 69.55; H, 9.65, 9.53.

A solution of osmium tetroxide (40 mg) in *t*-butanol (4 ml) was added to a solution of manool (400 mg) in *t*-butanol (320 ml). After the addition of a 0.5 *M* aqueous solution of periodic acid (40 ml), the mixture was brought to pH 6.0 by the addition of 0.5 *N* sodium hydroxide solution and kept at this pH by the addition of a phosphate buffer solution (500 ml composed of 357.5 ml of a 0.1 *M* potassium dihydrogen phosphate solution, 10 ml of a 0.5 *N* sodium hydroxide solution, and 132.5 ml of water). The clear mixture was left to stand for 8 h and then treated with a solution of sodium sulfite (2 g) in water (50 ml), stirred for 2 min, and extracted with ether. Isolation as above led to the diketone VI*b* (332 mg).[1]

Execution of the pH 6 experiment as above, except for the use of only 200 ml of *t*-butanol and 20 ml of periodic acid (the reaction mixture remaining a suspension throughout the experiment), yielded diketone VI*b* (272 mg) and an oil (XIV), eluted with pentane–ether (5:1), $[\alpha]_D$ +36.9° (*c*, 2.05); μ (neat) OH 2.85 (m), C=O 5.84 (s), CH=CH_2 10.08 (m), 10.90 (m); δ C—CH_3 singlets at 0.71, 0.84, 0.97, and 1.25 p.p.m., vinyl 12-line signal at 4.93, 4.97, 5.05, 5.08, 5.12, 5.15, 5.35, 5.38, 5.77, 5.93, 6.05, and 6.23 p.p.m.

Anal. Calcd. for $C_{19}H_{32}O_3$: C, 78.03; H, 11.03. Found: C, 77.74; H, 11.29.

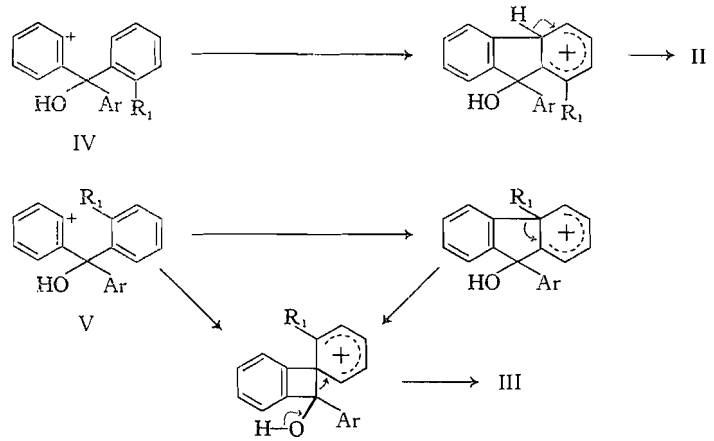
MOLECULAR REARRANGEMENT OF DIAZOTIZED *o*-AMINOPHENYLCARBINOLS

A. J. SISTI AND R. L. COHEN



Two new reaction paths[1] have recently been observed in the decomposition of diazonium salts: in certain instances, molecular rearrangement (2, 3), and a fragmentation reaction yielding a benzyne intermediate (2, 4).

The first example of the rearrangement involved the conversion of 9-*o*-aminophenylfluorenol into tribenzotropone (5). More recently (2), the scope of the rearrangement was extended to a group of *o*-aminophenylcarbinols (I), yielding substituted 9-fluorenols II, ketones III (resulting from molecular rearrangement), and phenols (eq. [1]).

[1] 

I II III

The previous study demonstrated the necessity of an *o*-substituent (only the *o*-methyl substituent was studied (I, $R_1 = CH_3$)) for the production of ketone III. These results (Table I (*a*–*e*)) suggested that the lifetime of the aryl cation formed by the loss of nitrogen is very short compared with the time required for rotational equilibrium within the molecule (2). The following rationale was postulated.

Structures IV and V represent conformations in which the unsubstituted *o*-position is within and without incipient bonding distance to the aryl cation.[2]

Two new *o*-substituents, chloro and ethyl, were introduced to increase further the scope of the rearrangement and to offer more evidence to substantiate the previously postulated rationale.

[1] *For the more established reactions of the highly reactive aryl cation, see ref. 1.*
[2] *Structures IV and V are not intended to imply that the two rings are coplanar.*

For personal use only.

The aminocarbinols listed in Table II were prepared from the corresponding Grignard reagents and acetyl anthranil, yielding the amido alcohols (6). The amido alcohols were subsequently hydrolyzed with alcoholic potassium hydroxide to the aminocarbinols.

The amino alcohols were diazotized in aqueous sulfuric acid and the diazonium salts were allowed to decompose at room temperature. Column chromatography on alumina was employed to separate the neutral materials.

Since all the diazonium salt decompositions were carried out in strong acid conditions, the heterolytic mechanism is most probably operating (1*c*).[3] The results are presented in Table I.

TABLE I

Yields of ketones and fluorenols from diazonium salts

	Amine I				
	R_1	R_2	R_3	% ketone III*	% fluorenol II†
a‡	H	H	H	0	46
b‡	H	OCH_3	H	0	48
c‡	CH_3	H	H	16.5 (15)	19
d‡	CH_3	CH_3	H	21.0 (16.6)	19
e‡	CH_3	OCH_3	H	28.6 (22.6)	21
f§	CH_3	OCH_3	CH_3	38 (27)	16
g	Cl	H	H	2.9	9.5
h	Cl	CH_3	H	8.8	9.9
i	Cl	OCH_3	H	11.0	8.7
j	CH_2CH_3	H	H	16.9 (13.0)	31.3
k	CH_2CH_3	OCH_3	H	33 (28)	28.4

*Yields in parentheses refer to recrystallized ketone; those without parentheses refer to chromatographed but not recrystallized material.
†In all cases, yields are based on recrystallized material.
‡Previously reported (2).
§This reaction, which was described previously (3), also gave a 7% yield of 2-(2,5-dimethyl-4-methoxybenzoyl)-2′,5′-dimethyl-4′-methoxyazobenzene.

The most significant feature of the results presented in Table I is that ketone is only obtained from the triphenylcarbinol derivatives possessing an *o*-substituent. The effect of the three *o*-substituents (chloro, methyl, and ethyl) cannot be solely electrical, since compound I*b*, containing the powerful electron-donating *p*-methoxyl group, yields no ketone. It may be noted that electron-donating substituents in the *p*-position of the migrating aryl group increase the yields of ketone significantly provided an *o*-substituent is present (I*d*, I*e*, I*h*, I*i*, and I*k*). In addition, one observes that ketone formation also appears to be dependent upon the electrical properties of the *o*-substituent (compare I*c* and I*j* with I*g*). These electrical effects are not unexpected since the rearrangement involves the migration of an aryl group to an electron-deficient site.

Another striking feature of Table I is that for a *given* *o*-substituent the yield of fluorenol remains unaltered when electron-donating *p*-substituents are introduced (I*g*–I*i*, I*c*–I*f*, and I*j*–I*k*). These data are consistent with the rationale previously postulated, based upon a very short lifetime for the aryl cation, the total number of free *o*-positions, and the relative populations of conformations IV and V. One additional observation, however, can be made. If the same relative population of conformations IV and V is assumed for R_1 = Cl, CH_3, and CH_2CH_3, the lower yield of fluorenol for *o*-chloro versus *o*-methyl and *o*-ethyl (I*g* versus I*c* and I*j*) may be ascribed to an adverse electrical effect.

The evidence presently available indicates that ketone formation resulting from the aryl cation is directly related to the total number of substituted *o*-positions and the electrical property of the *o*-substituent.

[3]*Recently an ion–diradical has been postulated as the intermediate (7).*

EXPERIMENTAL[4]

Aryl halides were prepared as follows: *o*-chlorobromobenzene (8), b.p. 197–200° (reported (8) b.p. 199–200°); 4-bromo-3-chlorotoluene (9), b.p. 75° at 2 mm (reported (9) b.p. 115–116° at 25 mm); 3-chloro-4-iodoanisole (10), b.p. 93–97° at 0.7 mm (reported (11) b.p. 127–130° at 6 mm); *o*-iodoethylbenzene (12), b.p. 56° at 0.7 mm (reported (12) b.p. 92–95° at 13 mm); 3-ethyl-4-iodoanisole, b.p. 125–126° at 5.5 mm (reported (10) b.p. 120–125° at 5 mm).

Synthesis of Acetamido Alcohols

All of the acetamido alcohols were prepared by the reaction of the appropriate arylmagnesium halide with acetyl anthranil (13). In each case a threefold excess of Grignard reagent was used. The ethereal solution of the Grignard reagent was cooled in an ice bath during the addition of a benzene solution of acetyl anthranil. The reactions were then completed by refluxing the solutions for 3 h followed by stirring at room temperature overnight. The reaction mixture was then hydrolyzed with an ammonium chloride solution, and the organic layer was separated and washed with 6 *M* sodium hydroxide followed by water. After the ether layer was dried over calcium sulfate and the solvent removed, the residue was crystallized, and recrystallized from benzene. The yields ranged from 18 to 32%. Three acetamido alcohols were characterized; the others were directly hydrolyzed to the amino alcohols listed in Table II.

The following acetamido alcohols were characterized.

2-Acetaminophenyldi-(2-chlorophenyl)carbinol had m.p. 188–189°.

Anal. Calcd. for $C_{21}H_{17}Cl_2NO_2$: C, 65.29; H, 4.44; N, 3.63. Found: C, 65.14; H, 4.55; N, 3.69.

2-Acetaminophenyldi-(2-chloro-4-methylphenyl)carbinol had m.p. 171–172°.

Anal. Calcd. for $C_{23}H_{21}Cl_2NO_2$: C, 66.68; H, 5.10; N, 3.38. Found: C, 66.57; H, 5.20; N, 3.40.

2-Acetaminophenyldi-(2-ethylphenyl)carbinol had m.p. 184–186°.

Anal. Calcd. for $C_{25}H_{27}NO_2$: C, 80.39; H, 7.29; N, 3.75. Found: C, 80.33; H, 7.28; N, 3.66.

Synthesis of Amino Alcohols

The amino alcohols listed in Table II were prepared by the hydrolysis of the corresponding acetamido alcohols. The hydrolysis was accomplished by refluxing the acetamido alcohols with a 20% alcoholic potassium hydroxide solution for 24–30 h. The mixture was then poured into water and extracted with ether, and the ether layer was dried over calcium sulfate. After removal of the ether the residue was crystallized from benzene – petroleum ether (b.p. 30–60°).

Diazotizations

The amino alcohols were diazotized in 100–150 ml of 5–10% sulfuric acid and 50 ml of dioxane at 0–5° with slightly more than an equivalent quantity of sodium nitrate. The aqueous acid (100–150 ml) was cooled to 0–5°, and the amino alcohol (8–17 mmoles) dissolved in 50 ml of dioxane was added. To the cooled solution was added the sodium nitrate in 10 ml of water. The solution was then allowed to stand at 0–10° for 1–2 h, after which time the solution was permitted to warm to room temperature and remain overnight. The mixture was then warmed to 40–50° to complete the decomposition (0.5–1 h). The mixture was extracted three times with ether and the ether extracts were washed with 5% sodium hydroxide to remove phenolic material, which was not characterized further. The dried ether solution was then evaporated and the residue examined as described below.

Products from Ig

The neutral residue was dissolved in 75% petroleum ether – benzene and adsorbed on alumina.[5] Elution with more of the same solvent mixture yielded 0.165 g (2.9%) of an oil, ν 1 685 cm^{-1} (chloroform). The oil resisted all attempts at crystallization. The ketone, however, was assigned the structure of *2-chloro-2′-(2-chlorophenyl) benzophenone* (III*g*).

Elution of the column with 70% benzene–chloroform gave an oil which was crystallized from benzene – petroleum ether, yielding 0.538 g (9.5%) of *1-chloro-9-(2-chlorophenyl)-9-fluorenol* (II*g*), m.p. 131–132°.

Anal. Calcd. for $C_{19}H_{12}Cl_2O$: C, 69.74; H, 3.70. Found: C, 69.44; H, 3.58.

A duplicate diazotization with Ig yielded essentially the same results: 3.2% ketone (III*g*) and 8.9% fluorenol (II*g*).

Products from Ih

The neutral residue was dissolved in equal volumes of benzene – petroleum ether and adsorbed on alumina. Elution with the same solvent mixture yielded 0.418 g (8.8%) of a yellow oil, ν 1 677 cm^{-1} (chloroform). The oil could not be crystallized; however, it was assigned the structure of *2-chloro-4-methyl-2′-(2-chloro-4-methylphenyl) benzophenone* (III*h*).

Elution of the column with benzene gave an oil which was crystallized from benzene – petroleum ether, yielding 0.470 g (9.9%) of *2-chloro-4-methyl-9-(2-chloro-4-methylphenyl)-9-fluorenol* (II*h*), m.p. 163–164°.

Anal. Calcd. for $C_{21}H_{16}Cl_2O$: C, 71.00; H, 4.54. Found: C, 70.88; H, 4.74.

[4]*Microanalyses were carried out by Spang Microanalytical Laboratory, Ann Arbor, Michigan. Melting points and boiling points are not corrected.*

[5]*All chromatograms described herein were conducted with ordinary Merck alumina (20 g/g of compound).*

THE STRUCTURE OF THE MALEIC ANHYDRIDE – ACETYLACETONE ADDUCT

R. D. Bailey and G. M. Strunz

The reaction of maleic anhydride with acetylacetone was reported by Berner (1) in 1946 to give rise to a 2:1 adduct, m.p. 180° (decomp.), $C_{13}H_{12}O_8$. Similarly, ethyl acetoacetate was shown to give rise to an analogous adduct, $C_{14}H_{14}O_9$. The structures I*a* and I*b*, respectively, were assigned to these adducts, largely on the basis of their degradation

Products from Ii

The neutral residue was dissolved in equal volumes of benzene – petroleum ether and adsorbed on alumina. Elution with benzene yielded 0.301 g (11%) of a light-yellow oil, ν 1 672 cm^{-1} (chloroform). The oil resisted crystallization; however, it was assigned the structure of *2-chloro-4-methoxy-2'-(2-chloro-4-methoxyphenyl) benzophenone* (III*i*).

Elution of the column with equal volumes of benzene–chloroform gave, after recrystallization from benzene – petroleum ether, 0.249 g (8.7%) of *2-chloro-4-methoxy-9-(2-chloro-4-methoxyphenyl)-9-fluorenol* (II*i*), m.p. 191–193°.

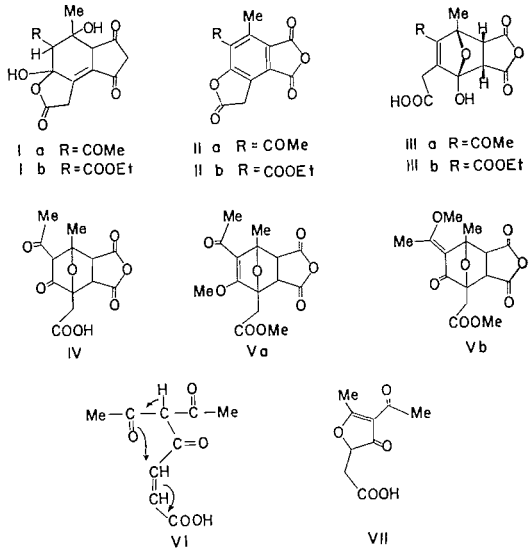
THE STRUCTURE OF THE MALEIC ANHYDRIDE – ACETYLACETONE ADDUCT



R. D. Bailey and G. M. Strunz

The reaction of maleic anhydride with acetylacetone was reported by Berner (1) in 1946 to give rise to a 2:1 adduct, m.p. 180° (decomp.), $C_{13}H_{12}O_8$. Similarly, ethyl acetoacetate was shown to give rise to an analogous adduct, $C_{14}H_{14}O_9$. The structures I*a* and I*b*, respectively, were assigned to these adducts, largely on the basis of their degradation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to the aromatic compounds II*a* and II*b* through the action of concentrated sulfuric acid. Recently, Bird and Molton (2) have proposed the bicyclic hemiketal structure III*b* for the ethyl acetoacetate adduct, the acetylacetone product being considered, by analogy, to be III*a*.

Both adducts have been found to yield a dimethyl derivative readily on treatment with ethereal diazomethane (1, 2). The product obtained by the British authors contains no hydroxyl group, and its structure has been proposed on the basis of its nuclear magnetic resonance spectrum in conjunction with mechanistic considerations. A rather unusual rearrangement is postulated to account for the formation of the aromatic substance II*b*. The formulation IV for the acetylacetone adduct appeared to us to be in closer accord with the results of Berner and Bird, and with the additional evidence described below. A close structural relationship between IV and I*a* is evident.

We have prepared the acetylacetone adduct, its dimethyl derivative, and the aromatic compound II*a* as described by Berner, and have established conclusively that the adduct is a β-dicarbonyl compound and that the diazomethane product is the enolether of a β-diketone, best formulated as IV and V (*a* and *b*), respectively.

The infrared spectrum of IV (KBr) shows broad absorption between 2 400 and 3 500 cm^{-1} and bands at 1 870, 1 835 (low intensity), 1 780, and 1 700 cm^{-1} (strong). A strong band at 1 230 cm^{-1} is in agreement with a cyclic five-membered ether and (or) anhydride (3). The ultraviolet chromophore (dioxane) clearly excludes the possibility that the compound is an α,β-unsaturated ketone. Absorption at 275 mμ (ε 2 100) is consistent with a slightly enolized β-dicarbonyl system.[1] Addition of a trace of aqueous base caused a change in the chromophore to λ_{max} 295 mμ (ε 11 400). Neutralization regenerated a chromophore closely similar to that of the starting material.

The dimethyl derivative V ($C_{15}H_{16}O_8$) shows infrared absorption (KBr) at 1 865, 1 830 (low intensity), 1 780, and 1 740 cm^{-1} (strong). Strong bands at 1 710 and 1 610 cm^{-1} are consistent with the carbonyl and C=C absorption, respectively, of the enolether formed by exocyclic enolization of an α-acetyl five-membered ketone (4).

[1]*The formulation IV allows for the existence of a lactol tautomer which might be involved in the enolization equilibrium.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The ultraviolet absorption (dioxane) at 276 mμ (ϵ 10 000) is in excellent agreement with the predicted chromophore.

Two possible structures (V*a* and V*b*) can clearly arise from the reaction of IV with diazomethane. That the crystalline product of this reaction was a mixture of both isomers became evident from a study of its nuclear magnetic resonance spectrum. The methyl and —CH_2— protons attached to the bridgehead positions show three- and two-proton singlets at 8.11 and 6.96 τ, respectively. The ester methyl appears as a singlet at 6.25 τ. A pair of singlets at 7.84 and 7.56 τ in the ratio 1:4, together integrating for three protons, accounts respectively for the methyl hydrogens of the acetyl side chain of V*a* and the corresponding methyl protons of V*b*. The enolether methoxyls of these isomers appear as singlets in the same ratio, at 6.03 and 6.12 τ. An AB pattern (partially hidden) centered at 6.47 τ (J = 7.9 c.p.s.) accounts for the remaining two protons. It is not possible, on the basis of this coupling constant, to determine whether the configuration of the adduct is *exo* or *endo* (5).

By varying the conditions of reaction it was possible to increase the ratio of V*a* to V*b* to approximately 2:1, as determined by nuclear magnetic resonance spectroscopy. So far, only the isomer V*b* has been obtained in a pure state.

Finally, the mass spectrum of the crystalline isomer mixture V appears to be in agreement with the assigned structures. A weak molecular ion peak with *m/e* 324 can be observed. The major peaks in the higher mass region correspond to ions with *m/e* 226, 167, and 154.

We consider that one possible mode of formation of IV might involve an initial attack by the enol of acetylacetone on a maleic anhydride carbonyl, giving VI. The latter could conceivably cyclize as shown, yielding VII, which, as its 3-hydroxyfuran tautomer, could undergo Diels–Alder addition of a second molecule of maleic anhydride, giving rise to IV.

EXPERIMENTAL

Melting points were determined on a hot stage apparatus and are uncorrected. Infrared spectra were determined on a Perkin–Elmer Infracord model 137B spectrophotometer. Ultraviolet spectra were obtained on a Beckman DK-2 spectrophotometer. Nuclear magnetic resonance spectra were measured with a Varian Associates 56.4 Mc.p.s. spectrometer. The mass spectrum was obtained on a Hitachi Perkin–Elmer RMU-6D mass spectrometer. Microanalyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Michigan.

The procedures of Berner (1) were followed for the preparation of IV, V, and II, and his experimental results were essentially duplicated.

Adduct IV had m.p. 176–181° (decomp.).

The dimethyl derivative V was prepared by addition of the powdered adduct IV (1.5 g) to approximately 5 equivalents of diazomethane in ether (200 ml). The crystalline product which separated had m.p. 142–150° and was used directly in the spectroscopic studies. An analytical sample (pure V*b*) was prepared by recrystallization from benzene, m.p. 148–154°.

Anal. Calcd. for $C_{15}H_{16}O_8$: C, 55.55; H, 4.97. Found: C, 55.47; H, 4.92.

By varying the concentration and excess of diazomethane, it was possible to vary the relative proportions of V*a* and V*b* formed. The presence of the isomer V*a* was manifested in both the infrared and nuclear magnetic resonance spectra.

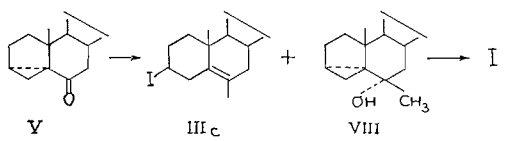
SYNTHESIS OF 6-METHYLCHOLESTA-3,5-DIENE; SOLVOLYSIS OF 6-METHYLCHOLESTERYL IODIDE[1]

GEORGE JUST AND EDWARD LEE-RUFF[2]

In connection with a study of the photolysis of substituted cholesta-3,5-dienes, we required a sample of 6-methylcholesteryl ethyl ether and adequate amounts of 6-methylcholesta-3,5-diene (I). The latter compound had been obtained by Bauslaugh (1) in an unsatisfactory yield.



We therefore investigated an alternate pathway. 6α-Methylcholestan-3β,6β-diol (II) (2), obtained as outlined in Reaction Scheme 1, was submitted to various dehydrating agents. Treatment of II with 10% ethanolic hydrochloric acid gave 6-methylcholesterol (III*a*) (2) and 6-methylcholesteryl chloride (III*b*) (3) in 67 and 20% yields, respectively.

REACTION SCHEME 1.

Reaction of 6-methylcholesterol with thionyl chloride gave di(6-methylcholesteryl) sulfite (IV). The same product was obtained by reacting diol II with thionyl chloride. Its structure was proven by hydrolysis to III*a*. Pyrolysis of sulfite IV gave 6-methylcholesterol (III*a*) and diene I. Pyrolysis of 6-methylcholesterol with anhydrous copper sulfate gave a 1:1 mixture of the desired diene I and di(6-methylcholesteryl) ether.

The most convenient sequence proved to be that depicted in Reaction Scheme 2.

REACTION SCHEME 2.

Reaction of 3α,5-cyclo-5α-cholestan-6-one (V) with methylmagnesium iodide gave 6β-methyl-3α,5-cyclo-5α-cholestan-6α-ol (VIII) (4) in a 75% yield. The minor product of this reaction was 6-methylcholesteryl iodide (III*c*). The assignment of the stereochemistry of alcohol VIII at C-6 was based on arguments similar to those used to explain the stereochemistry of the lithium aluminium hydride reduction of V (5). The formation of 6-methylcholesteryl iodide is easily rationalized, since the reaction medium contained iodide ions and a Lewis acid. Dehydration and rearrangement of the cyclopropyl carbinol was achieved by stirring alcohol VIII in dry benzene with phosphorus pentoxide. The desired 6-methylcholesta-3,5-diene (I) was obtained in over 90% yield.

*6-Methylcholesteryl Ethyl Ether; a Study of the Solvolysis of 6-Methylcholesteryl Iodide (III*c*)*

One of the by-products obtained above was 6-methylcholesteryl iodide (III*c*). Since a sample of 6-methylcholesteryl ethyl ether (VII*a*) was required for comparison purposes, we solvolyzed iodide IIIc in ethanol. The major product obtained was cycloether VI*a*, accompanied by small amounts of VII*a*. Cycloether VI*a* was not stable under the solvolysis conditions and was slowly transformed to VII*a*. When cycloether VI*a* was treated with acidified ethanol at room temperature, it was quantitatively converted into ether VII*a*. The methanolysis and hydrolysis of iodide III*c* proceeded in a similar fashion.

IIIc VIa, R=Et VIb, R=Me VIc, R=H VIIa, R=Et VIIb, R=Me

REACTION SCHEME 3.

The structure of 6-methylcholesteryl ether was proven by comparison with the product obtained from the reaction of the potassium salt of III*a* with ethyl iodide. The assignments of the structures of the cyclo compounds VI*a*–VI*c* were based on the infrared and nuclear magnetic resonance spectra (which all showed cyclopropyl absorptions at 3 080 and 3 020 cm^{-1} (infrared) and 0.4–0.6 p.p.m. (nuclear magnetic resonance)) and the fact that acid treatment resulted in the formation of cholesteryl derivatives (VII*a*, VII*b*, and III*a*).

When 6-methylcholesteryl *p*-toluenesulfonate was solvolyzed under conditions identical with those used for the hydrolysis of 6-methylcholesteryl iodide, the same relative yield of 6α-methyl-3α,5-cyclo-5α-cholestan-6β-ol (VI*c*) was obtained. It is therefore apparent that the same homoallylic carbonium ion is involved in both the iodide and tosylate solvolyses, and the low yields of VI*c* reported by Davis *et al.* can be rationalized by the decomposition of VI*c* to 6-methylcholesterol (III*a*) under the reported reaction and work-up conditions (4). These results are therefore quite similar to those reported by Summers in the spirostane series (6).

EXPERIMENTAL

The general experimental details have been given in ref. 7. All preparative thin-layer chromatography (t.l.c.) separations were performed with glass plates (20 × 20 cm) covered with silica gel (½ mm, E. Merck A.G.).

Acid Dehydration of Diol II

A solution of 1.5 g of diol II in 50 ml of ethanol containing 5 ml of concentrated hydrochloric acid was refluxed for 3 h. The reaction mixture was diluted with 200 ml of ether, washed with 5% aqueous sodium bicarbonate and water, and dried with anhydrous magnesium sulfate. The residue, after evaporation,

For personal use only.

crystallized from ether–hexane, giving 1.05 g of 6-methylcholesterol (III*a*), m.p. 131–135°. Recrystallization from hexane gave an analytic sample, m.p. 139–141°; the mixed melting point with an authentic sample showed no depression; ν 3 550 and 1 050 – 1 060 cm^{-1} (OH); δ 3.55 p.p.m. (1 H, multiplet, C_3—H), 2.90 p.p.m. (1 H, half of an AB quartet, C_4—H), 1.85 p.p.m. (1 H, singlet, exchangeable with D_2O, —OH), and 1.65 p.p.m. (3 H, singlet, C=C—CH_3). Crystallization of the mother liquor from ethanol–ether gave 300 mg of 6-methylcholesteryl chloride, m.p. 101–104°. Recrystallization from ethanol raised the m.p. to 105–106°; ν 847 cm^{-1} (C—Cl); δ 3.65 p.p.m. (1 H, multiplet, C_3—H), 3.0 p.p.m. (1 H, half of an AB quartet, C_4—H), and 1.62 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{28}H_{47}Cl$: C, 80.24; H, 11.21; Cl, 8.46. Found: C, 80.21; H, 11.21; Cl, 8.32.

Dehydration of Diol II with Thionyl Chloride – Pyridine

A solution of 200 mg of diol II in 15 ml of anhydrous pyridine was cooled to 0°, and 0.1 ml of thionyl chloride was added dropwise, with stirring. The reaction mixture was allowed to reach room temperature and the stirring was continued for an additional hour. The mixture was quenched with 20 ml of cold water, and the resulting white precipitate was filtered off, washed with water until neutral, and crystallized from ethanol–ether, giving 190 mg of di(6-methylcholesteryl) sulfite (IV), m.p. 191–192°; ν 1 200, 950, and 925 cm^{-1} (strong, sulfite); δ 4.25 p.p.m. (1 H, multiplet, C_3—H), 2.9 p.p.m. (1 H, half of an AB quartet, C_4—H), and 1.65 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{56}H_{94}SO_3$: C, 79.40; H, 11.17; S, 3.80. Found: C, 79.29; H, 10.95; S, 4.10.

Dehydration of 6-Methylcholesterol (IIIa) with Thionyl Chloride – Pyridine

The same procedures as for the thionyl chloride dehydration of diol II were used for the dehydration of 100 mg of 6-methylcholesterol (III*a*). This yielded 90 mg of the diester sulfite IV, identical in all respects with the sample obtained above.

Acid Hydrolysis of Diester Sulfite IV

A solution containing 100 mg of IV in 20 ml of ethanol and 2 ml of concentrated hydrochloric acid was refluxed for 1 h. The reaction mixture was worked up in the usual manner, yielding 70 mg of 6-methylcholesterol (III*a*), identical in all respects with an authentic sample.

Pyrolysis of Diester Sulfite IV

A melting point tube containing 2 mg of IV was heated to 205°. The pyrolysate was dissolved in ether. Quantitative t.l.c. showed two stains, one having an R_f value identical with that of 6-methylcholesterol. The ultraviolet spectrum showed diene absorptions at 236, 242, and 249 mμ.

Pyrolysis of 6-Methylcholesterol (IIIa)

An intimate mixture of 500 mg of 6-methylcholesterol (III*a*) and 500 mg of anhydrous cupric sulfate was heated to 200° for 20 min. The residue was extracted with benzene and the extract chromatographed on silica gel. Hexane eluted 260 mg of 6-methylcholesta-3,5-diene, which was crystallized from an ethanol–ether mixture, m.p. 86–88°; ν 3 040 and 1 650 cm^{-1} (C=C—H); λ_{max}^{EtOH} 236 mμ (ϵ 18 220), 242 mμ (ϵ 19 800), and 249 mμ (ϵ 13 900); δ 6.42 p.p.m. (1 H, doublet, J = 10 c.p.s., C=C_4—H), 5.80 p.p.m. (1 H, broad signal, C=C_3—H), and 1.72 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{28}H_{46}$: C, 87.88; H, 12.12. Found: C, 87.91; H, 12.28.

Hexane–benzene eluted 140 mg of di(6-methylcholesteryl) ether, which was crystallized from ether, m.p. 215–216°; ν 1 100 and 1 080 cm^{-1} (ether); δ 3.35 p.p.m. (1 H, multiplet, C_3—H), 2.87 p.p.m. (1 H, half of an AB quartet, C_4—H), and 1.65 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{56}H_{94}O$: C, 85.86; H, 12.10. Found: C, 85.86; H, 11.88.

6β-Methyl-3α,5-cyclo-5α-cholestan-6α-ol (VIII)

A solution of 5 g of 3α,5-cyclo-5α-cholestan-6-one (V) in 100 ml of ether was added dropwise to 120 ml of an ethereal solution of methylmagnesium iodide (3.2 g magnesium turnings, 8.8 ml methyl iodide). The solution was heated under reflux for 2 h. The excess reagent was destroyed by slowing adding 50 ml of 10% aqueous ammonium chloride. The ether layer was washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The oily residue was chromatographed on alumina (activity II–III, 140 g). Elution with hexane gave 6-methylcholesteryl iodide (III*c*) (1.1 g, 20%), m.p. 103–105°. Two crystallizations from ethanol–ether raised the melting point to 110–111°; δ 4.00 p.p.m. (1 H, broad signal, C_3—H), 2.95 p.p.m. (2 H, quartet, C_4—H), and 1.65 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{28}H_{47}I$: C, 65.88; H, 9.21; I, 24.81. Found: C, 65.93; H, 9.33; I, 24.94.

Elution with benzene–ether gave 3.7 g of 6β-methyl-3α,5-cyclo-5α-cholestan-6α-ol (VIII), identical in all respects with an authentic sample (4), m.p. 91–91.5°, $[\alpha]_D^{19}$ +38.2° (*c*, 0.87).

6-Methylcholesta-3,5-diene (I)

A solution of 3.5 g of 6β-methyl-3α,5-cyclo-5α-cholestan-6α-ol (VIII) in 100 ml of anhydrous benzene containing 3 g of phosphorus pentoxide was stirred for 3 h at room temperature. Ether extraction and crystallization from ethanol gave 3.2 g of 6-methylcholesta-3,5-diene (I), identical in all respects with the sample prepared above.

Ethanolysis of 6-Methylcholesteryl Iodide (IIIc)

A solution of 300 mg of iodide III*c* in 50 ml of absolute ethanol containing 200 mg of potassium acetate was refluxed for 1 h. The mixture was diluted with 150 ml of ether, washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residue was chromatographed on two t.l.c. plates (hexane–benzene (1:1)), giving 188 mg of oily 6β-ethoxy-6α-methyl-3α,5-cyclo-5α-cholestane (VI*a*), ν 3 080 and 3 020 cm^{-1} (cyclopropane), 1 115 and 1 085 cm^{-1} (ether); δ 3.39 p.p.m. (2 H, two overlapping quartets, O—CHH′—CH_3) and 0.4–0.6 p.p.m. (multiplet, cyclopropyl protons).

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 84.03; H, 12.12.

6-Methylcholesteryl Ethyl Ether (VIIa)

From 6-Methylcholesterol (IIIa)

To a solution of 180 mg of 6-methylcholesterol (III*a*) in 50 ml of anhydrous benzene was added 200 mg of potassium chips. The mixture was refluxed for 3 h and cooled to room temperature, after which 1 ml of ethyl iodide was added. The mixture was refluxed for a further 24 h. After the solution was cooled, absolute ethanol was slowly added to destroy the excess potassium. The mixture was diluted with 100 ml ether, washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated. The residue (131 mg) was chromatographed on one t.l.c. plate (benzene), giving 52 mg of 6-methylcholesteryl ethyl ether (VII*a*), m.p. 95–96°; ν 1 105 cm^{-1} (ether); δ 3.42 p.p.m. (2 H, quartet, O—CH_2—CH_3), 2.80 p.p.m. (1 H, multiplet, C_3—H), and 1.55 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 83.95; H, 12.10.

From Cycloether VIa

A solution of 100 mg of cycloether VI*a* in 25 ml of absolute ethanol containing 0.5 ml of 72% perchloric acid was stirred overnight. The resulting precipitate was filtered off, washed with water, and crystallized from ethanol–ether, giving 75 mg of 6-methylcholesteryl ethyl ether (VII*a*), identical in all respects with the sample prepared above.

Methanolysis of 6-Methylcholesteryl Iodide (IIIc)

A solution of 300 mg of iodide III*c* in 50 ml of absolute methanol containing 200 mg of potassium acetate was stirred at room temperature for 24 h. The reaction mixture was worked up in the usual manner, giving 290 mg of an oil, which was chromatographed on two t.l.c. plates (hexane–benzene (1:1)), yielding 135 mg of oily 6β-methoxy-6α-methyl-3α,5-cyclo-5α-cholestane (VI*b*), ν 3 080 and 3 020 cm^{-1} (cyclopropane), 1 089 cm^{-1} (ether); δ 3.11 p.p.m. (3 H, singlet, O—CH_3) and 0.3–0.6 p.p.m. (multiplet, cyclopropyl protons).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. Found: C, 83.96; H, 12.06.

Acid Reaction of Cycloether VIb

The same procedures were followed as for the acid rearrangement of cycloether VI*a* (100 mg of VI*b* being used). This gave, after crystallization from methanol–ether, 65 mg of 6-methylcholesteryl methyl ether, m.p. 101–102°; ν 1 105 cm^{-1} (ether); δ 3.20 p.p.m. (3 H, singlet, O—CH_3), 2.75 p.p.m. (1 H, multiplet, C_3—H), and 1.57 p.p.m. (3 H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. Found: C, 84.00; H, 12.05.

Hydrolysis of 6-Methylcholesteryl Iodide (IIIc)

A solution of 200 mg of iodide III*c* in 25 ml of acetone containing 5 ml of water and 50 mg of potassium bicarbonate was stirred for 72 h. This was worked up in the usual manner to give 184 mg of an oily residue. Chromatography of this residue on two t.l.c. plates (benzene) yielded 147 mg of oily cycloalcohol VI*c*, ν 3 620, 1 105, and 1 020 cm^{-1} (alcohol), 3 080 and 3 020 cm^{-1} (cyclopropane); δ 0.2–0.5 p.p.m. (multiplet, cyclopropyl protons).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.08. Found: C, 84.06; H, 11.91.

Acid Rearrangement of Cycloalcohol VIc

A solution of 100 mg of cycloalcohol VI*c* in 50 ml of ether containing 1 ml of 72% perchloric acid was stirred overnight. The solution was diluted to 100 ml with ether, washed with 5% aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure, giving 95 mg of 6-methylcholesterol (III*a*), identical in all respects with the sample prepared above.

Solvolysis of 6-Methylcholesteryl p-Toluenesulfonate

The tosylate of 6-methylcholesterol was prepared according to the procedures of Davis *et al.* (4). A solution of 200 mg of the tosylate (m.p. 128–133°) in 25 ml of acetone containing 5 ml of water and 50 mg of potassium bicarbonate was stirred for 72 h. The usual work-up gave 194 mg of an oily residue, which was chromatographed on two t.l.c. plates, yielding 63 mg of unreacted 6-methylcholesteryl *p*-toluenesulfonate and 90 mg of cycloalcohol VI*c*, identical in all respects with the sample prepared above.

A CONVENIENT METHOD FOR THE PREPARATION OF OPTICALLY ACTIVE BENZYL-α-*d* ALCOHOL

SAUL WOLFE AND ARVI RAUK

Optically active benzyl-α-*d* alcohol was synthesized some years ago and the levo enantiomer shown to have the *R* absolute configuration (I) by Streitwieser and his co-workers (1). Their method involved the preparation of benzaldehyde-*d* from benzonitrile (2), the reduction of (+)-camphor to (−)-isoborneol with lithium aluminium hydride (3), and then asymmetric reduction of the benzaldehyde-*d* with isobornyloxymagnesium bromide (4). (−)-Benzyl-α-*d* alcohol, $[\alpha]_D$ −0.715° (neat), was obtained after a lengthy isolation procedure. The optical purity of this material cannot be better than 45%, since Mosher and his co-workers have now found (5) that the optically active benzyl-α-*d* alcohol produced in the reduction of benzaldehyde-*d* with actively fermenting yeast has $[\alpha]_D^{24}$ 1.58° (neat). The same workers also obtained (+)-benzyl-α-*d* alcohol, $[\alpha]_D^{26}$ 0.32° (neat), in a 16% yield (average of two runs) from the reaction of benzaldehyde-α-*d* with the optically active Grignard reagent from (+)-1-chloro-2-methylbutane.

During another investigation, we recently had to prepare optically active benzyl-α-*d* alcohol. Since high optical purity was not essential for this study, an alternative to the Streitwieser procedure was worked out and forms the subject of this note. The new synthesis, which proceeds with 30% stereospecificity, has the advantage of providing the dextro alcohol in 1 day's working time, with all the reactions being performed in a single vessel. The deuterium source is sodium borodeuteride; from 0.5 g of this compound is obtained 1.1 g of (+)-benzyl-α-*d* alcohol. The actual reducing agent is (−)-diisopinocampheyldeuterioborane (II), prepared from (+)-α-pinene and deuterated diborane, the latter in turn prepared in tetrahydrofuran by the reduction of boron trifluoride with sodium borodeuteride.

Brown and his co-workers have shown (6, 7) that hydroboration of olefins with undeuterated II followed by the usual oxidative work-up (8) leads to optically active alcohols and (−)-isopinocampheol. The reduction of methyl ketones III to optically active secondary alcohols (11–30% excess of the *R* enantiomer, i.e. IV) was reported in a brief communication (9).[1] By analogy with this work, the reduction of benzaldehyde (VI) by II is expected to produce VII, i.e. *S*-(+)-benzyl-α-*d* alcohol.

No volatile compounds were obtained directly from the reaction of II with benzaldehyde, even after prolonged treatment with sodium hydroxide. Benzyl alcohol and isopinocampheol were readily obtained, however, when this alkaline mixture was treated with

[1]*Although it is not specifically stated in this communication that the reducing agent was (−)-diisopinocampheylborane and not the (+)-isomer V, we infer that the former was, in fact, used, since the preparation of V was not described until somewhat later (7).*

During another investigation, we recently had to prepare optically active benzyl-α-*d* alcohol. Since high optical purity was not essential for this study, an alternative to the Streitwieser procedure was worked out and forms the subject of this note. The new synthesis, which proceeds with 30% stereospecificity, has the advantage of providing the dextro alcohol in 1 day's working time, with all the reactions being performed in a single vessel. The deuterium source is sodium borodeuteride; from 0.5 g of this compound is obtained 1.1 g of (+)-benzyl-α-*d* alcohol. The actual reducing agent is (−)-diisopinocampheyldeuterioborane (II), prepared from (+)-α-pinene and deuterated diborane, the latter in turn prepared in tetrahydrofuran by the reduction of boron trifluoride with sodium borodeuteride.

Brown and his co-workers have shown (6, 7) that hydroboration of olefins with undeuterated II followed by the usual oxidative work-up (8) leads to optically active alcohols and (−)-isopinocampheol. The reduction of methyl ketones III to optically active secondary alcohols (11–30% excess of the *R* enantiomer, i.e. IV) was reported in a brief communication (9).[1] By analogy with this work, the reduction of benzaldehyde (VI) by II is expected to produce VII, i.e. *S*-(+)-benzyl-α-*d* alcohol.

No volatile compounds were obtained directly from the reaction of II with benzaldehyde, even after prolonged treatment with sodium hydroxide. Benzyl alcohol and isopinocampheol were readily obtained, however, when this alkaline mixture was treated with

[1]*Although it is not specifically stated in this communication that the reducing agent was (−)-diisopinocampheylborane and not the (+)-isomer V, we infer that the former was, in fact, used, since the preparation of V was not described until somewhat later (7).*

hydrogen peroxide. Apparently, the borate ester IX is considerably more susceptible to hydrolysis than is VIII, the presumed initial product of the reduction. (+)-Benzyl-α-*d* alcohol, $[\alpha]_D^{22}$ 0.33° (*c*, 10 in chloroform) was isolated by a countercurrent procedure, using petroleum ether and water, followed by chloroform extraction of the aqueous phase. Since (−)-isopinocampheol is the second product of the sequence of reactions, the observed dextro rotation of the benzyl alcohol is real and indicates a minimum stereospecificity for the reduction of 30%, assuming that rotations in chloroform and neat are comparable and correcting for the use of pinene which was 70% optically pure.

The direction of specificity in the reduction of benzaldehyde is thus the same as that observed earlier with the methyl ketones (9). It is noteworthy that both of these results are consistent with the model used by Brown and his co-workers to explain the stereospecific conversion of olefins into alcohols (7).

According to this model, (−)-diisopinocampheylborane can be represented as shown in X, where S and S′ are the hydrogens at C_3 and $C_{3'}$, M and M′ are the methylene groups at C_2 and $C_{2'}$, and L and L′ are the methyl groups at C_4 and $C_{4'}$. If it is assumed that the reduction of benzaldehyde by II proceeds via a four-centered transition state, then the two possibilities are XI and XII. In each of these, one of the substituents attached to the carbonyl group points towards L and the other substituent points towards L′. However, it is evident upon examination of molecular models that phenyl and L in XII are in closer proximity than are phenyl and L′ in XI. Therefore, it is concluded that XI, which leads to the observed *S*-benzyl-α-*d* alcohol, is more favorable sterically.

EXPERIMENTAL

To a suspension of finely powdered sodium borodeuteride (0.5329 g, 4.25 mmoles) in 25 ml of tetrahydrofuran (freshly distilled from lithium aluminium hydride) in a three-necked flask fitted with a pressure-equalizing dropping funnel, magnetic stirrer, thermometer, and condenser fitted with a calcium chloride drying tube was added dropwise, during a 20 min period at room temperature, a solution of freshly distilled boron trifluoride etherate (2.14 ml, 2.41 g, 5.67 mmoles) in 25 ml of dry tetrahydrofuran. Apart from a slight rise in temperature, there was no apparent reaction. The white suspension was stirred for 1 h and then a solution of 4.63 g (5.39 ml, 11.33 mmoles) of (+)-α-pinene, $[\alpha]_D^{25}$ 36° (71.3% optically pure (10)), in 25 ml of dry tetrahydrofuran was added dropwise, over a 20 min period. Again there was no apparent reaction apart

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from a slight rise in temperature. The white suspension was stirred for 4 h at room temperature and cooled to 0°; a solution of freshly distilled benzaldehyde (1.72 ml, 1.80 g, 5.67 mmoles) in 25 ml of dry tetrahydrofuran was then added dropwise, during a 20 min period. A transient pale-green color appeared upon the addition of each drop of the benzaldehyde solution. The cooling bath was then removed and the reaction mixture was stirred overnight. Then, 5 ml of 3 *N* NaOH was added, the mixture was warmed to 50°, and 5 ml of 30% H_2O_2 was added dropwise.[2] After 1 h the clear colorless tetrahydrofuran layer was decanted from the viscous aqueous phase. The aqueous phase was extracted several times with ether and the combined organic extracts were concentrated to yield a viscous oil. This was shaken with a mixture of 100 ml of water and 50 ml of petroleum ether (b.p. 40–60°), and subjected to countercurrent extraction, using five separatory funnels. The aqueous phase was then extracted with chloroform, and the chloroform extract was dried over anhydrous magnesium sulfate and evaporated to give 1.63 g (88%) of a clear colorless oil which had a slightly negative rotation. The countercurrent procedure (three separatory funnels) and the chloroform extraction were therefore repeated, and the product then showed $[\alpha]_D^{23}$ 0.12° (*c*, 10 in chloroform). Distillation gave 1.10 g (59%) of benzyl-α-*d* alcohol, $[\alpha]_D^{22}$ 0.33° (*c*, 10 in chloroform), identified by gas chromatography and by its infrared and nuclear magnetic resonance spectra. When the optical purity of the α-pinene is taken into account, the stereospecificity of the present reduction is 30%, i.e. $\frac{100}{71} \times \frac{0.33}{1.58} \times 100$.

CHLOROMETHYL–PHOSPHORUS COMPOUNDS SYNTHESIS AND INFRARED SPECTRA

Arlen W. Frank[1] and Irving Gordon

Chloromethyl–phosphorus compounds are of interest because of their accessibility from hydroxymethyl–phosphorus compounds and their unique chemical properties. The synthesis and infrared spectra of these compounds are discussed in this note.

Thionyl chloride is widely used for the replacement of hydroxyl by chlorine in organic compounds, but its use with organophosphorus compounds containing hydroxymethyl substituents sometimes gives surprisingly poor results. Hydroxymethylphosphonic acid, for example, gives a 56.6% yield of chloromethylphosphonic dichloride (I) when treated with thionyl chloride in the presence of pyridine (1), but no reaction takes place when the

CHLOROMETHYL–PHOSPHORUS COMPOUNDS SYNTHESIS AND INFRARED SPECTRA

Arlen W. Frank[1] and Irving Gordon

Chloromethyl–phosphorus compounds are of interest because of their accessibility from hydroxymethyl–phosphorus compounds and their unique chemical properties. The synthesis and infrared spectra of these compounds are discussed in this note.

Thionyl chloride is widely used for the replacement of hydroxyl by chlorine in organic compounds, but its use with organophosphorus compounds containing hydroxymethyl substituents sometimes gives surprisingly poor results. Hydroxymethylphosphonic acid, for example, gives a 56.6% yield of chloromethylphosphonic dichloride (I) when treated with thionyl chloride in the presence of pyridine (1), but no reaction takes place when the

[1]*Present address: Ohio Wesleyan University, Delaware, Ohio.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pyridine is absent (2). Tris(hydroxymethyl)phosphine oxide gives tris(chloromethyl)phosphine oxide (II) in only a 32–33% yield (3). Thionyl chloride is unsuitable for converting tetrakis(hydroxymethyl)phosphonium chloride into tetrakis(chloromethyl)phosphonium chloride (III), although it works well with other phosphonium salts containing hydroxymethyl groups (4).

We have now examined the missing member of this series, bis(hydroxymethyl)phosphinic acid. Treatment of this compound in a benzene suspension with thionyl chloride at reflux (procedure A) gave a good yield (75%) of bis(chloromethyl)phosphinic chloride (IV), provided, however, that sufficient time was allowed for the very viscous phase which formed to redissolve completely. The viscous intermediate tended to ball on the stirrer and climb the walls of the reaction vessel. Little difficulty was experienced as long as sufficient space was left above the surface of the liquid to allow for this.

These observations prompted a reexamination of the other members of the series to see whether they too formed a viscous, gummy phase, which might account for the low yields reported in the literature.

Contrary to Prat *et al.* (2), hydroxymethylphosphonic acid did react with thionyl chloride, giving a viscous, gummy substance similar in appearance to the one described above. It did not break, however, even after 25 h of refluxing. Tris(hydroxymethyl)phosphine oxide and tetrakis(hydroxymethyl)phosphonium chloride did not form viscous, gummy phases, but the products were partly liquid and yielded only 30.5% of II and 12% of III, respectively. The liquid portions contained sulfur as well as chlorine. It seems likely that the gummy or liquid products of these reactions represent sulfite cross-links between hydroxymethyl groups, as reported by Kuznetsov and Faizullin (5).

The formation of the gummy, viscous intermediate in the bis(hydroxymethyl)phosphinic acid reaction could be avoided by reversing the order of addition (procedure B). When the acid was added in portions to the thionyl chloride at reflux in the absence of a solvent, IV was obtained in a 93% yield. With III, however, no improvement in the yield was noted.

The detection of product formation in this work was facilitated by the discovery that the CH_2 deformation band in the infrared spectra of the chloromethyl–phosphorus compounds was shifted from its usual position at 1 465 cm^{-1} (6) to 1 400 cm^{-1}. The $ClCH_2$—P band occurred at 1 400 $\pm$ 3 cm^{-1} in most of the 20 compounds examined (Table I). In general, it was insensitive to the state of oxidation of the phosphorus and to the nature of the other substituents, with the exception of chlorine, which caused a shift to an even lower frequency (1 385 – 1 395 cm^{-1}). The band was absent in dichloromethylphosphonic dichloride.

The presence of a band in the neighborhood of 1 400 cm^{-1} should not, of course, be construed as proof of the presence of a $ClCH_2$—P group, in the absence of other supporting evidence, for conflicts in this region of the spectrum are inevitable.

EXPERIMENTAL

Melting points were taken on a Fisher–Johns apparatus, and are corrected. The thionyl chloride, unless otherwise stated, was purified by distillation from boiled linseed oil. The hydroxymethyl–phosphorus compounds were stripped of excess water on a steam bath under vacuum, and dried to constant weight.

Bis(chloromethyl)phosphinic Chloride (IV)

Procedure A

Bis(hydroxymethyl)phosphinic acid (252 g, 2 moles) was mixed with 2 l of benzene and distilled until about 500 ml of distillate was collected, to remove any water present as the azeotrope. Thionyl chloride (834 g, 7 moles) was then added dropwise over a 5 h period at reflux. The reaction mixture was kept at reflux until the gas evolution subsided (10 h) and the viscous contents, which had collected on the stirrer and climbed the walls of the reaction vessel, had completely redissolved. At the end, the solution was clear. The solvent was

stripped off and the product distilled, giving 274 g (75%) of IV, b.p. 104–106° at 2 mm, n_D^{25} 1.5196. A portion of this product was redistilled for analysis.

Anal. Calcd. for $C_2H_4Cl_3OP$: C, 13.24; H, 2.22; Cl, 58.64; P, 17.08. Found: C, 13.32; H, 2.15; Cl, 58.9; P, 16.6.

Its infrared spectrum (neat) contained bands at 522 (vs) (P—Cl), 1 260 (vs) (P=O), and 1 389 (s) ($ClCH_2$—P) cm^{-1}. Moedritzer (8) prepared IV, b.p. 98–101° at 1 mm, from chloromethylphosphonous dichloride and paraformaldehyde in a 53.5% yield, and from bis(chloromethyl)phosphinic anhydride and phosphorus pentachloride in a 84.5% yield.

Procedure B

Bis(hydroxymethyl)phosphinic acid (126 g, 1 mole) was added in small portions to 595 g (5 moles) of technical-grade thionyl chloride over a 4 h period at reflux. Gas evolution was heavy, but no viscous phase separated. The reaction mixture was held at reflux until the gas evolution subsided (6 h), and was then distilled, giving 175 g (1.47 moles) of recovered thionyl chloride, b.p. 76–79°, n_D^{25} 1.5169, followed by 169 g (93%) of IV, b.p. 131–133° at 11 mm, n_D^{25} 1.5198.

Anal. Calcd. for $C_2H_4Cl_3OP$: Cl, 58.6 (total), 19.6 (hydrolyzable); P, 17.1. Found: Cl, 59.0 (total), 19.6 (hydrolyzable); P, 16.5.

The identity of the product was confirmed by hydrolysis to the known acid, bis(chloromethyl)phosphinic acid, m.p. 79–80° (lit. (8) m.p. 78°), and by esterification to the known ester, ethyl bis(chloromethyl)phosphinate, b.p. 104–106° at 1.5 mm, n_D^{25} 1.4780 (lit. (8) b.p. 115–116° at 1.5 mm).

Infrared Spectra

The infrared spectra were obtained on a Beckman IR-4 instrument (liquids neat and solids in Nujol). The $ClCH_2$—P band was readily distinguishable from the 1 378 cm^{-1} Nujol band, provided the latter was not too strong. The compounds in Table I not mentioned in the text were obtained from commercial sources or prepared by standard literature methods.

KINETICS AND MECHANISMS OF REACTIONS CATALYZED BY PANCREATIC RIBONUCLEASE

EILEEN N. RAMSDEN AND KEITH J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received January 19, 1966

ABSTRACT

A kinetic study has been made of the ribonuclease-catalyzed hydrolyses of three cyclic nucleotides, cytidine-2′,3′-phosphate, uridine-2′,3′-phosphate, and N^6,$O^{5'}$-diacetyl cytidine-2′,3′-phosphate. Rates were measured at pH values ranging from 6 to 8.5. The variation of the kinetic parameters with pH showed that the free enzyme possesses two active groups, having pK values of 5.4 and 7.25. When the enzyme–substrate complex is formed, the pK values of the groups are increased to 6.6 and 8.4. The pK values identify these groups as imidazole groups and show that two histidine residues are present at the active site. Since both increase in pK on complex formation, it is concluded that the acid imidazole group binds the substrate, but that the basic imidazole group cannot be concerned in substrate binding and must function only in the hydrolytic step. The results indicate that the pyrimidine base is concerned in the hydrolytic step and not solely in binding, as had been postulated. It is concluded from all of the evidence that four specific sites are present at the active center of the enzyme; three are involved in binding and one in catalysis. It is proposed that the active site of ribonuclease is composed of: the histidine residue in position 12, which catalyzes the hydrolytic step; the histidine residue in position 119, which binds the 2′-ribose oxygen atom in the substrate; the lysine residue in position 41, which binds the phosphate group or anion; and the aspartic acid residue in position 121, which binds the nitrogen atom at N^1 in the pyrimidine base. A mechanism for enzyme–substrate complex formation and subsequent hydrolysis is proposed.

INTRODUCTION

The degradation of ribonucleic acid by pancreatic ribonuclease was shown by Vandendriessche (1) to be a multistage reaction with complex kinetics. In the course of the degradation, the 3′-pyrimidine nucleoside phosphodiesters are converted to the 3′-phosphomonoesters in two steps. Markham and Smith (2) and Brown and Todd (3) have shown that in the first step the diesters are converted to the cyclic 2′,3′-diesters; in the second step the cyclic diesters are hydrolyzed to the 3′-monoesters. The action of ribonuclease on ribonucleic acid is illustrated in Fig. 1. It is to be noted that if in the second stage H_2O is replaced by R′OH, the process is of the same character as the reverse of the first stage. It is therefore likely that the activated complex for the first stage is analogous to that for the second.

For reaction to occur, a pyrimidine base must be part of the nucleotide, and the phosphate ester linkage must be in the 3′ position. The essential structure for the substrate for the first stage of the reaction is represented in Fig. 2. Findlay *et al.* (4) explain this specificity in terms of a specific binding to the enzyme, and consider that the pyrimidine is not involved in the subsequent reaction. Witzel (5) on the other hand concludes that the pyrimidine base is concerned in the catalytic step.

The object of the present work was to throw further light on the reaction mechanism, in

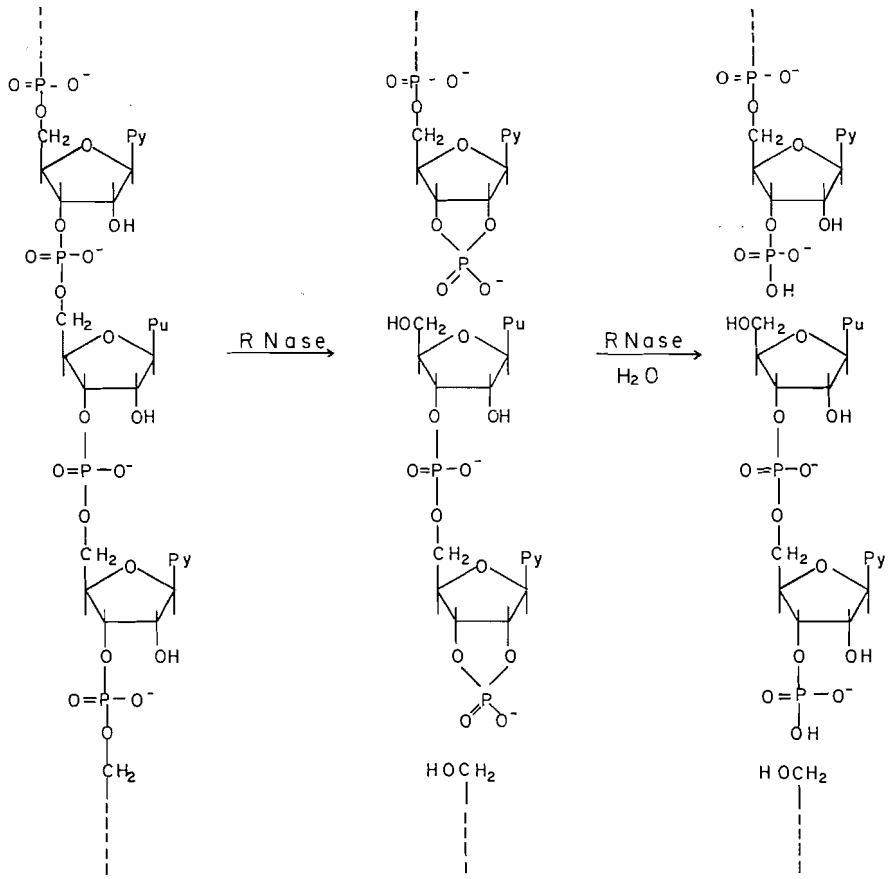

FIG. 1. Action of ribonuclease on ribonucleic acid. The pyrimidine bases (cytosine and uridine) and the purine bases (adenine and guanidine) are represented by Py and Pu respectively.

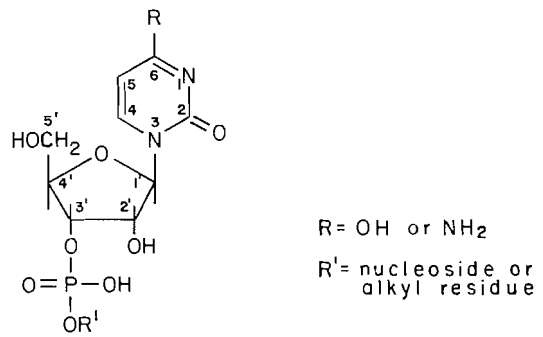

FIG. 2. Specific structure for a substrate of ribonuclease.

particular on the participation of the various groups in the binding and catalytic processes. It has been done with the three nucleotides represented in Fig. 3: (I) cytidine-2′,3′-phosphate (R = NH_2), (II) uridine-2′,3′-phosphate (R = OH), and (III) N^6,$O^{5'}$-diacetyl cytidine-2′,3′-phosphate (R = $NHCOCH_3$). A comparison of the inductive, mesomeric, and electromeric effects of the three R substituents leads to the conclusion that the polarity of the carbonyl group in the pyrimidine base will be greatest in I and least in III. If the reaction of the enzyme with the substrate depends on the presence of the carbonyl group, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

seems to be indicated by the specificity of ribonuclease for pyrimidine nucleotides, one would expect a slower reaction for the acetylated substrate. If, as postulated by Findlay *et al.* (4), the only function of the carbonyl group is to bind the substrate to the enzyme, the three substrates will differ in the value of the Michaelis constant, K_m, but not very much in the value of the rate constant k_2 for the subsequent catalytic step. If Witzel (5) is correct in concluding that the carbonyl group is involved in the hydrolytic step, the values of the rate

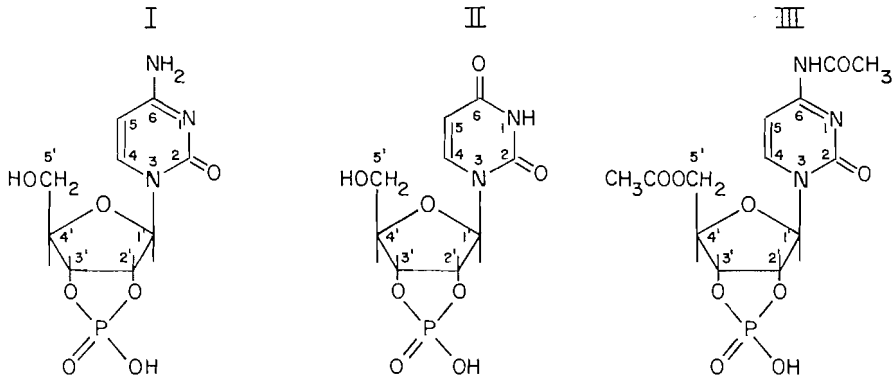

FIG. 3. Substrates employed in this work: (I) Cytidine-2′,3′-phosphate, (II) uridine-2′,3′-phosphate, (III) N^6,$O^{5'}$-diacetyl cytidine-2′,3′-phosphate.

constant k_2 for II and III will be lower than the value for I. That the changes in R have relatively little effect on the phosphate group is shown by the similarity of the acid dissociation constants of the phosphate group reported by Jordan (6). The substrates differ, however, in that I and II can exist in the form of zwitterions, whereas III cannot.

EXPERIMENTAL

Materials

Water was double distilled from glass, boiled out, and kept under nitrogen. AnalaR grades of anhydrous sodium sulfate, standard hydrochloric acid, and standard sodium hydroxide solution were used. The sodium hydroxide solution was opened each time under nitrogen, and the concentration was checked at intervals.

Ribonuclease A was supplied by Nutritional Biochemicals. Cytidine-2′,3′-phosphate and uridine-2′,3′-phosphate were supplied by Schwarz Bioresearch as the barium salts and converted to the sodium salts by precipitation with sodium sulfate solution. N^6,$O^{5'}$-Diacetyl cytidine-2′,3′-phosphate was prepared according to the method of Michelson (7).

Measurement of Reaction Rates

The pH-stat method was used. A Radiometer titrator TTT1a and titrigraph SBR 2c were used to control and record the addition of sodium hydroxide as reaction progressed. The cell was surrounded by a jacket through which circulated water at 20° from a thermostatted bath. Inserted into the cell were a glass electrode (Radiometer 202 C), a calomel electrode, a stirrer, a lead for sodium hydroxide solution, and a lead for nitrogen. The nitrogen was washed with alkali and then with water before it was passed in a slow stream over the surface of the reaction mixture. Sodium hydroxide (0.02 *N*) was delivered from a Radiometer syringe burette (SBU 1a) which gave a 100% scale reading for 0.50 ml. Manual addition, from a syringe, of a small volume of *N* acid or *N* alkali brought the pH to 0.1 below the desired value, and this was followed by adjustment to the exact value by the machine. The pH was read on a scale expander (Radiometer PHA 630 Ta) calibrated to 0.01 pH unit. The electrodes were standardized against potassium dihydrogen phosphate – sodium hydroxide buffer at pH 7.00. The ionic strength was adjusted to 0.20 with sodium sulfate solution.

After precipitation of the barium in the cytidine-2′,3′-phosphate barium salt by sodium sulfate, the substrate was made up to a standard volume in 1/3 *M* sodium sulfate solution. Ribonuclease was employed in a 1/3 *M* sodium sulfate solution, since the presence of an electrolyte helps to prevent the adsorption of ribonuclease on glass (8). Volumes of 1 ml of substrate solution and 1 ml of enzyme solution were used to make up a 10 ml reaction mixture in the cell.

The measured rate of addition of sodium hydroxide is not equal to the true rate of hydrolysis on account of titration of cytidine-3′-phosphate at pH values in the vicinity of the pK of this product of hydrolysis. A correction factor was used at each pH, using pK values of 6.00 and 5.88 for the secondary phosphate dissociations of cytidine-3′-phosphate and uridine-3′-phosphate respectively (6).

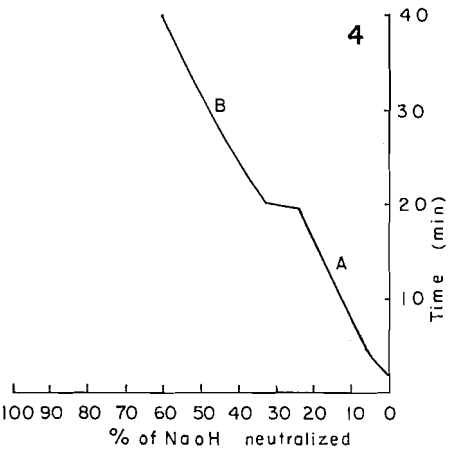
RESULTS

The results were interpreted in terms of a scheme for combination of an enzyme molecule and a substrate molecule to form a complex which reacts to give the product. The scheme can be expressed as



$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P \quad .$$

The rate equation for this sequence of reactions is

$$v = \frac{\tilde{k}_2[E]_0[S]}{\tilde{K}_m + [S]},$$

where $\tilde{k}_2$ is the rate constant for the reaction of ES, $[E]_0$ the initial enzyme concentration, [S] the substrate concentration, and $\tilde{K}_m$ the Michaelis constant, equal to $(k_{-1} + k_2)/k_1$.

The parameters $\tilde{k}_2$ and $\tilde{K}_m$ were determined from a plot of $[S]/v$ against [S] according to one of the methods of Lineweaver and Burk (9). A typical recording for the hydrolysis of cytidine-2′-3′-phosphate is shown in Fig. 4. The gradual decrease in rate is caused by product inhibition, but the recording is sufficiently linear to allow the initial rate to be obtained. The plot of $[S]/v$ against [S] for this substrate is shown in Fig. 5. The intercept on the $[S]/v$ axis is $\tilde{K}_m/\tilde{k}_2[E]_0$, and the gradient is $1/\tilde{k}_2[E]_0$.

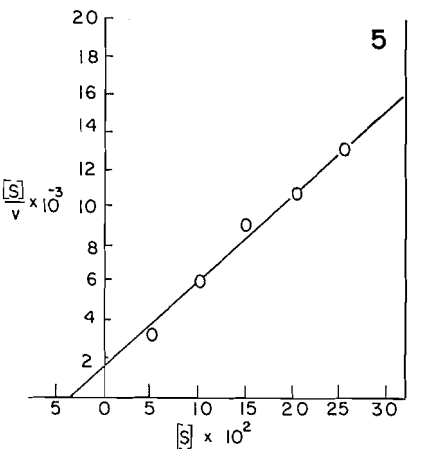


FIG. 4. Chart recording for the hydrolysis of cytidine-2′,3′-phosphate (2×10^{-2} *M*) in the presence of ribonuclease (0.5×10^{-7} *M*): (A) at pH 6.50, (B) at pH 6.75.

FIG. 5. Plot of $[S]/v$ against [S] for the hydrolysis of cytidine-2′,3′-phosphate at pH 6.50.

Information about the reactive groups in the enzyme can be obtained by studying the effect of changes in pH upon the rate of reaction. If the enzyme can exist in three states of ionization, E, EH, and EH_2, and the enzyme–substrate complex ES also has three states of ionization, then for a scheme which can be represented as

$$\begin{array}{ccc} & \overset{K_b}{\rightleftharpoons} & \overset{K_a}{\rightleftharpoons} \\ EH_2 & EH & E \\ & k_1[S] \uparrow\downarrow k_{-1} & \\ & \overset{K_b'}{\rightleftharpoons} & \overset{K_a'}{\rightleftharpoons} \\ EH_2S & EHS & ES \\ & & \downarrow k_2 \\ & & EH + P \end{array}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the steady state analysis (10) gives the rate expression:

$$v = \frac{k_2[E]_0[S]}{K_m\left(1 + \frac{[H^+]}{K_b} + \frac{K_a}{[H^+]}\right) + [S]\left(1 + \frac{[H^+]}{K_b'} + \frac{K_a'}{[H^+]}\right)}.$$

From this it follows that the experimentally determined parameters $\tilde{k}_2$ and $\tilde{K}_m$ are related to the pH-independent constants k_2 and K_m by the equations:

$$\tilde{k}_2 = \frac{k_2}{1 + \frac{[H^+]}{K_b'} + \frac{K_a'}{[H^+]}}$$

$$\tilde{K}_m = \frac{K_m\left(1 + \frac{[H^+]}{K_b} + \frac{K_a}{[H^+]}\right)}{1 + \frac{[H^+]}{K_b'} + \frac{K_a'}{[H^+]}}$$

$$\frac{\tilde{k}_2}{\tilde{K}_m} = \frac{k_2}{K_m\left(1 + \frac{[H^+]}{K_b} + \frac{K_a}{[H^+]}\right)}.$$

The variation with pH of log $\tilde{k}_2$, p$\tilde{K}_m$, and log $(\tilde{k}_2/\tilde{K}_m)$ allows the values of K_a', K_b', K_a, and K_b to be determined. The curves have an axis of symmetry, and the slopes approach $+1$ at low pH values and -1 at high ones.

TABLE I

Values of $\tilde{k}_2$ and $\tilde{K}_m$ for cytidine-2′,3′-phosphate at 25° and $I = 0.20$

8.00	4.0±0.4	3.1 ±0.3	130±10
8.25	1.7±0.2	1.3 ±0.1	135±10

The values of the pH-dependent kinetic parameters for cytidine-2′,3′-phosphate are given in Table I, and are plotted against pH in Fig. 6. In drawing these curves use has been made of the fact that they must be symmetrical and that the limiting slopes are $+1$ and -1.

The results for uridine-2′,3′-phosphate are shown in Table II and Fig. 7. The results are uncertain at pH 7.0 and 7.25. The values of $\tilde{K}_m$ are of the order of 10^{-1} M, and the limiting velocity could not be attained since there is a concentration of substrate beyond which the precipitation of barium as barium sulfate is incomplete. The $\tilde{k}_2/\tilde{K}_m$ values could be obtained accurately from plots of rate against [S], but the individual values could be obtained less accurately. The procedure used at these pH values was to plot either $1/v$

against 1/[S] or [S]/v against [S] and to force the line to pass through the value of [S]/v at [S] = 0, obtained from the plots of rate against [S].

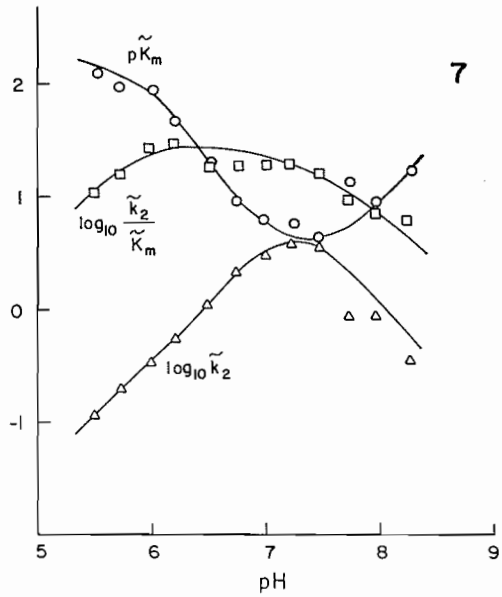

FIG. 6. Variation with pH of the logarithms of the kinetic parameters for the hydrolysis of cytidine-2′,3′-phosphate at 25° and $I = 0.20$.

FIG. 7. Variation with pH of the logarithms of the kinetic parameters for the hydrolysis of uridine-2′,3′-phosphate at 25° and $I = 0.20$.

The substrate N^6,$O^{5'}$-diacetyl cytidine-2′,3′-phosphate acts as a buffer from pH 6 to 7, and the method could not be used over this range. Results obtained at pH 8.0 are shown in Table III.

The pK values derived from the curves in Figs. 6 and 7 are given in Table IV. The pH independent parameters, k_2, K_m, and k_2/K_m are given in Table V. In calculating the values for N^6,$O^{5'}$-diacetyl cytidine-2′,3′-phosphate from the $\tilde{k}_2$ and $\tilde{K}_m$ values at a single pH, the assumption was made that this substrate involves the same groups in the enzyme, with the same values of pK_a, pK_b, pK_a', and pK_b' as for the other two substrates. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

seems a reasonable assumption, since the results for the other two substrates are very similar and $N^6,O^{5'}$-diacetyl cytidine-2′,3′-phosphate resembles cytidine-2′,3′-phosphate more than does uridine-2′,3′-phosphate.

DISCUSSION

The pK values of the groups in the enzyme that participate in the reaction are characteristic of imidazole groups, of which one must be active in the basic form and one in the acidic form. This conclusion was reached by Findlay *et al.* (11) on the basis of their work on the effect of solvent on the pK values of the enzyme. They showed that the protonated forms of both groups are cationic, which can only mean that one imidazole is acting in its non-protonated, and the other in its protonated, form.

TABLE III

Values of $\bar{k}_2$ and $\bar{K}_m$ for $N^6,O^{5'}$-diacetyl cytidine-2′,3′-phosphate at 25° and $I = 0.20$

pH	$\bar{k}_2$ (s^{-1})	$\bar{K}_m \times 10^2$ (M)	$\bar{k}_2/\bar{K}_m$
8.05	0.069±0.007	2.1±0.2	3.3±0.3

TABLE IV

pK values of ionizing groups at the active site of the enzyme

Cytidine-2′,3′-phosphate		
Free enzyme	$pK_b = 5.40$:	$pK_a = 7.25$
Enzyme–substrate complex	$pK_b' = 6.75$:	$pK_a' = 8.40$
Uridine-2′,3′-phosphate		
Free enzyme	$pK_b = 5.62$:	$pK_a = 7.50$
Enzyme–substrate complex	$pK_b' = 6.80$:	$pK_a' = 7.85$

TABLE V

Comparison of kinetic parameters for three substrates

	k_2 (s^{-1})	$K_m \times 10^2$ (M)	k_2/K_m
Cytidine-2′,3′-phosphate	7.2 ±0.7	0.87±0.09	810±80
Uridine-2′,3′-phosphate	2.1 ±0.6	4.6 ±1.5	44 ±4
$N^6,O^{5'}$-Diacetyl cytidine-2′,3′-phosphate	0.10±0.01	0.46±0.05	22 ±2

The fact that the pK of the acidic imidazole group increases on complex formation (i.e. $pK_a' > pK_a$) for both cytidine-2′,3′-phosphate and uridine-2′,3′-phosphate suggests that the proton on the imidazole forms a hydrogen bond with a group on the substrate: as a result, it is more difficult for the proton to leave.

The increase in pK of the basic group for both substrates, on the other hand, indicates that this group cannot become bound to a group on the substrate, since it would then be more difficult for the nitrogen atom to become protonated, and pK_b' would be less, and not greater, then pK_b. In the mechanism proposed later, this increase in the basicity of the basic imidazole group, on complex formation, is attributed to the fact that the nitrogen atom is brought into close proximity to two oxygen atoms on the substrate, and to an oxygen atom belonging to a water (or alcohol) molecule.

It is to be noted from Table V that the structure of the pyrimidine base has more effect on the catalytic constant k_2 than on the Michaelis constant K_m. The sequence of k_2 values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is cytidine > uridine ≫ N^6,$O^{5'}$-diacetyl cytidine, which is the order of polarity of the carbonyl groups. The sequence of K_m values is uridine ≫ cytidine > N^6,$O^{5'}$-diacetyl cytidine, which means that the uridine compound is much less strongly bound than the other two substrates. In the cytidine and N^6,$O^{5'}$-diacetyl cytidine compounds there can be zwitterion formation, with consequent enhancement of the binding power of the phosphate group; this is not possible with the uridine compound.

Mechanistic Information

Before considering the modes of interaction between the enzyme and substrate molecules during the reactions, it is convenient to summarize the main mechanistic information that must be taken into account:

(1) The specificity of the enzyme is for nucleotides of pyrimidine bases.

(2) The bond broken when the cyclic phosphate is hydrolyzed is the $C^{2'}$—OP bond (2, 3).

(3) A molecule of water or alcohol must participate in the reaction; in the latter case, the alcoholysis of a cyclic phosphate, the process is the reverse of the cyclic phosphate formation from the diester.

(4) Two histidine residues are involved in the reaction, one with the imidazole group in its acid form and the other with it in the basic form.

(5) Both the basic and acidic groups experience an increase in pK when the complex is formed.

(6) The rates for the three substrates studied in the present work and for others studied by Witzel and Barnard (12), show some variation in K_m and a much greater variation in k_2.

(7) Ukita *et al.* (13) have found significant variations in the efficiencies of inhibitors, as summarized in Table VI (cf. Fig. 8).

(8) The reaction is inhibited by zinc and copper ions (14).

(9) The cyclization of cytidine-3′-cytidine-5′-phosphate is much faster than the subsequent hydrolysis of the cytidine-2′,3′-phosphate formed (15).

(10) Chemical modification of known amino acid residues in the enzyme leads to loss of activity: further details are considered later.

The Binding Sites

To explain the inhibitor results of Ukita *et al.* (13), it is necessary to postulate three binding groups. Since all bases similar to uracil, possessing a —CO—NH—CO— group, inhibit reaction, there must be a site which binds to —CO—NH—CO—. The N^1—H bond is weakened by the polarity of the adjacent carbonyl groups, and it is very likely that this forms a hydrogen bond to a basic site on the enzyme. As cytidine is an inhibitor, whereas cytosine is not, there must be a sugar-binding site in the enzyme, and as 2′-deoxycytidine has half the inhibitory property of cytidine, this site probably binds the 2′-oxygen atom. The fact that 2′-deoxycytidine still has the ability to inhibit suggests that in this compound, where there is no hydrogen bond formation between the carbonyl group in the base and the 2′-hydroxyl group in the ribofuranose ring, there is free rotation about the N—$C^{1'}$ bond so that the 3′-OH group can occupy a position close to that occupied by the 2′-OH group in cytidine. Inhibition by inorganic phosphates shows that there must be a phosphate-binding site in the enzyme. Nucleotides are better inhibitors than nucleosides and purine and pyrimidine bases. A comparison of cytidine-2′-phosphate and uridine-2′-phosphate shows that, although cytidine-2′-phosphate can be bound to two of the proposed sites and uridine-2′-phosphate to three sites, the attachment at two sites must be sufficient to hold the molecule of cytidine-2′-phosphate in the position occupied by the substrate on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

enzyme. Also, zwitterion formation is possible in the cytidine phosphates (cf. Jordan (16)), and this will increase the binding by the phosphate anion in regions close to the isoelectric point.

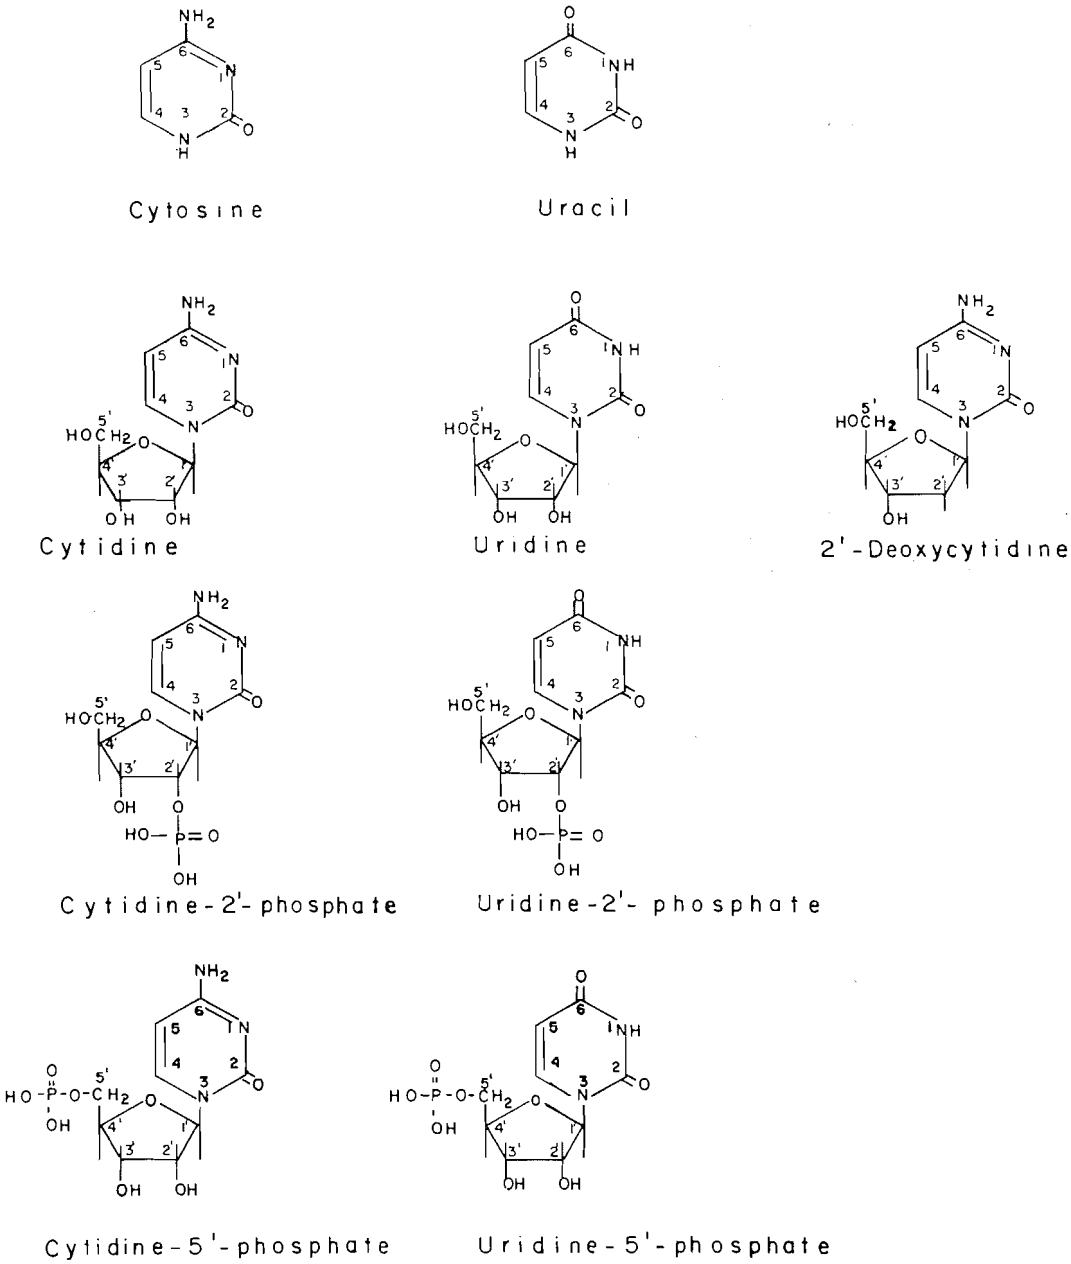

FIG. 8. The structures of some inhibitors of the enzymatic hydrolysis of cytidine-2′,3′-phosphate.

Inhibition studies thus establish a need for three binding groups, and kinetic studies demonstrate the participation of two groups, of which one, the basic imidazole, cannot fulfil any of these substrate-binding functions. It is, therefore, necessary to postulate a

total of at least four groups, three involved in binding and one, the basic imidazole, in basic catalysis.

TABLE VI

Inhibition indices obtained by Ukita *et al.* (13) in the hydrolysis of cytidine-2′,3′-phosphate

Inhibitor	Inhibition index
Cytosine	0
Cytidine	37
2′-Deoxycytidine	19
Cytidine-2′-phosphate	82
Cytidine-5′-phosphate	68
Uracil	24
Uridine	29
Uridine-2′-phosphate	80
Uridine-5′-phosphate	57

Schemes for the structure of the ES complex for cytidine-2′,3′-phosphate and for uridine-2′,3′-phosphate are proposed below and illustrated in Fig. 9. The two substrates are different in that there is no binding by the pyrimidine base in cytidine-2′,3′-phosphate. The ring nitrogen, N^1, requires a basic site for binding. The ribose oxygen, $O^{2'}$, requires an acid site when it occurs in a $C^{2'}$—O—P grouping; it also requires an acid site when it occurs in a $C^{2'}$—O—H grouping, since the H atom is hydrogen bonded to the C^2=O group. The acid imidazole group, which is in evidence from the kinetics, can perform this function. The phosphate group can occur as  , which could form a hydrogen bond with an acid or a basic site, or as  , which could form a hydrogen bond with an acid site or with a basic group containing a hydrogen atom, such as $-NH_2$. There is so much

FIG. 9. The suggested modes of enzyme–substrate complex formation for (I) cytidine-2′,3′-phosphate and (II) uridine-2′,3′-phosphate.

evidence for the participation of a lysine residue that it is reasonable to assign to it the function of binding the phosphate group or anion. Anfinsen (17) reported that dinitrobenzylation of the lysine residue in position 41 in the amino acid sequence determined by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Redfield and Anfinsen (18) and by Hirs *et al.* (19) destroyed the enzymatic activity, and that the lysine in position 41 does not react in the presence of phosphate ion. Hirs (20) showed that the ϵ-amino group of the lysine in position 41 is extremely reactive to alkylating reagents, and he deduced that it is part of or close to the anion-binding site in the active center. Reaction of this ϵ-amino group deactivates ribonuclease, and cytidylic acid protects ribonuclease from this deactivation. Hirs deduced that the lysine residues in positions 7 and 41 are close together in the enzyme from the fact that, although the lysine in position 7 does not react with alkylating reagents, it will react after the lysine in position 41 has been alkylated; this he attributed to a local unfolding of the enzyme molecule. The binding of the phosphate group by the basic group, a role which the lysine residue in position 41 seems able to play, must be a step in complex formation which is too fast to be rate determining. The binding of the pyrimidine N^1H by a basic site must also be a fast step. It is possible that the aspartic acid residue at position 121 performs this function since both Stein (21) and Anfinsen (22) have presented evidence that this residue is necessary for enzyme activity and since the carbonyl group would be able to form a strong hydrogen bond with a >NH group.

There is a great body of evidence to support the participation of the histidine residues at positions 12 and 119 at the active site. Richards and Vithayathil's (23) work on photooxidation of individual groups places the histidine in position 12 at the active site. Barnard and Stein (24) made a study of the deactivation following reaction of histidine with bromoacetate and placed the histidine in position 119 at the active site. Crestfield *et al.* (25) showed that alternative products in the reaction with bromoacetate are N^1-carboxymethyl histidine-119 and N^3-carboxymethyl histidine-12, and he deduced that the two histidine residues are 5 Å apart in the enzyme. The kinetics indicate the participation of two histidine residues. The fact that, on alkylation of the histidine in position 119, enzyme activity is destroyed, but the enzyme retains the ability to combine with substrate and inhibitors, as shown by shifts in the ultraviolet spectra studied by Ross *et al.* (26), indicates that it is the histidine in position 12 which binds the substrate, while the histidine in position 119 has a catalytic function.

The Catalytic Step

Complex formation is followed by hydrolysis. In the proposed mechanism, shown in Fig. 10, the carbonyl group of the pyrimidine ring holds a molecule of water or alcohol, by hydrogen bonding, in a favorable position close to the $O^{2'}$—P bond which is to be broken. The function of the basic imidazole group is to weaken further the H—OH or H—OR bond and assist in the transfer of the hydrogen atom from the molecule of water or alcohol to the 2′-oxygen atom of the sugar ring. The weakening of the H—OH or H—OR bond renders the hydroxyl or alkoxyl group sufficiently nucleophilic to attack the electrophilic phosphorus atom. In consequence, the $O^{2'}$—P bond, already weakened through binding of the acid imidazole group to $O^{2'}$, breaks and the 2′-oxygen atom forms a bond with the H atom.

The basic catalytic function of the imidazole group is exercised without the addition of a proton and consequent reionization of the group. It is envisaged as a lowering of the energy barrier to the transfer of a proton from the alkoxyl or hydroxyl oxygen to the sugar oxygen by first attracting the proton away from the alkoxyl oxygen and then releasing it to the sugar oxygen. When the imidazole nitrogen atom enters into an enzyme–substrate complex in which the nitrogen is in close proximity to three oxygen atoms, these negative atoms facilitate the approach of a proton and increase the basicity of the imidazole nitrogen.

This type of interaction can thus explain the increase in pK of the basic imidazole group on complex formation.

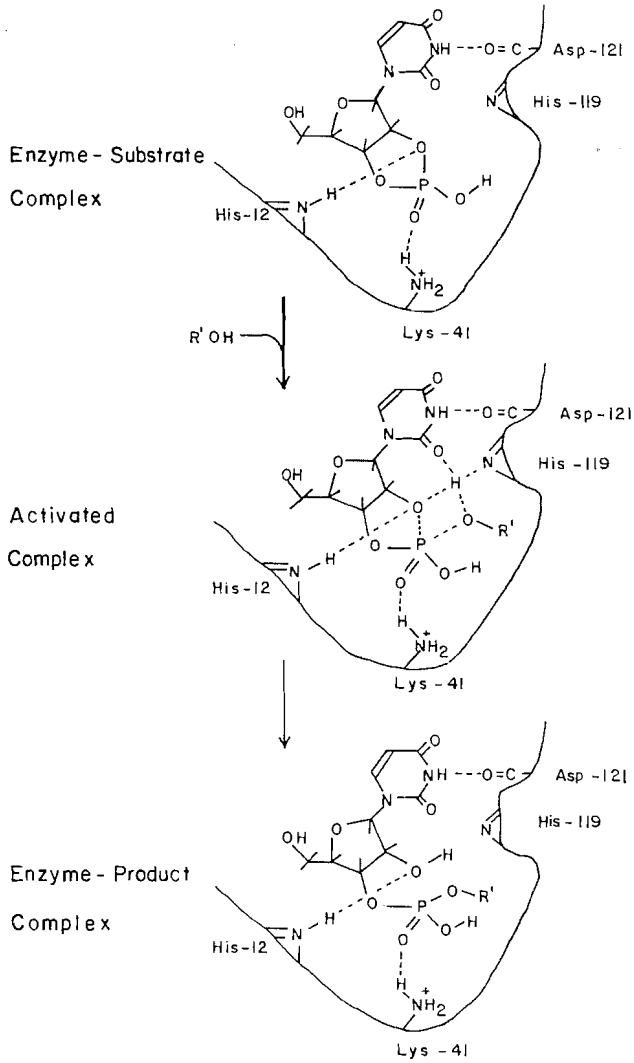

FIG. 10. The suggested mechanism of the catalytic step. In the activated complex the histidine-119 N atom, the oxygen atom of the water or alcohol molecule, the O atom attached to $C^{2'}$, and the O atom attached to C^{2} are envisaged as being roughly at the corners of a regular tetrahedron. In this way the histidine N atom aids the proton transfer.

Inhibition by zinc and copper ions (14) fits into this scheme, in that Tanford (27) has shown that zinc ions can be bound by an imidazole ring, and Ross *et al.* (26) have shown by a spectrophotometric study that zinc ions form a complex with the enzyme and with the enzyme–product complex.

Comparison with Other Mechanisms

In the mechanism proposed by Witzel (5) and by Witzel and Barnard (12), the substrate is bound to the enzyme only at the phosphate group. The carbonyl group of the pyrimidine ring functions by holding a molecule of water in the correct position for an attack on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

P—$O^{2'}$ bond, as in the mechanism proposed here. The imidazole groups are concerned only in the binding and not in the subsequent catalytic step.

There are two important features of the reaction that do not support this point of view. One is that binding only at the phosphate group does not account for the properties of known inhibitors, as discussed earlier. Secondly, if the C^2=O group is the only one involved in the catalytic step, the variations of the catalytic constants $\tilde{k}_2$ with pH would not reflect the changes in state of ionization of the enzyme: they would only relate to changes in the state of ionization of the substrate. There would be no reason why the $\tilde{k}_2$ values would vary with pH in much the same way for the different substrates. In fact, the groups in cytidine and uridine phosphates do not change their states of ionization over the pH range of 6 to 8 (6).

Shugar and Fox (28) suggested that the polarity of the carbonyl group is enhanced by coordination from a basic group in the enzyme to N^1H in uridine-2′,3′-phosphate or to —NH_2 in cytidine-2′,3′-phosphate. A combination of this type is not in accordance with the fact that cytidine is not an inhibitor.

Findlay *et al.* (4) proposed a specific binding to the enzyme at the pyrimidine nitrogen: the acid imidazole binds the 2′ oxygen atom, as in the present mechanism, while the basic imidazole holds a molecule of water. It was proposed that during the catalytic step the basic imidazole supplies electrons to break the H—OH bond, thus facilitating attack by the nucleophilic oxygen on the electrophilic phosphorus atom; electrons from the bond that is broken are attracted by the acidic imidazole.

The proposed specificity site, at N^1, is not, however, in accordance with the inhibition work (13), which shows that cytosine is not an inhibitor. In addition, since the carbonyl group is not envisaged as playing any role in reaction, substrates differing in the pyrimidine group R would be expected to differ in K_m rather than in k_2; this is contrary to the results of Barnard and Witzel (15) and to the present results.

The type of mechanism proposed by Findlay *et al.* is not one that would be expected to be of very high efficiency. During the catalytic step, the protonated imidazole group is considered to transfer its proton completely to the substrate, which in turn transfers a proton to the basic imidazole group. The enzyme thus ends up in an unnatural state of ionization, and will at once reionize. Since the pK values of the two groups differ by about 2 units the production of the enzyme in this unnatural state of ionization is done at the expense of about $2RT = 2.8$ kcal per mole of free energy, and this would have an adverse effect on the rate of a factor of about $10^{-2800/RT} = 10^{-2}$. This argument does not, of course, exclude mechanisms such as that of Findlay *et al.*: it merely shows that, other things being equal, a mechanism will be more efficient if the acidic and basic groups simply facilitate proton transfers without themselves undergoing a change in state of ionization. The mechanism proposed in the present paper is a scheme of this kind.

DEUTERIUM ISOTOPE EFFECTS ON HYDROGEN BONDING[1]

SURJIT SINGH[2] AND C. N. R. RAO[3]
Department of Chemistry, Indian Institute of Technology, Kanpur, India
Received March 7, 1966

ABSTRACT

The interaction of phenol and phenol-*d* with a number of donors of varying basicity has been studied in terms of the equilibrium constants, ΔS^0, ΔH^0, $\Delta\nu_{OH}$, and $\Delta\nu_{OD}$ and various aspects of deuterium isotope effects on hydrogen bonding have been discussed. The deuterium isotope effects are found to vary markedly with the basicity of the donor and the results are discussed in terms of the zero point contributions to the K_H/K_D.

INTRODUCTION

While isotope effects on chemical equilibria and kinetics have been reported in a variety of systems in the literature, information on deuterium isotope effects on hydrogen bonding, XH...Y, is limited. Bellamy and Rogasch (1) and Dahlgram and Long (2) have reported that deuterium bonds are comparatively weaker than the hydrogen bonds. Josien and co-workers (3) as well as Creswell and Allred (4) have found higher values of the equilibrium constants and the enthalpy and entropy changes for deuterium bonds in alcohols–hexamethylbenzene and fluoroform–tetrahydrofuran systems. Literature data (5) on self-association, however, show lower values of equilibrium constants and enthalpies for deuterium bonds.

In the models for proton transfer reactions, Westheimer (6) and Bigeleisen (7) have considered the importance of the symmetric stretching frequencies of X...Y in describing deuterium isotope effects. Recent work of Bader (8) has shown the possible importance of bending modes as well. We have now examined deuterium isotope effects on the thermodynamics (K, ΔH^0, ΔS^0) of hydrogen bonding equilibria as well as the frequency shifts of the stretching vibrations for the interaction of phenol with a number of donors, Y, of varying basicity. The dependence of isotope effects on the basicity of the donors was expected to throw some light on the importance of various zero point contributions to K_H/K_D.

EXPERIMENTAL

All the chemicals, with the exception of tetra-*n*-heptylammonium iodide and tetramethylthiourea, were commercially available and were purified before use. Tetraheptylammonium iodide was kindly provided by Professor P. V. R. Schleyer and tetramethylthiourea by Dr. M. J. Janssen. Deuterated phenol, C_6H_5OD, was prepared by repeated exchange of phenol with D_2O (supplied by Atomic Energy Establishment, Bombay). The exchange was found to be 80% by measurement of the intensity of the free OH stretching band at different concentrations as well as by quantitative estimation of the D_2O content of the water obtained by the combustion of the sample.

Infrared measurements in the OH and OD stretching regions were obtained with a Carl–Zeiss UR-10 spectrophotometer with LiF optics. The equilibrium constants of hydrogen bond formation were calculated using the expression similar to that of Becker (9) and the uncertainties in K are within ±10%. The optical densities of the monomer OH and OD bands in phenol and phenol-*d* solutions (solvent, CCl_4; concentration ~0.007 *M*) and in their solution with different donors of known concentration were measured in the overtone region using a Cary-14R spectrophotometer fitted with variable temperature cells (path length 10 cm). From the data on equilibrium constants at three temperatures (in the range 5–45 °C with an uncertainty in temperature of ±1 °C) the enthalpy of hydrogen bond formation was calculated. The uncertainty in enthalpy values was ±0.5 kcal mole^{-1}. The uncertainty in frequency shifts ($\Delta\nu_{OH}$ and $\Delta\nu_{OD}$) was ±5 cm^{-1}.

The experimental procedure and details of the method of evaluation of the equilibrium constants have been discussed in other publications from this laboratory (10).

RESULTS AND DISCUSSION

Thermodynamic data on the interaction of phenol and phenol-*d* with donors have been summarized in Table I along with the frequency shifts of the OH and OD stretching vibration bands, $\Delta\nu_{OH}$ and $\Delta\nu_{OD}$. It can be seen that the enthalpy of formation of 1:1 complexes is always greater in the case of hydrogen bonding than in deuterium bonding. This may be due to the longer O...Y distance in the deuterated species. The overlap in the hydrogen bond is expected to be greater than in the deuterium bond (11) and crystals containing deuterium bonds often show expansion of the unit cell (12, 13). Rightly enough, it has been pointed out that the barrier height in the double minimum potential (14) for the transfer of deuterium would be higher than for proton transfer due to the lower zero point energy of the O—D bond (15, 16).

The ratio of the equilibrium constants, K_H/K_D, is found to vary from donor to donor (Table I) and there appears to be no rule that the ratio be greater than unity. The results of this study show that the varied values of K_H/K_D in the literature probably are all valid and that K_H/K_D is a function of the basicity of the donor. The entropy change ΔS^0 is, however, always greater for the deuterium bonds than for the hydrogen bonds. The variation in equilibrium constants has to be interpreted in terms of the contributions from both the ΔH^0 and ΔS^0 since $\Delta F^0 = -RT \ln K = \Delta H^0 - T\Delta S^0$.

The frequency shift, $\Delta\nu_{OH}$, is always greater than $\Delta\nu_{OD}$. While this is in line with the earlier observation that $\Delta H^0_{OH...Y}$ is greater than $\Delta H^0_{OD...Y}$, the $\Delta\nu_{OH}$ and $\Delta\nu_{OD}$ do not show any simple linear relation with the ΔH^0 values. This is not unexpected since the linearity between $\Delta\nu_{OH}$ and ΔH^0 holds good only in a limited range of ΔH^0 (or $R_{O...Y}$) for the interaction of the same acceptor (proton donor) with donors of comparable basicity (ionization potential) (10). It should also be pointed out that $\Delta\nu_{OH}$ or $\Delta\nu_{OD}$ is determined by the barrier height in the double minimum potential and is not strictly related to the ΔH^0. It is quite conceivable to have a situation where the barrier height (or $\Delta\nu$) varies with little or no variation in $R_{X...Y}$ (or ΔH^0) (10).

Since the theories of Westheimer, Bigeleisen, and Bader on isotope effects refer to rate processes, they cannot be applied to the equilibrium data reported in this study. The isotope exchange equilibrium constant can, however, be estimated fairly accurately by employing the expression from statistical thermodynamics in terms of partition functions.

By neglecting all the factors in the partition functions other than the zero point energy contributions, one can write the expression for K_H/K_D for the equilibrium exchange reaction,

[1] $$C_6H_5OH + C_6H_5OD...Y \rightleftharpoons C_6H_5OD + C_6H_5OH...Y$$

[2] $$K_H/K_D = \exp -(\sum\Delta\nu_{XHY} + \sum\Delta\nu_{XH})/2kT,$$

where $\Delta\nu = \nu_H - \nu_D$ and the subscript XHY and XH refer to the hydrogen-bonded species and the free X—H monomer respectively. The sum in each case is over all the vibrations affected by isotopic substitution. In the case of the free monomer, these vibrations are the ν_{OH}, δ_{OH}, and γ_{OH}, and in the bonded species, the ν_{OH} is reduced appreciably from the monomer value. On hydrogen bonding δ_{OH} increases a little while γ_{OH} increases markedly. By using Δ' to denote the difference $\nu_H - \nu_D$ and Δ to denote the frequency change on hydrogen bonding, eq. [2] can be rewritten as

[3] $$2kT \ln (K_H/K_D) = -\Delta\Delta'\nu_{OH} - \Delta\Delta'\delta_{OH} - \Delta\Delta'\gamma_{OH}$$

†Values of ionization potentials were taken from refs. 17–20.
‡The value of ionization potential of tetraheptylammonium iodide was estimated to be 6 ± 1 eV from the electronic spectrum of alkali iodide (21). The ionization potential of free I^- is, however, equal to minus the electron affinity of free iodine atom (3.2 eV).
§Data for dimerization.

In eq. [3]

$$\Delta\Delta'\nu_{OH} = [\nu_{OH(XHY)} - \nu_{OD(XDY)}] - [\nu_{OH(XH)} - \nu_{OD(XD)}]$$

and $\Delta\Delta'\nu_{OH}$ is negative since ν_{OH} decreases on hydrogen bonding. The terms $\Delta\Delta'\delta_{OH}$ and $\Delta\Delta'\gamma_{OH}$ are both positive since δ_{OH} and γ_{OH} increase on hydrogen bonding. Further, when $K_H/K_D > 1$ the proton is more tightly bound in the monomer, and when $K_H/K_D < 1$ it is more tightly bound in the complex. The deuterium is always concentrated in the species which has the largest zero point energy difference. Since only data on ν_{OH} have been obtained in the present study, it is not possible to discuss all the major zero point contributions; but the observed isotope effects can be understood in terms of the known isotope effects on the three vibrations discussed earlier.

If the isotope effects in terms of K_H/K_D, $\Delta H^0_{OH...Y}/\Delta H^0_{OD...Y}$ or $\Delta\nu_{OH}/\Delta\nu_{OD}$, are plotted against the ionization potentials of the donors (as measures of basicities), the plots show minima around 8.5 eV. It is difficult to rationalize the observation of these minima. The minima are likely to be fallacious since ionization potentials are probably not good measures of base strengths. On the other hand one may be justified in using $\Delta\nu_{OH}$ or $\Delta H^0_{OH...Y}$ as the measure of base strengths of the donors (10*a*).

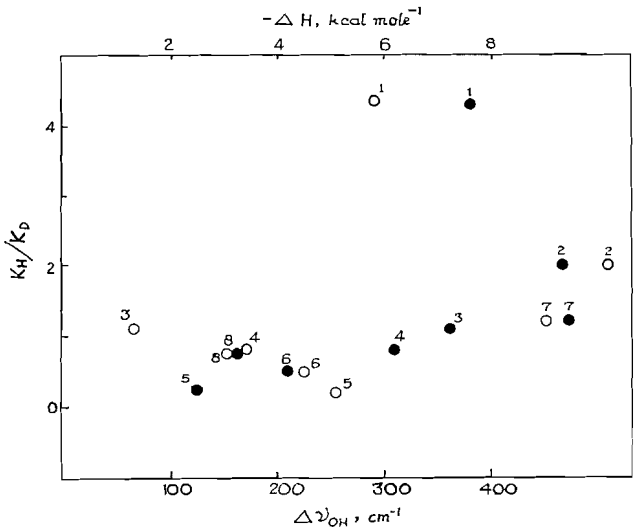

FIG. 1. Correlation of equilibrium isotope effect in hydrogen bonding with base strengths (in terms of $\Delta\nu_{OH}$ and enthalpies of formation of hydrogen bonds). ○, K_H/K_D vs. ΔH^0; ●, K_H/K_D vs. $\Delta\nu_{OH}$.

A plot of K_H/K_D against $\Delta\nu_{OH}$ or $\Delta H^0_{OH...Y}$, Fig. 1, shows that some proportionality exists (with the exception of the charged donor $(C_7H_{15})_4N^+I^-$ which falls out of line) between these quantities. This appears to be reasonable; as the hydrogen bond becomes stronger, the ν_{OH} is decreased and the γ_{OH} is increased. Apparently, for weak bases, the increase in γ_{OH} is greater than the decrease in ν_{OH} and the converse is true for the stronger bases. The positive slopes of the plots in Fig. 1 indicate that the proton is more tightly bonded in the free acid than in the hydrogen-bonded complex. This is indeed a new and interesting result, which needs to be examined more carefully by theory and further experimentation.

ACKNOWLEDGMENTS

The authors are thankful to the Council of Scientific and Industrial Research, India, for the award of a research grant. The authors' thanks are due to Dr. M. J. Janssen of Netherlands and Prof. P. V. R. Schleyer of Princeton University for gift samples of

tetramethylthiourea and tetraheptylammonium iodide respectively. Thanks are also due to Dr. A. B. King and Dr. J. G. Larson of the Gulf Research Laboratory, Pittsburgh, for determining the ionization potentials of tetramethylthiourea and triphenyl phosphine by the electron impact method.

The authors are particularly thankful to one of the referees for his suggestions regarding the interpretation of K_H/K_D.

PHASE TRANSITIONS OF ADSORBATES

I. SPECIFIC HEAT AND DIMENSIONAL CHANGES OF THE POROUS GLASS – WATER SYSTEM[1]

G. G. LITVAN

Division of Building Research, National Research Council, Ottawa, Canada

Received March 24, 1966

ABSTRACT

The specific heat and dimensional changes of the porous 96% silica glass – water system were measured simultaneously between −35 °C and +2 °C with coverages of 1.6, 4.0, 5.3, and 7.7 molecular layers. The specific heat of the adsorbate below the transition range was found to be higher than that of ice. No phase change was detected with the lowest concentration. At the higher coverages, transition always occurred near −9.5° and was of the anomalous first order type. The values of the specific latent heat of fusion, calculated by assuming that two monolayers do not freeze, are 49.4, 54.4, and 55.5 cal g^{-1}, depending on the concentration. The correlation between the results of calorimetric and dimensional change measurements was considered satisfactory.

INTRODUCTION

Phase transitions of water adsorbed on porous glass differ from those of other adsorbates in at least two aspects: (*a*) water has several freezing ranges (1, 2) while benzene (3) and xenon (1) have one, and (*b*) its melting point is not concentration dependent as is that of helium on jeweller's rouge (4), argon (5), nitrogen (6), and methane (7) on rutile. This anomalous behavior and the importance of the freezing phenomenon from a practical point of view seemed to warrant further studies.

The thermal properties and the dimensional changes of the partially and fully saturated systems were simultaneously measured to facilitate the correlation of the results.

EXPERIMENTAL

Apparatus

The adiabatic calorimeter incorporating a Tuckerman-type optical extensometer (8), manufactured by American Instrument Co., Silver Spring, Maryland, was similar to that described in ref. 2 but with several modifications. Instead of using the phototube controllers, the temperature of the envelope and the tube was regulated by a microswitch in the heating circuit actuated by a disc mounted on the slidewire shaft of a 0.1 mV Speedomax recorder and governed by the amplified e.m.f. of a seven-junction thermopile. The apparent temperature difference between the calorimeter and envelope was ±0.001 °C. In addition, the temperature of the reference block and the bath was made to follow automatically that of the calorimeter without the need of manual adjustments. Adiabatic conditions were thus better maintained during temperature changes.

The reported (2) 0.1° temperature lowering of the calorimeter that occurred overnight was eliminated. The temperature remained either constant or increased by 0.01° overnight so that the state of the adsorbate was not altered from one of desorption to one of adsorption.

Precision and Accuracy

The degree of precision increased as the tests progressed; the final precision varied between ±2% and ±0.02% depending on the working temperature range. The accuracy was determined by measuring the heat capacity of sodium chloride and it was found to be ±0.2%.

Materials

The porous 96% silica glass had a nitrogen surface area of 112.5 $m^2 g^{-1}$. The pore-size distribution, calculated from the nitrogen isotherm (9) showed that 66% of the total pore volume consisted of pores with radii between 28 and 20 Å. The distribution curve had a maximum at 21 Å. Prior to each series of measurements the glass was heated to 400 °C in air to burn off organic impurities and subsequently evacuated at 10^{-5} mm pressure for at least a day.

The water used was purified by several vacuum distillations. The amount adsorbed was determined with the aid of a burette (3), instead of gravimetrically (2).

CALCULATIONS

The heat capacity of the adsorbate was calculated by taking the difference between the heat capacity of the calorimeter system with and without the adsorbate. The total heat capacity of the system is given by the formula due to Morrison *et al.* (10).

$$[1] \qquad \frac{dQ}{dT} = c_{p_{cal}} + c_{p_g} + c_{N_s} - q_{st}\frac{dN_s}{dT} - V_g\frac{dp}{dT}$$

where

Q = heat supplied

$c_{p_{cal}}$ = heat capacity at constant pressure of the calorimeter and adsorbent

c_{p_g} = heat capacity at constant pressure of the gaseous phase

N_s = number of moles sorbed

c_{N_s} = heat capacity of the adsorbed phase at constant amount sorbed

q_{st} = isosteric heat of sorption

p = vapor pressure

T = temperature

V_g = volume of gaseous phase in the calorimeter.

Because of the experimental difficulties due to the small water vapor pressures at low temperatures, no data are available for q_{st}, N_s, and p. The maximum value, however, of dN_s/dT was $<1 \times 10^{-5}$ mole deg^{-1} and that of dp/dT was 0.14 mm deg^{-1} calculated with the saturation vapor pressure data (V_g = 310 ml). Consequently, the second, fourth, and fifth terms on the right-hand side of eq. [1] were considered negligible. The validity of the assumption that the adsorbent is inert, i.e. its heat capacity is not altered by the presence or the state of the adsorbate, was accepted due to necessity.

RESULTS

The heat capacity of the adsorbed water in fixed concentrations of 0.0511, 0.1266, 0.1676, and 0.2431 g/g were determined between −35 and +2 °C while heating the system. The system with the highest concentration was saturated. These concentrations are equivalent to 1.6, 4.0, 5.3, and 7.7 layers, respectively. Measurements of the fifth series with 0.1810 g/g (5.7 layers) were interrupted due to malfunctioning of the compressor. The specific heat vs. temperature plot is shown in Fig. 1.

The specific heat at temperatures below the heat anomaly is, in all cases, higher than that of bulk ice (0.45 cal deg^{-1}) but at temperatures above the anomaly it closely approaches the value of bulk water. For reasons yet unexplained the curve for 0.1676 g/g concentration lies above the others.

With the lowest amount of water present, equivalent to 1.6 layers, no anomaly takes place. At higher concentrations anomalously large heat absorption occurs, beginning a few degrees below −20 °C and extending over a temperature range of ~12 deg. The curve ascends gradually but descends sharply after the maximum which is near −9.5°. Normal behavior, except for a small minimum, is resumed at about −7°.

The entropy changes,

$$\int_{243}^{T} \frac{c_p}{T} dT,$$

are shown in Fig. 2 and the entropy of fusion values are given in column 5 of Table I.

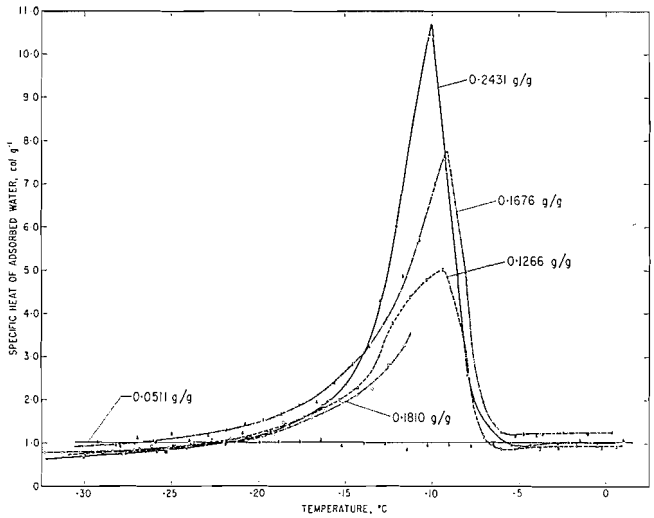

FIG. 1. Specific heat of adsorbed water vs. temperature. The numerical values indicate the water content of the adsorbent.

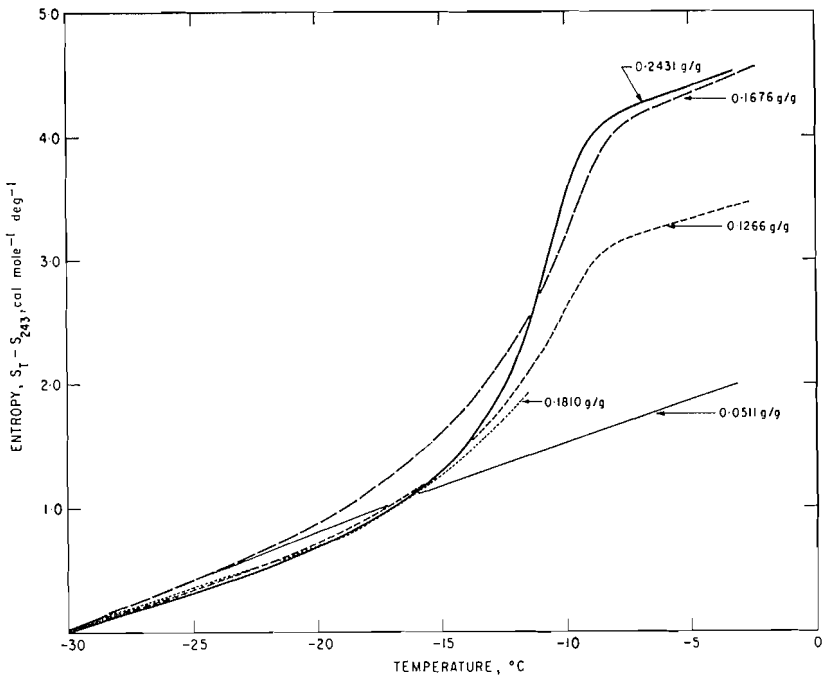

FIG. 2. Entropy change, $S_T - S_{243}$, of adsorbed water vs. temperature.

The latent heats of fusion (column 3, Table I) were determined by graphical integration of the area between the c_p vs. T curve and a straight line connecting the points at $-30°$ and -7 °C.

Figure 3 shows the expansion isosteres (fractional length changes plotted against temperature). At the lowest concentration no anomaly can be detected. In the case of higher concentrations, two anomalies occurred on cooling, one around $-20°$ and the other around $-7°$.

TABLE I

Specific latent heat and entropy of fusion of adsorbed water

Water adsorbed (g/g)	No. of layers	Heat of fusion (cal g^{-1})		Entropy of fusion (cal $mole^{-1}$ deg^{-1})
0.0511	1.6	0.0*	0.0†	
0.1266	4.0	26.32*	49.40†	1.74
0.1676	5.3	33.75*	54.42†	2.32
0.2431	7.7	41.82*	55.55†	2.76
Bulk		79.67		5.26

*Values calculated by assuming that all the water present has transformed.
†Values calculated by assuming that an amount of water equivalent to two monolayers has not transformed.

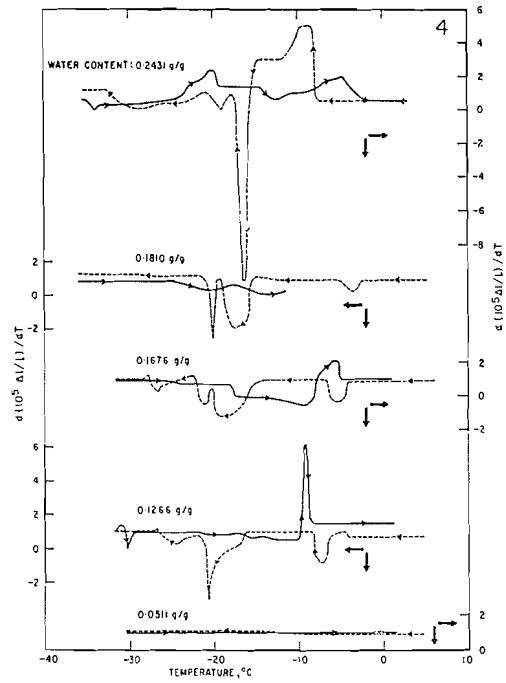

FIG. 3. Expansion isosteres. Individual points omitted.
FIG. 4. Derivative of the expansion isosteres.

From the temperature derivative of the fractional length changes (Fig. 4) it is apparent that the expansion occurring at high temperature is concentration dependent: it shifted to higher temperature and decreased in magnitude with increasing water concentration, and it vanished at saturation. This finding is in line with one previous study (1) but is only in partial agreement with another (2) where on the saturated system anomaly was found at −7°. The other anomaly, which always occurs around −20°, seems to have not one but two maxima at approximately −19° and −21° as indicated by Figs. 3 and 4.

On warming, only one expansion was observed around −8° and it became broader with increasing concentration. Pronounced hysteresis is exhibited with all except the lowest concentrations.

DISCUSSION

Absence of Transition

The finding that no transition occurs at a coverage of 1.6 layers is in accordance with findings of previous calorimetric (4–7) and dimensional change (1) measurements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Presumably, the strong adsorbent–adsorbate interaction prevents the water from rearrangement necessary for transition. It is remarkable that the water–glass system behaves similarly in this respect to the rutile–nitrogen (5) and rutile–argon (6) systems where the onset of freezing occurs after the coverage exceeds two layers.

Heat of Fusion

When calculating ΔH the question arises whether the first two layers still do not suffer phase change with coverages exceeding this value. It is conceivable that the attractive forces between the solid and the first layers, at higher concentrations, are weakened by the water–water interaction and consequently the adsorbate achieves the mobility required for ice formation. The latent heat of fusion was, therefore, calculated in two ways: by assuming that (*a*) all the water froze and (*b*) only the water in the third and subsequent layers froze.[2] The results are given in columns 3 and 4 of Table I and the mean latent heat of fusion is plotted as the function of the water concentration in Fig. 5. For the present, assumption (*b*) is accepted without direct evidence. There are indications, however, that support this view.

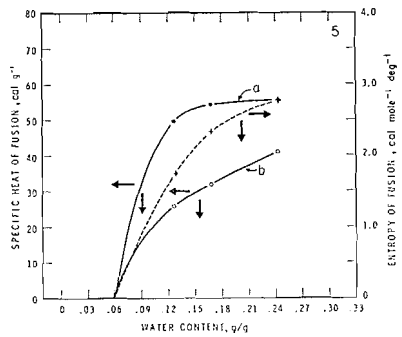

FIG. 5. Specific heat of fusion and entropy of fusion vs. water content (see test for explanation).

If the attractive force holding the adsorbate in the surface is higher than a first order function of the distance, the heat of fusion vs. concentration curve is expected to be of the saturation type as is the case with assumption (*b*) but not with (*a*) (Fig. 5). In addition, considering that in the bulk state the specific heat of water is approximately twice that of ice the high specific heat of the adsorbate at temperatures below the melting point may be viewed as an indication of the presence of unfrozen water.

Antoniou (2), when calculating the results for the saturated system, assumed the heat of fusion of the adsorbed water to be the same as that of the bulk and that the observed net heat change was therefore low because not two but three water layers remained unfrozen. Earlier extensometric measurements (1) showed, however, that the onset of freezing occurs at a coverage between 1.3 and 2.3 layers. Furthermore, application of this concept to the present case results in the improbable finding that 2.7, 3.1, and 3.7 layers, respectively, remained unfrozen, i.e. the amount of unfrozen water increased with increasing concentration.

The values for the heat of fusion are less than that for bulk ice; even at saturation they reach only ~70%. In other systems, such as argon–rutile (5), methane–rutile (7), and nitrogen trifluoride – anatase (11), ΔH is equal to the value for the bulk substance, presumably because of weaker adsorbent–adsorbate interaction.

[2]*For the specific heat of the unfrozen water in the first two layers the experimental values determined in the series with the lowest concentration were used.*

For personal use only.

The small entropy of fusion values show that less disordering occurs in the adsorbed than in the bulk state. Since the absolute values are not known it cannot be decided whether the state of the solid or liquid or both phases are responsible for the smaller difference.

The transition is of the anomalous first order type (12) as indicated by the shape of the c_p vs. T curve. At least two conditions can account for such phase changes: (*a*) gradual disordering of a homogeneous phase and (*b*) the existence of domains with different properties.

Expansion Isosteres

The results of the length change measurements are in general accord with those obtained when cooling to −180 °C (1). Because in the present study the system was cooled only to −35 °C, the agreement implies that the portion of the water that froze below −35° also melted in the same region and had no detectable effect on the melting process at high temperatures.

The shape of the expansion isosteres (Figs. 3 and 4) changes gradually with concentration. The curve for the saturated system shows one special feature, namely, a contraction occurring on cooling near −16°. It is noteworthy that the disappearance of the menisci at saturation does not cause more significant changes.

In contrast to Antoniou's finding (2) the correlation between the expansion isosteres and heat capacity curves can be considered as satisfactory. At low temperatures the slope of the expansion isostere changes gradually corresponding to the slow increase of c_p. The expansion due to melting begins at the temperature of the maximum heat capacity (−9.5°) and takes place in the region where the c_p curve shows a minimum which is characteristic of anomalous transitions.

ACKNOWLEDGMENTS

The author is indebted to Mr. P. J. Sereda for helpful discussions, to Mr. B. Hurley for carrying out most of the measurements, and to Mr. H. F. Slade for technical assistance. This contribution is published with the approval of the Director, Division of Building Research, National Research Council of Canada.

CATALYTIC HYDRODESULFURIZATION OF THIOPHENE

VI. COMPARISONS OVER MOLYBDENUM DISULFIDE, COBALT MOLYBDATE, AND CHROMIA CATALYSTS[1]

S. KOLBOE[2] AND C. H. AMBERG[3]

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received June 25, 1965

ABSTRACT

The hydrodesulfurization of thiophene over five molybdenum disulfide catalysts, an alumina-supported cobalt molybdate, and a chromia catalyst has been investigated. Comparisons on the basis of equal surface areas showed that desulfurization activity did not vary a great deal. It was established mainly by working at very low conversion levels that 1,3-butadiene was a product over all these catalysts, and that a mixture of butadiene, the three *n*-butenes, and *n*-butane constituted the actual *primary* reaction product. The reaction rate is strongly dependent on conversion, probably as the result of small quantities of product H_2S, the rate decreasing by a factor of 100 in going from 0.01% to 5% conversion in a typical flow experiment. A strong enhancement of the rate over MoS_2 was noted in the presence of oxygen.

INTRODUCTION

Following a series of studies of the hydrodesulfurization of thiophene over cobalt molybdate catalysts previously carried out in this laboratory (1–3) it was found to be of interest to investigate the catalytic properties of molybdenum disulfide itself, as this may well be the most important constituent in the sulfided cobalt molybdate.

Most of the experiments to be described below were carried out in the steady state and using much lower reaction rates than before; for this reason some comparative measurements using alumina-supported cobalt molybdate and pure chromia were included, these being the catalysts employed in the previous studies (1–5).

EXPERIMENTAL

(i) Apparatus

Modifications of the flow system which has been previously described (1) made it possible to pass a complete range of H_2/He mixtures through a thiophene saturator at flow rates varying from 1 to 200 ml/min at or near atmospheric pressure, flows and pressures being measurable with 1% precision or better. As before, pulse injection into a system in the steady state could take place from a syringe through a serum cap at the top of the microreactor. In addition, a simple syringe holder has been constructed, which permits additions to be sufficiently slow so that new steady states can again be attained over periods of several minutes. This is done by moving forward the plunger of the syringe with a screw (1 mm per turn) continuously or intermittently, depending on the requirements of a particular system. For the analysis of tail gases, when they are not passed directly to the gas chromatographic column, a commercial sampling valve (Perkin–Elmer) has now been incorporated in the apparatus.

The range of the apparatus was considerably extended by adding a flame ionization detector as an alternative to the Gow-Mac thermal conductivity detector. The flame ionization detector was a copy of one previously used by one of us (S. Kolboe. Unpublished). Using this combination of detectors, product concentrations from 3×10^{-12} up to 5×10^{-6} mole/ml (5×10^{-5} to 80 torr) were measurable; combined with the full range of flows available, reaction rates (product concentration $\times$ flow rate) from 5×10^{-14} to 1×10^{-3} mole/s were attainable, and these then represented the extreme limits of the apparatus.

An 8 ft propylene carbonate column (25% w/w) for C_4 analysis was used at 0 °C, the temperature being somewhat lower than that used earlier to minimize "bleeding" from the stationary phase, and a 6 ft squalane column (25% w/w) at 80–100 °C was again used for the analysis of sulfur compounds.

(ii) Catalysts

I. MoS_2 - "Molykote", a finely divided solid lubricant, used as received.

II. MoS_2 (Anachemia), as received.

III. Catalyst II doped with 1 mole % cobalt. Prepared by making a slurry with an aqueous solution of cobalt nitrate, drying, outgassing at 400–500 °C and then heating in a sealed quartz ampoule to 650 °C for 4 h.

IV. MoS_2 made by heating MoS_3 to 400 °C in a H_2/He mixture (6).

V. Prepared by heating catalyst IV to 650 °C for 1 h in a H_2/He mixture.

VI. Prepared by heating catalyst V to 800 °C for 12 h in a sealed quartz ampoule.

Although no changes in activity were observable in catalysts I–VI after the first 1 to 2 h of desulfurization at 300 °C, measurements were not made until after the first 5–10 h to ensure constant activity.

VII. Cobalt molybdate on alumina, Girdler No. G35A (1) crushed from pellets and using −65 mesh portion. Contains 1.3% Co + 6.1% Mo. Activated by heating in hydrogen to 400 °C and then stabilized (i.e. sulfided) with thiophene and H_2 for 16 h at a flow rate of 5 ml/min.

VIII. Chromia gel. Prepared by slowly adding a 10% ammonia solution to a 20% $Cr(NO_3)_3$ solution until pH = 9.0, filtering, washing, and drying.[4] Activated by slowly heating to 400 °C in hydrogen, and stabilized like catalyst VII.

The B.E.T. surface areas as well as spectrographic analyses of the catalysts are shown in Table I. The percentages given are an indication of order of magnitude only.

All catalysts gave reproducible results and nos. I, II, III, V, VI, and VII showed no decrease in activity after being in use for 2 to 3 weeks.

(iii) Reagents

Thiophene, Eastman; this contained some C_4 impurities which were largely removed by bubbling dry air through the liquid until about one-third of it had evaporated. Any C_4 compounds remaining were negligible even for measurements at very low conversion. The other impurities have been reported in (2).

C_4 hydrocarbons, Phillips research grade; used as received. Hydrogen, Matheson Ultrapure; used as received. Helium, Matheson; dried over Anhydrone.

RESULTS AND DISCUSSION

In contrast to the work reported previously in this series, conditions were now chosen so as to achieve much lower reaction rates and conversions in order to avoid the complications arising from secondary reactions. This was made possible by the increase in analytical sensitivity and it was also, in part, facilitated by using low-area catalysts.

No appreciable cracking was noted for any of the catalysts, and quantities of isobutylene and isobutane formed were negligible. There was no indication of any polymerization of unsaturated hydrocarbons. The product distribution of the *n*-C_4 hydrocarbons depended greatly on the catalyst and the conditions of a given experiment.

Attempts to run the reactor under differential conditions failed because of the extremely strong dependence of reaction rate on conversion even down to very low conversions, as shown in Fig. 1 for all catalysts. This strong dependence on conversion is believed to be caused by the H_2S formed in the reaction. Hydrogen sulfide addition experiments have shown that this gas strongly depresses the reaction rate. The effect appears to be of the right magnitude for explaining the conversion behavior; unfortunately it has not been possible to reproduce the curves shown in Fig. 1 by independent H_2S additions, because

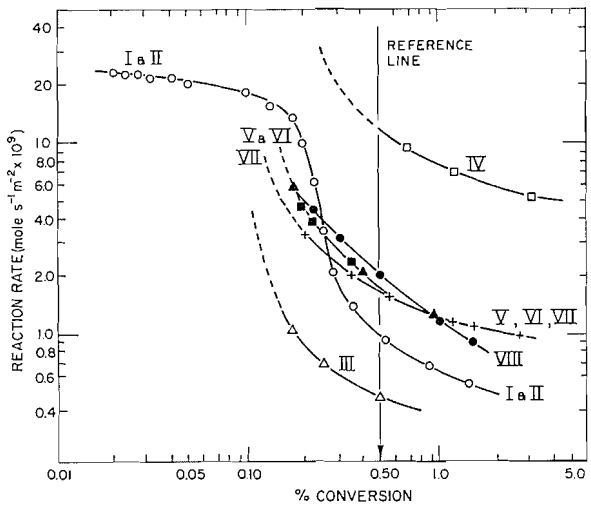

FIG. 1. Thiophene desulfurization as a function of conversion over various catalysts at 288 °C. Partial pressures: thiophene 20 torr; hydrogen 740–770 torr. Flows ranged from 2 to 200 ml/min, catalyst weights from 6 mg to 1.5 g. Roman numerals correspond to catalyst numbers. Extrapolations shown are based on measurements at 10–20 °C lower temperatures (identical curve shapes).

the required concentrations would have to be too small (the partial pressures of H_2S would have to lie in the region 0.02 to 0.2 torr). It has been possible to eliminate from consideration the effects of diffusion in the gas phase or in catalyst pores, temperature gradients within porous catalyst particles or from catalyst surface to ambient, as well as C_4-hydrocarbons generated by complete desulfurization of the 0.02% butanethiol impurity present in the thiophene. This was done by calculations and some ancillary experiments, such as employment of constant weight-to-flow ratios for different weights of catalyst.

It can be seen from Fig. 1 that unambiguous comparisons of catalyst activity cannot be made. However, for approximate comparisons under the same experimental conditions a region in which the curve shapes are similar has been arbitrarily selected (see "Reference Line" at 0.5% conversion); these comparative rates have been assembled in Table II. The most striking fact emerging from that table is the relatively slight variation of activities based on unit surface area of catalyst (column 5), particularly when compared with the rates based on unit weight of catalyst which vary by three orders of magnitude (column 4). This can be considered significant despite the uncertainties in the comparison of different catalysts discussed in connection with Fig. 1. Unless one makes the usual assumption that for the supported cobalt molybdate, VII, substantial coverage of the alumina surface has resulted from the impregnation processes employed, the good agreement in that case must be regarded as fortuitous. We are confident, however, that the assumption is correct and the comparison justified. The similarity in rates of desulfurization over all the catalysts

TABLE II

Reaction rates at 0.50% conversion and 288 °C. Hydrogen and thiophene pressures: 740 and 20 torr respectively; hydrogen flow rate: ~20 ml/min. Catalyst amounts varied from 10 mg to 1.5 g to give a total surface of 2–5 m^2

No.	Type	B.E.T. area ($m^2\ g^{-1}$)	Reaction rate (10^9 molc $s^{-1}\ g^{-1}$)	Reaction rate (10^9 mole $s^{-1}\ m^{-2}$)
I	MoS_2(Molykote)	2.2	2.2	1.0
II	MoS_2(Anach.)	3.3	3.0	0.90
III	MoS_2 + 1% Co	3.3	1.65	0.5
IV	MoS_2 from MoS_3(400°)	154	1 600	11
V	IV (650°)	67	107	1.6
VI	IV (800°)	12	18	1.5
VII	Cobalt molybdate on alumina (Girdler G35A)	241	400	1.65
VIII	Cr_2O_3	150	300	2.0

is strongly suggestive of the same basic mechanism being operative in all cases. In this connection it may be noted that an apparent activation energy of 24 kcal/mole was determined over catalyst V (MoS_2) in agreement with previously published values of 25 kcal/mole over VII (1) and 24 kcal/mole over a Cr_2O_3 catalyst (4) similar to VIII.

It is interesting to note, in passing, the decrease in activity per unit area when catalyst IV was pretreated by reduction in a H_2/He mixture at a higher temperature (catalyst V, 650°). In view of the common origin of the catalysts this decrease can be considered significant. It could be due to improved reduction, or to thermal destruction of unstable surface states in the MoS_2 crystallite, of surface impurities, or of micro-cracks accessible only to N_2; or combinations of these factors. Further sintering (catalyst VI, 800°), although decreasing the surface area by a factor of more than 5, had virtually no effect on activity per unit area or in other words on the catalytic nature of the surface.

The present set of experiments has thrown new light on the distribution of C_4 hydrocarbons over the various catalysts. Previously, both the *n*-butenes and *n*-butane had been identified as reaction products over a cobalt molybdate identical with catalyst No. VII (1), as well as over a chromia similar to No. VIII (4); moreover, butadiene had been found over chromia, and identified on catalyst VII during infrared studies carried out while the reaction was in progress (R. A. Siddiqui and C. H. Amberg. Unpublished). It had been assumed at the time that butadiene would occur in the gas phase also over the cobalt molybdate catalyst in significant amounts, but that it was being hydrogenated too fast for detection. Butadiene has now been definitely identified as a gas phase product over all the catalysts used.

Even though the C_4 distribution depends strongly on conditions, a single set is given in Table III for the same conditions as those specified in Table II for purposes of comparison.

In the earlier experiments in this series, the distribution of the *n*-butenes had always been close to equilibrium (1), although a tendency for 1-butene and *cis*-2-butene to occur slightly in excess had been observed (3). Present conditions of steady-state operation at very short contact times strongly accentuate this tendency, so that the distributions are far from equilibrium. Thus it can be calculated from Table III that the observed quantity of 1-ene exceeded the equilibrium value by factors of 3–6 (equilibrium distribution: 13.2% 1-ene, 32.2% *cis*-2-ene, 54.6% *trans*-2-ene).

The dependence of C_4 distribution on conversion can be appreciable even at conversions as low as 0.5%; this is borne out by Fig. 2, which is shown as an example. Care should be

TABLE III

Distribution of C_4 hydrocarbons from thiophene at 0.50% conversion and 288 °C. Hydrogen and thiophene pressures: 740 and 20 torr, respectively; hydrogen flow rate: ~20 ml/min

Catalyst	Butadiene (%)	1-Butene (%)	*cis*-2-Butene (%)	*trans*-2-Butene (%)	Butane (%)
I	6.2	42.6	21.7	22.0	9.1
II	6.9	42.5	22.3	19.2	8.8
III	8.4	55.6	14.0	17.4	4.7
IV	7.2	39.9	16.7	23.5	12.7
V	4.0	28.5	22.0	36.5	9.5
VI*	—	—	—	—	—
VII	2.2	47.5	19.8	24.3	6.2
VIII	7.7	31.3	11.8	11.8	37.4

*Product distributions for catalyst VI were only roughly surveyed, but did not appear to show significantly different trends.

taken not to extrapolate the curves in Fig. 2 to zero conversion, because in the interval not shown here, abnormal and yet completely reproducible inflections of the curves have been observed for some catalysts, for which we have at present no reasonable explanation. Catalysts IV, V, VI, and VII exhibited essentially the same dependence upon conversion as is demonstrated in Fig. 2, while catalysts I, II, III, and VIII varied to a lesser extent with conversion.

Consecutive reactions—if by this we mean further reaction with a product molecule which has been present in the gas phase—were found not to be the prime reason for the changing product distribution with conversion. Thus the isomerization and hydrogenation rates of 1-butene over catalyst V were examined by slowly admitting the gas to the reactor, simultaneously with the thiophene, and under the same conditions as were indicated for Fig. 2 except for a conversion level of 0.4%. It had been shown previously that olefins do

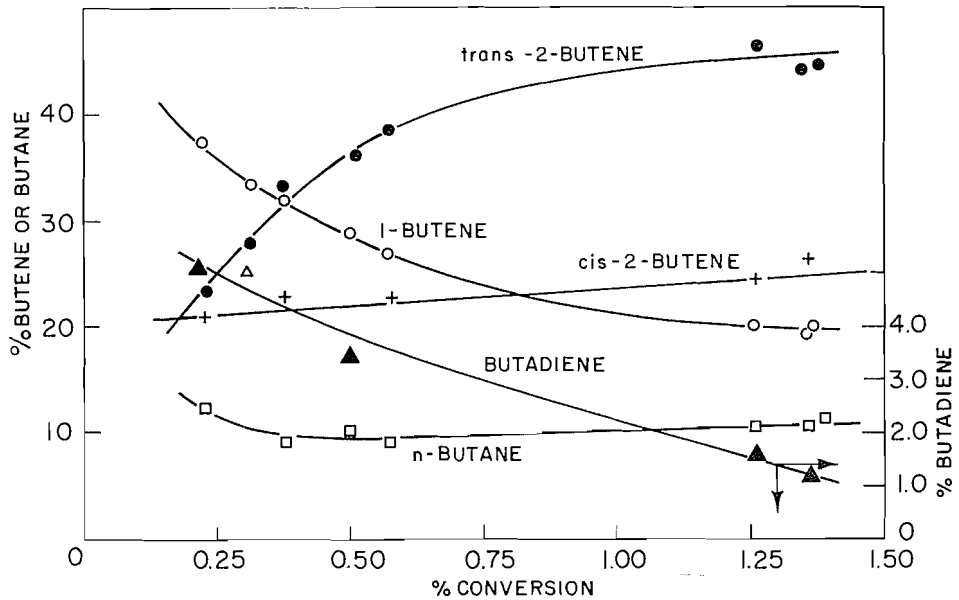

FIG. 2. Product distribution as a function of thiophene conversion over MoS_2 catalyst V at 288 °C. Partial pressures: thiophene 20 torr; hydrogen 740 torr. Flows 5–200 ml/min. Catalyst weights 20 and 75 mg.

not much affect the rate of hydrodesulfurization (1) and, in any case, the concentration of the added 1-butene was only about 1% of that of the thiophene. In this way no more than 1–2% of the added 1-butene was isomerized to *cis*- or *trans*-2-butene, the isomerization following first-order kinetics. No hydrogenation of the added butene could be detected. From somewhat different experiments performed with butadiene on the other hand one may deduce that a fair amount of gas-phase butadiene, say between 25 and 50%, would be hydrogenated under the above conditions. It must then be concluded that distributions of the type shown in Fig. 2 are essentially primary product distributions of the C_4 hydrocarbons as desorbed from the catalyst, the only exception being the fast reacting butadiene which shows too low a value. Considering that no hydrogenation of butene could be detected, it is remarkable that the fully hydrogenated butane forms a significant fraction of the reaction products. Since the other catalysts exhibited the same reaction pattern it can be stated that all of them yield a *primary* product consisting of a mixture of 1,3-butadiene, the three *n*-butenes, and *n*-butane. This result had been anticipated by an indirect calculation using data from experiments over chromia (4).

The fact that 1,3-butadiene was identified over all our catalysts (in amounts of up to 60%, depending on conditions) might indicate, as has been argued previously, that it is the first C_4-hydrocarbon formed from thiophene. If this is so, however, it can now be seen that only a part of the butadiene molecules can have desorbed from the surface prior to further hydrogenation. This is borne out by the following experiments over catalyst No. I: Butadiene was admitted to the system which was in the steady state with respect to thiophene desulfurization. The distribution of the butenes coming from the added butadiene was evaluated and found to be similar to that arising from thiophene desulfurization, but significantly lower in 1-butene (Table IV).

TABLE IV

Product distributions from thiophene and from added 1,3-butadiene over catalyst No. I at 320 °C and 1.5% conversion. Partial pressures: thiophene 20 torr, H_2 200 torr, He 540 torr; flow rate of hydrogen/helium carrier gas: 20 ml/min; catalyst weight: 1.5 g

Reactant	1-Butene (%)	*cis*-2-Butene (%)	*trans*-2-Butene (%)	Butane (%)
Thiophene	50.0	19.0	25.5	5.8
Thiophene (butenes only)	(53)	(20)	(27)	
1,3-Butadiene*	40	22	37	<0.5

*Mean of two experiments in which amount of butadiene added was, respectively, equal to and three times the total C_4 yield from thiophene.

The table shows that the behavior of butadiene is analogous to that of 1-butene, in that complete hydrogenation of the free gas can be almost totally suppressed under conditions in which thiophene desulfurization can still give rise to significant amounts of butane, provided these conditions are appropriately selected. Similar results were observed over catalyst V, which leads us to believe that the phenomenon is a general one for all our catalysts.

If we accept that the first C_4-hydrocarbon product from thiophene is adsorbed 1,3-butadiene, then the different product distributions from thiophene and from added butadiene shown in Table IV can only arise from two different surface configurations of the adsorbed butadiene molecule. Similar reasoning would apply to butenes from thiophene on the one hand, and butenes added or derived from hydrogenated butadiene on the other, if

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and only if the hydrogenation route of thiophene proceeds through adsorbed butene. This is so, because thiophene can be made to yield butane under conditions where gas phase butene will not hydrogenate further. The above arguments are not invalidated by the possibility of a sulfur-containing adsorbate, say of the type

$$-S-CH=CH-CH=CH_2,$$

preceding the butadiene, if the latter is to be regarded as an intermediate member of the hydrogenation sequence (3). However, if butane were to be formed directly from the adsorbed diene-thiol a much more complex desulfurization mechanism than had been envisaged so far would have to be proposed. This will be discussed in a later publication (S. Kolboe. To be published).

It was noted previously that olefin hydrogenation was strongly suppressed in the presence of H_2S over supported cobalt molybdate (catalyst VII), and to a much lesser extent over chromia (4). The selective effect of H_2S has now been observed over pure MoS_2 (catalyst VI) and so may be assumed to be general for MoS_2 catalysts. The fact that butadiene was always fully hydrogenated to butenes and butane in the earlier studies was due to the very different reaction conditions employed then.

In an effort to reexamine the poisoning effect of ammonia on the desulfurization reaction (3) a 10 μl pulse of conc. aqueous NH_3 was injected into a steady-state system operating over catalyst IV (100 mg catalyst; 250 °C; hydrogen flow: 25 ml/min; partial pressure of thiophene: 20 torr). No effect whatever could be found after 2 min. On examining the hydrogenation and isomerization of 1-butene (pulse addition) in the absence of thiophene but otherwise under similar conditions over catalyst VI, an effect was observed with ammonia solution, but this lasted only about 10 min; moreover, water addition produced a similar effect. As before, H_2S acted as a much stronger and long-lasting poison.

The above observations indicate that the activity of pure MoS_2 does not reside in acid sites of the Brønsted type: one would not expect fast desorption of NH_3 from such sites at the relatively low temperatures employed. This is in contrast to the strong and persistent effect of pyridine found earlier with the cobalt molybdate on alumina catalyst (3). If the earlier results are to be interpreted on the basis of acid-site poisoning in the Brønsted sense—as was implied at the time—then it becomes necessary to invoke cooperative effects arising from the acidic sites of the alumina. This would be compatible with the fact that only a partial poisoning of the supported catalyst was observed. Obviously, however, a

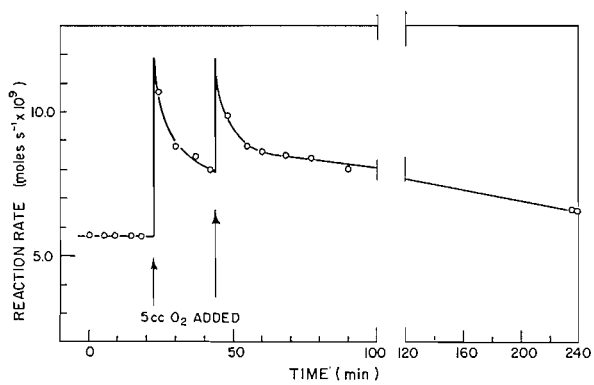

FIG. 3. Effect of oxygen pulses on the rate of desulfurization of thiophene over MoS_2 catalyst V at 289 °C and 1.2% conversion. Partial pressures: thiophene 20 torr; hydrogen 740 torr. Flow 21 ml/min. Catalyst weight 75 mg.

more detailed study is required before specific sites can be identified with any degree of confidence.

Finally it is worthy of note that oxygen addition, as demonstrated in Fig. 3, led to an immediate doubling of the desulfurization rate over catalyst V, followed by gradual return to the initial rate over a period of hours. At the same time the product composition was completely unchanged, indicating that desulfurization and hydrogenation sites, if distinct from each other, were affected to the same extent. Isomerization was too close to equilibrium for significant conclusions to be drawn regarding the sites pertinent to that reaction. Similar experiments performed during butene hydrogenation resulted in the same qualitative behavior, but the effect was much more marked in that the hydrogenation rate was increased by a factor of 50–100. We have at present no explanation of these results. However, since oxygen is a strong electron acceptor, it is tempting to find an answer in terms of the electronic properties of MoS_2 which is to be regarded as a semiconductor. An indirect promotion through water formation can probably be ruled out, because under all conditions which were tried water was found to act as a poison.

ACKNOWLEDGMENTS

We thank D. Kulawic for the measurement of surface areas and P. Tymchuk for spectrographic analyses.

Reçu le 20 avril 1966

RÉSUMÉ

On a étudié, à l'aide de calculs électroniques de formes de raies, les effets d'anisotropies hyperfines sur les spectres de résonance paramagnétique électronique de radicaux allyliques polyorientés. Les formes de raie calculées s'avèrent fortement dépendantes de l'orientation relative des tenseurs, donc susceptibles de caractériser les structures isomériques possibles. La comparaison entre les spectres calculés après introduction de l'anisotropie de **g** et ceux mesurés pour différents composés monoéthyléniques irradiés aux γ a permis d'identifier les radicaux allyliques produits et de montrer que, dans la plupart des cas, ces radicaux gardent la configuration géométrique de la molécule initiale.

ABSTRACT

The effect of the hyperfine coupling anisotropy on the shape of the electron spin resonance spectra of randomly oriented allyl radicals has been studied by means of electronic computer calculation. The line shape has been shown to be strongly dependent on the relative orientation of the tensor axes, and it can be used, therefore, to characterize the structural isomerism of the radical. The comparison of the computed spectra, taking account of the **g** tensor anisotropy, with the spectra recorded after γ irradiation of several monoethylenic compounds, allowed the identification of the produced allyl radicals and showed that, in most cases, these radicals keep the geometrical configuration of the corresponding undamaged molecules.

I. INTRODUCTION

Bien que les spectres de résonance paramagnétique electronique (r.p.e.) des radicaux produits dans des échantillons liquides (p.ex., 1) ou monocristallins (p.ex., 2, 3) fournissent des informations des plus précises sur la structure électronique et géométrique des espèces, ainsi que sur leurs interactions avec l'environnement, les physico-chimistes sont souvent amenés à faire des expériences sur des solides polycristallins ou amorphes. L'interprétation des spectres obtenus dans ces conditions peut présenter cependant de grandes difficultés, en raison d'effets d'anisotropie qui peuvent soit élargir plus ou moins asymétriquement les composantes, soit donner naissance à des singularités susceptibles d'être attribuées par erreur à une structure hyperfine mal résolue. Depuis une quinzaine d'années, un certain nombre d'études, aussi bien expérimentales que théoriques, ont été faites sur ce problème (p.ex., 4, 5). Les choses se simplifient considérablement lorsqu'on n'a qu'un petit nombre de tenseurs, de préférence axiaux, à axes principaux confondus, et que les raies "satellites" (p.ex., 5*d*) sont négligeables et l'élargissement des composantes (p.ex., 4*d*, 5*a*, 5*c*, 5*d*), peu important. Dans le cas, général, de plusieurs tenseurs hyperfins orientés dans tous les sens, avec possibilité de raies "satellites" et élargissement élémentaire important, le problème devient analytiquement inextricable, et sa seule méthode d'approche est le calcul électronique. Dans un article antérieur (6), on a étudié les diverses possibilités offertes par le calcul électronique des formes de raie associées à des

[1]*B.P n° 2, 91 Gif-sur Yvette.*
[2]*23 rue du Maroc, Paris 19e.*

hamiltoniens de spin supposés. Nous nous proposons ici de fournir une nouvelle application de cette méthode, à l'étude systématique des spectres de radicaux allyliques polyorientés.

Ce travail comporte deux parties: dans la première, on analyse les spectres calculés, pour l'ensemble des radicaux allyliques possibles à protons σ (p.ex., 8) seulement, en négligeant l'anisotropie de $\mathbf{g}$; dans la seconde, on se sert des spectres calculés pour identifier, après introduction de l'anisotropie de $\mathbf{g}$, les radicaux allyliques produits par irradiation γ de composés monoéthyléniques.

II. ANALYSE DES SPECTRES CALCULÉS

Nous allons étudier maintenant la structure des spectres calculés pour des radicaux produits par substitution aux protons du radical allyle de groupes ne contribuant pas à la structure hyperfine et ne perturbant pas les densités de spin π (p.ex., 8) sur les carbones centraux. Ces radicaux peuvent être définis par la donnée des positions des protons restants, repérés par leurs numéros dans la Fig. 1.

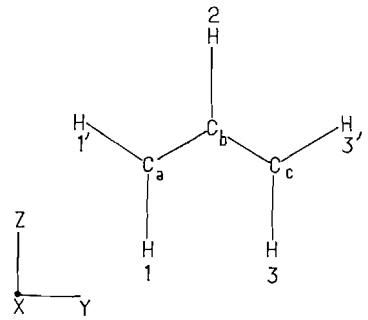

FIG. 1. Formule développée plane du radical allyle, avec représentation des axes principaux des tenseurs de H_1, H_2 et H_3.

Des radicaux de ce type ont été mis en évidence dans différentes matrices rigides (5*c*, 7). Un certain nombre d'études, tant expérimentales (1, 3) que théoriques (p.ex., 8), ont montré que la densité de spin π sur le carbone médian est négative et de l'ordre du tiers de celles, positives, sur les carbones extrêmes. Ces densités ne varient guère par substitution de groupes carboxyliques à des hydrogènes de l'allyle ($\rho_a = \rho_c = 0.58$, $\rho_b = -0.16$ pour l'allyl (1); $\rho_a = \rho_c = 0.57$, $\rho_b = -0.19$ pour le dérivé dicarboxylé en 1′,3′ (3)). Le paramètre Q_σ de l'interaction σ–π (p.ex., 8) n'étant pas non plus très modifié par de telles substitutions (1, 3), les couplages ne varieront guère quand on décrira la série ainsi constituée. Nous avons alors adopté, pour valeurs principales moyennes des tenseurs hyperfins:

pour les positions 1, 2 et 3, les valeurs mesurées sur le composé obtenu par substitution de groupes carboxyliques en 1′, 3′ (3):

$$c^x_{1,3} = -12.5\ \text{G},\ c^y_{1,3} = -18.9\ \text{G},\ c^z_{1,3} = -6.4\ \text{G},$$

$$c^x_2 = +2.5\ \text{G},\ c^y_2 = +6.1\ \text{G},\quad c^z_2 = \pm 4.3\ \text{G};$$

pour les positions 1′ et 3′, celles mesurées en 1 et 3 (3) modifiées pour tenir compte de la différence des interactions dipôlaires de 1 et 1′ avec ρ_c et, symétriquement, de 3 et 3′ avec ρ_a, soit:

$$c^x_{1',3'} = -13.0\ \text{G},\ c^{y',y''}_{1',3'} = -17.8\ \text{G},\ c^{z',z''}_{1',3'} = -5.8\ \text{G},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

y' et y'' et z' et z'' désignant, respectivement, les directions perpendiculaires et parallèles aux liaisons $C_aH_{1'}$ et $C_cH_{3'}$. De cet ensemble de valeurs principales, on déduit les couplages isotropes:

$$a_{1,1',3,3'} = -12.45 \text{ G}, \quad a_2 = +4.3 \text{ G}.$$

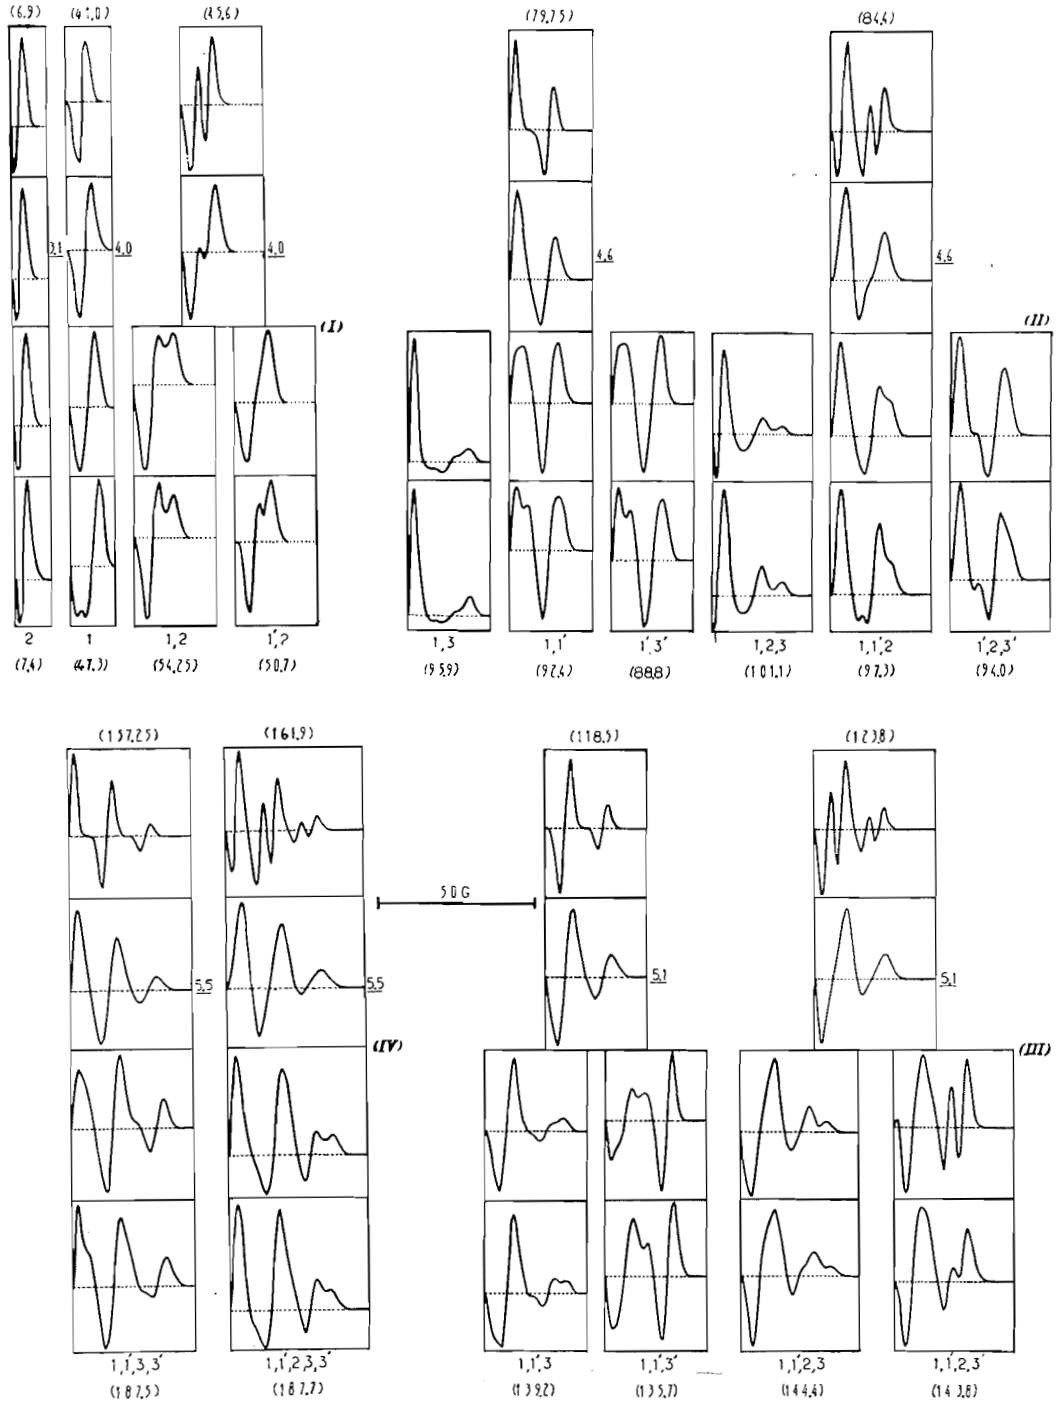
Négligeant, ainsi, les effets spécifiques des substituants sur la distribution des densités de spin dans la molécule, nous avons, en particulier, considéré comme équivalents des protons symétriques par rapport au plan passant par l'axe médian et perpendiculaire au plan moléculaire, ce qui réduit le nombre des cas possibles. En outre, dans ce paragraphe, nous n'avons pas du tout tenu compte de l'anisotropie de $\mathbf{g}$, et, quant au reste, nous avons, pour les différents cas étudiés (Fig. 2), considéré les modifications subies par le spectre "isotrope" (ligne 1) à mesure que l'on introduit les différents effets liés à l'anisotropie des $\mathbf{c}_i$: l'élargissement *moyen* des composantes (ligne 2), leur élargissement *spécifique* (ligne 3), et les transitions du type $\Delta M_s = 1$, $\Delta M'_I = 1$ (ligne 4) (M'_I désignant la projection du spin nucléaire sur la résultante du champ externe et du champ interne créé par le spin électronique orienté). Nous définissons l'élargissement *moyen* comme un élargissement supplémentaire donné par:

$$[1] \qquad \sigma = 2\left(\frac{1}{3} M_2^d\right)^{1/2} = \left(\frac{1}{3}\sum_i \frac{1}{3}\sum_u (b_i^u)^2\right)^{1/2},$$

où les b_i^u sont les valeurs principales des parties dipôlaires des $\mathbf{c}_i$, M_2^d est le deuxième moment lié aux parties dipôlaires des tenseurs hyperfins, et le coefficient $\frac{1}{3}$ provient d'une optimisation de sa contribution à l'élargissement des différentes raies pour les différentes structures. Cette largeur s'ajoute à la largeur *élémentaire*, λ, pour donner la largeur *globale*, Λ, suivant la relation:

$$[2] \qquad \Lambda = (\sigma^2 + \lambda^2)^{1/2}$$

où λ a partout été pris égal à 3 G. Les spectres de la ligne 4 sont calculés pour la bande X ($H_c = 3\,300$ G, $H_p = 5.02$ G).



Avant de passer à l'analyse des spectres calculés, nous allons rappeler brièvement les notions de champs stationnaires et de deuxièmes moments, qui seront utilisées dans l'interprétation de certains d'entre eux. On démontre que, si un radical a un seul système d'axes privilégié pour ses tenseurs, les positions des singularités de son spectre polycristallin seront liées de manière simple aux valeurs principales de ceux-ci (p.ex., 4, 5), en raison du fait que les positions des raies "monocristallines" sont stationnaires par rapport à tout changement d'orientation quand le champ externe est aligné suivant l'un des axes (orientations canoniques) (p.ex., 2, 3). Les diagrammes de champs stationnaires consistent alors en la superposition des raies correspondant à ces orientations canoniques, à l'exclusion de toutes les autres (p.ex., 6, 9). On ne pourra constituer de diagrammes de champs stationnaires lorsque les tenseurs auront des axes principaux très différents, ou que les transitions "interdites" ($\Delta M_S = 1$, $\Delta M'_I = 1$), d'intensités toujours nulles aux orientations canoniques (p.ex., 2), contribueront de façon notable au spectre polycristallin. Nous utiliserons aussi la notion de deuxième moment: si $F(H)$ est une courbe d'absorption "polycristalline", son deuxième moment est défini par la relation:

$$[3] \qquad M_2 = \int_{-\infty}^{+\infty} F(H)(\Delta H)^2 \, dH,$$

et il est donné, en l'absence d'anisotropie de $\mathbf{g}$, et pour des noyaux de spin $\frac{1}{2}$, par l'expression (5*d*, 6):

$$[4] \qquad M_2 = \frac{1}{12}\sum_i \sum_u (c_i^u)^2 + \frac{\lambda^2}{4}.$$

FIG. 2. Formes de raie calculées, à l'aide de tenseurs hyperfins normalisés pour l'ensemble des radicaux allyliques possibles possédant des protons σ seulement. La position de ceux-ci est indiquée au bas de chaque colonne, à l'aide de la numérotation apparaissant Fig. 1. Seules les dérivées premières des courbes d'absorption ont été représentées. Les tenseurs hyperfins de H_1, H_2 et H_3 (Fig. 1) utilisés dans le calcul sont ceux mesurés sur un monocristal d'acide glutaconique irradié (3) omission étant ici faite de léger défaut de parallélisme entre leurs axes; ceux de H_1' et H_3' sont ceux de H_1 et H_3 modifiés pour tenir compte de l'interaction dipôlaire plus faible avec la densité de spin π sur le carbone opposé (la disposition relative de leurs axes étant déduite de la symétrie du système). Le tenseur **g** a été partout négligé, seule une moitié de chaque spectre étant alors calculée. Les spectres où l'on a tenu compte des transitions du type $\Delta M_I' = 1$ sont calculés pour la bande *X* seulement. La largeur monocristalline a été prise égale à celle qui fournira (courbe φ de la Fig. 4) la reconstitution la plus fidèle du spectre polycristallin expérimental (courbe *f* de la Fig. 4) de l'acide glutaconique irradié. Ligne 1: l'anisotropie des couplages hyperfins est omise; ligne 2: il en est tenu compte seulement par un élargissement supplémentaire moyen des composantes (souligné); ligne 3: l'anisotropie des couplages hyperfins est explicitement introduite, mais les transitions du type $\Delta M_I' = 1$, quoique non toujours "satellites" sont ici aussi négligées; ligne 4: on tient compte de toutes les transitions possibles. Les deuxièmes moments totaux des première et dernière lignes, exprimés en G^2, sont indiqués entre parenthèses.

Nous avons déjà employé cette expression pour définir la largeur globale des composantes isotropes d'un spectre.

Les différentes formes de raie calculées pour le cas d'un proton unique localisé en la position 2 sont constituées (Fig. 2,I) par une bande simple, de largeur sensiblement constante (comparer les seconds moments calculés pour les lignes supérieure et inférieure). Ceci n'est pas étonnant, si l'on considère que:

(*a*) la contribution au second moment de $\mathbf{c}_2$ est faible comparée à celle (2.25 G^2) de la largeur adoptée pour les composantes (ligne 2);

(*b*) la distance (0.9 G) entre les champs stationnaires correspondant aux trois valeurs principales de $\mathbf{c}_2$ est très inférieure à cette même largeur (ligne 3);

(*c*) la transition du type $\Delta M'_I = 1$ (qui se situe vers 5 G) est à une distance de la singularité la plus extrême (vers 3 G) elle aussi sensiblement inférieure à λ, et ne peut donc en être distinguée (ligne 4).

Le cas d'un proton unique en position 1 ou 1′ est un peu plus compliqué. Si, en effet, pour ce cas il n'y a guère de différence entre les spectres calculés aux lignes 1, 2 et 3—les distances entre champs stationnaires étant encore de l'ordre (3.1 G) de l'élargissement élémentaire—l'introduction de la transition supplémentaire produit (ligne 4) une complication du spectre, cette transition se produisant au voisinage (5.0 G) du champ stationnaire intermédiaire (6.4 G) de la bande principale.

Dans les colonnes suivantes, nous avons ajouté au proton 1, puis 1′, le proton 2 (les figures des deux premières lignes sont communes aux deux colonnes). La différence, sensible, entre les spectres relatifs aux différentes structures provient moins des écarts, petits, entre les valeurs de $\mathbf{c}_1$ et celles de $\mathbf{c}_{1'}$ que de l'écart, considérable, entre les orientations de leurs axes par rapport à ceux de $\mathbf{c}_2$. Le spectre correspondant à la structure 1,2 calculé sans raies "satellites" s'explique aisément par la méthode des champs stationnaires (Fig. 3*a*). Les spectres des deux autres structures pourraient eux aussi donner lieu à un diagramme approché de champs stationnaires, considérant que la plus petite valeur principale de chaque tenseur est, à 30° près, orientée comme la plus grande valeur principale de l'autre, les axes intermédiaires étant toujours confondus (ce qui explique que l'on n'observe que trois bandes binômiales sans structure). L'introduction des transitions supplémentaires modifie les spectres dans le même sens dans les deux cas. Comme on pourra le vérifier aussi dans les colonnes qui suivent, le remplacement de la partie anisotrope des tenseurs par un élargissement moyen supplémentaire (ligne 2) peut, dans certains des cas, permettre de reproduire, à peu de chose près, la moyenne des spectres calculés sans les transitions supplémentaires (ligne 3) (mais, naturellement, elle ne permet pas de distinguer entre les différentes structures).

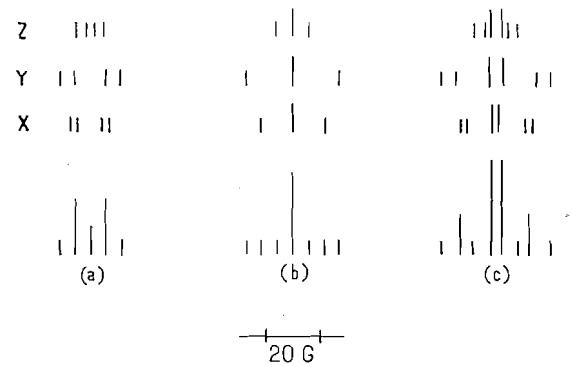

FIG. 3. Champs stationnaires des spectres des différentes structures radicalaires allyliques à liaisons C—H parallèles: (*a*) 1,2; (*b*) 1,3; (*c*) 1,2,3. De haut en bas sont indiqués les champs de résonance correspondant aux différentes orientations canoniques, indiquées à gauche en marge; les hauteurs des raies sont évaluées compte-tenu des dégénérescences. On a fondu, dans les derniers diagrammes (où les différents schémas sont superposés), les raies dont les distances sont inférieures à la largeur utilisée dans les calculs de formes de raie présentés dans Fig. 2. Les raies "satellites" ont été partout négligées.

Les trois colonnes qui suivent (Fig. 2,II) présentent les spectres calculés pour les trois structures comportant deux protons sur les carbones extrêmes 1,3; 1,1′ et 1′,3′. Remarquons que la légère différence entre les spectres calculés pour ces deux dernières est uniquement due aux petites différences entre les valeurs principales des tenseurs primés et non primés, les axes principaux ayant les mêmes orientations relatives dans les deux cas. Le spectre de 1,3 est, par contre, très différent, la bande centrale du triplet étant, cette fois, très mince—du même ordre de largeur que les composantes—et les deux bandes extrêmes, larges et bien structurées. Ces particularités peuvent aisément s'expliquer par des champs stationnaires très prononcés dans ce cas, les tenseurs étant strictement équivalents et ayant leurs axes parallèles (Fig. 3*b*). Les trois inflexions de chaque bande latérale correspondent, au recouvrement près, aux positions différentes de chaque raie extrême aux trois orientations canoniques, tandis que la raie centrale, la plus intense, garde la même position à toutes les orientations. Pour les structures 1,1′ et 1′,3′, on ne peut appliquer qu'un diagramme approché de champs stationnaires, considérant que les deux protons sont, à 30° près, à angle droit: on arrive à expliquer ainsi la quasi-isotropie de la bande latérale et l'élargissement de la bande centrale. On peut encore noter que, comme on pouvait s'y attendre, d'après une remarque antérieure, l'introduction des raies "satellites" a, sur les spectres, un effet d'autant plus marqué que, toutes choses égales d'ailleurs, les champs stationnaires sont moins prononcés.

Si l'on ajoute un proton 2 aux structures qui viennent d'être décrites, on obtient les spectres présentés dans les colonnes qui suivent (Fig. 2,II). Le premier de ces spectres, calculé pour la structure 1,2,3 sans raies "satellites", peut encore s'expliquer par des champs stationnaires prononcés (Fig. 3*c*). On constate que, par l'introduction du proton 2, le pic central de chaque bande extrême se relève et s'élargit au détriment de sa singularité externe, tandis que la bande centrale se dédouble et s'élargit en recouvrant partiellement les singularités internes. Comme prévu, les raies "satellites" ne modifient pas fondamentalement ce schéma. Nous verrons plus loin (Fig. 4) l'effet produit par l'anisotropie de **g**. Les spectres des deux autres structures peuvent, eux aussi, être utilement comparés aux spectres des structures correspondantes sans proton 2. Le changement produit par l'introduction du proton 2 est plus considérable pour la structure 1,1′,2, où

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$\mathbf{c}_2$ a les mêmes axes que $\mathbf{c}_1$, que la structure 1′,2,3′, où $\mathbf{c}_2$ a des axes intermédiaires entre ceux de $\mathbf{c}_{1'}$ et ceux de $\mathbf{c}_{3'}$ (et contribue donc surtout à élargir les bandes) et ce, aussi bien avec que sans raies "satellites". Bien entendu, la méthode des champs stationnaires n'est alors pas applicable.

Les deux premières colonnes de la Fig. 2,III se rapportent aux structures comportant trois protons sur les carbones extrêmes. La structure "en étoile," 1,1′,3′, devrait fournir des spectres très semblables à ceux calculés avec les seuls couplages isotropes (lignes 1 et 2), puisque, pour cette structure, les anisotropies hyperfines se compensent pour donner à toute orientation les mêmes décalages. Mais, curieusement, ce n'est pas ce qui se produit; les spectres 1,1′,3 ressemblent le plus aux spectres isotropes; la bande centrale est à peine élargie, seule la bande extrême acquérant une structure. Pour 1,1′,3′, la bande latérale reste bien isotrope, mais la bande centrale s'élargit en se structurant, faisant perdre au spectre son allure de quartet binômial. La méthode des champs stationnaires n'étant guère ici utilisable, on ne peut comprendre ces singularités qu'en se référant aux spectres, plus simples, des structures 1,3 et 1′,3′. Nous aurons à utiliser plus loin la différence, considérable, des spectres correspondant à ces deux structures, dans l'identification des radicaux produits par irradiation de poudres polycristallines.

L'adjonction d'un proton en 2 dans les structures qui précèdent produit une modification des spectres très sensible pour le composé "en étoile", mais plus légère—sensible surtout aux extrêmités—pour l'autre. Ici encore, c'est le spectre du dernier qui paraît le mieux reproduit dans l'approximation des composantes isotropes élargies (ligne 2), à l'épaulement latéral près. Les spectres de 1,1′,2,3 et de 1,1′,2,3′ peuvent encore être utilement comparés à ceux, précédemment étudiés, des structures 1,2,3; 1,1′,2 et 1′,2,3′. Pour 1,1′,2,3′, l'introduction des raies "satellites" paraît agir surtout en élargissant simplement les composantes. Ces spectres nous serviront eux-aussi ultérieurement.

Si l'on a deux protons sur chaque carbone extrême (Fig. 2,IV), une seule structure est possible, et l'on obtient par le calcul complet un spectre d'allure quasi-binômiale (dernière ligne de la première colonne). L'interprétation détaillée de ce spectre n'étant guère possible, nous ne nous y attarderons pas, retenant seulement que plus le nombre de protons d'un radical sera grand, mieux le spectre pourra être reproduit, à un élargissement moyen supplémentaire près, à l'aide de simples couplages isotropes. L'adjonction à ce composé d'un proton en 2, pour aboutir au radical allyle lui-même, n'apportera (deuxième colonne) que des différences de détail à la structure des spectres, en particulier un dédoublement de la bande extrême.

III. IDENTIFICATION DES RADICAUX PRODUITS

1. *Conditions expérimentales*

Nous avons irradié par les rayons γ du ^{60}Co une série de composés monoéthyléniques, afin de comparer les spectres théoriques décrits dans le paragraphe précédent à des spectres expérimentaux.

Les produits utilisés étaient l'alcool allylique, les acides crotonique, citraconique, mésaconique, glutaconique, itaconique et *trans*-aconitique, et l'anhydride *cis*-aconitique. A part le premier et le dernier composés, tous ont été purifiés par recristallisation dans l'eau ou l'acétone puis dessication sous vide pendant 24 heures. Les échantillons étaient dégazés et scellés sous vide avant irradiation dans des tubes en silice "Spectrosil".

Les irradiations ont été effectuées à 77 °K avec des doses allant de 2 à 3 Mrads et jusqu'à 10 Mrads pour les composés donnant des radicaux peu stables à température ordinaire.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Les mesures étaient effectuées à l'aide d'un spectromètre fonctionnant à 9 250 MHz, le champ magnétique étant mesuré par un magnétomètre à résonance nucléaire (Varian F 8) relié à un fréquencemètre. Les échantillons, pendant les mesures, étaient refroidis par l'azote liquide à 77 °K, et, entre 95 °K et 300 °K, en les plaçant dans un cryostat à azote refroidi situé dans la cavité du spectromètre.

2. Résultats obtenus

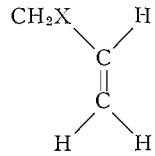
Nous avons rassemblé dans le Tableau I les différents types de composés étudiés et de radicaux allyliques pouvant en dériver par ruptures de liaisons simples, si l'on fait abstraction d'isomérisations éventuelles. Ces composés sont classés selon les nombres et positions des substituants. Les autres radicaux pouvant se former par arrachement d'hydrogène ou de groupement oxygéné sont de type σ. Il peut aussi se former des radicaux π, saturés, par addition sur la double laison éthylénique.*

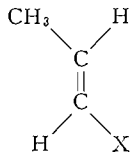
Nous avons comparé les spectres obtenus par irradiation aux spectres étudiés dans le paragraphe précédent. Pour réaliser un meilleur accord entre spectres expérimentaux et théoriques, nous avons dû modifier la largeur monocristalline des composantes et introduire l'anisotropie de **g**. Les valeurs principales de ce tenseur étant sensiblement les mêmes, à l'approximation de Stone (10) près, pour tous les radicaux de cette série, nous avons adopté, simplement, pour ces valeurs celles mesurées sur un monocristal du composé dicarboxylé en 1′,3′ (3), soit:

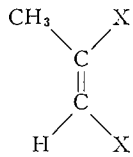
$$g_x = 2.0021, \qquad g_y = g_z = 2.0036,$$

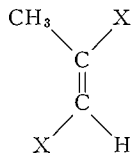
les axes principaux étant sensiblement ceux de $\mathbf{c}_1$, $\mathbf{c}_2$ et $\mathbf{c}_3$, définis prédédemment.

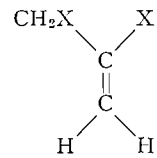
Les résultats obtenus sont les suivants (Fig. 4).

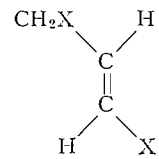


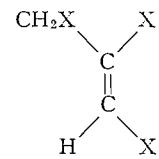


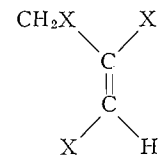






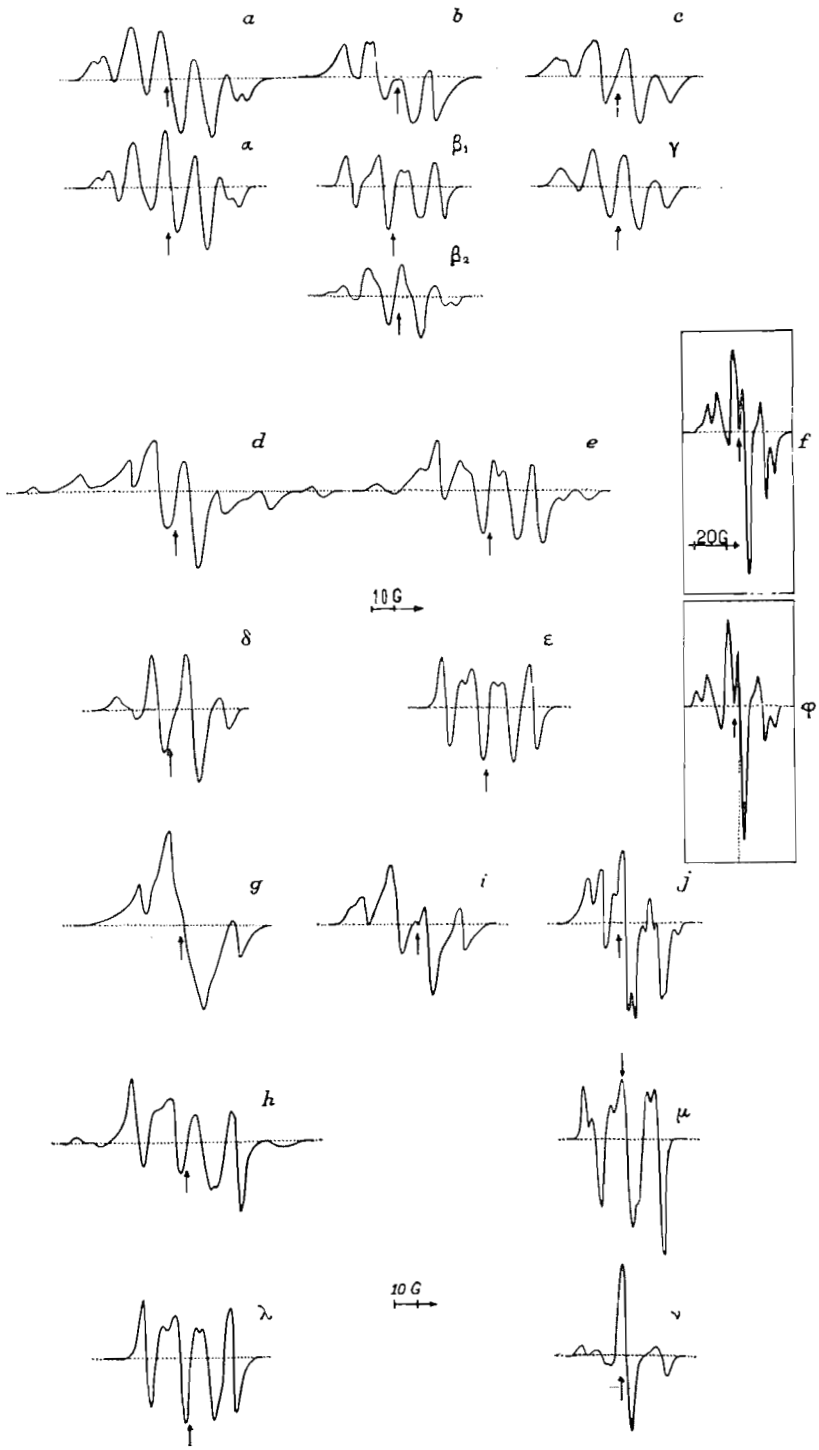






I,1, X = OH, alcool allylique (CH_2=CH—CH_2OH). Le spectre de l'alcool allylique irradié à 77 °K a été interprété (11) comme la superposition des spectres de l'allyle (CH_2=CH=CH_2) et de l'hydroxyallyle (CH_2=CH=$CHOH$). Par réchauffement progressif à 150 °K, ce spectre se transforme en un quartet dont les raies sont approximativement écartées de 12 à 13 G, correspondant au radical hydroxyallyle (11). Celui-ci pourrait présenter les deux formes: 1,1′,2,3 et 1,1′,2,3′; le spectre enregistré à 150 °K (courbe *b*), dont la résolution est optimum, fait nettement ressortir, à cette température, la prédominance de la deuxième forme (courbe β_1) sur la première (courbe β_2). La photolyse à 2 537 Å des radicaux produits par l'irradiation de l'alcool allylique conduit, au contraire, à une transformation du spectre observé à 77 °K en celui du radical allyle (11) (courbe *a*), en bon accord avec le spectre calculé pour cette structure (courbe α). Le nombre des radicaux étant inchangé, ceci est l'indice d'une transformation des radicaux hydroxyallyle, absorbant dans l'ultraviolet, en radicaux allyle.

I,2, X = COOH; acide trans-crotonique (CH_3—CH=CH—$COOH$). L'irradiation de l'acide *trans*-crotonique à 77 °K fournit un spectre complexe et mal résolu, que nous n'avons pu interpréter. La résolution de ce spectre augmente avec la température, et l'on obtient vers 0 °C un quartet binômial d'écart hyperfin 12–13 G (courbe *c*). Aucun des spectres calculés pour les deux formes isomères 1,1′,2,3 (courbe β_2) et 1,1′,2,3′ (courbe β_1), ne concordant de manière satisfaisante avec l'expérience, on a cherché à réaliser un meilleur accord en superposant, en proportions variables, les spectres correspondant à ces deux structures. Le meilleur accord est obtenu avec des proportions respectives de 60 et 40% (courbe γ). Ainsi, il semble qu'il y ait isomérisation partielle du squelette



**On trouvera une définition des notions de radicaux π, radicaux σ, protons π, protons σ, densités de spin π, etc., dans, par exemple, les réfs. 8 et 13.*

FIG. 4. Identification des radicaux allyliques produits par irradiation de composé monoéthyléniques. Les lettres latines indiquent les spectres mesurés, les lettres grecques, les spectres calculés. Les traits marqués sous les spectres—expérimentaux et théoriques—indiquent le champ de résonance du DPPH (g = 2.0036). Les spectres théoriques sont calculés avec les mêmes couplages hyperfins et les mêmes champs de résonance qu'en Fig. 2 mais en tenant compte, cette fois, de l'anisotropie de **g** (supposée la même que celle mesurée sur un monocristal d'acide glutaconique irradié (3)). La largeur monocristalline, variable, est indiquée séparément pour chaque espèce. (*a*): alcool allylique irradié aux γ à 77 °K puis photolysé à 2 537 Å; (α) radical allyle (λ = 3.5 G, raies "satellites" négligées). (*b*): le même que précédemment mais réchauffé à 150 °K après irradiation; (β_1) et (β_2): radicaux 1,1′,2,3′ et 1,1′,2,3 (λ = 3.5 G et raies "satellites" introduites seulement dans le premier cas, où l'on néglige le proton 2). (*c*): acide *trans*-crotonique irradié à 77 °K puis réchauffé à 300 °K; (γ): mélange de 0.6(1,1′,2,3′) + 0.4(1,1′,2,3) (λ = 4.5 G et pas de raies "satellites"). (*d*), (*e*) et (*f*): acides citraconique, mésaconique et *trans*-glutaconique irradiés à température ordinaire; (δ), (ϵ) et (φ): radicaux 1,1′,3; 1,1′,3′ et 1,2,3 (λ = 4 G, 3.5 G et 3 G respectivement; raies "satellites" incluses dans le dernier cas seulement). (*g*), (*h*), (*i*) et (*j*): spectres mesurés après irradiation de l'acide *trans*-aconitique à 77 °K (*g*) et à 300 °K (*h*) et de l'anhydride *cis*-aconitique à 77 °K (*i*) et à 300 °K (*j*); (λ), (μ) et (ν): spectres calculés pour les structures 1,1′,3′ (λ = 3.5 G), 1,3′ (λ = 2.5 G) et 1,3 (même largeur), raies "satellites" incluses.

de l'acide crotonique lorsqu'on irradie à basse température puis qu'on réchauffe. Cette transformation n'apparaît qu'au voisinage de la température ordinaire, en même temps que les radicaux se recombinent.

II,1, X_2 et $X_{3'}$ = COOH, acide citraconique. Le spectre obtenu à 77 °K consiste principalement en un triplet binômial aux bandes écartées de 14 G, mais lorsqu'on élève progressivement la température, on observe un dédoublement des raies et, à partir de 150 °K, on obtient un quartet binômial aux raies écartées de 10 à 11 G (Fig. 5). Cette

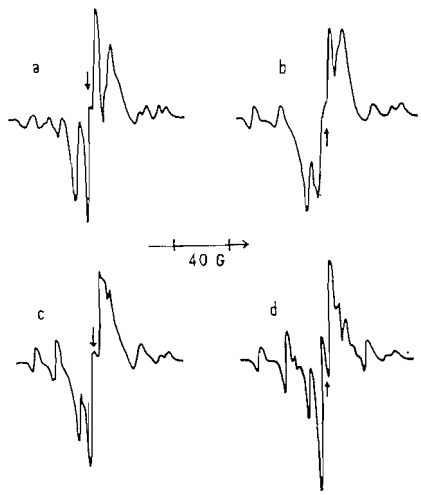

FIG. 5. Evolution réversible avec la température des spectres de l'acide citraconique irradié à 77 °K aux γ: (*a*) 77 °K; (*b*) 130 °K; (*c*) 140 °K; (*d*) 180 °K.

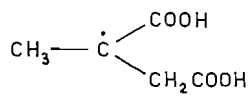
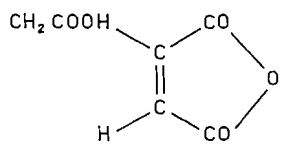


transformation, réversible entre 77 et 200 °K, peut s'expliquer par un non-planéité du radical initialement produit et une évolution progressive par réchauffement vers une forme plane, plus stable (l'interaction de l'électron célibataire s'effectuant principalement avec deux protons σ d'un CH_2 dans le premier cas et les trois protons σ du radical plan dans le second). A température ordinaire, le spectre (courbe *d*) comprend principalement un quartet binômial, qui peut être raisonnablement comparé à celui calculé pour la structure 1,1′,3 (courbe δ). Les bandes parasites observées à toutes température à 30–60 G de la partie centrale des spectres pourraient être dues à la présence, en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

abondance moindre, d'un autre radical, formé par addition sur la double liaison éthylénique. Aux basses températures, la faible interaction de l'électron célibataire avec le proton 2 est prouvée par l'écart réduit des bandes, qui indique une densité de spin π notablement inférieure à 1 sur le carbone a (donc partiellement délocalisée sur C_c), et par le dédoublement partiel de la bande centrale (Fig. 5). La déviation de la planéité est donc faible. La continuité entre les parties principales des spectres mesurés entre 77 et 150 °K (Fig. 5) n'indique pas nécessairement que la transformation entre radical plan et radical distordu se fasse de manière continue; elle peut en effet se faire entre positions privilégiées, seules les proportions respectives des différentes formes variant continûment. Les spectres mesurés étant brouillés par des espèces parasites, et les spectres théoriques correspondant aux deux hypothèses dépendant de nombreux paramètres, il semble difficile de déterminer de manière simple laquelle est vérifiée. Lorsque l'acide citraconique est irradié à 77 °K et réchauffé à température ordinaire ($T \approx 280$ °K), ou irradié à cette température, le spectre obtenu est un quartet, qui ne redonne pas de triplet par refroidissement.

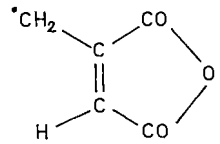
II,2, Acide mésaconique. Contrairement aux spectres obtenus avec l'acide citraconique, les spectres mesurés avec l'acide mésaconique varient assez peu avec la température. A température ordinaire, ils peuvent raisonnablement se comparer (courbe *e*) au spectre calculé pour la structure 1,1′,3′ (courbe ϵ). Ici encore se superpose au spectre allylique celui d'un autre radical, vraisemblablement aussi, saturé.



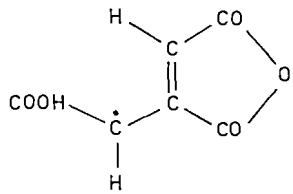
II,3, Acide itaconique. A température ordinaire, l'irradiation de ce composé donne un radical non allylique, de structure

(12). L'examen du spectre obtenu après irradiation à 77 °K suggère la formation simultanée d'un radical allylique, que nous n'avons pu identifier. De ceux que nous avons étudiés, ce composé est le seul avec l'alcool allylique qui contienne un groupe $=CH_2$, qu'on sait être particulièrement propice aux additions sur la liaison double.

II,4, Acide trans-glutaconique. La conformation *cis* ou *trans* du composé commercial n'est pas spécifiée, mais on sait qu'après recristallisation dans l'eau on obtient toujours le deuxième isomère. Le spectre obtenu après irradiation est indépendant de la température d'irradiation, de la température de mesure et du fait que l'acide utilisé a été recristallisé ou non (courbe *f*). Ce spectre, qui consiste principalement en un triplet de doublets, correspond visiblement à une seule espèce. Comme prévisible, il est très proche de celui calculé pour la structure 1,2,3 (courbe φ), toutes les données utilisées dans les calculs étant précisément celles mesurées sur un monocristal de ce composé (3). Ce résultat, conforme à celui démontré par Heller et Cole (3), indique que l'acide glutaconique est bien de la forme *trans*, la formation du radical 1,2,3 n'étant raisonnablement compatible qu'avec cette hypothèse.

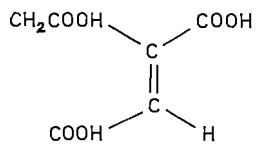


III,1, Anhydride cis-aconitique.

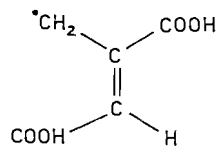


Le spectre enregistré après irradiation à 77 °K est un quartet mal résolu, d'écartement moyen 13 G, dont la résolution augmente avec la température. Sa forme (courbe *i*) est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



plus proche de celle de la courbe correspondant à la structure 1,1′,3 (courbe δ) que de celle correspondant à la structure 1,1′,3′ (courbe λ). Le radical principal formé dans ces conditions serait donc:



Par irradiation à température ordinaire avec des doses quatre fois plus élevées, on obtient un spectre beaucoup moins intense, comportant trois bandes principales (courbe j). Nous avons comparé ce spectre à ceux calculés pour les structures 1,3′ (courbe μ) et 1,3 (courbe ν). Le spectre expérimental paraît en meilleur accord avec la première forme qu'avec la seconde. Le radical formé serait donc:

III,2, Acide trans-aconitique.

L'irradiation à basse température donne un spectre mal résolu (courbe g), comprenant une bande centrale de 15 G de large et un spectre dont on ne distingue que les bandes extrêmes. Lorsqu'on élève la température, on observe une disparition progressive de la bande centrale, les deux bandes extrêmes étant conservées. Celles-ci s'avèrent faire partie d'un quartet de bandes d'écartement moyen 14 G, le spectre alors obtenu étant semblable à celui qu'on peut obtenir directement par irradiation à température ordinaire (courbe h). Ce dernier est très voisin de celui calculé pour la forme 1,1′,3′ (courbe λ), et correspond donc au radical:

Encore stable à température ordinaire, ce radical pourrait masquer celui qui résulterait, comme pour l'isomère *cis*, de l'arrachement d'un hydrogène. La large raie centrale observée à basse température pourrait être due au radical ·COOH.

IV. CONCLUSIONS

La reproduction exacte des formes de raie expérimentales des radicaux obtenus était rendue difficile par les approximations faites sur les paramètres de l'hamiltonien de spin et la présence, inévitable, d'autres radicaux, souvent non allyliques.

Le meilleur accord était obtenu pour le radical dérivé de l'acide glutaconique, pour lequel les valeurs exactes des tenseurs étaient connues et dont on savait qu'il était le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

seul formé par l'irradiation. On peut cependant remarquer que, pour tous les composés que nous avons étudiés, la comparaison entre les spectres expérimentaux et théoriques nous a permis d'établir de manière à peu près sûre la nature des radicaux allyliques produits, et de déterminer leur configuration—*cis* ou *trans*—généralement la même que celle de la molécule initiale. La seule exception observée était celle du radical dérivé de l'acide *trans*-crotonique, dont le spectre a été interprété comme résultant de proportions comparables de radicaux de deux types. Remarquons d'ailleurs que ce spectra était pris au voisinage de la température de disparition des radicaux, zône dans laquelle les mouvements moléculaires, qui tendent à se libérer, peuvent faciliter l'isomérisation.

γ-RADIATION-INDUCED HYDROGEN EXCHANGE REACTION IN LIQUID CYCLOHEXANE – HYDROGEN CHLORIDE SOLUTIONS

J. W. FLETCHER AND G. R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 15, 1966

ABSTRACT

The overall exchange reactions

$$HCl + c\text{-}C_6D_{12} \rightarrow DCl + c\text{-}C_6D_{11}H$$

and

$$DCl + c\text{-}C_6H_{12} \rightarrow HCl + c\text{-}C_6H_{11}D$$

have been initiated by radiolysis and measured by a nuclear magnetic resonance spectroscopic method. The reactions occur by a chain mechanism, with a chain length of $\sim 10^4$ in a 1 *M* solution of hydrogen chloride in cyclohexane. The mechanism is complex.

The exchange reaction can also be initiated by the photolysis of chlorine or of hydrogen chloride.

A chain exchange reaction does not occur between c-C_6H_{12} and DI, D_2S, or ND_3. These results are consistent with the suggestion that the exchange reaction in the cyclohexane – hydrogen chloride system occurs by a free radical chain mechanism.

This type of exchange reaction can cause difficulties in isotopic tracer studies.

INTRODUCTION

In recent studies of the effects of mineral acids on the radiolysis of organic compounds (J. W. Fletcher, unpublished results) it was noted that a radiation-induced hydrogen exchange reaction occurred between hydrogen chloride and cyclohexane. The reaction has a long chain-length in the liquid phase. Since this type of exchange reaction may give erroneous results in isotopic tracer studies, it was of interest to conduct a more detailed kinetic investigation.

The platinum-catalyzed exchange of H and D between c-C_6H_{12} and DCl is a relatively slow reaction (1).

EXPERIMENTAL

Materials

Eastman Spectrograde cyclohexane and Phillips Research grade cyclohexane treated with sulfuric acid to remove olefins were used in these experiments. They both gave the same results. The cyclohexane was saturated with D_2O then dried in vacuum with P_2O_5 which had been transferred in a dry atmosphere.

The perdeutero-cyclohexane, deuterium chloride, perdeutero-ammonia and deuterium sulfide were used as received from Merck, Sharpe and Dohme. Matheson hydrogen chloride and chlorine were fractionated in vacuum before use.

Deuterium iodide was prepared by heating deuterium and iodine with a platinum oxide powder catalyst.

Technique

The exchange reaction was followed by nuclear magnetic resonance (n.m.r.) spectroscopic observation of the buildup or loss of HCl.

The n.m.r. tubes were cleaned with a 3:1 solution of sulfuric and nitric acids and rinsed several times with doubly distilled water. They were then evacuated and heated to about 450 °C, then cooled. Approximately 0.1 ml of D_2O was distilled into each tube and left for 24 h to exchange with the H_2O on the walls. The D_2O was then pumped out and the tubes were heated to about 450 °C.

In the filled cells, the vapor space was kept to less than 10% of the total cell volume, to reduce the amount of hydrogen chloride in the vapor. The high acid concentration samples were contained in heavy wall n.m.r. tubes, to prevent breaking by the HCl pressure.

The acid concentrations are reported in units of molarity (*M*).

RESULTS

The results of each experiment were plotted in such a way that the pseudo-first order exchange rate constants were obtained.

In the c-C_6H_{12}–DCl system, the formation of HCl was observed. Representative samples, with different DCl concentrations, are shown in Fig. 1.

In the c-C_6D_{12}–HCl system, the destruction of HCl was observed. Representative samples, with different HCl concentrations, are shown in Fig. 2.

To verify that the reaction was indeed an exchange reaction, both the formation of c-$C_6D_{11}H$ and the disappearance of HCl were measured in one c-C_6D_{12}–HCl sample.

[1] $$c\text{-}C_6D_{12} + HCl \rightarrow c\text{-}C_6D_{11}H + DCl$$

The amount of c-$C_6D_{11}H$ formed was found to be equal to the amount of HCl destroyed. In Fig. 3, one set of points represents log ($[HCl]_0/[HCl]$), the other represents log ($[HCl]_0/[HCl]_0 - [c\text{-}C_6D_{11}H]$), and the two sets of points are equivalent to each other.

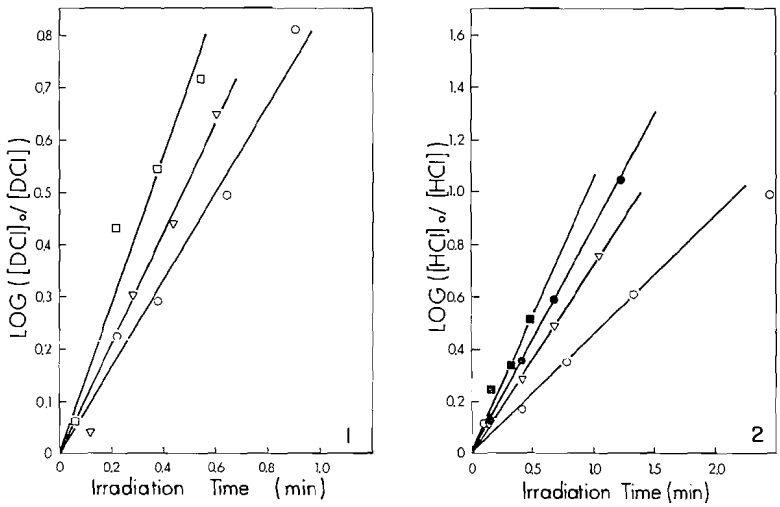

FIG. 1. Exchange of DCl with c-C_6H_{12}. $[DCl]_0$ represents initial DCl concentration. [DCl] = $[DCl]_0$ − [HCl]. Dose rate = 6.08×10^{17} eV/ml min. (□) $[DCl]_0 = 0.177$ M; (△) $[DCl]_0 = 0.200$ M; (○) $[DCl]_0 = 0.310$ M.

FIG. 2. Exchange of HCl with c-C_6D_{12}. $[HCl]_0$ represents initial HCl concentration. Dose rate = 6.08×10^{17} eV/ml min. (■) $[HCl]_0 = 0.075$ M; (●) $[HCl]_0 = 0.139$ M; (△) $[HCl]_0 = 0.351$ M; (○) $[HCl]_0 = 1.780$ M.

The initial rates of the exchange reactions were determined by multiplying the initial acid concentrations by the pseudo-first order rate constants obtained from the slopes of plots such as those in Figs. 1–3 ($k = 2.3 \times$ slope). The initial rates of exchange are plotted against initial acid concentration, at different dose rates, in Figs. 4 and 5. At all dose rates, and in both the c-C_6H_{12}–DCl and the c-C_6D_{12}–HCl systems, the rate–concentration plots have maxima.

The dose rate dependence of the c-C_6H_{12}–DCl exchange reaction is shown in Fig. 6. The rate of the reaction is proportional to approximately the first power of the dose rate.

The length of the chain is indicated by G(exchange) $= 1 \times 10^5$ at $[DCl]_0 = 0.5$ M, and a dose rate $= 6.08 \times 10^{17}$ eV/ml min. The addition of carbon tetrachloride to the system greatly decreased the rate of the exchange reaction (Table I). Carbon tetrachloride was more than 50-fold better as an inhibitor than was $CDCl_3$ (Table I).

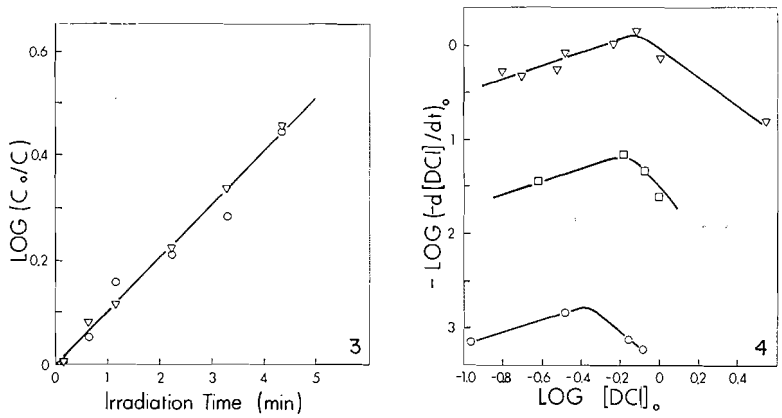

FIG. 3. Formation of c-$C_6D_{11}H$ and destruction of HCl in c-C_6D_{12}–HCl. Dose rate = 6.08×10^{17} eV/ml min. C_0 = initial concentration of HCl = 4.25 M. (△) C = [HCl]; (○) $C = C_0 - [c\text{-}C_6D_{11}H]$.

FIG. 4. The rate of exchange of DCl with c-C_6H_{12} as a function of DCl concentration at different dose rates. (△) 6.08×10^{17} eV/ml min; (□) 5.35×10^{16} eV/ml min; (○) 6.25×10^{14} eV/ml min.

TABLE I

Rate of exchange of c-C_6H_{12} with DCl in the presence of CCl_4 and of $CDCl_3$ ([DCl] = 0.5 M; dose rate = 6.08×10^{17} eV/ml min)

Concentration of additive (M)	$(dc/dt) \times 10^3$
0	1 000
$[CCl_4] = 0.080$	31
$[CCl_4] = 0.62$	6.7
$[CDCl_3] = 1.00$	355

The rate of formation of c-$C_6D_{11}H$ in n-C_6H_{14} containing 25 mole % c-C_6D_{12} and 0.30 M HCl was 1000-fold smaller than it was in a solution of 0.30 M HCl in c-C_6D_{12} (Table II). The corresponding reduction in neo-C_6H_{14} solvent was 200-fold (Table II).

Photolysis of a DCl–c-C_6H_{12} solution in a quartz tube with a 600 W mercury resonance lamp gave complete hydrogen exchange in 5 min. Under these conditions in an initially 1 M DCl solution, the final concentration of the major chain-termination product $C_6H_{11}Cl$ was 1×10^{-3} M. This indicates that the chain length was $\geqslant 10^3$.

TABLE II

Rate of exchange of c-C_6D_{12} with HCl in solution in n-hexane and in neo-hexane ([c-C_6D_{12}] = 25 mole %; [HCl] = 0.3 M; dose rate = 7.8×10^{17} eV/g min)

Solvent	$(d[c\text{-}C_6D_{11}H]/dt) \times 10^3$	G(exchange)
n-C_6H_{14}	0.44	50
Neo-C_6H_{14}	2.38	260
Pure c-C_6D_{12}	520	5.2×10^4

The exchange between DCl and c-C_6H_{12} was also induced by the photolysis of Cl_2, using a high-pressure mercury lamp and a Pyrex reaction cell. Complete exchange was observed in a solution 1 M in DCl and 10^{-2} M in Cl_2. This result indicated a chain length of greater than 10^2. More dilute solutions of Cl_2 were not used because of the difficulty of measuring small quantities of Cl_2.

For personal use only.

A 1 *M* solution of DI in *c*-C_6H_{12} was irradiated for 40 min at a dose rate of 6.08×10^{17} eV/ml min. Within experimental error no exchange was observed, so $G(\text{exchange}) < 30$ in this system.

Similarly, no exchange was observed in a 0.3 *M* solution of D_2S in *c*-C_6H_{12}, after 11 h irradiation at 6.08×10^{17} eV/ml min. Thus, $G(\text{exchange}) < 1.5$ in this system.

In a 0.3 *M* solution of ND_3 in *c*-C_6H_{12}, $G(ND_2H) = 0.8$, within a factor of two.

DISCUSSION

The chain length of the hydrogen exchange reaction between hydrogen chloride and cyclohexane is of the order of 10^4 when the hydrogen chloride concentration is about 1 *M*. No reasonable ionic chain mechanism could be devised to explain the results. The most reasonable free radical chain-propagation steps are

$$[2] \qquad c\text{-}C_6H_{11} + DCl \rightarrow c\text{-}C_6H_{11}D + Cl$$

$$[3] \qquad Cl + c\text{-}C_6H_{12} \rightarrow HCl + c\text{-}C_6H_{11} \quad .$$

High concentrations of HCl (or DCl) inhibit the exchange (Figs. 4 and 5). This might be due to the formation of HCl_2,

$$[4] \qquad Cl + HCl \rightleftarrows HCl_2,$$

which would be less efficient in propagating the chain than is Cl, but which could enter into a chain-termination reaction.[1]

If chain termination occurred by the reactions [5]–[7],

$$[5] \qquad 2c\text{-}C_6H_{11} \rightarrow \text{products}$$

$$[6] \qquad Cl + c\text{-}C_6H_{11} \rightarrow \text{products}$$

$$[7] \qquad 2Cl + M \rightarrow Cl_2 + M,$$

the rate of exchange should have varied as (dose rate)$^{0.5}$. However, the rate of reaction varied approximately as (dose rate)$^{1.0}$ (Fig. 6). This is probably due to inhibition of the reaction by a trace of impurity, which is often observed in long chain processes (2, p. 356).

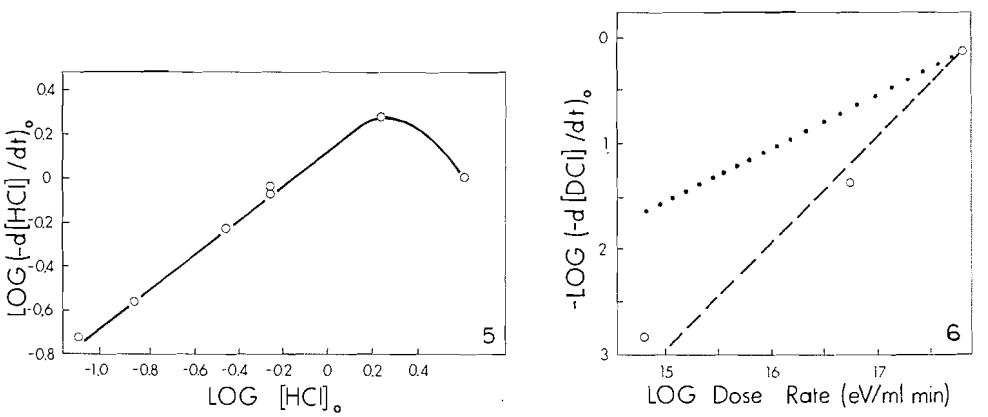

FIG. 5. The rate of exchange of HCl with *c*-C_6D_{12} as a function of HCl concentration at a dose rate of 6.08×10^{17} eV/ml min.

FIG. 6. The rate of exchange of DCl with *c*-C_6H_{12} as a function of dose rate. $[DCl]_0 = 0.3$ *M*. The slope of the broken line is 1.0; that of the dotted line is 0.5.

[1]*It was pointed out by a referee that inhibition could also be caused by association of the* HCl *molecules in the more concentrated* HCl *solutions. The rate of reaction of* *c*-C_6H_{11} *radicals with free* HCl *would probably be faster than with hydrogen-bonded* HCl. *The n.m.r. absorption frequency of the* HCl *proton was observed to shift to lower* τ*-values as the* HCl *concentration was increased. This confirms that the amount of association increased with increasing* HCl *concentration.*

For personal use only.

The inhibition caused by carbon tetrachloride (Table I) can be explained by reactions [8]–[9].

[8] $$c\text{-}C_6H_{11} + CCl_4 \rightarrow c\text{-}C_6H_{11}Cl + CCl_3$$

[9] $$CCl_3 + c\text{-}C_6H_{12} \rightarrow CCl_3H + c\text{-}C_6H_{11}$$

CCl_3 is evidently a less efficient chain carrier than is c-C_6H_{11} and the chain length is shortened.

$CDCl_3$ is a less efficient inhibitor than is CCl_4 because the former is a less efficient chain-transfer agent than is the latter (2, p. 152).

The exchange of hydrogen between c-C_6D_{12} and HCl occurs five times more efficiently in neo-hexane solvent than it does in n-hexane solvent (Table II). This is consistent with the proposed free radical mechanism if the Cl atoms react predominantly with secondary hydrogens on the hydrocarbons.

[10] $$Cl + CH_3CH_2CH_2CH_2CH_2CH_3 \rightarrow HCl + sec\text{-}C_6H_{11}$$

[11] $$Cl + CH_3C(CH_3)_2CH_2CH_3 \rightarrow HCl + CH_3C(CH_3)_2\dot{C}HCH_3$$

The number of secondary hydrogens on a n-hexane molecule is four times as great as the number on a neo-hexane molecule.

Photolysis of DCl by the 1 847 Å mercury line or of Cl_2 by visible light produces atoms which initiate the chain exchange reaction. The Cl atoms undergo reaction [3] and the D atoms also react to produce cyclohexyl radicals.

One would not expect a free radical chain exchange reaction to occur between c-C_6H_{12} and DI, D_2S, or ND_3 because of the inefficiencies of the endothermic propagation steps [12]–[14].

[12] $$I + c\text{-}C_6H_{12} \rightarrow HI + c\text{-}C_6H_{11}$$

[13] $$DS + c\text{-}C_6H_{12} \rightarrow HDS + c\text{-}C_6H_{11}$$

[14] $$c\text{-}C_6H_{11} + ND_3 \rightarrow c\text{-}C_6H_{11}D + ND_2$$

No chain exchange reaction was observed in these systems.

All the experimental results are thus consistent with the suggestion that the hydrogen exchange between cyclohexane and hydrogen chloride occurs by a free radical chain mechanism.

Deuterated polar compounds have been (3, 4) and are currently being used as ion scavengers in radiolysis systems. The amount of ion scavenging that occurs is estimated from the yield of HD or of D_2 produced during radiolysis. This study illustrates the necessity to be aware of the possibility of exchange reactions in these systems. We conclude, however, that exchange reactions did not vitiate the results obtained by using ND_3 (3) or D_2S (4).

KIHARA POTENTIAL AND LENNARD-JONES AND DEVONSHIRE EQUATION OF STATE OF LIQUIDS AND DENSE GASES

ISAMU NAGATA[1]
William Marsh Rice University, Department of Chemical Engineering, Houston, Texas
Received April 28, 1966

ABSTRACT

The Kihara potential has been applied to the Lennard-Jones and Devonshire cell theory in place of the Lennard-Jones potential. The expressions for the internal energy, heat capacity, and entropy, as well as the compressibility, are given in excess over those of a perfect gas. A comparison between experimental data and the present theory is made.

INTRODUCTION

It has been shown that the Kihara potential is in general better than the Lennard-Jones potential in the calculation of crystal properties (1), virial coefficients (2), and gas hydrate dissociation pressures (3). An extensive study on the Lennard-Jones and Devonshire cell theory has been carried out by Wentorf *et al.* (4); therefore the detailed discussion of this theory seems to be unwarranted. The present investigation shows how the formulae in the theory are altered by substituting the Kihara potential for the Lennard-Jones potential and compares the theoretical results with some of the experimental properties of argon.

CELL THEORY FOR THE KIHARA POTENTIAL

For simplicity only a spherical model for the Kihara potential is considered and it is further assumed that a molecule with spherical core of radius c roams in the cell and that the Z nearest neighbors distributed on the surface of the cell are point molecules. The interaction energy between the molecule in the cell and a molecule on the surface is assumed to be expressed by the Lennard-Jones 12–6 form as a function of the shortest distance between the molecules.

$$\Phi(R,c) = 4\epsilon\left[\frac{\sigma^{12}}{(R-c)^{12}} - \frac{\sigma^{6}}{(R-c)^{6}}\right] \qquad [1]$$

R is the distance between the center of the molecule in the cell and that of a surface molecule. ϵ is the potential minimum and σ is the position where $\Phi(R,c) = 0$. We obtain the spherically symmetrical potential for a molecule located a distance r from the center of the cell from eq. [2].

$$\psi(r) = \frac{Z}{4\pi}\int_0^{2\pi}\int_0^{\pi}\Phi(R,c)\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \qquad [2]$$

The origin of the coordinate system used in eq. [2] is the center of the cell. The detailed explanation on how to carry out the integral is given elsewhere (5). θ and ϕ are the orientation angles. If we consider a face-centered cubic lattice for the cell and take the contribution of the second- and third-shell molecules to the potential function into consideration, $\psi(r)$ is expressed as (4)

$$\psi(r) - \psi(0) = \sqrt{2}\epsilon\left[\left(\frac{N\sigma^3}{v}\right)^4 L(y) - 2\left(\frac{N\sigma^3}{v}\right)^2 M(y)\right], \qquad [3]$$

[1]*Present address: Department of Chemical Engineering, Kanazawa University, Kanazawa, Japan.*

where $\sqrt{2}v = Na^3$, $y = (r/a)^2$, $c^* = c/a$, and a is the cell radius.

[4] $$L(y) = l(y) + (1/128)l(y/2) + (2/729)l(y/3)$$

[5] $$M(y) = m(y) + (1/16)m(y/2) + (2/27)m(y/3),$$

where $l(y)$ and $m(y)$ are given by McKoy and Sinanoğlu (6)

[6] $$l(y) = \frac{c^*}{20y^{1/2}}\left[\frac{1}{(1-y^{1/2}-c^*)^{10}} - \frac{1}{(1+y^{1/2}-c^*)^{10}}\right] - \frac{1}{(1-c^*)^{11}} + \frac{1}{22y^{1/2}}\left[\frac{1}{(1-y^{1/2}-c^*)^{11}} - \frac{1}{(1+y^{1/2}-c^*)^{11}}\right] - \frac{c^*}{(1-c^*)^{12}}$$

[7] $$m(y) = \frac{1}{8y^{1/2}}\left[\frac{1}{(1-y^{1/2}-c^*)^{4}} - \frac{1}{(1+y^{1/2}-c^*)^{4}}\right] - \frac{1}{(1-c^*)^{5}} + \frac{c^*}{10y^{1/2}}\left[\frac{1}{(1-y^{1/2}-c^*)^{5}} - \frac{1}{(1+y^{1/2}-c^*)^{5}}\right] - \frac{c^*}{(1-c^*)^{6}}.$$

Then we can obtain the expression for Pv/NkT by eq. [8].

[8] $$\frac{Pv}{NkT} = 1 - \left(12\frac{\epsilon}{kT}\right)\left\{2.4090\left(\frac{N\sigma^3}{v}\right)^2\left[\frac{1}{(1-c^*)^5} + c^*\left(\frac{2}{(1-c^*)^6} + \frac{c^*}{(1-c^*)^7}\right)\right] - 2.0219\left(\frac{N\sigma^3}{v}\right)^4\left[\frac{1}{(1-c^*)^{11}} + c^*\left(\frac{2}{(1-c^*)^{12}} + \frac{c^*}{(1-c^*)^{13}}\right)\right]\right\} - \left(48\frac{\epsilon}{kT}\right)\left[\left(\frac{N\sigma^3}{v}\right)^2\left(\frac{g_M}{g}\right) - \left(\frac{N\sigma^3}{v}\right)^4\left(\frac{g_L}{g}\right)\right] - \left(12v\frac{\epsilon}{kT}\right)\left[\left(\frac{N\sigma^3}{v}\right)^4\left(\frac{g_{L'}}{g}\right) - 2\left(\frac{N\sigma^3}{v}\right)^2\left(\frac{g_{M'}}{g}\right)\right]$$

For the one-shell calculation the factors of 2.4090 and 2.0219 of eq. [8] must be replaced by a factor of 2 (4). The functions g, g_L, g_M, $g_{L'}$, and $g_{M'}$ were calculated from the following formulas:

[9] $$g = \int_0^{0.30544} y^{1/2}\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[10] $$g_L = \int_0^{0.30544} y^{1/2}L(y)\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[11] $$g_M = \int_0^{0.30544} y^{1/2}M(y)\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[12] $$g_{L'} = \int_0^{0.30544} y^{1/2}\frac{\partial L(y)}{\partial v}\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[13] $$g_{M'} = \int_0^{0.30544} y^{1/2}\frac{\partial M(y)}{\partial v}\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy.$$

If $c = 0$, then $g_{L'} = 0$ and $g_{M'} = 0$ ($\partial L(y)/\partial v = 0$ and $\partial M(y)/\partial v = 0$ at $c = 0$), and eq. [8] reduces to that for the point molecule model described by Wentorf *et al.* (eq. [2] of ref. 4).

For personal use only.

It is convenient to define pressure, temperature, and volume in reduced forms.

[14] $$P^* = (Pv/NkT)T^*/v^*$$

[15] $$T^* = kT/\epsilon$$

[16] $$v^* = v/N\sigma^3$$

The expressions for the thermodynamic functions in excess over those of a perfect gas such as internal energy E', internal heat capacity c_v', and internal entropy S' are given easily (4, 7).

[17] $$E' = \tfrac{1}{2}N\psi^*(0) + N\chi(v,T)$$

Here $\frac{1}{2}\psi'(0)$ is the potential energy per molecule when all the molecules are at the centers of their cells.

[18] $$\psi^*(0) = \sqrt{2}\epsilon\left\{\frac{1.0109}{v^{*4}}\left(\frac{1}{(1-c^*)^{11}} + \frac{c^*}{(1-c^*)^{12}}\right) - \frac{2.4090}{v^{*2}}\left(\frac{1}{(1-c^*)^5} + \frac{c^*}{(1-c^*)^6}\right)\right\}$$

$\chi(v,T)$ is the average potential energy in a cell referred to the potential at the center as zero. The factors 1.0109 and 2.4090, which are obtained for the Lennard-Jones potential and are assumed to be valid for the Kihara potential in the present investigation, must be replaced by 1 and 2, respectively, for the one-shell calculation (4).

[19] $$\chi(v,T) = \sqrt{2}\epsilon\left[\frac{1}{v^{*4}}\left(\frac{g_L}{g}\right) - \frac{2}{v^{*2}}\left(\frac{g_M}{g}\right)\right]$$

[20] $$c_v' = \frac{\partial E'}{\partial T} = Nk\left(\frac{12}{T^*}\right)^2\left[\frac{1}{v^{*8}}\left(\frac{g_L{}^2g - g_L{}^2}{g^3}\right) - \frac{4}{v^{*6}}\left(\frac{g_{LM}g - g_Lg_M}{g^2}\right) + \frac{4}{v^{*4}}\left(\frac{g_M{}^2g - g_M{}^2}{g^2}\right)\right]$$

[21] $$g_{LM} = \int_0^{0.30544} y^{1/2}L(y)M(y)\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[22] $$g_M{}^2 = \int_0^{0.30544} y^{1/2}M(y)M(y)\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[23] $$g_L{}^2 = \int_0^{0.30544} y^{1/2}L(y)L(y)\exp\{-[\psi(r) - \psi(0)]/kT\}\,dy$$

[24] $$S'(v,T) = [N\chi(v,T)/T] + Nk\log(2\pi\sqrt{2}g)$$

These relations may be used as a basis for the calculation of the respective thermodynamic functions.

NUMERICAL CALCULATIONS

Simpson's rule was used in the numerical integration involved in the present investigation. All numerical calculations were programmed for the Rice University Research Computation Laboratory IBM 7040. The energy parameters and core size of the Kihara potential determined from second virial coefficient data for argon (2) are $\epsilon/k = 147.2$ °K, $\sigma = 2.946$ Å, $c = 0.184$ Å. The nearest distance between argon molecules in the critical region is 4.5 Å (8). The calculated critical values are compared with experimental results in Table I. This table shows that the present investigation results in unsuccessful prediction of critical constants.

Tables II to V show the results for Pv/NkT, E', c_v', and S' at 0 °C, 75 °C, and 150 °C together with experimental values and the results by Wentorf *et al.* (4). It is apparent that the assumption underlying the Lennard-Jones and Devonshire theory is applicable at high temperatures and high densities. These tables demonstrate that the results of the three-shell calculation are often not so good as the results of the one-shell calculation and that the present more complicated approach often does not give appreciably better agreement with the experimental values than the original simple Lennard-Jones and Devonshire theory.

KINETICS OF HYDROGEN ABSTRACTION FROM PROTON DONORS BY DPPH[1]

SURJIT SINGH, K. R. BHASKAR, AND C. N. R. RAO[2]
Department of Chemistry, Indian Institute of Technology, Kanpur, India

Received April 28, 1966

ABSTRACT

The kinetics and energetics of the interaction of DPPH with a variety of hydroxylic compounds have been investigated by electronic and e.s.r. spectroscopy. Deuterium isotope effects on the kinetics have been examined. A model involving hydrogen bonded complexes has been suggested for the hydrogen abstraction reaction.

INTRODUCTION

The interaction of DPPH with proton donors has been investigated by several workers (1–6) in recent years, although there is limited information on the energetics of the reaction. While it was believed earlier (2) that the interaction of proton donors with DPPH involved hydride ion transfer and formation of carbonium ions, recent work of Russell and co-workers (3, 4, 6) has shown that this reaction involves the formation of radicals by hydrogen abstraction from a hydrogen bonded complex initially formed between the proton donors and DPPH. Thus, Russell and coworkers (6) have identified the formation of the stable 2,4,6-tri-*t*-butylphenoxy radical in the interaction of 2,4,6-tri-*t*-butylphenol with DPPH by electron spin resonance (e.s.r.) spectroscopy.

We have now investigated the kinetics and energetics of the interaction of DPPH with a variety of proton donors: (i) substituted phenols with varying basicity, (ii) sterically hindered phenols, (iii) 4-substituted-2,6-di-*t*-butylphenols, (iv) sterically hindered alcohols, (v) ortho-substituted (intramolecularly hydrogen bonded) phenols, and (vi) aniline and aniline-d_2, phenol and phenol-*d*, and oxalic acid and oxalic acid-d_2.

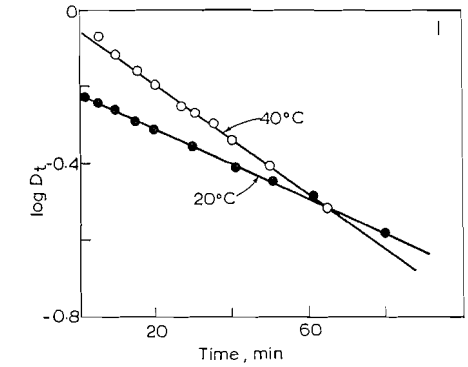
In addition to providing useful kinetic information, these studies were expected to throw some light on the nature of the hydrogen bonded complexes which act as intermediates or activated complexes in the hydrogen abstraction reaction.

EXPERIMENTAL

DPPH was prepared by the lead oxide oxidation of diphenyl picryl hydrazine. 2,2,4,4-Tetramethyl-3-isopropyl-3-pentanol was prepared by the method described in the literature (7). Deuterated compounds were obtained from the Atomic Energy Establishment, Bombay. All the other chemicals used were obtained commercially and were purified before use.

DPPH gives violet colored solutions in organic solvents and is stable up to about 80 °C. The solutions show an absorption maximum around 520 mμ with an extinction coefficient of $\sim$12 000 l mole^{-1} cm^{-1}. Another high intensity absorption maximum appears at $\sim$330 mμ. The 520 mμ band was used to determine the concentration of DPPH in the kinetic studies of the interaction of DPPH with proton donors.

The measurements of electronic spectra were made with a Beckman DU spectrophotometer, fitted with a variable temperature cell compartment. The pseudo-first order kinetics of interaction of DPPH with proton donors were followed (for less than the first 30–40% of the reaction) in carbon tetrachloride solutions in the presence of excess of proton donors. The concentration of DPPH was generally $\sim 10^{-5} M$ while that of proton donors varied between $\sim 10^{-4}$ and $\sim 0.1 M$. The rate constants for the second order reactions were then calculated employing an expression similar to that of McGowan, Powell, and Raw (2).



$$k_{II} = \frac{2.303}{t} \log \frac{a}{a - x} \times \frac{1}{D}$$

$$= \frac{2.303}{t} \log \frac{D_0}{D_t} \times \frac{1}{D}$$

[1]*Taken in part from the Ph.D. Thesis of S. Singh submitted to the Indian Institute of Technology, Kanpur.*
[2]*To whom all correspondence should be addressed.*

where a and $(a - x)$ are the initial and final molar concentrations of DPPH after t minutes when D moles of proton donor has been allowed to react with it. Typical plots of log D_t against time are shown in Fig. 1.

The rate constants were also calculated by noting the rate of disappearance (decrease in the peak height of the first derivative curve) of the electron spin resonance signal of DPPH with time. Generally, there was no interference in the e.s.r. spectrum due to the phenoxy or other radicals, except in the case of 2,4,6-tri-*t*-butylphenoxy radical (6). Since the kinetics in such cases were also examined by electronic spectroscopy, there was no difficulty in obtaining good rate constants. Typical e.s.r. signals of DPPH as a function of time in presence of phenol are shown in Fig. 2. A Varian H-4500 spectrometer operating at 100 kc/s was employed for this purpose.

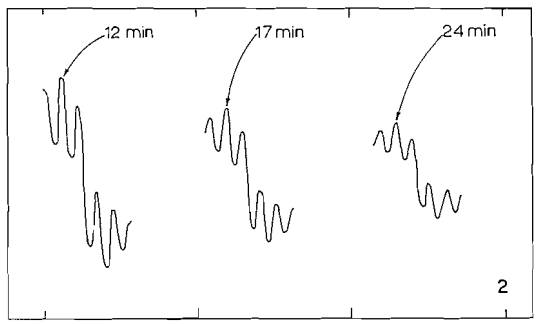


FIG. 1. Typical first order plots for the reaction of DPPH with 2,6-di-*t*-butylphenol at two temperatures.
FIG. 2. Time dependence of the e.s.r. signal of DPPH ($\sim 10^{-4}$ M) in the presence of phenol (~ 0.05 M, solvent CCl_4).

The rate constants have an uncertainty less than $\pm 10\%$. Reverse reactions of phenoxy and other radicals do not affect the k values appreciably since the proton donors were present in excess and since the rate data were taken only for the initial few percent of the reaction. Rate constants were determined at three temperatures in the 20–40 °C range and the energy of activation was calculated using the Arrhenius equation. Rate constants at only one temperature have been shown in the tables for purpose of brevity. The uncertainty in the energy of activation is ± 1 kcal mole^{-1}.

The hydrogen bonding data given in Tables I–VI are from the studies in this laboratory (7, 8).

RESULTS AND DISCUSSION

The interaction of a proton donor, RXH, with DPPH may be visualized to proceed as follows. (i) The RXH first forms a hydrogen bonded complex, X—H...N, with DPPH. (ii) the hydrogen of this complex is then transferred completely to the nitrogen atom forming the hydrazine and a radical, through a transition state where the X—H bond is more polarized than in the initial hydrogen bonded complex. Such an activated complex may be considered to be similar to the symmetrical hydrogen bond X...H...N. (iii) The facility with which the hydrogen abstraction takes place is determined by several factors. A low free energy of formation (ΔF^0) of the initial hydrogen bonded complex should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

increase the rate constant since the rate will be proportional to the concentration of the hydrogen bonded species. Strong hydrogen bonds (high enthalpy of formation of the complex, $-\Delta H^0$) should lower the energy of activation, E_a, for the hydrogen abstraction reaction since a stronger hydrogen bond will approximate a symmetrical hydrogen bond more closely. The stability of the radical produced by hydrogen abstraction should also favor the hydrogen abstraction due to obvious thermodynamic reasons. All these ideas regarding the hydrogen abstraction reaction between DPPH and proton donors have been summarized in the form of a potential energy diagram in Fig. 3. In the present discussion the reverse reaction of the phenoxy or other radicals with the hydrazine (6) will not be considered, and the rate data presented are only for the forward reaction of DPPH with the proton donors.

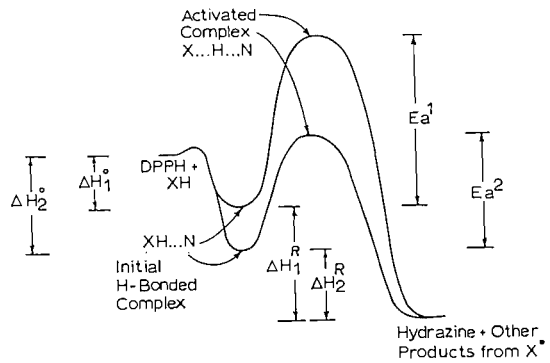

FIG. 3. Potential energy diagram for the interaction of DPPH with proton donors. DPPH and a proton donor XH initially form a hydrogen bonded complex XH...N which then forms an activated complex, X...H...N ($R_{X...H}$) R_{X-H}) resembling a symmetric hydrogen bond. Two cases have been considered, one with a high and another with a medium value for the enthalpy of formation ($-\Delta H^\circ$)of the initial hydrogen bonded complex. The energy levels of the hydrazine and other products formed by the new radicals are shown to be the same for both cases for the purpose of simplicity. ΔH^R is the enthalpy change for the reaction giving rise to the hydrazine and the products from X•.

From these arguments it is clear that one should not expect a simple relationship between the data on hydrogen bonding and the kinetics of hydrogen abstraction. However, in certain systems, one may see some relation between the ΔH^0 (also $\Delta\nu_{OH}$) and ΔF^0 of hydrogen bonding and the energy of activation. In systems where the radicals produced have nearly the same stabilities, it is possible that ΔH^0 of hydrogen bonding as well as $\Delta\nu_{OH}$ may be inversely proportional to the energy of activation for hydrogen abstraction.

Interaction of DPPH with p-Substituted Phenols

The kinetic data for the interaction of DPPH with *p*-substituted phenols are given in Table I. It can be seen that there is no simple relationship between the rate constant or the energy of activation and the electrical properties of the *p*-substituents. This is probably due to the operation of several of the factors discussed earlier. Comparison of these kinetic data with the hydrogen bonding data of these proton donors with benzophenone, however, shows that *p*-chlorophenol which forms the strongest hydrogen bond (being the most acidic of the four phenols studied) does not show the lowest value of the energy of activation.

Interaction of DPPH with Sterically Hindered Phenols and Alcohols

The data for the interaction of DPPH with sterically hindered phenols are given in Table II. Although there is no simple relationship between the rate constants or the energies of activation with the bulk of the ortho substituents, it can be seen that the

2,6-di-*t*-butylphenol which forms the strongest hydrogen bond (high $-\Delta H^0$) shows the lowest energy of activation for hydrogen abstraction. The rate constant, however, is low in this case probably due to the very low equilibrium constant of formation of the hydrogen bonded complex.

The kinetics of hydrogen abstraction of a sterically hindered alcohol with DPPH are compared in Table III with the data on ethanol.

Although the reaction of ethanol gives complex products, one can treat the reaction as of pseudo-first order. The value of k has been given here only to show the large difference

in rates between the two alcohols. The sterically hindered alcohol shows a much faster rate. The energy of activation is high possibly because of a lower enthalpy of formation of the hydrogen bonded complex.

It has been found earlier that there was no systematic variation of the equilibrium constant or the $\Delta\nu_{OH}$ in the hydrogen bonding equilibrium of *p*-substituted 2,6-di-*t*-butylphenols with donors (7). It is interesting to see, however, that the energy of activation of hydrogen abstraction varies roughly in the same fashion as the $\Delta\nu_{OH}$ (Table IV). 2,4,6-Tri-*t*-butylphenol is slightly out of line and the value of the energy of activation is not as low as one would have expected.

*The rate constant determined by e.s.r. was found to be 0.003 min^{-1}.

Interaction of DPPH with Intramolecularly Hydrogen Bonded ortho-Substituted Phenols

Studies on the intramolecularly hydrogen bonded ortho-substituted phenols show that hydrogen can be abstracted from even the stronger intramolecular hydrogen bonds (Table V). 2,6-Dichlorophenol which can exist only in the bonded *cis* form, shows a much lower rate constant as well as energy of activation for hydrogen abstraction compared with ortho-chlorophenol which can exist either in the *cis* (hydrogen bonded) or the *trans* form. It appears as though the E_a decreases with an increase in the energy of the intramolecular hydrogen bond. 2-Nitrophenol which probably has the strongest intramolecular hydrogen bond also shows the lowest value of E_a. It is possible that in the case of 2-nitrophenol, it forms the strongest intermolecular hydrogen bond with DPPH as well. The low rate constant, however, is likely to be due to the low concentration of the hydrogen bonded species with DPPH since it will be more difficult to break a strong intramolecular hydrogen bond.

Deuterium Isotope Effects on the Hydrogen Abstraction Reaction

The results in Table VI clearly show that deuterium substitution lowers the rate constant for hydrogen abstraction and increases the E_a considerably. The k_H/k_D ratio varies

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

anywhere between 1 and 12. The lowering of the rate constant by deuterium substitution can be understood in terms of the kinetic isotope effects discussed in the literature (11). It is interesting to note that the equilibrium constants and enthalpies of formation of intermolecular hydrogen bonds are also considerably decreased by deuterium substitution (12).

TABLE VI

Deuterium isotope effects*

*CCl_4 was used throughout as the solvent except in the case of oxalic acid where CH_3CN was used.
†McGowan, Powell, and Raw (2) have treated the reaction of primary amines with DPPH as a third order reaction. In the present study it has been found that better fits of the rate data are obtained if the reaction is treated as second order.
‡In oxalic acid there is the possibility of formation of a diradical which would mean a third order reaction. Here, values have been calculated assuming a second order reaction only.

Entropy of Activation of the Hydrogen Abstraction Reaction

In all the systems examined in the present study, the entropies of activation for hydrogen abstraction calculated from the Eyring equation (11) are large negative numbers. This appears reasonable since the activated complex (symmetric hydrogen bond) is more polar than the initial hydrogen bond complex between the proton donor and DPPH (Fig. 3).

CONCLUDING REMARKS

Although the hydrogen abstraction reaction of DPPH with proton donors seems to be fairly well understood (3–6), the detailed mechanism of the interaction is difficult to establish from kinetic studies alone. While it is possible to visualize a plausible mechanism (Fig. 3), the kinetics in most instances seem to be affected by more than one factor. In some instances, however, it is possible to show some relation between the kinetic data and the hydrogen bonding data.

COORDINATION COMPOUNDS OF OLEFINS WITH ANHYDROUS SILVER SALTS

III. KINETICS OF THE GAS–SOLID REACTION PRODUCING $AgBF_4.2C_3H_6$[1]

C. A. JULL, R. J. KOMINAR,[2] N. K. MAINLAND,[3] AND H. W. QUINN[4]

ABSTRACT

A study has been made of the pressure and temperature dependence of the rate of combination of propylene with silver tetrafluoroborate to produce $AgBF_4.2C_3H_6$. Dependent upon the prior history of the salt, the reaction may proceed via predominantly diffusion control, predominantly kinetic control, or a combination of the two mechanisms. With both mechanisms, the adsorption of the olefin on the salt surface appears to exert a rate-controlling influence.

INTRODUCTION

For many years there has been much interest in the kinetics of gas–solid reactions. The resulting investigations have covered both reversible and irreversible combination and dissociation reactions. Those effected prior to 1955 have been well reviewed by Garner (1).

While many investigators (2–6) have concerned themselves with the kinetics of dissociation, study of the combination reactions has received more attention in recent years. The reactions investigated have included the rehydration of $CuSO_4$ (7), $NiSO_4$ (8), alum (9), and K_2CO_3 (10), the formation of $CaCO_3$ and $CdCO_3$ (11) and of the ammoniates of $CdCl_2$ (11) and $AgNO_3$ (12) and the reaction of UF_6 with NaF (14).

Although most of these studies have resulted in determination of the temperature dependence of the reaction rates as expressed by the activation energy, relatively few have included an adequate assessment of the pressure dependence. With combination reactions in particular such information might be expected to provide a better basis for discussion of the reaction mechanism.

Our interest in the coordination compounds formed by interaction of olefins with silver tetrafluoroborate (15, 16) and the observation that these could be formed reversibly by exposure of the solid salt to olefin vapor suggested the applicability of this system to a study of the kinetics of the gas–solid reaction. This paper reports on the temperature and pressure dependence of the rate of the propylene combination reaction,

$$\tfrac{1}{2}AgBF_4 + C_3H_6 \rightarrow \tfrac{1}{2}AgBF_4.2C_3H_6 \ (\Delta H^\circ = -10.08 \text{ kcal/mole } C_3H_6).$$

The product of this reaction, having a 1:2 silver ion to olefin ratio, has earlier (15) been established to be the most stable propylene complex of $AgBF_4$.

EXPERIMENTAL

Anhydrous silver tetrafluoroborate was prepared from silver fluoride and boron trifluoride according to the method of Olah and Quinn (17) with the exception that it was recovered by fractional crystallization from the nitromethane solvent rather than by complete removal of the solvent under vacuum.

Propylene and cyclohexene were Phillips pure grade materials of 99% minimum purity. Prior to use they were dried by passage in the vapor phase through a column packed with phosphorus pentoxide and freeze-degassed at liquid nitrogen temperature.

Procedure

The 200–600 mg sample of silver salt, wet with petroleum ether, was placed in a quartz pan suspended from a quartz spiral of sensitivity 5.571 mg/mm and evacuated. The spiral was enclosed in a jacketed chamber thermostatted to ±0.1 °C by liquid pumped from a constant temperature bath capable of control over the range from −5° to 60 °C. After suitable treatment of the sample in order to achieve reproducible kinetics (*vide infra* under Preparation of Sample), propylene was admitted at constant pressure through two solenoid valves in series actuated by platinum contacts in mercury manometers. By maintaining the pressure in the first manometer at not more than 10 mm above the system pressure, surging upon opening of the second valve was prevented and the system pressure could be controlled to ±0.5 mm.

The spiral extension was measured to ±0.02 mm with a cathetometer.

Preparation of Sample

Experimentation established that, in order to obtain kinetic reproducibility, it was necessary to expose the sample of $AgBF_4$ to several complex formation–dissociation cycles. As illustrated in Fig. 1, the rate of the combination reaction is much more rapid in the second cycle than in the first. An explanation of this will be offered in the Discussion section. Microscopic examination of the $AgBF_4$ crystals has revealed that the complex formation–dissociation cycle results in a net volume expansion (the linear dimensions increase by a factor of about 1.3) and the particles appear to develop a very rough surface. The B.E.T. plots of krypton adsorption isotherms at liquid nitrogen temperature (18) revealed, as the result of a single formation–dissociation cycle, an increase of almost 40-fold (from 0.1 to 3.9 m^2/g) in the surface area of the salt. While the X-ray diffraction powder patterns of the salt are identical in samples taken before and after this cyclic operation, that obtained with the before sample is spottier in character indicating larger particle size than in the after sample.

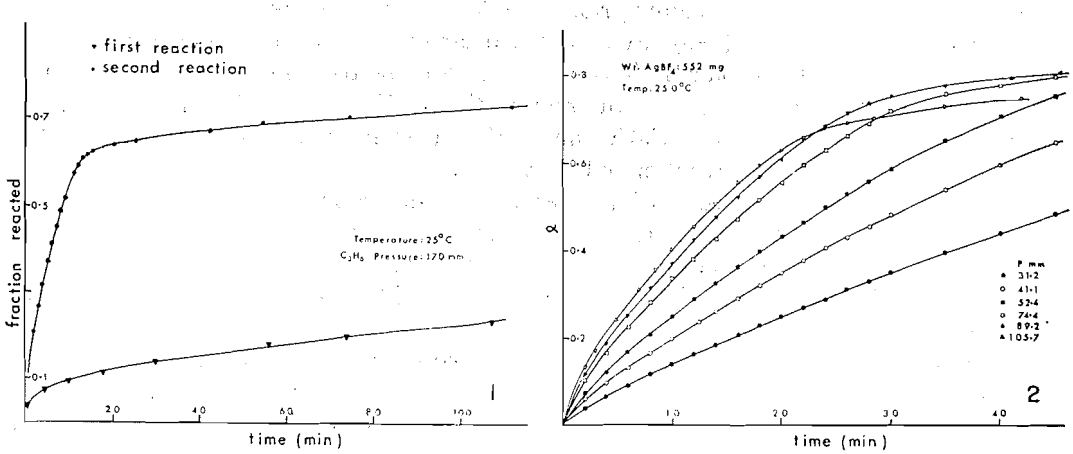

FIG. 1. Plot of fraction reacted versus time for consecutive reactions illustrating the effect of activation.
FIG. 2. Plot of fraction reacted versus time for propylene-activated $AgBF_4$ (sample 2).

The lattice expansion attending complex formation followed by contraction upon dissociation apparently results in breakdown of the crystal or particle size of the $AgBF_4$ thus creating more surface area and probably a rather porous structure. After four or five such cycles, the reaction rates are quite reproducible indicating no further change in the surface structure of the salt.

For the benefit of further discussion, the process of development of the solid surface will be termed activation. With each sample employed, the activation process was effected at 25 °C and, regardless of the temperature at which the rate data for the combination reactions were obtained, the subsequent dissociation step was carried out at 25 °C.

To evaluate the dependence of the kinetics of the propylene complex upon the activation history of the salt, some samples were activated with cyclohexene, an olefin molecule larger than propylene, by formation and dissociation of the complex $AgBF_4.2C_6H_{10}$. As might be expected, there is a greater volume expansion of the salt when this complex forms than is observed with propylene.

RESULTS

Rate determinations on propylene-activated samples of $AgBF_4$ were made at temperatures over the range from 2.3 to 55.0 °C and at pressures of C_3H_6 from about 13 to 200 mm Hg.

Figure 2 shows the plot of the fraction (α) of $AgBF_4$ reacted versus time in minutes for a typical sample at 25 °C and at a number of pressures. It is evident that there is no induction period required for the reaction and that the rate decreases continuously from the beginning. Some of the higher pressure lines are observed to intersect lower pressure ones at α values of 0.6 to 0.7.

Of the various expressions which have been employed for treatment of rate data for gas–solid reactions (1, 5, 6, 14, 19), the linear rate law,

$$1 - (1 - \alpha)^{1/3} = k_1 t,$$

has been found to apply for this reaction for values of α up to at least 0.4 and ranging upward to greater than 0.9, dependent upon the prior history of the sample. For spherical particles, k_1 is inversely proportional to the particle radius. The data of Fig. 2 deviate from the linear plot of $1 - (1 - \alpha)^{1/3}$ versus time (Fig. 3) only above $\alpha = 0.7$ with the exception of those obtained at the highest pressure when deviation occurs at about $\alpha = 0.55$. It has been found in general that this deviation occurs at lower values of α for the higher pressure determinations.

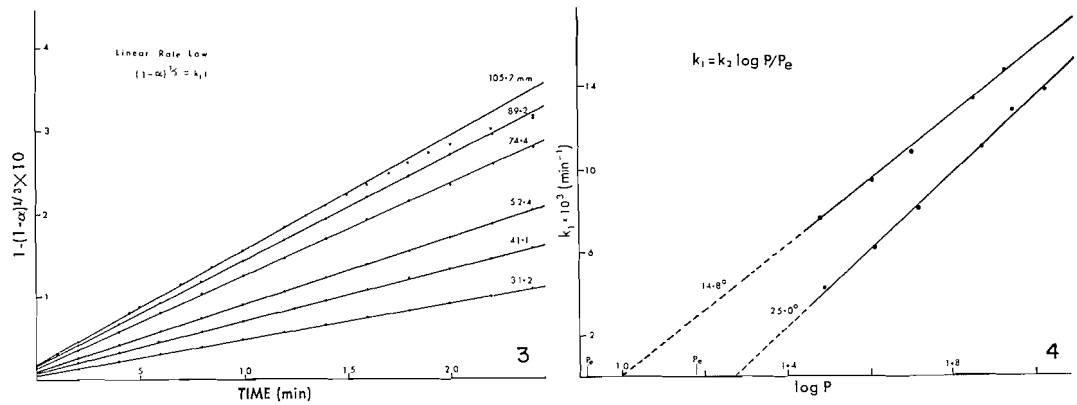

FIG. 3. Linear rate law plots of the data of Fig. 2.
FIG. 4. Pressure dependence of the slope of the linear rate law plots.

The value of the slope, k_1, has been found to be directly proportional to the logarithm of the applied pressure, P (Fig. 4). The linear plot of k_1 versus log P intersects the log P axis at a point just slightly above that corresponding to log P_e, the equilibrium dissociation pressure of the complex. (The equilibrium pressure–temperature relationship for $AgBF_4 \cdot 2C_3H_6$ is

$$\log P_e \text{ (mm)} = 8.5661 - 2202.8/T,$$

yielding P_e values of 8.27 mm at 14.8 °C and 15.1 mm at 25.0 °C.)[5] The slopes and intercepts of these plots were obtained by a least squares treatment of the k_1 vs. log P data. While one would expect k_1 to be positive at any pressure greater than P_e, one might try to rationalize the intercept on the log P axis at a point above P_e in terms of the sample temperature being somewhat above that of its surroundings because of the exothermic nature of the reaction. This discrepancy would diminish, however, as the reaction proceeded and also would be more marked at higher than at lower pressures. The fact that with the most reactive samples, the linear law plots have been found to be linear up to

[5]*Data obtained in this laboratory.*

$\alpha = 0.9$ suggests that the sample temperature must remain essentially constant throughout the reaction. Also, the good fit of the k_1 vs. log P data to a straight line suggests that the temperature is essentially constant over the range of pressures employed. Despite the small discrepancy, one can consider that the expression

$$[1] \qquad k_1 = k_2 \log P/P_e$$

very nearly expresses the pressure dependence of the reaction rate at constant temperature, with k_2 as the temperature-dependent rate constant. As Fig. 4 illustrates, k_2 increases slightly with increasing temperature, from 15.8×10^{-3} min^{-1} at 14.8 °C to 18.6×10^{-3} min^{-1} at 25.0 °C. Similar behavior is demonstrated in Fig. 5 by data obtained with a different sample over a wider temperature range.

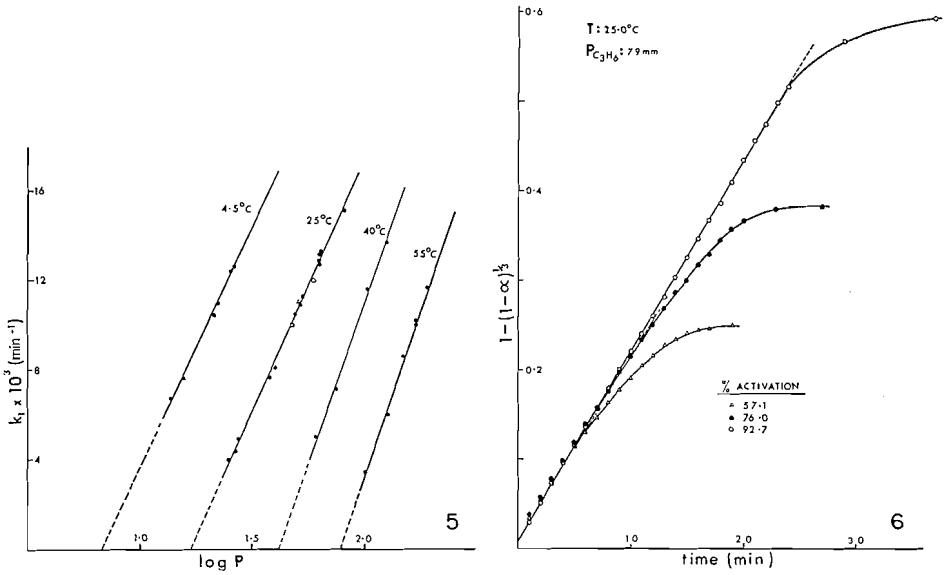

FIG. 5. Temperature dependence of the k_1 versus log P plot (sample 10). (25 °C points, ○, □, △, obtained after determinations at 4.5, 40, and 55 °C respectively).
FIG. 6. Effect of varying cyclohexene activation on range of applicability of linear rate law.

TABLE I

Dependence of rate constant k_2 on sample weight and history (25 °C)

Sample No.	Activating olefin	Sample weight (mg)	$10^3 k_2$ (min^{-1})
3	Propylene	228	31.9
1	Propylene	513	21.4
2	Propylene	552	18.6
4	Cyclohexene	232	40.5
8	Cyclohexene	340	31.4

It has been observed (Table I) that the value of k_2 at a given temperature generally increases with decreasing sample weight and that for samples of comparable weight it is somewhat greater for cyclohexene activation.

In an attempt to determine the dependence of the reaction kinetics upon the activation history of the $AgBF_4$, the kinetics of the propylene reaction were determined on a sample

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

after varying amounts of cyclohexene activation. The results are shown in Fig. 6. While the rate, k_1, increases somewhat from 19.2×10^{-3} min^{-1} to 20.9×10^{-3} min^{-1} upon increasing the extent of activation from 57.1% to 92.7%, there is a more marked effect on the value of α at which deviation from the linear rate law occurs. This increases from 0.34 at 57.1% activation to 0.88 at 92.7% activation.

It was found that with complete cyclohexene activation, deviation did not occur below $\alpha = 0.9$.

Deviation of the data from the linear rate law indicates the onset of a second rate-controlling process. It has been observed by others (10, 14, 19) that gas–solid reactions can be in part or largely subject to diffusion control. The rate of the reaction is thus assumed to be a function of the thickness of the product layer through which diffusion must occur and the rate data are often found to obey the parabolic rate law

$$[1 - (1 - \alpha)^{1/3}]^2 = k_d t.$$

For spherical particles, k_d is inversely proportional to the square of the particle radius.

Treatment of the data for the propylene–$AgBF_4$ combination reaction according to the parabolic rate law has established that for non-activated samples, a plot of $[1 - (1 - \alpha)^{1/3}]^2$ versus time is linear over most of the reaction. The data obtained for the first reaction depicted in Fig. 1 obey the parabolic law after only 7.5% reaction. It was found impossible, however, to determine the pressure and temperature dependence of k_d for non-activated $AgBF_4$ since each determination required a new sample, slightly different from the others in physical characteristics.

While in general it was found that the activated samples of $AgBF_4$ gave rate data which deviated from the linear rate law at the higher values of α, most of these did not obey the parabolic rate law alone over a significant range of α. With one sample, however, a plot of the rate data according to the parabolic law demonstrated linear regions from which values of the rate constant, k_d, for the diffusion-controlled reaction could be obtained. The data for determinations at several pressures at 25.0 °C are shown in Fig. 7. The upward deviation from the parabolic law at high values of α may indicate some opening up of the sample due to expansion.

In Table II are reported data at 25.0 °C for the slopes, k_1, of the linear law plots, the value of α, α_1, at which deviation from the linear law begins, the slope, k_d, of the parabolic

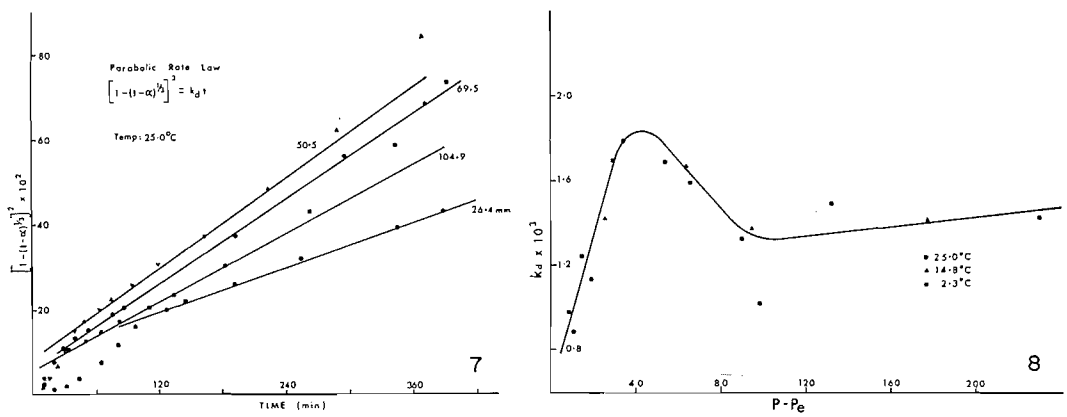

FIG. 7. Parabolic rate law plots (sample 1).

rate law plots and the range of values of α, α_2 to α_3, over which that law applies (for sample 1 of Table I). It is apparent that while α_1 decreases somewhat with increasing propylene pressure, there is a much more marked decrease in α_2, the value of α at which the diffusion-controlled reaction alone obtains; this changes from 0.85 at 26.4 mm Hg to 0.50 at 245.2 mm Hg. The earlier observation that the α versus time plots for higher pressure determinations intersected those at lower pressures might be explained by the earlier onset of diffusion control at higher pressures.

TABLE II

Kinetic data for propylene combination reaction at 25.0 °C (sample 1)

Pressure (mm Hg)	Linear rate law		Parabolic rate law		
	10^3k_1 (min^{-1})	α_1*	10^3k_d (min^{-1})	α_2†	α_3†
26.4	4.12	0.523	0.90	0.847	0.959
34.1	6.30	0.518	1.14	0.780	0.947
50.5	10.2	0.587	1.79	0.810	0.972
69.5	13.3	0.462	1.69	0.689	0.995
104.9	17.1	0.474	1.32	0.687	0.910
147.0	20.2	0.458	1.48	0.580	0.912
245.2	23.1	0.423	1.41	0.497	0.907

*The quantity α_1 is value of α at which deviation from linear law observed.
†The quantities α_2 and α_3 are respectively the lowest and highest values of α for which the parabolic law applies.

With this sample, as with all others, k_1 varies logarithmically with P ($k_2 = 21.4 \times 10^{-3}$ min^{-1} and, by extrapolation, $k_1 = 0$ when $P = 16.7$ mm Hg). The value of k_1 at the highest value of P fell below the linear k_1 vs. log P plot.

Over a short range of pressure, k_d was found to vary essentially linearly with P, subsequently passing through a maximum and decreasing to a point beyond which there was little dependence on pressure. The variation of k_d with $P - P_e$ at various temperatures is illustrated in Fig. 8. The temperature dependence of k_d is not very marked.

DISCUSSION

While the parabolic rate law describes the reaction kinetics for most of the reaction of propylene with non-activated samples of $AgBF_4$, the linear rate law applies for most of the reaction with activated samples. The linear rate law indicates a kinetically controlled reaction since the rate is proportional to the area, and thus to the concentration of unreacted salt, at the reaction interface. The parabolic rate law, on the other hand, indicates a diffusion-controlled reaction. The effect of varying degrees of activation (Fig. 6) upon the value of α at which deviation from kinetic control is observed establishes a progressive change from diffusion to kinetic control as activation proceeds.

There is marked similarity between the variation with pressure of the rate constant, k_d, for the diffusion-controlled reaction (Fig. 8) and the well-known variation of the diffusion coefficient with amount of adsorption for transport of a gas through a porous plug on which it is adsorbed. This phenomenon has been reviewed by Field, Watts, and Weller (20). It has been observed that the diffusion coefficient increases with surface coverage, reaches a maximum at the monolayer coverage and shows relatively little variation with further adsorption. This behavior has been interpreted in terms of transport via a surface diffusion process, the rate of which increases with increasing adsorption until the monolayer is formed with very little further change as a result of multilayer adsorption.

As a result of this similarity, it is suggested that, for those samples of $AgBF_4$ which demonstrate diffusion control, the rate-controlling mechanism is the surface diffusion of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

adsorbed gas molecules through the pore structure rather than diffusion through the reaction product. It would be expected that the activation process which involves an expansion followed by a contraction of the salt lattice would markedly change the pore structure of the salt particles. The observed net volume expansion and increased surface area as well as the decreased particle size of the sample resulting from activation indicate that the original salt particles have been converted to expanded porous bodies composed of smaller particles.

When the activated salt is reacted with propylene, the C_3H_6 molecules must be able initially to reach the reaction interface without being subject to the control of surface diffusion. As the reaction proceeds, however, the concommitant lattice expansion reduces the average pore size and, at some point in the reaction, surface diffusion begins to play a rate-controlling role. The observation that diffusion control occurs at lower values of α at the higher pressures can be explained by the greater adsorption at those pressures which brings surface diffusion into play at an earlier stage. Similarly in nonactivated or semi-activated samples, earlier onset of diffusion control can be explained by a greater proportion of small pores in the system. The fact that most activated samples have not demonstrated significant regions of pure diffusion control indicates that they contain some pores of diameter sufficiently large that, even toward the end of the reaction, the propylene molecules can pass through without being subject to the control of surface diffusion. The observation that deviation from the linear rate law occurred at higher values of α for cyclohexene-activated than for propylene-activated samples can equally well be attributed to a larger average pore diameter in the former.

The observation by Pavlyuchenko and Torgonskaya (13) that the reaction

$$AgNO_3 + 3NH_3 \rightarrow AgNO_3.3NH_3$$

is entirely diffusion-controlled at -20 °C and 0 °C but initially, kinetically controlled at 25 °C and 56 °C suggests that the diffusion control in this system may be also the result of adsorption; with increasing temperature, the decreasing adsorption will reduce the controlling effect of surface diffusion.

The adherence of the rate data to the linear rate law for much of the reaction of activated salt indicates that the contracting sphere model (21) may be satisfactorily employed to visualize the reaction mechanism. It has been reported by several investigators (6, 11) that, for kinetically controlled reactions, the rate is often directly proportional to the difference between the imposed pressure and the equilibrium dissociation pressure of the compound, i.e. for combination reactions to $P - P_e$. Our observation that the rate at constant temperature, k_1, is proportional to log P suggests that the driving force is something other than the simple pressure differential between the outside of the reacting particle and the reaction interface. The log P relationship suggests, in fact, that the propylene molecules are supplied to the reaction interface from an adsorbed film on the particle surface. The earlier indication that surface diffusion may be the rate-controlling process when diffusion control is operative further substantiates the view that the gas is adsorbed on the solid surface. It has been recognized (1) that adsorption of the gaseous component on the surface of a solid will affect the rate of a dissociation reaction. While it is not surprising, then, that for this combination reaction the propylene is adsorbed, it is nonetheless interesting that the reaction rate demonstrates a pressure dependence that may be that shown by the adsorption process.

Of the adsorption isotherms which might apply for this system, the two most probable are the Freundlich isotherm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$\log \theta = AT \log P + BT \quad [2]$$

and the Temkin isotherm

$$\theta = A'T \log P + B'T \quad [3]$$

where θ represents the surface coverage. The Freundlich isotherm is based on the assumption that the heat of adsorption, q, decreases logarithmically with increasing θ, while the Temkin isotherm assumes a linearly decreasing q (22) and is valid only when θ is approximately 0.5. Because of the reaction of C_3H_6 with $AgBF_4$, it has not been possible to determine directly the form which the adsorption isotherm takes in this system.

For the sake of simplicity one might tend to assume that the rate of reaction is proportional to the difference between the amounts of adsorption at P and P_e, i.e.,

$$k_1 = k'(\theta_P - \theta_{P_e}). \quad [4]$$

Equation [4] in combination with equation [1] suggests Temkin adsorption. Because, however, the Temkin isotherm is valid only in the vicinity of 50% surface coverage, it is unlikely that it can adequately represent the rate-determining adsorption process. This is particularly so if the maximum in the k_d versus $P - P_e$ plot (Fig. 8) can be considered to represent the point at which monolayer formation is complete.

The suggestion then that the Freundlich isotherm may apply infers that k_1 is proportional to the difference between the heats of adsorption at P and P_e rather than to the difference between the surface coverages, i.e.,

$$k_1 = K(q_P - q_{P_e}). \quad [5]$$

From eqs. [1], [2], and [5], one deduces the expression

$$k_2 = KAT. \quad [6]$$

The observed dependence of the magnitude of k_2 on sample size may be due to a decrease in the surface area to weight ratio as the sample size increases.

It has been observed by a number of investigators (1) that, for a truly reversible dissociation reaction at a solid–solid interface, the activation energy is equivalent to the heat of reaction. Consequently, it has been suggested (1) that there should be zero activation energy for the reverse combination reaction. Since the $AgBF_4.2C_3H_6$ complex formation is reversible, one would then expect this combination reaction to show zero activation energy also.

An Arrhenius plot of the values of k_2 from Fig. 5 shows considerable scatter about a straight line with a slope such that the activation energy calculated therefrom is <2 kcals/mole. It is probable then that the temperature dependence of k_2 is simply that of the adsorption of propylene as suggested by eq. [6].

It is apparent that, for Freundlich adsorption as defined by eq. [2], T/k_2 should be constant. It was found, however, that for the propylene reaction, T/k_2 decreases with increasing temperature (Table III). Halsey (23) has stated that if the partition function for the adsorbed molecules is not constant but is a function of θ, the Freundlich isotherm can be of the form

$$\log \theta = A \frac{T}{(1 - rT)} \log P + B \frac{T}{(1 - rT)}$$

where r is a constant. Should this expression apply for adsorption in the propylene–$AgBF_4$ system, one would predict a linear decrease of T/k_2 with increasing T. With the exception of the point at 40 °C the data of Table III obey this relationship.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE III

Variation of rate constant k_2 with temperature (data of Fig. 5 after correction for adsorption)

T (°K)	$10^3 k_2$ (min^{-1})	$10^{-4} T/k_2$
277.7	17.9	1.55
298.2	21.4	1.39
313.2	26.8	1.17
328.2	29.2	1.12

The temperature and pressure dependence of the rate data certainly indicate that the propylene is being supplied to the reaction interface from an adsorbed film rather than from the gas phase. The earlier suggestion that, if Freundlich adsorption applies, the rate of reaction is proportional to the difference between the heats of adsorption at P and P_e may be suggestive of the mechanism of transport of the olefin molecules from the particle surface to the reaction interface. If the transfer involves successive combination and dissociation reactions between the olefin molecules and silver ions in the salt lattice, it is possible that the activation energy for the initial dissociation step is provided by the heat of adsorption. Because of the electronic interaction involved, the olefin molecules can be considered, at least to the point of monolayer formation, to be chemisorbed rather than just physically adsorbed on the salt surface, and the heat of adsorption would probably exceed the value of $\Delta H°$ for complex formation ($\simeq$10 kcal/mole) since lattice energy changes would be less for surface reaction than for bulk complex formation.

Although the suggested mechanism is very speculative, this study has established that the rate of reaction of propylene with silver tetrafluoroborate is markedly dependent upon the adsorption state of the system whether the reaction is kinetically controlled or diffusion controlled. This same behavior might be expected for many other gas–solid combination reactions since a marked adsorption of the gas on the solid surface would be anticipated.

ACKNOWLEDGMENT

The authors are very grateful to Dr. H. Watts for helpful discussion relating to the diffusion control observed in this study.

CYCLOBUTADIENE–METAL COMPLEXES

PART VIII.[1] SYNTHESIS OF TETRAPHENYLCYCLOBUTADIENE NICKEL HALIDES BY LIGAND-EXCHANGE REACTIONS

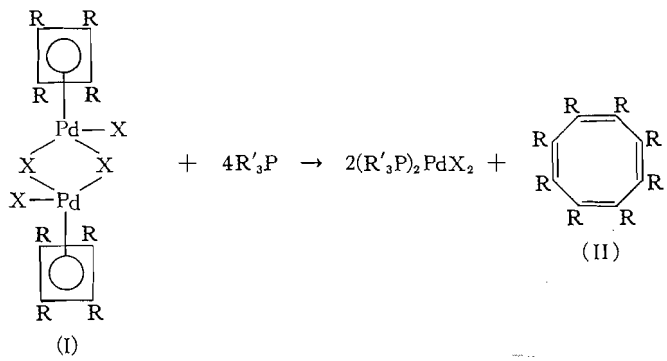
D. F. POLLOCK AND P. M. MAITLIS[2]

Chemistry Department, McMaster University, Hamilton, Ontario

Received July 5, 1966

ABSTRACT

The preparation of cyclobutadiene nickel halide complexes $(R_4C_4NiX_2)_2$, where R is phenyl or substituted phenyl, by reaction of the palladium complexes, $[R_4C_4PdX_2]_2$, with a *tert*-phosphine metal complex, e.g. $(n\text{-}Bu_3P)_2NiX_2$, is described. The reaction proceeds according to the equation



$$[R_4C_4PdX_2]_2 + 2(Bu_3P)_2NiX_2 \rightarrow [R_4C_4NiX_2]_2 + 2(Bu_3P)_2PdX_2.$$

Possible mechanisms are suggested.

INTRODUCTION

When this work was started (1962), little was known about the chemistry of cyclobutadiene–metal complexes, mainly because of the difficulty in preparing representative complexes with (*a*) different substituents on the four-membered ring and (*b*) different metals complexed to the cyclobutadiene. The problems associated with the synthesis of various substituted cyclobutadiene complexes of a given metal have now been largely overcome though serious practical difficulties often remain (1). The syntheses used were for the most part specific for one metal, and in order to obtain a series of complexes with the same ligand attached to different metals it was necessary to devise a means of transferring the cyclobutadiene ring from one metal to another. This problem has been solved to a great extent by the ligand-transfer reactions which have been described previously (2). Before the discovery of these reactions, however, we developed the novel ligand-exchange reactions which form the subject of this paper.

The preparation and properties of the tetraphenylcyclobutadiene palladium halides (I, R = Ph) have been adequately described by ourselves (3) and others (4). One of the most interesting reactions which these compounds undergo is with a *tert*-phosphine (5). In refluxing benzene the cyclobutadiene–palladium bond is broken and the products isolated are the bis(*tert*-phosphine)palladium halides and a dimer of tetraphenylcyclobutadiene, later identified as octaphenylcyclooctatetraene (II, R = Ph) (6).

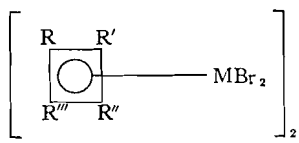
[2]*Author to whom correspondence should be addressed.*



This reaction, which proceeded in high yield, suggested that if the phosphine complex of a metal in which the phosphine was labile were used in place of the free phosphine it might be possible to get complete exchange of ligands between the two metals, thus

[2] $$(R_4C_4PdX_2)_2 + 2(R'_3P)_2NiX_2 \rightarrow (R_4C_4NiX_2)_2 + 2(R'_3P)_2PdX_2 \ .$$

(I) (III) (IV) (V)

RESULTS

Preliminary experiments with $(R'_3P)_2NiX_2$, where X = halogen and R′ = Ph or $(R'_3P)_2$ = $Ph_2PCH_2CH_2PPh_2$, indicated that this exchange was feasible. The products from these reactions, though, were nearly impossible to separate. However, use of $(n\text{-}Bu_3P)_2NiBr_2$ as the source of the phosphine also led to the desired reaction and gave products which were easy to separate. The reaction was most conveniently carried out in refluxing chlorobenzene; a color change from red [the color of the mixture of the cyclobutadiene complex (I, R = Ph) and the nickel complex (III)] to green [mainly the color of IV since V is yellow] occurred very rapidly. Heating was continued for 2 h to ensure completion of the reaction. After removal of the chlorobenzene the products were separated either by chromatography or by solvent extraction, the complex (V, R′ = *n*-Bu) being exceedingly soluble whereas IV (R = Ph) was only slightly soluble in most solvents. The nickel complex (IV, R = Ph) was identified by analysis and by comparison with an authentic sample. This reaction was extended to the synthesis of other complexes (IV, R = *p*-ClC_6H_4, *p*-$MeOC_6H_4$, and *p*-$CH_3C_6H_4$, and VI, M = Ni)[3] since the required palladium complexes were readily accessible by modification of the routes used to prepare I (R = Ph).

(VI)

The bromide complexes (I, X = Br) were usually used and the yields ranged from 72–90%. In one case (I, R = Ph, X = Cl), the chloride complex was used; here the yield was slightly lower than for the bromide. These reactions are, however, probably quantitative, since in no case was any by-product detected, and the lower yields obtained are due to some difficulty in isolating and purifying the products.

The results are presented in Table I.

DISCUSSION

The first step in both the ligand-displacement reaction (eq. [1]) and in the ligand-exchange reaction (eq. [2]) is probably the attack of a phosphine at the palladium. In the latter case this must be formed by dissociation of the nickel complex.

$$(R'_3P)_2NiX_2 \rightleftharpoons R'_3P + R'_3PNiX_2$$

Once the phosphine is complexed to the palladium the metal–cyclobutadiene bond is weakened since, despite a number of attempts, no stable tetraphenylcyclobutadiene palladium halide – phosphine complexes, $R_4C_4PdX_2PR'_3$, could be obtained. The next

[3] *VI (M = Ni) was prepared from VI (M = Pd) which was obtained from palladium chloride and o-methoxydiphenylacetylene. VI is therefore probably a mixture of the 1,2-bis(o-anisyl)-3,4-diphenylcyclobutadiene (R = R′ = o-anisyl, R″ = R‴ = phenyl) and the 1,3-bis(o-anisyl)-2,4-diphenylcyclobutadiene (R = R″ = o-anisyl, R′ = R‴ = phenyl).*

TABLE I

Ligand-exchange reactions

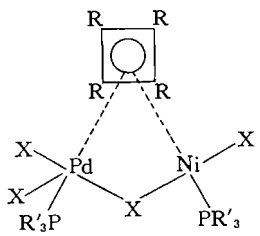
Reactants			Analysis of product, $[R_4C_4NiX_2]_2$					
			Found			Calculated		
$[R_4C_4PdX_2]_2$	$(n\text{-}Bu_3P)_2NiX_2$	Yield (%)	C	H	Mol. wt.	C	H	Mol. wt.
R = Ph, X = Br	X = Br	90	58.27	3.40	—	58.49	3.51	—
R = Ph, X = Cl	X = Cl	82	69.02	4.32	—	69.18	4.16	—
R = *p*-ClC_6H_4, X = Br	X = Br	72	47.03	2.34	1 390	47.24	2.26	1 425
R = *p*-$MeOC_6H_4$, X = Br	X = Br	77	54.87	4.50	1 340	54.97	4.26	1 390
R = *p*-MeC_6H_4, X = Br	X = Br	73	56.74	3.98	1 210	56.61	4.16	1 262
VI, M = Pd	X = Br	75	56.56	3.62	1 220	56.72	3.81	1 270

step, however, is less obvious since there are two main mechanisms by which the reaction can proceed. The first assumes that free tetraphenylcyclobutadiene is transiently formed and that this then adds to a coordinatively unsaturated nickel complex.

$$4R'_3P + [R_4C_4PdX_2]_2 \rightarrow 2(R'_3P)_2PdX_2 + 2R_4C_4$$

Either

$$R_4C_4 + R'_3PNiX_2 \rightarrow \tfrac{1}{2}[R_4C_4NiX_2]_2 + R'_3P.$$



Or

$$2R_4C_4 \rightarrow R \text{ (VII)} R \rightarrow \text{II.}$$

(VII)

The formation of the cyclooctatetraene (II) can be visualized as arising by a similar route.

The second reaction path does not assume that the cyclobutadiene becomes completely detached from the metal at any time but rather that it proceeds via an intermediate such as VIII in which both metals are attached to the ring (either from the same side, as shown, or from opposite sides).

(VIII)

Pettit and his co-workers (7) have recently obtained evidence to show that free cyclobutadiene, obtained by oxidation of its iron tricarbonyl complex, is capable of existence, though only for a short time. This might suggest that a free tetraphenylcyclobutadiene, which would be expected to be more stable than cyclobutadiene itself, would be capable of existing for a short time and might well be an intermediate in the above reaction. However, attempts to trap any tetraphenylcyclobutadiene produced from I, according to eq. [1], with a dienophile have been surprisingly unsuccessful (8). Adducts have been obtained but in low yield and usually together with II despite the large preponderance of the dienophile. In some cases, however, even the expected adducts are not found; thus reaction of tetraphenylcyclobutadiene palladium bromide (I, R = Ph, X = Br) with tributylphosphine in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

refluxing benzene gave no trace of hexaphenylbenzene when conducted in the presence of a 10 *M* excess of diphenylacetylene. A 92% yield of the cyclooctatetraene (II, R = Ph) was obtained. One of us has recently suggested (9) that the diradical (VII) supposed to be the precursor to II may well be formed inside a metal complex and that the successful reactions with dienophiles may also start when both dienophile and the cyclobutadiene are complexed to the metal.

This argument, accompanied by the absence of any by-products in the ligand-exchange reactions, notably II, makes us favor the second mechanism for the ligand-transfer reaction. Further studies are in progress which it is hoped will shed some light on this problem.

Attempts to extend these reactions to form the cyclobutadiene complexes of cobalt(II) and iron(II) have not, as yet, proved successful.

EXPERIMENTAL

The palladium complexes (I, R = Ph) and (I, R = *p*-ClC_6H_4) were prepared by published methods (3). The remaining complexes were prepared from the acetylenes in similar ways, full details of which will be published shortly. Since the method of carrying out the ligand-exchange reactions did not vary greatly, a representative procedure is given. The results of the other reactions are presented in Table I.

Tetraphenylcyclobutadiene Nickel Bromide (IV, R = Pd, X = Br)

A suspension of 1.0 g (0.8 mmole) of tetraphenylcyclobutadiene palladium bromide dimer in 200 ml of chlorobenzene was refluxed for 5 min under nitrogen to remove air dissolved in the solvent. 1.0 g (1.6 mmoles) of bis(tri-*n*-butylphosphine)nickel bromide (10) was added; the solution changed color from red to dark green almost immediately. Refluxing was continued for 2 h to complete the reaction.

The hot solution was then filtered (negligible residue) and the volume of the filtrate reduced to 50 ml on a rotary evaporator. This solution was then chromatographed on a silica column. Methylene chloride eluted the yellow and extremely soluble bis(tri-*n*-butylphosphine)palladium bromide, whereas the less soluble tetraphenylcyclobutadiene nickel bromide (IV, R = Ph, X = Br) was eluted by 1:1 methylene chloride – tetrahydrofuran. The yield of the cyclobutadiene nickel halide dimeric complex was 0.83 g (0.72 mmole, 90%). The identity of the complex was shown by analysis (a molecular weight determination was not possible because of its insolubility), decomposition point 317°, and comparison of the infrared spectrum with that of an authentic sample (11). Crystalline bis(tri-*n*-butylphosphine)palladium bromide was isolated in 46% yield, but the mother liquors still contained a large amount of this very soluble compound. The identity of the phosphine complex was established by comparison of its infrared spectrum with that of an authentic sample; it had m.p. 71–73°, mixed melting point with an authentic sample 72–74°.

Formation of Octaphenylcyclooctatetraene (II, R = Ph) in the Presence of Diphenylacetylene

Tetraphenylcyclobutadiene palladium bromide dimer (I, R = Ph, X = Br) (0.30 g, 0.24 mmole) and diphenylacetylene (0.86 g, 4.8 mmoles) were refluxed in 100 ml of benzene under nitrogen. Tri-*n*-butylphosphine (0.20 g, 0.98 mmole) was added; the suspension rapidly turned yellow and the solid dissolved. The solution was refluxed for 30 min and then filtered hot to leave 0.11 g of a white crystalline solid shown to be octaphenylcyclooctatetraene (II, R = Ph) by its infrared spectrum. The solvent was removed on a rotary evaporator and the residue extracted with a few milliliters of ethanol in which both the cyclooctatetraene (II, R = Ph) and hexaphenylbenzene are totally insoluble. The insoluble residue (0.05 g) was shown to be exclusively octaphenylcyclooctatetraene by its characteristic infrared spectrum. Total yield of II (R = Ph) obtained was 0.16 g, 92% theoretical. Thin layer chromatography of the ethanol-soluble material showed the presence only of bis(tributylphosphine)palladium bromide and diphenylacetylene.

ACKNOWLEDGMENT

We thank the National Research Council for their support of this work, Johnson, Matthey and Mallory for the loan of palladium chloride, and M and T Chemicals for a gift of tributylphosphine.

KINETIC ASPECTS OF THE COPOLYMERIZATION OF TETRAHYDROFURAN WITH PROPYLENE OXIDE. I

L. P. BLANCHARD, J. SINGH,[1] AND M. D. BAIJAL[2]
Département de Génie Chimique, Université Laval, Québec, P.Q.
Received December 14, 1964, and, as revised, July 11, 1966

ABSTRACT

Tetrahydrofuran and propylene oxide were copolymerized in the presence of the catalyst boron fluoride ethyl ether, and various co-catalysts, such as 1,2-propanediol, 1,3-propanediol, and 1,4-butanediol. Ethylene chloride was used as a solvent and as an internal reference for analytical purposes. Reactions were carried out at 0 °C and at atmospheric pressure. Monomer concentrations were determined by vapor phase chromatography, and copolymer molecular structure analyses were carried out by physical and chemical methods including infrared spectroscopy, vapor pressure osmometry, hydroxyl end-group analysis, and chemical reduction of unsaturated linkages.

The homopolymerization of tetrahydrofuran did not take place, whereas that of propylene oxide proceeded at a rapid rate. In the copolymerization of tetrahydrofuran with propylene oxide, the rate of disappearance of tetrahydrofuran was found to be independent of its concentration, but varied directly with the concentration of propylene oxide. Under similar conditions, the rate of disappearance of propylene oxide was found to be (*a*) proportional to the square of its concentration, and (*b*) inversely proportional to the concentration of tetrahydrofuran.

Reactivity ratios varied between 1.3 and 1.8 for propylene oxide and between 0.1 and 0.6 for tetrahydrofuran. Molecular weights obtained by vapor pressure osmometry ranged between 460 and 740, and those obtained by hydroxyl end-group analysis ranged between 520 and 1 660. Infrared spectra confirmed the presence of hydroxyl groups and ether linkages in the copolymers prepared. Results on terminal unsaturation were negative.

RÉSUMÉ

La copolymérisation du tétrahydrofuran et de l'oxyde de propylène fut effectuée en présence du catalyseur l'éthérate du fluorure de bore, et de cocatalyseurs tels le 1,2-propanediol, le 1,3-propanediol et le 1,4-butanediol. Le chlorure d'éthylène servait de solvant et d'étalon interne pour fins d'analyse. Les concentrations de monomères furent suivies, en fonction du temps, par la chromatographie en phase vapeur. L'analyse des copolymères a porté surtout sur l'étude de la structure au moyen de techniques physiques et chimiques telles que la spectroscopie infrarouge, l'osmométrie à tension de vapeur, l'analyse chimique des groupements hydroxyles terminaux et la réduction chimique des liaisons doubles.

L'homopolymérisation du tétrahydrofuran n'a pu être effectuée, tandis qu'avec l'oxyde de propylène seul, dans les conditions de réaction adoptées, la réaction s'est poursuivie à grande vitesse. Dans la copolymérisation du tétrahydrofuran avec l'oxyde de propylène, la vitesse de disparition du tétrahydrofuran était indépendante de sa concentration et variait directement avec la concentration d'oxyde de propylène. Dans les mêmes conditions, la vitesse de disparition de l'oxyde de propylène était (*a*) proportionnelle au carré de sa concentration et (*b*) inversement proportionnelle à la concentration du tétrahydrofuran.

Les rapports de réactivité de l'oxyde de propylène ont varié de 1.3 à 1.8 et ceux du tétrahydrofuran de 0.1 à 0.6. Les poids moléculaires obtenus par osmométrie à tension de vapeur étaient compris entre 460 et 740 et ceux obtenus par analyse chimique des groupements hydroxyles terminaux entre 520 et 1 660. Les spectres infrarouges ont confirmé la présence des groupements hydroxyles et des liaisons éther internes.

Les résultats des tests d'insaturation terminale ont été négatifs.

INTRODUCTION

Copolymerization reactions of alkylene oxides and tetrahydrofuran with boron fluoride ethyl ether as catalyst have been investigated by a number of groups (1–4); no work, however, has been reported on the kinetics of the copolymerization reaction of tetrahydrofuran with propylene oxide. Copolyetherdiols obtained from the copolymerization

[1]*Present address: Department of Agriculture, Government of Canada, Ottawa, Canada.*
[2]*National Research Council Postdoctorate Fellow.*

of alkylene oxides and tetrahydrofuran have been used in the preparation of polyurethanes (1, 3). It has been reported (1) that diols prepared from tetrahydrofuran and propylene oxide present two advantages when used as intermediates in the preparation of polyurethanes. They reduce cold hardening or crystallinity in the solid, and facilitate efficient mixing and good molding of the uncured ingredients.

Since the mechanism of preparation of these low molecular weight copolyetherdiols has not been established yet, the copolymerization reaction of tetrahydrofuran with propylene oxide was studied. The results obtained throw light (*a*) on the chemistry of preparation, and (*b*) on the composition and structure of these polyols.

EXPERIMENTAL

Materials

The following substances were used for this study:

(*a*) comonomers: propylene oxide (Anachemia, polymerization grade), tetrahydrofuran (Anachemia, b.p. 64–66°);

(*b*) catalyst: boron fluoride ethyl ether (Eastman, purified);

(*c*) co-catalysts: 1,2-ethanediol (Fisher, U.S.P.), 1,2-propanediol (Fisher, U.S.P.), 1,3-propanediol (Eastman, practical), 1,4-butanediol (Eastman, practical);

(*d*) solvent: ethylene dichloride (Fisher certified reagent).

Methods

Solvent and comonomers were always blended in equal molar ratios (0.4 mole of ethylene chloride (EC) with 0.4 mole of tetrahydrofuran – propylene oxide mixtures). These mixtures were prepared in the following

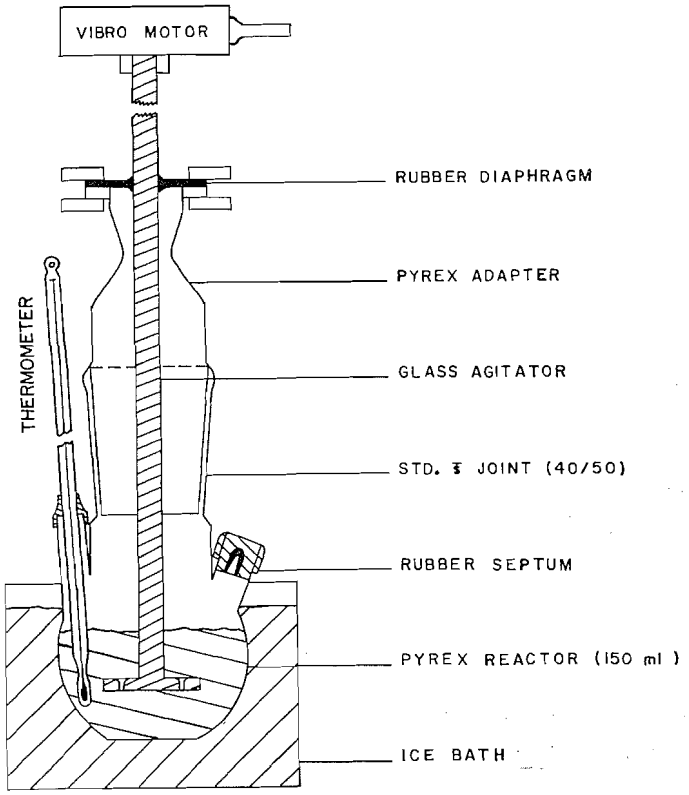

FIG. 1. Schematic diagram of reactor used for polymerization reactions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molar ratios: 1:0, 1:1, 1:2, 1:4, 2:1, 4:1, and 0:1. The amount of catalyst added was usually 7×10^{-4} mole, and that of co-catalyst was always 2.4×10^{-2} mole (6 mole % of the comonomers charged).

The reactions were carried out at 0 °C and at atmospheric pressure in a 150 ml round bottom pyrex flask with three openings (Fig. 1). One of the lateral openings was covered with a self-sealing rubber septum through which reactants were admitted and samples were withdrawn by Luer-Lok syringes for analysis, the other opening was used to insert a thermometer. The large mouth of the flask served to introduce an all-glass stirrer activated by an appropriate vibro motor.

The disappearance of reactants was followed with a Perkin–Elmer vapor fractometer (model 154-C) equipped with thermistor detectors, a Westronics two-pen recorder (type DU/11A) and a Self-Organizing-Systems electronic integrator (type RI 220). Five microliter samples of the reactants, withdrawn with a Hamilton syringe (type 705N), were separated on a column (P.E. type R), 2 m long ($\frac{1}{4}$ in. outside diameter), containing polypropylene glycol (UCON LB-550-X), and maintained at 125 °C. Helium was used as the carrier gas at a flow rate of 100 cc/min. Calibration curves for quantitative estimations were prepared by a simple method involving pure substances alone (5). The concentrations at zero time were obtained from reference mixtures having no catalyst. When concentration changes became insignificantly small, the reaction was presumed to be terminated, and this was taken as the completion time of the reaction. Residual reactants and solvent were removed from the copolymer by evaporation under reduced pressure and at room temperature, first using a water aspirator and later a high-vacuum mechanical pump.

The rates of disappearance, D_1 and D_2, for tetrahydrofuran and propylene oxide during the copolymerization reactions were obtained from the initial slopes of monomer concentration versus time curves.

Reactivity ratios of propylene oxide (r_1) and tetrahydrofuran (r_2) were obtained by using experimental data at 5% conversion of propylene oxide. The composition of the copolymer formed at this point was calculated from the amount of each comonomer consumed. The ratio of the comonomers in the mixture, on the other hand, was assumed to be that existing when $2\frac{1}{2}$% of the propylene oxide was consumed. The Mayo and Lewis copolymerization equation (6) was transformed[3] to isolate one of the reactivity ratios, then used to trace a line of r_2 versus r_1. This procedure was followed for the various comonomer mixtures studied, and the points of intersection of these lines yielded average values for the monomer reactivity ratios.

Number-average molecular weights of the copolymers were determined by a Mechrolab vapor pressure osmometer (Model 301A) and by hydroxyl end-group analysis using the phthalation procedure (7).

The vapor pressure osmometer was operated at 37 °C with methyl ethyl ketone. The calibration constant of the instrument 440 ohms/mole l was obtained by using substances of known molecular weights: polypropylene glycols (PPG 425 and 2 025), polyethylene glycols (PEG 200, 600, and 1 000), and benzil (210). The molecular weights of copolymers were obtained using the standard method described in the vapor pressure osmometer manual.

Molecular weights by hydroxyl end-group analysis were determined assuming 100% bifunctionality. This assumption was supported in part by negative unsaturation tests.

Qualitative tests for unsaturation in the copolymer were made by two methods, one using bromine in carbon tetrachloride, and the other using aqueous solutions of potassium permanganate. Quantitative estimations using mercuric acetate in methanol were made at the Canadian Armament Research and Development Establishment (C.A.R.D.E.).

Infrared spectra of the liquid copolymers were obtained at C.A.R.D.E., in Valcartier, Quebec, with a Perkin–Elmer double-beam recording spectrophotometer (Model 21) equipped with sodium chloride optics.

RESULTS AND DISCUSSION

The effect of the concentration of catalyst on the rate of copolymerization was investigated to determine the concentration range in which isothermal conditions could be maintained. This range and the completion time for each reaction, with rates of disappearance of each monomer, is given in Table I. The initial rates of disappearance of tetrahydrofuran (D_1) and propylene oxide (D_2) have been plotted as a function of the concentration of catalyst in Fig. 2. To a first approximation, these rates follow a first order law.

The homopolymerization of tetrahydrofuran could not be brought about under the reaction conditions adopted[4] (Fig. 3). Other reports (8, 9), however, show that it can be polymerized in a highly acidic medium. Homopolymerization of propylene oxide under the

[3]*Modified Mayo and Lewis equation:* $r_2 = [M_1]/[M_2][d[M_2]/d[M_1](1 + [M_1]r_1/[M_2]) - 1]$ *where* $[M_1]$ = *propylene oxide (PO), and* M_2 = *tetrahydrofuran (THF).*

[4]*The reaction conditions adopted were: 2:1:1 (EC:THF:PO)* $+ 7 \times 10^{-4}$ *mole (catalyst)* $+ 2.4 \times 10^{-2}$ *mole (co-catalyst), 0 °C and atmospheric pressure.*

TABLE I

The influence of the concentration of boron fluoride ethyl ether on the completion time of the copolymerization reaction at 0 °C in 2:1:1 mixtures of ethylene chloride, tetrahydrofuran, and propylene oxide, along with 1,2-propanediol

Concentration of catalyst (mole/l) × 10^2	Completion time of the reaction (min)	D_1(THF) × 10^3 (moles/l min)	D_2(PO) × 10^3 (moles/l min)
0.24	2 686	2.4	4.4
0.50	507	7.6	11.6
1.00	487	13.8	21.6
1.50	148	21.8	32.0

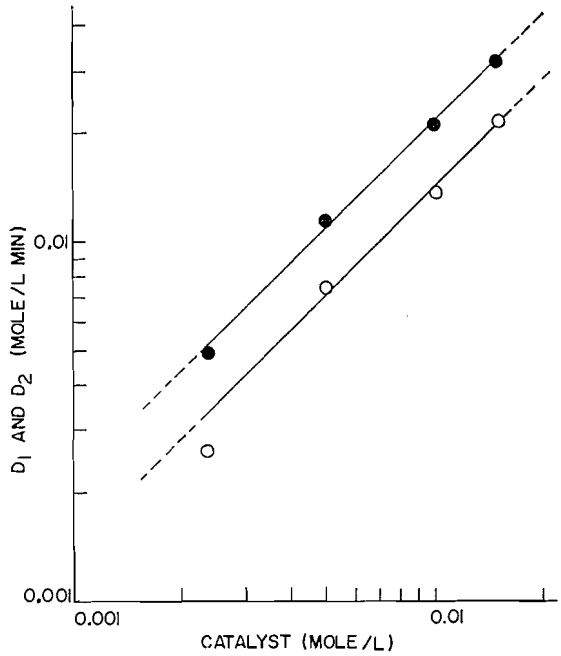

FIG. 2. Influence of the concentration of catalyst on the initial rates of disappearance of comonomers. The reactions were carried out at 0 °C, in 2:1:1 mixtures of EC:THF:PO, in the presence of 1,2-propanediol. (●) D_2(PO), (○) D_1(THF).

reaction conditions adopted[4] proved to be a very fast reaction (Fig. 3). These observations are understandable in the light of thermodynamic calculations of Small *et al.* (10) who pointed out that the opening of five-membered rings as found in tetrahydrofuran calls for more drastic reaction conditions than those required for the opening of three-membered rings as in propylene oxide.

After attempts to homopolymerize each monomer were completed, monomer mixtures were copolymerized in the presence of different diols. Monomer concentrations, as determined by gas chromatography, are given as a function of time in Figs. 4, 5, and 6. These figures show that the consumption of tetrahydrofuran ceases when propylene oxide has

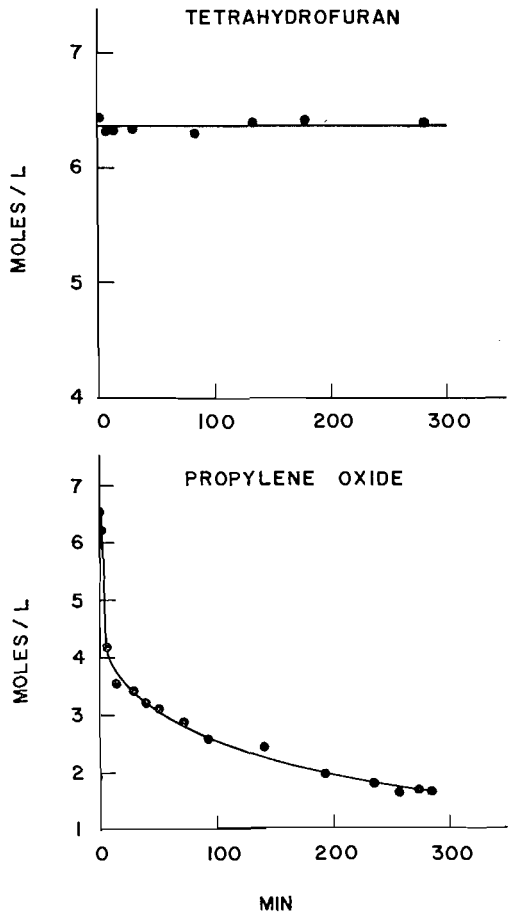

FIG. 3. Concentration versus time plots for the homopolymerization of tetrahydrofuran and propylene oxide. The reactions were carried out at 0 °C, in the presence of 1,3-propanediol.

been totally consumed. This observation emphasized the fact that the presence of propylene oxide is essential for the consumption of tetrahydrofuran under the reaction conditions adopted.[4]

The rates of disappearance of comonomers (D_1 and D_2) have been plotted as a function of their initial concentrations in Figs. 7 and 8. For the three co-catalysts used, the rate of disappearance of propylene oxide was found to be (*a*) proportional to the square of its initial concentration, and (*b*) inversely proportional to the initial concentration of tetrahydrofuran when the concentration of the latter does not exceed 3 moles/l. Above this value, this rate rapidly goes to zero. The rate of disappearance of tetrahydrofuran, on the other hand, varies directly with the initial concentration of propylene oxide but is independent of its initial concentration.

Various plots obtained using the modified Mayo and Lewis equation are given in Fig. 9 for the three diols. The average reactivity ratios obtained from these plots are given in Table II. The variation observed in the reactivity ratios may be explained in terms of the

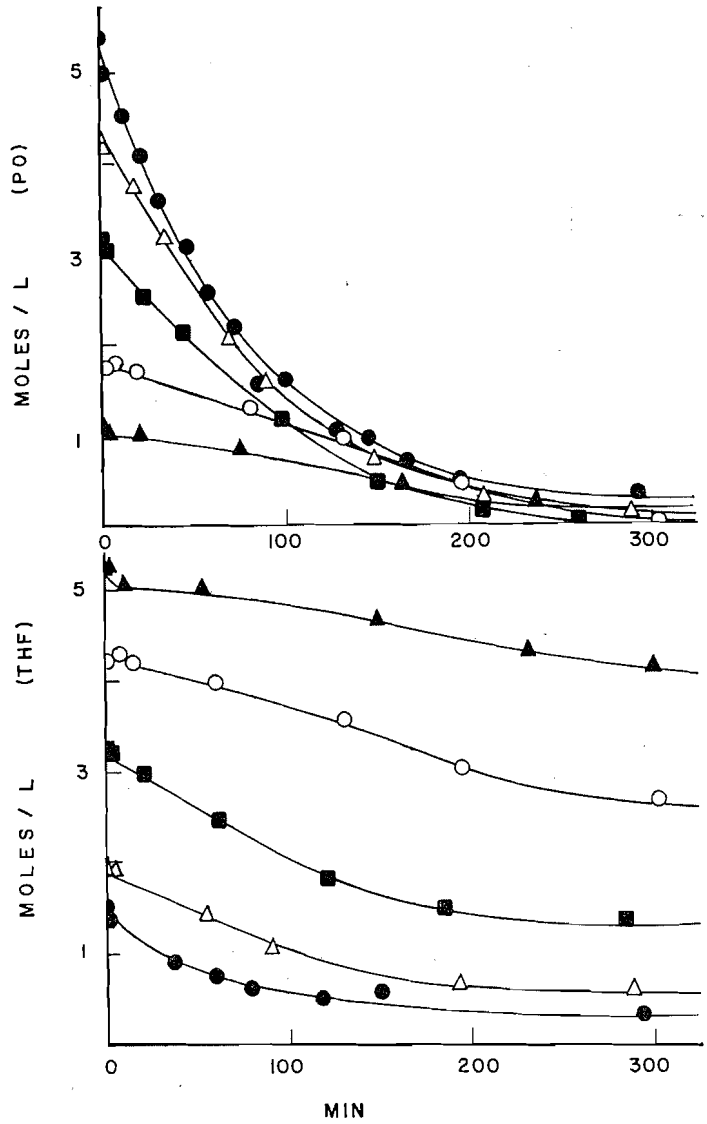

FIG. 5. Concentration versus time plots for the copolymerization of tetrahydrofuran with propylene oxide. The reactions were carried out at 0 °C, in the presence of 1,3-propanediol. Ratios THF:PO are: (▲) 4:1, (○) 2:1, (■) 1:1, (△) 1:2, (●) 1:4.

end effects resulting from the production of low molecular weight species. It is probable that r_2 is equal to the reciprocal value of r_1, and that the most probable value of r_2 is 1/1.5 or about 0.67.

The molecular weights determined by means of the vapor pressure osmometer and hydroxyl end-group analysis are given in Table III.

Variation of the comonomer ratio influences the molecular weights somewhat. From 1:1 to 1:4, the molecular weight remains essentially constant, and from 1:4 to 4:1 it decreases.

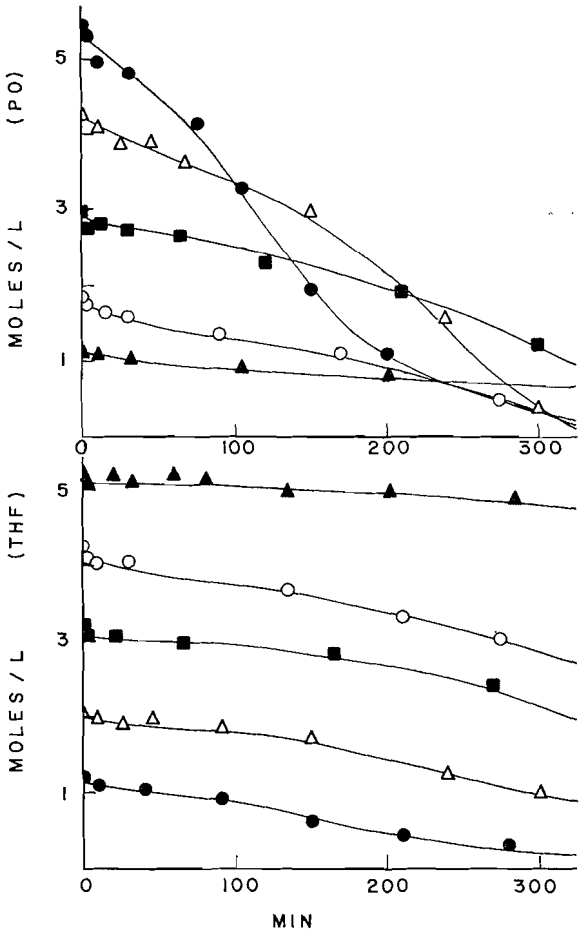

FIG. 6. Concentration versus time plots for the copolymerization of tetrahydrofuran with propylene oxide. The reactions were carried out at 0 °C, in the presence of 1,4-butanediol. Ratios THF:PO are: (▲) 4:1, (○) 2:1, (■) 1:1, (△) 1:2, (●) 1:4.

The use of different co-catalysts does not substantially alter the molecular weights of the copolyetherdiols obtained, except in the case of ethanediol. Increasing the concentration of catalyst does not affect the molecular weights. This agrees with the work of Murbach and Adicoff (3) who obtained similar results with copolymers of tetrahydrofuran and ethylene oxide. As a whole, the experimental molecular weights are low but this is due to the large amount of co-catalyst used.

There is considerable discrepancy between the molecular weights obtained by vapor pressure osmometry and hydroxyl end-group analysis. A preliminary gel permeation chromatographic analysis of the copolyetherdiols prepared in this laboratory has indicated that there is a secondary product (of low molecular weight) formed during these copolymerization reactions. The discrepancy between the molecular weight values is due to the dilution effects introduced by the low molecular weight product (11).

Infrared spectra of tetrahydrofuran – propylene oxide copolymers were recorded.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

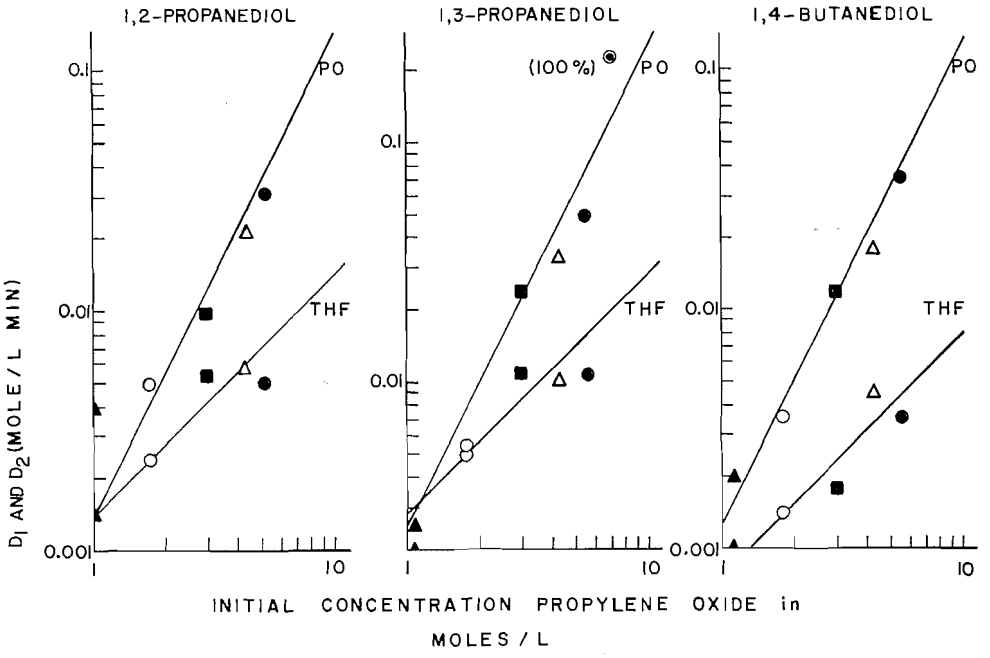

FIG. 7. Rates of disappearance of tetrahydrofuran and propylene oxide (D_1 and D_2) as a function of the initial concentration of propylene oxide. The reactions were carried out at 0 °C, in the presence of 1,2-propanediol, 1,3-propanediol, and 1,4-butanediol. Ratios THF:PO are: (▲) 4:1, (○) 2:1, (■) 1:1, (△) 1:2, (●) 1:4.

Bands were observed at the following wave numbers:

(*a*) 1 110 cm^{-1}: strong and broad, carbon oxygen – carbon ether linkages;

(*b*) 1 380 and 1 450 cm^{-1}: weak, symmetrical, and unsymmetrical deformation of CH_2 and CH_3 groups;

(*c*) 2 850 cm^{-1}: strong, carbon hydrogen stretching;

(*d*) 3 440 cm^{-1}: weak, hydroxyl stretching.

No bands were observed to indicate the presence of unsaturation.

The mechanism of this acid-catalyzed copolymerization of tetrahydrofuran with propylene oxide has been described elsewhere (12). The main features of this mechanism are: (i) 'Initiation' leading to the formation of oxonium ion intermediates; (ii) 'Propagation' involving ring-opening reactions and copolymer formation; (iii) 'Termination' involving the formation of a loose complex of the anion (nucleophile) with the oxonium-terminated copolymer, and subsequent reorganization to yield hydroxyl-terminated copolymer.

THE REACTIONS OF ACTIVE NITROGEN WITH ETHYLENE AND DEUTERATED ETHYLENES[1]

KENNETH D. FOSTER, P. KEBARLE, AND H. B. DUNFORD
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 30, 1966

ABSTRACT

The reaction of active nitrogen with ethylene and deuterated ethylenes has been investigated by use of a mass spectrometer. The rate of disappearance of atomic nitrogen in the presence of ethylene appears to obey the equation

$$-\mathrm{d[N]}/\mathrm{d}t = k_{app}[\mathrm{N}]\,[\text{ethylene}]_0,$$

where k_{app} is an apparent second order rate constant and $[\text{ethylene}]_0$ is the initial concentration of added ethylene. However, exceptions to this equation are found at 0.6 Torr either for short reaction times or for small concentrations of added ethylene, and apparently for short reaction times at 2.6 Torr when a large excess of ethylene is added. Where the above equation is obeyed, $k_{app} = (3 \pm 1) \times 10^{-13}$ cc molecule^{-1} s^{-1}. The formation of C_2D_4 in the reaction of active nitrogen with C_2D_3H is interpreted as further evidence for the importance of hydrogen atom reactions in intermediate steps of the reaction of active nitrogen with ethylene.

INTRODUCTION

The reaction of active nitrogen with ethylene has been studied by several workers (1–3). The initial steps in the reaction were believed to be

[1] $$\mathrm{N} + \mathrm{C_2H_4} \rightarrow \mathrm{HCN} + \mathrm{CH_3}$$

[2] $$\mathrm{N} + \mathrm{CH_3} \rightarrow \mathrm{HCN} + 2\mathrm{H} \quad .$$

The yield of hydrogen cyanide from the reaction of active nitrogen with excess ethylene has been taken as a measure of the nitrogen atom content in active nitrogen. However, the nitric oxide titration consistently indicates higher values for the nitrogen atom concentration (3). The possibility that the discrepancy is caused by catalyzed recombination of nitrogen atoms in the presence of ethylene has been ruled out on the ground that the $\Delta[\mathrm{N}]/[\mathrm{HCN}]$ ratio is independent of the initial nitrogen atom concentration (1, 3). Herron (1) detected H atoms with a mass spectrometer in the reaction of active nitrogen with ethylene. He proposed the following reactions in addition to [1] and [2].

[3] $$\mathrm{H} + \mathrm{C_2H_4} \rightarrow \mathrm{C_2H_5}$$

[4] $$\mathrm{H} + \mathrm{C_2H_5} \rightarrow 2\mathrm{CH_3}$$

[5] $$\mathrm{N} + \mathrm{C_2H_5} \rightarrow \mathrm{C_2H_4} + \mathrm{NH}$$

[6] $$\mathrm{N} + \mathrm{NH} \rightarrow \mathrm{N_2} + \mathrm{H}$$

followed by atom and radical termination reactions.

There remain, however, certain puzzling features of the discrepancy between the NO and HCN methods of measurement of nitrogen atom concentrations (4) and in particular of the mechanism of the reaction of active nitrogen with ethylene. In an attempt to resolve some of these problems, we report here on the use of a mass spectrometer to examine the reaction of active nitrogen with C_2D_4, C_2D_3H, and C_2H_4, as well as the results of product analyses obtained by using the combined techniques of gas–liquid chromatography and mass spectrometry.

[1]*Presented at the 49th Canadian Chemical Conference, Saskatoon, Saskatchewan, June, 1966. Financial support from the National Research Council is acknowledged.*

EXPERIMENTAL

Linde prepurified nitrogen was passed through a U trap filled with glass helices. In most experiments the trap was maintained at −195°. Nitric oxide was purified by repeated distillation through U traps at −160°. Reagent grade C_2D_4 and C_2D_3H (Merck, Sharpe and Dohme of Canada) were degassed prior to use. C_2H_4 was purified by repeated distillation through U traps at −130°.

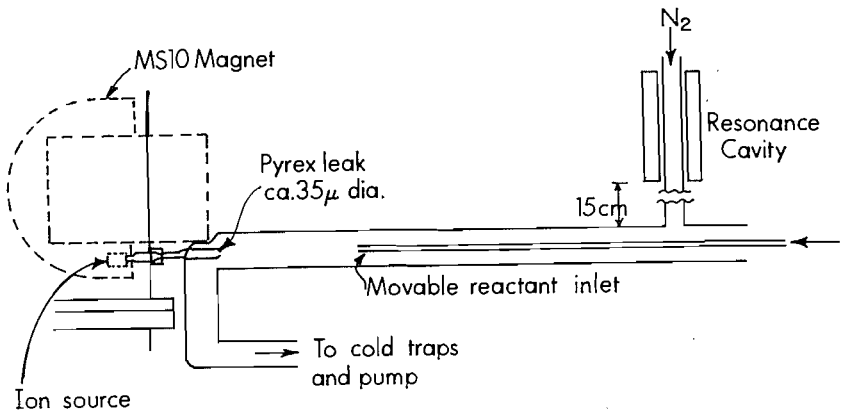

FIG. 1. Diagram of reaction system.

Nitrogen was partially dissociated in a fast-flow system by passage through a microwave resonance cavity (Ophthos Instrument Co.) coupled with a microwave exciter (Baird Atomic) of 2 450 Mc/s output. It then passed into a cylindrical reaction vessel of 18 mm inside diameter where a movable reactant inlet was located. Downstream from the inlet, a leak into the mass spectrometer was located. A diagram of the reaction chamber coupled to the mass spectrometer is shown in Fig. 1. The MS 10 instrument was modified so as to locate the leak as close as possible to the ion source. A 5 cm long pyrex lead was used between the leak and ion source. This lead could not be made shorter because of the design of the spectrometer. The ion source of the MS 10 instrument, which is normally of quite open construction, was closed off by the insertion of metal strips which formed the walls of an ion box. This was done since the pumping speed near the ion source is only moderate (approximately 15 l/s). The closed construction increased the probability that only freshly arriving sample entered the ion source. All mass spectrometric determinations on this instrument were conducted with an electron beam energy of 20 eV, except for ionization efficiency studies. The sensitivity of the mass spectrometer to various gases was determined from parent peak heights observed after mixing known amounts of the gases with the correct amount of nitrogen. Experiments were performed at 0.6 and 2.6 Torr of nitrogen. Flow rates of nitrogen in the reaction tube were 34.5 and 225 μmoles/s, respectively, which gave average linear velocities of 422 and 666 cm/s at the two different pressures. Flow rates of reactants were calculated from their partial pressures and the flow rate of molecular nitrogen, based on the assumption that the latter remained unchanged upon the addition of reactant. The sensitivity of the mass spectrometer to nitrogen atoms was determined by use of the nitric oxide titration.

For a typical experiment, the nitrogen flow and discharge were started. When a constant ion current at $m/e = 14$ was obtained, reactant was added through a fine control needle valve (Edwards High Vacuum Corp.) behind the movable inlet tube. A constant reactant flow rate was maintained by keeping the liquefied reactant at some low temperature such that it had a constant vapor pressure of ca. 100–200 Torr behind the Edwards valve.

The correlation between peak height at $m/e = 14$ from active nitrogen and afterglow intensity was tested. A portable photosensitive search head (Photovolt Corporation), strapped to the reaction tube near the mass spectrometer leak, was used to make the relative intensity measurements. The photo search head, placed upstream from the ethylene inlet, was also used to obtain relative initial nitrogen atom concentrations in some experiments where the ratio of N atoms destroyed to ethylene destroyed was studied as a function of initial nitrogen atom concentration.

In some experiments, products of the reaction were collected in a trap cooled in liquid nitrogen, then fractionated by distillation through a U trap at −130°. Products volatile at −130° were separated by gas–liquid chromatography on a medium activity silica gel column. Products not volatile at −130° were separated on a dibutyl maleate column. Fractions obtained from the gas–liquid chromatographic apparatus were then analyzed on a mass spectrometer. A few of these experiments were conducted specifically to test for C_2D_4 formation in the reaction of active nitrogen with C_2D_3H. For these experiments a medium activity silica gel column 10 ft in length was used. Mass spectra of the ethylene fractions were taken, both

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from the reaction and from blank experiments in which the discharge was off. Parent peak heights at $m/e = 32$ and 31, corrected for the blank were used as measures of C_2D_4 and C_2D_3H concentrations, respectively.

RESULTS AND DISCUSSION

The ionization efficiency curves for $m/e = 14$, obtained with the discharge on and off, showed clearly the presence of ^4S nitrogen atoms in active nitrogen. The voltage separation of the curves below 0.1% intensity was about 9.7 eV, which is very close to $D(N_2) = 9.75$ eV. We did not observe a discontinuity corresponding to that found by Jackson and Schiff (5). However, this may be due to the difference in excitation sources, since these authors used the more energetic condensed discharge.

A good linear plot was obtained when afterglow intensity was plotted against the square of the $m/e = 14$ ion current (6). In experiments conducted at 0.6 Torr, with the incoming nitrogen passed through the glass helices at −196°, it was found that the NO titration indicated no decay of atomic nitrogen along the reaction tube in the absence of reactant.

Traces of acetylene and ethane were observed as products volatile at −130° (7). Traces of ammonia were detected in the less volatile fraction. The predominant reaction product was always hydrogen (or deuterium) cyanide. Some ion current at $m/e = 41$, believed to be CH_3CN (1), was observed.

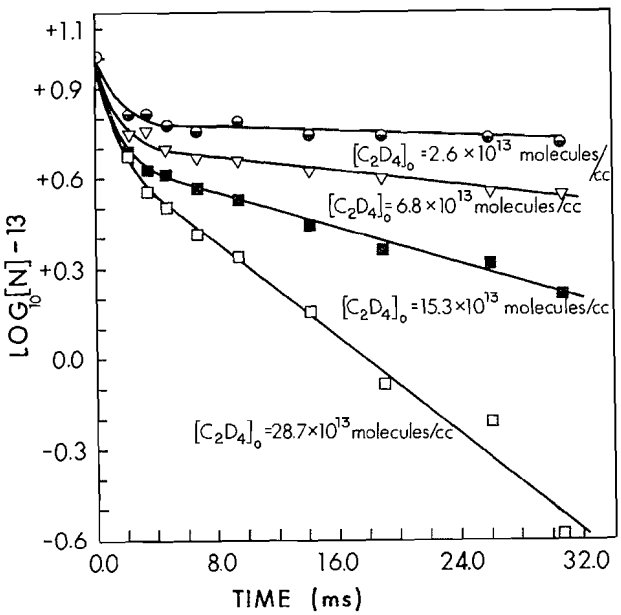

FIG. 2. Pseudo first order decay of N atoms at $P_{N_2} = 0.63$ Torr.

The deuterated ethylenes make no contribution to the $m/e = 14$ ion current and so their use facilitated precise measurement of the decay of atomic nitrogen in the reaction zone. The rates of decay of N atoms at 0.63 Torr total pressure for different rates of input of C_2D_4 are summarized in Fig. 2.[2] A feature of these logarithmic plots of nitrogen atom concentration vs. time is the transition, at a reaction time of about 4 ms, from a process

[2]*Photocopies of all of the original data discussed in this paper may be obtained in tabular form upon request to: Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada.*

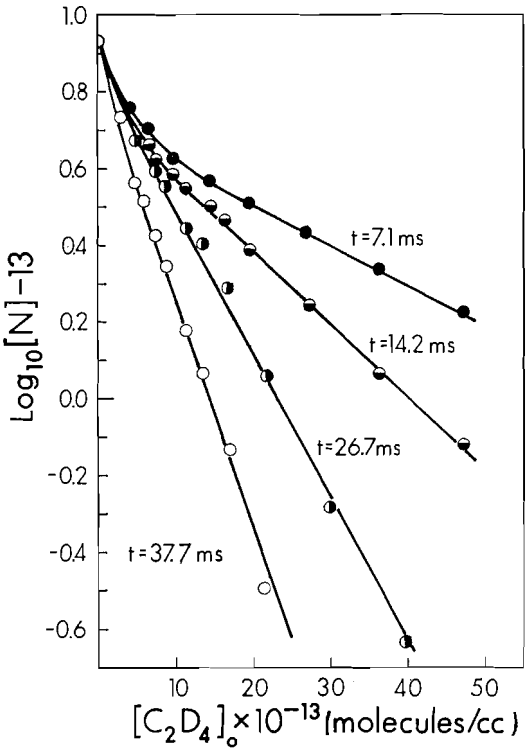

FIG. 3. Logarithmic dependence of N on $[C_2D_4]_0$ at P_{N_2} = 0.63 Torr.

(or processes) of apparent order greater than one to apparent first order decay of nitrogen atoms. One might suspect, however, at this low pressure, that this phenomenon may not be chemical in nature but possibly due to anomalous flow behavior at low ethylene input rates. The concentration of nitrogen atoms for zero reaction time is obtained from a measurement of the nitrogen atom concentration in the absence of C_2D_4. Since the C_2D_4 decomposition is always less than 13% of the initial concentrations of ethylene, $[C_2D_4]_0$, we can divide the slopes of the linear portions of the four plots in Fig. 2 by the appropriate values of $[C_2D_4]_0$, multiply by 2.303, and obtain four values of an apparent second order rate constant. These are given in Table IA. In Fig. 3, each of the curves was obtained at a fixed position of the reactant inlet by varying the partial pressure of ethylene. A slight but discernible trend to apparent order higher than first for N-atom decay is present for small values of $[C_2D_4]_0$ in Fig. 3. For higher values of $[C_2D_4]_0$, linear logarithmic plots are observed. By use of the appropriate reaction times four values for the apparent second order specific rate constant for the rate of decay of N atoms in the presence of C_2D_4 at 0.6 Torr total pressure are obtained from the linear plots in Fig. 3. These values are also given in Table IB.

The rate of decay of N atoms for two different $[C_2D_4]_0$ values at a total pressure of 2.6 Torr is shown in Fig. 4 and is plotted in logarithmic form in Fig. 5. The linear portions of the latter curves lead to apparent second order rate constants, shown in Table IC, in good agreement with those observed at low pressure. As shown in Fig. 4, the initial rate of disappearance of N atoms appears to be zero order at 2.6 Torr for the higher value of $[C_2D_4]_0$. Thus, the higher than first order disappearance of N atoms in the presence of ethylene was only observed for short reaction times at 0.6 Torr.

TABLE I

Apparent second order specific rate constants, k_{app}, for the disappearance of nitrogen atoms in the presence of ethylene, in cc molecule^{-1} s^{-1}

(A) $[N]_0 = 10.2 \times 10^{13}$ atoms/cc, $P_{N_2} = 0.63$ Torr

$[C_2D_4]_0$ (molecules/cc)	k_{app}
2.6×10^{13}	2.1×10^{-13}
6.8×10^{13}	2.0×10^{-13}
15.3×10^{13}	2.2×10^{-13}
28.7×10^{13}	3.0×10^{-13}

(B) $[N]_0 = 8.6 \times 10^{13}$ atoms/cc with C_2D_4, $P_{N_2} = 0.63$ Torr

t (ms)	k_{app}
7.1	3.5×10^{-13}
14.2	3.2×10^{-13}
26.7	3.2×10^{-13}
37.7	3.2×10^{-13}

(C) $[N]_0 = 10.8 \times 10^{13}$ atoms/cc, $P_{N_2} = 2.6$ Torr

$[C_2D_4]_0$ (molecules/cc)	k_{app}
13.6×10^{13}	3.5×10^{-13}
31.4×10^{13}	5.1×10^{-13}

(D) $[N]_0 = 72 \times 10^{13}$ atoms/cc, $P_{N_2} = 2.6$ Torr, $t = 21.2$ ms

	k_{app}
"Poisoned" system	4.4×10^{-13}
"Unpoisoned" system	4.4×10^{-13}

(E) Herron's result (8) multiplied by two

$k_{app}(2k_1)$
1.9×10^{-13}

All of the above results were obtained using nitrogen which was passed through glass helices at −196°. Some of the results obtained using C_2D_3H as reactant were obtained with the glass helices maintained at room temperature, so that traces of water vapor were admitted into the vacuum system. These experiments can be described as occurring in a "poisoned" system, whereas when the liquid nitrogen was placed on the nitrogen line, the experiments can be described as occurring in an "unpoisoned" system. For experiments in the "poisoned" system, the nitrogen atom concentration was approximately 60% higher than it was when the system was "unpoisoned", for the same power output on the microwave exciter.

The decay of N atoms in the presence of varying amounts of C_2D_3H, summarized in Fig. 6, is shown in the form of a logarithmic plot in Fig. 7. The same apparent second order specific rate constant for the rate of disappearance of N atoms is obtained from the plots in Fig. 7 for the poisoned and unpoisoned systems and is shown in Table ID. The effect of poisoning appears to be negligible on the reaction of active nitrogen with ethylene. It might be noted that the concentration of N atoms used in studying the reaction with

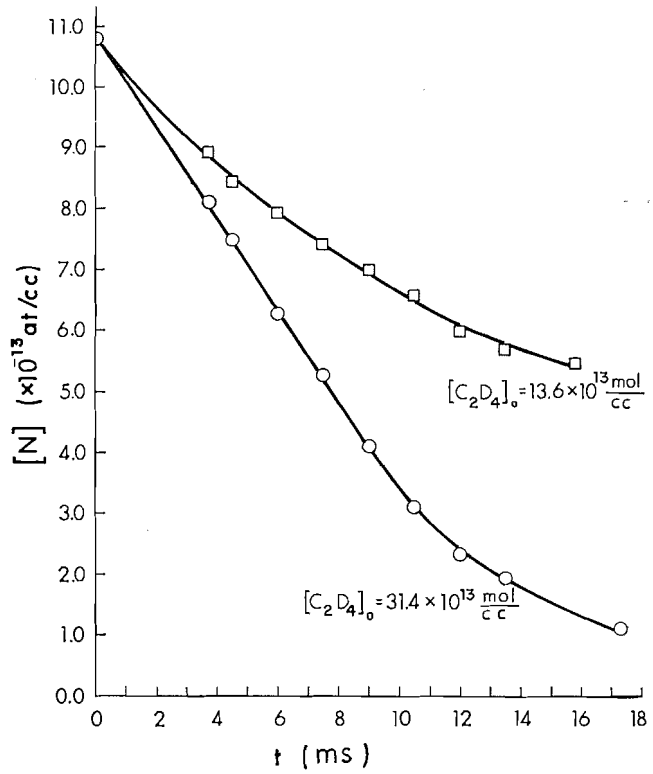

FIG. 4. Decay of N atoms in the presence of C_2D_4 at P_{N_2} = 2.6 Torr.

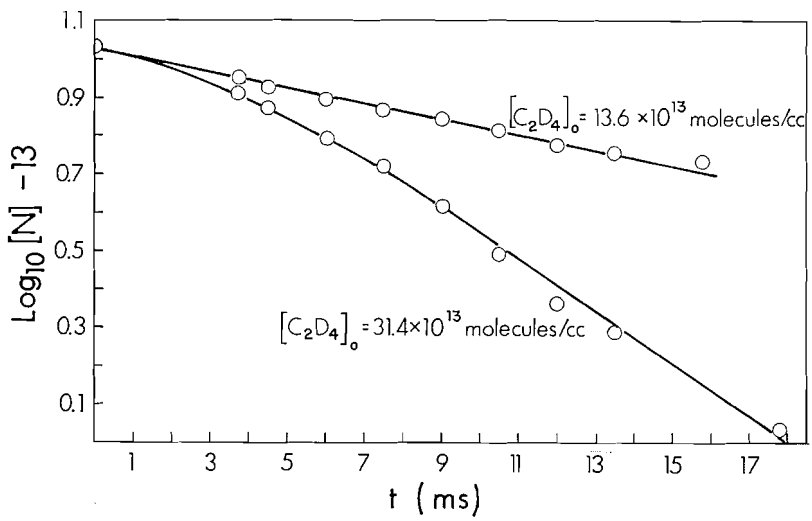

FIG. 5. Logarithmic decay of N atoms in the presence of C_2D_4 at P_{N_2} = 2.6 Torr.

C_2D_3H was roughly eight times that used when C_2D_4 was the reactant. Within experimental error, the same *apparent* second order specific rate constant for the rate of disappearance of N atoms in the presence of ethylene is obtained under a wide variety of experimental conditions, as is apparent from the data of Table I. The constants reported in Table I were obtained where our data appeared to fit the rate expression

$$-\mathrm{d[N]}/\mathrm{d}t = k_{app}[\mathrm{N}]\,[\mathrm{ethylene}]_0.$$

However, no assumptions about the actual reaction mechanism have been made.

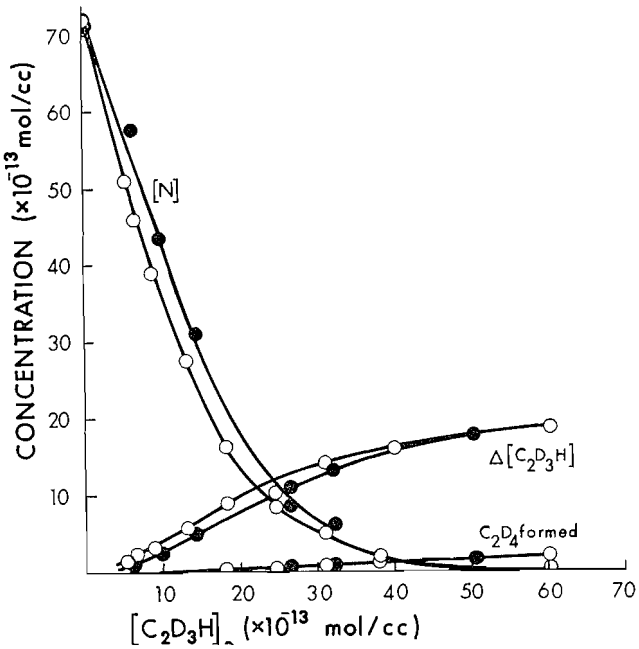

FIG. 6. Dependence of reagent concentrations on $[C_2D_3H]_0$ for poisoned (○) and unpoisoned (●) systems at P_{N_2} = 2.6 Torr. Reaction time 21.2 ms.

The rate constant for N-atom disappearance in the reaction of active nitrogen with ethylene, measured by Herron (8), is directly comparable to our apparent rate constants when multiplied by two, since he assumed in this earlier work that two N atoms disappear for every ethylene molecule destroyed. This apparent specific rate constant is also reported in Table IE. The interpretation of apparent specific rate constants in terms of reaction mechanisms is discussed below.

The Accuracy of the NO Titration and HCN Yields as Measures of N-Atom Concentration

The NO titration has been shown by the electron spin resonance work of Westenburg and deHaas (9) and by the work of Elias (10) to give an accurate measure of N-atom concentrations in active nitrogen produced in a microwave discharge. There appeared to be evidence, however, that $A^3\Sigma_u^+$ nitrogen molecules with a half-life of about 0.1 s are formed in a condensed discharge in appreciable amounts (11). The reaction of these triplet state molecules with nitric oxide was postulated by Fersht and Back (4) to account for their experimental results. It has been pointed out by Brennan and Kistiakowsky (12) that the data on triplet state nitrogen molecules (11) is also consistent with a mechanism in which

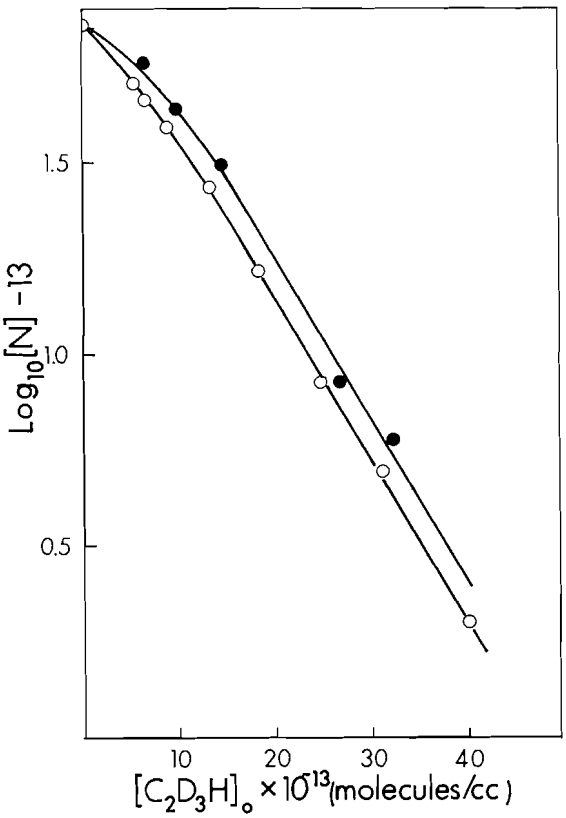

FIG. 7. Logarithmic dependence of [N] on $[C_2D_3H]_0$ for poisoned (○) and unpoisoned (●) systems at P_{N_2} = 2.6 Torr. $[N]_0 = 72 \times 10^{13}$ atoms/cc; reaction time 21.2 ms.

they are formed almost exclusively by nitrogen atom recombination, and have a collisional half-life of the order of a millisecond, a conclusion which they reach from their own studies. With such a short half-life, the concentration of $A^3\Sigma_u^+$ molecules would not be large enough to compete with atomic nitrogen in its extremely rapid reaction with NO (13), as postulated by Fersht and Back.[3]

In the case of C_2D_3H, the amount of C_2D_4 formed does not alter the conclusions we draw from Fig. 8, which shows a plot of $\Delta[N]/\Delta(C_2D_3H]$ vs. $[C_2D_3H]_0^{-1}$. Herron's results show a similar dependence of $\Delta[N]/[HCN]$ on $[C_2H_4]_0$. If nitrogen atoms only disappeared with the resultant formation of hydrogen (or deuterium) cyanide, then the plot in Fig. 8 would have zero slope and an intercept of two. It can be seen that the plot has a finite slope, and that for the highest rates of input of ethylene the ratio $\Delta[N]/\Delta[C_2D_3H]$ is about four. We also conclude that the NO titration always indicates the correct N-atom concentration in active nitrogen which exhibits the normal Lewis–Rayleigh afterglow.

On the Mechanism of the Reaction of Active Nitrogen with Ethylene

We have reexamined the apparent independence of $\Delta[N]/[HCN]$, or of approximate equivalence, $\Delta[N]/\Delta[C_2D_4]$, on the initial concentration of atomic nitrogen. The results

[3]*It has recently been postulated that triplet state nitrogen molecules are destroyed rapidly in the reaction (14)*

$$N + N_2^* \rightarrow N_2 + N.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

are shown in Fig. 9. It can be seen that $\Delta[N]/\Delta[C_2D_4]$ varies with $[N]_0$, particularly at low flow rates of ethylene. These results indicate that catalyzed recombination of atomic nitrogen can occur in its reaction with ethylene, but that catalysis tends not to occur in the presence of a large excess of ethylene, in agreement with the data of Verbeke and Winkler (3). That the intercept in Fig. 9 is >3 provides strong evidence in support of Herron's conclusion that the extent of HCN production is not a valid measure of the nitrogen atom concentration in active nitrogen.

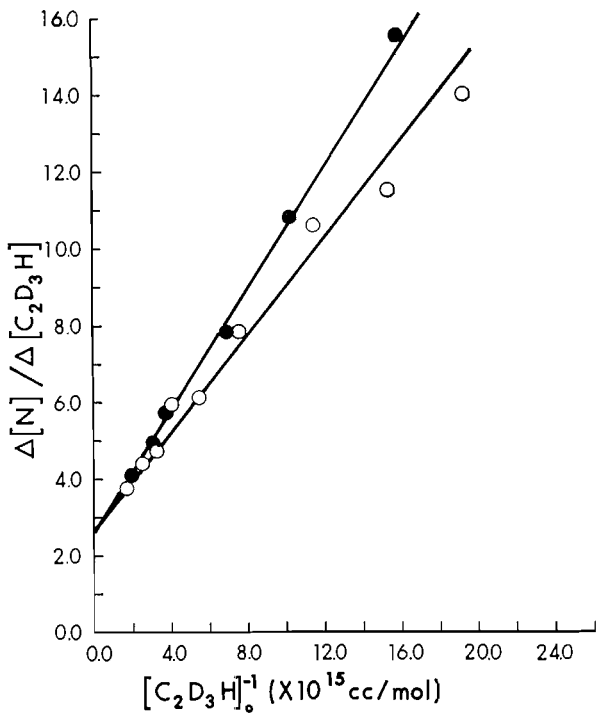

FIG. 8. Dependence of $\Delta[N]/\Delta[C_2D_3H]$ ratio on the reciprocal of the initial ethylene input. $P_{N_2} = 2.6$ Torr; $[N]_0 = 72 \times 10^{13}$ atoms/cc. (○) Poisoned system; (●) unpoisoned system.

In no experiments, either in a poisoned or in an unpoisoned system, was it possible to detect deuterium atoms in the reaction system. The MS 10 instrument is not suited for detection of hydrogen atoms ($m/e = 1$) unless it is modified so that a higher accelerator voltage is attainable. Such a modification was not made. A concentrated effort was not made to detect other radicals such as CH_3 ($m/e = 15$) or C_2H_5 ($m/e = 29$) in our system. Since our molecular leak is a substantial distance from the ion source (5 cm), radicals recombining bimolecularly would probably evade detection. There are various possible explanations for the generation of C_2D_4 in the reaction of active nitrogen with C_2D_3H. A plausible intermediate for C_2D_4 formation would appear to be the ethyl radical, C_2D_4H, which requires deuterium atom addition to C_2D_3H for its formation. Abstraction of its hydrogen atom by a nitrogen atom (analogous to reaction [5] proposed by Herron) or by a deuterium atom could occur. Alternatively, the exchange reaction $D + C_2D_3H \rightarrow C_2D_4 + H$ might take place. In any case, the presence of deuterium atoms is required. Although we have been unable to observe directly the presence of H or D atoms in our studies, the production of C_2D_4 in the reaction of active nitrogen with C_2D_3H provides further evidence

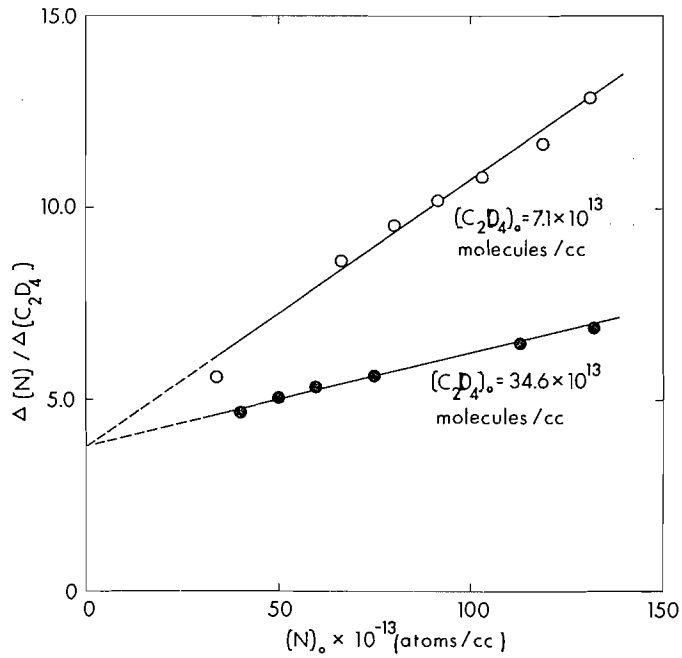

FIG. 9. Dependence of $\Delta[N]/\Delta[C_2D_4]$ on $[N]_0$. P_{N_2} = 2.6 Torr; reaction time = 42 ms.

in support of Herron's conclusion that hydrogen atoms play a role in the reaction of active nitrogen with ethylene (1).

The precise role of hydrogen atoms remains in doubt, however. The addition of hydrogen atoms to active nitrogen is known to destroy atomic nitrogen and yield ammonia (15). Yet Herron's Figs. 1 and 4, shown in ref. 1, show the same concentration of atomic nitrogen reaching the ion source of the mass spectrometer whether or not hydrogen is mixed with the nitrogen passing through the discharge. There must be an enhanced concentration of atomic nitrogen at the discharge when hydrogen is present to account for this result. Preliminary experiments in this laboratory with a separate discharge for hydrogen have shown that the initiation of the hydrogen discharge depletes the [N] by ca. 40%. Therefore, the enhanced yield of HCN when hydrogen is added is perhaps not entirely attributable to the effect of atomic hydrogen.

Our data can be compared with that obtained in the recent contribution by Herron (1) if we assume that his mechanism is correct. For example, if we evaluate our data obtained from the reaction of active nitrogen with C_2D_3H in a similar manner to Herron's use of his integrated rate expression, we obtain a value of $k_1 = 1.7 \times 10^{-14}$ cc molecule^{-1} s^{-1}, compared with his value of $k_1 = 1.2 \times 10^{-14}$ cc molecule^{-1} s^{-1} for reaction [1]. However, since there remain many unexplained features of the reaction of active nitrogen with ethylene (16), such an evaluation should be treated with caution.

PLATINUM(II) COMPLEXES CONTAINING α-HYDROXYACETYLENES

A. D. ALLEN AND T. THEOPHANIDES[1]
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario
Received April 14, 1966

ABSTRACT

The structures of complexes of the types M[$PtCl_3$ac] and *trans*-[$PtCl_2$ac(amine)], where ac = a tertiary α-hydroxyalkyl- or α-methoxyalkyl-acetylene, are described. The coordination of the ligands to the metal is through both the triple bond and the hydroxyl groups. The infrared spectra of the complexes in the O—H stretching region (3 000 – 3 800 cm^{-1}) and the effect on the spectra of the addition of bases to solutions of the free ligand and complexes strongly indicate that the hydroxyl groups are coordinated through the oxygen atom to the metal.

Structures of complexes of the types M[$PtCl_3$ac] and *trans*-[$PtCl_2$ac(amine)], where ac = a tertiary α-hydroxyalkyl- or α-methoxyalkyl-acetone, have recently been discussed in some detail (1). Such compounds have been known for many years (2, 3) and the unexpected stability of the complex formed by the dihydroxyacetylene HO.Me_2C—C≡C—CMe_2.OH has been attributed to a direct interaction between the hydroxyl groups and the rest of the complex, in addition to coordination by the triple bond to the metal. To account for the lowering of the O—H stretching frequency on coordination (by about 125 cm^{-1}) Chatt and his co-workers (4) originally suggested either (*a*) coordination by the oxygen of the hydroxyl groups to the metal atom, or (*b*) hydrogen bonding between the hydroxyl groups and the metal atom. In their recent paper (1) these authors propose that the interaction is (*c*) a hydrogen bond between the hydroxyl groups and the *cis*-chlorines of the complex, and they give diagrams showing the three possible interactions. Possibility *a* is rejected on the basis of infrared evidence that the hydrogen of the hydroxyl group is not free to form a hydrogen bond with a base such as dioxane (0.1 *M*) in carbon tetrachloride. We shall show that this is not the case if higher concentrations of base, or stronger bases, are used. It was also found that the hydroxyl proton resonance in the complex *trans*-[$PtCl_2$ac.py] (py = pyridine) is at lower field than in the free ligand, consistent with structures *a* or *c* but not with *b*, and that it did not change with concentration. The free ligand shows a decrease in τ value for the hydroxyl hydrogen as the concentration is increased, and since this ligand obviously contains free hydroxyl groups this contrast in behavior was taken as evidence that the proton was intramolecularly bonded in the complex. It appeared that this evidence could only be explained on the basis of structure *c*, involving hydrogen bonds to the *cis*-chlorines. Our infrared spectra (Table I) show that, whereas intermolecular hydrogen bonding between the hydroxyl groups of the free glycol is essentially absent at low concentrations in chloroform, a strong band due to this interaction appears when higher concentrations are used (up to 1 *M*). This accounts for the change in the nuclear magnetic resonance spectrum. By contrast the above complex shows only one band at 3 479 cm^{-1} (Table I) even in a saturated solution in $CHCl_3$ or $CDCl_3$, indicating that intermolecular hydrogen bonds do not form between the molecules of the complex. This is consistent with both of the structures *a* and *c*, since in structure *a* the oxygen atoms of the hydroxyl groups are already coordinated to the metal atom. There is, therefore, little possibility of hydrogen

bonding between one molecule and another, at room temperature, and a constant spectrum and proton resonance signal would be expected. This evidence does not, therefore, distinguish between structures *a* and *c*.

The proposed structure *c* was supported (1) by a study of the platinum(0) compound [$Pt(PPh_3)_2$ac], where ac = MeEtC(OH)C≡CC(OH)MeEt. The O—H stretching frequency in this compound is identical with that of the free glycol, showing that the hydroxyl groups are not directly involved in bonding, and, incidentally, showing that coordination by the triple bond alone does not affect the O—H stretching frequency. Thus it is clear that the platinum atom in this compound does not interact with the hydroxyl groups. This cannot be taken as evidence that coordination of oxygen to the metal does not occur in the bivalent platinum chloro complexes, since it is well known that the nature of the metal atom in the two types of complexes is very different. For example, the acetylene–platinum(0) compounds are strongly stabilized by electron-withdrawing groups attached to the triple bond (5), but acetylene–platinum(II) compounds are stabilized by electron-releasing groups in the coordinated acetylene. This implies, as one might expect, a much greater electron-accepting power of the metal in the platinum(II) complexes, and hence the tendency to coordinate the oxygen atom of the hydroxyl group will be similarly greater than in the platinum(0) compound. Chatt *et al.* (1) found that stepwise substitution of phenyl for the α-methyl groups in the hydroxyacetylene gives rise to complexes of the same form in which the O—H stretching frequency is progressively lowered. They concluded that the phenyl groups reduce the donor capacity of the triple bond, and that this is partly offset by a strengthening of the hydroxyl-group interaction. A reduction in the donor capacity of the triple bond would result in the platinum atom bearing an increased positive charge: this would tend to strengthen a coordinate bond from oxygen to the metal, which would lead to a greater lowering of the O—H stretching frequency, as observed. The presence of an increased positive charge on the metal would also increase the covalency of the bond between the metal and the *cis*-chlorines, which would reduce the tendency of the chlorines to form a hydrogen bond wih the hydroxyl groups. We would, therefore, expect the presence of phenyl groups to weaken the hydroxyl-group interaction if it occurred through an intramolecular hydrogen bond with the *cis*-chlorines, and the O—H stretching frequency would not be lowered to the same extent. This is contrary to the experimental results.

It was felt that the published data ruled out structure *b*, but that it did not distinguish clearly between structures *a* and *c*. We have, therefore, examined the infrared spectra of a series of compounds of this general type and have studied the effect of addition of bases to solutions containing them. Our results indicate very strongly that structure *a*, involving coordination by oxygen to the metal atom, is correct.

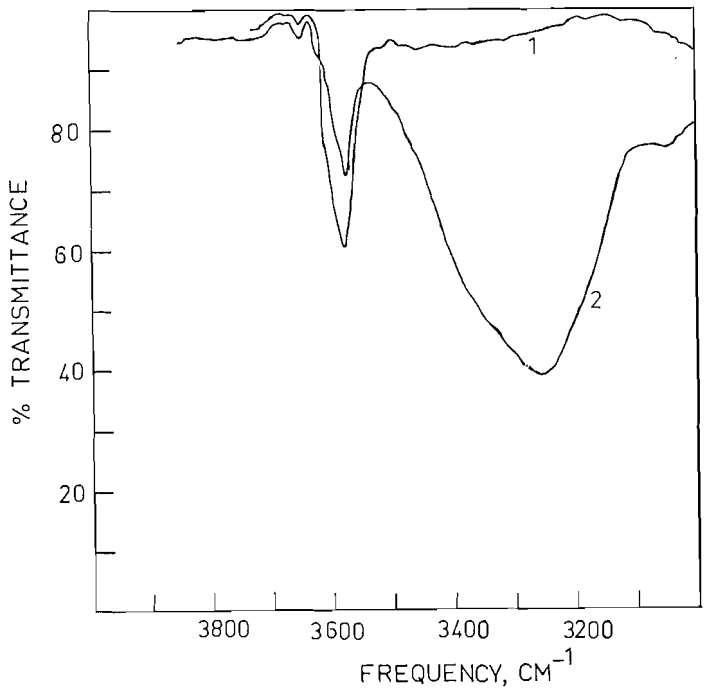

FIG. 1. Spectra of $Me_2C(OH)C{\equiv}CC(OH)Me_2$: (1) in benzene, (2) in benzene + 20% pyridine.

To simplify the discussion we shall deal first with one case, the compound *trans*-[$PtCl_2$ac.py] (where ac = the glycol $Me_2C(OH)C{\equiv}CC(OH)Me_2$), and its spectra in benzene with and without the addition of bases. Figure 1 shows the spectra of a dilute solution of the glycol in benzene and in benzene containing 20% (by volume) pyridine. In benzene the glycol has a single sharp peak at 3 578 cm^{-1}, the O—H stretching frequency of the free hydroxyl group: in the presence of pyridine this peak is reduced in intensity but remains at essentially the same frequency (3 575 cm^{-1}). The appearance of an additional strong broad band at about 3 255 cm^{-1} shows that considerable, but not complete, hydrogen bonding occurs between the hydroxyl groups and the base. The fact that some free hydroxyl groups persist, even in the presence of a high concentration of a strong base, is no doubt due to the fact that these are essentially tertiary alcohols so that steric hindrance tends to decrease the degree of association. Spectra of the complex formed by this glycol in the same solutions are shown in Fig. 2*a*. In benzene there is a single sharp band at 3 482 cm^{-1}, about 100 cm^{-1} lower than for the free ligand. The shape of this band is much more typical of a free hydroxyl group than of a hydrogen-bonded hydroxyl group, which are commonly strong but broad bands. The occurrence of this single sharp band shows clearly that the interaction of the hydroxyl group with the rest of the complex is essentially complete, i.e. any equilibrium between free and bound hydroxyl groups is very strongly displaced towards the bound hydroxyl groups. This implies that the interaction is energetically important in the total binding of the ligand. When pyridine is added this band is

immediately reduced in intensity, but remains at the same frequency (3 481 cm^{-1}) and a new strong broad band appears at about 3 210 cm^{-1}, 45 cm^{-1} lower than in the free ligand with pyridine. On standing at room temperature in the presence of this base (Fig. 2*a*), both bands slowly increase in frequency until the spectrum is the same as that of the free ligand in this medium, indicating that the glycol has been displaced from the complex. It is clear from the shape and position of the bands that, on the addition of pyridine, the glycol forms a hydrogen bond to the base while it is still an integral part of the complex.

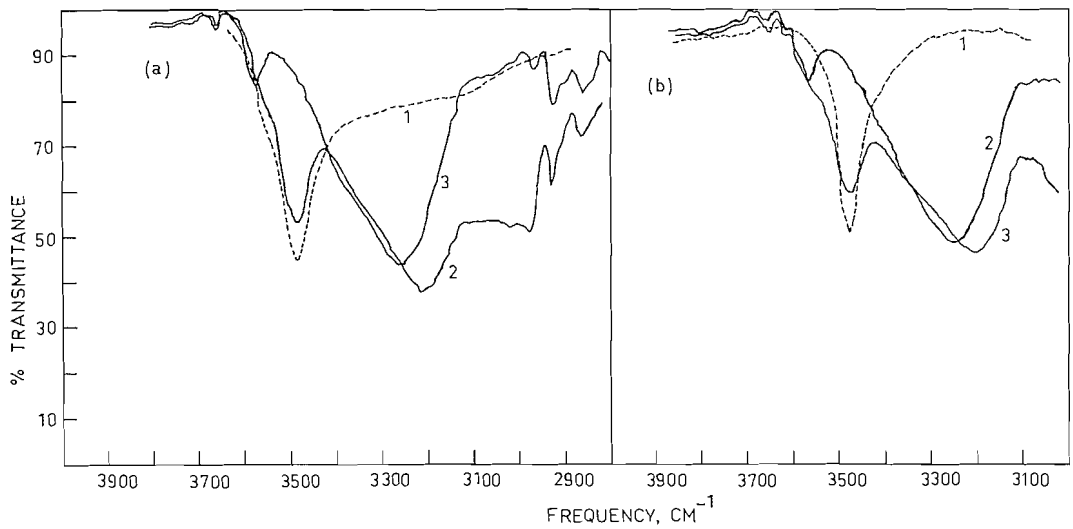

FIG. 2. (*a*) Spectra of *trans*-[$(Me_2C(OH)C{\equiv}CC(OH)Me_2)PtCl_2py$]: (1) in benzene, (2) in benzene + 20% pyridine (immediately), (3) in benzene + 20% pyridine (after 8 h). (*b*) Spectra of *trans*-[$(Me_2C(OH)C{\equiv}CC(OH)Me_2)PtCl_2$(2,6-lut)]: (1) in benzene, (2) in benzene + 20% pyridine (after 12 h), (3) in benzene + 20% pyridine (immediately).

We can discount the possibility that the pyridine causes rupture of an intramolecular hydrogen bond (e.g. to chlorine) and then forms a new hydrogen bond to the "freed" hydroxyl group. The only link between the glycol and the complex would be through the triple bond, and it is extremely unlikely that this could cause the hydrogen bond to pyridine to be 45 cm^{-1} lower than that for the free ligand with pyridine. The O—H stretching frequency observed by Chatt *et al.* (1) in their platinum(0) compound, in which only the triple bond is involved in the metal–ligand bond, is in exactly the same position as the free ligand, and it is well established that drastic changes in the nature of the organic group to which a hydroxyl group is attached produce very small changes in the O—H stretching frequency (6). The clear difference in the position of this hydrogen-bonded band in the free and bound glycol can only be accounted for if the hydroxyl groups are simultaneously linked to both the complex and the added base, and this is only possible if the oxygen of the hydroxyl groups is coordinated to the metal, leaving the hydrogen free to form a hydrogen bond to the base. It is also significant that the hydrogen bond to the base is formed immediately (in the time necessary to record the spectrum) and that the spectrum then changes slowly with time. If a hydrogen bond to the *cis*-chlorines were the important stabilizing factor in the link between the glycol and the metal, it is unlikely that the compound could exist for so long after this bond had been broken and in the presence of so large an excess of a powerful reagent. The relative intensities of the bands

shown in Fig. 2*a* provide an indication that, as expected from steric reasons, the extent of hydrogen bonding to the added base is greater with the free ligand than its complex.

Table I summarizes the above data, and shows the results obtained with other solvents and bases. Steric effects are shown clearly when 2,6-lutidine (2,6-lut) is used instead of pyridine either as part of the complex or as the reagent, or both. The spectra of the complex [PtacCl$_2$2,6-lut] in benzene and with added pyridine closely resembles that of the pyridine complex (see Fig. 2*b* and Table I). When this complex is treated with 2,6-lutidine (Fig. 3) the spectrum remains essentially the same for several days and the complex can be recovered from the solution.

The spectra of the free glycol and the complexes in mixtures of benzene–ether or carbon tetrachloride with ether and dioxane give similar results (Table I). It is clear from these spectra that the oxygen bases do form hydrogen bonds to the coordinated glycol, but that they do so to a lesser extent than the stronger nitrogen bases.

Table II records data on the stretching frequencies ν_{O-H}, $\nu_{C\equiv C}$, and $\nu_{C=C}$ to several α-hydroxy compounds (free ligands and their complexes) in carbon tetrachloride, and shows the changes in frequency ($\Delta\nu$) that occur on coordination.

A number of other observations have been made on these systems, some of which help in the interpretation of their structure.

(i) Spectra of the analogous bromo complexes *trans*-[PtacBr$_2$(amine)] (Table II) show O—H stretching frequencies which are almost identical with those of the chloro complexes. If there were a hydrogen bond to the halogen we would expect a greater difference in the two complexes (9).

(ii) A structure in which there are hydrogen bonds to the *cis*-chlorines involves some twisting $(CH_3)_2C(OH)$— group about the axis of the triple bond, and might be expected to give rise to different resonance signals for the two sets of methyl hydrogens. We find only one resonance signal for these protons at room temperature and at $-50°$ (10) which indicates a symmetrical environment.

(iii) Complexes containing the methoxy ether of the glycol K[PtCl$_3$($Me_2C(OMe)$-$C{\equiv}CC(OMe)Me_2$)] and *trans*-[PtCl$_2$(amine)($MeOME_2CC{\equiv}CCMe_2OMe$)] are at least as stable as the complexes of the glycol (11), which is surprising if hydrogen bonding is

important. In their latest paper Chatt *et al.* (1) propose, from dipole moment evidence, that the methoxyl groups are directed away from the rest of the complex, and do not take part in the bonding. Our experiments do not shed further light on the structure of this compound, but circumstantial evidence indicates a great similarity between the nature of the bonding in the hydroxy and methoxy compounds. It is difficult to predict the effect the methyl group would have on the ability of oxygen to coordinate the metal, because of conflicting steric and electronic effects. If, in contrast to the glycol, only the triple bond is involved in the bonding and this is strong enough to compensate for the absence of hydrogen bonding, we would expect the frequency of the triple bond to be very strongly affected on coordination. In fact the reduction in the triple bond stretching frequency is greater for the glycol (about 200 cm^{-1}) than it is for the dimethyl ethyl of the glycol (100–150 cm^{-1}). Data for the stretching frequencies ν_{C-H} (of the methoxyl group) and $\nu_{C{\equiv}C}$ for the methoxy ether and its compounds are given in Table III.

(iv) Infrared spectra in the OH stretching region of the salt $K[PtacCl_3]$ in the solid state at 300 °K and 90 °K are shown in Fig. 4. At room temperature the OH stretching frequency is split into two sharp bands at 3 523 and 3 453 cm^{-1} possibly because of a coupling of the vibrations of the two hydroxyl groups. At 90 °K the above two bands become sharper and more intense and also a third new broad band appears at 3 270 cm^{-1}. It is difficult to explain the presence of the new medium strength band at 3 270 cm^{-1} which is observed on cooling the sample at 90 °K. A possible explanation is that it could be the result of intermolecular hydrogen bonding, which may be possible at this low temperature because of a contraction in the interionic distances of the crystal.

(v) Complexes with allyl alcohol, an α-hydroxyolefin, are very similar to those of the α-hydroxyacetylenes (Table IV). The spectra in the OH stretching frequency region show the same behavior.

We conclude from these studies that the interaction of the α-hydroxyl groups, in the complexes, is through coordination of the oxygen atom to the metal. We consider that no other structure can account for the spectral observations we have made, and that this structure is consistent with all previously published data.

EXPERIMENTAL

Materials

Most of the compounds used have been reported previously (11, 12). The following compounds were prepared by similar methods.

trans-Dibromo-(2,5-dimethyl-3-hexyne-2,5-diol)2,6-lutidine platinum(II): yellow-orange prisms, recrystallized from ether, m.p. 140–142°.

Anal. Calcd. for $C_{15}H_{23}O_2Br_2NPt$: C, 29.8; H, 3.8; Br, 26.4. Found: C, 30.8; H, 3.3; Br, 25.2.

trans-Dichloro-(3,6-dimethyl-4-octyne-3,6-diol)2,6-lutidine platinum(II): bright yellow, recrystallized from ether, m.p. 115–118°.

Anal. Calcd. for $C_{17}H_{27}O_2Cl_2NPt$: C, 37.6; H, 5.0. Found: C, 37.5; H, 5.2.

trans-Dichloro-(3,6-diethyl-4-octyne-3,6-diol)pyridine platinum(II); yellow, recrystallized from ether, m.p. 53–56°.

Anal. Calcd. for $C_{17}H_{27}O_2Cl_2NPt$: C, 37.5; H, 5.0. Found: C, 36.6; H, 4.9.

trans-Dichloro-(3,6-diethyl-4-octyne-3,6-diol)2,6-lutidine platinum(II): yellow, recrystallized from ether, m.p. 126°.

Anal. Calcd. for $C_{19}H_{31}O_2Cl_2NPt$: C, 39.9; H, 5.5. Found: C, 39.6; H, 5.4.

trans-Dichloro-(2,5-dimethyl-2,5-dimethoxy-3-hexyne)2,6-lutidine platinum(II): yellow, m.p. 140–145° (decomp.).

Anal. Calcd. for $C_{17}H_{27}Cl_2O_2NPt$: C, 37.6; H, 5.0. Found: C, 37.5; H, 4.9.

trans-Dichloro-(2,5-dimethyl-2,5-dimethoxy-3-hexyne)pyridine platinum(II): yellow, m.p. 95–97° (lit. m.p. 101–103° (decomp.) (1)).

Anal. Calcd. for $C_{15}H_{23}Cl_2O_2NPt$: C, 34.9; H, 4.5. Found: C, 34.5; H, 4.25.

Spectra

Infrared spectra were recorded with a Perkin–Elmer 221 prism-grating spectrometer using standard settings, calibrated against polystyrene film. For the solid state spectrum at 90 °K a Perkin–Elmer 21 spectrometer was used. A conventional low temperature cell (13) was used for the spectrum at liquid nitrogen temperature.

DEPENDENCE OF BOND ANGLES ON OVERLAP INTEGRALS FOR SOME COVALENT HYDRIDES

D. A. HUTCHINSON
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received June 27, 1966

ABSTRACT

An explicit relationship, between bond angles and overlap integrals, is developed for covalent hydrides of C_{3v} and C_{2v} symmetries. From this relationship it is argued that the bond angle depends on the overlap integrals of s and p functions with hydrogen 1s functions. The results of calculations of these overlap integrals are given; the calculations were first performed with Slater functions and repeated with approximate self-consistent-field functions. Arguments, based on the results of these calculations, are advanced as an additional explanation of why ammonia and water have larger bond angles than phosphine and hydrogen sulfide.

1. INTRODUCTION

The simplest description of bonding in the NH_3, H_2O, PH_3, and H_2S molecules is provided by the overlap of p orbitals of the central atom with H-atom 1s orbitals. This description predicts bond angles of 90° in all cases. Heath and Linnett (1) showed that repulsive interactions between the H atoms make a significant contribution to the opening of the bond angle from 90° in the case of H_2O. The bond lengths of NH_3 and H_2O are shorter than the bond lengths of PH_3 and H_2S, thus the HH repulsive interactions in NH_3 and H_2O should be larger than those for PH_3 and H_2S. An additional contribution to larger HH repulsions for NH_3 and H_2O is that the NH and OH bonds have more ionic character than the PH and SH bonds. The greater ionic character of the NH and OH bonds is due to the higher electronegativity of the N and O atoms. The larger HH repulsive interactions for NH_3 and H_2O provide one explanation why the HNH bond angle, 107°, exceeds the HPH bond angle, 93.5°, and why the HOH bond angle, 104.5°, exceeds the HSH bond angle, 92°. The values for the bond angles are quoted from Sutton's (2) tables.

A more accurate view of bonding in the above covalent hydrides is provided by viewing the bond as the overlap of an H atom 1s orbital with a hybrid orbital of the central atom. The angle between a pair of hybrid orbitals is related to the amounts of s and p orbitals in each hybrid. Also, the overlap integral between a hybrid orbital and an H atom 1s orbital depends on the amounts of s and p orbitals in each hybrid. Thus if the strength of a bond is related to the overlap integral, then the bond strength depends on the bond angle through the hybridization. Moreover, the relative values of the overlap integrals of a p orbital and an s orbital with an H-atom 1s orbital will affect the bond angle. The details of these arguments are presented in the next section.

2. HYBRIDIZATION AND BOND ANGLES

The general expression

$$[1] \qquad |t_r\rangle = U_{1r}|\mathrm{s}\rangle + U_{2r}|\mathrm{p}_x\rangle + U_{3r}|\mathrm{p}_y\rangle + U_{4r}|\mathrm{p}_z\rangle$$

for a hybrid orbital $|t_r\rangle$, consisting of s and p orbitals, suggests that 16 arbitrary coefficients are involved in the description of four hybrid orbitals. However, as a matter of convenience one usually imposes four normalization conditions and six orthogonality constraints

$$\langle t_r|t_s\rangle = \delta_{rs}.$$

Now the hybridization of an s and three p orbitals involves only six independent variables.

The 16 transformation coefficients U_{jr} form an orthogonal 4×4 matrix if the orthonormality constraints are imposed. An $n \times n$ orthogonal matrix M and an $n \times n$ antisymmetric matrix A both have $n(n+1)/2$ independent elements. Ferrar (3) shows that if $(1 + A)$ is non-singular, then an $n \times n$ orthogonal matrix M can be constructed from an $n \times n$ antisymmetric matrix A by the prescription

$$M = (1 - A)(1 + A)^{-1}.$$

This procedure allows one to express each transformation coefficient U_{jr} as a function of six independent variables. It is possible to simplify the situation even further (4). Three conditions are required to orient the hybrids $|t_1\rangle$, $|t_2\rangle$, $|t_3\rangle$, and $|t_4\rangle$ with respect to the basis vectors $\boldsymbol{i}, \boldsymbol{j}$, and $\boldsymbol{k}$ defining the x, y, and z directions. These three conditions are not relevant because the physically significant features of the hybrid orbitals are the amounts of s and p character in each hybrid orbital and the orientations of the hybrid orbitals with respect to each other. Rotation of the basis vectors $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$ will alter neither the s and p characters of the hybrid orbitals nor the relative orientations of the hybrid orbitals. Of the six independent hybridization parameters, only three are of physical interest. The other three can be fixed by choosing a particular set of basis vectors $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$; the choice is motivated by the consideration of convenience. The result of a particularly convenient choice of basis vectors $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$ are the hybrid orbitals

$$\begin{aligned} |t_1\rangle &= N(|\mathrm{s}\rangle - \lambda_1|\mathrm{p}_x\rangle - \lambda_2|\mathrm{p}_y\rangle - \lambda_3|\mathrm{p}_z\rangle), \\ |t_2\rangle &= N(\lambda_1|\mathrm{s}\rangle + |\mathrm{p}_x\rangle - \lambda_3|\mathrm{p}_y\rangle + \lambda_2|\mathrm{p}_z\rangle), \\ |t_3\rangle &= N(\lambda_2|\mathrm{s}\rangle + \lambda_3|\mathrm{p}_x\rangle + |\mathrm{p}_y\rangle - \lambda_1|\mathrm{p}_z\rangle), \\ |t_4\rangle &= N(\lambda_3|\mathrm{s}\rangle - \lambda_2|\mathrm{p}_x\rangle + \lambda_1|\mathrm{p}_y\rangle + |\mathrm{p}_z\rangle), \\ N &= (1 + \lambda_1^2 + \lambda_2^2 + \lambda_3^2)^{-1/2}. \end{aligned} \qquad [2]$$

The directional p orbitals behave as vectors whereas the s orbital is spherically symmetric. Consequently the directional properties of a hybrid orbital arise from the contributions of the p orbitals. The direction, with respect to the basis vectors $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$ of the general hybrid orbital $|t_r\rangle$ of eq. [1], is given by the unit vector

$$\boldsymbol{e}_r = (U_{2r}^2 + U_{3r}^2 + U_{4r}^2)^{-1/2}(U_{2r}, U_{3r}, U_{4r}).$$

The angle θ_{rs} between two hybrid orbitals $|t_r\rangle$ and $|t_s\rangle$ is given by

$$\begin{aligned} \cos\theta_{rs} &= \boldsymbol{e}_r \cdot \boldsymbol{e}_s \\ &= \left(\sum_{i=2}^{4} U_{ir}^2\right)^{-1/2}\left(\sum_{j=2}^{4} U_{js}^2\right)^{-1/2}\sum_{k=2}^{4} U_{kr}U_{ks}. \end{aligned} \qquad [3]$$

A more extensive discussion on angles between hybrid orbitals can be found in a paper by Coulson (5).

For the remainder of this discussion the hybrid orbitals $|t_3\rangle$ and $|t_4\rangle$ are chosen as the hybrids involved in bonds between a central atom A and an H atom. It is convenient to use the difference ϕ_{34} between the angle θ_{34} and 90°,

$$\phi_{34} = \theta_{34} - 90°, \qquad [4]$$

instead of θ_{34} itself. The relationship between ϕ_{34} and the hybridization parameters is

$$\sin\phi_{34} = \lambda_2\lambda_3(1 + \lambda_1^2 + \lambda_2^2)^{-1/2}(1 + \lambda_1^2 + \lambda_3^2)^{-1/2}, \qquad [5]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

this follows immediately from eqs. [2], [3], and [4]. The overlap integral $\langle t_4|h\rangle$ between the hybrid orbital $|t_4\rangle$ and the hydrogen 1s orbital $|h\rangle$ is

$$\langle t_4|h\rangle = N(\lambda_3\langle s|h\rangle + (1 + \lambda_1^2 + \lambda_2^2)^{1/2}\langle p_\sigma|h\rangle). \quad [6]$$

$|p_\sigma\rangle$ is a p orbital in the direction of the hybrid orbital $|t_4\rangle$. From eqs. [5] and [6] it is seen that the bond angle and overlap integrals are related through the hybridization parameters λ_j.

The four molecules of interest have either C_{3v} symmetry or C_{2v} symmetry. A consequence of either symmetry is that the hybridization can be described by a single parameter μ. In the case of C_{3v} symmetry, the three hybrids which bond to the H atoms, say $|t_2\rangle$, $|t_3\rangle$, $|t_4\rangle$, are equivalent; that is each one has the same amount of s character. Consequently

$$\lambda_1 = \lambda_2 = \lambda_3 = \mu. \quad [7]$$

The angle ϕ and the overlap integral $\langle t_4|h\rangle$ are obtained by substituting eq. [7] into eqs. [5] and [6] respectively,

$$\sin\phi = \mu^2(1 + \mu^2)^{-1}, \quad [8]$$

$$\langle t_4|h\rangle = (1 + 3\mu^2)^{-1/2}(\langle s|h\rangle + (1 + 2\mu^2)^{1/2}\langle p_\sigma|h\rangle). \quad [9]$$

From eqs. [8] and [9], the overlap integral can be written directly in terms of the deviation ϕ of the bond angle from 90°

$$\langle t_4|h\rangle = (1 + \sin\phi)^{-1/2}(\langle s|h\rangle\sin^{1/2}\phi + \langle p_\sigma|h\rangle). \quad [10]$$

If the same arguments are used for the case of C_{2v} symmetry, an identical result is obtained for the overlap integral in terms of ϕ. Whereas for a C_{3v} hydride $0 \leqq \phi \leqq 30°$, for a C_{2v} hydride $0 \leqq \phi \leqq 90°$.

Although hybridizing the s and p orbitals increases the energy of the central atom, a greater amount of energy is recovered from the formation of a more stable bond; a large overlap integral is associated with a strong chemical bond. If the ratio $\langle s|h\rangle/\langle p_\sigma|h\rangle$ is large, energy considerations will favor a larger deviation ϕ from 90° for the bond angle than if the ratio $\langle s|h\rangle/\langle p_\sigma|h\rangle$ is small.

The ratio $\langle 2s|h\rangle/\langle 2p_\sigma|h\rangle$ for NH_3 and H_2O is larger than the ratio $\langle 3s|h\rangle/\langle 3p_\sigma|h\rangle$ for PH_3 and H_2S. These results are valid for both Slater functions and Clementi's (6) approximate self-consistent-field (s.c.f.) functions. Thus, the preceding arguments offer an additional explanation why the bond angles of NH_3 and H_2O exceed those of PH_3 and H_2S. The results of calculations of the relevant overlap integrals are presented in the following section.

3. OVERLAP INTEGRALS

The overlap integrals were first calculated with orthogonalized Slater functions; the simple Slater functions were orthogonalized by the Schmidt procedure. The orbital exponents were determined by applying Slater's (7) rules. The bond lengths, used in the overlap integral calculations, were obtained from Sutton's (2) tables; these bond lengths are given in Table I. The results of the calculations for orthogonalized Slater functions are also given in Table I.

The argument, for relative bond angles based on the ratio $\langle s|h\rangle/\langle p_\sigma|h\rangle$ of overlap integrals, would be more convincing if the results are also valid for atomic functions other than orthogonalized Slater functions. Clementi (6) has published results for approximate s.c.f. functions which employ a basis set consisting of several Slater-type orbitals (s.t.o.'s). Clementi's 2s function consists of two 1s and four 2s s.t.o.'s and his 2p function consists of

TABLE I
Results of overlap integral calculations

	Function			Function	
	Slater	Clementi		Slater	Clementi
NH in NH_3 (R = 1.905 atomic units)			OH in H_2O (R = 1.811 atomic units)		
$\langle 2s\|h\rangle$	0.546	0.555	$\langle 2s\|h\rangle$	0.508	0.521
$\langle 2p_\sigma\|h\rangle$	0.406	0.456	$\langle 2p_\sigma\|h\rangle$	0.348	0.413
PH in PH_3 (R = 2.685 atomic units)			SH in H_2S (R = 2.521 atomic units)		
$\langle 3s\|h\rangle$	0.504	0.459	$\langle 3s\|h\rangle$	0.507	0.460
$\langle 3p_\sigma\|h\rangle$	0.523	0.550	$\langle 3p_\sigma\|h\rangle$	0.496	0.511

four 2p s.t.o.'s. The 3s function consists of one 1s and seven 3s s.t.o.'s and the 3p function consists of one 2p and seven 4p s.t.o.'s. For the calculations in this paper the values chosen for the various orbital exponents and expansion coefficients were Clementi's results for the ground states of the N, O, P, and S atoms. The results of the calculations of the respective overlap integrals with Clementi's functions are also given in Table I.

After the preceding calculations were completed, the referee pointed out to the author that the qualitative nature of the results in Table I are still valid if a different value for the orbital exponent of the hydrogen 1s function is chosen. In numerous molecular calculations an orbital exponent of 1.2 is preferable to one of unity; it would be useful to know what effect this has on the results. If an orbital exponent of 1.2 is chosen for the hydrogen 1s orbital, the overlap integrals with the Clementi functions are somewhat less, but the relative magnitudes in the 2s/2p series and the 3s/3p series remain the same. In addition, the referee's results indicate that only minor variations occur if one chooses the Clementi functions for states, other than the ground state, of the lowest electronic configurations of the nitrogen, oxygen, phosphorous, and sulfur atoms.

Since both the orthogonalized Slater functions and the fairly sophisticated Clementi functions lead to the same conclusion, namely

$$[11] \qquad (\langle 2s|h\rangle/\langle 2p_\sigma|h\rangle > (\langle 3s|h\rangle/\langle 3p_\sigma|h\rangle)$$

for NH_3 versus PH_3 and H_2O versus H_2S, it seems probable the result would be valid for any reasonable choice of atomic functions. Thus, arguments based on the result of eq. [11] contribute toward an explanation of the observation that the bond angles in NH_3 and H_2O are respectively larger than those of PH_3 and H_2S. In Table I it is interesting to note that for N and O, the $\langle 2s|h\rangle$ overlap integral is considerably larger than the $\langle 2p_\sigma|h\rangle$ overlap integral. Conceivably, this could provide an appreciable contribution towards the large deviations of the HNH and HOH bond angles from 90°. For PH_3 and H_2S, the small deviations from 90° most likely arise mainly from HH repulsions since the $\langle 3s|h\rangle$ overlap integral is smaller than the $\langle 3p_\sigma|h\rangle$ overlap integral. As a last word, it should be kept in mind that the arguments presented in this paper, while perhaps interesting, are subsidiary to those based on repulsions between the H atoms and other causes such as the variation of the kinetic energy term.

ACKNOWLEDGMENTS

The author is grateful to Professor C. A. Coulson for some valuable discussions and in addition for many helpful suggestions which led to an improvement on the original manuscript. Also the author thanks the referee for performing a number of additional calculations, the results of which add support to the conclusions of this paper.

INFRARED ABSORPTION OF SINGLE CRYSTALS OF ANHYDROUS SODIUM FORMATE

T. L. CHARLTON[1] AND K. B. HARVEY
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 6, 1966

ABSTRACT

The infrared absorption of single crystals of sodium formate has been measured in the region of 250 cm^{-1} to 4 000 cm^{-1}. Thin sections cut perpendicular to the unique axis were employed and spectra were recorded with light polarized at various angles in this plane. It has been possible to assign unambiguously all of the infrared active internal fundamentals of the formate ion including the overlapping ν_2 and ν_5 modes. In addition, three lattice modes at 57, 107, and 138 cm^{-1} have been identified.

RÉSUMÉ

On a étudié par spectroscopie infrarouge des cristaux uniques de formiate de sodium dans la région de 250 à 4 000 cm^{-1}. L'absorption par des lames minces taillées perpendiculairement à l'axe unique a été mesurée en lumière polarisée à divers angles dans ce plan. On a réussi à identifier sans ambiguité toutes les fréquences fondamentales de l'ion formiate actives en infrarouge, y compris les modes ν_2 et ν_5 qui se recouvrent. De plus on a enregistré trois vibrations du réseau cristallin à 57, 107 et 138 cm^{-1}.

INTRODUCTION

The vibrational spectrum of sodium formate has been the subject of investigation of a number of workers (1–9) but only in Newman's studies were single crystals and polarized radiation used. Some of the results are summarized in Table I. It should be noted that we have assigned the symbol ν_1 to the C—H stretching frequency in conformity with the usual convention. Some confusion has arisen in the past due to the assignment of ν_1 to the lower C—O stretching frequency which in Table I is given the symbol ν_2.

The overall agreement in the frequency and the assignment of the fundamentals is quite good. The major exception is the assignment by Newman (8) of the higher frequency member of the pair of bands in the 1 350 – 1 400 cm^{-1} region to ν_2. This assignment based on the apparent activity of this mode in the crystal is in conflict with the assignments of Fonteyne (2) and Bernstein (4) who attributed the 1 380 cm^{-1} absorption to ν_5. The latter authors based their assignments on a vibrational analysis (2) and Raman depolarization ratios (4). Bernstein quotes measured depolarization ratios of 0.29 and 0.80 for the 1 349 cm^{-1} and 1 380 cm^{-1} scattering respectively. This is clear-cut evidence for the assignment of the 1 349 cm^{-1} scattering to the symmetric C—O stretching mode ν_2.

Ito and Bernstein also observed many overtones and combinations in the infrared absorption spectrum of crystalline sodium formate and a number of these are also listed in Table I. We have altered the assignments in some cases to give better agreement with the spectrum of the deutero-formate ion. In addition Bernstein observed several combination and difference bands involving low frequency lattice modes at 60 cm^{-1} and 140 cm^{-1}.

Crystal Structure of Sodium Formate

The crystal structure of sodium formate is described by Zachariasen (10) as being monoclinic and belonging to the space group $C\,2/c$ (C_{2h}^6). The cell parameters and the coordinates of the generating atomic positions of sodium formate are listed below. The hydrogen atom positions were calculated by us on the assumption of a value of 1.09 Å for the C—H bond length.

Space group: $C\,2/c$ (C_{2h}^6)
$a = 6.19$ Å; $b = 6.72$ Å; $c = 6.49$ Å; $\beta = 121°42'$
Generating positions:
Origin at $\bar{1}$ on glide plane n.
8 O atoms at: (0.043, 0.194, 0.185)
4 Na^+ ions at: (1/4, −0.139, 1/4)
4 C atoms at: (1/4, 0.283, 1/4)
4 H atoms at: (1/4, 0.445, 1/4)

As shown in Fig. 1, the symmetry axis of the formate ions is co-linear with the twofold axis of the crystal while the plane of the molecule is approximately perpendicular (103°) to the c axis. The formate ion parameters were calculated by us to be r(C—O) = 1.27 Å and $\angle$OCO = 124°.

Since the unit cell of Fig. 1 is compound, an alternative unit cell based on a lattice with shorter translation vectors may be chosen. The single unit of pattern of such a cell forms

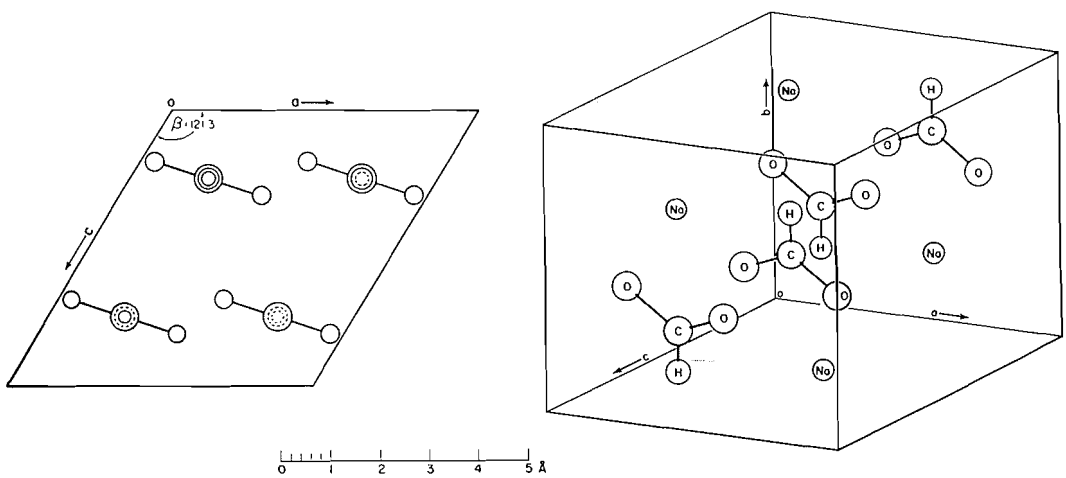

FIG. 1. Crystal structure of sodium formate.

the basis for the vibrational analysis. As shown in Fig. 2, each unit of pattern contains two formate ions and two sodium ions symmetrically related by a center of symmetry. The space group is $P\,\bar{1}$ (C_i^1) and the cell parameters are $a = 4.57$ Å, $b = 6.72$ Å, $c = 6.49$ Å, $\alpha = 90°$, $\beta = 110°52'$, and $\gamma = 42°40'$. The higher overall symmetry of the structure is reflected in the nonaccidental value of 90° for the angle α. In the unit of pattern each sodium ion is separated by a distance of 2.80 Å from the hydrogen atom of the formate ion on the same twofold axis. The distances between the atoms related by the center of symmetry are: r(Na—Na) = 3.57 Å; r(H—H) = 5.22 Å; r(C—C) = 7.07 Å; r_1(O—O) = 8.25 Å; r_2(O—O) = 7.68 Å. A distance of 2.50 Å separates the sodium ion from the oxygen atoms of the formate ion in the adjacent unit of pattern lying on the same twofold axis. The nearest oxygen atoms of formate ions lying on adjacent twofold axes are somewhat closer than this at 2.35 Å and 2.45 Å.

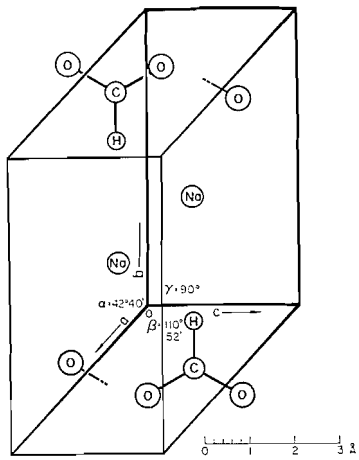

FIG. 2. Primitive unit cell of sodium formate. The b and c axes are the same as those of the centered unit cell of Fig. 1.

EXPERIMENTAL

Preparation of Crystals

Reagent grade (Baker and Adamson) sodium formate was used without further purification except the removal of insoluble impurities by filtration. The crystals studied were obtained by crystallization from aqueous solution at 40° C to avoid forming the dihydrate which has been reported obtained at temperatures below 28 °C (11). Using specially selected untwinned seed crystals and slow evaporation (several weeks) of the aqueous solution large crystals of tabular habit 2 to 10 mm wide, 20 to 30 mm long, and 2 or 3 mm thick were obtained. X-Ray diffraction photographs showed that the principal face of these crystals was the (010) face elongated in the c direction.

Crystals with as few internal flaws as possible were selected and reduced to the proper thickness by grinding. To accomplish this the flat crystal was glued to a rock-salt window with C.I.L. Household Cement and a planar surface obtained by grinding on successively finer grades of emery paper (150 C, 360 A and 4/0). The surface was then polished on a ground glass lap and finally on a velvet lap using fine abrasives. The kerosene used as a lubricant in these operations also served to protect the slightly hygroscopic sodium formate.

The crystal was next removed from the rock-salt window, using acetone as a solvent for the cement, and the polished surface glued to the window. This required considerable care since shrinkage of the cement on drying often led to glue-free pockets between the crystal and the window. The crystals usually cracked through lack of support at these points during the final grinding and polishing. We are still looking for a more satisfactory glue for this application. The second face of the crystal was prepared in the same manner as the first except that considerably more care was required in the final stages. In regions where the glue did not absorb, it was possible to examine the spectrum of the crystal and the polishing process was continued until the desired intensity of absorption was observed.

The thin crystal was now floated free of the rock-salt window in an acetone bath, placed over a slit 10 mm × 2 mm in a brass disc and glued sparingly at the edges. The disc was designed to fit the keys on the spectrometer mounting so that it could be placed as close to the entrance slit as possible.

For personal use only.

A polarizing microscope was used to determine the relative orientation of the crystal axes and to confirm the quality of the crystal. In all cases the crystals were clear, except for surface scratches, and exhibited sharp extinction. Observation of interference figures also allowed us to confirm that crystals were ground to within 1° or 2° of the perpendicular of the axis of observation. The thickness of the crystals was measured on a Zeiss Light-section microscope and found to be approximately 40 μ.

Infrared Spectrometer

Spectra were recorded in the region of 4 000 to 250 cm^{-1} using a Perkin–Elmer 421 spectrometer with two dual-grating interchanges. The polarizer, constructed in our shop, consisted of two three-sheet stacks of 0.5 mm silver chloride plates mounted in the form of a V (12) to prevent displacement of the spectrometer beam. Measurements in the visible region against a Wollaston prism indicate that <5% of the component perpendicular to the desired component and the beam is passed. Measurements of the convergence of the sample beam showed that <1% of the component parallel to the beam direction would be introduced by the convergence.

The spectrometer was calibrated against known spectra (13) at the scanning speeds and response times used in obtaining the crystal spectra to minimize errors due to response time effects. Spectral slit widths are indicated for the individual spectra. The error of measurement is estimated to be ± 2 cm^{-1}; much smaller, in most cases, than the uncertainty introduced due to the overlapping of adjacent bands.

RESULTS AND DISCUSSION

Vibrational Analysis

The primitive unit cell of sodium formate contains 10 atoms so that there will be a total of 30 vibrations. Under the factor group or finite space group (C_{2h}) the structure of the representation formed by the cartesian coordinates is $\Gamma = 6a_g + 9b_g + 6a_u + 9b_u$ (Table II). If the unique axis of the crystal (b) is chosen to coincide with the y axis of the

TABLE II

Character table and factor-group analysis for sodium formate

C_{2h}	E	C_2	i	σ_h	n_i*	$n_i(T)$	$n_i(T')$	$n_i(R')$	n_i'	
a_g	1	1	1	1	6	0	2	1	3	$\alpha_{xx}\alpha_{yy}\alpha_{zz}\alpha_{xz}$
b_g	1	−1	1	−1	9	0	4	2	3	$\alpha_{yz}\alpha_{yx}$
a_u	1	1	−1	−1	6	1	1	1	3	T_y
b_u	1	−1	−1	1	9	2	2	2	3	T_x, T_z

*where n_i = total number of vibrations of symmetry species i under the factor group analysis,
$n_i(T)$ = number of purely translational modes of symmetry species i,
$n_i(T')$ = number of lattice modes of translational origin of symmetry species i,
$n_i(R')$ = number of lattice modes of rotational origin of symmetry species i, and
n_i' = number of internal formate vibrations of symmetry species i.

Cartesian system then the translation in the y direction (T_y) will be of species a_u while T_x and T_z are of species b_u. The remaining translational motions yield nine normal vibrations: $2a_g + 4b_g + a_u + 2b_u$. Rotational motions of the ions give six normal vibrations: $a_g + 2b_g + a_u + 2b_u$. This leaves 12 normal vibrations associated with internal motions of the formate ions $3a_g + 3b_g + 3a_u + 3b_u$. There are in other words 12 internal formate ion vibrations and 15 lattice vibrations. These are illustrated schematically in Fig. 3 for the unit of pattern shown in Fig. 2. Since most of these vibrations should be observable in the Raman or infrared spectra of the crystal they have been numbered consecutively from ν_1 to ν_{27}. Where possible the usual numbering convention has been followed but until more quantitative data is available the numbering of the lattice modes must be regarded as only tentative.

The 12 internal normal vibrations may be considered to arise from 6 normal vibrations of the "free" formate ion through a dynamic crystal effect resulting from the presence of two formate ions in the unit of pattern. The two ions may execute the same internal vibration in phase or out of phase to give crystal modes of g or u symmetry respectively. Since the g modes are Raman active and the u modes infrared active the Raman and infrared spectra will in principle be different in frequency. In practice, the observed frequencies

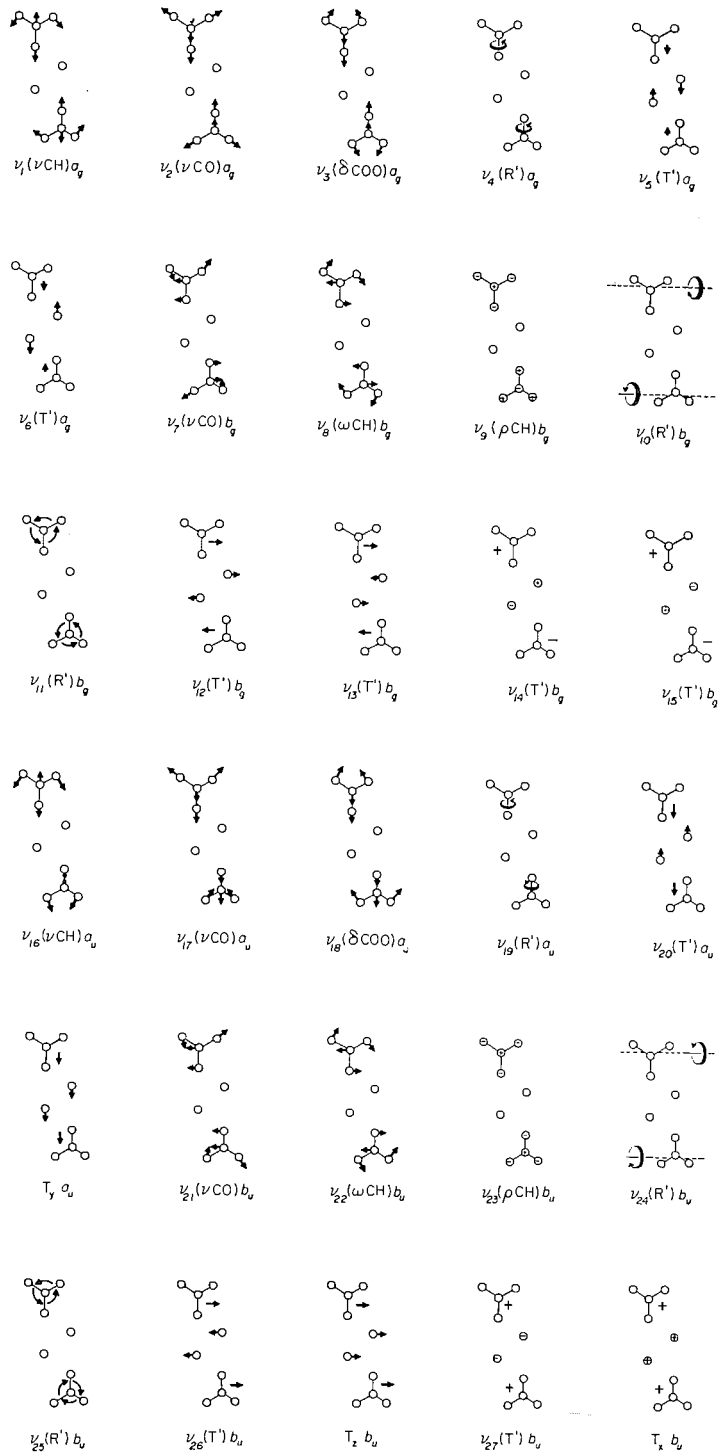

FIG. 3. Normal vibrations of the sodium formate crystal. See text regarding the numbering of the lattice vibrations and the form of ν_{10} to ν_{15} and ν_{24} to ν_{27}.

are not expected to differ by more than a small amount, but this difference will be a direct measure of the dynamic crystal effect or correlation field splitting.

In the same way the three possible rotations of the "free" formate ion are doubled to give three g and three u lattice modes of rotational origin. Because of its symmetry, the sodium ion may execute translational but not rotational motion hence there are 12 lattice modes of translational origin. Three of the u modes are pure translations, however, so that there will be only 3 infrared active lattice modes of translational origin but 6 Raman active modes of this type.

Single Crystal Spectra

In considering the spectra of single crystals it is necessary to take account of the orientation of the ions with respect to the crystal axes. The formate ions lie on sites of C_2 symmetry with the symmetry axis of the ion collinear with the unique axis of the crystal (Table III). As a result the totally symmetric modes of the "free" ion of species a_1 become a_g (ν_1,ν_2,ν_3) and a_u ($\nu_{16},\nu_{17},\nu_{18}$) in the crystal and are most strongly infrared active for light polarized with the electric vector parallel to the $y(b)$ direction. There should be no absorption for light polarized in the $xz(ac)$ plane.

Since the crystal is monoclinic there is no unique axis in the ac plane and the b_1 and b_2 modes of the free ion are not distinguished by group theoretical analysis of the vibrations of the crystal. Thus, each of the asymmetric modes gives rise to a b_g and a b_u mode in the crystal. The intensity behavior with polarized light will be quite different, however, for the in-plane and out-of-plane "free" ion modes. The in-plane internal modes (ν_{21},ν_{22}) will show maximum infrared absorption for light polarized with the electric vector parallel to the plane of the molecule and perpendicular to the twofold axis. On the other hand, absorption due to the out-of-plane vibration (ν_{23}) will be a maximum with the electric vector perpendicular to the plane of the molecule.

The intensity behavior of the lattice modes is not as easily predicted as that of the internal modes. The two a_u modes arising from translation parallel to the twofold axis (ν_{20}) and rotation about the twofold axis (ν_{19}) will show maximum absorption for light polarized parallel to this axis. In the case of the four b_u modes (ν_{24} to ν_{27}), however, the directions of translation and the axes of rotation of the vibrations are constrained only to the $ac(xz)$ plane. The pairs of transition moments will be perpendicular to one another but their orientation relative to the crystal axes will be a function of the physical parameters of the system. (This behavior may be compared with that of the refractive index ellipsoid of a monoclinic crystal. The two are obviously related.) The actual vibrations will, therefore, be linear combinations of those illustrated. Similar considerations apply, of course, to the corresponding Raman active vibrations.

While the crystal field effects are relatively minor, the intensity variations arising from the orientation of the ions in single crystals will be quite large and readily observable experimentally. Even relative intensity measurements will permit unambiguous assignment of the frequencies of the fundamental vibrations. More important perhaps is the fact that such data will also fix uniquely the orientation of the formate ion in the crystal.

Combinations and Overtones of Internal Fundamentals

All of the first overtones will be of a_g symmetry and inactive in the infrared spectrum (Table IV). Combinations of the corresponding in-phase (g) and out-of-phase (u) pairs such as $\nu_1 + \nu_{16},\nu_2 + \nu_{17}$ etc. will be infrared active and their frequency should be approximately the same as the corresponding overtones; $2\nu_{16} \simeq \nu_1 + \nu_{16}$ etc. These will be of a_u symmetry, however, and it is unlikely they will be observed for the ac cut crystals used in this investigation.

In the same way it can be deduced that any combination of the infrared active (u) modes or any combination of the Raman active (g) modes will have a_g or b_g symmetry and be infrared inactive. The remaining combinations will all be infrared active but the combinations $a_g + a_u$ or $b_g + b_u$ will have a_u symmetry and are unlikely to be observed. This leaves 18 combinations of b_u symmetry ($b_g + a_u$ or $a_g + b_u$) which will be infrared active. These occur in pairs with approximately the same frequency ($\nu_7 + \nu_{16} \approx \nu_1 + \nu_{21}$ for example) so that only nine absorption peaks (possibly doubled) arising from combinations of internal fundamentals are to be expected.

In principle the frequencies of the infrared inactive a_g and b_g modes could be inferred from the infrared active combinations. Any such estimate must be very rough, however, because the anharmonicity and crystal field splitting will be of the same order of magnitude.

Combinations of Internal Fundamentals and Lattice Modes

Sum and difference modes of the low-frequency lattice vibrations and the internal fundamentals will give rise to a series of weaker peaks on the high- and low-frequency sides of the absorption peak assigned to the internal fundamental. The transition probabilities for the difference modes are the same as those of the corresponding sum modes but the intensities are expected to be less because of the smaller populations of the excited lattice-mode energy levels at which the transitions originate.

The satellite structure of an internal a_u mode will, in principle, exhibit 15 peaks in the infrared spectrum arising from combinations: 3 of species a_u, $(a_u + a_g)$; $6b_u$, $(a_u + b_g)$; $2a_u$, $(a_g + a_u)$; and $4b_u$, $(a_g + b_u)$. Only the 10 b_u modes should be observable with the electric vector of the polarized light perpendicular to the b axis. There will in addition be 10 corresponding difference modes.

The situation is similar for an internal b_u mode. The 15 possible active combinations with lattice modes are: $3b_u$, $(b_u + a_g)$; $6a_u$, $(b_u + b_g)$; $2b_u$, $(b_g + a_u)$; and $4a_u$ $(b_g + b_u)$. Only the five b_u modes should be observable with the ac cut crystals, along with the five corresponding difference modes.

It should be noted that extending the arguments of the factor group analysis to the combinations and overtones is open to criticism since the implicit assumption that the wave-vector k is zero may not be valid in these cases.

Assignment of Internal Fundamentals

The symmetric modes ν_{16}, ν_{17}, and ν_{18} of a_u symmetry should be inactive for light polarized in the ac plane but because of the slight convergence of the spectrometer beam they are observed as weak but very sharp peaks at 2 831 cm^{-1}, 1 376 cm^{-1}, and 782 cm^{-1}

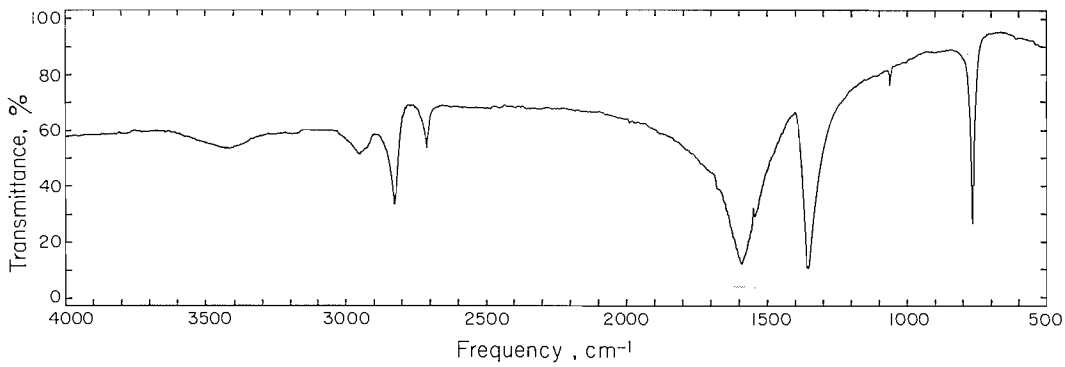

FIG. 4. Infrared absorption of powdered sodium formate. The spectral slit width varies from approximately 2.3 cm^{-1} in the high-frequency region to a minimum of 1.0 cm^{-1} in the low-frequency region.

respectively. All three of these peaks change very little in intensity as the angle of polarization relative to the c axis is changed (Fig. 5). The peaks adjacent to ν_{16} at 2 950 cm^{-1} and 2 720 cm^{-1}, for example, vary markedly in intensity as the polarizer angle is changed in the manner expected of b_u modes. Confirmation of these assignments is provided by noting that the three a_u fundamentals are much more prominent in the powder spectrum than in the single crystal spectra.

The wagging mode, ν_{22}, overlaps the symmetric C—O stretching mode ν_{17} and in the powder spectrum the two are very difficult to resolve. Figure 5*a* shows clearly, however, that ν_{17} is at 1 376 cm^{-1} and that the lower frequency component of the overlapping bands is of b_u symmetry. Since the intensity of absorption is a maximum when the polarized light vector is parallel to the plane of the molecule it must be an in-plane mode and we have assigned it to ν_{22}. The frequency of maximum absorption is estimated to be at 1 356 cm^{-1}. The order of these assignments is in agreement with the results of Newman but is the reverse of all other assignments. The assignments of Bernstein's Raman spectrum are supported by the measured depolarization ratios suggesting that solvent effects produce a downward shift of about 27 cm^{-1} in $\nu_{17}(\nu_2)$ while $\nu_{22}(\nu_5)$ undergoes an upward shift of 24 cm^{-1}.

The remaining in-plane mode, $\nu_{21}(\nu\mathrm{CO})b_u$, is overlapped by absorption arising from combination modes. The absorption peak is strong and relatively broad for light polarized in the plane of the molecule making difficult an accurate estimate of the frequency of maximum absorption. The value of 1 595 cm^{-1} quoted in Table V is the frequency of a weak shoulder observed in spectra taken with the electric vector of the polarized light nearly perpendicular to the plane of the molecule.

The only out-of-plane mode, $\nu_{23}(\rho\mathrm{CH})b_u$, is readily identifiable as absorbing at 1 066 cm^{-1} since this peak exhibits maximum intensity when the polarized light vector is perpendicular to the plane of the molecule. This is the least strongly absorbing of all of the internal fundamentals and is observed in powder spectra only with difficulty.

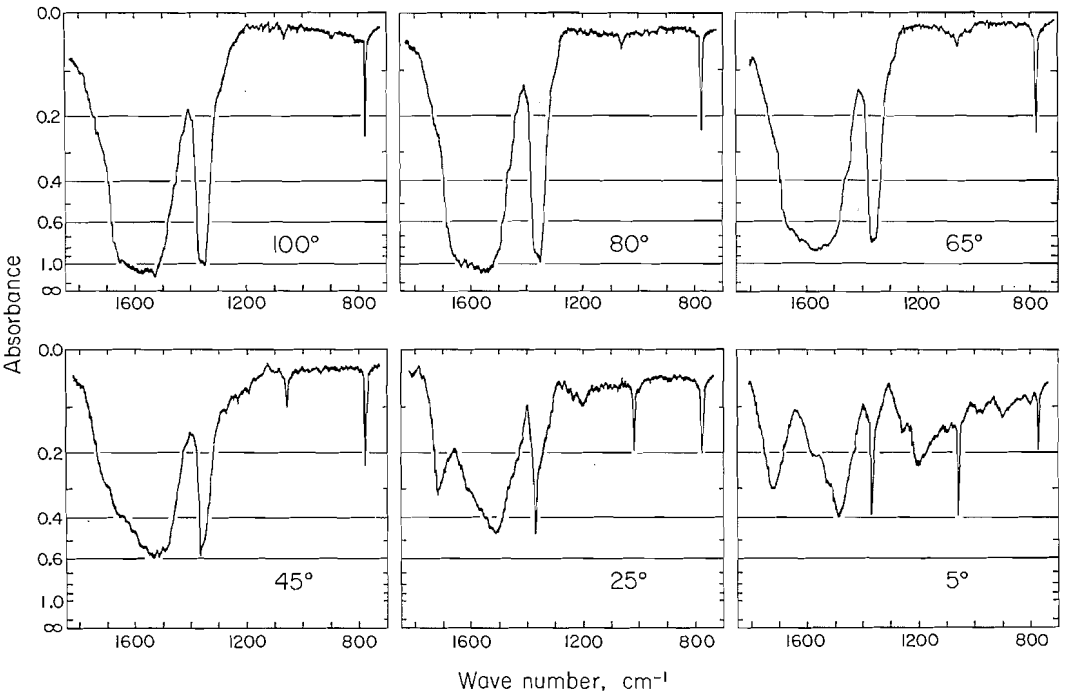

FIG. 5*a*. Infrared absorption of a thin section of sodium formate cut perpendicular to the *b* axis. The electric vector of the polarized light is perpendicular to the *b* axis and at the angles indicated to the *c* axis: 700 – 1 900 cm^{-1} region, spectral slit width approximately 1.1 ± 0.2 cm^{-1}.

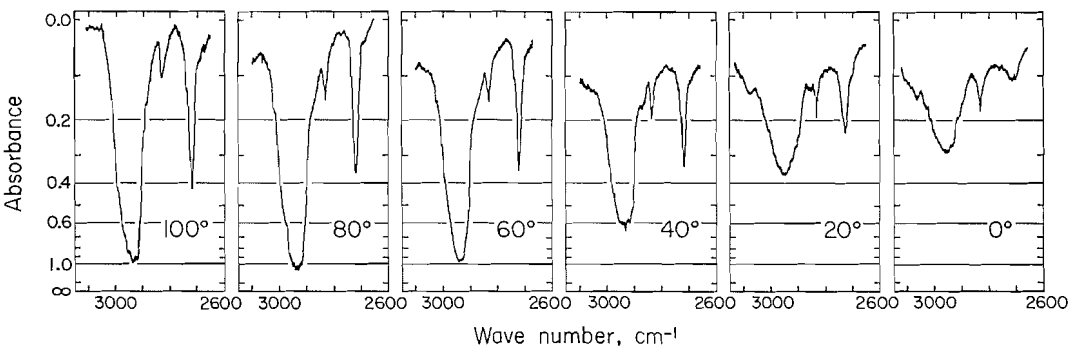

FIG. 5*b*. As for Fig. 5*a*, for the 2 600 – 3 200 cm^{-1} region, spectral slit width approximately 1.8 ± 0.2 cm^{-1}.

Assignment of Combinations

Spectra obtained under optimum conditions (small spectral slit width, slow scanning speed etc.) exhibit a larger number of absorption peaks, in addition to the fundamentals, which range in intensity from medium to very weak. Only those reproducible in several traces taken from the same sample and in samples of different thickness are reported here. Most of these absorption peaks must arise from b_u modes but very little information is available regarding the direction of the transition moment because of the overlapping which occurs. The majority of the weaker peaks were observed in spectra taken with the light polarized parallel to the *c* axis of the crystal but this is undoubtedly due to the

$\nu_6(\rho CH)b_2$	$\nu_{23}(\rho CH)b_u$	1 066

relative weakness of the absorption of the in-plane b_u modes, ν_{21} and ν_{22}, under these conditions.

Since all of the first order combinations involve Raman active modes, it is difficult to make definitive assignments. The assignments of Table VI were made on the assumption that the frequencies of the corresponding Raman and infrared active internal modes were approximately the same. Results obtained in this laboratory on calcium formate (T. L. Charleton and B. K. Harvey, to be published) indicate that the correlation field splitting is small so that this assumption is probably reasonable.

TABLE VI

Infrared absorption of single crystals of sodium formate

Assignment	Wave number (cm^{-1})	Assignment	Wave number (cm^{-1})	Assignment	Wave number (cm^{-1})

	1 284	$\nu_3+\nu_{22}$	2 146		3 687
$\nu_{22}-57$	1 303	$\nu_3+\nu_{21}$	2 354	$\nu_1+\nu_{23}$	3 882
ν_{22}	1 357	$\nu_2+\nu_{23}$	2 428		
			2 445		

The majority of the absorption peaks observed arise from combinations of internal formate modes with pure lattice vibrations. We have been able to identify three of these at 57 cm^{-1}, 107 cm^{-1}, and 138 cm^{-1}. These are to be compared with the two observed by Bernstein at 60 cm^{-1} and 140 cm^{-1}.

Clearly, a complete explanation of the crystal vibrational spectrum of sodium formate will require considerably more data. To this end we are currently investigating: (i) the Raman spectrum, (ii) the long-wavelength infrared spectrum, and (iii) the effect of temperature on the infrared spectrum of sodium formate.

THE CORRELATION OF ABSORPTION SPECTRA AND STRUCTURE OF COPPER(II AND I)-2,2′-BIQUINOLINE COMPLEXES IN ACETONE MEDIA

G. H. FAYE

Analytical Chemistry Subdivision, Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received April 15, 1966

ABSTRACT

A study of the absorption spectra of copper(II and I)–2,2′-biquinoline complexes in acetonic media has revealed that in the presence of excess ligand the predominant structure for both oxidation states of copper is probably that of a trigonal bipyramid. A crystalline mono-biquinoline complex containing pseudo-octahedrally coordinated copper(II) has been isolated from solutions containing chloride ion. Evidence has been obtained that suggests the existence of a tris-biquinoline–copper(I) complex in which one biquinoline acts as a monodentate ligand.

INTRODUCTION

Although 2,2′-biquinoline (Biq) is used widely as a reagent for the spectrophotometric determination of copper(I), the complexes formed in the copper–Biq system do not seem to have been well characterized. For example, the author has found only a single reference (1) to a copper(II)–Biq complex. This is surprising because a comparison of the structure of bulky Biq complexes with those formed with unsubstituted bipyridine and phenanthroline and with their 2,9-substituted derivatives should be of interest to coordination chemists.

The author has recently used elementary ligand field theory in the interpretation of the spectra of copper(II)–halogeno (2) and phenanthroline (Phen) (3) complexes and it seemed worthwhile to use the same approach in an attempt to elucidate the nature of the species formed in the copper–Biq system.

The results of the present work indicate that in an acetone medium, copper(II) forms a pseudo-octahedral mono-Biq complex and a trigonal bipyramidal bis-Biq complex. It is considered that in the presence of chloride ion the binuclear species $[(Biq)_2Cu—Cl—Cu(Biq)_2]^{3+}$ containing five-coordinate copper(II) forms, and this rearranges in the presence of excess chloride to give crystalline $CuBiqCl_2$ and $[Cu(Biq)_2Cl]^+$. A study of charge transfer bands (including that used for analytical purposes) suggests that copper(II) forms a bis- and tris-Biq complex, each being trigonal bipyramidal but with one monodentate Biq in the tris species.

EXPERIMENTAL

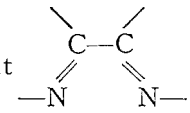
With the exception of solutions of Biq in acetone and freshly prepared aqueous solutions of ascorbic acid, the materials, apparatus, and experimental procedure were similar to those described previously in spectrophotometric studies of copper(II)–halogeno (2) and Phen (3) complexes in acetone media.

As in previous work, extinction coefficients were calculated using total copper concentrations.

Preparation and Properties of $CuBiqCl_2$

As indicated later in the paper, solid $CuBiqCl_2$ is formed under certain conditions in copper–Biq–chloride systems in acetone solutions. For analytical and X-ray diffraction studies, samples of this material were prepared at room temperature by mixing 50 ml of a 2×10^{-4} *M* solution of $CuCl_2.2H_2O$ in acetone with a similar volume of a 2×10^{-4} *M* acetonic solution of Biq. The orange acicular crystals that formed immediately were allowed to settle for several minutes and were then recovered in a filter crucible, washed with acetone, and dried at approximately 100 °C. Approximately 80% of the copper was recovered in the product.

The orange material formed as above was found on analysis to contain 16.3% Cu and 18.0% Cl and to contain one molecule of Biq per copper. Therefore, the crystalline material may be formulated as $CuBiqCl_2$, a compound that requires 16.4% Cu and 18.2% Cl.



X-ray diffraction studies indicate that $CuBiqCl_2$ is monoclinic, and the tentative unit-cell dimensions are: $a = 13.7$ Å, $b = 15.2$ Å, $c = 7.90$ Å, and $\beta \simeq 90°$. The extinctions are consistent with the space group $P2_1/n$.

RESULTS AND DISCUSSION

Copper(II)–Biq Complexes

In Acetone Solutions

Octahedral Mono- and Trigonal Bipyramidal Bis-Complexes

Because the functional or "bonding" unit  is common to Biq and variously substituted bipyridines (Bips) and phenanthrolines (Phens), it is to be expected that the structure and "d–d" absorption spectra of corresponding copper(II) complexes formed with such ligands should be qualitatively similar. Indeed, spectra A and B in Fig. 1 are directly analagous to copper(II)–Phen complexes formed under similar conditions (3).

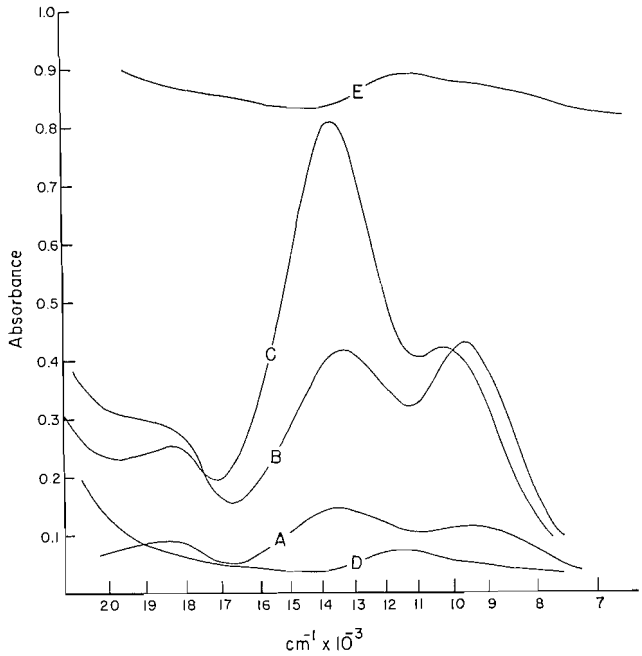


FIG. 1. d-d spectra of copper(II)–biquinoline complexes.

		$[Cu^{2+}]_{total}$	[Biq]/[Cu^{2+}]	[Cl^-]/[Cu^{2+}]	Band max. (cm^{-1})	$\sim \epsilon_{max}$ (l/mole cm)
A	$[CuBiq(OH_2)_3solv]^{2+}_{oc}$	4×10^{-3} *M*	0.8	—	13 700	40
B	$[Cu(Biq)_2solv]^{2+}_{trig\ bipy}$	4×10^{-3} *M*	2.5	—	13 300 and 9 650	110
C	$[Cu(Biq)_2Cl]^{2+}_{trig\ bipy}$	4×10^{-3} *M*	4.0	1.0	13 600 and 10 250	200
D	$CuCl_2.2H_2O$ + Biq in acetone $[CuBiqCl_2(solv)_2]_{\sim oct}$	4×10^{-4} *M*	—	—	11 500	150
E	$CuBiqCl_2$ (Nujol mull)	—	—	—	11 500	—

Spectrum A is considered to be due largely to the pseudo-octahedral complex $[Cu(Biq)(OH_2)_3ac]^{2+}$. Evidence for a 1:1 combination of Cu(II) and Biq is given in Fig.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2*a*. As in previous studies (2, 3), undried reagent grade acetone was used as the solvent and this was the source of the waters in the mono-Biq species.

Spectrum B is that of an approximately trigonal bipyramidal entity, $[Cu(Biq)_2solv]^{2+}$. Figure 2*a* confirms the conclusion, based on the comparison of spectrum B with that of the bis-Phen complex (3), that the absorbing species is a 2:1 entity.

That a pseudo-octahedral bis-Biq complex is not detected when $[Biq]/[Cu^{2+}] > 1$ is considered to be due partly (as previously for the copper(II)–Phen system (3)) to the greater ligand field stabilization energy inherent in a trigonal bipyramidal structure.

From Fig. 2*a* it is evident that there is no tendency for a pseudo-octahedral tris-species to form and this is probably a consequence of steric hindrance introduced by the projecting carbocyclic parts of Biq. This finding is similar to that of James and Williams (1), who found no evidence for a 3:1 complex with Phen substituted in the 2,9-positions.

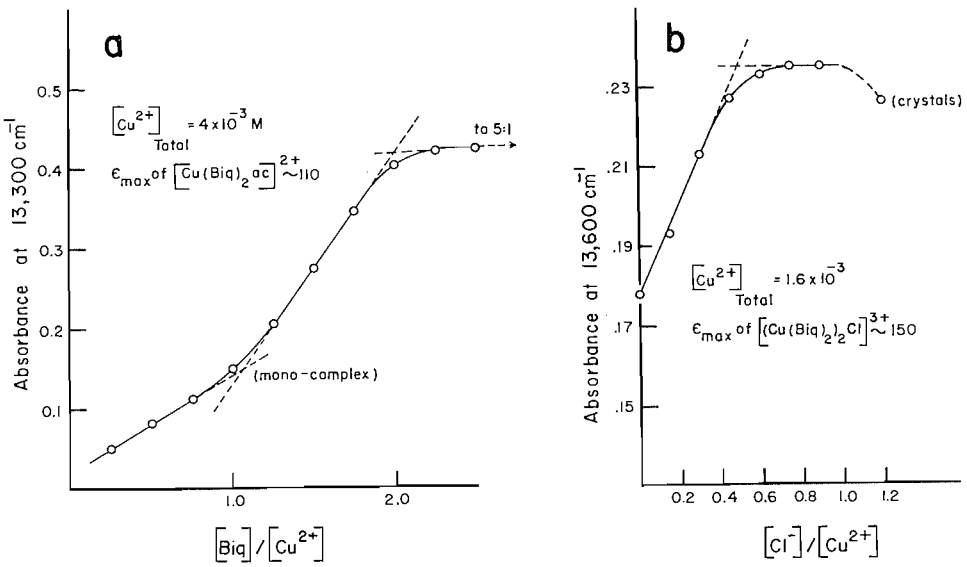

FIG. 2. Mole ratio plots.

It will be seen later that the shoulder at 18 300 cm^{-1} in spectrum B is an electron-transfer band due to the bis(Biq)–copper(I) complex. It is estimated that approximately 1% of the total copper existed as the cuprous complex at the time of the scan of spectrum B.

In the $Cu(ClO_4)_2$–Phen system in acetone solutions (3) a turquoise crystalline compound, $[Cu(Phen)_2ClO_4]ClO_4$, forms when $[Phen]/[Cu^{2+}]$ is in the range 1 to 3. A corresponding solid is not formed under comparable conditions in the $Cu(ClO_4)_2$–Biq system, and this is probably a consequence of the larger size of the bis-Biq complex.

In Acetone – Hydrochloric Acid Solutions

Trigonal Bipyramidal Bis-Biq–Monochlorocopper(II) Complex

On the addition of an acetone solution of hydrochloric acid (10^{-3} *M*) to a solution in which $[Biq]/[Cu^{2+}] \geqslant 2$ the spectrum of the absorbing species gradually changes from B to C in Fig. 1 as $[Cl^-]/[Cu^{2+}]$ is increased to ~ 1. As $[Cl^-]/[Cu^{2+}]$ is increased from 1 to 2.5, an increasing fraction of the total copper (original concentration 10^{-3} *M* or higher) forms the orange crystalline compound $CuBiqCl_2$. The spectrum of the copper complex remaining in solution is qualitatively the same as C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From the two bands and their energies, it is evident that spectrum C is also due to an essentially trigonal bipyramidal entity, one in which Cl^- has replaced a solvent molecule in the trigonal plane to give $[Cu(Biq)_2Cl]^+$ (or possibly a dimer as we will see below).

Solid $CuBiqCl_2$

The single maximum (and its energy) in the mull spectrum (E) of $CuBiqCl_2$ in Fig. 1 suggests that Cu(II) is in an approximately octahedral environment, i.e. probably in a unit such as that depicted in Fig. 3.

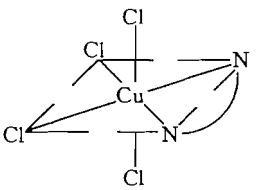

FIG. 3. Immediate environment of copper(II) in $CuBiqCl_2$.

Evidence for Dimer

The effect of adding Cl^- to an acetone solution containing $[Cu(Biq)_2solv]^{2+}$ is shown in Fig. 2*b*. The plot indicates that the combining ratio of chloride to copper is 0.5 and this strongly suggests the formation of a chloride-bridged dimer containing two trigonal bipyramidal units, i.e. $[(Biq)_2Cu—Cl—Cu(Biq)_2]^{3+}$.

From the experimental evidence cited above, it is proposed that the following reactions occur as $[Cl^-]/[Cu^{2+}]$ is increased from 0 to 1.5 in an acetone solution containing the trigonal bipyramidal species, $[Cu(Biq)_2solv)^{2+}$:

$$2[Cu(Biq)_2solv]^{2+} + Cl^- \rightleftarrows [(Biq)_2Cu—Cl—Cu(Biq)_2]^{3+}$$

$$+ Cl^-$$

$$\Updownarrow$$

$$2[Cu(Biq)_2Cl]^+ + Cl^- \leftrightarrows CuBiqCl_2 + [Cu(Biq)_2Cl]^+ + Biq.$$

The Study of Charge-Transfer Bands of Copper(II)–Biquinoline Complexes

Figure 4 shows some charge-transfer bands arising from the copper(II)–Biq complexes discussed above. Mole ratio vs. absorbance plots confirmed that spectra A and B are those bis-Biq complexes and spectrum C is that of a mono-complex.

Because the frequency of the band maxima (28 000 cm^{-1}) remains constant and the ϵ_{max} values are approximately proportional to the number of Biqs per copper (i.e. 2.2–2.5 $\times$ 10^4 l/mole cm per Biq) it is concluded that the bands represent charge-transfer processes within the coordinated Biq molecules. From A it is apparent that there are three closely spaced components within the band and these have their maxima at approximately 28 600, 28 000, and 27 200 cm^{-1} respectively. It is of interest to note that the intensity of the three transitions are such as to give a band of high symmetry in spectrum C. As we will see later three similar transitions occur in copper(I)–Biq complexes and this is further evidence that the charge-transfer processes are not of the ligand $\rightarrow$ metal type (because the d orbitals of Cu(I) are filled).

Spectra C and C-1 are those of solutions in which the absorbing species was considered to contain hexa-coordinated copper(II) in $[CuBiqCl_2(solv)_2]$. It is to be noted that a few minutes after scanning C-1, orange crystals formed which proved to be $CuBiqCl_2$ (D and E in Fig. 1). The shoulder at approximately 25 000 cm^{-1} is probably due to a $Cl^- \rightarrow Cu(II)$ charge-transfer process as its ϵ value is of the same order of magnitude as those of other copper(II) halogeno complexes (2).

COPPER(I)–BIQ COMPLEXES

A number of spectrophotometric methods for the determination of copper are based on the formation of the purple bis-Biq–copper(I) complex (4–6), a species whose structure has been assumed to be that of a regular tetrahedron (7).

The resolvable charge-transfer bands arising from the copper(I)–Biq species formed in water–acetone (A and A-1) and in acetone (B) solutions are given in Fig. 5; these will be discussed in some detail later. The band at approximately 18 500 cm^{-1} is responsible for the purple color and is the one used for analytical purposes.

While the present study is concerned mainly with the constitution and geometry of the species formed in the copper–Biq system, certain aspects of the work in the water–acetone medium, to be described below, were undertaken with the hope that the results might have some analytical value.

Reduction of Copper with Ascorbic Acid

In many analytical methods involving Biq, hydroxylamine hydrochloride or hydrazine hydrochloride is used to reduce copper(II) to copper(I) in an aqueous solution having a pH $> \sim 4$. The copper(I) solution is then shaken with a solution of Biq in a solvent such as amyl alcohol, whereupon the purple complex forms in the organic phase.

Biq is essentially insoluble in water but has a relatively high solubility in acetone, therefore it was decided to attempt the formation of the purple species in a mixture of the two solvents and thereby avoid the necessity of the extraction step.

Preliminary experiments indicated that ascorbic acid added to an aqueous solution of

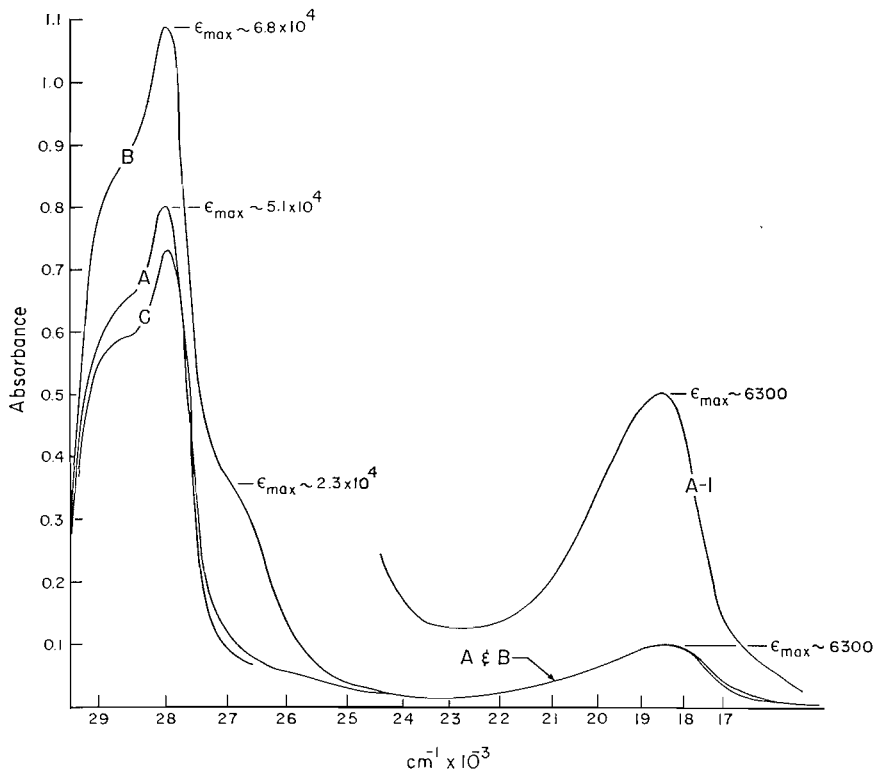

FIG. 5. Charge-transfer spectra of Cu(I)–Biq complexes.

		$[Cu]_{total}$	[Biq]/[Cu]	Band max. (cm^{-1})	$\sim \epsilon_{max}$ (l/mole cm)
A	$[Cu(Biq)_2solv]^+$	1.6×10^{-5} *M*	5	28 000	5.1×10^4
A-1	$[Cu(Biq)_2solv]^+$	8×10^{-5} *M*	5	18 500	6.25×10^3
B	$[(Biq)_2CuBiq]^+$	1.6×10^{-5} *M*	5	28 000	6.8×10^4
				~27 000 (s)	2.3×10^7
C	$[Cu(Biq)_2solv]^+$	1.6×10^{-5} *M*	2	~27 000 (s)	2.3×10^7

$CuCl_2.2H_2O$ is effective as a reducing agent for copper over a considerably greater pH range (1.4 to 9+) than is hydroxylamine, therefore ascorbic acid was used in subsequent experiments.

Frequently in analytical practice the aqueous copper-bearing sample solution contains an appreciable concentration of chloride ion, therefore an aqueous stock solution of $CuCl_2.2H_2O$ was used in the mixed-solvent experiments rather than one of copper perchlorate. It can be assumed that the initial complex was mainly $[Cu(OH_2)_6]^{2+}$ (8).

By measuring the absorbance of test solutions at 18 500 cm^{-1} ($\epsilon_{max} \sim 6\,300$ l/mole cm), it was established that excess ascorbic acid added as a freshly prepared aqueous solution or as crystals effects essentially complete formation of the purple bis-Biq–copper(I) complex when added to a water–acetone solution containing copper(II) and excess Biq, and when the mole fraction of water is 0.5–0.85. At mole fraction < 0.5 it is considered that conditions are suitable for the coordination of chlorines in the copper complex and this inhibits the reducing power of the ascorbic acid. At mole fraction > 0.85, Biq crystallizes from solution.

A plot of the mole ratio of ascorbic acid:total copper vs. absorbance measured under conditions such as those described above clearly indicated that 1 mole of ascorbic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reduces 2 moles of copper(II). This suggests the possibility of ascorbic acid (asc) acting as a bridge between two trigonal bipyramidal bis-Biq–copper(I) groups at the time of reduction, i.e. $[(Biq)_2Cu—asc—Cu(Biq)_2]^{2+}$.

In experiments similar to those above but using a stock solution of $Cu(ClO_4)_2$ in acetone, it has been found that crystalline ascorbic acid is an effective reducing agent in acetone solution (no water added) containing $[Cu(Biq)_2solv]^{2+}$. In this medium too, 0.5 mole of ascorbic acid reduces 2 moles of copper(II).

Speculations on the Existence of a tris-Biq–Copper(I) Complex Containing One Monodentate Biq

Spectra A and B in Fig. 5 are those of the complexes formed in water–acetone ($CuCl_2.2H_2O$) and in acetone ($Cu(ClO_4)_2$) media respectively. The mole ratio plots for the 28 000 cm^{-1} bands are given in Fig. 6 and from these it is evident that combining ratios of [Biq]:[Cu^+] are 2 and 3 for the species giving rise to spectra A and B respectively. However, similar plots for the 18 500 cm^{-1} band indicate a 2:1 combination of Biq and Cu(I) for both complexes in the presence of excess Biq.

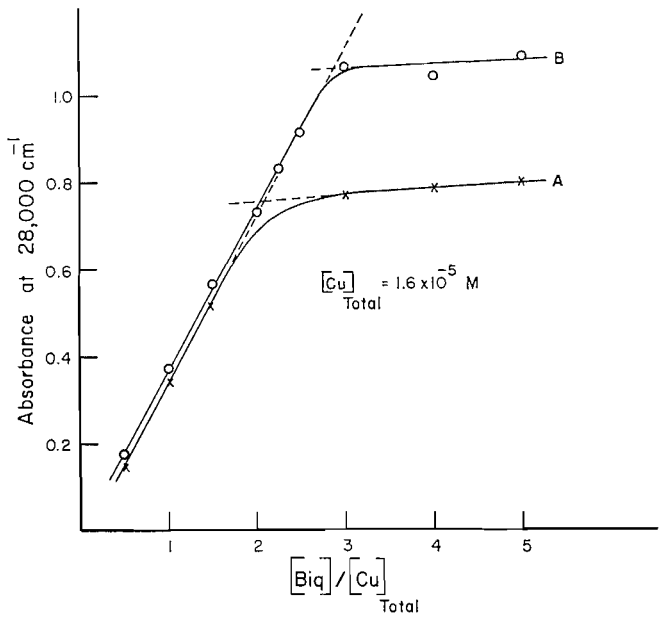

FIG. 6. Mole ratio plots. (A) Complex formed in H_2O–acetone medium in which mole fraction of H_2O = 0.5 and $[Cl^-]/[Cu^{2+}]$ = 2. (B) Complex formed in acetone solution initially containing $[Cu(Biq)_2solv]^{2+}$.

The apparent anomaly can be resolved by a study of the three-transition band between 25 000 – 29 000 cm^{-1}. As in the case of the copper(II) complexes, the electronic transitions are considered to occur within the bound Biq molecules because their frequency changes little with radical changes in the nature of the complex.

It was pointed out previously that the ϵ value of the 28 000 cm^{-1} maximum increased by $\sim 2.3 \times 10^4$ l/mole cm for each bound Biq in the copper(II) species. The same relationship holds for the copper(I) complexes as values of 5×10^4 and 6.8×10^4 l/mole cm are consistent with Biq:Cu(I) ratios of 2 and 3 respectively for complexes giving spectra A and B in Fig. 5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is of interest to note that the 27 200 cm^{-1} transition in the spectra of copper(II) complexes in Fig. 4 (see A especially) is absent in spectra A and C of the bis-Biq–copper(I) species shown in Fig. 5. However, in spectrum B, a shoulder at 27 200 cm^{-1} with $\epsilon \sim 2.3 \times 10^4$ l/mole cm appears and this is evidently the result of the bonding of a third molecule of Biq.

To account for the formation of a tris-Biq–copper(I) complex, it seems necessary to assume that the structure remain essentially that of a trigonal bipyramid because an approximately octahedral one is sterically unlikely. However, the five-coordinate structure requires that two Biq molecules be bound in a bidentate fashion and a third "dangling" Biq be bound by a single Cu—N bond in the trigonal plane. This proposal is supported by the fact that the band with maximum at 18 500 cm^{-1} seems to be associated with the two bidentately bound Biq molecules.

Spontaneous Reduction of Copper(II) by Biq

During the work on the copper(II)–Biq complexes, it was observed that the purple color (18 500 cm^{-1}) of the bis-Biq–copper(I) species formed gradually in the test solutions and it appeared that Biq acted as the reducing agent.

Experiments with 1.6×10^{-5} M solutions of $Cu(ClO_4)_2$ in acetone showed that after 20 h approximately 80% of the copper was present as the purple complex when $[Biq]/[Cu]_{total} = 3$. However, under similar conditions, but with sufficient Cl^- added to make $[Cl^-]/[Cu_{total}] = 1$, only about 50% of the copper existed as the cuprous species.

That the rate of reduction is decreased in the presence of Cl^- suggests that the partial transfer of charge from bound chlorines to copper(II) renders a similar process from Biq to copper(II) less efficient.

Although the experimental evidence presented above does not conclusively establish the existence of trigonal bipyramidal copper(I)–Biq complexes, such a structure seems to be more likely than the tetrahedral one proposed, without evidence, for the bis-species (7).

ACKNOWLEDGMENTS

The author thanks Mr. J. F. Rowland, Physical Chemistry Section, Mineral Sciences Division, for the X-ray work performed on crystalline $CuBiqCl_2$ and George F. Morris, Analytical Chemistry Research Branch, Department of Agriculture, for the determination of chlorine on samples of the same material.

THE SUBSTITUENT EFFECT ON VICINAL PROTON COUPLING CONSTANTS IN MONOSUBSTITUTED BENZENES

ROBERT R. FRASER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received July 4, 1966

ABSTRACT

The magnitude of the coupling constants between adjacent ring protons in several monosubstituted benzenes has been determined. The values for the interaction between protons ortho and meta to the substituents were in the range of 8.1–8.4 c.p.s. The interaction between protons in the meta and para positions varied from 7.27–7.8 c.p.s. Although the relative insensitivity of these coupling constants to the character of the substituent precludes any accurate assessment of the cause of this variation, the changes in coupling constants are thought to be mainly a reflection of changes in π-electron distribution.

The nuclear spin–spin interaction between adjacent protons in an aromatic ring (vicinal coupling constant, J) has been examined from both the theoretical and experimental point of view. McConnell (1) has proposed that the interaction occurs primarily through the sigma bonds. He estimated the contribution to vicinal coupling by the pi electrons to be of the order of 0.5 c.p.s. in benzene, using valence-bond calculations. A large number of spectra of aromatic compounds have been analyzed, and the vicinal coupling constants were found to fall in the range of 7 to 10 c.p.s. (2). Two systematic studies of the variations in J with a change in substituents have been reported (3, 4). Martin and Dailey (3) examined the spectra of over 40 disubstituted benzenes. From a detailed analysis of these spectra they found the variation in J with structure to be rather small, less than 2 c.p.s. They concluded this to be an indication of the invariant geometry of the ring. Cox (4) found that, in a number of para disubstituted benzenes, the coupling constants increased with increasing substituent electronegativity. Similar electronegativity effects have been noted in furans (5), thiophenes (2), and pyridines (6). It is noteworthy that the vicinal coupling constants are known for only 2 monosubstituted benzenes, biphenyl (7) and phenylacetylene (8). We wish to report the determination of J_{vicinal} for several additional compounds.

The exact analysis of a five-spin system is rather tedious and, in instances where chemical shifts are small, may be of limited accuracy. We have used the technique of "massive deuteration" (9) to produce benzene derivatives from whose spectra the coupling constants are readily obtained. Previously, massive deuteration was employed to enable the accurate determination of chemical shifts by observing the single peaks due to the ortho, meta, and para isomers of monoprotiotetradeuterioaniline and phenol (10). To obtain the vicinal coupling constants, one requires vicinal diprotiotrideuterio compounds. These are obtained in the following manner as, for example, in the case of fluorobenzene. Aniline-d_7 was prepared by reaction with heavy water in the presence of platinum. Four such exchanges gave 99% deuterated aniline. This material was converted to fluorobenzene-d_5 via the diazonium fluoborate. The fluorobenzene-d_5 was then reacted with ordinary water and platinum for 3.5 h at 85 °C and the product was found to consist of 56% fluorobenzene-d_5, 33% d_4, 10% d_3, and 1% d_2 by mass spectral analysis. The nuclear magnetic resonance spectrum of this material was measured during simultaneous irradiation of the deuterium nuclei to remove all coupling between hydrogen and deuterium

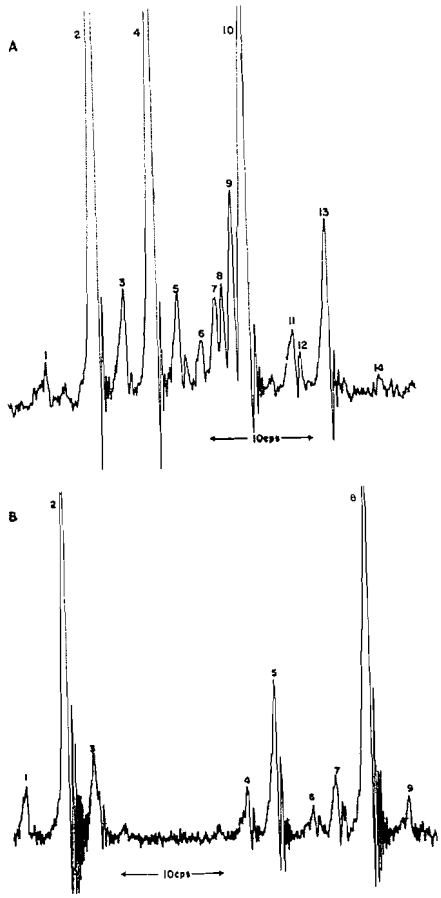

FIG. 1. (A) Spectrum of "massively deuterated" fluorobenzene; (B) spectrum of "massively deuterated" aniline.

nuclei. This spectrum is shown in Fig. 1A. Peaks 2 and 4 comprise the doublet ($J_{\text{H-F}_{\text{meta}}} = 5.7 \pm 0.09$ c.p.s.) for the protons meta to fluorine in fluorobenzene-d_4. Peaks 9 and 13 are the doublet ($J_{\text{H-F}_{\text{ortho}}} = 9.05 \pm 0.07$ c.p.s.) representing the lesser concentration of protons ortho to fluorine in fluorobenzene-d_4. The single peak 10 shows no resolvable splitting ($J_{\text{H-F}_{\text{para}}} = 0$ c.p.s.) and is due to para monoprotonated product. It is from the 10% of d_3 material that the vicinal coupling constants are determined. The peaks 1, 3, 5, 7, 8, 11, 12 represent the absorption of 2,5,6-trideuteriofluorobenzene. These appear as the AB part of an ABX spectrum and as such are readily analyzed as two pairs of AB patterns, one resulting from fluorine nuclei with spin 1/2, the other resulting from fluorine nuclei with spin $-1/2$. One of the eight lines is obscured by peak 2. The coupling constant, $J_{3,4}$[1] is equal to the separation between peaks 1 and 3, 7 and 11, 8 and 12 and has the value 7.48 ± 0.07 c.p.s. Unfortunately, the proportion of 3,4,5-trideuteriofluorobenzene is too small to allow an accurate determination of $J_{2,3}$ which is estimated to be 8.4 ± 0.25 c.p.s. (peak 11 obscures two of the four peaks due to the ortho protons). The others are peaks 6 and 14. It is interesting to note that one can obtain all

[1]*We wish to use subscripts to denote the position of the two interacting protons in relation to the substituent in position 1. Thus, $J_{3,4}$ represents the coupling between protons meta and para to the substituent.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

H—F coupling constants, two H—H coupling constants, and three chemical shifts from this one spectrum. By calculating ν_{para} from the AB patterns of trideuterio compound and comparing it with ν_{para} for tetradeuterio material, it is found that the effect of replacing a vicinal proton by deuterium is to increase the chemical shift by 0.08 c.p.s. In aniline the same effect is 0.10 c.p.s. (This isotope effect is small compared with the geminal isotope effect of 0.75 c.p.s. (11).)[2]

The spectrum of deuterated aniline is shown in Fig. 1B. Here peaks 2, 5, and 8 represent meta, para, and ortho isomers of monoprotiotetradeuterioaniline. Peaks 1, 3, 4, and 6 represent the AB pattern for 4,5,6-trideuterioaniline and peaks 1, 3, 7, and 9 the AB pattern for 4,5,6-trideuterioaniline. The coupling constants $J_{2,3}$ and $J_{3,4}$ are given by the separation of peaks 7 and 9, and 4 and 6 respectively. The other substituted benzenes were analyzed in the same way and all the results are shown in Table I. Only the deuterated anilines and nitrobenzenes contained a sufficient concentration of ortho protons to allow determination of $J_{2,3}$. Table I also contains for comparison the coupling constants reported for biphenyl (7), phenylacetylene (8), and benzene (12).

TABLE II

Coupling constants for aniline in various solvents

Solvent	$J_{2,3}$	$J_{3,4}$
Neat	8.09±0.05	7.38±0.04
Carbon tetrachloride	8.08±0.04	7.39±0.05
Deuterochloroform	8.06±0.05	7.45±0.08
Methanol	8.17±0.05	7.38±0.07
Dimethyl formamide	8.09±0.11	7.29±0.07

The possibility that $J_{vicinal}$ might be solvent dependent was investigated in view of the recent report by Hutton and Schaefer (13) on such an effect for para-nitroanisole. The results which are given in Table II show that for aniline there is no detectable variation in $J_{2,3}$ or $J_{3,4}$ with a change in solvent.

[2]*One must also consider the possibility of an isotope effect on the vicinal coupling constant. This has always been assumed to be unobservable, an assumption which is supported by the observation that the effect of deuterium substitution on* J^{13}_{C-H} *in toluene is less than 0.4 c.p.s. or 0.3% of its value, 126 c.p.s. (11). A vicinal isotope effect would be expected to be an order of magnitude smaller.*

According to Karplus (14), the size of a vicinal coupling constant depends on many structural features including carbon–carbon bond lengths, bond angles, hybridization, electronegativity of substituents, average excitation energy, π-electron distribution, and molecular vibrations. Within the range of compounds we have studied, the variation in the first three factors is minimal. This is illustrated by the data of Bak and co-workers (15, 16) who analyzed and interpreted the microwave spectrum of fluorobenzene and benzonitrile. In all portions of the molecule the bond angles deviate less than 2 degrees and the bond lengths deviate less than 0.01 Å from those of benzene. If we assume then that geometrical effects are relatively constant, we can consider our results in relation to the remaining variables.

The data in Table I reveals two effects which the substituents exert on vicinal coupling. Replacement of a hydrogen by each substituent causes an increase in $J_{2,3}$ and a decrease in $J_{3,4}$ except for cyano and ethynyl which do not affect $J_{3,4}$ and $J_{2,3}$ respectively. It is unlikely that the electronegativity of a substituent would be of major importance in influencing $J_{3,4}$ via the σ electrons, since the effect would have to be transferred through two intervening carbon–carbon bonds. Indeed the $J_{3,4}$ values do not appear to correlate well with the substituent electronegativities, particularly for the nitro group. This can be seen from a consideration of dimethylamino, nitro, and cyano substituents which cause $J_{3,4}$ to increase in that order, even though nitro is far more electronegative than either of the other two groups. Of the remaining factors affecting vicinal coupling constants, a change in π-electron distribution would best explain the observed variations. The larger value of $J_{2,3}$ over $J_{3,4}$ could be a reflection of a larger bond order in this position. Calculations for nitrobenzene (17) and aniline (18) predict slightly larger bond orders between ortho and meta carbon atoms, than between meta and para carbon atoms. There does appear to be some relation between the size of $J_{3,4}$ and the Taft σ_R values (19) with the nitro group again providing the exception. These parameters are a measure of the electron-donating (negative) or electron-withdrawing (positive) ability of the substituent, through resonance interaction with the aromatic π-electrons. The observed correlation between $J_{3,4}$ and σ_R would therefore be a reflection of a relation between $J_{3,4}$ and π-electron density as influenced by the substituent. It must be emphasized that the above discussion pertains to coupling constants which vary over a narrow range only slightly greater than the limits of accuracy of the measurements. For this reason, reliable conclusions cannot be made with certainty. With this in mind we can only say that the observed variation in coupling constants is consistent with a variation in π-electron density. McConnell's estimate of the π-electron contribution to J is likely conservative.

Recently Cohen and Schaefer (20) published an interesting review in which they examined the effect of electronegativity (E) on vicinal coupling constants. They were able to show that in aliphatic and olefinic compounds an increase in E caused an increase in $J_{2,3}$ and a slight decrease in $J_{3,4}$. From the works of Cox and of Martin and Dailey they pointed out that in aromatic compounds, too, an increase in E caused an increase in $J_{2,3}$. They further proposed that the results for ortho dihalobenzenes suggested that again $J_{3,4}$ will decrease with an increase in E. Our data provides evidence that such is *not* the case. Rather, the effect of π-electron distribution appears to be of equal if not greater importance than electronegativity.

Finally, we would like to compare our results for fluorobenzene with those already in the literature. Bak, Shoolery, and Williams (21) found $J_{H-F_{ortho}} = 9.4$, $J_{H-F_{meta}} = 5.8$, and $J_{H-F_{para}} = 0$. They also reported $J_{2,3} = 8.9$ but were not able to determine $J_{3,4}$. Since their accuracy was quoted as ± 0.2 c.p.s., our results are in ageement with theirs.

EXPERIMENTAL

All spectra were measured on a Varian DA-60 nuclear magnetic resonance spectrometer equipped with an external locking system for field stabilization. Double irradiation experiments were carried out using an NMR Specialties SD-60 spin decoupler operating at 9.2 Mc.p.s. Each coupling constant is reported as the average of at least six and usually eight traces. The samples were measured as neat liquid whenever the amount available permitted, otherwise they were measured as solutions of maximum possible concentration in cyclohexane. The experimental details of the deuteration methods are reported in a separate paper (22). Deuterated nitrobenzene was obtained by oxidation of deuterated aniline by the peracetic method of Emmons (23).

DOUBLE AND TRIPLE RESONANCE EXPERIMENTS ON 2-BROMO-5-CHLOROTOLUENE

SIGNS OF THE RING AND RING-METHYL PROTON COUPLING CONSTANTS

G. KOTOWYCZ[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received July 15, 1966

ABSTRACT

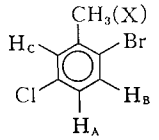
Tickling and decoupling (triple resonance) techniques show that the ortho, meta, and para proton coupling constants have the same sign in 2-bromo-5-chlorotoluene. If the ortho coupling in the ring is positive, then decoupling experiments show that the methyl proton couplings to the ring protons in the ortho and para position to the methyl group are negative, while that to the meta position is positive. These signs are in agreement with the σ–π exchange polarization mechanism.

INTRODUCTION

Long range coupling between the methyl and ring protons in substituted benzenes is known (1–3). Hoffman (1) attributed such coupling in mesitylene to hyperconjugation. Calculations by McConnell (4, 5) invoked a σ–π exchange polarization mechanism for long range couplings like the para coupling of ring protons. Acrivos (6) found that the magnitudes of the ring-methyl proton couplings in mesitylene were predicted satisfactorily by the same mechanism, as did Cohen and McLauchlan (3) for 2-carbomethoxy-5,6-dimethylbenzofuran. Theory (5, 6) also predicts the signs of the couplings. While the relative signs of methyl proton couplings with protons on the furan (7) and thiophene rings are known (8, 9), such is not the case for the benzene ring, although there have been a few careful determinations of the magnitudes of these couplings (3, 10).

The ortho coupling between the protons on the benzene ring is positive (11–13) as are the meta and para couplings in all known cases (14–17). We describe experiments here which determine the sign of the ring-methyl proton couplings and of the meta and para couplings relative to the ortho coupling in 2-bromo-5-chlorotoluene.

EXPERIMENTAL



Measurements were made on a degassed, 10 mole % solution of 2-bromo-5-chlorotoluene in carbon disulfide, with tetramethylsilane (TMS) as internal reference. Decoupling and tickling experiments, some of them involving triple resonance, were performed with a DA-60-I Varian spectrometer according to standard procedures (18–22). The temperature of the sample was 28.5 °C as determined using an ethylene glycol sample.[2]

RESULTS

The parameters obtained are (shifts relative to internal TMS):

$\nu_A = -6.919 \pm 0.005$ p.p.m.
$\nu_B = -7.317 \pm 0.005$ p.p.m.
$\nu_C = -7.097 \pm 0.005$ p.p.m.
$\nu_X = -2.313 \pm 0.005$ p.p.m.

J_{AB}[3] $= +8.48 \pm 0.03$ c.p.s. $= J_{H,H}^{o}$
$J_{AC} = +2.55 \pm 0.03$ c.p.s. $= J_{H,H}^{m}$
$J_{BC} = +0.33 \pm 0.03$ c.p.s. $= J_{H,H}^{p}$

$J_{CX} = -0.63 \pm 0.03$ c.p.s. $= J_{H,CH_3}^{o}$
$J_{BX} = +0.40 \pm 0.03$ c.p.s. $= J_{H,CH_3}^{m}$
$J_{AX} = -0.58 \pm 0.03$ c.p.s. $= J_{H,CH_3}^{p}$

Figure 1 gives the ring proton spectrum using the frequency sweep mode. It is a loosely coupled ABC part of an $ABCX_3$ spectrum. The ring-methyl proton couplings were therefore found from this spectrum by simple spacing rules and were found to reproduce the methyl proton spectrum satisfactorily (Fig. 4A). The errors given above are standard deviations obtained from a large number of runs.

In Fig. 2*b*, the methyl protons have been decoupled and the resulting ABC ring proton spectrum, analyzed exactly by the method of Castellano and Waugh (23), gave the parameters above. The calculated spectrum is shown in Fig. 2*c*. In Fig. 2*a*, the A, B, and C quartets are labelled and the spin states of the two neighboring protons during each transition are indicated, assuming all ring couplings positive.

Figure 3 gives the spectrum obtained by tickling transition B1 of the ring proton spectrum while the methyl group is decoupled. The observed spectrum shows that the ring proton couplings are all of the same sign. Similar tickling experiments on other transitions served to confirm this result.[4]

Fig. 4A shows the single resonance spectrum of the methyl group. The lines are numbered from low to high field. Because of the magnitudes of the ring–methyl couplings there is overlapping of two transitions in two cases, resulting in six instead of eight observed transitions. In Fig. 4B, the quartet centered on B1 (Figs. 1 and 2*a*), arising from the long range coupling between the methyl protons and proton B, is irradiated by a decoupling field. Transitions 5 and 6 of the methyl resonance collapse into a single line, showing that $J_{H,CH_3}{}^o$ and $J_{H,CH_3}{}^p$ are of opposite sign to the ring proton couplings. In Fig. 4C, a similar decoupling field is applied to the quartet centered on transition A1. Transitions 3 and 5 collapse and overlap transition 4 in the methyl resonance, showing that $J_{H,CH_3}{}^m$ is of the same sign, while $J_{H,CH_3}{}^o$ is of opposite sign, to the ring proton couplings. (A confirming experiment was performed by irradiating the quartet centered on transition C1.)

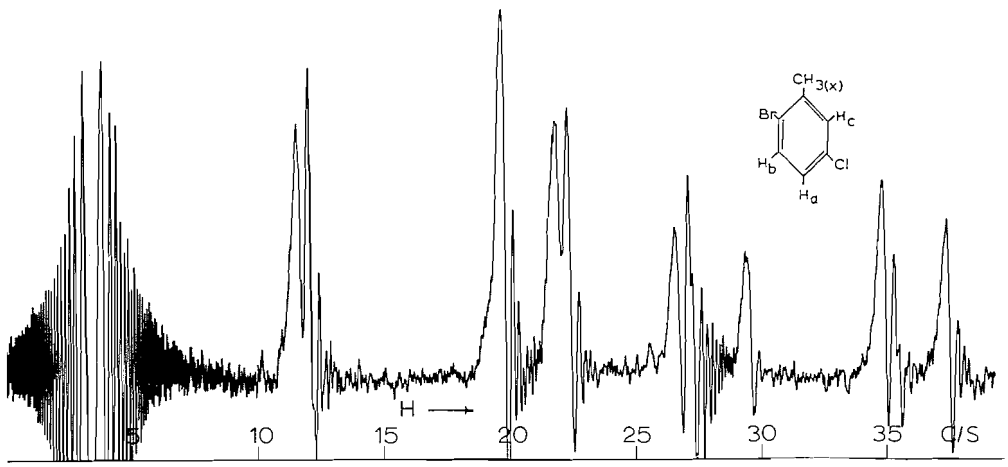

FIG. 3. Spectrum obtained by tickling transition B1 of the ring proton spectrum while the methyl group is decoupled, a triple resonance. The spectrum is observed by sweeping the frequency ω_1, the methyl group is decoupled with a second oscillator at its resonant frequency ω_2, while the spin tickling is carried out by a third frequency irradiating transition B1 at its resonant frequency ω_3.

In summary, if $J_{H,H}{}^o$ is positive, the other two ring couplings are positive. The couplings between the methyl and the ortho and para ring protons are negative, while the coupling with the meta proton is positive.

[4]*Freeman and Anderson (20) describe the arguments needed to find the relative signs. B2 is obscured by tickling B1, but there is no doubt that B1 is the tickled transition in Fig. 3.*

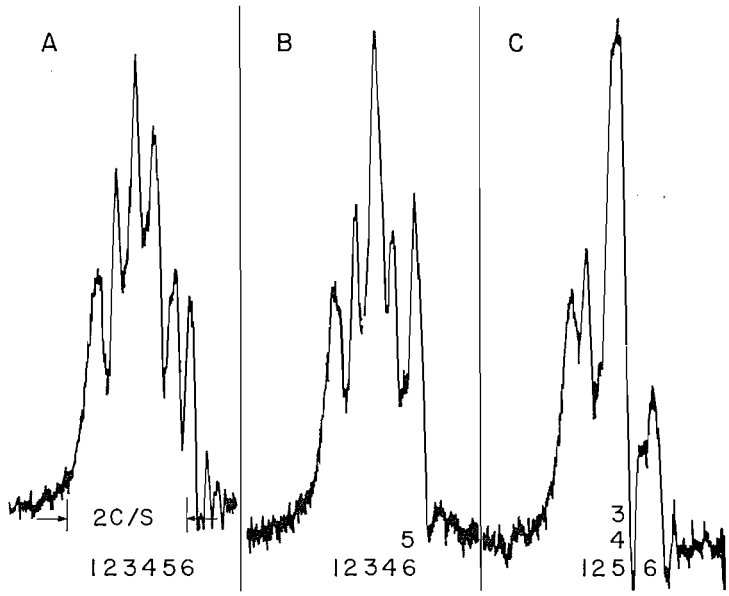

FIG. 4. The methyl group proton spectrum observed by sweeping the frequency ω_1. The lines are numbered from low to high field. (A) Unperturbed spectrum. (B) The methyl group proton spectrum observed when the decoupling frequency ω_2 irradiates the quartet centered on transition B1 which arises from the long range coupling between the methyl protons and proton B. Transitions 5 and 6 collapse into a singlet. (C) Spectrum observed with the quartet centered on transition A1 decoupled. Transitions 3 and 5 collapse and overlap transition 4.

DISCUSSION

Our conclusion from spin tickling and detailed spectral analysis of the same sign, presumably positive, of couplings within the ring agrees with earlier work on substituted benzenes using spectral analysis (14–16) and decoupling techniques (17). The suggestion is that $J_{H,H}^{p}$ arises from a σ–π mechanism (5, 6) since coupling through the σ electrons alone is expected to be negligible (4, 24).

The signs found for the ring-methyl proton couplings are in agreement with the Dirac vector model (25), more likely to be relevant to long range "through-bond" couplings (26). The simple molecular orbital calculation (4, 27) of the σ–π interaction predicts negative values for J_{H,CH_3}^{o} and J_{H,CH_3}^{p} as we find, but $J_{H,CH_3}^{m} = 0$. The latter is supported by data on acenaphthene (27). However, the more refined calculations (5, 6) predict J_{H,CH_3}^{m} to be positive and this is supported by our results.

Cohen and McLauchlan came to a similar conclusion from the proton spectrum of 2-carbomethoxy-5,6-dimethylbenzofuran but their argument was based on the magnitude of J_{H,CH_3}^{m} only (3). The signs obtained here agree with those found in methylfurans and methylthiophenes (7, 9). The sign reversal of the coupling to the para proton when the methyl group replaces a hydrogen is also in agreement with a valence-bond calculation by Karplus (24).

FORMATION OF ^{7}Be IN NUCLEAR REACTIONS INDUCED BY 85-MeV PROTONS[1]

M. S. LAFLEUR, N. T. PORILE,[2] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received July 6, 1966

ABSTRACT

Cross sections were measured for the formation of ^{7}Be in targets bombarded with 85-MeV protons. The variation of these cross sections with the mass and neutron-to-proton ratio of the target was investigated.

Cross-section calculations were performed on the assumption that ^{7}Be is emitted from the irradiated target as an evaporated particle. Calculated and measured cross sections were in good agreement for medium and heavy targets ($A > 55$). The calculation underestimated the production of ^{7}Be in light targets ($27 < A < 55$).

I. INTRODUCTION

The emission of multiply charged fragments ($Z > 3$) has been observed in many nuclear reactions induced by projectiles with a wide range of energies. There is no consensus on the mechanism of fragment emission; its characteristics have been explained both in terms of slow and fast reactions.

Cross sections for fragment formation have been calculated on the assumption that fragments are evaporated from the excited products of the knock-on cascade. Monte Carlo calculations of nuclear evaporation (1) have been modified to include the emission of complex particles (2–4) and the calculated relative cross sections were in good agreement with the dependence on target mass displayed by the experimental values in most cases. Recently Katcoff *et al.* (5) performed a detailed cascade–evaporation calculation to predict angular and energy distributions of ^{8}Li fragments emitted from targets irradiated with GeV protons. The calculated and experimental energy distributions agreed at the peak energies but the shape of the distributions differed at the low- and high-energy ends of the spectra. Because of the failure of the calculation to account for the emission of high-energy fragments and its inability to match the strong forward peaking of the angular distribution, the authors concluded that either a substantial fraction of the fragments is emitted by a process other than evaporation, or the emission is by a mechanism intermediate between evaporation and fast fragmentation.

The asymmetry of fragment angular distributions has been interpreted as due to the quasi-elastic ejection of fragments on the assumption of the existence of instantaneous substructures in the nucleus; fragments are produced by the nuclear cascade process. Makarov (6) performed a calculation based on the cascade model with allowance for various groupings inside the nucleus, assuming some probability for their production and a momentum distribution for each grouping within the nucleus. The calculation could not be carried out completely because of the lack of data for the differential scattering cross sections for all the particles participating in the cascade. However, the calculation was able to predict kinematic relations such as the energy spectra of particles emitted at a certain angle and the relation between the energy and emission angle of the scattered particles. A comparison of the calculated and experimental results indicated that, for incident protons of less than 100 MeV, the fragments are produced by collisions with

[1]*Financial assistance received from the National Research Council of Canada.*
[2]*Present address: Department of Chemistry, Purdue University, Lafayette, Indiana.*

secondary nucleons. The decrease in asymmetry with energy was also attributed to this process.

There has been little radiochemical investigation of fragment emission induced by low-energy protons. We have chosen to study the variation of the ^{7}Be formation cross section with target mass for 85-MeV incident protons. The process of fragment emission is simplified at this energy, since the nuclear cascade is not yet well developed and since the energy is well below the threshold for meson production. At the present time, the lack of knowledge of the relevant differential scattering cross sections prohibits the calculation of cross sections for fragment formation according to a cascade process and it is not possible to determine fully the applicability of this mechanism. As a detailed test for the mechanism of evaporation, the dependence of cross section on the neutron-to-proton ratio of the target was investigated in a restricted mass region, and comparisons made with evaporation calculations.

II. EXPERIMENTAL

(A) Targets and Irradiations

Nuclei were chosen to span the nuclear mass range from oxygen ($A = 16$) to uranium ($A = 238$) with special interest in nuclei with masses from 48 to 65. For this mass region and incident particle energy, fragment emission is not obscured by the formation of fragments as residues while the expected cross sections indicate reasonable counting rates. Target nuclei are listed in Table I.

*Approximate thickness estimated for CuO powder.

Contamination of the target material by medium and heavy elements, determined by spectroscopic analysis,[3] is negligible as is shown in Table I. However, a spectroscopic analysis does not detect the presence of many light elements which have a relatively high ^{7}Be formation cross section. Such contamination may lead to false cross-section values, especially for the heavier targets. The oxygen layer on metal foils is a particular problem. All foils were cleaned to remove this layer and the targets were stored in an oxygen-free environ-

[3]*The authors are indebted to Brookhaven National Laboratory for these analyses.*

ment until irradiation. To detect the presence of gross light-element contamination, the difference in the shape of the excitation functions of light and heavier nuclei was exploited. Oxygen, a representative light element, was irradiated at proton energies from 30 to 85 MeV. The resultant excitation function is shown in Fig. 1. For our purposes the significant portion of the function is its negative slope from 65 to 85 MeV. The excitation function of ^{7}Be from a heavier element, aluminium, shown in Fig. 2, was constructed using our two cross-section values and the values of other workers. In this case the slope of the function is positive from 65 to 85 MeV. Previous high-energy results show that the cross section for formation of ^{7}Be from targets

heavier than aluminium always increases with energy up to the BeV region while the slope of the curve increases with increasing target mass. As a test for oxygen (and other light-element contamination), all targets were irradiated at 65 as well as at 85 MeV. If the resultant excitation functions in this energy region are plotted for all the targets, the slopes of the functions are expected to increase with increasing target mass. It was anticipated that any deviations from this trend would indicate gross oxygen contamination. The presence of oxygen in the target would increase the cross-section value at 65 MeV relative to the value at 85 MeV.

All target nuclei with the exception of oxygen were irradiated as foils. The reaction $^{27}Al(p,3pn)^{24}Na$ was used to monitor the proton beam, and the cross-section values given by Cumming (15) were used.

The enriched copper (99.9% ^{63}Cu) was obtained from Oak Ridge National Laboratory.

The target assembly consisted of three foils of aluminium (5.44 mg/cm^2 each) and three foils of the target element (x mg/cm^2 each). Thus the target foil and the monitor foil were both sandwiched between guard foils which served to minimize ^7Be loss by recoil from the target and to eliminate ^7Be gain by recoil from the aluminium foil. The monitor guard foils were used to avoid ^{24}Na recoil loss.

Generally the target was irradiated downstream from the monitor foil. For several irradiations an additional monitor (with guard foils) was placed downstream from the target foil but no difference was observed in the activity of the 'forward' and 'backward' monitor foils.

The foils were stacked, clamped, and carefully cut to ensure alignment, especially at the leading edge. The distribution of activity from the leading edge was determined, and accordingly after irradiation the first 1/8 in. of the leading edge was cut off and used. This portion, which was retained for use, contained 96% of the foil activity. The variation in foil area presented to the beam was found to be of the order of 1%.

On the basis of the activity distribution, ^7Be recoil loss from the leading edge was calculated to be less than 0.5%.

The thickness, x, of the target was chosen by imposing two limiting conditions, one tending to minimize x, the other to maximize it.

(i) Beam degradation.—x was chosen so that the energy degradation of the beam was less than the energy spread of the McGill synchrocyclotron (±2 MeV). The degradation of 85-MeV protons in various materials was estimated from the data of Aron *et al.* (16).

(ii) Recoil loss of ^7Be.—x was also chosen so that the target was thick enough to minimize loss of ^7Be from the foil surface. To estimate the recoil loss from the total target assembly (target plus guard foils), an approximation of the Sugarman, Campos, and Wielgoz (17) expression was used.

$$2W(F + B) = R, \qquad [1]$$

where $W = 3x$ = thickness of target foil stack, F = recoil loss in the forward direction (with respect to the beam), B = recoil loss in the backward direction, and R = range of recoil fragment.

To calculate the range of ^7Be in various target materials, it was assumed that the ^7Be fragments were emitted with energy equal to the coulomb barrier. The range–energy curves of Hower (18) for ^9Be in Al and Au were used to get approximate values for ^7Be. It was always possible to choose W so that the recoil loss from the target stack was less than 5% while satisfying the first condition. Hence the recoil loss from the target foil itself was negligible. Foil thicknesses used are given in Table I.

Oxygen was irradiated as CuO powder wrapped in gold foil. The 'specpure' CuO was obtained from Johnson, Mathey and Co., Ltd. Impurities are listed in Table I as detected by spectrographic analysis. To correct for ^7Be produced from copper and gold, blank irradiations of Cu powder in gold foil were made at 70 and 85 MeV. The reaction $^{65}Cu(p,pn)^{64}Cu$ was employed to monitor the beam and Meadows' cross-section values, as corrected by Meghir and Yaffe (19), were used as standards.

Irradiations were performed using the internal beam of the McGill synchrocyclotron. To produce observable amounts of ^7Be the irradiation time for each target was estimated on the basis of the expected cross section and the beam intensity of approximately 5×10^{12} protons/s. The duration of bombardments was ½ to 2 h. The energy of the incident protons was obtained from a known radius–energy relation (20).

(B) Chemical Separations

(1) Beryllium

The target was dissolved in a suitable acid and a known amount of beryllium carrier (about 15 mg) was added.

Separation methods given by Baker, Friedlander, and Hudis (12) were used to purify ^7Be from other radioactive nuclides.

The major contaminating activity in aluminium targets is ^{22}Na. Its 511-keV annihilation γ-ray interferes with the measurement of the 477-keV γ-ray of ^7Be. Beryllium and aluminium were separated from sodium by precipitation of beryllium and aluminium hydroxides with ammonia. Aluminium was precipitated as $AlCl_3.6H_2O$ by addition of ether and HCl (gas). Beryllium was then purified by extracting basic beryllium acetate with chloroform. The chloroform was evaporated, the residue dissolved in acid, and $Be(OH)_2$ was precipitated with a slight excess of ammonia.

The separation from all other targets (CuO, Ti, V, Fe, Ni, Co, Cu, Ag, Au, and U) was essentially the same. $Be(OH)_2$ was precipitated a number of times with ammonia. The final precipitate was dissolved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

concentrated hydrochloric acid and the solution was passed through a Dowex-1X-10 ion–exchange column. $Be(OH)_2$ was again precipitated and dissolved, then a ferric hydroxide scavenging precipitation with NaOH performed. Beryllium acetylacetonate was extracted in the presence of excess ethylenediaminetetraacetic acid at pH 4–5 into benzene. Beryllium was back-extracted with 6 *N* HCl and $Be(OH)_2$ was precipitated after evaporation steps with nitric acid and the separation steps were repeated if the ^{7}Be sample was not radiochemically pure.

The chemical yields of beryllium were determined by the spectrophotometric method described by Sandell (21) using the complexing agent *p*-nitrobenzeneazoorcinol.

(2) Sodium

Chemical separation of sodium from the aluminium monitor foils was not necessary. Because of the short half-lives of other radioactive nuclides likely to be produced in the bombardment, no interfering activity is present if ^{24}Na ($t_{1/2}$ = 15 h) is measured 24 h after bombardment.

(3) Copper

It was necessary to separate the copper monitor from the CuO targets. After $Be(OH)_2$ precipitation, $Cu(OH)_2$ was precipitated from the solution, dissolved in concentrated HCl, and evaporated to a small volume. The copper was then purified by absorption on a Dowex-1X-10 column with 4.5 *M* HCl and elution from the column with 1.5 *M* HCl.

The chemical yields of the copper were determined by titration with the disodium salt of ethylenediaminetetraacetic acid using a murexide indicator (22).

(C) Activity Measurements

The activity of all samples was obtained by γ-ray scintillation spectrometry.

^{7}Be decays by K-capture to ^{7}Li with 10.32% of the decays going to the 477-keV state and the remainder to the ground state (23). The decay is characterized by a 53.6-day half-life. The internal conversion coefficient is negligibly small ($\alpha_K = 5.8 \times 10^{-7}$).

Since a high detection efficiency was required, the activity of ^{7}Be samples was measured using a $1\frac{3}{4}$ in. × 2 in. NaI(Tl) crystal with a center well 5/8 in. in diameter and $1\frac{1}{2}$ in. deep in conjunction with a single channel pulse-height analyzer set to accept pulses about the 477-keV photopeak.

A standard ^{7}Be source was used to calibrate the well counter and to check its day-to-day stability. The absolute gamma activity of the standard source was obtained in two ways: (i) The activity of the source was measured by a 3 in. × 3 in. NaI crystal coupled to a 100-channel pulse-height analyzer. The assembly had been calibrated to yield the detection efficiencies for gamma rays of various energies by Grant (24), who had calibrated the counter for standard gamma sources against a $4\pi\beta$ proportional counter. (ii) The absolute gamma activity of a standard ^{7}Be source was determined by Dr. D. Santry[4] of the Chalk River Nuclear Laboratory of Atomic Energy of Canada Limited. The two independent measurements agreed within 5%.

The background counting rate of the counter was about 14.5 c.p.m. Samples with net count rates as low as 2 c.p.m. could be measured with reasonable accuracy.

The purity of ^{7}Be samples was indicated by the 53.6-day half-life found. The decay was followed for at least seven half-lives. The gamma activity of sufficiently active samples was checked on the 100-channel analyzer and the resultant spectra compared with that of the standard ^{7}Be source.

The 1.368-MeV γ-ray of ^{24}Na was detected and measured by the 100-channel analyzer assembly.

A γ–γ coincidence counter was used to measure the 511-keV annihilation γ-radiation of ^{64}Cu. The γ-γ coincidence unit was calibrated against a $4\pi\beta$ counter using ^{22}Na.

III. RESULTS

The gamma activities at the end of bombardment were converted to disintegration rates and cross sections were determined in the usual manner.

Errors involved in the cross-section determinations may be classified as systematic and random.

(1) Systematic Errors

Systematic errors are associated with monitor cross sections, detection efficiencies, branching ratios, internal conversion coefficients, and half-life values.

The limit quoted by Cumming (15) for the reaction ^{27}Al(p,3pn)^{24}Na cross section is ±6.5%, whereas the limit quoted by Meghir (25) for the reaction ^{65}Cu(p,pn)^{64}Cu is ±14%. An error of ±5% was quoted by Grant (24) for the determination of the detection efficiency of the 3 in. × 3 in. crystal. An error of ±5% was also assessed for the detection

[4]*The authors are indebted to Dr. Santry for performing the measurement.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

efficiency of the well crystal. Taylor and Merritt (23) cite an error of ±1% for their value of the branching ratio of ^{7}Be. The errors in the branching ratio values for ^{24}Na and ^{64}Cu have been given as ±1% and ±2% (25) respectively. The magnitude of other systematic errors was negligible.

(2) Random Errors

Random errors are connected with light-element contamination, gamma activity determinations, chemical yields, foil thickness measurements, alignment accuracy, and dilution factors.

The error associated with light-element contamination of the target is difficult to assess in most cases. In the following section it is seen that there is evidence of light-element contamination of certain targets. The corresponding cross-section values for ^{7}Be production from these targets were corrected for ^{7}Be production from the light-element contamination. In each case an estimate was made of the uncertainty associated with the measured cross-section value. At least 10 000 counts were accumulated in each gamma measurement so that statistical fluctuations in the count rate were reduced to ±1%. The error in the determination of the area of the 1.368-MeV photopeak was estimated to be ±6%. An error of ±3% was assigned to count rates determined by coincidence technique (26). Chemical yields were determined in duplicate and sometimes in triplicate. They agreed within 3–5%. The uncertainty in the determination of superficial density was ±1%. The variation in foil area presented to the beam was 1%. The error associated with pipetting and diluting was ±1%.

The total error was calculated by taking the square root of the sum of the squares of the individual errors cited above for both ^{7}Be and the monitor. The uncertainty in the measured cross sections for ^{7}Be from oxygen was estimated to be ±17% (the monitor was copper). The lower limit of the uncertainty in the measured cross sections for ^{7}Be from the other targets was estimated to be ±13% (the monitor was aluminium). The uncertainty associated with the cross-section values corrected for light-element contamination is given in the following section. Table II contains the results of the cross-section measurements. The ^{7}Be cross section, $\sigma_{^{7}\mathrm{Be}}$, is listed for each target and relevant proton bombarding energy, E_{p}. The mean value of the cross section, $\bar{\sigma}_{^{7}\mathrm{Be}}$, is given if more than one cross section was obtained at a given energy; the deviation of cross-section values from the mean is also given. Duplicate measurements agreed within the limits estimated above.

The presence of oxygen and (or) light-element contamination in the target was indicated by the comparison of the cross-section measurements at 65 and 85 MeV. The cross-section values are plotted as a function of energy in Fig. 3. For each target a straight line drawn through the points approximates the excitation function in the energy region. As previously discussed in Section II, A, the slope of the excitation function for ^{7}Be formation is expected to be a function of target mass. In Fig. 3, the slope of the O(p,^{7}Be) excitation function is negative; the slope of the Al(p,^{7}Be) excitation function is positive, whereas the slope of the excitation functions of ^{7}Be from V, Ni, Co, and Cu increase in steepness with increasing target mass. However, the slope of the Ti(p,^{7}Be) excitation function is steeper than expected from the general trend, whereas the Ag(p,^{7}Be) excitation function is much flatter than expected.

Titanium is known to have a tenacious surface layer of oxygen. The observed ^{7}Be cross section for the two irradiations at 85 MeV was higher than expected. Therefore for the irradiation at 65 MeV the surface of the target was cleaned after as well as before irradiation. To obtain a corrected cross-section value at 85 MeV, denoted $(\bar{\sigma}_{^{7}\mathrm{Be}})_{\mathrm{c}}$, the cross-section value at 65 MeV was then extrapolated to 85 MeV using a straight line of the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

slope as the V(p,^{7}Be) excitation function. The error associated with the corrected cross-section value was large, estimated to be ±40%.

*Obtained by calculation from experimental values for ^{63}Cu and Cu.

For the Ag(p,^{7}Be) reaction, the measurements at 65 and 85 MeV were made under the same conditions. The similarity of the two results definitely indicates light-element contamination in the silver target. It was assumed that at 65 MeV the measured ^{7}Be was produced mainly from the light elements. The amount of ^{7}Be produced from light elements at 85 MeV was calculated by extrapolating the measured cross-section value at 65 MeV to 85 MeV using a straight line with the same slope as the O(p,^{7}Be) excitation function; this cross-section value was then subtracted from the observed cross section to yield an estimate of the ^{7}Be cross section from silver. The error associated with the corrected cross-section value is also very large, estimated to be ±100%.

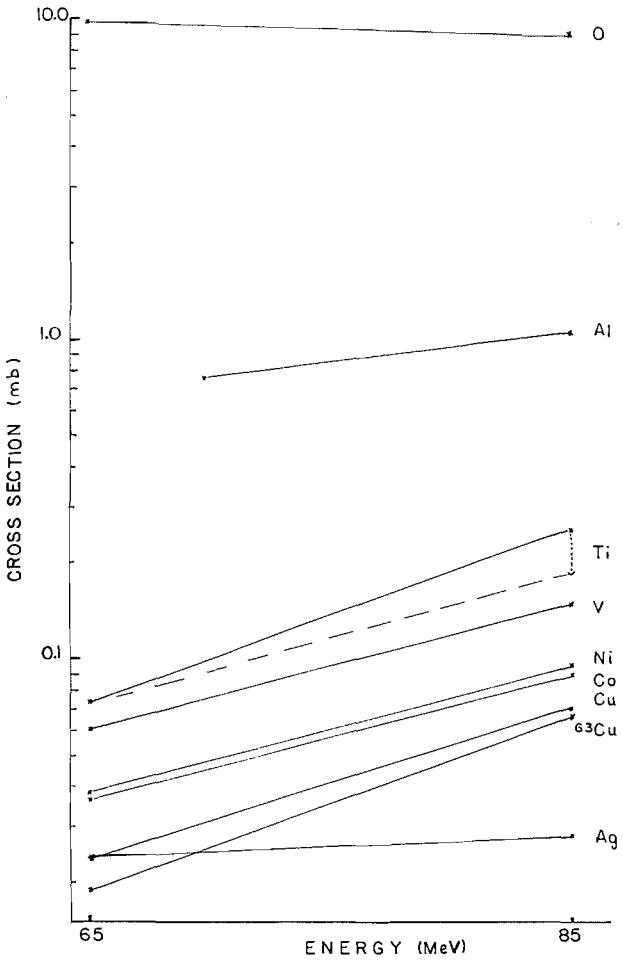

FIG. 3. ^{7}Be cross sections plotted against energy of the incident proton.

The same procedure was used to obtain a very rough estimate of the ^{7}Be cross section from gold. The error associated with the corrected cross-section value was estimated to be $\pm 300\%$.

It was not possible to obtain even an estimate of the cross-section value for uranium because of the low ^{7}Be production and the high contamination of the target.

The variation of the ^{7}Be formation cross section with target mass number A is shown in Fig. 4 for bombarding protons of 65 and 85 MeV energy. The uncertainty in the cross-section value is shown by the vertical bar.

III. DISCUSSION

(A) Evaporation Calculations

According to evaporation theory (27), the cross section for the emission of ^{7}Be from an excited nucleus is given by

$$[4] \qquad \sigma_{^{7}\mathrm{Be}} = \sigma_{F} \times \frac{\Gamma_{^{7}\mathrm{Be}} + \Gamma_{^{7}\mathrm{Be}^{*}}}{\sum_{j} \Gamma_{j}},$$

where σ_{F} = formation cross-section of the excited nucleus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

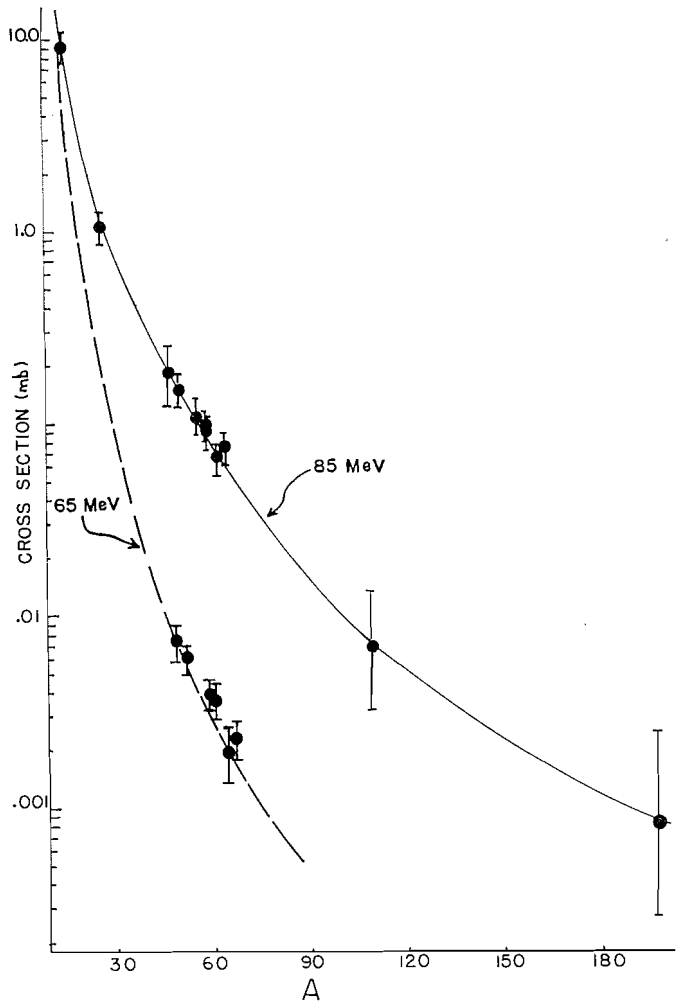

FIG. 4. Cross section plotted against mass number, A, for the production of ^{7}Be in targets irradiated with 65- and 85-MeV protons.

Γ_j = emission width for particle j

$$= \frac{g_j m_j}{\pi^2 \hbar^3} \int \sigma^*(E_j) \times \frac{\omega(E_f)}{\omega(E_i)} \times E_j \times \mathrm{d}E_j \qquad [5]$$

where g_j = number of spin states of particle j, m_j = mass of particle j, $\sigma^*(E_j)$ = cross section for the inverse reaction, E_j = kinetic energy of particle j, $\omega(E_f)$,$\omega(E_i)$ = level densities of the final and initial nuclei at their respective excitation energies.

$\Gamma_{^{7}\mathrm{Be}^*}$ refers to the excited state of ^{7}Be, 0.43 MeV above the ground level. (The production of excited states of heavy particles as well as the ground state must be considered.)

The starting point for evaporation calculations is the spectrum of excited nuclides left after the completion of the knock-on cascade.

The *maximum* energy available for the evaporation of ^{7}Be from a residual nucleus (i.e. the maximum kinetic energy of the outgoing ^{7}Be) may be approximated as (28):

$$R_{^{7}\mathrm{Be}} \sim E^* - Q_{^{7}\mathrm{Be}} - \delta_{^{7}\mathrm{Be}}, \qquad [6]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where E^* = excitation energy of residual nucleus, $Q_{^7Be}$ = separation energy of ^7Be from residual nucleus, $\delta_{^7Be}$ = nucleon-pairing correction.

According to the sharp cutoff approximation, the *minimum* kinetic energy of a ^7Be particle is given by the effective coulomb barrier, $k_{^7Be}V_{^7Be}$.

The difference between the maximum and minimum energy may be regarded as the energy available for a residual nucleus to evaporate a particle. The factor $(R_{^7Be} - k_{^7Be}V_{^7Be})$ was estimated for residual nuclei which were formed by specific types of cascades. Average excitation energies of residual nuclei, calculated by Metropolis *et al.* (29), were used to give an average value of $R_{^7Be}$. The factor $k_{^7Be}V_{^7Be}$ was calculated in the manner described in the following section. The estimation was performed for 82-MeV protons incident on the targets Al, Cu, and U, and the results are shown in Table III.

TABLE III

Average energy available for the evaporation of ^7Be from residual nuclei formed by specific-type cascades (82-MeV incident protons)

	$\bar{R}_{^7Be} - k_{^7Be}V_{^7Be}$ (MeV)		
Type of cascade	Al	Cu	U
Compound nucleus formation	49.8	49.4	40.5
p,n	0.7	10.2	7.2
p,p′	−0.5	3.4	−4.6
p,2n	−2.7	−1.2	−10.6
p,pn	−12.0	−11.6	−22.8
p,2p	−14.6	−14.4	

As seen in Table III, it is unlikely that ^7Be will be evaporated from nuclei which have been formed with the ejection of cascade particles. To simplify the present calculation, it is assumed that ^7Be is evaporated solely after compound nucleus formation.

Energy considerations also suggest that ^7Be is most probably evaporated from the compound nucleus itself but may also be evaporated from the product nuclei formed by particle evaporation.

(1) Cross Section for the Formation of ^7Be from the Compound Nucleus

The cross section for the emission of ^7Be from the compound nucleus was calculated according to eq. [4]: The important factors to be evaluated in this equation are the inverse cross section and the level density.

(i) $\sigma^*(E)$ – inverse cross section.—The inverse cross section was assumed equal to the total reaction cross section for particles incident upon a nucleus in its ground state.

The variation of charged-particle capture cross sections with energy and atomic number was approximated according to the well-known sharp cutoff expression

$$[7] \qquad \sigma^*(E_j) = \begin{cases} 0 & \text{for } E_j < k_jV_j \\ \pi R^2(1 + c_j)(1 - k_jV_j/E_j) & \text{for } E_j > k_jV_j \end{cases}$$

where c_j and k_j are parameters that are functions of atomic number, z, and V_j is the coulomb barrier. Dostrovsky, Fraenkel, and Friedlander (28) determined the values of the parameters c_j and k_j for protons, alphas, ^3H, and ^3He particles by the best fit of eq. [7] to tabulated continuum theory cross sections of Shapiro (30) and Blatt and Weisskopf (31). The classical barrier, V, was calculated by the formula

$$[8] \qquad V = zZe^2/R,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where z, Z = atomic number of outgoing particle and residual nucleus respectively, e = electron charge, and $R = r_0A^{1/3} + \rho$ = interaction radius between nucleus and charged particle. r_0 was set equal to 1.5×10^{-13} cm, ρ was taken equal to zero for protons and equal to 1.2×10^{-13} cm for all other emitted particles, and A = mass number of residual nucleus.

No calculations have been performed to evaluate the dependence of the reaction cross-section of ^{7}Be on energy and atomic number. Therefore the parameters $c_{^{7}\mathrm{Be}}$ and $k_{^{7}\mathrm{Be}}$ were determined in the following way:

Experimentally the reaction of 85-MeV protons incident on various targets was studied. The reaction is represented as p(A,^{7}Be)B. ^{7}Be was emitted with kinetic energies ranging from $k_{^{7}\mathrm{Be}}V_{^{7}\mathrm{Be}}$ (the energy required to overcome the coulomb barrier) to $R_{^{7}\mathrm{Be}}$ (the maximum kinetic energy of emission given in eq. [10]). The computer program of D. R. Sachdev[5] was used to evaluate the reaction cross-section of ^{7}Be incident on various targets, B, with energy ranging from $k_{^{7}\mathrm{Be}}V_{^{7}\mathrm{Be}}$ to $R_{^{7}\mathrm{Be}}$. The calculation followed the outline described by Thomas (32) for the square-well potential model. Thomas found reasonable agreement with experiment for the radius parameter $r_0 = 1.5 \times 10^{-13}$ cm, hence this value was used. The computation was performed by an IBM 7040. For each target the reaction cross section of ^{7}Be was evaluated at 1-MeV intervals between the energy limits. In Fig. 5 the calculated cross section of ^{7}Be is plotted as a function of energy for ^{7}Be particles incident on $^{42}_{19}$K. As is shown in the figure a good fit to the curve was obtained using eq. [7] with $(1 + c_{^{7}\mathrm{Be}}) = 0.974$ and $k_{^{7}\mathrm{Be}} = 0.983$. The classical barrier was calculated using eq. [8] with $\rho = 2.43 \times 10^{-13}$ cm (33). The calculated cross-section curve was fitted with eq. [7] for each case of interest and the resultant values of $1 + c_{^{7}\mathrm{Be}}$ and $k_{^{7}\mathrm{Be}}$ are listed in Table IV.

TABLE IV

Parameters in eq. [11] for ^{7}Be cross sections

A	Z	$1 + c_{^{7}\mathrm{Be}}$	$k_{^{7}\mathrm{Be}}$

In every instance a good fit to the calculated curve was obtained and the fit was always remarkably good in the low-energy region where the sharp cutoff approximation is the weakest.

The energy and mass number dependence of neutron capture cross sections as given by continuum theory (31) was approximated according to Dostrovsky *et al.* (28).

$$\sigma^*(E_n) = \alpha(1 + \beta/E_n)\pi R^2, \qquad [9]$$

where $\alpha = 0.76 + 2.2A^{-1/3}$, and $\beta = (2.12A^{-2/3} - 0.050)/(0.76 + 2.2A^{-1/3})$ MeV.

[5]*The authors are indebted to Mr. D. R. Sachdev for the use of his computer program.*

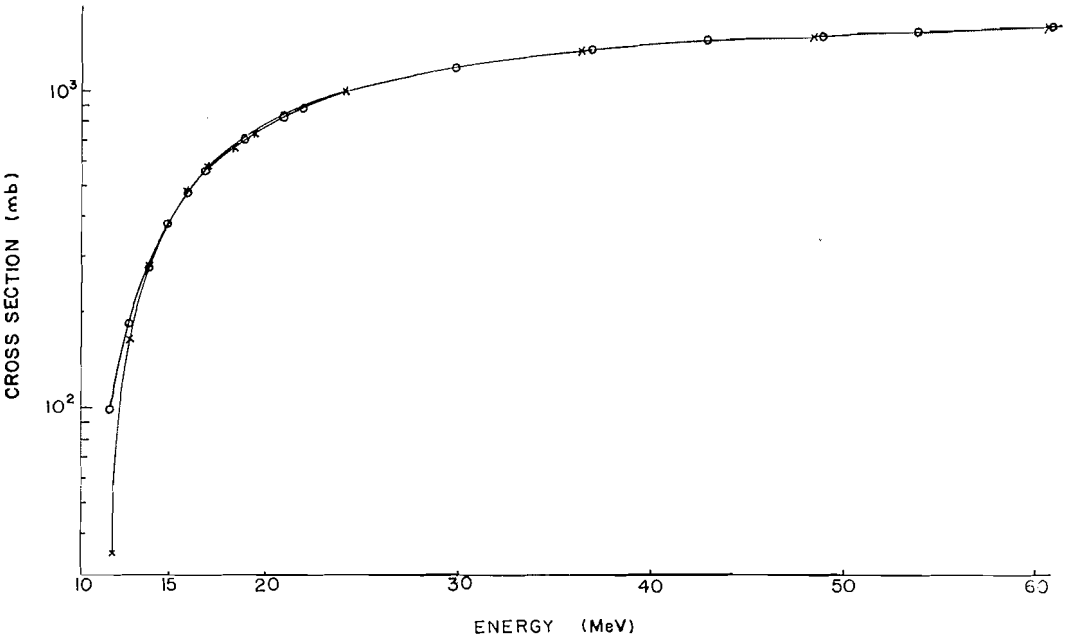

FIG. 5. Reaction cross section for ^{7}Be particles incident on $^{42}_{19}$K as a function of energy. (○) Cross section computed according to outline described by Thomas (32) for the square-well potential model, (×) $\sigma = \pi R^2(1 + c_{^7\mathrm{Be}})(1 - k_{^7\mathrm{Be}}V_{^7\mathrm{Be}}/E_{^7\mathrm{Be}})$.

(ii) $\omega(E)$ – level density.—We have chosen to use a level density formulation based on the Fermi-gas model (34–36).

$$\omega(E) = C(E - \delta)^{-2} \exp\left[2\{a(E - \delta)\}^{1/2}\right], \qquad [10]$$

where C = constant, E = excitation energy, a = level density parameter, and $\delta = 0$ for odd–odd nuclei and $\delta > 0$ for all other types. The value of δ is usually taken to be the pairing energies for neutrons and protons. Cameron's (37) tabulation of pairing energies for even values of Z and N has been used in the present calculations.

In order to explain the effect of shell structure on level densities observed at the neutron binding energy, the level density parameter has been formulated by Newton (38) and Lang (35) as

$$a = 0.0748(\bar{j}_n + \bar{j}_p + 1)A^{2/3}, \qquad [11]$$

where $\bar{j}_n$ and $\bar{j}_p$ are mean values of the spins of the neutron and proton shell-model states which correspond to a particular $A = N + Z$. The values of $\bar{j}_n$ and $\bar{j}_p$ are obtained from Klinkenberg's (39) shell-model scheme based on a study of nuclei in or near their ground states. The influence of shell effects is expected to disappear with increasing excitation energy, but it is not known up to what energies shell effects are important.

Two values of the level density parameter have been used in the present calculation: $a = A/10$ and $a = 0.0748\,(\bar{j}_n + \bar{j}_p + 1)A^{2/3}$.

The emission width was computed by substituting the inverse cross section as given by eqs. [7] and [9] and the level density as given by eq. [10] into eq. [5].

$$\Gamma_j = \frac{g_j m_j}{\pi\hbar^2} r_o^2 A_j^{2/3} \times (E - \delta_o)^2 \exp\left[-2\{a_o(E - \delta_o)\}^{1/2}\right] C_j \qquad [12]$$

$$\times \int_{k_jV_j}^{E_j} (E_j + \beta - k_jV_j) \exp\left[2\{a_j(E - Q_j - \delta_j - E_j)\}^{1/2}\right](E - Q_j - \delta_j - E_j)^{-2} \times dE_j,$$

For personal use only.

where subscripts o and j refer to the original and residual nucleus respectively. For neutrons, C_j denotes α and $k_j = 0$; for protons, C_j denotes $(1 + c_j)$ and $\beta = 0$.

Because the integration of eq. [12] in closed form is not possible, its integral was approximated by the summation:

$$[13] \quad \sum_{k_j V_j}^{R_j} (E_j + \beta - k_j V_j) \exp\{2(a_j(E - Q_j - \delta_j - E_j)]^{1/2}\} (E - Q_j - \delta_j - E_j)^{-2} \Delta E_j.$$

The summation was performed by an IBM type 7040 computer for $E_j = 0.1$ MeV. Sample emission widths were calculated for values of ΔE_j ranging from 0.01 to 1.0 MeV. Emission width was plotted as a function of ΔE_j and the value of the emission width for $\Delta E_j = 0$ was determined by extrapolation. It was found that the emission width calculated for $\Delta E_j = 0.1$ MeV differed from the estimated emission width for $\Delta E_j = 0$ MeV by 0.001%. Smaller values of ΔE_j greatly increased the computer time required to perform the summation.

Separation energies, Q, were computed on the basis of experimental atomic mass data compiled by Konig *et al.* (40). For nuclei for which experimental mass values were not available, masses computed from Levy's (41) empirical mass formula were used.

The emission width was determined for two values of the level density parameter. For $a = 0.0748\ (\bar{j}_n + \bar{j}_p + 1)A^{2/3}$, emission width was determined for neutrons, protons, deutrons, tritons, alphas, ^{3}He, ^{7}Be, and ^{7}Be* particles. The probability of ^{7}Be emission,

$$P_{^7\mathrm{Be}} = \frac{\Gamma_{^7\mathrm{Be}} + \Gamma_{^7\mathrm{Be}^*}}{\sum_j \Gamma_j},$$

was then calculated. The inclusion of the emission width of tritons and ^{3}He particles to the sum $\sum_j \Gamma_j$ made little difference to the value obtained for $P_{^7\mathrm{Be}}$. Hence for the level density parameter $a = A/10$, emission width determination was confined to neutrons, protons, deuterons, alphas, ^{7}Be, and ^{7}Be* particles.

The formation cross section of the compound nucleus was determined according to

$$[14] \quad \sigma_F = \sigma_R F_{CN},$$

where σ_R = proton-reaction cross section, and F_{CN} = fraction of reaction which yields compound nucleus formation.

The proton-reaction cross section was calculated using eq. [7] with $r_o = 1.5 \times 10^{-13}$ cm.

The fraction yielding compound nucleus formation was obtained from the results of the Monte Carlo calculations on intranuclear cascades of Metropolis *et al.* (29) and Turkevich (42).

The calculated quantities for the proton-reaction cross section, σ_R, the fraction of compound nucleus formation, F_{CN}, the probability of ^{7}Be emission from the compound nucleus, $(P_{^7\mathrm{Be}})^{CN}$, and the cross section for ^{7}Be emission from the compound nucleus, $(\sigma_{^7\mathrm{Be}})^{CN}$, are presented in Table V.

For the level density parameter $a = 0.0748(\bar{j}_n + \bar{j}_p + 1)A^{2/3}$, calculated and experimental ^{7}Be cross sections are plotted as a function of target mass number, A, in Fig. 6. This value of the level density parameter fails to predict the observed variation of cross section for ^{7}Be formation with target element. There is no relation between calculation and experiment. The shell effects observed at low energies and represented by the Newton–Lang formulation do not persist then to the excitation energies encountered here. This was predicted by Ericson (43), who cautioned about the use of the Newton formula for excitation energies much above neutron-binding energies.

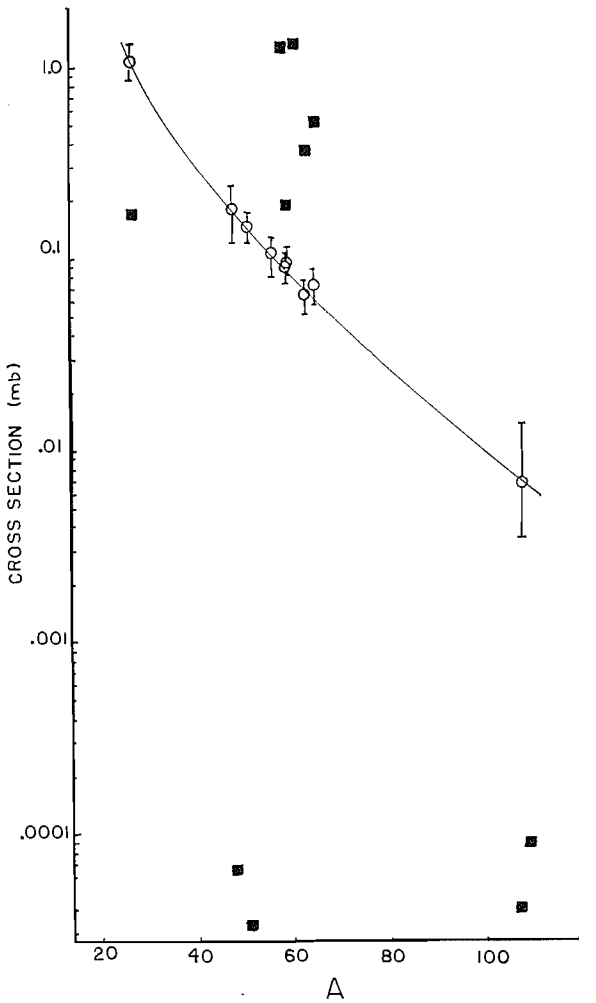

FIG. 6. Cross sections plotted against mass number, A. (○) Experimental cross-section values, (■) calculated cross sections for ^{7}Be formation from the compound nucleus, $(\sigma_{^7\mathrm{Be}})^{\mathrm{CN}}$, for $a = 0.0748(\bar{j}_n + \bar{j}_p + 1)A^{2/3}$.

(2) Estimate of the Total Cross Section for Formation of ^{7}Be

The contribution to the ^{7}Be cross section for ^{7}Be evaporated after particle emission was estimated in the following approximate manner:

In the first step of the evaporation chain, the compound nucleus de-excites by evaporating a particle of varying kinetic energy. The excitation energy of the product nucleus so formed is a function of this kinetic energy. The most probable kinetic energy, E_{mp}, of the evaporated particle has been given by Dostrovsky, Fraenkel, and Friedlander (28) as

$$[15] \qquad E_{mp} = V + a_j^{-1}[(a_j R_j + 1/4)^{1/2} - \tfrac{1}{2}],$$

where $V = k_j V_j$ for charged particles, and $V = -\beta$ for neutrons. For each compound nucleus of interest, the most probable excitation energy of the product nuclei formed by neutron, proton, deuteron, and alpha emission was thus determined. The probability of ^{7}Be emission from each product, $(P_{^7\mathrm{Be}})j$, at its most probable excitation energy, was calculated as in the preceding section.

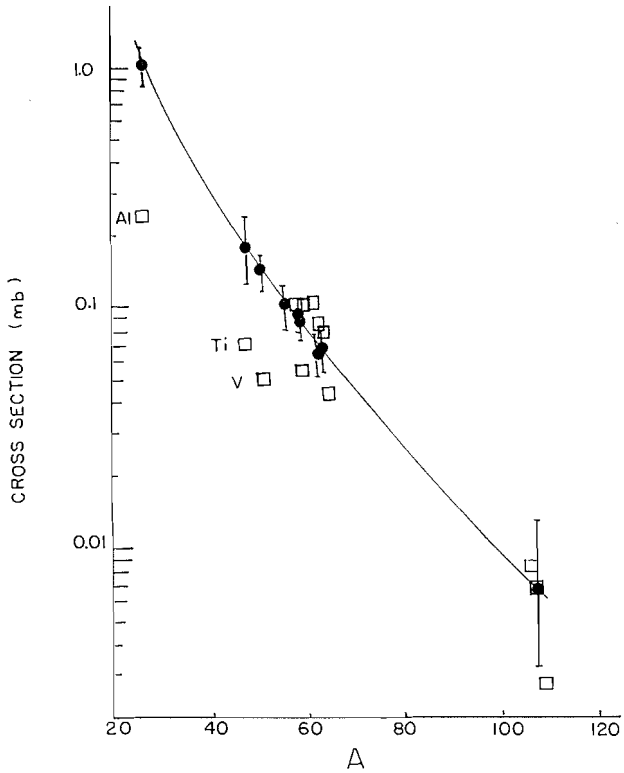

FIG. 7. Cross section plotted against mass number, A. (●) Experimental cross-section values, (□) calculated cross sections for $a = A/10$.

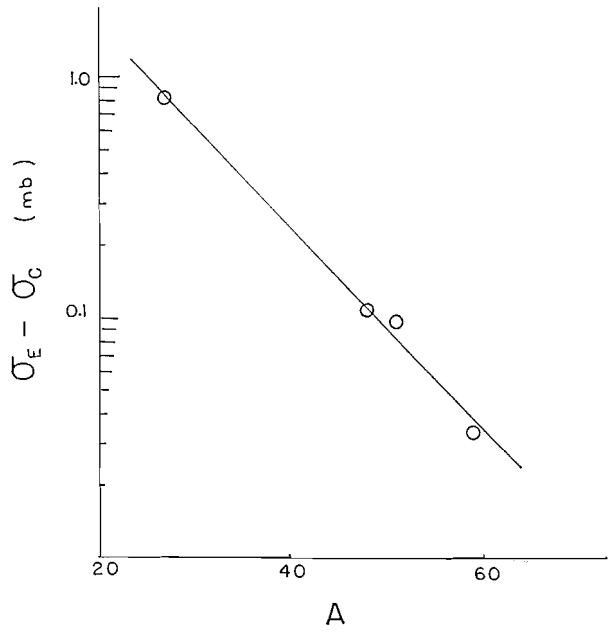

FIG. 8. ($\sigma_E - \sigma_C$) plotted against mass number, A.

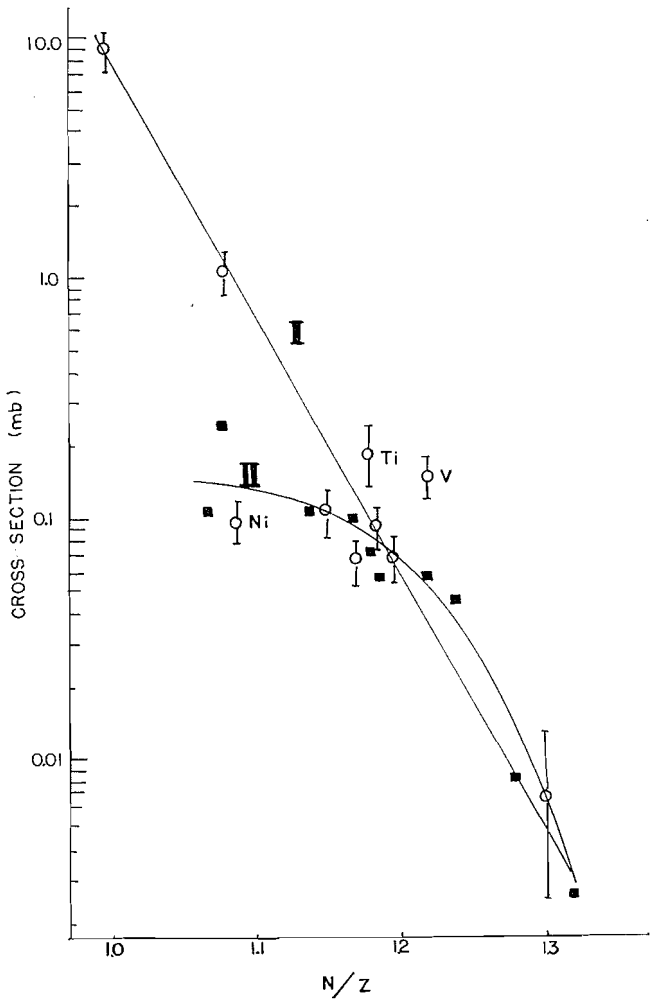

FIG. 9. Cross sections plotted against target neutron-to-proton ratio, N/Z. (○) Experimental cross-section values, (■) calculated cross sections for $a = A/10$.

The contribution from ^{7}Be emission further along the evaporation chain was assumed to be negligible on the basis of energy considerations.

The total ^{7}Be cross section was then estimated to be:

$$[16] \quad \sigma_{^{7}\mathrm{Be}} = \{(P_{^{7}\mathrm{Be}})^{\mathrm{CN}} + (P_{\mathrm{n}})^{\mathrm{CN}}(P_{^{7}\mathrm{Be}})^{\mathrm{n}} + (P_{\mathrm{p}})^{\mathrm{CN}}(P_{^{7}\mathrm{Be}})^{\mathrm{p}} + (P_{\mathrm{d}})^{\mathrm{CN}}(P_{^{7}\mathrm{Be}})^{\mathrm{d}} + (P_{\alpha})^{\mathrm{CN}}(P_{^{7}\mathrm{Be}})^{\alpha}\}\sigma_{\mathrm{F}}.$$

The cross section for ^{7}Be formation, $\sigma_{^{7}\mathrm{Be}}$, was estimated according to eq. [16] for the level density parameter $a = A/10$ and is given in Table V.

In Fig. 7, calculated and experimental ^{7}Be cross sections are plotted as a function of target mass number, A. With the exception of the light elements there is reasonable agreement between calculated and experimental values. However, the experimental points vary smoothly with A, whereas the calculated points are scattered. Scatter of the experimental points may be masked by the experimental error. Dostrovsky *et al.*[4](4)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

found that cross sections for fragment production in irradiations with high-energy protons were a smoother function of the target neutron-to-proton ratio, N/Z, than the target mass, A. In the following section, experimental and calculated ^{7}Be cross sections are plotted as a function of N/Z.

The calculation underestimates the production of ^{7}Be from the light targets Al, Ti, and V. The underestimation does not seem to be due to the fact that the contribution of ^{7}Be evaporation following knock-on cascade was neglected. Examination of Table V indicated that after the knock-on cascade more energy is available for ^{7}Be evaporation from irradiated Cu than Al. In Fig. 8, the difference between the calculated and experimental ^{7}Be cross sections, $(\sigma_E - \sigma_C)$, is plotted against target mass number, A. Although the points are limited and the errors are large, the trend seems to indicate a straight line, suggesting that a mechanism other than evaporation contributes to the formation of ^{7}Be in these targets.

(B) Variation of the Cross Section for ^{7}Be Emission With The Neutron-to-Proton Ratio of the Target

Dostrovsky *et al.* (4) observed a dependence of the cross section for the formation of the neutron-excess fragments ^{9}Li, ^{16}C, and ^{17}N on the neutron-to-proton ratio of the target in irradiations with GeV protons. Hence calculated ($a = A/10$) and experimental values of the ^{7}Be cross section are plotted as a function of target neutron-to-proton ratio, N/Z, in Fig. 9. A straight line, I, may be drawn through the experimental points for the targets O, Al, Co, Cu, and Ag. There is considerable scatter of the rest of the points about this line. Points for the neutron-rich targets Ti and V are above the line. The point for the neutron-poor Ni is substantially below the line.

However, as was shown in Fig. 8, it seems highly possible that a mechanism other than evaporation contributes significantly to the production of ^{7}Be in the irradiated targets Al, Ti, and V, while spallation accounts for a large fraction of the production of ^{7}Be from O. A curve, II, may be drawn through the experimental points for the remaining targets as well as the calculated points.

The variation of ^{7}Be cross section with target neutron-to-proton ratio seems to suggest that more than one mechanism is responsible for ^{7}Be formation. However, the data are too limited to be conclusive.

As shown in Fig. 7, evaporation theory does predict the N/Z dependence of ^{7}Be cross sections for medium mass targets ($A > 55$). According to evaporation theory, the dependence of cross section on target neutron-to-proton ratio arises primarily from differences in the binding energies of ^{7}Be in the evaporating nuclei. The decrease in cross section with target mass for the neutron-deficient fragment ^{7}Be may be partly attributed to the fact that, as the target mass increases, the neutron-to-proton ratio of the fragment becomes further removed from the neutron-to-proton ratio of the stability valley of the target region (the decrease in cross section is also attributable to the increase in the factor $k_{^7\mathrm{Be}}V_{^7\mathrm{Be}}$).

(C) Concluding Remarks

The present work adds to the evidence that more than one mechanism contributes to fragment formation. Evaporation as a mechanism for ^{7}Be emission from medium and heavy targets ($A > 55$) has successfully predicted cross-section magnitudes and the variation of cross section with the neutron-to-proton ratio of the target. However, the latter does not uniquely indicate an evaporation mechanism. Indeed the asymmetry of fragment angular distribution (44) contradicts such a process.

This asymmetry has suggested that fragments are produced by the direct process of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the scattering of nucleons on nucleon clusters. The effect of collisions with clusters is expected to be more important in interactions with light nuclei where the cascade is likely to consist of one, two, or three collisions. In heavy nuclei, collisions with single nucleons are expected to increase with target mass. This explains the decrease in fragment asymmetry with increase in target mass, and, for the non-evaporation mechanism, the decrease in fragment production with target mass shown in Fig. 8.

ACKNOWLEDGMENTS

The authors wish to thank Professor R. E. Bell, Director, Foster Radiation Laboratory, for permission to use the McGill synchrocyclotron, and Mr. R. H. Mills, who cheerfully performed the irradiations. One of us (M. S. L.) wishes to thank the National Research Council of Canada for studentships held during 1959–1963.

CHEMICAL SHIFT CHANGES IN FLUOROANIONS OF SOME DIAMAGNETIC SALTS[1]

RIZWANUL HAQUE AND L. W. REEVES

INTRODUCTION

In most processes occurring in electrolyte solutions the nuclear magnetic resonance signal observed for a solvent or solute nucleus is a time average of all environments rather than a series of separate peaks. Gutowsky and Saika (1) used this fact to measure dissociation constants of acids and Shoolery and Alder (2) interpreted the changes in chemical shift of the proton resonance in water as a function of the concentration of diamagnetic electrolyte added as a sum of several time-averaged processes. In this note we shall present results pertaining to the solute resonance peaks in simple and complex fluoroanions.

For the solvent proton resonance (3–6) changes in chemical shift are due to breaking of hydrogen bonds and a polarization effect due to the distortion of water molecules near a positive ion. Axtmann (7) has correlated the proton chemical shift changes in water with the pK of the salt. Taube and co-workers (8–10) and Connick and co-workers (11–14) have

[1]*Research supported by the National Research Council of Canada and the Petroleum Research Fund of the American Chemical Society.*

measured both the relaxation characteristics and the resonance positions for enriched ^{17}O water in aqueous solutions of electrolytes. They have been able to determine hydration numbers of diamagnetic cations and rates of exchange of water molecules between the bulk solution and the first coordination sphere.

In this work we shall present some chemical shift measurements as a function of concentration for the fluorine magnetic resonance in the ions F^-, BF_4^-, and SiF_6^{2-} with a variety of cations. Shoolery and Alder (2) made similar measurements on potassium fluoride solutions. Later studies of Carrington and co-workers (15, 16) and Connick and Poulson (17) indicated that the direction of the ^{19}F chemical shift change for KF and NaF in water were in opposite sense. The chemical shift change to low field for KF in water was reversed at high concentrations ($>5\ m$), however, and Craig and Richards (18) note a change in chemical shift with time when glass sample tubes are used. No satisfactory explanation of the unique ^{19}F chemical shift behavior of KF in water has been advanced.

Solvent resonances from ^{17}O or ^{1}H isotopes in water have been correlated to a certain extent with ionic size or polarizability (3–5, 19) of dissolved electrolytes. Since ions can approach to close distances in concentrated electrolyte solutions, it would seem appropriate to attempt some correlation of 1 m ^{19}F shifts with the factor (charge/radius^3) for the cation.

EXPERIMENTAL

Materials

Solutions were prepared by dissolving a known weighed quantity in double-distilled water. NaF, NH_4F, and KF were analytical grade B.D.H. reagents. Most of the fluoroborates were supplied by Allied Chemical Company, N.Y. Fluoroborate solutions were standardized by precipitation as nitron fluoroborate. Most of the hexafluorosilicates were prepared by dissolving carbonates or hydroxides of metal in hexafluorosilicic acid and further crystallization (20).

Apparatus and Technique

^{19}F spectra were recorded on a Varian HR-60 spectrometer at 56.4 and 40 Mc. Chemical shifts were measured by side-band technique and details are given earlier (21). Samples were kept in a 3 mm internal diameter pyrex nuclear magnetic resonance tube. All the chemical shifts were measured using a fine capillary of 10 m KF (for F^- ion), saturated $NaBF_4$ (for BF_4^- ion), or 3.3 m $ZnSiF_6$ (for SiF_6^{2-} ion) as an external standard. For each sample an average of five or six spectra were recorded and the mean of chemical shift was taken. The experiments were performed at room temperature ($\approx$ 25 °C).

RESULTS AND DISCUSSION

The ^{19}F chemical shift for the anions F^-, BF_4^-, and SiF_6^{2-} have been measured as a function of concentration in water for several cations. The results for the fluoroborates and hexafluorosilicates are shown in Fig. 1. The results for the fluorides are not plotted but will be quoted in terms of their shifts at 1 m concentration. The dilution shift curves are not linear in general over the range 0 to 1 m. Any interionic effects will, if present, dominate the chemical shift change although rearrangements of solvent may also occur around the ion. The trend of shifts is to low field with fluoroborates and hexafluorosilicates but two salts of small univalent cations Li^+ and Na^+ give high field shifts. With the fluoroborates there is an obvious trend of increasing low field shift with the size of the cation. To introduce some order into these shifts we have taken the shift change from 0 to 1 m concentration for each salt and plotted this against the charge/(radius)^3 of the cation in Fig. 2. In this way any connection between the chemical shift changes and ability of the cation to polarize the anion will be evident. At present the results are scattered and limited by the solubility and availability of the necessary salts. Definite trends can be observed. This is most clearly seen for the fluoroborates of cadmium, tin, and lead. As the cation of the same charge increases in size the 1 m shift to low field is more pronounced. Formation of inner sphere complexes where the anion replaces water of hydration at the

cation is suggested. The larger the cation of the same charge the more the equilibrium for this process will favor ion pairs.

$$[M[H_2O)_x]^{n+} + A^{m-} \rightleftharpoons [M(H_2O)_{x-y}A]^{(n-m)+} + yH_2O$$

Further evidence for ion pair formation with the heavy metal ions can be inferred from the fact that the ^{19}F resonance of the BF_4^- ion shows a partially collapsed scalar coupling to the ^{11}B nucleus. The electric field gradient of T_d symmetry is perturbed by the adjacent positive ion and the increased rate of quadrupolar relaxation of the ^{11}B nucleus results in a collapse of ^{11}B—^{19}F coupling. This effect has been previously observed by Muetterties and Packer (22) for the salts of AsF_6^- ion.

In salts of the same anion, the cation of smallest size produces an overall change in chemical shift which is small. It is likely that these ions do not form inner sphere complexes and thus the large chemical shift changes in the anion due to a cation in close proximity are absent. The preservation of the T_d symmetry in $NaBF_4$ at all concentrations is indicated by a long transverse relaxation time T_2 with resolution of a sharp quartette, the components of which have a line width ~ 0.5 c.p.s. Close contact between cation and anion is ruled out (21).

Changes in chemical shift with concentration in the salts of SiF_6^{2-} are always small even with the large and polarizable Ag^+ ion. This is particularly pronounced in the Zn^{2+} and Mg^{2+} salts, where we expect outer sphere complexes since these ions are strongly hydrated.

An unusual feature of the results presented in Fig. 1(B) is the fact that at infinite dilution the chemical shift is unique in $NaBF_4$ solutions. This effect has been noted before (21, 23). The exceptional variation of the coupling constant and chemical shift changes with concentration in this salt have been presented separately (21, 23).

field of the medium. Temperature studies on this molecule throw some doubt on this explanation (15). In the case of directly bonded nuclei, Evans (2) presents evidence that hydrogen bonding is a factor in the solvent dependence of $^{13}C—^{1}H$ coupling in chloroform, whereas Bell and Danyluk (14) argue for the dependence of $^{13}C—^{1}H$ and $^{13}C—^{19}F$ couplings in *cis*- and *trans*-dichlorofluoroethylene on the reaction field of the solvent.

Coyle, Johannesen, Brinckman, and Farrar (16) demonstrate a substantial change in the $^{29}Si—^{19}F$ coupling in SiF_4 as a function of solvent and suggest that specific interactions between solute and solvent molecules may be responsible. Since SiF_4 is nonpolar, the data afford an opportunity to see whether intermolecular dispersion interactions affect the coupling, perhaps by a mechanism similar to that affecting the chemical shift (17–21). The calculation of these interactions involves a knowledge, among other things, of the polarizability, the ionization potential, certain absorption frequencies, and intermolecular distances of approach for the solute–solvent system. For most of the solvents employed by Coyle *et al.* (16) this information is not available.

However, Buckingham, Schaefer, and Schneider (17) find a rough proportionality between the gas-to-solvent shift of methane in a number of halogenated solvents and the heat of vaporization, H_b, of the solvent at its boiling point chosen to approximate "corresponding" states. H_b is a measure of the interaction between like solvent molecules but, if the interactions are simple dispersion forces, a proportionality of the corresponding interaction of the solvent molecules with the common solute molecule may be expected. H_b can be calculated from the formula

$$[1] \qquad H_b \text{ (cal)} = 17.0T_b + 0.009T_b^2,$$

as shown by Hildebrand and Scott (22). Linder (23) shows that there is a rough correlation between the dispersion free energy and the energy of vaporization of the solvent. By this means it can be tested whether the change in the $^{29}Si—^{19}F$ coupling is dependent on dispersion forces in solution.

In Fig. 1 the values of the $^{29}Si—^{19}F$ coupling in SiF_4 from Coyle *et al.* (16) are plotted versus H_b as obtained from the boiling points of the solvent. The mean deviation from the illustrative straight line is about 10% of the total variation of the coupling. The measurements were made at 28 °C and those solvents with calculated H_b values of less than 6 kcal/mole all boil below this temperature at 1 atm. The largest scatter occurs in this region of the plot.[2] Note also that a considerable variation of the coupling with temperature is found in $CClF_3$ (see Fig. 1). As the density of the solvent changes the dispersion interactions will also change, as is found in chemical shift measurements (24).[3] Further, the concentration of SiF_4 may deviate considerably from the estimated 15% (16) in this region. Finally, the calculated H_b is not a completely faithful measure of dispersion interactions between the nonpolar SiF_4 molecule and the, for the most part, polar solvent molecules.[4]

In view of the above remarks we consider the plot to indicate that the variation in the $^{29}Si—^{19}F$ coupling can be attributed mainly to time varying electric fields, i.e. dispersion interactions, which alter the net electronic state of the SiF_4 molecule. Because of the scatter in Fig. 1, however, specific interactions with donor solvent molecules cannot be ruled out in all cases.

From Fig. 1 it is evident that the magnitude of the $^{29}Si—^{19}F$ coupling in c.p.s. increases as the intermolecular dispersion interactions increase. For first row nuclei, Pople and

[2] C_6F_6 *deviates particularly strongly, as do those molecules containing* only *fluorine as halogen.*
[3] *A better temperature of measurement would be at the boiling point of each solvent.*
[4] *Thus, chloroform, with a dipole moment of 1.02 D, has an electrostatic energy of 0.24 kcal/mole at its normal boiling point (23).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Santry (25) calculate a negative reduced coupling to fluorine, which is the coupling in c.p.s. divided by the product of the magnetogyric ratios of the coupled nuclei. Since this product is negative for Si—F, the measured coupling in c.p.s. will be positive[5] *if* the Pople and Santry theory holds. In terms of their theory, an increased dispersion interaction with solvent molecules leads to a lower excitation energy between the highest bonding and lowest anti-bonding molecular orbitals in the Si—F bond (this may be a result of the expansion of the electron clouds in the molecule by the dispersion interactions). Such a possibility should stimulate someone with ^{19}F resonance equipment to make similar measurements on CF_4.

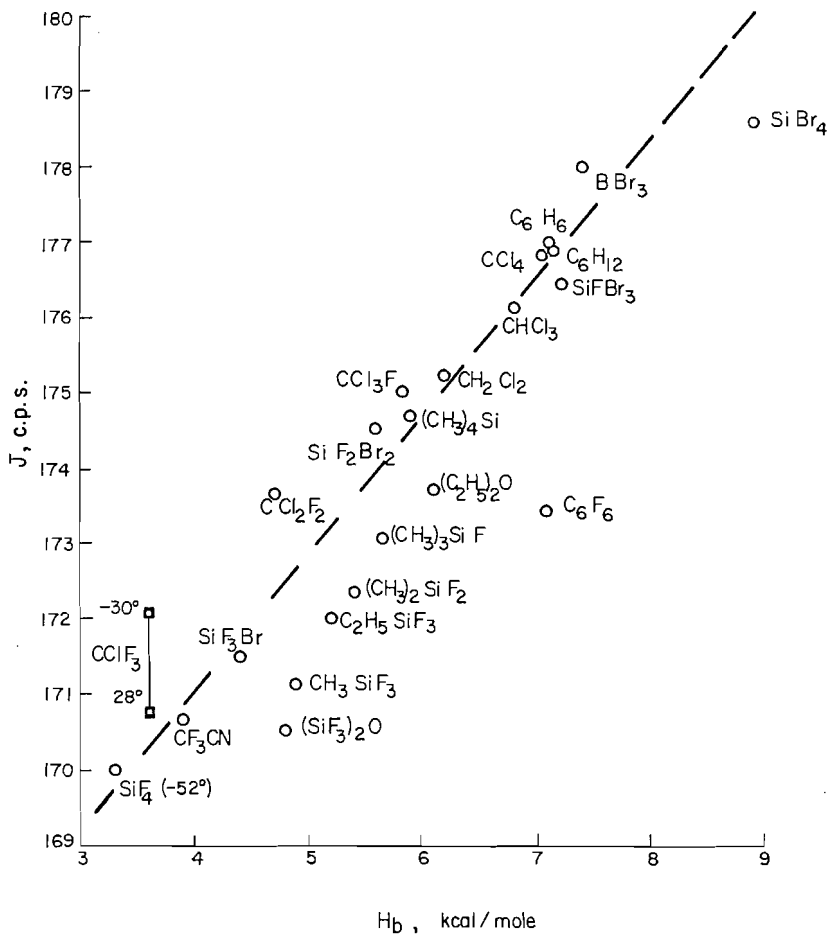

FIG. 1. The ^{29}Si—^{19}F coupling constant in c.p.s. in SiF_4 is plotted versus the heat of vaporization, H_b, in kcal/mole of the solvent as calculated from eq. [1] in the text. The concentrations are roughly 15% and the temperature of measurement, unless otherwise indicated, is 28 °C. The precision of the coupling constant values is at least ±0.1 c.p.s.

PREPARATION AND CHARACTERIZATION OF SOME BINARY AND TERNARY COMPLEXES OF BENZOYLTRIFLUOROACETONE AND PHOSPHORUS ESTERS[1]

G. N. RAO AND N. C. LI

As part of our program (1–3) on the investigation of metal complexes involved in solvent extraction, we report here the preparation and characterization of several binary and ternary metal complexes of benzoyltrifluoroacetone and phosphorus compounds. The isolation and investigation of solid complexes are important because any information about their stoichiometry, stability, solubility, and spectral characteristics is a contribution to the problems of synergism in solvent extraction.

EXPERIMENTAL

Materials

Benzoyltrifluoroacetone (HBTA), tri-*n*-octyl phosphine oxide (TOPO), and triphenyl phosphine oxide (TPPO) were obtained from Peninsular ChemResearch, Inc. Their infrared spectra agree with those reported in the literature. Carbon tetrachloride, benzene, and acetone were Spectranalyzed Fisher Certified.

Instrumental

Infrared spectra were obtained with a Perkin–Elmer Model 137 spectrophotometer using Nujol mull. Absorption spectra were taken on a Cary Model 14 spectrophotometer with 5 cm cells at room temperature (25°). Proton magnetic resonance measurements were obtained with an A-60 NMR spectrometer. Chemical shifts of the signals were measured with respect to tetramethylsilane as an internal standard.

PREPARATION AND CHARACTERIZATION OF SOME BINARY AND TERNARY COMPLEXES OF BENZOYLTRIFLUOROACETONE AND PHOSPHORUS ESTERS[1]

G. N. RAO AND N. C. LI

As part of our program (1–3) on the investigation of metal complexes involved in solvent extraction, we report here the preparation and characterization of several binary and ternary metal complexes of benzoyltrifluoroacetone and phosphorus compounds. The isolation and investigation of solid complexes are important because any information about their stoichiometry, stability, solubility, and spectral characteristics is a contribution to the problems of synergism in solvent extraction.

EXPERIMENTAL

Materials

Benzoyltrifluoroacetone (HBTA), tri-*n*-octyl phosphine oxide (TOPO), and triphenyl phosphine oxide (TPPO) were obtained from Peninsular ChemResearch, Inc. Their infrared spectra agree with those reported in the literature. Carbon tetrachloride, benzene, and acetone were Spectranalyzed Fisher Certified.

Instrumental

Infrared spectra were obtained with a Perkin–Elmer Model 137 spectrophotometer using Nujol mull. Absorption spectra were taken on a Cary Model 14 spectrophotometer with 5 cm cells at room temperature (25°). Proton magnetic resonance measurements were obtained with an A-60 NMR spectrometer. Chemical shifts of the signals were measured with respect to tetramethylsilane as an internal standard.

[1]*This investigation was supported by the U.S. Atomic Energy Commission Contract No. AT(30-1)-1922. Paper No. NYO-1922-36.*

Preparation of Solid Complexes

The following compounds have *not* been reported previously.

Binary Complexes

$UO_2(BTA)_2$.—To a solution of uranyl acetate (4.24 g) in 100 ml water, HBTA (4.32 g) in 50 ml ethanol was added slowly with stirring. The yellow precipitate which was formed immediately was filtered off, washed with water and ethanol, and dried over P_2O_5 in a vacuum desiccator. When this compound was heated at 115° for 2 h, the anhydrous compound $UO_2(BTA)_2$ was obtained; m.p. 156°. The infrared spectrum of this compound shows no peaks in the OH-stretching region.

Anal. Calcd. for $UC_{20}H_{12}O_6F_6$: C, 34.28; H, 1.73. Found: C, 34.32; H, 2.12.

The following binary complexes were prepared in a similar manner.

$Cd(BTA)_2.2H_2O$.—Anal. Calcd. for $CdC_{20}H_{16}O_6F_6$: C, 41.50; H, 2.65; Cd, 19.44. Found: C, 41.45; H, 2.80; Cd, 19.50. Melting point 99°.

$Zn(BTA)_2.2H_2O$.—Anal. Calcd. for $ZnC_{20}H_{16}O_6F_6$: C, 45.18; H, 3.43; Zn, 12.31. Found: C, 45.01; H, 3.36; Zn, 12.45. Melting point 118°.

$Pb(BTA)_2$.—Anal. Calcd. for $PbC_{20}H_{12}O_4F_6$: C, 37.70; H, 1.90. Found: C, 37.83; H, 2.00. Melting point 194°.

Ternary Complexes

$UO_2(BTA)_2.TOPO$.—Uranyl acetate (4.24 g) dissolved in 100 ml water was shaken with 100 ml of a hexane solution containing HBTA (4.32 g) and TOPO (3.87 g). The intense yellow-colored hexane layer was separated and evaporated to about 1/10 of its volume. The ternary complex separated out after keeping the hexane solution for 1 day in a refrigerator. The solid was filtered off, washed with hexane, and dried over P_2O_5 in a vacuum desiccator; m.p. 59°.

Anal. Calcd. for $UC_{44}H_{63}O_7F_6P$: C, 48.60; H, 5.84. Found: C, 48.73; H, 5.78.

The following compounds were prepared in the manner described for $UO_2(BTA)_2.TOPO$.

$UO_2(BTA)_2.TBP$.—Anal. Calcd. for $UC_{32}H_{39}O_{10}F_6P$: C, 39.74; H, 4.06. Found: C, 39.80; H, 3.96. Melting point 89°.

$Zn(BTA)_2.TPPO$.—Anal. Calcd. for $ZnC_{38}H_{27}O_5F_6P$: C, 58.95; H, 3.51; Zn, 8.45. Found: C, 59.15; H, 3.71; Zn, 8.33. Melting point 168°.

$Cd(BTA)_2(TPPO)_2$.—Anal. Calcd. for $CdC_{56}H_{42}O_6F_6P_2$: C, 61.20; H, 3.82; Cd, 10.23. Found: C, 61.30; H, 3.89; Cd, 10.30. Melting point 185°.

In the above preparations with TPPO as adduct, benzene was used instead of hexane. The metal content was analyzed by complexometric titration with ethylenediaminetetraacetic acid. Analysis for carbon and hydrogen was done by A. Bernhardt, Germany.

$Cd(BTA)_2.TOPO$ and $Zn(BTA)_2.TOPO$ were obtained as oils. The proton magnetic resonance spectrum of $Zn(BTA)_2.TOPO$ in CCl_4 was integrated and the ratio of the vinyl proton signal in BTA to those of the tri-*n*-octyl protons in TOPO was 2:50 (calcd. 2:51). The agreement between the experimental and calculated ratios establishes the ratio of BTA:TOPO in $Zn(BTA)_2.TOPO$.

RESULTS AND DISCUSSION

Infrared Spectra

The infrared spectra of most of the complexes reported in this paper were measured as Nujol mulls. The spectra of $Cd(BTA)_2.2H_2O$, $Zn(BTA)_2.2H_2O$, and $Mn(BTA)_2.2H_2O$ show broad peaks in the 3 350 – 3 500 cm^{-1} region, which are assigned to the OH-stretching frequency of coordinated water. For the ternary complexes $UO_2(BTA)_2.TBP$, $UO_2(BTA)_2.TOPO$, $Cd(BTA)_2(TPPO)_2$, $Cd(BTA)_2.TOPO$, $Zn(BTA)_2.TPPO$, and $Zn(BTA)_2.TOPO$, the 3 500 cm^{-1} region is free of absorption, indicating the absence of coordinated water in these adducts.

The displacement of the phosphoryl (P → O) stretching frequencies in TBP, TPPO, and TOPO to lower frequencies, on formation of the above ternary complexes, had been observed. This could indicate that oxygen is bonded directly to the metal, and has been pointed out by Ferraro and Healy (4) for the ternary complexes of metal thenoyltrifluoroacetone–phosphorus ester.

Since previous investigators (5–7) have discussed the relation between the order of carbonyl stretching frequency to the stability order of metal acetylacetonates, it is interesting to examine such a relation for the metal benzoyltrifluoroacetonates, $M(BTA)_2.2H_2O$. The order of C=O stretching frequency is: Cd = Zn = Pb, 1 613; Mn, 1 610; Cu, 1 597 cm^{-1}. On the other hand, the order (8) of stability constants (as log of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formation constants) is: Zn, 7.30; Cd, 7.60; Mn, 8.20; Cu, 13.2. Thus it is seen that a qualitative relation exists between the strength of metal–oxygen bond, as obtained from stability constants, and the frequency of the perturbed carbonyl absorptions. On the other hand the magnitudes of the frequency shifts do not match the differences in stability constants, so that there is no apparent quantitative agreement. Nakamoto, McCarthy, and Martell (7) have assumed that for the metal acetylacetonates, correlation of stability with frequency would occur only for metals of similar covalent radii and similar mass.

Visible Spectral Studies

The visible spectra of $Cu(BTA)_2$ in benzene, in the presence of varying amounts of TBP, reveal the presence of a single well-defined isosbestic point at 611 mμ. A plot of ϵ at 675 mμ vs. 1/[TBP] gave a limiting value of $\epsilon_\infty = 61.7$. By the method of Graddon and Watton (9), we have calculated the equilibrium constant K of the reaction

$$Cu(BTA)_2 + TBP = Cu(BTA)_2.TBP$$

to be 80.7 ± 2.2 l mole^{-1}.

The visible spectra of $Cu(BTA)_2$ (2×10^{-3} M in benzene) in the presence of increasing amounts of TOPO ($2\text{–}100 \times 10^{-3}$ M) were also obtained. In contrast to the $Cu(BTA)_2$.TBP system, however, no single isosbestic point was observed. With increasing amount of TOPO, the spectra shifted to longer wavelengths. The intensity of absorption maxima increased and then decreased as the concentration of TOPO was increased. The possibility of formation of adducts containing more than 1 mole of TOPO is indicated. In the region of [TOPO] = $4\text{–}15 \times 10^{-3}$ M, the equilibrium constant of the reaction

$$Cu(BTA)_2 + TOPO = Cu(BTA)_2.TOPO$$

was determined to be 770 ± 45. When the adduct is TPPO instead of TOPO, the visible spectra gave results similar to the TOPO system, and the value of K was determined to be 505 ± 65 l mole^{-1} at 25°.

The values of K for $Cu(BTA)_2$.TBP, $Cu(BTA)_2$.TPPO, and $Cu(BTA)_2$.TOPO indicate therefore that the electron-donor ability of the phosphorus compounds increases in the order TBP < TPPO < TOPO, and is in agreement with the order of stability constants found for $Cu(TTA)_2$.TBP, $Cu(TTA)_2$.TPPO, and $Cu(TTA)_2$.TOPO (10), where TTA is thenoyltrifluoroacetone anion. This order also agrees with the finding of Li, Wang, and Walker (3) that in the Zn–TTA system, the efficiency in synergistic solvent extraction on adding a phosphorus compound falls in the order: TBP < TPPO < TOPO.

Solubility Studies

The binary $M(BTA)_2$ and $M(BTA)_2.2H_2O$ complexes are slightly soluble in carbon tetrachloride, benzene, chloroform, hexane, alcohol, and water, but dissolve in acetone and dimethyl sulfoxide. The metal–BTA adducts with TOPO, however, are highly soluble in hexane and CCl_4. This enhanced solubility in the nonpolar organic phase of neutral metal–BTA chelates caused by adduct formation with a phosphorus compound is considered to play an important part in the synergistic extraction of metals, and has been pointed out for metal–TTA systems by Walker and Li (2).

ACKNOWLEDGMENTS

The authors thank the U.S. Atomic Energy Commission for support of this research, and acknowledge the assistance of a U.S. National Science Foundation equipment grant for the purchase of a Cary Model 14 spectrophotometer. We also wish to thank Dr.

THE INITIATION OF PROPYLENE PYROLYSIS

R. M. Marshall, J. H. Purnell, and B. C. Shurlock

Possible homogeneous initiation steps in the pyrolysis of propylene are:

[1] $$C_3H_6 \rightarrow CH_2{=}CH{-}\dot{C}H_2 + H\cdot$$

[2] $$C_3H_6 \rightarrow CH_3\cdot + C_2H_3\cdot$$

[3] $$C_3H_6 \rightarrow CH_2{=}\dot{C}{-}CH_3 + H\cdot$$

[4] $$2C_3H_6 \rightarrow CH_2{=}CH{-}CH_2\cdot + n\text{-}C_3H_7\cdot \quad .$$

Reaction [3] may be discounted immediately since, although its A factor is likely to compare with that of [1], its activation energy must be substantially higher because there is no possibility of resonance stabilization of the resulting radicals.

Until recently, reaction [1] has been favored over all others (1) because of the belief that the allyl resonance energy (Q) was about 22 kcal mole^{-1} (2). Recent kinetic studies (3), however, yield results which are more consistent with a value of about 12 kcal mole^{-1}. This finding leads us to reassess the relative importance of reactions [1] and [2] and it is appropriate also to consider reaction [4], since the reaction comparable with [−4], involving ethyl and allyl radicals, has recently been studied (4).

The thermochemical data employed in the calculations are listed in Table I.

In the absence of reliable values for the entropy and enthalpy of vinyl and of allyl radicals we assume that these are the same as those of the parent olefin except where symmetry and electron degeneracy corrections are needed. As is usual in considering radical–radical reactions, reactions [−1] and [−2] are regarded, at this stage, as proceeding with no energy of activation and with unit collision efficiency. For the disproportionation reaction [−4] calculations, we have employed the measured ratio of disproportionation to combination for the similar reaction of ethyl with allyl at 150 °C (4), whereas for the combination reaction we have again made the assumption stated above. On this basis we obtain the rate parameters listed in Table II.

TABLE II

Calculated rate parameters

	Reaction		
	[1]	[2]	[4]
$\text{Log}_{10}A$*	15.7	17.8	14.4
E†	$100-Q$	94	$63-Q$

*Units of cc mole s.
†Units of kcal mole^{-1} rounded to nearest whole number.

At 873 °K, roughly the midpoint of the temperature range used in static experiments, the tabulated data yield $k_2 = 10^{-5.7}$ s^{-1}. In order that $k_1 > k_2$ it follows that $E_1 < 85$ kcal mole^{-1}. Thus $Q > 15$ kcal mole^{-1}. It follows that reaction [2] is, if anything, to be considered more important than [1] if recent estimates of Q are to be accepted. However, even allowing for the possible uncertainties in the calculations, it is quite certain that reaction [2] can never be neglected in comparison with [1] on the basis of present evidence.

Assuming that $Q = 12$ kcal mole^{-1}, the calculated rate of reaction [4] at about 100 mm Hg initial pressure at 873 °K is $10^{-9.8}$ mole cc^{-1} s^{-1} which may be compared with the calculated rate of reaction [2], $10^{-11.4}$ mole cc^{-1} s^{-1} for the same conditions. Obviously, therefore, reaction [4] would appear to be highly favored over [1] and [2]. However, this conclusion does not accord with the kinetic evidence.

The overall order of propylene pyrolysis in the region of 873 °K is 1.4 (1*c*, 10) and is pressure independent over the range 7–300 mm Hg. Goldfinger *et al.* (11) have shown that such a result is consistent with any of the possibilities shown in Table III.

TABLE III

Possibilities for propylene pyrolysis in the region of 873 °K

	Initiation order	Radicals involved in termination	Overall order
(*a*)	1	$\beta\beta$	3/2
(*b*)	2	$\beta\mu$	3/2
(*c*)	2	$\beta\beta$M	3/2

A detailed analytical investigation (10) of propylene pyrolysis has shown that the major termination reaction is the combination of methyl with allyl radicals, i.e. $\beta\beta$ in the above terminology. Hence, only case *a* is acceptable.

It thus follows that our calculated rate of reaction [4] must be much too high and hence also that of [−4]. This implies, in contrast to the assumptions made earlier, that radical combination reactions involving allyl proceed with either or both entropy and energy of activation. This conclusion is also drawn from different evidence elsewhere (10).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A consequence of the above considerations is that the rate of reaction [1] is also overestimated in the calculation. Thus reaction [2] should be considered the predominant initiation step on the basis of present evidence. The measured rate (10) of methyl–allyl combination, $10^{-10.4}$ mole cc^{-1} s^{-1}, at 100 mm Hg and 873 °K is found to be of the same order of magnitude as the presently calculated rate of reaction [2] in the same conditions, which must be regarded as reasonable agreement in view of the uncertainties in the thermochemical data available. Finally, since the overall rate of pyrolysis of 100 mm Hg propylene at 873 °K is $10^{-8.7}$ mole cc^{-1} s^{-1} (10), it is apparent that the pyrolysis of propylene must be regarded as a long-chain process.

ERRATUM: ^{35}Cl AND ^{37}Cl MAGNETIC RESONANCE OF SIMPLE CHLORINE COMPOUNDS

Yasukazu Saito

(Ref. Can. J. Chem. 43, 2530 (1965))

A standard value of the chemical shift of chlorine magnetic resonance obtained by extrapolating the quadrupole coupling constants of a series of chloromethanes to zero in the equation

[i] $$\delta = \delta_d + K(\Delta E^{-1})(e^2qQ)$$

was reported previously (1).

Since the author considered that the standard value of δ_d derived above corresponded to a hypothetical state with spherical distribution of electrons of chlorine atom (not anion), a correction term was added in order to obtain the chemical shift of spherical

ERRATUM: ^{35}Cl AND ^{37}Cl MAGNETIC RESONANCE OF SIMPLE CHLORINE COMPOUNDS

Yasukazu Saito

(Ref. Can. J. Chem. 43, 2530 (1965))

A standard value of the chemical shift of chlorine magnetic resonance obtained by extrapolating the quadrupole coupling constants of a series of chloromethanes to zero in the equation

$$\delta = \delta_d + K(\Delta E^{-1})(e^2qQ) \quad [i]$$

was reported previously (1).

Since the author considered that the standard value of δ_d derived above corresponded to a hypothetical state with spherical distribution of electrons of chlorine atom (not anion), a correction term was added in order to obtain the chemical shift of spherical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chlorine anion by use of Dickinson's (2) calculation. Indeed, the paramagnetic term of the Ramsey (3) equation becomes zero if the distribution of electrons of the atom has spherical symmetry. However, the above hypothetical state is not appropriate to be taken as the standard state, since the free atom has one electron missing from the closed shell, and all chlorine compounds, including chloromethanes and chlorine aqueous ion, ought to have a common reference from the viewpoint of chemical bonds. Either the free chlorine ion or the chlorine nucleus should be regarded as the standard state of chlorine chemical shifts (4–6). The purpose of this note is to correct the results reported in ref. 1, and for this purpose the free chloride ion is adopted as the standard reference state. This state is derived, in accordance with eq. [1], by extrapolating the experimental chlorine resonance measurements for various compounds to zero quadrupole coupling constant. Since the experimental chemical shift data, δ, were measured relative to aqueous chloride ion, extrapolation according to eq. [1] yields δ_d, the diamagnetic shift of the free chloride ion relative to aqueous chloride ion. The value of δ_d, the diamagnetic screening of the free chloride ion relative to the bare nucleus, has been calculated by Dickinson (2) to be +1.15 p.p.t. (parts per thousand).

The extrapolated value for δ_d obtained from Fig. 1 of the previous paper (1) is 2.60 p.p.t. This is a more accurate value than the former value, 2.90 p.p.t., which was erroneously given as −2.90 p.p.t. in the earlier paper (1).

When Saika and Slichter's (4) equation

[ii] $$\delta_p = -(2/3)(e^2\hbar^2/m^2c^2)(1 - i)\langle r^{-3}\rangle_{av}\Delta E^{-1},$$

where i is the ionic character of the atom, is applied to some chlorine compounds, calculated values of chlorine chemical shifts can be derived from the extrapolated value. The results are shown in Table I.

TABLE I

Paramagnetic shifts in some chlorine compounds

Compound	Ionic character* (%)	ΔE† (eV)	Shift (p.p.t.) Calcd.	Obs.
Cl_2	0.0	3.67	−2.17	−2.91
CCl_4	7.0	5.25	−1.41	−3.16
$CHCl_3$	8.8	5.42	−1.34	−3.01
CH_2Cl_2	11.7	5.77	−1.22	−2.82
CH_3Cl	17.1	6.0	−1.1	−2.64

*Data were taken from ref. 10.
†Data of electronic absorption were used, including an assumed value for CH_3Cl from extrapolation. References were cited in the previous paper (1).

The paramagnetic contribution to the chemical shift of the chlorine aqueous ion due to hydration is −2.60 p.p.t. and this value can be compared with the analogous parameter for the fluorine ion shown by Saika and Slichter (4) to be −1.45 p.p.t. Paramagnetic shifts of simple chlorine compounds on the present revised basis are compared with the corresponding fluorine compounds in Fig. 1. Experimental data of fluorine chemical shifts (7–9) were rearranged, with Saika and Slichter's F^- ion as standard.

The author is very much indebted to Dr. R. G. Kidd for pointing out the error and ambiguity in the previous paper and is also thankful to Dr. W. G. Schneider and Dr. A. Saika for their comments.

THE ELECTROLYSIS OF *o*-HALOGENOPHENYL-SUBSTITUTED ACIDS

R. G. WOOLFORD AND W. S. LIN

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received June 15, 1966

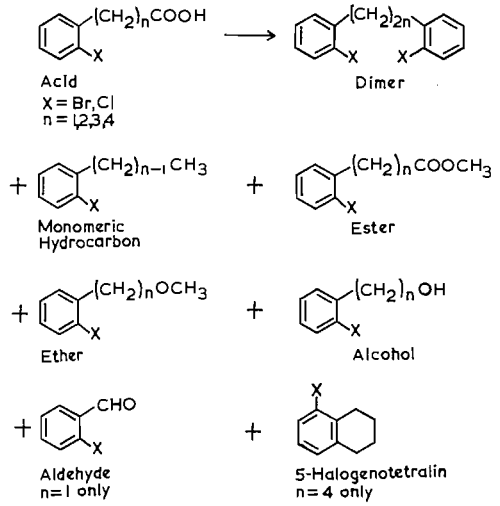
ABSTRACT

The synthesis and electrolysis of a series of *o*-chloro- and *o*-bromo-phenyl-substituted acids with two to five carbon chain lengths have been studied. The main products, under the experimental conditions used, were the Kolbe dimers. A complete isolation and identification of all of the important by-products is recorded. Methanol and methanol–pyridine were the solvents for electrolysis.

This work represents the first study of the behavior of aromatic halogen substituents during the Kolbe electrolysis. In contrast to many reactions involving aliphatic halogen substituents, no free halogen was produced and no products were obtained, even in trace amounts, where halogen had been lost from the aromatic nucleus. During this investigation, 18 previously unreported compounds were synthesized and their properties were determined.

Recently, there has been an increase in interest in the electrolysis reactions of aryl-substituted aliphatic acids (refs. 1–4 and articles cited therein). In part, this interest has involved efforts to observe other than normal Kolbe coupling reactions, and in particular to study phenyl migration in free radicals and homolytic cyclization of the radicals involved. No studies were undertaken with halogenated aromatic rings.

Past work (5, 6) has shown that halogen is readily lost during electrolysis of some ω-halogenated aliphatic acids. It was expected that halogen would be more stable and thus less easily lost from an aromatic ring than from an aliphatic chain. However, because of the complete lack of work in this area, it was felt worthy of investigation. As a start, efforts were concentrated on *o*-chloro- and *o*-bromo-phenyl-substituted acids of two to five carbon chain lengths. It was hoped to learn something of the radicals produced, their reactions, and to what extent this class of organic acids might be used in the synthesis of Kolbe-type halogenated hydrocarbons.



It is difficult to produce and separate large quantities of pure ortho isomers from the ortho–para mixture obtained on direct halogenation of an aromatic ring. Thus, the acids used were all synthesized from starting materials with the halogen substituent already on the ring.

Two new acids were prepared: 4-*o*-bromophenylbutanoic acid and 5-*o*-bromophenylpentanoic acid. All other acids had been synthesized previously. Misra and Shukla (7) prepared *o*-halogenated phenylacetic acids by reacting *o*-halogenated benzyl bromide and chloride with sodium cyanide; hydrolysis gave the desired acids. This method was used to prepare the necessary substituted acetic acids and extended to produce the halogenophenylbutanoic acids.

Various workers (8–11) have synthesized *o*-halogenophenylpropanoic acids from the corresponding *o*-halobenzyl halides and diethyl malonate, although not on the scale of reaction used in the present work. Granger (12) extended the method to prepare 5-*o*-chlorophenylpentanoic acid, but gave no experimental details. The necessary propanoic and pentanoic acids were prepared by this route.

The *o*-halogenophenyl-substituted acids were electrolyzed in methanol and methanol–pyridine solution. The products are illustrated in Reaction Scheme 1, and the yields are described in Table I.

REACTION SCHEME 1.

Previous electrolyses of *o*-substituted phenylacetic acids have indicated that the size of the ortho substituent is a very important factor in dimer formation. If the group is small, considerable dimer is formed; if the group is large, little or no dimer is formed. The best yield of dimer from the electrolysis of phenylacetic acid itself (i.e. when the ortho substituent is hydrogen) was 55% in methanol solvent (13) and 59% in dimethylformamide (4). Mesitylacetic acid (i.e. two *o*-methyl groups) gives (4) 44% dimer, and 2,4,6-triisopropylphenylacetic acid (i.e. two *o*-isopropyl groups) gives only 31% dimer (4). Wladislaw (2) found that the bulky nitro substituent in 2-nitrophenylacetic acid suppressed dimer formation completely; this was also true with nitro groups in the 2,4-positions, but with a 4-nitro substituent alone, 33% dimer was produced. However, this effect may not be entirely a steric one, since a 3-nitro substituent also suppresses dimer formation completely (Wladislaw concluded that more information was needed to justify any general discussion of how substituents influence the electrolysis products from substituted phenylacetic acids). In our work, an *o*-bromo substituent, which is relatively large, but still smaller than nitro, suppresses dimer formation but does not completely eliminate it. An *o*-chloro substituent, which is considerably smaller, allows more dimer formation, but still less than that with unsubstituted phenylacetic acid. Any steric hindrance vanishes once the chain length of the acid is increased by one carbon or more; this is borne out in most cases by the increased yields of dimer for the other *o*-halogenophenyl-substituted acids studied.

In the past, the Kolbe reaction of an acid RCOOH has been regarded usually as a relatively simple free-radical process involving the production, at the anode, of radicals

*Calculated in the usual manner based on the amount of acid reacting. The yields of unidentified polymeric fractions are based on a weight ratio exclusively (i.e. weight polymer/weight acid reacting) and hence cannot be regarded as accurate; they do give a good indication of the extent of polymer formation.

†M = methanol; M–P = methanol–pyridine.

‡The term polymer is used for convenience. The fraction consists of ether-insoluble material that settles on the electrodes during electrolysis plus the high-boiling, tarry residue left when the total neutral product is first distilled. Sodium fusion tests and infrared spectra showed the presence of halogen and ortho aromatic substitution in both components, but no further identification was made.

§No trace of unsubstituted tetralin was found.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

RCOO· and R· and their subsequent reaction. In methanol solvent, oxidation of CH_3O^- or CH_3OH to CH_3O· has been an additional factor assumed to be important in product formation and subsequently confirmed (e.g. ref. 14 and articles contained therein). However, recent studies indicate that the Kolbe reaction is often a much more complicated process, or at least it has the potential to be so under the experimental conditions used. Where R· is a normal primary alkyl radical, the formation of products can be reconciled with radical intermediates; except under strong alkaline conditions (the Hofer–Moest reaction, where alcohol production is the major process), there is little experimental evidence to suggest appreciable further oxidation of such a primary radical to R^+. Where R· is secondary, tertiary, allylic, or benzylic, there is considerable evidence to suggest that further oxidation to R^+ is an important factor in at least some of the product formations (for an excellent summary of possible reaction paths, see ref. 4). Eberson (15, 16) and others (17, 18) have also shown that, under the usual Kolbe conditions, not only $RCOO^-$ and solvent but also un-ionized RCOOH and added substrate such as aromatic rings, as well as primary R·, can be oxidized easily to R^+. These latter processes do not always occur to a marked extent even though the experimentally applied voltage is sufficient. However, sometimes they can be important. For example, in the acetoxylation of aromatic substrates under Kolbe conditions (15, 17, 18), instead of a simple radical attack of CH_3COO· on ArH, the reaction involves a two-electron transfer from ArH to the anode, giving ArH^{2+}, which reacts with acetate ion to give $ArOCOCH_3$ and H^+.

In the present work involving electrolysis of *o*-halogenophenyl-substituted acids, the products are those that have been explained traditionally by free-radical intermediates, e.g. $Ar(CH_2)_nCOO$· attack on methanol to give methyl esters, and, by decarboxylation, production of $Ar(CH_2)_{n-1}CH_2$·, which reacts with an identical species to give dimer, with methanol to give monomeric hydrocarbon[1] by hydrogen abstraction, and with CH_3O·, from the oxidation of methanol, to give methyl ether. For the acids other than the substituted phenylacetic acids, there is no evidence to suspect any major involvement of carbonium ions, although they cannot be ruled out completely. We could postulate ether formation by $Ar(CH_2)_{n-1}CH_2^+$ attack on methanol, or tetralin formation by cyclization of $Ar(CH_2)_{n-1}CH_2^+$, but this would involve oxidation of primary radicals to carbonium ions. The reactions are more probably radical combination of $Ar(CH_2)_{n-1}CH_2$· and CH_3O·, and radical cyclization of $Ar(CH_2)_{n-1}CH_2$· to give the substituted tetralin. Bunyan and Hey (1) found that unsubstituted 5-phenylpentanoic acid, on electrolysis, gave small amounts (3.8–4.5%) of tetralin, and postulated radical cyclization in its production. We isolated similar low yields (3.5–7.0%) of the corresponding 5-halogenotetralins.

The formation of alcohols was small, which is in accord with past work. In an acid medium, alcohol formation is rarely pronounced and appears to come from reaction with the small amounts of water, either present in the methanol solvent or else often added to decrease cell resistance and improve current flow. Aldehyde products have only been important when aryl-substituted acetic acids were used; this was explained (19) on the basis of peroxide formation from the more stable benzyl-type radicals produced. *o*-Bromo- and *o*-chloro-phenylacetic acids both gave aldehyde products in a low yield (only a trace from *o*-chlorophenylacetic acid), and no aldehydes were detected in any of the other reactions.

The electrolysis products from the *o*-halogenophenylacetic acids were similar to those

[1]*Commonly used to describe this by-product and used here to indicate the character of the side chain even though a halogen substituent is present on the ring.*

from the longer chain acids and can be explained by purely radical processes. However, electrolytically generated benzyl radicals appear to be oxidized to carbonium ions with great ease; hence, carbonium ion intermediates should not be ruled out, especially in ether formation. It should be noted that we did not isolate, as have other workers with substituted phenylacetic acids, products which clearly are not derived from radical processes.

In all of our electrolyses, ester formation was small; although control reactions indicate ester formation to be minor in the absence of the passage of current, it could possibly take place by attraction of the un-ionized acid to the anode and reaction there with methanol. Other workers (1, 2) have encountered polymer formation during electrolysis, although our yields of polymer were never as high as have been reported (up to 90%). Polymer formation seems to occur readily when phenyl substitution is present. Our results and those of other workers could possibly involve oxidation of the aromatic ring, leading to high-boiling, polymeric products. This is only speculation, however, and further comment must await a more detailed analysis of the polymeric fractions obtained. No other products were isolated where oxidation of the aromatic ring was involved.

Two conclusions regarding the effect of the *o*-halogen substituent on electrolysis reactions of phenyl-substituted acids can be made. First, the halogen substituent is perfectly stable during electrolysis; no products, even in trace amounts, were found in which either chlorine or bromine was displaced from the aromatic ring. Even in the case of the substituted pentanoic acids, where internal cyclization of the alkyl radical occurs to give small yields of tetralins, it was always hydrogen which was displaced, never halogen. This stability is not surprising, but it is the first time it has been demonstrated by experimental work. Secondly, there is a more-uniform spread of yields among all of the normal by-products than other workers have usually found during Kolbe-type electrolyses, where often only one by-product (usually the ester) predominates. This spread of products is possibly due to the increase in the molecular weight of the acids used when a halogen substituent is present. The acid therefore moves through the solution to the electrodes more slowly and the electrolysis is less efficient. The solvent carries more than its normal share of the current. Methoxy radical concentration, and hence ether formation, increases. Also, a decrease in the alkyl radical concentration at the electrode occurs and attack on the solvent takes place more readily, with a resultant decrease in dimer formation. However, with the *o*-halogenophenylacetic acids, the stability of the benzyl-type radical or carbonium ion may be a more important factor in determining the products.

The work described herein represents the first detailed study of the electrolyses of a series of *o*-halogenophenyl-substituted acids. The low yields and spread of products probably mean that the reactions should not be regarded as good synthetic ones for the production of the appropriate Kolbe dimers. In some individual cases, however, since other synthetic methods for these compounds do not exist presently, the reactions might be used conveniently for small-scale preparations.

EXPERIMENTAL

Physical constants and analytical data for new compounds are given in Table II. Melting points were determined on a Leitz hot stage and are corrected; boiling points are uncorrected. Analyses were performed by Schwarzkopf Mircoanalytical Laboratory, Woodside, New York. Infrared spectra were taken with Beckman IR-5 and IR-9 infrared spectrophotometers. An Aerograph Autoprep model 700 gas chromatograph was used with either a 10 or 20 ft × ⅜ inch column of 30% SE-30 silicone gum rubber on 60–80 mesh Chromosorb W; separated components were collected by means of the fraction collector, with external cooling.

Syntheses of o-Halogenophenyl-Substituted Acids

o-Halogenophenyl-Substituted Acetic and Propanoic Acids

o-Bromo- and *o*-chloro-phenylacetic acids, prepared according to the procedure of Misra (7), had melting points of 104–105.5° and 94–95°, respectively. Misra found melting points of 104–105.5° and 93–94°. The malonate procedure (9, 10) gave 3-*o*-bromophenylpropanoic acid, m.p. 96–98° (lit. m.p. 97–98° (9)), and 3-*o*-chlorophenylpropanoic acid, m.p. 95–96.5° (lit. m.p. 95–96° (10)).

4-o-Bromophenylbutanoic Acid

3-*o*-Bromophenylpropyl bromide (94.0 g, 0.34 mole), prepared by the procedure of Beeby and Mann (20), was added to sodium cyanide (20.0 g, 0.40 mole) in 40 ml of hot water and 100 ml of ethanol over 30 min. The mixture was heated under reflux for 5 h, cooled, and filtered. Ethanol was distilled under vacuum, giving crude 4-*o*-bromophenylbutanonitrile, which was heated under reflux with a solution of equal volumes (80 ml each) of concentrated sulfuric acid, acetic acid, and water for 12 h, and set aside overnight. An oily layer separated after addition of 1 000 ml of water. This layer and two ethereal extracts of the aqueous layer were dried over magnesium sulfate. Distillation gave a colorless liquid, b.p. 124–130° at 1.5 mm, which solidified when allowed to stand. Purified 4-*o*-bromophenylbutanoic acid (67.2 g, 81%) was obtained by recrystallization from carbon tetrachloride (Table II).

4-o-Chlorophenylbutanoic Acid

By a reaction similar to that described above, 4-*o*-chlorophenylbutanoic acid, m.p. 92–93.5°, was obtained (lit. m.p. 94–95° (21)).

5-o-Bromophenylpentanoic Acid

The malonate procedure described in refs. 9 and 10 was used, although on a larger scale, and gave 146 g (72%) of diethyl 3-*o*-bromophenylpropylmalonate (b.p. 186–201° at 1.5 mm) from 190 g (0.68 mole) of 3-*o*-bromophenylpropyl bromide. Hydrolysis and decarboxylation of the crude malonic acid gave 5-*o*-bromophenylpentanoic acid, b.p. 146–162° at 1.0 mm, m.p. 40–42°. Recrystallization from carbon tetrachloride gave 74.6 g (61%) of pure acid (Table II).

5-o-Chlorophenylpentanoic Acid

In a similar manner, 3-*o*-chlorophenylpropyl bromide (200 g, 0.86 mole) gave diethyl 3-*o*-chlorophenylpropylmalonate (154 g, 58%), b.p. 185–190° at 1.5 mm. Hydrolysis and decarboxylation yielded 5-*o*-chlorophenylpentanoic acid, b.p. 155–160° at 0.6 mm, m.p. 43–46°. Recrystallization from carbon tetrachloride gave m.p. 45.5–46.5° (lit. m.p. 46°, b.p. 166–167° at 1.0 mm (12)) and a yield of 73.4 g (61%).

Syntheses of Authentic Reference Compounds

Esters of o-Halogenophenyl-Substituted Acids

Concentrated sulfuric acid (2 ml) was added cautiously to 1.5–2.0 g of the appropriate acid in 15 ml of methanol. Heating under reflux for 1 h and work-up in the usual manner gave the pure ester, on distillation, in yields of 85–90%. Esters of all the acids previously described were prepared. New compounds are listed in Table II.

4-o-Bromophenylbutan-1-ol

4-*o*-Bromophenylbutanoic acid (10 g, 0.041 mole) in 100 ml of anhydrous ether was added to a stirred suspension of lithium aluminium hydride (2.5 g) in 100 ml of anhydrous ether, maintaining gentle reflux. The reaction mixture was heated under reflux for 1 h. After removal of 100 ml of ether, the cooled reaction mixture was hydrolyzed with 20 ml of water, followed by 50 ml of 10% sulfuric acid. After filtration, the ethereal layer was separated, washed with 10% sodium carbonate solution and then water, and dried over magnesium sulfate. Distillation gave 7.79 g (83%) of pure 4-*o*-bromophenylbutan-1-ol (Table II).

4-o-Chlorophenylbutan-1-ol

Preparation from 4-*o*-chlorophenylbutanoic acid, as described above, gave a colorless liquid, b.p. 113–115° at 0.9 mm, n_D^{25} 1.5351 (lit. b.p. 150–151° at 12 mm (22) and b.p. 97–98° at 0.7 mm (23)).

3-o-Bromophenylpropyl Methyl Ether and 3-o-Chlorophenylpropyl Methyl Ether

The 3-*o*-halophenylpropyl bromides were methylated with sodium methoxide (20). The resulting bromoether had b.p. 68–71° at 0.5 mm, n_D^{25} 1.5334 (lit. b.p. 127–129° at 15 mm (20)), and the chloroether is described in Table II.

4-o-Bromophenylbutyl Methyl Ether

4-*o*-Bromophenylbutan-1-ol (3.0 g, 0.0014 mole) was dissolved in methyl iodide (20 ml) and stirred with silver oxide (6.0 g) and anhydrous calcium sulfate (10 g) for 24 h. The crude product was chromatographed on silicic acid (2.5 × 20 cm), with benzene as eluent. Evaporation of the first 50 ml of eluent left a colorless liquid, which was distilled to give 1.23 g (36%) of the pure ether (Table II).

4-o-Chlorophenylbutyl Methyl Ether

4-*o*-Chlorophenylbutan-1-ol was methylated as described immediately above. Similar purification gave the ether (Table II).

Electrolysis of o-Halogenophenyl-Substituted Acids

General Method of Electrolysis

The cell used was fully described previously (6). The acid was dissolved in methanol, along with enough sodium to produce 5% neutralization. By using a D.C. supply of 50–80 V, 0.5–1.0 A was passed for about

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

3 times the theoretical. The temperature was kept below 40°. During the electrolysis, insoluble, apparently polymeric material deposited on the anode, causing the current to fall below the stated minimum periodically. The current was stopped, the anode deposit removed, and the reaction started again.

Isolation of products into acidic and neutral fractions was carried out as described before (6), except that continuous ether extraction for 24 h gave the neutral component. Negligible starting material was usually returned. The neutral fraction was distilled under vacuum, giving four to five major fractions plus a non-distillable, tarry residue.

Isolation and Identification of Products

Two general procedures were used to purify the crude distillation fractions from above. Gas–liquid chromatography (g.l.c.) indicated that the substituted acetic and propanoic acid products were fairly well separated by the first distillation. The first three fractions were redistilled and the fourth recrystallized or treated to column chromatography. The *o*-bromophenylacetic acid reaction is described in detail as representative, and others similar to it in only enough detail to show some physical constants and important variations. The substituted butanoic and pentanoic acid products were not well separated by the first distillation, and chromatography was necessary, both column and g.l.c. with fraction collection. The 4-*o*-bromophenylbutanoic acid reaction is representative, and other similar ones are only briefly described. Percentage yields are found in Table I. In some cases, the yields were estimated from the relative peak areas of the g.l.c. chromatograms, but wherever possible, the actual weights of pure collected fractions were used.

The products were identified by matching g.l.c. behavior, physical constants, and infrared spectra with those of authentic samples as well as literature values. The infrared spectra were as expected and are not described. New compounds were submitted for elemental analysis (see Table II for analysis figures and physical constants). As an additional confirmation of the identity of the esters, small-scale hydrolysis to the free acids and mixed melting points were used.

Electrolysis of o-Halogenophenyl-Substituted Acetic and Propanoic Acids

Electrolysis of *o*-bromophenylacetic acid (20.0 g, 0.093 mole) in 150 ml methanol yielded four initial distillation fractions: 1, 1.46 g, b.p. 40–59° at 0.35 mm; 2, 1.34 g, b.p. 60–85° at 0.35 mm; 3, 1.05 g, b.p. 95–115° at 0.35 mm; 4, 0.55 g, b.p. 125–135° at 0.35 mm. The tarry residue weighed 3.95 g, and 4.13 g (22%) of starting acid was returned. Polymeric material (2.35 g) deposited on the anode during the reaction. Fraction 1 was a mixture of *o*-bromobenzaldehyde (1.06 g) and methyl *o*-bromobenzyl ether (0.40 g), as estimated by g.l.c. Redistillation of *o*-bromobenzaldehyde gave b.p. 49–50° at 0.2 mm, n_D^{25} 1.5931 (lit. b.p. 118–119° at 12 mm, m.p. 22° (24)). Gas–liquid chromatography indicated that fraction 2 was methyl *o*-bromobenzyl ether containing some ester. After the ester was removed by basic hydrolysis, the ether was redistilled, b.p. 65–66° at 0.2 mm, n_D^{25} 1.5505, 1.08 g (lit. b.p. 106–107° at 16 mm (25)). Fraction 3 was mainly methyl *o*-bromophenylacetate, and redistillation gave 0.98 g. Fraction 4 was passed through a silicic acid chromatography column (20 × 2.5 cm). Elution with 1:1 *n*-hexane–benzene gave 2,2′-dibromodibenzyl (0.42 g), which, on recrystallization from methanol, had m.p. 84–84.5° (lit. m.p. 84.5° (20)).

The electrolyses of *o*-chlorophenylacetic, 3-*o*-bromophenylpropanoic, and 3-*o*-chlorophenylpropanoic acids were similar. The following variations in procedure or in physical constants are noteworthy: 2-*o*-bromophenylethyl methyl ether had n_D^{25} 1.5429 (no literature value) and 1,4-di-*o*-(bromophenyl)-butane was chromatographed on neutral alumina with elution by hexane; methyl 3-*o*-chlorophenylpropanoate had b.p. 65–66° at 0.3 mm, n_D^{25} 1.5170 (lit. b.p. 255° (26)), and no column chromatography was necessary, only recrystallization, to give 1,4-di-(*o*-chlorophenyl)-butane, m.p. 53.5–54° (lit. m.p. 51–52° (27)).

Electrolysis of o-Halogenophenyl-Substituted Butanoic and Pentanoic Acids

Electrolysis of 4-*o*-bromophenylbutanoic acid (15.0 g, 0.062 mole) in 130 ml methanol yielded four initial distillation fractions: 1, 2.43 g, b.p. 40–80° at 0.4 mm; 2, 1.83 g, b.p. 70–98° at 0.3 mm; 3, 1.84 g, b.p. 106–135° at 0.3 mm; 4, 1.92 g, b.p. 186–200° at 0.3 mm. The tarry residue weighed 1.71 g to go with 2.35 g deposited during electrolysis. Fraction 1 was chromatographed on the alumina column previously described, and eluted with hexane to give *o*-bromo-*n*-propylbenzene, 0.95 g, b.p. 51–52° at 0.7 mm, n_D^{25} 1.5405 (lit. b.p. 217–220°, n_D^{25} 1.5395 (28)), as well as 1.38 g of a yellow liquid, which appeared to be identical (by g.l.c.) with fraction 2 and was added to it. Fraction 2, now 3.22 g, was separated by g.l.c. with temperature programming from 200 to 300° on the 10 ft column; the yields were estimated from the chromatogram. *o*-Bromo-*n*-propylbenzene (0.35 g), 3-*o*-bromophenylpropyl methyl ether (1.33 g), 3-bromophenylpropan-1-ol (0.17 g), and methyl 4-*o*-bromophenylbutanoate (0.74 g) plus an unidentified component (0.71 g) were obtained. Fraction 3 was redistilled, giving 1.56 g of methyl 4-*o*-bromophenylbutanoate. Fraction 4, on recrystallization from methanol, gave 1.72 g of 1,6-di-(*o*-bromophenyl)-hexane.

The electrolyses of 4-*o*-chlorophenylbutanoic, 5-*o*-bromophenylpentanoic, and 5-*o*-chlorophenylpentanoic acids were similar, but, for the latter two acids, the g.l.c. separations were carried out on the 20 ft column at 250–320° and 200–300°, respectively. Significant variations in physical constants were: *o*-chloro-*n*-propylbenzene, b.p. 33–35° at 0.5 mm, n_D^{25} 1.5130 (lit. b.p. 79° at 10 mm, n_D^{16} 1.5213 (29)), and *o*-chloro-*n*-butylbenzene, b.p. 38–40° at 0.3 mm, n_D^{25} 1.5117 (lit. b.p. 53–54° at 2 mm, n_D^{25} 1.5087 (30)).

THE CHEMISTRY OF YLIDS

XV. MECHANISM OF THE REACTION OF IMINOPHOSPHORANES WITH CARBONYL COMPOUNDS[1-3]

A. WILLIAM JOHNSON[4] AND SIMON C. K. WONG

Division of Natural Sciences, University of Saskatchewan, Regina Campus, Regina, Saskatchewan, and Chemistry Department, University of North Dakota, Grand Forks, North Dakota

Received July 19, 1966

ABSTRACT

The pK_a values of two series of iminophosphoranes, *N*-(substituted phenyl)-iminotriphenylphosphoranes (VI) and *N*-phenyliminotri-(substituted phenyl)-phosphoranes (VII), have been correlated with σ^0 and σ, respectively, giving ρ values of +3.5 and +9.3. A kinetic study of the reaction of VI and VII with benzaldehydes indicates that a betaine intermediate (V) is involved. The rate-limiting step of the reaction changes, the result of a delicate balance between the nucleophilicity of the nitrogen atom and the electrophilicity of the phosphorus atom. The involvement of $d\pi$–$p\pi$ bonding is indicated.

INTRODUCTION

In earlier papers in this series (1), we have been concerned with the chemistry of methylenephosphoranes (phosphonium ylids) (I), especially those characteristics that reflect the nature of the "ylid bond". Our attention has focused on the basicity and nucleophilicity of the ylid carbanion as influenced by its substituents. We report herein the initial results of our parallel investigations of the chemistry of iminophosphoranes (phosphinimines) (II). The latter are isoelectronic with phosphonium ylids.

I II

Iminophosphoranes were first prepared by Staudinger and Meyer (2) in 1919. As indicated in a recent review (3), several groups have examined the chemistry of iminophosphoranes qualitatively. These results have indicated the substances to be typical nucleophiles, undergoing reactions such as alkylation, acylation, halogenation, and protonation all on the nitrogen atom. However, there has been no correlation of structure with nucleophilicity in the imines. We report such a correlation in this work.

Staudinger and Meyer (2) had reported that *N*-phenyliminotriphenylphosphorane reacted with diphenylketene to yield triphenylketenimine and triphenylphosphine oxide (eq. [1]). Since that early work, only a few others have studied the reaction between imino-

$$\begin{array}{ccc} C_6H_5N{=}P(C_6H_5)_3 & & C_6H_5N{=}C{=}C(C_6H_5)_2 \\ + & \rightarrow & + \\ (C_6H_5)_2C{=}C{=}O & & (C_6H_5)_3PO \end{array} \qquad [1]$$

phosphoranes and carbonyl compounds to form Schiff bases and phosphine oxides (4–9). Nonetheless, it has become a useful and well-accepted reaction. Its scope has been expanded to include reaction with ketones, aldehydes, isocyanates, carbon dioxide, and carbon

disulfide. In all cases, a C=N bond is formed to replace a C=O or C=S bond, the driving force appearing to be the formation of phosphine oxide or sulfide.

It has been assumed (8, 9), without valid proof, that the mechanism of these reactions parallels that of the Wittig Reaction between methylenephosphoranes and carbonyl compounds to yield olefins and phosphine oxide (3, 10). Specifically, it has been assumed that the carbonyl carbon undergoes attack by the nitrogen of the imine to yield a betaine intermediate (V). The latter was thought to be converted into products by oxygen transfer to phosphorus (see eq. [3] in Discussion).

We have undertaken a detailed study of the mechanism of the reaction of iminophosphoranes with carbonyl compounds. We report herein the preparation of the necessary imines and our initial kinetic studies on the reaction.

RESULTS

A series of *N*-(substituted phenyl)-iminotriphenylphosphoranes (VI) were prepared in 55–90% yields by reaction of triphenylphosphine with the appropriate substituted phenyl azide, a procedure originally used by Staudinger and Meyer (2) (eq. [2]). A series of *N*-phenyliminotri-(substituted phenyl)-phosphoranes (VII) also were prepared in 60–87% yields, but by reaction of phenyl azide with the appropriate substituted triphenylphosphine. The properties of these imines are listed in Table I and the Experimental.

$$(C_6H_5)_3P + XC_6H_4N_3 \rightarrow (C_6H_5)_3P{=}NC_6H_4X + N_2 \qquad [2]$$

$X{-}C_6H_4{-}N{=}P(C_6H_5)_3$

VI*a* X = *p*-NO_2
VI*b* X = *m*-NO_2
VI*c* X = *m*-Cl
VI*d* X = *p*-Br
VI*e* X = H
VI*f* X = *p*-CH_3
VI*g* X = *p*-CH_3O

$C_6H_5N{=}PR_3$

VII*a* R = *m*-$CH_3C_6H_4$
VII*b* R = C_6H_5
VII*c* R = *p*-BrC_6H_4
VII*d* R = *p*-ClC_6H_4

The pK_a values of the hydrochlorides of the two series of imines were determined by potentiometric titration in 95% ethanol solution. The pK_a values ranged from 4.55 to 8.36 and are reported in Table I. These determinations were confirmed by using a spectrophotometric method (11). A plot of pK_a versus σ^0 gave a ρ value of +3.5 for the imines of type VI, and a plot of σ versus pK_a gave a ρ value of 9.3 for those of type VII (Figs. 1 and 2).

The imines (VI and VII) all reacted with *p*-nitrobenzaldehyde to yield the expected and known substituted *N*-(*p*-nitrobenzylidene) anilines in 60–95% yields (see Experimental). The rate of disappearance of VI*e* in its reaction with *p*-nitrobenzaldehyde was determined in absolute ethanol at 40.5° by potentiometric titration of the imine. The reaction was second order, first order each in imine (VI*e*) and in aldehyde. The reaction was subject to a solvent effect, the k_{rel} values in ethanol, chloroform, and benzene being 29:15:1, respectively.

Activation parameters for the reaction of VI*e* with benzaldehyde were obtained from the rate data taken at three temperatures (30, 40.5, and 50 °C). The E_a was 8.46 kcal/mole and the $\Delta S^{\ddagger}$ was −42.0 e.u. at 40.5°. Rate data were accumulated for the reaction of VI*e* with a series of substituted benzaldehydes (Table II). A plot of log k/k_0 versus σ gave a Hammett plot with a ρ value of +2.1.

The effect of the imine structure on the rate of reaction with *p*-nitrobenzaldehyde was examined. The rate constants are summarized in Table I. A Hammett plot for the *P*-phenyl substituents (i.e. VII) versus σ gave a ρ value of −0.70 (Fig. 3). A similar plot for the *N*-phenyl substituents did not give a straight line, the curve being concave down (Fig. 4).

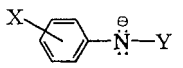
DISCUSSION



Basicity of Iminophosphoranes

As indicated in Fig. 1, the pK_a values of the *N*-(substituted phenyl)-iminotriphenyl-phosphoranes (VI) correlated well with σ^0, the "normal substituent constant" (14), giving a ρ value of +3.5. This is equivalent to saying the imine basicities also correlated and

implies, as expected, that the more delocalization given the anionic center, the less basic is that imine (and the more acidic is its conjugate acid).

The observation that the use of σ values or σ^- values gave rise to less-satisfactory correlations with the pK_a values of VI is significant. The point for the *p*-nitro imine (VI*a*) lay below the line when the σ value of +0.78 was used, above the line when the σ^- value of +1.27 was used, and nearly on the line when a σ^0 value of +0.82 was used. A value of +0.92 would have fallen on the best line. This observation is consistent with that of van Bekkum *et al.* (15), who observed that in a series of reactions the substituent constant for the *p*-nitro group varied from 0.766 to 1.378 depending on the degree of resonance interaction of the substituent with the reaction site. Clearly, there is more than a simple inductive interaction between the imine group and the nitro group in VI*a*. There would appear to be a demand for some, but not an excessive amount of, resonance interaction (the amount being considerably less than that required for a phenoxide ion).

The successful use of σ^0 values in the correlation of pK_a values of VI attests to the modest demand for delocalization exerted by the nitrogen anion on the *N*-phenyl substituents. The modest level of this demand probably is due in part to the fact that nitrogen is able to sustain a charge. The major factor, however, probably is a result of the phosphonium group providing considerable stabilization for the anionic center by virtue of $p\pi$–$d\pi$ overlap between phosphorus and nitrogen. Stewart and O'Donnell (16) have reported similar behavior for the *N*-(substituted phenyl)-2,4,6-trinitroanilines (VIII), the acidities of which correlated with σ^0. In this instance, the modest demand for delocalization by the substituent was attributed to the presence of the highly stabilizing 2,4,6-trinitrophenyl

VI, Y = $(C_6H_5)_3P$

VIII, Y = $C_6H_2(NO_2)_3$ (2,4,6)

group. We previously observed that σ^0 would correlate with the pK_a values for substituted fluorenyltriphenylphosphonium bromides, the phosphonium group providing a major source of stabilization for the carbanion (1).

The ρ value of +3.5 from the plot of the pK_a values of VI versus σ^0 is smaller than the +5.0 value obtained by us (1) for the triphenylphosphoniumfluorenylide system. This is to be expected when the anionic center is changed from carbon to nitrogen. However, the value is larger than the +1.7 value reported by Stewart and O'Donnell (16) for the acidity of the *N*-(substituted phenyl)-2,4,6-trinitroanilines (VIII). The difference may imply that the triphenylphosphonium group provides somewhat less delocalization than does the 2,4,6-trinitrophenyl group for the anionic center. Concomitantly, the substituents (X in VI and VIII) would be called on for more interaction in VI than in VIII, leading to a larger ρ value.

As indicated in Fig. 2, the pK_a values of the *N*-phenyliminotri-(substituted phenyl)-phosphoranes (VII) were linearly correlated with a ρ value of +9.3. The effect per substituent is one-third as large, the ρ value being +3.1. This observation indicates that electron-withdrawing substituents on the *P*-phenyl groups decrease the basicity of the nitrogen anion. We attribute this stabilization of the phosphinimine to $p\pi$–$d\pi$ overlap between the filled 2p-orbitals of nitrogen and the vacant 3d-orbitals of phosphorus. Furthermore, the sign of the ρ value is consistent with the proposal by Craig and Magnusson (17) that the attachment of more electronegative groups to a phosphonium atom would permit better $d\pi$-bonding. Such a correlation was observed in our earlier work with phosphoniumfluorenylides (1), and the generalizations indicated therein probably apply to this work. We conclude that a measure of imine basicity is a convenient and reliable indication of the degree of $p\pi$–$d\pi$ overlap in the imine P—N bond.

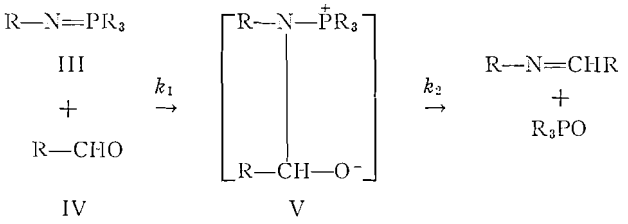
The ρ value per substituent of +3.1 is larger than that of +1.7 found for the correlation of the pK_a values of the 9-fluorenyltri-(substituted phenyl)-phosphonium salts. This is to be expected, however, since fluorene is more acidic than aniline.

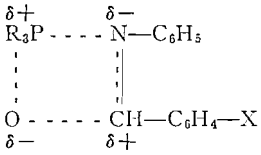
The mode of interaction of the *P*-phenyl groups and their substituents with the phosphorus atom in VII is made apparent by these results. Normally, when a substituent interacts through a benzenoid ring with an electron-deficient center, linear free energy correlations are best obtained by using σ^+ values (18, p. 203). In spite of the direct attachment of an electron-deficient phosphorus atom to the benzenoid ring in VII, the pK_a values did not correlate with σ^+. Furthermore, a better correlation was obtained with σ than with σ^0 values. Together these observations indicate that there is little direct resonance interaction between the *P*-phenyl substituents and the phosphorus atom. The conclusion is similar to that drawn in the fluorenylide case (1); the phosphorus substituents were exerting mainly an inductive effect on the phosphorus atom, although it undoubtedly contained both a σ and a π component.



It may be concluded that the basicity of iminophosphoranes is dependent on the nature of both the nitrogen and phosphorus substituents. There can be stabilization of such structures by delocalization of the charge from nitrogen by inductive effects, by $p\pi$–$p\pi$ overlap with nitrogen substituents, and by $p\pi$–$d\pi$ overlap with phosphonium groups.

The results from this work and our earlier work on fluorenylides (1) are pertinent to the question of electronic interactions of organic substituents with quaternary phosphorus. We conclude, on the basis of earlier arguments (3, 19), that there is $p\pi$–$d\pi$ resonance interaction between quaternary phosphorus and a carbanion (in ylids) or a nitrogen anion (in iminophosphoranes). However, at the same time we conclude from our own work that interaction of the same quaternary phosphorus atom with phenyl substituents is of a different nature, devoid of strong resonance interactions. This interaction can be rationalized by the proposal that there is little $p\pi$–$d\pi$ overlap between the phenyl group and phosphorus, perhaps caused by steric interference in the ring orientation required for maximum overlap. (This would leave inductive effects as the major observed mode of interaction.) Alternatively, there may be $p\pi$–$d\pi$ interaction between phenyl and phosphorus, but the effects created thereby are inefficiently reflected at the carbanion (the carbanion is our probe to the phosphorus atom by a measure of its basicity). This latter view is consistent with earlier work (20) in phosphoryl systems, in which it was concluded that substituents could conjugate weakly with phosphorus but that there was no direct conjugation with the phosphorus–oxygen bond. There is insufficient evidence available at present to permit a choice between these (and perhaps other) rationalizations.

Reaction with Carbonyl Compounds



The substituted iminophosphoranes (VI and VII) all reacted with a series of benzaldehydes. A typical reaction, that between *N*-phenyliminotriphenylphosphorane (VI*e*) and *p*-nitrobenzaldehyde in ethanolic solution, was first order in each component. The reaction rates were subject to a solvent effect, in that the reaction was twice as fast in ethanol as in chloroform, and 30 times as fast in ethanol as in benzene. These observations are analogous to those made by Speziale and Bissing (10) for the reaction of carbethoxymethylenetriphenylphosphorane with benzaldehyde. They are consistent with a proposal of increased charge localization in the transition state. In other words, these data are in agreement with the proposed intermediacy of a betaine (V). It is also consistent with the latter's formation in the slow step of the reaction (i.e. $k_2 > k_1$).

The reaction of *N*-phenyliminotriphenylphosphorane (VI*e*) with benzaldehyde showed

[3] 

a small activation energy (8.46 kcal/mole) and a large negative entropy of activation (−42.0 e.u. at 40.5°). This trend also was found by Speziale and Bissing for the Wittig reaction (10). It indicates that the transition state probably is highly structured (i.e. the phosphorus and oxygen probably are eclipsed as a result of electrostatic attraction). Rate-limiting betaine formation implies considerable concentration of charge, which would require significantly increased solvation. Both of these factors would lead to a negative entropy of activation. Furthermore, they also imply that $k_2 > k_1$.

The substituent effect observed by reacting various benzaldehydes with *N*-phenyliminotriphenylphosphorane also indicated that $k_2 > k_1$. A ρ value of +2.1 was obtained (Table II) from a plot of log k/k_0 versus σ for substituted benzaldehydes. The sign of the ρ value indicates that the aldehyde was subjected to nucleophilic attack on the carbonyl carbon in the slow step. The magnitude of the ρ value compares favorably with that (+2.7) reported by Speziale and Bissing (10) for the Wittig reaction, a reaction involving slow, reversible betaine formation and rapid betaine decomposition. The ρ value is larger than, and of the opposite sign to, that expected for a reaction in which the second step, betaine decomposition, was the slow step ($k_1 > k_2$). In such an instance, a transition state such as IX would be involved. The effect of electron-donating groups (X) would be to lower the energy of the

IX

species and speed the reaction. Our observations are just the opposite.

A plot of $-pk_{BH^+}$ for the substituted benzaldehydes (21) versus log k/k_0 for the reaction between VI*e* and the appropriate benzaldehydes gave a straight line with a slope of +0.85. This observation clearly ruled out an alternate mechanism involving nucleophilic attack by carbonyl oxygen on phosphorus. It is consistent with the proposed nucleophilic attack by imine on the carbonyl carbon in the rate-limiting step.

Additional evidence for betaine formation being the slow step was provided by a Hammett plot of log k/k_0 versus σ for the reaction of a series of *N*-phenyliminotri-(substituted phenyl)-phosphoranes (VII*a*–VII*d*) with *p*-nitrobenzaldehyde (Table I). A ρ value of −0.70 was obtained, the effect per substituent being one-third as large. The sign of the ρ value indicates that electron-withdrawing groups slowed the reaction. On the basis of our pK_a studies, it would be expected that such substituents would decrease the nucleophilicity of the imine. Reduced nucleophilicity would be expected to decrease k_1, but the same substitution would be expected to increase the rate of betaine decomposition (k_2) (22). That the former expectation was reflected in the observed data argues for betaine formation (k_1) being the slow step of the reaction.

The small magnitude of the reaction constant, especially when contrasted with the large ρ value for the pK_a values of the same imines (VII), may be indicative that, although betaine formation may be the slow step ($k_2 > k_1$), there is not much difference between k_1 and k_2. The smaller magnitude of the ρ value for the effect of benzaldehyde substituents compared with that reported by Speziale and Bissing (10) supports this hypothesis. The smaller solvent effect (a factor of 29 from benzene to ethanol in this work compared with a factor of 927 from benzene to ethanol reported by Speziale and Bissing (10)) also is consistent with the difference in k_1 and k_2 being less than that for ylids. It would appear that the *P*-phenyl substituents in VII are exerting opposing effects on the two steps of the reaction, betaine formation and betaine decomposition, thereby causing little change in k_{obs}.

The effect of the *N*-phenyl substituents in VI on the rate of reaction of imines with *p*-nitrobenzaldehyde clearly indicated a change in mechanism and supports the hypothesis that k_1 and k_2 are very similar. A plot of log k/k_0 versus σ for the substituents *p*-nitro, *m*-nitro, *m*-chloro, *p*-bromo, and hydrogen in VI gave a straight line with a ρ value of -2.4. This indicated that the more nucleophilic imine (VI*e*) reacted fastest, as would be expected for $k_2 > k_1$, i.e. imine nucleophilicity was reflected mainly in the first (and slow) step. However, a plot of log k/k_0 versus σ for the substituents *p*-methoxy, *p*-methyl, and hydrogen gave a straight line with a ρ value of $+0.95$. This observation, the more nucleophilic imine (VI*g*) giving a slower rate, is inconsistent with betaine formation being the slow step. The complete plot is concave down, a pattern previously observed for a change in the rate-limiting step but not for a complete change in the mechanism of a reaction (18, pp. 189–190; 23).

The pattern of substituent effects elaborated above may be rationalized as follows. With unsubstituted imine (VI*e* and VII*b*) betaine formation may be the rate-limiting step (i.e. $k_2 > k_1$). Accordingly, changes in the solvent polarity and changes in the electrophilicity of the carbonyl group would be reflected in k_{obs}. Under a fixed set of conditions (i.e. a common solvent and common aldehyde), changes in the imine structure theoretically could be reflected to the greatest degree in k_1 or k_2. Imine structure affects k_1 through alterations in the nucleophilicity such that electron-withdrawing substituents on the *P*-phenyl or *N*-phenyl groups decrease the electron density both on phosphorus and on nitrogen. This leads to a less nucleophilic nitrogen (i.e. smaller k_1) but to a phosphorus more susceptible to oxyanion attack (i.e. larger k_2). Thus, k_1 remains the rate-limiting step, and alterations in k_1 are reflected directly in k_{obs}. However, electron-donating substituents on the *P*-phenyl or *N*-phenyl groups increase the electron density about both phosphorus and nitrogen. This leads to a more nucleophilic nitrogen (i.e. larger k_1) but to a phosphorus less susceptible to oxyanion attack (i.e. smaller k_2). Therefore, k_2 becomes the rate-limiting step, and alterations in k_2 are reflected directly in k_{obs}.

On the basis of this rationale, the change of the rate-limiting step can be explained. At some point, as the electron density on nitrogen becomes sufficiently large, the rate-limiting step changes from betaine formation to betaine decomposition. Examination of our data indicates that $k_2 > k_1$ when the *P*-phenyl group carries any kind of substituent and when the *N*-phenyl group carries no substituent or an electron-withdrawing substituent. When the *N*-phenyl group carries electron-donating substituents it appears that $k_1 > k_2$.

The situation just described is not novel. Similar changes in the rate-limiting step appear to prevail in methylenephosphoranes (3). Whereas "stabilized" phosphonium ylids such as carbomethoxymethylenetriphenylphosphorane (10) and fluorenylidenetriphenylphosphorane (24) react with carbonyl compounds by a mechanism involving

rate-limiting betaine formation, non-stabilized ylids such as methylenetriphenylphosphorane undergo the same reaction but with rapid betaine formation and rate-limiting decomposition (25). However, the work reported herein on the reaction of iminophosphoranes with carbonyl compounds is the first describing a change in the rate-limiting step through a continuous series of "ylidic" substances.

We are continuing our study of this reaction with a view to investigating its reversibility, elaborating further on the relative values of the rate constants, and providing more convincing evidence for the intermediacy of a betaine.

EXPERIMENTAL

General

Melting points are uncorrected. Analyses were performed by Alfred Bernhardt Microanalytical Laboratory, Mülheim (Ruhr). All pH determinations were carried out with a Beckman model 76 expanded-scale pH meter equipped with glass and saturated calomel electrodes and standardized with a standard buffer of pH 7.02 at 25° in an aqueous medium.

Preparation of Iminophosphoranes

The *N*-phenyliminotri-(substituted phenyl)-phosphoranes (VII) were prepared by adding an ethereal solution of the phosphine to an equimolar ethereal solution of phenyl azide (26). After the solution was heated under reflux for 2 h to ensure complete evolution of the nitrogen, the solvent was evaporated and the residue was crystallized from absolute ethanol.

The phosphines required for these syntheses have been described in our earlier work (1).

N-Phenyliminotri-(*m*-tolyl)-phosphorane, pale-yellow microcrystals, m.p. 135–136°.

Anal. Calcd. for $C_{27}H_{26}PN$: C, 82.00; H, 6.59; P, 7.85; N, 3.54. Found: C, 81.13; H, 6.53; P, 8.26; N, 3.70.

N-Phenyliminotri-(*p*-bromophenyl)-phosphorane, yellow microcrystals, m.p. 166–167°.

Anal. Calcd. for $C_{24}H_{17}PNBr_3$: C, 48.90; H, 2.88; P, 5.25; N, 2.38; Br, 40.60. Found: C, 48.62; H, 2.98; P, 5.05; N, 3.14; Br, 40.98.

N-Phenyliminotri-(*p*-chlorophenyl)-phosphorane, pale-yellow microcrystals, m.p. 160–161°.

Anal. Calcd. for $C_{24}H_{17}PNCl_3$: C, 63.00; H, 3.72; P, 6.56; N, 3.10; Cl, 23.30. Found: C, 62.97; H, 3.73; P, 6.57; N, 3.27; Cl, 23.46.

The *N*-(substituted phenyl)-iminotriphenylphosphoranes (VI) were prepared by adding an ethereal solution of triphenylphosphine to an equimolar ethereal solution of the substituted phenyl azide. After the solution was heated under reflux for 2 h and the nitrogen evolution had ceased, the solvent was removed *in vacuo* and the residue was crystallized from absolute ethanol. By this means the seven imines (VI*a*–VI*g*) listed in Table I were prepared. In all cases the physical constants agreed with those in the literature.

The substituted phenyl azides were prepared from the appropriate substituted aniline by treatment with nitrous acid and then sodium azide as previously described (27). The crude azides were isolated, but not purified, and then treated directly with triphenylphosphine.

pK_a Determinations

Three different methods were employed. The most reproducible method was back titration, whereby 0.1 mmole of imine was dissolved in 40 ml of absolute ethanol. After the addition of 6.5 ml of 0.0205 *N* hydrochloric acid, the solution was titrated with 0.0173 *N* potassium hydroxide. A plot of the volume of titrant versus pH was prepared. From this titration curve the point of half-neutralization could be determined. At that point the concentration of imine and its conjugate acid would be equal. Therefore, the pK_a of the imine would equal the pH of the solution (28). The pK_a values so obtained are reported in Table I.

The imines also were titrated directly with 0.0205 *N* hydrochloric acid. The pK_a values thereby determined were consistently lower than those obtained by back titration, although a plot of pK_a versus σ gave nearly the same ρ value (+3.3).

Spectrophotometric determination of the pK_a values of the imines was carried out as reported in our earlier work (1). The pK_a values thereby obtained were within 0.3 pK_a unit of those reported in Table I. A plot of pK_a versus σ gave nearly the same ρ value (+3.3).

Reaction of Imines with Aldehydes

A general procedure was used for all such reactions. A solution of 2.5 mmoles of imine and 2.5 mmoles of aldehyde in 50 ml of ethanol was heated under reflux for 3 h. Evaporation of half of the solvent and then cooling the rest led to the precipitation of the Schiff base. Reaction of *p*-nitrobenzaldehyde with the imines VI*a*–VI*g* gave the following products, respectively: 80% of *p*-nitro-*N*-(*p*-nitrobenzylidene)-aniline, m.p. 200–201° (lit. (29) m.p. 199–200°); 77% of *m*-nitro-*N*-(*p*-nitrobenzylidene)-aniline, m.p. 154–155° (lit. (29) m.p. 152–153°); 60% of *m*-chloro-*N*-(*p*-nitrobenzylidene)-aniline, m.p. 110–111° (Anal. Calcd. for $C_{13}H_9N_2O_2Cl$: C, 59.80; H, 3.45; N, 10.70; Cl, 13.20. Found: C, 59.48; H, 3.44; N, 10.51; Cl, 12.77); 84% of *p*-bromo-*N*-(*p*-nitrobenzylidene)-aniline, m.p. 159–160° (lit. (30) m.p. 160–161°); 68% of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

N-(*p*-nitrobenzylidene)-aniline, m.p. 91–91.5° (lit. (31) m.p. 93°); 78% of *N*-(*p*-nitrobenzylidene)-*p*-toluidine, m.p. 123–124° (lit. (30) m.p. 122.5°); and 95% of *N*-(*p*-nitrobenzylidene)-*p*-anisidine, m.p. 134–135° (lit. (32) m.p. 139°). Reaction of benzaldehyde with VIe gave *N*-benzylideneaniline in an 82% yield, m.p. 49–50° (lit. (33) m.p. 48°).

Kinetic Measurements

Reagent-grade materials were used and purified where necessary. Ethanol was distilled from magnesium filings.

The rates of reaction of the imines (VI and VII) with the benzaldehydes were determined by following the rates of disappearance of the imine. The imine concentration was determined by quenching the reaction solution with hydrochloric acid and then back titrating as described for the pK_a determinations. In control experiments it was shown that the ethanol–water ratio did not influence this titration between 5% and 50% water. Furthermore, the presence of the other reactant, the benzaldehyde, or the presence of the products, *N*-benzylidene aniline and the phosphine oxide, did not alter the reliability of this titration.

The order of the reaction was determined by the differential method (34, p. 14). The integrated form of the rate equation for a second-order reaction was used to calculate the reaction rates (34, p. 12). Standard means were used to obtain the energy (E_a) and entropy ($\Delta S^{\pm}$) of activation (35), the reaction temperatures being 30.0 ± 0.2°, 40.5 ± 0.2°, and 50.0 ± 0.2°.

In a typical experiment 0.5 mmole of the imine and 0.5 mmole of the aldehyde were separately dissolved in exactly 100 ml of absolute ethanol and brought to 40.5 ± 0.2° in a water bath shaker. For the $t = 0$ determination 20 ml of each solution was withdrawn with a syringe and added to a beaker containing 6.5 ml of 0.0205 *N* hydrochloric acid. The acid converted the imine into its conjugate base, thereby preventing any reaction with the aldehyde. The quenched solution was then titrated potentiometrically with 0.0173 *N* potassium hydroxide. The remaining ethanolic solutions of imine and aldehyde were mixed in the water bath. Aliquots were withdrawn periodically, quenched with 6.5 ml of standard hydrochloric acid, and then titrated potentiometrically.

The reaction rates are recorded in Table I.

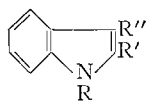
THE CHEMISTRY OF THE INDOLE GRIGNARD REAGENT

I. THE REACTION OF INDOLE MAGNESIUM IODIDE WITH ETHYL CHLOROFORMATE[1]

S. KAŠPÁREK[2] AND R. A. HEACOCK

Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia

Received July 22, 1966



ABSTRACT

In contrast to previous reports in the literature, it has been shown that both 1- and 3-carbethoxyindole are obtained from the reaction of indole magnesium iodide with 1 or 2 moles of ethyl chloroformate. The formation of 1-carbethoxyindole was favored at low temperatures (i.e. −10°), whereas maximum yields of 3-carbethoxyindole were obtained at 10°. Significant quantities of 1,3-dicarbethoxyindole are only formed in the presence of 2 equivalents of ethyl chloroformate and when the reaction is carried out at higher temperatures (i.e. 35°).

Paper and gas–liquid chromatographic systems have been developed for the qualitative and quantitative analysis of mixtures containing indole, 1-, 2-, and 3-carbethoxyindole, and 1,3-dicarbethoxyindole.

The main product of the reaction between indole magnesium iodide and ethyl chloroformate was originally reported to be 2-carbethoxyindole (I) by Oddo and Sessa more than 50 years ago (1). However, Majima and Kotake subsequently claimed that the major product was not I but 3-carbethoxyindole (II) (2, 3), and that under ideal conditions yields of up to 78% of this ester could be obtained (3). The Japanese authors further reported that 1,3-dicarbethoxyindole (III) was invariably formed together with the monoester II, and that when the reaction was carried out in the presence of 2 moles of ethyl chloroformate the diester III was formed in sufficient quantity to allow its isolation from the final reaction mixture by fractional crystallization (3).

In the 36 years that have elapsed since Majima and Kotake's second paper appeared, several authors have employed essentially the same method for the preparation of II, without reporting precise reaction conditions or yields obtained (cf. refs. 4–6). However, Brown and Garrison claimed that the procedure described by Majima and Kotake was

I R = R'' = H; R' = $COOC_2H_5$
II R = R' = H; R'' = $COOC_2H_5$
III R' = H; R = R'' = $COOC_2H_5$
IV R = R' = R'' = H
V R = $COOC_2H_5$; R' = R'' = H
VI R = $CONH_2$; R' = R'' = H
VII R = $C_6H_5CONHCO$; R' = R'' = H

unsatisfactory and that better results were obtained by carrying out the reaction between −15 and −5° (5) instead of at the higher temperature (up to 35°) employed previously by the Japanese workers. Noland and Rieke prepared II by Majima and Kotake's method in an unspecified yield, but reported that the melting point of II could be raised from 118–119° to 126–127° by chromatographic purification on alumina (6).

In our hands, the yields of II obtained by the interaction of ethyl chloroformate and indole magnesium iodide, under the conditions previously described, were lower than anticipated. This fact, together with the general confusion in the literature on this subject, indicated that a comprehensive investigation of the effect of the systematic variation of several of the more important reaction parameters on the nature and composition of the

[1]*Issued as N.R.C. No. 9219.*
[2]*National Research Council Postdoctorate Fellow, 1965–1967.*

products would be of value. A series of experiments was therefore performed in which the reaction between equivalent quantities of indole magnesium iodide and ethyl chloroformate was carried out at a number of different temperatures (between −10 and 20°) for a series of reaction times (between 5 and 140 min). The reaction mixtures were worked up in the usual way, and in each case the products were analyzed by means of paper and gas–liquid chromatographic procedures.

Satisfactory separations of authentic samples of all possible expected components of the reaction mixtures (i.e. indole (IV), 3-carbethoxyindole (II), 1,3-dicarbethoxyindole (III), and 2-carbethoxyindole (I)) could readily be obtained by radial paper chromatography with a formamide/(benzene – light petroleum (1:1)) system (cf. ref. 7). The chromogenic reagents commonly employed for the detection of indoles on developed chromatograms, such as Ehrlich's reagent, cinnamaldehyde, and *p*-dimethylaminocinnamaldehyde, were unsatisfactory in this case, since I, II, and III gave either no color or weak ill-defined colors with these reagents. However, these esters and unchanged indole gave characteristic colors with Gibb's reagent (*N*,2,6-trichloro-*p*-quinoneimine) and could easily be located on developed chromatograms by spraying with this reagent.

Gas–liquid chromatography has not so far been employed extensively for the analysis of indole derivatives, but simple indoles have been separated satisfactorily with silicone oil (8, 9) or "Versamid 900" (10, 11) as stationary phases. In the current investigation it was observed that IV and the esters I, II, and III could be separated on a 6 ft × $\frac{1}{8}$ in. column with the silicone gum rubber (SE-30) (5% on Chromosorb W) as the stationary phase. This stationary phase has previously been employed for the gas chromatography of tryptamine derivatives (12).

Paper chromatographic analysis of the products obtained from the interaction of indole magnesium iodide and 1 or 2 moles of ethyl chloroformate invariably indicated the presence of at least three main components (II, IV, and a substance or substances which travelled with the solvent front, gave a yellow color with Gibb's reagent, and was assumed to be the diester III). It appeared, at first, that gas chromatographic analysis of the reaction mixtures confirmed these results, but a careful study of the temperature dependence of the retention times of indole (IV), authentic samples of the expected reaction products I, II, and III (see Fig. 3), and the components of the reaction mixtures (see Fig. 1) indicated that, although II and IV were always present among the reaction products, the third main product was not the diester III. The gas chromatographic investigation further showed that, unless the reaction was carried out with 2 moles of ethyl chloroformate, only traces of III were formed (see Table II), and that only when the reaction was carried out at 35° were significant quantities of III formed (see Fig. 1B).

A careful reexamination of the paper chromatographic behavior of all the substances under investigation indicated that the component of the reaction mixture previously assumed to be III gave a somewhat different shade of yellow color with Gibb's reagent, and that the colored derivative was more stable than that obtained from an authentic sample of III. It was not possible to differentiate between these two compounds on formamide- or dimethylformamide-treated paper with a variety of nonpolar running solvents (see Table I).

The preparation of suitable calibration curves enabled a quantitative analysis of the reaction mixtures to be made by gas–liquid chromatography. In this manner it was ascertained that, in the reaction between indole magnesium iodide and 1 mole of ethyl chloroformate, between 20 and 30% of the original indole (IV) was invariably recovered unchanged, and that the yields of 3-carbethoxyindole (II) varied between 27 and 45%, the

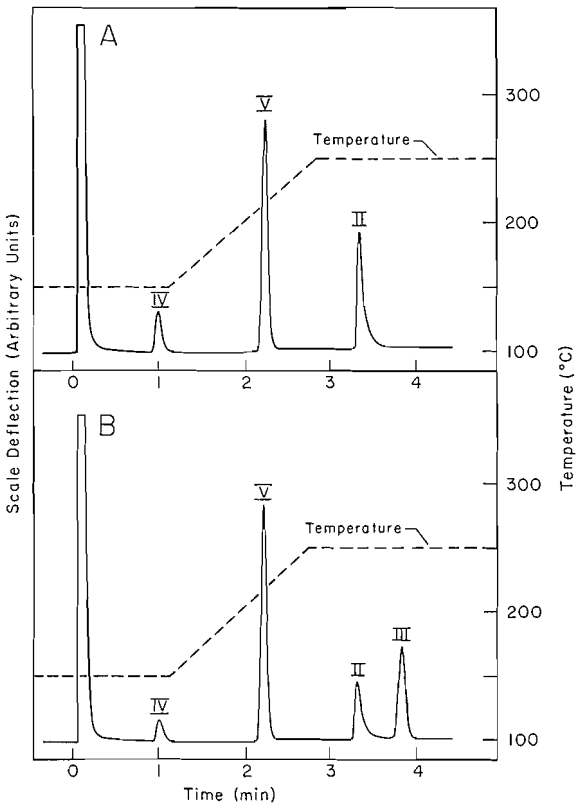

FIG. 1. Gas–liquid chromatograms of the ether-soluble products from the reaction of indole magnesium iodide with (A) 1 or 2 moles of ethyl chloroformate at temperatures below 0°, and (B) 2 moles of ethyl chloroformate at 35°. II = 3-carbethoxyindole; III = 1,3-dicarbethoxyindole; IV = indole; V = 1-carbethoxyindole.

maximum yield of II being obtained when the reaction was carried out at 10° for 100 min. This finding is in contrast to one of the more recent previous reports, which suggests that low temperatures favor the formation of II (5). However, under all the reaction conditions studied, significant quantities of the third component were always formed, and it appeared to be the main product when the reaction was carried out below −5°. It was possible to separate this substance from the other components by column chromatography on alumina or "Polyclar AT". The infrared spectrum of this product, which was obtained as a colorless oil, exhibited a strong ester carbonyl peak at 1 735 cm^{-1}, but showed no peaks in the NH stretching region. The proton magnetic resonance (p.m.r.) spectrum of the oil indicated the presence of four aromatic protons and the indole α and β protons (see Fig. 2) (cf. refs. 13–17). The spectroscopic results, together with the microanalytical data, suggest that the new product is the hitherto undescribed 1-carbethoxyindole (V),[3] which was obtained in a 30–40% yield and which gave indole (IV) on hydrolysis with aqueous alkali and a white crystalline solid, probably indole-1-carboxamide (VI), on treatment with aqueous ammonia. A substance reported to be the amide VI had previously been obtained by Dutcher and Kjaer by the hydrolysis of *N*-benzoylindole-1-carboxamide (VII) (18). However,

[3]*At the conclusion of our investigation we became aware of the fact that, although 1-carbethoxyindole had not previously been described in the literature, it was available commercially from the Regis Chemical Co., Chicago, Illinois, U.S.A.*

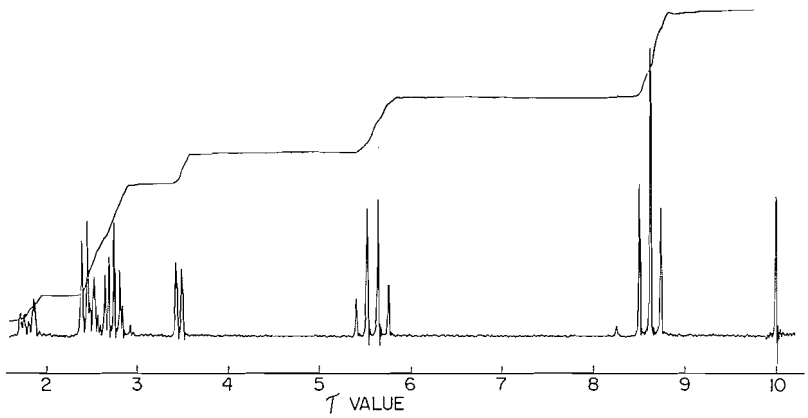

FIG. 2. The p.m.r. spectrum of 1-carbethoxyindole (V) in $CDCl_3$ (recorded on a Varian A-60-A instrument with tetramethylsilane as an internal standard).

these authors reported a slightly different melting point and different ultraviolet spectroscopic data for their product (18).

In conclusion, it may be stated, with regard to the reaction between indole magnesium iodide and either 1 or 2 moles of ethyl chloroformate, that (*i*) at low temperatures (i.e. $< -5°$) and for reaction times between 5 and 60 min the main product is 1-carbethoxyindole (V); (*ii*) 3-carbethoxyindole (II) is always formed, but in yields not exceeding 46%, the formation of II being favored by higher reaction temperatures (ca. 10°); (*iii*) some unreacted indole was always recovered unchanged; and (*iv*) significant quantities of 1,3-dicarbethoxyindole (III) are only formed when the reaction is carried out at temperatures of not less than 35° with 2 moles of ethyl chloroformate.

EXPERIMENTAL

The infrared spectra were recorded on a Perkin–Elmer model 237 recording spectrophotometer; the ultraviolet spectra were recorded on either a Bausch and Lomb "Spectronic 505" or a Beckman DU spectrophotometer, and the p.m.r. spectrum on a Varian A-60-A instrument.

Carbethoxyindoles

3-Carbethoxyindole (II)

A solution of indole-3-carboxylic acid (3 g) in dry ethanol (125 ml), saturated with hydrogen chloride, was boiled under reflux, in the dark, under anhydrous conditions for 2 h. The deep-red solution was then evaporated to dryness *in vacuo*, the residues were dissolved, as far as possible, in ether (200 ml), and the ether solution was washed with aqueous sodium bicarbonate solution and water. Recrystallization of the solid obtained on concentration of the dried (Na_2SO_4) ether solution from 50% ethanol gave 3-carbethoxyindole (1.57 g, 45%), m.p. 123–124°, ν_{max}^{Nujol} 3 250 cm^{-1} (NH) and 1 670 cm^{-1} (C=O), $\lambda_{max}^{C_2H_5OH}$ 282 and 288 mμ. As far as the authors are aware, there are no previous reports in the literature of the preparation of 3-carbethoxyindole by the direct esterification of indole-3-carboxylic acid, the compound having previously been obtained by the Grignard reaction described in this paper. The literature melting points for 3-carbethoxyindole are 118–119° (2), 124° (19), and 126–127° (6).

2-Carbethoxyindole (I)

2-Carbethoxyindole (m.p. 121–123°, ν_{max}^{Nujol} 3 300 cm^{-1} (NH) and 1 690 cm^{-1} (C=O), $\lambda_{max}^{C_2H_5OH}$ 293 mμ) was prepared by the method of Fischer and Pistor (20).

1,3-Dicarbethoxyindole (III)

1,3-Dicarbethoxyindole (m.p. 103–104°, ν_{max}^{Nujol} 1 750 and 1 715 cm^{-1} (C=O); $\lambda_{max}^{C_2H_5OH}$ 274, 285, and 292 (sh) mμ) was prepared by the method of Majima and Kotake (3).

1-Carbethoxyindole (V)

Freshly distilled ethyl chloroformate (1.1 ml) in dry ether (5 ml) was added, with stirring, at −10° during 15 min to indole magnesium iodide (prepared from indole (1.18 g) by the method of Doyle *et al.* (21)) in dry ether (10 ml). After 90 min at a temperature between −9 and −5°, crushed ice was added; the reaction mixture was acidified with dilute acetic acid and extracted with ether (3 × 30 ml). The combined ether extracts were washed with aqueous sodium bicarbonate and water, dried (Na_2SO_4), and concentrated *in*

For personal use only.

vacuo. The residue was dissolved in benzene (5 ml) and adsorbed on "Polyclar AT"[4] (24 × 3 cm). Elution of the column with benzene – light petroleum[5] (1:3) (100 ml) gave 1-carbethoxyindole (0.75 g, 40%), which was obtained as a colorless oil (b.p. 150–151° at 13–14 mm)[6] on vacuum distillation of the crude product, ν_{max}^{Nujol} 1 735 cm^{-1} (C=O); $\lambda_{max}^{C_2H_5OH}$ 254, 260, 284, and 291 mμ ($\epsilon_{max}^{C_2H_5OH}$ 10 898, 10 599, 3 693, and 5 365). The p.m.r. spectrum in $CDCl_3$ indicated the presence of six protons in the region between τ 1.78 and 3.45; the doublet of doublets observed at τ 3.45 with splittings of 3.7 ($J_{2,3}$) and 0.7 ($J_{3,7}$) c.p.s. can be assigned to the β indole proton, and the complex multiplet with an average τ value of 1.78 is probably caused by the 7-proton (cf. ref. 22). The signals caused by the α indole proton and the remaining aromatic protons are observed as a complex series of peaks between τ 2.83 and 2.34 (see Fig. 2).

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.85; N, 7.40. Found: C, 69.62; H, 5.65; N, 7.64.

Indole (0.3 g) and 3-carbethoxyindole (0.6 g) could also be obtained by further elution of the column with benzene – light petroleum (1:1) mixtures and benzene, respectively.

Ammonolysis of 1-Carbethoxyindole

A suspension of 1-carbethoxyindole (0.7 g) in concentrated aqueous ammonia solution (20 ml) was stirred at room temperature for 8 h. A white solid was obtained which gave indole-1-carboxamide (VI) (0.2 g) as colorless plates, m.p. 174–175° (hot stage microscope), after repeated recrystallizations from ether – light petroleum (b.p. 60–80°); ν_{max}^{Nujol} 3 340, 3 175 (amide NH_2), 1 728, 1 625, 1 605, 1 588, and 1 530 cm^{-1}; $\lambda_{max}^{C_2H_5OH}$ 256, 262, 284, and 292 mμ.

Anal. Calcd. for $C_9H_8N_2O$: C, 67.49; H, 5.03; N, 17.49. Found: C, 67.85; H, 4.72; N, 17.65.

Dutcher and Kjaer obtained a product described as indole-1-carboxamide by the alkaline hydrolysis of *N*-benzoyl-(1-carbamylindole) (VII), but reported a melting point (198–199°) and ultraviolet spectroscopic absorption maxima (18) which differed from those obtained in the current investigation.

Alkaline Hydrolysis of 1-Carbethoxyindole

A suspension of 1-carbethoxyindole (0.1 g) in 10% aqueous sodium hydroxide (10 ml) was heated on a boiling water bath for 1 h. The reaction mixture was cooled, neutralized with dilute sulfuric acid, and extracted with ether. Paper and gas–liquid chromatographic examination of the dried (Na_2SO_4) ether extracts indicated the presence of indole and unchanged 1-carbethoxyindole.

Paper Chromatography

The R_f values of 1-, 2-, and 3-carbethoxyindole and of 1,3-dicarbethoxyindole are given in Table I. The following notes apply.

Radial development with a suitable nonpolar solvent on paper pretreated with either formamide or dimethylformamide was used, the general procedure being the same as that described for the indole derivatives by Heacock and Mahon (7) (development time ~30 min). The esters (and indole) could be located on the developed chromatograms by spraying with Gibb's reagent (a 2% solution of *N*,2,6-trichloro-*p*-quinoneimine in ethanol).

Gas–Liquid Chromatography

Determination of Retention Times

A Varian Aerograph model 204 dual-column instrument fitted with two hydrogen-flame ionization detectors was used. The 6 ft × ⅛ in. stainless-steel columns (5% SE-30 on 60–80 Chromosorb W) were used independently. The injector and detector temperatures were maintained at 270 and 250°, respectively. The nitrogen carrier gas flow rate was 14 ml/min and the hydrogen flow rate was 25 ml/min. The column was maintained at the appropriate temperatures during the determination of the relative retention times of I, II, III, IV, and V as a function of the column temperature. The dependence of the retention times of these compounds on column temperature is shown in Fig. 3.

[4]*"Polyclar AT" is a cross-linked polyvinylpyrrolidone, obtained from Chemical Developments of Canada Ltd. (Montreal). Similar separations could be obtained on activated alumina (Peter Spence, type "H", 100–200 mesh).*

[5]*British Drug Houses Analar grade (b.p. 60–80°).*

[6]*The commercial product (Regis Chemical Co.) has a boiling point of 155° at 14 mm. The melting point of 153–155° quoted in the 1965 Regis Chemical Co. catalogue was due to a misprint (personal communication from Dr. W. F. Gannon).*

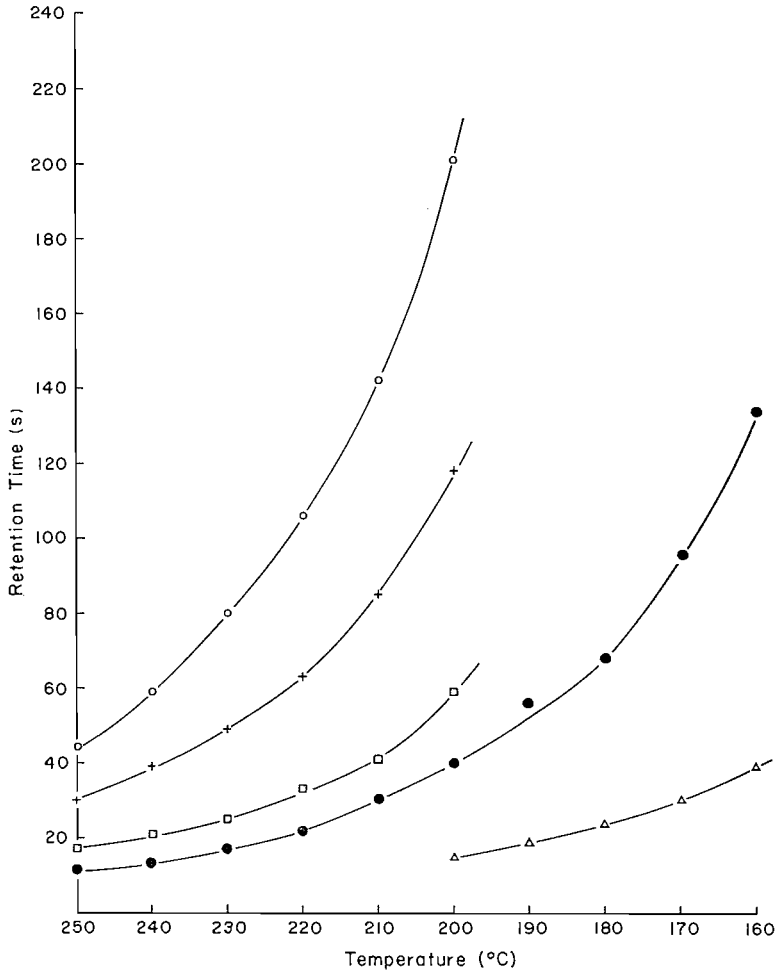

FIG. 3. Temperature dependence of the retention times (measured from the leading edge of the solvent peak) of: △, indole; ●, 1-carbethoxyindole; □, 2-carbethoxyindole; +, 3-carbethoxyindole; ○, 1,3-dicarbethoxyindole.

Analysis of Reaction Products

The reaction between indole magnesium iodide (prepared from 1.18 g indole) and ethyl chloroformate (1.1 ml) was carried out for the times and at the temperatures specified in Table II, in the manner described above for the preparation of 1-carbethoxyindole. The resulting mixture of products was dissolved in absolute ethanol (200 ml), and 1 μl samples of this solution were used for both qualitative and quantitative analysis. The gas flow rates and the temperatures of the injection compartment and the detector were as previously specified.

For *qualitative* analysis, the temperature of the column was maintained at 150° after injection of the sample until the peak caused by indole was observed; the column temperature was then raised during 105 s to 250° and finally maintained at this temperature for several minutes. The second peak observed (when the column temperature reached ca. 220°) was caused by 1-carbethoxyindole, and finally peaks caused by 3-carbethoxyindole and 1,3-dicarbethoxyindole, respectively, were observed with the column temperature at 250°.

For *quantitative* analysis of all four possible components of the reaction mixture, suitable calibration curves were prepared by the peak height method. A slight modification of the procedure used for the qualitative analysis was employed for the quantitative work. One sample was used for the determination of indole and 1-carbethoxyindole, and a second sample for the determination of the other two components. In the first case, the sample was injected with the column temperature at 150°; after the indole peak was observed the temperature was rapidly raised to 220° to obtain the peak caused by 1-carbethoxyindole. In the second case, the peaks caused by 3-carbethoxyindole and 1,3-dicarbethoxyindole were obtained with isothermal runs at

250°, the early peaks caused by the other two components being disregarded. The two-stage procedure was used to ensure maximum peak sharpness; some tailing of the peaks caused by 3-carbethoxyindole and 1,3-dicarbethoxyindole was observed when the initial column temperature was 150°. Each value was based on an average of not less than six determinations. In each case the yields of all the products could be estimated by reference to the calibration curves, and the results are shown in Table II.

TABLE II

Reaction temperature (°C)	Time required for the addition of ethyl chloroformate (min)	Reaction time (min)	% yield*	
			II	V
−10	5	0	27.0	32.8
−10	5	60	30.0	39.6
−10	5	90	30.0	36.0
0	10	30	29.6	32.8
0	10	60	28.6	32.8
0	10	90	29.6	34.4
0	10	120	33.9	31.8
10	10	30	30.7	31.8
10	10	60	35.0	31.8
10	10	90	46.6	32.8
10	10	120	43.4	35.4
20	20	30	37.0	31.8†
20	20	60	39.0	31.8†
20	20	90	37.0	31.8†
20	20	120	37.0	34.4†

*In all cases 20–30% of the original indole was recovered unchanged. II = 3-carbethoxyindole; V = 1-carbethoxyindole. These yields are considerably higher if one allows for the recovered starting material.
†Traces of 1,3-dicarbethoxyindole formed.

THE REACTION OF SULFUR DICHLORIDE WITH *cis,cis*-1,5-CYCLOOCTADIENE

F. LAUTENSCHLAEGER
Dunlop Research Centre, Sheridan Park, Ontario
Received March 28, 1966

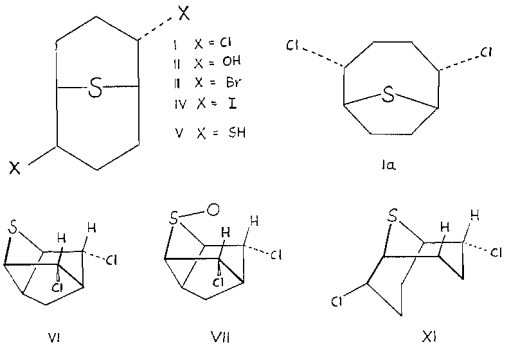
ABSTRACT

Transannular additions of sulfur dichloride to various cyclic and bicyclic di- and poly-olefins have been disclosed recently. Our observations on the reaction product from *cis,cis*-cyclooctadiene are reported inasmuch as they supplement the previous findings.

INTRODUCTION

Attempts to synthesize novel sulfur-containing heterocyclic compounds have led us to the observation of the transannular addition of sulfur dichloride to bicycloheptadiene (2). This addition reaction of sulfur dichloride provides a convenient synthesis for a large number of novel cyclic β,β'-dichlorosulfides (1–4). The versatility of that reaction and unusual features of the reaction products were reported recently (4).

RESULTS AND DISCUSSION



One of the first questions in the structural evaluation of the products from the intramolecular addition reaction of a diolefin with sulfur dichloride is to ascertain which of the possible ring systems is formed. For this, a simple approach was considered, which is of general validity for the resulting ring systems and is of particular value if the reaction products cannot be converted into a known sulfide.

Addition to a cyclic diolefin can lead to a dichlorosulfide with both chlorine atoms either on one side (I*a*) or on both sides (I) of the sulfur atom. Two sulfoxides should be obtained in the first case, but only one in the latter, provided a symmetric diolefin such as *cis,cis*-cyclooctadiene-1,5 is considered. The sulfoxides are interconvertible with triethyloxonium fluoroborate in the first case, but no isomer is obtained in the second case. In the nuclear magnetic resonance spectrum, shielding by the sulfoxide oxygen affects either both CHCl groups or none in the first type, but only one CHCl group should be affected in the second. An example of the first type is the reaction product from bicycloheptadiene (2). The product obtained from cyclooctadiene-1,5, the structure of which was demonstrated by a sequence of unambiguous reactions (1, 3), provides an example of the second type.

The nuclear magnetic resonance spectrum of I at 70 °C on a Varian A-60 spectrophotometer shows a multiplet for the —CHCl— proton at 4.62 p.p.m., whereas its sulfone IX (1) exhibits that proton at 4.43 p.p.m. In contrast, the nuclear magnetic resonance spectrum of its sulfoxide VIII (1) at 70 °C in hexachlorobutadiene shows two resonances for the —CHCl— groups, of equal intensity, at 4.63 p.p.m. and 4.06 p.p.m., respectively. The chemical shifts are independent of temperature (20 and 150 °C) and remain unchanged on dilution (5 and 10 mole %). The magnitude of the observed shielding effect of the sulfoxide oxygen on the —CHCl— group (Δ = 0.57 p.p.m.) is in very good agreement with that effect observed on *exo,exo*-4,8-dichloro-2-thiatricyclo[3.2.1.$0^{3,7}$]octane 2-oxide (VII) (Δ = 0.53 p.p.m.) (2), suggesting the similar proximity of the sulfoxide oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to the hydrogen of the —CHCl— group in both ring systems, and therefore identical configuration of the chlorine atoms with respect to the sulfur atom and identical conformation. In contrast, in the hypothetical sulfoxides of I*a*, the proton of both —CHCl— groups is symmetrically oriented with respect to the sulfoxide oxygen in all conformations, provided the chlorine groups are *cis* to each other. The significant shielding of only one —CHCl— group cannot therefore be explained on the basis of the [4.2.1] ring system.

As expected, attempted inversion of the sulfoxide to an isomer by its reaction with triethyloxonium fluoroborate failed (5). The successful inversion of a tricyclic β,β-dichlorosulfoxide under identical conditions was reported previously (2).

Although a dipole moment determination is not expected to distinguish between the [4.2.1] and [3.3.1] ring systems, conclusions about the conformation and configuration of the dichlorosulfide can be drawn from the observed moment if the [3.3.1] system is accepted. The twin-chair conformation for I has been suggested on the basis of the coupling constants between the proton of the —CHCl— group and the adjacent methylenic protons (3), and on the basis of the 'abnormal' infrared band at 1 485 $\pm$ 5 cm^{-1} (1) which results from non-bonding interaction between the two methylenic groups in that conformation. This conclusion is supported by the observed dipole moment.

A moment of 0.85 D for I in benzene at 20 °C is very close to the value of 0.8 D for VI (1). The thiane ring in the latter compound has a rigid chair conformation, with both chlorine atoms equatorial (2). Inspection of molecular models of I and VI shows that the resultant moment of both chlorine groups forms an angle of 180° with the moment angle of C—S—C in the twin-chair conformation XI and in the rigid system VI. The observed moment is therefore best explained by the assumption of a twin-chair conformation for I. The moment is lower than calculated (1.4 D), assuming group moments of 1.8 D for C—Cl (6) and 1.6 D for C—S—C (7). Moments of 1.6 D and 1.9 D are calculated for the chair–boat and boat–boat conformations of I, respectively. For a configuration with the chlorine groups *trans* to each other, a moment of 2.6 D is calculated for the chair–boat conformation, 2.1 D for the chair–chair conformation, and 1.3 D for the boat–boat conformation. The isomer with both chlorine atoms *cis* to each other and *cis* with respect to the sulfur atom would show moments of 3.7 D for the chair–chair, 3.8 D for the chair–boat, and 1.6 D for the boat–boat conformations.

The dichlorosulfide I was shown to exhibit the characteristic reactivity of β,β'-dichlorosulfides towards nucleophilic substitution (1). The diol II can be obtained in polymorphic forms with melting points from 188 to 256 °C. The low-melting polymorph melts with decomposition by elimination of water. A sample melting close to that reported by Weil (1) was obtained by hydrolysis with aqueous sodium carbonate. Recrystallization of the low- and high-melting species from toluene did not affect their melting points. Whereas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the high-melting polymorph is unaffected by crystallization from methanol or water, the melting point of the low-melting polymorph is increased to 248–250 °C on a single crystallization from methanol and to 215–220 °C on crystallization from water. Both diols show identical infrared absorption in potassium bromide, although in Nujol small differences in the relative intensities of several peaks appear, particularly those of the three unidentified peaks at 865, 880, and 895 cm^{-1}. Both the higher and lower melting polymorphs show a single peak for the OH stretching frequency at 3 443 $\pm$ 2 cm^{-1} in dioxane and at 3 620 $\pm$ 2 cm^{-1} in carbon tetrachloride. The diol was oxidized to its sulfone X with hydrogen peroxide in glacial acetic acid. The nuclear magnetic resonance spectrum of the sulfone X shows a single resonance at 4.45 p.p.m. in pyridine for the proton alpha to the hydroxy group, which is 0.13 p.p.m. downfield from the resonance of that proton in the diol II.

The dimercaptan V was obtained from the dichlorosulfide I via its thiouronium salt in a yield of 41%.

Attempts to isolate the isomeric [4.2.1] ring system were unsuccessful. The absence of the isomeric dichlorosulfide I*a* in the reaction product of sulfur dichloride and cyclooctadiene was indicated by gas chromatographic analysis, which shows a single peak for I. Also, no evidence for the [4.2.1] ring system was found in products resulting from heterolytic substitution reactions in which isomerization via an intermediate episulfonium ion was expected (8). The diol II was recovered from its solution in 97% sulfuric acid in a yield of 68% by neutralization with aqueous sodium bicarbonate. Treatment of II with concentrated hydrochloric acid leads to I in a yield of 97%. The crude product shows a melting point of 99–101 °C, compared with 101–102 °C for I. Similarly, the bromide III and the iodide IV (1) were obtained from II in yields of 80 and 64%, respectively, by use of the corresponding acids. The iodide IV is identical with the product obtained from the chloride I with sodium iodide in acetone. Hydrolysis of the iodide IV with aqueous sodium bicarbonate leads to II in a yield of 60%.

The participation of the free electrons on sulfur in the stabilization of the carbonium ion is demonstrated by comparison of the reactivity in nucleophilic reactions of sulfide versus sulfoxide and sulfone. In contrast to the dihydroxysulfide II, the dihydroxysulfone X can be recovered unchanged from its solution in concentrated hydrochloric acid. Also, the dichlorosulfoxide VIII is not hydrolyzed in hot aqueous sodium carbonate, although rapid hydrolysis of I to II proceeds under these conditions.

The absence of the [4.2.1] ring system is surprising if an episulfonium ion is involved in the addition of sulfur dichloride to the diene and in substitution reactions. Both the [4.2.1] and [3.3.1] ring systems of bicyclononane were isolated in the acetolysis of 4-cyclooctene-1-methylbrosylate (9), and a bridged intermediate was suggested on the basis of the observed products. Analogous to the reaction of sulfur dichloride with bicycloheptadiene, an *endo* approach of the chlorosulfenium ion (10) is suggested in the addition step. The flexibility of the bicyclic ring system obtained from cyclooctadiene allows the formation of a configuration and conformation of the most favorable staggering of the carbon–hydrogen bonds, which could be the deciding factor in the observed formation of the [3.3.1] ring system in preference to the [4.2.1] ring system, and which distinguishes between the reaction of sulfur dichloride with cyclooctadiene and that with bicycloheptadiene.

EXPERIMENTAL

The dielectric constants were determined with the instruments described earlier (11). The melting points were determined in a Hallenkamp block and are uncorrected. Gas chromatographic analysis was carried out on a Perkin–Elmer 800 chromatograph at 175 °C, with Apiezon as the stationary phase and helium as the carrier gas.

2,6-Dichloro-9-thiabicyclo[3.3.1]nonane (I)

A suspension of 1.75 g (0.01 mole) of the diol II (m.p. 188 °C) in 50 ml of concentrated hydrochloric acid was stirred for 8 h at room temperature, and the product was filtered off and air-dried to give 2.05 g (97%) of I, m.p. 99–101 °C. The product was identified as I by mixed melting point with a sample obtained from the reaction of cyclooctadiene-1,5 and sulfur dichloride, and by its infrared absorption in potassium bromide. Gas chromatographic analysis of that product and a crude reaction product of sulfur dichloride and cyclooctadiene showed a single peak for I.

This agrees with the result of the thin-layer chromatography reported by Corey and Block (3).

9-Thiabicyclo[3.3.1]nonane-2,6-diol (II)

(*a*) To a refluxing solution of 6.2 g (0.05 mole) of sodium carbonate in 100 ml of water was added 10.5 g (0.05 mole) of I, with high-speed stirring, over a period of 10 min. A clear solution formed, from which colorless crystals separated when it was cooled, yield 7 g (80%), m.p. 189 °C (decomp.). The aqueous solution was continuously extracted with diethyl ether to give another 1.1 g (13%) of the dihydroxy compound, m.p. 205 °C (decomp.).

Anal. Calcd. for $C_8H_{14}O_2S$: C, 55.13; H, 8.10; S, 18.40. Found (for the fraction with m.p. 189 °C): C, 55.36; H, 8.02; S, 18.52.

(*b*) Hydrolysis under the same conditions in a repeat experiment led, with a yield of 87%, to a diol having m.p. 252–253 °C.

Anal. Found: C, 55.20; H, 8.15; S, 18.3.

(*c*) To a solution of 5.3 g (0.025 mole) of I in 100 ml of tetrahydrofuran were added 10 ml of water and 2 g of sodium bicarbonate. The suspension was refluxed, with stirring, for 64 h, and evaporated to dryness on a rotary evaporator; the residue was ground and exhaustively extracted with 400 ml of benzene. After evaporation of the benzene solutions, 1.6 g of II was obtained, m.p. 188 °C (decomp.). The benzene-insoluble residue was extracted three times with 50 ml of acetone. On evaporation, another 2.35 g of II was obtained, m.p. 254–256 °C. When a solution of the high-melting product in boiling methanol or water was allowed to evaporate, the melting point of the recovered material was unchanged. Similar solutions of the low-melting material led to a product with a melting point of 248–250 °C after recovery from methanol, and 215–220 °C after recovery from water.

(*d*) A suspension of 12 g (0.03 mole) of IV in 100 ml of water containing 16.8 g (0.2 mole) of sodium bicarbonate was stirred under reflux for 10 min. The solution was filtered to remove traces of undissolved material, and continuously extracted with diethyl ether. The ether solution was dried with magnesium sulfate and evaporated to give 3.4 g (65%) of II, m.p. 255–257 °C, shown by its infrared absorption in potassium bromide and by mixed melting point to be identical with the product described under method *c*.

II (2 g) was dissolved in 10 g of 97% sulfuric acid at room temperature. The clear, colorless solution was allowed to drop into 50 ml of a saturated sodium bicarbonate solution with rapid stirring, the internal temperature being kept at 5–10 °C. The resulting suspension was continuously extracted with diethyl ether, and the extract was dried and evaporated to give 1.6 g (80%) of a product which, on exhaustive sublimation, yielded 1.28 g (64%) of diol, m.p. 196–203 °C (decomp.). The diol was identified as II by its infrared spectrum in potassium bromide and Nujol.

2,6-Dibromo-9-thiabicyclo[3.3.1]nonane (III) from II with Hydrobromic Acid

In 50 ml of fuming hydrobromic acid was dissolved 3.5 g (0.02 mole) of II (m.p. 255–257 °C). The suspension was stirred for 2 h and filtered, and the residue was washed with water and dried over calcium chloride to yield 5.8 g (97%) of product, m.p. 124 °C (decomp.). By sublimation, 1.2 g of polymeric material was separated. An analytical sample was obtained by recrystallization of 2.5 g from 25 ml of hexane, m.p. 136–137.5 °C.

Anal. Calcd. for $C_8H_{12}SBr_2$: C, 32.02; H, 4.03; Br, 53.27; S, 10.68. Found: C, 32.21; H, 3.89; Br, 53.05; S, 10.60.

2,6-Diiodo-9-thiabicyclo[3.3.1]nonane (IV) from II with Hydriodic Acid

Into 50 ml of 47% hydriodic acid was stirred 3.5 g (0.02 mole) of II (m.p. 255–257 °C). After the solution was stirred for 2 h at room temperature, the colorless product was filtered off, washed with water, and dried over calcium chloride to yield 7.8 g (99%), m.p. 128 °C (decomp.). Sublimation (an initial colored fraction was discarded) produced a colorless sample, yield 5 g (64%), m.p. 143–145 °C.

The product was shown to be identical by mixed melting point and infrared absorption with the product obtained from I with potassium iodide (1).

9-Thiabicyclo[3.3.1]nonane-2,6-thiouronium Chloride

To a solution of 4.22 g (0.02 mole) of I in 100 ml of ethanol was added 6.1 g (0.08 mole) of thiourea; the suspension was refluxed for 14 h, allowed to cool to room temperature, and filtered; the residue was washed with ethanol and air-dried to give 4.8 g (61%), m.p. 232 °C (decomp.) (A). The solvent was evaporated from the combined ethanol solutions, and the crystalline residue was extracted with 50 ml of tetrahydrofuran and 50 ml of hot ethyl acetate to leave another 2.4 g (30%) of product, m.p. 200–212 °C (decomp.) (B).

Anal. Calcd. for $C_{10}H_{20}S_2N_4Cl_2$: H, 5.51; S, 26.48. Found: H, 5.30; S, 26.83.

2,6-Dimercapto-9-thiabicyclo[3.3.1]nonane (V)

To a solution of 5.4 g (0.015 mole) of the thiouronium salt A in 25 ml of water was added 25 ml of concentrated ammonium hydroxide. Traces of insoluble material were filtered off and the filtrate was acidified with dilute hydrochloric acid, with cooling, the internal temperature being kept between +5 and +10 °C. The crystalline product was separated with 20 ml of methylene chloride, and the extract was washed with water, dried with magnesium sulfate, and evaporated to give 2.5 g of a crystalline product, m.p. 25–43 °C. Sublimation gave 1.5 g (41%) of V, m.p. 44–46 °C. An analytical sample was obtained by drying over paraffin chips and repeated sublimation.

Anal. Calcd. for $C_8H_{14}S_3$: C, 46.55; H, 6.84; S, 46.61. Found: C, 46.84; H, 6.88; S, 46.86.

Attempted Hydrolysis of VIII

A suspension of 2.27 g (0.01 mole) of VIII in a solution of 10 g of sodium carbonate in 50 ml of water was refluxed, with high-speed stirring, for 30 min. After the solution was cooled, 2.05 g of VIII was recovered, m.p. 121.5–122.5 °C, identified as VIII by mixed melting point and by its infrared absorption.

Attempted Conversion of VIII

To a solution of 3 g (0.013 mole) of VIII in 50 ml of methylene chloride was added 2.85 g (1.5 moles) of triethyloxonium fluoroborate (12). After the solution had stood for 8 h, 1.5 g (26%) of a crystalline adduct was filtered off, m.p. 163 °C (decomp.). On complete evaporation, another 3.2 g of product was obtained.

Anal. Calcd. for $C_{10}H_{17}Cl_2F_4OS$: C, 35.0; H, 5.00. Found: C, 34.8; H, 5.07.

To a solution of 0.2 g of sodium hydroxide (0.05 mole) in 20 ml of water was added 1.1 g (0.0032 mole) of the adduct. After the solution was stirred at 30 °C for 15 min, the crystalline product was filtered off, washed with water, and air-dried to give 0.7 g (96%) of VIII, m.p. 122.5–123.5 °C. The product was identified by mixed melting point and by its infrared and nuclear magnetic resonance spectra in carbon tetrachloride.

2,6-Dihydroxy-9-thiabicyclo[3.3.1]nonane 9,9-Dioxide (X)

To a solution of 17.5 g (0.1 mole) of II (m.p. 255–257 °C) in 500 ml of glacial acetic acid was added 17 g of 50% aqueous hydrogen peroxide. The solution was stirred at room temperature for 48 h and then allowed to evaporate to dryness to give 20 g (100%) of crude X, m.p. 160–190 °C (decomp.); 15 g was recrystallized from 80 ml of dioxane to give a first fraction of 4 g. A second fraction of 4 g was obtained by reducing the volume of the dioxane solution to 40 ml. An analytical sample was obtained by a second recrystallization from dioxane and drying at 60 °C and 0.1 mm for 54 h. The compound is discolored when heated above 250 °C.

Anal. Calcd. for $C_8H_{14}SO_2$: C, 46.57; H, 6.83; S, 15.54. Found: C, 46.87; H, 6.79; S, 15.53.

The dihydroxysulfone X is recovered unchanged from its solution in concentrated hydrochloric acid (0.5 g in 5 ml) after evaporation of the solution.

ACKNOWLEDGMENTS

The author is greatly indebted to Prof. J. K. Stille and Prof. N. Kharasch for the discussions of various aspects of this work, to Prof. G. F Wright for measuring the dielectric constants of I, to Dr. R. T. Woodhams for guidance and encouragement, to members of the analytical departments of the Dunlop Research Centre and the Ontario Research Foundation for supplying spectroscopic data, and to Dr. E. Weil of Hooker Chemical Corporation for a copy of his manuscript on 2,6-dichloro-9-thiabicyclo[3.3.1]-nonane in advance of publication.

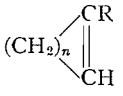
REACTIONS OF OZONIDES

IV. OZONIZATION OF ALKYLCYCLOALKENES[1,2]

D. G. M. DIAPER
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario

Received July 20, 1966



ABSTRACT

Oxidative ozonolysis of some 1-alkylcyclopentenes, 1-alkylcyclohexenes, and 1-methylcycloheptene gives keto acids ($RCO(CH_2)_nCOOH$) and by-product derived esters now identified as $RCO(CH_2)_nCOO(CH_2)_nCOR$. The mechanisms of formation of esters from zwitterion and carbonyl intermediates are discussed in terms of dimeric zwitterions. Cycloalkanones also present in the neutral by-product are attributed to alkylidenecycloalkanes.

INTRODUCTION

A flexible unambiguous general method for the synthesis of keto acids uses oxidation of the ozonolysis products from 1-alkylcycloalkenes in participating solvents (1). Attempts to extend this method to the preparation of diketoalkanedioic acids and alkylalkanedioic acids (2) met with little success, chiefly because of a side reaction giving a nonacidic by-product other than the anticipated keto aldehyde (3). By-product formation was more serious for reactions involving two rings than for those involving one, not only because of greater by-product yields but also because of complication of the problem of isolating the desired dioic acid.

These side products have now been studied in the oxidation of the olefins I*a*–I*e* and of 1,2-dimethylcyclohexene, and four hypotheses of their origin were considered. The first concerns the possible participation of the equilibrium endocyclic isomer of the starting material (for example, ethylidenecyclohexane in 1-ethylcyclohexene). The second postulates cyclodehydration or dimerization of keto aldehyde intermediates II*a*–II*e*. The third and fourth hypotheses both suggest ester formation, either through "abnormal molozonide stabilization", as put forward by Fields for unsubstituted cycloalkene ozonization (4), or through peracid and peranhydride intermediates, as suggested by Pasero (5–8), giving III*a*–III*e*.

EXPERIMENTAL

Preparation of 1-Alkylcycloalkenes

The required alkylmagnesium bromide (0.5 mole) was treated during 4–5 h with the cycloalkanone (0.45 mole) in ether containing 30–40% benzene at −20 to −10°. These conditions help to minimize reduction of the ketone to the secondary alcohol (9) and minimize clogging of the flask with precipitate. After the mixture was mechanically stirred for 1 h at room temperature, it was added to ice, water, and ammonium chloride (1.5 moles) and quickly separated. Work-up of the Grignard reaction with acid causes premature dehydration. The ether and benzene were removed from the washed and dried solution, and the residual liquid was fractionally distilled through a 12 in. Widmer column to separate the 1-alkylcycloalkanol from the secondary alcohol and unchanged ketone. 1-Ethylcyclohexanol was obtained as a solid, m.p. 34.5–35° (lit. (10) m.p. 33°), and purified by low-temperature crystallization from petroleum ether. The others were liquid. All were dehydrated by heating under reflux without solvent in the presence of a few milligrams of iodine under a water separator. When reaction was complete, the liquid was again fractionated. The physical constants were as follows: I*a*, b.p. 74–77°; I*b*, b.p. 110–111°, n_D^{21} 1.4490; I*c*, b.p. 137°, n_D^{20} 1.4599; I*d*, b.p. 105.5° at 751 mm, n_D^{24} 1.4410; I*e*, b.p. 136–139°, n_D^{20} 1.4578; 1,2-dimethylcyclohexene, b.p. 136°, n_D^{20} 1.4578. Each was examined by vapor-phase chromatography (v.p.c.) and infrared spectroscopy to detect alcohol and ketone impurities. Fractionation was repeated, if necessary, until these were absent. The olefins were stored at 0° in the dark under nitrogen.

Oxidative Ozonolysis

The olefin (10–20 g) dissolved in dry methylene chloride (50–100 cc) was ozonized to completion, as shown by the rapid evolution of iodine in a potassium iodide trap and by the failure of an aliquot to decolorize a bromine solution. The solvent and ozone were removed by entrainment in a dry nitrogen stream at room temperature and finally by evaporation under reduced pressure. The residual viscous water-white liquid was divided by weight into two approximately equal portions. One was oxidized by slowly raising the temperature to 95° while a very slow stream of oxygen was passed through (5) (autoxidized sample). The other (performic acid oxidation sample) was diluted with ether (5–10 g in 50 cc) and treated with formic acid (10 cc) and 70% hydrogen peroxide in excess (10 cc). Heat was evolved. It was allowed to stand at room temperature for 3 days, after which aldehyde could no longer be detected. The autoxidized samples were generally found to be free of aldehyde after 24 h at 95° with a slow stream of oxygen passing through, but were treated for a further 24 h if necessary. Each sample was divided into acidic and nonacidic fractions for titration.

The v.p.c. traces of the neutral products from I*a*, I*b*, and I*c* showed two minor volatile substances in each case (identified as the starting material and corresponding ketone). The infrared spectra had broad or double peaks in the carbonyl region. Negative aldehyde tests were obtained from the autoxidized products and from those oxidized with performic acid, but a trace of aldehyde was detected in each of the products from the emulsion ozonization. The neutral fractions were tested with silver nitrate and found to be free of halogen. Saponification titrations in ethanol with approximately 0.1 g aliquots were performed with 0.2 *N* ethanolic potassium hydroxide, and the results, expressed as percentage yields of esters III, are presented in the first two columns of Table I.

TABLE I

Ester by-products in ozonization

	Ester yields (% of starting material)		
	Autoxidation in O_2	Performic acid oxidation	Emulsion
1-Methylcyclopentene (I*a*)	8.13	4.42	0.34
1-Methylcyclohexene (I*b*)	16.7	6.05	0.21
1-Methylcycloheptene (I*c*)	17.4	5.32	0.55
1-Ethylcyclopentene (I*d*)	22.0	7.18	0.37
1-Ethylcyclohexene (I*e*)	11.6	7.02	0.81
1,2-Dimethylcyclohexene	0.58	0.31	0.44

There was a polymeric peroxide fraction in the performic acid oxidation experiments (for example, 4.38 g of acid, 0.76 g of peroxy polymer, and 0.25 g of neutral product were obtained from 7.5 g of 1-methylcycloheptene). The peroxide was insoluble in ether and in aqueous potassium carbonate, but dissolved in acetone.

Emulsion Ozonization

The third column of Table I contains the ester values of samples of alkylcycloalkenes ozonized in an aqueous alkaline emulsion. For example, 10 g of 1-methylcycloheptene was suspended in 60 cc of water containing 5.6 g of sodium hydroxide, 10 cc of hydrogen peroxide (70%), and 0.1 g of non-ionic detergent.

Ozone was passed through at 0° until the upper layer was reduced in bulk to about 1 cc of a viscous scum. The nonacidic hexane-soluble fraction was separated for the saponification titration. In each case, there was a considerable amount of fluffy white insoluble polymeric peroxide.

Isolation and Saponification of $CH_3CO(CH_2)_5COO(CH_2)_5COCH_3$

The neutral fraction (4.74 g) from autoxidation at 95° of the ozonization product from 1-methylcycloheptene (18.97 g) was distilled without fractionation at 150–170° and 0.4 mm. The saponification titration value of this distillate was 3.03 meq/g (theory 3.71). It was redistilled in a micro-apparatus with the thermometer as the fractionating element,[3] and the middle fraction, b.p. 159–167° at 0.6 mm, had a saponification titration value of 3.40 meq/g. Its nuclear magnetic resonance (n.m.r.) spectrum had a sharp singlet, attributable to CH_3CO, at 2.08 p.p.m. (cf. 2.12 for methyl isobutyl ketone) and broad signals (attributed to CH_2O and CH_2CO) superimposed downfield and the other methylenes upfield. There were no signals attributable to aldehyde or vinylic protons. A bromine test was negative and permanganate decolorization was slow.

A sample (1.3 g) was saponified and the acid product converted into the semicarbazone, m.p. 124–125° (decomp.) when recrystallized from ethanol.

Anal. Found: N, 19.17; acid equiv. 218. $C_9H_{17}O_3N_3$ requires N, 19.52; acid equiv. 215.

The oily residue from the neutral saponification layer had a peak attributable to ketone carbonyl in its infrared spectrum. It was treated in ether with a large excess (0.5 g) of lithium aluminium hydride and the product, after solvent removal (0.11 g), was treated with phenyl isocyanate. The phenylurethane melted at 93–95°, undepressed on admixture with authentic heptane-1,6-diol phenylurethane obtained from methyl 6-ketoheptanoate (m.p. 95–96°).

The presence of 7-ketooctanal was demonstrated through a solid derivative as follows. The unoxidized ozonization product of another sample of 1-methylcycloheptene was treated with 2,4-dinitrophenylhydrazine, giving the bis-2,4-dinitrophenylhydrazone of 7-ketooctanal, m.p. 152–153° when recrystallized from pyridine – carbon tetrachloride.

Anal. Found: N, 21.33. $C_{20}H_{22}O_8N_8$ requires N, 21.59.

In a similar way, the neutral product from the oxidative ozonolysis (autoxidation method) of 1-methylcyclohexene was distilled (b.p. 135–145° at 0.4 mm) (2.92 meq ester/g before distillation and 3.61 after; theory 4.13). Its n.m.r. spectrum similarly showed a singlet at 1.90 p.p.m. and broad CH_2 signals on each side. Aldehyde and vinylic proton signals were not observed. The ester was hydrolyzed and the acid product was found to give a methyl ester whose v.p.c. retention time was identical with that of authentic methyl 6-ketoheptanoate. Hexane-1,5-diol was identified with an authentic sample by v.p.c. of their trifluoroacetyl derivatives. The authentic sample was obtained by reduction of methyl 5-ketohexanoate; the reduction mixture was saponified and the neutral material distilled. The phenylurethane could not be crystallized.

1-Methylcyclopentene gave a neutral by-product, b.p. 130–145° at 12 mm (4.01 meq ester/g; theory 4.68), whose n.m.r. spectrum was similar. Resolution was poorer because of its low solubility in carbon tetrachloride containing 1% tetramethylsilane, the solvent used for all spectra. Its acidic hydrolysis product was 5-ketohexanoic acid, and the reduced neutral hydrolysis product gave a phenylurethane melting at 126–128° (lit. (21) m.p. 124.5–126°).

Ozonolysis of 1,2-Dimethylcyclohexene

When treated as above, the oxidative ozonolysis product was almost entirely free from acid. The emulsion ozonization mixture contained a white fluffy peroxide which decomposed when heated. The ester values were negligible and the product was not examined further.

DISCUSSION OF RESULTS

The equilibrium concentration of methylene cyclopentane in 1-methylcyclopentene is 0 (11), 0.6 or 0.7 (12), and 0.8% (13). For methylenecyclohexane in 1-methylcyclohexene it is 3 or 5 (11), 0 (14), and 1.8% (13), and the heat of conversion is 3.6 kcal. For 1-methylcycloheptene the isomer was found in 1.27 or 1.33% concentration (15). The exocyclic olefin concentration in 1-ethylcyclopentene and 1-ethylcyclohexene is, respectively, 10.9% (13) and 6 (11) or 8.5% (13) or 0.5% (14). Even so, they are not large enough to account for all the neutral by-product observed. 1,2-Dimethylcyclohexene has no detectable exocyclic olefin impurity. In all cases, the gas chromatogram of the neutral product of oxidative ozonolysis showed some of the corresponding ketone (for example, cyclohexanone from 1-methylcyclohexene and 1-ethylcyclohexene), and the reaction route is doubtless through the carbonyl and zwitterion fragments of scission of the exocyclic olefin. Present

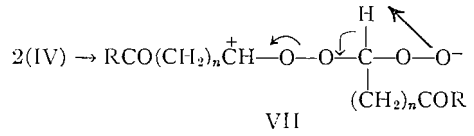
evidence indicates that inductive effects would favor cycloalkanone production, and possible fates of zwitterion fragments will be discussed later. Cycloalkanone was not the major constituent.

Self-condensation of keto aldehyde II*a* would give 2-cyclohexenone, II*b* 1-acetylcyclopentene, and II*c* 1-acetylcyclohexene. These compounds have the common feature of a conjugated unsaturated carbonyl system, and would be expected to have an appropriate strong absorption peak in the ultraviolet. No such peak was detected in the ultraviolet spectra of the neutral products from oxidative ozonolysis of the corresponding olefins. Furthermore, the n.m.r. spectra did not show the expected characteristic vinylic proton triplet. These n.m.r. data also rule out bimolecular keto aldehyde condensation products.

Acyl chlorides are among the products of the reaction of ozone with aldehydes in halogenated solvents (16), but were not present in the neutral fraction of the present study, which was free of halogen.

Saponification titration (Table I) showed that a major neutral by-product contained ester groups. Fields (4) found an 8% yield of valerolactone from oxidative ozonization of cyclohexene, and 15% of 7-hydroxyheptanoic acid from cyclooctene (under hydrolyzing conditions). Interestingly, no ester side products were detected in emulsion oxidative ozonolysis of cyclohexene-4,5-dicarboxylic acid, and another ozonization study of acidic cyclohexene derivatives (17) shows peracids to be the main product. For production of esters from unsubstituted cycloalkenes, a mechanism of ring enlargement and "abnormal molozonide stabilization" has been put forward (4). Such a mechanism would predict that product yields would depend markedly on the size of the original ring. No such correlation was found in the cases studied. Analogous "abnormal molozonides" from the substrates I*a*, I*b*, and I*c* would be acetates of ω-hydroxyaldehydes or formates of ω-hydroxyketones. The anticipated n.m.r. signals of the HCO protons were not found.

Identification of the major neutral by-product as the diketo ester III rests on four pieces of evidence. The saponification equivalents are in reasonable agreement with the theoretical, and the n.m.r. signals agree with this structure. Isolation of the keto acid after saponification and identification of the neutral saponification product through the derived diol confirm the structure. Such ester products are analogous to those reported by Pasero from oleic acid derivatives and are thought to be formed by the following process (5–8):



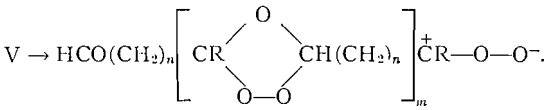
$$RCHO \rightarrow RCO_3H \rightarrow (RCO)_2O_2 \rightarrow RCOOR + CO_2.$$

There is an important difference between the compounds of the present study and those hitherto studied. The carbonyl and zwitterion fragments of the latter were separate, and it was only aldehydes that were invoked as the ester precursors. Here the carbonyl and zwitterion residues are joined in the same molecule, and the possibilities of derivation of ester from both functions will now be discussed.

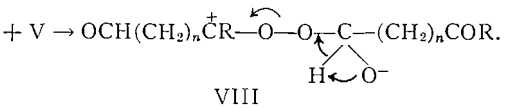
The Criegee ozonization mechanism would predict the two carbonyl zwitterions IV and V to be the key intermediates in conversion of the immediate ozonization product (here represented as a 1,2,3-trioxolane) such as VI into both the keto acid and diketo ester end products observed. Present evidence about inductive effects on the direction of cleavage would predict that V would be formed in a greater concentration than IV, but, irrespective of relative proportions, possible mechanisms must be considered for the reduction of the zwitterion function of V to ketone and conversion of the zwitterion function of IV into aldehyde, acid, or peracid, the latter being the precursor of the ester function observed (5).

The oxidation level of the zwitterion function is two electrons higher than that of an aldehyde or ketone, and equal to that of an acid or its anion. It is two electrons below the peracid level. The environment in the present study was in all cases an oxidizing one.

In non-participating solvents, two processes for the interaction of two zwitterion fragments have been proposed. Dimeric ring peroxide (18) is the product of one process, and mutual reduction to two carbonyl products with oxygen evolution is the other (19). Monoalkylated zwitterions, of which IV is an example, undergo mutual reduction more easily than dialkylated zwitterions, to which class V belongs (20). Both processes call for an initial dimeric zwitterion to be formed (for example, VII) by condensation of two



VII



zwitterions IV. Break-up of VII as shown can give an aldehyde function and a peracid function. A route for conversion of zwitterion IV into both keto acid and diketo ester end products is thus possible, for aldehyde is autoxidized to peracid and the latter is the common precursor of acid and ester. VII can also break up to give 1 mole of oxygen and 2 moles of keto aldehyde II, as previously suggested (19, 20).

A product resembling VII can be obtained by condensation of the negative oxygen of zwitterion V with the positive carbon atom of zwitterion IV. Its decomposition will give keto aldehyde and keto peracid fragments identical with those derived from VII.

Carbonyl–zwitterion reversible condensation processes offer several plausible routes for the conversion of the zwitterion function of V into ketonic carbonyl. Self-condensation to give a monomeric ozonide having a 1,2,4-trioxolane system as part of a bridged ring is unlikely on steric grounds for the larger rings. If it occurred, however, dissociation to give IV is one possible route for conversion of zwitterion into ketone. A sterically more likely reaction of V with itself is polymerization as follows:

The rings of the polymer can similarly dissociate to give ketone functions. Condensation of V with II will proceed as follows:

VIII

VIII may close the trioxolane ring and reopen to give a ketonic carbonyl as discussed above. It may also decompose as shown by the arrows, giving keto aldehyde as before, but keto acid this time rather than peracid. In effect, the zwitterion function has thus been reduced to ketone with simultaneous oxidation of the aldehyde to acid. VIII will be formed in preference to the isomeric condensation product of II and V because the aldehyde function is more susceptible to nucleophilic attack than the ketone function.

The observed products of alkylcycloalkene oxidative ozonolysis are thus explicable in terms of the Criegee intermediates if zwitterion–carbonyl and zwitterion–peracid conversion through dimeric zwitterions occurs as indicated.

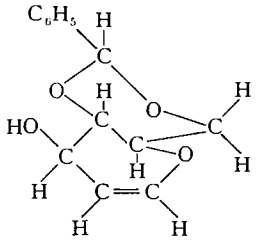
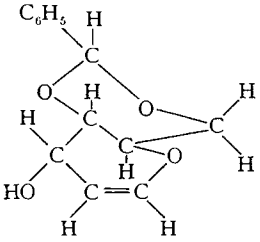
THE PREPARATION OF 4,6-*O*-BENZYLIDENE-D-GLUCAL AND THE REACTION OF METHYLLITHIUM WITH METHYL 2,3-ANHYDRO-4,6-*O*-BENZYLIDENE-α-D-ALLOPYRANOSIDE



M. SHARMA[1] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received July 6, 1966

ABSTRACT



4,6-*O*-Benzylidene-D-glucal has been prepared by the reaction of benzaldehyde with D-glucal. The reaction of commercial methyllithium with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside produces the C_2-methylated 1,2-unsaturated compound 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-*ribo*-hexopyranose. Their structures have been proven by first-order analyses of their nuclear magnetic resonance spectra.

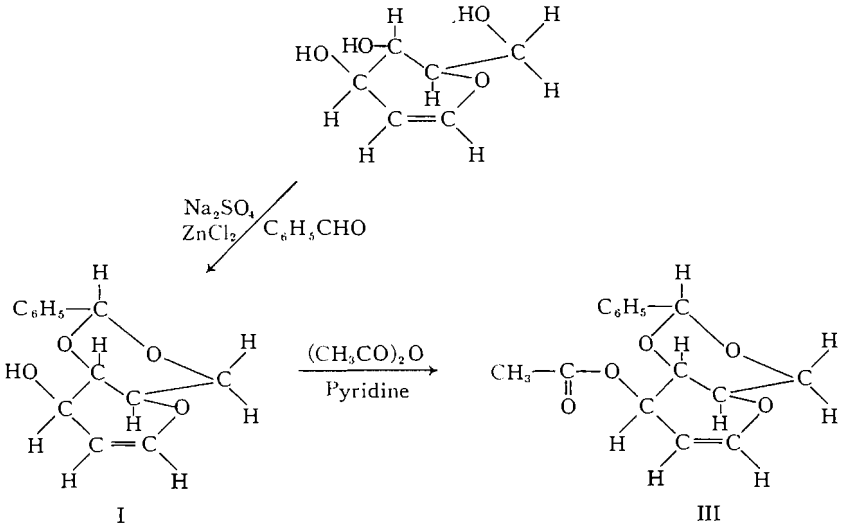
INTRODUCTION

4,6-*O*-Benzylidene-1,2-didehydro-1,2-dideoxy-D-*arabino*-hexopyranose (4,6-*O*-benzylidene-D-glucal, I) and 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-D-*ribo*-hexopyranose (4,6-*O*-benzylidene-D-allal, II) were required as reference compounds for some work in progress in our laboratories.

I

II

Compound II has been prepared recently by the reaction of methyllithium with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (1). However, to our knowledge, no report exists describing the formation of compound I. This paper shows a successful preparation of I and, as well, our results of a reexamination of the reaction of methyllithium with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside.



RESULTS AND DISCUSSION

4,6-O-Benzylidene-D-glucal (I)

The reaction of freshly distilled benzaldehyde with D-glucal in the presence of anhydrous zinc chloride and anhydrous sodium sulfate gave I in a 30% yield (Reaction Scheme 1). The following evidence supported the structure assigned.

The infrared spectrum in $CHCl_3$ showed a rather narrow band at 3 590 cm^{-1} (OH), and a sharp, intense band at 1 645 cm^{-1}. The latter agrees with the position (~1 650 cm^{-1}) and intensity (strong) of the absorption band that is found generally for glycals and which is caused by their vinyl ether structural feature, $-\overset{|}{C}-\underset{|}{C}=\underset{|}{C}-O-$ (2). The infrared spectrum in Nujol showed two broad overlapping bands with maxima at 3 190 cm^{-1} and

[1]*Postdoctorate Fellow.*

REACTION SCHEME 1.

3 290 cm^{-1} (OH), a sharp, intense band at 1 650 cm^{-1} (—C—C=C—O—), and two sharp bands at 697 cm^{-1} and 747 cm^{-1} characteristic of the 4,6-*O*-benzylidene aromatic group (3).

Integration of the 60 Mc.p.s. nuclear magnetic resonance (n.m.r.) spectrum in $CDCl_3$ gave a ratio of aromatic protons to total protons of 5 to 14. The H_1 and H_2 signals appeared as an AB spectrum consisting of a pair of doublets centered at τ 3.67 and τ 5.27 ($J_{1,2}$ = 6 c.p.s.) and both split by the allylic H_3 ($J_{1,3}$ = 1.8 c.p.s. and $J_{2,3}$ = 2.0 c.p.s.). The aromatic protons appeared as a multiplet between τ 2.35 and τ 2.83. The benzylidene proton signal was a sharp singlet at τ 4.43, and the OH proton gave a broad "singlet" at τ 7.32 (half width, 6 c.p.s.). The remaining proton signals appeared as a complicated multiplet between τ 5.4 and τ 6.3. In pyridine, the n.m.r. spectrum at 60 Mc.p.s. (Fig. 1) gave a clearly separated signal for the H_3 proton centered at τ 5.23 (multiplet), and signals for the H_1 and H_2 quartets at τ 3.58 and τ 4.98 (Table I). At 100 Mc.p.s., the H_3 signal was clearly resolved into a pair of triplets each showing additional small splitting caused by long-range coupling.[2] Double irradiation definitely showed that this proton was coupled to both H_1 and H_2, and thus identified it as H_3. The spectrum (Fig. 1) was amenable to first-order analysis[3] and gave the observed chemical shifts and coupling constants shown in Table I. The large values of $J_{3,4}$ (7.5 c.p.s.) and $J_{4,5}$ (~9.0 c.p.s.) support the *trans* diaxial arrangement of the protons on C_3 and C_4 as well as the half-chair H1 structure (4) shown in I.

[2]*"Virtual coupling" (J. I. Musher and E. J. Corey, Tetrahedron, 18, 791 (1962)) with* C_5H *may be responsible for the multiplicity of the signal for* H_3 *beyond that of a pair of triplets.*

[3]*Although first-order analysis is generally not recommended unless the ratio of the chemical shift difference (δ) to the coupling constant (J) is >6 (E. D. Beker, J. Chem. Educ., 42, 591 (1965)), a number of papers have appeared in which reasonable values of couplings and chemical shifts have been extracted by using first-order analysis even though in some cases* $\delta/J < 6$ *(D. Horton and W. N. Turner, J. Org. Chem., 30, 3387 (1965); R. J. Abraham, K. A. McLauchlan, L. D. Hall, and L. Hough, Chem. Ind. London, 213 (1962); R. J. Ferrier, W. G. Overend, and G. H. Sankey, J. Chem. Soc., 2830 (1965); L. D. Hall, Advan. Carbohydrate Chem., 19, 58 (1964)). In the present work, the configuration of the molecules is known. The similarities in the structures of all six molecules, and recognition of repetitive patterns of signals for such key positions as* H_3, H_{6c}, *and* H_{6a}, *along with a comparison of the multiplets with those expected, enabled us to pick out a unique arrangement in each case which agreed with the structure. The general agreement in the first-order analysis among the six spectra led us to believe that this approach was reasonably sound.*

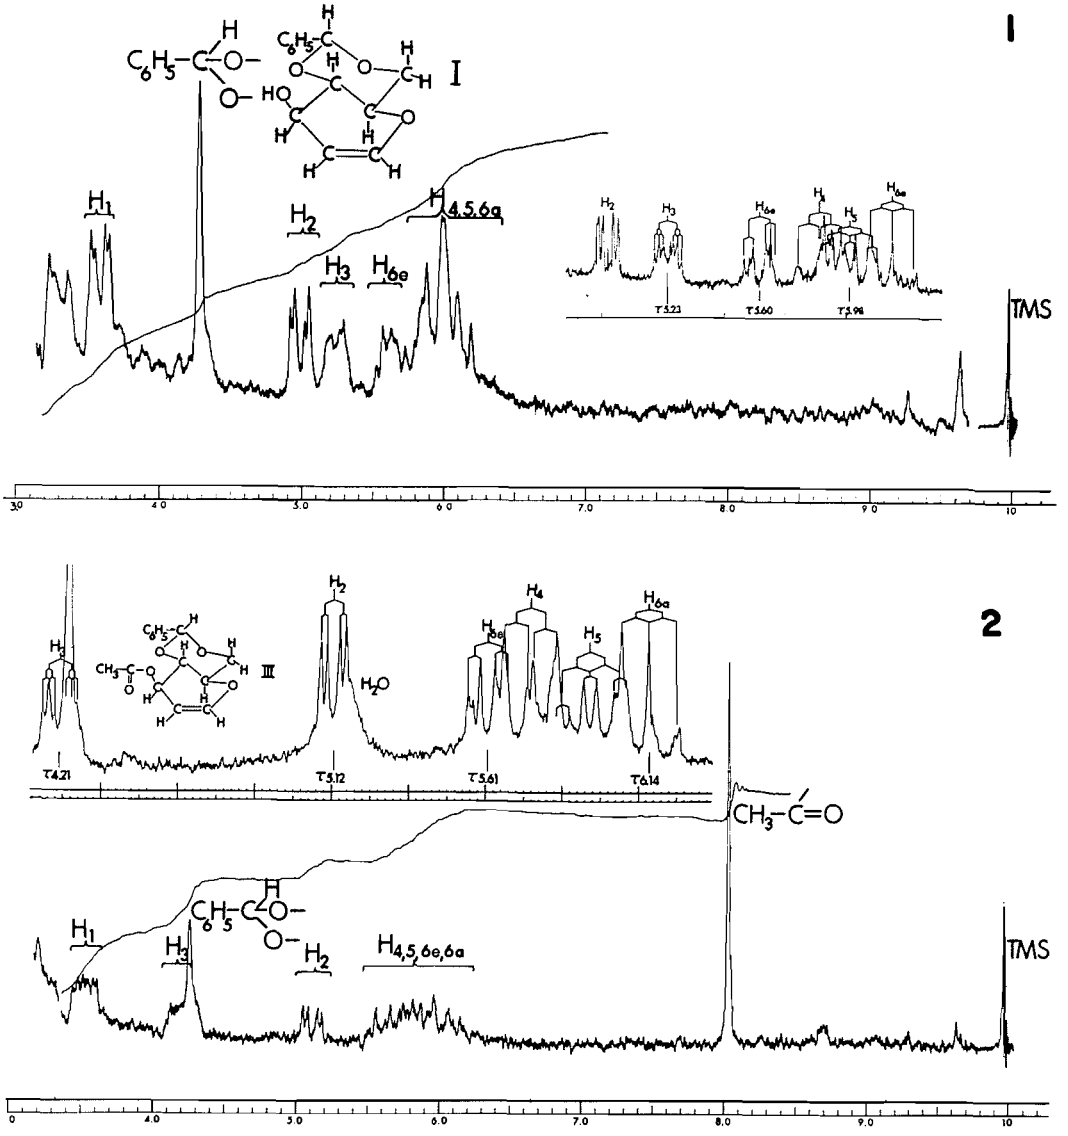


FIG. 1. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-D-*arabino*-hexopyranose (I) in pyridine. Inset, 100 Mc.p.s. spectrum in pyridine.

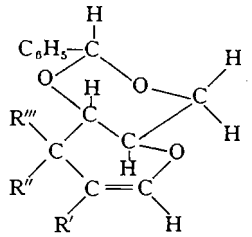

FIG. 2. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 3-*O*-acetyl-4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-D-*arabino*-hexopyranose (III) in pyridine. Inset, 100 Mc.p.s. spectrum in pyridine.

Acetylation of I gave III, whose infrared spectrum in Nujol showed no absorption for OH. Strong bands appeared at 1 652 cm^{-1} (—C—C=C—O—) and 1 742 cm^{-1} (C=O). The presence of the 4,6-*O*-benzylidene group was indicated by bands at 698 cm^{-1} and 753 cm^{-1}. Double irradiation was used to locate the signals for specific protons in the 100 Mc.p.s. spectrum of III in pyridine (Fig. 2). A first-order analysis was possible and gave the observed coupling constants and chemical shifts shown in Table I. The large values of

*s = singlet; d = doublet; t = triplet; q = quartet; sx = sextet.
†In Nujol; calibrated against polystyrene, 1601 cm^{-1}; S = strong.

$J_{3,4}$ (7.5 c.p.s.) and $J_{4,5}$ (9.0 c.p.s.) are in agreement with the *trans* diaxial arrangement of the protons attached to C_3, C_4, and C_5. The signal for the proton on C_3, upon acetylation of the C_3—OH group, was shifted markedly downfield (from τ 5.3 (Fig. 1) to τ 4.21 (Fig. 2)), providing proof that the OH group at C_3 was unsubstituted in II and hence that the benzylidene group involved the hydroxyl functions on C_4 and C_6.

The above information leaves no doubt that 4,6-*O*-benzylidene-D-glucal has been formed by the reaction of D-glucal with benzaldehyde under our conditions.

The Reaction of Methyllithium with 2,3-Anhydro-4,6-O-benzylidene-α-D-allopyranoside

The reaction of commercial methyllithium[4] with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV) according to the directions described in the literature (1), or by adding the methyllithium to an ether solution of IV directly, gave a compound whose analytical data showed it to be 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-*ribo*-hexopyranose (V) rather than II (Reaction Scheme 2).

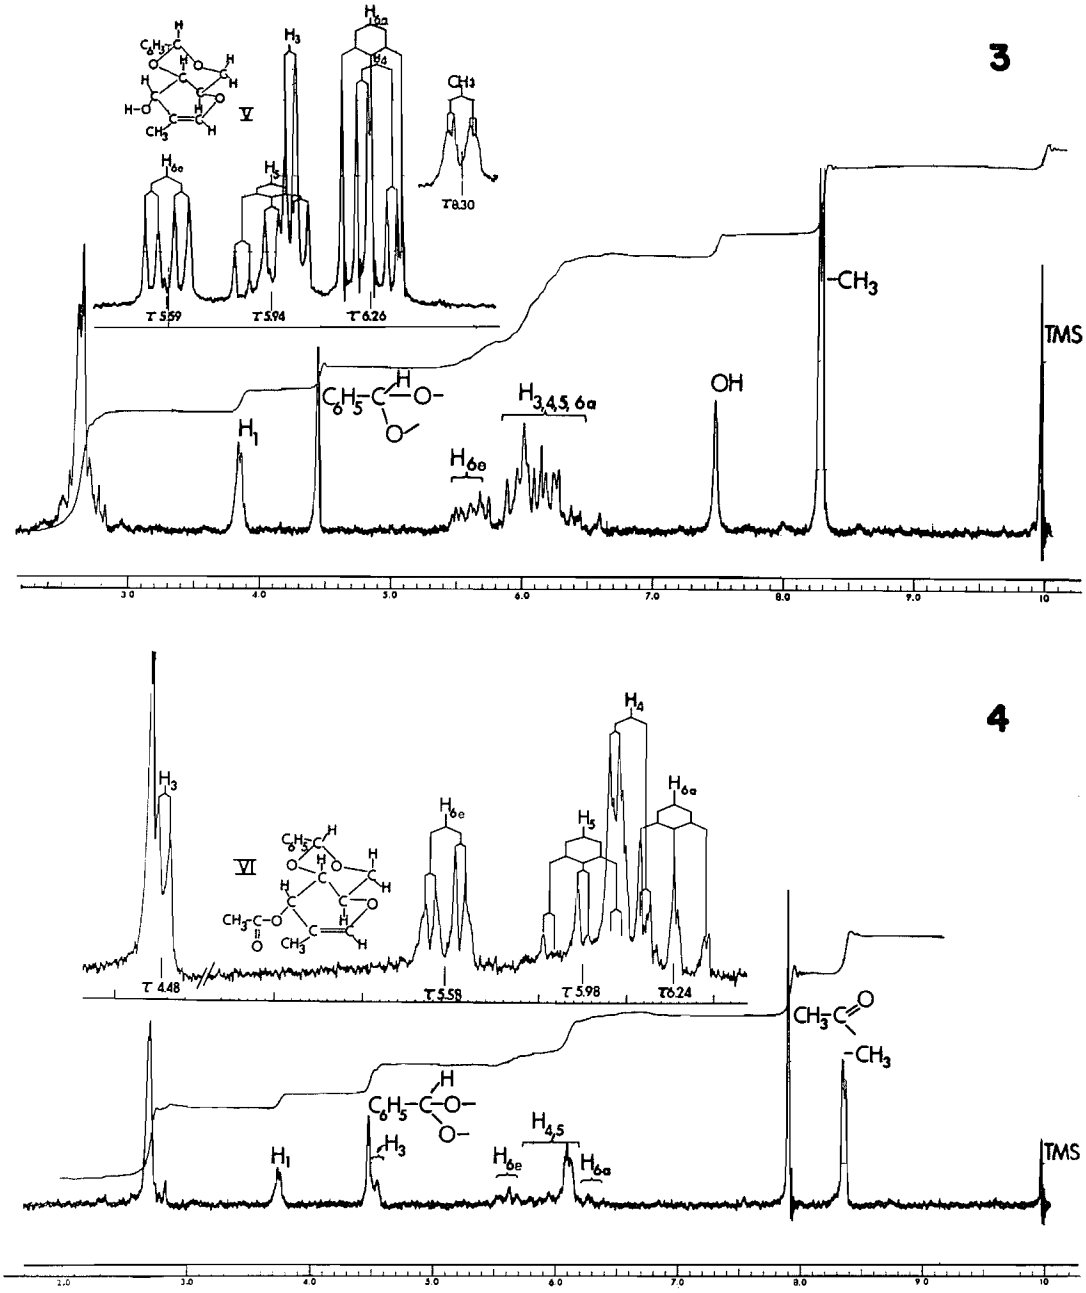
REACTION SCHEME 2.

The infrared spectrum in Nujol showed a broad band at 3 550 cm^{-1} (OH), a sharp, intense band at 1 670 cm^{-1} (vinyl ether), and bands at 698 cm^{-1} and 753 cm^{-1} (benzylidene). The n.m.r. spectrum in $CDCl_3$, with the aid of spin decoupling and resolution of the signals at 100 Mc.p.s., was amenable to complete first-order analysis (Fig. 3). The observed chemical shifts and coupling constants are listed in Table I. The coupling constants $J_{3,4}$ (3.5 c.p.s.) and $J_{4,5}$ (9.5 c.p.s.) are in agreement with the half-chair H1 structure V.

Acetylation of V gave VI, whose infrared spectrum showed no absorption in the OH region; strong absorption occurred at 1 742 cm^{-1} (C=O) and 1 668 cm^{-1} (vinyl ether) as

[4]*Obtained from the Lithium Corporation of America via Alfa Inorganics Inc., 8 Congress Street, Beverly, Massachusetts, U.S.A.*

well as at 755 cm^{-1} and 697 cm^{-1} (benzylidene). First-order analysis of the n.m.r. spectrum (Fig. 4) in $CDCl_3$ gave coupling constants and chemical shifts (Table I) in complete agreement with the half-chair H1 structure VI. Acetylation of C_3OH shifted the C_3H signal markedly from τ 5.99 to τ 4.48.



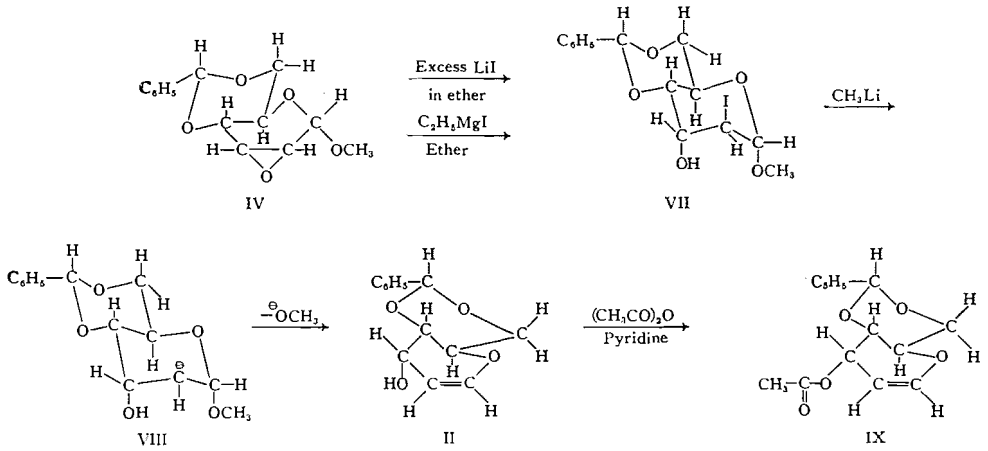


FIG. 3. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-*ribo*-hexopyranose (V) in $CDCl_3$. Inset, 100 Mc.p.s. spectrum in $CDCl_3$.

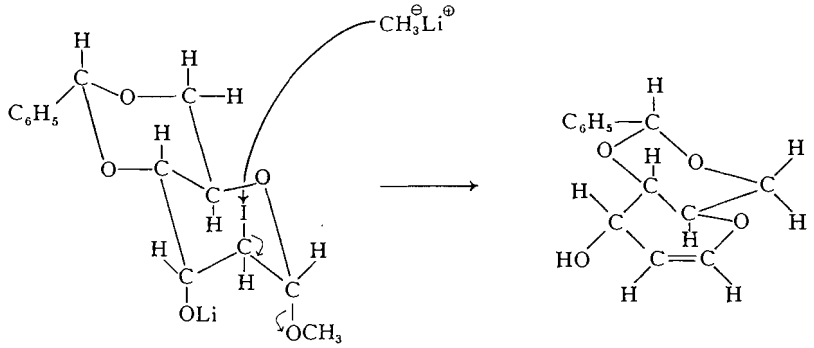
FIG. 4. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 3-*O*-acetyl-4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-*ribo*-hexopyranose (VI) in $CDCl_3$. Inset, 100 Mc.p.s. spectrum in $CDCl_3$.

The formation of V rather than II and the fate of the rest of IV are under investigation and will be reported upon later.



Compound II could be obtained by the reaction of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV) with methyllithium prepared according to the directions of Feast *et al.* (1), or by the reaction of commercial methyllithium with the iodohydrin VII. The iodohydrin could be prepared according to published directions (5) by the reaction of ethylmagnesium iodide with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV), or more conveniently by treatment of an ether solution of IV with lithium iodide in fourfold excess to force the equilibrium towards VII. No doubt, the conversion of VII into II involved lithium–iodine exchange to produce the carbanion VIII, which would eliminate the methoxide anion to form the α,β-unsaturated ether II (Reaction Scheme 3).[5] The formation of II by the reaction of the 2,3-anhydroallopyranoside IV with methyllithium, as found by Feast *et al.* (1), will be discussed in an early communication by R. U. Lemieux of our department.

REACTION SCHEME 3.

First-order analysis of the n.m.r. spectra of II (Fig. 5) and its acetylated derivative IX (Fig. 6) gave the coupling constants and chemical shifts listed in Table I. These, along with the infrared spectra, corroborated the structures II and IX. In both cases, the coupling constants $J_{3,4}$ (3.5 c.p.s. and 3.0 c.p.s.) and $J_{4,5}$ (9.5 c.p.s.) support the "gauche" arrangement of H_3 and H_4 and the *trans* diaxial configuration of H_4 and H_5.

[5]*The referee pointed out that IX might be obtained via a concerted reaction such as*

rather than by stepwise formation of the carbanion intermediate.

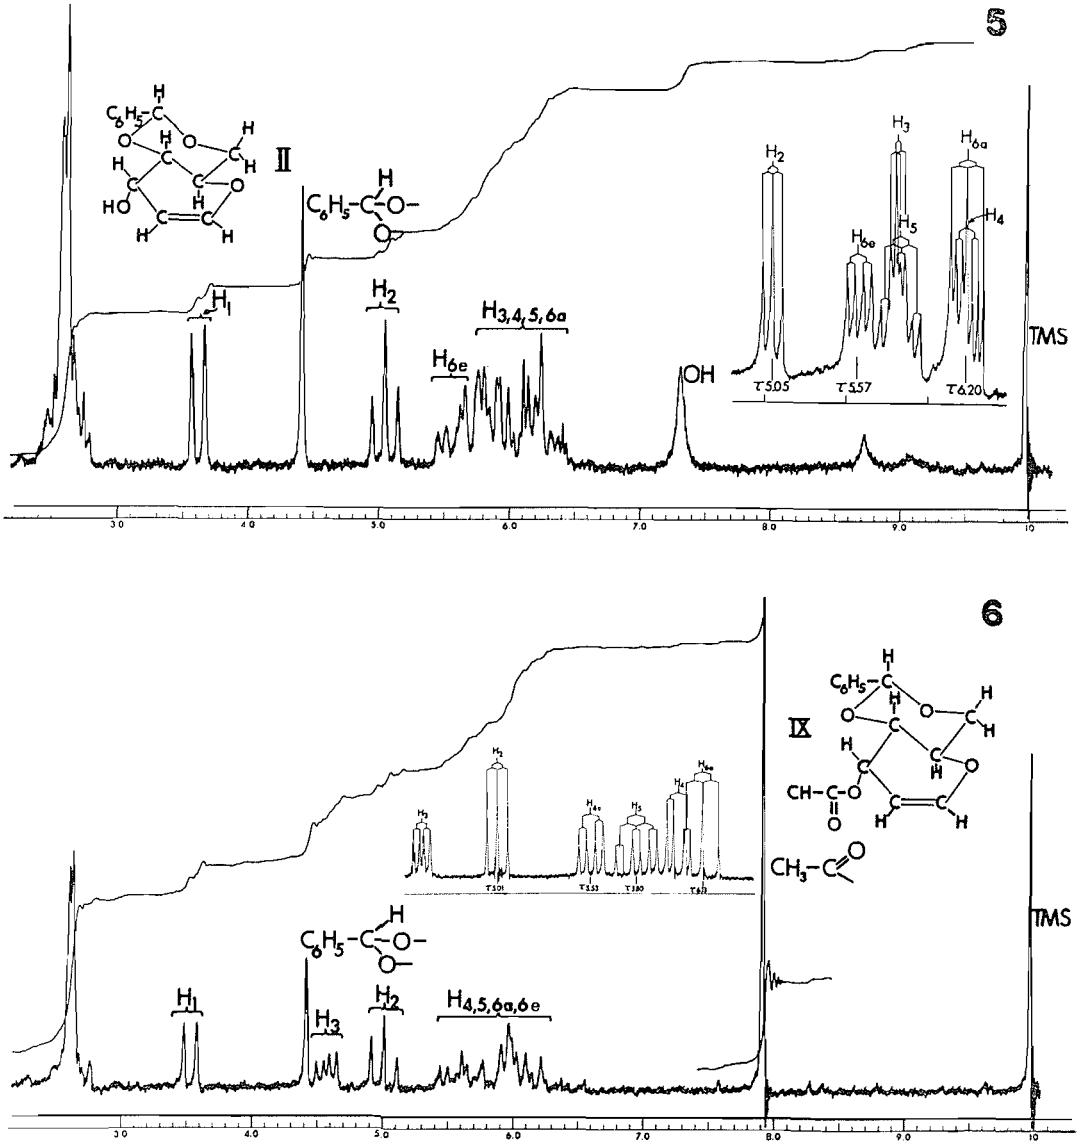


FIG. 5. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-D-*ribo*-hexopyranose (II) in $CDCl_3$. Inset, 100 Mc.p.s. spectrum in $CDCl_3$.

FIG. 6. Nuclear magnetic resonance spectrum at 60 Mc.p.s. of 3-*O*-acetyl-4,6-*O*-benzylidene-1,2-didehydro-1,2-dideoxy-D-*ribo*-hexopyranose (IX) in $CDCl_3$. Inset, 100 Mc.p.s. spectrum in $CDCl_3$.

It is interesting that in compounds I and III, where H_3 and H_4 are *trans* diaxial, the signal for H_4 is downfield from that for H_5, whereas in compounds II and IX as well as V and VI, where H_3 is "gauche" to H_4, the H_4 signal lies upfield from that for H_5. This observation has been of some utility in locating both the H_4 and H_5 signals in several compounds to be reported upon later.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were obtained with a model 421 Perkin–Elmer spectrometer. Nuclear magnetic resonance spectra were obtained with Varian Associates A60 and HR100 spectrometers. Elemental analyses were performed by Miss Darlene Roberts, Department of Chemistry, University of Alberta, Edmonton. Rotations were found with a Perkin–Elmer model 141 polarimeter.

D-*Glucal*

The following modification of the published procedure (6) gave better results.

Pure tri-*O*-acetyl-D-glucal (5 g) (7) was stirred at room temperature for 18 h with anhydrous sodium carbonate (5 g) in dry methanol (75 ml). The mixture was filtered and the solid residue washed with dry methanol. The combined washings and filtrate were freed from methanol and the residue was extracted with hot ethyl acetate. When this extract was concentrated under reduced pressure and allowed to stand in the refrigerator, 2.0 g (70%) of D-glucal slowly separated as crystals. These were pure enough for the next reaction, m.p. 57–59° (lit. m.p. 57–59° (6)). A mixed melting point gave no depression.

4,6-O-Benzylidene-D-glucal (I)

A mixture of pure D-glucal (1 g), benzaldehyde freshly distilled under nitrogen (2 ml), freshly fused zinc chloride (600 mg), and anhydrous sodium sulfate (heated to drive off residual moisture) (500 mg) was stirred for 12 h at room temperature under nitrogen. (The presence of the dry sodium sulfate was thought to be necessary to remove water which might otherwise react with the glucal double bond. Later experiments showed that its absence made little difference in the yield of product.) The solid materials, except sodium sulfate, slowly dissolved, giving a pale-green solution. An aqueous solution of sodium carbonate (10%, 10 ml) was stirred into the mixture, which then stood for 10 min. The white precipitate of zinc hydroxide was removed by filtration, and washed with water and then with ether. The organic layer was separated from the combined washings and filtrate and the aqueous portion (~50 ml) extracted with ether (5 × 50 ml). The combined ether solutions were washed twice with water and then dried (Na_2SO_4). The ether was removed and the residue was freed from benzaldehyde by passage of the material through a column of neutral alumina (grade II, 15 g) and elution of the column with *n*-hexane until the eluent was free from benzaldehyde. The 4,6-*O*-benzylidene-D-glucal was removed from the column with diethyl ether. Evaporation of the ether gave a colorless solid, m.p. 136–138°, yield 31%. Crystallization from ether–hexane raised the melting point to 142–143°; $[\alpha]_D^{27}$ −20° (*c*, 1 in $CHCl_3$).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.70; H, 6.02. Found: C, 66.72; H, 5.77.

3-O-Acetyl-4,6-O-benzylidene-D-glucal (III)

To 4,6-*O*-benzylidene-D-glucal (120 mg) in dry pyridine (2 ml) was added acetic anhydride (0.5 ml), and the mixture was allowed to stand at room temperature for 12 h. It was then poured into ice water, from which, after 1 h, was obtained a solid (100 mg, 70%). The solid was separated, washed with water, and crystallized from acetone–hexane, m.p. 136–137°, $[\alpha]_D^{27}$ −85° (*c*, 1 in $CHCl_3$).

Anal. Calcd. for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84. Found: C, 65.19; H, 5.50.

4,6-O-Benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-ribo-hexopyranose (V)

To a suspension of 2 g of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV) (8) in anhydrous ether (50 ml) was added an ether solution of methyllithium (100 ml of a 4.5% solution, Lithium Corporation of America) at 0 to 5° under a nitrogen atmosphere. Ten minutes later the mixture was refluxed for a period of 8 h, during which time the alloside slowly dissolved. The yellow mixture was poured slowly, with stirring, into ice water (50 ml). The ether layer was separated and the aqueous portion extracted four times with ether. The combined ether layers were washed with water, dried (Na_2SO_4), and freed from solvent. The residual syrup, upon trituration with hexane, gave a crystalline solid, m.p. 120–122° (400 mg, 22%). Crystallization from ether–hexane gave 370 mg (20%) of material melting at 126–127°; $[\alpha]_D^{27}$ +175° (*c*, 1 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 67.52; H, 6.25.

3-O-Acetyl-4,6-O-benzylidene-1,2-didehydro-1,2-dideoxy-2-methyl-D-ribo-hexopyranose (VI)

Acetic anhydride (0.5 ml) was added to a solution of V (120 mg) in dry pyridine (2 ml). The mixture was left overnight at room temperature, and then poured into ice water. After 1 h, the crystalline product was separated by filtration, washed with water, and air-dried (120 mg, 85%), m.p. 70–72°. When crystallized from hexane it melted at 74–75° (100 mg, 76%); $[\alpha]_D^{27}$ +185° (*c*, 1 in $CHCl_3$).

Anal. Calcd. for $C_{16}H_{18}O_5$: C, 66.20; H, 6.25. Found: C, 66.42; H, 6.16.

Methyl 4,6-O-Benzylidene-2-deoxy-2-iodo-α-D-altropyranoside (VII)

A mixture of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV) (1.32 g) and dry lithium iodide (2.6 g) in anhydrous ether (80 ml) was refluxed for 1 h. The clear solution was cooled, washed with water until neutral to litmus, and then dried (Na_2SO_4). Removal of the ether gave a syrup which crystallized on trituration with hexane (1.5 g, 76%), m.p. 102–104°. Recrystallization from ether–hexane gave a melting point of 104–105° (lit. m.p. 105–106° (5)). A mixed melting point was undepressed.

Attempted Methylation of the 2-Iodoaltroside VII

To a solution of VII (1.96 g) in 1,2-dimethoxyethane (40 ml, distilled from potassium metal) and methyl iodide (5 g) was added sodium hydride (0.5 g, obtained as a 55% dispersion in mineral oil, from which the mineral oil was first removed with dry hexane). A white solid appeared immediately after the addition of the first portion of the sodium hydride. After the addition of the hydride, the mixture was stirred for 2 h at room temperature and filtered; then the residue (1 g) was washed with water. Crystallization from chloroform–ether gave methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, m.p. 199–200°. A further quantity was

recovered from the filtrate, total yield 89%. A mixed melting point with an authentic sample (8) was undepressed. No methylated material was obtained.

*4,6-O-Benzylidene-1,2-didehydro-1,2-dideoxy-*D*-ribo-hexopyranose (4,6-O-Benzylidene-*D*-allal, II)*

Method A

To a stirred solution of the 2-iodoaltroside VII (1.95 g) in dry ether (50 ml), cooled in an ice bath, was added moderately slowly and under nitrogen a solution of *n*-butyllithium (10 ml of a 15% solution). The solution slowly became cloudy. It was refluxed for 2 h, cooled, and poured into ice water. The ether layer was separated and the aqueous portion extracted with ether. The combined ether solutions were washed with water, dried (Na_2SO_4), and freed from ether. The light-yellow syrupy residue crystallized slowly as fine long needles. Recrystallization from ether–hexane gave a melting point of 84–85°; yield 1.1 g (93%). A mixed melting point with an authentic sample (1) was undepressed.

When methyllithium replaced *n*-butyllithium, similar results were obtained.

Method B

A mixture of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (IV) (3.5 g) and dry lithium iodide (6 g) in anhydrous ether (250 ml) was stirred and refluxed under nitrogen for 1 h. The clear, light-yellow solution was cooled in an ice bath; to this was added an ether solution of *n*-butyllithium (40 ml of a 15% solution) at a moderate rate. After the addition, the cloudy solution was refluxed for 2 h, cooled, and poured into ice water. The ether layer was separated and the aqueous portion extracted with ether. The combined organic layers were washed with water, dried (Na_2SO_4), and freed from solvent. The semisolid residue (3.0 g, 94%) was crystallized from ether–hexane, m.p. 84–85°, yield 2.85 g (89%).

Similar results were obtained when methyllithium was added in place of *n*-butyllithium.

Example of the Method for the First-Order Analysis (with Compound IX)

The signal at low field (τ 3.54) is no doubt caused by H_1. The signal for H_3 was located by its change of position from τ 5.81 (for compound II) to τ 4.57 on acelylation of II to produce IX. The signal for H_2 must then be that at τ 5.01.

Irradiation at τ 3.54 (H_1) converted the triplet at τ 5.01 (H_2) into a doublet ($J_{2,3}$ = 5.7 c.p.s.). Irradiation at τ 4.57 (H_3) changed the triplet at τ 5.01 (H_2) to a doublet ($J_{1,2}$ = 6.0 c.p.s.). Irradiation at τ 4.57 converted the quartet at τ 6.05 into a doublet with a coupling of 9.5 c.p.s. ($J_{4,5}$), eliminating the two small couplings of 3.5 c.p.s. ($J_{3,4}$) and thus indicating that the signal for H_4 was at τ 6.05 and that H_3 and H_4 have an equatorial–axial (gauche) steric relationship. The large coupling of 9.5 c.p.s. is no doubt caused by coupling of H_4 with H_5, thus indicating that these protons are *trans* diaxial.

The quartet at τ 5.53 is most likely that for H_{6e} since it agrees with the expected quartet for H_{6e}, and the triplet at τ 6.18 would be that expected for H_{6a} if this proton were coupled equally to H_{6e} and H_5. On this assumption, H_5 must be centered at τ 5.80 with $J_{4,5}$ = 9.5 c.p.s. (as indicated above) and $J_{5,6a}$ = 9.5 c.p.s., giving a triplet which, in turn, is split by coupling of H_5 with H_{6e} by 4.5 c.p.s. caused by their gauche arrangement.

Irradiation at τ 5.53 (H_{6e}) caused a strong collapse at both the τ 5.80 and τ 6.18 regions.

With the aid of this information, and the use of similar reasoning along with a careful comparison of all of the spectra, the HR100 spectra of the remaining compounds were analyzed to give multiplets which agreed reasonably well with those expected.

ACKNOWLEDGMENTS

PHOTOCHEMICAL TRANSFORMATIONS OF DIENES

VII. STEREOCHEMISTRY OF ADDITION OF ALCOHOL, AND EFFECT OF SUBSTITUENTS AND ACIDS ON THE PHOTOCHEMISTRY OF CHOLESTA-3,5-DIENES[1,2]

G. BAUSLAUGH,[3] G. JUST, AND E. LEE-RUFF[4]

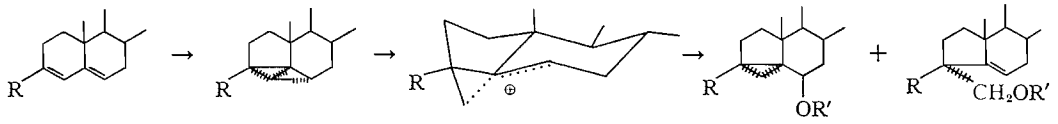
Received July 19, 1966

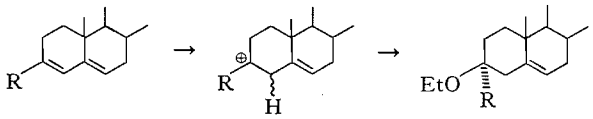
ABSTRACT



Results for the photolysis of 6-methylcholesta-3,5-diene are described. The photolysis of these and other dienes proceeds by a unimolecular process, giving bicyclobutanes, or a bimolecular process, giving carbonium ions. Reaction of the bicyclobutane with a protic solvent results in stereospecific incorporation of a proton (4β), whereas direct abstraction of a proton by a photo-excited species results in non-stereospecific abstraction. In the presence of small amounts of acid, more or in part new products, derived from the bimolecular pathway, are obtained.

It was noted that the normal chromatographic elution sequence (alumina) of epimeric alcohols was reversed when thin-layer chromatography (silica gel) was used.

The photolysis of cholesta-3,5-dienes (I) proceeds through at least two different pathways: a unimolecular process (A) and a bimolecular process (B), in which a photo-excited species abstracts a proton from solvents such as alcohols.



Process A is characteristic of the photolysis of cholesta-3,5-diene (I*a*), which gives bicyclobutane (II*a*) in at least a 75% yield (1). Treatment of II*a* with water or alcohol gives homoallylic carbonium ion III*a*, in which the protonation has occurred stereospecifically (2). Coordination with solvent then gives ethers or alcohols IV*a* and V*a* (R′ = H or C_2H_5).

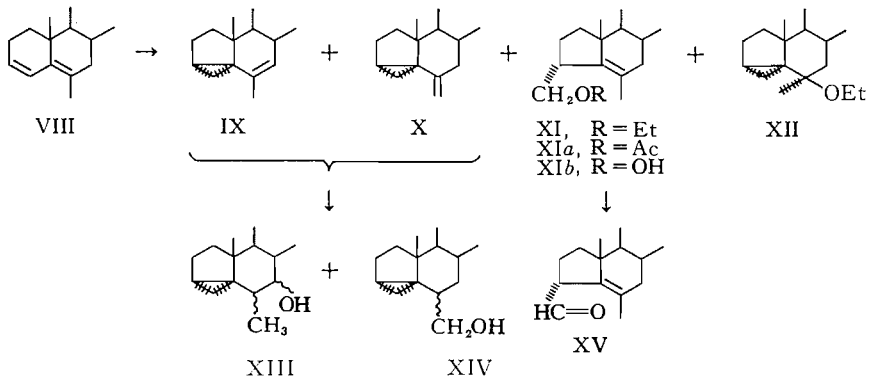
Mechanism A

I*a*, I*b* II*a*, II*b* III*a*, III*b* IV*a*, IV*b* V*a*, V*b*

Mechanism B

I*b*, I*c* VI*b*, VI*c* VII*b*, VII*c*

a, R = H; *b*, R = CH_3; *c*, R = OCH_3 or OC_2H_5



Process B is typical of the photolysis of 3-alkoxycholesta-3,5-dienes (I*c*) (3). No bicyclobutane can be detected in that reaction. An excited polar species abstracts a proton from solvent non-stereospecifically, giving a carbonium ion (VI), which then coordinates with solvent.

In this paper, we shall examine the influence of a 6-methyl substituent on the photoreaction. The stereochemistry of the protonation and of the coordination of solvent will be discussed, as well as the effect of acid on the photolysis.

Photolysis of 6-Methylcholesta-3,5-diene (VIII)

The photolysis of diene VIII (4) in a pentane–ethanol mixture gave two ethers XI and XII in 17 and 5% yields, and two hydrocarbons IX and X in 40 and 20% yields, respectively. The ether with the lower yield was identified as 6β-ethoxy-6α-methyl-3β,5-cyclo-5β-cholestane (XII) by spectroscopic means,[5] and by analogy with similar reactions of cholesta-3,5-diene (20). This is the expected product from the ethanolysis of the bicyclobutane intermediate formed from VIII.

The second major photoether was identified as 3α-ethoxymethyl-6-methyl-A-norcholest-5-ene (XI), also an expected photo product, based on the following evidence. Treatment with boron trifluoride etherate in acetic anhydride (5) converted XI into 3α-acetoxymethyl-6-methyl-A-norcholest-5-ene (XI*a*) in a quantitative yield.

The magnetic non-equivalence of protons B and C, including the large difference in the values of J_{AB} and J_{AC} in the nuclear magnetic resonance (n.m.r.) spectrum of acetate XI*a* (Fig. 1), indicated that the rotation of the acetoxymethyl group was hindered.

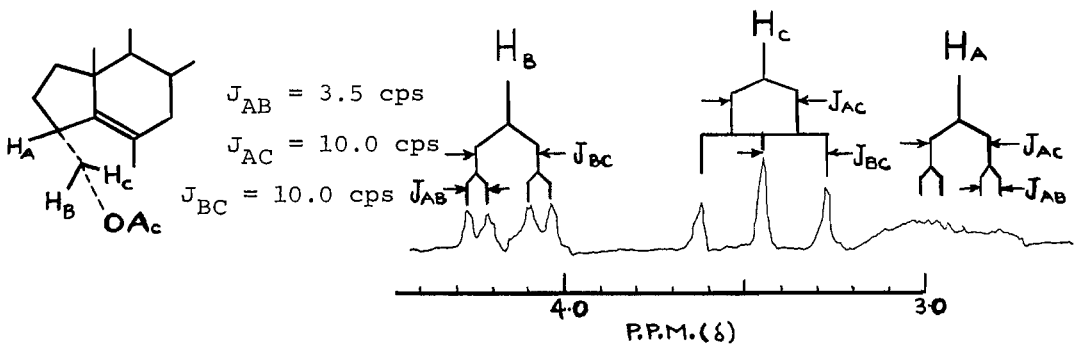

FIG. 1. Nuclear magnetic resonance spectrum of acetate XI*a*.

Acetate XI*a* could be hydrolyzed to alcohol XI*b*. Alcohol XI*b*, upon re-acetylation, gave acetate XI*a*, and was converted into photoether XI by treating its potassium salt

with ethyl iodide. A mild Jones oxidation of alcohol XI*b* gave aldehyde XV. The alcohol XI*b* was stable to manganese dioxide and to 10% ethanolic hydrochloric acid, indicating that it was not allylic (6, 7). Dehydration with phosphorus pentoxide in pyridine converted XI*b* into the cycloolefin IX, whereas treatment with phosphorus pentoxide in benzene gave 6-methylcholesta-3,5-diene (VIII). This latter reaction was also observed with the corresponding 3α-hydroxymethyl-A-norcholest-5-ene (1*a*). These dehydrations most likely proceed through the intermediacy of a homoallylic carbonium ion similar to III, which, under acidic conditions (phosphorus pentoxide – benzene), would rearrange to diene VIII.

The hydrocarbon fraction from the photolysis could not be resolved into its two components on a preparative scale. However, thin-layer chromatography (t.l.c.) did reveal two overlapping stains of slightly different colors. Vapor-phase chromatography (v.p.c.) showed two sharp peaks with an intensity ratio of 2:1. The major and less-polar olefin was assigned the structure of 6-methyl-3β,5-cyclo-5β-cholest-6-ene (IX), and the more polar olefin the structure of 6-methylene-3β,5-cyclo-5β-cholestane (X), based on n.m.r. and infrared spectral data. Hydroboration of the olefin mixture gave, in low yields, two alcohols, XIII and XIV, which were separated on a silica gel column and identified by n.m.r. and infrared spectra.

Stereochemistry

Mechanism A

The highly strained bicyclobutane derivatives II*a* and II*b* are rapidly solvolyzed in protic solvents. The stereochemistry of solvolysis products of the type IV and V has been well established (8). Using alcohol IV*a* (R′ = H), Dauben and Wipke (2) showed that the n.m.r. coupling constants between the proton at C_6 and those at C_7 were typical of a 6β alcohol ($J_{AX} = J_{BX} = 3$ c.p.s.). We oxidized alcohol IV*a* (R′ = H) to ketone XVI, which was then reduced with lithium aluminium hydride to the previously unreported alcohol XVII. Alcohol XVII could be reoxidized to ketone XVI, and hence was epimeric with alcohol IV*a*. The n.m.r. spectrum of alcohol XVII showed typical coupling constants

(9) (10.8 and 4.2 c.p.s.) for an axial 6β proton, and therefore confirmed the 6β configuration for the hydroxyl group in IV*a*. Supporting evidence was obtained by observing the position of the peak of the C_{19} methyl group in the n.m.r. spectrum of epimers IV*a* (R′ = H) and XVII. In IV*a* (R′ = H) the peak was located at 1.2 p.p.m., whereas in XVII it was found at 1.0 p.p.m. The lower field position is indicative of a 6β substituent (e.g. see ref. 10).

Lead tetraacetate oxidations of steroidal 6β alcohols are known to give 6β,19 ethers (11). When 3β,5-cyclo-5β-cholestan-6β-ol (IV*a*) was treated with lead tetraacetate, a 66%

yield of the cyclic ether XVIII was obtained. However, the 6α alcohol XVII gave the same ether in a comparable yield, indicating the unreliability of this method for stereochemistry assignments. Also, t.l.c. (on Merck silica gel G) showed that the 6α alcohol XVII (equatorial) moved faster than its 6β epimer IV*a*. This result is somewhat unexpected since the axial epimer usually has a higher chromatographic mobility on aluminium oxide. Kosower and Winstein (12), for example, showed that 3α,5-cyclo-5α-cholestan-6β-ol has a higher mobility on aluminium oxide than its 6α epimer. However, these 3α,5-cyclo compounds also showed the reverse order of mobility when chromatographed on thin-layer silica gel.

Dauben and Wipke (2) studied the stereochemistry of the addition of hydrogen to C_4 by carrying out the solvolysis in heavy water, giving IV*a*-4-d_1 (R′ = H). They tentatively assigned the 4β configuration to the deuterium on the basis of the coupling constant between the remaining C_4 proton and the C_3 proton, assuming that the *trans* coupling in cyclopropanes is always smaller than the *cis* coupling. However, typical chemical shift values for bicyclo[3.1.0]hexanes (20) suggested the opposite assignment. We have obtained more conclusive evidence by examining the n.m.r. spectra of XVII and XVII-4-d_1. Whereas in the spectrum of alcohol IV*a* peaks for both C_4 cyclopropyl protons appeared (+0.31 and −0.22 p.p.m.) and no higher field signal was present in the monodeuterated product, both XVII and XVII-4-d_1 showed absorption for only one C_4 proton. Hence the proton in XVII which becomes deuterated in XVII-4-d_1 is shifted to an abnormally low field by the presence of a 6α-hydroxyl group. Models show that a 6α-hydroxyl group is in close proximity to the 4β proton, and therefore the deuterium is in the 4β position. To show that the disappearance of one of the two C_4 protons was caused by a 6α substituent, we examined the spectra of the 6β-acetoxy-, 6β-benzoyloxy-, 6β-ethoxy-, and unsubstituted 3β,5-cyclo-5β-cholestanes. All showed both C_4 proton signals.

When 6β-ethoxy-3β,5-cyclo-5β-cholestane-4β-d_1 (IV*a*-4β-d_1, R′ = Et) was hydrolyzed with acid and the resulting ring-contracted alcohol V*a*-4β-d_1 (R′ = H) converted into its *p*-toluenesulfonate and solvolyzed in aqueous acetone, the n.m.r. spectrum of the resultant cycloalcohol IV*a*-4β-d_1 (R′ = H) showed one doublet at 0.32 p.p.m., indicating that the deuterium was still attached to the 4β position. This proves that at no stage in the solvolysis is there a classical carbonium ion which would have altered the stereochemistry at C_4.

We therefore believe that the most likely mechanism for the solvolysis of the bicyclobutanes II involves initial protonation at the 4β position to give homoallylic carbonium ion III, followed by attack of solvent at C_4 or C_6, as demonstrated by Whitham (8).

Mechanism B

The photolyses of 3-alkoxycholesta-3,5-dienes (I*c*) in alcohol give 3,3-dialkoxycholest-5-enes (VII*c*). Deuterium labelling experiments showed non-stereospecific addition of deuterium at C_4 (3*b*). The photolysis of 3-methylcholesta-3,5-diene (I*b*) is reported (13) to give 20% of products derived from bicyclobutane II*b* (mechanism A) in which deuterium has been introduced stereospecifically at C_4, and 20% of 3β-ethoxy-3α-methylcholest-5-ene (VII*b*) (mechanism B). We now have obtained evidence that deuterium addition in VII*b* is nonspecific by carrying out the photolysis in deuterated ethanol. The n.m.r. spectrum of VII*b* (Fig. 2) shows half of the expected AB quartet, with peaks at 2.68 and 2.45 p.p.m. The spectrum of VII*b*-4-d_1 shows a peak of one-half the relative area of the previous two at their approximate center of gravity.

Therefore, dienes I*b* and I*c* both apparently react in part by a similar mechanism (mechanism B), which likely involves bimolecular reactions between an excited state and ethanol.

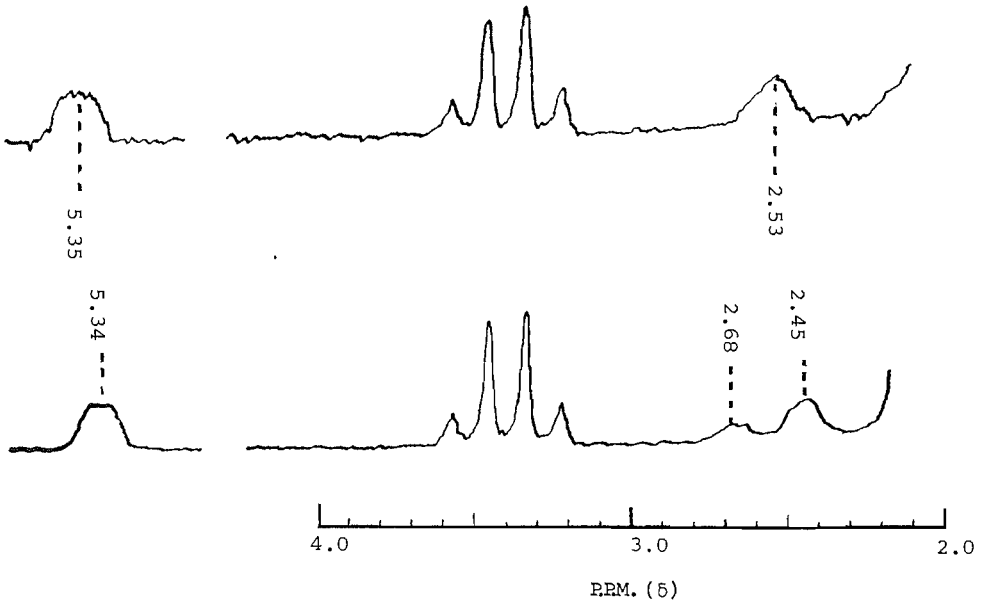

FIG. 2. Nuclear magnetic resonance of ethers VII*b* and VII*b*-4-d_1.

Effect of Acid on the Photolyses of Cholesta-3,5-dienes

To test the hypothesis that a polar excited state abstracts a proton from solvent in a bimolecular reaction, we carried out the photolysis of 3-methylcholesta-3,5-diene (I*b*) in acidic ethanol. The yield of ether VII*b* increased from about 20% (in pure ethanol) to 37%.

Photolysis of cholesta-3,5-diene in ethanol gives only bicyclobutane cleavage products IV and V. However, photolysis in acidic ethanol gave 29% of ether IV*a* (R′ = Et), traces of ether V*a* (R′ = Et), and 31% of a new ether, 3β-ethoxycholest-4-ene. The structure was confirmed by hydrogenation of this ether in the presence of sodium nitrite to suppress hydrogenolysis (14). Cholestane and 3β-ethoxycholestane were obtained and identified by comparison with authentic samples, the latter being obtained by reduction of cholesteryl ethyl ether. More cholestane was obtained when no sodium nitrite was added to the hydrogenation mixture.

The photolysis of 6-methylcholesta-3,5-diene (VIII) is similar to that of cholesta-3,5-diene in that it gave only products IX, X, XI, and XII derived from a bicyclobutane of type II. When the photolysis of this diene was carried out in acidic ethanol, 6-methylcholesteryl ethyl ether was formed in a 20% yield in addition to 30% of the ring-contracted ether XI.[6] The structure of the former ether was proven by comparison with a synthetic sample (4).

The starting material and all products from the photolyses of dienes I*a*, I*b*, and VIII were subjected to the acidic reaction conditions. None of the polar reaction products VII*b*, 3β-ethoxycholest-4-ene, and 6-methyl-cholesteryl ethyl ether were obtained.

It seems, therefore, that the formation of 3β-ethoxycholest-4-ene, 3β-ethoxy-3α-methylcholest-5-ene (VII*b*), ketal VII*c*, and 6-methylcholesteryl ethyl ether from dienes I*a*, I*b*, I*c*, and VIII, respectively, proceeds by a bimolecular reaction mechanism.

From the photolyses of 3-substituted cholestadienes, it appears that strong electron-donating substituents favor the bimolecular mechanism (OEt > CH_3 > H). Since

[6]*Ether XII is not stable to acidic ethanol and is transformed into XI.*

For personal use only.

6-methylcholestadiene resembles cholestadiene (Table I), it must be concluded that the effect of substituents in the polar excited state is localized.

TABLE I

Comparison of product yields from mechanisms A and B in the photolyses of cholesta-3,5-dienes

Diene	In neutral media		In acidic media	
	Total yield of products from mechanism A (%)	Total yield of products from mechanism B (%)	Total yield of products from mechanism A (%)	Total yield of products from mechanism B (%)
Cholesta-3,5-diene (I*a*)	75	0	29	31
3-Methylcholesta-3,5-diene (I*b*)	20	20	9	37
3-Alkoxycholesta-3,5-diene (I*c*)	0	65–90	—	—
6-Methylcholesta-3,5-diene (VIII)	87	0	30	20

EXPERIMENTAL

For general experimental details, see ref. 15. All v.p.c. experiments were performed on a F and M laboratory chromatograph model 700 under the following conditions: glass column (6 ft × ¼ in.) packed with silicon gum SE-30 on Chromosorb W; column temperature 280°; injection port temperature 300°; detector temperature 300°; helium flow 50 ml/min. All preparative t.l.c. separations were performed with glass plates (20 × 20 cm) covered with silica gel (½ mm, E. Merck AG).

Photolysis of 6-Methylcholesta-3,5-diene (VIII) in Ethanol–n-Pentane

Diene VIII (3 g) in 100 ml of spectrograde *n*-pentane and 400 ml of absolute ethanol was irradiated with a 450 W high-pressure mercury arc lamp[7] until there was no appreciable absorption in the ultraviolet between 200 and 400 mμ (96 h). Evaporation gave an oily residue (3.05 g), which was chromatographed on alumina (activity II–III, 100 g). Elution with hexane gave 1.9 g of a hydrocarbon mixture containing 6-methyl-3β,5-cyclo-5β-cholest-6-ene (IX) and 6-methylene-3β,5-cyclo-5β-cholestane (X). Vapor-phase chromatography resolved two sharp peaks with retention times of 57 and 77 s and relative areas of 2:1; ν 3 030 (C=C_7—H), 3 070, 1 645, and 885 cm^{-1} (C=CH_2); δ 1.67 p.p.m. (singlet, C=C—CH_3), 0.25 p.p.m. (doublet, J = 5 c.p.s., C_4 cyclopropyl H in IX), and 0.6 p.p.m. (doublet, J = 5 c.p.s., C_4 cyclopropyl H in X). In addition, signals for vinyl protons at 5.36 p.p.m. (doublet, J = 11 c.p.s., C_7—H) and 5.06 and 4.45 p.p.m. (finely split singlet, J = 2 c.p.s., C_6=CH_2) appeared with relative areas of 1:1, respectively.

Benzene eluted 0.663 g of an oil which contained a mixture of ethers. This mixture was separated by preparative t.l.c. (benzene). The faster moving band (130 mg) was identified as 6β-ethoxy-6α-methyl-3β,5-cyclo-5β-cholestane (XII); ν 3 010, 3 075 (cyclopropane), and 1 080 cm^{-1} (C—O—C); δ 0.0 p.p.m. (2H, overlapping doublets, cyclopropyl protons) and 3.32 p.p.m. (2H, poorly resolved quartet, C_6—O—CH_2). Ether XII was quite labile towards traces of moisture so that no satisfactory analysis could be obtained.

The slower moving band (505 mg, XI) could not be crystallized; ν 1 108 cm^{-1} (C—O—C); δ 1.60 p.p.m. (3H, singlet, C=C—CH_3), 2.85 p.p.m. (2H, doublet, ethoxymethyl protons), and 3.40 p.p.m. (2H, quartet, O—*CH_2*—CH_3); v.p.c. showed one peak with a retention time of 118 s.

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 83.82; H, 12.06.

3α-Acetoxymethyl-6-methyl-A-norcholest-5-ene (XIa)

To 8 ml of acetic anhydride and 1.5 ml of boron trifluoride etherate cooled to −18° was added a solution of 200 mg of ether XI in 2 ml of anhydrous ether. The reaction mixture was stirred for 3 min at −18°. An ice chip was carefully added and the mixture was stirred at room temperature for a further 2 h. The reaction mixture was diluted with 50 ml of ether and the ethereal solution washed with water, 5% aqueous sodium carbonate, and water. The ethereal solution was then dried over anhydrous magnesium sulfate and evaporated under reduced pressure, giving 190 mg of amorphous 3α-acetoxymethyl-6-methyl-A-norcholest-5-ene (XI*a*); ν 1 230, 1 030, and 1 735 cm^{-1} (acetate).

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38. Found: C, 81.32; H, 11.23.

3α-Hydroxymethyl-6-methyl-A-norcholest-5-ene (XIb)

A solution of 100 mg of acetate XI*a* in 30 ml of 5% methanolic potassium hydroxide was heated under reflux for 3 h. Extraction and evaporation gave 97 mg of an oil which crystallized from methanol–ether,

[7]*The lamp was cooled by running water in a quartz jacket, supplied by Hanovia Lamp Division, 100 Chestnut St., Newark, New Jersey. The container was further cooled by immersion in a cold-water bath.*

For personal use only.

m.p. 109–110°; ν 3 640, 1 165, and 1 015 cm^{-1} (primary OH); δ 1.59 p.p.m. (3H, singlet, C=C—CH_3), 2.93 p.p.m. (1H, multiplet, C_3—H), and 3.45 p.p.m. (2H, multiplet, CH_2—OH).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.08. Found: C, 84.02; H, 12.08.

Acetylation of alcohol XI*b* (5 mg) with pyridine and acetic anhydride overnight gave acetate VII*a*, identical in all respects with a sample obtained above from photoether XI.

Attempted Dehydration of Alcohol XIb with Acid

A solution of 5 mg of alcohol XI*b* in 10 ml of absolute ethanol containing 1 ml of concentrated hydrochloric acid was heated under reflux for 4 h. Starting material was recovered.

Attempted Oxidation of Alcohol XIb with Manganese Dioxide

A solution of 10 mg of alcohol XI*b* in 5 ml of tetrahydrofuran containing 50 mg of manganese dioxide (21) was heated under reflux overnight. Filtration of the manganese and evaporation of the ether gave starting material.

Etherification of Alcohol XIb

To a solution of 10 mg of alcohol XI*b* in 5 ml of anhydrous benzene were added potassium chips (100 mg). The mixture was stirred and heated under reflux for 2 h. Ethyl iodide (1 ml) was added and the reaction mixture was refluxed for an additional hour. The mixture was cooled and ethanol was slowly added to decompose the excess potassium. Ether extraction gave an oily residue, which was purified by t.l.c. (benzene). The fast-moving band (2 mg) was identified as 3α-ethoxymethyl-6-methyl-A-norcholest-5-ene (XI). Its infrared spectrum was identical with that of photoether XI, and v.p.c. gave identical retention times.

Oxidation of Alcohol XIb

To a solution of 80 mg of alcohol XI*b* in 5 ml of acetone (freshly distilled over potassium permanganate) cooled to −10° was added dropwise 0.5 ml of Jones reagent (22) diluted with 2.5 ml of acetone. The solution was stirred for 10 min at −10°, after which 1.3 ml of 2-propanol was added followed by 7.5 ml of water. Ether extraction and purification by t.l.c. (benzene) gave 35 mg of 3α-formyl-6-methyl-A-norcholest-5-ene (XV), m.p. 82–84°; ν 2 830, 2 700, and 1 720 cm^{-1} (saturated aldehyde); λ_{max}^{EtOH} 214 mμ (ϵ 2 500); δ 9.24 p.p.m. (3H, singlet, C=C—CH_3).

Anal. Calcd. for $C_{28}H_{46}O$: C, 84.35; H, 11.63. Found: C, 84.22; H, 11.50.

Dehydration of Alcohol XIb

(a) With Phosphorus Pentoxide and Benzene

To a solution of 10 mg of alcohol XI*b* in 5 ml of anhydrous benzene was added 100 mg of phosphorus pentoxide. The mixture was stirred at room temperature for ½ h. This was worked up in the normal manner, giving 8 mg of 6-methylcholesta-3,5-diene (VIII), identified by comparison with an authentic sample.

(b) With Phosphorus Pentoxide and Pyridine

A solution of 7 mg of alcohol XI*b* in 5 ml of anhydrous pyridine containing 100 mg of phosphorus pentoxide was heated under reflux for 4 h. After addition of 5 ml of water to the cooled solution, it was extracted with ether. Evaporation gave 7 mg of an oil showing an infrared spectrum identical with that of the hydrocarbon fraction obtained from the photolysis, except that peaks for the exomethylene group at 3 070 and 885 cm^{-1} were missing. Vapor-phase chromatography showed that the retention time was identical with that of hydrocarbon IX.

Dehydration of 3α-Hydroxymethylcholest-5-ene with Phosphorus Pentoxide in Benzene

The same procedures used for the dehydration of alcohol XI*b* with phosphorus pentoxide in benzene were followed to give cholesta-3,5-diene (19) in a quantitative yield.

Hydroboration of the Photo-olefin Mixture (IX and X)

Diborane, generated by the addition of 1.52 g of sodium borohydride in 30 ml of diglyme to 7.2 g of boron trifluoride etherate in 40 ml of diglyme, was passed through a solution of 50 ml of ether containing 1 g of the photo-olefin mixture (IX and X) over a period of 30 min. The reaction mixture was stirred at room temperature for a further 30 min. To this solution, 4 ml of 3 *M* aqueous sodium hydroxide was added followed by the slow addition of 4 ml of 30% aqueous hydrogen peroxide. The mixture was extracted with ether, and the ethereal extract was washed with water until neutral, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure, giving a colorless oil which was chromatographed on silica gel. Hexane eluted 0.900 g of starting material. Benzene–ether eluted 80 mg of an oil identified as alcohol XIII; ν 3 600, 1 000 (hydroxyl), and 3 050 cm^{-1} (cyclopropyl); δ 3.45 p.p.m. (1H, broad multiplet, $C_7(OH)H$), 0.00 p.p.m. (multiplet, C_4 cyclopropyl protons), and 0.50 p.p.m. (multiplet, C_3 cyclopropyl proton).

Ether eluted 50 mg of an oil identified as alcohol XIV; ν 3 630, 1 010 (hydroxyl), and 3 060 cm^{-1} (cyclopropyl); δ 3.60 p.p.m. (2H, doublet, C_6—CH_2—O) and 0.40 p.p.m. (multiplet, C_4 cyclopropyl protons).

3β,5-Cyclo-5β-cholestan-6β-ol (IVa)

A solution of 5.7 g of cholesta-3,5-diene (I*a*) in wet pentane was irradiated under a helium atmosphere until no diene could be detected by ultraviolet (14 h). Chromatography on alumina (activity II–III) gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

two crystalline samples: 3β,5-cyclo-5β-cholestan-6β-ol (IV*a*) in a 30–40% yield from the early hexane–benzene (1:1) fractions, and 3α-hydroxymethyl-A-norcholest-5-ene (V*a*) in a 10–20% yield from the later hexane–benzene (1:1) fractions.

The photoalcohol IV*a* was purified by forming the benzoate (benzoyl chloride and pyridine). The benzoate was purified by crystallization several times from ether, and was then reconverted into the alcohol IV*a* by refluxing for 1 h in 25 ml of 5% methanolic potassium hydroxide under nitrogen. Addition of water and extraction with ether yielded a residue, which was purified by t.l.c. (hexane–ether, 9:1). Slow crystallization from ether gave crystals, m.p. 98–100°; $[\alpha]_D$ +21.1° (*c*, 1.61 in $CHCl_3$) (lit. (16) m.p. 98–100.5° and $[\alpha]_D$ 23°); ν_{CCl_4} 3 622 (OH stretching) and 1 032 cm^{-1} (C—O stretching). The n.m.r. spectrum showed C_4 cyclopropyl quartets at +0.35 (*J* 3.0 and 4.6 c.p.s.) and −0.14 p.p.m. (*J* 4.6 and 7.4 c.p.s.). The equatorial C_6 proton appeared at 3.39 p.p.m. as a poorly resolved quartet.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.87; H, 11.99. Found: C, 84.28; H, 12.09.

The photoalcohol was identical in all respects (melting point, t.l.c., infrared, n.m.r.) with the solvolysis product prepared by Whitham (16).

For purposes of examining their n.m.r. spectra, the following derivatives of IV*a* were prepared.

3β,5-Cyclo-5β-cholestan-6β-acetate

3β,5-Cyclo-5β-cholestan-6β-ol (290 mg) was left overnight in 4 ml of pyridine and 2 ml of acetic anhydride. The solution was then poured into 100 ml of ice water, left for 1 h, and extracted twice with 100 ml portions of ether. The ether phases were washed five times with 5% hydrochloric acid, twice with 5% sodium hydroxide, and twice with water (100 ml each). Drying with sodium sulfate and removal of the solvent left an oily residue of 315 mg. Crystallization from hexane gave 86 mg of the acetate, m.p. 91.5–92.0°; ν_{CCl_4} 1 735, 1 225, and 1 020 cm^{-1} (acetate); δ_{CCl_4} 1.98 p.p.m. (acetate methyl group), and 0.40 and 0.05 p.p.m. (poorly resolved quartets, C_4 cyclopropyl protons).

Anal. Calcd. for $C_{29}H_{48}O_2$: C, 81.24; H, 11.29. Found: C, 81.33; H, 11.27.

3β,5-Cyclo-5β-cholestan-6β-benzoate

3β,5-Cyclo-5β-cholestan-6β-ol (600 mg) was left for 3 h in 5 ml of pyridine and 2.5 ml of bonzoyl chloride. After the solution was poured into ice water and allowed to stand for an additional hour, the benzoate was extracted twice with 100 ml portions of ether. The ether phases were washed twice with 5% sodium hydroxide (100 ml each) and once with water. Drying and removal of the solvent gave a crude, oily product which was crystallized from ether–methanol, giving 318 mg, m.p. 125–125.5°; $[\alpha]_D$ +9.9° (*c*, 0.87 in $CHCl_3$); ν_{CCl_4} 1 710, 1 260, and 1 110 cm^{-1} (benzoate); δ_{CCl_4} 8.17 and 7.56 p.p.m. (benzoate), unresolved peaks at 4.89 p.p.m. (C_6 proton), poorly resolved quartets at 0.49 and 0.19 p.p.m. (C_4 cyclopropyl protons).

Anal. Calcd. for $C_{34}H_{50}O_2$: C, 83.21; H, 10.27. Found: C, 83.01; H, 10.36.

3β,5-Cyclo-5β-cholestan-6-one (XVI)

To a solution of chromium trioxide (100 mg) in 1 ml of chilled pyridine was added, with stirring, a solution of 120 mg of 3β,5-cyclo-5β-cholestan-6β-ol (IV*a*) in 4 ml of pyridine. Stirring was continued for 30 min, and then the mixture was allowed to stand for 16 h. Water and ether were added (100 mg of each) and the ether layer was washed five times with 10% hydrochloric acid (50 ml each) and twice with water. Drying and removal of the solvent left an oily residue, which was crystallized several times from hexane to give XII, m.p. 107–108°; $[\alpha]_D$ +111° (*c*, 0.63 in $CHCl_3$) (lit. (16) m.p. 109–110°, $[\alpha]_D$ +80°); ν_{CCl_4} 1 705 cm^{-1} (ketone); $\delta_{benzene}$ several weak peaks at 0.51 and 0.22 p.p.m. (C_4 cyclopropyl protons).

Anal. Calcd. for $C_{27}H_{44}O$: C, 84.31; H, 11.53. Found: C, 83.93; H, 11.53.

3β,5-Cyclo-5β-cholestan-6α-ol (XVII)

3β,5-Cyclo-5β-cholestan-6-one (45 mg) was dissolved in 7 ml of dry ether, and 10 mg of lithium aluminium hydride was added. After the solution was stirred for 2 h, the excess hydride was destroyed with a little ethyl acetate. Water and ether (100 ml of each) were added, and the ether phase was washed with 5% sodium hydroxide (100 ml), 2% hydrochloric acid (100 ml), and water, and then dried with sodium sulfate. An oily residue of 45 mg was obtained. Crystallization from hexane gave about 20 mg of XVII, m.p. 130–132°; $[\alpha]_D$ +34° (*c*, 0.93 in $CHCl_3$); ν_{CCl_4} 3 622 (OH stretching) and 1 110 cm^{-1} (C—O stretching); δ 3.95 p.p.m. (quartet, 6β proton, $J_{6\beta,7\alpha}$ 10.2 c.p.s., $J_{6\beta,7\beta}$ 4.8 c.p.s.) and 0.11 p.p.m. (quartet, 4α cyclopropyl proton).

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.87; H, 11.99. Found: C, 83.27; H, 11.89.

The 6α alcohol (XVII) was oxidized as described for the 6β alcohol (IV*a*). The ketone was identical with XVI (mixed melting point, t.l.c., infrared).

3β,5-Cyclo-5β-cholestan-6β,19-oxide (XVIII)

A sample of lead tetraacetate was dried for several hours under vacuum, and then 50 mg was added to a solution of 120 mg of 3β,5-cyclo-5β-cholestan-6β-ol (IV*a*) in dry benzene. The mixture was refluxed for 20 h, after which the excess lead tetraacetate was destroyed with 2 ml of ethylene glycol. The insoluble residue was filtered off and washed with benzene. Ether (100 ml) was added to the filtrate and it was washed once with 5% sodium bicarbonate and twice with water (100 ml each). The ether phase was dried with sodium sulfate and, after removal of the solvent, yielded 125 mg of an oily residue. Separation on one thin-layer plate (hexane–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ether, 9:1) gave 80 mg of XVIII, which was crystallized from ethyl acetate – methanol to give 40–50 mg, m.p. 78–81°; $[\alpha]_D$ +37° (*c*, 1.06 in $CHCl_3$); infrared showed cyclopropyl absorption at 3 020 and 3 050 cm^{-1}, and no peaks could be definitely assigned to the ether group. The n.m.r. spectrum in benzene showed two groups of ether absorption, a complex absorption at 3.98 p.p.m., and a doublet at 3.40 p.p.m. However, when taken in pyridine, as suggested by Slomp and Mackellar (17), the C_6 proton showed up as an unevenly split band around 4.00 p.p.m., and the AB quartet for the two nonequivalent C_{19} protons was clearly seen at 3.15 and 3.49 p.p.m. (J_{AD} 6.9 c.p.s.). Similar observations were made by Tadanier (11) for the n.m.r. spectra of 6β,19-oxido-3α,5-cyclo-5α-steroids. Complex cyclopropyl absorption from about 0.2 to 0.7 p.p.m. was also noted in the n.m.r. spectrum of XVII.

Anal. Calcd. for $C_{27}H_{44}O$: C, 84.31; H, 11.53. Found: C, 84.11; H, 11.64.

The 6α alcohol XVII, when treated with lead tetraacetate, also gave XVIII in a similar yield. The product was identified by mixed melting point and comparison of its thin-layer chromatograph and infrared spectrum with an authentic sample of XVIII (from the 6β alcohol).

6β-Ethoxy-3β,5-cyclo-5β-cholestane-4β-d_1 (IVa-4β-d_1, R′ = Et)

Cholesta-3,5-diene (I*a*) (6 g) was irradiated in *n*-pentane–deuterioethanol (9:1) until the reaction was 90% complete (21 h). Chromatography on 300 g of silica gel gave 2.5 g of crude IV*a*-4β-d_1 (R′ = Et); this was further purified by t.l.c., with hexane as eluent. Crystallization from hexane gave 420 mg of pure IV*a*-4β-d_1 (R′ = Et), m.p. 102–104°. The identity was verified by mixed melting point with an authentic sample of IV*a* (R′ = Et) (from previous photolyses), and by t.l.c. and infrared spectra. The n.m.r. spectrum showed only a doublet at 0.37 p.p.m. (*J* 3.1 c.p.s.) in the cyclopropyl region, and was otherwise identical with that of IV*a* (R′ = Et).

3α-Hydroxymethyl-A-norcholest-5-ene-4-d_1 (Va-d_1, R′ = H)

6β-Ethoxy-3β,5-cyclo-5β-cholestane-4β-d_1 (120 mg) was dissolved in a solution of 50 ml of acetone and 5 ml of water, and 12 mg of *p*-toluenesulfonic acid was added. After the solution was refluxed overnight, water and ether were added (100 ml of each). The ether phase was washed twice with 5% sodium hydroxide (100 ml each) and once with water, and then dried with magnesium sulfate. Separation on one thin-layer plate (hexane–ether, 3:2) gave 100 mg of 3α-hydroxymethyl-A-norcholest-5-ene-4-d_1 (V*a*-d_1, R′ = H), m.p. 102–103°. This had an identical thin-layer chromatograph and infrared spectrum with a sample of V*a* (R′ = H) obtained by solvolysis (16), and the mixed melting point showed no depression.

3β,5-Cyclo-5β-cholestan-6β-ol-4β-d_1 (IVa-4β-d_1, R′ = H)

The tosylate of the ring-contracted alcohol V*a*-d_1 (R′ = H) was prepared by allowing the alcohol to stand for 24 h in 5 ml of pyridine containing 100 mg of *p*-toluenesulfonyl chloride. Water (100 ml) was added, the tosylate was extracted with ether (100 ml), and the ether phase was washed five times with 5% hydrochloric acid (50 ml each) and twice with water. After the ether phase was dried with magnesium sulfate, it yielded a residue of 100 mg which was dissolved in a solution of 15 ml of acetone, 5 ml of water, and 500 mg of potassium acetate. The solution was refluxed overnight, and then 100 ml of water was added. Extraction by ether (100 ml) gave a solution which, after it was washed with 100 ml of 10% sodium bicarbonate and dried, yielded a residue, which was immediately separated on one thin-layer plate (hexane–ether, 3:2), giving 46 mg of IV*a*-4β-d_1 (R′ = H), m.p. 96–98°. This product was identified by comparison (mixed melting point, t.l.c., and infrared) with a sample of IV*a* (R′ = H) (from solvolysis (16)). The n.m.r. spectrum showed, in the cyclopropyl region, one doublet at 0.00 p.p.m. Otherwise, the spectrum was the same as that for IV*a* (R′ = H).

3β,5-Cyclo-5α-cholestan-6α-ol-4β-d_1 (XVII-4β-d_1)

Oxidation of the deuterated 6β alcohol IV*a*-4β-d_1 and reduction of the resulting ketone XVI-4β-d_1 to the 6α alcohol XVII-4β-d_1 were carried out as for the non-deuterated compounds. The identity of XVII-4β-d_1 was established by comparing its melting point, infrared spectrum, and thin-layer chromatograph with those of XVII. The n.m.r. spectrum of XVII-4β-d_1 was indistinguishable from that of XVII.

3β,5-Cyclo-5β-cholest-6-ene

6β-Ethoxy-3α,5-cyclo-5β-cholestane (IV*a*, R′ = Et) (840 mg) was dissolved in hexane and passed through a column of 50 g of alumina (activity I). Elution with a total of 300 ml of hexane gave 274 mg, m.p. 105–107°, of the crystalline hydrocarbon 3β,5-cyclo-5β-cholest-6-ene (lit. (1*a*) m.p. 109.5–110.2°).

3β,5-Cyclo-5β-cholestane

Platinum oxide (150 mg) was added to a solution of 254 mg of 3β,5-cyclo-5β-cholest-6-ene in 20 ml of acetic acid, and the mixture was shaken under 55 p.s.i. of hydrogen at 30° for 10 h. The platinum oxide was filtered off, ether (100 ml) was added, and the solution was washed three times with 5% sodium hydroxide (50 ml each) and twice with water. After the solution was dried, an oily residue of 245 mg was obtained; this was crystallized from acetic acid to give 185 mg of 3β,5-cyclo-5β-cholestane, m.p. 77–78°. Infrared showed only a saturated hydrocarbon. The n.m.r. spectrum showed the two C_4 cyclopropyl proton quartets at 0.00 and 0.42 p.p.m.

6β-Ethoxy-3α-methyl-3β,5-cyclo-5β-cholestane-4β-d_1 (IVb-4β-d_1, R′ = Et) and 3β-Ethoxy-3α-methylcholest-5-ene-4-d_1 (VIIb-4-d_1, R′ = Et)

A solution of 10 g of 3-methylcholesta-3,5-diene (I*b*) in 550 ml of *n*-pentane–deuterioethanol (9:1) was irradiated in a helium atmosphere for 48 h, at which time no diene chromophore could be detected in the ultraviolet. Removal of the solvent gave an oil which was chromatographed on 500 g of silica gel. Benzene eluted first 850 mg of crystalline IV*b*-4β-d_1 (R′ = Et), and then about 200 mg of crystalline[8] VII*b*-4-d_1 (R′ = Et).

Recrystallization of the first fraction from hexane gave 322 mg of IV*b*-4β-d_1 (R′ = Et), m.p. 123–126°. The sample was identified by comparison of its melting point, thin-layer chromatograph, and infrared spectrum with those of an authentic sample of IV*b* (R′ = Et) (10). The n.m.r. spectrum showed one cyclopropyl proton as a singlet, around 0.50 p.p.m. The rest of the spectrum was identical with that of IV*b*. Recrystallization of the second chromatographic fraction from hexane gave 120 mg of VII*b*-4-d_1 (R′ = Et), m.p. 120–122°. This was also identified by comparing its melting point, thin-layer chromatograph, and infrared spectrum with those of an authentic sample of VII*b* (R′ = Et) (13); ν 2 170 cm^{-1} (C_4—D). The n.m.r. spectrum of VII*b*-4-d_1 (R′ = Et) is reproduced in Fig. 2.

Photolysis of 3-Methylcholesta-3,5-diene (Ib) in Acid

3-Methylcholesta-3,5-diene (I*b*) (500 mg) dissolved in 500 ml of ethanol and 1 ml of 72% perchloric acid was photolyzed under helium until 10% of the original diene remained (7 h). Ether (500 ml) was added, and the solution was washed twice with 500 ml portions of 5% sodium hydroxide and twice with water. After the solution was dried with magnesium sulfate, the solvent was removed and the resulting oil separated on three thin-layer plates (hexane–ether, 39:1). Crystalline products of 6β-ethoxy-3α-methyl-3β,5-cyclo-5β-cholestane (IV*b*, R′ = Et) and 3β-ethoxy-3α-methylcholest-5-ene (VII*b*, R′ = Et) were obtained in yields of 9% (50 mg) and 37% (190 mg), respectively. These products were identified by mixed melting points and comparison of their thin-layer chromatographs and infrared spectra with those of authentic samples of IV*b* (R′ = Et) and VII*b* (R′ = Et).

A 500 mg sample of I*b* was photolyzed in an identical manner, except that no acid was added until the photolysis was completed (7 h). The same work-up procedure was then followed, and the yields were 7% (40 mg) of IV*b* (R′ = Et) and 13% (70 mg) of VII*b* (R′ = Et).

Samples of the diene I*b*, ether IV*b* (R′ = Et), and ether VII*b* (R′ = Et) (50 mg each) were allowed to stand for 2 days in 50 ml of ethanol containing 0.1 ml of 72% perchloric acid. No change in the samples could be detected by t.l.c.

Photolysis of Cholesta-3,5-diene (Ia) in Acid

Cholesta-3,5-diene (I*a*) (2.9 g) was photolyzed in 500 ml of ethanol and 1 ml of 72% perchloric acid under helium until 3% of the original diene remained (5 h). Ether (1 l) was added and the solution was washed with water, twice with 5% bicarbonate, and again with water (500 ml each). The ether phase was dried with sodium sulfate and the solvent removed, giving 3.1 g of an oil. Chromatography on 100 g of alumina (activity II–III) gave, in the hexane eluate, 2.3 g of a crude mixture of 6β-ethoxy-3β,5-cyclo-5β-cholestane (IV*a*, R′ = Et) and 3β-ethoxycholest-4-ene. Separation by t.l.c. (hexane–ether, 39:1) yielded 29% of IV*a* (R′ = Et) (identical with an authentic sample (1*a*) according to mixed melting point, infrared spectrum, and t.l.c.) and 31% of 3β-ethoxycholest-4-ene (pure by t.l.c.). Two crystallizations of this ether from ethyl acetate gave a product, m.p. 63°; $[\alpha]_D$ +27° (*c*, 0.78 in $CHCl_3$); ν_{CCl_4} equally intense peaks at 1 092 and 1 110 cm^{-1} (ether); $\delta_{pyridine}$ a singlet for one proton at 5.64 p.p.m. (C_4 vinyl proton), a weak, highly split band at 4.03 p.p.m. (C_3 proton), and a quartet centered at 3.68 p.p.m. (ethoxy quartet).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.96; H, 12.17. Found: C, 83.02; H, 11.73.

Hydrogenation of 3β-Ethoxycholest-4-ene

Hydrogenation was carried out on 200 mg of 3β-ethoxycholest-4-ene in 50 ml of acetic acid under 60 p.s.i. of hydrogen, with 150 mg of platinum oxide as catalyst. Sodium nitrite (15 mg) was added to suppress hydrogenolysis and the mixture was shaken for 27 h at room temperature. The platinum oxide was filtered off and ether (100 ml) was added. Washing three times with 5% bicarbonate (50 ml each) and twice with water, drying with sodium sulfate, and removal of the solvent gave a residue which was separated on one plate (hexane). Cholestane (38 mg, R_f 1) and 3β-ethoxycholestane (130 mg, R_f 0.25) were obtained.

The cholestane sample was crystallized twice from methanol, m.p. 78–79° (lit. (7) m.p. 80°). The melting point was undepressed when mixed with an authentic sample of cholestane. The 3β-ethoxycholestane fraction was crystallized twice from ethyl acetate – methanol, m.p. 80–81°; $[\alpha]_D$ +16.7° (*c*, 0.56 in $CHCl_3$) (lit. (18) m.p. 81–83°, $[\alpha]_D$ +23.8°); ν_{CCl_4} 1 097 and 1 115 cm^{-1} (ether); δ_{CCl_4} a two-proton quartet at 3.33 p.p.m. (ethoxy) and a highly split, weak absorption at about 3.00 p.p.m. (C_3 proton). The sample was identical (melting point, mixed melting point, t.l.c., and infrared) with a sample prepared by hydrogenating cholesteryl ethyl ether.

Anal. Calcd. for $C_{29}H_{52}O$: C, 83.56; H, 12.59. Found: C, 83.94; H, 12.54.

A hydrogenation was also carried out on 33 mg of 3β-ethoxycholest-4-ene in 10 ml of acetic acid with 25 mg

[8]*The low yield of the reaction is probably due to the fact that the deuterioethanol, prepared from diethyl sulfate and deuterated water, still contained some sulfuric acid or sulfur dioxide.*

For personal use only.

of platinum oxide under 55 p.s.i. of hydrogen. No sodium nitrite was added, resulting in considerably more hydrogenolysis. The product consisted of 15 mg of cholestane and 18 mg of 3β-ethoxycholestane.

Photolysis of 6-Methylcholesta-3,5-diene (VIII) in Acidic Ethanol

Diene VIII (1.1 g) in 500 ml of ethanol–pentane (10:1) containing 1 ml of 72% perchloric acid was photolyzed for 72 h, when only 16% of the original diene absorption at 242 mμ remained. The solution was evaporated to 50 ml, diluted with 200 ml ether, and washed with 5% aqueous sodium bicarbonate and water. The etheral solution was dried over anhydrous magnesium sulfate and evaporated under reduced pressure, giving 1.05 g of an oily residue, which was chromatographed on alumina (activity II–III, 30 g). Elution with hexane gave a hydrocarbon fraction (200 mg) which contained 80% of unreacted diene (ultraviolet and infrared spectra). Benzene eluted 0.520 g of an oil which contained a mixture of ethers. This mixture was separated by preparative t.l.c. (benzene). The faster moving band (310 mg) was identified as ring-contracted ether XI, by comparison with a sample obtained previously. The slower moving band (200 mg) crystallized from ethanol–ether, m.p. 95–96°, and was identical with 6-methylcholesteryl ethyl ether (mixed melting point and infrared and n.m.r. spectra) prepared from 6-methylcholesterol (4).

ACTION DES ORGANOMAGNÉSIENS SUR LES COMPOSÉS β-DICARBONYLÉS

I. OBTENTION DES β-DIOLS BITERTIAIRES PAR ACTION DES ARYLMAGNÉSIENS ET DES ALKYLMAGNÉSIENS SUR LES β-DICÉTONES SYMETRIQUES

P. Canonne et H. Bilodeau
Département de Chimie, Université Laval, Québec, Québec

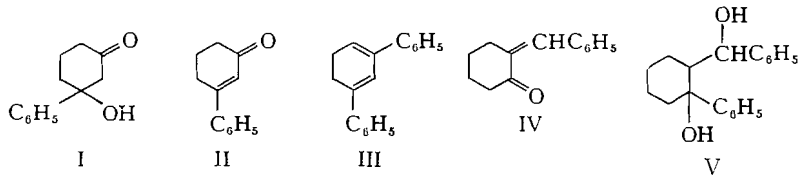
Reçu le 25 janvier 1966

RÉSUMÉ

La réaction d'addition des organomagnésiens au dibenzoylméthane et à l'acétylacétone a été réétudiée. Outre les produits de scission, nous avons constaté, dans le cas de l'acétylacétone, la présence de β-diols. Le dibenzoylméthane n'a conduit qu'à l'obtention de l'hydroxycétone.

ABSTRACT

The addition of Grignard reagents to dibenzoylmethane and acetylacetone has been reinvestigated. Apart from cleavage products, it has been found that, in the case of acetylacetone, the reaction leads to the corresponding β-ditertiary diols. On the other hand, dibenzoylmethane yields only the β-hydroxyketone.

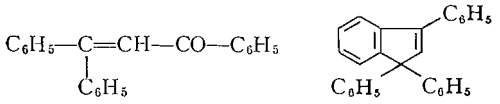


INTRODUCTION

L'action des organomagnésiens sur les cétones est considérée, depuis de nombreuses années, comme la meilleure méthode de préparation des alcools tertiaires. A l'opposé, les études consacrées à l'action des organomagnésiens sur les β-dicétones ont été très peu poussées. Pourtant, les β-hydroxycétones et les β-diols, ainsi que les composés qui en dérivent, présentent à cause de leurs propriétés un intérêt non négligeable pour la synthèse organique.

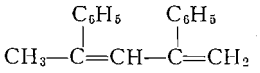
Aussi avons-nous jugé utile, dans le cadre d'une reprise de l'étude de l'action des organomagnésiens sur les composés β-dicarbonylés, de compléter les travaux précédents par des expériences originales.

Après avoir rappelé les recherches de Zelinski (1), Smedley (2) et Vorländer *et al.* (3), en 1931 Kohler et Erickson (4) publièrent que des dicétones non substituées, tel le dibenzoylméthane, réagissaient avec deux molécules du réactif de Grignard pour fournir des β-hydroxycétones, alors que les dicétones substituées formaient des produits de scission. L'action de l'iodure de méthylmagnésium sur l'acétylacétone donnait naissance à l'hydroxycétone correspondante (hydroxy-4 méthyl-4 pentanone-2) avec un rendement de 92%.



En 1948, Woods et Tucker (5), en faisant agir le bromure de phénylmagnésium sur la cyclohexanedione-1,3, isolèrent trois produits (I, II et III).

Chaney et Astle (6) traitèrent (1951) le bromure d'éthylmagnésium avec quatre dicétones asymétriques du type R—CO—CH_2—CO—CH_3 (R = C_2H_5, *n*-C_5H_9, *t*-C_4H_9 et C_6H_5). Ils obtinrent des mélanges d'hydroxycétones, sauf dans le cas où R = C_6H_5.



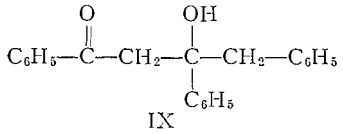
Aucun de ces produits ne fut isolé; les auteurs tentèrent, cependant, de les identifier par les produits de scission, qui sont des cétones connues.

Dreiding et Nickel (7) obtinrent en 1954, en faisant réagir le bromure de phénylmagnésium sur l'hydroxyméthylène-2 cyclohexanone et son éther isopropylique, deux composés (IV et V). Une année auparavant (1953), Dreiding et Hartman (8) avaient annoncé la présence de glycols lors de la réduction de composés β-dicarboxylés par l'hydrure de lithium et d'aluminium.

VI

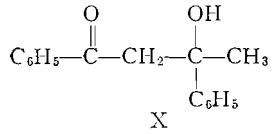
VII

VIII



Au cours d'un examen de l'action du bromure de phénylmagnésium en grand excès et dans le benzène sur les β-cétoesters d'une part et sur les β-dicétones d'autre part, Freeman (9) rapporta la préparation de la β-phénylchalcone (VI) et du triphényl-1,1,3 indène (VII) à partir du dibenzoylméthane. Avec l'acétylacétone et dans les mêmes conditions, il obtint une huile jaune qui ne fut pas purifiée mais qui, déshydratée avec de l'anhydride acétique, donna la diphényl-2,4 pentadiène-1,3 (VIII). Dans les conditions habituelles et dans l'éther, la même réaction conduisit à la formation de la phényl-4 hydroxy-4 pentanone-2, qui fut déshydratée en la cétone insaturée et fut ainsi caractérisée (1958).

Au cours du présent travail, nous avons réétudié la réaction de Grignard sur les β-dicétones afin de (*i*) isoler et caractériser les β-hydroxycétones autrement que par la scission ou la déshydratation; (*ii*) déterminer un procédé d'obtention des diols; et (*iii*) formuler, si possible, une hypothèse originale sur la formation de ces diols.



RÉSULTATS

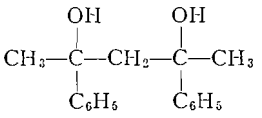
Nous avons fait agir le bromure de phénylmagnésium, le bromure de benzylmagnésium et l'iodure de méthylmagnésium sur l'acétylacétone et sur le dibenzoylméthane choisis, à dessein, pour leur structure différente.

Les deux β-hydroxycétones IX et X ont été aisément obtenues à partir du dibenzoyl-

IX

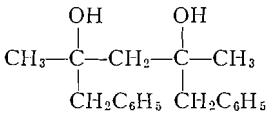
X

méthane sous l'action des trois magnésiens. Leur pureté a été contrôlée par chromatographie sur couches minces. Leur structure a été démontrée à l'aide des spectres infrarouge et de résonance magnétique nucléaire.



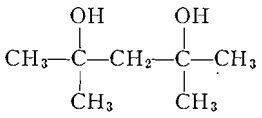
Les produits huileux obtenus à partir de l'acétylacétone furent distillés sous pression réduite. Dans la première fraction, on trouva des cétones de scission sans aucune trace de l'acétylacétone de départ. La deuxième fraction se composait, en majeure partie, de β-hydroxycétones encore impures. Etant donné la relative fragilité de ces composés, leur purification par distillation et par chromatographie en phase gazeuse à l'échelle préparatoire ne s'est pas avérée concluante. (Nous poursuivons actuellement d'autres travaux de purification.)

Dans la troisième fraction, des cristaux se déposèrent par refroidissement; ils correspondent à deux des β-diols bitertiaires (XI et XII); le troisième β-diol (XIII), impur,

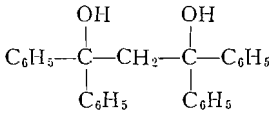


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

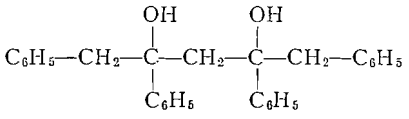
était un liquide. Les structures des β-diols XI et XII ont été établies à l'aide de leurs spectres infrarouges et de résonance magnétique nucléaire, et leur pureté fut contrôlée par chromatographie sur couches minces. Une preuve supplémentaire de structure a été apportée en faisant agir l'iodure de méthylmagnésium sur le dibenzoylméthane. Après purification et caractérisation de l'hydroxy-3 phényl-3 butyrophénone (X), l'addition de ce produit à une autre solution d'iodure de méthylmagnésium conduisit à un β-diol bitertiaire identique au XI, dont les spectres infrarouge et de résonance magnétique nucléaire sont rigoureusement superposables.



Avec le dibenzoylméthane, aucun des trois diols XI, XIV et XV ne put être isolé des milieux réactionnels des trois organomagnésiens. Pour identifier les produits recherchés



XI



XII

XIII

XIV

XV

(XIV et XV), nous avons entrepris leur synthèse par voie indirecte, de la même manière que nous avions procédé pour le produit XI.

Remarquons que chacune de nos expériences fut refaite trois fois et que, aux erreurs expérimentales près, les résultats concordent.

DISCUSSION

Des résultats mentionnés ci-dessus, il apparaît qu'il existe une différence marquée entre les comportements respectifs du dibenzoylméthane et de l'acétylacétone à l'égard des réactifs de Grignard. L'acétylacétone produit des hydroxycétones et des β-diols bitertiaires, alors que le dibenzoylméthane donne seulement des hydroxycétones et aucun diol isolable.

Ces résultats nous permettent de confirmer certains travaux rapportés dans la littérature (1, 2, 7, 8) et de faire disparaître une contradiction apparente avec certains autres résultats (4–6, 9).

En effet, si l'idée qu'un diol peut être formé à partir d'un composé β-dicarbonylé provient de Zelinsky (1), il n'utilisa pas les organomagnésiens pouvant conduire à des β-diols solides et assez facilement isolables.

Nous sommes, en outre, tentés de faire une corrélation entre ces résultats et le pourcentage de la forme dicétonique de l'équilibre cétoénolique de l'acétylacétone. Nous savons, d'une part, que l'acétylacétone se trouve sous deux formes tautomères possibles (la forme dicétonique et la forme cétoénolique, cette dernière en majeure partie sous forme chélatée (10–14)). D'autre part, le pourcentage de chaque forme éthérée en solution est de 85:15 (10, 12), tandis que le dibenzoylméthane existe seulement sous sa forme énolique entièrement chélatée; ce qui conduit à formuler l'hypothèse selon laquelle les diols correspondent à la forme dicétonique de l'équilibre tautomère tandis que les hydroxycétones correspondent à la forme cétoénolique. Cette hypothèse, si elle est vérifiée, nous conduira à une seconde: les réactifs de Grignard réagissent si rapidement que l'équilibre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reste inchangé, ou encore, les vitesses de réaction des deux groupements (dicétonique et cétoénolique) sont égales.

Nous espérons que nos travaux postérieurs permettront d'apporter quelques nouvelles contributions à l'étude des réactions des organomagnésiens sur les β-dicétones, de vérifier éventuellement nos hypothèses, et dans l'affirmative de les préciser.

PARTIE EXPERIMÉNTALE

Les points de fusion ont été déterminés dans des tubes capillaires au moyen d'un appareil Thomas Hoover; ils ne sont pas corrigés. Les spectres infrarouges ont été pris à l'aide d'un appareil Beckman à double faisceau, modèle IR-4. Les spectres de résonance magnétique nucléaire ont été pris avec un appareil Varian, modèle A-60, en solution dans le deutériochloroforme. Les déplacements chimiques sont exprimés en parties par million, le tétraméthylsilane servant de référence. La position des signaux correspondant au proton "hydroxyle" a été mise en évidence par addition d'eau lourde. La chromatographie sur couches minces a été réalisée sur des plaques de gel de silice G de Merck, les révélateurs étant la lumière ultraviolette et l'acide sulfurique concentré, ainsi que leur combinaison.

Diphényl-2,4 pentanediol-2,4 (XI)

Une solution de Grignard est préparée sous atmosphère d'azote à partir de 18 g (0.75 g-atome) de tournures de magnésium et 118 g (0.75 mole) de bromobenzène dans 400 ml (3.75 moles) d'éther anhydre.

Après filtrage de l'excès de magnésium, on ajoute lentement 25 g (0.25 mole) d'acétylacétone diluée dans 100 ml d'éther anhydre pour éviter des projections sur les parois du ballon. Une agitation vigoureuse est maintenue tout en surveillant la température afin qu'elle ne dépasse pas 5 °C et en ayant soin de placer le dispositif réactionnel sous atmosphère d'azote. On chauffe ensuite à reflux pendant 1 h et l'on agite à la température ambiante pendant 12 h. Si les précautions ont été respectées lors de l'addition, le milieu réactionnel reste en solution.

L'hydrolyse se fait avec une solution saturée de chlorure d'ammonium à une température ne dépassant pas 5 °C. On extrait trois fois la couche aqueuse avec 100 ml d'éther; puis on lave deux fois avec 100 ml d'eau saturée de chlorure de sodium. On sèche sur sulfate de magnésium anhydre et l'on évapore l'éther et le benzène sous vide. Une huile jaune (60 g) est recueillie. Après distillation sous vide poussé (0.05 mm Hg) à une température ne dépassant pas 100 °C, des fractions liquides sont obtenues (40 g) qui contiennent des composés cétoniques (acétophénone et β-hydroxycétone). Le résidu, dont le point d'ébullition est supérieur à 100 °C, est traité sous vide (0.05 mm Hg) par 100 ml d'éther de pétrole (p.é. 37–55 °C). Des cristaux jaune-brun se forment immédiatement; on refroidit et l'on filtre. On obtient ainsi un composé (9 g) dont le spectre montre seulement une bande OH. Après purification, on isole 8 g d'un solide blanc qui cristallise en paillettes, p.f. 106 °C.

La pureté de ce composé (diphényl-2,4 pentanediol-2,4) a été contrôlée par chromatographie sur couches minces avec le *n*-hexane et l'acétate d'éthyle (90:10) comme solvants, en prenant comme témoins le biphényle, l'acétophénone et la benzophénone. Aucun de ces produits n'a souillé le composé pur. La pureté de ce β-diol bitertiaire a été contrôlée par résonance magnétique nucléaire. Il présente, outre les signaux dûs aux protons aromatiques, trois singulets à 1.22, 2.37 et 4.05 p.p.m. correspondant, respectivement, aux groupements méthyles, méthylène et hydroxyle, dont le pourcentage se trouve dans un rapport de 40:8.5:8.5:28. Le spectre infrarouge présente une bande à 3 475 cm^{-1} (OH) et une à 1 170 cm^{-1} (COH).

Anal. Calc. pour $C_{17}H_{20}O_2$: C, 79.90; H, 7.80. Trouvé: C, 79.52; H, 7.61.

Diphényl-1,5 diméthyl-2,4 pentanediol-2,4 (XII)

La solution de Grignard est préparée en prenant soin de maintenir le dispositif toujours sous courant d'azote, et en maintenant l'éther en faible ébullition et en grande quantité pour éviter la formation du dibenzyle. On utilise 124.7 g (0.75 mole) de bromure de benzyle, 18 g (0.75 g-atome) de tournures de magnésium et 690 ml (6.5 moles) d'éther. Après filtrage de l'excès de magnésium, on ajoute 25 g (0.25 mole) d'acétylacétone dissous dans 100 ml d'éther anhydre en prenant les mêmes précautions que précédemment et en travaillant lentement.

Après hydrolyse et évaporation du solvant, on obtient une huile jaune (65 g) que l'on distille à pression réduite (0.05 mm Hg). On recueille ainsi des fractions volatiles, constituées en majeure partie de la β-hydroxycétone et de la phénylacétone. On arrête la distillation lorsque la température augmente, c'est-à-dire avant qu'elle atteigne 100 °C. On obtient 9.6 g d'un résidu qui se solidifie en refroidissant et donne des cristaux incolores après traitement à la Norit A et recristallisation dans un mélange d'éthanol et d'eau (80:20). La pureté de ce composé (diphényl-1,5 diméthyl-2,4 pentanediol-2,4) a été contrôlée par son point de fusion (94 °C) et par son spectre infrarouge, qui ne présente aucune bande cétonique mais, par contre, les bandes à 3 475 cm^{-1} (OH) et à 1 175 cm^{-1} (COH). La chromatographie sur couches minces ne révèle aucune contamination par des composés voisins. Le spectre de résonance magnétique nucléaire présente, outre les protons aromatiques, trois singulets à 1.30 p.p.m. (CH_3), 2.78 p.p.m. (CH_2) et 3.08 p.p.m. (OH), ainsi qu'un multiplet de 1.50 à 2.00 p.p.m. (H_2), dans un rapport de protons de 65:10:10:40:22:106.

Anal. Calc. pour $C_{19}H_{24}O_2$: C, 80.29; H, 8.44. Trouvé: C, 80.11; H, 8.38.

Hydroxy-3 phényl-3 butyrophénone (X)

Selon la méthode habituelle, la solution de Grignard a été préparée à partir de 4.3 g (0.177 g-atome) de magnésium et 25.1 g (0.177 mole) d'iodure de méthyle dans 147 ml (1.416 moles) d'éther anhydre. Après filtrage des traces de magnésium, on ajoute lentement et à la température ambiante 10 g (0.0442 mole) de dibenzoylméthane dissous dans 100 ml d'éther. Après addition, on chauffe à reflux pendant 3 h; puis on refroidit dans la glace et hydrolyse avec une solution saturée de NH_4Cl à une température ne dépassant pas 5 °C. Après extraction et évaporation du solvant, on obtient une masse cristalline (10 g). Une recristallisation dans l'éther de pétrole (p.é. 37–55 °C) donne des paillettes incolores d'hydroxy-3 phényl-3 butyrophénone, p.f. 59–60 °C.

Cette masse cristalline a été chromatographiée sur plaques de gel de silice G avec un mélange de *n*-hexane et d'acétate d'éthyle, et ne révélait aucune trace du β-diol bitertiaire (diphényl-2,4 pentanediol-2,4).

Le spectre infrarouge présente une bande à 1 663 cm^{-1} (C=O) et une à 3 450 cm^{-1} (OH). Le spectre de résonance magnétique nucléaire montre les signaux dûs aux protons aromatiques et deux singulets à 1.60 p.p.m. (CH_3) et 4.8 p.p.m. (OH) ainsi qu'un multiplet de 3.1 à 3.92 p.p.m. (CH_2), dont les intensités sont dans un rapport de 34:11:3:111.

Anal. Calc. pour $C_{16}H_{16}O_2$: C, 80.01; H, 6.66. Trouvé: C, 79.54; H, 6.32.

Diphényl-2,4 pentanediol-2,4 (XI)

A la solution de Grignard préparée à partir de 1 g de magnésium et 6 g d'iodure de méthyle, selon la méthode habituelle, on ajoute 2.4 g d'hydroxy-3 phényl-3 butyrophénone (X) en solution dans l'éther puis on chauffe à reflux pendant 3 h. Après hydrolyse et évaporation de l'éther, on obtient une huile qui cristallise par addition d'éther de pétrole (1.5 g). Après recristallisation dans un mélange d'éthanol et d'eau, on obtient des cristaux blancs dont le point de fusion est de 106 °C.

Hydroxy-3 diphényl-3,3 propiophénone (XVI)

Dans les conditions habituelles, une solution de Grignard est préparée à partir de 6.5 g (0.266 g-atome) de magnésium, 40 g (0.25 mole) de bromobenzène et 165 ml (1.6 mole) d'éther anhydre. A la température ambiante, on ajoute lentement 15.7 g (0.07 mole) de dibenzoylméthane dissous dans 100 ml d'éther; puis on chauffe à l'ébullition pendant 1 h. La solution est maintenue sous agitation pendant 1 nuit. Après hydrolyse de la manière habituelle et évaporation de l'éther et du benzène, on recueille 19.5 g d'une huile jaune contenant des cristaux. On refroidit le tout, puis ajoute de l'éther de pétrole pour aider à la cristallisation. Après filtrage et recristallisation dans un mélange de méthanol et d'eau, on obtient un solide blanc (12.4 g), l'hydroxy-3 diphényl-3,3 propiophénone, p.f. 119–119.5 °C (3, 4).

Une chromatographie sur couches minces de ces cristaux et du mélange réactionnel ne donne qu'une tache jaune-foncé par pulvérisation d'acide sulfurique, tandis que le diol correspondant à un R_f inférieur se colore en bleu-vert en utilisant le gel de silice comme support et un mélange de *n*-hexane et d'acétate d'éthyle (90:10) comme éluant. Le spectre infrarouge présente une bande d'absorption à 1 670 cm^{-1} (C=O) et une à 3 475 cm^{-1} (OH). En résonance magnétique nucléaire, on retrouve, outre les signaux dûs aux protons aromatiques, deux singulets à 3.92 p.p.m. (CH_2) et à 5.43 p.p.m. (OH) dans un rapport de 7:3.5.

Anal. Calc. pour $C_{21}H_{18}O_2$: C, 83.45; H, 5.95. Trouvé: C, 83.31; H, 5.86.

Déshydratation de l'hydroxy-3 diphényl-3,3 propiophénone et préparation de la diphényl-3,3 acrylophénone (VI)

On dissout 1 g d'hydroxy-3 diphényl-3,3 propiophénone (XVI) dans 25 ml de benzène anhydre; puis on ajoute 5 ml d'anhydride acétique et 2 gouttes d'acide sulfurique concentré. La déshydratation est instantanée à la température ambiante. L'excès d'anhydride acétique est détruit par 50 ml d'eau. On extrait à l'éther (50 ml); puis on lave avec du bicarbonate de sodium à 10% et avec de l'eau saturée de sel et l'on cristallise dans l'éthanol. On obtient ainsi la β-phénylchalcone (VI), p.f. 86–87 °C (9), dont le spectre ultraviolet révèle le système des chalcones et le spectre infrarouge présente à 1 655 cm^{-1} une bande de groupement cétonique conjugué. En résonance magnétique nucléaire, on retrouve trois singulets dans la région de 7 p.p.m. qui correspondent bien aux protons aromatiques.

Anal. Calc. pour $C_{21}H_{16}O$: C, 88.73; H, 5.63. Trouvé: C, 88.32; H, 5.49.

Tétraphényl-1,1,3,3 propanediol-1,3 (XIV)

La solution de Grignard est préparée dans les conditions habituelles à partir de 6.5 g (0.266 g-atome) de magnésium, 40 g (0.25 mole) de bromobenzène et 200 ml (1.9 moles) d'éther anhydre. On ajoute lentement 15.8 g (0.050 mole) de l'hydroxycétone XVI dissoute dans 150 ml d'éther et l'on chauffe à reflux pendant 45 min; puis on laisse sous agitation pendant 1 nuit à la température ambiante. Après hydrolyse et évaporation, on obtient une huile (18.4 g) qui cristallise par addition de *n*-hexane. Après cristallisation dans l'éthanol et l'eau, on obtient un solide blanc, le tétraphényl-1,1,3,3 propanediol-1,3 (XIV), p.f. 124 °C (4, 15). La pureté de ce diol a été établie par chromatographie sur couches minces dans un système de *n*-hexane et d'acétate d'éthyle comme solvants. Seule la présence du diol est révélée par la tache bleu-vert caractéristique de ce composé sous pulvérisation d'acide sulfurique. Le R_f est beaucoup plus petit que celui de l'hydroxycétone de départ et que celui du diphényle.

Le spectre infrarouge présente une bande d'absorption à 3 450 cm^{-1} (OH) et le spectre de résonance magnétique nucléaire montre, à part les protons aromatiques à 7–15 p.p.m., deux singulets à 3.36 p.p.m. (CH_2) et à 4.10 p.p.m. (OH) d'intensité de 17 mm chacun.

Anal. Calc. pour $C_{27}H_{24}O_2$: C, 85.27; H, 6.31. Trouvé: C, 85.01; H, 5.49.

For personal use only.

Hydroxy-3 diphényl-3,4 butyrophénone (IX)

Une solution de Grignard est préparée dans les mêmes conditions qu'habituellement à partir de 6.5 g (0.266 g-atome) de magnésium, 31.55 g (0.25 mole) de chlorure de benzyle et 200 ml (1.9 moles) d'éther anhydre. On ajoute lentement 7 g (0.0312 mole) de dibenzoylméthane dissous dans 50 ml d'éther anhydre. Par le procédé décrit précédemment, on obtient 5.1 g de cristaux blancs d'hydroxy-3 diphényl-3,4 butyrophénone, p.f. 122 °C.

Le spectre infrarouge présente une bande à 1 660 cm^{-1} (CO) et une à 3 450 cm^{-1} (OH). En résonance magnétique nucléaire, on a deux singulets à 3.12 p.p.m. (CH_2) et à 4.9 p.p.m. (OH), non couplés, et un multiplet de 3.05 à 4.08 p.p.m. (CH_3) qui est couplé avec les protons précédents. L'intensité de ces protons est proportionnelle pour chaque type de proton et prouve donc la pureté du composé. Cette pureté a été contrôlée par chromatographie sur couches minces en utilisant un système de *n*-hexane et d'acétate d'éthyle (90:10) comme solvant.

Anal. Calc. pour $C_{22}H_{20}O_2$: C, 83.55; H, 6.32. Trouvé: C, 83.33; H, 6.21.

Tétraphényl-1,2,4,5 pentanediol-2,4 (XV)

A la solution de Grignard préparée de la façon habituelle à partir de 6.5 g (0.266 g-atome) de magnésium, 31.54 g (0.25 mole) de chlorure de benzyle et 165 ml (1.6 moles) d'éther anhydre, on ajoute 15.8 g (0.05 mole) de l'hydroxycétone IX dissous dans 150 ml d'éther. On chauffe pendant 45 min et laisse sous agitation pendant 1 nuit. Après hydrolyse, on obtient une huile (18.1 g) qui cristallise par addition de *n*-hexane, le tétraphényl-1,2,4,5 pentanediol-2,4, p.f. 141 °C. La structure de ce diol a été prouvée par le spectre infrarouge (bande à 3 475 cm^{-1} (OH)) et par le spectre de résonance magnétique nucléaire, qui présente un singulet à 3.55 p.p.m. (OH) et deux multiplets légèrement superposés, entre 2.45 et 3.45 p.p.m., dûs aux groupements CH_2. L'intensité de ces signaux est proportionnelle au nombre de protons. La pureté de ce diol a été également contrôlée par chromatographie sur couches minces (*n*-hexane – acétate d'éthyle (90:10)).

Anal. Calc. pour $C_{29}H_{28}O_2$: C, 85.29; H, 6.85. Trouvé: C, 85.03; H, 6.75.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches pour l'aide financière apportée sous forme de subventions. Nous exprimons notre gratitude au Dr L. C. Leitch et à son collaborateur M. R. N. Renaud pour la mesure des spectres de résonance magnétique nucléaire, ainsi qu'à M. H. Seguin pour les analyses élémentaires.

^{13}C N.M.R. STUDIES

VIII. ^{13}C SPECTRA OF SOME SUBSTITUTED ANISOLES[1,2]

K. S. DHAMI[3] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received July 29, 1966

ABSTRACT

The ^{13}C nuclear magnetic resonance spectra of a series of 40 substituted anisoles have been obtained to investigate the effects of substitution on the aromatic and methoxyl carbon shieldings. This work extends our studies on the variations of chemical shifts of carbon nuclei in side chains of aryl derivatives. The question of steric hindrance to conjugative interaction of a methoxyl group with an aromatic ring is considered on the basis of the present results. Evidence of a steric effect in compounds in which *both* ortho positions are substituted is presented.

INTRODUCTION

As an extension of a general survey of the ^{13}C chemical shifts for a variety of aromatic systems, it was of interest to examine the effects of substitution on the shieldings of the methoxyl and aryl carbon nuclei in a series of anisoles. There are two major features to be investigated. Lauterbur has demonstrated the existence of an additive relationship for the effects of substituents on aryl carbon shieldings in a number of benzene derivatives (1, 2), which holds very well provided the substituent groups are not ortho to each other (1–5). Since the chemical shifts for the aromatic carbons in several monosubstituted benzenes have been reported by Spiesecke and Schneider (6), it is possible to predict the shieldings in other derivatives by using these data and assuming additivity. It seemed worthwhile to test these predictions for a number of anisoles, since only a few have been reported (1, 7). For the same series we have determined the variation of the methoxyl carbon shieldings with substitution to find if these are sensitive to substituent polarity. Proton nuclear magnetic resonance studies have shown that methoxyl proton shifts are linearly related to the Hammett σ parameter (8).

The second feature concerns the effects of substituents on carbon shieldings in ortho-substituted systems. In general, it is found that the shielding effects of substituents on the aryl carbons are no longer additive, but it appears that the magnitude of the deviation from additivity is a crude measure of the steric hindrance to electronic interactions (2–5, 9). An examination of the ^{13}C spectra of a series of ortho-substituted anisoles could therefore provide information on the steric inhibition of resonance of the methoxyl function. In addition, changes in the shielding of the methoxyl carbon nucleus itself should provide information about this point.

For these reasons the ^{13}C spectra of 11 meta- and para-substituted anisoles, 14 ortho-substituted examples, and 15 diortho-substituted anisoles have been obtained. The chemical shifts for the methoxyl and aryl carbon nuclei have been measured. These results are the subject of this paper.

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra

The ^{13}C spectra were determined at a spectrometer frequency of 15.085 Mc/s with samples containing ^{13}C in natural abundance. The detailed procedure has been described (3). For the most part, the spectra were obtained with the neat liquids. In the case of solids, saturated solutions in either CS_2 or $CHCl_3$ were examined.

[1] *For part VII in this series, see G. W. Buchanan, D. A. Ross, and J. B. Stothers, J. Am. Chem. Soc., in press.*
[2] *Some of these results were reported at the 47th annual conference of the Chemical Institute of Canada, Kingston, Ontario, 1964.*
[3] *Petroleum Research Fund Predoctorate Fellow, 1962–1964.*

Two solutes were studied in each of these to test for the presence of a significant solvent effect. The shielding data are given on the CS_2 scale (δ_{CS_2} = 0 p.p.m.) and are judged to be accurate to ±0.5 p.p.m.

Materials

Anisole and its 3-methyl, 4-methyl, and 4-bromo derivatives are commercially available and were used directly. Most of the others were prepared from the corresponding phenol by methylation with dimethyl sulfate by the method outlined below. A few of the hindered phenols were methylated by reaction of the phenoxide with methyl iodide as described by Kornblum and Seltzer (10). 2,6-Dimethyl-4-nitro- and 2,6-di-*t*-butyl-4-nitro-anisole were prepared according to the sequence reported by Bruice *et al.* (11), in which the 2,6-dialkyl phenol is converted into its 4-bromo derivative, methylated, and then treated with nitric acid in acetic anhydride to give the desired compound. For five of the compounds which have not been reported previously, the method of preparation, their physical properties, and analytical data are collected in Table I. For the others, their properties agreed well with those reported in the literature.

Methylation Procedure

To the phenol (0.11 mole) dissolved in 20 ml of Claisen's alkali (12) was added dimethyl sulfate (0.12 mole). The mixture was refluxed for 3 h, cooled, and poured over chipped ice. After ether extraction, the combined ethereal extracts were washed with 20% NaOH and water, and dried over $CaCl_2$. After removal of the solvent, the product was distilled *in vacuo* on a 16 in. spinning-band column.

RESULTS

The observed chemical shifts for the aromatic and methoxyl carbon nuclei for the meta- and para-substituted anisoles are given in Table II. The data for a number of ortho-substituted examples appear in Table III, and the results for 15 diortho-substituted anisoles are collected in Table IV. These three types will be considered separately in the Discussion; for clarity, the aromatic and methoxyl carbon nuclei are discussed under separate sub-headings. Since some of the compounds are solids and were examined as saturated solutions in either $CHCl_3$ or CS_2, two solutes, anisole and *p*-nitroanisole, were run in both solvents; the results are given in Table V.

DISCUSSION

The effects of structure on ^{13}C shieldings in general have been reviewed recently (13), and the present results are considered on the basis of these general trends. Following the discussion of the chemical shift results, the question of steric hindrance to resonance interaction of a methoxyl group with an aromatic ring is considered in the light of these and other recent findings for related compounds (2–5, 9).

Meta- and Para-Substituted Anisoles

Aromatic Carbon Nuclei

For the ^{13}C spectrum of anisole itself, the unequivocal assignment of the appropriate absorption peaks to specific nuclei has been established by Spiesecke and Schneider (6), and the present data are in excellent agreement with these, except for the shielding of C-1, the carbon bearing the methoxyl group. Our value is intermediate between the two which have been reported (1*b*, 6) and, after a number of measurements, we feel that it is reliable within our limits of experimental uncertainty. The observed chemical shift changes caused by the methoxyl group at the various positions on the aromatic ring relative to the shift of benzene carbons have been discussed (1*b*, 6) and require no further comment. It is important, however, to draw attention to the pronounced shielding at the para position, indicative of electron release to the ring by methoxyl.

The data for the mono-substituted anisoles included in Table II provide more examples to confirm the existence of the additive nature of substituent effects on aryl carbon shieldings. Most of these are para-substituted examples, for which the assignments are straightforward and unequivocal because the effects of substituents at the meta positions are known to be small (1–6). Thus the absorption for C-2 and C-6 is expected to be centered

*Saturated solution in $CHCl_3$.

close to the value found for anisole, 79.6 p.p.m., and the remaining doublet in the aromatic region of these spectra must arise from C-3 and C-5. The assignment of the two singlets for each of C-1 and C-4 follows readily because of the marked deshielding effect of the methoxyl group on C-1. In each case, this peak is the lowest field signal in the aromatic region. The assigned shifts may be compared with those predicted by the assumption of additivity of substituent effects at the various aromatic positions. The latter values are calculated from the changes observed for the monosubstituted cases by using the data in the literature (3, 5, 6). For example, the aryl carbons in chlorobenzene exhibit absorption at -6.4, -0.2, -1.0, and $+2.0$ p.p.m., relative to benzene, for C-1 (C—Cl), the ortho carbons, the meta carbons, and the para carbon, respectively (6). For p-chloroanisole, the calculated values for the aryl shieldings (the results for anisole itself being used as the base case) become 66.6 (C-4), 63.9 (C-3, C-5), 78.6 (C-2, C-6), and 35.9 (C-1) p.p.m. from CS_2. These values agree closely with those observed for p-chloroanisole (see Table II), with the largest

discrepancy being 1.7 p.p.m. for the C-4 nucleus. A similar comparison of the results in Table II with calculated shieldings shows that, with two exceptions, the deviations are <2 p.p.m. Somewhat larger deviations of 2.6 and 2.3 p.p.m. are found for C-1 in *p*-vinylanisole and C-3 and C-5 in *p*-nitroanisole, respectively. This difference for the vinyl derivative may be an indication that the electronic effect of the vinyl group is reversed in this system relative to that for styrene itself. This possibility was discussed in our earlier paper on the ^{13}C spectra of substituted styrenes (5). An additional feature of the *p*-vinylanisole results is that the difference between the calculated and observed shifts for C-4 is 2.0 p.p.m. Both of these differences are negative in the sense that the calculated shielding is greater than the experimental figure, indicative of a lower electron density at these positions than that predicted, in agreement with the above hypothesis.

In summary, it is found that, of the 32 comparisons between the calculated and experimental results for the para-substituted examples, 30 are within 2 p.p.m. Thus one can

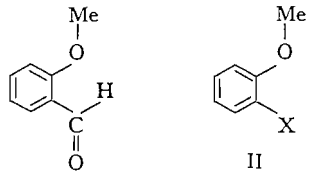
conclude that Lauterbur's original suggestion (1*b*) that this additive relation can be used to predict aromatic carbon nuclear shieldings receives further confirmation.

For the two meta derivatives, the deviations between the experimental shifts and those calculated are less than 1.7 p.p.m. Since the additive relation is utilized for the assignments in these cases, the agreement cannot be taken as evidence in support of the additivity of substituent effects. For these cases, specifically labelled materials would be required to make unequivocal assignments. In view of the apparent generality of the additive relation, however, it appears that the present assignments are the most probable.

Methoxyl Carbons

The assignments for the methoxyl carbon absorptions present no difficulty. Because of the effective deshielding by oxygen, these appear in a region of the spectrum which, for this series, is devoid of other absorption patterns. From the data in Table II it is apparent that the methoxyl carbon chemical shifts are not highly sensitive to meta and para substitution on the ring. The methoxyl absorption is found over the rather narrow range of 136.2–139.2 p.p.m., which is about half the shielding change observed for the β-carbon in similarly substituted styrenes (5). There is little doubt that the electron density about the methoxyl oxygen nucleus depends on the ring substituent, and it would be surprising indeed if this were not reflected, however slightly, at the methoxyl carbon. It is expected that electron-withdrawing groups on the ring decrease the shielding at the oxygen nucleus, since the conjugative electron release by oxygen will be enhanced, and therefore the methoxyl carbon would also be deshielded. Although this general trend is observed, the changes are small. A plot of the methoxyl carbon shifts versus the Hammett σ values for the various substituents reveals an approximate relation between the two parameters, but a good linear correlation is not obtained. The situation is not improved if σ^+ values are employed. This finding is interesting in the light of the report that methoxyl proton shifts show a fair correlation with σ values for a series of substituted anisoles (8). For the carbon shieldings, however, we can only conclude that these exhibit a weak dependence on substituent polarity, and that other factors may exert some influence.

Ortho-Substituted Anisoles



Aromatic Carbons

For the ortho-substituted anisoles having only one substituent ortho to the methoxyl group, the observed aryl carbon shieldings differ somewhat from those predicted by assuming additivity of the substituent effects. The deviations between the calculated and observed values, however, appear to follow a definite pattern.

At the C-4 and C-5 positions the observed shieldings are, for the most part, within 1.5 p.p.m. of the calculated values and, for more than half of these, the deviations are <0.5 p.p.m. This is true even for those cases in which substituents are bonded to these nuclei. But for two exceptions, a similar situation obtains for the C-3 shieldings. The exceptions are 2,3-dimethyl-4-chloroanisole and 2-formylanisole, for which the differences between the calculated and observed shifts are $+4.2$ and $+3.8$ p.p.m., respectively (i.e. the absorption is found at significantly higher field than that calculated). This change for 2,3-dimethyl-4-chloroanisole is analogous to the behavior found for other aromatic systems (1, 3–5) in which a substituted aryl carbon is flanked by two substituted aromatic nuclei, and apparently may be attributed to the crowding of the substituent methyl groups. For 2-formylanisole, it seems probable that the preferred planar conformation will be that in which the carbonyl oxygen and methoxyl methyl group are as far apart as possible. In this conformation (I), the carbonyl oxygen will be relatively close to C-3 and could affect its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

shielding. Since the data for suitable model compounds are lacking, it is not possible to confirm this proposal at the present time, but it would appear to be a reasonable suggestion.

I II

The shieldings found for C-6 are interesting because, in all examples, the observed values lie at higher field than those calculated. The differences range from +1.7 to +4.6 p.p.m. The average deviation is +3.4 p.p.m., more than twice that normally found for meta- and para-substituted molecules. In these ortho-substituted cases, however, the C-2 substituent could interfere with the methoxyl group such that the preferred conformation would be that in which the methoxyl carbon is "turned away" from the ortho group, as in II. It appears reasonable to suggest, therefore, that the consistent shift of the C-6 nuclei to higher field is caused by the location of the methoxyl carbon. If a planar conformation is assumed, the distance separating the methoxyl and C-6 carbon nuclei is approximately the same as that between two ortho-oriented methyl groups on an aromatic ring. For the latter case, it is well established that these nuclei are abnormally shielded (1, 3–5, 14). The remarkable consistency of the data for the C-6 nuclei suggests a common origin for this shielding effect in all cases.

The remaining aromatic carbons, C-1 and C-2, exhibit moderate departures from the behavior predicted by the additive relation. For C-1, the deviations are not much larger than the worst cases in the meta- and para-substituted series, ranging up to a maximum of ±3 p.p.m. There is no obvious trend with substituent and, in a few cases, the differences are less than 1 p.p.m. At C-2, however, all of the experimental values are lower than those calculated, and the differences range from −0.3 to −5.2 p.p.m., with an average deviation of −2.6 p.p.m. It is interesting that this change is directionally opposite to that found for the C-6 nuclei, and it is conceivable that at least part of the difference is caused by the conformation of the methoxyl group. For anisole and its meta- and para-substituted derivatives, the methoxyl group can exist in two possible planar conformations, the relative populations of which will be comparable. Thus, if the methoxyl carbon exerts a shielding effect through space at the ortho carbons, the effect will be comparable at both positions. In an ortho-substituted compound, however, one of the planar conformations (II) may be much more stable than the other, and it follows that C-6 will become more shielded relative to C-2 owing to the suggested effect operative through space. As found for C-6, the deviations for the C-2 shieldings are consistently in one direction, a fact that is required by our proposal but, of course, does not confirm it.

Methoxyl Carbons

As the results in Table III show, the presence of an ortho substituent produces virtually no change in the methoxyl carbon chemical shift relative to the value for anisole itself. With one possible exception, all of these values are indistinguishable within the limits of our experimental error. The exception is 2,3-dimethylanisole, whose methoxyl absorption is found at 137.8 p.p.m. in comparison with that of anisole at 138.8 p.p.m. Since, in general, closely crowded carbons tend to absorb at higher field than chemically similar but less-crowded carbons, it appears, therefore, that the preferred conformation for these examples

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is that in which the distance between the methoxyl carbon and the ortho substituent is a maximum (as in II).

Diortho-Substituted Anisoles

Aromatic Carbons

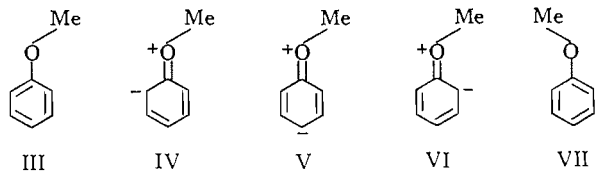
This particular series of compounds was chosen for study because there is no ambiguity in the assignments of the absorption patterns to specific carbon nuclei. For most cases, the strongest doublet in the aromatic region arises from the meta carbons (C-3, C-5), and the strongest singlet is the absorption of the ortho carbons (C-2, C-6). As before, the lowest field singlet is the C-1 signal, and the remaining pattern arises from C-4. Only in the case of the tetramethyl and pentamethyl derivatives is there a chance of incorrect assignments, for which the ortho and meta carbons could perhaps be reversed. We have assigned these signals on the basis of previous results for polymethylated benzene derivatives (3–5). No major conclusions drawn from these results, however, depend on these particular assignments.

In contrast to the results for each of the two preceding series, most of the aryl carbon shieldings for the 2,6-disubstituted examples differ markedly from the values calculated by assuming additivity of the substituent effects. Uniformly large differences, in the range of -5.8 to -9.5 p.p.m., are found for the C-2 and C-6 nuclei. It is interesting that all are negative in the sense that the signals appear at lower field than predicted. A similar uniformity is found for the differences between the calculated and observed shieldings of the para carbons (C-4), for which the deviations are in the range of -0.6 to -5.4 p.p.m. At the other sites, the deviations are not directionally uniform, but rather range from -8.1 to $+8.6$ p.p.m. and there are few cases in which the differences are less than ± 1.5 p.p.m. Clearly, the additive relationship breaks down completely. It follows, therefore, that the electronic effect of one or more substituents has been altered substantially. Since the differences between the calculated and observed shieldings are negative at the 2, 4, and 6 positions in every case, it is reasonable to conclude that the major factor causing these deviations is a perturbation of the interaction of the methoxyl group with the aromatic ring. This conclusion is based on the fact that alkyl groups do not affect the shielding of aryl carbons ortho to the substituted center nearly as much as the methoxyl group, which shields the ortho carbons by 14.7 p.p.m. in anisole. The deviations of up to -9.5 p.p.m. for the C-2 and C-6 nuclei clearly indicate that the methoxyl – aryl ring interaction is altered for the 2,6-disubstituted series.

Methoxyl Carbons

There are marked changes in the methoxyl carbon shieldings for this series, in distinct contrast to the behavior observed for each of the preceding groups of substituted anisoles. A strong dependence of these shieldings on the size of the ortho substituent is apparent from the data in Table IV. The absorption pattern for the methoxyl carbon nucleus is shifted to progressively lower field as the bulk of the ortho substituents increases from methyl to isopropyl to *t*-butyl. The observed range of 6.8 p.p.m. (128.1–134.9 p.p.m.) is much larger than that found for either of the other series, and the lowest field signals (i.e. the 2,6-di-*t*-butyl derivatives) are 10 p.p.m. downfield from that of the anisole methoxyl carbon.

It is interesting that the data fall into a number of separate groupings depending on the ortho substituents. With the *p*-NO_2 derivatives as exceptions, the 2,6-di-*t*-butyl compounds exhibit methoxyl absorption at 128.8 ± 0.3 p.p.m., the 2,6-di-isopropyl examples at 131.8 ± 0.3 p.p.m., and the 2,6-dimethyl cases at 134.6 ± 0.3 p.p.m., excluding the two



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

durene derivatives. The latter, 2,3,5,6-tetramethyl- and 2,3,4,5,6-pentamethyl-anisole, absorb at 133.0 p.p.m. It would appear that the additional methyl groups at the 3 and 5 positions tend to accentuate the deshielding trend, although both were examined in solution, which may account for part of the difference between these and the other 2,6-dimethylated examples. For the two *p*-NO_2 examples, the low-field shift of 1.0–1.7 p.p.m. relative to the corresponding 2,6-dialkyl compounds is slightly less than the difference between *p*-nitroanisole and anisole when the latter are examined in the same medium (see Table V), and can be attributed to the electron-withdrawing inductive effect of the NO_2 grouping. In any event, there is a clear dependence of the methoxyl carbon shieldings on the size of the ortho substituents for those cases in which both ortho positions are substituted.

It is more difficult, however, to account for the trend to lower field relative to the less highly substituted examples. The origin of this deshielding effect is not evident to us, although its significance with respect to the question of the most probable conformations of these structures may be intimated. This aspect is considered in the concluding section of this paper. To judge from the aryl carbon shieldings it appears that conjugative electron release by oxygen to the aromatic ring is strongly affected by the presence of two ortho substituents, and it follows that the hybridization of the oxygen may be altered in the more hindered systems. If the electron-releasing tendency is reduced, one would expect the methoxyl carbon to be more shielded; if the hybridization of the oxygen is changed from something close to sp^2 to sp^3, one would expect the shielding of the methoxyl carbon to increase. Both expectations are contrary to the experimental results. This raises the question of whether the shift to lower field could arise from a "through space" effect of the ortho alkyl carbon nuclei. If so, it would be a remarkably large factor if the above suppositions are reasonable. Because of a lack of suitable model compounds, it is difficult to estimate the importance of a field effect, but it is known that closely crowded methyl carbons tend to absorb at *higher* field than in chemically equivalent but less-crowded systems (3, 5, 14). Thus, the qualitative rationalizations normally used to interpret ^{13}C nuclear shieldings predict variations opposite to those found for the methoxyl carbon shifts in the 2,6-disubstituted examples. Perhaps the appearance of more data for related systems will provide an answer for these apparently anomalous observations.

Steric Inhibition of Resonance

In the preceding discussion, a number of observations were noted which indicate that the interaction of the methoxyl oxygen with the benzene ring is altered in the highly substituted examples relative to that in the meta-, para-, and mono-ortho-substituted cases. For a compound in which there is no interference by substituents, several canonical forms can be written. The more important of these are shown as structures III–VII.

III IV V VI VII

Besides these, there are three, corresponding to IV–VI, having the methyl group as in VII, and two other Kekulé forms corresponding to III and VII. The aromatic shieldings for anisole are readily explicable in terms of the contributing forms IV–VI, since an increase in the electron density is expected at the ortho and para positions, and since these positions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

are considerably shielded in the anisole molecule relative to the value for benzene carbons. In addition, the methoxyl carbon absorbs at lower field than that found for methoxyl groups in many saturated systems.[4] Any factor which could interfere with the conjugative electron release from oxygen to the ring may be expected to decrease these relatively high shieldings at the ortho- and para-carbon nuclei. Changes in the shift of the methoxyl carbon would also be expected. The results of the present series can be considered on this basis.

It would seem reasonable to assume that the interactions of the substituents are normal for all cases in which the additive relationship holds for the aryl carbon chemical shifts. In particular, one could expect the shielding of the carbon para to the methoxyl group to reflect a significant perturbation of the methoxyl – aryl ring interaction. If electron release from the methoxyl oxygen were reduced, the para-carbon shielding would be expected to decrease. Although a similar change should be observed for the ortho carbons, predictions are more difficult because of the very real possibility that a part of the observed shielding arises through a field effect of the methoxyl function. Support for this argument is given by the data for the 2-substituted series, for which it is found that the para-carbon results are in good agreement with those calculated by assuming additivity of the substituent effects, whereas the ortho-carbon values are not. The consistency of the deviations for C-2 and C-6, as discussed earlier, point to the existence of an appreciable influence of the methoxyl group through space. We conclude, therefore, that the conjugative interaction of the methoxyl group with the aromatic ring is operative in the mono-ortho-substituted examples, although there may be only one planar conformation (II) in which this interaction can be appreciable. The fact that the methoxyl carbon shieldings are very similar for all of these mono-substituted examples (meta, para, and ortho) is completely consistent with this conclusion.

For the 2,6-disubstituted derivatives, the observed shielding changes strongly suggest an important difference in the electronic interactions. For each case, the para carbon absorbs at lower field than that expected, and the deviations from the calculated values are large (up to -5.4 p.p.m.). Similar trends for the para-carbon shieldings in other hindered aromatic derivatives have been noted previously (2–4) and have been attributed to steric inhibition of resonance. For the present series, the changes are precisely those expected for cases in which the contribution of resonance form V is small. The relatively large differences in the methoxyl carbon shieldings are also indicative of a major change in the electronic nature of the methoxyl oxygen. To illustrate the magnitude of these differences, a summary of the methoxyl carbon shieldings for a number of the examples relative to the methoxyl shift for anisole are given in Table VI. From these data it is clear that appreciable changes occur upon the introduction of substituents at both ortho positions. Furthermore, the magnitude of the change for a particular case is strongly dependent on the size of the ortho groups. The maximum difference is found for the 2,6-di-*t*-butyl derivatives. We conclude, therefore, that there is steric interference of the ortho groups with the methoxyl function in the 2,6-disubstituted anisoles such that electron release by the methoxyl oxygen is significantly reduced.

One of the more usual approaches to an investigation of steric hindrance to conjugative interactions is an examination of the electronic spectra of a series of model compounds. The question of steric inhibition of resonance in substituted anisoles has been studied by a number of workers by using ultraviolet spectroscopy, and a marked decrease in the molar extinction coefficient (ϵ_{max}) of the absorption near 260–270 mμ has been attributed to a steric effect (15–17). A comparison of these data with the ^{13}C shielding results reveals a

very good linear correlation between the ϵ_{max} values and the methoxyl carbon shieldings, as illustrated in Fig. 1. The existence of this relation offers further support for our conclusion regarding steric hindrance to resonance in the 2,6-disubstituted systems.

Another report bearing on this question has appeared (18) and warrants comment in the light of our present results. Baliah and Uma claim, on the basis of dipole moment data for some anisoles, that a single ortho substituent causes an exaltation of methoxyl conjugation with the aryl ring. These authors, however, have chosen to ignore the small, but nevertheless real, contribution of an ortho substituent to the total dipole moment of the molecule,

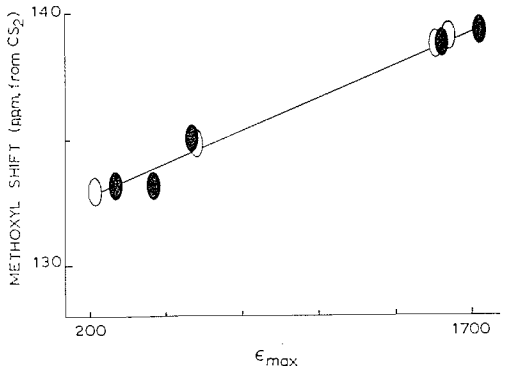

FIG. 1. Plot of methoxyl carbon shieldings versus ϵ_{max} of the ultraviolet absorption near 260 mμ. LEGEND: ●, ultraviolet data from ref. 16; ○, data from ref. 18.

and we suggest that this neglected factor may be sufficient to account for the observations. We find it difficult to accept the concept of an exaltation of conjugation by ortho-alkyl substitution. On the basis of our ^{13}C results and the available ultraviolet spectral data, it appears that significant differences in the conjugative interaction of the methoxyl group with the aromatic ring occur only if both ortho positions are occupied by substituents.

RÉSUMÉ

En se basant sur des données de nature surtout spectrale, on a déjà conclu à une addition *cis* du chlore à la benzoquinone. Le *cis*-dichlorure, en solution alcoolique, se transformerait en son isomère *trans*, qui par la suite s'énoliserait en l'hydroquinone correspondante. Après avoir répété les travaux antérieurs et isolé les intermédiaires et les produits de la réaction en solution alcoolique, nous pouvons réaffirmer que, dans diverses conditions, le *trans*-dichlorure est le seul isomère décelable formé lors de la chloration. Les changements observés en solution alcoolique sont dûs à une élimination suivie d'une réduction photochimique. L'étude des dibromures correspondants à conduit à des conclusions semblables.

ABSTRACT

It has been proposed, mainly on the basis of spectral evidence, that the addition of chlorine to *p*-benzoquinone gives the *cis*-dichloride, and that in an alcoholic solution this substance isomerizes to the *trans*-dichloride, which then enolizes to the corresponding hydroquinone. Upon reexamination of the evidence and isolation of the intermediates and end products of the reaction in an alcoholic solution, it can now be reasserted that the *trans*-dichloride is the only detectable isomer resulting from chlorination under various conditions. The observed changes in an alcoholic solution have been proven to be the result of elimination followed by photochemical reduction. Similar conclusions have been reached in the case of quinone dibromides.

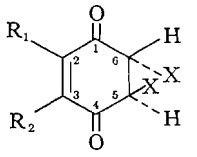
Il est bien connu, depuis la fin du siècle dernier, que l'action du chlore et du brome sur les quinones conduit à des produits d'addition 1,2 (1–3). Plus tard, l'oxydation permanganique des dichlorures de *p*-benzoquinones en acide *dl*-dichlorosuccinique permettait à Dimroth *et al.* (4) de leur assigner la configuration *trans*. En 1954, ter Borg (5) aurait isolé les deux isomères du dichlorure de la benzoquinone; il leur assigna les configurations *cis* et *trans* et élabora une interprétation des transformations observées en solution alcoolique.

Selon ter Borg, l'isomère *cis* s'obtiendrait par la méthode de Clark (3) et se décomposerait à 120° (λ_{max} 250 mμ (ϵ 4 300)); l'action du chlorure de sulfuryle sur l'hydroquinone donnerait l'isomère *trans* (λ_{max} 252 mμ (ϵ 14 750)), qui se décomposerait à 130°. De plus, il nie catégoriquement l'existence d'un dichlorure qui, pourtant, avait été décrit à plusieurs reprises, p.f. 143° (2) et 146° (3, 4). L'hypothèse de la transformation du *cis*-dichlorure en l'isomère *trans* et finalement en 2,3-dichlorohydroquinone est basée sur l'examen périodique du spectre d'absorption dans l'ultraviolet de cette substance en solution alcoolique.

Dans le cadre d'un projet sur les 2,3-dihydroquinones, nous avons répété le travail de ter Borg, mais nous n'avons pu reproduire ses résultats en dépit de nombreuses tentatives. Nous pouvons, en conséquence, proposer les mises au point suivantes.

Préparation des dihalogénures de quinones

Nous avons refait la préparation du dichlorure de la *p*-benzoquinone d'après la méthode de Clark (3), une méthode préconisée également par ter Borg. Nous y avons apporté en outre un grand nombre de modifications (variations de température et de vitesse d'addition, emploi de divers solvants, etc.) sans réussir à isoler autre chose que le dichlorure décrit par Clark. De plus, lors d'une réaction faite à $-20°$, nous avons obtenu ce dichlorure pur directement du milieu réactionnel (λ_{max} 230 mμ (ϵ 9 800)). Cette seule et même substance s'obtient également par l'action du chlorure de sulfuryle sur l'hydroquinone et par celle du dichlorure d'iodobenzène, qui donne généralement un produit d'addition *cis* (6), sur la



p-benzoquinone. Des résultats semblables ont été obtenus pour les dichlorures de la toluquinone, de l'*o*-xyloquinone et de la α-naphtoquinone, de même que pour les dibromures de ces quinones. En outre, des préparations présentant les caractéristiques décrites par ter Borg ont été obtenues à l'occasion, mais leur spectre infrarouge a démontré qu'elles étaient impures et contenaient des quantités certaines d'hydroquinones.

Spectroscopie

Ter Borg avait signalé et étudié la variation du spectre d'absorption dans l'ultraviolet du dichlorure de la benzoquinone en solution alcoolique. Toutefois, le spectre que nous avons observé diffère sensiblement de celui déjà publié. Les bandes d'absorption notées par ter Borg (5) pour le dichlorure de la benzoquinone (λ_{max} 250 mμ (ϵ 4 300)), par Vischer (7) pour le dibromure de la benzoquinone (λ_{max} 256 mμ) et par Andrews *et al.* (8) pour le dibromure de l'*o*-xyloquinone (λ_{max} 275 mμ (ϵ 8 300)) sont identiques à celles que nous avons observées environ 1 h après la préparation de la solution et correspondent aux monohalogénoquinones correspondantes. Des solutions fraîches de ces trois substances révèlent des bandes d'absorption à 230 mμ, à 220 mμ et à 225 et 271 mμ. Ces bandes persistent, par ailleurs, lorsque l'on emploie des solvants non polaires comme le *n*-hexane.

La différence marquée entre les dibromures et les dichlorures de quinones lorsque l'on tente de les énoliser nous a incité à en rechercher la cause par la détermination des caractéristiques spectrales de ces substances (Tableau I) et des dicétotétrahydronaphtalènes (Tableau II). Mais, en l'absence de toute indication dans la littérature sur la conformation des ènediones homocisoïdes, nous nous contenterons de signaler quelques effets.

TABLEAU I

	λ_{max}^{EtOH} (mμ)	$\lambda_{max}^{n\text{-hexane}}$ (mμ)	ϵ (*n*-hexane)	ν_{max}^{KBr} (cm^{-1})	$\nu_{max}^{CHCl_3}$ (cm^{-1})

Spectres ultraviolets

La cyclohex-2-ène-1,4-dione, λ_{max}^{EtOH} 233 mμ, $\lambda_{max}^{iso\text{-octane}}$ 219 mμ (9), donne lieu à un effet de solvant considérable; par contre, nous avons noté une absence de cet effet dans le cas des dihalogénures de quinones. On pourrait peut-être attribuer ceci à une faible polarité de ces molécules, qui serait compatible avec une conformation dans laquelle les atomes d'halogène seraient axiaux.

La règle modifiée de Fieser (10) s'applique bien aux dicétotétrahydronaphtalènes et assez bien aux dichlorures de quinones mais à condition de donner aux atomes de chlore un effet constant; ceci impliquerait que tous les dichlorures ont la même conformation. Elle ne s'applique pas aux dibromures car, à l'exception de celui de la *p*-benzoquinone, ils montrent deux bandes assez mal définies.

Spectres infrarouges

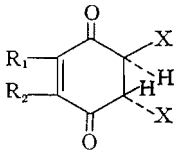
La cyclohex-2-ène-1,4-dione montre une bande, ν^{CCl_4} 1 690 cm^{-1}, qui concorde bien avec celle du dicétotétrahydronaphtalène, $\nu_{max}^{CHCl_3}$ 1 695 cm^{-1}; mais, toute corrélation entre l'orientation de l'atome d'halogène et la fréquence d'absorption du groupe carbonyle devient hasardeuse à défaut de substance isomère ou de structure établie auxquelles on peut se référer (cf. réf. 11, par exemple).

La régularité de la diminution de la fréquence $\nu_{C=O}$ (Tableau I) (11–12 cm^{-1} pour les dichlorures et 3–5 cm^{-1} pour les dibromures de quinones) suggère que dans chacun de ces groupes les substances ont la même conformation et que les différences de réactivité ne sont pas d'ordre conformationnel.

La 2,3,5,6-tetrabromocyclohexane-1,4-dione (1) et le composé chloré correspondant (3) ($\nu_{C=O}^{KBr}$ 1 750 cm^{-1} et $\nu_{C=O}^{KBr}$ 1 754 cm^{-1}, respectivement) montrent, par ailleurs, des bandes d'absorption caractéristiques de cétones α,α'-dihalogénées dans lesquelles les atomes d'halogène sont nettement équatoriaux (12).

Elimination

Par l'emploi de solutions alcooliques plus concentrées de dichlorures et de dibromures de quinones, nous avons pu, après la disparition de la bande d'absorption originale, isoler, pour quelques substrats, la monohalogénoquinone correspondante. La vitesse d'élimination augmente avec la proportion d'eau dans le solvant et aussi par addition d'halogénures alcalins. L'effet du fluorure de sodium est particulièrement frappant (Tableau III). Lorsque les solutions sont placées dans l'obscurité, la bande d'absorption, due à la quinone, ne varie plus pour toute fin pratique. Mais à la lumière, elle fait lentement place à une troisième bande dans la région caractéristique des hydroquinones. Dans quelques cas, cette hydroquinone a été isolée et était identique à la monohalogénohydroquinone correspondante.



La réduction photochimique des quinones est bien connue (réf. 13, par exemple) et ne surprend pas si ce n'est par sa facilité, car elle ne nécessite ni source lumineuse, ni lumière directe du soleil.

Enolisation

On a déjà souligné que le dibromure de la benzoquinone ne s'énolise pas en 2,3-bromohydroquinone (4, 5) et, en dépit de nombreuses tentatives, nous n'avons pu modifier ce résultat. Toutefois l'oxydation permanganique de ce dibromure de benzoquinone en acide

dl-dibromosuccinique lui assigne pourtant la même configuration qu'au dichlorure. Nous avons, par ailleurs, observé que les énolisations peuvent se faire rapidement au moyen de l'acide sulfurique concentré ou de l'acide bromhydrique sec dans l'éther. Dans ces conditions le dibromure de l'*o*-xyloquinone se transforme en 5,6-dibromo-*o*-xylohydroquinone, à l'instar des dichlorures. Par contre, avec le dibromure de la benzoquinone on peut isoler un intermédiaire passablement stable (il n'a pu être analysé), dont les caractéristiques spectrales seraient celles de la 2,3,5-tribromocyclohexane-1,4-dione. Dans les mêmes conditions expérimentales, cet intermédiaire se transforme éventuellement en 2,5-dibromohydroquinone; dans l'alcool, il se convertit en 2,5-dibromobenzoquinone. Il semble donc que le cours de la transposition puisse être plus complexe qu'on ne l'avait supposé (4) et que l'élimination d'un molécule de HBr soit suivie de l'addition 1,2 de cette substance à une autre molécule de dibromure plutôt qu'à la bromobenzoquinone. D'ailleurs, l'addition de HBr à la bromobenzoquinone donnerait surtout la 2,6-dibromohydroquinone (14) (Tableau IV).

PARTIE EXPÉRIMENTALE

Les points de fusion corrigés ont été déterminés en tube capillaire (appareil Thomas Hoover). Les spectres infrarouges ont été réalisés avec un appareil Beckman, modèle IR-4, et ont été calibrés à l'aide d'un film de polystyrène. Les spectres ultraviolets ont été déterminés avec un appareil Beckman, modèle DK-1A.

1. Addition du chlore aux quinones

Dichlorure de la p-benzoquinone (5,6-dichlorocyclohex-2-ène-1,4-dione)

Méthode A.—On fait barboter rapidement du chlore dans une solution de 10.8 g (0.1 mole) de *p*-benzoquinone dans 60 ml de chloroforme anhydre pendant 1 h à −20°. Après avoir entraîné l'excès de chlore dans un courant d'azote, filtré et lavé les cristaux avec un peu de chloroforme glacé, on obtient le dichlorure pur (10.8 g, 60%), p.f. 146.0–146.5° (litt. p.f. 143° (2), 146° (3)).

Méthode B.—On dissout la *p*-benzoquinone (10.8 g) dans un minimum de chloroforme sec (20 ml) à 25° et on sature de chlore un volume égal du même solvant. Après avoir réuni les deux solutions, on fait barboter du chlore dans le mélange pendant 10 min; puis on y ajoute 10 ml d'éther de pétrole (p.é. 30–60°). On isole le dichlorure (80%) comme ci-dessus, p.f. 145–146°.

Méthode C (5).—On ajoute goutte à goutte 24.0 g de chlorure de sulfuryle à une solution de 10.0 g de *p*-benzoquinone dans 100 ml d'éther anhydre. Après avoir agité pendant 1 h, on constate que la quinhydrone formée au début de la réaction s'est transformée en un précipité blanc du dichlorure. On refroidit, filtre et lave avec un peu d'éther glacé. Le dichlorure ainsi obtenu (40%) est pur, p.f. 146–146.5°.

Méthode D.—On ajoute par petites portions 5.5 g (0.02 mole) de dichlorure d'iodobenzène à une solution de 2.2 g (0.02 mole) de *p*-benzoquinone dans 20 ml d'acide acétique à 50°. Au moment de l'apparition d'une teinte rouge, on refroidit rapidement, on dilue avec de l'eau et l'on extrait avec du chloroforme (100 ml). Le dichlorure (1.5 g, 40%) cristallise dans un mélange de chloroforme et d'éther de pétrole (p.é. 66–70°), p.f. 145–146°.

Pour les autres dichlorures, l'emploi de la méthode B donne les meilleurs résultats. Toutefois dans chaque cas, les trois premières méthodes conduisent au même produit. Les rendements varient de 70 à 80%.

5,6-Dichloro-2-méthylcyclohex-2-ène-1,4-dione (dichlorure de la toluquinone), p.f. 134.5° (litt. p.f. 135–136° (3)). *5,6-Dichloro-2,3-diméthylcyclohex-2-ène-1,4-dione (dichlorure de l'o-xyloquinone)*, p.f. 194.5°. *2,3-Dichloro-1,2,3,4-tétrahydronaphtalène-1,4-dione*, p.f. 178–180° (décomp.) (litt. p.f. 176° (15)).

2. Addition du brome aux quinones

5,6-Dibromocyclohex-2-ène-1,4-dione (dibromure de la p-benzoquinone)

A une solution de 10.8 g (0.1 mole) de *p*-benzoquinone dans 200 ml de CCl_4 anhydre, on ajoute un mélange de 16.0 g de brome, de 150 ml de CCl_4 et de 15 ml d'éther anhydre. On évapore aussitôt sous vide la moitié du solvant et l'on précipite le dibromure par addition d'éther de pétrole (p.é. 30–60°), p.f. 84.5–85.0° (26.8 g, 100%). Après avoir cristallisé deux fois dans l'éther de pétrole (p.é. 66–70°), la substance fond à 85.5–86.0° (litt. p.f. 86° (1)). L'oxydation permanganique de cette substance d'après la méthode de Dimroth *et al.* (4) conduit à l'acide *dl*-dibromosuccinique, p.f. et p.f. mixte 165–167° (litt. p.f. 166–167° (16)).

Les autres dibromures se préparent de façon analogue; les rendements sont supérieurs à 90%.

5,6-Dibromo-2-méthylcyclohex-2-ène-1,4-dione (dibromure de la toluquinone), p.f. 62.5° (litt. p.f. 61–62° (3)). *5,6-Dibromo-2,3-diméthylcyclohex-2-ène-1,4-dione (dibromure de l'o-xyloquinone)*, p.f. 103–103.5° (litt. p.f. 104–105° (8)). *2,3-Dibromo-1,2,3,4-tétrahydronaphtalène-1,4-dione*, p.f. 100–101° (litt. p.f. 92° (15)).

3. Réactions des dihalogénures de quinones dans l'éthanol

Les transformations des dihalogénures de quinones en solution alcoolique contenant de 1 à 20% d'eau ont été étudiées par la détermination périodique des spectres d'absorption dans l'ultraviolet. Une solution strictement fraîche (t = 2 min) de chaque dihalogénure révèle une ou deux bandes d'absorption à des longueurs d'onde plus faibles que celles déjà mentionnées (5, 7, 8). Après un temps qui varie en fonction de la concentration en eau du solvant et sous l'effet des halogénures alcalins, ces bandes font place à l'absorption caractéristique des quinones monohalogénées correspondantes. Ces effets ainsi que celui de la lumière sur la persistance de ces dernières bandes sont résumés au Tableau III.

4. Identification des produits d'élimination et de réduction photochimique

Monohalogénoquinones

On dissout 3.0 g de dichlorure de la *p*-benzoquinone dans 100 ml d'éthanol à 80%. Après avoir agité pendant 1 h, on évapore l'alcool sous vide et l'on extrait le résidu avec du chloroforme. L'analyse chromatographique de cette solution (gel de silice, éther de pétrole (p.é. 30–60°)) ne révèle qu'un seul produit, la chloro-*p*-benzoquinone, p.f. et p.f. mixte 56–57° (litt. p.f. 57°), λ_{max}^{EtOH} 250 mμ (ϵ 12 500).

Dans les mêmes conditions, le dibromure de la *p*-benzoquinone se transforme en bromo-*p*-benzoquinone, p.f. et p.f. mixte 56.0–56.5° (litt. p.f. 55–56°), λ_{max}^{EtOH} 256 mμ (ϵ 11 600).

D'une solution de dichlorure de l'*o*-xyloquinone (0.8 g) dans 100 ml d'éthanol à 80%, on isole après 2 semaines la chloro-*o*-xyloquinone, p.f. et p.f. mixte 50.0–50.5°, λ_{max}^{EtOH} 267 mμ (ϵ 13 300).

D'une façon analogue, on obtient la bromo-*o*-xyloquinone, p.f. et p.f. mixte 41–42° (litt. p.f. 42–43° (8)), λ_{max}^{EtOH} 275 mμ (ϵ 13 400).

Monohalogénohydroquinones

On dissout 3.0 g de dichlorure de la *p*-benzoquinone dans 1 l d'éthanol à 80%. Après avoir laissé séjourner la solution à la lumière pendant 1 mois, on évapore l'alcool sous vide et l'on extrait le résidu avec du benzène. Après plusieurs cristallisations dans le chloroforme, la chlorohydroquinone est obtenue à l'état pur, p.f. et p.f. mixte 105° (litt. p.f. 106°), λ_{max}^{EtOH} 296 mμ. Di-acétate, p.f. et p.f. mixte 71.0–71.5° (litt. p.f. 72°).

De la même façon, le dibromure de la *p*-benzoquinone se transforme en bromohydroquinone, p.f. et p.f. mixte 112.5–113.5° (litt. p.f. 111°), λ_{max}^{EtOH} 296 mμ. Di-acétate, p.f. et p.f. mixte 75.0–75.5° (litt. p.f. 71–73°).

5. Enolisation des dihalogénures de quinones

Méthode A

On fait barboter de l'acide bromhydrique gazeux et sec dans une suspension de 5.4 g (0.05 mole) de dichlorure de la *p*-benzoquinone dans 100 ml d'éther anhydre jusqu'à ce que la substance se dissolve. On entraîne l'excès d'acide bromhydrique dans un courant d'azote, on évapore la solution à sec et l'on cristallise la 2,3-dichlorohydroquinone (5.2 g) dans le benzène, p.f. 147–148° (litt. p.f. 147–148° (17)).

On dissout la 2,3-dichlorohydroquinone dans un mélange d'eau et d'acide acétique et l'on y ajoute un excès d'une solution 1.3 *M* de $FeCl_3$ pour obtenir la 2,3-dichloro-*p*-benzoquinone (5.0 g), p.f. 101–102° (litt. p.f. 99–100° (14)).

Méthode B

On dissout par petites portions 2.2 g (0.02 mole) de dichlorure de la *p*-benzoquinone dans 25 ml d'acide sulfurique concentré à 0°. Après avoir agité pendant 20 min, on y ajoute 25 g de glace, on filtre et on lave le résidu avec très peu d'eau glacée. On obtient ainsi 2.1 g de 2,3-dichlorohydroquinone, p.f. 146–147°.

Méthode C

On dissout 10.0 g de dibromure de la *p*-benzoquinone dans 350 ml d'éther anhydre, on y fait barboter un courant rapide de HBr sec pendant 10 s et l'on agite à température ambiante pendant 30 min. On filtre et triture le résidu (7.5 g) dans de l'éther, p.f. 158–159° (décomp.), $\lambda_{max}^{EtOH\,95\%}$ 283 mμ; ν_{max}^{KBr} 1 750, 1 730 et 1 692 cm^{-1}. La substance n'est pas très stable; il n'a donc pas été possible de la soumettre à l'analyse élémentaire. Il s'agit sans doute de la 2,3,5-tribromocyclohexane-1,4-dione puisque le spectre infrarouge n'indique pas d'insaturation et qu'elle se transforme rapidement en 2,5-dibromohydroquinone par l'emploi de la méthode A décrite ci-dessus.

REMERCIEMENT

Nous remercions le Conseil National des Recherches pour l'octroi d'une bourse de recherche à l'un de nous (J. Y. S.) et de subventions.

METABOLITES OF PATHOGENIC FUNGI

V. ISOLATION AND TENTATIVE STRUCTURES OF VIOXANTHIN AND VIOPURPURIN, TWO COLORED METABOLITES OF TRICHOPHYTON VIOLACEUM[1,2]

F. BLANK, A. S. NG, AND G. JUST

Received August 3, 1966

ABSTRACT

Two new pigments, vioxanthin and viopurpurin, were isolated from *Trichophyton violaceum*, and tentative structures are proposed. Xanthomegnin was found to be the major component of the pigment mixture.

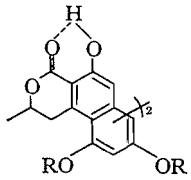
As part of our continuing program of investigating the constituents of dermatophytes, the pigments of *Trichophyton violaceum* Sabouraud, apud Bodin, 1902, have been studied.

Mycelium of *Trichophyton violaceum* was grown on a modified Sabouraud glucose medium, autoclaved, washed, freeze-dried, and milled. Extraction followed by chromatographic procedures yielded, in addition to large amounts of xanthomegnin (previously isolated from *T. megnini* in our laboratory (1)), two new pigments. A brownish-yellow pigment, vioxanthin, was obtained from the acetone extract, and the acetic acid extract yielded a dark-red pigment, viopurpurin. In addition, several other pigments were obtained and are being purified.

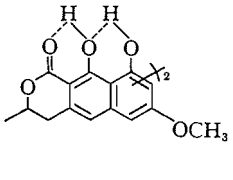
Vioxanthin

The molecular formula of vioxanthin is $(C_{15}H_{13}O_5)_2$. The molecular weight, which was determined by osmometry, and the nuclear magnetic resonance (n.m.r.) spectrum of vioxanthin, which indicated the presence of 13 protons, showed that the molecule consisted of two identical moieties linked by an odd number of bonds.

The n.m.r. spectrum of vioxanthin showed the presence of a $CH_3—\underset{\displaystyle O}{\underset{|}{CH}}—CH_2—Ph$ group (δ 1.50 p.p.m. (CH_3, doublet) and 2.96 p.p.m. and 4.70 p.p.m. (—CH_2— and —CH, multiplets)), two aromatic protons at 6.70 and 6.96 p.p.m., a methoxy group at 3.80 p.p.m., and two exchangeable protons at 9.70 and 13.84 p.p.m. The infrared spectrum showed a strong peak in the carbonyl region at 1 640 cm^{-1}, which shifted to 1 725 cm^{-1} upon acetylation. The carbonyl function is assigned to a hydrogen-bonded six-membered lactone[3] (2–4). Absorption at 3 415 cm^{-1} (CCl_4) caused by the phenol groups was not shifted upon dilution, indicating that all the hydroxy groups were hydrogen bonded.

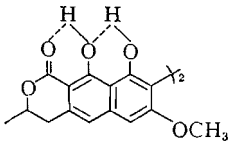


Vioxanthin formed a tetraacetate, ν 1 780 cm^{-1}, δ 2.00 and 2.46 p.p.m. The ultraviolet spectra of vioxanthin (λ_{max}^{EtOH} 268 mμ (ϵ 50 000) and 380 mμ (ϵ 14 000)) and its tetraacetate (λ_{max}^{EtOH} 262.5 mμ (ϵ 112 000) and 320 mμ (ϵ 27 000)) were uninformative, but compatible with a naphthalene derivative (6).



[1]*This work was supported by U.S. Public Health Service research grants 5 R01 AI 05378 and AI 04050, and a grant from the John A. Hartford Foundation, Inc., New York.*

[2]*For part IV in this series, see G. Bauslaugh, G. Just, and F. Blank, Nature, 202, 1218 (1964).*



[3]*The low-field exchangeable proton at 13.84 p.p.m. is in good agreement with a phenolic proton hydrogen bonded to a carbonyl function.*

If it is assumed that vioxanthin results from dimerization of two moieties formed from seven acetate units and that the oxygenation pattern is not altered during its biosynthesis, the following partial structures can be proposed.

It is known that the δ value of hydrogens ortho, meta, and para to phenolic hydroxyl groups is shifted upon acetylation towards lower field by 0–0.2, 0, and 0.4–0.5 p.p.m., respectively (5). The two aromatic protons in vioxanthin were shifted downfield upon acetylation by 0.4 and 0.54 p.p.m., respectively. We therefore conclude that the protons must have been para to the phenolic groups. These considerations suggest the following structure for vioxanthin (I).

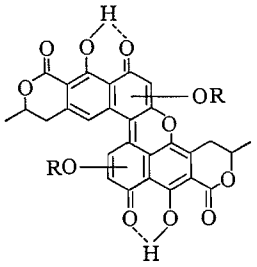
I

Viopurpurin

Viopurpurin is a very insoluble, dark-red pigment. Its insolubility precluded further purification; a n.m.r. spectrum could not be obtained for the same reason. Its infrared spectrum showed a peak at 1 725 cm^{-1} for a lactone and peaks at 1 675 and 1 635 cm^{-1} for a quinone function.

Upon acetylation, an orange triacetate was obtained. Elemental analysis and molecular weight determination by osmometry indicated the molecular formula $C_{35}H_{26}O_{14}$. The infrared spectrum of the triacetate showed the presence of phenolic acetates at 1 775 cm^{-1}, a lactone group at 1 725 cm^{-1}, and an α,β-unsaturated carbonyl or quinone function at 1 675 cm^{-1}. The n.m.r. spectrum indicated the presence of two lactone rings identical with those of vioxanthin, two acetate groups at 2.5 p.p.m. and one at 2.65 p.p.m., one methoxy group at 4.05 p.p.m., and two aromatic protons at 7.60 p.p.m. and 8.04 p.p.m.

Reductive acetylation with zinc in acetic anhydride gave dihydro-viopurpurin penta-acetate, which differed in its n.m.r. spectrum from the triacetate in that the two aromatic protons had almost merged (δ 7.63 p.p.m. (broad, 2H)). Its infrared spectrum showed strong peaks in the carbonyl region at 1 785 cm^{-1} and 1 730 cm^{-1} only.



One can conclude, therefore, that viopurpurin must be composed of two similar moieties, each consisting of a six-membered lactone ring fused to an aromatic or quinoid system, but differing in that one half has one methoxy and one phenolic hydroxy group, whereas the other half has two phenolic hydroxy groups. Since reductive acetylation resulted in the formation of two more acetate groups, the quinoid system must have extended over two rings. This extended chromophore is also reflected by the intense absorption in the visible region.

Analysis of the molecular formula ($C_{35}H_{26}O_{14} - 3C_2H_2O$ (acetate) $- CH_2$ (methoxy) $= C_{28}H_{18}O_{11}$) shows that the "stripped skeleton" of viopurpurin contains two halves linked by a double bond and a single bond. Since 10 oxygen atoms are accounted for by two lactones, four hydroxy groups (OCH_3 + 3OAc of the viopurpurin triacetate), and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extended quinone, the 11th oxygen must be an ether function, most likely linking the two ring systems.

At the present time, the scarcity of this pigment precludes further degradative work, but the available data suggest viopurpurin can be represented by the following structure (II).

II, R = H or CH_3

EXPERIMENTAL

Amberlite 120 ion-exchange resin was used for the ion-exchange column, and ion-exchange cellulose (No. 78 cm type 40, Carl Schleicher and Schuell Co.) for the washing columns. Infrared spectra were determined with a Perkin–Elmer model 337 grating spectrophotometer. All the spectra were taken in potassium bromide pellets. Nuclear magnetic resonance spectra were taken with a Varian A-60 n.m.r. spectrometer. Deuterated chloroform was used as the solvent. Ultraviolet spectra were measured with a Beckman recording spectrophotometer, model DK. Melting points were taken on a Kofler hot stage. Microanalyses were carried out by Beller Mikroanalytisches Laboratorium, Theaterstrasse 23, 34 Gottingen, Germany.

Trichophyton violaceum was grown in 500 ml Erlenmeyer flasks containing 250–300 ml of medium at room temperature for 5–6 weeks. The medium consisted of 4% crude glucose (cerelose), 2% neopeptone (Difco), 0.05% yeast extract (Difco), 0.005% inositol, 0.001% thiamine, and 2% agar. The cultures were autoclaved, and the harvested mycelium was washed free of adhering medium by boiling three times in water. After the mycelium was pressed, it was freeze-dried and milled in a ball mill.

The extraction was carried out by stirring dry powdered mycelium (first batch, 875 g; second batch, 286 g) at room temperature successively with hexane, diethyl ether, acetone, methanol, and glacial acetic acid. The yields are summarized in Table I.

TABLE I

Solvent	Time (days)	Yield (g)		Yield (% of dry mycelium)		Pigments isolated
		First batch	Second batch	First batch	Second batch	
Hexane	7	12.98	6.93	1.49	2.42	
Ether	7	13.41	4.5	1.53	1.57	
Acetone	2×7	15.9	5.4	1.82	1.89	Xanthomegnin, vioxanthin
Methanol	7	9.5	1.93	1.08	0.68	Xanthomegnin
Glacial acetic acid	2	45	3.7	5.14	1.29	Xanthomegnin, viopurpurin

Acetone Extract

The dried, brownish extract (5.4 g) was washed with hexane and diethyl ether to remove fatty materials. The residue was then dissolved in chloroform and the organic layer washed three times with each of the following: 3% aqueous HCl, distilled water, 5% aqueous Na_2CO_3 solution, distilled water, and 3% aqueous NaOH solution.

Evaporation of the washed chloroform extract gave 1.4 g of crude xanthomegnin, which, upon purification, was identified by comparison of its infrared spectrum with that of an authentic sample.

The 5% aqueous Na_2CO_3 solution wash and following water wash were acidified with concentrated HCl (pH 2) and extracted with diethyl ether. The ether solution was washed with water until it was neutral, and evaporated to dryness. The resulting solid (1.36 g) was washed with hexane to remove residual fatty materials. It was then extracted with carbon tetrachloride and the solution evaporated. The residual solid (1 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

from the carbon tetrachloride solution was dissolved in a minimum amount of chloroform. Judicious addition of diethyl ether and hexane resulted in the formation of a crystalline brownish material. Recrystallization from the same solvent system gave pure vioxanthin, m.p. 190–195° (decomp.), λ_{max}^{EtOH} 268 mμ (ε 50 000) and 380 mμ (ε 14 000).

Anal. Calcd. for $C_{30}H_{26}O_{10}$: C, 65.93; H, 4.80; O, 29.28; mol. wt. 546.51. Found: C, 66.04; H, 4.83; O, 29.10; mol. wt. (osmometric) 554.

Vioxanthin Tetraacetate

A solution of vioxanthin (50 mg) in 2 ml of pyridine and 6 ml of acetic anhydride was warmed to 60 °C for 15 min and stirred at room temperature overnight. Excess acetic anhydride was hydrolyzed by pouring the solution onto ice chips, with stirring. Filtration gave 45 mg of vioxanthin tetraacetate, m.p. 210 °C (decomp.), λ 262.5 mμ (ε 112 000) and 320 mμ (ε 27 000). No suitable solvent was found for recrystallization. An analytical sample was dried at 68 °C in a high vacuum overnight.

Anal. Calcd. for $C_{38}H_{34}O_{14}$: C, 64.00; H, 4.70; O, 31.30; mol. wt. 714.27. Found: C, 64.26; H, 4.66; O, 30.98; mol. wt. (osmometric) 752.

Methanol Extract

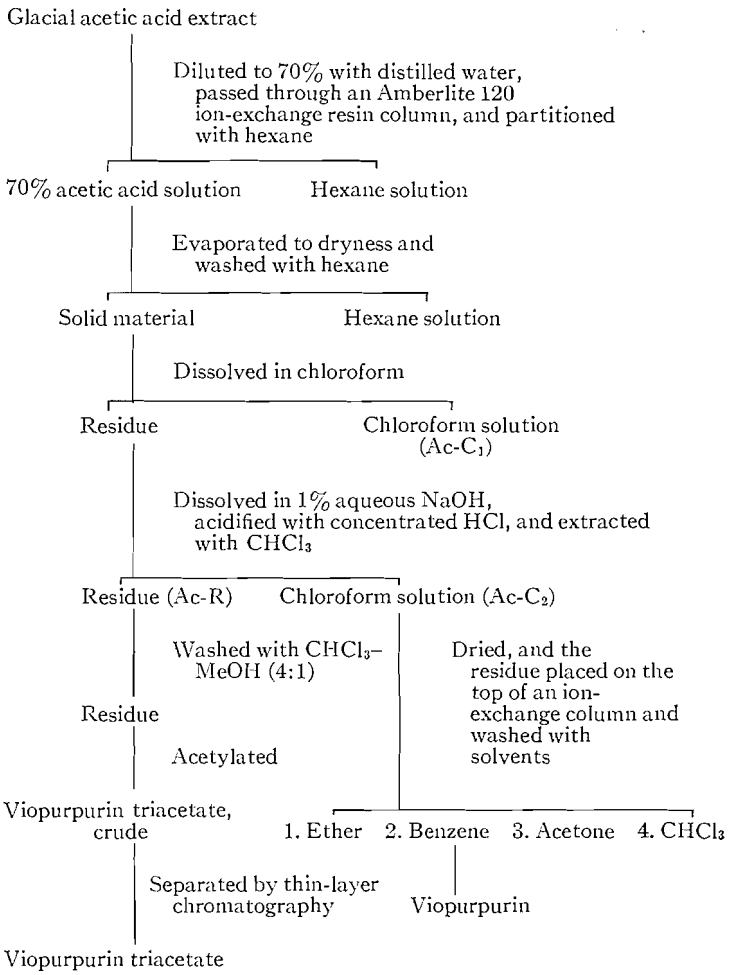
The crude methanol extract was washed successively with petroleum ether and diethyl ether to remove fatty materials. The solid residue (9.5 g) was dissolved in 1 l of chloroform, and 1 l of methanol was then added to the chloroform solution. The chloroform–methanol solution was passed through a 4 × 60 cm Amberlite 120 column. The organic solution was then partitioned with distilled water. From the organic layer, 6.0 g of solid was obtained. The residue was extracted successively in a Soxhlet extractor with petroleum ether, benzene, and chloroform. Each extraction was performed for a 2 day period. The benzene extraction was interrupted halfway, and the first fraction was combined with the ether extract.

The residual solid (2.89 g) from the ether extract and the first half of the benzene extract was dissolved in 1 500 ml of chloroform. The chloroform solution was then washed successively with 1% aqueous HCl, water–methanol (3:1 v/v), 1% aqueous Na_2CO_3 solution, 1% aqueous NaOH solution, and distilled water.

During the washing with the 1% aqueous Na_2CO_3 solution, a bluish insoluble solid precipitated. It was filtered off and, after being dried, weighed 1.1 g.

SCHEME 1. Isolation of xanthomegnin from the methanol extract.

Insoluble Bluish Precipitate from 1% Aqueous Na_2CO_3 Wash



The bluish residue (1.1 g) was dissolved in 5 ml of glacial acetic acid, the acetic acid was evaporated, and chloroform (700 ml) was then added to the resulting yellowish residue. The chloroform solution was washed with water, and methanol was added to destroy the emulsion formed. Evaporation gave 0.82 g of a residue. It was placed on the top of an ion-exchange cellulose column and washed successively with hexane, ether, acetone, and chloroform. The chloroform wash gave 304 mg of a solid. Crystallization from methanol gave 200 mg of xanthomegnin.

Glacial Acetic Acid Extract

The crude glacial acetic acid solution (2 800 ml) was diluted with 1 200 ml of water, and passed in two batches through a 4 × 60 cm Amberlite 120 ion-exchange resin column. The deionized aqueous acetic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution was partitioned with hexane to remove fatty materials. Evaporation of the acetic acid solution gave 45 g of a wet solid. This was reextracted with hexane to remove residual fatty materials, and then dissolved in chloroform (Ac-C_1).[4] The chloroform-insoluble residue was filtered off and dissolved in 1% aqueous NaOH. Careful acidification of the basic solution with concentrated HCl gave a dark-colored precipitate. The aqueous suspension was extracted with chloroform, and the insoluble residue (Ac-R,[4] 3.5 g) was filtered off. The chloroform solution was separated from the aqueous phase, giving, upon evaporation, 1 g of a residue (Ac-C_2).[4]

SCHEME 2.

Ac-R Fraction

The residue (3.5 g) was washed with chloroform–methanol (4:1) to remove soluble materials. A highly insoluble dark residue of impure viopurpurin (1 g) was obtained. It could not be purified further because of its insolubility, and was therefore acetylated by stirring overnight in 15 ml of acetic anhydride and 4 ml of pyridine. The excess anhydride was decomposed by pouring the solution onto ice chips, with stirring. The product was filtered off and washed with distilled water to give 500 mg of crude viopurpurin triacetate.

Ac-C_2 Fraction

Fraction Ac-C_2[4] (1 g) obtained above was put on a 3 × 30 cm ion-exchange cellulose column, and washed successively with ether, benzene, acetone, chloroform, and pyridine. The benzene fraction contained crude viopurpurin. A triacetate derivative (300 mg) was prepared by the method mentioned above.

[4]*Code numbers refer to Scheme 2.*

Purification of Viopurpurin Triacetate

A chloroform solution of crude viopurpurin triacetate was applied to silica gel plates which had been sprayed with 1% hydrochloric acid before brief activation. Benzene–acetone (7:3) was used for developing. A yellow-orange band was collected and the pigment dissolved out with chloroform. No suitable solvent was found for crystallization of viopurpurin triacetate, m.p. 280–285 °C; λ_{max}^{EtOH} 217 mμ (ε 5 600), 270 mμ (ε 9 300), and 277 mμ (ε 9 300).

Anal. Calcd. for $C_{35}H_{26}O_{14}$: C, 62.69; H, 3. 91; O, 33.40; mol. wt. 670.56. Found: C, 62.80; H, 3.78; O, 33.55; mol. wt. (osmometric) 698.

Reductive Acetylation of Viopurpurin Triacetate

To a solution of 70 mg of viopurpurin triacetate in 5 drops of pyridine and 15 ml of acetic anhydride, 200 mg of zinc dust was added in portions, with stirring. The mixture was allowed to stand for 30 h, filtered, and poured onto ice chips, with stirring, to hydrolyze the excess acid anhydride. After the ice had melted (1 h), the product was filtered off and washed with distilled water. After being dried, 61 mg of dihydroviopurpurin pentaacetate was obtained. It could not be recrystallized, m.p. 200–203 °C (decomp.); λ_{max}^{EtOH} 286 mμ (ε 30 200), 296 mμ (ε 39 400), and 365 mμ (ε 5 020).

Anal. Calcd. for $C_{39}H_{32}O_{16}$: C, 61.90; H, 4.26; O, 33.83; mol. wt. 756.65. Found: C, 61.00; H, 4.38; O, 33.70; mol. wt. (osmometric) 776.

ACKNOWLEDGMENT

We thank Mr. K. Valentin for taking the n.m.r. spectra.

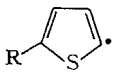
RADICALS DERIVED FROM HETEROAROMATIC SYSTEMS

I. THIENYL RADICALS

DONALD MACKAY
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 27, 1966



ABSTRACT

The decomposition of 3-thenoyl and 5-nitro-2-thenoyl peroxides in aromatic solvents leads to 3-thenoyloxy and 5-nitro-2-thenoyloxy radicals, which decarboxylate to some extent to 3-thienyl (I) and 5-nitro-2-thienyl (II*a*) radicals, respectively. Attack of these radicals on the solvent leads to the corresponding aryl thenoates and arylthiophenes. The Gomberg reaction of 5-carbomethoxy-2-thienylamine or the silver oxide oxidation of the related thienylhydrazine leads to 5-carbomethoxy-2-thienyl radicals (II*b*). A mechanism for the formation of biphenyl, formed in small quantities in the decomposition of 5-nitro-2-thenoyl peroxide in benzene, is proposed.

Little attention has been paid to homolytic reactions giving rise to free radicals with the unpaired electron on a heteroaromatic ring. The thermal decomposition of a few heterocyclic dicarbonyl peroxides in a variety of solvents has been studied as a possible route to such radicals (cf. the reactions of benzoyl peroxide). Thus, nicotinoyl peroxide leads to 3-pyridyl radicals in a good yield (1). 2-Furoyl peroxide, however, gave only intractable products in benzene (2). 2-Coumariloyl (3) and 5-methyl-1-phenyl-1,2,3-triazole-4-carbonyl (4) peroxides in aromatic solvents gave products derived from the related acyloxy radicals, but there was no conclusive evidence for decarboxylation of the latter. Likewise, 2-thenoyl peroxide reacts with solvents mainly through 2-thenoyloxy radicals, although there was also some indication of the involvement of 2-thienyl radicals (5). Other methods for generating heteroaryl radicals have apparently not been investigated. Evidence is now given for the production of the 3-thienyl (I), the 5-nitro-2-thienyl (II*a*), and the 5-carbomethoxy-2-thienyl (II*b*) radicals.

I

II*a*, R = NO_2
II*b*, R = CO_2CH_3

Schuetz and Teller (6) prepared a number of thenoyl peroxides, including 3-thenoyl and 5-nitro-2-thenoyl peroxides, and examined the kinetics of their decomposition in carbon tetrachloride; however, product analyses were not undertaken. The decomposition products of both these peroxides in representative aromatic solvents have now been investigated (Table I). 3-Thenoyl peroxide was decomposed in benzene, chlorobenzene, toluene, and thiophene, and its behavior was strikingly similar to that found for 2-thenoyl peroxide (5). Thus, carbon dioxide evolution was rather low (33 mole %[1] in benzene), and much amorphous high molecular weight material was formed in benzene and chlorobenzene, whereas in toluene and thiophene the reaction was cleaner and the yields of carboxylic acid were correspondingly higher. Aryl 3-thenoates were produced in all cases, in a very low yield (<2%) except in thiophene (13%), indicating nuclear attack of 3-thenoyloxy

[1] *Yields are based for convenience on the reaction*

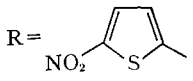
$$(RCO_2)_2 \rightarrow RCO_2^{\cdot} + R^{\cdot} + CO_2.$$

radicals on the solvent. From toluene, only the *o*-tolyl ester was isolated, but from chlorobenzene all three chlorophenyl 3-thenoates were shown to be formed, the *m*- and *p*-isomers predominating; from thiophene, the 2-thienyl ester seemed to be formed exclusively. In the chlorobenzene reaction a small amount of *phenyl* 3-thenoate was also produced, showing that the 3-thenoyloxy radical, like the 2-thenoyloxy radical (5), can displace halogen from halogenobenzene.

In contrast to the rather scanty evidence for the formation of 2-thienyl radicals by decarboxylation of 2-thenoyloxy radicals, clearcut evidence for the analogous formation of 3-thienyl radicals was provided by the production, albeit in a low yield, of 3-phenylthiophene in benzene, all three chlorophenylthiophenes in chlorobenzene, and 2,3′- and 3,3′-bithienyl in thiophene; in chlorobenzene, moreover, the *o*-isomer predominated, as is normally found (7) in a free-radical arylation process.

In the decomposition products from toluene the presence of traces of tolylthiophenes was inferred by gas–liquid chromatography (g.l.c.), but was not conclusively proven. The main product was bibenzyl (22%), formed from benzyl radicals derived by hydrogen abstraction from toluene, mainly by 3-thenoyloxy radicals; this accounted for the rather high yield of 3-thenoic acid. In addition, the carboxylic acid fraction contained a small amount of another acid, identified as 2- or 5-benzyl-3-thenoic acid (by decarboxylation to 2-benzylthiophene), which could arise by attack of benzyl radicals either on 3-thenoic acid or on undecomposed peroxide; the affinity of the thiophene nucleus for benzyl radicals has already been noted (5). Another minor reaction of the benzyl radicals in this decomposition was their coupling with 3-thenoyloxy radicals to give benzyl 3-thenoate.

The formation of thiophene in benzene and, more efficiently, in toluene represents further evidence for the involvement of 3-thienyl radicals in the peroxide decompositions (a control experiment showed that *no* decarboxylation of 3-thenoic acid to thiophene occurred under the conditions of these experiments). The source of hydrogen is undoubtedly the side chain in the toluene reaction; in benzene it is probably complex material obtained by radical (e.g. 3-thenoyloxy) *addition* to the substrate, a process which would lead to the accumulation of di- and tetra-hydrothiophene containing nuclei, providing a source of abstractable "aliphatic" hydrogen; such hydrogen would also account for the high yields of 3-thenoic acid, relative to those of diaryls and esters, in both the benzene and chlorobenzene reactions. Complex sulfur-containing material of this kind was found in earlier work (5) to cause reduction of 2-thenoyl peroxide to the anhydride, but no 3-thenoic anhydride could be detected in any of the present experiments.



The 2,3′- and 3,3′-bithienyls (7% and <1%, respectively) found in the decomposition in thiophene undoubtedly arise through attack of 3-thienyl radicals on the solvent, the relative degree of attack at the 3-position being much less than at the 2-position, as has been noted by other workers (8, 9). The isolation of 2,2′-bithienyl (9%), however, was rather unexpected as it implies the involvement of 2-thienyl radicals. This product is in accordance with a recent report by Griffin and Martin (9), who found that 2,2′- and lesser amounts of 2,3′-bithienyl were formed in the benzoyl peroxide phenylation of thiophene, and attributed their formation to a process of oxidation by the benzoyloxy radical of thiophene to the radical cation $C_4H_4S^{+\cdot}$, with ready conversion of this into the 2-thienyl radical $C_4H_3S^{\cdot}$ by benzoate anion. A similar process with 3-thenoate anion as the proton-removing species could occur here, leading to the 2,2′-bithienyl and to a *small part* of the 2,3′-bithienyl found; the yield of the latter (relative to that of the 2-isomer) is too great to be accounted for by this process alone. An alternative mechanism for the formation of the bithienyls from thiophene is proposed below.

The decomposition reactions of 5-nitro-2-thenoyl peroxide in benzene and in toluene (Table I) followed the general pattern described for 3-thenoyl peroxide. Carbon dioxide evolution was scanty (19%), and yields of the carboxylic acid, especially in toluene, were high, indicating that 5-nitro-2-thenoyloxy was the main radical species involved. Benzene was attacked to give the phenyl ester in a moderate yield (11%). In toluene, however, nuclear attack was not observed, the ester fraction consisting entirely of benzyl 5-nitro-2-thenoate (14%), and the yield of bibenzyl was correspondingly low (3%), suggesting that the 5-nitro-2-thenoyloxy radical has a very high affinity for the benzyl radical.

Like the 3-thenoyloxy radicals, the 5-nitro-2-thenoyloxy radicals decarboxylate to some extent; evidence for the resulting 5-nitro-2-thienyl radicals (II*a*) rests in the formation of 2-phenyl-5-nitrothiophene (5%) in benzene, and of 2-nitrothiophene (a trace) in toluene. The phenylnitrothiophene was not isolated, but its presence was confirmed by comparative g.l.c. with the mixture of the three isomeric phenyl-2-nitrothiophenes obtained in the decomposition of benzoyl peroxide in 2-nitrothiophene, the least volatile of these isomers being identical under all conditions with the product from the nitrothenoyl peroxide decomposition in benzene.

The isolation of biphenyl from the nitrothenoyl peroxide decomposition in benzene represents the first case in which a diaryl, Ar_2, of which both Ar groups are derived from a monocyclic[2] benzenoid solvent, ArH, has been detected in the products from the reaction of an aroyl peroxide. This implies the abstraction of phenyl hydrogen to give a phenyl radical, which then forms biphenyl with the solvent in the usual way. The direct abstraction of a hydrogen atom is a process requiring much energy, and seems unlikely. An alternative in which this is accomplished indirectly can be envisaged. If the product of the initial attack of the acyloxy radical on benzene (Scheme 1) is the σ-complex (III, R = 5-nitro-2-thienyl), as seems reasonable by analogy with the attack of the aryl radical in arylation (12), then deprotonation by carboxylate anion could occur to give the radical anion (IV), with concerted or subsequent loss of carboxylate anion from IV to give the phenyl radical (V). The loss of a stabilized leaving group (the anion) would constitute a driving force for III → V, which would be absent for the analogous σ-complex in an arylation reaction. The route III → V would compete with the "normal" process of the oxidation of III to product ester VI, which occurs either directly by abstraction of a hydrogen atom or, as now seems more likely (11, 12, 13), by disproportionation. In the decomposition of aroyl peroxides in benzene, esters (VI) are only trace products; this means that the amount of III formed is correspondingly very small, and hence biphenyl is unlikely to be detectable. This mecha-

SCHEME 1.

[2]*All three binaphthyls were isolated by Hey et al. from the decomposition products of benzoyl peroxide in naphthalene, their formation being attributed to hydrogen abstraction by benzoyloxy radicals to give the naphthyl radicals, which then attacked naphthalene (10); an alternative mechanism for this has been suggested by de Tar (11).*

nism could explain analogously the bithienyls obtained from thiophene in this work with 3-thenoyl peroxide[3] and in Griffin and Martin's (9) experiments with benzoyl peroxide, already described, as well as the binaphthyls found by Hey *et al.* (10) in the benzoyl peroxide decomposition in naphthalene. The dihydro derivative corresponding to III would be expected to form even more readily from thiophene and naphthalene than from benzene, and esters are in fact major products in all three decompositions (5, 10).

Most of the recognized routes to aryl radicals start ultimately either from the carboxylic acid by way of the aroyloxy radical which then loses CO_2, or from the amine by converting it into some arylazo derivative capable of losing nitrogen. Of the latter type, the alkaline decomposition of diazonium solutions (the Gomberg reaction) and the thermal decomposition of *N*-nitrosoacylarylamines have been the most widely used. An excellent alternative to these, giving good yields of diaryls in aromatic solvents, uses the oxidation of arylhydrazines with heavy metal oxides, particularly silver oxide, the azo intermediate involved being the diimide derivative ArN=NH (14).

Thienylamines are quite unstable unless the ring is also substituted with electron-withdrawing groups (15, p. 229); contrary to an earlier report (16), the diazotization of 2-thienylamine (as its stannichloride complex) does *not* proceed normally (17). This precludes the use of thienyldiazonium solutions as a route to unsubstituted thienyl radicals, either by the Gomberg reaction or by reduction to the thienylhydrazines. The only thienylhydrazines so far described have been prepared by displacement with hydrazine of suitably activated halogen, e.g. 3-nitro- and 3,5-dinitro-2-thienylhydrazines (18).

Reduction of methyl 5-nitro-2-thenoate gave the amine, which, as expected, was stable and could be diazotized. The diazonium solution, on treatment with benzene and alkali, gave methyl 5-phenyl-2-thenoate (8%) (the Gomberg product diagnostic of the radical 5-carbomethoxy-2-thienyl (II*b*)), and, on reduction with tin(II) chloride in concentrated hydrochloric acid, gave methyl 5-hydrazino-2-thenoate, which decomposed in air, but was stable as its hydrochloride. Oxidation of the hydrochloride, as a suspension in benzene, with silver oxide also gave the methyl phenylthenoate, in an excellent yield (85%). That the homolytic nature of this type of oxidation is unchanged when the hydrochloride is used in place of the free hydrazine (a modification which involves the immediate *in situ* liberation of the latter) was shown by oxidizing phenylhydrazine hydrochloride in nitrobenzene with silver oxide; the mixture of nitrobiphenyls was found to contain 54% of the *o*-isomer, in agreement with other phenylation procedures (7).

With 5-nitro-2-thenoic acid as a starting point, efforts were directed to making 5-nitro-2-thienylamine, and from it 5-nitro-2-thienylhydrazine, both of which would be expected to be stable and to provide potential sources of 5-nitro-2-thienyl radicals. The Schmidt reaction with hydrazoic acid, however, failed to give the amine, the carboxylic acid being recovered. 5-Nitro-2-thenoyl azide was readily prepared from the acid chloride and sodium azide, and in solution in inert solvents at temperatures above 70° it lost nitrogen. The Curtius rearrangement to 5-nitro-2-thienyl isocyanate had in fact evidently occurred, for the resulting solution gave the expected urethane and urea derivatives with methanol and aniline, respectively; however, efforts to isolate the isocyanate failed, only colored high molecular weight material being obtained when the solvent was evaporated. Similarly,

[3]*After the manuscript of this paper had been prepared, the decomposition products from 3-thenoyl peroxide in benzene were reexamined by g.l.c.; a small amount of biphenyl is in fact formed, in line with the result found for the nitrothenoyl peroxide in benzene. Furthermore, if the thenoyl peroxide decomposition is carried out in the presence of a large excess of added 3-thenoic acid, there is a substantial increase in the yield of biphenyl, relative to that of phenyl 3-thenoate, as would be predicted by Scheme 1.*

direct hydrolysis of the azide with aqueous hydrochloric or sulfuric acids led to intractable products and not the amine.

Most of the thiophene derivatives involved in this work have not been described previously. Detailed infrared studies on some of them in the region of 1 000 to 400 cm^{-1} have been reported elsewhere (19). The aryl esters of 3-thenoic and 5-nitro-2-thenoic acids listed in Table II, all of which are new, had carbonyl stretching frequencies (singlet or doublet) between 1 743 and 1 752 cm^{-1}, rather higher than the values typical for the aryl esters of aromatic carboxylic acids (20).

EXPERIMENTAL

General

Solvents were purified by conventional methods and fractionated. Melting points were taken on a Kofler block and are corrected. Gas–liquid chromatography was carried out on a Beckman GC-2A or an F & M 810 chromatograph. For high-resolution infrared spectra, either a Beckman IR-9 or a Perkin–Elmer 237 spectrometer was used.

3-Phenylthiophene was prepared by ring closure of sodium phenylsuccinate with phosphorus pentasulfide (21), and had m.p. 91° (lit. (21) m.p. 91–92°) after two crystallizations from petroleum ether;[4] *3-o-chlorophenylthiophene* was similarly prepared from the salt of *o*-chlorophenylsuccinic acid (22) of m.p. 171–173° (lit. (22) m.p. 173–174°) and had b.p. 103° at 1.0 mm, n_D^{20} 1.6394.

Anal. Calcd. for $C_{10}H_7ClS$: C, 61.7; H, 3.6; Cl, 18.2; S, 16.5. Found: C, 61.7; H, 3.7; Cl, 18.2; S, 16.7.

2,3′-Bithienyl was made as described by Teste and Lozac'h (23) and had m.p. 63–63.5° (lit. (23) m.p. 65°, (24) 61.5–63°) after crystallization from petroleum ether and then from aqueous ethanol. 3,3′-Bithienyl was kindly supplied by Professor S. Gronowitz, University of Lund, Sweden.

3-Thenoyl Chloride

Treatment of 3-thenoic acid (25), m.p. 138–139.5°, with thionyl chloride gave the acid chloride in an almost quantitative yield; purification by distillation and crystallization from petroleum ether gave large prisms, m.p. 52–52.5° (lit. (26) m.p. 51–52°).

Details of the method of preparation and physical constants of esters derived from the acid chloride are listed in Table II.

3-Thenoyl Peroxide

A mixture of the acid chloride (6.0 g), dissolved in ether (150 ml), and aqueous hydrogen peroxide (100 volumes, 5 ml) was cooled with crushed ice (50 g), and 1 *N* sodium hydroxide (45 ml, 1.1 equiv.) was added dropwise, with vigorous stirring and external cooling, over 15 min. After a further 30 min stirring, more ether (50 ml) was added, and the ethereal solution of the peroxide was separated, washed well with water, dried ($MgSO_4$),[5] and evaporated under reduced pressure. The crystalline residue (4.1 g) was dissolved in chloroform (20 ml) and precipitated by the addition, with stirring, of petroleum ether (40 ml) as colorless prisms (3.2 g, 62%), m.p. 121–122° (with decomposition) (detonation if determined in a capillary tube) (lit. (6) m.p. 120°); ν (CCl_4) 1 792 and 1 772 cm^{-1} (carbonyl doublet).

Anal. Calcd. for $C_{10}H_6O_4S_2$: equiv. wt. (iodometric) 127. Found: equiv. wt. 127.

3-Thenoic Anhydride

Treatment of 3-thenoic acid with a large excess of refluxing acetic anhydride gave 3-thenoic anhydride; it formed prisms, m.p. 55.5–56.5° (lit. (27) m.p. 54.5–56°), when recrystallized from petroleum ether.

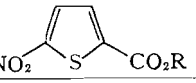
5-Nitro-2-thenoic Acid

2-Diacetoxymethyl-5-nitrothiophene was prepared as described by Tirouflet and Fournari (28) from 2-thenaldehyde (15, p. 509), and was recrystallized to a constant melting point of 73.5–74° (lit. (28) m.p. 73°) from ethanol or ether – petroleum ether as yellow prisms.

Anal. Calcd. for $C_9H_9O_6NS$: C, 41.7; H, 3.6. Found: C, 42.15; H, 3.7.

Hydrolysis with 4 *N* sulfuric acid gave 5-nitro-2-thenaldehyde, purified by steam distillation, as faintly yellow needles, m.p. 74–75.5° directly (lit. (28) m.p. 74°), unchanged on recrystallization from aqueous ethanol; ν (CCl_4) 2 840, 2 805 (aldehyde CH), and 1 695 cm^{-1} (carbonyl).

The diacetate (20 g) was vigorously stirred with 4 *N* sulfuric acid (200 ml) at 100°, and aqueous hydrogen peroxide (30 volumes, 100 ml) was run in over 30 min; a clear deep-yellow solution was obtained which was refluxed for a further 30 min with charcoal. The filtered solution, cooled to 0°, gave 5-nitro-2-thenoic acid (9.4 g, 70%, average over many runs) as light-yellow needles, m.p. 160–161°, raised to 160.5–161.5° (lit. (29) m.p. 157–158°) by further recrystallization from water and then from toluene. The use of hydrochloric instead of sulfuric acid gave a much less pure product.



[4] *Unless otherwise stated, b.p. 35–60°.*

[5] *Used as the drying agent throughout.*

5-Nitro-2-thenoyl Chloride

Refluxing the acid with an excess of thionyl chloride for 3 h gave the acid chloride (90%), which was distilled, b.p. 90–91° at 0.4 mm, and crystallized, m.p. 51–52° directly (lit. (29*b*) m.p. 52–53°), unchanged on recrystallization from ether – petroleum ether.

The esters prepared from the acid chloride are described in Table II.

5-Nitro-2-thenoyl Peroxide

To a solution of sodium carbonate (2.2 g, 0.02 mole) and aqueous hydrogen peroxide (100 volumes, 4 ml) in water (30 ml) was added crushed ice (30 g), followed by a solution of the acid chloride (3.8 g, 0.02 mole) in ether (10 ml); the whole was shaken vigorously for 20 min. Petroleum ether (10 ml) was added and the product was collected, washed with water, dried, and precipitated from solution in chloroform (15 ml) by the addition, with stirring, of petroleum ether (15 ml) as faintly lemon-yellow prisms (2.8 g, 80%), m.p. 121–121.5° (with decomposition) (violent detonation if determined in a capillary tube) (lit. (6) m.p. 120–122°).

Anal. Calcd. for $C_{10}H_4O_8N_2S_2$: equiv. wt. (iodometric) 172. Found: equiv. wt. 170.5.

5-Nitro-2-thenoic Anhydride

The acid chloride and an equivalent weight of the sodium salt of the acid were refluxed together in toluene for 1 h. The toluene-soluble material was crystallized 3 times from benzene, giving the *anhydride* as a buff crystalline powder, m.p. 134–135.5°; ν ($CHCl_3$) 1 800 and 1 720 cm^{-1} (carbonyl doublet).

Anal. Calcd. for $C_{10}H_4O_7N_2S_2$: C, 36.6; H, 1.2; N, 8.5. Found: C, 36.7; H, 1.25; N, 8.5.

5-Nitro-2-thenoyl Azide

A solution of the acid chloride (1.92 g) in acetone (10 ml) was run into a stirred solution of sodium azide (1.0 g, 1.5 equiv.) in water (5 ml). An oil separated and, after the mixture was stirred for 15 min, ice was added and the *azide* crystallized (1.83 g, 93%), m.p. 61–63°. It formed yellow prisms, m.p. 62–63°, on recrystallization from ether – petroleum ether; ν (CCl_4) 2 160 (azide) and 1 701 cm^{-1} (carbonyl).

Anal. Calcd. for $C_5H_2O_3N_4S$: C, 30.3; H, 1.0; N, 28.3. Found: C, 30.4; H, 1.2; N, 27.9.

The azide rapidly gave off 1 equivalent of nitrogen in refluxing benzene or toluene; the residue, on evaporation of the solvent, could not be crystallized, and developed an intense orange-yellow color in air. When a solution of the azide in toluene was refluxed briefly and then treated with dry methanol, the resulting solution gave *methyl 5-nitro-2-thienylcarbamate* as a deep-yellow solid, which, after crystallization from aqueous methanol and then benzene–chloroform, had m.p. 184–188° (with decomposition); ν ($CHCl_3$) 3 415 (NH) and 1 740 cm^{-1} (carbonyl).

Anal. Calcd. for $C_6H_6O_4N_2S$: C, 35.65; H, 3.0; N, 13.9. Found: C, 35.8; H, 3.1; N, 14.1.

When aniline was used in place of methanol, *N-phenyl-N'-(5-nitro-2-thienyl)-urea* was obtained, which gave small orange prisms when recrystallized from chloroform–methanol; this compound had no melting point, decomposing slowly at >230°; ν (Nujol) 3 225, 3 300 (NH), and 1 714 cm^{-1} (carbonyl).

Anal. Calcd. for $C_{11}H_9O_3N_3S$: C, 50.2; H, 3.45; N, 16.0; mol. wt. 263. Found: C, 50.4; H, 3.4; N, 15.3; mol. wt. 269.

Methyl 5-Amino-2-thenoate

A methanolic solution of 5-nitro-2-thenoic acid containing concentrated sulfuric acid was refluxed for 6 h and poured into water to give the methyl ester (directly pure), m.p. 74.5–75° (lit. (29*a*) m.p. 76°). A solution of the ester (5 g) in methanol (50 ml) was saturated with hydrogen chloride, and the gas stream was maintained while zinc (12 g, in coarse lumps) was added in portions over 30 min, with external cooling. The solution was allowed to stand for a further 30 min, and was then concentrated and treated with 2 *N* hydrochloric acid (100 ml). The slightly cloudy solution was clarified by shaking it with methylene chloride, from which unreacted ester (0.9 g) was recovered, and crushed ice and an excess of concentrated ammonia were added to the aqueous layer. The base was extracted with benzene and precipitated from the dried solution as the granular *hydrochloride* (2.6 g, 60%), m.p. 181–184° (with decomposition), unaltered by recrystallization from methanol, from which it formed colorless plates.

Anal. Calcd. for $C_6H_5O_2ClNS$: Cl, 18.3; N, 7.2. Found: Cl, 18.5; N, 7.1.

The hydrochloride, suspended in ether, was shaken with an excess of 3 *N* ammonia, and the ether layer was separated, washed well with water, dried, and evaporated, giving *methyl 5-amino-2-thenoate* (90%, based on hydrochloride), which crystallized as faintly buff needles, m.p. 85.5–86°, from ether – petroleum ether; ν (CCl_4) 3 480, 3 393 (NH), and 1 710 cm^{-1} (carbonyl).

Anal. Calcd. for $C_6H_7O_2NS$: C, 45.9; H, 4.5; N, 8.9. Found: C, 45.7; H, 4.4; N, 8.8.

Treatment of the amine with benzaldehyde in boiling aqueous methanol gave the *azine*, which formed deep-yellow prisms, m.p. 107.5–108.5°, when recrystallized from methanol.

Anal. Calcd. for $C_{13}H_{11}O_2NS$: N, 5.7. Found: N, 5.7.

Acetylation of the amine with acetic anhydride – acetic acid (1:1) gave the *N-acetyl derivative*, which, after two crystallizations from aqueous methanol, had m.p. 172–173°.

Anal. Calcd. for $C_8H_9O_3NS$: C, 48.2; H, 4.55; N, 7.0. Found: C, 48.3; H, 4.8; N, 7.1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Methyl 5-Hydrazino-2-thenoate Hydrochloride

The amine hydrochloride (1.9 g), dissolved in 12 *N* hydrochloric acid (20 ml), was diazotized by the addition of a solution of sodium nitrite (0.75 g, 1.1 equiv.) in water (10 ml), the internal temperature being kept between 0 and 5°. The hydrochloride dissolved to give an orange-red solution, which was filtered and then immediately added, with stirring, to a solution of tin(II) chloride (10 g) in 12 *N* hydrochloric acid (20 ml). A finely divided suspension formed rapidly, which was filtered off and washed with a small amount of cold 12 *N* hydrochloric acid. Crystallization from methanol containing a small amount of hydrochloric acid gave the *hydrazine hydrochloride* as colorless plates, decomposing above 183° without a definite melting point. Efforts to liberate the free hydrazine with base gave a solid which rapidly darkened and decomposed.

Anal. Calcd. for $C_6H_9O_2ClN_2S$: Cl, 17.0; N, 13.4. Found: Cl, 16.9; N, 13.2.

Equimolar amounts of the hydrochloride and benzophenone were refluxed in aqueous acetic acid to give the *hydrazone*, which crystallized as yellow prisms, m.p. 169.5–170°, from aqueous methanol.

Anal. Calcd. for $C_{19}H_{16}O_2N_2S$: C, 67.85; H, 4.8; N, 8.3. Found: C, 67.3; H, 5.0; N, 8.5.

Gomberg Reaction of Amino-ester in Benzene

The amine hydrochloride (0.79 g) was diazotized as above, and the diazonium solution was filtered and stirred into a mixture of benzene (50 ml) and a solution of an excess of sodium acetate (15 g) in water (30 ml); stirring was continued for over 18 h. The dark-colored benzene layer was washed with dilute sodium hydroxide, dried, and evaporated, and the residue was then refluxed in methanol with charcoal. The methanol solution yielded a light-orange solid (0.14 g), which, on crystallization from petroleum ether (b.p. 60–80°), gave *methyl 5-phenyl-2-thenoate* (0.070 g, 8%) as colorless prisms, m.p. 95–97°.

Anal. Calcd. for $C_{12}H_{10}O_2S$: C, 66.0; H, 4.6; S, 14.7. Found: C, 65.85; H, 4.6; S, 14.95.

Alkaline hydrolysis of a portion of the methyl phenylthenoate gave 5-phenyl-2-thenoic acid, which crystallized from toluene as small plates, m.p. 189–190° (lit. (30) m.p. 187–188°), and which, on decarboxylation with soda lime, gave 2-phenylthiophene, m.p. 34° on admixture with an authentic specimen.

Silver Oxide Oxidation of Hydrazino-ester Hydrochloride in Benzene

The hydrazine hydrochloride (1.05 g) was suspended in dry benzene (25 ml) in a vessel connected to a gas burette, and silver oxide (4.6 g, 4 equiv.) was added. The mixture was stirred for 3 h while the temperature was raised from 20 to 55°, by which time the evolution of nitrogen (91%) was complete, and was then refluxed for 30 min. The faintly yellow solution obtained on filtration was washed with dilute hydrochloric acid (the washings were found to contain no amine) and then with water. After the solution was dried and the solvent evaporated, a crystalline residue of almost pure methyl 5-phenyl-2-thenoate (0.83 g, 85%) was left, m.p. 94–96°, raised to 97–98° by recrystallization from petroleum ether (b.p. 80–100°); it was identical in all respects with the product from the Gomberg reaction.

Silver Oxide Oxidation of Phenylhydrazine Hydrochloride in Nitrobenzene

When the hydrochloride was stirred with silver oxide (2 equiv.) in nitrobenzene at 50°, an exothermic reaction occurred. The whole was then heated at 100° for 2 h and filtered. Gas–liquid chromatographic analysis (silicone gum rubber on Chromosorb W) showed all three nitrobiphenyls in the percentage ratios 54 ortho : 14 meta : 32 para.

Decomposition Reactions of 3-Thenoyl and 5-Nitro-2-thenoyl Peroxides

Dilute solutions of the peroxides in representative solvents were heated at temperatures up to 100° in the dark until decomposition was at least 97% complete (iodometric test). The residues, after removal of the solvent, were extracted with ether; the carboxylic acid was removed from the ethereal solution by repeated shaking with saturated aqueous potassium hydrogen carbonate, and was purified by crystallization from water (3-thenoic acid) or from aqueous ethanol (5-nitro-2-thenoic acid). The neutral ether-soluble fractions were worked up in each case as described below, and the products are summarized in Table I. All yields are in mole percentage of peroxide.

3-Thenoyl Peroxide

Benzene

A solution of the peroxide (15 g) in benzene (1 500 ml) was refluxed for 10 h. The carbon dioxide evolved (33%) was adsorbed on Carbosorb, dry nitrogen being used as the carrier gas. The solution was concentrated at atmospheric pressure and the distillate was analyzed colorimetrically for thiophene (<1%) with isatin – concentrated sulfuric acid (15, p. 16). The residue, on complete removal of the solvent, was extracted with ether (3.3 g insoluble polymer), the ethereal solution giving 3-thenoic acid (91%) and a neutral fraction (3.0 g), which was chromatographed on Norit – Hyflo Super Cel (1:1) with elution by petroleum ether (b.p. 60–80°) followed by chloroform. Only a crude separation was achieved, but re-chromatography on Norit alone gave 3-phenylthiophene as waxy plates, m.p. and mixed m.p. 90°, and phenyl 3-thenoate as prisims, m.p. and mixed m.p. 57°, both being crystallized from petroleum ether. Quantitative g.l.c. (Silicone 550 on C_{22} Firebrick) of the original neutral fraction gave the phenylthiophene (2.3%) and the ester (1.8%).

Toluene

The peroxide (2.55 g) was heated in toluene (255 ml) for 48 h. The first few milliliters of distillate collected at atmospheric pressure was shown by g.l.c. (silicone gum rubber on Chromosorb W) to contain 6% of thiophene. A control experiment, in which 3-thenoic acid was refluxed in toluene for 48 h, showed that no thiophene was produced by decarboxylation. The carboxylic acid fraction (1.95 g), m.p. 125–132°, could not be purified by crystallization, but the main component, 3-thenoic acid (ca. 150%), was isolated in a pure state by sublimation. A portion of the crude acid mixture was refluxed with copper powder in quinoline for 30 min, and the filtered solution was diluted with an excess of dilute hydrochloric acid and extracted with ether, the ethereal solution yielding, on evaporation at 100°, a discolored oil, identified as 2-benzylthiophene by comparison of its infrared spectrum with that of an authentic sample (31); it gave a chloromercuric deviative having m.p. and mixed m.p. 182–183° (32). This established that the acidic contaminant was 2- or 5-benzyl-3-thenoic acid. The neutral fraction (1.63 g) was chromatographed on alumina and eluted with petroleum ether, giving bibenzyl as the only crystalline substance, identified by its mixed melting point. Gas–liquid chromatographic analysis (diethylene glycol succinate on Chromosorb W) showed that this was the main volatile component (0.40 g, 22%), only minor peaks being observed which might be caused by benzyl- or tolyl-thiophenes; at longer retention times two further peaks appeared which comparative g.l.c. with reference samples showed to be caused by *o*-tolyl 3-thenoate (ca. 2%) and benzyl 3-thenoate (a trace). The *m*- and *p*-esters could not be detected.

Chlorobenzene

The peroxide (15 g) was heated in chlorobenzene (1 500 ml) for 30 h. Much tar was formed which was not ether soluble, and the carboxylic acid fraction, on precipitation from the bicarbonate extracts, also formed tar which could not be redissolved in ether; the soluble acid (63%) consisted of 3-thenoic acid only. The neutral ether-soluble material was an orange oil (1.6 g). A portion was chromatographed on Norit – Hyflo Super Cel (1:1) with elution by petroleum ether (b.p. 60–80°) and then chloroform. The first fractions were oily and consisted mainly of 3-chlorophenylthiophenes; the next fractions crystallized and were identified as phenyl 3-thenoate, which crystallized from petroleum ether as prisms, m.p. 55.5–57° and mixed m.p. 56–57° with authentic ester. The final fractions, presumably the chlorophenyl 3-thenoates, were noncrystalline and not amenable to further purification.

A further portion of the neutral oil (0.79 g) was refluxed for 16 h with methanolic sodium hydroxide. After removal of the methanol, the residue was separated into a neutral, a phenolic, and a carboxylic acid fraction. The neutral fraction consisted of a mixture of pure 3-chlorophenylthiophenes (0.44 g, 7.5%).

Anal. Calcd. for $C_{10}H_7ClS$: C, 61.7; H, 3.6; Cl, 18.2; S, 16.5. Found: C, 61.5; H, 3.7; Cl, 18.35; S, 16.6.

Gas–liquid chromatography (diethylene glycol succinate on Chromosorb W) showed 63% of the *o*-isomer, its identity being established by comparison with the synthetic isomer, and 37% of the *m*- plus *p*-isomers, the peaks for these being incompletely resolved. The phenolic fraction, on g.l.c. analysis, gave, in order, *o*-chlorophenol (corresponding to an overall yield of 0.4% *o*-chlorophenyl 3-thenoate), phenol (1.6%), and a mixture of *m*- and *p*-chlorophenyl esters (1.4%, incompletely resolved). The amount of the carboxylic acid fraction (0.29 g) corresponded with the amount of phenols.

Thiophene

Decomposition of the peroxide (4.0 g) in thiophene (100 ml) for 20 h gave 3-thenoic acid (134%) and neutral material, which was thoroughly extracted with hot petroleum ether. A portion of the extracts was chromatographed on Norit – Hyflo Super Cel (1:1) with petroleum ether and chloroform as eluents, giving initially liquid fractions and then crystalline 2-thienyl 3-thenoate, m.p. and mixed m.p. 48–48.5°, after recrystallization (twice) from petroleum ether. Re-chromatography of the liquid under the same conditions gave first a waxy solid melting from 30 to 50°, which was shown (infrared) to be a mixture of 2,2′- and 2,3′-bithienyls, and then pure 2,2′-isomer, mixed m.p. 32° with reference material. Quantitative g.l.c. (diethylene glycol succinate on Chromosorb W) of the original neutral fraction gave, in order, three initial unidentifiable peaks (all in the order of 2 to 7%) (possibly partially reduced bithienyls), 2,2′-bithienyl (8.9%), 2,3′-bithienyl (6.7%), a trace of 3,3′-bithienyl (<1%), and 2-thienyl 3-thenoate (13.4%).

5-Nitro-2-thenoyl Peroxide

Benzene

The peroxide (6.9 g) was refluxed in benzene (400 ml) for 48 h (19% carbon dioxide evolved). After removal of the 5-nitro-2-thenoic acid (104%), the neutral products were extracted with benzene and the benzene-soluble material was chromatographed on Norit – Hyflo Super Cel (1:1). Elution with petroleum ether (b.p. 60–80°) gave crystalline material consisting essentially of biphenyl (0.27 g), m.p. and mixed m.p. 68°, after crystallization from petroleum ether; further elution with petroleum ether – benzene (3:1) gave crystalline phenyl 5-nitro-2-thenoate (0.51 g, 11%), recrystallized from petroleum ether as prisms, m.p. 92–92.5°, undepressed on admixture with authentic ester.

Gas–liquid chromatographic analysis (silicone gum rubber on Chromosorb W) of the benzene solution of neutral products showed the biphenyl, a compound identified as 2-phenyl-5-nitrothiophene (see below), and the phenyl ester, but no 2-nitrothiophene.

Benzoyl peroxide (2 g) was heated in 2-nitrothiophene (10 g) for 48 h. The whole was then dissolved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

benzene, and benzoic acid was removed in the usual way. Distillation of the neutral solution to remove most of the 2-nitrothiophene gave a residue, which was chromatographed on alumina with ether – petroleum ether to give residual 2-nitrothiophene and then a mixture of isomeric phenylnitrothiophenes (directly pure) melting between 113 and 130°.

Anal. Calcd. for $C_{10}H_7O_2NS$: C, 58.5; H, 3.4; N, 6.8; S, 15.6. Found: C, 58.4; H, 3.7; N, 6.7; S, 15.3.

Gas–liquid chromatographic analysis showed three components; the least volatile was identical under all conditions of chromatography with the above compound found in the chromatogram of the nitrothenoyl peroxide decomposition products. This compound, 2-phenyl-5-nitrothiophene, was the least abundant of the three phenylation products, the ratios of which were, in order, 5:16:1.

Toluene

The peroxide (6.1 g) was heated in toluene (610 ml) for 48 h (19% carbon dioxide evolved). The carboxylic acid (122%) was removed, and the neutral residue from the toluene solution was dissolved in benzene and analyzed by g.l.c. (silicone gum rubber on Chromosorb W). The chromatogram showed 2-nitrothiophene (<1%, but a control experiment proved that it did *not* arise by decarboxylation of the acid), bibenzyl (3.4%), and the much less volatile benzyl ester, in larger amounts. Column chromatography on Norit – Hyflo Super Cel (1:1) with petroleum ether as eluent gave oily fractions containing 2-nitrothiophene and bibenzyl, and with petroleum ether – benzene as eluent gave crystalline benzyl 5-nitro-2-thenoate (14%), m.p. 90–90.5°, after recrystallization from petroleum ether, undepressed on admixture with reference ester, with which it had an identical infrared spectrum.

CYCLIZATIONS OF DIALDEHYDES WITH NITROMETHANE

XIII. SYNTHESIS OF TREHALOSE-TYPE DISACCHARIDES CONTAINING NITROGENOUS HEPTULOSES[1,2]

HANS H. BAER AND ALAUDDIN AHAMMAD[3]
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received July 25, 1966

ABSTRACT

The dialdehyde II that arises from a partial lead tetraacetate cleavage of sucrose has been cyclized with nitromethane to give a stereoisomeric mixture of nitro disaccharides IV via their sodium nitronates III. Upon catalytic hydrogenation a single amino disaccharide, α-D-glucopyranosyl 4-amino-4-deoxy-β-D-*gluco*-heptulopyranoside hydrochloride (V), was isolated. Various derivatives of the nitrogenous heptulose components of IV and V were prepared by methanolysis and hydrolysis. The configuration of V was established by a degradation of its *N*-acetylated hydrolysis product, 4-acetamido-4-deoxy-α-D-*gluco*-heptulose (VII), which gave 2-amino-2-deoxy-D-arabinose hydrochloride, and by reduction of VII, which gave the two epimeric acetamido heptitols XIII and XIV.

INTRODUCTION

In a continuation of studies concerned with the cyclization of dialdehydes with nitromethane (1), a method which has proved to be particularly useful for the synthesis of nitrogenous sugars and cyclitols (2, 3), it was decided to approach the synthesis of disaccharides that belong to the nonreducing trehalose type. This project appeared of interest not only from the viewpoint of broadening the scope of the nitromethane synthesis by application to the disaccharide field but also because of the discovery (4) of an antibiotic, α,α-trehalosamine (I), which stimulated research on nonreducing amino disaccharides, a class that has received scant attention to date.

It was considered that the dialdehyde II, which, according to Mitra and Perlin (5), is readily obtainable from sucrose by partial lead tetraacetate oxidation, should give rise to disaccharides of the general structure IV. This structure is related to I, although the nitrogen function is in a different position and the nitrogenous moiety is a heptulose rather than a hexose. Apart from any potential biological activity, the synthesis of such a structure would, in itself, be of interest. It would be the first example of an oligosaccharide containing a nitrogenous seven-carbon sugar. Moreover, the nitro and amino heptuloses that could conceivably be obtained from it should add to a relatively sparse knowledge about this type of sugar, of which the first few derivatives[4] have only recently become available (6).

RESULTS

Synthesis

Dialdehyde II was cyclized with nitromethane in methanolic solution in the presence of sodium methoxide, and a mixture of *aci*-nitro disaccharide sodium salts III was obtained in a yield of 58%. Since the glucose moiety of the original sucrose is not involved in the reactions leading to II and III, and since the configurations at C-2 and C-5 of the fructose

[1]*For part XII in this series, see ref. 1.*
[2]*A brief account of this work has been given by H. H. Baer before the International Symposium on Nitro Compounds, Warsaw, Poland, September 1963 (2). This work forms part of a Ph.D. thesis submitted by A. Ahammad to the University of Ottawa, Ottawa, 1964.*
[3]*Recipient of a Canadian Commonwealth Scholarship, 1961–1964.*
[4]*These are the 2,7-anhydro-4-nitro(and amino)-4-deoxy-β-D-heptulopyranoses with allo, altro, and gulo configurations.*

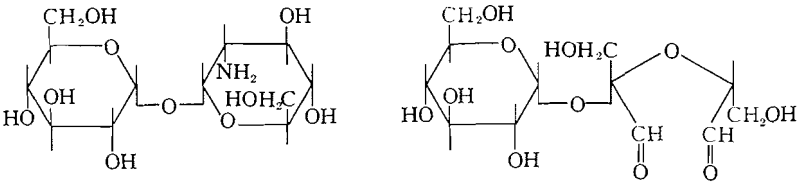
moiety can also be presumed to remain unaffected, the salts III may be designated as α-D-glucopyranosyl 4-*aci*-nitro-4-deoxy-β-D-heptulopyranoside sodium salts. Deionization of this mixture of nitronates gave an amorphous mixture of the corresponding free-nitro disaccharides IV; paper chromatography revealed the presence of two components in similar quantities.

Catalytic hydrogenation of IV to the corresponding amines proceeded readily, and from the hydrogenated mixture a pure disaccharide crystallized as the hydrochloride (yield, 23% based on starting sucrose). The compound proved to be α-D-glucopyranosyl 4-amino-4-deoxy-β-D-*gluco*-heptulopyranoside hydrochloride (V), as will be demonstrated in a subsequent section. *N*-Acetylation produced a crystalline *N*-acetate VI. One has to assume that at least a second, stereoisomeric amino disaccharide arose from the mixture IV, but no attempt has been made to isolate or characterize it.

Hydrochloric acid hydrolysis of V produced D-glucose and (amorphous) 4-amino-4-deoxy-D-*gluco*-heptulose hydrochloride. The former was detected by paper chromatography and the latter was characterized as the crystalline *N*-acetate, 4-acetamido-4-deoxy-α-D-*gluco*-heptulose (VII), after isolation by means of a cation-exchange resin. The anomeric configuration of VII was assigned on the basis of a downward mutarotation, $[\alpha]_D$ +66 → +55°.

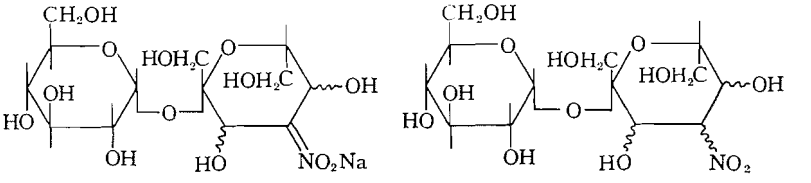
Methanolysis of V catalyzed by 5% hydrogen chloride gave crystalline methyl α-D-glucopyranoside and methyl 4-amino-4-deoxy-α-D-*gluco*-heptulopyranoside hydrochloride (VIII). The glycoside VIII gave a pentaacetate IX and was converted, by successive hydrolysis and *N*-acetylation, into the reducing acetamido sugar VII.

The same amino glycoside hydrochloride VIII was also obtained in another way. Methanolysis of the mixture of nitro disaccharides IV gave, besides methyl α-D-glucopyranoside, a nitro heptuloside X which crystallized upon purification via its 1,3;5,7-di-*O*-benzylidene derivative XI. Catalytic reduction of X in the presence of 1 equivalent of hydrochloric acid then produced VIII, thus proving X to be methyl 4-deoxy-4-nitro-α-D-*gluco*-heptulopyranoside.



The α-anomeric configuration of VIII (and therefore also of X) follows from a consideration of the molecular rotations. The disaccharide V (M_D +42 054) may be regarded as a methyl α-D-glucopyranoside (M_D +30 691) in which a 4-amino-4-deoxy-β-D-*gluco*-heptulopyranosyl residue (as its hydrochloride) has been substituted for the optically inactive methyl group. The difference in the M_D values (+11 363) may serve as an approximate value for the contribution made by the β-heptuloside moiety in the disaccharide. Since the M_D value of VIII (+25 613) is considerably more positive, it is concluded that VIII is the α-anomer.

Establishment of the gluco Configuration



The key compound used for the establishment of the configuration of V–XI was the reducing acetamido heptulose VII. It was necessary to determine only the stereochemistry at its carbon atoms 3, 4, and 5, the configuration at C-6 being known from the origin of the molecule, namely, the D-fructofuranosyl moiety of sucrose.

The configurations at C-4 and C-5 were elucidated, and that of C-6 was confirmed, by a partial lead tetraacetate (LTA) oxidation. Perlin and Brice (7) have demonstrated that ketoses are cleaved, by a limited amount of oxidant, preferentially between the reducing center and the adjacent ring carbon (and not the adjacent hydroxymethyl group). The degradation thus results in removal of the top two carbons of the ketose chain, producing a lower aldose. In the present case, VII gave rise to known 2-acetamido-2-deoxy-D-arabinose and, upon acid hydrolysis, to known 2-amino-2-deoxy-D-arabinose hydrochloride (XII).

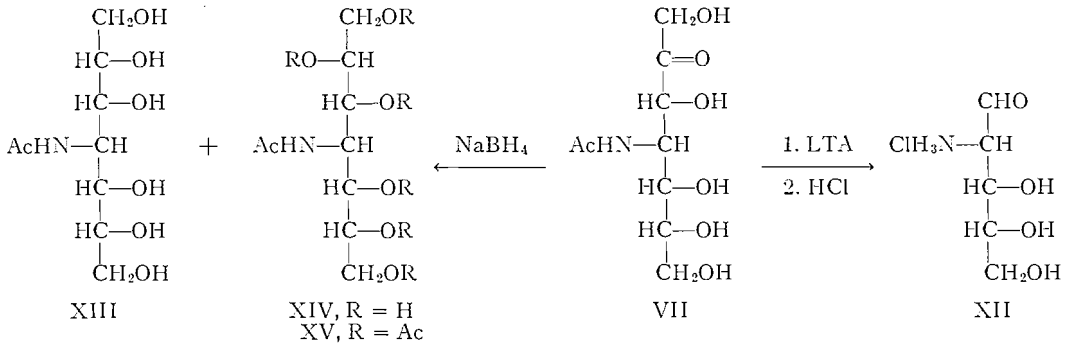
IX R = NHAc, R′ = Ac
X R = NO_2, R′ = H

XI



Since C-2, C-3, and C-4 in D-arabinosamine correspond to C-4, C-5, and C-6, respectively, in the heptulose, the only remaining configuration yet to be determined was at C-3. It was possible to make this assignment upon reduction of VII with sodium borohydride, whereby two epimeric 4-acetamido-4-deoxy heptitols (XIII and XIV) were formed.[5] One of these crystallized directly and was found to be *optically inactive*; the other was obtained from the mother liquor as an optically active ($[\alpha]_D$ +30°) crystalline heptaacetate. This result requires VII to possess the D-*gluco* configuration (i.e. the hydroxyl on C-3 to the right in the Fischer projection), for only then can an inactive (*meso*) heptitol arise. The inactive product must be 4-acetamido-4-deoxy-D-*glycero*-D-*gulo*-heptitol (XIII), and its active epimer must be 4-acetamido-4-deoxy-D-*glycero*-D-*ido*-heptitol (XIV). If VII had possessed the D-*manno* configuration (i.e. with the hydroxyl on C-3 to the left), then two optically active reduction products would have been expected.

EXPERIMENTAL

Melting points were determined in an electrically heated aluminium block apparatus. All evaporations were done *in vacuo* at 35–40° (bath temperature) unless otherwise indicated. Paper chromatography was performed by the descending technique on Whatman No. 1 paper. The nitro compounds were irrigated with 1-butanol – acetic acid – water (4:1:5 v/v/v, upper layer) and made visible by spraying with alkali (*N* sodium hydroxide – methanol – 1-butanol (1:4:5 v/v/v) and inspection under an ultraviolet lamp. The

[5] *We are obliged to Mr. F. Kienzle for carrying out these experiments.*

For personal use only.

amino compounds were irrigated with the Fischer–Dörfel system (8) and detected with ninhydrin (R_{gm} is the speed relative to glucosamine hydrochloride). The acetamido compounds were chromatographed with 1-butanol–pyridine–water (6:4:3 v/v/v) and indicated according to Pan and Dutcher (9).

Lead Tetraacetate Oxidation of Sucrose to Dialdehyde II (5)

To a solution of sucrose (10 g, 29.2 mmoles) in 500 ml of water was added 500 ml of glacial acetic acid and then, with vigorous stirring, 12.4 g (28 mmoles) of lead tetraacetate. The oxidation was allowed to proceed for 30 min at room temperature. Divalent lead was removed by stirring the solution with about 130 ml of Rexyn RG 50 (H^+ form). The filtrate was concentrated, and most of the remaining solvent was removed by several co-distillations with ethanol and toluene. A white solid was obtained that was suitable for the next step without purification, as a possible presence of some unreacted sucrose was considered unobjectionable.

α-D-Glucopyranosyl 4-aci-Nitro-4-deoxy-β-D-heptulopyranoside Sodium Salts (III)

The crude dialdehyde II (from 10 g of sucrose) was dissolved in 85 ml of absolute methanol. The solution was chilled in an ice bath, and 1.6 ml of nitromethane and 23 ml of sodium methoxide solution (3 g of sodium per 100 ml of methanol) were added, with stirring. The amounts of reagents added corresponded to 1 equivalent each, based on the amount of starting sucrose. A yellowish-white precipitate began to appear within about 15 min. Cooling and stirring were continued for 1 h, after which the stoppered flask was kept in a refrigerator for another 4 h. The precipitate was collected on a Büchner funnel, washed quickly with ice-cold methanol, and immediately placed in a vacuum desiccator. The dried product (III) weighed 7.2 g (yield, 58.5% based on sucrose), showed $[\alpha]_D^{23}$ +46.9° (*c*, 1 in water), and decomposed on heating, with darkening around 100° and foaming at 119–120°. Unless proper care is taken during isolation, the material tends to absorb moisture and become syrupy; when carefully washed and dried, however, the solid is fairly stable and can be stored in a desiccator in the cold. In an aqueous solution, the salt exhibits strong ultraviolet absorption which undergoes a peculiar bathochromic shift on heating (λ_{max} 250 → 299 mμ). This phenomenon has been investigated recently (10).

Anal. Calcd. for $C_{13}H_{22}O_{13}NNa$ (423.3): N, 3.31; Na, 5.43. Found: N, 3.26; Na, 5.39.

α-D-Glucopyranosyl 4-Nitro-4-deoxy-β-D-heptulopyranosides (IV)

Sodium salt III (5 g) was suspended in about 100 ml of methanol, and the suspension was treated at ice-bath temperature with an excess (50 ml) of Rexyn RG 50 (H^+ form) that had been washed well with methanol. The salt dissolved, and the deionized, faintly yellowish filtrate from the resin was evaporated to give a syrup that was further evaporated with two successive additions of ethanol. There resulted a near-colorless, hygroscopic froth which sintered at about 60° and foamed at 85°, $[\alpha]_D^{23}$ +73.4° (*c*, 1 in water). Paper chromatography showed two spots, R_f 0.23 and 0.30, presumed to represent stereoisomeric disaccharides IV.

α-D-Glucopyranosyl 4-Amino-4-deoxy-β-D-gluco-heptulopyranoside Hydrochloride (V)

A sample of the disaccharide mixture IV (1.26 g) in 5 ml of water was added to 31 ml of 0.1 *N* hydrochloric acid (1 equivalent) containing prehydrogenated catalyst from 1 g of platinum dioxide. Hydrogenation was performed, with efficient shaking, at normal temperature and pressure over a period of 3.5 h, during which 186 ml of hydrogen was consumed. The catalyst was filtered off and the solution was evaporated to give a colorless syrup. Excess acid was removed by several co-evaporations with water. Finally, the syrup was evaporated twice with ethanol to give a white solid that crystallized from methanol – ethyl acetate containing a few drops of water. The yield was 500 mg. The product was recrystallized by dissolution in the minimum amount of water and dropwise addition of glacial acetic acid to incipient turbidity, m.p. 197° (decomp.), R_{gm} 0.88, $[\alpha]_D^{23}$ +103.2° (*c*, 0.5 in water).

Anal. Calcd. for $C_{13}H_{26}O_{11}NCl$ (407.5): C, 38.31; H, 6.45; N, 3.43; Cl, 8.71. Found: C, 38.36; H, 6.58; N, 3.63; Cl, 8.62.

For personal use only.

α-D-Glucopyranosyl 4-Acetamido-4-deoxy-β-D-gluco-heptulopyranoside (VI)

Amino dissacharide hydrochloride V (314 mg) was dissolved in 4.5 ml of water and 0.6 ml of methanol. *N*-Acetylation (11) was carried out by treatment with 5 ml of Dowex-1 (CO_3^{2-} form) and 0.1 ml of acetic anhydride for 90 min, at 3°, with magnetic stirring. The resin was filtered off and washed exhaustively with water, and the combined filtrate and washings were stirred briefly with 2 ml of Dowex-50 (H^+ form). The filtrate was evaporated to a colorless syrup that was dehydrated with ethanol, giving an amorphous solid. Crystallization occurred from ethanol (2 ml) upon addition of a few drops of ethyl acetate, m.p. 151–152°, $[\alpha]_D^{23}$ +84° (*c*, 0.5 in water). The product VI was chromatographically uniform, R_f 0.32.

Anal. Calcd. for $C_{15}H_{27}O_{12}N$ (413.4): C, 43.57; H, 6.58; N, 3.39. Found: C, 43.52; H, 6.71; N, 3.23.

Hydrolysis of Disaccharide V

In a preliminary experiment, a 1% solution of V in 2 *N* hydrochloric acid was heated on a steam bath, and samples for chromatography were withdrawn from time to time. The absence of V was noted after 20 min of hydrolysis.

Disaccharide V (535 mg) in 50 ml of 2 *N* hydrochloric acid was heated on a steam bath for 50 min. The slightly yellow hydrolysate, which reduced Fehling solution strongly, was evaporated, the excess acid being removed by several subsequent evaporations with water. The resulting syrup was dissolved in 4 ml of water and poured onto a narrow column containing 22 ml of Rexyn RG 50 (H^+ form). The column was eluted with 250 ml of water at a rate of 30 drops per min. Evaporation of this eluate gave a syrupy residue that weighed 210 mg upon dehydration with absolute ethanol and drying in a high vacuum. The material gave a negative ninhydrin test and was indistinguishable from glucose on paper chromatograms sprayed with aniline hydrogen phthalate.

Elution of the column was then continued with 250 ml of *N* hydrochloric acid. The colorless, ninhydrin-positive eluate was brought to a syrup, and residual acid was removed by several evaporations with water. Finally, the syrup was evaporated with ethanol to give an amorphous powder (310 mg) of 4-amino-4-deoxy-D-*gluco*-heptulose hydrochloride, which failed to crystallize from common solvents.

4-Acetamido-4-deoxy-α-D-gluco-heptulose (VII)

The amorphous amino sugar hydrochloride just described was *N*-acetylated (11) by treating its solution in 8 ml of water and 1 ml of methanol with 9 ml of Dowex-1 (CO_3^{2-} form) and 0.18 ml of acetic anhydride. The procedure was the same as that given above for the preparation of VI. The *N*-acetate VII crystallized from ethanol (2 ml) containing a few drops of ethyl acetate, in a yield of 150 mg. Upon one recrystallization from ethanol it had m.p. 171–172° (decomp.), $[\alpha]_D^{23}$ +66.0 (3 min) → +55.0° (45 min, final; *c*, 0.5 in water), and R_f 0.48.

Anal. Calcd. for $C_9H_{17}O_7N$ (251.2): C, 43.02; H, 6.77; N, 5.58. Found: C, 43.10; H, 6.91; N, 5.70.

The compound reduced Fehling and Benedict solutions, but did not respond to an *o*-naphthoresorcinol test in which (nitrogen-free) ketoses usually produce a red color.

Methanolysis of Disaccharide V

A sample of disaccharide V (240 mg) was refluxed for 7.75 h with 20 ml of methanol containing 1 g of hydrogen chloride. The brown solution was brought to dryness, and the residue was evaporated with water several times, decolorized with activated charcoal, and brought to dryness again. From ethanol – ethyl acetate crystallized[6] 25 mg of needles having m.p. 173–174° (decomp.), R_{gm} 1.15, and $[\alpha]_D^{23}$ +98.0° (*c*, 0.5 in water). The identity of the product with methyl 4-amino-4-deoxy-α-D-*gluco*-heptulopyranoside hydrochloride (VIII) obtained from X (below) was confirmed by comparison of the infrared spectra and by an undepressed mixture melting point.

A second crop of crystals (30 mg) was deposited when the mother liquor was allowed to stand in a refrigerator, m.p. 158–160°, $[\alpha]_D^{23}$ +126.5° (*c*, 0.5 in water). Chromatographically, this crop showed only one ninhydrin-positive spot (R_{gm} 1.18). The infrared spectrum was slightly different from that of VIII. Possibly, the material was VIII accompanied by some methyl glucopyranoside; it was not investigated further.

Addition of some more ethyl acetate to the mother liquor and continued storage at 4° gave a third crop of crystals (20 mg), which melted at 161–162°. Recrystallization from ethanol gave needles of pure methyl α-D-glucopyranoside, m.p. 166°, $[\alpha]_D^{23}$ +158.0° (*c*, 0.5 in water), in agreement with the literature (12).

Methanolysis of the Disaccharide Mixture IV

Nitro disaccharide mixture IV (4.3 g) was refluxed for 3.5 h in 400 ml of methanol containing 8 g of hydrogen chloride. The dark-brown solution was treated with activated charcoal, whereby it became pale yellow; it was then evaporated, with several additions of water towards the end. The resulting syrup still was acidic; it was therefore dissolved in 100 ml of water, and the pH was adjusted to about 5 by stirring the solution with Amberlite IR-45 (OH^- form). The resin was washed well with water, the filtrate evaporated, and the syrupy residue freed from remnant water by means of ethanol. The material was then dissolved in a small amount of hot ethanol; addition of a little ethyl acetate and cooling (4°) gave 0.9 g of crystals that were identified, after one recrystallization from ethanol, as methyl α-D-glucopyranoside, having m.p. 166° and $[\alpha]_D^{23}$ +158.8° (*c*, 1 in water) (12).

[6] *Upon seeding with VIII that had been obtained from X (see a subsequent section).*

Methyl 1,3;5,7-Di-O-benzylidene-4-nitro-4-deoxy-α-D-gluco-heptulopyranoside (XI)

The ethanol – ethyl acetate mother liquor of the preceding experiment was presumed to contain X and probably one or more isomers. Evaporation gave a noncrystallizable syrup (3 g). Zinc chloride (3.6 g) and benzaldehyde (15 ml) were added to the syrup, and the mixture was stirred at room temperature for 24 h. Water (40 ml) and petroleum ether (20 ml, b.p. 30–60°) were then added, and the heterogeneous system was stirred for 15 min. This resulted in the separation of a semicrystalline mass, which was collected and washed twice with water and twice with petroleum ether. The crude product, when air-dried and recrystallized from chloroform, gave pure dibenzylidene derivative XI as fine needles (1.0 g), m.p. 285–286°. Compound XI was soluble in hot chloroform, hot dimethylformamide, and hot dioxane, but only sparingly so in hot ethanol. Solubility in cold solvents was very slight.

Anal. Calcd. for $C_{22}H_{23}NO_8$ (429.4): C, 61.53; H, 5.36; N, 3.26. Found: C, 61.45; H, 5.52; N, 3.18.

Methyl 4-Nitro-4-deoxy-α-D-gluco-heptulopyranoside (X)

A suspension of dibenzylidene derivative XI (3.05 g) in 450 ml of methanol–water (4:1 v/v) was magnetically stirred and heated under reflux with 18 g of Dowex 50W-X8 (H^+ form) for 44 h. Evaporation of the reaction solution gave a crystalline residue, which was freed from the last traces of water by two evaporations with ethanol. Recrystallization from ethyl acetate gave 1.39 g of debenzylidenated nitro glycoside X, m.p. 157–158°, $[\alpha]_D^{23}$ +102° (*c*, 0.5 in water). (For the ultraviolet absorption spectrum of X in alkaline solution and its change upon heating, see ref. 10.)

Anal. Calcd. for $C_8H_{15}O_8N$ (253.2): C, 37.95; H, 5.93; N, 5.53. Found: C, 38.19; H, 6.00; N, 5.60.

Methyl 4-Amino-4-deoxy-α-D-gluco-heptulopyranoside Hydrochloride (VIII)

Nitro glycoside X (1.13 g) in 5 ml of water and 45 ml of 0.1 *N* hydrochloric acid was hydrogenated with 0.60 g of prehydrogenated platinum dioxide catalyst. The hydrogen consumption at room temperature and atmospheric pressure was 300 ml. The filtrate was treated with a small amount of Amberlite IR-45 (OH^- form) to adjust the pH to about 5. Evaporation, ultimately with added ethanol, gave a crystalline residue, that was recrystallized from ethanol – ethyl acetate with a few drops of water to give 700 mg of fine needles of VIII, m.p. 170–172° (decomp.), R_{gm} 1.15, $[\alpha]_D^{23}$ +98.7° (*c*, 0.5 in water).

Anal. Calcd. for $C_8H_{18}NO_6Cl$ (259.5): C, 36.99; H, 6.93; N, 5.39. Found: C, 37.20; H, 6.93; N, 5.19.

Conversion of VIII into VII

Amino glycoside hydrochloride VIII (842 mg) was hydrolyzed with 85 ml of 2 *N* hydrochloric acid on a steam bath for 1 h. Removal of the acid by evaporation gave an amorphous, reducing amino sugar (R_{gm} 0.95), which was *N*-acetylated under the conditions described above for the preparations of VII and VI. In the present case, 19 ml of water, 2.25 ml of methanol, 0.42 ml of acetic anhydride, and 21 ml of Dowex-1 (CO_3^{2-} form) were employed. Acetamido sugar VII (550 mg) crystallized from 5 ml of ethanol upon addition of a small amount of ethyl acetate, m.p. 173–175° (decomp.), R_f 0.48, $[\alpha]_D^{23}$ +66.6 (3 min) → +53° (45 min, final; *c*, 0.5 in water). An undepressed mixture melting point and a comparison of infrared spectra confirmed its identity with VII obtained from V.

Methyl 4-Acetamido-4-deoxy-1,3,5,7-tetra-O-acetyl-α-D-gluco-heptulopyranoside (IX)

Amino glycoside hydrochloride VIII (250 mg) was acetylated in 5 ml of pyridine and 2 ml of acetic anhydride for 24 h at room temperature. The reaction mixture was poured onto 40 g of crushed ice and, after decomposition of the excess anhydride, it was extracted with four 15 ml portions of chloroform. The extract was dried over sodium sulfate and evaporated, the last traces of pyridine being removed by co-distillation with toluene. The pentaacetate IX was obtained as a gel from ethanol; drying in a high vacuum gave 140 mg of a microcrystalline white powder having m.p. 191–192°, R_f 0.86, and $[\alpha]_D^{23}$ +75° (*c*, 0.5 in chloroform).

Anal. Calcd. for $C_{18}H_{27}NO_{11}$ (433.4): C, 49.88; H, 6.28; N, 3.24. Found: C, 49.85; H, 6.37; N, 3.19.

Degradation of 4-Acetamido-4-deoxy-D-gluco-heptulose (VII) to 2-Amino-2-deoxy-D-arabinose Hydrochloride (XII)

Acetamido heptulose VII (249 mg) was dissolved in 2.1 ml of water, and 120 ml of glacial acetic acid was added. Into the stirred solution was introduced 444 mg (1 equivalent) of finely powdered lead tetraacetate. After 10 min a 10% solution of oxalic acid in glacial acetic acid was added dropwise until no more lead oxalate precipitated; stirring was continued for another 30 min. The lead oxalate was filtered off and washed with glacial acetic acid, and the filtrate was evaporated with several additions of water. The material so obtained was treated briefly with 12 ml of Dowex-1 (HCO_3^- form) in about 20 ml of water. The colorless filtrate and washings from the resin were combined, concentrated to a volume of 15 ml, and then warmed with 120 mg of sodium bicarbonate for 30 min at 50°. Upon deionization with Dowex 50W-X8 (H^+ form) and evaporation, a colorless syrup was obtained that gave a positive Morgan–Elson color test for 2-acetamido sugars and had the same mobility on paper as a co-chromatographed authentic sample[7] of 2-acetamido-2-deoxy-D-arabinose. The syrup was then hydrolyzed for 2 h on a steam bath with 21 ml of 0.3 *N* hydrochloric acid. The hydrolysate was brought to dryness and dissolved in a small amount of methanol. A few drops of

For personal use only.

ethanol were added, and crystallization was allowed to take place slowly in an open dish. Crystalline 2-amino-2-deoxy-D-arabinose hydrochloride (XII) was collected in a yield of 68 mg (washed with ethanol and dried). The melting point, 155–156° (decomp.), and rotation, $[\alpha]_D^{23}$ −123° (*c*, 0.5 in water), were in agreement with the literature data (13), m.p. 154–157° and $[\alpha]_D$ −124°. A mixed melting point with an authentic sample[7] was 155–156° (decomp.), and identical infrared spectra and R_{gm} values (1.08) were obtained.

*Sodium Borohydride Reduction of 4-Acetamido-4-deoxy-*D*-gluco-heptulose*

*4-Acetamido-4-deoxy-*D*-glycero-*D*-gulo-heptitol (XIII)*

Acetamido heptulose VII (100 mg) and sodium borohydride (100 mg) were dissolved in 7 ml of water at room temperature. After 18 h the solution was deionized with 5 ml of Rexyn RG 50 (H^+ form) and evaporated. The residue was evaporated six times with 10 ml portions of methanol to remove the boric acid. Slow crystallization of XIII occurred during several days when a concentrated aqueous solution was left in a small dish in the air. The crystals were isolated by trituration with water-containing ethanol and melted at 149–151°; yield, 47 mg. For analysis the product was recrystallized from 95% ethanol, giving long prisms that melted at 154°. Thin-layer chromatography on silica gel G with 1-butanol–pyridine–water (2:1.2:0.7 v/v/v) gave only one spot. The optical rotation was found to be zero in water (*c*, 1.3) as well as in half-saturated sodium tetraborate solution (*c*, 0.65).

Anal. Calcd. for $C_9H_{19}NO_7$ (253.3): C, 42.69; H, 7.56. Found: C, 42.62; H, 7.80.

*4-Acetamido-4-deoxy-1,2,3,5,6,7-hexa-O-acetyl-*D*-glycero-*D*-ido-heptitol (XV)*

The aqueous ethanol with which the crystals of XIII had been triturated for isolation gave, on thin-layer chromatography, a weak spot of XIII and a strong spot that moved more slowly and was presumed to represent the isomer XIV. Evaporation yielded 51 mg of an amorphous material having $[\alpha]_D^{23}$ +9.8° (*c*, 1.25 in water). The material was acetylated with 0.5 ml of acetic anhydride in 1 ml of pyridine (18 h, room temperature). Work-up by the common chloroform extraction procedure resulted in a syrupy acetate (XV), which crystallized as fine, colorless needles (30 mg, m.p. 139–140°) from ethyl acetate – petroleum ether (b.p. 30–60°). Recrystallization from the same solvents yielded 22 mg of XV melting at 140° and having $[\alpha]_D^{23}$ +30° (*c*, 0.8 in chloroform).

Anal. Calcd. for $C_{21}H_{31}NO_{13}$ (505.5): C, 49.90; H, 6.14. Found: C, 49.88; H, 6.31.

THE ORTON REARRANGEMENT IN APROTIC SOLVENTS

III. THE ACID-CATALYZED CHLORINATION OF ANISOLE BY A SERIES OF 4-SUBSTITUTED *N*-CHLOROACYLANILIDES

JOHN M. W. SCOTT AND JUNE G. MARTIN
Memorial University of Newfoundland, St. John's, Newfoundland

Received January 5, 1966

ABSTRACT

Anisole has been chlorinated with a sequence of chlorinating agents generated by the reaction of a series of 4-substituted *N*-chloroacylanilides (4-X-C_6H_4NClAc (X = Me, H, and CN)) with a series of carboxylic acids (R—COOH (R = CF_3, CCl_3, CH_2Cl, and CH_3)). The isomer ratios of the 2- and 4-chloroanisoles produced in these reactions have been measured for each *N*-chloroacylanilide – carboxylic acid pair, and are found to be dependent on the strength of the catalyzing acid but independent of the structure of the *N*-chloroacylanilide within the precision of the reported data. These observations are consistent with both the termolecular scheme proposed in part II of this series and the Soper mechanism. However, evidence derived from these and other observations suggests that the termolecular scheme is still the most probable mechanism for the chlorine transfer reaction.

INTRODUCTION

In a previous communication (1) the acid-catalyzed bromination of anisole by a sequence of reagents generated by the reaction of a series of 4-substituted *N*-bromoacylanilides (NBAA's) with a series of carboxylic acids was investigated. These experiments demonstrated that the product ratio of 2-bromoanisole to 4-bromoanisole depended on the structure of both the NBAA and the carboxylic acid, which suggested that the mechanism originally proposed by Soper and his co-workers (2) was inadequate. The new results were interpreted in terms of a product-determining termolecular transition state, and the mechanism involving the intermediate production of acylhypobromites was rejected. A similar study has now been carried out with a series of *N*-chloroacylanilides (NCAA's), and the results of this investigation are reported below.

EXPERIMENTAL

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Nuclear magnetic resonance spectra were measured on a Varian A.60 instrument, and peaks are reported on the τ scale.

Product analyses were determined by vapor-phase chromatography as described in part II (1) of the present series. The measurement of the product ratio (*R*) of 2- to 4-chloroanisole required the following instrument conditions: column oven 95 °C, detector oven 158 °C, and injector oven 184 °C. The inlet pressure was 20 p.s.i. and the flow rate was 25 ml He min^{-1}. The retention times for the three monosubstituted chloroanisoles and 2,4-dichloroanisole under these conditions are given in Table I. Biphenyl was used as an internal standard in the determination of the yield of the chloroanisoles with the following instrument conditions: column oven 139 °C, injector oven 196 °C, and detector oven 167 °C. The helium flow rate was the same as that given above. Under the latter conditions 4-chloroanisole had a retention time of 5.66 min, and biphenyl 8.30 min.

Materials

Acetanilides

The acetanilides used in the present study either were commercial samples or were obtained by acylation of the appropriate amine with acetic anhydride. The melting points of these materials were in satisfactory agreement with those previously reported.

N-Chloroacetanilides

The 4-substituted *N*-chloroacetanilides were prepared by dissolving the anilide in the minimum amount of 1,2-dimethoxyethane and adding this solution dropwise, with vigorous stirring, to a twofold excess of aqueous NaClO–$NaHCO_3$ cooled to 0 °C. The precipitated *N*-chloro compound was collected, thoroughly washed

with cold water, and then dried in a vacuum over anhydrous calcium chloride. Samples were then purified by crystallization from chloroform and light petroleum (b.p. 40–60°), and the active chlorine was determined iodometrically.

Chloroanisoles

2-Chloroanisole was obtained commercially. 3-Chloroanisole was prepared by the Sandmeyer reaction from 3-anisidine, and 4-chloroanisole was obtained by methylating 4-chlorophenol with dimethyl sulfate. 2,4-Dichloroanisole was prepared by chlorinating 4-chloroanisole in carbon tetrachloride. All these materials gave a single peak when examined by vapor-phase chromatography. The physical properties of these materials are reported in Table I.

Acid Solutions

These were identical with those used in part II of the present series.

Method

The reactions were carried out as described for the NBAA experiments (1). The thermostat temperature was raised to 50.00 ± 0.02 °C so that the reactions were complete in a convenient period of time. The chloroanisole isomer ratios for each NCAA–acid pair are reported in Tables II–IV together with the ratios for the photochemical chlorinations, which were considerably less than those observed for the acid-catalyzed substitutions. The photochemical R values for *N*-chloroacetanilide and *N*-chloro-4-methylacetanilide were identical, but the R value for *N*-chloro-4-cyanoacetanilide for the light-catalyzed reaction was smaller than that observed for the 4-methyl and the unsubstituted NCAA. In view of the fact that R (photochemical) $< R$ (acid-catalyzed) in all cases, this anomaly was not investigated further. The recovery of the nitrogen-bound chlorine as chloroanisoles averaged 80–90%. The fate of the remaining chlorine was not established, but the possibility of some rearrangement accompanying the chlorine transfer reaction cannot be ruled out (cf. part II and ref. 2).

TABLE I

The physical properties of some chloroanisoles

Substance	Boiling point (°C)	Retention time* (min)	Nuclear magnetic resonance data†	
			MeO	Aromatic protons
2-Chloroanisole	101 at 25 mm	12.90	6.39	2.6–3.5
3-Chloroanisole	84 at 13 mm	9.53	6.50	2.8–3.5
4-Chloroanisole	45 at 1 mm	10.32	6.47	3.66 (2H) 2.88 (3H)
2,4-Chloroanisole	—	29.57	—	—

*For instrument conditions see the Experimental.
†Neat samples containing tetramethylsilane.

Kinetic Experiments

Some kinetic experiments were carried out with *N*-chloroacetanilide and *N*-chloro-4-cyanoacetanilide by the method described in part II of this series. In neither case did the rate of disappearance of the NCAA obey first-order kinetics. Both compounds displayed the type of behavior described by Bell and Dankwerts (3), who used chlorobenzene as the solvent.

DISCUSSION

An examination of the results in Tables II–IV reveals that the R values for each individual NCAA are dependent on the structure of the catalyzing acid, and that the R values decrease as the pK_a of the catalyzing acid increases. In this respect the NCAA series is analogous to the NBAA series (1). For each NCAA the acid-catalyzed R values approximately obey a type of Brönsted equation of the form

$$\log R = \alpha \log K_a + C'', \quad [1]$$

where K_a is the dissociation constant of the acid and C'' is a constant. These correlations are illustrated graphically in Fig. 1, and the least-squares values of α and C'' for each NCAA are reported in Tables II–IV. In the NBAA series the Brönsted exponent α proved to be sensitive to the substituent at the 4-position of the NBAA, but, in contrast, the α

values for the NCAA's are identical within the precision of the present results. The operation of the Soper mechanism (eq. [2]) offers a tempting explanation of the insensitivity

[2] $$\mathrm{ArNClCOCH_3 + RCOOH \rightleftarrows ArNHAc + RCOOCl}$$
$$\mathrm{RCOOCl + C_6H_5OMe \rightarrow 2\text{-}ClC_6H_4OMe + 4\text{-}ClC_6H_4OMe + RCOOH}$$

of R to the structure of the NCAA. However, a more detailed examination of the problem suggests other possibilities. In part II of the present series, the Brönsted α appropriate to each 4-substituted NBAA was shown to correlate with the Brown and Okamoto σ^+ parameter, giving an equation of the form

[3] $$\alpha = \rho^+\sigma^+ + C',$$

where the symbols ρ^+ and σ^+ have their usual significance and C' is a constant. Combining eqs. [1] and [3] gives eq. [4], which provides a means of expressing the dependence of R on

[4] $$\log R = (\rho^+\sigma^+ + C') \log K_a + C''$$

both the structure of *N*-halogenoacylanilide and the carboxylic acid within the framework of a single equation. From the relationship

[5] $$\log R = \log \frac{2k_o}{k_p},$$

where k_o and k_p are, respectively, the specific rate constants for the product-determining step in the anisole chlorination at the 2 and 4 positions, it is possible to split eq. [4] into two separate equations of the form

[6] $$\log k_o = (\rho_o{}^+\sigma^+ + C_o') \log K_a + C_o''$$

and

[7] $$\log k_p = (\rho_p{}^+\sigma^+ + C_p') \log K_a + C_p'',$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where

[8] $$\rho^+ = \rho_o^+ - \rho_p^+,$$

[9] $$C' = C_o' - C_p',$$

and

[10] $$C'' = C_o'' + \log 2 - C_p''.$$

Equation [8] provides the basis for a systematic discussion of the dependence of the R parameter on the structure of the N-halogenoacylanilide in terms of the parameters ρ_o^+ and ρ_p^+. There are three distinct possibilities with regard to these parameters, which are conveniently summarized by eqs. [11]–[13]. The first condition (eq. [11]) is one in which the

[11] $$\rho_o^+ = \rho_p^+ = 0; \text{ therefore, } \rho^+ = 0$$

[12] $$\rho_o^+ = \rho_p^+; \text{ therefore, } \rho^+ = 0$$

[13] $$\rho_o^+ \neq \rho_p^+; \text{ therefore, } |\rho^+| > 0$$

rate constants k_o and k_p are completely independent of structural variations of the N-halogenoacylanilide; this is clearly a necessary condition for the operation of the Soper mechanism. The second possibility (eq. [12]) requires that k_o and k_p both have identical sensitivities to structural variations at the 4 position of N-halogenoacylanilide. This condition leads to the same situation with regard to the parameter ρ^+, i.e. $\rho^+ = 0$; this is now seen to be a necessary, but not a sufficient, condition for the operation of the Soper mechanism. The third possibility (eq. [13]) is that observed in the case of the NBAA series (1), and this situation is incompatible with a mechanism involving the intermediate production of acylhypohalites. In cases where both ρ_o^+ and ρ_p^+ are small, but where $\rho_o^+ \neq \rho_p^+$, the situation represented by eq. [13] will be difficult to distinguish from those represented by eqs. [11] and [12]; in these circumstances no clear-cut distinction between the Soper and the termolecular scheme (see part II) will be possible.

On the basis of other evidence, Dewar and Couzens (5, 6) have rejected acylhypobromites as intermediates in both the bromination and rearrangement reactions of NBAA's. Although the evidence for the rejection of hypochlorites in the case of NCAA's is less compelling, the reduction of the Brönsted exponent by the N—Cl link relative to the N—Br link (see Tables II–IV and ref. 1) is similar to the effect of electron-withdrawing substituents attached to the aromatic ring in the case of the NBAA's (1). We interpret this observation by postulating that the N—Cl linkage saturates this effect to the extent that various substituents attached to the para position of the aromatic ring of the NCAA's produce no *observable* change in the magnitude of the Brönsted exponents. This explanation of the small and constant Brönsted exponents in the NCAA series, combined with the close chemical analogy generally displayed by bromine and chlorine, suggests that a rejection of the termolecular scheme in favor of a rationalization of the experimental data based on the Soper mechanism would be premature. Any revival of the Soper mechanism must await the accumulation of less-ambiguous experimental evidence in its favor.

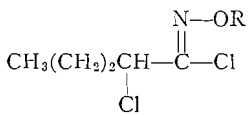
THE SYNTHESES OF 1-CHLORO-1-NITROALKENES

F. I. Carroll and J. A. Kepler
Natural Products Laboratory, Research Triangle Park, North Carolina
Received August 26, 1966

ABSTRACT



Chlorination of 1-nitroalkenes in acetic acid at 0° in the presence of hydrogen chloride gives the corresponding 1,2-dichloro-1-nitroalkanes in good yields. If the reaction is carried out at higher temperatures, an α-chlorohydroxamoyl chloride, resulting from the reaction of the nitroalkene with hydrogen chloride, is obtained as a side product. Base-catalyzed elimination of hydrogen chloride from the 1,2-dichloro-1-nitroalkenes gave the corresponding 1-chloro-1-nitroalkenes in high yields.

In a recent paper (1) we described an improved synthesis of 1,4-dinitro-1,4-dichlorobutadiene, a biologically active material.[1] As an extension of this work we have now prepared some simple 1-nitro-1-chloroalkenes (III) by the sequence shown in Reaction Scheme 1.

Reaction Scheme 1.

Chlorination of the nitroolefins (I) in carbon tetrachloride or acetic acid at r oom tem perature was very slow. Increasing the temperature to 40° did not accelerate the reaction to any appreciable extent. However, when hydrogen chloride and chlorine were simultaneously passed through an acetic acid solution of I (R = $CH_3(CH_2)_2$–), an exothermic reaction occurred. Distillation of the reaction mixture gave a 41% yield of the desired 1,2-dichloro-1-nitropentane and 20% of a higher boiling component C_5H_9ClNO. We have shown this product to be 2-chloropentanehydroxamoyl chloride (IV), based largely on the infrared spectrum, which showed absorption at 3 550 (OH) and 1 630 cm^{-1} (C=N), and the nuclear magnetic resonance (n.m.r.) spectrum, which showed a triplet at δ 4.70 (1H, J = 7 c.p.s., $-CH_2\underset{|}{CH}-Cl$) and a broad singlet at 8.73 p.p.m. (1H, OH) in addition to the methyl and methylene resonances. 2-Chloropentanehydroxamoyl chloride gradually decomposed, even at −10°, and a satisfactory analysis could not be obtained. Treatment of

IV, R = H

V, R =

[1]*The nature of this activity will be described in a future publication by H. W. Spurr and J. A. Durden, Olefins Division, Union Carbide Corporation.*

IV with phenylisocyanate gave the urethane V, which was quite stable. The analysis and infrared and n.m.r. spectra of this compound are in agreement with the assigned structure. Heath and Rose (2) have reported that nitroolefins containing an α-hydrogen are converted into the corresponding α-chlorohydroxamoyl chloride when treated with dry hydrogen chloride in anhydrous ether. The 2-chloropentanehydroxamoyl chloride (IV) we obtained undoubtedly arose from the reaction of hydrogen chloride with the 1-nitropentene, since a 54% yield of IV could be obtained by treating an acetic acid solution of I (R = $CH_3(CH_2)_2$–) with dry hydrogen chloride in the absence of chlorine. We found that this side reaction could be prevented and the yield of the 1,2-dichloropentane increased to 51% if the reaction was performed at ice-bath temperature with a solvent ratio of 375 ml of acetic acid for each 0.1 mole of nitroolefin. By using this procedure, the 1,2-dichloro-1-nitroalkanes listed in Table I were prepared. The n.m.r. spectra of these dichloro derivatives showed a doublet at δ 5.75–5.85 (1H, J = 8.5 c.p.s., —$CH(Cl)NO_2$) and a multiplet at 4.32–4.46 p.p.m. (1H, –CH_2–CH—CH—). Other physical constants are tabulated in Table I.

Treatment of the 1,2-dichloronitroalkanes with triethylamine or pyridine in ether gave the corresponding 1-chloro-1-nitroalkenes (III) in 70–88% yields. The n.m.r. spectrum of the olefins (III) showed a multiplet at δ 2.39–2.44 for the allylic methylene proton and a triplet at 7.39–7.49 p.p.m. (J = 7.5 c.p.s.) for the olefinic proton. The 1-chloro-1-nitroalkenes (III) prepared, along with their analyses and physical constants, are given in Table II.

EXPERIMENTAL

The melting points were obtained on a Kofler hot stage and are corrected. The boiling points are uncorrected. The infrared spectra were obtained with a Perkin–Elmer model 221 spectrophotometer. The n.m.r. spectra were obtained on a Varian A-60 spectrometer with samples dissolved in deuteriochloroform (internal standard, tetramethylsilane). The ultraviolet spectra were obtained with a Bausch and Lomb model 505 spectrophotometer. The gas chromatograms were run on a F & M model 700 chromatograph, and thin-layer chromatograms were obtained with silica gel HF. The microanalyses were carried out by Micro-Tech Laboratories, Inc., Skokie, Illinois.

Preparation of Nitroolefins

The nitroolefins used in the preparation of the 1,2-dichloro-1-nitroalkanes were prepared according to the procedure of Carroll *et al.* (3). The olefins were obtained in a reasonable yield and purity by one distillation.

Chlorination of 1-Nitropentene at Room Temperature

Chlorine and hydrogen chloride were passed simultaneously through a solution of 10.0 g (0.087 mole) of 1-nitropentene in 48 ml of acetic acid. The solution turned blue and the temperature rose to 85° and then dropped as the blue color disappeared. After ½ h, a vapor-phase chromatograph (6 ft column of 5% SE-30 on 60–80 Chromosorb P) indicated that all of the nitroolefin had reacted and showed two new peaks. Nitrogen was passed through the solution to displace the excess chlorine and hydrogen chloride. The acetic acid was separated from the products by distillation at 16 mm. The remaining liquid was distilled under a high vacuum to give 6.64 g (41%) of 1,2-dichloro-1-nitropentane (see Table I for analysis and physical constants), b.p. 61–62° at 3 mm, and 2.29 g (20%) of 2-chloropentanehydroxamoyl chloride, b.p. 50–51° at 0.05 mm. This compound gradually decomposed with the evolution of hydrogen chloride and precipitation of hydroxylamine hydrochloride.

A phenylurethan was obtained by heating a sample of 2-chloropentanehydroxamoyl chloride with phenylisocyanate, and was recrystallized from hexane, m.p. 96–98°. The infrared spectrum (CH_2Cl_2) showed absorption at 3 400 (NH) and 1 775 cm^{-1} (C=O). The n.m.r. ($CDCl_3$) showed a triplet at δ 0.92 (3H, J = 7.5 c.p.s., CH_3—CH_2), a multiplet at 1.41 (1.9H, CH_3CH_2), a multiplet at 2.0 (2.1H, CH_2CH—Cl), a triplet at 4.75 (1H, J = 7.5 c.p.s., CH_2CH—Cl), a multiplet at 7.31 (5.4H, Ar—H), and a singlet at 7.88 p.p.m. (1H, NH).

Anal. Calcd. for $C_{12}H_{14}Cl_2N_2O_2$: C, 49.84; H, 4.88; N, 9.69. Found: C, 49.69; H, 4.63; N, 9.84.

Preparation of 2-Chloropentanehydroxamoyl Chloride from the Reaction of 1-Nitropentene with Hydrogen Chloride

Hydrogen chloride was passed into a solution of 10 g (0.087 mole) of 1-nitropentene in 50 ml of acetic acid. The solution turned blue and the temperature rose to 85° and then dropped as the blue color disappeared.

The acetic acid and excess hydrogen chloride were removed under vacuum. The remaining liquid was distilled under a high vacuum to give 7.98 g (54%) of 2-chloropentanehydroxamoyl chloride (IV), b.p. 55–58° at 0.15 mm. The infrared and n.m.r. spectra were identical with those of IV prepared in the experiment above.

General Procedure for the Preparation of 1,2-Dichloro-1-nitroalkanes from 1-Nitroalkenes

The 1-nitroalkene (0.2 mole) was dissolved in 750 ml of acetic acid (distilled from potassium permanganate). The solution was cooled in an ice bath, and hydrogen chloride and chlorine were bubbled through the solution simultaneously. The reaction mixture was then subjected to thin-layer chromatography (petroleum ether – benzene (2:1)). When the reaction was complete (1–3 h), the ice bath was removed and the excess chlorine and hydrogen chloride were expelled from solution by passing nitrogen through the reaction mixture. The acetic acid was then removed on the freeze-dryer and the residual colorless oil distilled. The 1,2-dichloro-1-nitroalkanes were obtained as colorless liquids in reasonable yields (Table I).

A modified work-up procedure was used in the preparation of 1,2-dichloro-1-nitropentane. The reaction mixture was diluted with 3 l of water after the excess chlorine and hydrogen chloride had been expelled from the solution. The oily layer was separated, dissolved in ether, and dried over magnesium sulfate. The aqueous layer was washed with 3 × 500 ml of ether. The ether was removed on the flash evaporator, leaving an acetic acid solution of the desired product. This solution was concentrated to approximately one-half of its original volume by distillation at the water pump. The concentrate was further purified by distilling the acetic acid from it on a spinning-band column at 15 mm pressure. The pot residue from the spinning-band distillation was combined with the oil that separated upon dilution of the original acetic acid solution. Distillation of this mixture gave the desired product in a 51% yield. The infrared spectra of the 1,2-dichloro-1-nitroalkanes were all very similar and showed absorption at 1 570 and 1 360 cm^{-1} (saturated NO_2).

General Procedure for the Preparation of 1-Chloro-1-nitroalkenes from 1,2-Dichloro-1-nitroalkanes

The 1,2-dichloro-1-nitroalkane (0.05 mole) was dissolved in 500 ml of dry ether, and the solution was cooled in an ice bath. Triethylamine (0.05 mole) in 250 ml of dry ether was added dropwise to the well-stirred solution over a 1–3 h period. Filtration of the reaction mixture gave a quantitative yield of triethylamine hydrochloride. The filtrate was washed with dilute hydrochloric acid and 3 × 100 ml of water. The ether solution was dried and the solvent removed to give the desired products. The olefins were purified by vacuum distillation (Table II). The 1-chloro-1-nitroalkenes gradually decompose at room temperature, but seem to be relatively stable when kept at −10°.

Pyridine rather than triethylamine was used as the base for the preparation of 1-chloro-1-nitrohexene. Consequently, the reaction was allowed to proceed for a longer time and at room temperature.

The infrared spectra of the 1-chloro-1-nitroalkenes were all very similar and were characterized by the following bands: 1 630 (double bond) and 1 540 and 1 340 cm^{-1} (conjugated nitro).

ACKNOWLEDGMENTS

We thank Dr. Monroe E. Wall, Director of this laboratory, for his kind encouragement and support of this work. Part of the work was supported by the Union Carbide Chemicals Corporation, South Charleston, West Virginia. Expert technical assistance was provided by Mrs. Rebecca Stephenson.

SOME STEAM-VOLATILE COMPONENTS OF THE EXTRACTIVES FROM POPULUS TREMULOÏDES HEARTWOOD

R. A. Abramovitch and O. A. Koleoso

The extractives from the heartwood of *Populus tremuloïdes* (aspen poplar) have been the subject of a systematic investigation (1–3). It was shown that saponification of the acetone extractives gave a steam-volatile portion which could be resolved into four major components by gas-phase chromatography (1). It has since been established that one of the major components of this mixture was isophorone, which was an artifact formed during the extraction procedure. We now report a study of the composition of the steam-volatile fraction of the benzene extractives of the heartwood, from which fatty acids had been removed with sodium bicarbonate.

The mixture was subjected to a preliminary preparative gas chromatographic separation to give nine components, the first four of which were collected together as fraction I and later rechromatographed. The other peaks were collected individually as fractions II, III, IV, V, and VI, respectively (increasing retention times). Fractions IV and VI appeared to be mixtures which could not be resolved further and were not examined at this time. Fractions II, III, and V were rechromatographed on Apiezon L columns; II and V were single compounds, and III was resolved into four fractions: III^A, III^B, III^C, and III^D.

Compound II had bands in the infrared characteristic of a primary alcoholic group and a monosubstituted phenyl ring. Its nuclear magnetic resonance (n.m.r.) spectrum exhibited a 5H singlet at τ 2.9 and a 2H singlet at τ 5.7, suggesting that it was benzyl alcohol, which was confirmed by comparison of the spectra with those of an authentic sample. Similarly, compound III^A was shown to be phenol, and compound III^B β-phenylethanol. Compound III^C exhibited a weak band at 3 500 cm^{-1} (OH), a band of medium intensity at 2 720 cm^{-1} (C(=O)—H), and a strong band at 1 680 cm^{-1}, suggesting the presence of an α,β-unsaturated aldehyde function. It had an ultraviolet absorption maximum at 274 mμ, suggestive of an α- or β-hydroxy-α,β-unsaturated aldehyde (4). It formed a 2,4-dinitrophenylhydrazone and a semicarbazone, the melting points of which were very close to those of the corresponding derivatives of isophorone. The infrared and ultraviolet spectra of III^C, however, were quite different from those of isophorone. Unfortunately, there were insufficient amounts of III^C to carry out any further structural studies. Compound V had bands in the infrared characteristic of a phenolic hydroxyl group and a para-disubstituted benzene ring. Its n.m.r. spectrum showed a 4H quartet at τ 3.2, a 2H quartet at τ 7.5 (Ar—$C\underline{H}_2$—), and a 3H triplet at τ 8.9 (—CH_2—CH_3). These data were compatible with the compound being *p*-ethylphenol; this was confirmed by direct comparison with an authentic sample.

Fraction I was rechromatographed at a lower temperature and resolved into nine components (fractions I^A–I^I). Fractions I^B, I^D, I^F, and I^I were collected, since they were the most abundant (the first fraction was present in appreciable quantities but was clearly a mixture), and purified by further preparative gas chromatography. Fractions I^B and I^D were identified as *n*-hexyl and *n*-heptyl alcohols, respectively. Fraction I^F was not obtained

in sufficient quantities to permit its characterization, but its infrared absorption spectrum suggested the presence of a hydroxyl group and an α,β-unsaturated aldehyde function. The ultraviolet absorption maximum at 220 mμ indicated that the hydroxyl group was not on the α- or β-carbon of the α,β-unsaturated aldehyde. On the basis of its infrared and n.m.r. spectra, fraction I^I could be characterized as methyl benzoate; this was confirmed by comparison with an authentic sample.

None of the compounds isolated in this study were observed in the other fractions already investigated (1–3). The presence of phenol, *p*-ethylphenol, benzyl alcohol, and β-phenylethanol in the heartwood may be of taxonomic significance.

EXPERIMENTAL

Extraction and Isolation

The dried sawdust (8 kg) from *Populus tremuloïdes* heartwood was extracted continuously with benzene for 8 days. Evaporation of the solvent gave a brown semisolid residue (120 g, 1.5% by weight of the sawdust). This was steam-distilled for 5 h, the distillate being collected in an ice–salt mixture. The steam-distillate was extracted with ether, and the ether solution was shaken with a saturated aqueous sodium bicarbonate solution, washed with water, and dried ($MgSO_4$). Evaporation of the ether gave a yellow oil (4 g, 0.05% by weight of the sawdust).

Gas Chromatographic Separation of the Steam-Volatile Oil

A preliminary resolution was achieved on a 6 ft × $\frac{1}{4}$ in. column packed with 15% ethylene glycol adipate on Chromosorb W and operated at 150° and a helium flow rate of 46 ml/min. The first four components were collected together as fraction I. The last five (retention times 6, 7.2, 10.5, 13.7, and 14.5 min, respectively) were collected individually as fractions II, III, IV, V, and VI. Fractions II and III were rechromatographed on a 6 ft × $\frac{1}{4}$ in. column packed with 25% Apiezon L on Chromosorb W and operated at 145° and a helium flow rate of 20 ml/min. Fraction II gave a single component (retention time 11 min), collected as a colorless liquid (24 mg), b.p. 106° at 20 mm. Fraction III was resolved into four components: III^A, III^B, III^C, and III^D (retention times 7, 10.5, 16, and 41.5 min, respectively), III^A and III^C being the major ones. Fraction V was rechromatographed on a 6 ft × $\frac{3}{16}$ in. column packed with 20% Apiezon L on Chromosorb W and operated at 135° and a helium flow rate of 81 ml/min. Only a single peak, retention time 4.3 min, was observed. Fractions IV and VI could not be resolved cleanly into their components by using different columns.

Fraction I was rechromatographed on a 6 ft × $\frac{1}{4}$ in. column packed with 15% ethylene glycol adipate on Chromosorb W and operated at 125° and a helium flow rate of 60 ml/min. Nine peaks (corresponding to fractions I^A–I^I) were observed, the first of which was a broad band consisting of a mixture of compounds. The other peaks had retention times of 3.2, 4.2, 5.0, 6.0, 6.8, 8.0, 10.6, and 14 min, respectively. The fractions giving rise to peaks 2, 4, 5, 6, and 9 were collected and rechromatographed, and pure fractions I^B, I^D, I^F, and I^I were thus obtained.

Fraction II (Benzyl Alcohol)

The infrared and n.m.r. spectra were identical with those of authentic benzyl alcohol.

Fraction III^A (Phenol)

This fraction (22 mg), b.p. 75° at 14 mm, m.p. 39–40°, had bands in the infrared (liquid film) at 3 420 (s) (OH), 3 050 (w), 1 595 (s), 1 220 (s), 750 (s), and 690 cm^{-1} (s). In the ultraviolet it had a band at λ_{max} 272 mμ (95% ethanol), and the n.m.r. spectrum (measured on a CCl_4 solution) had a 5H doublet at τ 3.15 and a 1H singlet at τ 4.7. A direct comparison with phenol showed the two compounds to be identical in all respects.

Fraction III^B (β-Phenylethanol)

This fraction (20 mg) exhibited bands in the infrared (liquid film) at 3 350 (s), 3 070 (s), 3 030 (s), 2 940 (s), 2 880 (s), 1 600 (s), 1 490 (s), 1 450 (s), 1 370 (w), 1 170 (m), 1 040 (s), 740 (s), and 690 cm^{-1} (s), which corresponded to those of an authentic sample. The retention times of both compounds were also identical.

Fraction III^C

This was a colorless liquid (5 mg) whose infrared spectrum (liquid film) exhibited bands at 3 500 (br) (w), 3 020 (w), 2 960 (s), 2 920 (s), 2 860 (s), 2 720 (m), 1 680 (s), 1 635 (s), 1 450 (m), 1 375 (w), 1 155 (s), 1 140 (s), 1 005 (s), and 980 cm^{-1} (s). It absorbed at λ_{max} 274 mμ in the ultraviolet. The 2,4-dinitrophenylhydrazone, recrystallized from an ethyl acetate – ethanol mixture, had m.p. 138–139°. The semicarbazone (crystallized from aqueous ethanol) had m.p. 188–189°.

Fraction V (p-Ethylphenol)

This fraction (21 mg) had b.p. 104° at 13 mm and m.p. 44–45°. It exhibited the following bands in the infrared (KBr disk): 3 320 (s), 3 020 (w), 2 960 (s), 2 930 (s), 2 870 (s), 1 610 (s), 1 230 (s), 1 108 (s), and 820 cm^{-1} (s). It absorbed at 280 mμ in the ultraviolet (95% ethanol solution). The following CH lines were present in the n.m.r. spectrum: 4H quartet at τ 3.2, 2H quartet at τ 7.5, and a 3H triplet at τ 8.9. These data were identical with those for authentic *p*-ethylphenol.

Fractions I^B and I^D

Fraction I^B (18 mg), b.p. 58–60° at 11 mm, was shown by infrared and n.m.r. spectroscopy as well as by gas chromatography to be identical with *n*-hexyl alcohol. Similarly, fraction I^D (58 mg), b.p. 68–70° at 11 mm, was shown to be *n*-heptyl alcohol.

Fraction I^F

This was a colorless liquid (23 mg), b.p. 70° at 11 mm. It had infrared absorption bands (liquid film) at 3 500 (s), 2 960 (sh), 2 920 (s), 2 860 (s), 2 720 (m), 1 680 (s), 1 630 (s), 1 450 (s), 1 375 (m), 1 140 (s), 1 090 (m), 980 (s), and 720 cm^{-1} (m), and an ultraviolet absorption band at 220 mμ with shoulders at 274 and 320 mμ.

Fraction I^I (Methyl Benzoate)

The infrared and n.m.r. spectra and retention times of this fraction (17 mg, b.p. 76° at 13 mm) were identical with those of an authentic sample of methyl benzoate.

DERIVATIVES OF 4-AMINO-1-NAPHTHOL

M. A. Abdelkader, M. Khalifa, and Y. M. Abou-Zeid

Although 4-acetamido-1-ethoxynaphthalene, commonly known as naphthacetin, as well as the methoxy analogue has been found to possess analgesic properties, they are too toxic to be used as medicines (1), and the need arose for less-toxic derivatives. In the hope of realizing such an objective and because of the importance which has been attached to the use of succinimides as anticonvulsants (2, 3), the acetamido group was replaced by succinimido while the classical ether groupings were retained.

R = H, CH_3, C_2H_5, CH_2—CH=CH_2, or $COCH_3$
R′ = H or CH_3

Derivatives having the above general formula were synthesized by condensing succinic anhydride or the α,α-dimethyl derivative with the hydrochloride of 4-amino-1-naphthol.

Fractions I^B and I^D

Fraction I^B (18 mg), b.p. 58–60° at 11 mm, was shown by infrared and n.m.r. spectroscopy as well as by gas chromatography to be identical with *n*-hexyl alcohol. Similarly, fraction I^D (58 mg), b.p. 68–70° at 11 mm, was shown to be *n*-heptyl alcohol.

Fraction I^F

This was a colorless liquid (23 mg), b.p. 70° at 11 mm. It had infrared absorption bands (liquid film) at 3 500 (s), 2 960 (sh), 2 920 (s), 2 860 (s), 2 720 (m), 1 680 (s), 1 630 (s), 1 450 (s), 1 375 (m), 1 140 (s), 1 090 (m), 980 (s), and 720 cm^{-1} (m), and an ultraviolet absorption band at 220 mμ with shoulders at 274 and 320 mμ.

Fraction I^I (Methyl Benzoate)

The infrared and n.m.r. spectra and retention times of this fraction (17 mg, b.p. 76° at 13 mm) were identical with those of an authentic sample of methyl benzoate.

*All melting points are uncorrected.
†The microanalyses were performed by Dr. C. Janssen, Beerse, Belgium.

The resulting product was either acetylated by heating it with acetic anhydride or converted into the ether by treating the naphthoxide with the alkyl iodide or, alternatively, the free naphthol in acetone with the alkyl iodide in the presence of potassium carbonate. α,α-Dimethylsuccinic acid was prepared in 70% yield according to two reported procedures (4, 5). The dicarboxylic acid was converted into the anhydride in 80% yield by the acetyl chloride method (6*a*). α-Phenylsuccinic acid was prepared by Higson and Thorpe's procedure (6*b*) in an overall yield of 78%, calculated on the basis of the mandilonitrile. An attempt to convert it into the anhydride by the method of Dehn and Thorpe (7) did not give satisfactory results. However, the anhydride was obtained in 80% yield by heating the acid with excess acetic anhydride at 100° for 8 h instead of heating it at 140° for 6 h as reported (7). Among the methods reported for the acylation of amines with inner anhydrides is the direct fusion method (8). However, the aminonaphthol is oxidized by atmospheric oxygen, especially at the fusion temperature. To overcome this difficulty, the aminonaphthol was replaced by its hydrochloride and the succinoylation was successfully achieved by refluxing the hydrochloride with succinic anhydride or the α,α-dimethyl derivative in dry pyridine. On the other hand, when α-phenylsuccinic anhydride was used, no condensation took place with the hydrochloride or the aminonaphthol.

EXPERIMENTAL

4-Succinimido-1-naphthol and Derivatives

General Procedure

A mixture of equimolecular amounts of succinic anhydride (or the α,α-dimethyl derivative) and the hydrochloride of 4-amino-1-naphthol was suspended in dry pyridine (about 7 ml pyridine per 1 g mixture) and heated at 100° for 2–3 h. The pyridine was distilled off *in vacuo*, and the residue was crystallized from aqueous ethanol and then finally either acetylated or etherified as described above. The products were also crystallized from aqueous ethanol (see Table I).

THE STRUCTURE OF SUCCINYL DICHLORIDE

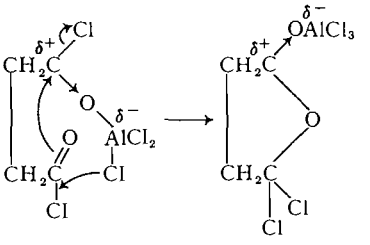
George H. Schmid

The existence of two forms of succinyl dichloride was originally proposed (1) to account for the cyclic products obtained in the reactions of succinyl dichloride with Lewis acids. The cyclic product could result from the small amount of the more reactive cyclic form of succinyl dichloride, which was in a facile equilibrium with the acyclic form.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Nuclear magnetic resonance has shown (2) that neat succinyl dichloride exists predominantly in the acyclic form (I). The possibility of an equilibrium between the proposed cyclic (II) and acyclic (I) forms of succinyl dichloride could not be ruled out, since it was

I II

not possible to detect nuclear magnetic resonance signals from both forms simultaneously. To obtain more information about this proposed equilibrium, it was desirable to obtain the cyclic form II. The reaction of succinyl dichloride with aluminium chloride seemed an attractive method to effect the isomerization of I to II by the [3.2.1] bicyclic path recently established by Newman (3) for similar isomerizations.

The infrared spectrum of a solution of aluminium chloride in succinyl dichloride is shown in Fig. 1. The principal bands in the carbonyl region are listed in Table I.

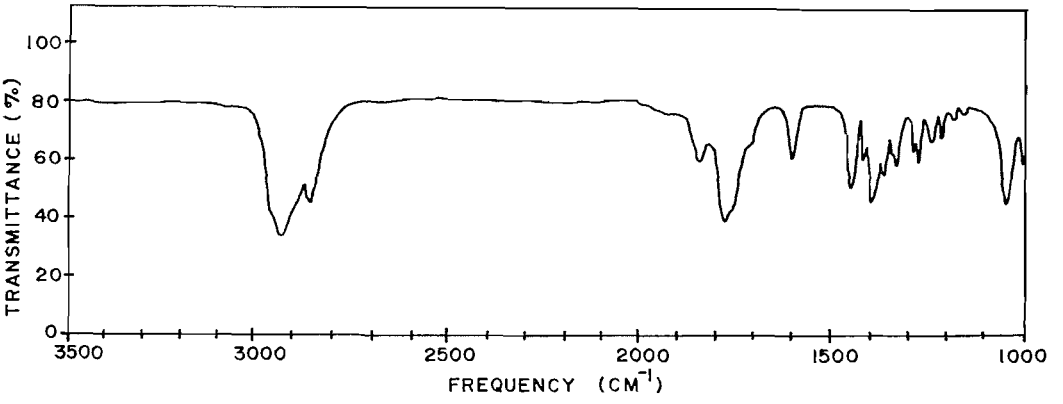


FIG. 1.

The addition of aluminium chloride to succinyl dichloride causes the appearance of a new absorption band in the infrared region at 1 601 cm^{-1}. This band can be attributed to a polarized complex between the acyclic succinyl dichloride and aluminium chloride. Such a

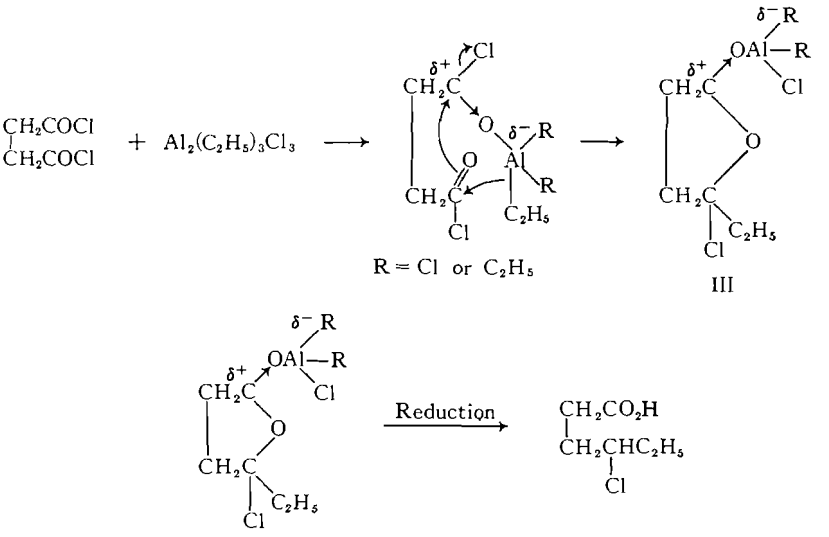
*m = medium, s = strong, vs = very strong, sh = shoulder.

band has been found by Cook (4) and Olah (5) in the infrared spectra of numerous acyl halides in the presence of Lewis acids. The lowering of the frequency of the carbonyl band when the complex is formed is 183 cm^{-1}. Shifts of $\nu_{C=O}$ of a similar magnitude in carbonyl – Lewis acid complexes have been reported by Susz and Cooke (6).



The cyclic form of succinyl dichloride, if formed, would be expected to show a strong γ-lactone carbonyl absorption band in the region of 1 800 cm^{-1} (7–9). No such band for the cyclic form is found in the infrared spectrum. There is a possibility that the strong carbonyl band at 1 783 cm^{-1} might hide the carbonyl band of the cyclic form. This possibility is ruled out by the nuclear magnetic resonance spectrum of a solution of succinyl dichloride and aluminium chloride in nitromethane. In addition to the nitromethane proton peak, there are two peaks. One, a singlet at 3.36 p.p.m., is caused by the excess succinyl dichloride. The other, a broad unresolved peak centered at 3.58 p.p.m., is consistent (5) with the formation of a polarized donor–acceptor complex with the acyclic form of succinyl dichloride. The protons of the cyclic form, if present, would be expected to be more shielded and should be found upfield from the acyclic form. The methylene, methoxyl, and methyl protons of cyclic pseudo methyl levulinate have been shown (2) to be upfield by approximately 0.30 p.p.m. from the acyclic methyl levulinate. The absence of peaks upfield from the proton peak of succinyl dichloride, in addition to the infrared data, rules out the presence of the cyclic isomer of succinyl dichloride.

There is really no reason to postulate the existence of a cyclic form of succinyl dichloride. Cyclic products can be accounted for by means of the [3.2.1] bicyclic reaction path starting with the acyclic form. For example, the mechanism of the reaction of succinyl dichloride with ethyl aluminium sesquichloride to form γ-chlorocaproic acid as the major product rather than the expected octane-3,6-dione has been postulated as starting from the cyclic form (10). An alternate mechanism is the reaction of succinyl dichloride with the

$$\begin{matrix}CH_2COCl\\ |\\ CH_2COCl\end{matrix} + Al_2(C_2H_5)_3Cl_3 \rightarrow \begin{matrix}Cl\\ |\\ CH_2CHC_2H_5\\ |\\ CH_2CO_2H\end{matrix} + \begin{matrix}CH_2CO_2CH_5\\ |\\ CH_2COC_2H_5\end{matrix}$$

aluminium compound to form a 1:1 polarized complex. This complex could react by a [3.2.1] bicyclic reaction path to form the cyclic complex (III), which could be reduced to the observed product. Further support for this mechanism is the fact that compounds of type III have been shown to exist predominantly in the cyclic form (2, 3). An analogous

[3.2.1] bicyclic mechanism starting with the acyclic form can be postulated for other reactions of succinyl dichloride with Lewis acids that result in cyclic products.

It is therefore unnecessary to postulate the existence of a cyclic form of succinyl dichloride, since (*i*) there is no physical evidence to support its existence, and (*ii*) the reaction products can be explained satisfactorily without its intervention.

EXPERIMENTAL

Boiling points are uncorrected. Nuclear magnetic resonance spectra were taken on a Varian A-60 spectrometer, with tetramethylsilane as an internal standard. Infrared spectra were taken on a Perkin–Elmer model 521 spectrophotometer.

Succinyl dichloride was prepared by the method of Cason and Reist (11) in an 80% yield, b.p. 65–67° at 2 mm (lit. (11) b.p. 65° at 5 mm).

Preparation of the Succinyl Dichloride – Aluminium Chloride Complex

All operations were carried out in a dry box. To 0.55 g (0.004 mole) of aluminium chloride was added 2.05 g (0.013 mole) of succinyl dichloride. The mixture was allowed to stand at room temperature, with occasional shaking, until all the aluminium chloride had dissolved. The infrared spectrum of the resulting oil was examined as the neat liquid between NaCl plates. The nuclear magnetic resonance sample was prepared by adding the liquid complex to nitromethane, which was purified by the method of Olah (5).

DIIMIDE REDUCTION OF 12-MEMBERED CYCLIC OLEFINS

H. NOZAKI, Y. SIMOKAWA, T. MORI, AND R. NOYORI

Diimide reduction (1) of *cis,trans,trans*-1,5,9-cyclododecatriene (II) gives *cis*-cyclododecene (IX) in preparative yields (2), whereas *cis,trans*-bicyclo[10.1.0]trideca-4,8-diene (XII) is completely inert to this treatment (3).[1] To gain further information regarding the selectivity in addition reactions of 12-membered cyclic olefins (3, 4), we have now investigated the diimide reduction of 1,5,9-cyclododecatriene isomers (I–IV) and *trans*- and *cis*-cyclododecenes (VIII and IX).

Reinvestigation of the reduction of *cis,trans,trans*-1,5,9-cyclododecatriene (II) was carried out under four different modes of generating diimide. These methods were (A) air oxidation of hydrazine hydrate in the presence of cupric salts (2*a*), (B) oxidation of hydrazine hydrate with 30% hydrogen peroxide (5), (C) thermal or basic decomposition of iodohydrazine in various solvents (6), and (D) decomposition of tosylhydrazine in the presence of bases (1). All products were analyzed by gas–liquid chromatography (g.l.c.) ($AgNO_3$-treated polyethylene glycol 6000), and the results are summarized in Table I. The relative retention times with reference to that of X are shown in parentheses under each structural formula.

The selective formation of *cis*-cyclododecene was consistently observed in every method of generating diimide irrespective of reaction temperatures and solvents. No detectable amount of the *trans* isomer VIII was formed. The first attack of diimide occurs at one of the *trans* bonds to produce *cis,trans* diene VI, which is further hydrogenated at another *trans* bond. Thermal decomposition of tosylhydrazine (method D) gives *p*-toluenesulfinic acid as a counterpart of the diimide species. This acid has been found to be an active reagent of *cis–trans* isomerization of olefins (7). Therefore, the presence of bases such as potassium carbonate is essential in method D; otherwise the selectivity is completely lost because of the isomerization of compounds at each reduction stage to thermally more stable isomers.

Of the four different methods, method D gave the highest yields of reduction products

[1]*This bicyclic diene has now been found to be inert under the conditions of methods B and D as well as those of method A previously reported.*

based on the diimide-generating reagents. In view of the ease in operation and of reproducible results, methods B and D were preferred in the following experiments.

Partial hydrogenation of *cis,cis,trans*-1,5,9-cyclododecatriene (III) (8) was expected to provide a means of preparing *cis,cis*-1,5-diene VII under such strictly preferential attack of the *trans* bond as observed with II. As shown in Table II, however, a fair amount of *cis,trans*-1,5-diene VI was produced by the attack of the *cis* bond. All-*trans* triene I (8) and all-*cis* triene IV (9) were also susceptible to diimide reduction. Facile formation of the totally saturated product X characterized the reduction of the all-*trans* isomer.

Table III involves the diimide reduction of a mixture of equal amounts of *trans*- and *cis*-cyclododecene (VIII and IX). The data clearly show that the *trans* olefin VIII is much more susceptible to the reduction than the *cis* isomer IX. The reduction similarly proceeded with *cis,trans*-1,3-cyclododecadiene (XI),[2] which yielded a considerable amount of completely saturated cyclododecane X. Presumably, the *cis* bond is nearly as reactive as the *trans* bond in the first attack of diimide on the 1,3-diene XI,[3] and *trans* monoene VIII produced by the attack of the *cis* bond is then converted into cyclododecane X.

In summary, we may conclude that the *trans* double bond is ordinarily much easier to reduce than the *cis* one in the diimide reduction of 12-membered cyclic olefins. The approach of the diimide molecule is very sensitive to the steric environment of the double bond to be attacked, as has been pointed out previously (12). Clearly, the ring structures outside of the reacting site are also controlling the susceptibility. This has been most dramatically exemplified by the behavior of XII, which is inactive toward the diimide reduction but smoothly reacts with carbenes and Simmons–Smith reagent at the *cis* bond (3, 4). Such an effect apparently distinguishes these large ring olefins from the ones of common rings or of open chains (13).

EXPERIMENTAL

Both all-*trans* triene I and *cis,cis,trans* triene III were prepared by isomerizing *cis,trans,trans* triene II photochemically (7, 8), and triene IV was prepared by the method of Untch and Martin (9). *trans*-Cyclododecene (VIII) was obtained by isomerization of the *cis* olefin IX (7). *cis,trans*-1,3-Cyclododecadiene (XI) (14) and authentic samples of 1,5-diene V (15) and VI (16) were prepared by known methods, respectively.

Though *cis,cis*-1,5-diene VII could not be isolated in an analytically pure state, the structure tentatively assigned was supported by the infrared spectrum of the mixture of IV, VII, and IX obtained by the reduction of all-*cis* triene IV, which indicated the absence of the *trans* double bond. Furthermore, ozonolysis of the same mixture yielded practically no products other than succinic acid, suberic acid, and dodecanedioic acid, which were identified as their respective methyl esters. Cyclododecane, m.p. 60–61°, was the sole isolable product obtained by exhaustive catalytic hydrogenation of this partial reduction mixture (IV, VII, and IX).

Gas–liquid chromatographic analyses of the recovered C_{12}-fractions were performed on a 2 m column of polyethylene glycol 6000 treated with silver nitrate, helium being used as the carrier gas at 130°. The results are summarized in Tables I–III.

Diimide reduction by means of air oxidation of hydrazine hydrate (method A) was carried out as previously described (2*a*). General procedures of the diimide reduction of cyclododecatrienes by means of methods B–D are illustrated below.

Oxidation of Hydrazine Hydrate by 30% Hydrogen Peroxide (Method B)

To a solution of each cyclododecatriene (0.8 g, 5 mmoles), 80% hydrazine hydrate (0.32 g, 5 mmoles), and 1% aqueous cupric sulfate (1 ml) in 99% ethanol (30 ml) kept at 0° was added 30% hydrogen peroxide at a rate of 0.1 ml per min, with stirring. For completion of the reaction, 0.6–0.8 ml hydrogen peroxide was required. After nitrogen evolution had ceased, the mixture was treated with water, and extracted with *n*-hexane. The hexane extracts were dried (Na_2SO_4), passed through a short alumina column, and distilled *in vacuo* to give 0.5–0.6 g of the C_{12}-fraction as a colorless oil, b.p. 100–110° at 13 mm, which was subjected to g.l.c. analysis.

Decomposition of Iodohydrazine (Method C)

To a mixture of each cyclododecatriene (1.6 g, 10 mmoles), 80% hydrazine hydrate (6 g, 96 mmoles), and

[2]*To the authors' best knowledge the only known example of diimide reduction of a conjugated diene is that of cyclopentadiene (see ref. 10).*

[3]*No example of 1,4-addition of diimide is known. For example, the reduction of sorbic acid gives mainly 4-hexenoic acid and Δ^2-isomer, 3-hexenoic acid not being detected (see ref. 11).*

For personal use only.

sodium hydroxide (2.0 g, 50 mmoles) in ethanol (100 ml), a 20% ethanol solution of I_2 was added dropwise at 20–25°, with stirring. The color of I_2 immediately disappeared. At the point when this color discharge was no longer perceptible, the mixture was treated with water and extracted with *n*-hexane. The combined extracts were washed with water and aqueous $Na_2S_2O_3$, dried (Na_2SO_4), and passed through a short alumina column. After concentration, the residual oil was distilled *in vacuo* to yield ordinarily 0.8–1.0 g of the C_{12}-fraction, b.p. 100–110° at 13 mm, which was analyzed by g.l.c.

Basic Decomposition of Tosylhydrazine (Method D)

To a mixture of each cyclododecatriene (0.8 g, 5 mmoles) and tosylhydrazine (0.8 g, 5 mmoles) in ethyl cellosolve (25 ml) was added saturated aqueous K_2CO_3 (0.8 g, 5 mmoles); then the mixture was heated at 95–100°, with stirring, until the gas evolution had ceased. The reaction mixture was treated with water and extracted with ether, and the ether extracts were washed with water, dried, and concentrated *in vacuo*. The residue was dissolved in *n*-hexane, and the hexane solution was passed through an alumina column and distilled to give 0.5–0.6 g of the C_{12}-fraction as a colorless oil, which was subjected to g.l.c. analysis.

Diimide Reduction of Cyclododecenes

An equimolar mixture of *trans*- and *cis*-cyclododecenes (VIII and IX) was prepared from each pure isomer and subjected to diimide reduction as shown below.

Method B

To a solution of cyclododecenes (50:50 mixture, 0.8 g, 5 mmoles), 80% hydrazine hydrate (1.0 g, 15 mmoles), and 1% aqueous cupric sulfate (1 ml) in ethanol (30 ml), 30% hydrogen peroxide was added at a rate of 0.1 ml per min, with stirring, at 0°. After 0.8 ml of hydrogen peroxide was added, the reaction mixture was diluted with water and extracted with *n*-hexane. The extracts were dried (Na_2SO_4) and distilled *in vacuo* to give a colorless oil (0.63 g, 79% recovery), b.p. 103–110° at 13 mm, which was subjected to g.l.c. analysis.

Method D

A solution of cyclododecenes (50:50 mixture, 0.8 g, 5 mmoles) and tosylhydrazine (0.8 g, 5 mmoles) in ethyl cellosolve (25 ml) containing K_2CO_3 (0.8 g, 5 mmoles) was heated at 95°, with stirring, for 5 h. The reaction mixture was treated with water and extracted with ether. The ethereal solution was washed, dried (Na_2SO_4), and concentrated. The residue was dissolved in a small amount of *n*-hexane, passed through a short alumina column, and distilled *in vacuo* to yield a colorless oil (0.58 g, 73% recovery), b.p. 101–106° at 13 mm, which was analyzed by g.l.c.

Diimide Reduction of cis,trans-1,3-Cyclododecadiene

A solution of the cyclododecadiene (0.8 g, 5 mmoles), tosylhydrazine (1.6 g, 10 mmoles), and aqueous K_2CO_3 (1.6 g, 10 mmoles) in ethyl cellosolve (25 ml) was heated at 95°, with stirring, during 7 h. The mixture was treated with water and extracted with ether. The combined extracts were washed, dried (Na_2SO_4), and concentrated *in vacuo*. The residual oil was dissolved in *n*-hexane and passed through an alumina column. The hydrocarbon fractions were collected and distilled to yield a colorless oil (0.52 g, 65% recovery), b.p. 100–105° at 13 mm, which was analyzed by g.l.c.

KINETICS OF THE DECOMPOSITIONS OF ETHANE AND PROPANE SENSITIZED BY AZOMETHANE

THE DECOMPOSITION OF THE NORMAL PROPYL RADICAL

M. C. LIN AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received June 14, 1966

ABSTRACT

The azomethane-sensitized pyrolysis of ethane was studied at low temperatures from 280 to 350 °C. Measurements were made of initial rates of formation of methane, nitrogen, and butane. From the rate of nitrogen production the rate constant for the azomethane decomposition into $2CH_3 + N_2$ was

$$k = 2.4 \times 10^{14} e^{-47600/RT} s^{-1}.$$

A similar study of the propane decomposition, at temperatures from 260 to 300 °C, led to the value

$$k = 6.0 \times 10^{14} e^{-48300/RT} s^{-1},$$

in satisfactory agreement. The rate of decomposition of the *n*-propyl radical into CH_3 and C_2H_4 was obtained by comparing the rates of formation of C_2H_4 and *n*-C_6H_{14}; the rate constant was

$$k = 3.47 \times 10^{13} e^{-31400/RT} s^{-1}.$$

The activation energy of 31.4 kcal/mole, together with that of 8.9 kcal/mole for the reverse reaction obtained by Brinton, leads to a value of 20.3 kcal/mole for the dissociation energy of *n*-CH_3—CH_2 at 0 °K, and to a value of 22.8 at 25 °C. The corresponding values for the heats of formation of the *n*-propyl radical are 28.4 kcal/mole at 0 °K, and 23.1 kcal/mole at 25 °C. The dissociation energy of *n*-$CH_3CH_2CH_2$—H is deduced to be 99.4 kcal/mole at 0 °K and 99.9 kcal/mole at 25 °C. An energy diagram is constructed for the various reactions of *n*-C_3H_7 and *i*-C_3H_7.

INTRODUCTION

Azomethane decomposes at a convenient rate between 250° and 350°, and is therefore a suitable sensitizer for the decomposition of substances giving rise to a chain carrier that decomposes readily in this temperature range (1). The decomposition of acetaldehyde, for example, occurs at a convenient rate at these temperatures in the presence of small amounts of azomethane (2, 3). The present paper describes studies of the azomethane-sensitized decompositions of ethane and propane. In the ethane decomposition, the ethyl radical decomposition, which has an activation energy of about 40 kcal/mole, does not occur sufficiently rapidly, but the investigation is of interest in providing information about the kinetics of decomposition of the azomethane molecule into a nitrogen molecule and two methyl radicals.

Propyl radicals, on the other hand, decompose more rapidly, and the study of the propane decomposition in the presence of azomethane therefore provides information about the kinetic parameters for the decomposition of this radical.

The activation energy for the decomposition of the *n*-propyl radical has been measured in a variety of ways, and values ranging from 20 to 35 kcal/mole have been obtained (4–8).

From this activation energy the carbon–carbon bond dissociation energy in the radical, $D^0(CH_3—CH_2CH_2)$, and the primary carbon–hydrogen bond energy in propane, $D^0(CH_3CH_2CH_2—H)$, can be deduced; values for the latter range from 110 to 95 kcal/mole. The present work leads to what is considered to be reliable values for these quantities.

EXPERIMENTAL

Apparatus

The reactions were studied in a conventional static system. The reaction vessel was a quartz bulb 511.5 ml in volume, enclosed in an electrically heated steel cylinder 2 cm in thickness. The temperature of the vessel was controlled within 0.2 °C with a Thermoelectric regulator. The pressure of the system after evacuation was measured by a Pirani gauge. Before each run, the system was evacuated to a pressure of less than 10^{-4} mm Hg.

Materials

Phillips research grade ethane and propane were subjected to several trap-to-trap distillations and were finally degassed thoroughly at −160 °C. Azomethane was obtained from Merck, Sharp and Dohme of Canada Limited. It was prepared in a similar manner to ethane and propane, but was degassed at a higher temperature (−130 °C) to remove all traces of ethane. The purified azomethane, which showed no impurity in vapor-phase chromatographic tests, was stored at −78 °C. The mixtures of azomethane and alkanes were stored in black-painted bulbs and were degassed from time to time.

Procedure and Analysis

The reaction was quenched by passing the reaction mixture through a spiral trap maintained at −196 °C. It was connected in series with a LeRoy still, a pump-down trap (−210 °C), a mercury-diffusion pump, and a Toepler pump with a gas burette. The noncondensable products, methane and nitrogen, were first measured with the gas burette and then analyzed by vapor-phase chromatography using a 1 ft 60–80 mesh silica gel column.

The condensable products resulting from the ethane decomposition were distilled in the LeRoy still at −160 °C. The residues from the distillation, mainly butane and the remaining fraction of ethane, were then transferred to the vapor-phase chromatograph. A 12 ft column of 30% (by weight) 2,5-hexane-dione was used at 0 °C.

The condensable products obtained from the propane decomposition were subjected to distillation at −135 °C. The C_2 fractions, ethane and ethylene, and parts of the C_3 fraction trapped in the −210 °C trap, were analyzed by vapor-phase chromatography with the same silica gel column as used in the methane determination. The residues of the distillation, containing mainly hexanes, azomethane, and other nitrogen compounds, were analyzed by vapor-phase chromatography using a 2 ft di-2-ethylhexylsebacate column maintained at 34 °C.

n-Hexane could be separated satisfactorily from two other possible isomers, diisopropyl and 2-methylpentane, whose peaks, however, overlapped each other. Appreciable amounts of $CH_3N_2C_4H_9$ were identified and measured by mass spectrometry. An attempt, which turned out to be unsuccessful, was made to separate diisopropyl from 2-methylpentane by using two of the 2 ft di-2-ethylhexylsebacate columns connected in series.

RESULTS AND DISCUSSION

The Ethane Decomposition

Ethane containing 0.507% azomethane was pyrolyzed at low temperatures from 280 to 350 °C. The products measured were nitrogen, methane, and butane. Initial rates were obtained by extrapolating the plots of rate against time to zero time, and the results are summarized in Table I.

The results are explained by the mechanism

[1] $$CH_3N_2CH_3 \rightarrow N_2 + 2CH_3$$

[2] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[3] $$CH_3 + CH_3 \rightarrow C_2H_6$$

[4] $$CH_3 + C_2H_5 \rightarrow C_3H_8 \text{ or } CH_4 + C_3H_6$$

[5] $$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \text{ or } C_2H_6 + C_2H_4 \quad .$$

Reactions between radicals and azomethane can be neglected in view of the low concentration of azomethane.

For personal use only.

That the rate of nitrogen formation is exactly first order with respect to azomethane was shown by plots of $\log_{10}([A]_0—[N_2])/[A]_0$ against time; $[A]_0$ is the initial concentration of azomethane and $[N_2]$ the concentration of nitrogen at time t. The value of the rate constant obtained from such plots agreed within 1% with the rate constant calculated from the initial rates of nitrogen production.

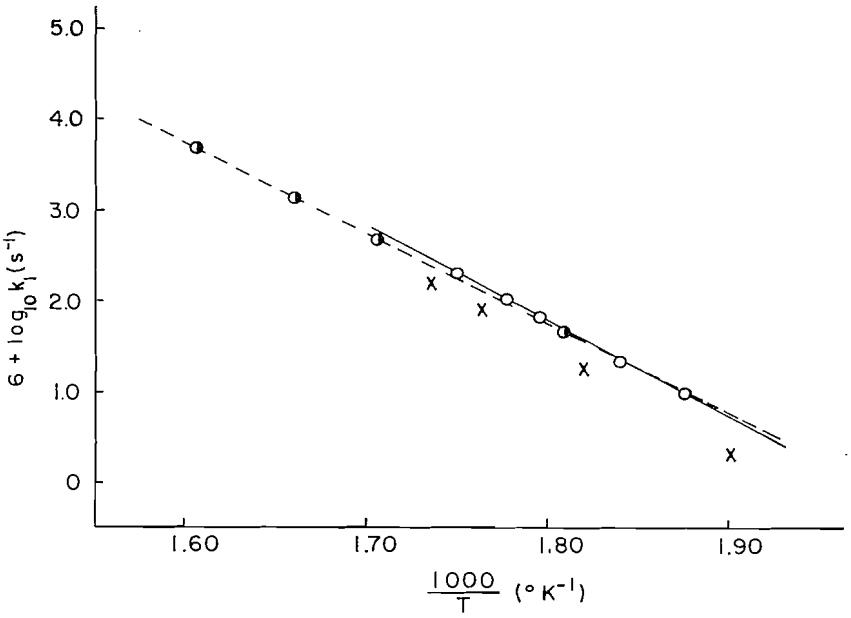

FIG. 1. Arrhenius plots of k_1 values obtained in different investigations: ◑, results obtained for ethane + 0.507% azomethane; ○, those for propane + 2.31 and 3.39% azomethane; ×, results of Forst and Rice (9) for the azomethane decomposition inhibited by nitric oxide.

An Arrhenius plot for these rate constants is shown in Fig. 1. The rate constant is given by

$$k_1 = 2.4 \times 10^{14}\, e^{-47600/RT}\ s^{-1}.$$

This differs significantly from the expression

$$k_1 = 1.9 \times 10^{17}\, e^{-55400/RT}\ s^{-1}$$

obtained by Forst and Rice (9) from a study of the azomethane decomposition inhibited by nitric oxide. The results of Forst and Rice are included in Fig. 1.

Owing to the difficulty of determining propane in the presence of a large excess of ethane, the rates of propane production were estimated from the rates of methane and butane formation using the relationship

[*i*] $$v^*_{C_3H_8} = \frac{k_4}{k_2[C_2H_6]k_5^{1/2}}\, v_{CH_4} v^{1/2}_{C_4H_{10}}.$$

Similarly the rate of combination of methyl radicals was calculated from

[*ii*] $$v^*_{C_2H_6} = \frac{k_3}{k_2^2}\,\frac{v^2_{CH_4}}{[C_2H_6]^2}.$$

The methane produced from reaction [4] amounts to less than 2% of the total, and was neglected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The rate constants used were

$$k_2 = 4.25 \times 10^{10}\, T^{1/2}\, e^{-11300/RT} \text{ cc mole}^{-1}\text{ s}^{-1} \quad (10)$$

$$k_3 = 2.2 \times 10^{13} \text{ cc mole}^{-1}\text{ s}^{-1} \quad (11)$$

$$k_4 = 4.2 \times 10^{13} \text{ cc mole}^{-1}\text{ s}^{-1} \quad (12)$$

$$k_5 = 2.0 \times 10^{13} \text{ cc mole}^{-1}\text{ s}^{-1} \quad (13).$$

Equations [*i*] and [*ii*] also allow one to calculate $2v_1$, the rate of methyl production, which is equal to the sum of the rates of the processes by which methyl radicals disappear:

[*iii*] $$2v_1 = v_{CH_4} + 2v^*_{C_2H_6} + v^*_{C_3H_8}.$$

The results are given in Table I, and it is to be seen that the ratio v_1/v_{N_2} is approximately unity as expected from the mechanism.

The Propane Decomposition

The work with propane was done with two azomethane–propane mixtures, one containing 2.31% of azomethane and the other 3.39%. The following products were observed and the rates of their formation were measured: nitrogen, methane, ethane, ethylene, *n*-hexane, diisopropyl [$(CH_3)_2CHCH(CH_3)_2$], and 2-methylpentane. Some initial rates of reaction are given in Table II.

The overall kinetics of the pyrolysis of propane has been studied by Laidler, Sagert, and Wojciechowski (14) and in the light of their reaction scheme the following mechanism can be proposed for the azomethane-sensitized reaction.

[1] $$CH_3N_2CH_3 \rightarrow N_2 + 2CH_3$$

[6*a*] $$CH_3 + C_3H_8 \rightarrow CH_4 + CH_3CH_2CH_2$$

[6*b*] $$CH_3 + C_3H_8 \rightarrow CH_4 + CH_3CHCH_3$$

[7] $$CH_3CH_2CH_2 \rightarrow CH_3 + C_2H_4$$

[8] $$2CH_3CH_2CH_2 \rightarrow CH_3CH_2CH_2CH_2CH_2CH_3$$

[9] $$CH_3CH_2CH_2 + CH_3CHCH_3 \rightarrow CH_3CH_2CH_2CH(CH_3)_2$$

[10] $$2CH_3CHCH_3 \rightarrow (CH_3)_2CHCH(CH_3)_2$$

[3] $$CH_3 + CH_3 \rightarrow C_2H_6$$

[11] $$CH_3 + CH_3CH_2CH_2 \rightarrow CH_3CH_2CH_2CH_3$$

[12] $$CH_3 + CH_3CHCH_3 \rightarrow CH_3CH(CH_3)_2$$

This mechanism is seen to account for the products obtained in the present investigation. Significant amounts of $C_4H_9N_2CH_3$ were formed, so that reactions such as

[13] $$CH_3 + CH_3N_2CH_3 \rightarrow CH_4 + CH_2N_2CH_3$$

[14] $$C_3H_7 + CH_2N_2CH_3 \rightarrow C_4H_9N_2CH_3$$

probably also occur. The radical $CH_3N_2CH_2$ will be stabilized by resonance, and will disappear largely by combination with radicals.

The double-logarithmic plot in Fig. 2 shows that the order of nitrogen production is again unity. The Arrhenius plot for the rate constants for the azomethane decomposition, obtained in the work with propane, was included in Fig. 1, and is shown to be consistent with the results found in the ethane experiments. The rate constant derived from the propane results can be expressed as

$$k_1 = 6.0 \times 10^{14}\, e^{-48300/RT}\, s^{-1}.$$

This is in satisfactory agreement with the result obtained with ethane.

Decomposition of the n-C_3H_7 Radical

The isopropyl radical is known to be much more stable than the *n*-propyl radical (15, 16); in the temperature range of the present experiments the process

[15] $$CH_3CHCH_3 \rightarrow CH_3 + C_2H_4$$

is 10^2 to 10^3 times slower than reaction [7]. The initial rate of formation of ethylene is therefore equal to the initial rate v_7 of reaction [7].

The rate of reaction [7] can be measured by using the relationship

[*iv*] $$v_{C_2H_4}/v_{n\text{-}C_6H_{14}}^{1/2} = k_7/k_8^{1/2}.$$

Typical yield–time plots for ethylene and *n*-hexane are given in Figs. 3 and 4. The rates of both processes decline rapidly as reaction proceeds, especially at higher temperatures; this is attributed to the decomposition of azomethane. Initial rates were obtained by the extrapolation of plots of rate against time, as shown in Fig. 5, and the results for all temperatures and pressures are given in Table III. As expected, the ratio $v_{C_2H_4}/v_{n\text{-}C_6H_{14}}^{1/2}$ is independent of the amount of azomethane in the system. It is also independent of pressure under the present conditions, although pressure dependence of k_7 has been observed by Kerr and Calvert (7) at below 15 mm pressure of $(n\text{-}C_3H_7)_2N_2$. The data in Table III, with k_8 taken as 2.2×10^{13} cc mole^{-1} s^{-1}, lead to

$$k_7 = 3.47 \times 10^{13}\, e^{-31400/RT}\ s^{-1}.$$

The Arrhenius plot is shown in Fig. 6.

$CH_3N_2CH_3$-sensitized decomposition of C_3H_8	3.47×10^{13}	31.4 ± 0.30	37.2	This work

*The values given are recalculated from the original results, using the value of 2.2×10^{13} cc $mole^{-1}$ s^{-1} for the rate constant of the n-C_3H_7 radical combination.

Table IV lists the very divergent kinetic parameters for the $CH_3CH_2CH_2$ decomposition, obtained by a variety of methods. Our activation energy agrees well with that estimated by Jackson and McNesby (17) from thermochemical data. It is much higher than the values of 20–22 kcal/mole obtained from the results of the mercury-photosensitized decomposition of propane (4, 8). The latter values are unreliable since they involve the assumption that the radical concentration is independent of temperature. In the present study, however, the concentration of the radical of interest was monitored by direct measurements of the rate of recombination.

Our activation energy is somewhat lower than the values obtained by Calvert and coworkers from studies with *n*-propionaldehyde (5) and azo-*n*-propane (7), and it is to be noted from Table IV that significantly higher rate constants were obtained in their work. It is possible that error arises in the aldehyde work from the presence of the radicals $CH_2CH_2CH_2CHO$ and CH_3CH_2CHCHO, which may decompose into $C_2H_4 + CH_2CHO$ and $CH_3 + CH_2CHCHO$ respectively; there would therefore be higher rates of formation of methane and ethylene. Similar side reactions may also occur in the azo-*n*-propane system. The work with propane is free from complications of this kind, especially since, as discussed above, the isopropyl radical breaks down very slowly.

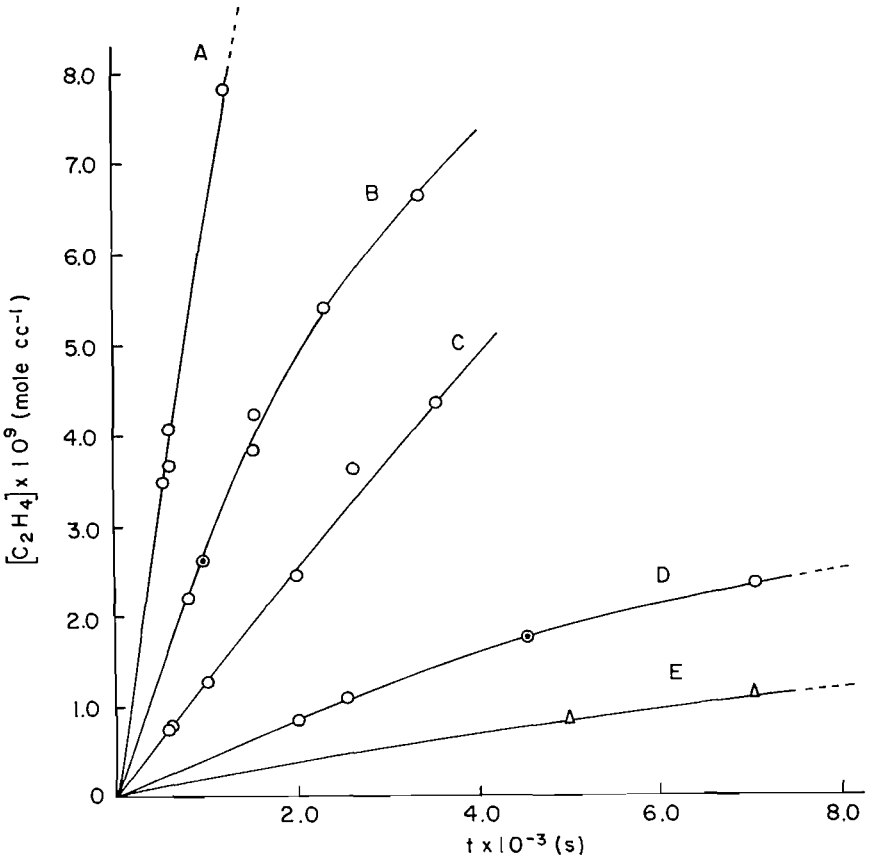

FIG. 3. Typical plots of yield against time for C_2H_4 formation at different temperatures and pressures. The results obtained from the 2.31% mixtures are shown as ○, and those from 3.39% as △. (A) 300.0 °C, 195.3 mm; (B) 290.0 °C, 195.5 mm; (C) 284.4 °C, 154.4 mm; (D) 270.5 °C, 154.7 mm; (E) 260.0 °C, 154.1 mm.

The Relative Concentrations of n-C_3H_7 and i-C_3H_7

The relative rates of production of i-C_3H_7 and n-C_3H_7 are given by (18)

[v] $$v_{6b}/v_{6a} = k_{6b}/k_{6a} = 0.43\, e^{1750/RT}.$$

This ratio is higher than unity in the temperature range of the present experiments. Estimates indicate, however, that the concentrations of i-C_3H_7 are lower than those of n-C_3H_7 at temperatures below about 550 °K. The ratio $[i\text{-}C_3H_7]/[n\text{-}C_3H_7]$ can be estimated from the relationship

[vi] $$[i\text{-}C_3H_7]/[n\text{-}C_3H_7] = (v_{10}/v_8)^{1/2} = (v_{\text{diisopropyl}}/v_{n\text{-}C_6H_{14}})^{1/2},$$

the rate constants k_8 and k_{10} being assumed equal. In the present study diisopropyl could not be determined by vapor-phase chromatography, because its peak was overlapped completely by that of 2-methylpentane; it was possible, however, to measure $v_9 + v_{10}$, the sum of the rates of formation of these substances. The rates of formation of diisopropyl were estimated using the relationship (19)

[vii] $$v_9/(v_8 v_{10})^{1/2} = 2.0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

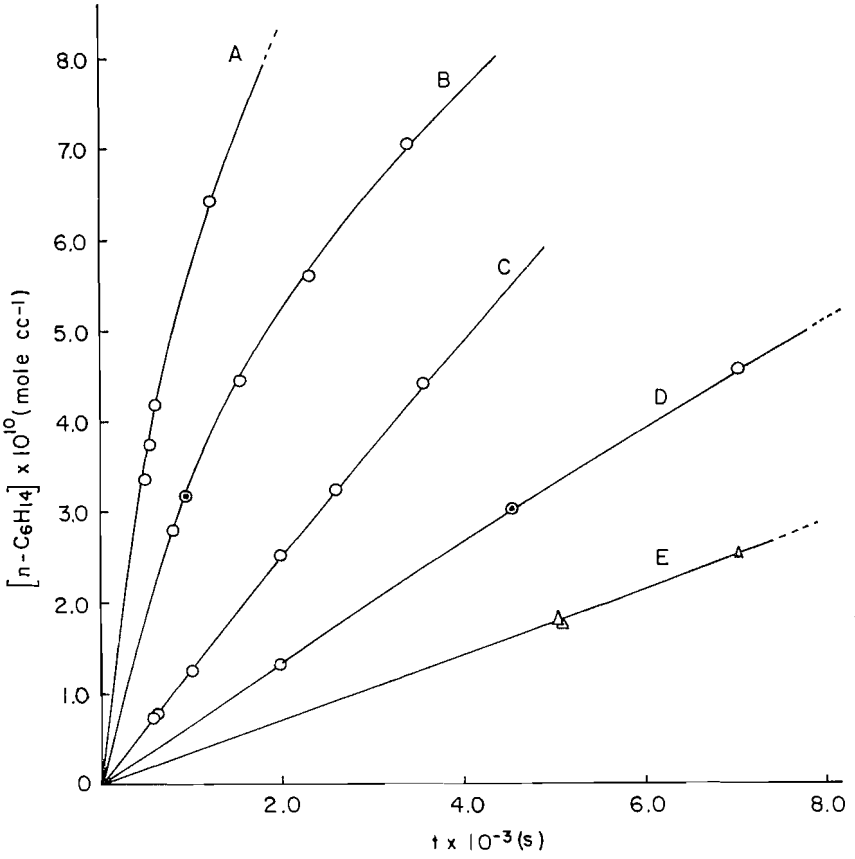

FIG. 4. Typical plots of yield against time for n-C_6H_{14} formation at different temperatures and pressures. The results obtained from the 2.31% mixture are shown as ○, and those from 3.39% as △. (A) 300.0 °C, 195.3 mm; (B) 290.0 °C, 195.5 mm; (C) 284.0 °C, 154.4 mm; (D) 270.5 °C, 154.7 mm; (E) 260.0 °C, 154.1 mm.

and from the known values of $v_9 + v_{10}$. The results obtained in this way are shown in Fig. 7, which leads to the relationship

[*viii*] $$[i\text{-}C_3H_7]/[n\text{-}C_3H_7] \approx 5 \times 10^6\, e^{-17000/RT}.$$

Frey, Danby, and Hinshelwood (20) found in work at higher temperatures that the reactions

[16] $$n\text{-}C_3H_7 + C_3H_8 \underset{[-16]}{\overset{[16]}{\rightleftharpoons}} C_3H_8 + i\text{-}C_3H_7$$

are sufficiently rapid that the radicals n-C_3H_7 and i-C_3H_7 are at equilibrium with one another. The present results, however, show that in the temperature range of our experiments the concentrations of these radicals differ from the equilibrium concentrations. If these reactions were so fast that equilibrium was established, the n-C_3H_7 radical concentration would be reduced to a few percent of that of i-C_3H_7, which is more stable by 3.5 kcal/mole (21). It therefore appears that under the present conditions reactions [16] and [−16] are not sufficiently rapid to establish equilibrium. The temperature coefficient of the ratio $[i\text{-}C_3H_7]/[n\text{-}C_3H_7]$, corresponding to 17 kcal/mole, is related to the increasing rate of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

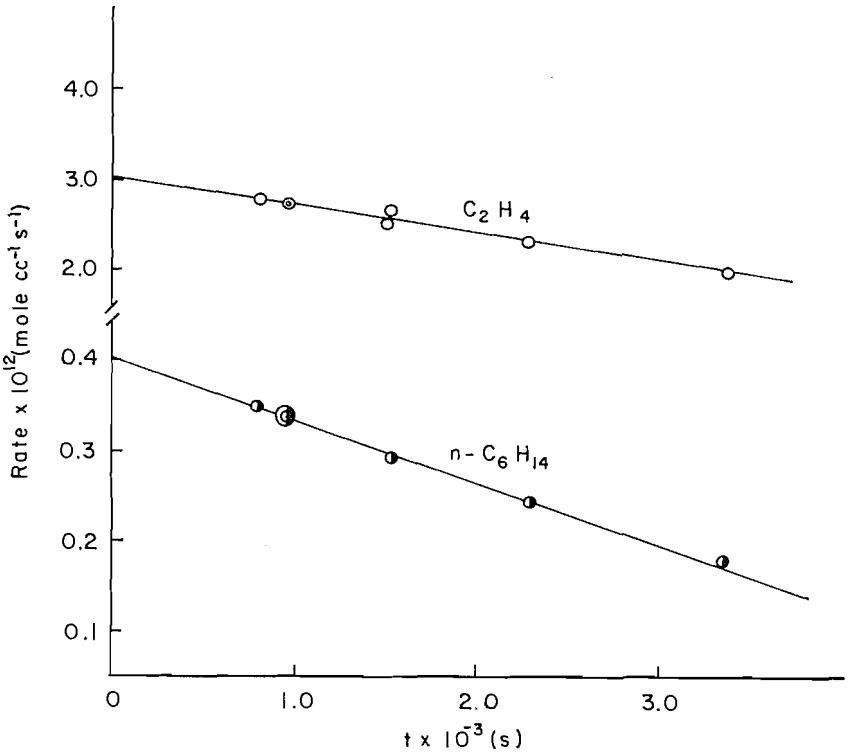

FIG. 5. Typical plots of rate against time for C_2H_4 and n-C_6H_{14} formation at 290.0 °C; 195.5 mm of 2.31% azomethane–propane mixture.

breakdown of the n-C_3H_7 radical as the temperature increases. This throws further light on why the procedure of Bywater and Steacie (4, 8) led to too low a value for E_7.

Energy Levels for the Reactions of Propyl Radicals

The activation energy $E_7 = 31.4$ kcal/mole is related to the standard enthalpy change ΔH_7^0 for reaction [7] by

$$[ix] \qquad \Delta H_7^0 = E_7 - E_{-7} + RT$$

$$[x] \qquad = \Delta H_{7,0}^0 + \int_0^T \Delta C_p^0 \, dT$$

where $\Delta H_{7,0}^0$ is the standard enthalpy change at 0 °K. By definition

$$[xi] \qquad \Delta H_{7,0}^0 = D_0^0(n\text{-}CH_3\text{—}CH_2CH_2)$$

where D_0^0 denotes the dissociation energy at 0 °K. Therefore,

$$[xii] \qquad D_0^0(n\text{-}CH_3\text{—}CH_2CH_2) = E_7 - E_{-7} + RT - \int_0^T \Delta C_p^0 \, dT.$$

At 550 °K (the middle of the present temperature range), substitution of $E_7 = 31.4$ and $\int_0^T \Delta C_p^0 \, dT = 3.3$ (on the assumption that C_p^0 is the same for n-C_3H_7 as for C_3H_8), and use of the heat capacities of C_2H_4 and C_3H_8 (22) and of CH_3 (23) gives

$$D_0^0(n\text{-}CH_3\text{—}CH_2CH_2) = 29.2 - E_{-7} \text{ kcal/mole.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

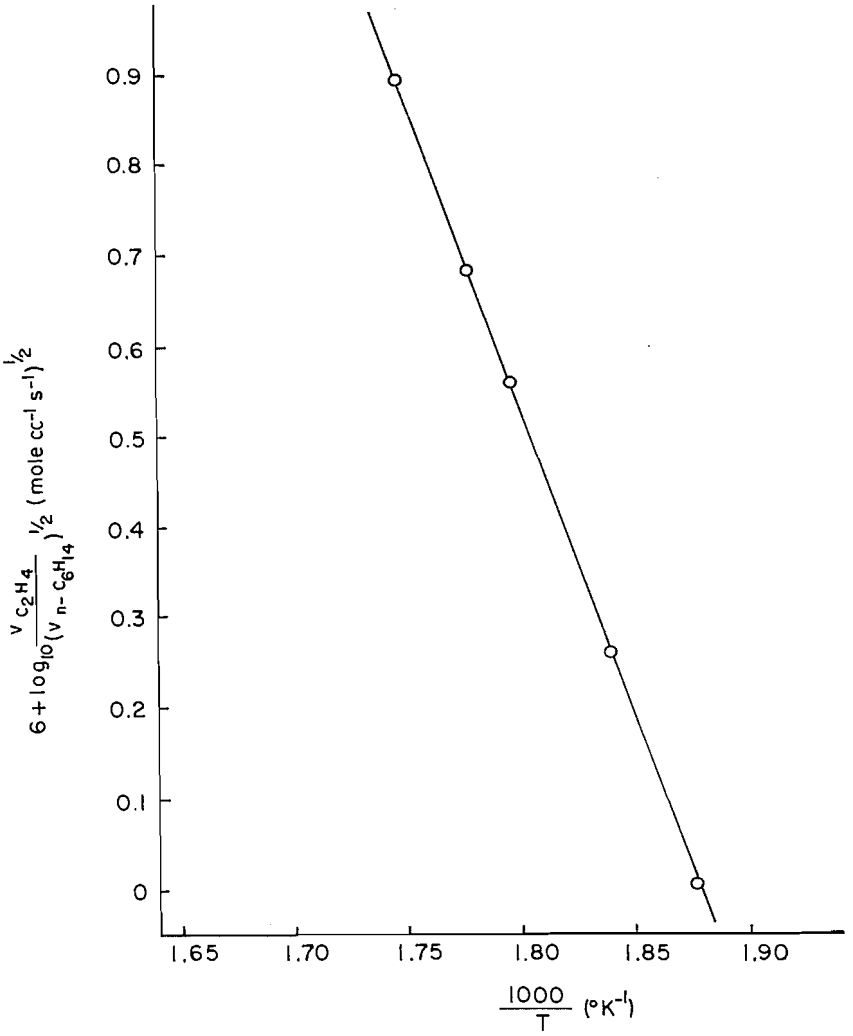

FIG. 6. Plot of $\log_{10} \frac{v_{C_2H_4}}{v_{n\text{-}C_6H_{14}}^{1/2}}$ against $1/T$.

Mandelcorn and Steacie (24) obtained a value of 7.0 ± 1.5 kcal/mole for E_{-7}, while Brinton (25), from a more extensive study, obtained a value of 8.9 kcal/mole, which is about the upper limit of the former.

Use of $E_{-7} = 8.9$ kcal/mole leads to

$$D_0^0(n\text{-}CH_3\text{—}CH_2CH_2) = 20.3 \text{ kcal/mole.}$$

This value together with $\Delta H_{f,0}^0(CH_3) = 34.2$ kcal/mole (26) and the heats of formation of ethylene and propane at 0 °K gives

$$\Delta H_{f,0}^0(n\text{-}C_3H_7) = 28.4 \text{ kcal/mole}$$

and

$$D_0^0(n\text{-}C_3H_7\text{—}H) = 99.4 \text{ kcal/mole,}$$

which is in excellent agreement with the value of 99.5 kcal/mole obtained by Stevenson

An energy diagram for the system of reactions involving the $n\text{-}C_3H_7$ and $i\text{-}C_3H_7$ radicals is shown in Fig. 8. It is based on the values derived above, on the fact that the difference between the primary and secondary C—H bond dissociation energies is 3.5 kcal/mole (21), and on the result that the activation energy for the addition of a hydrogen atom to propylene

[18] $$H + C_3H_6 \rightarrow CH_3CHCH_3$$

is 1.5 kcal/mole (29). The diagram relates to 298 °K.

The activated complexes for reactions [18] and

[19] $$H + CH_3CHCH_2 \rightarrow CH_3CH_2CH_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

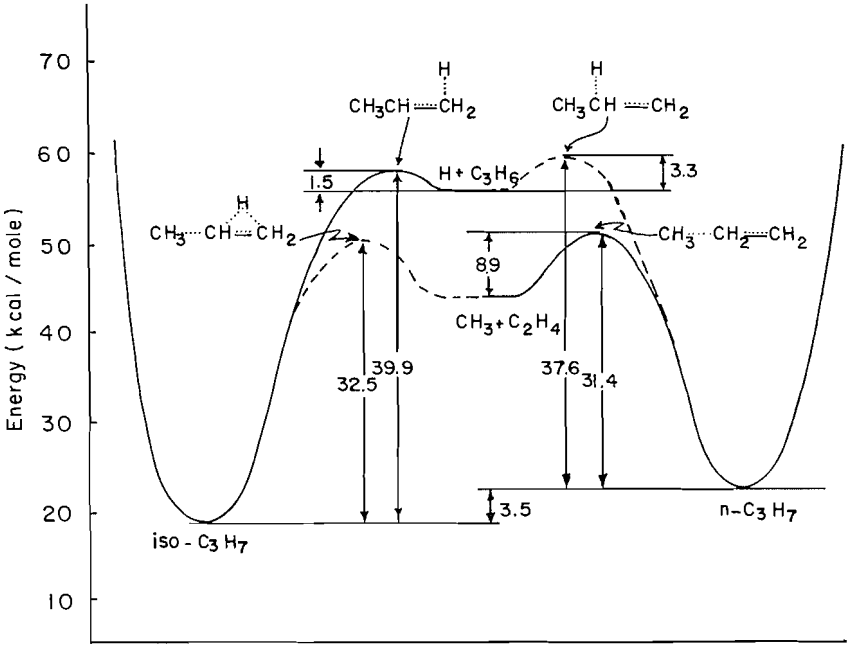

FIG. 8. Schematic energy diagram for the reactions of n-C_3H_7 and i-C_3H_7 radicals at 298.16 °K.

have structures that may be represented as

$$CH_3\overset{\overset{H}{|}}{C}H{=}CH_2 \quad \text{and} \quad CH_3\overset{\overset{H}{|}}{C}H{=}CH_2$$

Since the entropy of n-C_3H_7 at 298 °K is only 1.8 e.u. (entropy unit) greater than that of i-C_3H_7 (28), it is reasonable to assume equal entropies for these two activated complexes. From the relative rates of [18] and [19] it can then be estimated that the activation energy of [19] is about 3.3 kcal/mole, as compared with 1.5 for [18]. When a hydrogen atom reacts with propylene at room temperature there will therefore be formed 5% n-C_3H_7 and 95% i-C_3H_7 (30). These values lead to a value of 37.6 kcal/mole for the activation energy of the reverse of reaction [19] and of 39.9 kcal/mole for the reverse of that of reaction [18]. These values are about 3 kcal/mole higher from previously reported values (4, 6, 8, 15).

There is still controversy about the Arrhenius parameters for reaction [15].

[15] $$CH_3CHCH_3 \rightarrow CH_3 + C_2H_4$$

Kerr and Trotman-Dickenson (15) obtained

$$k_{15} = 2.0 \times 10^{10}\, e^{-29500/RT}\ s^{-1},$$

whereas Heller and Gordon (16) obtained

$$k_{15} = 1.0 \times 10^{12}\, e^{-32500/RT}\ s^{-1}.$$

In both investigations the frequency factor is low, probably because of the tightness of the structure produced during the simultaneous breaking of two bonds.

[15] $$CH_3CHCH_3 \rightarrow CH_3\text{---}\overset{\overset{H}{|}}{C}H\text{---}CH_2 \rightarrow CH_3 + C_2H_4$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Because of this low entropy of the activated state the reverse reaction is of negligible importance compared with

[−7] $$CH_3 + C_2H_4 \rightarrow CH_3CH_2CH_2$$

even though the reverse of [15] may be slightly favored energetically. No i-C_4H_{10} or diisopropyl was obtained in the reaction of CH_3 with ethylene (25).

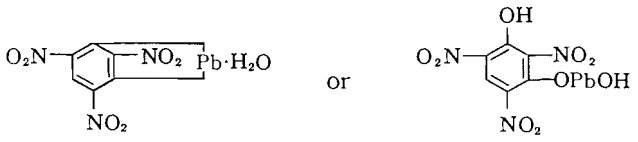
THE KINETICS OF SORPTION AND DESORPTION OF WATER VAPOR BY LEAD STYPHNATE



TED B. FLANAGAN
Chemistry Department, University of Vermont, Burlington, Vermont
Received June 6, 1966

ABSTRACT

The kinetics of dehydration and rehydration of lead styphnate monohydrate have been studied as a function of the number of cycles of dehydration and rehydration. The activation energy for dehydration of a repeatedly dehydrated sample is 14.6 kcal/mole compared with 21.7 kcal/mole for the virgin hydrate. Mechanisms for these sorption and desorption phenomena are discussed.

INTRODUCTION

In a previous study (1) of the dehydration of the primary explosive lead styphnate monohydrate, it was observed that the virgin monohydrate, as crystallized from solution,

(I) (II)

lost water at an approximately linear rate (100–130 °C). (I is the usually accepted structure of lead styphnate monohydrate; however, recent work indicates that II may be a more likely structure (1, 2).) The activation energy for the dehydration of virgin monohydrate is 21.7 kcal/mole (1). It was also noted that the subsequent dehydration of rehydrated samples occurred more readily and with different kinetics than the original dehydration (1). Because of the general paucity of information about such systems (3), i.e. systems capable of dehydration and rehydration (exclusive of true zeolites), the behavior of lead styphnate upon repeated cycles of dehydration–rehydration was investigated in some detail.

EXPERIMENTAL

The experimental apparatus was similar to the one previously described (1). The quartz helix balance (Microchemical Specialties, Berkeley, California) had a sensitivity of 1.0 cm/mg. After evacuation to 10^{-6} mm of mercury at room temperature, the samples (approximately 6 mg of powder, average particle size 7 microns) were dehydrated *in vacuo* at the temperature of the run. The preparation of the lead styphnate used for those studies has previously been described (1).

RESULTS

Dehydration

Figure 1 shows a series of dehydration runs with the same sample of lead styphnate monohydrate (119.3 °C). The rate of dehydration is greatly enhanced upon repeated dehydration–rehydration cycles until after approximately 6 or 7 cycles the rate appears to have become reproducible. In reality, however, the rate continues to increase slowly, e.g. after approximately 30 cycles the rate of dehydration increased to a value twice that of the apparent maximum rate shown in Fig. 1. It was noted earlier that the kinetics of dehydration are zero and first order, with respect to time, for the first (the original) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the second dehydration respectively (1). This finding was confirmed here and the rate of the dehydration is approximately the same as in the original study after storage for 3 years. The extent of the agreement of the dehydration data with a first order rate law increases with the number of cycles, e.g. in Fig. 1 curve *b* is described by a first order rate equation from approximately 10 to 75% dehydration whereas curve *c* is well described by a first order equation from 10 to 90%. The behavior shown in Fig. 1 is reproducible, i.e. another sample exhibited the same sequence of behavior with rates closely identical with those of Fig. 1 for each run of the sequence.

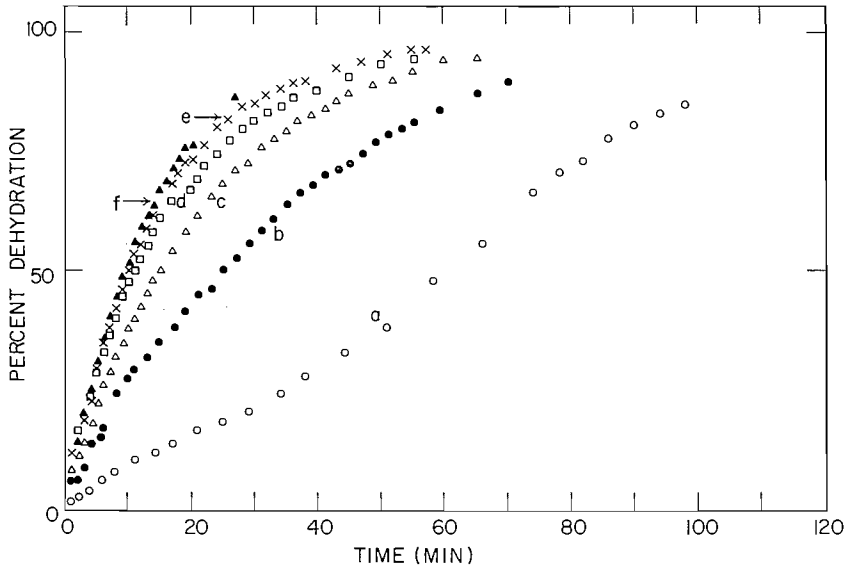


FIG. 1. Repeated dehydration runs of lead styphnate monohydrate (119.3 °C); *a* represents the dehydration of the virgin monohydrates and *b* represents the second dehydration run with the same sample, etc. The samples were rehydrated between runs at 22.5 °C and $P_r = 0.66$. Before dehydration the samples were evacuated at room temperature.

The change in the rate of dehydration after run *f* (curve *f*, Fig. 1) was small enough to allow the determination of a meaningful activation energy (Fig. 2). The determinations were made at random temperatures to minimize the effect due to the slow increase in rate. The first order rate constants are shown as an Arrhenius plot (Fig. 2); the energy of activation is 14.6 kcal/mole. The linearity of the plot suggests that self-cooling is not significant. Since the presence of small pressures of water vapor accelerates the virgin dehydration, impedance effects are believed to be negligible in this system. Evidence for this is that the addition of a series of pressures (20 mm to 150 mm) of methyl chloride accelerated the rate slightly, but the effect was not as marked as would be expected if impedance was a dominant feature of the reaction. Interruption and resumption of a run did not introduce any new features.

Rehydration

It was of interest to determine the kinetics of rehydration during the approach to "constant activity". Percent rehydration – time curves ($P_r = P/P_0 = 0.66$, where P is the actual vapor pressure employed and P_0 is the saturation water vapor pressure at 22.5 °C) are shown in Fig. 3. It is seen that, as for dehydration, the kinetics change

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

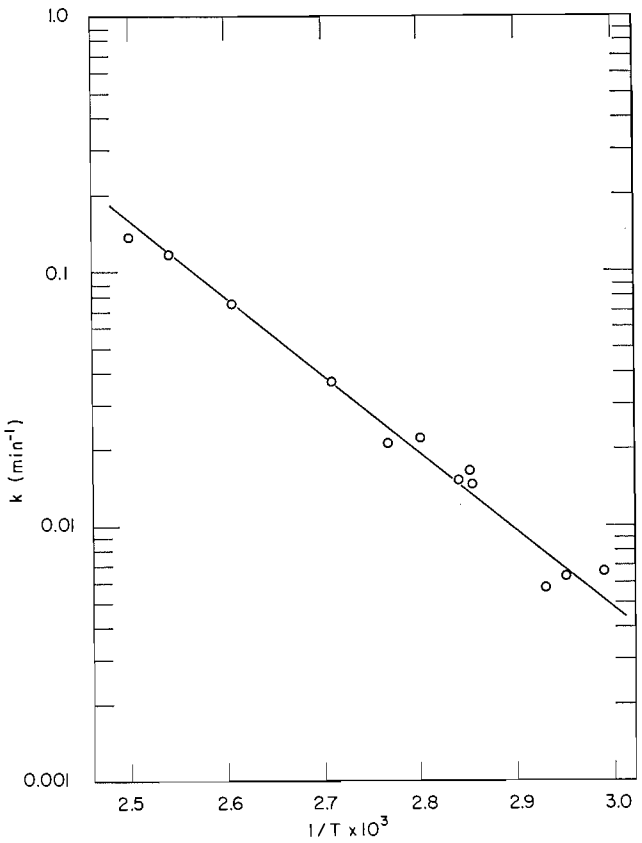

FIG. 2. The Arrhenius plot for the dehydration of a sample of lead styphnate monohydrate of "constant activity".

markedly with the number of cycles of dehydration–rehydration. After the initial rehydration, the data, e.g. curves *b* and *c*, may be described by a linear dependence of percent rehydration upon time as was reported earlier (1). (Since the kinetics were not systematically investigated as a function of the number of cycles of dehydration–rehydration in the earlier study, the linear rehydration rate was the only behavior noted in several runs with different samples.) The initial rehydration curve differs markedly from the subsequent curves. The amount of rehydration of this run in its initial stages is greater than for subsequent runs, whereas during the final stages of this rehydration the rate is slower than the subsequent runs.

After a sample of "constant activity" is attained, the dependence of percent rehydration upon time is best described by a diffusion-controlled slow step. The kinetics shown in curves *d* and *e* (Fig. 3) are well described by a $t^{\frac{1}{2}}$ rate law (4).

Equilibration with Water Vapor

During rehydration studies of the anhydride it was noted that rehydration did not go to completion under some conditions. This incomplete rehydration was investigated by allowing an anhydride of "constant activity" to equilibrate with a constant water vapor pressure (13.6 mm) at various temperatures for at least 24 h. Results are shown in Fig. 4 as a plot of log K versus $1/T$. K is taken as the percentage of water in the styphnate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

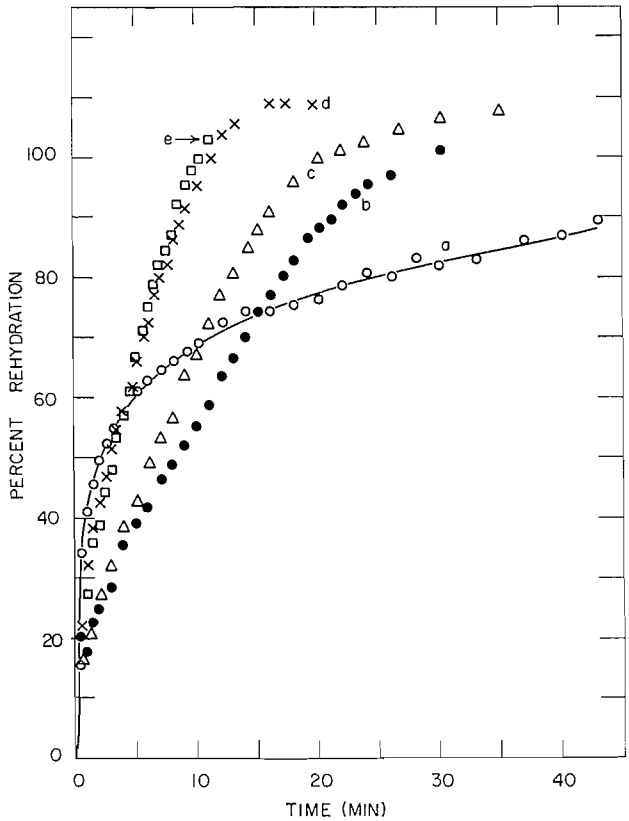

FIG. 3. Repeated rehydration runs of lead styphnate anhydride (22.5 °C, $P_r = 0.66$). The solid curve *a* shows the first rehydration run and *b* represents the second rehydration, etc. Before rehydration the samples were dehydrated *in vacuo* at 119.3 °C.

matrix; the water vapor pressure (constant) and factors for the conversion of percentage of water into concentration units are incorporated into the value of K. It should be noted that this approach is somewhat unorthodox for such a system, and if the anhydride and the monohydrate always existed as distinct crystalline phases one would not be able to vary the temperature at an arbitrary water vapor pressure (Fig. 4) because it would constitute a violation of the phase rule. Apparently below approximately 15% rehydration, the rehydrated species does not have the characteristics of a distinct crystalline phase. It can be argued that not enough time has been allowed for complete reaction; however, at lower temperatures where the rate processes are slower, complete rehydration occurs rapidly (Fig. 3).

The sharp increase of K below 70 °C (Fig. 4) should be noted. Several other determinations in the 60 to 65° temperature ranged showed that the rehydration went to completion and therefore supported the behavior exhibited in Fig. 4. Figure 5 shows the approach to equilibrium of a sample at a temperature in the nonlinear region of Fig. 4, 61.7°, compared with a run which did not go to completion, 73.2°. The acceleratory nature of the former curve indicates that a cooperative effect is operating. It is suggested that in the nonlinear region enough of the hydrate is found in localized regions of the lattice for it to attain the characteristics of a distinct phase, and therefore a violation of the phase rule occurs; further rehydration then readily occurs at the hydrate nuclei formed at localized regions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

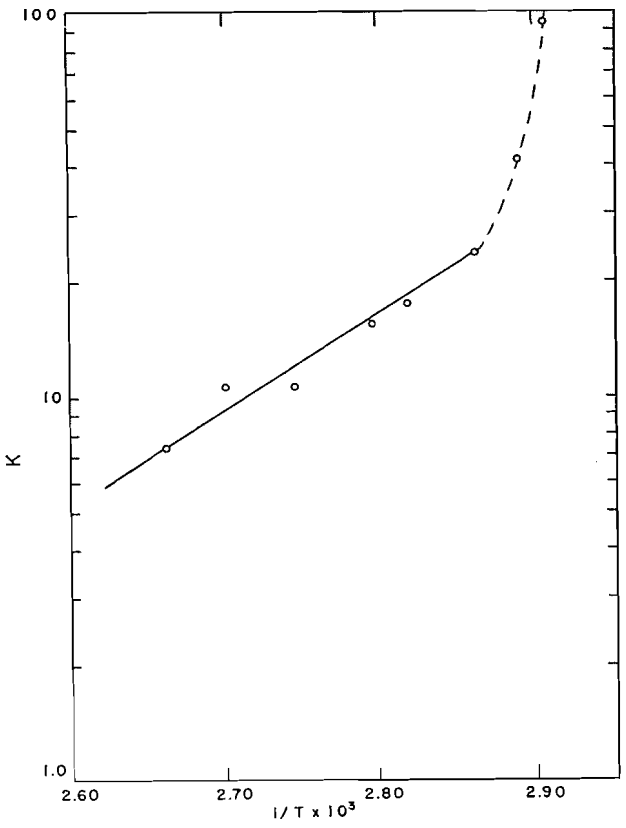

FIG. 4. A plot of the equilibration of water vapor (13.6 mm) with the anhydride as a function of temperature.

of the lattice. The acceleratory portion of Fig. 5 represents the rapid growth of the second phase. The subsequent kinetics and absolute rate of dehydration of the sample rehydrated at 61.7° were comparable with samples rehydrated at 22.5°, although the latter samples did not exhibit acceleratory behavior in their rehydration–time curves (Fig. 3).

The slope of the linear portion of the plot (75 to 100 °C, Fig. 4) yields a heat of ~ 12 kcal/mole. It seems reasonable that ~ -12 kcal/mole should represent ΔH for the recombination of water vapor with a styphnate matrix having the crystal structure of the anhydride, provided that this heat of recombination is independent of the percentage reaction over the range from 0 to 15% of sorbed water. Ideally, "sorption" isotherms should be determined at a series of temperatures to obtain the isosteric heats of "sorption"; in their absence, the limited equilibrium data of the present study should mainly be regarded as showing that an equilibrium is established between sorbed water and gaseous water under the conditions obtaining in Fig. 4 and that this equilibrium breaks down at a critical composition of sorbed water when the second solid phase appears.

Previous deductions based on examination of X-ray powder patterns of the anhydride and rehydrated species indicated that these species were closely similar (1). The evidence presented above shows, however, that these species can exist as distinct crystalline phases (Fig. 4). It must be concluded therefore that the hydrate and anhydride have very

For personal use only.

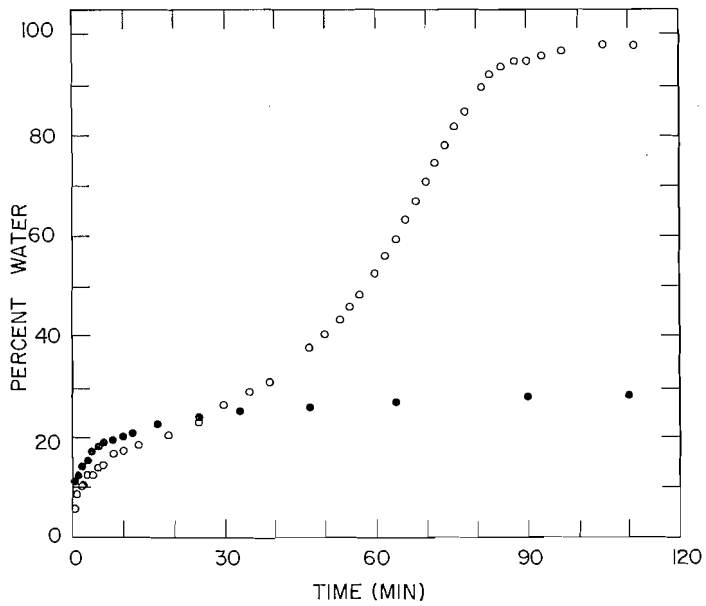

FIG. 5. Rehydration of lead styphnate (13.6 mm water vapor): (●) 73.2 °C, (○) 61.7 °C.

closely related structures as indicated by the ease of their interconversion and similarities of X-ray powder patterns.

Sorption of Other Vapors

The quasi-zeolitic behavior of lead styphnate indicates that lead styphnate may be capable of sorbing other vapors. Barrer and co-workers (5) have found that potassium benzene sulfonate monohydrate can sorb many vapors after dehydration. After dehydration *in vacuo*, the same sample used for the above studies was exposed to ethanol (22.5°) at $P_r = 0.66$. After approximately 60 h of equilibration, the extension of the helix indicated that $\alpha' = 10\%$ (where α' is the percentage reaction assuming a 1:1 addition compound); half of this ethanol was desorbed by evacuation at room temperature.

Methanol was sorbed to a much greater extent than ethanol and after equilibration for 20 h ($P_r = 0.66$, 22.5 °C), $\alpha' = 90\%$. The rates of both the sorption and the subsequent desorption were much slower than the corresponding reactions of water; the desorption of methanol is shown in Fig. 6 (114.0 °C). The run shown in Fig. 6 is the last of a series of methanol sorption and desorption runs. The dehydration run (114.0°) shown on Fig. 6 was made immediately after the methanol run and the rate was considerably faster than that of the dehydration runs prior to the methanol sorption studies, although these, too, were faster than the methanol desorption. A first rate equation describes the removal of methanol from near the commencement of the desorption to approximately 60% reaction.

DISCUSSION

It is of interest to consider the mechanism of dehydration of repeatedly dehydrated–rehydrated samples. A valid mechanism must account for the result that compared with the virgin dehydration process, which proceeds by an interfacial mechanism (1), the activation energy for dehydration of dehydrated–rehydrated samples is decreased by 7.3 kcal/mole while the absolute rate of dehydration is increased only by a factor of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

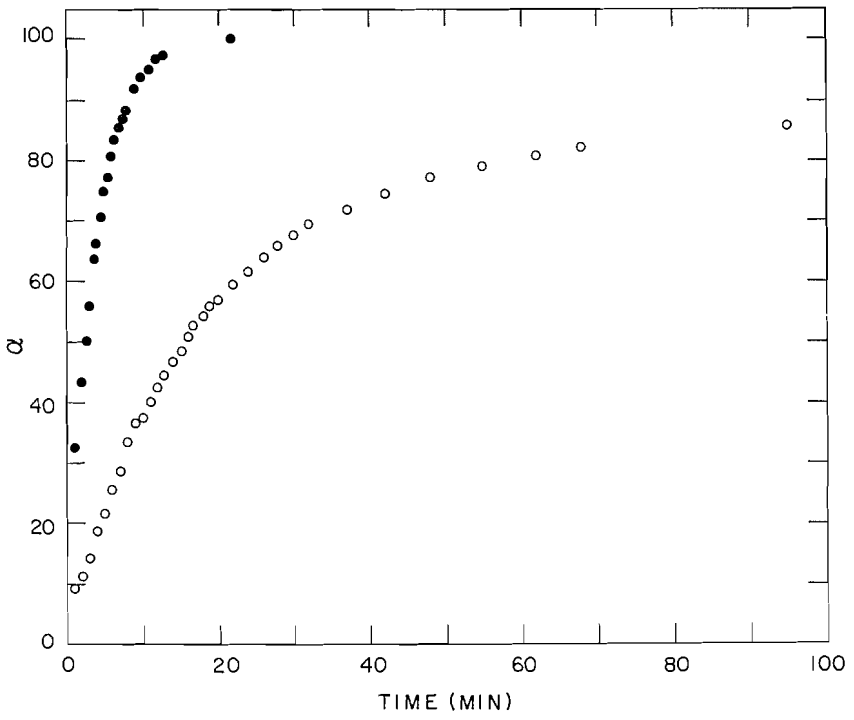

FIG. 6. Comparison of the desorption kinetics of methanol and water (114.0 °C): (○) methanol, (●) water.

approximately 7. This implies that an entirely new mechanism must be operative, since it is difficult to explain such changes by a normal interfacial mechanism. It should be mentioned that a true first order reaction, such as observed here for the entire dehydration process, is quite rare in solid state decomposition reactions, and since there appear to be only two mechanisms to account for these kinetics in this system they will be discussed in some detail below.

One possible mechanism which must be considered is random nucleation of the well-separated blocks of rehydrated material. In view of the tendency found in the styphnates for one-dimensional growth (1, 6), it is not unreasonable to suppose that after random nucleation, one-dimensional growth will occur. At small times such a mechanism leads to (7)

$$[1] \qquad \alpha = (2k_2/k_1c)[(\exp -k_1t) + k_1t - 1],$$

where k_1 and k_2 are the rate constants for growth and nucleation respectively and c is the dimension of the block in the growth direction. For $t > c/2k_2$ eq. [1] becomes (7)

$$[2] \qquad \alpha = 1 + (2k_2/k_1c)[1 - (\exp (k_1c/2k_2))](\exp -k_1t).$$

A plot of $\log (1 - \alpha)$ versus t gives first order kinetics with slope k_1 and intercept $\log \{(2k_2/k_1c)[(\exp (k_1c/2k_2)) - 1]\}$ from which $2k_2/c$ can be obtained. For eq. [2] to describe the data of the present investigation below 110 °C, $2k_2/c$ must be negative, which is untenable. In addition since eq. [1] itself does not fit the data at small times this implies that for eq. [2] to be applicable the blocks which were nucleated at $t = 0$ have decomposed immediately, again an unreasonable conclusion.

An alternative mechanism which leads to first order kinetics is that the entire reaction takes place by desorption of water molecules from the surface of the blocks. The surface, or some active fraction of the surface, is supplied by diffusion of highly mobile water molecules from within the rehydrated lattice. At any time the concentration of water molecules on the surface of the blocks is proportional to the fraction of hydrate within the blocks or, more accurately, the chemical potential of water on the surface is the same as the chemical potential within the solid blocks. The rate is proportional to the chemical potential. An activation energy for surface desorption of 14.6 kcal/mole is not unreasonable, i.e. it is comparable to the heat of the recombination of water with the anhydride lattice, $\sim$ 12 kcal/mole (Fig. 4). Furthermore, since only a small fraction of the surface need be active for this process, the absolute rate could be much smaller than would correspond to desorption from the entire surface. The important and unusual requisite for this mechanism is the high degree of mobility of water molecules within the rehydrated matrix. Water vacancies will be generated during dehydration and their mobility may be high, judging from the rapidity of the rehydration reaction at, for example, 22.5 °C (Fig. 3).

The remarkable ease of rehydration of this system is of considerable interest. In contrast to zeolitic systems, evidence has been presented here to indicate that two distinct solid phases can be formed. What is the nature of the transport processes which occur during rehydration? Are water molecules transported through the hydrate phase to the growing internal interface? These questions, which have relevance to non-zeolitic solid state rehydration processes in general, can be considered here only in a speculative fashion.

The results shown in Fig. 5 are of interest with regards to the mechanism of rehydration. The fact that a cooperative process occurs (61.7 °C) suggests that nucleation and growth are the slow steps and diffusion to the nuclei must be rapid. The rehydration behavior up to the onset of the autocatalytic portion is describable by a diffusion-controlled slow step. If the nuclei are situated within the anhydride matrix, growth of the nuclei could occur through the maintenance of an "equilibrium" concentration of water molecules within the anhydride matrix. That such an "equilibrium" concentration exists is shown by the "equilibrium" constant studies (Fig. 4). Because the nuclei are located within the anhydride matrix their formation and growth may be slow compared with diffusion resulting from internal strain. In contrast to 61.7 °C the rehydration behavior shown at lower temperatures, e.g. curves *d* and *e* of Fig. 3, is describable solely in terms of diffusion as the slow step, whereas it would be expected that here the nucleation and growth processes would be even slower relative to diffusion than at 61.7 °C. A possible explanation is that a different sequence of events occurs at the lower temperatures; because of the greater degree of supersaturation immediate nucleation occurs adjacent to the surface at low temperatures and diffusion now takes place through the hydrate lattice rather than through the anhydride lattice as at higher temperatures. Diffusion through the hydrate lattice proceeds via water vacancies. These vacancies are continually generated at the internal interface as rehydration proceeds. The assumption of a relatively constant supply of vacancies and the thickening hydrate layer which is formed as rehydration proceeds leads to the $t^{\frac{1}{2}}$ rate law.

ACKNOWLEDGMENTS

Since this is the last of several papers dealing with the kinetics of dehydration and decomposition of lead styphnate, this is an appropriate opportunity to acknowledge a

debt of gratitude to Dr. D. A. Young of Imperial College, London, for his stimulating and helpful comments concerning these papers.

XENON YIELDS IN THE FISSION OF HEAVY ELEMENTS BY MEDIUM-ENERGY PROTONS[1]

J. H. FORSTER,[2] N. T. PORILE,[3] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received July 7, 1966

ABSTRACT

Independent yields for ^{133}Xe and ^{135}Xe and cumulative yields for ^{133}I and ^{135}I in fission of ^{233}U, ^{235}U, ^{238}U, and ^{232}Th with protons of energies 20–85 MeV were measured. Values of Z_p, the most probable charge, were obtained by two different methods. The behavior of Z_p for ^{235}U and ^{233}U differed considerably from that of ^{238}U and ^{232}Th. Total chain yields were obtained for $A = 133$ and $A = 135$.

INTRODUCTION

A large contribution has been made to the study of fission by the measurement of the yields of fission products. Many more data are still required to improve the understanding of the distributions of fission products with their mass and charge and their dependence on excitation energy.

An important part of the existing data has been collected for the rare gases, krypton and xenon. They are both formed in good yield in fission and are particularly suitable for quick, efficient extraction after, or even during, an irradiation. In 1960, Momyer (1) reviewed the extensive radiochemistry of the rare gases and, more recently, many additional techniques have been reported (2–5). Very important data for the fractional cumulative yields of short-lived isotopes of krypton and xenon have been obtained by the emanation technique of Wahl *et al.* (6).

For thermal neutron fission, several measurements (7–11) have been made of the independent yield of ^{135}Xe and the cumulative yield (9, 12) of ^{133}Xe. For a few medium-energy systems, independent yields have been measured (10, 13) for ^{135}Xe and ^{133}Xe (10). Cumulative yields have been obtained for the iodine parents of these two xenon isotopes (10, 13–15). Cumulative yields of ^{133}Xe and ^{135}Xe have been measured (16) for the fission of ^{238}U by 14.7-MeV neutrons.

The present research was a radiochemical study of xenon yields in proton-induced fission of ^{323}Th, ^{238}U, ^{235}U, and ^{233}U, for which no values have been reported previously.

Nuclear charge distribution in the proton-induced fission of ^{235}U and ^{233}U at medium energies had not been studied heretofore. However, considerable data have been obtained in this laboratory for the charge distribution of fission products with $A = 130$–143, formed in proton-induced fission of ^{232}Th (15, 17) and ^{238}U (18, 19). The conclusions from these previous studies could usefully be compared with those, for the same fission systems, from the present work which involved different fission products and different correlation methods. The method used here to determine Z_p, the most probable charge, was similar to that of Storms (10) and of Nethaway and Levy (20). In all three of these studies insufficient yield data were available to construct charge distribution curves and they were assumed to be given by the Gaussian function

$$[1] \qquad f[Z] = \frac{1}{\sqrt{(\pi C)}} \exp\left[-(Z - Z_p)^2 C\right],$$

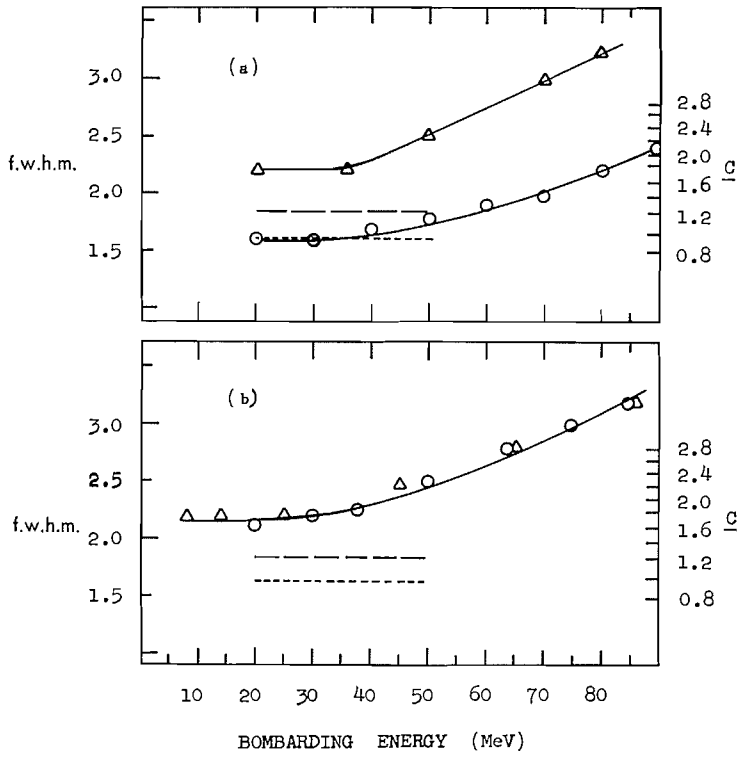

FIG. 1. (*a*) f.w.h.m. of function [1] from previous studies of charge distribution in the fission of ^{238}U with protons: (△) Davies and Yaffe (18); (○) Parikh (19). (*b*) f.w.h.m. of function [1] from previous studies of the fission of ^{232}Th with protons: (△) Pate, Foster, and Yaffe (15); (○) Benjamin (17). Shown for comparison in (*a*) and (*b*) are the f.w.h.m. used in other medium-energy fission systems: (— —) Storms (10); (--) McHugh (13). In (*a*) and (*b*), the alternative ordinates, f.w.h.m. and *C*, were related by eq. [1].

where $f[Z]$ represents the fractional chain yield of an isobar of charge Z. For the present systems, the value of C was estimated from empirical curves in the studies briefly reviewed below.

The first empirical charge distribution curves for individual mass chains were constructed by Wahl and co-workers (6, 21). They obtained the yields of two or three isobaric fission products and fitted the data to the function in eq. [1]. For 10 mass chains the average value of C was 0.86 ± 0.04. Wolfsberg (22) obtained similar empirical curves for fission induced by 14-MeV neutrons. McHugh (13) has made a precise mass spectrometric study of charge distribution in medium-energy fission for the initial 'compound nucleus' ^{236}U. He obtained for chain 135 the yields of iodine, xenon, and cesium and fitted the data to the same Gaussian function with C values from 0.9–1.0 for a range of excitation energy 18–40 MeV. Previous studies in our laboratory have shown a similar constancy in the width of charge distribution curves up to excitation energies of about 40 MeV, for proton-induced fission of ^{232}Th and ^{238}U. However, most of these curves now appear to be too wide, from the evidence of McHugh (13) and of Wolfsberg (22) and also from the latest of the studies in this laboratory (19), in which narrower curves were obtained. There is an interesting parallel here with the history of charge distribution at low energy, in which the earlier curves were shown to be too wide as more precise data were obtained.

The Gaussian curves used in several studies are characterized in Fig. 1 (*a* and *b*) by their full width at half maximum (f.w.h.m.) and the corresponding C value in eq. [1].

EXPERIMENTAL

1. Targets and Irradiation

The targets were irradiated in the internal circulating beam of protons in the McGill 82-in. synchrocyclotron. For ^{233}U, the target material was finely powdered uranium oxide (5–12 mg) wrapped in aluminium foil of surface density 5.5 mg/cm^2. These irradiations were not monitored, but in the other irradiations the beam intensity (0.5–1.0 μA) was monitored by the reaction $^{65}Cu(p,pn)^{64}Cu$ for the entire proton energy range of 20–85 MeV. The target foils of ^{232}Th, ^{238}U, and ^{235}U and the copper monitor foil had surface densities of 80.8, 46.4, 104.0, and 45.9 mg/cm^2 respectively. A target was assembled by clamping in an aluminium holder a copper monitor foil and a heavy metal foil held in an envelope of aluminium foil (5.5 mg/cm^2). The foils were pressed between aluminium plates in a vise and then carefully sheared to ensure edge alignment. The holder was screwed on to a water-cooled probe and positioned in the cyclotron tank at a radius corresponding to the required proton energy (23). The time of irradiation was from 5–25 min.

2. Chemical Processing

The irradiated target was rapidly removed from the cyclotron to the chemistry laboratory where it was sheared from the holder. The heavy metal and catcher foils were immediately introduced into the gas-sweeping apparatus. The copper foil was processed the following day.

Xenon

Two timed separations of xenon were made, sweeps (*a*) and (*b*), by techniques similar to those used by Dostrovsky and Stoenner (24). The procedure falls into three parts, shown schematically in Fig. 2.

Part 1. Extraction of Xenon and Krypton

To minimize the amount of xenon grown from iodine precursors, the rare gases were separated from the target and other fission products as quickly as possible after the bombardment, while still permitting a complete extraction from the target and catcher foils. Figure 3 gives more details of this part of the experiment. Helium was passed through the following components (from right to left in the figures).

(i) A mercury manostat which maintained the helium pressure at 2–3 cm above atmospheric.

(ii) A steel-float flowmeter capable of measuring rates of up to 100 cc/min.

(iii) A carrier gas injection system. This consisted of a standard column connected to a mercury manometer and a reservoir which contained the carrier gas of spec-pure xenon and krypton in known ratio. A known amount of carrier gas could be injected into the helium stream by diverting it through this system.

(iv) Dissolver and halogen trap. The helium flowed through tap T_1 into these units, each consisting of a simple bubbler attached to a removable flask and to a funnel for introducing liquids. The irradiated materials were put in the dissolver which was evacuated before the rapid introduction of an acid mixture of concentrated HCl, concentrated HNO_3, and 6 M HBr (15:5:1). During the addition of the acid the loss of rare gas was negligible because the initial attack of the foils was slow and was further inhibited by the aluminium wrapping. Helium containing a known amount of carrier gas had a flow rate of 80 cc/min. The metals could be dissolved in less than 5 min by heating the dissolver with an air-blower. Halogens which were swept out of the dissolver were held in the halogen trap containing a concentrated alkaline reducing solution (KOH and $KHSO_3$).

(v) Drier and purifier. The gas stream was purified and dried by solid KOH, CaO, and $Mg(ClO_4)_2$ and by an oil-free titanium sponge at 800 °C and copper oxide at 500 °C. The gases left the unit through tap T_2.

(vi) Adsorption column and thermal conductivity cell. The loading of xenon and krypton on to the adsorption column was indicated on a recorder in a simple bridge circuit by a Gow-Mac AEL 9677 thermal conductivity cell (T.C.C. in Figs. 2–4). The column was a glass U tube containing activated charcoal (Columbia, grade L, 40–60 mesh). This was cooled in liquid air and a similar cold trap used to purify the helium at the beginning of the flow system, while another was used as a safety trap at the end of the system.

At the end of sweep (*a*), taps T_1 and T_2 were closed and the helium stream diverted through taps T_3 and T_4 during part 2 of the experiment. The time, t_1, from the end of bombardment to the end of this sweep (*a*) was usually less than $\frac{1}{2}$ h. There was no further need for fast procedures; parts 2 and 3 each took about 1 h.

Part 2. Separation of Xenon from Krypton

This part of the experiment is outlined in Fig. 2, part 2, and described in more detail in Fig. 4, which also includes a table giving the temperatures, helium flow rates, and times used for the desorption of first the krypton and then the xenon. The separate fractions were collected on activated charcoal in cold traps 1 and 2, and the unloading was indicated on the recorder. Then, trap 2 was kept at liquid air temperature and evacuated for 10 min, which removed helium but caused no measurable loss of xenon.

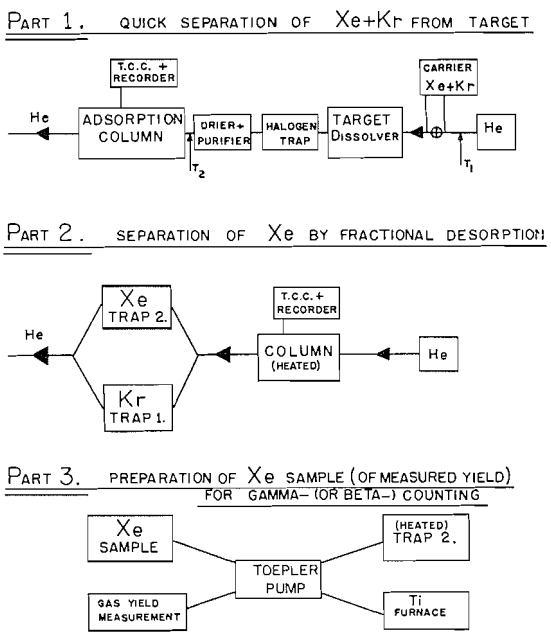

FIG. 2. Part 1: Quick separation of Xe + Kr from target. Part 2: Separation of Xe by fractional desorption. Part 3: Preparation of Xe sample (of measured yield) for gamma (or beta) counting.

Part 3. Preparation of Xenon Sample

Figure 2, part 3, gives a simple description of this part of the experiment. Trap 2 was heated to 120–150 °C for 45 min and the desorbed xenon transferred with an automatic Toepler pump to a quartz furnace for purification over oil-free titanium at 800–900 °C. The chemical yield of the cooled, purified xenon was measured in a gas burette and a sample for gamma spectrometry was prepared by condensing and sealing the xenon into a pyrex glass vial cooled in liquid air. These vials were of standard dimensions and had a volume of approximately 2 cc. Appendix B describes the preparation of xenon samples for beta activity measurements in a gas phase proportional counter.

After about 30 h a similar procedure was followed in which a sweep (*b*) was taken to prepare a sample of xenon formed purely from decay of iodine precursors. Taps T_1 and T_2 were reopened and for about 45 min helium was bubbled at a rate of 80 cc/min through the dissolver and halogen trap, both warmed with the air-blower. The procedure for the sweep (*b*) and the subsequent parts 2 and 3 was the same as described above. The time, t_2, was taken from the end of sweep (*a*) to the end of sweep (*b*).

Some further experimental details are now described. After a complete experiment the dissolver, halogen trap, purifier, and drier units were dismantled for cleaning, decontamination, re-greasing, and replacement of chemicals. When the apparatus was not in use, the adsorption of impurities on the charcoal was avoided by keeping the traps under vacuum and heated to about 120 °C. In an experiment the helium was passed through the tested flow system for about 1 h before the processing of a target.

The extraction of xenon in sweeps (*a*) and (*b*) was assumed to be quantitative. These techniques had been tested previously by Dostrovsky and Stoenner (24). In the present work the high efficiency of the xenon separation was confirmed by two methods. (i) Two xenon fractions were found by mass spectrometric analysis to contain only 1–2% of krypton. (ii) No xenon activity was detected in a krypton fraction from sweep (*a*). This sample was prepared in a sealed vial and the γ-activity measured only a few hours after bombardment. The 249-keV gamma ray of $^{135}Xe^{g}$ was not detected, though this had a very intense activity in the xenon fractions from sweep (*a*). It is unlikely that there was a significant loss of xenon from the target before processing. Recoiling fission products were held in the relatively thick aluminium catcher foils. Diffusion losses of xenon have been shown (25, 10, 13) to be very small for foil targets, though more significant for powdered targets of uranium oxide. No correction was made for these small losses; however, for ^{233}U they may have a small effect on the relative yields of iodine and xenon.

Copper

The copper foil was weighed and then dissolved and separated from other spallation products on an anion-exchange resin (26). The chemical yield was determined by ethylenediametetraacetic acid titrations with murexide indicator.

TABLE I

Xenon isotopes (27) contributing to the gamma spectra in the present study

Isotope	Half-life	Gamma energy (MeV)	% abundance	α_K	α_K/α_{LM}
$^{133}Xe^m$	2.3 d	0.233	100	4.4±1.4*	2.2
$^{133}Xe^g$	5.3 d	0.080	100	1.5±0.2	5
$^{135}Xe^g$	9.2 h	0.250	97	0.054	6.5
		(0.610)	3	—	—
$^{131}Xe^m$	12.0 d	0.164	100	29	2
$^{129}Xe^m$	8.0 d	0.196	100	10	2
$^{127}Xe^g$	36.0 d	0.173	25	0.13	—
		0.205	73	0.09	—
		(0.378)	21	0.01	—

*Experimental value which may be too low.

3. Radiation Measurements

The gamma activity of xenon and copper was measured by a 3 in. × 3 in. NaI crystal linked to a multichannel analyzer. Table I gives the xenon species that contributed to the gamma spectra in this work. The efficiency, for measurement of their gamma activities, was determined with a calibrated gas phase β-proportional counter. Appendix B describes these determinations and explains why the gamma and not the beta activity of fission product xenon was measured. The counting efficiency for the 511-keV annihilation radiation of ^{64}Cu (12.8 h) was known (23).

RESULTS AND DISCUSSION

For a xenon sample from sweep (*a*), a composite photopeak, due to the 249-keV gamma ray of $^{135}Xe^g$ and the highly converted 233-keV gamma ray of $^{133}Xe^m$, gave a decay curve with two components of half-lives 9.2 h and 2.3 d. The resolution of this curve became increasingly difficult for proton energies lower than 35 MeV, where the yield of ^{133}Xe decreased rapidly. Longer bombardments could not be used to increase the activity of $^{133}Xe^m$ because this would also increase the difficulties due to the growth of $^{133}Xe^g$ from ^{133}I. When most of the $^{133}Xe^m$ had decayed to the ground state, the 80-keV photopeak due to $^{133}Xe^g$ gave a simple decay curve with a half-life of 5.3 d. The gamma rays of $^{131}Xe^m$ and $^{129}Xe^m$ are highly converted and ^{127}Xe

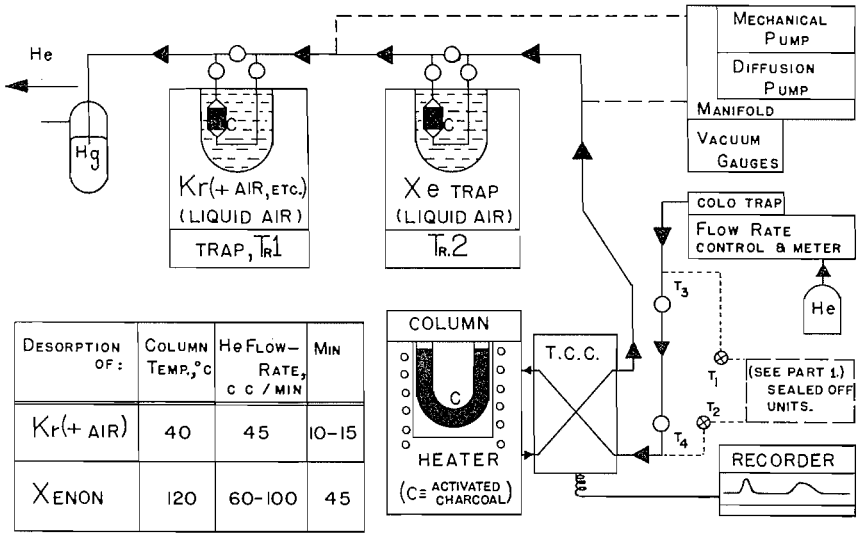

FIG. 4. Separation of Xe from Kr.

is formed in relatively low yield. The yield of more neutron-deficient isotopes increases with increasing proton energy and with decreasing (N/Z) of the target. However, these activities interfered significantly only above about 70 MeV for ^{235}U and above about 30 MeV for ^{233}U. A satisfactory correction could be made even in the worst case, ^{233}U with 70-MeV protons, in which the correction to the $^{133}Xe^{m}$ peak was about 25%. No such interference occurred in the samples of decay-product xenon from sweep (*b*).

For a xenon sample from sweep (*b*), a negligible amount of $^{133}Xe^{m}$ was detected. The 249-keV peak of $^{135}Xe^{g}$ and the 80-keV peak of $^{133}Xe^{g}$ decayed with half-lives of 9.2 h and 5.3 d respectively.

Appendix A describes the calculations of relative and absolute cross sections from the activity data.

Information was obtained on fission yields and their variations in chains 133 and 135, for the fission of ^{232}Th, ^{238}U, ^{235}U, and ^{233}U with protons of energy 20–85 MeV. A study of the relative independent yields of the isomers of ^{133}Xe will be published shortly.

The growth from ^{135}I was always relatively small during the short time $(t_0 + t_1)$. Figure 5 shows the excitation functions for ^{135}Xe (independent) and ^{135}I (cumulative). Table II and Fig. 6 give values of the ratio, $R_{c/I}{}^{135}$, of the cumulative yield of ^{135}I to the corrected independent yield of ^{135}Xe. This ratio was used in a new method to obtain values of Z_p, to be discussed later.

Table III gives the cross sections for the more complex chain 133, and Table II the cross sections for the 135 chain. For unmonitored irradiations, yields are shown relative to the cumulative cross section of ^{135}I, Y (experimental number). The simplified correction for growth from ^{133}I is given in Appendix A. This overcorrects slightly the yield of $^{133}Xe^{g}$, but the correction was of the same order as the experimental error.

The values of the cross section of $^{133}Xe^{m}$, and therefore of $^{133}Xe^{g}$ and of total ^{133}Xe, were dependent upon the value of α_K for the 233-keV γ-radiation from $^{133}Xe^{m}$. Rose's (30) theoretical value of 6.7 is much higher than the only reported (31) experimental value of 4.4 $\pm$ 1.4. Figure 7 shows the cross sections of ^{133}Xe with $\alpha_K = 4.4$ and 6.4 for the fission of

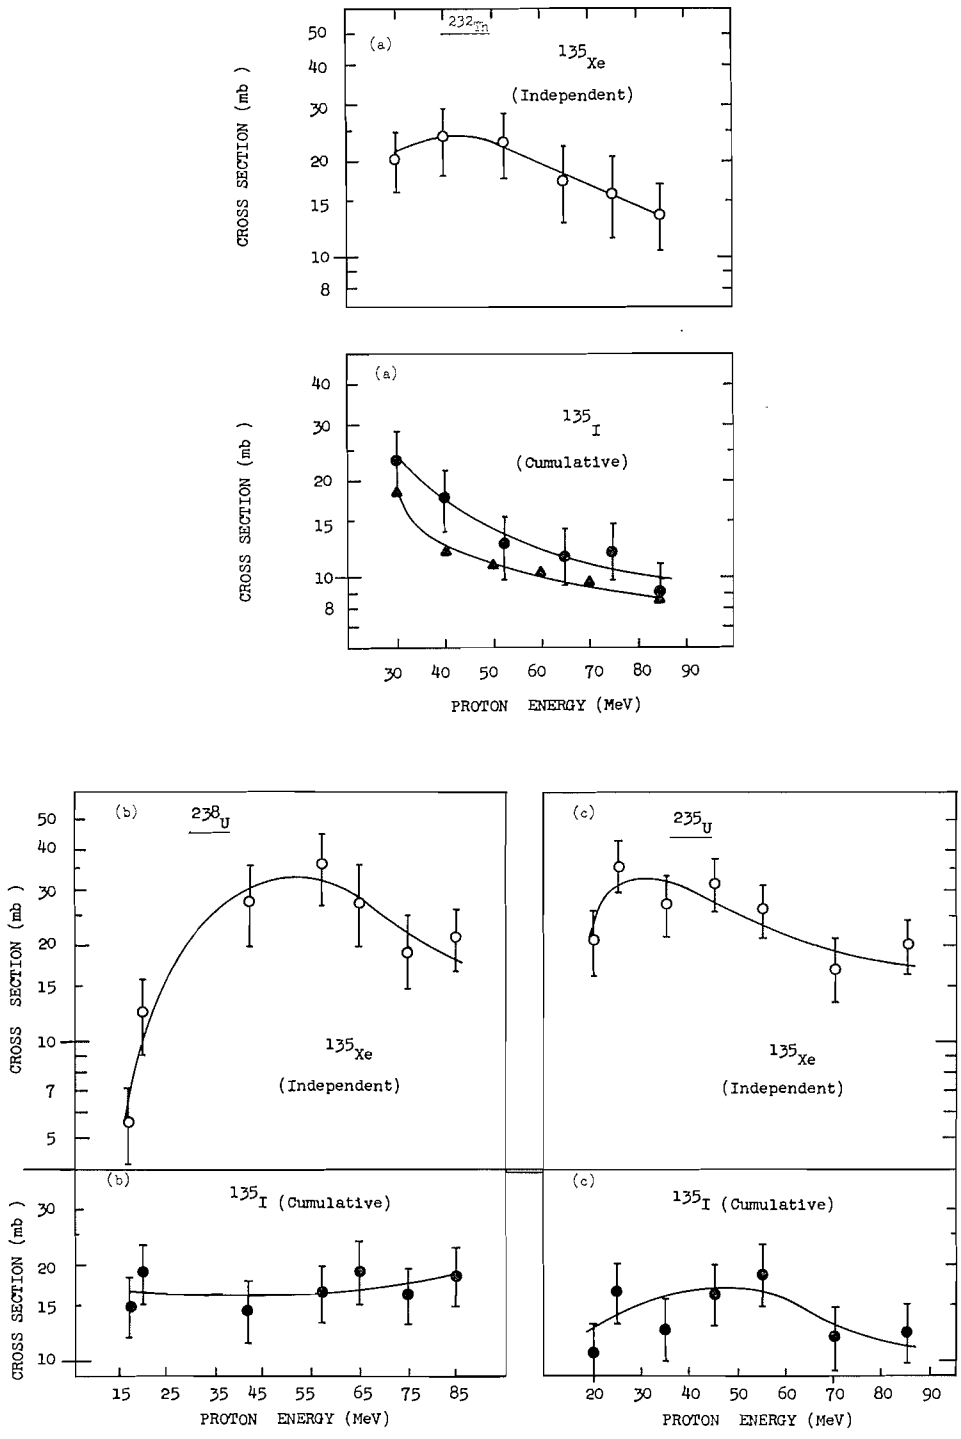

FIG. 5. Excitation functions for the cumulative formation of ^{135}I, and the independent formation of ^{135}Xe (corrected for growth from the decay of ^{135}I). (*a*) ^{232}Th: (●) present work; (▲) reference 15. (*b*) ^{238}U. (*c*) ^{235}U.

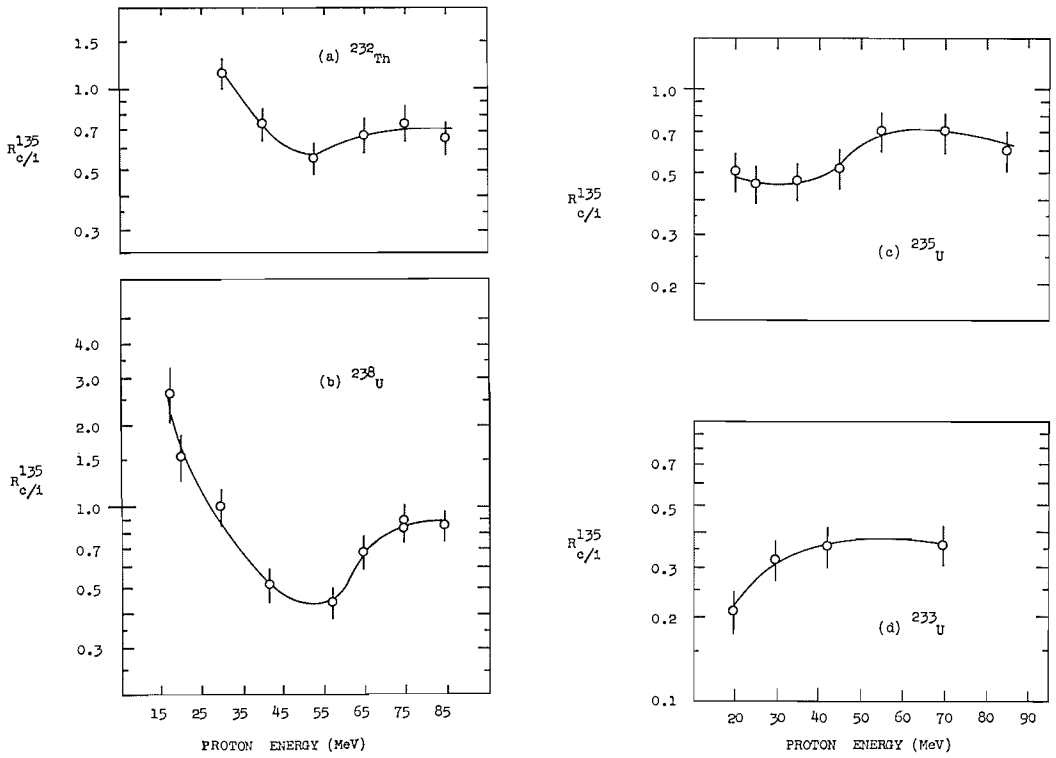

FIG. 6. Dependence of the relative formation of ^{135}I and ^{135}Xe upon proton energy, expressed in the form

$$R_{c/i}^{135} = \frac{\text{cumulative yield of } ^{135}\text{I}}{\text{independent yield of } ^{135}\text{Xe, corrected}}:$$

(*a*) ^{232}Th; (*b*) ^{238}U; (*c*) ^{235}U; (*d*) ^{233}U.

^{232}Th. It also shows that the uncertainty in α_K introduces only a relatively small error within the experimental error. Figure 8 gives the formation cross sections for ^{133}Xe in the fission of ^{238}U and ^{235}U. The uncertainty in α_K introduced only small errors in the ratio, $R_{c/i}^{133}$, of the cumulative yield of ^{133}I to the independent yield of ^{133}Xe. Figure 9 illustrates these ratios. The solid lines are for $\alpha_K = 4.4$ and, for ^{232}Th, the broken line is for $\alpha_K = 6.4$.

Only two of the excitation functions presented here have been reported previously. By a totally different method, using solid iodide sources, Pate, Foster, and Yaffe (15) determined the cumulative yields of ^{133}I and ^{135}I for the fission of ^{232}Th with 10–85 MeV protons. Their excitation functions are plotted in Figs. 5(*a*) and 7 and can be directly compared with the present data, since Meghir (29) has shown that little systematic error exists between the monitor cross sections used in the two studies. The previous results were slightly lower for ^{135}I and considerably lower for ^{133}I than the present values which were obtained from much simpler decay curves and are therefore probably more reliable.

The cross sections had an uncertainty of $\pm 25\%$, which was compounded from estimated errors in the beam monitoring, in the measurement of activities and chemical yields, and in analyses of γ-ray spectra and decay curves. The estimated uncertainty does not include the important systematic error due to uncertainty in the value of α_T for ^{133}Xe^m. A larger uncertainty existed for the lowest energy experiments in which activities were lower and decay

errors larger. The main conclusions in this paper depend not on absolute yields but on the yield ratios $R_{c/i}^{133}$ and $R_{c/i}^{135}$, which could be obtained with an uncertainty of $\pm 15\%$.

Determination of Empirical Values of Z_p

An empirical charge distribution curve could not be constructed with the present data which consisted, for each fission system, of an independent yield of xenon and a cumulative yield of iodine for the chains 133 and 135. However, values of Z_p and fractional chain yields were obtained empirically by two methods which assumed that, for the present systems with proton energies below 55 MeV, the charge distribution curves were given by eq. [1] with $C = 1.20 \pm 0.25$. These curves on a $(Z - Z_p)$ plot allowed a more systematic analysis of the data for all four targets than would have been possible with the known empirical curves on an N/Z plot, which are available only for ^{232}Th and ^{238}U. Above 55 MeV, no attempt was made to extract Z_p values, because at these energies the broader and possibly asymmetric charge distribution curves are not very well defined.

The basis of method 1 to determine Z_p empirically was the relationship between Z_p and the yield ratio $R_{c/i}^{A}$ which is defined by the expression:

$$R_{c/i}^{A} = \frac{\text{cumulative yield of beta parent}}{\text{independent yield of daughter}}.$$

*Very large uncertainty in $\sigma(^{61}Cu)$ at this energy.
†The simple growth correction is not satisfactory at this energy.

If one assumes that the charge distribution is given by eq. [1],

$$[2] \qquad R_{c/I}{}^{A} = \frac{\sum_{Z_i=(Z'-1)}^{Z_i=(Z'-6)} \exp\left[-(Z_i - Z_p)^2/C\right]}{\exp\left[-(Z' - Z_p)^2/C\right]},$$

where Z' is the nuclear charge of a daughter isobar, and therefore $(Z' - 1)$ is the charge of the negative-beta parent. Figure 10 shows functions of $R_{c/I}{}^{A}$ versus $(Z' - Z_p)$ computed with five C values from 0.7–1.9. Now, if $R_{c/I}{}^{A}$ is known experimentally for a pair of adjacent isobars (e.g. $^{133}I/^{133}Xe$) the corresponding value of $(Z' - Z_p)$ for the daughter isobar may be read from one of the functions for a particular C value. Figure 10 also demonstrates the dependence of the empirical value of Z_p on the width of the assumed charge distribution curve. When the daughter nuclide has $(Z' - Z_p) \approx +0.7$, the empirical value of Z_p is shown to be almost independent of C.

Method 2 to determine Z_p empirically was similar to that described by Storms (10) who determined Z_p in chains 133 and 135, from data similar to those in this work. Simple Bateman equations (32) were used to construct two lengthy expressions for the measured activities of $^{133}Xe^{g}$ from sweeps (*a*) and (*b*). The two simultaneous equations could be solved for Z_p by

*Using $\alpha_K = 4.4$ ($\alpha_T = 6.3$).

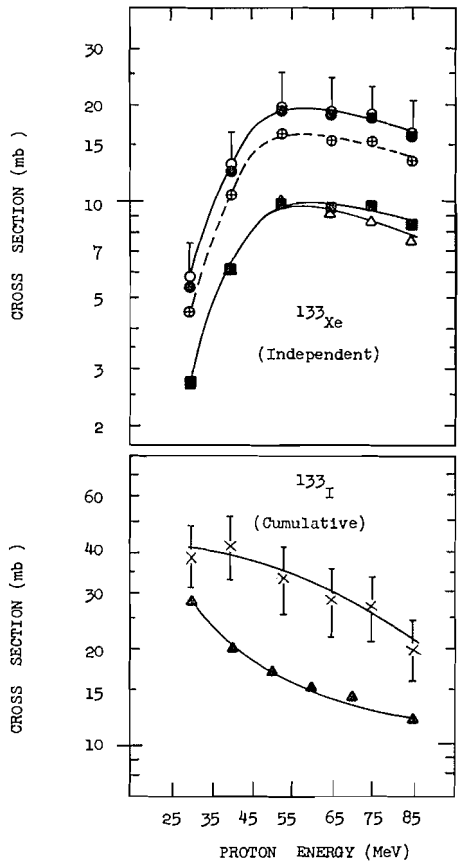

FIG. 7. Excitation functions for the cumulative formation of ^{133}I and the independent formation of ^{133}Xe^{m}, ^{133}Xe^{g}, and total ^{133}Xe from the proton-induced fission of ^{232}Th. $\alpha_K = 4.4$ ($\alpha_T = 6.3$): (△) overcorrected independent, ^{133}Xe^{g}; (■) independent, ^{133}Xe^{m}; (○) uncorrected independent total ^{133}Xe; (●) overcorrected independent total ^{133}Xe. $\alpha_K = 6.4$ ($\alpha_T = 9.3$): (⊕) overcorrected independent total ^{133}Xe; (×) cumulative cross sections of ^{133}I; (▲) reference 15.

assuming a Gaussian charge distribution for chain 133. The equations were similar to those used by Storms, except for a few minor revisions in parameters, but they were solved differently by a stepwise reiteration method. Initially, the value of $(Z - Z_p)$ for ^{133}Xe was set equal to +2.0 and was decreased in steps of 0.1, and finally in steps of 0.01, until the value of Z_p was consistent with the gamma activity data substituted in the two simultaneous equations. The above procedure and the method of programming it for the McGill I.B.M. 7044 computer were first tested with the simpler chain 135 and then applied to chain 133. The derived Z_p values for both chains were in excellent agreement with those from method 1.

Empirical Z_p Values for Chains 133 and 135

Table IV gives the value of $(Z - Z_p)$ for ^{133}Xe and ^{135}Xe, obtained empirically by method 2 with values of $C = 0.95$, 1.20, and 1.45. The table also gives the values obtained by method 1 with $C = 1.20$. The very good agreement between the two methods proved the reliability of method 1, which should be useful in future work, since accurate values of $R_{c/l}^{A}$ could be obtained for many pairs of adjacent isobars formed in fission. For the four targets studied, Fig. 11 shows the variation of Z_p with proton energy; the solid lines were obtained with

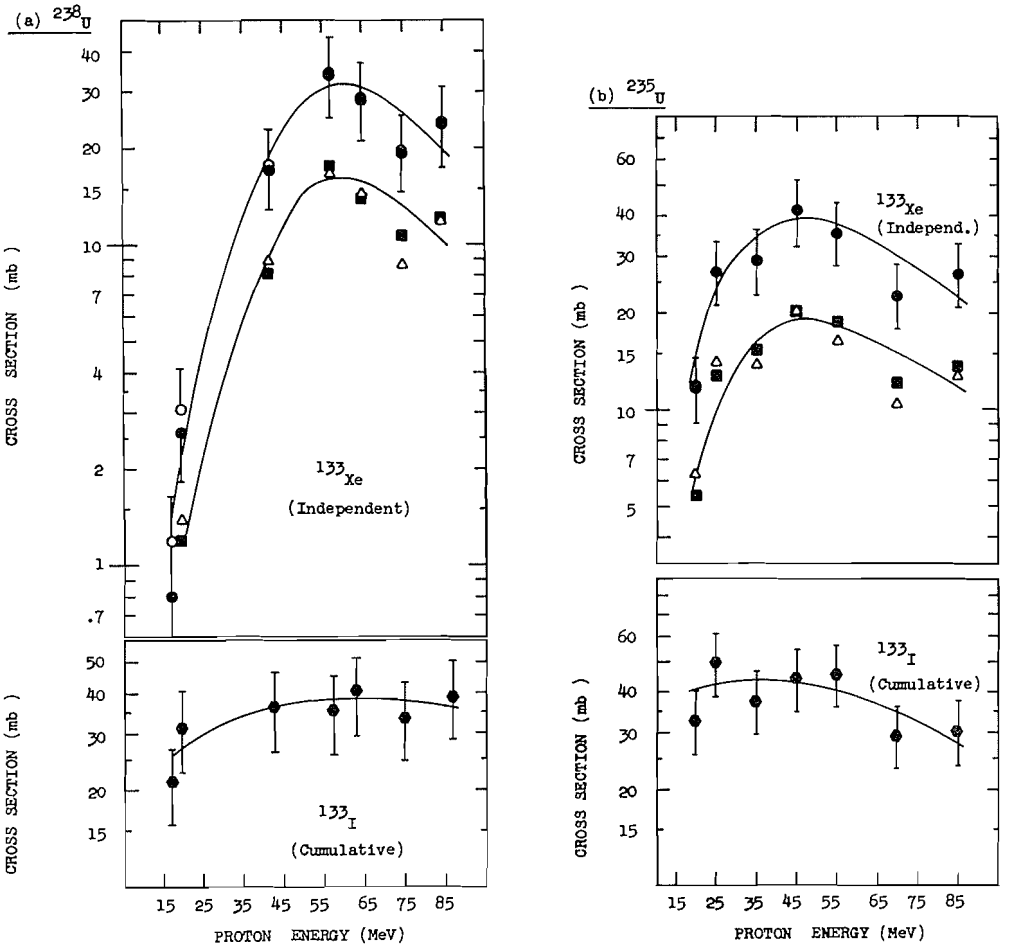

FIG. 8. Excitation functions for the cumulative formation of ^{133}I and the independent formation of ^{133}Xe^{m}, ^{133}Xe^{g}, and total ^{133}Xe: (*a*) ^{238}U; (*b*) ^{235}U. $\alpha_K = 4.4$ ($\alpha_T = 6.3$): (△) overcorrected independent, ^{133}Xe^{g}; (■) independent, ^{133}Xe^{m}; (○) uncorrected independent total ^{133}Xe; (●) overcorrected independent total ^{133}Xe.

$C = 1.20$ and the long and short broken lines with $C = 0.95$ and 1.45 respectively. The uncertainty in Z_p was estimated to be 0.1–0.2 charge units, depending on the value of $(Z - Z_p)$. As expected from Fig. 10, the variation of C had least effect on the empirical value of Z_p when $(Z - Z_p) \approx +0.7$, which for xenon isotopes reduces to $Z_p \approx 53.3$. For fission of ^{232}Th and ^{238}U, the displacement of the empirical value of Z_p from beta stability, Z_A, and the effect of proton energy are shown in Fig. 12 for the above results obtained with $C = 1.20$ and for results previously reported from this laboratory. Values of Z_A were taken from the same Z_A function (33, 34) which for Z_{133} and Z_{135} gave values 54.95 and 55.65. For ^{232}Th and ^{238}U, with protons of a particular energy the value of $(Z_A - Z_p)$ for chain 133 was approximately equal to that for chain 135. Thus, the change in Z_p for the mass chains 133 to 135 was about 0.7, since this was the corresponding change in Z_A. There is good agreement between the present and previous data for the same mass region. The rate of change of Z_p with energy, in this figure, was consistent with that obtained by McHugh (13) and by Nethaway and Levy (20) for some medium-energy fission systems.

*Large uncertainty in monitor cross section at this energy.
†At this energy, charge distribution curves probably have $C \geqslant 1.45$.

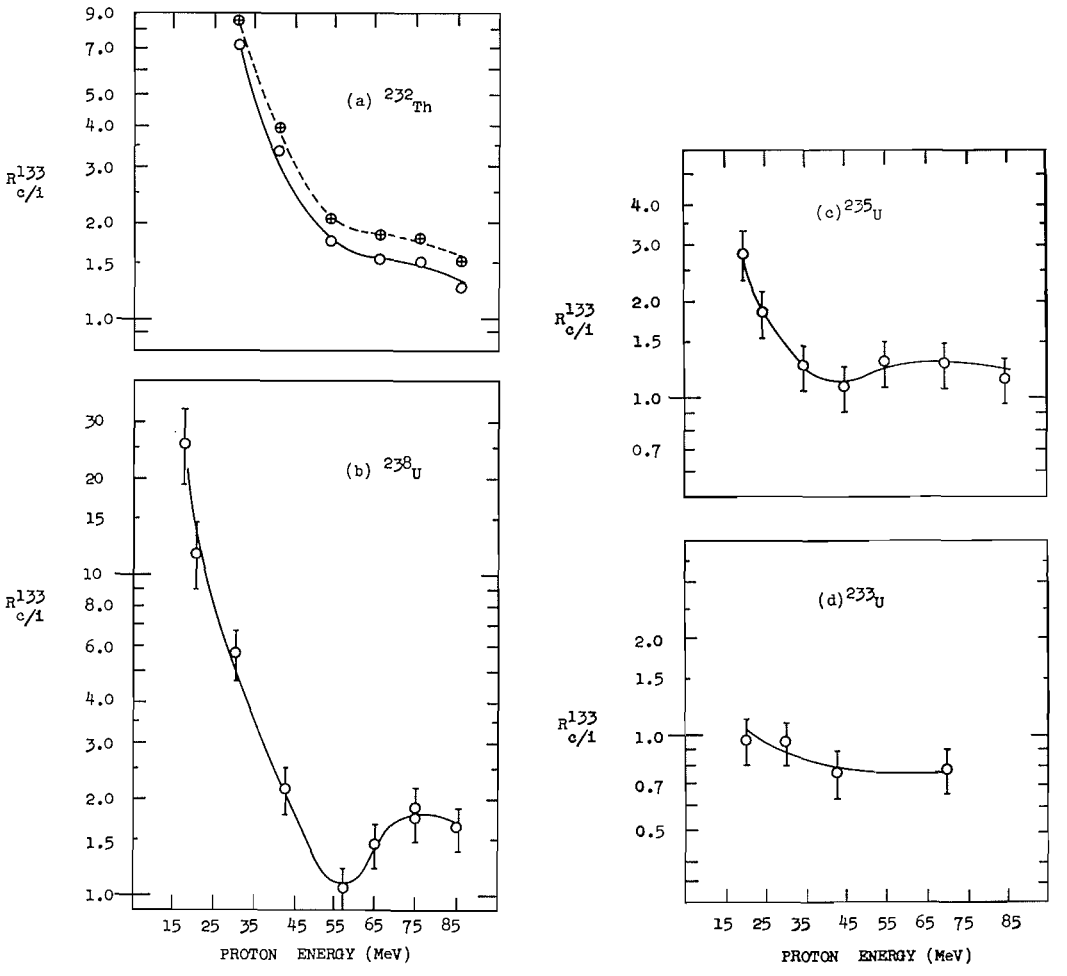

FIG. 9. The dependence of the relative formation of ^{133}I and ^{133}Xe upon proton energy

$$R_{c/I^{133}} = \frac{\text{cumulative yield of } ^{133}I}{\text{independent yield of } ^{133}Xe, \text{ overcorrected}};$$

(*a*) ^{232}Th; (*b*) ^{238}U; (*c*) ^{235}U; (*d*) ^{233}U. The data for ^{133}Xe were obtained with $\alpha_K = 4.4$ ($\alpha_T = 6.3$). In (*a*) the data were plotted also for $\alpha_K = 6.4$ ($\alpha_T = 9.3$): (○) $\alpha_K = 4.4$; (⊕) $\alpha_K = 6.4$.

For proton-induced fission of ^{235}U and ^{233}U, no Z_p values have been reported previously. However, the limited data collected here for these systems appear to be reliable because of the good agreement between previous and present data for ^{232}Th and ^{238}U. For the proton-induced fission of ^{235}U and ^{233}U, the variations of Z_p with energy are significantly different from the changes, which are now fairly well established, for the proton-induced fission of ^{238}U and ^{232}Th. Figure 12 shows that, at lower energies, the targets of lower (N/Z) had Z_p values closest to beta stability, but at 40–50 MeV the values of $(Z_A - Z_p)$ were almost equal for all four targets.

Observed charge distributions of fission products cannot yet be explained satisfactorily in terms of the distribution of charge at scission and the emission of pre- and post-fission neutrons. Little is known about neutron emission in the present fission systems, but rough

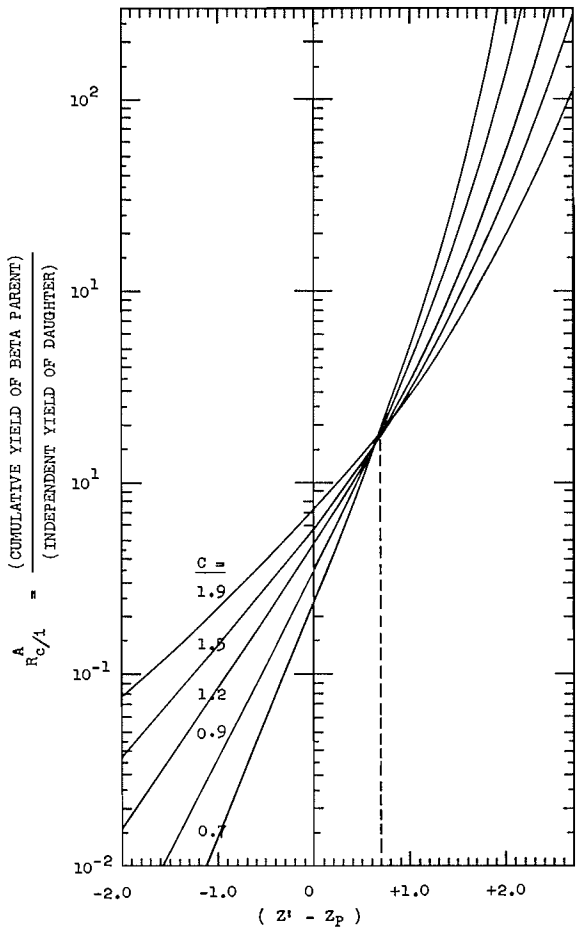

FIG. 10. Theoretical $R_{c/i}{}^A$ versus $(Z' - Z_p)$ from eq. [2] with values of $C = 0.7, 0.9, 1.2, 1.5$, and 1.9.

estimates could be made from the empirical Z_p values, if the latter were assumed to be given by the simple u.c.d. (unchanged charge division) postulate. This postulate (35) gives a very simple mechanism for fission in which the most probable initial fragments have the same value of (N/Z) as the fissioning nucleus. Although an exact formulation of this rule would involve a knowledge of the yields of pre- and post-fission neutrons, the rule may be closely approximated by the simplified expression

$$[3] \qquad (Z_p)_{f.p.} = (A_{f.p.}) \frac{(Z_{target} + Z_{projectile})}{(A_{target} + A_{projectile} - \bar{\nu}_T)} .$$

Here, $\bar{\nu}_T$ is the average total number of neutrons in a fission event leading to the fission product, f.p. The vertical lines on the right in Fig. 11 have divisions corresponding to values of Z_p for chains 133 and 135, which were postulated from eq. [3] with the values of $\bar{\nu}_T$ given by the numbers besides the lines. For a particular energy, the empirical Z_p was equated with a postulated Z_p in order to estimate directly from Fig. 11 the corresponding value of $\bar{\nu}_T$. Fig. 13 (*a* and *b*) shows the estimated average total neutron yields as a function of energy, obtained from two sets of data, one for chain 135 and the other for chain 133. There is evidence (21, 13) that for low- and medium-energy fission the u.c.d. postulate predicts values of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

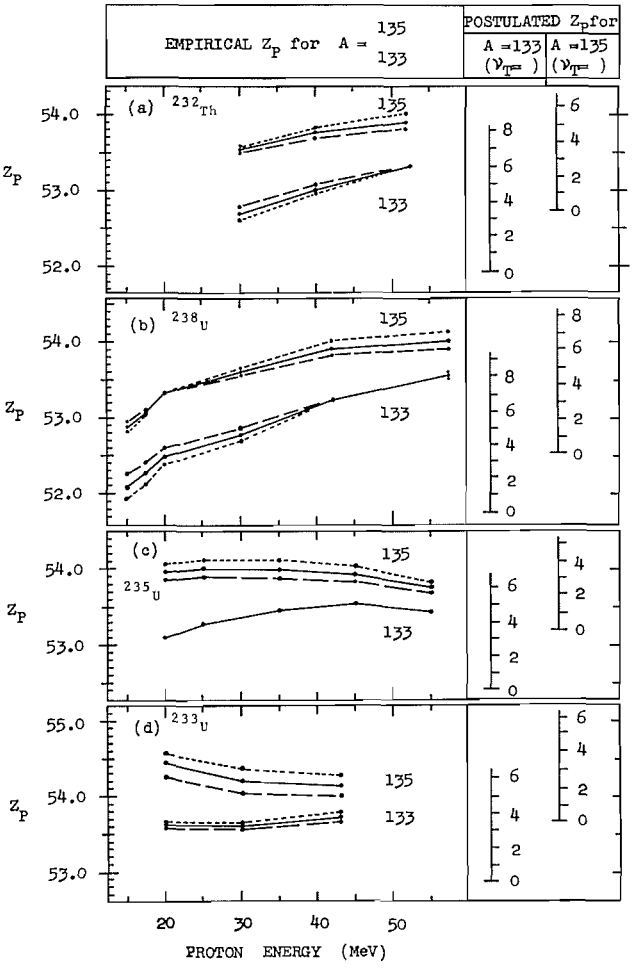

FIG. 11. The variation of the empirical value of Z_p with the proton energy: (*a*) ^{232}Th; (*b*) ^{238}U; (*c*) ^{235}U; (*d*) ^{233}U. The Z_p values were obtained by method 2: (——) $C = 0.95$; (—) $C = 1.20$; (--) $C = 1.45$. The divisions on the vertical lines, to the right of the figure, show Z_p values for chains 133 and 135 from the u.c.d. postulate. The numbers given beside these lines are the total number of fission neutrons, ν_T, used in postulating the corresponding Z_p values.

Z_p which are too high for heavy mass chains. Consequently the present rough estimates of $\bar{\nu}_T$ may be expected to be lower limits and serve primarily to compare the fission of the four targets. For ^{232}Th and ^{238}U, the rate of change with energy of $\bar{\nu}_T$ was consistent with the values, 0.13–0.16 neutrons per MeV, which have been reported previously for similar medium-energy fission systems (36–38). However, Fig. 13 shows that, as the energy increases, the rate ($d\bar{\nu}_T/dE$) is less for the targets of lower (N/Z). No attempt will be made to explain the rather surprising differences, for different targets, in the energy dependence of Z_p and $\bar{\nu}_T$ until the present preliminary conclusions have been confirmed by further work on ^{235}U and ^{233}U.

Fractional and Total Chain Yields for A = 133 and 135

For the monitored irradiations with proton energies below 55 MeV, total chain yields were determined by dividing the absolute cross sections by the fractional chain yields obtained

For personal use only.

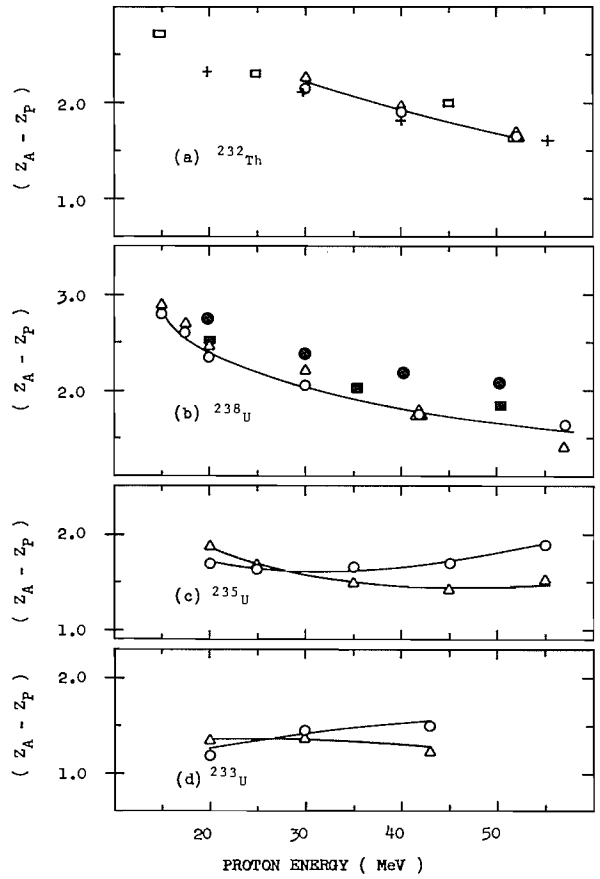

FIG. 12. The displacement of the empirical value of Z_p from beta stability, Z_A, and the effect of variations in the proton energy: (*a*) ^{232}Th; (*b*) ^{238}U; (*c*) ^{235}U; (*d*) ^{233}U. For the chains: (△) $A = 133$; (○) $A = 135$. (+) Reference 17; (□) ref. 15; (■) ref. 18; (●) ref. 19.

from the determined charge distribution curves. Table V gives these yields which were estimated to have an uncertainty of about 30%. Within this uncertainty, these data were consistent with a flat mass distribution in this mass region for fission of ^{232}Th and ^{238}U. James *et al.* (16) found that the chain yield for $A = 133$ was much higher than for $A = 135$, in the fission of ^{238}U with 14.7 MeV neutrons. However, their measurements for chain 133 may contain an error which is discussed in Appendix B.

For proton-induced fission, few chain yields have been reported previously. For ^{238}U, the present yields were in agreement with those, for the same mass region, determined previously in this laboratory (18, 19) and by Stevenson *et al.* (39). This agreement suggested there were no serious systematic errors in the present results.

ACKNOWLEDGMENTS

We are grateful to Prof. R. E. Bell, Director, Foster Radiation Laboratory, for permission to use the McGill synchrocyclotron and to Mr. R. H. Mills who cheerfully performed the irradiations. Our thanks go to Drs. I. Dostrovsky and R. Stoenner, Brookhaven National Laboratory, who gave much of their time advising us on experimental techniques. One of us

APPENDIX A

Equations to Calculate Relative and Absolute Cross Sections

A disintegration rate, D_N, of a product, N, was determined from the corresponding gamma activity, C_N, by the expression

$$[4] \qquad D_N = C_N \times \frac{1}{(\text{eff})} \times \frac{1}{Y_N} \times \frac{(1+\alpha_T)}{(\text{b.r.})}.$$

Here Y_N = the chemical yield of N, eff = photopeak efficiency for the particular source geometry, α_T = total internal conversion coefficient, b.r. = branching ratio. The values of eff for ^{64}Cu were known (28), but values for the xenon isotopes were determined as described in Appendix B.

The disintegration rate at the end of bombardment, $D_N{}^0$, was related to the formation cross section, σ_N, to the proton flux, F, and to the number, n_T, of target nuclei in the beam, by the expression

$$[5] \qquad D_N{}^0 = F n_T \sigma_N (1 - \exp - \lambda_N t_0)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Here λ_N is the decay constant of N, and the term $(1 - \exp -\lambda_N t_0)$ accounts for the decay of N during the bombardment of duration t_0. To obtain independent cross sections for the unshielded fission products, ^{135}Xe and $^{133}Xe^g$, the measured $D_{Xe}{}^0$ had to be corrected by subtracting the rates $((D_{Xe}{}^0)'$ and $(D_{Xe}{}^0)''$, due respectively to xenon which had grown from decay of the iodine parent during the times t_0 and t_1. Here t_1 is the time from the end of bombardment to the end of the first separation of xenon from iodine [i.e. to the end of sweep (*a*)]. These corrections are given by the equations

$$[6] \qquad (D_{Xe}{}^0)' = \frac{(D_I{}^0)_{cum}}{(1 - \exp -\lambda_I t_0)}\left[1 - \frac{\lambda_{Xe}\,(\exp -\lambda_I t_0) - \lambda_I\,(\exp -\lambda_{Xe} t_0)}{(\lambda_{Xe} - \lambda_I)}\right]$$

$$[7] \qquad (D_{Xe}{}^0)'' = (D_I{}^0)_{cum}\frac{\lambda_I}{(\lambda_{Xe} - \lambda_I)}\frac{(\exp -\lambda_I t_1)(\exp -\lambda_{Xe} t_2)}{\exp -\lambda_{Xe} t_1},$$

where $(D_I{}^0)_{cum}$ is the disintegration rate of the parent iodine nuclide at the end of bombardment. This value was obtained from the disintegration rate, $D_{Xe}{}^b$, at the end of sweep (*b*) for ^{135}Xe and $^{133}Xe^g$, by using the formula

$$[8] \qquad D_{Xe}{}^b = (D_I{}^0)_{cum}\frac{\lambda_{Xe}}{\lambda_{Xe} - \lambda_I}(\exp -\lambda_I t_1)[(\exp -\lambda_I t_2) - (\exp -\lambda_{Xe} t_2)].$$

The cumulative cross sections for ^{135}I and ^{133}I were obtained by substituting the corresponding values of $(D_I{}^0)_{cum}$ in eq. [5]. To use $(D_I{}^0)_{cum}$ from eq. [8] in eqs. [6] and [7], the assumption must be made that the decay precursors of iodine are very short-lived. This assumption is reasonable for the simple chain 135, but is not true for the more complex chain 133. In the latter chain, during the period $(t_0 + t_1)$ a fraction of the cumulative yield of ^{133}I is held back by the relatively long-lived isomers of ^{133}Te. Therefore the above correction procedure uses a value of $(D_{^{133}I}{}^0)_{cum}$ in eqs. [3] and [7] which is too high. Consequently the independent yield of $^{133}Xe^g$ is overcorrected and will be too low. This overcorrection introduces significant errors only when there is a large growth of $^{133}Xe^g$. Therefore the time t_1 was minimized in the present experiments. The above equations proved satisfactory for the present data.

A further correction for the growth resulting from decay of $^{133}Xe^m$ was made to the disintegration rate of $^{133}Xe^g$. This was given by

$$[9] \qquad (D_{^{133}Xe^g}{}^0)''' = [\lambda_{^{133}Xe^g}/(\lambda_{^{133}Xe^m} - \lambda_{^{133}Xe^g})][D_{^{133}Xe^m}{}^0].$$

Without a known value of F in eq. [5], only relative cross sections could be obtained.

Absolute Cross Sections

Absolute cross sections were measured for most irradiations by monitoring the proton beam with the reaction $^{65}Cu(p,pn)^{64}Cu$ with the revised cross sections of Meghir (29). Then F may be eliminated from eq. [5], if it is assumed that the same flux passed through the foil of copper and of the heavy metal target (h.m.t.). Then

$$[10] \qquad \sigma_N = \sigma_{^{64}Cu}\frac{D_N{}^0}{D_{^{64}Cu}{}^0}\frac{n_{^{65}Cu}}{n_{h.m.t.}}\frac{(1 - \exp -\lambda_{^{64}Cu} t_0)}{(1 - \exp -\lambda_N t_0)}.$$

The relative number of monitor and heavy target nuclei were given by

$$\frac{n_{^{65}Cu}}{n_{h.m.t.}} = \frac{(s.d.)_{Cu}}{(s.d.)_{h.m.t.}} \times \frac{(ab)_{^{65}Cu}}{(ab)_{h.m.t.}} \times \frac{A_{h.m.t.}}{A_{^{65}Cu}},$$

where s.d. is the surface density, A is the mass number, and ab is the abundance of the target isotope. For ^{65}Cu, ab equals 31.9% and, for the four heavy metals, ab was taken to be 100%.

The error caused in the present results for ^{235}U by the presence of about 5% of ^{238}U was estimated to be negligible.

APPENDIX B

Measurement of Beta Activity and Photopeak Efficiencies for Xenon

Efficiencies were determined for the photopeaks of energy 80 keV and 249 keV, due respectively to $^{133}Xe^g$ and $^{135}Xe^g$. Samples from sweep (*b*) were used for the measurements since they contained only $^{133}Xe^g$ and $^{135}Xe^g$. Their disintegration rates were measured with a gas phase beta proportional counter whose absolute efficiency was determined with a standard beta source of ^{85}Kr.

Equipment for Measurement of Beta Activity

The cylindrical glass counter was similar to one used previously (24, 29, 40, 41).

Beta samples were prepared in the same apparatus used for preparation of the gamma samples. The rare gas sample was measured in the gas burette and transferred with the Toepler pump to the counter. The pressure in the beta counter was then brought up to 1 atm with P-10 counting gas (argon/methane = 9/1). To obtain good plateau characteristics, the sample gases were first purified over titanium sponge at 850 °C. The plateau lengths were always about 200 V. The dead time of the counter was found by a paired-source method to be only about 20 μs.

The efficiency of the beta counter was found to be 97 $\pm$ 3% with samples of a standard beta source of ^{85}Kr. Previous studies (24, 40) used efficiencies of 98–100%. The active volume of the counter was found by weighing with toluene.

Efficiency of Xenon Photopeaks

A sample of xenon from sweep (*b*) was divided in the gas burette into a beta and a gamma sample. The absolute beta counting gave the disintegration rates for $^{135}Xe^g$ and $^{133}Xe^g$. The efficiency of the corresponding photopeaks was determined with an uncertainty of 10%. The efficiency for $^{133}Xe^g$ was confirmed in one experiment in which the gamma activity of a xenon sample was first measured for 12 d and then the vial broken *in vacuo* and quantitatively transferred to the beta counter. The efficiencies for the gas sample proved to be only slightly higher than for liquid samples of comparable geometry and gamma ray energy (28). The efficiency of the 233-keV photopeak was taken to be a few per cent higher than the measured value for the 249-keV gamma ray.

Measurement of Beta Activity of Xenon Produced in Fission

Although previous studies (10, 16) have measured fission product xenon with a beta counter, this technique was not used here, except for the above calibrations, because of the complexity of the decay curves for a sample from sweep (*a*). These contained the following components: (i) $^{135}Xe^g$ (9.2 h); (ii) $^{133}Xe^g$ (5.3 d), present at the end of separation (*a*), and grown from decay of $^{133}Xe^m$; (iii) $^{133}Xe^m$ (2.3 d); (iv) small but significant activities of longer-lived, more neutron-deficient xenon isotopes (Table I); these become more important at higher fission energies.

Storms (10) measured the beta activity of a xenon sample from 'sweep (*a*)' for only the first 2 d because his sample from 'sweep (*b*)' was then measured in the same counter. This was an unsatisfactory method because of the complexity of the beta decay curve in this early period, particularly as his samples often contained relatively short-lived krypton contamination. It was not surprising that his beta activity data did not indicate the presence of the 2.3-d $^{133}Xe^m$, but it was surprising that it was not detected in his gamma spectra. From his evidence he concluded that there was a negligible yield of $^{133}Xe^m$ in medium-energy fission.

For personal use only.

This assumption now appears to be wrong as indicated by the present work on ^{133}Xe and from general considerations of isomeric yield ratios in fission.

Similarly the beta activity data for ^{133}Xe measured by James *et al.* (16) should be reviewed. However, their samples were measured for a much longer time than those of Storms and the error introduced by neglecting $^{133}Xe^{m}$ may be fortuitously small.

A disadvantage of gamma counting in this work was that the measured independent cross sections for $^{133}Xe^{m}$, and therefore for $^{133}Xe^{g}$, were very dependent on the poorly defined α_K for the highly converted gamma radiation of $^{133}Xe^{m}$. Integral beta counting has been shown to be an unsuitable alternative method of measurement. However, measurement by a beta spectrometer of the conversion electrons would eliminate some difficulties due to other xenon isotopes and to low gamma activities of $^{133}Xe^{m}$. Furthermore, the isomer ratios obtained would be far less sensitive to the value of α_K.

PHOTOOXIDATION OF PROPIONALDEHYDE AT LOW PARTIAL PRESSURES OF ALDEHYDE

A. P. ALTSHULLER, I. R. COHEN, AND T. C. PURCELL

Laboratory of Engineering and Physical Sciences, Robert A. Taft Sanitary Engineering Center, U.S. Department of Health, Education, and Welfare, Cincinnati, Ohio

Received May 24, 1966

ABSTRACT

Propionaldehyde at partial pressures of from 0.0006 to 0.04 mm was photooxidized at 3 100 Å in the presence of 150 mm of oxygen. The major products were ethyl hydroperoxide and carbon monoxide. Acetaldehyde was formed at intermediate concentrations and formaldehyde, ethanol, methanol, hydrogen peroxide, and ethane were minor products. No ozone, peroxy acids, or diacyl peroxides could be detected.

The results can be explained on the basis of a free-radical mechanism. Certain radical disproportionation reactions which are often postulated are unimportant because of the low partial pressures of propionaldehyde. An alternative mechanism involving direct chemical reaction of an oxygen molecule with the triplet state of the propionaldehyde may be of some significance, but cannot account for all of the products obtained. The present results indicate the importance of alkyl hydroperoxides as products in photooxidations at low partial pressures of aldehyde in the presence of large excesses of oxygen.

The photooxidation of aldehydes has been the subject of several investigations in recent years (1). Little work has been done at very low concentrations of the aldehyde. It was of interest to ascertain whether the mechanism for aldehyde photooxidation would be the same or somewhat different at low concentrations of an aldehyde, but at high partial pressures of oxygen. These conditions are of especial significance in atmospheric chemistry.

A problem in work at very low concentration (0.75 to 50 p.p.m., or 0.0006 to 0.04 mm) is the need for extended periods of irradiation to allow conversions sufficient for measurement of products. Irradiation periods as short as 10 min were occasionally used, but more typically periods of 30 to 180 min were required. It is reasonable to expect that secondary reactions occurred, particularly during the longest irradiation periods with large percentages of conversion.

EXPERIMENTAL

The irradiations were carried out at 23 ± 1° in the same thermostatted system used previously (2). In most of the experiments reported in this work, each of the two parallel light banks consisted of sunlight fluorescent lamps with an intensity maximum at 3 100 Å. The K_d value ($K_d = \phi K_a$, ϕ is the primary quantum yield and K_a the rate of light absorption) based on the initial rate of photolysis of nitrogen dioxide in nitrogen, was 0.08 ± 0.02 min^{-1} when 28 sunlight fluorescent lamps were used.

The plastic container for the reaction mixture was fabricated from FEP (fluorinated ethylene–propylene copolymer) film (2). The volume of the initial mixture usually was 50 l; 100 l volumes were occasionally used in calibrations and special experiments. The redistilled propionaldehyde was injected into an air stream by means of microsyringes, and the cylinder air was metered into the plastic bag. In some preliminary experiments, irradiations were carried out on mixtures in pyrex flasks or in FEP containers covered by Mylar film. The propionaldehyde partial pressures used were 0.0006, 0.003, 0.02, and 0.04 mm. The propionaldehyde was diluted to 750 (± 10) mm total pressure and 150 mm partial pressure of oxygen.

Analyses for acetaldehyde, propionaldehyde, and ethanol were made with a flame-ionization detector after separation of the components at 25 °C on a column packed with bis-2(2-methoxyethyl)adipate on C-22 firebrick. Carbon monoxide was separated on a molecular sieve column, hydrogenated to methane, and analyzed with a flame-ionization detector (2). Peroxy-type compounds were analyzed by several variations of the potassium iodide and ferrous thiocyanate methods. Formaldehyde was determined by the chromotropic acid method (2). Hydrogen peroxide was analyzed by a modification of the titanous sulfate method (3). After each irradiation period, the container was removed from the irradiation chamber and samples were removed for subsequent gas chromatographic or colorimetric analysis. Replicate gas chromatographic analyses were made on each sample, and were used to determine whether any loss of products occurred in the

dark period. The losses during the periods of time needed for the analyses were small and were well within the usual variations in replicate measurements in the p.p.m. range.

The ethyl hydroperoxide and *n*-butyl hydroperoxide were synthesized by the literature procedures (4, 5). Refractive indices and active oxygen contents were determined. The purity of the ethyl hydroperoxide was 54%; that of the *n*-butyl hydroperoxide was 93%.

RESULTS

Gas chromatographic analyses indicated the presence of acetaldehyde and ethanol along with traces of methanol and ethane. Carbon monoxide was a major product, and formaldehyde a minor product. A peroxy-type substance was shown to be a major product, determined by several colorimetric methods.

The moles of propionaldehyde consumed per mole of propionaldehyde initially present are summarized in Table I. A small but consistent increase in rate (moles consumed averaged over the various irradiation periods) occurred with increase in propionaldehyde concentrations from 0.75 p.p.m. (0.0006 mm) to 50 p.p.m. (0.04 mm). The general shapes of the curves for rate versus irradiation time appear to be very similar over the concentration range investigated.

TABLE I

Consumption of propionaldehyde during photooxidation*

Average concentration level (p.p.m.)	Moles of propionaldehyde consumed per mole initially present for various irradiation periods				
	30 min	60 min	90 min	120 min	180 min
0.75	—	0.30	—	0.55	0.70
4.3†	0.17	0.33	0.45	0.56	0.73
20	0.21	0.36	0.51	0.56	0.78
50	—	0.36	0.51	0.58	—

*750 mm total pressure, 150 mm partial pressure of oxygen.
†10 min irradiation, 0.06; 20 min irradiation, 0.12.

Much of the acetaldehyde and most or all of the ethanol analyzed by chromatography are produced by thermal decomposition of the ethyl hydroperoxide in the chromatographic system rather than by photochemically induced reactions. This conclusion is based in part on the results obtained with vapor mixtures of ethyl hydroperoxide in the p.p.m. range in air. This type of decomposition is also suggested by measurements indicating that the uncorrected product yields greatly exceed the amount of propionaldehyde consumed.

The peroxy-type product formed from the photooxidation of low concentrations of propionaldehyde in 150 mm oxygen reacted slowly with both neutral potassium iodide reagent and molybdate-catalyzed potassium iodide reagent, but reacted rapidly with a modified ferrous ammonium sulfate reagent. Ozone, peroxy acid, and hydrogen peroxide all reacted very rapidly (complete reaction in 3 min or less) in the catalyzed iodide reaction, whereas the peroxy-type product continued to react slowly for many hours. Ozone and peroxy acid also reacted almost immediately with neutral potassium iodide; hydrogen peroxide reacted more slowly, but still much more rapidly than the peroxy-type product. The latter reacted rapidly with ferrous ammonium sulfate reagent, as did ozone, peroxy acid, and hydrogen peroxide. However, diacetyl peroxide reacted slowly with the ferrous ammonium sulfate reagent. The alkyl hydroperoxides, ethyl and *n*-butyl, reacted at essentially the same rate as this peroxy-type product with catalyzed potassium iodide and the neutral iodide reagent. These hydroperoxides reacted rapidly with ferrous ammonium sulfate reagent. Ethyl hydroperoxide and *n*-butyl hydroperoxide cannot be differentiated by means of these chemical reactions; however, in the chromatographic procedure used,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

n-alkyl hydroperoxides decomposed to form the aldehyde and alcohol having the same number of carbon atoms as the original hydroperoxide. The only aldehyde and alcohol detected in appreciable quantities from the reaction mixture were acetaldehyde and ethanol, which are products of the decomposition of ethyl hydroperoxide.

On the basis of these experimental results, ozone, peroxy acids, and diacyl peroxides can be excluded as significant products of the photooxidation of propionaldehyde at low partial pressures (0.0006 to 0.04 mm) in the presence of a large excess of oxygen. All of these measurements indicate that ethyl hydroperoxide is the major product containing the peroxy group.

The photooxidation of acetaldehyde also was investigated briefly in the same range of partial pressures as that used for propionaldehyde. Acetaldehyde photooxidized at about two thirds the rate of propionaldehyde to form a peroxy-type substance and formaldehyde as two of its major products. These two products were produced in almost equal amounts, and they accounted for somewhat over half of the acetaldehyde consumed. The photooxidation of formaldehyde also has been investigated and hydrogen peroxide identified as a significant reaction product (6). Traces of hydrogen peroxide were measured after large percentage conversions of propionaldehyde. Since formaldehyde was present as a minor product, it seems likely that the hydrogen peroxide was formed from the concurrent photooxidation of formaldehyde. These results indicate that small amounts of other peroxy-type substances were present in addition to the major oxidant, ethyl hydroperoxide, particularly after the larger conversions during the longer irradiation periods.

Most of the ethanol yields (0.05 to 0.2 mole of ethanol found per mole of propionaldehyde reacted) are believed to result from decomposition of the ethyl hydroperoxide. This conclusion is based on a comparison of the amounts of ethanol formed by passing either ethyl hydroperoxide or the reaction products directly into a chromatograph with the amounts formed by passing them first through a substrate of ferrous ammonium sulfate and then into the chromatograph. With the substrate, the amounts of ethanol obtained from either the ethyl hydroperoxide in air or the reaction products were reduced by two thirds to three quarters. Insignificant amounts of ethanol or acetaldehyde were lost when they were passed directly through the ferrous ammonium sulfate. This shift in composition probably results from a change in the relative amounts of homogeneous and heterogeneous decomposition occurring. The close similarity of results for ethyl hydroperoxide and reaction products indicates that most or all of the ethanol was not originally present as a photooxidation product. The ethyl hydroperoxide decomposed too slowly in the reaction container to account for these results. Therefore, it is believed that most of the decomposition occurred in the chromatographic system.

Formaldehyde was a minor product. Its yield increased from about 0.02 for 30 min irradiations to 0.06–0.07 for 180 min irradiations. Owing to the small concentrations produced, measurements could be made only at the higher reactant levels.

Carbon monoxide was a major product of the photooxidation of propionaldehyde in this study. Even at the shorter irradiation times, 1 mole of carbon monoxide was formed per mole of propionaldehyde consumed. At longer irradiation times the carbon monoxide yield exceeded 1.

At the lower propionaldehyde concentrations, 90 to 100% of the moles of propionaldehyde consumed could be accounted for as ethyl hydroperoxide (Fig. 1). High yields of ethyl hydroperoxide were obtained in both continuous and intermittent irradiations ranging from 10 to 180 min. However, the yield of ethyl hydroperoxide relative to propionaldehyde did decrease slowly with increasing irradiation time.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

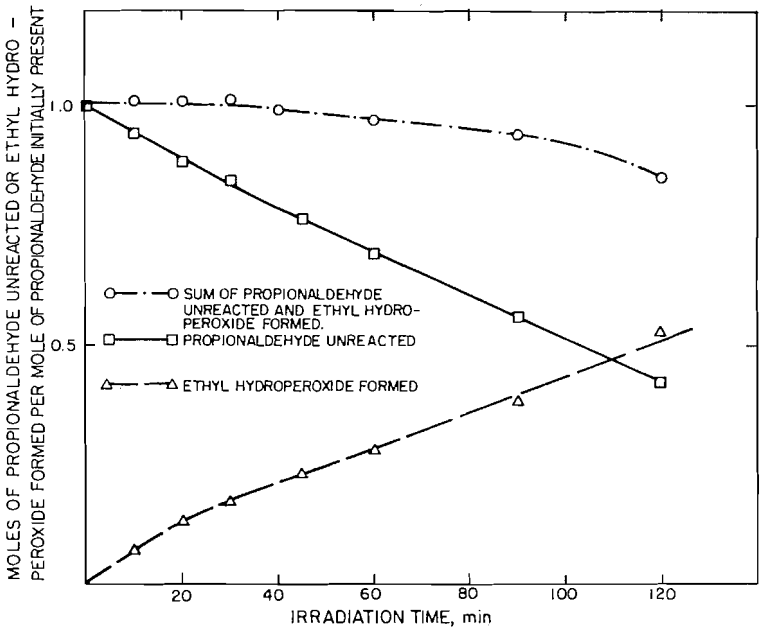

FIG. 1. Relative molar yields of unreacted propionaldehyde and of ethyl hydroperoxide formed after various reaction times. Initial conditions: propionaldehyde 0.003 mm; oxygen, 150 mm; total pressure, 150 mm.

At the higher propionaldehyde concentrations, the yield of ethyl hydroperoxide relative to propionaldehyde consumed varied from slightly below 0.5 to 0.8. Acetaldehyde was the only other two-carbon product detected, and it probably contributed the remainder of the two-carbon yield. Although no available procedure could accurately separate the photochemically produced acetaldehyde from that resulting from the decomposition of the ethyl hydroperoxide, significant amounts of acetaldehyde definitely were produced directly from the photooxidation.

DISCUSSION

The four primary processes usually considered in the photolysis of aldehydes (7) also should be considered in discussing the mechanism for the photooxidation of propionaldehyde.

$$C_2H_5CHO + h\nu \rightarrow C_2H_5CHO^*$$

[I] $$C_2H_5CHO^* \rightarrow CH_3CH_2 + HCO$$

[II] $$C_2H_5CHO^* \rightarrow C_2H_6 + CO$$

[III] $$C_2H_5CHO^* \rightarrow C_2H_4 + CH_2O$$

[IV] $$C_2H_5CHO^* \rightarrow CH_3 + CH_2CHO$$

Process [II] can occur to only a small extent, since less than 0.01 mole of ethane is produced per mole of propionaldehyde consumed. Therefore, very little of the large yield of carbon monoxide can be attributed to this reaction. Similarly, process [III] is excluded by the absence of ethylene as a detectable product. The formaldehyde produced must be formed by other processes. Process [IV] produces methyl radicals, which should react to form peroxymethyl radicals; these in turn could in part disproportionate and in part associate or decompose to produce substantial concentrations of formaldehyde or methanol. Since formaldehyde is a minor product, since only a trace of methanol is detectable, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

since no association product is detectable, process [IV] is at most of minor significance. Process [IV] has a primary quantum yield of 0.00 at 3 130 Å in the photolysis of propionaldehyde (7). Since the formaldehyde yield increases with increasing irradiation time, the formaldehyde and methanol are more likely formed by the photooxidation of acetaldehyde than by process [IV]. Thus, it appears that process [I] is by far the most important of these four processes, since the products observed can best be accounted for in terms of a mechanism involving this process.

One type of mechanism which is often used to explain photooxidation reactions involves a free-radical oxidation scheme. An alternative mechanism can involve direct chemical reaction of the oxygen molecule with the triplet state of the propionaldehyde. It can be postulated that an intermediate can be formed which will decompose into the two major products, ethyl hydroperoxide and carbon monoxide. While such a possibility is interesting, there is a lack of direct experimental evidence on the nature of chemical reactions of oxygen with the triplet state of aldehydes (1, 7, 8). This type of mechanism would not explain the presence of acetaldehyde and the small yields of other oxidation products. Nevertheless, chemical reaction of the oxygen with the triplet state must be considered as of some possible significance.

In considering a free-radical-type oxidation mechanism, the very low aldehyde pressures, high oxygen pressures, and inadequate light intensities in the present study tend to reduce the significance of certain reactions involving radical species. Because of the very low levels of radical concentrations, some of the reactions between radicals are not likely to be as important as they may be under other experimental conditions.

Since process [I] appears to be the only important primary process leading to products, the following steps can be suggested.

[1] $$C_2H_5CHO + h\nu \rightarrow C_2H_5CHO^*$$

[2] $$C_2H_5CHO^* \rightarrow C_2H_5 + HCO$$

The peroxyethyl radical should be formed (1, 8), particularly in the presence of high partial pressures of oxygen as in the present work.

[3] $$C_2H_5 + O_2 \rightarrow C_2H_5O_2^* \rightarrow C_2H_5O_2$$

Several possible reactions of formyl radical have been suggested (1), but only its reaction with oxygen to form carbon monoxide will be considered.

[4] $$HCO + O_2 \rightarrow CO + HO_2$$

Since 1 mole of carbon monoxide is produced per mole of formyl radical formed at smaller percentage conversions, reactions leading to carbon dioxide or to CHO_3 and then formic acid could not be significant.

Ethyl hydroperoxide can be formed by several steps which have been proposed. However, a reaction which is compatible with the experimental results is as follows.

[5] $$C_2H_5O_2 + HO_2 \rightarrow C_2H_5OOH + O_2$$

This reaction has been suggested by Watson and Darwent (9), Turner *et al.* (10), and Gray (11) to explain ethyl hydroperoxide formation in the mercury-photosensitized oxidation of ethane and ethylene. In reviewing the reactions of alkyl peroxy radicals, McMillan and Calvert (8) conclude that it is unlikely that alkyl peroxy radicals abstract hydrogen from molecules in low temperature reactions. The substances normally produced from reactions of the acyl radical formed by the hydrogen abstraction from propionaldehyde were not identified in this study.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

At higher aldehyde concentrations (0.02 and 0.04 mm) or at higher percent conversions (greater than 50%), acetaldehyde becomes a significant product although ethyl hydroperoxide yields always exceed acetaldehyde yields. Acetaldehyde yields were higher than ethanol yields.

The often proposed disproportionation of RO_2 radicals

[6] $$2RO_2 \rightarrow 2RO + O_2$$

is needed to provide RO radicals which in turn react to form acetaldehyde. However, the disproportionation of RO_2 radicals must be significantly less important than their reaction to form ethyl hydroperoxide. The alkoxy radical levels should be lower than the RO_2 and HO_2 radical concentration levels. Consequently, disproportionations of RO with itself or with RO_2 should not be important. Such reactions lead to equal yields of ethanol and acetaldehyde or of ethyl hydroperoxide and acetaldehyde. Such yields are not in accord with the present experimental results. Reaction of the ethoxy radical with oxygen to form acetaldehyde appears more likely.

[8] $$C_2H_5O + O_2 \rightarrow CH_3CHO + HO_2$$

Acetaldehyde also could be formed by the reaction

[9] $$C_2H_5 + O_2 \rightarrow C_2H_5O_2^* \rightarrow CH_3CHO + OH,$$

but this reaction is unlikely to be important in room temperature reactions.

The small amount of ethanol which may be attributed to direct reaction could come from ethoxy radical disproportionation, but the reaction

[10] $$C_2H_5O + HO_2 \rightarrow C_2H_5OH + O_2$$

may be more important.

The formation of HO_2 radicals by reactions [4] and [8] exceeds its consumption by reaction [5] in experiments at higher aldehyde levels (0.02 and 0.04 mm) or larger percentage conversions (greater than 50%) at the lower levels (0.0006 and 0.003 mm). Although traces of hydrogen peroxide were detected after larger conversions (probably from formaldehyde photooxidation), no hydrogen peroxide could be detected earlier in the reaction. Therefore, gas-phase reaction of HO_2 radicals with themselves to produce hydrogen peroxide (and oxygen) is of no importance. Wall reactions of HO_2 radicals must be suggested to account for their consumption.

Acetaldehyde photooxidation would be a likely source of the additional carbon monoxide when its yield exceeds 1 as it does at large percentage conversions. The small yield of formaldehyde also can be attributed to its formation as a product of the photooxidation of acetaldehyde.

There is little point in discussing the various reactions leading to peroxyacetic acid or diacyl peroxides (12–15). These products could not be detected in the present investigation. Since ozone also was not detected, the reaction of RO_2 with oxygen to produce ozone could not have been significant (1, 8).

The present results differ from those of McDowell and co-workers (12–14) and of Calvert and Hanst (15). These investigators reported peroxy acids and diacetyl peroxide as products, but no hydroperoxides as products from the photooxidation of acetaldehyde (12, 13, 15) and propionaldehyde (14). Johnston and Heicklen (16) in a study of the photooxidation of acetaldehyde at lower partial pressures detected methyl hydroperoxide. Their measurements show a marked increase in methyl hydroperoxide relative to methanol, formic acid, and acetic acid as the partial pressure of the aldehyde decreases from 18 to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

0.4 mm and as the partial pressure of oxygen increases. These latter measurements suggest that results similar to those found in the present study should be obtained in the photooxidation of acetaldehyde at very low partial pressures.

The present results provide evidence for the importance of alkyl hydroperoxides as major products in photooxidations at very low partial pressures of aldehyde. The results also indicate that reactions [4] and [5] may be very important steps in the photooxidation of aldehydes.

ACKNOWLEDGMENT

We wish to thank Dr. J. J. Bufalini for the preparation of *n*-butyl hydroperoxide and for a number of helpful suggestions.

CHEMICAL REACTIONS IN ELECTRICAL DISCHARGES[1]

II. THE STRUCTURE OF THE POSITIVE COLUMN IN D-C. GLOW DISCHARGES THROUGH FAST-FLOWING GASES

JOZEF L. PEETERS,[2] HOWARD W. RUNDLE,[3] AND JACQUES M. DECKERS
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario

Received September 30, 1965

ABSTRACT

After a brief summary of recent advances in the structure of the positive column of a d-c. glow discharge, general expressions are derived for rates of reaction and excitation produced by electron impact. These rate equations are expressed in terms of the easily measured electrical parameters of the discharge. Such expressions will be used in future studies of chemical reactions occurring in the positive column; a qualitative comparison to experiment is given, where possible.

A general expression for the axial electric field in the positive column is obtained by equating the energy gained by the electrons in this field to that lost by collisions. The main assumption made is that axial electron concentration be constant along the column.

In the second part of the paper, calculations are done which indicate that ion and electron concentration gradients exist in the positive column adjacent to the anode. It is pointed out that such a phenomenon will be pronounced only under special conditions of low transverse and high axial field, and will be enhanced with fast-flowing gases.

A sample calculation is presented using the expression for the rate of electronic excitation of a species by electron impact, assuming a Maxwell–Boltzmann energy distribution for the electrons and constant elastic and inelastic collision cross sections.

1. INTRODUCTION

In this paper we concern ourselves with the structure of the positive column of a d-c. glow discharge through fast-moving gases. Under such fast-flow conditions appreciable axial pressure and velocity gradients are found. If a gas or gas mixture, in which composition changes could take place, is passed through the discharge, a concentration gradient is established because of the finite rate of chemical reactions. Ionization processes also occur with finite rates and thus result in a gradient of the number density of charged species. Because of the occurrence of these gradients we shall observe changes in the physical and electrical properties of the discharge, or in the composition of the gases which pass through the discharge, as a function of the distance from the entrance point of the gas. From the measurement of these changes we can then derive the rates of the processes from which the observed phenomena are only the consequence. By making successive measurements at increasing distances from the entrance point of the gases in the discharge the actual rate of these processes can then be calculated. In other instances the observed quantity is solely determined by the local value of the parameters in the discharge. This is the case in particular for the emission of optically allowed transitions. These observations then provide us with the actual rate directly, without having to resort to differential measurements.

In a first paper in this series Bois D'Enghien and Deckers (1) have shown that when a methane–oxygen mixture was passed through the positive cloumn of a d-c. glow discharge the intensity of emission of the carbon monoxide spectrum increased while the gases proceeded downstream from the entrance point in the discharge. It was further established

that the emission intensity was proportional to the carbon monoxide mole fraction in the mixture; it is thus feasible to measure rates of chemical reactions occurring in the discharge. In this laboratory Ailliet and Deckers (2) have shown that changes in the intensity of emission of CO bands in fast-flowing $CO–O_2$ mixtures result from changes in the electron energy distribution. Methods for studying the field in the positive column, the electron energy distribution, and reactions under fast flow conditions have (1) or will (3) be reported. In this paper, after attempting to modify existing theories so as to take into account these fast-flow conditions, we derive suitable kinetic expressions which will allow us to obtain quantitative data for the rate of processes occurring in the discharge.

2. THEORY

(A) General

Before breakdown, the electric field in a gas is equal to the potential applied to the electrodes divided by the electrode separation. If the applied field is strong enough, an electron, generated in the gas by an external agent such as a cosmic ray or an energetic photon, will be accelerated and produce an increasing number of positive ions and electrons or negative ions, in equal number. The resulting plasma will partially screen the field, increasing its value near the electrodes and decreasing it in what is known as the positive column. In the positive column the electrons will initially diffuse laterally and reach the walls much faster than the heavy positive ions, setting up a transverse field. The ambipolar diffusion process, first proposed by Schottky (4, 5) in 1924, provides a mechanism by means of which ions and electrons will recombine at the walls. Besides the recombination at the wall, recombination in the gas phase will also occur in three-body collisions or in dissociative two-body collisions (6). The longitudinal field supplies energy to the electrons and in ionizing collisions with neutral molecules more electron–ion pairs will be produced. If the screening action of the plasma is too large not enough ions will be produced to maintain a steady-state concentration; thus the longitudinal field will be the one in which the electrons draw just enough energy from the field so that the rate of ionization equals the rate of loss of ions through recombination.

Spenke (7) has taken into account stepwise ionization processes and Seeliger (8) the presence of negative ions in electronegative gases. Further refinements and generalizations were proposed by Ecker (9), Ludwig (10), and Allbrecht, Ecker, and Müller (11).

Druyvesteyn and Penning (12, 13) attempted calculations of the longitudinal field by equating the energy loss through elastic and inelastic collisions to the energy gained by electrons from the field. Mohler (14) ascribed the difference between the power supplied to the discharge and that carried to the walls to losses by radiation. In a particular case, Schottky (5) himself showed that about 20% of the energy drawn from the field by the electrons was used in producing ions.

Seeliger and Wichmann (15) investigated the existence of two types of discharges in oxygen and Seeliger (8) points out the existence of negative ions in oxygen. Now, the rate of diffusion of the negative charges to the walls will be reduced when negative ions are formed; hence the ambipolar diffusion will also be reduced and the average lifetime of the positive ions increased; the longitudinal field, necessary to maintain a steady-state positive ion concentration is thus decreased. Rundle *et al.* (3) in this laboratory have obtained evidence for the existence of even more than two types of discharges in oxygen.

In a static gas, conditions are uniform along the positive column (16). Wilhelm (17) showed that the constancy of the longitudinal field was a consequence of the quasi-neutrality of the plasma; he also had to assume that the motion of charged particles was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

only conditioned by diffusion in the field. To our knowledge the only paper in the literature dealing with measurements of the electrical properties in the positive column through fast-flowing gases is one by Maier (18) in which evidence is presented that the electrical conditions are not uniform in the positive column. In particular, he found a variation of the axial electric field along the positive column.

After having obtained an expression for the rates of reactions[4] induced by electron impact, we shall derive an expression for the influence of pressure and gas velocity upon the electric parameters, such as field and density of charged particles in the positive column.

(B) Energy-Transfer Processes

In this section we consider transfer of energy under various forms from the electrons to the gas molecules in the discharge, which is a system not in equilibrium (11, 19). Electrons having energy E will collide inelastically with molecules AB_i and result in molecules AB_j (i and j specifying all quantum numbers of the initial and final states respectively). In such a collision the electron loses energy E_{ij}. If $E_{ij} > 0$ (the electron energy is smaller after collision) the collision is referred to as an inelastic collision of the first kind. The inverse process is then a collision of the second kind, also called a superelastic collision. In a system in equilibrium a consequence of the principle of microreversibility is that both processes should occur with equal frequency. Because the positive column is not in equilibrium, there will be an excess of collisions of the first kind as was pointed out by Rompe and Schon (19). The overall energy balance will thus only be affected by the effective number of collisions, which is the excess of the number of collisions of the first kind over those of the second kind (Ludwig (10, 20)).

If, in an inelastic collision, the vibrational energy imparted to AB is larger than the bond energy or if AB_j is an antibonding electronic state, AB will dissociate into A + B (where A and B are atoms, molecules, radicals, and (or) ions). A very large number of different collisions ij are possible in a gas. The amount of energy lost by an electron in exciting the rotational or vibrational states of a molecule is always small compared with the electron's energy (21). Sampson (22) calculated the rotational energy loss to be anywhere between 100% and a negligible percentage of that due to elastic collision. In a particular case Anderson and Goldstein (23) using microwave techniques estimated the fractional energy loss to be about 5.5 times as large as the loss via elastic collisions for slow electrons ($E < 0.4$ eV). Losses via vibrational energy transfer are also small unless there exists a short-lived compound negative ion state, as found by Schultz (24, 25) for nitrogen and carbon monoxide. Even then, only vibrational levels below the energy of the compound state will be excited. Lifetimes of vibrationally excited ground state molecules are large and it is thus not excluded that cumulative excitation will take place. It is, however, not clear a priori if dissociation into atoms could take place via such a "ladder climbing" process. Since collision cross sections for electronic excitation are often rather large (of order 10^{-16} cm^2) (21), it is more probable that dissociation will occur more readily via excitation into an antibonding state.

The cross section for elastic collisions is of the order of 10^{-16} to 10^{-15} cm^2 (26). Because of the large mass ratio between the colliding partners the energy lost in such collisions will always be small (26, p. 44). For excitation of electronic states, however, the cross sections

[4]*In this paper the term reaction should be taken very broadly, including such processes as dissociation of molecules, excitation (electronic, vibrational, rotational), and ion production after electron impact. The electrons will be considered as a reacting species and treated as such in the rate laws.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for electrons having energies above the threshold may become comparable to (if not larger than) the elastic collision cross section. In this case, once an electron acquires an energy E_{ij} from the field, the average number of elastic collisions it will suffer before undergoing the inelastic collision ij will be much smaller than the number of elastic collisions suffered during the time that it took the electron to acquire the energy E_{ij}.

The number of inelastic collisions per unit time and unit volume for electrons having an energy E is equal to the number density of electrons n_e times the ratio of the electron speed $(2E/m)^{1/2}$ to their free path $l_e \equiv (n_i Q_{ij})^{-1}$ where Q_{ij} is the inelastic collision cross section for process ij and n_i the number density of species i. If $f(E)\,dE$ is the fraction of electrons having energy between E and $E + dE$ (27) and dn_{ij}/dt is the rate of change of n_i due to process ij then

$$\frac{dn_{ij}}{dt} = n_i n_e \int_0^\infty f(E) Q_{ij} \left(\frac{2E}{m}\right)^{1/2} dE = k_{ij} n_i n_e. \qquad [2.1]$$

k_{ij} can be considered a rate constant averaged over the electron energy distribution. Thus

$$k_{ij} = \int_0^\infty f(E) Q_{ij} (2E/m)^{1/2}\, dE. \qquad [2.2]$$

If an electron takes a time t_{ij} to gain the energy E_{ij} from the field in the positive column we can define

$$f_{ij} = k_{ij} t_{ij}. \qquad [2.3]$$

Since k_{ij} is a bimolecular rate constant having dimensions of unit volume per number of molecules (inverse of a number density) per unit of time, f_{ij} will have the dimensions of the inverse of a number density. The discussion of the true significance of f_{ij} will be postponed till the end of Section 2D. Substituting [2.3] into [2.1] we obtain

$$dn_{ij}/dt = (f_{ij}/t_{ij}) n_i n_e. \qquad [2.4]$$

This explicitly shows that the number of inelastic collisions per unit volume will be inversely proportional to the time it takes the electron to acquire the energy involved in the inelastic collision.

The electron concentration is related to the current density J by

$$J = n_e \bar{v}_e e, \qquad [2.5]$$

where $\bar{v}_e$ and e are the drift velocity and the charge of an electron respectively. We consider the contribution of positive and negative ions to the overall current density to be negligibly small because of their much smaller drift velocities $\bar{v}_+$ and $\bar{v}_-$. We obtain from [2.4] and [2.5]

$$dn_{ij}/dt = f_{ij} J n_i / \bar{v}_e e t_{ij}. \qquad [2.6]$$

We proceed to calculate the rate of energy loss in the gas.

(i) Energy Loss in Elastic Collisions

$\bar{K}$ is the fraction of energy lost by an electron of energy E per elastic collision averaged over the impact parameter. The number of collisions suffered by an electron of energy E per unit time is given by $(\sum n_i Q_{0i})(2E/m)^{1/2}$, where Q_{0i} is the elastic collision cross section for molecules i. Thus, the energy lost per unit time and volume in elastic collisions is equal to

$$-\left(\frac{dE}{dt}\right)_{el} = n_e \left(\frac{2}{m}\right)^{1/2} \int_0^\infty f(E) \bar{K} E^{3/2} (\sum n_i Q_{0i})\, dE. \qquad [2.7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(ii) Energy Loss in Inelastic Collisions

$$[2.8]\qquad -\left(\frac{dE}{dt}\right)_{inel} = n_e \sum_i \sum_j \frac{dn_i}{dt} E_{ij} = n_e \sum_i \left(n_i \sum_j k_{ij} E_{ij}\right)$$
$$= n_e \left(\frac{2}{m}\right)^{1/2} \sum_i n_i \left(\sum_j E_{ij} \int_0^\infty f(E) E^{1/2} Q_{ij}\, dE\right).$$

The energy loss in elastic collisions is proportional to the mass ratio $2m/M$ of the electron and its collision partner. This factor is never larger than 10^{-3} and is more often of order 10^{-5}. Since this corresponding ratio is of order one for collisions involving an ion, they will lose energy almost as fast as they gain it and very few energetic ions will be found in the gas.

(C) The Axial Field

In the absence of a field the scattering of electrons by a gas will be isotropic because each direction of impact is equally probable. Only if concentration gradients arise will an average electron drift result from diffusion processes. If an axial field is applied, the electrons will be accelerated between collisions and their flight path will be bent in the direction of the field. The projection of the free path on the field axis is thus the sum of two terms: the projection of the free path in the absence of a field and a net displacement along the field due to the acceleration suffered by the electron in the direction of the field. This displacement or drift in the field for an electron of energy E between two collisions averaged over all directions of motion (but not over the energy distribution) will be referred to hereafter as the drift distance λ. If the field is not too strong we can express the overall drift of the electrons as the sum of an isotropic term resulting in a zero drift and the average axial drift $\lambda(E)$ times the number of collisions per unit time. In writing this we neglect the possible anisotropy in the scattering which is introduced because the impact velocity vectors will no longer be completely random but somewhat peaked in the field direction. The error thus introduced, due to the "persistence of velocity", could become important at very low pressures or in very large fields.

The acceleration in a field X suffered by an electron is equal to Xe/m. If $t_E(E)$ is the time between collisions for an electron of energy E, the drift distance λ between two collisions is equal to $Xet_E^2/2m$. The time between two collisions t_E is equal to the ratio of the free path to the average speed. Thus $t_E = m^{1/2}(\sum n_i Q_{0i})^{-1}(2E)^{-1/2}$. The drift distance is then equal to

$$[2.9]\qquad \lambda = \frac{Xe}{4} \frac{1}{E(\sum n_i Q_{0i})^2}.$$

The energy gain per electron between two collisions dE/dN is equal to the force Xe times the displacement λ. The number of collisions is given by $1/t_E$. Per unit time and volume the energy gain becomes

$$[2.10]\qquad \frac{dE}{dt} = \frac{dE}{dN} n_e \frac{dN}{dt} = \frac{(Xe)^2 n_e}{(8m)^{1/2}} \int_0^\infty \frac{f(E)\, dE}{E^{1/2}(\sum n_i Q_{0i})}.$$

Equating the energy gained from the field [2.10] to that lost by collisions [2.7] + [2.8] and solving for X we obtain

$$[2.11]\quad X = \frac{2}{e}\left\{\frac{\sum_i \left[n_i \sum_j E_{ij} \int_0^\infty f(E) E^{1/2} Q_{ij}\, dE\right] + \sum_i \left[n_i \int_0^\infty f(E) \bar{K} E^{3/2} Q_{0i}\, dE\right]}{\int_0^\infty f(E) E^{-1/2} \left(\sum_i n_i Q_{0i}\right)^{-1} dE}\right\}^{1/2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The derivation of this equation implicitly assumes n_e to remain constant over the distance in which the electron acquires the energy E_{ij}. This calculation was first suggested by Mierdel (28) and was further extended by Wasserrab (29). It neglects the kinetic energy lost by the electrons hitting the wall. As long as the average electron temperature is not too large ($kT <$ ionization energy) the number of ionizing collisions will be much smaller than the total number of other inelastic collisions. The average energy per electron will also be smaller than the energy lost in an ionizing collision. In the absence of volume recombination, for each ionizing collision one electron hits the wall and thus the kinetic energy lost by the electrons to the wall will only be a very small fraction of the total energy lost in the gas and can then be neglected in the above calculation. All other energy losses, particularly the energy lost at the wall by ion recombination, are included in the energy balance. In fact Schottky (5) estimated the longitudinal field by equating the energy lost by the electrons in ionizing collisions to the energy liberated at the wall by the recombination of ions and electrons.

At low pressures the losses through elastic collisions are small compared with the losses through inelastic collisions (16, p. 133) and the second term on the right-hand side of [2.11] can be neglected. At higher pressures the number of elastic collisions will increase and both terms have to be considered. Also noteworthy is the fact that X is independent of the electron concentration.

(D) Rate of Excitation

In the absence of energy losses during elastic collisions an electron having an energy E will gain an energy E_{ij} from the field during the time t_{ij}. This time can be calculated using [2.10]:

$$[2.12] \qquad t_{ij} = \int_0^{t_{ij}} \mathrm{d}t = \frac{(8m)^{1/2}}{(Xe)^2} \int_{E_i}^{E_i+E_{ij}} \frac{\mathrm{d}E}{\int_0^\infty \frac{f(E)\,\mathrm{d}E}{E^{1/2}\sum_i n_i Q_{0i}}} = \frac{8m^{1/2}\,E_{ij}}{(Xe)^2 \int_0^\infty \frac{f(E)\,\mathrm{d}E}{E^{1/2}\sum_i n_i Q_{0i}}}.$$

If energy losses in elastic and (or) inelastic collisions are taken into account, one obtains an expression similar to [2.12] with two additional terms subtracted from the denominator; these terms contain the integrals appearing in [2.7] and [2.8]. Unless one or more of the n_i's are very large (high pressures) these terms are small: the term representing the loss through elastic collision contains $\bar{K}$ which is of order 10^{-5} and cross sections figuring in the third term are small (21).

[2.12] shows that t_{ij} is independent of the initial energy E of the electron. If we assume Q_{0i} independent of the impact energy of the electron, the value of the integral in the denominator becomes

$$\left(\sum n_i Q_{0i}\right)^{-1} \int_0^\infty f(E)\,E^{-1/2}\,\mathrm{d}E = \left(\sum n_i Q_{0i}\right)^{-1} \overline{1/E^{1/2}}.$$

Thus

$$[2.13] \qquad t_{ij} = \frac{(8m)^{1/2}\sum n_i Q_{0i}}{(Xe)^2\,\overline{1/E^{1/2}}} E_{ij}.$$

The drift velocity of an electron is equal to the drift distance between two collisions as given by [2.9] divided by the time between two collisions. The averaging over the electron energy distribution gives

$$[2.14] \qquad \bar{v}_e = \frac{Xe}{(8m)^{1/2}} \int_0^\infty \frac{f(E)\,\mathrm{d}E}{E^{1/2}\sum_i n_i Q_{0i}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This expression can also be obtained from [2.10] if we recall that $dE/dt = JX = n_e e \bar{v}_e X$. If we substitute [2.12] and [2.14] into [2.6] we obtain the rate expression for a process ij

$$[2.15] \qquad \frac{dn_{ij}}{dt} = \frac{f_{ij}\, Jn_i X}{E_{ij}} = \alpha_{ij} \frac{JX}{E_{ij}},$$

where $\alpha_{ij} = n_i f_{ij}$. If j is any state in the ionizing continuum this equation becomes identical to that used by Schottky (5) when he states that the rate of formation of ion pairs is proportional to a fraction of the current density and the potential gradient and inversely proportional to the ionization energy (his eq. [7]). We have shown here that this equation is quite general and applicable to any inelastic collision process.

An alternate expression for the rate of production of excited species is obtained by combining expression [2.1] with [2.14] and [2.5]:

$$[2.16] \qquad \frac{dn_{ij}}{dt} = \frac{4Jn_i \int_0^\infty f(E)\, Q_{ij} E^{1/2}\, dE}{Xe^2 \int_0^\infty f(E)\, E^{-1/2} \left(\sum n_i Q_{0i}\right)^{-1} dE}.$$

If observations are made in flowing gases through the discharge, the substitution $dt = dx/v_s$ (where v_s = stream velocity) can be made in all above expressions giving then the steady-state expressions.

Further insight into the meaning of f_{ij} and α_{ij} can be obtained by equating [2.15] to [2.16] and solving for f_{ij}

$$[2.17] \qquad f_{ij} = \frac{4E_{ij} \int_0^\infty f(E) Q_{ij} E^{1/2} dE}{X^2 e^2 \int_0^\infty f(E) E^{-1/2} \left(\sum n_i Q_{0i}\right)^{-1} dE}.$$

The value of the field was obtained in [2.11]. We obtain after multiplying by n_i

$$[2.18] \qquad \alpha_{ij} = n_i f_{ij} = \frac{\int_0^\infty f(E) E^{1/2} n_i Q_{ij} E_{ij}\, dE}{\int_0^\infty f(E) E^{1/2} \sum_i \left(n_i \sum_j Q_{ij} E_{ij}\right) dE}.$$

If we multiply both the denominator and the numerator of the right-hand side of [2.18] by $n_e(2/m)^{1/2}$ the denominator is equal to [2.8] and represents the energy spent in inelastic collisions per unit time and volume. The numerator is then the energy spent in the particular process ij and the dimensionless quantity α_{ij} represents the fraction of the total energy spent by electrons per unit volume and time on process ij. [2.15] then means that at constant field and current a constant fraction of the energy will be dissipated in process ij. f_{ij} and α_{ij} are functions of the electron energy distribution.

(E) The Pressure Gradient Due to the Flow

It is nearly impossible to determine a priori the conditions of the gas, or the pressure gradient downstream of the discharge. Indeed, a certain amount of cooling of the gas will occur for that part of the expansion which takes place adiabatically. On the other hand gas heating will occur as a result of electrons losing energy in elastic collisions or in inelastic collisions followed by energy-transfer processes. In addition to this a certain degree of turbulence will exist which will reduce the importance of transverse gradients in the concentration and the velocity of the gases in the tube.

As we are mainly interested experimentally in the stream velocity, and the way it varies while the gases proceed downstream, we prefer to measure the pressure gradient at a number of takeoff points along the discharge tube. Any decrease in pressure will be the result of a density decrease corrected for any change in temperature. The increase in stream velocity is then given empirically by the decrease in pressure. For analytical purposes it is convenient to have a mathematical expression to fit the measurements; this is easily done by expressing the pressure as a power series

$$p = \sum_n p_n x^n. \qquad [2.19]$$

If v_s is the stream velocity, D (in volume units per unit time at 760 Torr) the measured total flow of the gas admitted to the discharge, and A the cross section of the tube, then

$$v_s(x) = \frac{D}{A} \frac{760}{\sum_n p_n x^n}. \qquad [2.20]$$

(F) Ion and Electron Concentration in the Positive Column and Influence of the Flow

We assume the discharge tube to be cylindrical and of radius R. An ion formed at a distance r from the axis will drift in the transverse field during its lifetime τ a distance

$$R - r = \int_0^\tau (\bar{v}_+)_{Tr}(x,r)\, dt. \qquad [2.21]$$

x is the distance along the axis from the boundary separating the anode layer from the positive column. $(\bar{v}_+)_{Tr}$ and $(\bar{v}_+)_A$ are the drift velocities of the ions in the transverse and axial fields respectively. During this time τ an ion will drift a distance Λ in the axial direction where Λ is given by

$$\Lambda = \int_0^\tau (\bar{v}_+)_A(x,r)\, dt. \qquad [2.22]$$

In order to express $R - r$ as a function of x we calculate τ. Since $(\bar{v}_+)_A = dx/dt$, we have

$$\tau = \int_0^\tau dt = \int_0^x \frac{dx}{(\bar{v}_+)_A}. \qquad [2.23a]$$

By introducing this value of τ in the expression of $R - r$ (eq. [2.21]) we obtain the value of r as a function of x.

We can similarly write

$$\tau = \int_0^\tau dt = \int_r^R \frac{dx}{(\bar{v}_+)_{Tr}}. \qquad [2.23b]$$

When $r = 0$, that is when the ion is formed on the axis, $\tau \equiv \tau_0$. If this value τ_0 is introduced into [2.22] we obtain the maximum value of $\Lambda \equiv \Lambda_0$.

Although we have assumed a turbulent flow field, the molecular velocities are normally very much smaller than the ion drift velocities and we thus neglect the perturbation of the ion concentration profile due to turbulence of the gas stream. This approximation begins to break down in very small fields ($\lesssim 1$ V cm^{-1}). Under very fast flow conditions v_s, the stream velocity, cannot be neglected in the previous equations; $(\bar{v}_+)_A$ will then have to be replaced by the sum of the drift velocity and the stream velocity, viz. $(\bar{v}_+)_A + v_s$. Unless $\Lambda \ll (R - r)$, the ion concentration will increase in that part of the positive column in the vicinity of the anode. The above condition is realized when the transverse field is much larger than the axial field. This is usually the case in wide tubes in discharges through monatomic gases. However, in discharges through molecular gases or in dis-

charges in tubes of medium or small diameter (say less than 3 cm) and in electronegative gases, the transverse field is rather small and the last condition is nearly always realized. The ion concentration will then increase over a distance Λ_0 from the anode. We now calculate approximately the magnitude of this increase in concentration. In the absence of negative ions Schottky (5) has shown that, in a static gas, the ion number density $(n_+)(x, r)$ at a distance r from the axis of the discharge tube is equal to the ion density on the axis $n_+(x, 0)$ times a Bessel function of zero order in $r(a/D_a)^{1/2}$ (16, p. 122).

$$[2.24] \qquad (n_+)_{r=r} = (n_+)_{r=0} J_0[r(a/D_a)^{1/2}],$$

where D_a is the ambipolar diffusion coefficient and a the number of ions produced per unit time per electron. When $r(a/D_a)^{1/2} = 2.405$ the value of the Bessel function is zero and for larger values of $r(a/D_a)^{1/2}$, the function becomes negative. Since ion concentrations that are negative have no physical meaning we impose the further boundary condition that at $r = R$, the radius of the discharge tube, $R(a/D_a)^{1/2} = 2.405$. Thus

$$[2.25] \qquad (n_+)_{r=r} = (n_+)_{r=0} J_0\left(2.405 \frac{r}{R}\right).$$

Inherent in Schottky's theory is the assumption of uniform production of ions in a section of the discharge perpendicular to the axis.

We now calculate the increase in ion concentration when $0 < x < \Lambda_0$. The number of positive ions in a slice across the discharge of width dx at the point of entry of the gases in the positive column will be given by the integral from 0 to R, of the ion concentration in a ring $2\pi r\, dr$, viz.

$$\int_0^R 2\pi r n_+(0,0)\, J_0\left(2.405 \frac{r}{R}\right) dr\, dx.$$

At a point $x = x$ we obtain a similar expression with the term $n_+(x,0)$ replacing $n_+(0,0)$. The difference between these two terms is equal to the excess of ions formed over those lost by recombination at the walls. The number of ions formed while the gas proceeds from $x = 0$ to $x = x$ is given by [2.15] in which we make the substitution $dt = dx/(v_s + (\bar{v}_+)_A)$. v_s is given by [2.20]. The number of ions lost in this slice is equal to the number of ions which have reached the wall. Thus

$$[2.26] \quad \int_0^R 2\pi r n_+(0,0)\, J_0(2.405)\, dr\, dx = \int_0^R 2\pi r n_+(0,0)\, J_0\left(2.405 \frac{r}{R}\right) dr\, dx + \int_0^x \sum_i \frac{f_i}{v_s + (\bar{v}_+)_A} n_i \frac{JX}{E_1} \left\{ \int_0^R 2\pi r\, dr\, dx \right\} dx - \frac{1}{x} \int_0^x \int_r^R 2\pi r n_+(x,0)\, J_0\left(2.405 \frac{r}{R}\right) dr\, (dx)^2.$$

The second term on the right-hand side of this equation expresses the production of ions in the discharge, E_1 being the ionization energy; the last term is the loss term. Since $n_+(x,0)$ is independent of r we can integrate all terms with respect to r. If we remember that $xJ_0(x)\, dx = d(xJ_1(x))$ (30) and that $J_1(2.405) = 0.519$, eq. [2.26] becomes

$$[2.27] \quad n_+(x,0) = n_+(0,0) + 2.316 \int_0^x \frac{\sum_i f_i}{v_s + (\bar{v}_+)_A} \frac{n_i JX}{E_1} dx - \frac{1}{x} \int_0^x n_+(x,0) \left\{ 1 - \frac{1}{0.519} \frac{r}{R} J_1\left(2.405 \frac{r}{R}\right) \right\} dx.$$

For personal use only.

In the above two equations the value of r in terms of x is given by [2.21] and [2.23a]. When $x = \Lambda_0$ this becomes

$$[2.28] \quad n_+(\Lambda_0,0) = n_+(0,0) + 2.316 \int_0^{\Lambda_0} \sum_i \frac{f_i}{v_s + (\bar{v}_+)_A} \frac{n_i JX}{E_i} \, dx - \frac{1}{\Lambda_0} \int_0^{\Lambda_0} n_+(x,0) \, dx.$$

For values of $x > \Lambda_0$ no further increase in ion concentration will occur if f_i is independent of x; that is the electron energy distribution remains constant.

If negative ions are present or volume recombination occurs Seeliger (8) has shown that the Bessel concentration profile will change to that given by an elliptic function. Qualitatively, however, this will not affect the above conclusions and we have not attempted to solve the equations under these conditions.

(G) Radical Concentration in the Positive Column

In addition to ions, a large number of molecules in excited states, atoms, and radicals will be formed in the discharge. The radicals formed in an impact may either further dissociate during subsequent electron impacts or they may react chemically with other molecules either in the gas phase or at the walls. Excited species will lose energy through the emission of photons. Steady-state conditions will be established as soon as the rate of production becomes equal to the rate of loss. The production term will be of the form [2.15] if the collision cross section for the reactive collision with an electron having the necessary energy is of the same order of magnitude as the elastic cross section for less energetic electrons; E is then the dissociation energy of the bond being broken. If dissociation occurs via an antibonding state this energy will be somewhat larger. The loss term will be the sum of all the rate expressions describing the disappearance of radicals or excited species. Some of these terms will be first-order in the radical concentration (reaction of radicals with other (stable) molecules or emission of a photon); second-order terms describe radical recombination in tri-body collisions or in radiative processes.

We assume that whenever a first-order process leading to the disappearance of radicals produced in the discharge can occur, the magnitude of the rate term will be such that it dominates the loss term; other terms, second order in radical concentration, will be, at most, small correction terms. Under these conditions concentration gradients and diffusion processes will be negligibly small. Only if no first-order process can occur (such as in the dissociation of a diatomic gas in the discharge), will recombination reactions become important. Recently Young and Sharpless (31) have obtained evidence that, even at low pressures, tri-body recombination processes have to be taken into account. Whenever the lifetime of an excited molecule or radical is small, deactivation will occur mostly via emission of a photon. Under these conditions the emission intensity will be proportional to the total concentration of the radical in the gas phase, unless a simultaneous production of the radical or molecule in the excited state takes place via a reactive collision or an energy-transfer process (chemiluminescent emission[5]).

Whenever processes first order in the radical concentration dominate the loss term, the change in number density with distance of an excited species or a radical n_i will be given by

$$[2.29] \quad \frac{dn_i}{dx} = \frac{f_i}{v_s + (\bar{v}_+)_A} \frac{n_i JX}{E_i} - k_{im}' n_i n_m.$$

[5] *Under fast-flow conditions the number of collisions between an impurity and excited molecules during the time the gas moves a small distance is small and hence excitation of these impurities via energy-transfer and chemiluminescent processes will be characterized by an emission intensity which increases over a greater distance than processes in which the excited state is produced by electron impact directly.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

k_{im}' is the bimolecular rate constant for the reaction of radical i (number density n_i) with molecules of type m (number density n_m). If one of the k_{im}' values in the loss term is very large and leads to a stable product, monitoring the increase in the number density of the product will permit a measure of the magnitude of the production term.

3. DISCUSSION AND COMPARISON WITH EXPERIMENT

In Section 2 we have derived a set of equations which will be helpful in evaluating and interpreting experimental results obtained in this laboratory. Although a detailed analysis at this time is not yet possible, it was felt necessary to present in an accompanying paper (3) the results of a general survey of the oxygen discharge, in which evidence is presented for some of the models which were analyzed in this paper. The extent of the inhomogeneous zone in the positive column due to the increase in the ion concentration in the vicinity of the anode, as analyzed in Section 2F, is controlled primarily by the size of the ratio of the longitudinal electric field to the transverse field. We have found that many discharge modes are possible in an oxygen discharge, and in one of them the above ratio is much larger than 1. In this discharge we have also obtained evidence of an increasing ion concentration at the head of the positive column, which is as expected. In most gases (especially the inert gases), however, the field ratio is much smaller and hence the inhomogeneous region will be much shorter; its observation will then become much more difficult, if at all possible. It should be pointed out that the stream velocity of the gas will cause an extension of this region, but this effect will be much smaller than the effect of the ratio of the electric fields. Quantitative calculations cannot be performed for oxygen as yet because of the presence of negative ions (32, 33). The eqs. [2.24] to [2.28] will have to be rederived for a non-Bessel ion-density profile (34).

We will also be interested in analyzing the results of spectroscopic and other measurements performed in this laboratory on flowing gases in the discharge. From [2.15] it is seen that a change in the emission intensity of a spectral feature in the positive column can be due to a change in any of the parameters appearing in that equation. By choosing a system which experimentally gives X and J constant, it is possible to study chemical reactions and excitation processes in the discharge. A chemical reaction causes a change in n_i, and the rate of these processes can thus be determined by monitoring this change. Two interfering effects are possible: (i) significant pressure gradients can be produced along the column if the tube diameter is relatively small and the pumping capacity large (they introduce a nonchemical change in the value of n_i); and (ii) any change in the electron energy distribution function would cause a change in the $\alpha_{ij} = n_i f_{ij}$ factor. In ref. 1 an example is given where it was shown that changes in the intensity of emission of atomic oxygen lines were proportional to the concentration of atomic oxygen while in ref. 2 it was shown that the change in intensity of emission of CO in a carbon monoxide – oxygen mixture was due to changes in the f_{ij} factor.

If the electron energy distribution is Maxwellian it can be written in terms of an electron temperature T, viz.

$$[3.1] \qquad f(E) = 2E^{1/2}(\pi k^3 T^3)^{-1/2} \exp(-E/kT).$$

We further assume that in a first approximation the elastic collision cross section Q_0 is constant. Experimentally it is found that $Q_0(E)$ varies by a factor of 2 or 3 over the energy range over which there is an appreciable population of electrons (26). The inelastic collision cross section can also be approximated by a constant in the interval $E_{ij} < E < \infty$ because at very high energy the electron population becomes vanishingly small; for values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of $E < E_{ij}$ the inelastic collision cross section is zero. Under these assumptions eq. [2.16] can be written

$$[3.2] \qquad \frac{dn_{ij}}{dx} = AkT\left(\frac{E_{ij}}{kT} + 1\right)\exp\left(-E_{ij}/kT\right),$$

where k is the Boltzmann constant and

$$[3.3] \qquad A = 4Jn_i \sum n_i Q_{ij} Q_{0i}/(v_s Xe^2).$$

The drift velocity [2.14] becomes

$$[3.4] \qquad \bar{v}_e = Xe/[(2\pi mkT)^{1/2} \sum n_i Q_{0i}].$$

If changes in the emission intensity of a species present in the discharge is due to a change in the electron temperature along the positive column, we can write the ratio of [3.2] for two values of x as

$$[3.5] \quad \ln \frac{(dn_{ij}/dx)_{x=0}}{(dn_{ij}/dx)_{x=x}} = \ln \frac{T_0}{T} + \left(\ln \frac{E_{ij}}{kT_0} + 1\right) - \left(\ln \frac{E_{ij}}{kT} + 1\right) - \frac{E_{ij}}{k}\left(\frac{1}{T_0} - \frac{1}{T}\right).$$

If the lifetime of the excited state j is short enough, we can put $\sum_i dn_{ij}/dx$ for all excitation processes leading into the state j proportional to the emission intensity from this state at any point in the discharge. Thus

$$[3.6] \qquad \ln \frac{I}{I_0} = \ln \frac{E_{ij} + kT}{E_{ij} + kT_0} - \frac{E_{ij}}{kT_0}\left(\frac{T_0 - T}{T}\right).$$

E_{ij} is the energy of excitation of level j, and i is the ground state of the emitting species. If T_0 is known we can thus calculate the drop in temperature associated with a given change in the intensity of emission along the positive column. If we assume E_{ij} to be about 12 eV and T to be 10 000 °K the decrease in temperature which accounts for a drop in intensity of about 40% is of the order of 200 °K while if $T_0 = 50\,000$ °K, the required decrease in electron temperature is about 4 000 °K.

ACKNOWLEDGMENTS

The authors wish to thank Professor J. P. Valleau for many stimulating discussions. He also read the manuscript and made many suggestions for its improvement.

It is a real pleasure to acknowledge support in the form of grants from the United States Air Force through the Office of Scientific Research (Propulsion Research Division), from the National Research Council of Canada, and from the University of Toronto.

One of us (J. L. P.) is indebted to Professor A. Van Tiggelen of the University of Louvain (Belgium) for allowing a year's leave of absence to study at the University of Toronto.

CHEMICAL REACTIONS IN ELECTRICAL DISCHARGES

III. THE POSITIVE COLUMN IN D-C. GLOW DISCHARGES THROUGH OXYGEN[1]

H. W. RUNDLE, K. A. GILLESPIE, R. M. YEALLAND, R. SOVA, AND J. M. DECKERS

Received June 6, 1966

ABSTRACT

Discharges through fast-flowing oxygen have been investigated. It has been shown that the electrical field remains constant in the positive column of a particular mode, even in the presence of a large pressure gradient. It was found that five types of discharges could be distinguished and they can be characterized by fluctuations of the voltage at the electrodes. These oscillations are linked with the absence or presence of travelling waves in the column. The conditions of existence of the various discharges are outlined. It has also been shown that the structure of the positive column is not as homogeneous as previously thought. In particular, even at constant field, changes in the electron temperature and the number density of charged species are shown to occur. The change in electron temperature and the presence or absence of oscillations have been shown to affect the rate of production of atomic oxygen and the emission intensity of the spectrum of these discharges.

1. INTRODUCTION

In this paper we report our observations on the positive column of a glow discharge through fast-flowing oxygen. In 1927 Güntherschulze (1) reported the existence of two types of d-c. glow discharges in oxygen. In fairly narrow tubes he observed a grey-green discharge, whereas in wide tubes the discharge appeared violet. In that paper he also pointed out that the longitudinal field in the positive column was much larger in the grey-green discharge than in the violet one. Seeliger (2) and Seeliger and Wichmann (3) further investigated these two discharges and found that with increasing pressure and (or) with decreasing current, the discharge characterized by a high value of the field in the positive column (hereafter referred to as the high field discharge) would switch to the low field discharge. They described the high field discharge as blue and having a core lightly violet, whereas the low field discharge was described as grey blue. In the high field discharge the local value of the field, constant in time, was equal to the value of the field averaged over the whole length of the positive column; whereas in the low field discharge the local field value could deviate by as much as 20% from the average value. The high field discharges displayed predominantly the atomic oxygen spectrum and no ozone formation was observed. The low field discharge displayed the "negative band spectrum" and formed ozone in substantial amounts. Although they (2, 3) mentioned that oxygen could form negative ions, they did not suggest a mechanism by which these negative ions could be responsible for the occurrence of the two types of discharges.

Thompson (4, 5) has estimated the influence of the presence of negative ions on the positive column and he has shown both experimentally and theoretically that the transverse field in the presence of negative ions is much smaller than it is in non-electronegative gases. The ratio of the number density of negative ions to electrons under his operating conditions was estimated to be about 20 to 1. The influence of negative ions on the conditions in the positive column was further discussed theoretically by Albrecht and Ecker (6).

Oscillatory phenomena, occurring in the d-c. glow discharge, were observed by Dieke, Loh, and Crosswhite (7) and by Loh and Dieke (8); the correlation between the oscillations of the current density or the applied voltage and the emitted light intensity was established by Donahue and Dieke (9) and shown to be due to fast-moving striations ($\sim 10^5$ cm s^{-1}), even when the column appeared uniform and unstriated to the naked eye. Pekarek and Šicha (10) established the presence of fast-moving striations in the low field discharge described by Seeliger and Wichmann. No oscillations were found to occur in the high field discharge. Recently Miller (11) presented some data on the value of the electrical field in the positive column as a function of current and pressure.

We have extended these observations and found the oxygen discharge to be even more complicated. More specifically, there are two different low field discharges; the mixed discharges described by Seeliger and Wichmann (3) have some features which would indicate that they should be considered as a distinct type of discharge.

These various discharges can best be distinguished by the oscillations of the potential at the anode. They are characteristic of the type of discharge. In some instances, this oscillation was periodic with a frequency between 5 and 100 kcycles, whereas in other cases it could be completely aperiodic or totally absent. Under otherwise identical conditions the different types of discharges were shown to have different concentrations of oxygen atoms. This clearly established the importance of a better understanding and characterization of the positive column of the glow discharge itself, before attempting to investigate chemical effects produced by the discharge. Indeed, it has been shown by Peeters *et al.* (12) that in order to account quantitatively for the rate of excitation of molecules and for the rate of chemical reactions induced by electron impact in the discharge, the electron number density, the field, and the electron energy distribution must be determined.

2. EXPERIMENTAL

(A) Gas Supply and Handling

Oxygen, tapped from a cylinder (British Oxygen of Canada Ltd.), was passed through a trap, cooled by an acetone – dry ice bath, and used without further purification. In some instances Matheson ultra high purity oxygen was used. It was stated to be at least 99.95% pure, the impurities being N_2 (7.9 p.p.m.), CH_4 (15.8 p.p.m.), CO_2 (3.8 p.p.m.), Kr (13 p.p.m.), and other impurities combined (less than 0.9 p.p.m). After being metered by a capillary flowmeter, the gas expanded to the working pressure through a needle valve and entered the discharge tube through a side arm upstream of the electrode. After passing through the discharge tube, the gases were pumped out via another side arm by a mechanical pump. A throttling valve in the line to the pump allowed us to change the gas velocity and the pressure in the discharge tube. The pressure could be measured at either end of the discharge tube by means of a tilting-type McLeod gauge.

(B) The Discharge Tube

The discharge tubes were made from Pyrex tubing of various diameters. At both ends of the tube (Fig.1) the electrodes entered via rubber stoppers. These electrodes consisted of copper wire 2 mm in diameter and slightly tapered at the end. A small amount of vacuum grease coated part of the electrodes to facilitate sliding through the rubber stopper. In a few experiments the vacuum pump was connected to the downstream end of the discharge tube by moving the electrode into a side arm. This arrangement did not affect the conditions upstream of the location of the side arm, and permitted the use of electrodes with larger surfaces without interference with the gas stream. Use of these large surface electrodes would often stabilize the discharge. This arrangement was always used when we measured the number of oxygen atoms produced in the discharge.

In several discharge tubes, probes were sealed in every 5 to 10 cm. They consisted of small pieces of platinum wire of 0.1 to 0.25 mm diameter coated with Pyrex glass; the outside diameter of the coated probe was between 1 and 1.5 mm. The tip of the probe was left exposed over a length of 2 to 3 mm and was located as closely as possible to the axis of the discharge tube. To ensure a good vacuum seal at the Pyrex–platinum interface, the outside of the seal was further coated with glyptal paint.

The discharges were sustained by means of NJE regulated variable power supplies (model S326, 327 or 328). A chain of resistors in series with the discharge permitted us to adjust the resistance of the overall circuit. This was of great use when trying to obtain a particular type of discharge when more than one type could be sustained under the operating conditions. The current through the discharge could be adjusted most easily by varying the setting at the power supply.

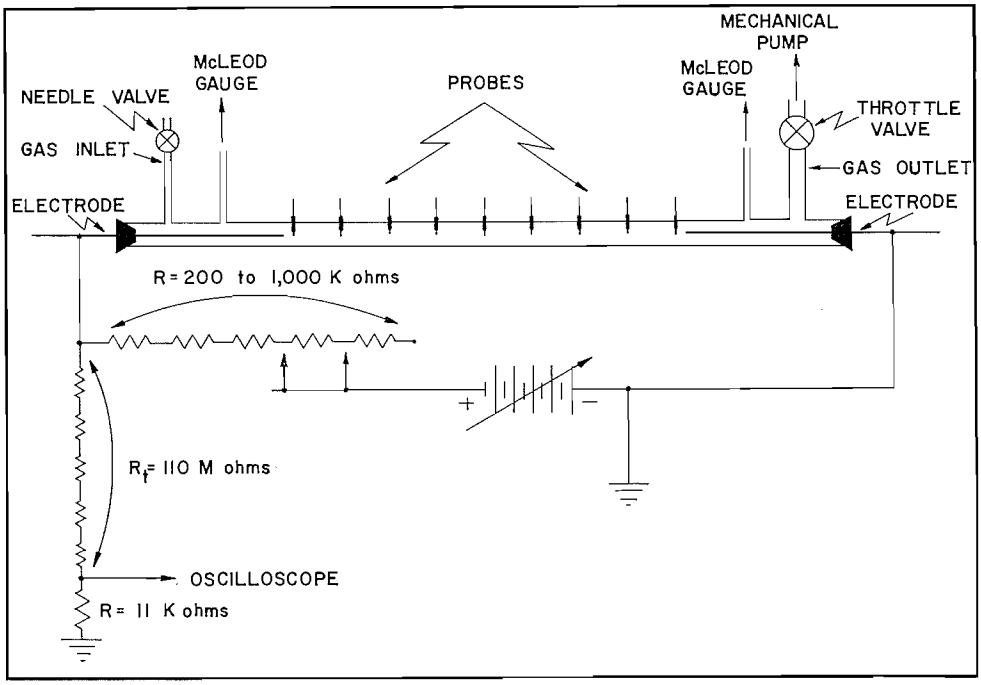

FIG. 1. Schematic of the apparatus.

For spectral measurements, a monochromator (Jarrell-Ash model 82000 with grating blazed at 5 000 Å) was mounted underneath the discharge tube. The spectrum was then recorded by either an 1P21 or an 1P28 photomultiplier tube.

(C) Field Measurements

The fields in the positive column were measured by two methods: the moving electrode and the floating potential techniques. The moving electrode technique consisted of increasing the distance between the two electrodes and measuring the increase in voltage necessary to maintain the discharge at constant current.

The electrode separation was increased a few centimeters at a time and the field determined either by measuring the slope of a plot of voltage versus electrode separation or by fitting a first-order equation to the experimental data by least squares using the IBM 7094 computer of the University of Toronto. The derivative of this equation was then equal to the field.

When using the floating potential technique, we measured the floating potential at a number of probes sealed every few centimeters in the discharge. The fields were then determined either from a plot of the measured potential versus probe location or, as above, by fitting the best first-order equation using the method of least squares. Voltage measurements were made with a Keithley model 610R electrometer, using when necessary, a 1000–1 divider probe having an input impedance of 10^{12} Ω.

(D) Langmuir Probe Measurements

By superimposing small voltages on one of the probes sealed in the discharge tube and by measuring the current drawn from the probe, we obtained the "Langmuir characteristics", from which electron temperatures could be calculated, assuming an equilibrium energy distribution. To superimpose a small voltage on the probe, a large resistance board was mounted in parallel with the discharge tube. It consisted of an arrangement of various size precision resistors. The power supply was left floating for these measurements and one of the takeoffs of this bleeder network, close to the floating potential of the probe, was grounded. The probe was then successively connected to various points of the bleeder and the current drawn from the discharge was measured by means of a Lange multiflex galvanometer (type MG1; sensitivity 2×10^{-8} A per scale division). The potential at the probe was simultaneously measured by means of a Cimron model 6200 A digital voltmeter. With this instrument measurements were always taken on the 0 to 10 V scale to insure an input resistance of 10^{12} Ω (at balance).

(E) Oscillations

To observe and measure the oscillations of the current and voltage, an oscilloscope (Tektronix RM 561 or Philips PM 3230) was connected by means of a voltage divider network (of input impedance not less than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

10^8 Ω) to the off-ground electrode. Enough energy could also be picked up by the probe of the oscilloscope when it was located unconnected (as an antenna) close to the discharge tube itself, although background noise and other spurious signals were also picked up this way.

(F) Measurement of the Oxygen Atom Concentration

When the atomic oxygen produced in the discharge was measured, the downstream electrode was always mounted in a side arm of the discharge tube; the atom concentration was then measured a short distance downstream of the discharge region itself. Two different methods were used: the isothermal calorimeter probe technique (developed by Tollefson and Le Roy (13) and adapted to oxygen by Elias, Ogryzlo, and Schiff (14)) and the gas titration technique (developed by Kaufman (15, 16)).

The catalytic probe used in the isothermal calorimeter was tungsten wire coated with freshly prepared silver. Under these conditions Elias *et al.* (14) indicated that atoms and molecules in excited states would not be deactivated in measurable amounts at the probe. To establish the efficiency of the probe, a small amount of NO was added to the oxygen flow and the green glow due to the recombination reaction $NO + O \rightarrow NO_2^* \rightarrow NO_2 + h\nu$ fell off quite sharply at the probe, when viewed in total darkness. NO_2^* denotes an electronically excited NO_2 molecule.

The power supply for the bridge was an NJE QR-36-10, the potentiometer a Leeds and Northrup K33, and the bridge null detector a Lange multiflex type MG1 galvanometer (1 μV off-balance sensitivity). The probe itself could be moved closer to, or farther from, the discharge in order to determine the amount of recombination taking place between the discharge and the probe.

Gas titrations, using NO_2, were done through a small gas inlet located about 10 cm downstream of the side arm in which the downstream electrode was located. The extinction point of the NO_2 glow was determined by eye or by using a photomultiplier tube.

3. RESULTS

(A) General Survey of Types of Oxygen Discharges

In this section we will qualitatively categorize the various types of oxygen discharges that we observed between 0.5 and 5 Torr, listing their properties and the conditions under which they are obtained. A comparison of these results with those obtained by Seeliger and Wichmann (3) appears in Section 4.

These results are primarily those of observations taken in discharge tubes of 10 to 15 mm diameter and at a current density of about 5×10^{-3} A cm^{-2}. The pressure region investigated was 0.5 to 5 Torr, measured near the anode at the entrance point of the gas into the discharge. A pressure gradient of not more than 0.4 Torr (depending on the electrode separation, the stream velocity of the oxygen, and the tube diameter) was always present; the values quoted for the pressure were those taken at the anode unless otherwise stated. To observe the various types of discharges the mass flow of oxygen and the discharge current density were kept constant while the pressure was varied using the throttling valve in the pumping line. This was done for several mass flows of between 0.5 and 2.0 cm^3 s^{-1} at standard temperature and pressure, which represent upstream velocities in the range of 0 to 10 m s^{-1}. The observations are summarized in Table I and the different types of discharges have been assigned Roman numerals.

Below 1.5 Torr the type I discharge occurs exclusively. The positive column is a fairly intense pink color and appears uniform and unstriated at higher stream velocities. At lower stream velocities several stationary striations would appear on the anode side of the platinum probes and would become more prominent at lower pressures. The electric field in the column is quite constant and has values between 20 and 60 V cm^{-1} depending on the pressure (fields of this magnitude are referred to as high fields in Table I). No oscillations occur in the range 10 to 10^7 c.p.s. (other than some residual 60 c.p.s. noise of amplitude less than 0.01% of the anode potential). Under favorable conditions of electrode separation and current, it is often possible to obtain the type I discharge up to pressures of about 4 Torr. Above 1.5 Torr the high field discharge becomes unstable in that it might spontaneously shift to a type II or type III discharge. This phenomenon of switching to other types of discharges is less likely to occur at higher flow velocities and is also

TABLE I
Type of discharge and characteristics

Type	Pressure range (Torr)	Color of the positive column	Electric field in the positive column	Anode oscillations	
				Frequency (kcycles)	Amplitude (% of anode voltage)
I	0.5–4.0	Pink	High	Absent	
II	1.5–5.0	Grey-violet	Low	10–100	5–10% (20–100 *V*)
III	2.5–5.0	Grey-violet	Lower than II	Aperiodic	
IV*a*	1.6–1.8	Predominantly pink	High at anode lower at cathode		(200–400 *V*)
IV*b*	2.0	Pink near cathode grey-violet near anode	Low at anode higher at cathode	5–10	15–25%

sensitive to the presence of foreign material (e.g. sputtered copper or copper oxide from the electrodes) on the tube wall. To observe the high field discharge, the discharge tube had to be cleaned periodically with dilute nitric acid (followed by copious rinsing with distilled water).

Type II discharges are characterized by periodic oscillations of the anode potential in a frequency range of 10^4 to 10^5 c.p.s. The amplitude is small (5–10% of the anode voltage) and the wave form is rather complex. Although the oscillation frequency and the amplitude of the oscillations would remain fairly constant under given conditions, exact reproduction of the pattern is difficult, owing to a marked dependence upon discharge conditions. The electric field in the positive column is constant and in the range of 10 to 15 V cm^{-1} (referred to as low field discharge in Table I). The color of the column is quite different from that of type I discharges, but at the currents used its intensity is so low that the best description we could give it is a grey-violet color. It appears completely uniform and exhibits neither stationary nor visible moving striations under any conditions of pressure and gas stream velocity. The low field discharge, which is usually obtained, is the type III discharge. It is in many respects similar to a type II discharge, the main distinguishing feature being that the anode oscillations are completely aperiodic. The pressure ranges in which these two types of discharges are observed are almost the same, and spontaneous switching back and forth between the two discharges can occur. Again, switching to another type of discharge could be induced by the presence of a Tesla coil, keeping the potential across the discharge electrodes low compared with what is required for a type I discharge. The positive column is visually indistinguishable from a type II discharge and the electric field is in the same range.

In addition to the above types of oxygen discharges, two distinct transition regions could be observed. These have been labelled type IV*a* and IV*b* discharges in Table I.

Type IV*a* occurs over a wide pressure range (2–5 Torr) and has a characteristic anode oscillation which is nearly sinusoidal (although at times more or less distorted depending on the other discharge parameters). The frequency is lower than that of type II discharges ($\sim 10^4$ c.p.s.) but the amplitude of the oscillations is considerably larger (15 to 30% of the anode voltage). The electric field in the positive column is not constant axially. The positive column has two distinct regions, each of which has a different constant field. It is

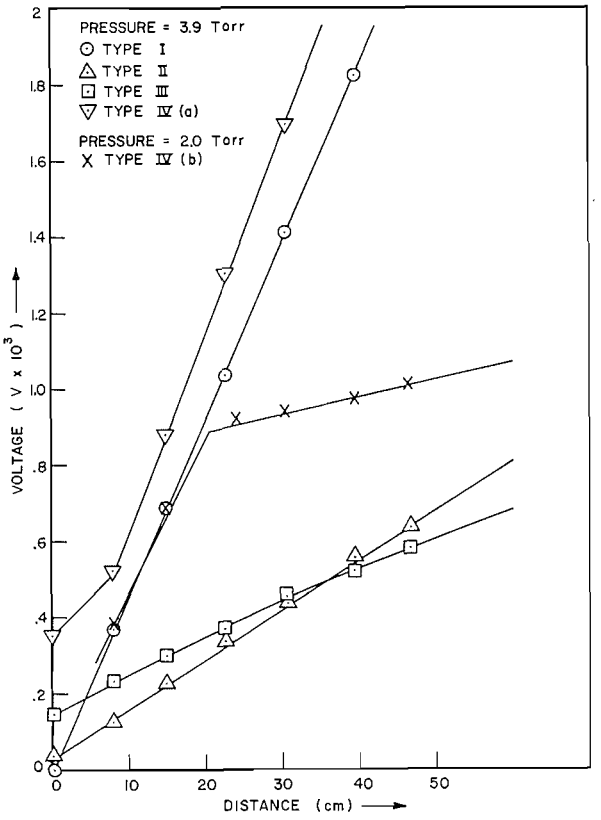

FIG. 2. Probe voltage versus distance along the positive column (from cathode to anode) for the various types of discharge. Tube diameter 12.6 mm; current density 7.4×10^{-3} A cm^{-2}; flow velocity 224 cm s^{-1}.

higher near the anode, and the value of the higher field is generally greater than the field of a type I discharge under similar conditions. The color of the column is predominantly pink and appears uniform, but because of the low intensity it is possible that it does contain some grey violet. A curious point of interest is that the platinum probes about halfway along the discharge tube (near the center of the column) would invariably be surrounded by a glow in this type of discharge. Unless the discharge parameters were changed very slowly the discharge would merely pass from a type II or type III directly into a type I discharge or vice versa, without establishing the characteristic pattern of a type IV discharge on the oscilloscope.

In addition to the above discharge, another more obvious transition type of discharge (IV*b*) could be obtained over a very narrow pressure range (1.5–2 Torr). The positive column is a visible mixture of pink near the cathode and grey violet near the anode. The electric field is high in the pink region and low in the grey violet. The low field part is similar to that of the type II or type III discharge but the value of the high field seems less than that of a type I discharge. Indeed, the anode oscillation was visibly flickering back and forth between the aperiodic pattern of the type III discharge and the kcycle pattern of the above-mentioned type IV*a* discharge. In many cases this made it impossible to obtain reliable field values. The probes near the center of the tube that would be glowing for the type IV*a* discharge would have a flickering glow in step with the anode flickering.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The region of stability of the type IV discharges often depends on other discharge parameters such as electrode separation and current. If the electrode separation is too small, only the low field discharge will appear. When the electrode separation is increased it is always the higher field portion of the positive column which extends.

Some rough measurements were taken at other tube diameters (up to 2.5 cm), and the observations are comparable. Values of the high and low field discharges will both increase or decrease when the radius of the discharge tube is decreased or increased respectively.

When very small amounts (0.1%) of gases more electronegative than O_2 such as NO_2 or Br_2 were added to the oxygen passing through a type I discharge at pressures at which other types of discharges could be obtained, the transition would immediately occur. At pressures below those at which type II or III discharges could be sustained, oscillation resembling those of type IV discharges would sometimes appear and the current density would increase. However, the operating conditions could not be made stable enough to actually measure the field.

(B) Field Measurements

Fields were measured by two methods: the moving electrode and the floating probe. Fields measured by both methods in identical discharges compare rather favorably, and the disagreement between the two methods could usually be traced to the accuracy to which the pressure, the flow, and the current density in the discharge could be reproduced or measured. Table II gives some values of fields measured by the floating probe technique at various discharge pressures and two values of the current. These measurements were taken at a stream velocity of 336 cm s^{-1}. It was observed that changing the stream velocity within the range investigated (1 to 10 m s^{-1}) had little effect on the field of a type I discharge. Several values of the fields in the different types of discharges are given for

comparison. Figure 2 illustrates the various types of discharge, giving some of the voltage versus distance curves from which the field values were calculated. The curves are labelled as to the type of discharge they represent and many of the features of the electrical field, which were mentioned in Section 3A, can be seen in them. Particularly noteworthy are the linearity of the type I, the change of the field in the type IV*a*, and the slight curvature of the type III curve.

As can be seen from Table II, there is a marked influence of the pressure on the value of the field in a type I discharge. The field is observed to increase with pressure approximately as $P^{2/3}$. To a slightly smaller degree there is also an influence of the pressure on the high field part of the type IV*a* discharge. Further studies on the pressure dependence of the field are now being carried out and will be reported when completed. The one curious feature to note is that despite the strong dependence of the field on the pressure and its slight dependence on the stream velocity, it remains constant along the positive column even in the presence of large pressure gradients.

This was particularly apparent in those measurements which were made at high flow velocities in a fairly narrow tube (inside diameter 7 mm) using the moving electrode technique. Under these conditions the pressure gradient is large (up to 1.5 Torr), and we expected the value of the field to be determined by the local pressure. However, this is not so, since a plot of applied potential versus electrode separation is linear within experimental error.

(C) Langmuir Probe Measurements

Figure 3 shows typical Langmuir characteristics taken in the positive column of a type I discharge in the immediate vicinity of the anode. The linearity of these curves establishes that the electron energy distribution is Maxwellian and hence an electron temperature has significance. Pressure limitations on the interpretation of the Langmuir characteristics restricted all probe measurements to type I discharges in the pressure range of 0.5 to 1.5 Torr.

Our results indicate that the electron temperature increases immediately adjacent to the anode (<1.0 cm) and then begins to decrease in the next few centimeters. Langmuir characteristics were also taken at various intervals further along the column (up to 30 cm from the anode). However, these curves became increasingly nonlinear beyond about 3 to 5 cm; a temperature could thus not be measured nor its variation established over the entire length of the positive column. The nonlinearity of the characteristics shows that the energy distribution becomes non-Maxwellian. It is probable that negative ions being formed by electron attachment are responsible for this behavior. An actual measurement of the distribution by the method of Boyd and Twiddy (17) should clarify the situation. The Langmuir characteristics have established that the electron temperature increases before decreasing along the positive column away from the anode. This variation will be interpreted in Section 4 in the light of other experimental observations made in this laboratory.

(D) Atom Concentration Measurements

Atom concentrations were measured by two methods: the calorimetric probe and the NO_2 gas titration technique. With the probe technique a 15 mm inside diameter discharge tube was connected at the downstream end to a tube 30 mm inside diameter in which the probe itself was mounted. The atom concentration was found to be independent of the probe location in the measuring section over a distance of 40 cm. It was thus concluded that no measurable amount of recombination occurred in the measuring section.

The isothermal probe was found to be more accurate than the NO_2 titration method.

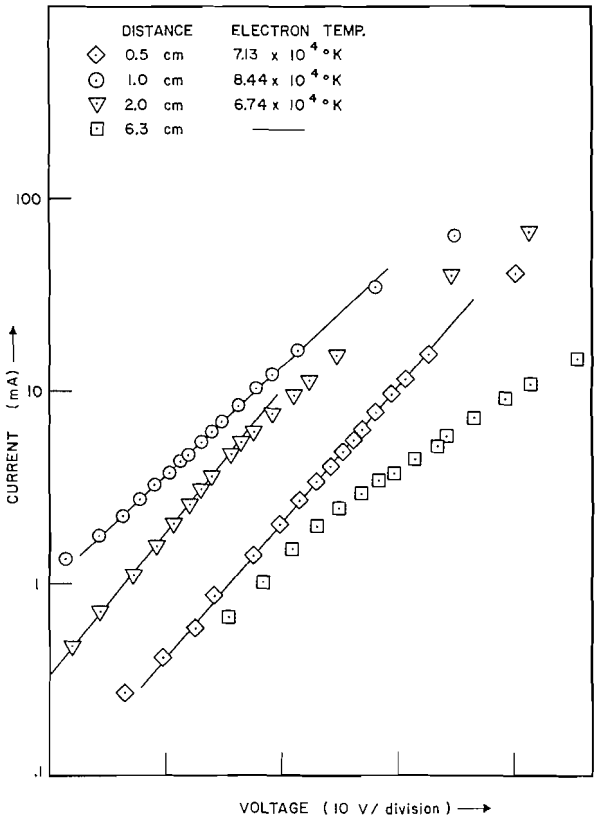

FIG. 3. Langmuir characteristics taken at various distances from the anode. Tube diameter 12.6 cm; current density 3.2 A cm^{-2}; pressure 1.0 Torr at anode.

However, for the particular probes used, only relatively small oxygen atom flows could be measured. Hence, both techniques were employed. The titration method was found to be relatively insensitive particularly in the presence of the yellow-green afterglow sometimes observed in the oxygen discharge (see Section 3E) and then its accuracy is questionable since both the NO_2 glow and the afterglow appear rather similar to the eye. The type of discharge had a significant influence upon the dissociation of oxygen. In Fig. 4 the percent dissociation is plotted against discharge current for a type I and a type IV discharge at various linear flow velocities. These results were obtained by means of NO_2 titration techniques. Hardly any dissociation could be detected in type II or III discharges.

By the probe technique the influence of the length of the positive column on the oxygen atom concentration was determined for various values of the current density (Fig. 5). As can be seen the percent dissociation increases linearly except during the first 15 cm. This decrease in slope in the first 15 cm is to be noted and is to be correlated with the decrease in electron temperature (see Section 4). For all discharges reported in this section the yellow-green afterglow was observed.

(E) Spectral Observations

General speaking only atomic oxygen lines were observed in any type of discharge although their emission intensity was very different. In type I and IV discharges a fair number of atomic oxygen lines were observed. In type II or III discharges the emission intensity was only 2 to 10% of that in type I or IV discharges and hence only the most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

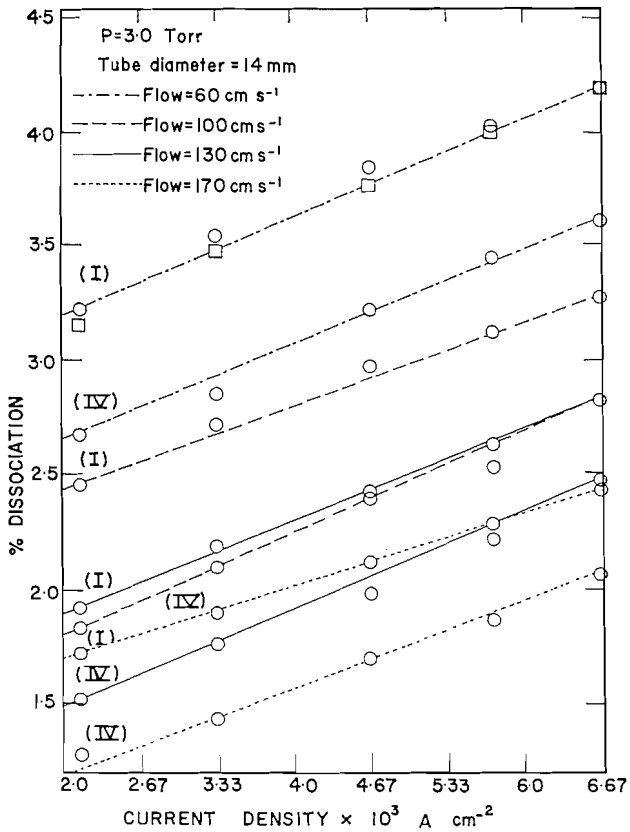

FIG. 4. Percent dissociation of oxygen versus discharge current in mA for a type I and a type IV discharge.

intense lines could then be observed. Even when using ultra pure oxygen containing less than 7.9 p.p.m. N_2, the second positive band system of N_2 could be observed at the downstream end of the discharge. Within the sensitivity of our apparatus no emission of the oxygen negative band spectrum has been observed.

Noteworthy is the fact that at times a yellow-green afterglow was observed. Under these conditions part of the positive column of the type I discharge was also yellowish green. This was particularly apparent at the downstream end, as if the emission was increasing with distance from the anode. The column was uniformly pink near the anode and towards the cathode the yellow-green glow would appear at the walls. Proceeding along the column, this glow spread to fill the tube. In larger tubes, the pink core would hardly be visible although in small tubes it could always be seen, no matter how strong the yellow glow. The presence or absence of the yellow glow under identical conditions does not seem to affect any of the parameters which we have measured, including the spectrum. The spectral features of the glow could not be measured with our equipment because their intensity was less than the noise level of our amplifier and recorder.

4. DISCUSSION OF THE RESULTS

In this section we discuss and interpret the observations reported in Section 3. In a previous paper in this series, Peeters *et al.* (12) have analyzed a model of the positive column. We shall make use of the equations derived in that paper and refer to them by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

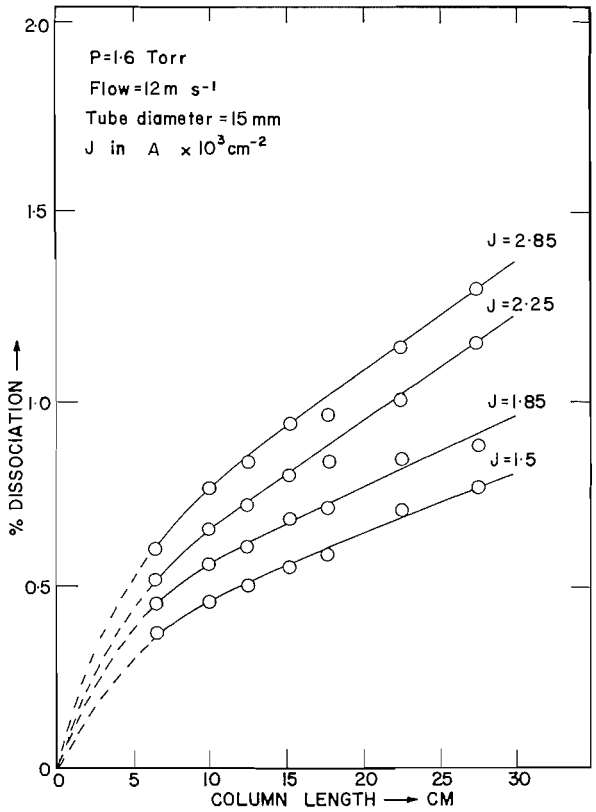

FIG. 5. Percent dissociation of oxygen versus positive column length.

preceding the numbering of the relevant equation by II. The meaning of the symbols is also the same as in II.

(A) General

Our observations of the various types of discharges in oxygen and the conditions under which they occur agree quite well with the observations of Seeliger and Wichmann (3). Discharge type I is their "H" form and types II and III are both the "T" form. The transition-type discharges containing H and T forms we have labelled type IV. In all cases, values of the field and conditions for occurrence of the various discharges agree. The most striking observation is the correlation existing between the different types of oscillations and the values of the field. These oscillations indicated two "T" types of discharges as the current density in the discharge varied with the type of oscillation. The discrepancies in the color of the discharge might be due to the lower currents used in our experiments.

A correspondence between voltage oscillations and moving striations has been established (18) and the oscillations observed here agree well with the findings of Pekarek and Šicha (10) in the different forms of the discharge in oxygen.

(B) The Electron Temperature

Since the radial field in oxygen has been shown to be very small (Thompson (4, 5), and also verified in this laboratory), Poisson's equation can be written in its one dimensional form

$$\nabla^2 V = \frac{\partial X}{\partial x} = \frac{e}{\epsilon_0}(n_+ - n_- - n_e),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where X is the axial field; n_+, n_-, and n_e the number densities of positive ions, negative ions, and electrons respectively; ϵ_0 the permittivity of free space; and e the electron charge. Hence, for a constant field X, any change in the concentration of positive ions will be balanced by an equal change in the concentration of negative species.

As the current density J is conserved and neglecting the part of the current carried by ions, it follows from [II 2.5] that an increase in n_e implies a decrease in the electron drift velocity $\bar{v}_e$ which, at constant gas density, then further implies an increase in the electron temperature [II 3.4]. Over relatively short distances ($\sim$5 cm) the pressure drop is negligible and the field remains constant, and so an increase in the positive ion concentration should be accompanied by an electron temperature rise in the vicinity of the anode. In II an analysis of the structure of the positive column in the area adjacent to the anode indicated an increase in the positive ion concentration. The observed increase in electron temperature is thus in agreement with this model.

Further downstream, the increasing nonlinearity of the Langmuir characteristics indicates a distribution of the electron energy which becomes progressively non-equilibrium. We think that this is due to the formation of negative ions. Thompson (4) has indicated that in an oxygen discharge the ratio n_-/n_e can be as high as 20/1. At constant field and positive ion density, this corresponds to an effective decrease of the electron temperature. Measuring the actual energy distribution will permit the verification of this hypothesis. But although we cannot conclude anything about the behavior of the electron energy distribution function further down the positive column, we expect it to shift to lower average energies in view of the following experimental observations previously mentioned: the rate of production of atomic oxygen remains constant except for a decrease over the first 15 cm and the change in the rate of production of oxygen atoms is the same as the change in the rate of growth of the emission intensity of atomic oxygen lines.

(C) The Field in the Positive Column

In the high field type I discharge the field is seen to increase monotonically with pressure (see Table II) and to be relatively independent of the flow velocity in the region studied. The surprising feature, however, is that the field remains constant along the whole positive column even in the presence of a pressure gradient. The measurements made in tubes of narrow diameter having large pressure gradients established this with certainty, since no variation in the field could be detected.

If [II 3.1] is introduced into [II 2.11] it is seen that the field should be a monotonically increasing function of the electron temperature. However, in the derivation of [II 2.11] it is implicitly assumed that the electron number density remains constant over the distance in which the electron gains an energy E_{ij} from the field (E_{ij} is the energy lost by an electron in an inelastic collision). The constancy of the current density J [II 2.5] implies that for any change in the drift velocity due to a change in the field, an opposite change in the electron number density will take place. As long as no space charge can develop, type I discharges are observed. The other types of discharges are oscillatory in character and striations travel along the column. Pekarek (19) has developed a theory which links the striations with oscillations travelling along the column. It is thus somewhat surprising that the time-average value of the field remains constant. The relation which is deduced in II between the electrical field and the electron temperature is to be used with caution, as the results of this work indicate that it cannot be applied under all conditions.

(D) The Production of Oxygen Atoms and the Emission Spectrum

The importance of properly characterizing the type of discharge when using it as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tool to produce atoms, radicals, or other metastable or excited species is apparent from Figs. 4 and 5. Indeed, when the discharge is switched from a type I to a type IV discharge, the amount of atoms produced is significantly reduced and no dissociation is observed in type II or III discharges.

Bois D'Enghien and Deckers (20) previously reported that the emission intensity of certain bands or lines (e.g. atomic oxygen) increased linearly with the length of the positive column. The assumption was made that for oxygen the emission intensity of these lines was proportional to the atomic oxygen concentration. This assumption has now been confirmed as it can be seen from Fig. 5 that the atomic oxygen concentration varies linearly with distance.

The rate of production of oxygen atoms has been shown to decrease over the first 10 to 15 cm from the anode (as mentioned in Section 4C). The decrease in the rate of production of oxygen atoms is paralleled by a decrease of the emission intensity of the atomic oxygen lines, adding further support to the proportionality existing between the concentration of atomic oxygen and the emission intensity. We ascribe this decrease to the suspected change in electron temperature.

SUMMARY

We have shown that there exist more than two types of d-c. glow discharges through oxygen. The type of voltage oscillation at the anode is characteristic of the type of discharge. The electric field is different under a given set of conditions for the different types of discharges. The amount of oxygen atoms produced also depends on the characteristics of the discharge. The electron temperature varies at constant field near the anode.

THE DEUTERIUM ISOTOPE EFFECT AND THE MOLECULAR DYNAMICS OF WATER IN BENZENE

D. C. MOULE[1]

Research Chemistry Branch, Atomic Energy of Canada, Limited, Chalk River, Ontario

Received August 24, 1966

ABSTRACT

Infrared spectra of H_2O and D_2O in benzene have been recorded and the solubilities of light and heavy water in benzene from 10 to 50 °C measured. Isotope fractionation factors for the distribution of HDO and H_2O between the vapor and liquid benzene phases were calculated from the relative solubilities and the vapor pressure ratios of pure H_2O and D_2O. The isotope equilibrium data was fitted to the expression $\ln \alpha = -A/T^2 + B/T$ and interpreted by the Bigeleisen formulism. The intramolecular B term was determined from the solvent shifts of the near infrared frequencies and the intermolecular A term calculated by a least squares fit to the isotope equilibrium data. Spectral and equilibrium data were combined to give 220 $cm^{-1} \simeq \nu_{Ry} > \nu_{Rx} > \nu_{Rz} \geq 120$ cm^{-1}.

INTRODUCTION

Kirschenbaum (1) has reported the solubilities of H_2O and D_2O in a series of organic solvents at room temperature. For some of the solvent systems it was found that HDO distributes preferentially from the liquid organic phase into the vapor phase by as much as 5%, whereas for other superficially similar systems it was found that HDO fractionates preferentially into the liquid phase. A theory of the phase equilibrium isotope effect for polyatomic molecules which could be applied to such two-component two-phase systems has recently been developed by Bigeleisen (2). In the simplest form of this theory isotope separation factors are expressed in terms of the $3N - 6$ normal vibrational modes in the liquid and vapor phases and the 3 external translational and the 3 librational condensed phase modes. Equilibrium isotope effect data can be compared and combined with the spectroscopic observations on the two phases and can provide information about the molecular dynamics of the condensed phase.

The benzene–water system was chosen as a representative example in which to confirm and extend the existing solubility results, and obtain information about the dynamics of water in liquid benzene. From an understanding of this system one might be able to predict whether large enough separation factors could occur in other solvent systems to make two-component two-phase equilibria a potentially useful method for separating heavy water from natural water.

EXPERIMENTAL

In a previous paper (3) the solubility of H_2O in C_6H_6 in the temperature range 10 to 50 °C was measured. The method used was an isotope dilution technique in which a quantity of benzene saturated with light water was equilibrated with a known amount of heavy water and the concentration change in the D_2O measured by infrared difference spectroscopy. Water solubility was calculated from the concentration change in the heavy water, and the quantities of heavy water and benzene. The solubility of D_2O in benzene has been measured in a similar fashion with light water replacing heavy water as the isotope exchange medium. It was estimated that the solubility of H_2O in C_6H_6 could be determined to ±0.8%, and D_2O in C_6H_6 to ±0.6%.

Far infrared spectra of H_2O and D_2O in C_6H_6 were recorded from 340 cm^{-1} to 95 cm^{-1} with a Perkin–Elmer 301 spectrophotometer. The path length of the infrared cells was approximately 3 mm and the benzene solutions were saturated with water at 20 °C. Near infrared spectra of H_2O and D_2O in C_6H_6 were obtained on a Perkin–Elmer 521 spectrophotometer. Path length of the water-saturated benzene solution was approximately 1 mm. The D_2O deformation mode ν_2 could not be observed because the 1 200 cm^{-1} region was opaque to infrared radiation.

RESULTS

The solubilities of light and heavy water in benzene in parts per million (p.p.m.) by weight over the range 10 to 50° are given in Table I.

TABLE I

The solubilities of light and heavy water in benzene as a function of temperature

	Solubilities (p.p.m. by weight)	
T (°C)	H_2O	D_2O
9.44	442.5	388.4
14.98	530.2	475.3
20.10	639.2	581.5
24.54	726.0	665.2
29.52	848.0	790.3
34.88	1 017.1	941.7
40.06	1 177.8	1 134.6
43.78	1 333.7	1 268.3
49.45	1 570.6	1 495.8

Frequencies of the band centers of the modes υ_1, υ_2, and υ_3 of H_2O and υ_1 and υ_3 of D_2O in C_6H_6 are listed in column 3 of Table II along with the band origins of corresponding vapor phase modes (4) in column 2. Columns 4 and 5 show the solvent shift υ(vapor) − υ(benzene) and reduced solvent shifts [υ(vapor) − υ(benzene)]/υ(benzene). A value for $\upsilon_2(D_2O)$ in benzene was estimated from the assumption (5) that $\Delta\upsilon_2/\upsilon_2(H_2O) = \Delta\upsilon_2/\upsilon_2(D_2O)$.

TABLE II

Infrared frequencies of H_2O and D_2O in the vapor phase and in liquid benzene. Solvent shifts and reduced solvent shifts

	Mode	υ(vapor) (cm^{-1})	υ(benzene) (cm^{-1})	$\Delta\upsilon$ (cm^{-1})	$\Delta\upsilon/\upsilon \times 10^2$
H_2O	υ_1	3 656.7	3 594.8±1	61.9	1.722
	υ_2	1 594.6	1 602.8±0.5	−8.2	−0.512
	υ_3	3 755.8	3 681.5±1	74.3	2.018
D_2O	υ_1	2 671.5	2 630.1±0.5	41.4	1.574
	υ_2	1 178.3	1 184.3±1*	−6.0	−0.512
	υ_3	2 788.1	2 734.3±0.5	53.8	1.968

*Estimated from reduced solvent shift.

Far infrared spectra of H_2O and D_2O in C_6H_6 from 320 cm^{-1} to 100 cm^{-1} are shown in Fig. 1. Broad peaks, centered at 220 cm^{-1} and 170 cm^{-1} respectively, appear in the spectra which are devoid of structure.

DISCUSSION

The isotope separation factors for the fractionation of H_2O and HDO in the equilibria

are related through

$$\alpha_1 = \alpha_2\alpha_3, \quad [1]$$

where

$$\alpha_1 = [(H_2O)/(HDO)]_{C_6H_6}/[(H_2O)/(HDO)]_{liq} \quad [2]$$

$$\alpha_2 = [(H_2O)/(HDO)]_{vap}/[(H_2O)/(HDO)]_{liq} \quad [3]$$

$$\alpha_3 = [(H_2O)/(HDO)]_{C_6H_6}/[(H_2O)/(HDO)]_{vap} \quad [4]$$

and the symbolism $(H_2O)_{C_6H_6}$ denotes the mole fraction of light water in benzene.

For equilibrium 2, the law of the isotope mean is assumed (6) and

$$\alpha_2 = \left[\left(\frac{P_{H_2O}}{P_{D_2O}}\right)\left(1 + \frac{P(B - V)}{RT}\right)\left(\frac{1 - (C_6H_6)_{H_2O}}{1 - (C_6H_6)_{D_2O}}\right)\right]^{1/2}, \quad [5]$$

where P_{H_2O} and P_{D_2O} are the vapor pressures of H_2O and D_2O, B the second virial coefficient for water vapor, which is assumed to be isotopically invarient, and V the molar volume of water in the condensed phase. The terms $(C_6H_6)_{H_2O}$ and $(C_6H_6)_{D_2O}$ are the solubilities of benzene in light and heavy water introduced through Raoult's law to correct for the vapor pressure lowering of water by dissolved benzene.

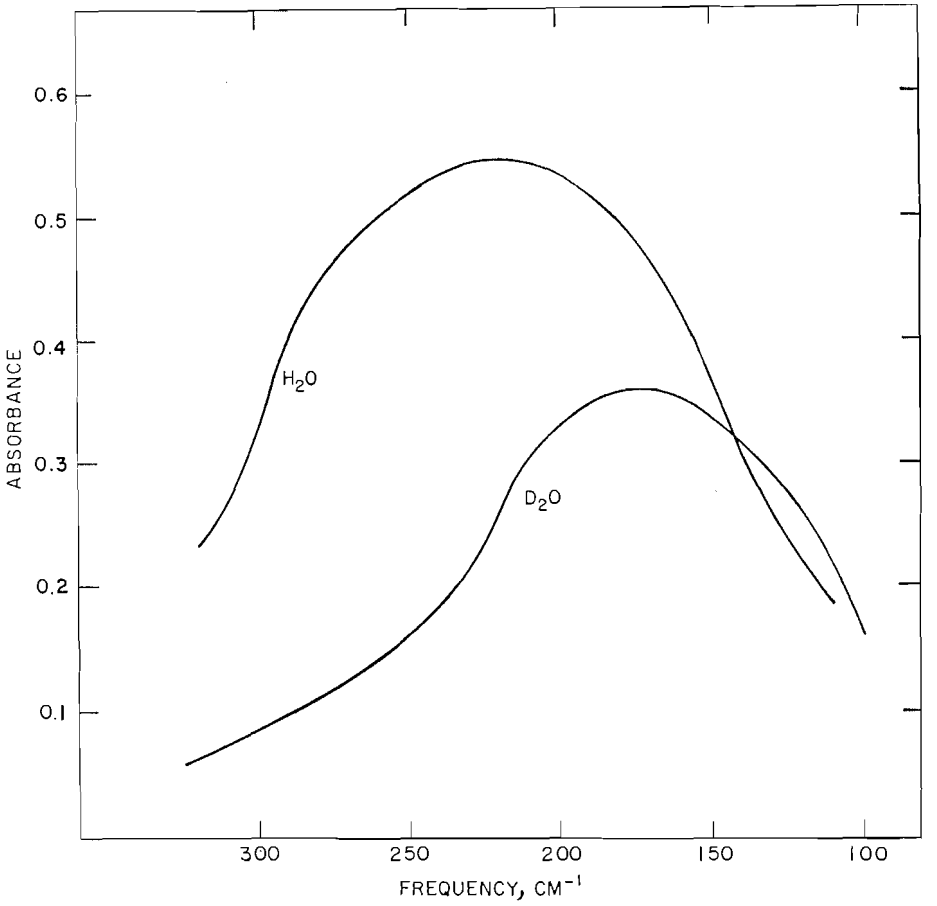

FIG. 1. Far infrared spectra of H_2O and D_2O in C_6H_6.

A theoretical treatment of the isotope fractionation of H_2O and HDO between the liquid phases of nonideal systems such as triethylamine–water has been given by Linderstrom-Lang (7). Applied to the benzene–water equilibrium his treatment yields

$$[6] \qquad \alpha_1 = \left[\left(\frac{(H_2O)_{C_6H_6}}{(D_2O)_{C_6H_6}}\right)\left(1 + (H_2O)_{C_6H_6}\frac{\partial \ln \gamma[(H_2O)_{C_6H_6}]}{\partial (H_2O)_{C_6H_6}}\right)\right]^{1/2}.$$

The first factor is the ratio of the molar solubilities of light and heavy water in benzene, while the second expresses the degree of ideality of water in benzene, $\gamma[(H_2O)_{C_6H_6}]$ being the activity coefficient of water in benzene.

There does exist some controversy over the state of water in benzene. On the basis of viscosity and specific volume measurements (8) and infrared data (9) it has been proposed that water is predominantly polymerized in benzene solution at concentrations near the solubility limit. On the other hand, evidence from infrared spectra (10) and freezing point (11) and vapor pressure measurements (12) indicate that water is monomeric in benzene. This difficulty appears to have been settled recently by Christian, Affsprung, and Johnson (13), who used an isopiestic method to measure the solubility of water in benzene over a range of partial pressures. These authors found $\ln \gamma[(H_2O)_{C_6H_6}]/(H_2O)_{C_6H_6} = 0$, which indicates that polymer formation is very improbable.

TABLE III
Fractionation factors

T (°C)	α_1	α_2	α_3	α_4
9.44	1.125	0.9159	1.030	1.061
14.98	1.114	0.9227	1.028	1.057
20.10	1.105	0.9292	1.027	1.055
24.54	1.101	0.9327	1.027	1.055

34.88	1.096	0.9420	1.032	1.065
40.06	1.075	0.9462	1.017	1.034
43.78	1.082	0.9488	1.027	1.055
49.45	1.080	0.9525	1.029	1.059

Values of α_2 calculated from the vapor pressure ratio data for H_2O and D_2O (14), molar volume of liquid H_2O (14), the second virial coefficient of water vapor (15), and the solubility data for benzene in H_2O and D_2O (W. J. Wallace, unpublished data) are shown in the third column of Table III. Separation factors α_1 obtained from eq. [6] and the solubility data of Table I are listed in column 2 while α_3 calculated from eq. [1] is given in the fourth column of Table III. To compare the observed fractionation effect with that calculated from spectroscopic data we use the fraction factor

$$[7] \qquad \alpha_4 = [(H_2O)/(D_2O)]_{C_6H_6}/[(H_2O)/(D_2O)]_{vap}.$$

This represents the isotope fractionation when water is present in the system only as H_2O and D_2O, and is given with sufficient accuracy as

$$[8] \qquad \alpha_4 = \alpha_3^2.$$

Values of α_4 are listed in the last column of Table III.

Fractionation Factors from Spectroscopic Data

To relate α_4 to the hindered translational, librational, and vibrational frequencies of water in the condensed phase, we employ the equilibrium isotope effect theory for polyatomic molecules, which has been developed by Bigeleisen (2). The reduced partition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

function ratio in this theory is expressed as a product over the $3N - 6$ internal and the 6 external reduced partition function ratios for each phase. In the liquid phase the molecules are assumed to be a collection of harmonic oscillators, each molecule possessing 3 hindered translational and 3 librational frequencies. In the gas phase all these frequencies are zero. The $3N - 6$ internal or normal vibrations of a polyatomic molecule retain their gas phase identity in the liquid phase although slightly shifted in frequency. When the external vibrations are small with respect to the experimental temperature ($h\upsilon/kT \lesssim 1$) and the internal vibrations large ($h\upsilon/kT > 1$), the phase equilibrium isotope effect equation reduces to the simple form

$$\ln \alpha_4 = -A/T^2 + B/T, \qquad [9]$$

provided that molar volume effects and vibrational anharmonicities are neglected. The intermolecular term, A, is given by

$$A = \frac{1}{24}\left(\frac{hc}{k}\right)^2 \sum^{3} \{[\upsilon(H_2O)^2 - \upsilon(D_2O)^2]_{trans} + [\upsilon(H_2O)^2 - \upsilon(D_2O)^2]_{rot}\}, \qquad [10]$$

where the summation extends over the 3 hindered translational and the 3 librational frequencies in the condensed phase. The intramolecular term B is given as

$$B = \frac{hc}{2k} \sum^{3N-6} \{[\upsilon(H_2O) - \upsilon(D_2O)]_{vap} - [\upsilon(H_2O) - \upsilon(D_2O)]_{C_6H_6}\}, \qquad [11]$$

the summation being taken over all of the internal frequencies in the separate phases.

Because of the scatter in the experimental data, it was not feasible to fit α_4 to the two-parameter eq. [9]. Instead B was determined from the solvent shifts of the normal frequencies and inserted into eq. [9], then A was obtained by a least squares fit of α_4 to the expression in only one parameter. The external frequencies derived from A were then compared with the transitions observed in the far infrared spectra.

From the solvent shifts for H_2O and D_2O in benzene listed in Table II and eq. [11], a value of $B = 27.91 \pm 1.97$ °K² was obtained. The least squares fit gave $A = 3\,600 \pm 580$ °K². The resulting fractionation factor curve and the experimental fractionation data are illustrated in Fig. 2.

To factor out the translational contribution from eq. [10] an estimate of 90 cm^{-1} was made for the hindered translational frequencies of water in benzene. On the supposition that the mass dependence of the translational frequencies is a function only of the molecular weight (2) and that the translational modes are degenerate, the translational contribution to A is 214 ± 30 °K². The equilibrium isotope effect for librational motion is $3\,600 - 214 = 3\,386 \pm 581$ °K².

In the simple case where the hydrogen-bonded proton lies in a field which is cylindrically symmetrical about the O—H · · · C group, it can be shown that to a good approximation the three frequencies will be equal (16). It follows from eq. [9] and from the approximation that the librational frequencies are inversely proportional to the square root of the average moments of inertia that $\upsilon_{Rx} = \upsilon_{Ry} = \upsilon_{Rz} = 166 \pm 14$ cm^{-1}.

From the isotope shift of the far infrared bands, illustrated in Fig. 1, $\upsilon(H_2O)/\upsilon(D_2O) = 1.29$; thus the rotational-like nature of the motion is established and the bands are assigned to a superposition of modes Ry and Rx. The Rz liberation does not involve a change in dipole moment and is not therefore infrared active. The lack of agreement between the observed centers of the far infrared bands and the calculated librational frequencies demonstrates that the average librational frequencies are widely different and that one librational frequency, presumably υ_{Rz}, must be about 120 cm^{-1}.

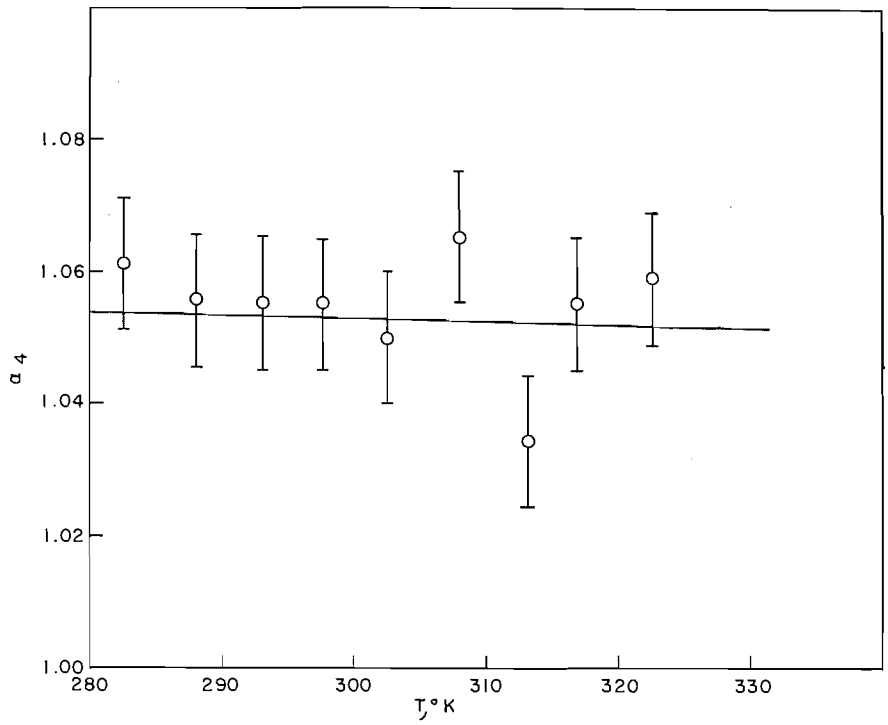

FIG. 2. The observed and calculated fractionation factors.

Van Hook and Phillips (17) have recently obtained separation factors for the distribution of C_2H_6 and C_2D_6 between the vapor phase and a variety of liquids by gas–liquid partition chromatography. They found that the isotope separation was strongly solvent dependent and that C_2H_6 was preferentially fractionated into the vapor phase with increasing solvent polarity. A similar correlation is evident in Table II. In the benzene–water system $\alpha_4(25\ °C) = 1.055$, whereas in a highly polar solvent such as liquid water, the fractionation changes direction and $\alpha_2^2(25\ °C) = 0.8699$. This is reflected in the inter- and intra-molecular terms for water in liquid water (18) and water in benzene, $A_{C_6H_6}/A_{H_2O} = 3600/33630$ and $B_{C_6H_6}/B_{H_2O} = 27.91/70.87$, which shows that the solvent shift contribution to the isotope effect is less sensitive to changes in solvent polarity than the corresponding contribution from librational motion. From eq. [9] and this correlation it follows that the most favorable solvent for separating HDO from natural water would be a nonpolar aliphatic hydrocarbon.

ACKNOWLEDGMENTS

The author wishes to thank Drs. J. E. Bertie and E. Whalley of the National Research Council, Ottawa, for recording the far infrared spectra, and Dr. R. N. Jones, also of N.R.C., for measuring the centers of the near infrared bands. The help of Mr. W. M. Thurston in constructing the absorption cell is acknowledged.

ARSENIDES OF THE TRANSITION METALS

VIII. SOME BINARY AND TERNARY GROUP VIII DIARSENIDES AND THEIR MAGNETIC AND ELECTRICAL PROPERTIES

S. L. BENNETT[1] AND R. D. HEYDING

Department of Chemistry, Queen's University, Kingston, Ontario

Received May 13, 1966

ABSTRACT

The diarsenides of the cobalt and nickel families have been synthesized for magnetic susceptibility studies. The diffraction pattern of the low-temperature modification of nickel diarsenide differs from that of the mineral pararammelsbergite, although the space group is apparently identical and the unit cell dimensions comparable (orthorhombic D_{2h}^{15}-*Pbca*; $a = 5.770 \pm 0.007$, $b = 5.838 \pm 0.006$, $c = 11.419 \pm 0.008$ Å). These binary diarsenides exhibit temperature dependent diamagnetic or weakly paramagnetic behavior. Temperature dependence of electrical resistivity indicates that $PdAs_2$ is metallic while $PtAs_2$ is a semiconductor with an energy gap of ~0.17 eV.

Substitutional solid solution limits have been determined for various Group VIII transition metal atoms in the pyrite phases $PdAs_2$ and $PtAs_2$, and in the skutterudites $RhAs_3$ and $IrAs_3$. There is no substitution by Ru or Os in $PdAs_2$, by Ni or Pt in $PdAs_2$, by Ru or Ag in $RhAs_3$, or by Os in $IrAs_3$. Very limited substitutions were observed for Rh and Ag in $PdAs_2$, Pd in $PtAs_2$, Pd in $RhAs_3$, and Pt in $IrAs_3$. The limit of Co substitution in $PdAs_2$ is 8.2 ± 0.3 atom %, and of Ni in $PdAs_2$, 56.7 ± 0.3 atom %.

In the $Co_xPd_{1-x}As_2$ system, a temperature-dependent paramagnetic contribution corresponding to approximately one uncompensated spin per cobalt ion has been attributed to the t_{2g}^5 low-spin configuration of the Co ion in the pyrite structure. In the $Ni_xPd_{1-x}As_2$ system, the temperature-independent paramagnetic contribution by the nickel ions is not completely understood.

INTRODUCTION

The diarsenides of palladium and platinum crystallize in the C2 pyrite structure (1–3), while the monoclinic diarsenides of the cobalt family (4) are believed to be isomorphous with the EO_7 arsenopyrite-type diantimonides of Co, Rh, and Ir (5) and diphosphides of Rh and Ir (6).[2] Nickel diarsenide is polymorphic. The high-temperature modification, β-$NiAs_2$ (rammelsbergite), has the orthorhombic C18 marcasite structure with an abnormally large c/b ratio in comparison with the iron family marcasites. The low-temperature modification, α-$NiAs_2$, also orthorhombic, has been shown (7, 8) to have the same unit cell dimensions as the mineral pararammelsbergite (9, 10). A complete structure analysis of this modification has not yet been reported.

With the exception of the nickel compounds, the dipnictides of the nickel family form pyrite structures with octahedral configuration of pnigogen atoms about the metal atoms. These compounds and the cobalt family MZ_3 skutterudites are the only transition metal pnictides in which the metal atoms are completely surrounded by non-metal atoms, precluding metal–metal interaction.[3] In the arsenopyrite structure exhibited by the cobalt family dipnictides, pairs of metal atoms can be recognized, while in the marcasite structure exhibited by the iron family dipnictides, one-dimensional chains of metal atoms exist parallel to the c axis of the crystal. Recently, Hulliger and Mooser (11, 13) and

[1]*Present address: Department of Chemistry, University of Kansas, Lawrence, Kansas.*

[2]*The unit cell dimensions for* $CoAs_2$ *reported earlier (4) are in error. The correct values are:* $a = 5.918 \pm 0.005$; $b = 5.876 \pm 0.002$; $c = 5.964 \pm 0.005$ Å; $\beta = 116°27' \pm 5'$. *Complete structural analyses of the cobalt family diarsenides have not been reported.*

[3]*In their recent review article, Hulliger and Mooser list* $NiAs_3$ *as a skutterudite with metallic properties (11). However, in studies on the binary* Ni–As *system, Holmes (7), Heyding and Calvert (8), and Yund (12) did not observe any compound with this composition or structure.*

Pearson (14) have used the concepts of ligand field theory to explain virtually all of the structural, magnetic, and electrical properties of these compounds, including the diarsenides, which are diamagnetic or weakly paramagnetic (15, 16).

In an earlier paper, the homogeneity limits and the magnetic and electrical properties of the substituted cobalt skutterudites $(Ni,Co)As_3$, $(Fe,Co)As_3$, and $(Fe,Ni)As_3$ were reported (17). The substitution of iron or nickel for cobalt made it possible to examine the properties of these elements in an octahedral field, that is, in the absence of metal–metal interactions. Obviously, other transition metals might be examined in a similar manner by substitution in $RhAs_3$ or $IrAs_3$, or in the pyrite diarsenides $PdAs_2$ and $PtAs_2$, provided the range of solid solution were relatively large. In this paper we report the results of attempts to substitute several transition metal atoms for Rh and Ir in the triarsenides, and for Pd and Pt in the diarsenides, and record the magnetic properties in those two systems in which appreciable substitution was obtained. The magnetic susceptibilities of the diarsenides of Pd, Pt, Co, Rh, and Ir, and the electrical properties of Pt and Pd diarsenide have been redetermined.

EXPERIMENTAL

Sample Preparation

All elements were high purity (99.99+%). The arsenic was obtained from Cominco; Rh, Pd, Pt, Ag from A. D. Mackay Inc.; Co, Ni from Johnson, Matthey and Co.; Ru, Os, Ir from Engelhard Ind. Spectrographic analyses for arsenic revealed, in p.p.m., Si, 20; Fe, 5; Ni, 5; Ag, 5; and for the transition metals, the maximum impurities were Si, 20; Fe, 50; and Cu, 10.

The arsenic was sublimed and condensed under high vacuum to effect purification and to obtain a predominance of the amorphous forms which are easy to grind and handle. The charge was initially heated at 250 °C to remove traces of As_2O_3 that formed during manipulations, and then heated at ~400 °C. The arsenic was stored *in vacuo*.

Specimens were prepared in 2 g quantities by weighing calculated amounts of arsenic and metal powders and sealing in Vycor or quartz tubes under high vacuum. After an initial treatment at ~400 °C, the temperature was raised to 750°. After a week the samples were quenched, ground thoroughly, sampled for Debye–Scherrer patterns, resealed under vacuum, and annealed for periods of 1 week. This procedure was repeated until all diffraction lines due to extraneous phases had been eliminated and consecutive photographs showed no change in lattice parameter(s). Three annealing periods were generally sufficient for complete reaction. Most systems were investigated up to $x = 0.40$, except the Ni–Pd, Rh–Pd, and Pd–Pt diarsenide systems, for which the complete composition ranges were prepared.

Debye–Scherrer patterns were obtained in 11.46 cm Norelco cameras using Cu Kα ($\lambda(K\alpha_1) = 1.5405$ Å) radiation.

Magnetic Susceptibilities

Magnetic susceptibilities were determined by the Faraday (Curie) method using Henry pole caps described earlier (18). Apparent changes in weight were determined in a closed system under dry nitrogen at 380 torr using an Ainsworth vacuum semimicro balance, equipped with a transducer, acting as a null-point instrument. Temperatures were controlled to ±2° in the temperature range 84 to ~550 °K. Measurements were taken at high fields ($B_{min} > 8\,000$ G) in five field gradients, dB^2/dx, ranging from 30.3 to 48.8 $kG^2\,cm^{-1}$. The apparent susceptibilities were plotted against $1/(B_{max} + B_{min})$ and extrapolated to infinite field, allowing χ_g^∞ to be determined. The variation in the susceptibilities of all samples with field was $\sim 0.003 \times 10^{-6}$ cgs e.m.u./g; the loss in sample weight at the higher temperatures was <0.1%; the error in χ_g^∞ was $\pm 0.003 \times 10^{-6}$ cgs e.m.u./g.

The field was calibrated with a high-purity copper cylinder (impurities in p.p.m., Fe, 1; O, 1, H; 0.4; Ni, 1; and the balance <10) of the same dimensions and in the same position in the field as subsequent samples. The absolute mass susceptibility of Cu has been determined by Henry *et al.* (19, 20).

The powdered samples (~1 g) were contained in a light quartz bucket, which was calibrated as a function of magnet excitation current and temperature. Quartz as a container material has the advantage of an almost temperature-independent susceptibility.

RESULTS AND DISCUSSION

1. Solid Solution Studies

Results of the search for substitutional solid solutions in the cubic di- and tri-arsenides are summarized in Table I. Appreciable and unambiguous regions were observed in only

*No change in parameter.

2 of 14 systems studied. It is clear that $4d^6$ and $5d^6$ ions in the pyrite structure are not readily replaced by $4d^4$, $4d^5$, $5d^4$, and $5d^5$ ions.[4] It is remarkable that the $4d^6$ and $5d^6$ ions (Pd^{4+} and Pt^{4+}) are not mutually interchangeable even though both binary diarsenides have the same structure and almost the same unit cell volume, while there is appreciable mutual substitution of $3d^6$ and $4d^6$ ions (Ni^{4+} and Pd^{4+}) although the end members are not isostructural.

The phases observed above the solid solution regions (if formed) are those to be expected, except in the $Rh_xPd_{1-x}As_2$ system. In this system, the composition $x = 0.05$ yielded two pyrite phases: $PdAs_2$, with no change in parameter (5.985 Å), and a rhodium-substituted phase with a smaller parameter (5.976 Å). The compositions $0.10 \leqslant x \leqslant 0.50$ consisted of the latter pyrite phase and a skutterudite phase having the same parameter as pure $RhAs_3$ (8.452 Å). The composition $x \sim 0.55$ was single phase skutterudite, and with increasing Rh concentration, the phases present were skutterudite and $RhAs_2$. The diffraction patterns imply that in the three phase system skutterudites of the form $Rh_{0.55}Pd_{0.45}As_{3-y}$ exist with $y \sim 1$. The type of defect structure is not as yet known.

For the systems in which appreciable substitutions were obtained, (Co,Pd)As_2 and (Ni,Pd)As_2, precise lattice parameters were obtained by Nelson–Riley extrapolations. The results are summarized in Table II. Plots of these room temperature parameters as a function of composition (Figs. 1 and 2) show the limits of solid solution at 750 °C to be $x = 0.082 \pm 0.003$ in the system $Co_xPd_{1-x}As_2$, and $x = 0.567 \pm 0.003$ in the system $Ni_xPd_{1-x}As_2$. Extrapolation of these data to $x = 1.00$ gives a unit cell parameter of the hypothetical C2 pyrite $CoAs_2$ of $5.74_5 \pm 0.01$ Å, and a cell volume (189.6 ± 1.0 Å^3) slightly larger than that of the stable monoclinic diarsenide (185.7 ± 0.5 Å^3). Similarly, the unit cell dimension of the hypothetical C2 $NiAs_2$ is 5.796 ± 0.002 Å, and a cell volume (192.0 ± 0.2 Å^3) comparable to those of β-$NiAs_2$ (195.3 ± 0.3 Å^3) and α-$NiAs_2$ (192.3 ± 0.5 Å^3 for $Z = 4$; *vide infra*).

[4]*The formal cation oxidation number in the ionic model of the pyrite dipnictides is +4.*

*From pyrite pattern in the two-phase region.

In the $Pd_xNi_{1-x}As_2$ system beyond the homogeneous pyrite phase, both α-Pd- and β-Pd-substituted nickel diarsenides were observed. The α,β transformation temperature is raised by the substitution of Ni by Pd (see Table III). The transformations in $Ni_{0.8}Pd_{0.2}As_2$ and $Ni_{0.9}Pd_{0.1}As_2$ were found to be relatively rapid (<8 d at 785°; <21 d at 750°; <50 d at 650 °C). As Yund observed (12), the transformation of β-$NiAs_2$ to α-$NiAs_2$ is extremely sluggish; no trace of the low-temperature modification could be detected after annealing at 500 °C for 150 d.

2. The Binary Diarsenides. Pararammelsbergite and α-$NiAs_2$

The end members in the above systems, $PdAs_2$, $CoAs_2$, α-$NiAs_2$, and β-$NiAs_2$, and the compounds $PtAs_2$, $RhAs_2$, and $IrAs_2$ were synthesized with great care to ensure that the preparations were single phase.[5] Unit cell dimensions for these compounds are given in Table IV.

TABLE IV

Unit cell dimensions of the nickel and cobalt family diarsenides

Compound	Structure	a (Å)	b (Å)	c (Å)	β
β-$NiAs_2$	Orthorhombic C18	4.758±0.007	5.794±0.008	3.543±0.005	
α-$NiAs_2$	Orthorhombic	5.770±0.007	5.838±0.006	11.419±0.008	
$PdAs_2$	Cubic C2	5.984_5±0.001			
$PtAs_2$	Cubic C2	5.967±0.001			
$CoAs_2$	Monoclinic EO_7(?)	5.91_4±0.03_5	5.87_1±0.01	5.96_4±0.03_5	116.5°±0.5
$RhAs_2$	Monoclinic EO_7(?)	6.06_4±0.03_9	6.08_7±0.02_4	6.15_3±0.03_4	114.8°±0.5

Because the β ⟶ α-$NiAs_2$ transformation is slow, α-$NiAs_2$ was prepared by prolonged reaction of the elements below the transformation temperature with frequent grinding. The heating sequence: 2 d at 300 °C, 10 d at 400°, and a total of 61 d at 500 °C with periodic regrinding of the sample, produced the low-temperature modification free of NiAs and As. However, the diffraction pattern of this synthetic α-$NiAs_2$ did not agree well with the diffraction pattern of pararammelsbergite (10). Some additional reflections were present, and some of the intensities of reflections common to both patterns were at variance. It was shown that oxide, arsenate (24), and arsenite (25) impurities were absent, and that annealing the synthetic specimen at 600 °C produced pure β-$NiAs_2$. In studies on additional preparations, the parameters were found to be unchanged whether this phase was in equilibrium with NiAs or As, indicating a narrow homogeneity range.

[5]*The neighboring metal-rich phases, where known, are paramagnetic (21); the* MAs_3 *phases are diamagnetic (17). Polycrystalline arsenic is weakly paramagnetic at low temperatures and weakly diamagnetic at high temperatures (22, 23).*

*Intensities determined by recording microphotometer; accuracy 5–10%. The reflections denoted by (*a*) are not present in the standard ASTM pattern for pararammelsbergite. The intensities of the reflections denoted by (*v*) were estimated visually because of poor photometric resolution.

†As_2O_3 overlap.

The focusing camera diffraction pattern is given in Table V. The pattern can be indexed on the orthorhombic pararammelsbergite cell, with all reflections, including the 'additional' reflections, conforming to the space group D_{2h}^{15}-*Pbca*. The unit cell volume is 384.6 ± 1.1 Å^3. With a cell content of eight formula units, the crystallographic density is 7.20 ± 0.02 g cm^{-3}. The observed density, measured by a helium displacement method (26), was 7.25 ± 0.07 g cm^{-3}.

Using these unit cell dimensions for α-$NiAs_2$, the enthalpy of the α,β transformation can be recalculated, using Yund's values for the parameters of β-$NiAs_2$, the transformation temperature (863 °K at 1 atm), and dP/dT for the univariant pararammelsbergite–rammelsbergite–niccolite curve of 45.5 bar deg^{-1} (12). Assuming the thermal expansion coefficients of the two forms are approximately equal, $\Delta V = 0.45 \pm 0.11$ cm^3 mole^{-1} and $\Delta H = 0.42 \pm 0.1$ kcal mole^{-1}. The $\alpha \rightarrow \beta$ transformation is too slow to be observed by differential thermal analysis.

3. *Magnetic Susceptibilities*

The System $Co_xPd_{1-x}As_2$

The magnetic properties of several compositions within the solid solution region of the $Co_xPd_{1-x}As_2$ system are shown in Fig. 3. $PdAs_2$ exhibits slightly temperature dependent diamagnetism. As Co is substituted for Pd, a paramagnetic contribution to the susceptibility is evident, especially at low temperatures. This behavior is indicative of the presence of localized moments on the solute ions.

To facilitate the interpretation of the magnetic data, the following terms are introduced (27): χ_M = molar susceptibility; $\chi_{xCo^{4+}}$ = paramagnetic susceptibility of cobalt in solid solution at a concentration of x cobalt ions; $\chi^D_{Co^{4+}}$ and $\chi^D_{Pd^{4+}}$ = diamagnetic core susceptibility per gram ion of cobalt and palladium; $\chi^D_{PdAs_2}$ = diamagnetic contribution

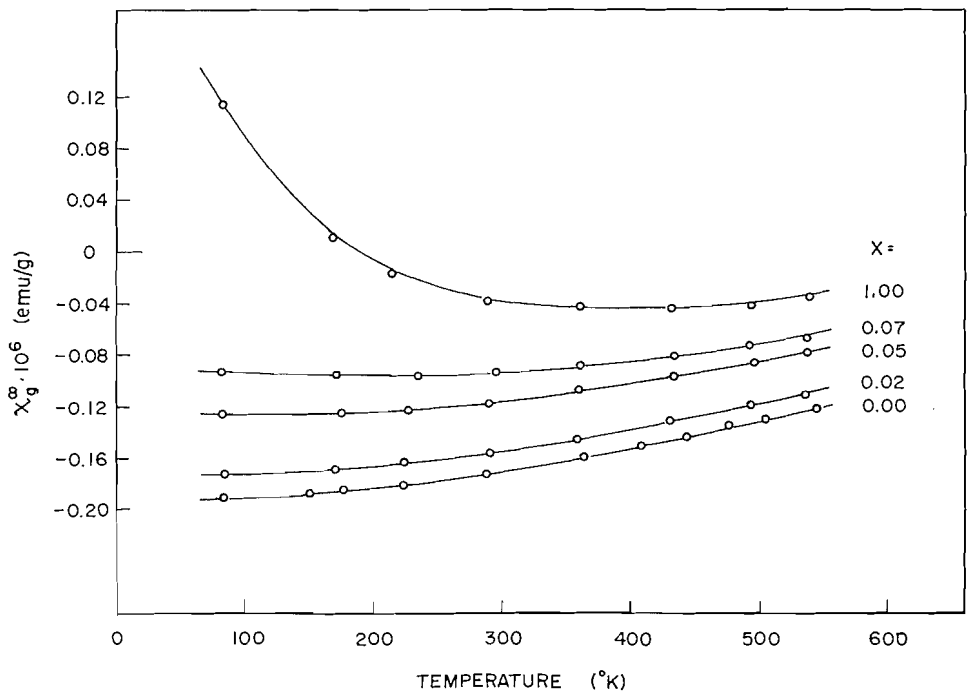

FIG. 3. Mass susceptibilities of $Co_xPd_{1-x}As_2$ solid solutions and of $CoAs_2$ as a function of temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

per gram molecule of $PdAs_2$; χ^D_x = diamagnetic contribution per gram molecule of solid solution defined by x cobalt ions. One can write

$$\chi_{xCo^{4+}} = \chi_M - \chi^D_x. \quad [1]$$

Now, χ^D_x can be written, using the additivity of diamagnetism, as

$$\chi^D_x = \sum_i n_i \chi^D_i + \varphi, \quad [2]$$

where n_i is the number of ions, χ^D_i is the diamagnetism of the ions, and φ is the structure term. Applying eq. [2] to the pyrite solid solution $Co_xPd_{1-x}As_2$,

$$\chi^D_x = [\chi^D_{Pd^{4+}} + \chi^D_{As_2^{4-}} + \varphi] + x\chi^D_{Co^{4+}} - x\chi^D_{Pd^{4+}},$$
$$= \chi^D_{PdAs_2} + x[\chi^D_{Co^{4+}} - \chi^D_{Pd^{4+}}].$$

The first term on the right-hand side represents the experimental molar susceptibility of $PdAs_2$[6] in which the term φ has necessarily been included. The diamagnetic contribution of the polyanion As_2^{4-} need not be known. Substituting into eq. [1],

$$\chi_{Co^{4+}} (\equiv \chi_{Co}) = (1/x)[\chi_M - \chi^D_{PdAs_2}] - \chi^D_{Co^{4+}} - \chi^D_{Pd^{4+}}. \quad [3]$$

Thus the molar susceptibility of $PdAs_2$ ($\chi^D_{PdAs_2}$) is subtracted from the molar susceptibility of $Co_xPd_{1-x}As_2$ (χ_M) at the temperature corresponding to the measured values of the latter. From these values are subtracted the difference in diamagnetic core susceptibilities of the cobalt and palladium ions. The latter have been calculated by the Slater–Angus method (28):

$$\chi^D_{Co^{4+}} \times 10^6 = -12.0 \quad \text{and} \quad \chi^D_{Pd^{4+}} \times 10^6 = -26.0 \text{ cgs e.m.u./gram-ion.}$$

For paramagnetic susceptibilities obeying the Curie–Weiss law $1/\chi = (T - \theta_w)/C$, a plot of $1/\chi_{Co}$ versus T gives a straight line of slope $1/C$. The graphs of $1/\chi_{Co}$ versus T are shown in Figs. 4 and 5 for the compositions $x = 0.05$ and 0.07.[7] The data have been fitted to a straight line by the method of least squares. For the composition $x = 0.05$, $1/\chi_{Co} = (T + 832)/0.307$. Since $p_{eff} = 2.83\sqrt{C}$ (where p_{eff} is the effective magnetic moment

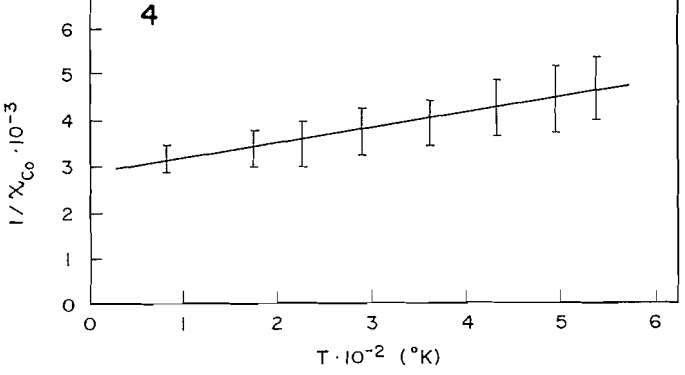

FIG. 4. Reciprocal paramagnetic susceptibility versus temperature for the composition $Co_{0.05}Pd_{0.95}As_2$.

[6]*Neither the magnitude of* χ^D *for* $PdAs_2$ *nor the temperature dependence of the susceptibility of* $PdAs_2$ *can, of course, be calculated with any certainty. That there is an electronic contribution to the susceptibility is also borne out by the resistivity data of* $PdAs_2$ *(vide infra).*

[7]*The magnetic data for the composition* $x = 0.02$ *has not been used to obtain an estimate of* p_{eff} *since the increase in susceptibility at low temperatures is almost within experimental error.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

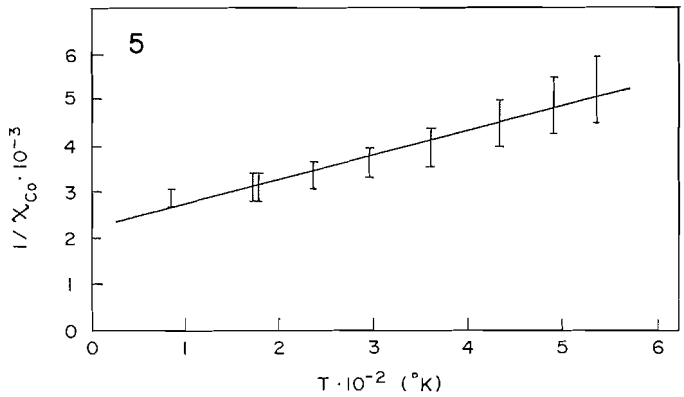

FIG. 5. Reciprocal paramagnetic susceptibility versus temperature for the composition $Co_{0.07}Pd_{0.93}As_2$.

per gram atom of Co), $p_{eff} = 1.5_7 \pm 0.4\ \mu_B$. For the composition $x = 0.07$, $1/\chi_{Co} = (T + 429)/0.196$, and $p_{eff} = 1.2_5 \pm 0.4\ \mu_B$.

The average value of p_{eff} is $1.4 \pm 0.4\ \mu_B$, and is, within experimental error, the moment arising from one free electron ($1.73\ \mu_B$), using the spin-only formula. Thus, as Co is substituted for Pd in $PdAs_2$, there is a temperature-dependent paramagnetic contribution to the susceptibility, which is attributed to the d^5 low-spin configuration of the cobalt atom in the pyrite structure. It is to be emphasized that the distance between metal atoms is large, and metal–metal interactions are precluded.

The System $Ni_xPd_{1-x}As_2$

The magnetic properties of several compositions within the solid solution region of the system $Ni_xPd_{1-x}As_2$ are shown in Fig. 6. In this system, a d^6 cation is being substituted by another d^6 cation, and one does not expect a paramagnetic contribution as in the foregoing system. With increased substitution of Ni for Pd, there is a progressive paramagnetic contribution to the susceptibility, but not of the Curie–Weiss type.

From the graph of gram susceptibilities versus temperature, values of χ^{∞}_M have been plotted against composition in Fig. 7, for the (randomly selected) temperatures $T = 84$, 290, 400, and 530 °K. Applying eq. [2] to this system,

$$\chi^D_x = \chi^D_{PdAs_2} + 14.2 \times 10^{-6}x,$$

where $\chi^D_{Ni^{4+}} \times 10^6 = -11.8$ cgs e.m.u./gram-ion, also calculated by the Slater–Angus method. This line is also shown in Fig. 7 for $T = 290$ °K. Now the increase in paramagnetism is much greater than that allowed for by the difference in diamagnetic core susceptibilities alone. However, only a rough estimate of this temperature-independent paramagnetic contribution can be made. If one assumes that the departure from linearity above $x \sim 0.3$ is anomalous, then extrapolation (for $T = 290°$) from $x = 0$ to $x = 1.0$ gives $\chi_M \times 10^6 = +35 \pm 5$ e.m.u./mole, and from eq. [3], $\chi_{Ni} \times 10^6 = +65 \pm 6$ e.m.u./gram-atom. The molar susceptibility is of the same order as that obtained for β-$NiAs_2$ (*vide infra*). The departure from linearity may be a result of the contraction of the crystal lattice on substitution of Ni for Pd. In $PdAs_2$ the As–As distance is 2.43 Å, i.e., twice the arsenic single bond radius. Provided the parameter of the As positions in the lattice is not altered on the formation of the solid solution, this interatomic distance is reduced to 2.38 Å at the homogeneity limit. If any compression of the arsenic pairs does occur, then neither φ nor $\chi^D_{As_2^{4-}}$ will be independent of concentration of Ni in the lattice, and eq. [2] will not be valid.

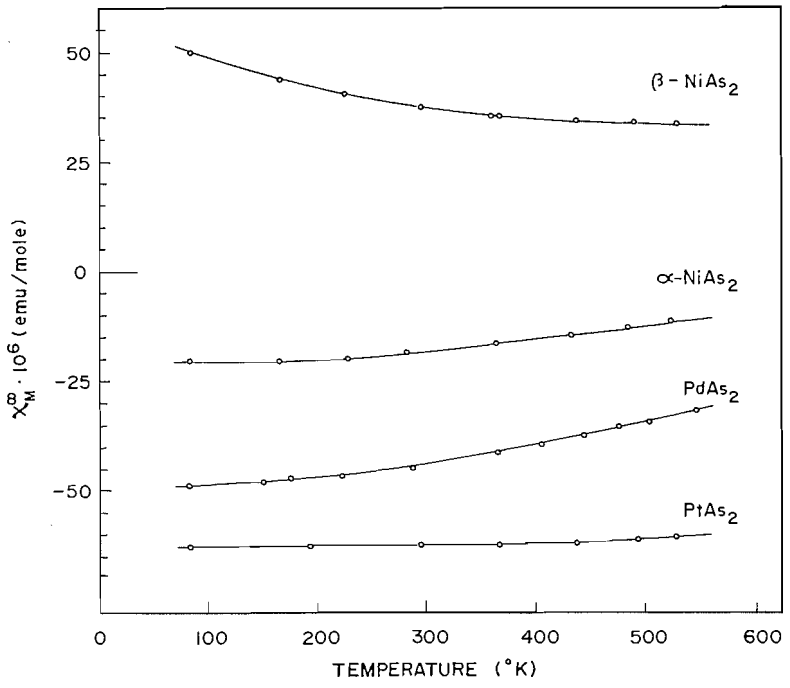

FIG. 9. Molar susceptibilities of the nickel family diarsenides as a function of temperature.

regions, but this is dependent upon the core diamagnetic susceptibility correction employed. To obtain an estimate of the magnetic moment in such cases, it is customary to replace the Curie–Weiss law by the expression $p_{eff}^2 = 8.01\chi_M T$, and p_{eff} approaches, with increasing temperature, the magnetic moment of the ion.[8] Even using the limiting diamagnetic corrections $\chi^D_{Ni^0} = -43.2$; $\chi^D_{Pd^0} = -52.7$; $\chi^D_{As^{3-}} = -63.3$ e.m.u./g ($\times 10^6$), p_{eff} approaches $\sim 0.8\ \mu_B$ at 550 °K for both β-$NiAs_2$ and $CoAs_2$. These values are maxima and are very approximate; nevertheless it is clear that these compounds have a magnetic moment of only a fraction of a Bohr magneton.

4. The Resistivity of $PdAs_2$ and $PtAs_2$

The resistivities of $PdAs_2$ and $PtAs_2$ shown in Fig. 10 were determined by a four probe method described by Pleass and Heyding (17). $PdAs_2$ is metallic in behavior, while $PtAs_2$ is semiconducting. Assuming $\rho \propto \exp(E_g/2kT)$ in the high-temperature region, an energy gap, E_g, of 0.17 eV is obtained for the latter. Hulliger (13, 15) reported that $PtAs_2$ was a semiconductor with an energy gap of 0.5 eV, and that $PdAs_2$ was "possibly metallic". More recently, Johnston *et al.* (29) measured the resistivity of $PtAs_2$ up to 1 200 °K, and found that the conductivity changed from *p*- to *n*-type at about 800 °K.

5. The Hulliger–Mooser–Pearson Model

Hulliger and Mooser (11, 13) and Pearson (14) have proposed that the metal ions in d^6 pyrites are in the low spin t_{2g} state, and that such compounds should be diamagnetic or weakly paramagnetic. The data for $PdAs_2$ and $PtAs_2$ are consistent with the model. Moreover, the substitution of a d^5 ion (Co^{4+}) for a d^6 ion (Pd^{4+}) in the pyrite structure introduces a moment indicating that the five non-bonding electrons in the d^5 ion are also in the t_{2g} energy levels. In the arsenopyrite-type diarsenides of the cobalt family, these authors suggest that the two singly occupied d levels of the neighboring cations in a hypothetical low-spin d^5 marcasite split up into a filled bonding and an empty antibonding level, giving rise to the cation pairs in the arsenopyrite structure. The pairing of the odd d electron gives each metal a filled t_{2g}^6 configuration, and consequently diamagnetic properties. Again the model is consistent with the observed susceptibilities of $CoAs_2$, $RhAs_2$, and $IrAs_2$.

Definitive comments on the magnetic behavior of α-$NiAs_2$ require a knowledge of its crystal structure. In all probability the lattice will be found to contain the arsenic pairs characteristic of all Group VIII diarsenides. The observation can be made that for the orthorhombic cell $a \sim b \sim c/2$, and a is approximately the dimension one would expect for a pyrite-type $NiAs_2$. The structure may be more closely related to the C2 structure than to the C18 structure.

According to the rule evolved by Pearson and Mooser for the semiconducting bond, all of the C2 and EO_7 diarsenides are potential semiconductors. The compounds $PdAs_2$ (metallic) and $PtAs_2$ (semiconducting) constitute an excellent example of the 'necessary-but-not-sufficient' nature of the rule. While the form of the Brillouin zones will be identical in both crystals, the rule does not predict the magnitude of the energy gap between the first zone (i.e., the valence band) and the second (the conduction band). If the periodic lattice potential is so small that energy states exist in the second zone below the maximum energy states in the first, the conduction and valence bands will be contiguous and metallic behavior will be observed. In isomorphous non-transition metal semiconductors and compound semiconductors the energy gap decreases with increasing atomic number in any

[8]*While this treatment of weak paramagnetic data is conventional, it has little merit other than to indicate the magnitude of the paramagnetic contribution expressed in terms of a spin-only model, regardless of the actual source of the moment.*

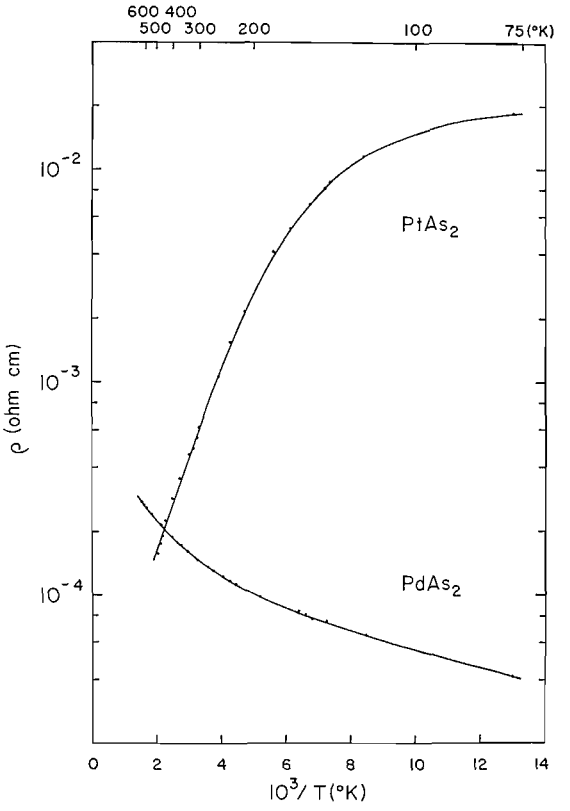

FIG. 10. Temperature dependence of resistivity of $PdAs_2$ and $PtAs_2$.

family, because the lattice potential energy decreases with increasing ionic radius. In these transition metal compounds, however, increasing atomic number of the metal ion from $PdAs_2$ to $PtAs_2$ is accompanied by an increase in lattice potential, because of the higher charge density associated with the $4f^{14}5d^6$ configuration of the Pt^{4+} ion. An increase in the magnitude of the energy gap in any family of transition metal semiconductors is to be expected when the transition metal ion in the second long period is replaced by the corresponding metal ion in the third long period.[9]

NOTE ADDED IN PROOF: Least squares lattice parameters and probable errors of α-$NiAs_2$, determined with an IBM 7040 computer (Univ. of Kansas), are $a = 5.770 \pm 0.001$, $b = 5.838 \pm 0.001$, and $c = 11.419 \pm 0.002$ Å.

ACKNOWLEDGMENTS

A COMPARISON OF OPTIMIZATION METHODS FOR FITTING CURVES TO INFRARED BAND ENVELOPES[1]

J. PITHA[2] AND R. NORMAN JONES
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received August 8, 1966

ABSTRACT

A comparison has been made of seven numerical methods of fitting infrared absorption band envelopes with analytical functions using nonlinear least squares approximations. Gauss and Cauchy (Lorentz) band shape functions are used, and also sum and product combinations of the two. The methods have been compared with respect to both the degree of convergence and to the computation time needed to achieve an acceptable fit.

The most effective method has matched the overlap envelope of a steroid spectrum containing 16 bands; this necessitated the optimization of 65 variables. More complex spectra can be dealt with by a "moving subspace" modification in which only the parameters of a group of adjacent bands are adjusted at one time. Automatic computer programs have been written for five of the methods, and for the moving subspace modification. These will be published elsewhere.

If the computed curve is convoluted with the spectral slit function before making the least squares calculations, the distortion of the observed spectrum caused by the finite spectral slit width can be corrected. In some cases this method of diminishing the slit distortion is better than direct methods, particularly when dealing with strongly overlapped bands.

INTRODUCTION

In many applications of absorption spectrophotometry it is desirable to separate overlapping bands, and to approximate the band envelope by an analytical function. The simplest way to do this is by trial and error. Suitable mathematical functions are chosen for the component bands, the positional and shape parameters are adjusted empirically, and the contour of the composite band envelope is compared graphically with the measured spectrum. Moderately complex band systems have been analyzed in this fashion, both in vibrational spectra (1) and in electronic spectra (2). A more sophisticated adaptation of this method uses an analog computer to generate the component curves and match the band envelopes (3–5), but greater precision and flexibility can be introduced with digital techniques, and it is these that will concern us here.

In 1962 a general method for computing spectroscopic band envelopes was described by Stone (6) and further developed by Papoušek and Plíva (7).[3] Some aspects of this technique have been discussed by us previously (8) and also by Biggers and co-workers (9, 10). The basic mathematical problem is not specific to optical spectrophotometry, and similar methods have been applied to the approximation of electron paramagnetic resonance (11–13), nuclear magnetic resonance (14), and mass spectra (15), as well as to optical rotatory dispersion curves (16) and the envelopes of chromatographic recordings (17, and other references therein). Mathematically the problem calls for the application of least squares analysis to nonlinear functions, using iteration to achieve an acceptable fit. There is an extensive literature on this subject (18, 19), but no criteria exist for selecting the most efficient method for our particular purpose. Some comparisons of the effectiveness of different methods can be gleaned from the recent general literature on numerical analysis (20, 21) and from other specific applications, notably to automated lens design (22, 23).

In this article we compare seven techniques of nonlinear least squares analysis for fitting the envelopes of singlet and multiplet infrared absorption band systems.

METHODS AND RESULTS

Choice of the Band Shape Function

The theoretical treatment of infrared band shapes for condensed phase systems has been reviewed recently (24), and experimental measurements (25–27) support theory in indicating that isolated absorption bands are of Cauchy (Lorentz) form, on which secondary factors of both physical and instrumental origin impose a Gaussian perturbation. These basic shape functions are commonly expressed in the form

$$A(\nu)_c = a(b_c^2 + (\nu - \nu_0)^2)^{-1} \quad [1]$$

and

$$A(\nu)_g = a \cdot b_g^{-2} \cdot \exp\,[-(\nu - \nu_0)^2 \cdot \ln 2 \cdot b_g^{-2}], \quad [2]$$

in which ν_0 is the position of the band center, $2b$ the width of the band at half-maximal intensity, and a/b^2 the peak height.

For the least squares analysis it is preferable to generalize the variables as $x_1, x_2, \ldots x_n$. If we identify x_1 with the peak height, x_2 with the position of band center, x_3 and x_4 with band width parameters, eqs. [1] and [2] transform to

$$A(\nu)_c = x_1 \cdot (1 + x_3^2(\nu - x_2)^2)^{-1} \quad [3]$$

$$A(\nu)_g = x_1 \cdot \exp\,[-x_4^2(\nu - x_2)^2], \quad [4]$$

where $x_3 = b_c^{-1}$ and $x_4^2 = \ln 2 \cdot b_g^{-2}$.

The Gaussian perturbation of the Cauchy profile is most elegantly controlled by the Voigt convolution function (24, 28), or it can be developed theoretically in terms of correlation functions (29), but these are awkward to handle numerically. The product function $A(\nu)_p$ (eq. [5]), introduced by Abramowitz and Baumann (25), is more easily dealt with. This function was also employed by Papoušek and Plíva (7).

$$A(\nu)_p = x_1(1 + x_3^2(\nu - x_2)^2)^{-1} \cdot \exp\,[-x_4^2(\nu - x_2)^2] \quad [5]$$

In this equation the shape is defined by $x_3/(x_3 + x_4)$ which has a value of unity for a Cauchy curve and zero for a Gauss curve. There is no simple expression for the half-width, but it can be easily evaluated by an iterative process. We have used this product function in most of our calculations, but we have also investigated the sum function $A(\nu)_s$ (eq. [6]), which has five variables.

$$A(\nu)_s = x_1(1 + x_3^2(\nu - x_2)^2)^{-1} + x_5 \cdot \exp\,[-x_4^2(\nu - x_2)^2] \quad [6]$$

The contours of single Cauchy bands convoluted with a triangular slit function have been matched in good approximation by $A(\nu)_s$, with the restraining condition that x_4/x_3 is constant.[4] This reduces the number of adjustable parameters to four, as for $A(\nu)_p$.

Several methods are available for the treatment of asymmetric bands. Certain types of asymmetry can be conveniently controlled by introducing additional sets of parameters $(x_1 \ldots x_n)_i$, corresponding to additional bands; this is obviously the most physically meaningful way to take care of asymmetry resulting from weak unresolved bands. Cabana

[4]*Graphs of the error function ϕ plotted against x_4/x_3 in typical cases exhibit a broad flat minimum with x_4/x_3 in the range 0.7 to 0.8.*

and Sandorfy (30) dealt with the problem in a purely numerical way by using the Cauchy function [3] with different values of x_3 for $\nu > x_2$ and $\nu < x_2$. Stone (6) relaxed the requirement that the baseline must be horizontal and linear and used a function of the form

$$[7] \qquad E(\nu, \boldsymbol{x}) = \alpha + \beta\nu + \gamma\nu^2 + \sum_{j=1}^{N} A(\nu)_j,$$

where $E(\nu,\boldsymbol{x})$ defines the complete band envelope composed of N component bands each characterized by $A(\nu)_j$. This is an empirical, but effective, way to take account of slight asymmetries, particularly in systems where N is small.

The shape functions discussed above are all expressed in terms of absorbance, $\log_{10}(T_0/T)_\nu$, where T_0 is the intensity of the radiation entering and that leaving the sample and passing through the monochromator. Although it is desirable to store the finally computed intensity indices as absorbance ordinates, there are at least two reasons which make it preferable to perform the optimization computations in units of transmittance $(T/T_0)_\nu$.

$$(TT_0^{-1})_\nu = \exp[-2.303E(\nu,\boldsymbol{x})]$$

In these calculations the ordinates of the synthesized band envelope are summed from the individual component bands in absorbance units, and then converted to transmittance before evaluating the differences.

The first and main reason for computing in transmittance is because experiments with rotating sector photometers (31) have shown that for both single and double beam spectrometers the signal to noise ratio is approximately constant in transmittance, whereas on an absorbance scale it increases at high absorbance values and introduces maximal errors at the peaks. The second advantage of calculating in transmittance units is that it makes it practical to correct for the finite spectral slit distortion by convoluting the computed band envelope with the spectral slit function after each iteration, and performing the least squares analysis with respect to this convoluted band envelope. The synthesized band envelope then conforms to the "true" spectrum. For certain types of overlapping band systems this may be a more effective way of correcting for the finite slit distortion than methods based on the direct recovery from the experimentally measured spectrum (32–34). An illustration is given later in this paper.

EXPERIMENTAL

Our digitized spectra are obtained with a Perkin–Elmer model 521 spectrophotometer and digital data recorder. This permits the encoding of the spectra on eight-hole paper tape at constant wavenumber intervals in the range 10–0.1 cm^{-1}. In practice, logistical considerations of scanning rates and computation time limit this to minimal intervals of 0.5 cm^{-1} for extensive spectral ranges, though intervals of 0.2 or 0.1 cm^{-1} have occasionally been used over short wavenumber ranges. The intensity is encoded linearly in transmittance to three decimal places. The simulated curves considered in this paper were computed at 0.5 cm^{-1} intervals and the intensities rounded to 0.001 to conform with these conditions. The encoding of the transmission data to this order of precision is justified by the analysis of measurements obtained with a sector photometer (31), which has shown that the standard deviation in the reproducibility of the transmittance can be reduced below 0.002, if the random noise is averaged by repeated scanning.

The several techniques of least squares analysis discussed below were tested on a variety of simulated band systems and are illustrated for the set of singlet, quadruplet, and septuplet bands shown in Fig. 1. The characteristics of these curves are summarized in Table I.

*The true values are listed first followed by the starting values in parentheses. x_1 = peak height in units of $\ln (T_0/T)_\nu$; x_2 = position of band center in cm^{-1}; x_3 and x_4 = band shape parameters (see eq. [5]); α = baseline displacement (see eq. [7] ($\beta = \gamma = 0$)).

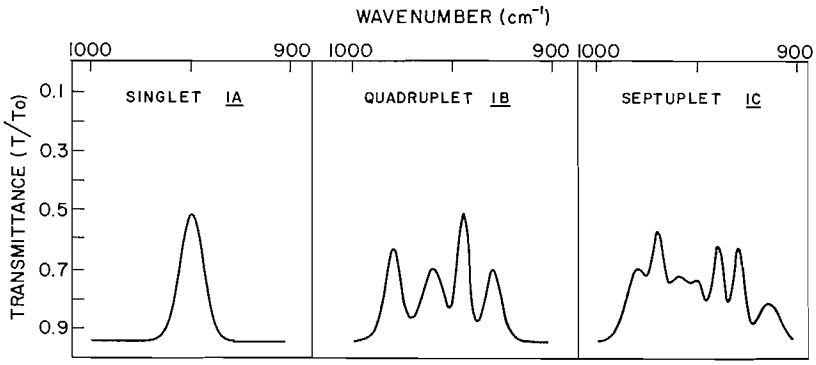

FIG. 1. Synthesized test curves.

The most effective method was tested on a 16-band section of the spectrum of 5β-androstan-17-one measured in carbon disulfide solution (Fig. 2). It becomes uneconomic in time, and possibly ineffective, to attempt to deal directly with spectra much more complex than this, but a system involving a "moving subspace", capable of computing longer sections of spectra, was later developed. The computer programs, which will be published separately (35), were written in Fortran IV and the computations were performed on an IBM 360–/50 computer.

Description of the Numerical Methods

Infrared band envelopes involve a large number of variables, but the accuracy of each ordinate measurement is relatively low, and these factors determine the most efficient method of computation. If $A(\nu)_p$ is used, or $A(\nu)_s$ with the restraining condition that x_3/x_4 is constant, a minimum of $4P$ variables are required to describe the envelope generated from P bands. This may be increased to $4P + 1$, $4P + 2$, or $4P + 3$ if, by the method of Stone (6), the baseline is freed from zero and, by addition of the α, $\alpha + \beta$, or $\alpha + \beta + \gamma$ terms, it is allowed to shift horizontally or with linear or quadratic slope.[5]

The agreement between the observed and calculated band envelope is given by

$$\phi = \sum_{i=1}^{M} f_i^2, \qquad [9]$$

where $f_i = I_i(\text{obs.}) - I_i(\text{calcd.})$, and M is the number of ordinate measurements. These ordinates will normally be in transmittance units, and we may consider that a maximal significant fit is achieved when $\phi \leqslant S^2 \cdot M$ (in which S is the standard deviation of the transmittance measurements). If this is taken as 0.002, the fit is optimized when $\phi \leqslant 4.10^{-6} M$. This is a conservative estimate, based on repetitive scan measurements with rotating sectors and, under normal conditions of recording it will be raised by the higher noise levels on the measured spectra (cf. Fig. 7).

The seven methods we have examined differ in the numerical procedure for optimization. In general they converge more rapidly with the ordinate data in absorbance than in transmittance units. This is to be expected since the absorbance functions are less seriously nonlinear, and the degree of nonlinearity has crucial importance for the efficiency

[5]*The use of the non-zero baseline is permissible if the sole purpose of the numerical analysis is to record the spectrum in a condensed form from which it can be regenerated. It is less acceptable if the analysis is intended to yield information of physical significance in the vibrational analysis of the absorbing molecule. One must also caution that these techniques of numerical analysis may lead to more than one acceptable solution, depending on the choice of the starting values. Again this is immaterial for documentational purposes, but the uniqueness of the solution would need to be checked carefully before any detailed physical interpretation is attempted.*

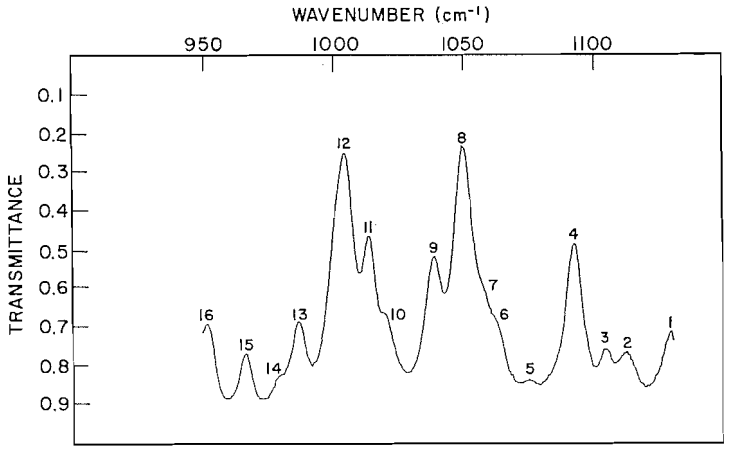

FIG. 2. Sixteen-band test spectrum of 5β-androsten-17-one in carbon disulfide solution. The curve was plotted from the digital tape by an S.D.S. 920 computer and Moseley plotter. The lettering and scales were added.

of the numerical procedures (21). In dealing with very complex band envelopes it may be necessary to take account of this, but we have preferred to work in transmittance units for the reasons discussed in the section on Methods and Results. In some cases the sum function (holding x_3/x_4 constant) converged more rapidly than the product functions, but there is an open question of choosing the x_3/x_4 value. The product function does not require this and was used in most of the calculations.

The mathematical discussion will be restricted to brief summaries of the methods, and the original papers should be consulted for details. Our nomenclature and symbolism are based on those used by Feder (22).

If ϕ is the function to be minimized, $\boldsymbol{x} = x_1, x_2 \ldots x_N$ is the vector of variables, $\boldsymbol{f}$ the vector of differences, where $f_i = I_{i(\text{obs})} - I_{i(\text{calcd})}$, we may write $\boldsymbol{f}^T \cdot \boldsymbol{f}$ for ϕ in eq. [9].

The central factor in the calculations is the $M \times N$ matrix $\boldsymbol{A}$ of partial derivative elements, where

$$A_{jk} = \partial f_j / \partial x_k, \qquad [10]$$

in which M is the total number of ordinate data points and N the total number of variables. Normally $M \gg N$. In the example of the septuplet band of Fig. 1C, $M = 200$ and $N = 28$ for a zero baseline, or $N = 31$ for non-zero values of α, β, and γ of eq. [7]. It is also necessary to define a matrix $\boldsymbol{B}$ where

$$\boldsymbol{B} = \boldsymbol{A}^T \cdot \boldsymbol{A}, \qquad [11]$$

and the vector $\boldsymbol{G}$ in which

$$\boldsymbol{G} = \boldsymbol{A}^T \cdot \boldsymbol{f} = 0.5 \text{ grad } \phi. \qquad [12]$$

Further discussion of these basic quantities and their interrelationships will be found in Feder's review article (22). The numerical calculations involve $\boldsymbol{B}$ and $\boldsymbol{G}$ only. To obtain these it is not necessary to store the complete $\boldsymbol{A}$ matrix in the computer. Memory places for one row only of the $\boldsymbol{A}$ matrix are needed; and $\boldsymbol{B}$ and $\boldsymbol{G}$ can be built up by gradual summation (36).

Method I

This was the first method we tested [8], and the calculations were performed in absorbance units.[6] It is a slight modification of the method described by Stone (6), in that we used the product function $A(\nu)_p$, whereas he used either pure Cauchy or pure Gauss functions.

The iteration step in the $(m + 1)^{th}$ convergence cycle is

$$\boldsymbol{x}_{m+1} = \boldsymbol{x}_m - p\boldsymbol{C}^{-1} \cdot \boldsymbol{G}_m, \quad [13]$$

where $\boldsymbol{C}$ is the diagonal matrix formed from $\boldsymbol{B}$ by setting the off-diagonal terms to zero. The scalar p determines the length of the step along the scaled gradient. If it is too large ϕ will not converge, but if it is too small the convergence will be slow. Stone commenced each iteration with a trial value of p (usually $p = 1$) and if the step was divergent he halved p progressively until convergence was obtained. In our experience this proved impractical in some cases, since it was necessary to reduce p to a value where the convergence became vanishingly small. Under these circumstances the overall minimization was improved when some of the parameters were held constant for a few cycles. Studies of several examples by this method revealed that the curve fit could be improved in all cases, but only exceptionally to a degree comparable with the experimental error of measurement. With highly inaccurate starting values, one or more bands might be eliminated by an extreme change in one of the variables (as for example displacement of a band position by 1 000 cm^{-1}). The calculated spectrum in the experimental range is then no longer sensitive to changes of the parameters of this band, and the band ceases to contribute to subsequent cycles of iteration. This difficulty can be overcome by setting quiescent boundary conditions (22).

Method II

This is an adaptation of the conjugated gradient method of Hestenes and Stiefel (37), which has been extensively employed in other applications of numerical analysis (22, 38). The iterative process is shown in eqs. [14]–[16].

$$\boldsymbol{D}_0 = -\boldsymbol{G}_0 \quad [14]$$

$$\boldsymbol{D}_m = -\boldsymbol{G}_m + (\boldsymbol{G}_m^2/\boldsymbol{G}_{m-1}^2) \cdot \boldsymbol{D}_{m-1} \quad [15]$$

$$\boldsymbol{x}_{m+1} = \boldsymbol{x}_m + h \cdot \boldsymbol{D}_m, \quad [16]$$

where h is chosen so that

$$\boldsymbol{D}_m^T \cdot \boldsymbol{G}_{m+1} = 0. \quad [17]$$

The technical difficulty in this method is the problem of choosing the scalar h. Feder (22) recommended that h be initially evaluated for a linear approximation of the system and then improved by interpolation. However, we found that for our functions such precalculated values of h could be in error by several orders of magnitude. In test cases, plots of $\boldsymbol{D}_m^T \cdot \boldsymbol{G}_{m-1}$ against h exhibited maxima, so that an interpolation starting from such a precalculated value of h may lead in the wrong direction. We overcame this difficulty by checking the degree of nonlinearity by eq. [18], by which $\boldsymbol{f}$ can be evaluated for linear conditions.

$$\boldsymbol{f}_{m+1} = \boldsymbol{A}(\boldsymbol{x}_{m+1} - \boldsymbol{x}_m) \times \boldsymbol{f}_m \quad [18]$$

If the value of ϕ computed from eq. [18] differed widely from the value of ϕ obtained by the calculation, the precalculated value of h was diminished by several orders of magnitude ($\sim 10^{-3}$) and this value used to improve h by interpolation.

[6] *All other calculations discussed in this paper were performed in transmittance units.*

For personal use only.

We found this method gave better results than method I, but it was slower than methods III–VII examined later. A second disadvantage is that, in some cases, numerical errors accumulated to the point where a meaningful solution was lost. This is apt to happen when the components of $\boldsymbol{D}$ are widely different. Methods III–VII are less sensitive in this respect. Method II makes modest demands on the computer memory capacity, but because of the accumulation of errors it is not recommended for large systems, even when they are linear (38).

Method III

This method uses the procedure of Levenberg (39), which requires that the changes of the variables $\Delta\boldsymbol{x}^T \cdot \Delta\boldsymbol{x}$ be minimized as well as ϕ. Papoušek and Plíva (7) have devised a semiautomatic program based on this method. It calculates in absorbance units and has been applied to the five-component envelope of the C—H stretching bands in the infrared spectrum of *n*-decane.

The iteration step is

$$[19] \qquad \boldsymbol{x}_{m+1} = \boldsymbol{x}_m - (\boldsymbol{B}_m + p\boldsymbol{I})^{-1} \cdot \boldsymbol{G}_m,$$

with the scalar p chosen to minimize ϕ at each step. To make this method operate efficiently, a rapid procedure is needed to determine the optimal value of p. Papoušek and Plíva evaluated ϕ for a range of values of p and selected the best one. In our initial experiments we used a one-dimensional search, as described by Spang (19), but later we developed an interpolation procedure which is described in the Appendix. Method III proved to be superior to both I and II, but it failed to converge satisfactorily in some cases. Out of a series of 40 tests on systems containing 20–400 data points and 3–7 unknowns, three cases were encountered in which the convergence was extremely slow. It was also impracticably slow when used in the moving subspace technique developed for dealing with long band envelopes.

Method IV

This method was developed by Marquardt (40). The iteration step is

$$[20] \qquad \boldsymbol{x}_{m+1} \cdot \boldsymbol{C}_m^{1/2} = \boldsymbol{x}_m \cdot \boldsymbol{C}_m^{1/2} - (\boldsymbol{C}_m^{-1/2} \cdot \boldsymbol{B}_m \cdot \boldsymbol{C}_m^{-1/2} + p\boldsymbol{I})^{-1} \cdot \boldsymbol{G}_m \cdot \boldsymbol{C}_m^{-1/2}.$$

It differs from method III in that the matrix $\boldsymbol{C}$ is introduced as a scaling factor; $\boldsymbol{C}$ is the diagonal matrix formed from $\boldsymbol{B}$ by setting the off-diagonal terms to zero (cf. eq. [13]). The lowest value of p still giving a convergent ϕ is used. This method is available as I.B.M. SHARE program No. 3094, but as so written it could not be used with the large number of unknowns required in our application, and we reprogrammed it *ab initio*. This proved to be one of the more effective methods, as is seen from Figs. 3–5.

Method V

This is also a modification of method III. It was developed by Meiron (23) and employs different damping factors on different variables. The iteration step is

$$[21] \qquad \boldsymbol{x}_{m+1} = \boldsymbol{x}_m - (\boldsymbol{B}_m + p\boldsymbol{C}_m)^{-1} \cdot \boldsymbol{G}_m.$$

Here the unity matrix of method III is replaced by the matrix $\boldsymbol{C}$. This change takes account of the hyper-ellipsoidal form of the function ϕ which slows the convergence of method III. Equation [21] can be derived from eq. [20] by a simple algebraical transformation, and methods IV and V are mathematically equivalent. In V the *value of p producing the lowest value of* ϕ is determined at each step, whereas IV utilizes *the lowest value of p*. It is this operational difference that leads to more rapid convergence with method V.

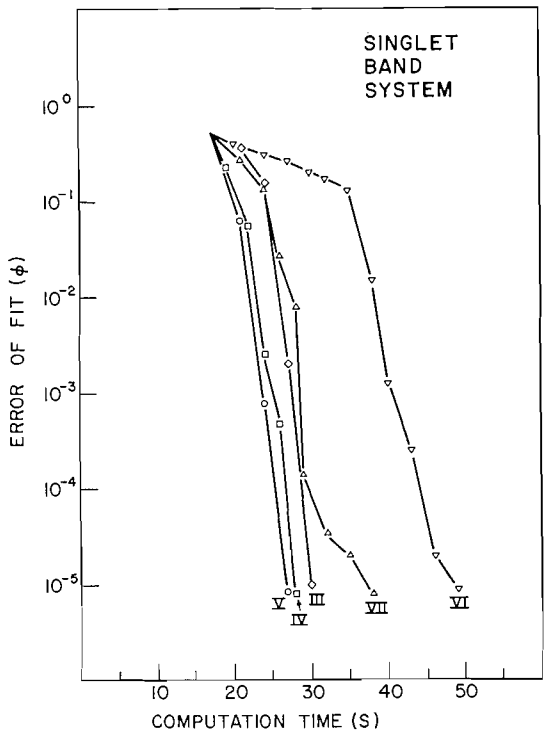

FIG. 3. Convergence of methods III–VII for the singlet band system. Consecutive iterations are indicated.

Our program normalizes the matrix (see eq. [20]), and automatically determines the optimal value of p as described in the Appendix. This method gives significantly faster convergence than any of the others we have investigated, as is seen from Figs. 3–5. Occasionally, where there were large differences in the magnitude of the diagonal elements of the $\boldsymbol{B}$ matrix, numerical difficulties developed during the computation, and it was then necessary to revert to method III.

Method VI

This is a metric variation method developed by Fletcher and Powell (41), and is based on the earlier work of Davidson (42). This method has been used extensively and has been claimed to be highly efficient (21).

The iteration step is

$$[22] \qquad \boldsymbol{x}_{m+1} = \boldsymbol{x}_m - h \cdot \boldsymbol{H}_m \cdot \boldsymbol{G}_m.$$

Here $\boldsymbol{H}_m$ modifies the metric of the parameter space. Initially $\boldsymbol{H}_0$ is a unity matrix and is iterated (41) to approximate the behavior of ϕ near the minimum point $\boldsymbol{x}_{\min}$.

$$[23] \qquad \boldsymbol{x}_{\min} - \boldsymbol{x} = -\boldsymbol{H} \cdot \boldsymbol{G}$$

The scalar h is adjusted to minimize ϕ in each iteration step.

Fletcher and Powell have used this method to obtain rapid convergence of systems of 100 variables. We have written it as an automatic program, but found it less efficient than method V in dealing with our $A(\nu)_D$ function, as is seen from Figs. 3–5.

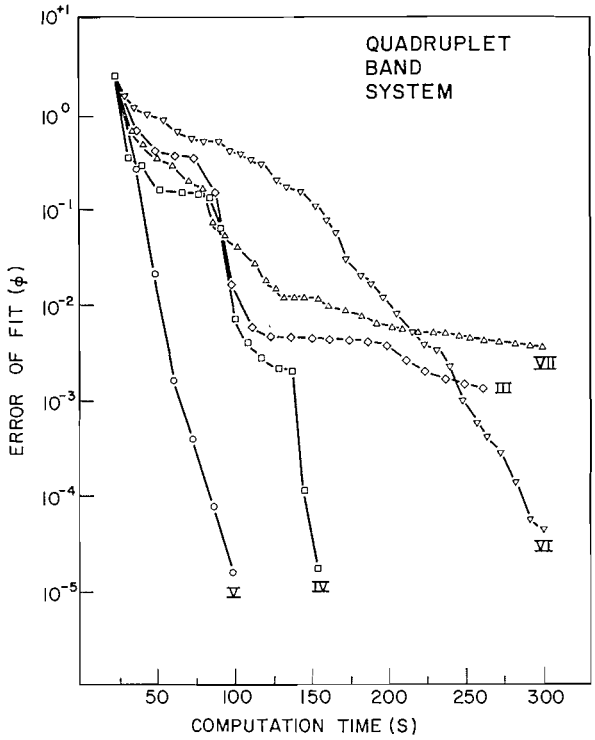

FIG. 4. Convergence of methods III–VII for the quadruplet band system. Consecutive iterations are indicated.

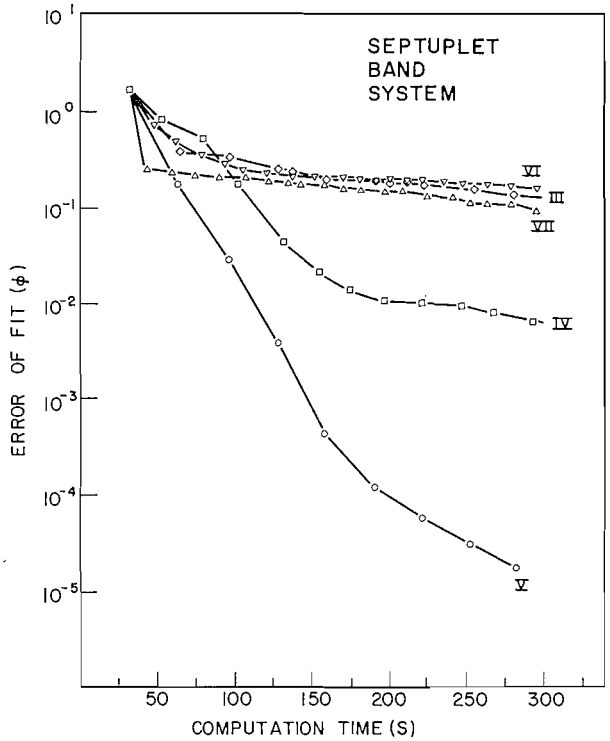

FIG. 5. Convergence of methods III–VII for the septuplet band system. Consecutive iterations are indicated.

Method VII

An analysis of the performance of method VI on the examples shown in Figs. 3–5 demonstrates the known fact (41) that the method is inefficient in the initial stages during which profound changes occur in the $\boldsymbol{H}$ matrix. In comparison with method III the iteration step takes less time and this only increases slowly with an increasing number of variables. It seemed reasonable to anticipate that the convergence in the initial stages might be accelerated by replacing $\boldsymbol{H}_0$ by $(\boldsymbol{B}_m + p\boldsymbol{I})^{-1}$ from method III (cf. eq. [19]). A duplex method was therefore developed using method III for the initial stages and later converting to method VI. It is seen from Figs. 3–5 that this does improve the slow initial stages of convergence of method VI, but not sufficiently to make it comparable with method V.

Comparison of the Methods

Reference has been made to the test cases of the singlet, quadruplet, and septuplet band systems of Fig. 1, and these may now be examined more closely. These curves were each synthesized from 200 data points and they were smooth to the limit of the rounding error (0.0005 transmittance units). The five most effective methods (III–VII) have been written as fully automatic programs in Fortran IV (35), using a standard form of input and output. The programs terminate the calculations when $f_{i(\max)} < 0.001$, or if a preselected time interval is exceeded. In Figs. 3–5 ϕ is plotted against the recorded computation time with the successive iterations indicated.

Figure 3 shows that for the single band all five methods converge rapidly. For 4 bands (Fig. 4) and 7 bands (Fig. 5) method V converges much faster than any of the others, and achieves an optimal significant fit in 3 iterations. Though methods IV and VI ultimately converge sufficiently in the 4-band case, 11 and 29 iterations are required respectively and neither of these methods can deal effectively with the 7-band system. Since this work was completed, Box (21) has compared the efficiency of eight optimization methods on highly nonlinear functions. Only one of his methods was identical with those we examined: this was the Davidson–Fletcher–Powell method (our method VI), which he found consistently better than his other seven. Since, in our hands, methods IV and V were superior to method VI, one is led to conclude that they would also be more efficient for our purpose than any of the other methods Box investigated.

Altogether about 100 sets of calculations have been made with a wide range of starting parameters. If these were too far removed from the true values, some of the bands were lost, as was noted in the discussion of method I. In general methods III–V were more stable in this respect than methods II, VI, and VII. Occasionally, when using the product function $A(\nu)_p$, negative values of x_3 and x_4 resulted (cf. eq. [5]), but this was not mathematically significant, since these variables enter the computations only as squared terms. The use of the sum function $A(\nu)_s$ occasionally resulted in negative Gauss components, but this could be avoided by diminishing the starting values of x_1 and x_5. The high stability of methods III–V may be associated with the fact that method III tends to follow closely the "natural valley path" of the parameter space (43), and the other methods presumably behave likewise.

In method VI, the final form of $\boldsymbol{H}$ describes the dependence of $\boldsymbol{G}$ on $\boldsymbol{x}$ near the minimum, and so provides an estimate of the precision of the final values of $\boldsymbol{x}$ (42). For methods III–V the procedure of Quenouille can be used to calculate the standard errors in the $\boldsymbol{x}$ vector terms (44). We have not pursued this because we were concerned only with the overall agreement, and this can be estimated sufficiently from ϕ, and $f_{i(\max)}$, the magnitude and wavenumber position of which was recorded by our programs.

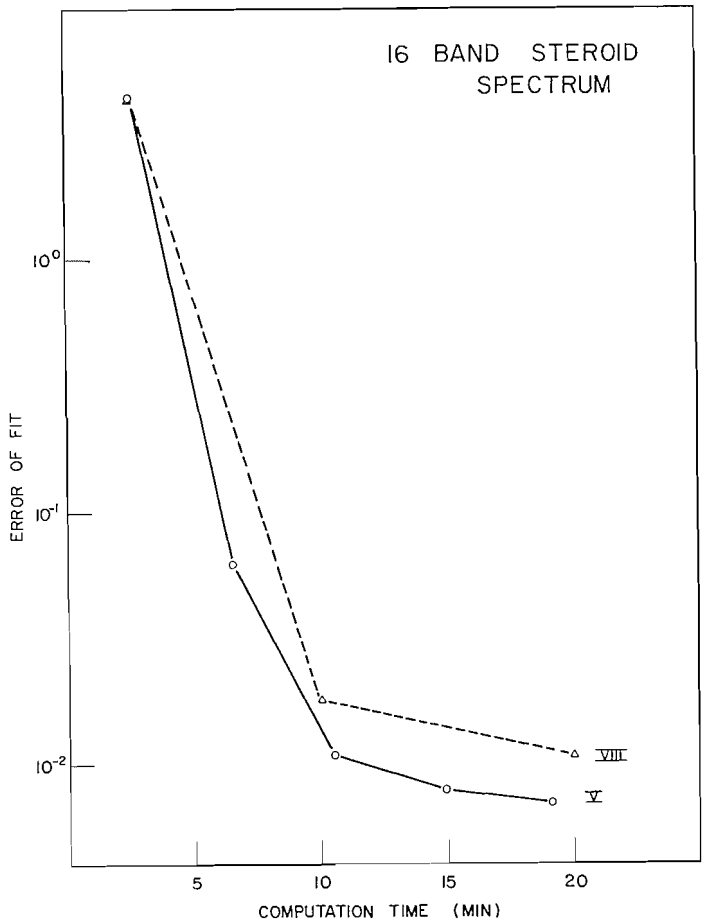

FIG. 6. Convergence of methods V and VIII for the 16-band steroid spectrum. (—) Method V. Consecutive iterations are indicated. (Two minutes must be added to the indicated times for the terminal output of the program.) (--) Method VIII. Terminal values after two consecutive 10 min computation periods are indicated.

Extension to the Analysis of Complex Real Spectra

Method V was found to deal effectively with the spectrum of 5β-androstan-17-one shown in Fig. 2. Sixteen bands can be discerned in the wavenumber range 1 132 – 950 cm^{-1}, and the matching of this band envelope calls for the optimization of 65 variables. Each iteration cycle was completed in approximately 4 min and the convergence is shown by the solid line of Fig. 6. Starting with guessed values of peak absorbance and band position taken from the normalized digital output from the spectrophotometer (34), and a guessed product band shape of 90% Cauchy/10% Gauss, 17 min computation reduced ϕ from 4.401 to 0.00788 and the maximal transmittance discrepancy ($f_{t(max)}$) from 0.287 to 0.016. A further 27 min computation only reduced these values slightly to 0.00723 and 0.0156. The error spectrum after 17 min is shown in Fig. 7A. In considering this it must be remembered that significant noise is present in the real band envelope as is seen from Fig. 2. The synthesized curve is smooth to the level of the round-off error, and it is difficult to separate the discrepancy due to the difference in the noise levels on the two curves from that associated with the misfit of the synthetic band envelope. A better indication of this misfit is provided by Fig. 7B

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which shows the residual error after both the real spectrum and the synthesized band envelopes have been separately smoothed with a 5-point quadratic smoothing function. Earlier work (34) has shown that this type of smoothing induces only minor distortion in the shape of the band envelope, but diminishes the random noise, as is seen from Fig. 7C. The starting and ending values of the 65 variables are listed in Table II.

The Multiplet Method (Method VIII)

Comparison of the iteration time for method V in Figs. 2–6 suggests that the direct use of method V on still more complex band systems would become excessively slow. We have not investigated these yet but the difficulty in dealing with more complex spectra can be largely overcome by using a "moving subspace" method. In this (method VIII) the guessed variables for all the bands are initially introduced into the computation and the spectrum is treated as a whole. The variables of only a limited number of adjacent bands (usually four) are adjusted at one time; the α baseline term is included, but not β or γ. After a predetermined number of iterations with one of the standard methods the active subspace is moved to a neighboring set of bands, usually with one band overlap, and the minimized variables from the first section are incorporated into the $\boldsymbol{x}$ vector. This process is progressed cyclically through the spectrum and ϕ is computed throughout for the complete band system. As found previously, only method V was generally effective for optimizing the subspace variables. Method VIII was programmed to print out the variables after computing for a preselected time (usually 10 min) and the progress of the intermediate iterations was not monitored.

Method VIII was tested on the 16-band steroid system using the same starting values as for method V, and the convergence is shown by the broken line in Fig. 6. After 20 min, using 4-band subspace, ϕ was reduced to 0.011 and $f_{i(\max)}$ to 0.017, which compares satisfactorily with method V. Changing from a 4-band to a 3-band or 5-band subspace in the second 10 min cycle had negligible effect, and a third 10 min cycle produced no additional improvement. In a second series of calculations the guessed starting values for the peak heights were arbitrarily diminished by 10% to make a gross initial adjustment for the band overlap, but this also had no significant influence on the outcome after 10 min of computation.

It is seen from Table III that many of the parameters obtained by this calculation differ from those obtained by the direct application of method V to the complete spectrum. This suggests that these calculations may have led into a different minimization valley, or that the same minimum has been approached from a different direction. It demonstrates that the parameters obtained from nonlinear least squares analysis are not unique.

The major difference between the two sets of data summarized in Table III is the baseline parameter α. The systematic differences in the peak intensities (Δx_1) are clearly correlated with this, as also are the greater half-widths in the method VIII series. If the α variable had been omitted, and the computed curve constrained to lie on the zero baseline, the numerical agreement between the two sets of data would have been improved. This indicates the importance of the baseline in analyzing band shapes and intensities; it also suggests that uncertainty about the baseline position is the cause of much of the variation noted in experimental measurements of infrared band intensities (27). The error spectrum using method VIII is almost identical with that recorded for method V in Fig. 7 (A and B), except for a small region between 1 090 and 1 120 cm^{-1}.

Still other solutions are to be expected, and we have experimental evidence for this. In one series of calculations on the Fig. 2 curve we reduced ϕ to 0.0048 and $f_{i(\max)}$ to 0.0123,

†The guessed values placed the inflection correctly on the right side of the band center.
‡The guessed values placed the inflection on the left side of the band center but this was corrected in the computations.
‖The guessed band shape was 50% Cauchy/50% Gauss but the Gaussian component was rejected in the computation.

but this necessitated starting values that had been refined by extensive preliminary calculations on separate sections of the spectrum. Where possible we have preferred to use starting values for x_1 and x_2 taken directly from the digitized output data from the spectrometer together with reasonable rounded values for x_3 and x_4; this gives an objectively defined starting point for the iterations. A search for better starting values is only attempted if the values of ϕ and $f_{i(\max)}$ obtained in this way are unacceptable in relation to the noise levels and other experimental errors in the measured spectrum.

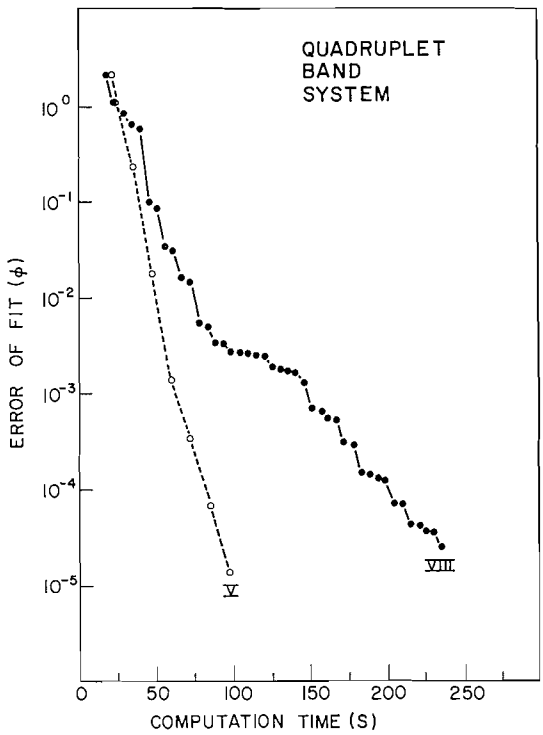

FIG. 8. Convergence of methods V and VIII for the quadruplet band system, using 2-band subspace for method VIII.

At present we cannot indicate at what degree of complexity method VIII surpasses method V. On the 16-band steroid spectrum they are almost equally efficient, with method V having a slight advantage. We have also compared methods V and VIII on the 4-band system of Fig. 1B using a 2-band subspace for method VIII. The convergence rates are compared in Fig. 8, and here method V is clearly the better, though method VIII does achieve an acceptable solution. The general superiority of method VIII probably becomes decisive around 17–20 bands, but this boundary may not be sharply defined and may depend on the type of computer used, particularly on its ability to deal with the $N \times N$ matrix $\boldsymbol{B}$. Beyond a certain degree of complexity the computation time for method VIII should increase approximately linearly with the number of bands, or with the total wavenumber scan, since the wing contributions of the more remote bands will become negligible.

Corrections for Slit Function Distortion

The measured spectrum is subject to systematic errors, the most important of which is the distortion resulting from the use of a finite spectral slit width. This may be expressed

$$T(\nu)_{\text{obs}} = \int p(\nu,\nu') \cdot T(\nu')_{\text{true}} \cdot d\nu', \qquad [25]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where $p(\nu,\nu')$ is the normalized spectral slit function. There is an extensive literature dealing with numerical methods of solving this equation for $T(\nu)_{true}$ (24, 32–34).

Instead of trying to obtain $T(\nu)_{true}$ directly, it is possible to use the least squares approximation method to obtain an analytical expression for $T(\nu)_{true}$ instead of $T(\nu)_{obs}$. To do this, the synthesized band envelope, derived from the initial guessed variables, is convoluted with the slit function before minimization of the variables, and this procedure is repeated at each iteration step. We thus obtain a band envelope which, after convolution with the slit function, conforms with the observed spectrum and is therefore equivalent to $T(\nu)_{true}$ within the limits of the approximation. The additional calculation slows the computation to an extent dependent on the type of numerical integration used.

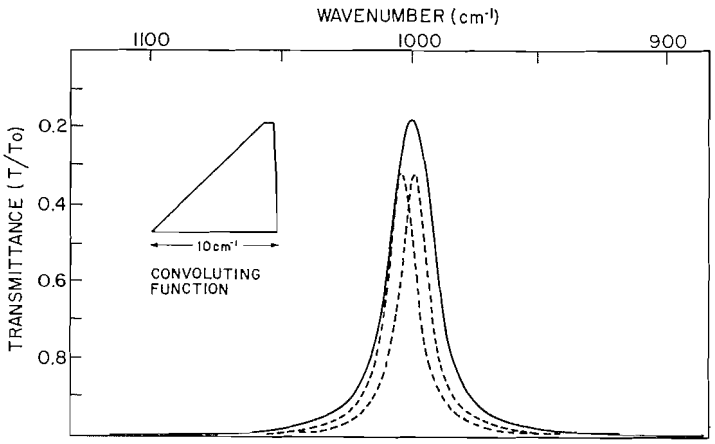

FIG. 9. Curves illustrating the analytical separation of closely overlapping bands generated from a doublet convoluted with a trapezoidal function.

We have tested this method on a few simple cases, but have concluded that for the more complex types of band envelope it is preferable to correct the measured spectrum directly by the pseudo-deconvolution method of numerical analysis discussed previously (34). On the other hand this method has proved to be very effective in dealing with band envelopes composed of a small number of strongly overlapped components.

This is illustrated by the example shown in Fig. 9 and Table IV. Here the slightly asymmetric single-peaked band envelope was constructed from a symmetrical pair of component bands by addition, with subsequent convolution using the highly asymmetric trapezoidal "convoluting function" shown in Fig. 9. In the computations, the presence of the two component bands was assumed, initial guessed variables were chosen, and the resultant curve adjusted by method V, convoluting with the trapezoidal function before evaluating ϕ, B, and G at each step. Highly satisfactory recoveries of the equivalent pair of component bands were obtained using widely different starting values, as is seen from the indices listed in Table IV. The "true" summation band was approximated from these by addition, with a maximal transmittance error less than 0.001.

CONCLUSIONS

With digital computers, it is possible to generate analytical expressions that will fit the contours of infrared band envelopes with a precision approaching that of the statistical uncertainty of the data measurements. The number of component bands that can be handled with reasonable speed will depend on the computing facilities available. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

computation time increases rapidly with the number of bands when the spectrum is analyzed as a single unit, and if the number of bands exceeds 17–20 it probably becomes more efficient to use a cyclical method, varying the parameters of a limited number of bands at a time. The choice of the initial guessed variables does not appear to effect the rate of convergence critically, though our experimental evidence for this is limited, particularly for the more complex band systems. More than one statistically acceptable solution is possible, and it would seem prudent to choose the starting values with care, since this should help to achieve a solution having the maximum physical meaning. Economic factors would appear to set the upper limit to the size of spectrum that can be handled by method VIII. The accuracy of the fit could almost certainly be improved by the use of closer wavenumber intervals. In all our work we have held this interval constant at 0.5 cm^{-1}. This was done mainly for technical reasons associated with the digital encoding of the spectrum. The use of smaller intervals (0.2–0.1 cm^{-1}) would considerably increase the computing time.

In this paper we have emphasized the digital approach to fitting band envelopes, though analog methods are also being used to deal with systems of moderate complexity (5). Analog methods could certainly help in recognizing weak component bands and in rapidly establishing input values for calculations of the kind discussed here.

The complete description of an infrared absorption spectrum containing P component bands by $4P$ or $4P + 1$ band "indices" would appear to be technically feasible and from these indices the spectrum can be regenerated on any chosen ordinate and abscissal scale using simple computing facilities: the limitations would seem to be economic rather than scientific. The spectroscopic value of this type of band classification will be determined by the extent to which each component band can be shown to have physical significance in relation to the vibrational behavior of the molecule, and this aspect of the problem needs careful and cautious investigation.

ACKNOWLEDGMENTS

We wish to thank Dr. S. D. Baxter and his colleagues at the N.R.C. Computation Center for their assistance with the computation measurements and also Mr. E. R. R. Somorjai, Dr. H. Stone, and Dr. C. M. Woodside are also gratefully acknowledged.

APPENDIX

Methods III and V. Selection of the Optimal Value of p

At the beginning of the computation ϕ_{initial} is calculated from the starting values of the variables. In the first cycle we arbitrarily set $p_0 = 10^{-1}$ and use it to compute $\phi_0(1)$ from eqs. [19] or [21]. If $\phi_0(1) < \phi_{\text{initial}}$ we take as second choice for p_0 the value $p_0(2) = p_0(1) \times 10^{-2}$, but if $\phi_0(1) \geqslant \phi_{\text{initial}}$ we take instead $p_0(2) = p_0(1) \times 10^{3}$. For the third trial value of p_0 we take $p_0(3) = p_0(1) \times 0.5$ or $p_0(3) = p_0(2) \times 0.5$ whichever gives the smaller value of ϕ_0. Having in this way obtained three values for p_0, the two which give the lower values for ϕ_0 are selected and interpolated with a cubic polynomial in the following manner. The coordinates ϕ and p^{-1} are used and the two best values of (ϕ, p^{-1}) provide two points defining the interpolation curve. The remaining condition is the relation that as $p^{-1} \rightarrow 0$, $\phi_m \rightarrow \phi_{m-1}$ and $d\phi_m/dp^{-1} = -2\boldsymbol{G}^T \cdot \boldsymbol{G}$, from which the slope of the cubic interpolation curve and its intercept with the y axis are known (39).

An additional value of p is obtained from the minimum of this interpolation curve, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the corresponding ϕ computed. Normally the ϕ_0 calculated from this p_0 will be the lowest, but not necessarily so. Of the several values of p obtained by the above process, *that giving the lowest* ϕ is accepted, and the variables adjusted on this basis for the next cycle. The same procedure for obtaining the optimal value of p is followed in subsequent cycles, except that the p used in the preceding cycle is taken as starting point, instead of the arbitrarily chosen value of 10^{-1}.

ABSTRACT

The spectral behavior of *o*- and *p*-nitroanaline adsorbed on various alkaline earth compounds has been studied by reflectance spectroscopy. Regular bathochromic shifts in the diffuse reflectance spectra have been observed for the absorption maxima in the visible region in order of increasing size of the adsorbent cation. Progressive removal of coadsorbed moisture which competes for active adsorbent sites resulted in an enhancement of the bathochromic shifts. The intensity of the absorption maxima as measured by peak heights was found to be dependent upon the size of both cations and anions of the adsorbents. Interpretation of observed phenomena was advanced in terms of electronic polarization theory and varying surface area of the adsorbents.

INTRODUCTION

In recent studies Zeitlin and co-workers (1–3) have measured the reflectance spectra of various nitrophenols and their salts on a series of alkaline earth oxides and alkaline metal carbonates. In this work bathochromic shifts were reported for the absorption maxima of nitrophenols on both series with increasing size and decreasing effective nuclear change of the cation. These shifts proved to be more pronounced for mononitrophenols than for di- or tri-nitrophenols. The relative magnitude of the shifts was interpreted in terms of electronic polarization theory. Similar phenomena, however, were not observed for the sodium salts of the nitrophenols upon adsorption on alkaline metal carbonates. Zeitlin and Lieu (3) postulated that the spectra of the salts are those of the phenoxide anions in the adsorbed state, with little or no differentiating effect evident on the part of the cations.

To obtain a broader base for the support of the interpretation of Zeitlin and co-workers, it was decided to investigate nitro compounds containing a functional group other than OH. Nitroanilines were chosen as models for the study with the hope that data obtained with these compounds which contain a hydrogen bonded to nitrogen would reveal, on comparison with phenols, a common pattern of behavior upon adsorption on solid surfaces. It was also hoped to be able to correlate the height of absorption peaks with the cationic and anionic sizes of various adsorbents, an aspect not considered in the work with nitrophenols.

EXPERIMENTAL

The *p*-nitroaniline and *o*-nitroaniline used in this study were Eastman Organic Chemicals, recrystallized until the melting points indicated satisfactory purity. The adsorbents used and their sources were: beryllium oxide, anhydrous purified grade, Fisher Scientific Co.; magnesium oxide and calcium oxide, reagent grade, Baker Chemical Co.; strontium and barium oxide, anhydrous, purified grade, Fisher Scientific Co.; magnesium carbonate and magnesium sulfate, Baker analyzed reagent grade. The adsorbents were ground for approximately 15 min in an agate mortar to achieve a fine state of subdivision and then sieved through fine mesh screens; 200-mesh powders were used throughout this investigation. Samples of the pure adsorbent were dried at 300 and 600 °C to evaluate the effect of moisture on the systems to be examined. Additional samples were obtained in an air-dry state by exposure to ambient temperatures and humidity.

Samples of the preheated adsorbent were transferred to a desiccator containing P_2O_5. The nitroaniline, the pre-dried equipment, and the desiccator were placed in a dry box dried by dynamic adsorption through

activated silica gel for 12 h. In the dry box 0.04 g of the nitroaniline, which was weighed quickly on a Mettler balance to 1 mg to minimize moisture uptake before transfer to the dry box, was mixed thoroughly with 0.05 mole of each adsorbent in a mortar for about 1 min to attain a uniform distribution. The primary visual change that occurred was a rapid intensification of the color of the amine upon adsorption. Preliminary examination of the system showed that a period of about 1 h was sufficient to achieve a satisfactory state of equilibrium. The cell employed to pack the samples was similar to that described by Barnes *et al.* (4). The edges of the aluminium planchet were coated with silicon grease.

The diffuse reflectance spectra were measured with an automatic recording DK-2 spectrophotometer equipped with the standard reflectance attachment.

Magnesium oxide served as the reference standard throughout the investigation. The reproducibility was studied by measuring four replicates under similar conditions. The wavelength readings obtained for the adsorption maxima were reproducible to ± 3 mμ. The samples were measured again after 24 h exposure to the atmosphere and the spectra compared with that obtained from air-dry samples to establish whether a reversible adsorption process was taking place.

RESULTS AND DISCUSSION

Figures 1–4 contain the reflectance spectra of *o*- and *p*-nitroaniline adsorbed on the various adsorbents. Table I shows the absorption maxima of *o*-nitroaniline adsorbed on a series of alkaline earth oxides measured 1 h after mixing and preparation of the samples under various conditions.

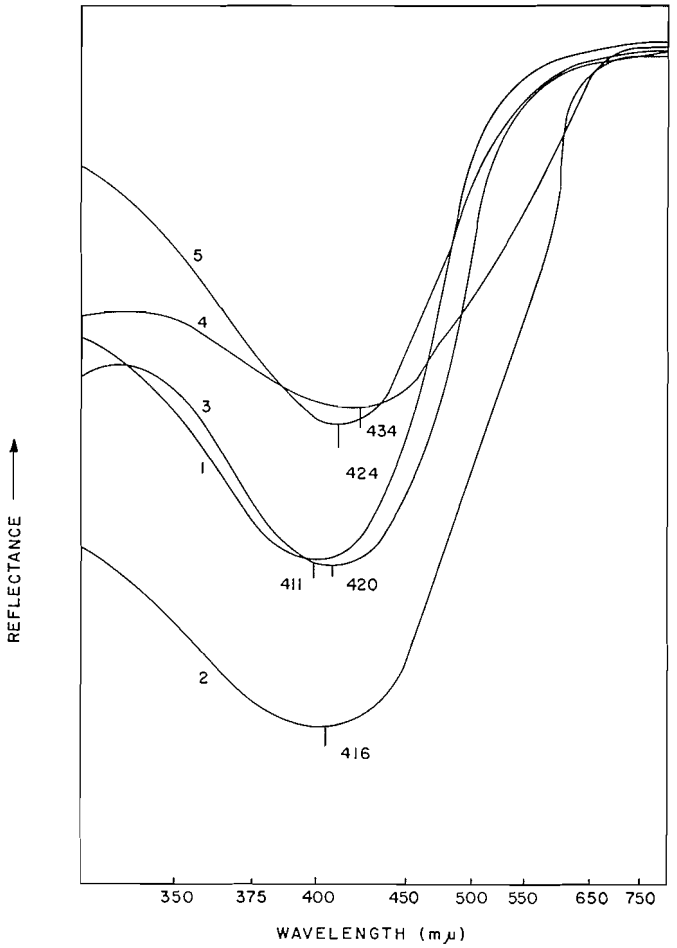

FIG. 1. Reflectance spectra of 0.04 g *o*-nitroaniline adsorbed on 0.05 mole of (1) BeO, (2) MgO, (3) CaO, (4) BaO, (5) SrO of 200-mesh particle size and regenerated at 300 °C.

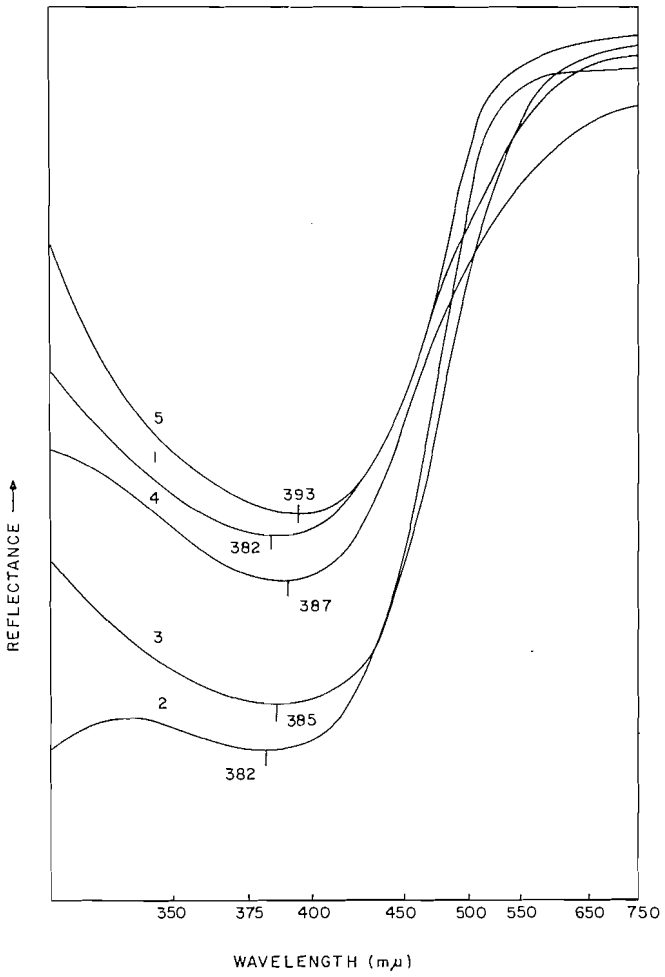

FIG. 2. Reflectance spectra of 0.04 g *p*-nitroaniline adsorbed on 0.05 mole of (1) BeO, (2) MgO, (3) CaO, (4) SrO, (5) BaO of 200-mesh particle size and regenerated at 300 °C.

An examination of the data in Table I shows a relatively small but evident bathochromic shift in going from smaller to larger cations. The actual order is BaO > SrO > CaO > MgO > BeO and agrees with the data found for *o*-nitrophenol on the same adsorbents (2). The same tendency is observed for a series of alkaline metal carbonates in connection with free nitrophenols (1, 3). The arguments which were put forward in these papers to account for the effect of the cations on the adsorbed species could therefore apply for both *o*- and *p*-aniline, which behaved similarly (Fig. 2). The acidity of the hydrogens on the amino nitrogen being weak, any stretching of the hydrogen–nitrogen bond as a result of the polarizing effect from the cations would be expected to be relatively light. Ionization and actual salt formation should be ruled out. It appears likely that the degree of perturbation of the nitrogen to hydrogen bond, which presumably involves stretching in varying degrees, is governed by the effective nuclear charge of the alkaline earth cation. The spectral data (Table I) show also the effect of the pretreatment of the adsorbent, which includes heating of the alkaline earth oxides at 300 °C and 600 °C prior to mixing with the

For personal use only.

adsorbate, and the preparation of an air-dry system in which equilibration at room temperature and atmospheric moisture was achieved. A shift to larger wavelengths was observed in going from metaloxide (MO) air dry → MO 300 °C → MO 600 °C (see Table I). The results agree with the findings of Zeitlin *et al.* (2) for *o*-nitrophenol adsorbed on alkaline earth oxides.

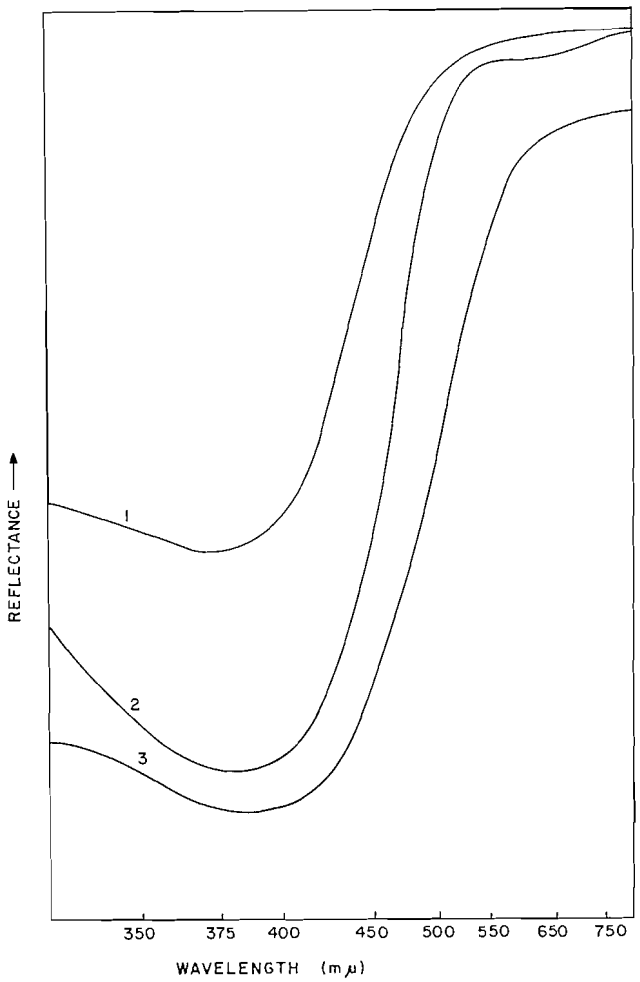

FIG. 4. Reflectance spectra of 0.04 g *p*-nitroaniline adsorbed on 0.05 mole of (1) $MgSO_4$, (2) $MgCO_3$, (3) MgO of 200-mesh particle size and regenerated at 200 °C.

The extent of this shift is believed to be governed by the amount of water coadsorbed with the adsorbate. According to Kortüm and co-workers (5–7), who observed similar phenomena on different systems, an equilibrium condition which is moisture dependent exists between unadsorbed and adsorbed species relative to the active adsorbent. The heat treatment results in partial or complete removal of the coadsorbed water which competes for the active surface sites and hence the nitroaniline is more effectively and directly exposed to the polarizing action of the adsorbent. It is believed that a transition from physical adsorption resulting from van der Waals forces to chemisorption, which takes place in the first monomolecular layer, is occurring. This phenomenon was tested for reversibility by exposing the dry sample to atmospheric humidity. After a period of 24 h the spectra were again identical to those obtained from air-dry systems. Similar observations were reported in 1932 by de Boer (8), who observed a reversible adsorption process for *p*-nitrophenol on $BaCl_2$ and suggested a non-destructive mode of adsorption.

In contrast to the previous studies of adsorption phenomena of nitrophenols (1–3), which were carried out on a qualitative base, it was attempted in this paper to ascertain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

whether a correlation existed between intensity of the absorption maxima of the mononitroanilines and the adsorbent used. Figures 1 and 2 show the relative peak heights for equal mole ratios of *p*- and *o*-nitroaniline with alkaline earth oxides of 200-mesh particle size and measured under the same conditions (i.e. 300 °C regeneration) versus MgO as a reference standard. The observed trend shows a decrease in color intensity in the order MgO > CaO > SrO > BaO for both *p*- and *o*-nitroanilines with BeO being the only exception to the rule. Observation of such a trend is not new. Kortüm and Vogel (6) reported an increase in intensity of the absorption maxima of malachite green – *o*-carbonic acid lactone adsorbed on alkaline metal chlorides and sulfates of the same grain size in the order LiCl > NaCl > KCl > RbCl > CsCl and $MgSO_4$ > $CaSO_4$ > $BaSO_4$.

An explanation for the trends exhibited would be provided by the polarization theory whereby the intensity of the color formation is a function of the differentiating nuclear charge exerted by the various cations of the adsorbents. If the adsorption model which was used to explain the influence of moisture on changes in reflectance spectra is valid, it is reasonable to assume that the specific active surface of the adsorbent should exert an influence. The fact that BeO does not fit into the scheme supports such an assumption, since it is known that the alkaline earth oxides with the exception of BeO crystallize with the rock salt structure. In contrast BeO has the 4.4 coordinated zinc blend structure (9).

Further support is lent to this view by the spectra shown in Figs. 3 and 4, which exhibit a decrease in peak height with increasing size of the *anion* in the order MgO > $MgCO_3$ > $MgSO_4$ for both *p*- and *o*-nitroaniline.

EUROPIUM OXALATE ION ASSOCIATION IN WATER

P. G. MANNING
Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada
Received March 4, 1966

ABSTRACT

The partitioning of radiotracer $^{152/154}$Eu between aqueous sodium oxalate (Na_2L) solutions and toluene solutions of thenoyltrifluoroacetone (HTTA) has been studied as a function of the oxalate concentration. The pH of the aqueous phase was controlled by means of sodium acetate – acetic acid mixtures and the ionic strength (I) by NaCl or $NaClO_4$.

At low ionic strengths (~ 0.05) and $[L] \sim 10^{-4}$ M EuL^+ formed, but at $I = 0.95$ and $[L] \sim 10^{-3}$ M EuL_2^- also formed. Stability constants for the 1:1 and 1:2 (metal:ligand) complexes are reported.

The magnitudes of the stepwise stability constant ratios are discussed.

INTRODUCTION

Rare earth – oxalate complexing in solution has been studied extensively by Crouthamel and Martin (1) and by Sekine (2). The absolute magnitudes of the stability constants of the complexes cannot be compared directly because of the vastly different ionic strengths used in these works. However, the ratios of the stepwise stability constants are clearly at variance (Table I). The stepwise stability constant is defined as

$$K_n = [EuL_n]/[EuL_{n-1}][L], \quad [1]$$

where L is the ligand.

TABLE I
Stability constant ratios for oxalate complexes

Crouthamel and Martin		Sekine	
Ce	360	La	4.7
Nd	800	Eu	6.6
Yb	500	Lu	11

Bjerrum (3) has shown that for simple complexes

$$P = K_1{:}K_2 = S \times T \times R, \quad [2]$$

where S is a statistical factor and T is a measure of the work done in bringing a charged ligand from infinity to its equilibrium position in the 1:2 complex against the repulsive force exerted by already bound ligands. For singly charged ligands that bind to rare earth or transition metal ions it has been shown that $T = 1.6$ (4, 5). If the cation has N available sites and if, for example, the ligand is monodentate, $S = 2 \times N/(N - 1)$, i.e. $S > 2$. The factor of 2 arises because the probability of a ligand's leaving the 1:2 complex is twice that of a ligand's leaving the 1:1. The R factor, termed the rest effect, covers those contributions to P that are neither statistical nor electrostatic. R will be an important entity in stepwise reactions where, for example, the cation coordination number changed. Steric hindrance and metal–ligand covalency are other obvious contributors to R. The magnitudes of the ratios of the stepwise stability constants are discussed later in this paper.

The solvent extraction – radiotracer technique has proved useful in the study of rare earth ion association reactions in solution (6). The method is particularly applicable in the

present work because of the low solubility of europium oxalate. In this work [Eu] $\sim 10^{-7}$ M and [oxalate] $\sim 10^{-4}$ M.

EXPERIMENTAL

The experimental techniques have been described in detail in earlier publications (7). The organic phase was 0.035 M thenoytrifluoroacetone in toluene. Sodium perchlorate prepared from $HClO_4$ and NaOH was used to maintain a constant ionic strength, although in some "runs" at low I NaCl was used. The pH was kept constant by means of a 0.0040 M sodium acetate – acetic acid mixture. At low I values the pH was 4.69 and at high I the pH was 5.42. Sodium oxalate and sodium chloride were dried at 110 °C prior to use. All reagents were of analytical reagent grade, except for HTTA which was recrystallized from hexane. $^{152/154}$Eu of high specific activity was purchased from the Radiochemical Centre, Amersham, England.

The aqueous and pre-equilibrated organic phases were shaken for 3 h in erlenmeyer flasks fitted with polytetrafluoroethylene sleeves. The phases were separated and assayed for $^{152/154}$Eu with an annular-type scintillation assembly coupled to an automatic sample changer. At least 20 000 counts were recorded, giving a standard deviation of $\pm 0.7\%$. The temperature was 25 ± 0.5 °C.

THEORY

The distribution coefficient is defined as

$$D = [\mathrm{Eu}]_o/[\mathrm{Eu}]_w, \qquad [3]$$

where "o" and "w" designate organic and aqueous species respectively. Distribution coefficients were generally reproducible to $\pm 2\%$, although when [L] = 0 errors were greater, possibly because of tracer adsorption on the walls of the glass vessels. For this reason, at least two determinations were made of the distribution coefficient at [L] = 0.

When [L] = 0 and omitting ionic charges,

$$D^0 = \frac{[\mathrm{Eu(TTA)_3}]_o}{([\mathrm{Eu}] + [\mathrm{EuA}])_w}, \qquad [4]$$

where A = acetate ion. Only the 1:1 EuA species forms under these experimental conditions (7).

In the presence of oxalate,

$$D = \frac{[\mathrm{Eu(TTA)_3}]_o}{([\mathrm{Eu}] + [\mathrm{EuA}] + [\mathrm{EuL}] + [\mathrm{EuL_2}] + \ldots)_w}. \qquad [5]$$

From eqs. [1], [3], [4], and [5] it can be readily shown that (7)

$$F((D^0/D) - 1)/[\mathrm{L}] = K_1 + K_1K_2[\mathrm{L}] + \ldots, \qquad [6]$$

where F is a correction factor for lanthanide–acetate complexing; F is given by the equation

$$F = 1 + K_1'[\mathrm{A}], \qquad [7]$$

where K_1' is a stability constant for EuA.

Equation [6] shows that a plot of $F((D^0/D) - 1)/[\mathrm{L}]$ against [L] is horizontal if only EuL forms, linear with positive slope if EuL_2 forms, and curved, of ever-increasing curvature, if EuL_3 also forms.

RESULTS AND DISCUSSION

In Table II are listed D and [L] values for europium oxalate systems at different ionic strengths. Free oxalate concentrations were calculated from the expression

$$C_L/[\mathrm{L}] = 1 + ([\mathrm{H^+}]f_H f_L/K_{a2}f_{HL}), \qquad [8]$$

where C_L is the total ligand concentration, K_a is the dissociation constant of oxalic acid (8),

and f_H and f_L are activity coefficients. A second term involving $K_{a1} \times K_{a2}$ gives an insignificant contribution to $C_L/[L]$. The Davies' form of the Debye–Huckel expression (9) was used to calculate f values, namely

$$[9] \qquad -\log f = 0.509z^2\left(\frac{I^{1/2}}{1 + I^{1/2}} - 0.3I\right),$$

where z is the ionic charge. The $C_L/[L]$ values at different ionic strengths are listed in Table II. Free acetate ion concentrations were estimated from the relationship

$$[10] \qquad C_A/[A] = 1 + [H^+]f_H f_A/K_a',$$

where K_a' is the dissociation constant of acetic acid ($= \sim 1.74 \times 10^{-5}$ (10)).

To calculate F at low ionic strengths, K_1' values were evaluated by adjusting the K_1' value of Kolat and Powell (11) at $I = 0.1$ to the relevant I using eq. [9]. The applicability of eqs. [8] and [9] to the present work has been discussed in an earlier publication (6).

Plots of $F((D^0/D) - 1)/[L]$ against [L] were horizontal at the lower ionic strengths, indicating that EuL only formed. It follows from eq. [6] that when $K_2 = 0$, $1/D \propto [L]$. The best straight line of a $1/D$ against [L] plot was determined by the method of least squares. This method gave D^0 and also D at a given [L], and K_1 values were calculated by direct substitution of the parameters in eq. [6]. The K_1 values determined at different ionic strengths are listed in Table III, together with the thermodynamic K_1 value estimated using Davies' activity expression (9).

TABLE III
Stability constant for europium–oxalate complexes

	I					
	0.027	0.036	0.052	0.054	0.061	0.95
$10^{-5}K_1$	5.95	4.50	2.70	3.10	2.05	0.75
$10^{-2}K_2$						5.8
$K_1:K_2$						130
$10^{-6}K_1$ (thermodynamic)	3.85	3.60	2.95	3.55	2.55	
Average K_1 (thermodynamic) $= 3.3\ (\pm 0.5) \times 10^6$						

The thermodynamic K_1 value of 3.3×10^6 for europium oxalate (this work) may be compared with the K_1 values for Ce, Nd, and Yb oxalates of 3.3×10^6, 16×10^6, and 20×10^6 respectively, these values being those determined by Crouthamel and Martin (1). Europium lies between Nd and Yb in the rare earth series, so that agreement between our work and the solubility work of Crouthamel and Martin is poor. Thermodynamic K_1 values have also been reported (12, 13) for Erbium oxalate (6.6×10^4) and Yttrium oxalate (3.3×10^6), and this lack of agreement is characteristic of published K_1 values for these oxalate systems. Thus for Cerium oxalate, solubility measurements at $I = 2$ (14) give $K_1 = 1.1 \times 10^6$, whereas ion exchange measurements at $I = 1$ (15) give $K_1 = 1.1 \times 10^4$. A stability difference of two orders of magnitude seems impossibly large to be attributed to activity coefficients. However, our K_1 value for europium oxalate is in good agreement with that estimated for Y (3.3×10^6) by Feibush and co-workers (13) from solubility measurements.

Our solvent extraction results at $I = 0.95$ show that $EuC_2O_4^+$ and $Eu(C_2O_4)_2^-$ are formed, and K_1 and K_1K_2 values were estimated from the intercept and slope of a plot of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the left hand side of eq. [6] against [L]. The K_1 and K_2 values are listed in Table III. The K_1' value for EuA^{2+} has not been reported at $I = 1$ or $I = 2$, and Sonesson's K_1' value (16) for SmA^{2+} at $I = 2$ has been used. The F values were calculated, therefore, on the basis that $K_1' = 100$. The $C_L/[L]$ correction is small (3%), so that the calculation of activity coefficients at $I = 0.95$ using the Davies' equation (9) should not introduce too great an error. The estimated error in the quoted stability constants is probably less than 20%. Our K_1 value ($= 7.5 \times 10^4$) is in accord with the results of Sekine ($K_1 = 6 \times 10^4$ (2)).

The K_1:K_2 ratios are of interest, however. Our K_1:K_2 value at $I = 0.95$ is 4 times smaller than the values of Crouthamel and Martin and 20 times larger than the K_1K_2 value of Sekine (Tables I and II). A sampling of the P values for transition metal oxalates, listed in the Chemical Society tabulations of stability constants (17), shows that $P \sim 200$. Consequently, it would seem that P values in the range 100–500 are correct for rare earth and transition metal oxalates.

In an earlier publication it was shown that a T value = 1.6 explained the magnitudes of P values for rare-earth and transition metal complexes with some α-hydroxymonocarboxylates (4). This T value was also valid for some transition metal amino acid complexes (5). The T factor was independent of the nature of the (singly charged) ligand, and this was part of the evidence put forward to show that the factor of 1.6 was of mainly electrostatic character. Bjerrum (18) has shown that

$$\log T \propto \frac{e^2}{D_c r} \times \frac{1}{kK_T},$$

where e is the ligand charge, r the equilibrium separation of the ligands D_c the dielectric constant, k the Boltzmann constant, and K_T the absolute temperature. Assuming that r(oxalate) $\sim r$(α-hydroxymonocarboxylate), log T(oxalate) = 4 log T(α-hydroxymonocarboxylate), or T(oxalate) $= 1.6^4 \sim 6.5$. Hence, for six-coordinated metal ions, P(calcd.) $= 4.8 \times 6.5 \sim 30$, whereas for eight-coordinated ions, P(calcd.) $= 3.5 \times 6.5 \sim 25$. These P(calcd.) values are considerably smaller than the P(obs.) values ($= 130$) determined in this investigation. The P(calcd.) values are an order of magnitude smaller than the P(obs.) values of Crouthamel and Martin (1) and also the P(obs.) values for transition metal oxalates (17). Sekine's (2) results are indicative of a large stabilizing effect in the second association stage, but our P(obs.) values are in better agreement with those of Crouthamel and Martin (1) and those for transition metal oxalates (17). If $T = 1.0$, as has been suggested by Powell and Rowlands (19) from an analysis of P values for rare earth 1-hydroxycyclopentane carboxylic acid complexes, Sekine's results would be in fair agreement with theory. However, 1-hydroxycyclopentane carboxylic acid does not associate with rare earths in the same way as do the simpler hydroxymonocarboxylates, and it would be dangerous to put great faith in this T value ($= 1.0$). It is significant that the P(obs.) values for four transition metal 1-hydroxycyclopentane carboxylic acid complexes[1] average at 3.5 ± 0.2, suggesting a T value ~ 1.5. Sekine's (2) results would indicate that $R \sim 0.25$, and it is difficult to postulate a mechanism that preferentially aids the second associate stage. Such reactions as the disruption of the cation hydration sheath or changes in metal–oxalate bond length would be expected to confer increased stability on the 1:1 complex. It would seem, therefore, that rest effects are present in these rare earth and transition metal oxalate systems. Bjerrum (3) defined the rest effect as the influence of bound ligands on the binding power of the metal ion. Steric effects are negligible in these systems. It is possible that the strength of the metal–ligand bond is different in the first

and second states of ion association. This effect would be due to a lengthening of the M—L bond length in the 1:2 complex, and, in the extreme case, one can imagine the M—L bonding changing from low covalent character in the 1:1 complex to more electrostatic character in the 1:2 complex.

CONCLUSION

Stepwise stability constants have been determined for europium–oxalate complexes in water. The solvent extraction – radiotracer technique was employed. The magnitudes of the ratios of stepwise stability constants suggest that the 1:2 complexes are weaker than expected from statistical and electrostatic considerations. The suggestion is made that the M—L bond length is greater in the 1:2 complex than the 1:1.

ACKNOWLEDGMENTS

The author is grateful to Mr. David Hanes, a summer student at the Mines Branch, for his mature assistance in the experimental aspects of this work.

MASS SPECTROMETRIC STUDY OF SUBLIMING SELENIUM[1]

H. FUJISAKI,[2] J. B. WESTMORE,[3] AND A. W. TICKNER
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received May 31, 1966

ABSTRACT

In the mass spectrum of the vapor from grey selenium subliming in the temperature range 102 to 187 °C all possible Se_n^+ ions between $n = 1$ and $n = 8$ were detected in measurable quantities. The ions Se_5^+, Se_6^+, Se_7^+, and Se_8^+ arise mainly from ionization of the corresponding parent molecules, which are believed to be cyclic. At 175 °C the composition of the vapor is $Se_5 \leqslant 29.0\%$, $Se_6 \geqslant 57.5\%$, $Se_7 \geqslant 11.4\%$, and $Se_8 \geqslant 2.0\%$. Thermodynamic data are reported for the sublimation of these molecules. Small amounts of Se_9^+ and Se_{10}^+ were also detected.

INTRODUCTION

In the condensed state, selenium can exist in a wide variety of different forms. The thermodynamically stable form at temperatures up to the melting point is grey, metallic, or hexagonal selenium (1, 2). In this variety the selenium atoms form spiral chains (3, 4) in which adjoining atoms form normal single bonds.

Red crystalline selenium is monoclinic and two forms have been found (5, 6). The α form is composed of Se_8 rings (7). According to Burbank (7) the β form consists of open Se_8 chains but Marsh, Pauling, and McCullough have found closed Se_8 rings. There appears to be little difference between the α and β forms (8). Monoclinic selenium transforms to grey selenium, taking 15 days at 80 °C and 12 h at 120 °C (9, 10). At 150 °C the transformation is rapid (11).

Vitreous selenium is formed by rapid cooling of molten selenium. Although various views on its structure have been proposed (12–18) it seems certain that the chain structure found in grey selenium exists in this variety but the chains have become enmeshed and intertwined. When it is dissolved in iodine the average length of the selenium chain is about 100 atoms (19). Vitreous selenium transforms to grey selenium, taking 20 days at 43°, 72 h at 55°, 12 h at 70° (10), and 1 h at 100 °C (20).

Red amorphous selenium also contains chains of selenium atoms (21), the spirals being slightly deformed and randomly placed along the axis of the chain (22). Berthelot (23) distinguishes two varieties of amorphous selenium.

Contradicting values have been given for the density of selenium vapor (24–29). However, all results indicate progressive dissociation into smaller molecules as the temperature rises.

Vapor pressures have been measured by several methods (29–38). Determinations involving the Knudsen technique involve a knowledge of the vapor composition and will be in error if the incorrect assumption is made. It has been proposed (30) that below 550 °C the vapor consists of Se_8 and between 550 and 800 °C the vapor consists of Se_6 and Se_2 in equilibrium. Metzger (39) has found that the average molecular weight of freely evaporating selenium is consistent with the formula $Se_{5\text{ to }6}$. On the basis of electron diffraction studies on selenium vapor at low pressures, Howe and Lark-Horovitz (40) propose Se_6

rings to be present in the vapor. In a high frequency electrodeless discharge through selenium vapor at 10^{-4} to 10^{-5} Torr a band system which has been attributed to the molecule Se_4 has been found (41). An incomplete study of the mass spectrum of the vapor over grey selenium at 200 °C has been published (42) in which the ions Se_n^+ (n = 1 to 10) were found. No attempt was made to interpret the results. Thus, the composition of selenium vapor has not yet been established.

EXPERIMENTAL

The apparatus and method described previously by Mann and Tickner (43) were used with a few minor modifications (44). Experiments on powdered samples were performed in the seven-holed molybdenum crucible described in ref. 44. The ionizing electron beam passes through the vapor inside the effusion cell. This arrangement has the advantage of higher sensitivity over conventional arrangements in which the electron beam intersects the vapor beam outside the effusion cell. It is thus possible to work at lower temperatures and pressures. The apparatus is more suited to measuring the composition of the vapor leaving the surface than to measuring equilibrium compositions. Experiments on tablet samples were performed in a special sample holder designed so that the surface was parallel to, and about 2 mm from, the electron beam and so that very few collisions of vapor with the crucible wall would occur before ionization.

The selenium, in the form of small pellets, was obtained from the American Smelting and Refining Company and was 99.999% pure. X-ray diffraction showed the material to be amorphous, but a few faint lines were present because of some surface devitrification. Some initial sublimation experiments in the temperature range 120 to 185 °C were performed with the crushed sample. On removal from the mass spectrometer X-ray diffraction showed that extensive crystallization to the hexagonal form had occurred. In view of the preceding discussion this is not surprising. Since the sample must be maintained at these temperatures for a number of hours while the experiment is performed, it was not possible to study the sublimation of vitreous selenium. Consequently, this work is a study of the sublimation of grey selenium, 99.999% pure, annealed for 4 weeks at 150 °C in an evacuated quartz tube. The sample was kindly prepared by Dr. J. B. Taylor of this division. The samples were crushed to give particles passing through 100 mesh and retained on 200 mesh screens. Examination under a microscope showed the particles to be reasonably homogeneous in size and regular in shape. A specific area of the sample could be estimated though, because of irregularities in the surface, considerable uncertainty exists as to the true surface area. By placing the sample in just the center hole, or all seven holes, of the crucible, the effective area of the vaporizing surface could easily be varied.

Some experiments were also performed on red monoclinic selenium and tablets of monoclinic selenium, which were prepared by melting and casting in thin cylindrical forms 8 mm in diameter and 2 mm in thickness, in an evacuated quartz tube. These samples were also prepared by Dr. Taylor. In the mass spectrometer, these samples gave results not significantly different from the hexagonal form and it was found, not surprisingly, that they had indeed reverted to the hexagonal form.

RESULTS AND DISCUSSION

I. Mass Spectrum of the Vapor from Hexagonal Selenium

The mass spectrum was scanned up to $m/e \simeq 1\,000$ for electrons of 40 V energy. Ion currents due to the species Se_n^+, where n = 1 to 10, were found. Those for n = 9 and n = 10 were very small. The ratio of the ion currents for the different species was difficult to estimate accurately since selenium has six isotopes of masses 74, 76, 77, 78, 80, and 82. Moreover, since under the conditions of operation the resolving power of the instrument was less than 150, the mass spectra of the heavier ions species were largely unresolved. An estimate of the ion current ratios was obtained by assuming that the measured maximum ion current for the group of masses at each ion species was proportional to the relative abundance of the commonest mass of the group. It was also assumed that mass discrimination effects in the mass spectrometer were small. For 40 V electrons at 175 °C the results obtained are shown in Table I and compared with those of Goldfinger and Jeunehomme (42).

II. Appearance Potentials of the Ions

The ionization efficiency curves for Se_n^+ (n = 1 to 8) together with those of Xe^+ and Hg^+ are shown in Fig. 1 for electron energies up to 20 V. Appearance potentials were determined by the method of Lossing, Tickner, and Bryce (45) and corrected so that xenon

Se_9^+		≃9.8	0.3	3.06	0.03	—	—
Se_{10}^+				Too small to be recorded			

*Relative ion currents ($Se_6^+ = 100$) for 70 V electrons at 200 °C.

had the literature value of 12.13 V (46). In this way the appearance potential of mercury (simultaneously introduced as a check in some final experiments) was found to be 10.45 V, in agreement with the spectroscopic ionization potential of 10.43 V (46). The appearance potentials of the ions Se_5^+, Se_6^+, Se_7^+, and Se_8^+ lie close together and much lower than the other ions and lower than the spectroscopic ionization potential of 9.81 V (46) for atomic selenium. The positions of the Se^+, Se_2^+, Se_3^+, and Se_4^+ curves indicate that these ions are electron impact fragments of a heavier species, although the shapes of the Se^+ and Se_2^+ curves at low electron energies may indicate the presence of small concentrations of Se and Se_2 in the vapor. Support for this view is given by an appearance potential of 10.21 V for Se_2^+ from the vapor over CdSe, which is shown to contain Se_2 molecules (47). As in the case of As_4 these small molecules probably arise by decomposition of a heavier molecule on the mass spectrometer filament (48, 44).

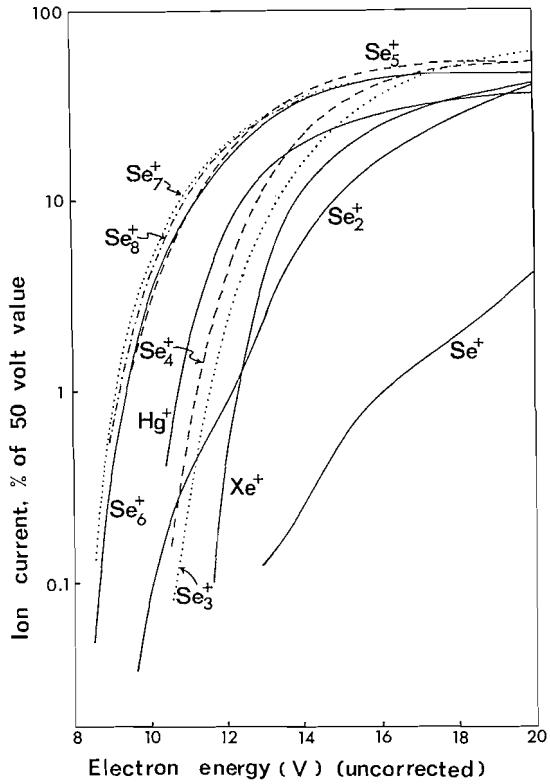

FIG. 1. Ionization efficiency curves for ions from vapor over selenium at 165 °C.

III. Variation of Partial Pressures with Temperature

The ion current due to a substance can be used as a quantity proportional to its concentration over a considerable temperature range as long as conditions in the ion source do not change. In practice, the efficiency of the ion source was found to vary with temperature and a reference concentration of xenon was maintained by allowing the gas to leak in from a reservoir in the sample line. The ion currents used in determining variations in partial pressure were obtained from the equation

$$I = I_m \times \frac{I_{Xe}^0}{I_{Xe}} \left(\frac{T^0}{T}\right)^{1/2} \frac{P_{Xe}}{P_{Xe}^0},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where I_m is the measured ion current at temperature T, I_{Xe} is the $^{132}Xe^+$ ion current at temperature T and reservoir pressure P_{Xe}, and the superscript zero indicates the corresponding quantities under the reference conditions. The temperature correction arises from the dependence of the steady state xenon concentration inside the effusion cell on temperature. Since the sample pressure is proportional to concentration multiplied by temperature then the sample pressure is proportional to IT. Hence, temperature coefficients can be obtained by plotting log IT against $1/T$. For each ion, log IT was plotted against $1/T$; the results for one experiment are shown in Fig. 2. For several experiments the results are summarized in Table II. The following conclusions may be drawn. The most abundant ion, Se_6^+, has one of the smallest temperature coefficients. The ions Se^+, Se_2^+, Se_3^+, and Se_4^+, which are known from their appearance potentials to be formed by fragmentation, have temperature coefficients of comparable magnitude and are presumably formed mainly from Se_6^+. The ion Se_5^+ has a significantly higher temperature coefficient than Se_6^+. In view of its low appearance potential, it is formed mainly by ionization of Se_5 molecules. It is not possible to estimate the contribution to Se_5^+ of fragmentation of heavier molecules but it is probably small, otherwise marked curvature of the log IT vs. $1/T$ plot for Se_5^+ would have been noticed. Support for this conclusion is given by the fragmentation of sulfur molecules under electron impact (49) where $S_5^+ < 0.25\%$ of S_6^+ when formed from S_6. Larger amounts of S_5^+ are formed from S_7 and S_8 but for selenium the corresponding parent molecules are present in low amounts. However, it is only possible to calculate an upper limit for the relative concentration of Se_5 in the vapor. Se_6^+ arises mainly from Se_6 molecules, contributions from fragmentation of heavier molecule ions being negligible. Similarly, Se_7^+ and Se_8^+ arise mainly from Se_7 and Se_8 molecules. (It is shown later that they are not formed in ion–molecule reactions.)

TABLE II

Slopes of log IT vs. $1/T$ plots for selenium ions from vapor over grey selenium (mean of 20 experiments covering the temperature limits 102 to 187 °C)

Ion	Slope (deg)
Se^+	7 530±150
Se_2^+	7 550±110
Se_3^+	7 705±100
Se_4^+	7 400±100
Se_5^+	7 920± 85
Se_6^+	7 410± 90
Se_7^+	8 390±100
Se_8^+	8 720±145

It has been shown previously (44) that the steady state pressure, p, in the effusion cell is given by

$$p = \frac{P}{1 + f/\alpha},$$

where P is the equilibrium vapor pressure, f is the ratio of effective effusion area to effective sample area, and α is the accommodation coefficient. The variation of p with temperature is then given by

$$\frac{\mathrm{d} \log p}{\mathrm{d}\,(1/T)} = -\frac{1}{2.303R}\left[\Delta H + \Delta H'\left(1 - \frac{1}{1 + f/\alpha}\right)\right],$$

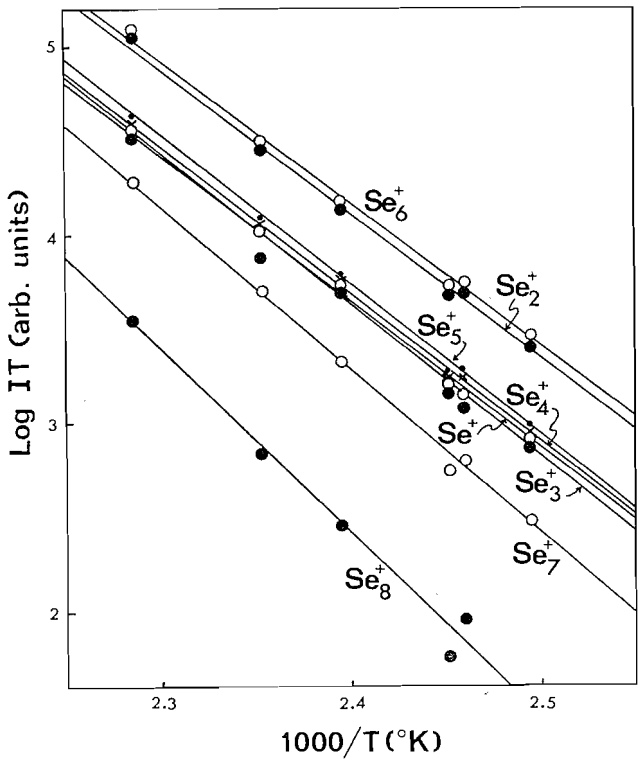

FIG. 2. Temperature coefficients for selenium ions (electron energy 40 V).

where ΔH is the heat of sublimation and $\Delta H'$ is the heat of a surface reaction which occurs before sublimation. The activation energy of sublimation is $\Delta H + \Delta H'$. The effect of varying f has been discussed before (44). It was found that neither the temperature coefficients nor the ion current ratios Se_5^+/Se_6^+, Se_7^+/Se_6^+, and Se_8^+/Se_6^+ varied as f was changed. Since the temperature coefficient for the sublimation of Se_6 in these experiments is close to the equilibrium value determined by other workers, it is concluded that the selenium species Se_5, Se_6, Se_7, and Se_8 have accommodation coefficients close to unity, $\Delta H'$ is very small, and the experimentally determined temperature coefficient does not depend on the value of f.

IV. Test for Ion–Molecule Reactions

It was verified that the ions Se_7^+ and Se_8^+ were not formed in ion–molecule reactions by measuring relative ion currents as a function of the voltage on a repeller electrode mounted inside the effusion chamber, 2 to 3 mm from the electron beam and opposite the ion-withdrawal slit. Little dependence on repeller voltage was found, whereas the current due to an ion formed in an ion–molecule reaction is proportional to the inverse square root of the repeller voltage (50, 51). Thus, at 165 °C, the temperature of the measurements, ion–molecule reactions are of little importance.

V. Calculation of Thermodynamic Quantities

Because of the complexity of the mass spectrum any numbers assigned to the composition of the vapor and heats of sublimation of each species may not be very precise. If we assume that Se_5, Se_6, Se_7, and Se_8 molecules have similar fragmentation patterns when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ionized, an assumption justified by the similarity of the ionization efficiency curves for Se_5^+, Se_6^+, Se_7^+, and Se_8^+, the ion currents due to Se_5^+, Se_6^+, Se_7^+, and Se_8^+ can be used as a measure of the relative concentrations of the respective molecules in the vapor. Such an approximation is probably good for Se_6, Se_7, and Se_8 but likely to be high for Se_5. Consequently, the value for Se_5 will be an upper limit and the values for the other molecules will be lower limits. In the absence of other data, it was assumed that the relative ionization cross sections of the other molecules were proportional to the number of atoms contained in them. The results are summarized in Table III. According to this approximation the molecules leaving the surface would have an average of 5.90 atoms of selenium at 175 °C, in good agreement with the value found by Metzger (39) for freely subliming selenium.

TABLE III

Heats of sublimation and relative abundances of subliming selenium molecules

Species	ΔH_{418} (kcal/mole)	Relative abundance at 175 °C	% in vapor at 175 °C
Se_5	36.2±0.5	50.6	29.1
Se_6	33.8±0.5	100.0	57.5
Se_7	38.4±0.5	19.7	11.4
Se_8	39.9±0.7	3.5	2.01
Se_9	—	0.02	0.012

For correcting the thermodynamic data to 298 °K the heat capacities of the gaseous molecules are required. For Se_6 an average value for the temperature range 298 to 418 °K was estimated from data given by Stull and Sinke (52). The vibrational contribution to C_p is about 90% of its maximum value and a similar contribution was assigned to the vibrational parts of C_p for Se_5, Se_7, and Se_8. These values, and heats of sublimation corrected to 298 °K, are given in Table IV. Stull and Sinke select heats of sublimation of 35.38 and 34.12 kcal/mole for Se_6 and Se_2, respectively, to give the best fit with entropy and vapor pressure data of other workers, with Se_6 being the most abundant species at the temperatures considered here. These results are consistent with those given here but the current results suggest that the equilibrium vapor composition is more complex than this, and an attempt will be made to present some more satisfying thermodynamic data. Furthermore, the conclusions of Illarionov and Lapina (29), who report equilibrium constants involving Se_2, Se_4, Se_6, and Se_8 vapor molecules, should be treated with suspicion.

The variation of vapor pressure with temperature is given by

$$\log \frac{P_T}{P_{298}} = -\left(\frac{\Delta H_{298}^0 - 298\Delta C_p}{2.303R}\right)\left(\frac{1}{T} - \frac{1}{298}\right) + \frac{\Delta C_p}{R} \log \frac{T}{298},$$

where the symbols have their conventional meanings. Unfortunately the present apparatus does not allow measurement of absolute vapor pressures. Consequently the relative partial pressures at 298 °K were calculated from those at 448 °K given in Table III, and their sum was equated to the value for Se_6 at 298 °K given by Stull and Sinke. The rest of the thermodynamic data in Table IV were then evaluated.

VI. Mechanism of the Sublimation

A mechanism of the sublimation is proposed which is consistent with the observed results. It is significant that the molecules Se, Se_2, Se_3, and Se_4 are not found in the subliming vapor, yet Se_5 is the second most abundant species. It is recalled that the solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

phase used in these studies consists of spirally wound chains of selenium atoms. A selenium atom at the end of a chain has an unpaired electron. A cyclic molecule could therefore be formed by the end selenium atom forming a bond with a selenium atom further along the chain at the same time that the bond between the latter atom and its neighbor is broken.

TABLE IV

Thermodynamic data for the sublimation of grey selenium

Species	Average C_p from 298 to 418 °K (cal deg^{-1})	Average ΔC_p (cal deg^{-1})	ΔH_{298}^0 (kcal/mole)	ΔF_{298}^0 (kcal/mole)	ΔS_{298}^0 (cal mole^{-1} deg^{-1})
Se_5	23.9	−8.2	37.2	21.8	51.7
Se_6	29.5	−9.0	34.9	20.6	48.0
Se_7	35.1	−9.9	39.6	23.2	55.1
Se_8	40.7	−10.6	41.2	24.8	55.1

Such a molecule would be held to the surface by van der Waals forces and could readily leave the surface. Such a process would be expected to be more energetically favorable than the formation of diradical chain molecules. Ignoring d orbital contributions the hybridization of a selenium atom in a chain or a ring will be mainly sp^3, and with two lone pairs the Se—Se—Se angle should be somewhat smaller than 109° 28′. In grey selenium this angle is 105°. A planar Se_5 ring requires bond angles of 108° and since any strains could be removed by puckering of the ring the molecule will be relatively unstrained. Similarly, Se_6 and larger cyclic molecules will be unstrained. Large strains would be present in a planar Se_4 ring, which could only be partially relieved by folding of the ring since then large repulsions between lone electron pairs would occur.[4] Thus molecules containing 5 or more atoms should be formed more readily than small molecules if the molecules are assumed to be cyclic. This is consistent with the results which show that 98% of the vapor subliming at 175 °C is composed of Se_5, Se_6, and Se_7 molecules. Dissociation of these molecules by collision with the walls of the effusion cell will be negligible at this temperature.

VII. Comparison with Sulfur Vapor

The mass spectrum of the vapor over sulfur shows that the vapor is as complex as that over selenium. Berkowitz and Marquart (53) have studied the equilibrium composition of sulfur vapor and summarized the results of earlier workers. They find the molecules S_2, S_3, S_4, S_5, S_6, S_7, and S_8, plus insignificant but detectable amounts of S_9 and S_{10}. The major species were S_8, S_6, and S_7 respectively. Free evaporation of sulfur has also been studied (49). Rhombic sulfur, which contains S_8 units, gives rise solely to S_8 vapor molecules. Engel's sulfur, which contains S_6 units, produces only S_6 vapor molecules. The evaporation coefficients of S_6 and S_7 from rhombic sulfur are very small, presumably because of a surface reaction in which they are formed from S_8. In the case of selenium the rate of transition of the unstable allotropes to the stable hexagonal form is too rapid to permit measurement of the composition of the subliming vapor from these unstable forms.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Dr. J. B. Taylor for supplying the selenium samples and to Dr. L. D. Calvert for X-ray diffraction studies and helpful discussion of the crystalline states of these materials.

[4]*In a non-planar molecule with* Se—Se—Se *angles of 105° and* Se—Se *bond distances of 2.35 Å as found in grey selenium, the distance between the non-bonded selenium atoms in cyclic* Se_4 *would be 3.74 Å, which is less than twice the van der Waals radius of 2.00 Å. Since the lone pair orbitals of these atoms are directed toward each other considerable repulsion would exist.*

CONTRIBUTION À L'ÉTUDE DES SPECTRES DE VIBRATION DU DIBENZOFURANNE

GISÈLE DAVIDOVICS, JACQUES CHOUTEAU ET HENRI REYMOND

Laboratoire de Chimie Physiologique B.M.P.V. et Centre Technique de Spectrographie Infrarouge; Département de Chimie Organique, Faculté des Sciences de Marseille, France

Reçu le 20 juillet 1966

RÉSUMÉ

La plupart des fréquences de vibration fondamentales du dibenzofuranne ainsi que leur type de symétrie ont été déterminés par l'analyse des spectres infrarouges entre 4 000 et 200 cm^{-1} sous différents états, vapeur, liquide, solution et cristal, et par l'étude de la polarisation des raies Raman à l'état dissous.

ABSTRACT

The majority of fundamental vibration frequencies of dibenzofuran and their symmetry types were determined by the analysis of infrared spectra in vapor, liquid, solution, and solid states, and from the study of polarization ratios of Raman lines in the dissolved phase.

Les spectres infrarouges du dibenzofuranne ont été enregistrés de 4 000 à 400 cm^{-1} sous les états solution et vapeur, et jusqu'à 200 cm^{-1} en phases liquide et solide. Le spectre Raman du dibenzofuranne dissous a également été réalisé.

L'analyse de la structure rotationnelle des bandes d'absorption, de la polarisation des raies de diffusion et du dichroïsme en lumière polarisée d'un film cristallin orienté, nous ont permis de déterminer, pour la plupart des vibrations fondamentales de la molécule de dibenzofuranne, la classe de symétrie à laquelle elles appartiennent.

Les études par spectroscopie infrarouge de cette molécule sont peu nombreuses et ne concernent que quelques fréquences (1–4). Briggs et Colebrook (1) en relèvent quatre entre 1 300 et 840 cm^{-1}, Barnes *et al.* (2) et Groenewege (3) une entre 800 et 700 cm^{-1}, et Tschamler et Leutner (4), une également vers 1 200 cm^{-1}.

Les spectres de diffusion Raman du dibenzofuranne à l'état liquide (5), dissous (6) ou cristallisé (7), ont été publiés mais n'ont pas été analysés.

Teplyakov et Trisov (8) ont essayé de déterminer certaines des vibrations fondamentales et harmoniques du dibenzofuranne en comparant les spectres de phosphorescence obtenus par eux avec le spectre Raman publié par Donzelot et Chaix (5).

I. THÉORIE

D'après Cullinane et Plummer (9) et Merkel et Wiegan (10) la molécule de dibenzofuranne est vraisemblablement plane; elle aurait donc la symétrie C_{2v}. Le Tableau I résume pour cette classe de symétrie le nombre de vibrations appartenant à chaque type de symétrie et leur activité en spectroscopies Raman et infrarouge.

Le calcul des moments principaux d'inertie réalisé avec des paramètres choisis par comparaison avec le furanne (11) et le diphénylène (12) a permis de fixer l'orientation des axes principaux d'inertie (petit, moyen et grand) du dibenzofuranne, qui sont respectivement parallèles aux directions oy, ox, oz (cette dernière perpendiculaire au plan de l'hétérocycle) portées sur la Fig. 1.

On sait que dans le spectre infrarouge à l'état gazeux, la structure de vibration rotation des bandes d'absorption dépend de l'orientation du moment de transition M_x, M_y, M_z par rapport aux axes principaux d'inertie de la molécule (13). C'est ainsi que pour le dibenzofuranne, aux vibrations de symétrie A_1 doivent correspondre des bandes de type B, aux

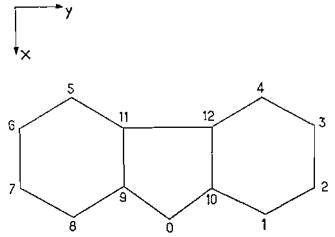

FIG. 1.

vibrations de mode B_1 des bandes de type A et aux oscillations de symétrie B_2 des enveloppes de type C.

II. RÉSULTATS EXPÉRIMENTAUX

Les spectres infrarouges de 1 700 à 200 cm^{-1} du dibenzofuranne sont représentés à l'état gazeux et liquide sur la Fig. 2, à l'état dissous sur la Fig. 3, à l'état solide et de cristal orienté sur la Fig. 4.

La Fig. 3 comporte également le spectre Raman du dibenzofuranne dissous dans le benzène.

La Fig. 5 représente les spectres infrarouges du dibenzofuranne sous différents états (liquide, solution, solide) dans la région de 3 150 à 3 000 cm^{-1}.

Les fréquences infrarouges (sous différents états) et Raman sont groupées dans les Tableaux II à IV. La structure des bandes à l'état gazeux, les coefficients d'extinction molaires et la polarisation des raies Raman sont indiqués dans le Tableau II.

Nos attributions sont résumées dans le Tableau V.

III. ATTRIBUTION DES VIBRATIONS

La distinction entre vibrations de symétrie A_1, B_1, B_2, A_2 a pu être faite à l'aide des critères suivants:

(1) Dans le spectre infrarouge à l'état vapeur, les enveloppes des bandes de vibration rotation correspondant aux mouvements de symétrie A_1, B_1, B_2 doivent être respectivement de types B, A et C, ainsi que nous l'avons dit ci-dessus.

(2) Les raies Raman polarisées doivent résulter de vibrations de mode A_1.

(3) Les vibrations de type A_2 sont actives dans le spectre de diffusion seulement; on peut les attendre en général au dessous de 1 100 cm^{-1}.

(4) Les vibrations de symétrie A_1, B_1, B_2 que leur structure rotationnelle ou la polarisation des raies Raman n'a pas permis de caractériser, ont pu être différenciées par l'étude en lumière polarisée du spectre infrarouge d'un film cristallin orienté.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(5) Les vibrations de valence ν(CH) doivent se manifester dans la région de 3 100 à 3 000 cm^{-1} (14). Dans le cas d'un couplage entre tous les vibrateurs CH, on peut attendre quatre mouvements de mode A_1 et quatre mouvements de mode B_1 (Tableau I). Par suite, au dessous de 1 700 cm^{-1}, 40 fréquences fondamentales infrarouges (16 A_1, 15 B_1, 9 B_2) et 49 fréquences fondamentales Raman, dont 9 de type A_2 sont attendues respectivement.

(A) Région de 1 700 à 200 cm^{-1}

(1) Spectres infrarouges sous les états vapeur, liquide et solution, et spectre Raman à l'état dissous (Fig. 2 et 3) (Tableau II)

Vibrations de symétrie A_1

La structure de type B des bandes de vibration rotation à 1 241 et 1 146 cm^{-1} ainsi que la polarisation des raies Raman correspondantes permettent d'attribuer ces fréquences à des mouvements de mode A_1. Les raies de diffusion polarisées à 1 485, 1 442, 1 307, 1 183, 1 098, 1 012, 847 et 746 cm^{-1} sont également attribuables à des vibrations de symétrie A_1; notons que par suite de leur faible intensité dans le spectre infrarouge, ou de recouvrements, les structures rotationnelles sont peu visibles pour ces fréquences.

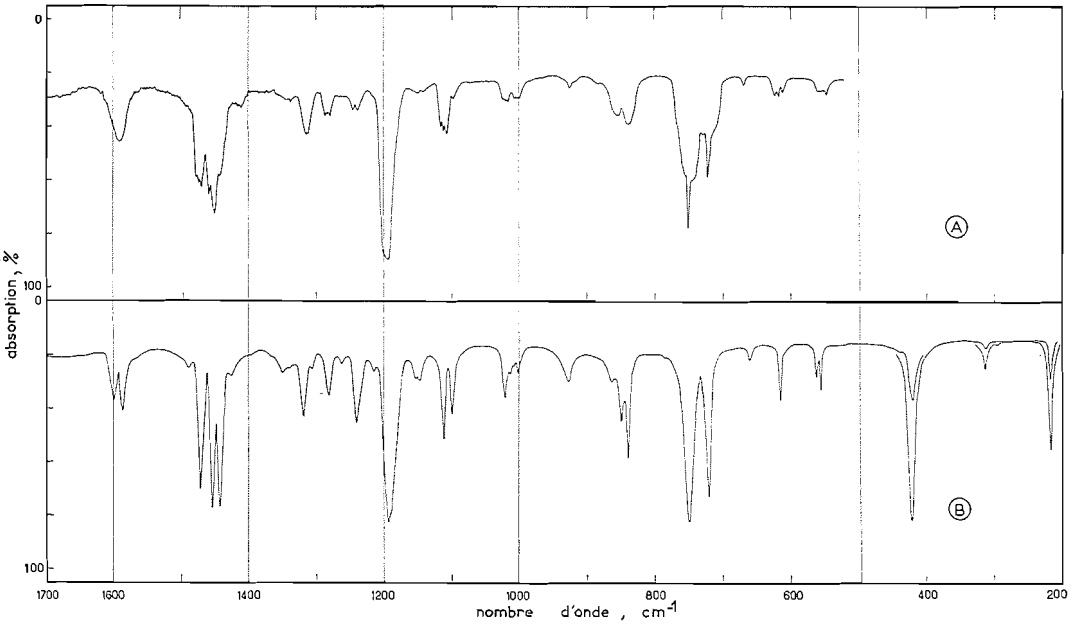

FIG. 2. Spectres infrarouges du dibenzofuranne de 1 700 à 200 cm^{-1}: (A) à l'état gazeux, (B) à l'état liquide, sous des épaisseurs de $\sim$ 10, 25 et 125 μ.

Vibrations de symétrie B_1

Nous attribuons à des oscillations de la classe B_1 les sept bandes d'absorption à 1 470, 1 318,[1] 1 282, 1 110, 1 022, 1 002 et 614 cm^{-1} en raison de leur structure rotationnelle de type A et les trois raies de diffusion à 1 635, 1 589 et 1 352 cm^{-1} en raison de leur dépolarisation. On remarque que la fréquence infrarouge correspondant à la forte raie de diffusion à 1 635 cm^{-1} est absente (Fig. 2, Tableau II).

[1]*Le spectre infrarouge du dibenzofuranne en solution montre deux bandes d'absorption à 1 318 cm^{-1} (ϵ = 100) et 1 306 cm^{-1} (ϵ = 18); une seule bande est observée à l'état vapeur à 1 312 cm^{-1}. Cette dernière, en raison de l'intensité faible du maximum à 1 306 cm^{-1}, ne peut correspondre qu'à la fréquence 1 318 cm^{-1} du spectre à l'état dissous.*

*Fréquences observées dans le spectre à l'état liquide.

†Ces fréquences sont tirées de ref. 5.

Vibrations de symétrie B_2

On peut attribuer à des oscillations de la classe B_2 les maximums infrarouges à 750 et 721 cm^{-1} qui donnent lieu dans le spectre à l'état gazeux à des enveloppes de type C. La bande de vibration rotation à 926 cm^{-1} semble également avoir une enveloppe de type C, elle pourrait donc appartenir à une vibration de type B_2.

Notons que Barnes *et al.* (2) et Groenewege (3) situent une vibration de déformation hors du plan γ(CH) du dibenzofuranne à 750 cm^{-1}.

For personal use only.

Vibrations de symétrie A_2

Aucun maximum d'absorption infrarouge n'ayant été observé à 451 et 734 cm^{-1}, les raies Raman observées à ces fréquences sont attribuables à des vibrations de mode A_2.

(2) Spectres infrarouges du dibenzofuranne à l'état solide (Fig. 4) (Tableau III)

Les spectres infrarouges du dibenzofuranne solide (dispersé dans du bromure de potassium) et liquide sont très peu différents. La plupart des bandes d'absorption du spectre du liquide se retrouvent dans celui du solide: trois doublets, cependant, vers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

753–746 cm^{-1}, 568–564 cm^{-1} et 424–420 cm^{-1} se fondent en trois bandes d'absorption simples dans le spectre à l'état liquide. La présence des deux composantes dans le spectre du solide est sans doute due à un effet de cristal.

Un film cristallin orienté de dibenzofuranne a été réalisé; son spectre infrarouge présente par rapport au spectre du liquide des différences notables: en particulier, le spectre du cristal orienté ne comporte pas de bandes d'absorption de fréquences voisines de 1 586, 1 470, 1 353, 1 318, 1 282, 1 110, 1 022, 1 002 et 614 cm^{-1} qui ont été attribuées au cours de cette étude à des vibrations de symétrie B_1.

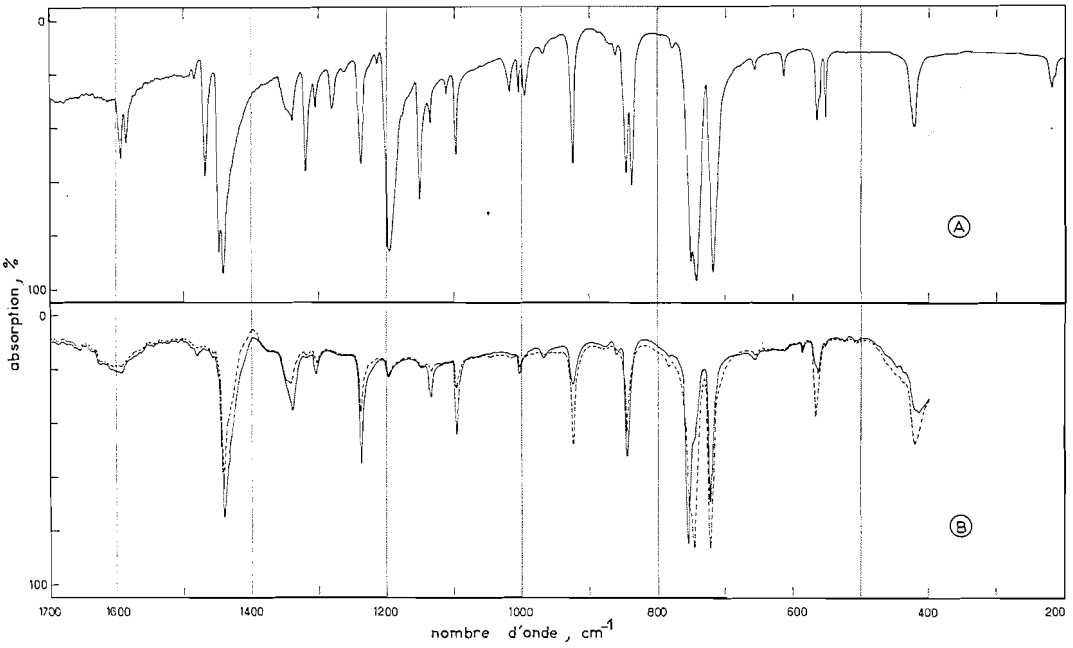

FIG. 4. Spectres infrarouges du dibenzofuranne (région 1 700 à 200 cm^{-1}) à l'état solide: (A) non orienté, (B) orienté: (- -) vecteur électrique ($\perp$), (—) vecteur électrique (||).

Le spectre du cristal orienté a été étudié en lumière polarisée pour deux orientations orthogonales du vecteur électrique. On voit sur les spectres de la Fig. 4 que pour la direction dite parallèle (||), du vecteur électrique, les bandes d'absorption de fréquences 1 485, 1 443, 1 306, 1 241, 1 146, 1 100, 1 012 et 850 cm^{-1}, relatives à des mouvements de symétrie A_1, sont plus intenses que lorsque le vecteur électrique est perpendiculaire ($\perp$) à cette première direction. Inversement, les bandes d'absorption correspondant aux vibrations de mode B_2 à 750 et 721 cm^{-1} ont une intensité maximum pour cette même orientation perpendiculaire ($\perp$) du vecteur électrique.

La structure cristalline du dibenzofuranne n'ayant pas été déterminée à notre connaissance, une interprétation rigoureuse du spectre du film cristallin orienté que nous avons réalisé est impossible, puisque le groupe spatial, le nombre et l'orientation des molécules dans la maille ne sont pas connus. Cependant, en raison du peu de différence constaté entre les spectres du dibenzofuranne sous les états solide et liquide, le couplage entre les vibrations des molécules dans la maille paraît négligeable, pour le plus grand nombre de mouvements, et le modèle de gaz "orienté", dans lequel la molécule est considérée comme isolée dans le cristal, semble applicable: donc, on peut admettre, que les vibrations de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

même symétrie, doivent donner lieu à des maximums d'absorption, présentant un dichroïsme analogue, dans chaque classe de symétrie.

Vibrations de symétrie A_1

D'après ce qui précède, nous pensons que l'on peut attribuer à des mouvements de mode A_1 les maximums de fréquences 1 599, 1 345, 964, 863 et 659 cm^{-1} présentant un dichroïsme (||).

Vibrations de symétrie B_1

Nous attribuons à des oscillations de mode B_1 les bandes d'absorption vers 1 452, 1 196, 1 151, 840 et 555 cm^{-1} observées dans le spectre du dibenzofuranne liquide et qui manquent ou sont faibles dans le spectre du cristal orienté.

La fréquence 1 196 cm^{-1} a été attribuée par Tschamler et Leutner (4) à la vibration antisymétrique ν_a(C—O—C), ce qui est en accord avec notre interprétation.

Vibrations de symétrie B_2

En raison de leur dichroïsme, semblable à celui des bandes provenant des vibrations de mode B_2 à 750 et 722 cm^{-1}, les maximums à 926, 561 et 421 cm^{-1} doivent pouvoir être attribués à des mouvements de symétrie B_2. La bande faible à 782 cm^{-1} pourrait également, étant donné son dichroïsme, appartenir à une vibration de la classe B_2. Nous avions vu précédemment que la bande à 926 cm^{-1} avait une structure rotationnelle de type C probable.

(3) Discussion

L'analyse des spectres infrarouges (vapeur et solide) et du spectre Raman du dibenzofuranne a permis de dénombrer entre 1 700 et 200 cm^{-1} 15 vibrations de type A_1, 15 de type B_1, et, respectivement, 6 et 2 vibrations de modes B_2 et A_2. Mis à part les mouvements de mode A_2, 3 vibrations de mode B_2 et une de mode A_1 n'ont donc pas été identifiées.

Aux trois vibrations de mode B_2 on peut probablement faire correspondre les fréquences basses à 314, 295 et 218 cm^{-1}. Les deux premières sont communes aux spectres infrarouge et Raman, et la raie de diffusion à 295 cm^{-1} est nettement dépolarisée; la troisième fréquence n'est observée que dans le spectre infrarouge.

Les maximums de modes A_1 et B_1 sont attribuables à des oscillations de noyau et de déformation des hydrogènes dans le plan. Par analogie avec les composés aromatiques, on peut, en première approximation, situer les huit vibrations de déformation δ(CH) dans l'intervalle 1 300 – 1 000 cm^{-1}; cependant, la fréquence 1 196 cm^{-1} doit appartenir à une vibration de noyau mettant plus particulièrement en jeu la liaison (C—O—C), ainsi que nous l'avons indiqué (4).

Les vibrations de noyau et des hydrogènes hors du plan sont de symétries B_2 et A_2; les attributions faites pour les dérivés du benzène permettent de penser qu'aux vibrations γ(CH) devraient correspondre des fréquences comprises entre 926 et 726 cm^{-1}; au nombre de huit, si les vibrateurs CH sont couplés, et de quatre, s'ils sont indépendants.

(B) Region de 3 200 à 3 000 cm^{-1}

On peut envisager trois hypothèses pour interpréter les spectres de vibration du dibenzofuranne dans la région des oscillations de valence ν(CH).

(*a*) Tous les vibrateurs CH de la molécule sont couplés et donnent naissance à huit vibrations dont quatre de mode A_1 et quatre de mode B_1.

(*b*) Les vibrateurs CH d'un seul noyau sont couplés et donnent lieu à quatre vibrations de fréquences distinctes: deux de symétrie A_1 et deux de symétrie B_1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*c*) Les vibrateurs CH sont indépendants ce qui entraîne encore quatre vibrations de fréquences différentes : deux de symétrie A_1 tandis que les deux autres ont chacune deux composantes dirigées suivant les axes o*x* et o*y* de la molécule.

(1) Spectres infrarouges à l'état liquide et solution

Les spectres à l'état liquide et dissous (1 *M*) montrent cinq bandes d'absorption dont une bande faible à 3 064 cm^{-1}, dont l'intensité et la fréquence varient peu avec la dilution (Tableau IV).

TABLEAU IV

Fréquences de vibration du dibenzofuranne de 3 150 à 3 000 cm^{-1} sous différents états

	3 028 m	3 031 (23)	3 031 (27)	3 029 m	3 028 m	∥	A_1 ν(CH)
				3 018 m	3 017 m	⊥	Combinaison

NOTE : Les fréquences infrarouges à l'état dissous sont suivies du coefficient d'extinction molaire apparent. La fréquence Raman est suivie de l'intensité de la raie et du facteur de dépolarisation. F = forte, m = moyenne, f = faible, ff = très faible, e = épaulement.

(2) Spectre infrarouge à l'état vapeur

Le spectre de vibration rotation montre un massif d'absorption dont la structure rotationnelle est difficile à définir.

(3) Spectres Raman

Une raie de diffusion polarisée est présente dans les spectres Raman de la solution, à 3 068 cm^{-1} ; Behringer et Brandmuller (7) en observent une également à cette fréquence dans le spectre du solide.

(4) Spectres infrarouges à l'état solide

Les spectres sous les états solide et liquide diffèrent sensiblement dans la région de 3 150 à 3 000 cm^{-1} ; ceux du solide montrent en effet trois bandes d'absorption qui n'apparaissent pas dans le spectre du liquide à 3 117, 3 036 et 3 018 cm^{-1}, dues soit à un effet de cristal, soit à des modes de combinaison. On observe également une inversion d'intensité des deux maximums à 3 069 et 3 064 cm^{-1} ; ce dernier, intense dans le spectre du solide devient très faible dans les spectres sous les états liquide et dissous.

Les spectres entre 3 150 et 3 000 cm^{-1} du dibenzofuranne solide et à l'état de cristal orienté sont identiques. Or, nous avons vu précédemment (région de 1 700 à 400 cm^{-1}) que les bandes d'absorption qui apparaissaient simultanément dans le spectre du solide et dans celui du cristal orienté résultaient de vibrations de symétrie soit A_1, soit B_2. Il semblerait donc que le spectre infrarouge du dibenzofuranne ne présente pas d'absorptions de mode B_1 dans la région des vibrations de valence ν(CH), ce qui serait compatible avec l'hypothèse des vibrateurs (CH) indépendants seulement. Cependant, l'étude en lumière polarisée, des bandes d'absorption observées dans cette région, n'apporte aucune certitude. Le dichroïsme des maximums à 3 028, 3 049 et 3 069 cm^{-1} est assez net et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

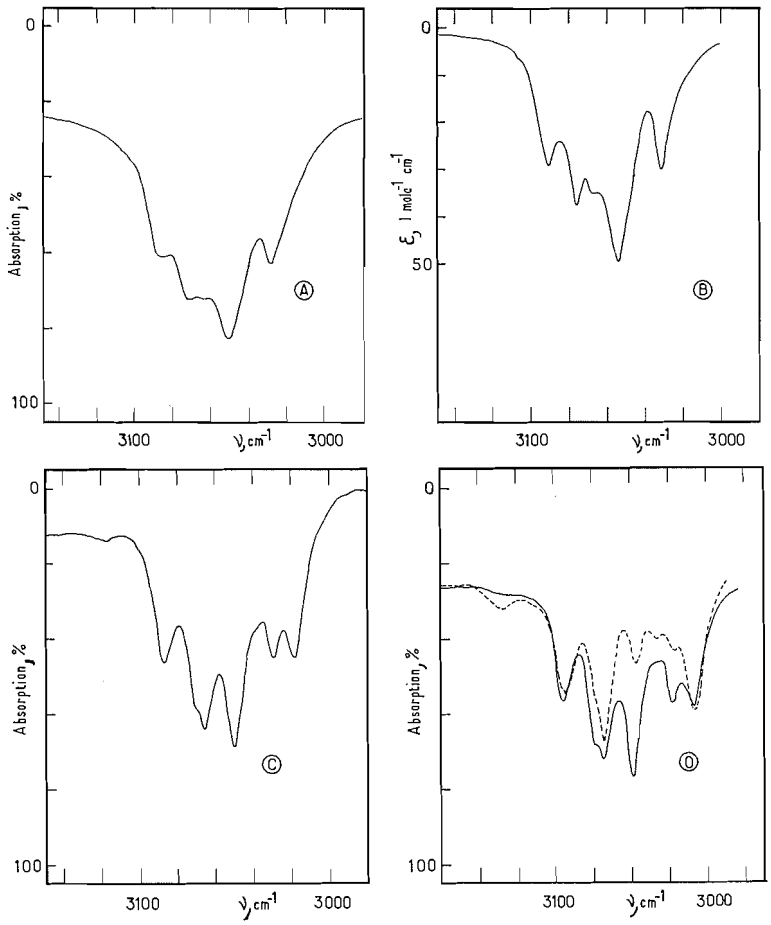

FIG. 5. Spectres infrarouges du dibenzofuranne dans la région de 3 150 à 3 000 cm^{-1}, sous les états: (A) liquide, (B) solution à 1 *M*, (C) solide (dans l'hexachlorobutadiène), (D) cristal orienté: (—) vecteur électrique (∥), (- -) vecteur électrique (⊥).

semblable à celui des vibrations de type A_1 (Fig. 5 et Tableau IV). La forte bande d'absorption de fréquence 3 064 cm^{-1} qui correspond vraisemblablement à la raie Raman polarisée à 3 068 cm^{-1}, du spectre à l'état dissous, devrait aussi appartenir à une vibration de mode A_1, bien que son dichroïsme ne permette pas de l'affirmer (Fig. 5).

(4) Discussion

Dans l'hypothèse des vibrateurs CH indépendants, il faudrait admettre que les autres maximums observés entre 3 150 et 3 000 cm^{-1} sont dus à des vibrations de combinaison ou à des effets de cristal, ce qui est certainement le cas pour les bandes à 3 017, 3 036 et 3 117 cm^{-1} qui n'apparaissent que dans le spectre du solide, mais rien ne permet de rattacher à des modes de combinaison l'absorption à 3 086 cm^{-1}, ni les épaulements à 3 108 et 3 100 cm^{-1} du spectre à l'état dilué.

CONCLUSION

Cette étude nous a permis de situer la plupart des vibrations de modes A_1, B_1, B_2 du dibenzofuranne (Tableau V).

1 012 (*a*)	1 110		
964 (*a*)	1 022		
863	1 002		
850 (*a*)	840		
746 (*a*)	616		
659	555 (*a*)		

NOTE: les fréquences marquées (*a*) et (*b*) sont attribuées par Teplyakov (8): (*a*) à des vibrations fondamentales, (*b*) à des vibrations fondamentales ou de combinaison.

Notre interprétation des spectres de vibration du dibenzofuranne, vérifiant l'hypothèse de la symétrie C_{2v} de cette molécule, confirme sa structure très probablement plane.

Bien qu'en première approximation les vibrateurs CH paraissent indépendants dans les vibrations de valence ν(CH), les spectres ne permettent pas de conclure définitivement à l'absence de couplage.

Nous n'avons observé que deux vibrations de mode A_2. Rappelons que dans le cas où les vibrateurs CH ne seraient pas couplés dans les mouvements hors du plan γ(CH), cinq vibrations de mode A_2 seulement de fréquences distinctes seraient attendues (Tableau I).

CONDITIONS EXPÉRIMENTALES

Le dibenzofuranne utilisé dans ce travail est un produit Fluka; recristallisé d'après la technique de Cass *et al.* (15), il a un point de fusion de 81.5 à 82°.

Les spectres infrarouges ont été enregistrés sur spectrophotomètres Perkin–Elmer, double faisceau, à deux réseaux, modèle 125 de 4 000 à 400 cm^{-1} et modèle 225 de 400 à 200 cm^{-1}.

Ils ont été réalisés:

(*a*) À l'état gazeux à l'aide d'une cellule chauffante Perkin–Elmer, de 5 cm d'épaisseur à fenêtres de KBr à une température d'environ 190 °C.

(*b*) À l'état dissous dans le tétrachlorure de carbone pour les régions de 3 100 cm^{-1} et 1 500–1 250 cm^{-1}, le tétrachlorure d'éthylène entre 1 800 et 1 500 cm^{-1}; le sulfure de carbone entre 1 250 et 400 cm^{-1}.

(*c*) À l'état liquide, avec une cuve chauffante Perkin–Elmer à une température voisine de 82°.

(*d*) À l'état solide, sous forme de pastille de bromure de potassium et, entre 450 et 200 cm^{-1}, de dispersion dans l'hexachlorobutadiène.

(*e*) À l'état de cristal orienté, par fusion et refroidissement du produit entre deux fenêtres de KBr. Un domaine bien orienté a été délimité en examinant les lames entre deux polaroïds croisés. Les spectres de ce cristal ont été réalisés en lumière polarisée au moyen de polariseurs de transmission Perkin–Elmer en AgCl. Pour le premier enregistrement ($\parallel$), le cristal a été orienté de telle sorte que l'intensité de la bande d'absorption à 1 440 cm^{-1} soit maximum; le cristal a été tourné de 90° dans la deuxième expérience ($\perp$) (cf. Fig. 4).

Les spectres Raman ont été réalisés à l'état dissous (1 *M*) dans le benzène et le tétrachlorure de carbone avec un spectrographe Hilger et Watts, Type E–612, le tube Raman mesurait 22 cm de long et 9 mm de diamètre intérieur. Un filtre de nitrite de sodium permettant de sélectionner la raie excitatrice à 4 358 Å du mercure a été utilisé.

Les spectres ont été photographiés sur plaques à partir desquelles un enregistrement a été effectué à l'aide d'un microphotomètre Hilger L 470.

Les facteurs de dépolarisation ont été mesurés par la technique d'Edsall et Wilson (16) et corrigés d'après la méthode de Rank et Kagarise (17).

NOTES

A STUDY BY ELECTRON PARAMAGNETIC RESONANCE SPECTROSCOPY OF RADICALS FORMED FROM ACETAMIDE AND FORMAMIDE[1]

P. SMITH AND P. B. WOOD

Previous electron paramagnetic resonance spectral studies in this laboratory have involved simple free radicals, with π-type delocalization, formed by hydroxyl-radical attack on aliphatic carboxylic esters (1) within an aqueous flow system, e.g. the radicals $\dot{C}H_2COOCH_3$ and $HCOO\dot{C}H_2$. For such radicals small long-range hyperfine couplings across the oxycarbonyl group were resolved. In an extension of the above work, this report presents the results for hydroxyl-radical attack on two simple aliphatic amides acetamide and formamide. Well-resolved spectra showing long-range couplings across the carbonyl group were obtained for both compounds. Acetamide gave a spectrum consistent with the radical $\dot{C}H_2CONH_2$; formamide, an absorption assigned to the radical $HC\dot{O}NH$. The latter appears to be the first case in which a radical resulting from abstraction of a hydrogen atom bonded to a nitrogen atom has been observed with aqueous flow techniques.

EXPERIMENTAL

The basic experimental arrangement has been described before (1). Hyperfine coupling constants were measured by means of the Varian Fieldial accessory. *g*-Factors were taken using a frequency meter (Hewlett Packard model X532B) by comparison with peroxylamine disulfonate on the assumption that its *g*-factor is 2.00550 (2), the procedure followed being similar to that of Sicilio *et al.* (3). The flow system was modified to include the mix-and-flow cell of Borg (4). Eastman white label acetamide was used as substrate before and after recrystallization from benzene – ethyl ether, the results obtained with both materials being indistinguishable. The formamide used as substrate was Fisher reagent grade. Unpurified formamide gave spectra suggesting the presence of a significant proportion of methanol impurity. This was effectively removed by fractional distillation under reduced pressure. The following reaction conditions were employed: total flow rate, 2–8 ml s^{-1}, this being kept equally divided between the two streams; reaction temperature, $25 \pm 2 - \sim 45$ °C; titanous chloride concentration in the reducing stream, 0.01–0.003 M; hydrogen peroxide concentration in the oxidizing stream, 0.04–0.3 M; added sulfuric acid concentration in both streams, 0.2–0.0 M. Apart from signal intensity changes, the only significant result produced by these variations was an improvement in the resolution of the small doublet splitting in the spectrum obtained from formamide, a consequence of lowering the titanous chloride concentration while raising that of the hydrogen peroxide to maintain a high enough signal level. Unless otherwise specified the results reported refer to the first listed value for each parameter. The substrates were included in both streams, the minimum concentrations necessary to quench the hydroxyl-radical signal being 1.0 and 0.4 M for acetamide and formamide, respectively.

[1]*This investigation was supported by United States Public Health Service Grant GM 07653, Division of General Medical Sciences.*

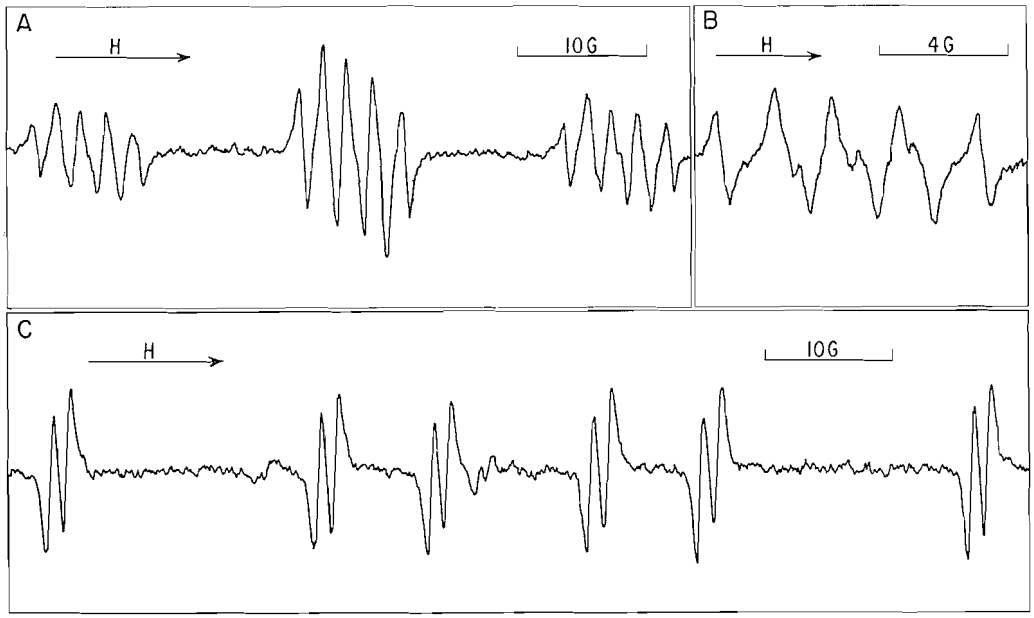

FIG. 1. First-derivative electron paramagnetic resonance spectra for the reaction of hydroxyl radicals with acetamide and formamide at 27 °C. (A) and (B). Acetamide. Concentrations in the reacting streams: CH_3CONH_2, 1.2 *M*; $TiCl_3$, 0.008 *M*; H_2O_2, 0.01 *M*; H_2SO_4, 0.1 *M*; (A) a complete spectrum; (B), a slower scan of the central quintet shown in (A) with reduced modulation. (C). Formamide. Concentrations in the reacting streams: $HCONH_2$, 0.4 *M*; $TiCl_3$, 0.006 *M*; H_2O_2, 0.2 *M*; H_2SO_4, 0.1 *M*.

RESULTS AND DISCUSSION

With acetamide as the substrate the spectrum observed under comparatively fast sweep conditions was a wide (21.3 G) triplet (1:2:1) of narrow ($\sim$ 2 G) apparent quintets (2:3:4:3:2), as shown in Fig. 1(A). Slower scans revealed that the central three lines of each quintet showed signs of extra, incompletely resolved splittings indicating a total of eight lines. For the central apparent quintet this feature is illustrated in Fig. 1(B). The size of the major triplet coupling and its intensity distribution are consistent with the radical $\cdot CH_2CONH_2$. For this radical trapped in irradiated amorphous acetamide Gordy and co-workers (5, 6) have found $a_H^{CH_2}$ to be $\sim$ 23 G (7). Moreover, in radicals of functional structure —ĊH—CO— values of 20–23 G for $a_H^{CH_2}$ are normal (1, 8), e.g. for the $\cdot CH_2COOH$ radical in aqueous solution $a_H^{CH_2}$ has been reported to be 21.3 G (1) and 21.7–21.8 G (8). The subsidiary eight-line patterns are attributed to the expected (1) π-type delocalization[2] which leads to hyperfine splitting due to the ^{14}N nucleus together with the possibility of extra splitting arising from coupling with the two amide protons. In this connection it would not be expected that more than two protons should be observed to couple under the employed reaction conditions since amides are very weak bases (10). The details of the eight-line patterns appear inconsistent with couplings of different size from ^{14}N and two equivalent protons, which would yield a triplet (1:1:1) of triplets (1:2:1). A more plausible interpretation is that they arise from a quartet (1:2:2:1) of doublets (1:1)

[2]*That* $a_H^{CH_2}(\cdot CH_2COOH)$ *is close to the size of* $a_H^{CH_2}(\cdot CH_2CONH_2)$ *suggests that about 10% of the unpaired electron density in* $\cdot CH_2CONH_2$ *is delocalized through the amide group, for a similar extent of delocalization into the carboxyl group occurs in the case of* $\cdot CH_2COOH$ *(1). The size of* $a_N(\cdot CH_2CONH_2)$ *is consistent with this extent of delocalization, for unit unpaired electron density on nitrogen in a planar radical gives* a_N *equal to 23.0 G (2). Furthermore, a recent single-crystal study (9) of the radical* $CH_2(CONH_2)\dot{C}HCONH_2$ *reports isotropic coupling constants,* $a_H^{CH_2}$ *and* a_N, *and a spin density on the α-amide-group nitrogen atom in general agreement with this present work.*

with coupling constants 2.0 and 2.5 G, respectively. The resultant overall theoretical intensity distribution (1:2:1:2:2:1:2:1) is in accord with that observed experimentally, considering the incomplete resolution achieved. A similar absorption would result if the ^{14}N nucleus and one amide-group proton had essentially equal coupling constants (2.0 G) and the remaining amide-group proton had a different coupling constant (2.5 G). Roughly equal splittings for ^{14}N and for protons bonded to ^{14}N are well known in the case of related radicals, e.g. $\cdot N_2H_4^+$ (2), $\cdot NH_3^+$ (11), and $\cdot ONH_2$ (12). The spectroscopic results obtained with acetamide are given in Table I.

TABLE I

Hyperfine coupling constants and g factors at 25 ± 2 °C for radicals formed by hydroxyl-radical attack on acetamide and formamide*

		Hyperfine coupling constants, G			
Radical	g-Factor†	$a_H^{CH_2}$	$a_N^{NH_2}$	$a_{H(1)}^{NH_2}$	$a_{H(2)}^{NH_2}$
$\cdot CH_2CONH_2$	2.0034	21.28	1.96‡	1.96‡	2.53‡

		Hyperfine coupling constants, G		
Radical	g-Factor	a_N^{NH}	a_H^{NH}	a_H^{CH}
$HC\dot{O}NH$	2.0016	21.65	30.55	1.22

*Each coupling constant given is the arithmetical mean of all measurements of that coupling constant taken from several field scans. Unless otherwise specified, the maximum uncertainty in each constant is ± ~0.05 G.
†The estimated maximum uncertainty is ±0.0002.
‡These values are not very precise because the absorption arising from the NH_2 group was only incompletely resolved; the maximum uncertainty in each of these values is estimated to be ±0.2 G.

The non-equivalence of the two amide-group protons is noteworthy and implies a considerable degree of hindered rotation about the C—N bond in the radical. Rotational isomerism arising from hindered rotation about the C—N bond is well established for many amides (12, 13). The π-type delocalization of the unpaired electron on to the nitrogen atom present in the radical $\cdot CH_2CONH_2$ should enhance this kind of rotational hindrance. Given this restriction to free rotation and the low molecular symmetry for this radical, assuming the normal planar-type structure of the parent molecule (10) to apply, the splittings from the two amide-group protons would not, a priori, be expected to be equal. The size of the ratio ($a_N/a_H^{NH_2}$) does not deviate far from the value of 1.06 expected for a planar radical with a sp^2-hybridized nitrogen atom (2). The fact that a_N and $a_H^{NH_2}$ for one amide-group proton are apparently equal, bearing in mind that the peak-to-peak line widths are ~ 0.5 G, must be coincidental.

The spectrum obtained from formamide was a wide (21.7 G) triplet of wide (30.6 G) doublets (1:1), each line of which displayed a narrow (1.2 G) doublet (1:1) splitting. A typical spectrum is shown in Fig. 1(C). Of the various conceivable, direct or indirect, products of hydroxyl-radical attack on formamide, the observed absorption seems most consistent with the radical $HC\dot{O}NH$. In view of the low reactivity toward hydroxyl radicals of acetamide relative to formamide, it is interesting that the site of hydrogen-atom abstraction is so clearly different for these two substrates. Perhaps the $HC\dot{O}NH$ radical is formed via some undetected species, e.g. by the rearrangement of the radical $\cdot CONH_2$. However, there is no evidence for any other radical species in spectra taken over the fullest possible range of conditions for both substrates. Other formyl substrates have been found to show particularly high reactivity in this reaction system. For example, formic acid is more reactive than acetic acid, their respective minimum molarities for quenching the hydroxyl-radical signal under conditions similar to those employed in this

work being 0.3 and 1.0 (P. Smith and P. B. Wood, unpublished results), in qualitative agreement with the relative reactivities of these acids toward hydroxyl-radical attack found by pulse radiolytic studies (14). However, the selectivity of hydroxyl-radical attack on these two acids has not yet been conclusively elucidated (1). The spectroscopic results obtained for formamide are given in Table I.

The value of a_N for HCONH is larger than those for the related radicals $\cdot NH_2$, $\cdot ND_2$, and $\cdot NF_2$ which have been studied in inert gas matrices at about 4 °K (15, 16). This is not considered to be inconsistent with the proposed assignment of the spectrum to HCONH, for it is clear that the size of a_N in radicals of this type is markedly dependent on radical structure (considerably larger ^{14}N couplings have been reported for iminoxy radicals in which a considerable proportion of the unpaired electron density is expected to reside on oxygen rather than nitrogen (17)). Further support for the proposed assignment is provided by the *g*-value for this radical, 2.0015, which is somewhat lower than those for species such as $\cdot NH_2$, 2.0048 (15), in harmony with the expected greater delocalization (18) of the unpaired electron in HCONH compared with $\cdot NH_2$. Extensive delocalization would result in a radical formally analogous to allyl, $\dot{C}H_2—CH=CH_2 \leftrightarrow CH_2=CH—\dot{C}H_2$, i.e. $O=CH—\dot{N}H \leftrightarrow \dot{O}—CH=NH$ in which the splitting from the central proton arises from exchange interaction with negative spin density on the central carbon nucleus (19). The formyl proton coupling constant in HCONH is approximately one quarter of that of the central proton in the allyl radical, suggesting that delocalization is appreciable but somewhat less than in allyl itself. π-Type delocalization should keep HCONH planar and thus constrict the formyl hydrogen atom to the modal plane of the π-system, thereby preventing any hyperconjugative interaction between the formyl hydrogen atom and the unpaired spin density on the nitrogen atom. It is hoped to present the results of molecular orbital treatments of the delocalization in radicals such as HCONH and $\dot{C}H_2CONH_2$ in a later publication dealing also with the extension of this investigation to a number of other simple aliphatic amides.
