Conclusion

The simple method of analysis of the near-infrared spectra outlined above and its applications to selected problems lead to the following conclusions: (*a*) the influence of large tetraalkylammonium ions on the hydrogen-bonding equilibrium of water is similar to the effect observed upon lowering the temperature. (*b*) the nature of solute–solvent interactions for the alkyl and aryl substituted salts studied is quite different; the aryl substituted salts do not exhibit a marked hydrophobic character. As in the case of simple 1:1 electrolytes, the influence of an anion on the water spectra is much greater than that of a cation. By comparison with alkali halides, the spectra suggest that $B\phi_4^-$ acts mainly as a structure breaker while ϕ_4As^+ has little specific effect on the water structure.

The sensitivity of the method seems greater than that which can be obtained from the fundamental stretching modes (29, 30). It thus appears justified to apply it to broader categories of solutes of actual interest.

The Determination of Calcium Carbide and its Dissociation Products in Fused Calcium Chloride

C. AKSARANAN, V. DOSAJ, D. R. MORRIS, AND S. H. WHITE[1]

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

Received October 30, 1970

The principal constituents in molten solutions of calcium carbide in calcium chloride have been determined. The analytical results were generally within order of magnitude agreement with calculations from thermodynamic data based upon a model in which the calcium carbide is thought to be dissociated according to the equation

$$CaC_{2\,(soln)} \rightleftharpoons Ca_{(soln)} + 2C_{(s)}$$

On a établi la nature des principaux constituants des solutions fondues de carbure de calcium dans le chlorure de calcium. Les résultats analytiques sont généralement en accord à l'intérieur d'une ordre de grandeur-avec les données thermodynamiques basées sur un modèle dans lequel on croyait que le carbure de calcium est dissocié suivant l'équation

$$CaC_{2\,(soln)} \rightleftharpoons Ca_{(soln)} + 2C_{(s)}$$

Canadian Journal of Chemistry, 49, 2014 (1971)

Introduction

Electrochemical and physico-chemical studies of solutions of calcium carbide in molten calcium chloride require an accurate knowledge of the concentration of calcium carbide and its probable decomposition products. Thermodynamic arguments (*vide infra*) predict that a small but significant concentration of calcium metal will be in equilibrium with calcium carbide dissolved in molten calcium chloride and a known activity of carbon (usually fixed by the crucible material). The form taken by the calcium metal in solution in calcium chloride is uncertain but "F centers" or lower valent forms of calcium ions have been suggested for calcium chloride – calcium (1, 2) and calcium fluoride – calcium melts (3).

The analytical procedure to determine the concentration of the principal constituents of the solution was a development of the method described by Edwards (4) and used later by Morris and Harry (5). A weighed sample of the solidified calcium carbide – calcium chloride solution was hydrolyzed in a closed system. A sample of the gases thus liberated was analyzed with a gas partitioner which was calibrated previously with hydrogen–acetylene mixtures. This method was preferred to those of Barber and Sloan (6) and Mitchell (7) because it permitted the direct, independent analysis of the calcium metal content, at the same time as the determination of the carbide content. Total chloride and free oxide were determined by conventional analysis of the hydrolyzed sample.

In this paper we report a model for calcium carbide – calcium chloride melts based on thermodynamic arguments and data obtained with the improved analytical procedure.

[1]Post Doctoral Fellow 1968–1970.

Experimental

(1) Apparatus

(a) Gas Generation Equipment

The equipment consisted of a 150-ml flask which was fitted with a rubber septum through which gas samples could be withdrawn by means of a Hamilton gas syringe. The flask could be connected by glass stopcocks to a manometer and a vacuum pump, or a source of dry argon. The flask was capped by a reservoir from which the hydrolyzing solution could be introduced. The glass lines in the system were kept to a minimum length to ensure their volume was small compared with the total volume of the apparatus. The total volume of the apparatus was determined by weighings using distilled water.

(b) Gas Analysis

A model 25V Fisher Gas Partitioner fitted with two columns was used for the acetylene–hydrogen analysis. The first column, 5 ft long, was packed with hexamethyl phosphoramide, the second 7 ft long was packed with 13X molecular sieve.

The partitioner was calibrated using mixtures of acetylene and hydrogen. Acetylene was generated in the gas apparatus from calcium carbide synthesized from the elements (8) using excess carbon to ensure the absence of free calcium. Analysis of the gas derived by hydrolysis from such material was found to be H_2-free. The mixtures were prepared by back-filling the apparatus to 1 atm

TABLE 1. Duplicate sample analysis, effect of sampling method

Sample designation	Composition				Sampling method
	Ca		CaC_2		
	Mole fraction	% Error	Mole fraction	% Error	
CCA-19	0.00027 0.00023	16	0.0107 0.0125	18	Drilling
CCA-1	0.00027 0.00026	4	0.0424 0.0455	7	Crucible

pressure with hydrogen (99.99% purity). Replicate samples of the mixtures (0.6 ml) were injected into the partitioner using a Hamilton gas syringe. A plot of peak height *vs.* composition was prepared and checked at frequent intervals.

Typical operating conditions for the gas partitioner were: argon flow rate, 100 ml/min; thermistor current, 5 mA; sensitivity, 50%; recorder span, 2 mV; operating temperature, ambient. The retention times were found to be: hydrogen, 1.8 min; acetylene, 14.0 min. The output from the gas partitioner was recorded continuously. Air contamination which occasionally occurred due to faulty loading of the instrument was immediately detected by the presence of oxygen and nitrogen peaks on the chromatogram.

(2) Analytical Procedure

Samples of the calcium carbide – calcium chloride solution equilibrated in a graphite crucible were obtained in two ways.

(*a*) A small graphite crucible supported inside the particular apparatus being used for the physico-chemical studies was dipped into the melt and quenched by quickly withdrawing the crucible to the cool part of the apparatus.

(*b*) Samples were drilled from the solidified melt after the experiment. When possible, this procedure was carried out in a dry box.

The sample of the calcium carbide – calcium chloride solidified melt (approximately 4 to 8 g) was accurately weighed in the dry box and transferred to the dried reaction flask which was quickly connected to the gas generation equipment. The apparatus was evacuated and the temperature and pressure noted. Twenty-five ml of distilled water were then added from the reservoir to completely hydrolyze the sample. The steady-state temperature and pressure were recorded (after about 1 h). The apparatus was brought to atmospheric pressure by filling with argon. Replicate samples (0.6 ml) of the gas mixture were transferred with a Hamilton gas syringe to the gas partitioner and the peak heights for hydrogen and acetylene recorded. The weights of calcium carbide and calcium metal in the sample were calculated from the measured gas composition, corrected to an argon free basis, and the known total volume of dry gases at N.T.P. A correction for the solubility of acetylene in water was made, based on the data given by Miller (9). The liquid in the reaction flask was acidified with 50 ml 1.0 *N* nitric acid and the solution diluted to 500 ml in a volumetric flask. The total basicity was obtained by back-titration of 10-ml aliquots with 0.1 *N* sodium hydroxide using methyl orange as indicator. The total oxide content was calculated from the difference between total basicity and the basicity due to hydrolysis of calcium metal and calcium carbide determined previously.

A further 10-ml sample was treated with a known excess of 0.1 *N* silver nitrate. The silver chloride was filtered off and the excess silver nitrate was determined volumetrically with 0.1 *N* ammonium thiocyanate and ferric ion as indicator. From this information the total chloride was determined.

Free carbon was separated by filtration from the residual solution, dried, and weighed.

Results and Discussion

The total errors of 3%, 3%, and 1% were estimated from the individual errors in the analytical procedure for CaC_2, Ca, and $CaCl_2$, respectively. The error in the reported figures of CaO content was estimated at 10%. Duplicate analyses are given (Table 1) for samples obtained by the two methods. The drilling was *not* carried out in a dry box, and the large errors probably result from hydrolysis of the sample by the damp air. Much more reasonable agreement between results was obtained from the crucible sampling technique and it is to be preferred.

A consideration of the available thermodynamic data relating to the solution equilibrium

$$CaC_2 \text{ (soln in } CaCl_2) \rightleftharpoons Ca \text{ (soln in } CaCl_2) + 2C \text{ (solid)}$$

will show that calcium metal in the dissolved state is an important species in solutions of calcium carbide dissolved in molten calcium chloride.

The standard free energy change for the above reaction, $\Delta G_{T_1}^0$, is related to the equilibrium constant K by the usual relations

$$[1] \quad \Delta G_{T_1}^0 = -RT \ln K = -RT \ln (\gamma_{Ca} N_{Ca} / \gamma_{CaC_2} N_{CaC_2})$$

where γ is the activity coefficient and N is the mole fraction of the respective species, R and T have their usual meanings. The standard state is

*Sample taken by drilling solidified melt; all others by graphite sampling crucible.

chosen as the pure liquid at the particular temperature, such that $\gamma \rightarrow 1$ as $N \rightarrow 1$. Graphite is assumed to be insoluble in the melt, and the container.

In order to calculate ΔG_{T1}^0, equations describing the standard free energy changes accompanying the processes

[2] $CaC_{2\,(s)} \rightarrow Ca_{(g)} + 2C_{(s)}$ ΔG_{T2}^0

[3] $Ca_{(g)} \rightarrow Ca_{(l)}$ ΔG_{T3}^0

[4] $CaC_{2\,(s)} \rightarrow CaC_{2\,(l)}$ ΔG_{T4}^0

as a function of temperature were obtained from the literature. At temperatures below the melting point of calcium metal (840 °C), the free energy change of the process $Ca_{(s)} \rightarrow Ca_{(l)}$ should be taken into account. However, this quantity is small compared to other uncertainties and is neglected.

Measurements of the calcium metal vapor pressure over calcium carbide in the temperature range 1300 to 1900 °K by Faircloth, Flowers, and Pummery (10) give

[5] $\Delta G_{T2}^0 = (49\,000 \pm 950) - (13.3 \pm 0.6)T$ cal/mol

The calcium vapor pressure data compiled by Hultgren *et al.* (11) give

[6] $\Delta G_{T3}^0 = [-37\,390 + 21.37T] \pm 400$ cal/mol

For process 4, Schlumberger (12) gives the heat of fusion of calcium carbide as 7680 cal/mol and Juza and Bunzen (13) give the melting point at 2140 °C. No data are available for ΔC_p, accordingly this was taken as 1.2 ± 0.5 cal/mol °K, the average of the various data listed by Janz (14) for a number of halides. These data give

[7] $\Delta G_{T4}^0 = [4790 + 7.35T - 2.76T \log T] \pm 200$ cal/mol

Combination of eqs. 5, 6, and 7 leads to

[8] $\Delta G_{T1}^0 = [6820 + 0.7T + 2.76T \log T] \pm 2000$ cal/mol

In order to calculate N_{Ca} (eq. 1) the activity coefficients γ_{CaC_2} and γ_{Ca} must be known. Barber and Sloan (6) reported the solubility of CaC_2 in $CaCl_2$ to be 10.4 mol% at 820 °C, hence $\gamma_{CaC_2} \simeq 10$. A value of γ_{Ca} may be estimated from the phase diagram for the Ca–$CaCl_2$ system (15). This neglects any effect due to the presence of CaC_2. The change of γ_{CaC_2} with temperature and composition has been neglected and the change of γ_{Ca} with composition has been neglected.

The results of some typical analyses determined by the experimental procedures outlined are presented in Table 2 together with the concentrations of calcium metal calculated from eqs. 1 and 8.

In most instances, the agreement between the calculated calcium metal concentration and that obtained by analysis is satisfactory. The analyses confirm the thermodynamic prediction that a small but significant concentration of calcium metal is in solution in molten calcium chloride when calcium carbide is dissolved in this solvent. The chemistry and electrochemistry of these solutions are more clearly understood using this model.

Studies on Some 2,1-Benzisoxazole Derivatives

D. M. McKINNON AND J. Y. WONG
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received January 26, 1971

7-Acetyl-3-methyl-2,1-benzisoxazole has been synthesized by reduction of 2,6-diacetylnitrobenzene. While the chemical properties of the compound indicate that it undergoes valency-tautomerism, spectroscopic studies indicate that this is a relatively slow process. Comparisons with other heterocyclic systems having similar properties are noted.

La réduction du diacétyl-2,6 nitrobenzène conduit à l'acétyl-7 méthyl-3 benzizoxazole-2,1. Alors que les propriétés chimiques de ce composé indiquent qu'il est sujet à une tautomérie de valence, les études spectroscopiques suggèrent que ce processus est relativement lent. Par comparaisons avec d'autres systèmes hétérocycliques on note qu'ils ont des propriétés semblables.

Canadian Journal of Chemistry, 49, 2018 (1971)

Theories of bonding in 6*a*-thiathiophthenes **1** have invoked the use of sulfur d-orbitals (1, 2) in the bonding of the central sulfur atom to explain their symmetry in solution as established by n.m.r. (3) and present evidence (4) indicates that they are in fact best represented by structure **1***a* rather than structures of type **1***b*. Similar considerations also appear to hold for an isothiazole derivative **2***a* (5) and for a benzo-1,2-thioxole derivative **2***b* (6). However, it is of interest to examine related compounds in which the central atom is incapable of valency shell expansion to determine to what extent their properties approach those of the 6*a*-thiathiophthenes **1**. These should possibly exhibit valency-tautomerism which has been proposed (7) to explain the properties of the thiathiophthenes. A suitable compound for examination is 7-acetyl-3-methyl-2,1-benzisoxazole (**3***a*), which has a structure of the required potential symmetry for n.m.r. examination and possesses similar electronic and structural features to some benzo-1,2-dithiolium derivatives (8) of the thiathiophthene system.

1*a* **1***b*

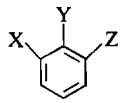
2-Nitroisophthaloyl chloride (**4***a*) reacted with ethyl ethoxymagnesiummalonate to provide the tetracarboxylic ester **4***b*. This was not isolated but provided, after acid hydrolysis, 2,6-diacetylnitrobenzene (**4***c*). This method is reported to be the most satisfactory for the preparation of *o*-nitroacetophenones (9). When the nitro compound was reduced, using stannous chloride in hydrochloric acid, 7-acetyl-3-methyl-2,1-benzisoxazole (**3***a*) and 2,6-diacetylaniline (**4***d*) were obtained after separation by chromatography. 2,6-Diacetylaniline (**4***d*) was obtained as the sole product when the reaction was performed at a higher temperature.

Although the ^1H n.m.r. spectrum of the 2,1-benzisoxazole **3***a* in deuterochloroform solution at 0° to 20° gave only one peak, indicating that



4

a X = Z = COCl; Y = NO_2
b X = Z = $COCH(CO_2Et)_2$; Y = NO_2
c X = Z = COMe; Y = NO_2
d X = Z = COMe; Y = NH_2
e X = Z = CONHMe; Y = NO_2
f X = Z = CSNHMe; Y = NO_2
g X = Z = CONHMe; Y = NH_2
h X = CONHMe; Y = NH_2; Z = CO_2^-; NH_3^+Me

the two methyl groups were equivalent, at other temperatures two peaks were obtained, indicating that the equivalence of the methyl groups was merely coincidental. The n.m.r. spectrum in hexadeuterobenzene, on the other hand, because of its aromatic solvent effects (10), gave a wide separation of the two methyl groups. Increasing the temperature by 150° brought these two methyl singlets together by only 0.32 τ, indicating that there is a rather high energy barrier to interconversion of the two identical valency tautomers. Similar results were obtained in perdeuterotoluene. Under no circumstances were we able to obtain an AB_2 type pattern from the protons on the aromatic ring. Only ABX types were evident.

Treatment of the 2,1-benzisoxazole **3***a* with phosphorus pentasulfide in carbon disulfide or pyridine gave another compound in which one oxygen had been replaced with sulfur. Examination of the i.r. spectrum indicated that a carbonyl group was present, hence the compound is probably the acyl-2,1-benzisothiazole **3***b* rather than the thioacyl-2,1-benzisoxazole **3***c*. The isolation of this can be rationalized by initial formation of the thioacyl compound **3***c* which under the conditions of the reaction undergoes valency-tautomerism to **3***b*. Although it has been demonstrated above that such tautomerism in these compounds is not detectable by n.m.r. this is not inconsistent with interconversion under the conditions of the chemical reaction. This reaction is related to the conversion of a 2,1-benzisoxazole into an acetylfuroxan (11) and some furoxan interconversions (12). Some 4-thioacyl-1,2-dithiole-3-thiones (8) also appear to undergo such tautomerism, and it has been recently demonstrated (13) that some 1,2,3-benzothiadiazole diazonium salts give rearranged products by such interconversions. The failure to demonstrate suitable symmetry in the 2,1-benzisoxazole **3***a* suggests that valency-tautomerism is inadequate in explaining the special properties of thiathiophthenes. Likewise, doubt is also cast on the existence of single-bond – no-bond resonance (3) in this system.

The 2,1-benzisothiazole **3***b* should be further sulfurized under the conditions of the reaction to 3-methyl-7-thioacetyl-2,1-benzisothiazole (**3***d*), but this is probably readily hydrolyzed back to **3***b* during the isolation procedure. Certain thiones are reported to undergo such hydrolyses (14). Compounds without substituents capable of interacting with the heterocyclic ring were not sulfurized under the conditions used. Thus 3-methyl-2,1-benzisoxazole was not converted to 3-methyl-2,1-benzisothiazole and was recovered when carbon disulfide was used as a solvent. Attempted sulfurization in pyridine caused extensive decomposition.

Reaction of the 2,1-benzisoxazole **3***a* with methylamine and aniline provided the benzopyrazoles **3***e* and *f* respectively, which, like the sulfurization above, could have been formed via the imines, **3***g* and *h*, followed by tautomerism to the acetylbenzopyrazoles. These compounds **3***e* and *f* might also have reacted with more imine to form imines **3***i* and *j* respectively but under the conditions of the work-up, hydrolysis of these to **3***e* and *f* would have occurred. These compounds exhibited C=O absorption in the i.r., indicating that they exist as acetylbenzopyrazoles rather than the isomeric imino-2,1-benzisoxazoles.

Attempts were also made to synthesize the amino-2,1-benzisoxazole derivative **3***k*. 2-Nitroisophthaloyl chloride reacted with methylamine to give *N,N'*-dimethyl-2-nitroisophthalamide (**4***e*). This was readily converted into the bis-thioamide **4***f*, but attempts to convert it directly to the 2,1-benzisoxazole **3***k* failed. Synthesis via the aminodiamide **4***g* was attempted, but no satisfactory method of reduction of the nitro group was found. Hydrogenation over Raney nickel in methanol gave an aromatic amine, but this was probably the compound **4***h* in which one amide function had been hydrolyzed, since it readily dissolved in water and effervesced on treatment with sodium bicarbonate.

Experimental

The i.r. spectra were performed on a Perkin–Elmer model 337 spectrophotometer in liquid paraffin mulls. The n.m.r. spectra were obtained on a Varian model 56/60A spectrometer and, unless otherwise stated, in deuterochloroform at 40°, using tetramethylsilane as an internal standard. The t.l.c. was performed using "Camag" silica-gel type D.S.F.5 supplied by Mondray Ltd. Development of plates, unless otherwise stated, was carried out using benzene with increasing proportions of chloroform. Melting points were obtained on a Fisher–Johns melting point apparatus.

2-Nitroisophthaloyl Chloride (4a)

2-Nitroisophthalic acid (25 g, 0.12 mol) (15, 16) was suspended in benzene (100 ml) and treated with thionyl chloride (30 ml). The mixture was refluxed until homogeneous then evaporated under reduced pressure. The crude material was recrystallized from benzene and was used for further reactions. Yield was almost quantitative.

2,6-Diacetylnitrobenzene (4c)

Magnesium turnings (9.3 g, 0.39 atoms), in a three-necked flask equipped with a magnetic stirrer and a reflux condenser, were treated with a mixture of anhydrous ethanol (10 ml) and carbon tetrachloride (1 ml). The mixture was warmed gently to start the reaction then anhydrous ether (300 ml) was added. A mixture of anhydrous ether (50 ml), ethyl malonate (60 g, 0.375 mol), and anhydrous ethanol (100 ml) was added at such a rate that rapid boiling was maintained. The mixture was heated under reflux for 3 h, when all the magnesium had dissolved.

To the solution was added dropwise over 15 min a solution of 2-nitroisophthaloyl chloride (45 g, 0.18 mol) in anhydrous ether (100 ml). Reflux was maintained for 4 h until the mixture became too viscous to stir. The cooled reaction mixture was treated with dilute sulfuric acid and the mixture extracted with ether. The dried extract on evaporation gave the tetracarboxylic ester **4b** as a viscous yellow oil. This was refluxed 4 h with a mixture of glacial acetic acid (120 ml) and concentrated sulfuric acid (15 ml), and water (80 ml). The cooled mixture was thrown on ice and the colorless precipitate was washed with water and recrystallized from ethanol, m.p. 160° (89%).

Anal. Calcd. for $C_{10}H_9NO_4$: C, 57.97; H, 4.35; N, 6.76. Found: C, 57.87; H, 4.54; N, 6.86.

The i.r. spectrum: 1700 (C=O), 1555, 1370 cm^{-1} (NO_2). The n.m.r. spectrum: τ 7.68 (6H singlet, two equivalent CH_3 groups), 2.84, 2.75, 2.63, 2.50 (3H bands, three aromatic protons, AB_2 pattern).

Reduction of 2,6-Diacetylnitrobenzene (3a)

Diacetylnitrobenzene (2.07 g, 0.01 mol) was added to a stirred solution of stannous chloride (8.2 g) in concentrated hydrochloric acid (21 ml) at 5°. A pale yellow precipitate was initially formed, but dissolved after 3 h. After 5 h the mixture was diluted with water (100 ml) and extracted with ether (3 × 50 ml). The dried ether extracts on evaporation gave a pale yellow solid which was examined by t.l.c. Three bands were evident under u.v. examination.

The first on elution gave 2,6-diacetylaniline as yellow crystals, m.p. 144° (8%).

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.79; H, 6.22; N, 7.91. Found: C, 67.73; H, 6.36; N, 8.09.

The i.r. spectrum: 1668 (C=O); 3310, 3450 cm^{-1} (NH_2). The n.m.r. spectrum: τ 7.48 (6H singlet, two equivalent CH_3 singlets), 2.01, 2.18, 3.37, 3.48, 3.60 (3H bands, protons on aromatic ring, AB_2 pattern). A better synthesis of this compound is described below.

The second band on elution gave the 2,1-benzisoxazole **3a** as colorless needles, m.p. 97° (38%).

Anal. Calcd. for $C_{10}H_9NO_2$: C, 68.77; H, 5.15; N, 8.00. Found: C, 68.37; H, 5.04; N, 7.94.

The i.r. spectrum: 1650 (tentatively C=N), 1695 cm^{-1} (C=O). The n.m.r. spectrum is described below.

A third band on elution gave only traces of material and was not further examined.

Nuclear Magnetic Resonance Spectral Data of 7-Acetyl-3-methyl-2,1-benzisoxazole (3a)

These were performed in degassed, sealed tubes. In deuterochloroform at 20°, τ 7.13 (6H singlet, two superimposed singlets), 3.11–1.83 (3H bands, protons on the aromatic ring, ABX pattern).

In hexadeuterobenzene at 20°, τ 7.95 (3H singlet, methyl protons on the heterocyclic ring), 7.10 (3H singlet, methyl protons on the acetyl group). At 0° the two methyl singlets were separated by τ 0.88, at 160° they were separated by 0.56.

In perdeuterotoluene at 20°, τ 7.84 (3H singlet, methyl protons on the heterocyclic ring), 7.19 (3H singlet, methyl protons on the acetyl group), 3.61–1.89 (3H bands, protons on the aromatic ring, ABX pattern). At −20° the methyl singlets were separated by τ 0.80, at 160° they were separated by 0.43.

The peaks at higher τ values in deuterobenzene and toluene were assigned to the methyl group on the heterocyclic ring since an n.m.r. spectrum of 3-methyl-2,1-benzisoxazole (17) in hexadeuterobenzene gave τ 7.74 (3H singlet, methyl group), 3.55–2.42 (4H bands, protons on the aromatic ring).

2,6-Diacetylaniline (4d)

2,6-Diacetylnitrobenzene (7.24 g, 0.035 mol) stannous chloride (30 g) and concentrated hydrochloric acid (80 ml) were heated at 90° for 2½ h. The orange mixture was neutralized with solid sodium carbonate and extracted with ether (3 × 100 ml). The ether extracts were washed with dilute sodium carbonate, with water, and dried over sodium sulfate. Evaporation gave a yellow powder which was recrystallized from water as yellow needles, m.p. 144° (76%).

Sulfurization of 7-Acetyl-3-methyl-2,1-benzisoxazole to form 7-Acetyl-3-methyl-2,1-benzisothiazole (3d)

The benzisoxazole (5 g, 0.0285 mol) in pyridine (80 ml) was refluxed with phosphorus pentasulfide (8 g) for 8 h. The mixture was cooled, poured into water, and extracted with chloroform (3 × 50 ml). The extract was washed with water (5 × 20 ml), dried, and evaporated to give a yellow oil which crystallized on standing, and was further purified by t.l.c. using chloroform as a developing solvent. Yellow crystals were obtained, m.p. 79° (75%).

For personal use only.

Anal. Calcd. for $C_{10}H_9NOS$: C, 62.83; H, 4.71; N, 7.33; S, 16.76. Found: C, 62.67; H, 4.84; N, 7.15; S, 16.76.

The i.r. spectrum: 1725 (C=O), 1635 cm^{-1} (tentatively C=N). The n.m.r. spectrum: τ 7.15, 7.17 (6H, two methyl singlets), 3.12–1.80 (3H bands, protons on the aromatic ring).

Similar results, but with lower yields (~15%), were obtained when sulfurization was performed in carbon disulfide.

Reaction of 7-Acetyl-3-methyl-2,1-benzisoxazole with Aniline. Preparation of 7-Acetyl-3-methyl-2-phenylbenzo[c]pyrazole (3f)

The benzisoxazole (0.5 g, 0.00285 mol) and aniline (0.6 g, 0.00645 mol) in glacial acetic acid (50 ml) were refluxed 16 h. The mixture was poured onto ice and extracted with ether (3 × 50 ml). The ether extracts were washed with saturated sodium carbonate solution, with water, and dried over anhydrous sodium sulfate. Evaporation gave a crude solid which was purified by t.l.c. Using a 5% solution of diethyl ether in chloroform as a developer. A band with a blue fluorescence in the u.v. was eluted and gave a pale yellow solid on evaporation, m.p. 120–122° (27%).

Anal. Calcd. for $C_{16}H_{14}N_2O$: C, 76.80; H, 5.60; N, 11.20. Found: C, 76.93; H, 5.75; N, 11.00.

The i.r. spectrum: 1698 cm^{-1} (C=O str). The n.m.r. spectrum, τ 7.31 (3H singlet, methyl group on the heterocyclic ring), 7.00 (3H singlet methyl on acetyl group), 2.42 (5H singlet, protons on phenyl group), 2.98–1.81 (3H bands, protons on the "benzo" ring, ABX pattern).

Reaction of 7-Acetyl-3-methyl-2,1-benzisoxazole with Methylamine. Preparation of 7-Acetyl-2,3-dimethylbenzo[c]pyrazole (3e)

The benzisoxazole (0.5 g, 0.00285 mol) and 40% aqueous methylamine solution (10 ml) in methanol (25 ml) were refluxed 16 h. The mixture was poured into ice, and extracted with ether (3 × 25 ml). The combined ether extracts were washed with water, dried, and evaporated to give a solid product. Purification was effected by t.l.c. using 16% diethyl ether in chloroform as a developer. A band with a blue fluorescence in the u.v. was eluted and gave on evaporation pale yellow crystals, m.p. 110–114° (34%).

Anal. Calcd. for $C_{11}H_{12}N_2O$: C, 70.21; H, 6.38; N, 14.89. Found: C, 69.97; H, 6.60; N, 14.67.

The i.r. spectrum: 1701 cm^{-1} (C=O str). The n.m.r. spectrum: τ 7.35 (3H singlet, methyl group on the heterocyclic ring), 7.09 (3H singlet, methyl on acetyl group), 5.82 (3H singlet, methyl on nitrogen), 3.01–1.92 (3H bands, protons on the aromatic ring, ABX pattern).

N,N'-Dimethyl-2-nitroisophthalamide (4e)

2-Nitroisophthaloyl chloride (16 g, 0.06 mol) in benzene (100 ml) was treated with 40% methylamine solution in water (200 ml). After the immediate vigorous reaction, the mixture was allowed to stand 1 h, then filtered. The precipitate was washed with cold water, dried, and recrystallized from dimethylformamide. Small colorless prisms were obtained, m.p. 273–275°, subliming above 250° (61%).

Anal. Calcd. for $C_{10}H_{11}N_3O_4$: C, 50.61; H, 4.64; N, 17.72. Found: C, 50.85; H, 4.61; N, 17.62.

The i.r. spectrum: 1636 (C=O), 3205 cm^{-1} (NH str).

N,N'-Dimethyl-2-nitroisothiophthalamide (4f)

N,N'-Dimethyl-2-nitroisophthalamide (5 g, 0.021 mol) in pyridine (60 ml) was refluxed with phosphorus pentasulfide (15 g) for 3 h. The mixture was poured into water and extracted with benzene (3 × 150 ml). The dried benzene extracts on evaporation gave a yellow oil which crystallized on standing. The crude product was recrystallized from methanol as lemon-yellow prisms, m.p. 204–206° (81%).

Anal. Calcd. for $C_{10}H_{11}N_2O_2S_2$: C, 44.65; H, 4.09; N, 16.61; S, 23.83. Found: C, 44.90; H, 4.36; N, 16.29; S, 23.93.

The i.r. spectrum: 1193 (tentatively C=S), 3191 cm^{-1} (NH str).

Reduction of N,N'-Dimethyl-2-nitroisophthalamide

The amide (2 g, 0.0084 mol) suspended in methanol (50 ml) was hydrogenated over Raney nickel (0.5 g) at 600 p.s.i. at 60° for 48 h in a pressure vessel with a glass liner. A yellow solution was obtained which on evaporation gave a yellow solid, which was crystallized from methanol. Colorless needles with a blue fluorescence in the u.v. were obtained. The compound partly melted at 158°, resolidified about 180°, and completely melted at 212°.

Anal. Calcd. for $C_{10}H_{15}N_3O_4$: C, 53.22; H, 6.66; N, 18.22. Found: C, 53.21; H, 6.71; N, 18.47.

Hydrogenation at lower temperatures, pressures, or shorter times gave erratic yields and products were contaminated with starting materials. Other methods of reduction, *e.g.* dissolving metal, hydride, were also tried but the extreme solubility of the products in polar or aqueous solvents made isolation unsatisfactory.

Attempted Sulfurization of 3-Methyl-2,1-benzisoxazole

3-Methyl-2,1-benzisoxazole (1 g) (17) and phosphorus pentasulfide (5 g) in carbon disulfide (10 ml) were refluxed for 6 h. Work-up provided only starting material.

When the reaction was performed in pyridine, extensive decomposition was evident. Examination of the products by t.l.c. gave only ill-defined bands which could not be properly separated.

We wish to thank Mr. R. Dickinson for the preparation of n.m.r. spectra, and the National Research Council of Canada for financial support. We also wish to thank Dr. T. Schaefer for helpful suggestions and advice.

Benzodiazocines. II.[1] The Synthesis of Some Hexahydro-1,4-benzodiazocines

J. M. MUCHOWSKI
Bristol Laboratories of Canada, Limited, Candiac, Quebec

Received January 14, 1971

The synthesis of some hexahydro-1,4-benzodiazocine derivatives by the dicyclohexylcarbodiimide (DCC) induced cyclization of the appropriate *N*-2-(2-aminophenyl)ethyl glycines is described. An analogous synthetic approach was used to prepare a hexahydro-1*H*-1,5-benzodiazonine derivative.

On rapporte la synthèse de quelques dérivés de l'hexahydrobenzodiazocine-1,4 qui sont obtenus par la cyclisation, induite par la dicyclohexylcarbodiimide (DCC), des *N*-[(amino-2 phényl)-2 éthyl] glycines appropriées. On a utilisé une méthode de synthèse analogue pour préparer un dérivé de l'héxahydro 1*H*-benzodiazonine-1,5.

Canadian Journal of Chemistry, 49, 2023 (1971)

The synthesis of a simple derivative of hexahydro-1,4-benzodiazocine was recently published (1). This paper describes an alternative, potentially more flexible, route to several members of the title ring system.

In the above connection, 2-(2-nitrophenyl)-ethyl bromide (**1**; see Scheme 1 and Table 1) was aminated with methylamine, and the secondary amine **4***a* thus produced was alkylated (see Scheme 2) with ethyl bromoacetate. Hydrolysis of the ester **5***a* was effected with hot hydrobromic acid, and the carboxylic acid **6***a* so produced was catalytically reduced to the diamino acid **7***a* which, without purification, was cyclized with DCC in pyridine. The use of solvents other than pyridine (*e.g.*, acetonitrile or dimethyl formamide) for this cyclization, did not result in the formation of significant amounts of the 1,4-benzodiazocine (**8***a*).

The ester **5***b* (Scheme 2) was prepared from ethyl bromoacetate and the sodium salt of the benzenesulfonamide **4***b*, which in turn was readily obtained from **1** via 2-(2-nitrophenyl)-ethyl azide (**2**, Scheme 1). Saponification of **5***b* gave the carboxylic acid **6***b* which was converted to the amino acid **7***b* in the usual manner. The DCC promoted cyclization of **7***b* proceeded readily in acetonitrile, but not in pyridine. We have no explanation for the pronounced influence of the solvent on the above cyclization reactions.

The structures of **8***a* and *b* were supported by the correct elemental analyses and molecular weights (Rast) and by i.r. and n.m.r. spectral data (see Table 2).

Whereas the lactam **8***a* was easily reduced by lithium aluminum hydride to the diamine **9**, no basic product was produced under the same conditions from **8***b*. Furthermore, attempts to prepare the parent (**8**, R = H, $n = 1$) system from **8***b*, by reductive removal of the benzenesulfonyl group with disodium naphthalenide (2), or by elimination of benzenesulfinic acid with sodium hydride (3) followed by borohydride reduction of the anticipated imine, were not

promising. The first procedure gave only a small amount[2] of a basic product, the second resulted in the formation of a stable insoluble (in dimethyl formamide) sodium salt. Further synthetic efforts in this area were discontinued.

The synthetic principles described above were extendable to the preparation of the first known 1,5-benzodiazonine derivative **8***c*, the structure of which was apparent from its elemental analysis, molecular weight, and spectral properties (see Tables 1 and 2).

Experimental

The melting points were determined in a Gallenkamp m.p. apparatus and are not corrected. 2-Nitrophenylacetic acid was purchased from the Aldrich Chemical Company.

2-(2-Nitrophenyl)ethanol

Ethyl-2-nitrophenylacetate (6), prepared from 2-nitrophenylacetic acid and ethanol containing sulfuric acid, was reduced to 2-(2-nitrophenyl)ethanol with sodium borohydride and aluminum chloride (7) in 80–85% yield (b.p. 105–110°/0.04 mm; lit. (8), b.p. 136°/2 mm). This alcohol can now be readily prepared in one step from 2-nitrotoluene and formaldehyde (9, 10).

2-(2-Nitrophenyl)ethyl Bromide (1)

2-(2-Nitrophenyl)ethanol (25.0 g, 150 mmol) and concentrated hydrobromic acid (125 ml, 47–49%) were maintained at gentle reflux for 2 h. The cooled mixture was diluted with water, the organic phase was separated, and combined with a dichloromethane extract of the aqueous phase. This solution was washed well with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was distilled *in vacuo* and the fraction (28.9 g, 84%), b.p. 85–93°/0.025 mm, was collected. The oil solidified spontaneously; it could be recrystallized from petroleum ether (b.p. 60–90°) at low temperature to give a solid m.p. 35–37° (lit. (4) m.p. 36–38°).

2-(2-Nitrophenyl)ethyl Azide (2)

Solutions of the above bromo compound (23.0 g, 100 mmol) in dimethyl sulfoxide (400 ml) and sodium azide (19.5 g, 300 mmol) in water (100 ml), were combined and heated on a steam bath for 6 h. The solution was diluted with water and extracted with benzene. The extract was washed well with water, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil (18.3 g, 95%; i.r. spectrum (neat), 2100 cm^{-1}) was used without purification.

2-(2-Nitrophenyl)ethyl Amine (3)

The conditions for this reduction were similar to those described by Horner and Gross (11).

A solution of the crude nitro azide (10.59 g, 55.1 mmol) and triphenylphosphine (14.43 g, 55.1 mmol) in anhydrous benzene (600 ml) containing several marble chips, was stirred at room temperature for 1 h, at 50° for 1 h, and at reflux temperature for 1 h. The solvent was removed *in vacuo*, acetic acid (180 ml) and concentrated hydrobromic acid (180 ml, 47–49%) were added to the residue, and the solution was heated at reflux temperature for 2 h. The solution was evaporated to a small volume *in vacuo*, water was added to the residue, and the mixture was extracted with dichloromethane. The aqueous phase was made basic with 2 *N* sodium hydroxide, the mixture was extracted with benzene, the extract was dried over sodium sulfate, and evaporated *in vacuo*. The residual, carbon dioxide sensitive, oil (7.42 g, 81%) gave a hydrobromide salt which had m.p. 159–161° after crystallization from acetonitrile.

N-Benzenesulfonyl-2-(2-nitrophenyl)ethyl Amine (4b)

To a stirred cooled solution of the crude nitro amine (7.42 g, 44.6 mmol) in dry pyridine (100 ml) was added benzenesulfonyl chloride (8.66 g, 49.1 mmol) at a rate such that the reaction temperature did not exceed 10°. After 14 h at 5° and 1 h at room temperature ice (10 g) was added to the solution and after an additional 1/2 h the solution was diluted with water and extracted with benzene. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was crystallized from 1:1 benzene:cyclohexane to give a solid, m.p. 85–86° (12.55 g, 92%) which contained a small amount of benzene of crystallization as shown by n.m.r. After drying for 24 h *in vacuo* at room temperature the sample still contained the same amount (1/12 mol) of benzene as shown by the n.m.r. spectrum and elemental analysis.

N-Methyl-2-(2-nitrophenyl)ethyl Amine (4a)

A solution of methylamine (31.0 g, 910 mmol) and 2-(2-nitrophenyl)ethyl bromide (23.0 g, 100 mmol) in acetonitrile (100 ml) contained in a pressure bottle, was maintained at 65 ± 5° for 21 h. The solvent was removed *in vacuo*, the residue was diluted with water, acidified with hydrochloric acid (10%), and then extracted with dichloromethane. The aqueous phase was made basic with sodium carbonate solution (200 g/l), the mixture was extracted with dichloromethane, the extract was dried over sodium sulfate and evaporated *in vacuo*. Evaporative distillation of the residue at 110–115°/0.25 mm gave a yellow oil (12.2 g, 68%). The hydrobromide salt was prepared in ether, and after crystallization from acetonitrile it had m.p. 171–173°.

Ethyl-N-2-(2-nitrophenyl)ethyl Sarcosinate (5a)

A solution of the secondary amine **4***a* (7.21 g, 40 mmol) and ethyl bromoacetate (6.70 g, 40.1 mmol) in acetonitrile (300 ml) containing anhydrous potassium carbonate (2.80 g, 20.3 mmol) was stirred at room temperature for 65 h. The mixture was evaporated *in vacuo*, water was added to the residue, this mixture was made basic with sodium carbonate solution (200 g/l) and then extracted with dichloromethane. The extract was shaken with 10% hydrochloric acid, the acid phase was made basic with sodium carbonate solution, and the liberated base was extracted into dichloromethane. The extract was dried over sodium sulfate, evaporated *in vacuo*, and the residual oil was evaporatively distilled at 120°/0.005 mm to give the product (8.04 g, 76%).

N-2-(2-nitrophenyl)ethyl Sarcosine Hydrobromine (6a)

A solution of the ester **5**a (8.04 g, 30 mmol) in concentrated hydrobromic acid (160 ml, 47–49%) was

[2]A basic substance (*ca.* 5%, m.p. 148–149°), which had i.r. absorptions ($CHCl_3$) at 3520, 3458, 3420, and 1686 cm^{-1}, was obtained. It was not investigated further.

For personal use only.

heated at gentle reflux for 16 h, and then reduced to a small volume *in vacuo*. The residual oil was taken up in acetonitrile and the solution was evaporated *in vacuo*. This procedure was repeated until the water was removed and a crystalline residue remained. The solid was crystallized from acetonitrile to give the product with m.p. 155–170° (dec.) (9.39 g, 92%). In spite of the wide melting range this material did not require further purification for use in the next step. Two crystallizations of this solid from acetonitrile raised the melting point to 170–172° (dec.).

4-Methyl-1,2,3,4,5,6-hexahydro-1,4-benzodiazocin-2-one (8a)

The above amino acid salt (9.39 g, 29.5 mmol) in ethanol (200 ml) containing palladium-on-charcoal (900 mg, 10%) was hydrogenated at room temperature and an initial hydrogen pressure of 45 p.s.i.g. After 1 h, the catalyst was removed by filtration through Celite, and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in dry pyridine (900 ml), the solution was cooled with stirring to 0°, and a solution of DCC (6.1 g, 29.6 mmol) in pyridine (40 ml) was added all at once. After 1 h at 0° and 48 h at room temperature, the mixture was filtered, the filtrate was evaporated *in vacuo*, the residue thus obtained was slurried with 10% hydrochloric acid and filtered. The filtrate was extracted with ether, the aqueous phase was made basic with sodium carbonate solution (200 g/l), and the base was extracted into dichloromethane. The extract was dried over sodium sulfate, evaporated *in vacuo*, and the residue was crystallized from cyclohexane containing a small amount of benzene. A white solid m.p. 103–105° (3.33 g, 59%) was obtained.

N-Benzenesulfonyl-N-2-(2-nitrophenyl)ethyl Glycine (6b)

Sodium hydride (1.92 g of a 55% dispersion in mineral oil) was washed free of the carrier with hexane and layered with dry dimethylformamide (125 ml). The solid benzenesulfonamide **4***b* (12.25 g, 40 mmol) was added portionwise over a 10 min period at 0° and then the solution was stirred at room temperature until hydrogen evolution was slow. Ethyl bromoacetate (6.68 g, 40 mmol) was then added at a rate such that the reaction temperature did not exceed 10°. The solution was then stirred at room temperature for 1 h, diluted with water, and extracted with benzene. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The oily ester (15.2 g, i.r. spectrum (neat) 1748 cm^{-1}) was saponified without purification.

A solution of the crude ester (4.95 g, 12.62 mmol) in 50% aqueous methanol (50 ml), which was 0.5 *N* in sodium hydroxide, was heated at reflux temperature for 4.5 h, the methanol was removed *in vacuo*, and the residue was diluted with water and extracted with benzene. The aqueous phase was made acidic with concentrated hydrochloric acid, extracted with dichloromethane, the extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue on crystallization from 50% aqueous ethanol gave 2.24 g (49%) of a solid, m.p. 145–147°.

4-Benzenesulfonyl-1,2,3,4,5,6-hexahydro-1,4-benzodiazocin-2-one (8b)

The above nitro acid (5.12 g, 14.1 mmol) was hydrogenated as before and the crude dried amino acid was dissolved in 800 ml of dry acetonitrile. Dicyclohexylcarbodiimide (2.90 g, 14.1 mmol) was added all at once to the stirred solution and after 18 h at room temperature the mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was slurried with acetonitrile (50 ml) filtered, the filtrate was evaporated *in vacuo* and the residue was crystallized from benzene. The product, m.p. 95–100° then solidifying and remelting at 172–173°, crystallized as the mono benzene solvate (4.32 g, 78%) as shown by n.m.r. A sample which was dried at 100° *in vacuo* for 18 h had m.p. 173–174° and was shown to be solvent free by n.m.r.

Ethyl-N-methyl-N-2-(2-nitrophenyl)ethyl-β-alanate (5c)

Ethyl acrylate (3.5 g, 35 mmol) was added at 0° to a solution of the methyl secondary amine **4***a* (6.13 g, 34 mmol) in absolute ethanol (35 ml). The solution was then left at room temperature for 65 h, the solvent was removed *in vacuo* and the residue was evaporatively distilled at 125°/0.005 mm to give a clear yellow oil (9.37 g, 98%). The acid oxalate was prepared in ethanol, and after crystallization from the same solvent it had m.p. 134–136°.

N-Methyl-N-2-(2-nitrophenyl)ethyl-β-alanine Hydrobromide (6c)

The amino ester (2.67 g, 9.53 mmol) in concentrated hydrobromic acid (55 ml, 47–49%) was heated at gentle reflux for 13 h. The amino acid hydrobromide was isolated in the manner described for **6***a*. Upon crystallization from acetonitrile, a solid, m.p. 183–186°, was obtained (2.85 g, 91%). Two crystallizations gave material with m.p. 184–186°.

5-Methyl-2,3,4,5,6,7-hexahydro-1H-1,5-benzodiazonin-2-one (8c)

The above amino acid hydrobromide (9.62 g, 28.8 mmol) was hydrogenated in the usual manner and a solution of the crude diamine in dry pyridine (900 ml) was treated at 0° with DCC (6.0 g, 29.1 mmol) in pyridine (100 ml) as before. After 1 h at 0° and 70 h at room temperature the reaction was worked-up as for **8***a*. A thick oil, which solidified on standing, was obtained. This material was extracted with boiling cyclohexane (2 × 100 ml), the hot solution was treated with charcoal, filtered, and evaporated *in vacuo*. The residue was crystallized from cyclohexane to give a solid (1.57 g), m.p. 99–102°. The cyclohexane insoluble residue from above and the mother liquor from the above crystallization were combined, evaporated to dryness *in vacuo*, and the residue was sublimed at 90–100°/0.001 mm. The sublimate (0.49 g) had m.p. 99–102°. The total yield of product was 29.5% of the theoretical.

4-Methyl-1,2,3,4,5,6-hexahydro-1,4-benzodiazocine (9)

A solution of the lactam **8***a* (1.193 g, 6.27 mmol) in anhydrous ether (250 ml) was added dropwise during a 1/2 h period to a stirred suspension of lithium aluminum hydride (1.2 g) in ether (50 ml). After 17 h at reflux temperature the excess hydride was destroyed at 0° by the cautious addition of water. The ether was decanted, combined with two ether washings of the solids, dried over sodium sulfate and evaporated *in vacuo*. The residue was evaporatively distilled at 95–105°/0.001 mm to give a colorless oil (0.902 g, 82%).

The high temperature (100°) n.m.r. spectrum of **8***b* was measured at the Chemistry Department, McGill University, Montreal, Quebec. We are grateful to Dr. K. Valentin for providing us with this service.

11-Hydroxy-*trans*-8-dodecenoic Acid Lactone, a 12-Membered-Ring Compound from a Fungus

R. F. VESONDER, F. H. STODOLA, L. J. WICKERHAM, J. J. ELLIS, AND W. K. ROHWEDDER

Northern Regional Research Laboratory, Agricultural Research Service, United States Department of Agriculture, Peoria, Illinois 61604

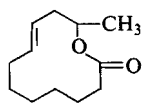
Received January 26, 1971

The 12-membered lactone of 11-hydroxy-*trans*-8-dodecenoic acid is formed when the fungus *Cephalosporium recifei* NRRL 5161 is grown on glucose solution.

On a observé que la lactone à douze chaînons de l'acide hydroxy-11 dodécèn-8-*trans*-oïque se forme lorsque l'on fait croître les champignons du *Cephalosporium recifei* NRRL 5161 dans des solutions de glucose.

Canadian Journal of Chemistry, 49, 2029 (1971)

Naturally occurring large-ring lactones were first described by Kerschbaum (1) in 1927. Since that time many more examples of this class of compounds have appeared, most of them macrolides. We now report the isolation of the monocyclic lactone **1** from a fungus.



1

The organism appears to belong to the group *Cephalosporium recifei*, based on morphological studies and production of yellow pigment. The fungus was grown for 35 days on a shaken malt–glucose medium. Ether extraction of the whole culture liquor gave an average of 1.7 g of a viscous yellow oil *A* per liter of culture liquor. Hexane extraction of *A* at room temperature gave a 14% yield of nonpolar oil *B*, silicic acid column purification of which yielded a colorless mobile liquid *C* (77%), shown by g.l.c. to be 95% **1**. Pure lactone **1** was obtained from fraction *C* in about 50% yield by preparative g.l.c.

The structure of **1** was established as follows: elementary analyses and the molecular ion peak of *m/e* 196 corresponded to a formula of $C_{12}H_{20}O_2$. The i.r. spectrum showed a band at 1735 cm^{-1}, indicative of either a lactone or an ester, and a band at 975 cm^{-1}, characteristic of a *trans* double bond. That the double bond was unconjugated was evident from the u.v. spectrum (end absorption only). Chemical studies are summarized in Scheme 1.

It was first established that **1** is a lactone, rather than an ester, by saponification to **3**, which was shown to be a 12-carbon acid by elementary analysis of its phenacyl derivative **4**.

Next, the size of the lactone ring was determined. The optical activity of **1** ($[\alpha]_D^{25}$ + 73.2°) required substitution on the lactone ring. The nature and the position of the substituent were arrived at by CrO_3 oxidation of **5** to the keto acid **6**, which gave iodoform and the acid **7** on treatment with hypoiodite.

Finally, the position of the double bond in **1** was ascertained by oxidation procedures (ozonolysis and $KMnO_4$–HIO_4), which led to 3-hydroxy-butyric acid (**8**) and suberic acid (**9**), both characterized as their benzhydrylamine salts.

Information on the mass spectra of simple large-ring lactones appears to be meagre, the only two compounds studied so far being cyclopentadecanolide and 12-stearolactone (2). In our work the fragmentation patterns appear to be compatible with the assigned structures. The low resolution spectra of **1** (Fig. 1) and its dihydro derivative **2** (Fig. 2) are plotted along with the atomic compositions (determined by high resolution peak matching). Large peaks occur in the spectrum of **1** at 152 and 98, due probably to rearrangements involving opening of the lactone ring and cleavage at the C_{10}—C_{11} bond to form the 152 peak and cleavage at the C_6—C_7 bond to give the 98 peak.

The 152 peak of **1** also shifts two mass units higher to 154 in **2**, while the 98 peak of **1** at the carbonyl end of the molecule remains at 98 in **2**.

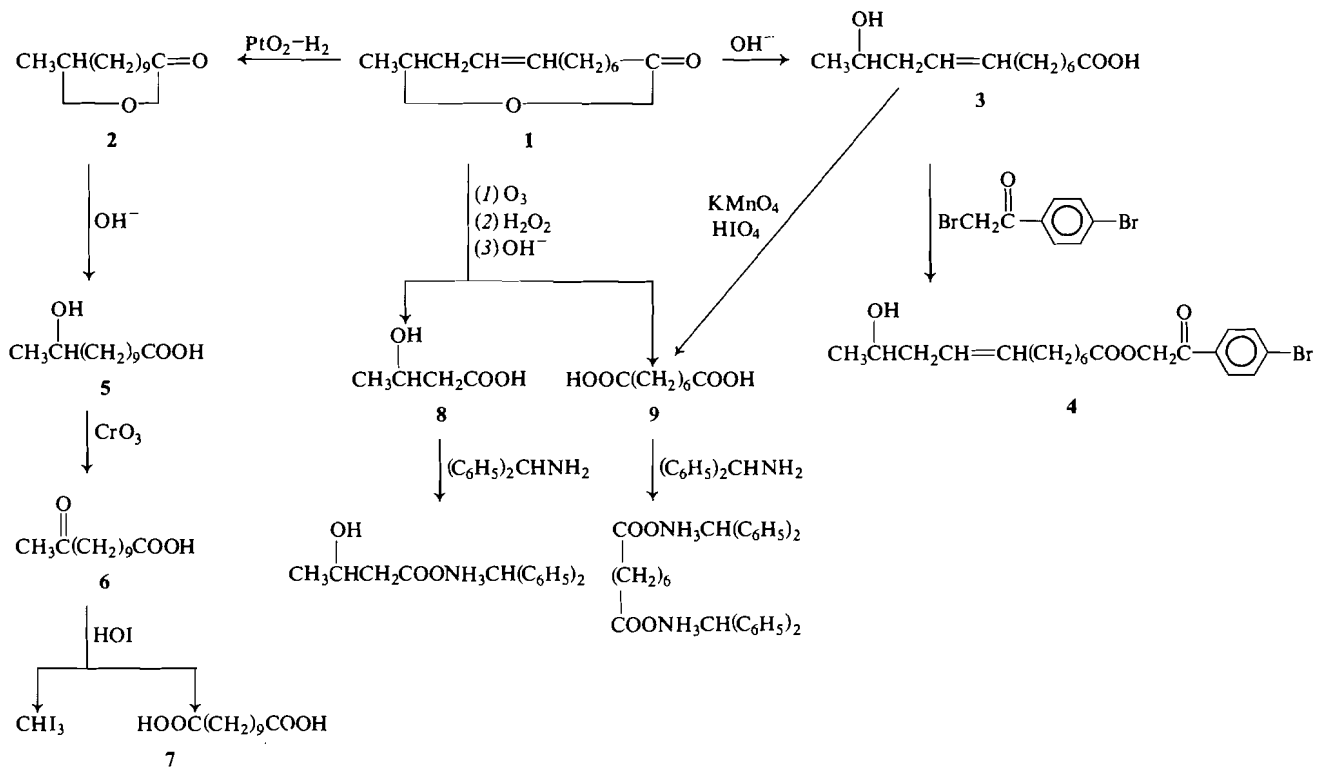

SCHEME 1

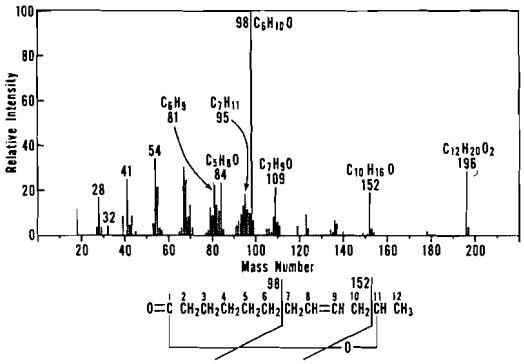

FIG. 1. Mass spectrum of lactone of 11-hydroxy-*trans*-8-dodecenoic acid (**1**).

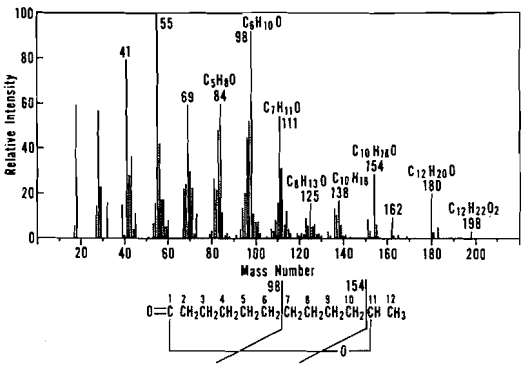

FIG. 2. Mass spectrum of lactone of 11-hydroxydodecanoic acid (**2**).

The 98 peak is the most intense peak in **1**, being three times the next highest peak; it is due to the weakening of the C_6—C_7 bond beta to the C_8—C_9 double bond. When the double bond is reduced, this cleavage is less selective and peaks appear at 84, 98, and 112 in **2**.

The mass spectrum, not shown, of the methyl ester of **3** had peaks at mass 74, 88%, and 87, 52%, characteristic of methyl esters. The molecular weight of the methyl ester is 228, but its spectrum did not show a molecular ion peak. Peaks were found at 210, 9%, due to loss of water; 184, 20%, due to loss of C_2H_4O; and at 152, 62%, due to further loss of methanol from the 184 peak. The loss of water, cleavage at the carbon-to-carbon bond adjacent to the OH, and the further loss of methanol from the chain cleavage fragment are all well-characterized fragmentations of methyl hydroxy esters, and these particular mass numbers indicate that the OH is on C-11 (3).

The simple large-ring lactones have found commercial application as fixatives in perfumes; this usage has stimulated considerable interest in their synthesis and properties (4).

Experimental

Melting points were determined on a Fisher–Johns[1] apparatus and are uncorrected. The i.r. spectra were recorded on Perkin–Elmer (Model 137) and Beckman (Model IR8) spectrophotometers. The g.l.c. analyses were carried out in a Packard 7401 gas chromatograph equipped with dual columns and independent flame-ionization detectors. Two columns were used: (*1*) 12 ft × 1/4 in.; 5% LAC-2-R 446 on Chromosorb W AW-DMCS; (*2*) 4 ft × 1/4 in., 5% Apiezon L on Chromosorb W AW-DMCS. The temperature of the inlet was 200 °C and that of the column oven was 190 °C. An Aerograph (Model 1520) gas chromatograph, equipped with a thermoconductivity detector, was used for preparative g.l.c. The column (6 ft × 1/4 in. stainless steel) was packed with 20% DEGS on 60/80 AW firebrick, and the temperature was maintained at 150 °C.

Mass spectra were measured on a Nuclide 1290 DF double focusing, high-resolution mass spectrometer operated with a 4460 V accelerating potential and at 70 V electron energy. The high-resolution mass determinations were made with a peak matching system based on using perfluorokerosene as an internal standard. The samples were run in an all-glass inlet at 200 °C.

The n.m.r. spectra were measured in a Varian HA-100 spectrometer and the u.v. was recorded with a Cary 14 spectrophotometer.

The Organism

The fungus was isolated in August 1960 from frass taken from the inside of a dead deciduous tree on the Livingston Ranch near Walker, Louisiana. It is designated as NRRL 5161 in the ARS Culture Collection here, and is judged to be a strain of *Cephalosporium recifei* on the basis of the following cultural characteristics: colonies on wheat germ agar and Czapek agar were white with a faintly pink center; on synthetic mucor agar the colonies became golden yellow with a white margin, and on malt extract agar and potato dextrose agar their color was dull yellow–orange. Long tapering phialides typically formed on the substrate hyphae. On most media small synnema were present, from which phialides also arose. Phialides were usually single or branched, and less frequently were verticillate. Conidia were borne in moist, colorless heads and were typically ellipsoidal and curved. They measured (2) 3–7 μ (9) in length and 1–3 μ (4) in width. Because of the yellow color, the strain is assigned to the *Cephalosporium recifei* group, as described by Sukapure and Thirumalachar (5).

Production of Crude Lactone A

The stock culture of the fungus was maintained on YM

agar slants (1% glucose, 0.5% peptone, 0.3% yeast extract, 0.3% malt extract, and 2% agar). A sterilized liquid medium (200 ml), consisting of 5% commercial glucose hydrate and 2% malt extract contained in 500-ml Erlenmeyer flasks, was inoculated with 0.1 ml of a cell suspension prepared from a 4-day-old YM slant culture and 1 ml of sterile distilled water. The flasks were incubated at 25 °C on a Gump shaker (180 r.p.m.; 1 in. radius). After 35 days growth the culture liquor was extracted with ether to give about 1.7 g of yellow viscous oil *A* per liter of medium.

*Isolation of Lactone of 11-Hydroxy-trans-8-dodecenoic Acid (**1**)*

Hexane extraction of oil *A* (10.0 g) at room temperature yielded 1.4 g of oil *B*, a portion (506 mg) of which was chromatographed on silicic acid (Bio-Sil A, 20 g), the eluting solvent being hexane–ether (95:5). The main fraction *C* (391 mg) was shown by g.l.c. to be 95% **1**; preparative g.l.c. of 167 mg *C* gave 88 mg of pure lactone of 11-hydroxy-*trans*-8-dodecenoic acid (**1**), a colorless mobile liquid, $[\alpha]_D^{25}$ +73.2° (*c*, 7.5, $CHCl_3$).

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.7; H, 10.4.

The u.v. spectrum: end absorption only. The i.r. spectrum (neat): 3010 (sh), 2978 (s), 2935 (s), 2850 (s), 1735 (s), 1450 (m), 1365 (m), 1225 (s), 975 cm^{-1} (s). The n.m.r. spectrum: doublet at δ 1.2 (methyl group attached to a carbon with one proton), 5.3 (two vinyl protons). Mass spectrum (Fig. 1): *m/e* 196 ($C_{12}H_{20}O_2$; found 196.1450, calcd. 196.1463).

*$KMnO_4$–HIO_4 Oxidation of 11-Hydroxy-trans-8-dodecenoic Acid (**3**)*

Fraction *C* (122 mg) refluxed 3 h with alcoholic KOH yielded 91 mg of hydroxy acid **3**, 47 mg of which was subjected to a von Rudloff (6) oxidation. The main product (26 mg) was shown by g.l.c. to consist of about 80% suberic acid. Identity was further established by conversion of 14 mg to the bisbenzhydrylamine salt (7) (28 mg; m.p. 172–174 °C), which was indistinguishable from an authentic sample.

*Ozonolysis of Lactone of 11-Hydroxy-trans-8-dodecenoic Acid (**1**)*

Ozone was passed for 45 s through a solution of fraction *C* (115 mg) in 5 ml ethanol and 1 ml ethyl acetate at 0 °C. The reaction mixture was taken to dryness, heated for 1 h at 95° with formic acid (98%, 3 ml) and H_2O_2 (30%, 0.2 ml), and kept overnight at room temperature. After additional heating (95 °C) for 35 min, the mixture was concentrated to 149 mg of oil, which was refluxed for 1 h with alcoholic KOH. Acidification and continuous ether extraction gave a first fraction of crude suberic acid (**9**) (44 mg; m.p. 133–138 °C). (Recrystallization: 26 mg, m.p. 140–142 °C; identity established by i.r. and mixture m.p.).

The second ether extract gave 65 mg of a semisolid. The third extract left 15 mg of oil ($[\alpha]_D^{25}$ −32° (*c*, 1, $CHCl_3$)), which was converted to the benzhydrylamine salt of **8** (m.p. 139–140 °C) the i.r. of which was identical with that of the corresponding salt prepared from *d,l*-3-hydroxybutyric acid.

*Hypoiodite Oxidation of 11-Ketododecanoic Acid (**6**)*

On hydrogenation (PtO_2; ethyl acetate), fraction *C* (101 mg) gave 67 mg of pure (g.l.c.) **2** (mass spectrum (Fig. 2): *m/e* 198 ($C_{12}H_{22}O_2$; found 198.1589; calcd. 198.1619). Saponification yielded 58 mg of hydroxy acid **5**, which was oxidized in 1 ml acetic acid with 0.56 ml of 0.53 *N* CrO_3–CH_3COOH for 1 h. When the resulting keto acid (57 mg) was subjected to the haloform reaction, it yielded 20 mg of iodoform, m.p. 123–124 °C. Ether extraction of the acidified reaction mixture gave 56 mg of solid, which g.l.c. analysis showed to be 48% 1,9-nonanedicarboxylic acid (**7**) and 62% unreacted 11-ketododecanoic acid (**6**).

*p-Bromophenacyl-11-hydroxy-trans-8-dodecenoate (**4**)*

11-Hydroxy-*trans*-8-dodecenoic acid (**3**) (18.5 mg) was converted to the *p*-bromophenacyl ester in acetone (15 min at 95°) by the dicyclohexylethylamine procedure (8). The crude product (22 mg; m.p. 60–68 °C) on crystallization from acetone–hexane gave 12 mg of *p*-bromophenacyl-11-hydroxy-*trans*-8-dodecenoate (**4**) (m.p. 73–74 °C).

Proton Magnetic Resonance Studies of Rotational Isomerism in Halotoluenes VIII. Stereospecific ^1H–^{19}F Coupling Constants and Conformations of some Fluoro and Chloro Derivatives of Benzalchloride

H. M. HUTTON, J. B. ROWBOTHAM, B. H. BARBER, AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received January 26, 1971

In solution the 2-fluoro-5-chloro-, 2-fluoro-6-chloro-3-nitro-, 2-fluoro-6-chloro-5-nitro-, and 2,4,5-trichloro-benzalchlorides prefer conformations in which the C—H bond of the side-chain lies in the plane of the aromatic ring. This C—H bond eclipses that ortho C—X bond (X = H, F, Cl) in which X is smaller than Y = H, F, Cl in the C—Y bond, also ortho to the dichloromethyl group. The long-range spin–spin coupling constants between the proton in the side-chain and the ring protons or fluorine nucleus are stereospecific. In particular, the coupling over four bonds between the side-chain proton and the ring fluorine is −0.3 Hz when the C—H and C—F bonds are arranged *cis* to each other but is −2.5 Hz when these bonds have a *transoid* planar arrangement.

En solution, la conformation privilégiée des fluoro-2 chloro-5, fluoro-2 chloro-6 nitro-3, fluoro-2 chloro-6 nitro-5 et trichloro-2,4,5 dichlorométhylbenzènes correspond à celle dans laquelle le lien C—H de la chaîne latérale est dans le plan du noyau aromatique. Ce lien C—H éclipsera plutôt le lieu ortho C—X (X = H, F, Cl) dans lequel X sera plus petit que Y = H, F, Cl du lien C—Y aussi ortho au groupe dichlorométhyle. Les constantes de couplage à longue distance entre le proton de la chaîne latérale et les protons ou les fluors du cycle sont stéréospécifiques. En particulier on peut noter que le couplage à travers quatre liaisons entre le proton de la chaîne latérale et le fluor du cycle est de −0.3 Hz quand le C—H et le C—F sont *cis* l'un par rapport à l'autre alors que cette constante est de −2.5 Hz quand ces liens sont dans un arrangement planaire *transoïde*.

Canadian Journal of Chemistry, 49, 2033 (1971)

Introduction

The primary purpose of this paper is the demonstration of **1***a*, **2***a*, **3***a*, and **4***a*, as opposed to **1***b*, **2***b*, **3***b*, and **4***b*, as the stable conformations in solution of 2-fluoro-α,α,5-trichlorotoluene (**1**), of 2-fluoro-3-nitro-α,α,6-trichlorotoluene (**2**), of 2-fluoro-5-nitro-α,α,6-trichlorotoluene (**3**), and of α,α,2,4,5-pentachlorotoluene (**4**), respectively. The demonstration depends mainly on the observed magnitudes of the long-range spin-spin coupling constants over five bonds between the methine proton and the ring protons, $J_m^{H,CHCl_2} \equiv {}^5J_m(\alpha,H)$. Semiempirical barrier calculations based on modified Buckingham and on van der Waals potential functions are compared with the conformational data. In addition, the four-bond couplings, $J_o^{F,CHCl_2}$, are shown to be negative and highly stereospecific.

Experimental

(1) Preparation of Compounds

Compound **1** was prepared by free radical chlorination of 2-fluoro-5-chlorobenzylchloride in a manner described previously (1) for the preparation of α,α,2,4,6-pentachlorotoluene. Compounds **2** and **3** were prepared by nitration under mild conditions of 2-chloro-6-fluorobenzalchloride. Compounds **2** and **3** were not separated but were isolated as a mixture by distillation, following separation from the aqueous layer.

(2) Proton Magnetic Resonance Spectra

Degassed samples of **1** as a 30 mol % solution in toluene-d_8, of an approximately 5:1 mixture of **2** and **3** as a 30 vol % solution in toluene-d_8, and of **4** as a 25 vol % solution in carbon disulfide, also contained internal TMS as internal reference. Spectra were calibrated by period-averaging techniques on a DA-60I spectrometer operated in the frequency sweep mode. In solution the proton spectra of **2** and **3** overlap but the transitions do not coincide so that their spectra can be analyzed reliably.[1] In addition the methine proton resonance of a 20 mol % solution of 2-fluoro-α,α,6-trichlorotoluene in toluene-d_8 was examined between −105 and 60 °C on an HA100-D spectrometer.

Relative sign determinations were made by the usual double and triple resonance experiments.

Results and Discussion

(1) Analysis of Spectra

Spectral analyses by LAOCOON3 (2) gave the values in Table 1. In an attempted evaluation of

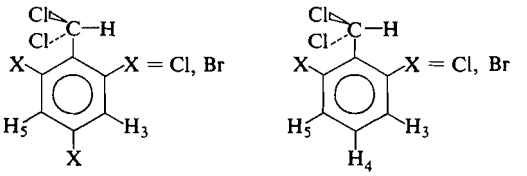
errors in the parameters, as given by LAOCOON3, lay between 0.001 and 0.014 Hz.

(2) The Long-range Coupling $^5J(\alpha,H)$ and Conformations

Potential energy calculations (3, 4) demonstrate that **5** and **6** are the stable conformers of these molecules and p.m.r. measurements (1, 5)



5 6

show that $^5J(\alpha,5) = 0.5$ Hz while $^5J(\alpha,3) \leq 0.1$ Hz (stereospecific couplings of similar magnitude over five bonds involving aldehydic (6), hydroxyl (7), and amino protons (8, 9) in aromatic systems demonstrate their preponderant dependence on geometry instead of on hybridization or on the nature of the side-chain atoms). Now $^5J(\alpha,H) \leq 0.05$ Hz in **1**, **2**, and **4** but $^5J(\alpha,H) = 0.4$ Hz in **3** (see Table 1). Therefore the *a* forms of these molecules are more stable than the *b* forms.

(3) Potential Energy Calculations

Potential energy calculations based on a van der Waals function (3, 4) predict that **2***a* and **3***a* are more stable than **2***b* and **3***b* by about 3 kcal/mol. Consequently the absence of any observable coupling from the side-chain proton to the meta proton in **2** is entirely reasonable. Similar conclusions hold for **4***a* and *b*. Calculations (3) based on a modified Buckingham potential suggest that **1***a* is more stable than **1***b* by about 1 kcal/mol, in only qualitative agreement[2] with the observed $^5J(\alpha,H) = 0.05$ Hz.

(4) Torsional Oscillations and $^4J(\alpha,H)$, $^6J(\alpha,H)$

The potential energy computations also indicate that torsional oscillation about the equilibrium position (C—H_α in plane) is largest for **1***a* and smallest for **2***a* and **3***a*. It is generally accepted (10, 11) that negative π electron contributions to $^4J(\alpha,H)$ and $^6J(\alpha,H)$ are smallest when the C—H_α bond lies in the plane of the ring and are largest when this bond lies parallel to the pπ orbital on the bonded ring carbon atom. The value for $^6J(\alpha,H)$ is -0.16 Hz in **1** but is undetectably small in **2** or **3**. These facts are in agreement with the potential energy calculations, which indicate substantially larger torsion angles about the sp^2–sp^3 carbon–carbon bond in **1** than in **2** or **3**. Because the difference in coupling constants is small and because the two substituents on the side-chain can affect (10) the magnitude of the π contribution to $^6J(\alpha,H)$ in a complex way, a quantitative treatment of the torsion angles will not be attempted.

The $^4J(\alpha,H)$ value is -0.4 Hz in **1** and **4**, suggesting a negative σ contribution to this coupling in conformations **1***a* and **4***a* because the negative π contribution should not differ by more than 0.1 Hz (12–15) for $^4J(\alpha,H)$ and $^6J(\alpha,H)$.

(5) The Stereospecificity of $^4J(\alpha,F)$

In *cis*-1-fluoropropene (16), pentafluorobenzaldehyde (17), pentafluorotoluene (17), 2-fluoro-4-iodo-5-nitrotoluene (18), and 2-fluoro-3-methylpyridine (19), the coupling over four bonds, $^4J(\alpha,F)$, lies between $+1$ and $+3$ Hz. Previous work (18, 19) indicates a positive π electron contribution to this coupling. In contrast to the above molecules, $^4J(\alpha,F) = -0.3$ Hz in **1***a* with a *cisoid* arrangement of the C—H_α and the C—F bonds while $^4J(\alpha,F) = -2.5$ Hz in **2***a* and **3***a* where the two bonds are in a planar transoid arrangement.

In the planar configuration the π contribution is small (10) so that a negative σ electron contribution to $^4J(\alpha,F)$ remains as the explanation for the large negative value observed in **2***a* and **3***a*. Scale drawings based on standard geometries give an internuclear H_α—F distance of 2.35 Å for a planar arrangement in **1***a*, indicating an overlap of 0.2 Å of the H_α and F atoms. It is therefore possible that in **1***a* there is a substantial positive "through-space" component (20–23) in $^4J(\alpha,F)$, thereby accounting for its smaller magnitude in this molecule. Alternative rationalizations would invoke a difference in the negative σ contribution to $^4J(\alpha,F)$ in the *cisoid* and *transoid* coupling path or an appreciably larger torsion angle in **1***a* with a larger positive π contribution to $^4J(\alpha,F)$ in this molecule.

[2]Calculations (3) using a van der Waals potential suggest the opposite and are presumably wrong. Mannschreck and Ernst, in a private communication, demonstrate that optimization of the molecular geometry for each rotational angle about the sp^2–sp^3 carbon–carbon bond yields reliable ground state energy differences between conformers.

(6) Temperature Studies on 2-Chloro-6-fluorobenzalchloride

The p.m.r. spectrum is very complex even in toluene-d_8 solution at 100 MHz. But a 2.6 Hz splitting of the H_α resonance, arising from coupling to fluorine over four bonds as in **2** or **3**, is evident in this solution (in contrast to other solvents where the H_α resonance occurs in the ring proton region). This splitting remains constant at 2.6 $\pm$ 0.2 Hz between -105 and 60 °C at 100 MHz. Comparison with the data for **2** and **3** suggests that the conformation analogous to **2***a* and **3***a* is the predominant one over this temperature range and, by comparison with $^4J(\alpha,F)$ for **1**, that the calculated energy difference of 3 kcal/mol between the two planar conformations of **2** and **3** is at least semiquantitatively correct.

(7) Chemical Shifts and Coupling Constants in the Ring

The spectra were taken in toluene-d_8 where the aromatic solvent induced shifts resulted in spectra amenable to analysis and to unequivocal multiple resonance experiments. The observed proton chemical shifts are similar to those discussed recently for numerous benzene derivatives dissolved in benzene-d_6 (24). The coupling constants between ring protons and between ring protons and the fluorine nuclei follow the regularities summarized by Wasylishen and Schaefer (25).

A Semi-theoretical van der Waals Equation for Calculation of Vapor–Liquid Equilibria at High Pressures

J. H. VERA[1] AND J. M. PRAUSNITZ

Department of Chemical Engineering, University of California, Berkeley, California

Received January 12, 1971

An equation of the van der Waals type is derived and applied to the calculation of vapor–liquid equilibria at elevated pressures. For the hard-sphere part of the equation the theoretical relation of Carnahan–Starling is used. The effect of intermolecular forces is represented by the usual van der Waals term but the "constant a" is permitted to vary with temperature and density as dictated by the experimental PVT data for argon; this variation of the "constant a" is generalized for other simple fluids through corresponding states. While this treatment is of little interest for representing the configurational properties of pure fluids, it is useful for calculating the properties of simple fluid mixtures. Illustrative vapor–liquid equilibrium calculations are performed for binary and ternary mixtures of nitrogen, argon, and oxygen at 6 and 18 atm.

On déduit une équation de type van der Waals qu'on applique au calcul des équilibres liquide–vapeur aux pressions élevées. Pour la partie sphère rigide de l'équation, on utilise la relation théorique de Carnahan–Starling. L'effet des forces intermoléculaires est représenté par le paramètre habituel de van der Waals, mais la "constante a" est ajustable en fonction de la température et de la densité comme l'exigent les données PVT expérimentales pour l'argon; par les états correspondants on généralise aux autres fluides simples cette variation de la "constante a". Le présent traitement présente peu d'intérêt pour la représentation des propriétés configurationnelles des fluides purs, par contre il est utile pour le calcul des propriétés des mélanges de fluides simples. A titre d'exemple, on a effectué des calculs d'équilibre liquide–vapeur pour des mélanges binaires et ternaires d'azote, d'argon et d'oxygène, à 6 et 18 atm.

Canadian Journal of Chemistry, 49, 2037 (1971)

In recent years extensive work has been done on the theory of simple fluids (1–6). It has been shown that the structure of a real fluid is similar to that of a hard-sphere fluid; that is, the distribution of molecules in space is determined primarily by the molecule's repulsive forces while the attractive forces may be considered to produce a uniform potential field which holds the molecules together. This view is remarkably similar to that proposed by van der Waals 100 years ago and therefore several modern theories of fluids and fluid mixtures are called "augmented" or "modified" van der Waals theories.

In this work we discuss a semi-theoretical treatment of simple mixtures which extends the work of Snider and Herrington (7). Unlike most previous work, our treatment is not limited to liquids at low pressures but is applicable also to high pressure vapor–liquid equilibria, including the critical region. Further, our treatment is in analytical form which is useful for implementation on an electronic computer.

[1]Present address: Universidad Técnica del Estado, Santiago, Chile.

Equation of State and Chemical Potential

Pure Component

The compressibility factor z of a pure fluid is given by an expression of the van der Waals type

$$[1] \qquad z = \frac{Pv}{RT} = z^{HS} - \frac{a}{RTv}$$

where z^{HS} is the compressibility factor of a hard-sphere fluid at temperature T and molar volume v. The van der Waals a is a constant only in the zeroth approximation (8); it depends on both temperature and volume.

For z^{HS} we use the theoretical expression of Percus and Yevick as modified by Carnahan and Starling (9)

$$[2] \qquad z^{HS} = \frac{1 + \xi + \xi^2 - \xi^3}{(1 - \xi)^3}$$

with

$$[3] \qquad \xi = b/4v$$

and $b = (2/3)\pi N_A \sigma^3$, where N_A is Avogadro's number and σ is the molecular diameter.

To find a, we use a reduced version of a highly accurate empirical equation of state proposed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Strobridge for nitrogen (10) and used also by Gosman for argon (11). This equation is of the form

$$[4] \qquad z^{SG} = z(T_R, v_R)$$

where the reduced temperature $T_R = T/T_c$ and the reduced volume is v/v_c; subscript c stands for critical and superscript SG for Strobridge–Gosman. Details of the reduced equation of state (based on the properties of argon) are given in Appendix 1. From eq. 1 we have

$$[5] \qquad a = RTv[z^{HS} - z^{SG}]$$

where z^{SG} is found from eq. 4 and z^{HS} from eq. 2.

Since eq. 5 has not incorporated any new information, for a pure component z calculated from eq. 1 is identical to z^{SG} calculated from eq. 4. Consequently the chemical potential of the pure component is just the one obtained from the generalized Strobridge–Gosman expression, eq. 4, and given in Appendix 1. The main practical advantage of eq. 5 as a complement to eq. 1 follows from extension to mixtures as discussed in the next section.

For a fluid at a particular T and v, the value of the van der Waals a depends on the value of σ as used in eq. 2. It is not at all obvious how to obtain the best, or most representative, value of σ from reduction of experimental data.

Our purpose is to write equations in terms of macroscopic parameters suitable for practical mixture calculations. We therefore define a proportionality factor L

$$[6] \qquad b = b/4 = Lv_c$$

Equation 3 then becomes

$$[7] \qquad \xi = L/v_R$$

Unfortunately, the value of a is very sensitive to the value chosen for L. Using the values of σ reported by Snider and Herrington (7) for simple fluids in the dense region, we obtain values for L in the range 0.15 to 0.18.

These values are about 40% larger than that obtained by Dymond and Alder (12, 13) from high-density, high-temperature volumetric data for argon. The results of Dymond and Alder suggest that $L = 0.116$. We find that when $L = 0.116$, we obtain smooth behavior of the van der Waals a when plotted against reduced density and reduced temperature as shown in Fig. 1. At very high densities a is negative, suggesting that

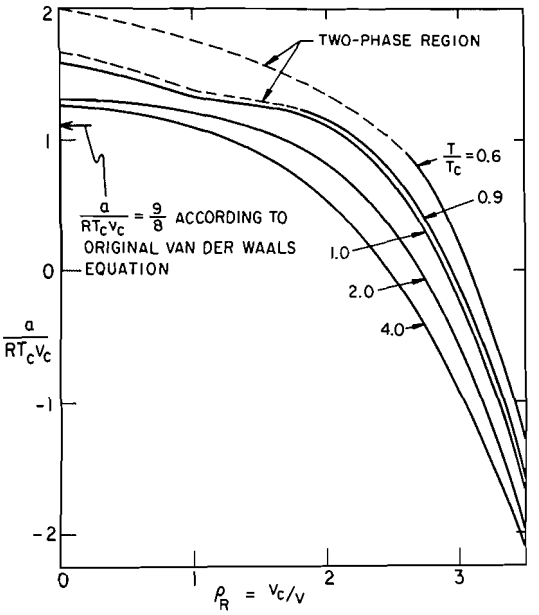

FIG. 1. Reduced van der Waals a as determined from Carnahan–Starling equation for z^{HS} and properties of argon (σ = 3.02 Å).

our value of L may be too low. However, larger values of L tend to give erratic plots of van der Waals a.

The large effect of the numerical value of L on the van der Waals a is illustrated in Fig. 2 which presents reduced values of a for argon at two temperatures. We see that the qualitative as well as quantitative variation of a with density is changed when L is increased from 0.116 to 0.150.

Mixtures

For a multicomponent mixture, following the original van der Waals suggestion, we write

$$[8] \qquad z_m = z_m^{HS} - \frac{\sum_{j,l} x_j x_l a_{jl}}{RTv_m}$$

where subscript m stands for mixture and x_j is the mole fraction of component j in the mixture.

The summation in the attractive term extends for both subindices from 1 to the number of components; for example, for a binary mixture eq. 8 becomes

$$[9] \qquad z_m = z_m^{HS} - \frac{a_{11}x_1^2 + 2a_{12}x_1x_2 + a_{22}x_2^2}{RTv_m}$$

The expression for z_m^{HS}, given by Carnahan and Starling (9), is

$$[10]\quad z_m^{HS} = \frac{1 + \xi_m + \xi_m^2}{(1-\xi_m)^3} - \frac{\xi_m\left(\sum_k x_k b_k^{2/3}\right)^3}{v_m^2(1-\xi_m)^3} - \frac{3}{v_m(1-\xi_m)^3}\sum_{j,l} x_j x_l (b_j^{1/3} - b_l^{1/3})^2 \left[2b_{jl}^{1/3} + \frac{b_j^{1/3} b_l^{1/3}}{v_m}\sum_k x_k b_k^{2/3}\right]$$

where

$$[11]\quad \xi_m = \frac{1}{v_m}\sum_k x_k b_k$$

Equation 10 differs from that derived by Lebowitz and Rowlinson (14) (Percus–Yevick compressibility equation) only in the second term; in Lebowitz and Rowlinson's expression this term does not appear.

Generalizing eq. 6 we write

$$[12]\quad b_{jl} = L v_{c_{jl}}$$

where $v_{c_{jl}}$ is given by

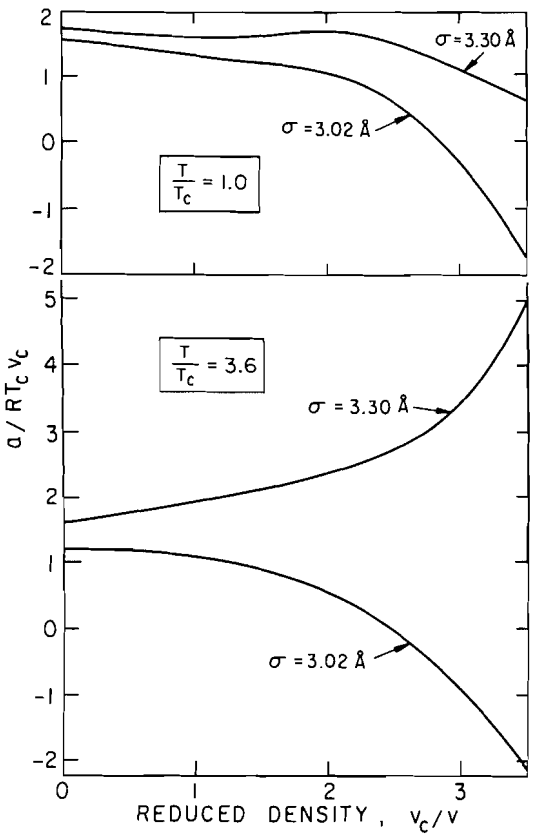

FIG. 2. Reduced van der Waals a for argon at two temperatures for different values of σ. When σ = 3.02 Å, L = 0.116; when σ = 3.30 Å, L = 0.150.

$$[13]\quad v_{c_{jl}}^{1/3} = \left(\frac{v_{c_j}^{1/3} + v_{c_l}^{1/3}}{2}\right)[1 - s_{jl}]$$

In eq. 13, s_{jl} is a dimensionless binary distance parameter characterizing the j–l interaction; s_{jl} may be positive or negative but its magnitude is small compared to unity.

The van der Waals coefficient a_{jl} is obtained from a generalization of eq. 5

$$[14]\quad a_{jl} = RTv_m[z_{jl}^{HS} - z_{jl}^{SG}]$$

where z_{jl}^{HS} is given by eq. 2 with $\xi_{jl} = b_{jl}/v_m$; z_{jl}^{SG} is given by eq. 4 with $T_{R_{jl}} = T/T_{c_{jl}}$ and $v_{R_{jl}} = v_m/v_{c_{jl}}$.

$T_{c_{jl}}$ is given by

$$[15]\quad T_{c_{jl}} = (T_{c_j}T_{c_l})^{1/2}[1 - k_{jl}]$$

where k_{jl} is a dimensionless energy parameter characteristic of the j–l potential; k_{jl} is usually a positive number small compared to unity.

The chemical potential of a component i in a multicomponent mixture can be written in the form

$$[16]\quad \mu_i = \mu_i^{ig} + \mu_i^{HS} + \mu_i^{F}$$

As described by Lebowitz and Rowlinson (14), μ_i^{ig} is the ideal-gas contribution to μ_i and μ_i^{HS} is the work of putting one mole of species i into a hard-sphere fluid. The chemical potential μ_i^F represents the effect of intermolecular forces.

For a Carnahan–Starling hard-sphere fluid the term μ_i^{HS} was obtained by just adding to the equivalent expression derived by Lebowitz and Rowlinson (14) the corrections due to the extra term in eq. 10.

The chemical potential μ_i^F was obtained using the standard thermodynamic relations

$$[17]\quad \mu_i^F = \left(\frac{\partial A^F}{\partial n_i}\right)_{T,V,n_j}$$

and

$$[18]\quad P^F = -\left(\frac{\partial A^F}{\partial V}\right)_{T,n}$$

where A^F is the contribution to the Helmholtz energy and P^F is the contribution to the total

pressure arising from intermolecular forces between real, rather than hard-sphere molecules. From eq. 18

$$[19] \qquad P^F = -\frac{\sum_{j,l} x_j x_l a_{jl}}{v_m^2}$$

The expressions for μ_i^{HS} and μ_i^F are given in Appendix 2.

There are two important differences between our equations and those of Snider and Herrington (7). As they use the Longuet–Higgins and Widom equation of state, the hard-sphere part in their treatment is that corresponding to the Percus–Yevick compressibility equation (2), and their van der Waals a is independent of volume. In our treatment we use the hard-sphere expression of Carnahan–Starling (9) which gives results remarkably close to the "exact" molecular-dynamics results of Alder (13). Further, we allow the "constant a" to depend on both temperature and volume as dictated by the empirical, reduced Strobridge–Gosman equation (11). Therefore, mainly as a result of the volume and temperature dependence of a, our equations can be used for calculation of vapor–liquid equilibria for mixtures of simple fluids at high pressures while those of Herrington and Snider are essentially restricted to the calculation of excess properties of liquid mixtures at low or modest pressures.

Results

Using the expressions developed in the previous section, vapor–liquid equilibrium calculations have been made for three binary systems and for one ternary system. The calculations are tedious but they can be made quickly with an electronic computer.

In this work we performed "bubble-point" calculations; that is, given the total pressure and the liquid-phase composition we find, by iteration, the equilibrium temperature and the vapor-phase composition. The three binary systems studied were nitrogen–argon, nitrogen–oxygen, and argon–oxygen.

Table 1 gives experimental and calculated results for the binary system nitrogen–argon; similar results were obtained for the binary systems nitrogen–oxygen and oxygen–argon. Values of the binary parameters s and k were obtained by fitting the bubble temperatures of each system. Table 2 gives experimental and calculated results for the ternary system nitrogen–argon–oxygen; all experimental values were reported by Wilson *et al.* (15). Agreement between calculated and experimental results is satisfactory but not outstanding. Failure to achieve better agreement is probably due to the fact that, contrary to our assumption in calculating a_m, these three fluids do not conform to two-parameter corresponding states with sufficient accuracy. Unfortunately, vapor–liquid equilibria are extremely sensitive to small changes in the constants a and b, in particular to small changes in a_{ij}.

While the van der Waals model is attractive because of its simplicity, the form of eq. 8 has a serious disadvantage for performing accurate calculations of the pressure; the two terms on the right-side of eq. 8 are often large and nearly equal and, as a result, a small error in either term can

*Characteristic binary parameters were obtained from binary-data reduction: nitrogen–argon: $s = -0.025, k = 0.005$; nitrogen–oxygen: $s = -0.035$, $k = 0.005$; argon–oxygen: $s = -0.012$, $k = 0.015$.

lead to a large error in the calculated pressure. If attention is confined to low-pressure fluids it is convenient to set $P = 0$ and to find constant values of a and b from experimental liquid-phase volumetric data as was done by previous workers. However, parameters obtained in this manner are not useful for calculations of vapor–liquid equilibria at advanced pressures. It appears then, that for accurate high-pressure phase-equilibrium calculations with an equation of the van der Waals type, primary attention must be given to a meaningful method for reducing pure-component experimental data to yield physically significant parameters.

B. Chemical Potential for a Pure Component from Strobridge–Gosman Reduced Equation

$$\frac{\mu - \mu^{ig}}{RT} = \frac{2C_{1T}}{v_R} + \frac{3}{2}\frac{C_{2T}}{v_R^2} + \frac{4}{3}\frac{C_8}{v_R^3} + \frac{6}{5}\frac{C_{3T}}{v_R^5} + \frac{1}{v_R^2}\left(C_{4T} + \frac{C_{5T}}{v_R^2} - \frac{C_{5T}}{2C_{16}}\right) e^{-C_{16}/v_R^2} + \frac{1}{2C_{16}}\left(C_{4T} + \frac{C_{5T}}{C_{16}}\right)(1 - e^{-C_{16}/v_R^2})$$

where μ^{ig} is the chemical potential of the ideal gas at the same temperature and volume and the constants are those given in Part *A*.

Appendix 2

A. The hard-sphere chemical potential of component i in a multicomponent mixture is

$$\frac{\mu_i^{HS}}{RT} = -\ln(1 - \xi_m) + z_m^{HS}\left(\frac{b_i}{v_m}\right) + \frac{9}{2}\frac{b_i^{2/3}A_1^2}{(1 - \xi_m)^2} + \frac{3(b_i^{2/3}A_2 + b_i^{1/3}A_1)}{(1 - \xi_m)} + \frac{\xi_m b_i A_1^3}{(1 - \xi_m)^3} - \frac{b_i A_1^3}{\xi_m^2(1 - \xi_m)} + \left(\frac{3\xi_m A_1^2 b_i^{2/3} - 2A_1^3 b_i}{\xi_m^3}\right)\ln(1 - \xi_m) + \frac{A_1^3(1 - 3\xi_m)b_i}{2\xi_m(1 - \xi_m)^3} + \frac{(2 - 3\xi_m)(3\xi_m A_1^2 b_i^{2/3} - A_1^3 b_i)}{2\xi_m^2(1 - \xi_m)^2}$$

where

$$\xi_m = \frac{1}{v_m}\sum_k x_k b_k$$

$$A_1 = \frac{1}{v_m}\sum_k x_k b_k^{2/3}$$

$$A_2 = \frac{1}{v_m}\sum_k x_k b_k^{1/3}$$

and z_m^{HS} is defined by eq. 10 in the text. The fourth term has been introduced in order to correct z_m^{HS} (from Percus–Yevick compressibility equation) to the Carnahan–Starling form. The last four terms are the correction to the expression of Lebowitz and Rowlinson (14) originated by the extra term in eq. 10.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

B. The contribution of intermolecular forces to the chemical potential of a component i in a multicomponent mixture is designated by μ_i^F

When the "constant a" is volume dependent as in this work

$$\frac{\mu_i^F}{RT} = 2\sum_k x_k F_{ik} - \sum_{j,l} x_j x_l \left(F_{jl} + v_m \frac{\partial F_{jl}}{\partial v_m} \right)$$

where

$$F_{jl} = n_T \int_\infty^V \frac{a_{jl}}{RTV^2}\, dV = \int_\infty^V \frac{(z_{jl}^{HS} - z_{jl}^{SG})}{V}\, dV; \quad [V = n_T v_m]$$

using eq. I-1 to determine a_{jl}, we obtain

$$F_{jl} = \frac{\xi_{jl}(3\xi_{jl} - 4)}{(1 - \xi_{jl})^2} + \frac{C_{1T_{jl}}}{v_{R_{jl}}} + \frac{C_{2T_{jl}}}{2v_{R_{jl}}^2} + \frac{C_{3T_{jl}}}{5v_{R_{jl}}^5} + \frac{C_8}{3v_{R_{jl}}^3} - \frac{C_{5T_{jl}}}{2C_{16}} \frac{1}{v_{R_{jl}}^2} e^{-C_{16}/v_{R_{jl}}^2} + \frac{1}{2C_{16}} \left(C_{4T_{jl}} + \frac{C_{5T_{jl}}}{C_{16}} \right) (1 - e^{-C_{16}/v_{R_{jl}}^2})$$

and

$$v_m \frac{\partial F_{jl}}{\partial v_m} = \frac{2\xi_{jl}(2 - \xi_{jl})}{(1 - \xi_{jl})^2} - \left[\frac{C_{1T_{jl}}}{v_{R_{jl}}} + \frac{C_{2T_{jl}}}{v_{R_{jl}}^2} + \frac{C_{3T_{jl}}}{v_{R_{jl}}^5} + \frac{C_8}{v_{R_{jl}}^3} + \frac{1}{v_{R_{jl}}^2} \left(C_{4T_{jl}} + \frac{C_{5T_{jl}}}{v_{R_{jl}}^2} \right) e^{-C_{16}/v_{R_{jl}}^2} \right]$$

where

$$\xi_{jl} = b_{jl}/v_m$$

$$v_{R_{jl}} = v_m/v_{c_{jl}}$$

The coefficients $C_{iT_{jl}}$ are those defined in Part *A* of Appendix 1, evaluated with $T_{R_{jl}} = T/T_{c_{jl}}$.

C. Equations of Section B, Appendix 2, in the special case where a is independent of volume

$$F_{jl} = n_T \int_\infty^V \frac{a_{jl}}{RTV^2}\, dV = -\frac{a_{jl}}{RTv_m}$$

Then

$$v_m \frac{\partial F_{jl}}{\partial v_m} = \frac{a_{jl}}{RTv_m}$$

and

$$\sum_{j,l} x_j x_l \left[F_{jl} + v_m \frac{\partial F_{jl}}{\partial v_m} \right] = 0$$

As a result of this simplification, we obtain

$$\frac{\mu_1^F}{RT} = -\frac{2\sum_k x_k a_{ik}}{RTv_m}$$

For a binary system

$$\frac{\mu_i^F}{RT} = -2\left(\frac{x_1 a_{11} + x_2 a_{12}}{RTv_m} \right)$$

Thermoelectric Studies of Silver Nitrate in Sodium Nitrate – Potassium Nitrate Eutectic Melt

L. G. BOXALL[1] AND K. E. JOHNSON

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

Received[2] July 22, 1970

The Seebeck coefficient, ε_T, of the thermocell $Ag(T)/AgNO_3$ in $NaNO_3$–KNO_3/Ag $(T + \Delta T)$ was measured as a function of silver nitrate concentration and temperature. Extrapolation of the results to unit mole fraction, N, of $AgNO_3$ gave the value $\varepsilon_T^0 = -277.5 - 0.136T$ °C (μV deg^{-1}).

For several mixed melts of $AgNO_3$ and an alkali nitrate the function $P = \varepsilon_T - \varepsilon_T^0 - (R/F) \ln N + \Delta\bar{S}^E$ was calculated and shown to be linear in N. P was extrapolated to finite values for the pure alkali nitrates.

Le coefficient de Seebeck ε_T de la thermopile $Ag(T)/AgNO_3$ dans $NaNO_3$–KNO_3/Ag $(T + \Delta T)$ a été mesuré en fonction de la concentration en nitrate d'argent et de la température. La valeur $\varepsilon_T^0 = -277.5 - 0.136T$ °C (μV deg^{-1}) est trouvée par extrapolation des résultats à la fraction moléculaire N de $AgNO_3$ égale à l'unité.

La fonction $P = \varepsilon_T - \varepsilon_T^0 - (R/F) \ln N + \Delta\bar{S}^E$ a été calculée pour plusieurs mélanges fondus de $AgNO_3$ et d'un nitrate d'alcalin; cette fonction varie de façon linéaire avec N. Par extrapolation on trouve des valeurs finies de P pour les nitrates d'alcalins purs.

Canadian Journal of Chemistry, 49, 2044 (1971)

The Seebeck coefficient, ε_T^0, for the pure fused silver nitrate thermocell has been measured by several workers (1–6) and others have studied the Seebeck coefficient, ε_T, of thermocells based on binary mixtures of silver nitrate with lithium nitrate (3, 7, 8), sodium nitrate (1, 6, 8–10), potassium nitrate (8, 11), rubidium nitrate (11), and thallium nitrate (12) and dilute solutions of silver nitrate in alkali nitrate eutectics and mixtures (13).

In this paper we report measurements of ε_T for silver nitrate in $NaNO_3$–KNO_3 eutectic and discuss these and similar data in terms of Dupuy's (5) derived relationship between ε_T and ε_T^0.

Experimental Procedure

Measurements were carried out with the furnace illustrated in Fig. 1, based on a U-shaped piece of glass tubing with each limb wrapped with separately controlled heating tapes. Two sintered glass discs were incorporated in the tubing to retard the thermal diffusion of the ions in the melt and a central tube facilitated the filling of the cell. To eliminate a.c. interference, the glass of the cell was wrapped with aluminum foil before attaching the heating tapes. The temperature of each limb of the cell could be varied independently by the use of two proportional controllers (Cole-Parmer), a maximum temperature gradient of 100 °C being possible.

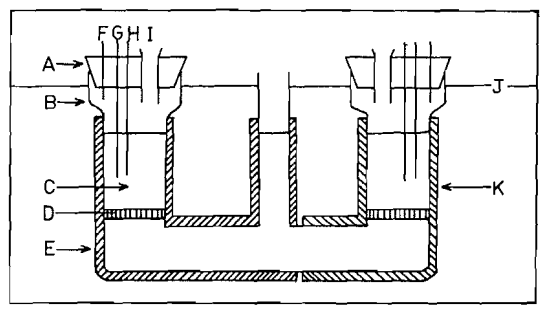

FIG. 1. Cell for thermoelectric studies; *A*, foil-wrapped rubber stopper; *B*, foil (earthed) wrapped Pyrex cell; *C*, melt; *D*, 20 mm, fine fritted disk; *E*, heating tape connected to left temperature controller, *F*, N_2 inlet; *G*, probe for melt temperature controller; *H*, thermocouple; *I*, glass-lined inlet for electrode compartment; *J*, upper level of insulation; *K*, heating tape connected to right temperature controller.

Thermal stability in each half cell was obtained 15 to 60 min after a temperature change. For each mixture a given temperature profile was applied with first the left-hand half of the cell and then the right-hand half the hotter of the two. Each run consisted of taking ΔT through the cycle $0 \rightarrow +50 \rightarrow 0 \rightarrow -50 \rightarrow 0$ °C. The average temperature of the cell was maintained to ± 2 °C and temperature and e.m.f. were recorded only after they had remained stable at ± 0.5 °C and 0.05 mV, respectively, for 15 min. Eight to ten points were recorded per run.

Sodium and potassium nitrates (Fisher Scientific, reagent grade) were twice recrystallized from water and dried *in vacuo* at 120 °C. Silver nitrate (Fisher Scientific, reagent grade) was dried *in vacuo* at 100 °C.

Results

The results for two runs at 275 ± 2 °C with a mole fraction of silver nitrate of 0.2 are combined in Fig. 2. The least squares fit of the data has a slope of -315 μV deg^{-1} and a standard deviation in the measured e.m.f. of 0.62 μV. ε_T values for seven different concentrations of silver nitrate were measured at four temperatures and the ε_T^0 values obtained by extrapolation to unit mole fraction of silver nitrate, N, were as follows

Temperature ±2 °C	$-\varepsilon_T^0$ ±5 μV deg^{-1}
275	314
300	320
325	321
350	325

The variation may be written as

$$\varepsilon_T^0 = -(277.5 \pm 0.7) - (0.136 \pm 0.025)T\ °C\ (\mu V\ deg^{-1})$$

with a standard deviation of 1.4 μV deg^{-1}. The increase in $|\varepsilon_T^0|$ of (0.042 ± 0.08)% deg^{-1} agrees with previous work (7).

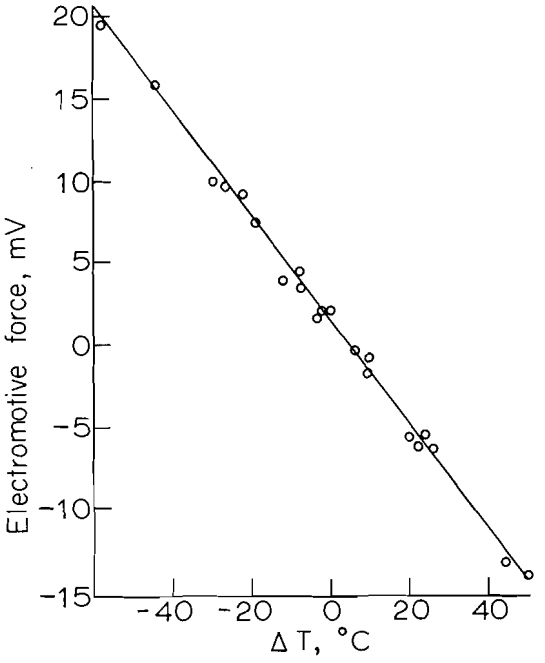

FIG. 2. Electromotive force of dilute silver nitrate thermal cell; mole fraction $AgNO_3$ = 0.20, solvent = (Na, K)NO_3, average temperature = 275 ± 2 °C.

Discussion

The relationship derived between ε_T and ε_T^0 has the form (5)

$$[1]\quad \varepsilon_T - \varepsilon_T^0 - \frac{R}{F}\ln N\gamma + \frac{\Delta\bar{H}^M}{FT} = \frac{1}{F}\Delta\left\{-\sum_i \frac{t_i s_i}{Z_i}\right\} = P$$

where γ is the activity coefficient of silver nitrate on the mole fraction scale, $\Delta\bar{H}^M$ is the partial molar excess enthalpy, t_i is the transport number of species i, Z_i is the valence of species i, s_i is the entropy of transport of species i, and the right-hand term is the difference between the summation for the mixture and that for pure silver nitrate. The expression may be rewritten

$$[2]\quad P = \varepsilon_T - \varepsilon_T^0 - \frac{R}{F}\ln N + \frac{\alpha}{F}(1-N)^2$$

where $\alpha(1-N)^2$ is the partial molar excess entropy, $\Delta\bar{S}^E$ (14).

Now $\Delta\bar{H}^M$ is obtainable for $LiNO_3$, $NaNO_3$, KNO_3, and $RbNO_3$ from the calorimetric measurements of Kleppa *et al.* (15) while the γ and α values may be derived from e.m.f. measurements (14, 16, 17). For the single alkali nitrates we have used both methods of calculating P for each mole fraction, N; $-\Delta\bar{H}^M$ from calorimetry (15) and γ from e.m.f. measurements (16, 17) or α from e.m.f. measurements (16, 17).[3] Since the α values came from studies involving only limited temperature variation, the former method which gave P values a few μV deg^{-1} more negative, seems preferable; except for $LiNO_3$ the difference is small. For $NaNO_3$–KNO_3 containing $AgNO_3$, $\Delta\bar{H}^M$ data are not available so that total reliance on e.m.f. measurements was necessary.

The resulting functions, P, appear to follow a linear dependence (Fig. 3) on alkali nitrate mole fraction; thus $P = x + (1-N)y$ with the values of x and y given in Table 1. We note that the variation for $NaNO_3$–KNO_3 is practically the same as for $NaNO_3$. The question remains as to the interpretation of x and $(x+y)$, the values of P for pure silver and alkali nitrate, respectively.

[3]We have shown for these systems (16) that $\gamma \to \gamma_{N=0}$ at low N in which case the variation of $\gamma_{N=0}$ with T yields α, thus $RT\ln\gamma_{N=0} = a - \alpha T$.

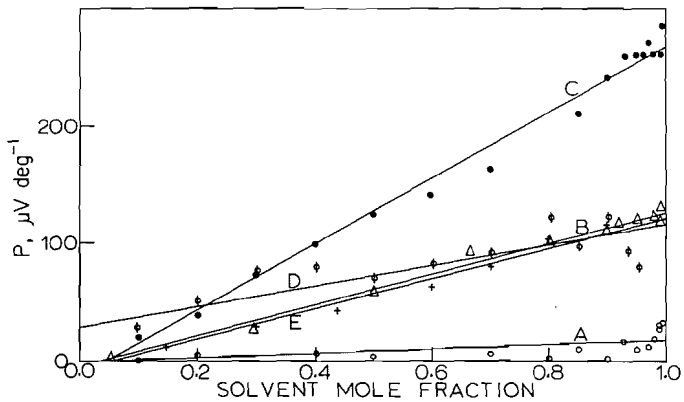

FIG. 3. The function $P = \varepsilon_T - \varepsilon_T^0 - (R/F) \ln N\gamma + \Delta\bar{H}^M/FT$ *vs.* $(1 - N)$ for the solvent systems *A* (○), $LiNO_3$ at 340 °C; *B* (△), $NaNO_3$ at 340 °C; *C* (●), KNO_3 at 360 °C; *D* (ϕ), $RbNO_3$ at 310 °C; *E* (+), $NaNO_3$–KNO_3 at 350 °C.

TABLE 1. Values of *P* according to its functional dependence

		$P = x + (1 - N)y$			$P = (1 - N)y^1$		
System	T °C	x	y	σ	y^1	σ	Reference
$LiNO_3$	340	−3.7±2.2	20.3± 6.6	8.9	16.0±2.8	8.8	8
$NaNO_3$	340	−6.6±1.7	133.0± 4.7	5.8	125.4±2.4	6.4	8
KNO_3	360	−14.5±2.8	283.9± 8.1	11.3	266.5±4.2	12.9	8
$RbNO_3$	310	27.3±5.1	90.0±16.0	18.4	127.0±9.8	22.6	11
(Na, K)NO_3	350	−8.6±3.0	132.3±10.2	8.5	119.4±5.8	9.2	This work

Equation 1 implies that x should be zero and its departure from this is clearly a measure of inconsistencies in the data. On the other hand, $(x + y)$ can be equated to the difference between the entropies of transport summations for pure alkali nitrate and pure silver nitrate, provided there is no parallel heterogeneous thermoelectric power (18). It is possible to write $x = 0$ with consequent changes in the errors and with the new y alone (y') then having the former significance of $(x + y)$. Table 1 carries the details of this formulation and the derived quantities $(x + y)$ and y' compare as follows

System	$x + y$	y'
$LiNO_3$	16.6	16.0
$NaNO_3$	126.4	125.4
KNO_3	269.4	266.5
$RbNO_3$	117.3	127.0
(Na, K)NO_3	123.7	119.4

The linearity in N of P may be fortuitous but could reflect the simplicity of interactions in the systems. It may be instructive to perform comparable measurements on a solvent system in which more than one metal ion/metal system is reversible.

This work was supported by the Defence Research Board of Canada under Contract No. 5412-07 and by the National Research Council of Canada through a Scholarship (to L.G.B.). We much appreciate discussions and clarification of the theoretical aspects of this study with A. R. Allnatt.

Flash Photolysis with Kinetic Mass Spectrometry

O. P. STRAUSZ, S. C. BARTON, W. K. DUHOLKE, H. E. GUNNING, AND P. KEBARLE
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 14, 1970

A flash photolysis apparatus coupled with a fast response conventional sector field mass spectrometer for the rapid time resolved detection of short-lived neutral transients is described. The utility of the apparatus is illustrated by the detection of the $Fe(CO)(NO)_3$ intermediate with a half-life of ~ 0.1 s in the flash photolysis of $Fe(CO)_5$ in the presence of NO.

On décrit un appareil susceptible de détecter les intermédiaires dans les expériences de photolyse éclair. Cet appareil résulte du couplage d'un système de photolyse éclair à un spectromètre de masse conventionnel. Le spectromètre, à analyseur magnétique, permet d'effectuer des balayages ultra rapides et possède un système de détection qui permet de mesurer le temps de vie de l'entité mesurée.

La détection de l'intermédiaire $Fe(CO)(NO)_3$, dont le temps de demi-vie est ~ 0.1 s, dans la photolyse de $Fe(CO)_5$ en présence de NO démontre les possibilités de l'appareil.

Canadian Journal of Chemistry, 49, 2048 (1971)

Introduction

Fast response kinetic mass spectrometry offers a useful technique complementary to kinetic absorption and emission spectroscopy for the detection and time-resolved kinetic study of short-lived intermediates of flash photochemical reactions. This application of kinetic mass spectrometry was first attempted but not pursued by Kistiakowsky and Kydd (1). More recently Meyer reported studies utilizing a flash photolysis – kinetic mass spectrometric apparatus (2).

The apparatus of Kistiakowsky and Meyer utilized a time-of-flight mass spectrometer with which mass scans could be obtained every 50 μs. Such rapid mass scanning allows in principle the time-resolved detection of reaction intermediates and reactants with half-lives which are considerably less than 1 ms. Unfortunately the very rapid scanning leads to an extremely large drop in detection sensitivity which in practice (*i.e.* with the detection devices used by the authors) limited the usefulness of the method.

The present apparatus was designed with more modest instrumental objectives. Time resolved ion detection was obtained by following the intensity of only one ion mass per photoflash. The much larger effective detection sensitivity obtained in this manner has to be paid for, by the fairly large number of repetitive flashes required to cover the pertinent ions.

The usefulness of the present instrument has been demonstrated through a number of preliminary reports dealing with the flash photolysis of COSe (3) in the presence of olefins, paraffins, and oxygen; COS (4) in the presence of olefins and acetylenes; cyclobutadiene–irontricarbonyl (5); and others (6).

The present article gives a detailed description of the apparatus and reports the detection of a novel transient nitrosyl iron carbonyl, $FeCO(NO)_3$.

Experimental

The apparatus, shown schematically in Fig. 1, consisted of a flash photolysis cell coupled to the specially constructed ion source of an Atlas CH4 spectrometer. Changes in the concentration of species of interest were monitored by photographically recording the oscilloscopic display of ion signal intensities at appropriate *m/e* values.

Photolysis Cell

The geometry of the coaxial flash lamp and photolysis cell and their attachment to the ion source of the mass spectrometer are shown in Fig. 2. The concentric walls of the photolysis cell were constructed from two standard glass-to-metal tubulations fitted with stainless steel O-ring seal flanges. Interchangeable quartz, Vycor or Pyrex inner walls were employed as required. The effective reaction zone was a volume of ~ 10 cc between the inner wall and the sampling orifice. The sampling orifice was a circular opening (~ 0.005 in. diameter) in a 0.002 in. thick disc of tantalum foil cemented over a small hole (~ 2 mm diameter) in the curved end of the outer wall. The vacuum side of the outer wall was silvered to provide a reflective and conductive surface.

Flash Lamp

The coaxial flash lamp was supported on the recess of the photolysis cell by a protective, coarse wire grid. The flash lamp circuitry consisted of a high voltage transformer, capacitors (one 10 μF and one 5 μF), and a triggering circuit. The capacitors were normally charged to 8000 V and the flash set off by triggering an ignitron (General Electric GL-7703) in series with the capacitor

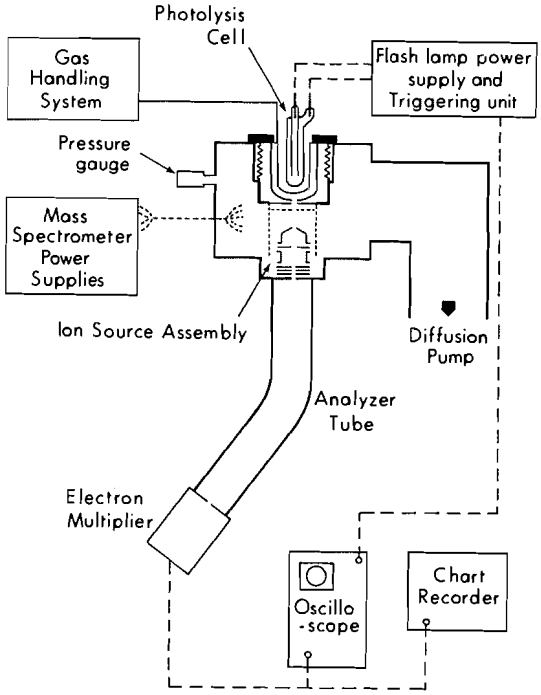

FIG. 1. Schematic illustration of apparatus.

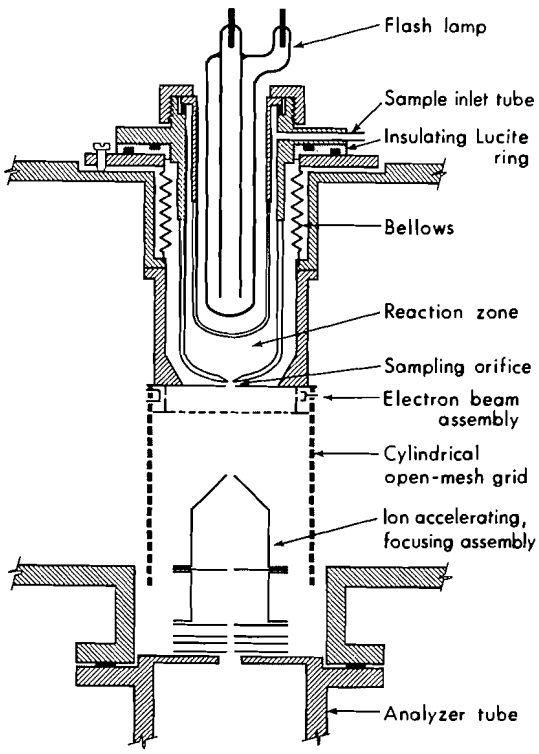

FIG. 2. Photolysis cell – ion source assembly.

and the lamp. The duration of the flash was approximately 60 μs.

Mass Spectrometer

The mass spectrometer was a conventional 60° sector magnetic deflection Atlas CH4 instrument, and only the specially constructed ion source need be described here. In order to provide a representative mass spectrum a sampling orifice should be sufficiently large to assure hydrodynamic flow, and ions should be formed predominantly from molecules just leaving the sampling orifice rather than from those which have suffered collisions with the wall or other molecules in the ion source. The ion source was designed with these criteria in mind.

As shown in Figs. 1 and 2, the photolysis cell – ion source assembly was enclosed in a large stainless steel chamber mounted on the analyzer tube of the mass spectrometer and evacuated by a 6 in. NRC oil diffusion pump fitted with a 6 in. NRC water-cooled baffle. The short 8 in. diameter pumping lead to the 10 in. diameter ion source vacuum chamber, combined with the above pumping units gives an estimated pumping speed of 500 l/s at the ion source. A flexible bellows attached to the flange supporting the photolysis cell permitted optimum adjustment of the sampling orifice relative to the ion source. The sampling orifice was located ~ 4 mm away from the ionizing electron beam directly above a 1 cm diameter mesh-covered hole in the repeller plate.

The ion source of the mass spectrometer operated at an accelerating voltage of 2 kV and the photolysis cell was also maintained at this voltage in order to prevent electrical discharges in the vicinity of the sampling orifice. The complete bottom of the ion source was made of an 80% transmission nickel grid. The tip of the first (conically shaped) electrode was placed 3 cm below the bottom of the ion source. This open ion source and electrode construction gives a large (gas) conductance (~ 500 l/s) out of the ion source.

A series of accelerating and focusing slits and deflection plates mounted on the analyzer tube completed the ion source assembly. The relative voltages of these electrodes were chosen to optimize sensitivity and mass resolution

Data Recording

Subsequent to magnetic separation of the ions, the ion current was amplified (~ 10^5) by an electron multiplier and then oscillographically displayed and recorded in one of two ways. Generally, a time-resolved ion intensity plot of a single *m/e* value was obtained by adjusting the mass spectrometer to the *m/e* value of interest prior to commencing the experiment. Alternatively a single scan of a preselected portion of the mass spectrum could be recorded within 200 ms after the flash occurred. In both modes of operation the oscilloscope was externally triggered by a signal from an induction coil on a lead of the flash lamp. The response time of the output circuitry was approximately 200 μs.

Gas Sampling

The open configuration of the ion source in conjunction with the large pumping system resulted in rapid removal of the sampled gas from the ionization region. This, and the proximity of the sampling orifice to the electron beam, resulted in ions being formed predominantly from molecules coming directly from the photolysis cell.

The approximate ratio of "beam molecules" to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

"scattered molecules" being ionized was determined as follows. With $\sim 10^{-2}$ Torr of argon diluted with some 10–20 Torr helium in the photolytic cell, the $m/e = 40$ ion intensity (I_1) and the pressure measured by the ionization gauge were recorded. The pressure measured by the ionization gauge corresponds to the pressure in the large vacuum housing containing the ion source. Because of the completely open construction of the ion source this pressure is also essentially equal to the pressure due to diffusely scattered molecules in the ion source since the geometry is such that practically no beam molecules are scattered by the walls of the ion source. In a second experiment with the reaction cell evacuated the same gas mixture was admitted by means of a valve directly to the ion source vacuum housing. The observed $m/e = 40$ ion intensity (I_2) was again recorded for an ion gauge pressure equal to that of the previous experiment. Then,

$$\frac{P_b + P_{s,1}}{P_{s,2}} = \frac{I_1}{I_2}$$

where P_b and P_s refer to partial pressures of beam and scattered background molecules, respectively, and I_1 and I_2 refer to $m/e = 40$ ion intensities. P_b/P_s was determined to be ~ 60, indicating that over 90% of the ions were formed from molecules coming directly from the photolytic cell.

With 20 Torr of helium in the photolysis cell the pressure measured on the ionization gauge was about 10^{-5} Torr. Between experiments the apparatus was evacuated to about 10^{-7} Torr.

Experimental Procedure

All reaction mixtures were prepared in the stainless steel gas handling system of the mass spectrometer. The reaction mixtures normally consisted of about 10 μ of $Fe(CO)_5$ (or other reactants) and 2.5 Torr of NO diluted to a total pressure of 20 Torr with helium to assure approximately isothermal conditions during the reaction. (Additional reactive substances were added in varying amounts in some experiments.) The purity of the reactants and the occurrence of any dark reaction prior to photolysis was checked mass spectrometrically.

After thorough mixing, the reaction mixture was allowed to flow through the photolysis cell, final adjustment of the instrument made, and the flash experiment performed. The validity of all experimental observations were confirmed by repeating the experiments with appropriate "blank" mixtures.

Results and Discussion

The observations included both time-resolved ion intensity plots of single m/e values and single scans of preselected portions of the mass spectrum of the gas mixture. The relatively simple spectra were readily interpreted without ambiguity in the assignment of mass peaks. Peak heights were assumed proportional to gas concentrations and because of the qualitative nature of the study a knowledge of absolute concentrations was not required.

Figures 3 to 5 are single scan records of the mass spectrum in the region of the $(Fe(CO)_4)^+$ fragment ion peak of $Fe(CO)_5$. Comparison of the intensity of m/e 166 $(Fe^{54}(CO)_4)^+$ before and after the flash (Figs. 3 and 4) indicates $\sim 75\%$ decomposition of the $Fe(CO)_5$ during flash photolysis of the gas mixtures. Upon photolysis of the $Fe(CO)_5$/NO mixture, new mass peaks appeared at m/e 172 and 174 (Figs. 3 and 4) but no new peaks resulted from photolyzing $Fe(CO)_5$ in the absence of NO (Fig. 5). Similar observations were made in the region of the parent peak (m/e 196), but no new peaks were detected here or at higher masses and so the mass peaks at m/e 172 and 174 were interpreted as parent peaks.

The mass peaks at m/e 172 and 174 can be

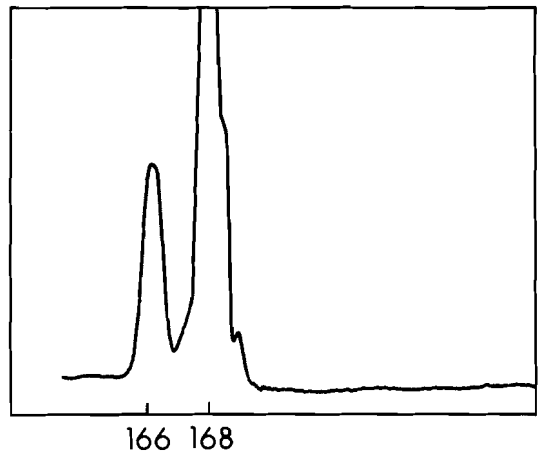

FIG. 3. Single scan, showing m/e 168 $(Fe(CO)_4)^+$ as largest peak, before flash; 500 mV full scale deflection, 100 ms full scale deflection, $Fe(CO)_5$/NO/He mix.

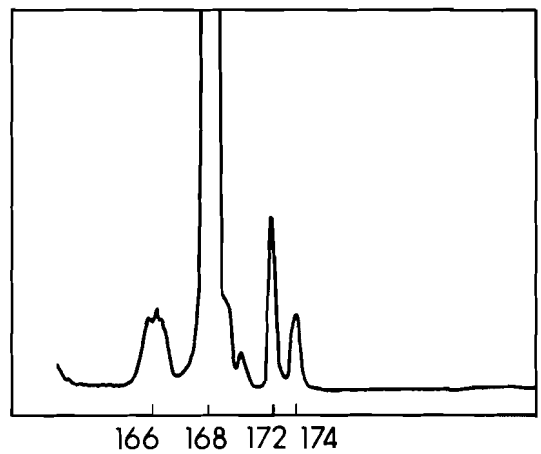

FIG. 4. As in Fig. 3, but immediately after flash. Note new peaks at 172 and 174; 500 mV, 100 ms, $Fe(CO)_5$/NO/He mix.

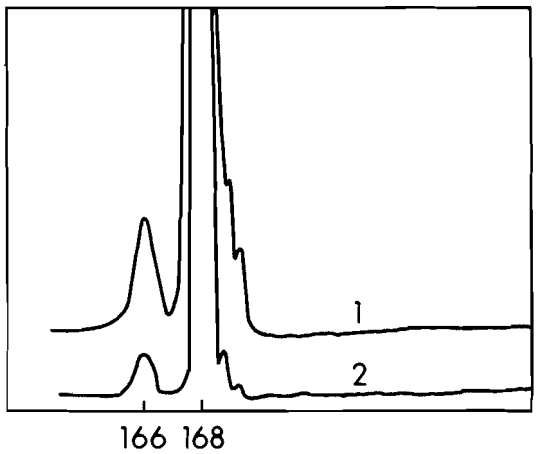

FIG. 5. As in Figs. 3 and 4 but without NO. Trace *1*, before flash; trace *2*, after flash; 500 mV, 100 ms.

unambiguously attributed to $Fe(CO)_2(NO)_2$ and $Fe(CO)(NO)_3$, respectively, and no other products were detected. $Fe(CO)_2(NO)_2$ is a known stable compound (7). The unstable $Fe(CO)(NO)_3$, however, is a novel structure whose composition seems to violate the noble gas rule for predicting the formulae of stable known coordination complexes (7). In these complexes nitric oxide forms a three-electron bond to the metal atom. Since CO is regarded as a two-electron donor, two NO are equivalent with three CO molecules as in $Fe(CO)_2(NO)_2$.

The stability of the two products was investigated by recording time-resolved ion intensities for $m/e = 172$ and 174. As seen from Fig. 6, $Fe(CO)_2(NO)_2$ shows no decay being a stable molecule whereas $Fe(CO)(NO)_3$, as shown in Fig. 7, decays with a half-life of ~75 ms.

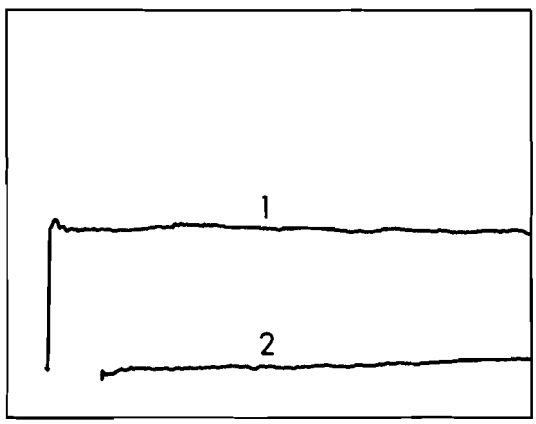

FIG. 6. *I m/e* 172 $(Fe(CO)_2(NO)_2)^+$ *vs.* time; 500 mV, 500 ms. Trace *1*, $Fe(CO)_5$/NO/He; Trace *2*, $Fe(CO)_5$/He.

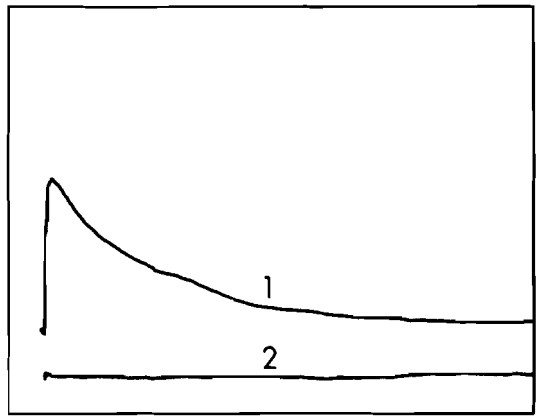

FIG. 7. *I m/e* 174 $(Fe(CO)(NO)_3)^+$ *vs.* time; 200 mV, 500 ms. Trace *1*, $Fe(CO)_5$/NO/He; trace *2*, $Fe(CO)_5$/He.

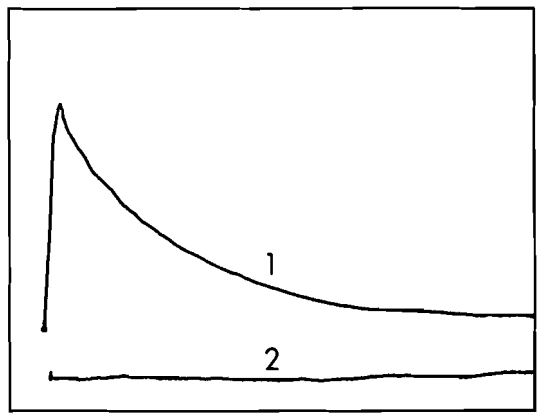

FIG. 8. *I m/e* 146 $(Fe(NO)_3)^+$ *vs.* time; 1 V, 500 ms. Trace *1*, $Fe(CO)_5$/NO/He; trace *2*, $Fe(CO)_5$/He.

Decay patterns of some of the fragment ions were also investigated. The decay curve for $m/e = 146$, $(Fe(NO)_3)^+$, shown in Fig. 8 gives a half-life of ~75 ms, in agreement with the decay of the parent molecule $Fe(CO)(NO)_3$. The temporal variation of another fragment ion $(Fe(CO)(NO)_2)^+$ at $m/e = 144$ depicted in Fig. 9 shows an initial decay after which it tends to level off at a fairly high residual value, indicating that it is a fragment common to both the $Fe(CO)(NO)_3$ and $Fe(CO)_2(NO)_2$ molecules.

The effect of varying the concentration of nitric oxide on the relative yield of the two product molecules was examined in one experiment; Fig. 10, in which the nitric oxide concentration was decreased by a factor of ten. This caused a decrease in the parent ion intensity ratio, $I(Fe(CO)(NO)_3)/I(Fe(CO)_2(NO)_2)$, by about a

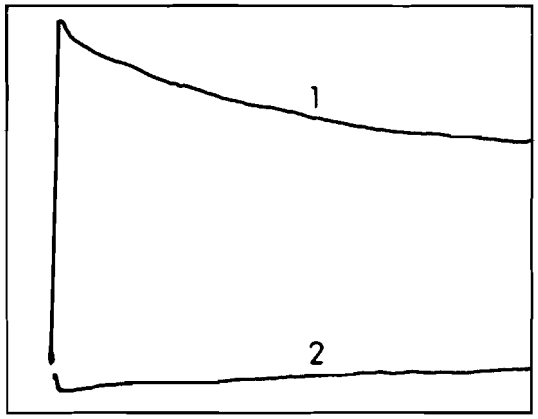

FIG. 9. *I m/e* 144 $(Fe(CO)(NO)_2)^+$ *vs.* time; 500 mV, 500 ms. Trace *1*, $Fe(CO)_5/NO/He$; trace *2*, $Fe(CO)_5/He$.

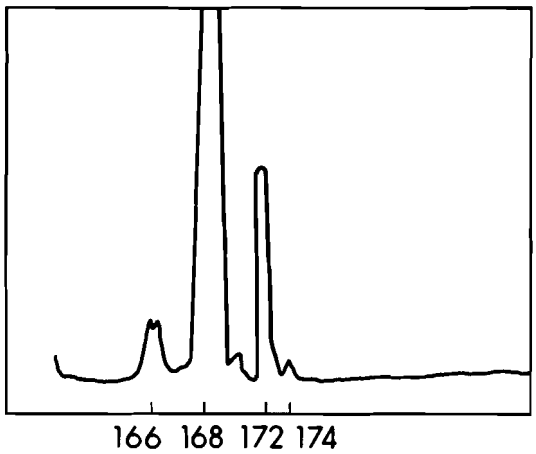

FIG. 10. As in Fig. 4 but NO concentration decreased by 10. Note change in 172/174 ratio.

factor of four. The trend is certainly in the right direction since the rate of the corresponding product molecules formation should be a linear function of nitric oxide concentration. The deviation from linearity, and the nearly equal yields of the $Fe(CO)_2(NO)_2$ complex at 0.25 and 2.5 Torr NO pressures suggest that the rate constant for the formation of this product is considerably higher than that for $Fe(CO)(NO)_3$ formation and that even at the lower nitric oxide pressure the scavenging of the $Fe(CO)_2$ intermediate is complete.

Finally, the possibility that the $Fe(CO)(NO)_3$ complex forms not as a neutral molecule, but as an ion, via ion–molecule reactions in the ion source was also explored. Experiments in which NO was admitted directly to the ion source have conclusively shown that $Fe(CO)(NO)_3$ does not form in the ion source and consequently it must form in the photolysis cell as a neutral entity.

The mode of decay of the unstable $Fe(CO)(NO)_3$ complex could not be established in the present study. A search for products such as CO_2, NO_2, or a dimeric form of the complex indicated that these molecules were not present and consequently it is assumed that decomposition occurs via dissociation to form Fe, CO, and NO.

Reports on the detection of additional novel inorganic molecules using the technique of flash photolysis – kinetic mass spectrometry will be forthcoming at a later date.

The authors thank the National Defence Board and the National Research Council of Canada for financial support and Mr. R. Kadlecz for helpful assistance.

The Excited Singlet State of Chloropentafluoroacetone; Quenching by Unsaturated Hydrocarbons

H. S. SAMANT AND A. J. YARWOOD
Department of Chemistry, McMaster University, Hamilton, Ontario

Received January 8, 1971

The fluorescence of chloropentafluoroacetone in the gas phase at 23 °C is quenched by the addition of certain olefins. The quenching rate constants of 17 unsaturated hydrocarbons for the first excited singlet state of chloropentafluoroacetone are reported. The molecules are divided into two classes on the basis of their quenching abilities, (*a*) olefins with only electron-withdrawing substituents and (*b*) olefins with electron-donating substituents. It is shown that the quenching by molecules in the latter group can be quantitatively correlated with the ionization potential (i.p.) of the quenching molecule. The relation is $\log k = 18.0 - 0.79$ (i.p.), *i.e.* a type of linear free energy relation is obeyed. This implies that the quenching by molecules containing only electron-donating substituents involves a charge-transfer complex.

La fluorescence de la chloropentafluoroacetone en phase gazeuse à 23 °C est inhibée par l'addition de certains hydrocarbures insaturés. On rapporte les constantes de désactivation de 17 hydrocarbures insaturés pour le premier singulet excité de la chloropentafluoroacétone. Les molécules sont classifiées en deux catégories selon leur efficacité de désactivation: (*a*) celles qui possèdent seulement des substituants attracteurs d'électrons et (*b*) celles avec des substituants donneurs d'électrons. On montre que la désactivation par les molécules du groupe *b* peut être reliée quantitativement au potentiel d'ionisation de la molécule désactivante, *i.e.* $\log k = 18.0 - 0.79$ (p.i.). Ceci semble indiquer que la désactivation par les molécules qui contiennent uniquement des substituants donneurs d'électrons se ferait par l'intermédiaire d'un complexe ou il y aurait transfert de charge.

Canadian Journal of Chemistry, 49, 2053 (1971)

Electronically excited molecules can be deactivated in bimolecular collisions with added quenching molecules, and the quenching effect on the singlet and triplet states of aromatic compounds has been extensively studied (1–4). Carbonyl compounds, particularly ketones and diketones, have also been investigated, and the quenching of the triplet states of alkyl ketones is an active research area at present (5–7). The quenching of the triplet states of ketones by olefins has been interpreted in various ways (5, 6) and can involve either energy transfer or deactivation (with or without the formation of a stable product).

The excited singlet states of ketones can also transfer energy to quenching molecules, *e.g.*, alkyl ketones can sensitize diketone fluorescence (8, 9). They can also be deactivated by olefins, and again the formation of a stable product depends on the nature of the quenching molecule (10–13).

We have recently reported (14, 15) luminescence studies of chloropentafluoroacetone and determined the rate constants for the processes removing the excited singlet state in the gas phase at room temperature. In this paper we report on the quenching effect of a series of unsaturated hydrocarbons on the excited singlet state of chloropentafluoroacetone in the gas phase and discuss the mechanism of the quenching.

Experimental

Material

Chloropentafluoroacetone (Allied Chemical) was purified by low temperature distillation and stored in the dark at 77 °K. The following olefins (C.P. grade) were supplied by Matheson Co. and were used after distillation at appropriate low temperatures: ethylene, propylene, but-1-ene, 2-methylpropene, and *cis*-but-2-ene. The Matheson Co. also supplied the 1,1-difluoroethylene, perfluorobut-2-ene, and the chloroethylene, which were also distilled at low temperature. Tetrachloroethylene (Eastman Organic Chemicals) was used after distillation at low temperature that removed inhibitor. The cyclohexene (Eastman Organic Chemicals) and hex-1-ene (Aldrich Co.) were passed through an alumina column and distilled under nitrogen. 2,3-Dimethylbut-2-ene (Chemical Samples Co.), trichloroethylene (Allied Chemical), and 1,3-cyclohexadiene (Aldrich) were distilled at low temperature. 1,3-Pentadiene (Matheson, Coleman and Bell) and benzene (Baker spectrophotometric grade) were deaerated.

Fluorescence Apparatus

The excitation source was a medium pressure mercury lamp (Hanovia #673A) used with a third order 313 nm interference filter (Baird Atomic). Fluctuations in the light intensity were monitored by reflecting a portion of the incident light from a Vycor plate onto a photocell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(RCA 935). The quartz cell was 1 cm long and was connected to a grease-free vacuum system that was saturated with mercury, since the pressures were measured on mercury manometers. The light passed through the cell and was condensed by a quartz lens onto a photocell (RCA 935). The emitted light passed through a glass filter (Corning 0-52) and was condensed by a quartz lens onto a photomultiplier (RCA 1P28) which operated at 800 V. The output of the photomultiplier was monitored by an electrometer (Keithley 610B). The relative fluorescence yield Q is defined as $(I_f - I_f^\circ)/(I_t^\circ - I_t)$ where I_t and I_f are the transmitted and emitted light intensities; the superscript indicates that the ketone was absent.

In the early studies the ketone and olefin diffused to reach equilibrium, while in some later experiments they were mixed using a magnetically driven double action glass pump.

Results

The chloropentafluoroacetone pressure in each quenching experiment was 200 ± 5 Torr and the temperature was 23 °C. The quenching ability of each olefin was investigated by adding increasing quantities of the olefin and noting the decrease in the fluorescence of the ketone. Figures 1–5 show plots of Q_0/Q *vs.* concentration of quenching olefin for the molecules studied, except perfluorobut-2-ene and cyanoethylene, which were very inefficient quenchers. None of the quenching molecules is expected to absorb 313 nm so no correction to the absorbed light intensity is necessary.

The lines shown on the figures are the best lines through the data points that include the data for the pure ketone.

Discussion

Chloropentafluoroacetone fluoresces but does not phosphoresce in the gas phase at room temperature (14) when excited in the π^*–n band. Thus, when chloropentafluoroacetone is excited at 313 nm and the total luminescence passed through a Corning 0-52 glass filter is monitored, this corresponds to direct measurement of the fluorescence. The mechanism proposed (14) to explain the fluorescence behavior of chloropentafluoroacetone is

[1]	$A + h\nu \rightarrow {}^1A_n$	I_a
[2]	${}^1A_n + A \rightarrow {}^1A_0 + A$	k_2
[3]	${}^1A_n \rightarrow$ Removal	k_3
[4]	${}^1A_0 \rightarrow A + h\nu_f$	k_4
[5]	${}^1A_0 \rightarrow$ Removal	k_5

It was shown that under appropriate conditions enhancement of the fluorescence could occur when high pressures of an added gas were present. However, in this study the ketone pressure was maintained at 200 Torr and this pressure corresponds to essentially complete deactivation of any vibrationally excited singlet states before emission occurs. So the quenching of electronically excited singlet state chloropentafluoroacetone molecules in low vibrational levels is discussed in this paper.

If the process

$$ {}^1A_0 + Q \rightarrow \text{Removal} \qquad k_6 $$

is added to the mechanism then a steady state treatment of the kinetics yields

$$ Q_0/Q = 1 + k_6\tau[G] $$

where τ is the actual lifetime of the excited singlet state in the absence of the olefin quencher, G, and is the reciprocal of the sum of the unimolecular processes removing the singlet ($k_4 + k_5$). Since τ has been determined experimentally to be 3.5×10^{-8} s (14), the quenching rate constant k_6 for each olefin can be determined from the slopes of the lines of Figs. 1–5.

Table 1 lists the quenching rate constants for the olefin quenchers and also shows the adiabatic ionization potentials of the quenching molecules. The rate constants reported are probably precise to about 5%. The errors are larger for those molecules which are inefficient quenchers or relatively involatile (so that only a restricted pressure range could be studied).

TABLE 1. Rate constants and ionization potential of quencher for ketone fluorescence

Quencher	k_6 (M^{-1} s^{-1})	Ionization potential (eV)
1,3-Pentadiene	9.7×10^{10}	8.68*
Ethylene	2.9×10^{9}	10.51†

Consider now the relative values of the quenching rate constants. In their study of the quenching of the fluorescence of hexafluoroacetone in the gas phase Ware and Lee (10) found that 1,3-pentadiene had the largest quenching rate constant with a value of 8.0×10^{10} M^{-1} s^{-1}. In comparison a rate constant of 9.7×10^{10} M^{-1} s^{-1} is observed for the quenching by 1,3-pentadiene of chloropentafluoroacetone fluorescence. The quenching behavior of the diolefin is similar in hexafluoro and chloropentafluoroacetone photolysis.

The straight chain mono-olefins that are unsaturated in the 1 position are an interesting series of molecules. The first comment concerns the much smaller value of k_6 for ethylene (2.9×10^9) as compared to that of the diolefin (9.7×10^{10}). There is a sharp increase in k_6 for propylene (2.3×10^{10}) as compared to ethylene and this is presumably due to the inductive effect of the methyl group on the double bond. However, further increase in the side chain only increases k_6 for but-1-ene to 2.4×10^{10} and for hex-1-ene to 2.9×10^{10}. This further emphasizes that a methyl group as a substituent on the double bond is almost as effective as an ethyl, or butyl group. Again the quenching of chloropentafluoroacetone fluorescence is similar to that of hexafluoroacetone fluorescence, since Ware and Lee found that the quenching constants for ethylene (4.1×10^9) and propylene (1.6×10^{10}) also differed significantly.

The effect of successive substitution of a hydrogen atom in ethylene by a methyl group can also be clearly seen in the sequence ethylene, propylene, 2-methylpropene, and 2,3-dimethyl-but-2-ene. The k_6 value for 2-methyl propene (4.8×10^{10}) is about twice that for propylene (2.3×10^{10}), while the value for 2,3-dimethyl-but-2-ene (1.7×10^{11}) is about 3.5 times larger than that of 2-methylpropene, so the effect of methyl substitution is not just additive.

The value of k_6 for 2-methylpropene (4.8×10^{10}) differs from that for *cis*-but-2-ene (5.6×10^{10}) by little more than the combined experimental error; again compatible with the quenching data for hexafluoroacetone, where 2-methylpropene and *cis*-but-2-ene were both found to be 3.5×10^{10} M^{-1} s^{-1}. However, the quenching of chloropentafluoroacetone fluorescence by but-1-ene (2.4×10^{10}) is much smaller and shows that not all butenes are equally efficient in deactivating the excited singlet state of the ketone.

The following mechanisms might explain the quenching effect of the olefins on the excited singlet state of chloropentafluoroacetone. They are similar to those suggested by Gandini and Kutschke (7) to explain the quenching effect of hydrocarbons on the triplet state of hexafluoroacetone.

(*1*) The ketone molecule transfers energy to the olefin to promote it to its first excited singlet state. However, the singlet state energy of chloropentafluoroacetone is about 83 kcal (14) and the first excited π^*,π singlet states of the olefins are at much higher energies (16). The probability of energy transfer with a very large endothermicity is negligible.

(*2*) The deactivation of the ketone is due to intersystem crossing to the triplet state of the ketone that is collisionally induced by the olefin. This, too, is unlikely as not all olefins, see below, are efficient quenchers of the ketone singlet state.

(*3*) The ketone molecule interacts with the olefin and a stable product may or may not be formed. This is the most likely explanation of the quenching behavior of the olefins and it is also compatible with the effect of methyl substitution on the quenching rate constant that was noted above. However, the most notable correlation is between the quenching constant of an olefin and its ionization potential. As the ionization potential of the quencher molecule decreases, its quenching rate constant in general is found to increase. A qualitative correlation of this type was also noted by Ware and Lee (10) in their

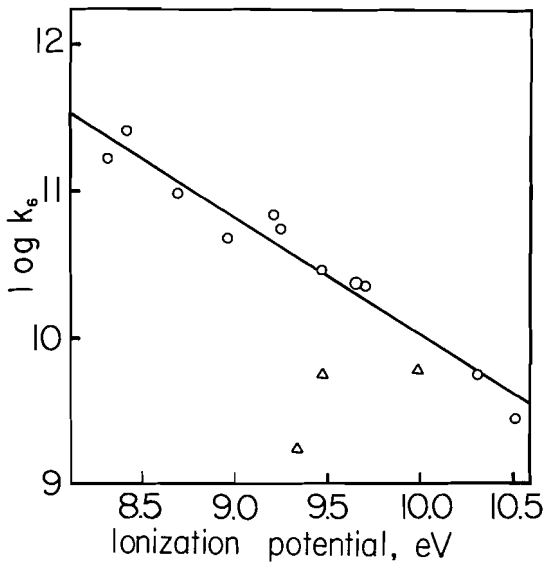

FIG. 6. Plot of logarithm of the quenching rate constant *vs.* ionization potential of quenching molecule. △, chlorinated ethylenes; ○, all other olefins.

study of the effect of olefin quenching on the first excited singlet of hexafluoroacetone. However, in the present study a larger number of quenching olefins has been studied and this allows a quantitative comparison between quenching rate constant and the ionization potential of the olefin. Figure 6 shows a plot of the logarithm of the quenching rate constant *vs.* the ionization potential of the olefin. It includes not only the data on the unsubstituted mono-olefins discussed above, but also the data on substituted olefins that are to be discussed below. If one restricts attention for the moment to the eight unsubstituted mono-olefins discussed above, then it is found that there is a linear relation between (log k_6) and the ionization potential (i.p.) of the olefin of the form $\log k_6 = 17.6 - 0.76$ (i.p.). The correlation factor for the line is 0.974 and the sigma values of the intercept and slope are 0.7 and 0.07, respectively.

In an attempt to confirm or reject the hypothesis the series of substituted olefins was investigated. The quenching rate constant for 1,1-difluoroethylene is compatible with the hypothesis. However, it was found that perfluorobut-2-ene is a very inefficient quencher. The ionization potential of perfluorobut-2-ene is not available but this molecule could well be an exception to the above hypothesis. The next series of molecules to be considered are the chlorinated olefins and the data for these molecules are shown by the triangles on Fig. 6. The data for both tetrachloroethylene and trichloroethylene are not in agreement with the above hypothesis. It was found that cyanoethylene was also an inefficient quencher. The exceptions to the hypothesis are molecules that have strong electron-withdrawing groups attached directly to the double bond and clearly the correlation between $\log k_6$ and the ionization potential is not valid for these molecules. This includes the behavior of perfluorobut-2-ene where the trifluoromethyl groups have a strong effect, but not 1,1-difluoroethylene which seems to obey the hypothesis. This could be due to the "back-bonding" effect by the fluorine lone pair electrons that allows the fluorine atom to act as a weak π electron donor (17) when it is substituted directly on the double bond.

Other unsubstituted unsaturated molecules were investigated to further test the hypothesis. The molecules chosen were cyclohexene, 1,3-cyclohexadiene, and benzene to check the effect of increasing the unsaturation. It can be seen from Table 1 that the quenching increases from cyclohexene (7.1×10^{10}) to cyclohexadiene (2.7×10^{11}) and decreases to 2.7×10^{10} M^{-1} s^{-1} for benzene. This behavior is in excellent accord with the ionization potentials of the quenching molecules. It confirms that there is a linear relation between the logarithm of the quenching rate constant and the ionization potential of the quenching molecule for unsubstituted olefins that do not contain electron-withdrawing groups. If one excludes the data for perfluorobut-2-ene, cyanoethylene, and chlorinated ethylenes then $\log k_6 = 18.0 - 0.79$ (i.p.) with sigma values of the intercept and slope of 0.6 and 0.06, respectively (the correlation factor is 0.97).

A similar correlation has been observed by Swarc and co-workers (18, 19) in the addition of the strongly electrophilic trifluoromethyl radical to mono-olefins and substituted benzenes. They also proposed that a charge-transfer interaction was involved in the process.

The electronically excited singlet state of the ketone interacts with the unsubstituted mono-olefins, cyclohexene, 1,3-cyclohexadiene, and benzene via a charge transfer mechanism. The correlation implies that there are only small changes in the pre-exponential factors for the different quenching molecules that obey the correlation. It also implies that the activation energy of the quenching reaction is linearly related to the

ionization potential of the quenching molecule. Note that 1,3-cyclohexadiene quenches the singlet state at practically every collision.

Ware and Lee (10) showed that there was a qualitative correlation between the rate constant for quenching hexafluoroacetone fluorescence and the ionization potential of the quenching molecule. However, they noted that the quenching rate constant decreased with increasing temperature. They introduced a mechanism that involved a collision complex that could either cause quenching or revert to an electronically excited ketone molecule and the ground state quencher molecule. The present data suggests that the collision complex in the quenching of chloropentafluoroacetone is removed mostly by the process that involves quenching.

It has been suggested (10) that similar mechanisms operate in the olefin quenching of the singlet and triplet states of hexafluoroacetone. So a correlation might exist between the ionization potential and the quenching rate constant of a quencher for the triplet states of hexafluoroacetone and chloropentafluoroacetone. The available data (7) on the quenching of the triplet of hexafluoroacetone are not inconsistent with such a correlation.

We thank Dr. K. O. Kutschke for communicating his results and the National Research Council of Canada for financial support.

Electron Spin Resonance Spectra of Azine – Alkali Metal Triple Ions in Ethereal Solvents

S. A. AL-BALDAWI AND T. E. GOUGH[1]

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received February 5, 1971

Electron spin resonance spectroscopy has been used to study triple ions formed between pyrazine and tetramethylpyrazine and the cations Li^+, Na^+, K^+ in dimethoxyethane, tetrahydrofuran, and 2-methyltetrahydrofuran. Differential line-broadening effects are reported within the hyperfine splitting patterns of the alkali metals incorporated into the triple ions, and a possible application of such effects to the study of ionic association is described.

La résonance paramagnétique électronique a été utilisée pour étudier les ions triples formés entre la pyrazine et la tétraméthyl-pyrazine et les cations Li^+, Na^+, K^+ dans le diméthoxyéthane. Des effets de largeur de raies différentielles sont observés parmi les écarts hyperfins des métaux alcalins incorporés dans les ions triples et une application possible de ces effets pour l'étude de l'association ionique est décrite.

Canadian Journal of Chemistry, 49, 2059 (1971)

Introduction

Recently, electron spin resonance (e.s.r.) spectroscopy has been used to demonstrate the existence, in ethereal solvents, of triple ions of the general formula Na_2A^+ where A may be *p*-benzosemiquinone, pyrazine or their methylated derivatives (1–3). From the hyperfine splitting patterns of the e.s.r. spectra it has been deduced that these triple ions have symmetrical structures, one cation associating with each electronegative site of the anion. A particularly interesting feature of such spectra is that the differential line-broadening effects, caused by molecular tumbling modulating the line-positions through anisotropies in the **g** and hyperfine tensors, are extremely pronounced. From these line-broadening effects it has been found possible, following the theory of Freed and Fraenkel (4, 5), to characterize the form of the hyperfine tensor of the sodium counter ions, and thence to deduce that these counter ions occupy positions along the O–O or N–N axes of the anions. In the present work we extend the range of counter ions to include lithium, potassium and, unsuccessfully, cesium, and indicate further information available from semi-quantitative analyses of line-width variations within the spectra.

Experimental

Pyrazine (P), tetramethylpyrazine (TMP), and sodium tetraphenylboride were purchased commercially and used without further purification. Lithium, potassium, and cesium tetraphenylborides were prepared by metathetical reactions between sodium tetraphenylboride and the appropriate alkali halide, following standard literature procedures (6). Dimethoxyethane (DME), tetrahydrofuran (THF), and 2-methyltetrahydrofuran (MeTHF) were purified by fractional distillation, dried by refluxing over sodium, and stored *in vacuo* in the presence of the sodium ketyl of benzophenone. Apparatus for the production of triple ions and the recording of their e.s.r. spectra were as described previously (3). Reduction by lithium was performed using lithium chips, introduced into the reduction apparatus in an argon-filled dry-box, and normally took a few hours to reach completion. Potassium tetraphenylboride was relatively insoluble in the ethereal solvents used, and so triple ions containing potassium were prepared by contacting a solution of the azine with a potassium film in the presence of a milky suspension of the tetraphenylboride. Overnight, the suspension cleared leaving a yellow solution having an intense e.s.r. spectrum. Cesium films were prepared in the reduction apparatus by heating mixtures of calcium filings and powdered cesium chloride *in vacuo*, and driving the cesium vapor through a sintered glass frit.

Results

The preparation and e.s.r. spectra of Na_2P^+ and Na_2TMP^+ in THF and in MeTHF have been reported previously (3). Using the techniques described in the experimental section the following additional triple ions were successfully observed: Li_2P^+ and Li_2TMP^+ in DME, THF, and MeTHF, K_2P^+ and K_2TMP^+ in THF. Attempts to produce Cs_2P^+ and Cs_2TMP^+ were unsuccessful in all three solvents; small additions of cesium tetraphenylboride to solutions of cesium–azine ion-pairs collapsed the cesium hyperfine structure and larger additions destroyed the e.s.r. signal completely. TABLE 1. Hyperfine splitting constants of hydrogen and nitrogen for azine triple ions at 20 °C*

		M_2P^+		M_2TMP^+	
Solvent	M	a_H (G)	a_N (G)	a_H (G)	a_N (G)
DME	Li	2.79	6.90	1.77	6.11
THF	Li	2.75	6.80	1.77	6.11
MeTHF	Li	2.78	6.89	—	—
THF	Na	2.70	7.12	1.78	6.19
MeTHF	Na	2.69	7.13	1.77	6.10
THF	K	2.65	7.13	1.79	6.10

*All values are accurate to ±0.03 G.

shows the e.s.r. spectrum of K_2P^+ in THF recorded at a sample temperature of −40 °C. The hyperfine septets generated by the two equivalent potassium nuclei are clearly visible on the $\tilde{M}_N = 0$ lines of spectrum, and just visible on the $\tilde{M}_N = -1$ components. Line broadening effects obscure the potassium hyperfine structure in the remainder of the spectrum.

For all the azine triple ion systems studied in the present work, the nitrogen and proton hyperfine splitting constants were, within the experimental error of ±0.03 G, independent of temperature. Measured values of these splitting constants are given in Table 1. However, alkali metal hyperfine splitting constants were found to be temperature dependent; to facilitate comparison between the various alkali metals, in Fig. 2 we have plotted observed metal hyperfine splitting constant divided by the appropriate atomic hyperfine splitting constant as a function of temperature for the triple ions M_2P^+ and M_2TMP^+ (M = Li, Na, K) in THF, the only solvent in which all these species are stable.

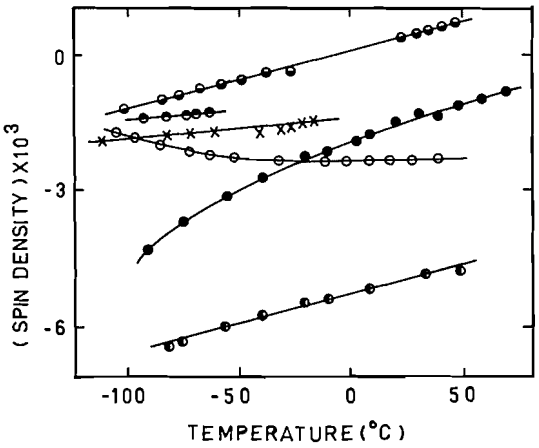

FIG. 2. Alkali metal hyperfine splitting constants in G divided by the corresponding atomic hyperfine coupling constants and given as a function of temperature for the following systems in THF: ◒, Na_2TMP^+; ◓, K_2TMP^+; ×, K_2P^+; ●, Li_2TMP^+; ○, Na_2P^+; ◐, Li_2P^+.

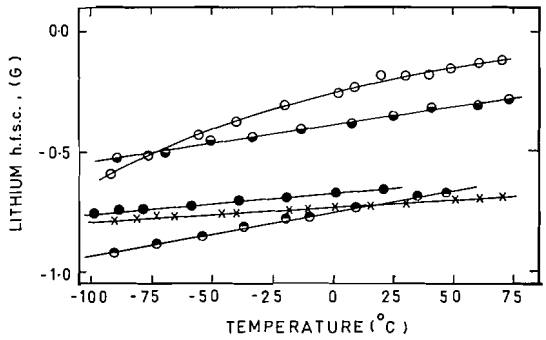

FIG. 3. Lithium hyperfine splitting constants in G as a function of temperature for the following systems: ○, Li_2TMP^+ in THF; ◒, Li_2TMP^+ in DME; ●, Li_2P^+ in DME; ×, Li_2P^+ in MeTHF; ◓, Li_2P^+ in THF.

The effect of solvent upon the alkali metal hyperfine splitting constants is shown for the lithium triple ions in Fig. 3; only Li_2P^+ could be formed in all three solvents used. The choice of signs for the metal hyperfine splitting constants follows from arguments previously listed (2, 3).

As had been previously observed, differential line-broadening effects were found to be very pronounced in the e.s.r. spectra of azine triple ions. In Fig. 4 the widths of the principle nitrogen lines (lines having spectral indices for all nuclei other than nitrogen equal to zero) relative to the width of the central $\tilde{M}_N = 0$ line are plotted as a function of $\tilde{M}_N$. The curves drawn through the data represent the least-squares fits of the data to equations of the form [1] proposed empirically by Barton and Fraenkel (7).

$$[1] \qquad W = 1.00 + A_N\tilde{M}_N + B_N\tilde{M}_N^2$$

Relative widths were determined by the stan-

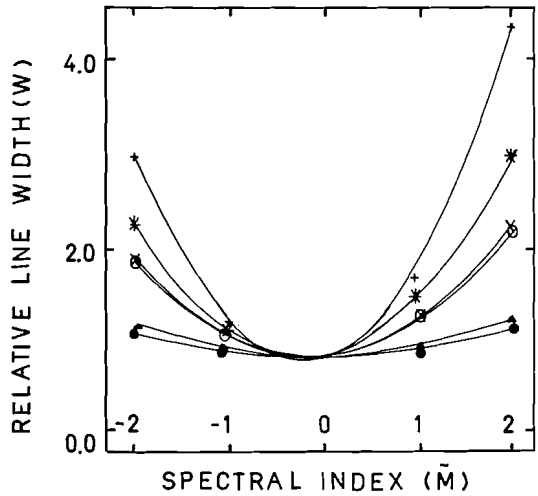

FIG. 4. The least-square fit of the experimental linewidths of the principle nitrogen lines relative to the center line ($\tilde{M} = 0$) to the equation $W = 1 + A\tilde{M}_N + B\tilde{M}_N^2$ for the following systems in THF at 10 °C: ▲ K_2TMP^+; ●, K_2P^+; ○, Na_2P^+; ×, Li_2P^+; ★, Na_2TMP^+; +, Li_2TMP^+. For the significance of A and B see text and Table 2.

dard method of measuring relative amplitudes of the first derivative presentation: values of A_N and B_N obtained from the least-squares fitting are given in Table 2. Values are not given for the potassium species because the unresolved potassium hyperfine structure prevents the determination of reliable values for A_N and B_N. Table 3 contains values of A_N, B_N, A_{Li}, and B_{Li} determined for Li_2P^+ at 10 °C in DME, THF, and MeTHF. For the MeTHF sample, overlapping lines at 10 °C prevented a direct accurate determination of the A and B values. Therefore, measurements were made at more favorable temperatures and interpolated to values at 10 °C; the interpolations were made by plotting the measured line-width parameters as functions of solvent viscosity/temperature, such plots being linear as predicted by the theory of Freed and Fraenkel (4). Values for the viscosity were taken from tables published by Szwarc (8).

TABLE 2. A_N and B_N values for azine triple ion at 10 °C in THF calculated by least square fit of the experimental relative line widths to the equation $W = 1 + A_N\tilde{M}_N + B_N\tilde{M}_N^2$

Triple ion	A	B
Li_2P^+	0.0854	0.2768
Li_2TMP^+	0.2863	0.6376
Na_2P^+	0.0767	0.2659
Na_2TMP^+	0.1632	0.4062

TABLE 3. Values of A_N, B_N, A_{Li}, and B_{Li} for Li_2P^+ in THF, MeTHF, and DME obtained from the equation $W = 1 + A\tilde{M} + B\tilde{M}^2$; sample temperature 10 °C

Solvent	A_N	B_N	A_{Li}	B_{Li}
DME	0.0792	0.1123	0.0157	0.0074
THF	0.0854	0.2768	0.0158	0.0164
MeTHF	0.0767	0.2659	0.0164	0.0260

Discussion

The isotropic metal hyperfine splitting constants for the lithium and sodium azine triple ions in Fig. 2 deserve little comment since they follow the expectations of our previous discussion (2, 3); a more negative value is obtained for the unsubstituted pyrazine because the counter-ion can approach closer to the molecular plane of the anion. Similarly, in spin density units, the lithium splitting is more negative than the sodium splitting, suggesting that the lithium cation forms a "tighter" triple ion than does sodium. This tighter character of the lithium triple ion is reflected in the nitrogen and hydrogen hyperfine splitting constants of Na_2P^+ and Li_2P^+; in the tighter associate more charge is localized into the $2p_z$ orbital of nitrogen thereby repelling spin into the $2p_z$ carbon orbitals, causing a decrease in a_N and an increase in a_H (see Table 1). This decrease in a_N has also been observed by Carrington (9); the situation is analogous to the behavior of the carbonyl groups of semiquinones (10–12) and ketyls (13, 14) under the influence of ionic association.

The potassium hyperfine splitting constant of K_2P^+ fits into the overall description of these systems with the assumption (*cf.* refs. 2 and 3) that da_K/dT is positive which means a_K must be negative. As can be seen from Fig. 1(b) any broadening of the central septet linear in $\tilde{M}_K$ is undetectable and so no check on the sign of a_K is available. However, for K_2TMP^+ in THF, pronounced high field broadening of the central septet was detected, thereby establishing (2, 3) that a_K is indeed negative for this system. It can be seen that the amount of spin density on the counter ion decreases smoothly with increasing M^+ radius for M_2P^+ which is as expected if one correlates the strength of the ionic interaction with the extent of spin transfer. However, such a correlation does not hold for the M_2TMP^+ species, indicating the difficulties inherent in the

interpretation of metal splitting constants. To interpret the data in Fig. 3 in terms of the effect of solvent upon the strength of the lithium–pyrazine interaction is obviously impossible.

The B_M values reported in Table 3 are a potential source of information concerning the strength of the lithium pyrazine interaction. B_M is a measure of the strength of the anisotropic dipolar interaction between lithium and the unpaired electron. Because the lithium nucleus is close to the N–N axis, this dipolar interaction is dominated (> 95%) by the spin density on nitrogen, and hence the magnitude of the lithium–electron dipolar interaction is an indication of the lithium–nitrogen distance and hence of the strength of the lithium–pyrazine interaction. However, B_M is also a function of the correlation time for molecular tumbling τ_R, and so to make comparisons between systems as to the strength of the lithium–pyrazine interaction it is first necessary to eliminate the effects of variations in τ_R. This is most readily done by dividing B_M by B_N, since both terms are linearly dependent upon τ_R provided (as is normally assumed (4)) that electronic non-secular terms may be neglected, and provided that the spin density on nitrogen is the same among the systems under comparison. Therefore, within these limitations, as the strength of the lithium–pyrazine interaction increases, so should the value of B_M/B_N. The data given in Table 3 allow an evaluation of this approach for Li_2P^+ in DME, THF, and MeTHF at 10 °C; values of B_M/B_N, calculated from this data, are plotted in Fig. 5 against the reciprocal of the dielectric constant of the solvent, taken from data compiled by Szwarc (8). The number of points in Fig. 5 is too few to prove a linear dependence of B_M/B_N upon $1/D$, but would seem to demonstrate the expected increase in the lithium–pyrazine interaction as the polarity of the solvent is decreased. Thus measurements of counter ion line-width broadening patterns can be a useful approach to the study of the strength of ionic interactions.

It should be noted that both the nitrogen and proton hyperfine splitting constants of the tetramethylpyrazine species are appreciably smaller than the corresponding values of the pyrazine species. This would seem to indicate that the value of Q_{Me} normally used for methyl substituted hydrocarbon radicals is not suitable for azine radical anions. However, more methyl substituted azine anions need to be studied before more quantitative conclusions can be arrived at.

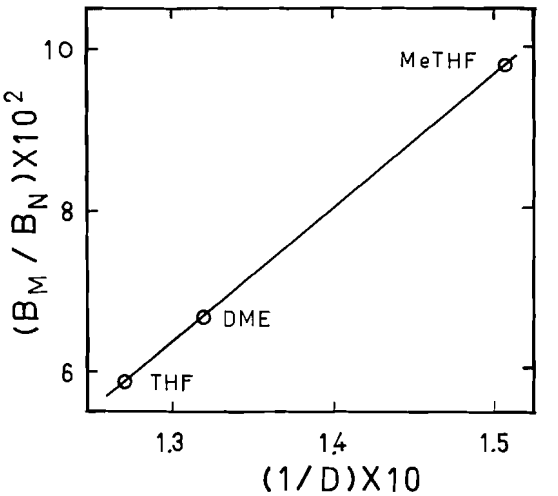

FIG. 5. The function B_M/B_N for the triple ion Li_2P^+ at 10 °C plotted as a function of the inverse dielectric constant of the solvent.

Reaction of *trans*-2-Acylaminocyclanols with Thionyl Chloride[1]

R. A. B. BANNARD, N. C. C. GIBSON, AND J. H. PARKKARI
Defence Research Establishment Ottawa, Ottawa, Canada

Received December 23, 1970

trans-2-Acetamidocyclohexanol (**1**; $n = 2$, R = CH_3) on addition to thionyl chloride in chloroform at 0° was converted rapidly and quantitatively to D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride (**2**; $n = 2$, R = CH_3) judging from shifts in the methyl proton resonances of the n.m.r. spectra of the amide and the reaction solution. The intermediate chlorosulfinate was estimated to have a half-life of less than 2.25 min. The oxazoline salt was isolated in 98% yield by sublimation of the crude product *in vacuo* and was identified by its i.r. and n.m.r. spectra and by its facile and almost quantitative hydrolysis to *cis*-2-aminocyclohexanol hydrochloride. The oxazoline salts **2** ($n = 1$, R = CH_3, C_6H_4-*p*NO_2 and $n = 2$, R = C_6H_5, C_6H_4-*p*NO_2) were readily obtained in 95% yield or better by the same general method and it was shown that the *trans*-2-acetamidocyclanols are the preferred starting materials for conversion to *cis*-2-aminocyclanol derivatives by the thionyl chloride inversion reaction. The oxazoline bases **4** ($n = 1$, R = CH_3, C_6H_4-*p*NO_2 and $n = 2$, R = CH_3, C_6H_4-*p*NO_2) were readily obtained in high yield from the corresponding salts and differences in the i.r. and n.m.r. spectral characteristics of the salts and bases are reported.

La D,L-méthyl-2 cyclohexano-4,5-*cis* oxazoline (**2**; $n = 2$, R = CH_3) est rapidement et quantitativement produite en ajoutant le chlorure de thionyle à 0 °C à l'acétamido-2 cyclohexanol-*trans* (**1**; $n = 2$, R = CH_3) dans du chloroforme. On estime que le demi temps de vie du chlorosulfinate intermédiaire est moins que 2.25 min. Ce résultat est mis en évidence par un glissement dans le signal des protons du groupement méthyle dans les spectres r.m.n., de l'amide et de la solution réactionnelle. Le chlorhydrate de l'oxazoline est isolé avec un rendement de 98% par la sublimation sous vide du produit brut. On a établi la structure du composé en se servant de données obtenues par spectroscopie i.r. et r.m.n. et on l'a vérifiée par une méthode d'hydrolyse simple qui conduit avec un rendement pratiquement quantitatif au chlorhydrate de l'amino-2 cyclohexanol-*cis*. On obtient facilement les chlorohydrates des oxazolines **2** ($n = 1$, R = CH_3, C_6H_4-*p*NO_2 et $n = 2$, R = C_6H_5, C_6H_4-*p*NO_2) avec des rendements d'au moins 95% en utilisant la même méthode générale et on a démontré que les acétamido-2 cyclanols-*trans* sont les produits de départ les plus utiles pour obtenir les dérivés d'aminocyclanol-2-*cis* par la réaction d'inversion à l'aide du chlorure de thionyle. On obtient facilement les bases oxazolines **4** ($n = 1$, R = CH_3, C_6H_4-*p*NO_2 et $n = 2$, R = CH_3, C_6H_4-*p*NO_2) avec de bons rendements à partir des sels correspondants et on décrit des différences dans les spectres r.m.n. et i.r. des sels et des bases.

Canadian Journal of Chemistry, 49, 2064 (1971)

In 1950, Johnson and Schubert (1) and McCasland and Smith (2) reported simultaneously and independently studies on the reaction between *trans*-2-benzamidocyclanols **1** ($n = 1, 2$, R = C_6H_5, C_6H_4-*p*NO_2) and thionyl chloride, which led by an inversion process to D,L-2-phenyl-4,5-*cis*-cycloalkanoöxazoline hydrochlorides **2** ($n = 1, 2$, R = C_6H_5, C_6H_4-*p*NO_2). Hydrolysis of the latter with aqueous hydrochloric acid proceeded with retention of configuration to provide low over-all yields (40–50%) of *cis*-2-aminocyclanol hydrochlorides **3** ($n = 1, 2$). These two groups of workers considered the oxazoline salts, which they found to be unstable and difficult to isolate in a pure condition, to arise by the internal S_N2 displacement of a hydroxyl or chlorosulfinate group by the oxygen atom of the amide carbonyl group. This viewpoint was strengthened by Winstein and Boschan's (3) classic study of the participation of the benzamido group in neighboring displacements in which they showed, among other things, that *trans*-2-benzamidocyclohexyl *p*-toluenesulfonate was converted almost quantitatively to the corresponding oxazoline tosylate in refluxing glacial acetic acid in 6 min. They also examined the reaction between *trans*-2-benzamidocyclohexanol and thionyl chloride at 0°, ultimately isolating *cis*-2-benzamidocyclohexanol in high yield by hydrolysis of the intermediate oxazoline hydrochloride **2** ($n = 2$, R = C_6H_5), which they considered to result by internal displacement of a chlorosulfinate group which had been introduced into the molecule by a rapid initial reaction of the hydroxyl group with thionyl chloride. These workers also determined the rate of displacement

[1]Issued as DREO Report No. 638.

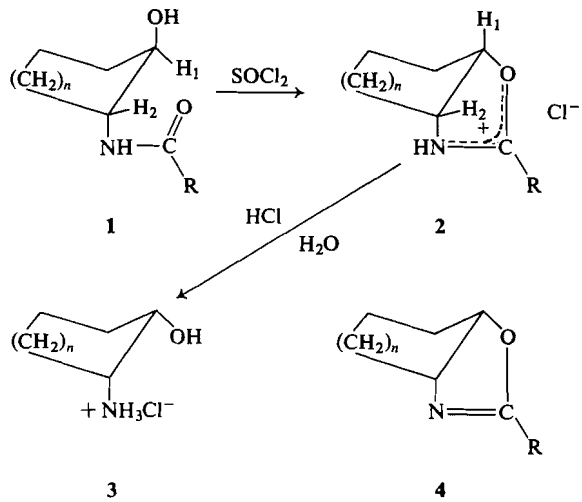
of the tosyl group from *trans*-2-benzamidocyclohexyl tosylate under solvolytic conditions in anhydrous ethanol at 74°, from which it was clear that the half-life of the substrate under these conditions is approximately 6.5 min at 74° or 1060 h at 0°. No effort was made, however, to study the rate of conversion of *trans*-2-acylaminocyclanols to the oxazoline salts by thionyl chloride.

We first became interested in the acylaminocyclanol – thionyl chloride reaction several years ago when one of us (4) briefly examined the conversion of *trans*-2-acetamidocyclohexanol (**1**; $n = 2$, R = CH_3) to *cis*-2-aminocyclohexanol and its derivatives by this means. The yields obtained at that time were significantly better than those reported by Johnson and Schubert (1) starting from the benzamido analogue but not nearly as good as that reported by Winstein and Boschan (3). Because of our continuing interest in the conversion of *trans*-2-acylaminocyclanols to their *cis*-analogues we decided to reexamine the reaction from two standpoints, firstly to attempt to develop it into a useful synthetic method, and secondly to attempt to obtain an approximate measure of the rate of the reaction. It occurred to us in the latter connection that it should be possible, in principle at least, to follow the rate of the reaction by observing either the rate of appearance of D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride (**2**; $n = 2$, R = CH_3), or the rate of disappearance of *trans*-2-acetamidocyclohexanol or the intermediate chlorosulfinate by looking for shifts in the methyl resonances in the n.m.r. spectrum of the reaction mixture.

We first examined the addition of *trans*-2-acetamidocyclohexanol (1 mol) dissolved in anhydrous chloroform to thionyl chloride (3.85 mol) at 0°.[2] Because of the exothermicity of the reaction even when moderated by the presence of the solvent, addition of the amide required 20 min. A sample taken immediately thereafter for n.m.r. examination revealed no trace of the starting material, judging from the complete absence of an acetamido methyl proton resonance



at τ 8.01, (Fig. 1*a*) and the presence of a new methyl resonance equivalent to three protons at τ 7.41, together with broad methine resonances at τ 4.90 and 5.91 and methylene resonances from τ 7.8–8.6 in the reaction solution (Fig. 1*b*). The spectrum was measured at intervals for a period of 48 h and although the solution, which was originally pale pink, gradually became deep red in color, there was no change in the appearance of the spectrum. The oxazoline hydrochloride **2** ($n = 2$, R = CH_3) could be isolated in quantitative crude yield, m.p. 98.5–100.5°, as described in the Experimental, 2 h after the addition of the amide had been completed and it was therefore concluded that the n.m.r. spectrum obtained within 5 min of completion of the addition indicated that the reaction had proceeded to completion within 25 min.

Subsequent experiments conducted on a semimicro scale at 0° in which the addition of the amide was completed in 1.25 min established that the reaction had proceeded to completion in less than 9 min from the start of addition of the amide, judging from the fact that the n.m.r. spectrum of the reaction solution was identical with that of Fig. 1*b*. Assuming that the formation of chlorosulfinate is virtually instantaneous and that four half-lives of the chlorosulfinate would be required to produce a spectrum of oxazoline salt apparently free of contaminants, it is concluded that the half-life of the chlorosulfinate cannot exceed 2.25 min at 0°. Thus the rate of oxazoline salt formation from the chlorosulfinate of the hydroxyamide **1** ($n = 2$, R = CH_3)

[2]These conditions represented the best features of procedures due to Winstein and Boschan (3) (temperature and molar proportions) and Elliott (5) (addition of amide in solvent). Most other workers (1–3, 6–8) have used portionwise addition of the amide to neat thionyl chloride.

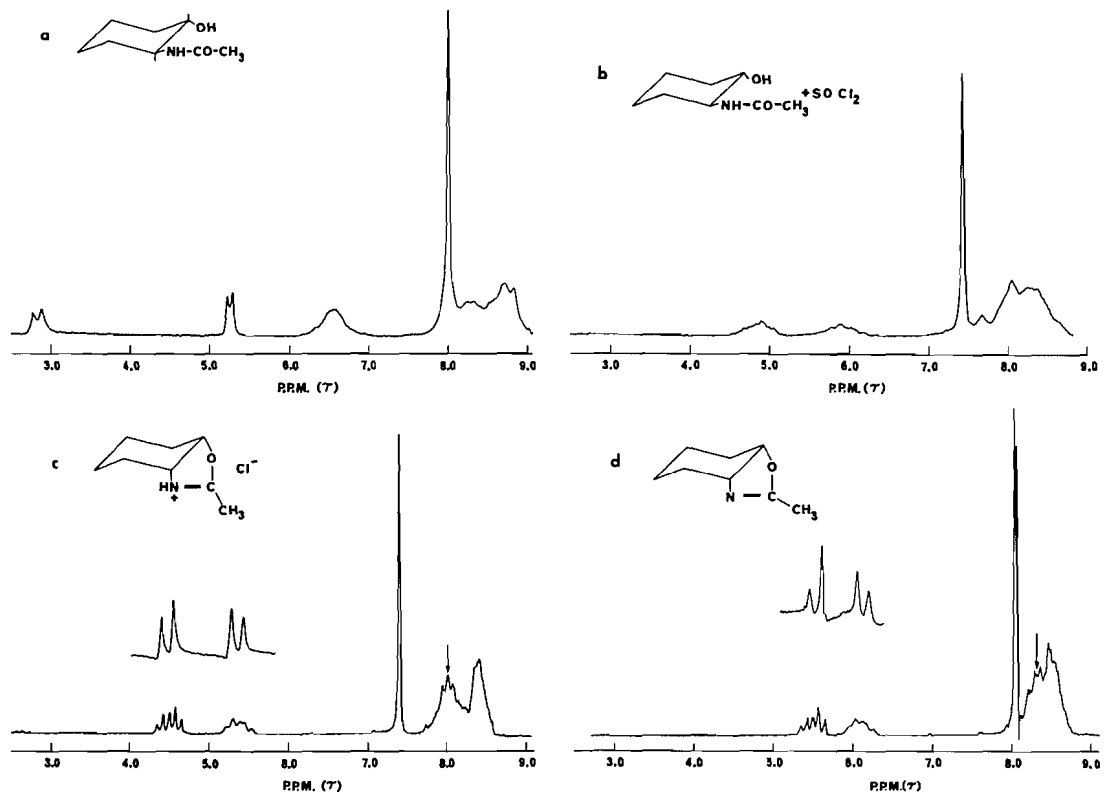


FIG. 1. (*a*) The 60 MHz n.m.r. spectrum of *trans*-2-acetamidocyclohexanol in chloroform.
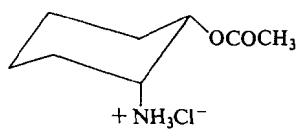
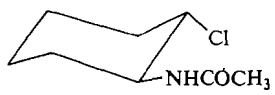
(*b*) The 60 MHz n.m.r. spectrum of *trans*-2-acetamidocyclohexanol + excess thionyl chloride in chloroform (recorded 25 min after initiation of the reaction).
(*c*) The 60 MHz Spectrum of D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride in chloroform (insert shows methine proton resonances resulting from irradiation of H-3 and -6 at τ 8.01).
(*d*) The 60 MHz n.m.r. spectrum of D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline in chloroform (insert shows methine proton resonances resulting from irradiation of H-3 and -6 at τ 8.30).

in chloroform – thionyl chloride is at least 2.8×10^4 times faster than by solvolysis of the hydroxyamide *p*-toluenesulfonate in ethanol at 0°.

The oxazoline salt **2** ($n = 2$, $R = CH_3$) is extremely hygroscopic and on attempted recrystallization from anhydrous chloroform – ether or absolute ethanol – ether decomposes with the formation of a difficultly separable mixture of D,L-*cis*-1-acetoxy-2-aminocyclohexane hydrochloride (**5**) and D,L-*trans*-1-chloro-2-acetamidocyclohexane (**6**). The *O*-acetylamine hydrochloride **5** probably results from a simple acidic partial hydrolysis of the oxazoline salt by traces of moisture in the solvents, with concomitant N → O acyl migration (9–12) and the chloroamide **6** is likely formed by opening of the ring by backside displacement of the oxazoline oxygen



5



6

by the chloride ion present in hot solutions of the salt (3, 5, 13). The crude oxazoline hydrochloride was readily purified by sublimation *in vacuo* and was obtained in 98% yield as a colorless crystalline solid, which was readily hydrolyzed quantitatively to *cis*-2-aminocyclo-

hexanol hydrochloride **3** ($n = 2$), by brief heating with 10% aqueous hydrochloric acid (*cf.* 1, 2, 4). This two-step reaction sequence thus provides an almost quantitative conversion of *trans*-2-acetamidocyclohexanol to *cis*-2-aminocyclohexanol hydrochloride.

The isolated oxazoline salt **2** ($n = 2$, R = CH_3) gave a much sharper spectrum (Fig. 1*c*) than that obtained directly from the reaction solution and some shifts in the positions of the resonances were noted presumably because of the removal of the thionyl chloride from the system.[3] For example, the methine resonances were now seen to be sharp (H-1) and broad (H-2) multiplets at τ 4.50 and 5.38 respectively. A sharp methylene triplet was now evident at τ 8.01, which decoupling experiments clearly indicated to be due to H-3*a*,*e* and -6*a*,*e* (see below).[4] The methyl resonance had shifted slightly to τ 7.40 and was now clearly seen to be a doublet ($J \approx 0.5$–0.8 Hz). Irradiation of H-2 caused this doublet to collapse to a singlet. Similarly, irradiation of the methyl doublet caused the broad multiplet at τ 5.38 to sharpen, confirming the long range coupling between H-2 and the methyl group. Irradiation of H-3*a*,*e* and -6*a*,*e* at τ 8.01 caused the methine multiplets at τ 4.50 and 5.38 to collapse to an AB quartet ($J_{1,2} = 8.5$–9.0 Hz).

The n.m.r. spectrum of the oxazoline free base **4** (R = CH_3, $n = 2$) (Fig. 1*d*) shows some significant differences (see Table 1) from that of the oxazoline hydrochloride **2** (R = CH_3, $n = 2$) from which it was readily prepared, *e.g.* the oxazoline methyl proton doublet is shifted upfield to τ 8.03 ($J \approx 1.5$ Hz). Irradiation of H-2, which is shifted upfield to τ 6.10, caused the methyl doublet to collapse to a sharp singlet, again indicating long range coupling between H-2 and the oxazoline methyl protons. The signal for H-1 is also shifted upfield to τ 5.50 and now appeared as a double triplet. Irradiation of the H-3*a*,*e* and -6*a*,*e* triplet at τ 8.30 caused the methine multiplets from H-1 and -2 to collapse to an AB quartet ($J_{1,2} \approx 8.5$ Hz).

The long range coupling between H-2 and the oxazoline methyl protons agrees with the observations of Weinberger and Greenhalgh (14) on the occurrence of long range coupling between methyl protons and methylene or methine protons attached to the carbon atom which is also attached to nitrogen in monocyclic oxazolines and thiazolines. Also, the change in chemical shift in the oxazoline methyl proton resonance observed for **2** and **4** (R = CH_3, $n = 2$)[5] is characteristic for such compounds (14). The magnitude of $J_{1,2}$ observed in the salt and free base is not at variance with the assignment of a *cis*-fused oxazoline–cyclohexane structure to **2** ($n = 2$, R = CH_3) since several heterocyclic ring systems (15–19), including 2-oxazolidine–cyclohexane (18) have recently been reported in which $J_{cis} > J_{trans}$ due to a combination of substituent electronegativity effects and dihedral angular variation between the protons.

Assuming a flexible *cis* cyclohexane–oxazoline ring fusion and free inversion of the cyclohexane ring, average coupling constants were assigned to the interacting methine and adjacent methylene protons. The chemical shifts of the methine protons and $J_{1,2}$ (8.5 Hz) were obtained from the experimental spectrum. Substitution of these values in a modified LAOCOON-2 computer program (20) resulted in a spectrum drawn by a Calcomp plotter which showed good correspondence with the methine resonance pattern of the experimental spectrum, thus supporting the *cis*-fused ring structure. Assumption of a rigid *trans*-fused ring structure with appropriate values for the coupling constants and chemical shifts in a similar analysis gave poor correspondence with the methine resonances of the experimental spectrum.[6]

[3]Removal of the excess reagent and solvent *in vacuo* from the reaction mixture immediately after completion of the amide addition gave, on reconstitution in deuterochloroform, a spectrum identical with Fig. 1*c*.

[4]The approximate coincidence of the signals due to the methylene protons H-3 and -6 in 1,2-disubstituted cyclohexanes and cyclopentanes is not generally observed. However, this behavior was noted for such protons in all the cyclopentano- and cyclohexano-oxazolines examined herein.

[5]In structure **2** a proton is shown attached to the nitrogen atom, following the designation used for oxazolinium salts used in refs. 1–3. A referee has pointed out that the occurrence of long range coupling between methyl and H-2 in both the salt **2** and in the base **4**, the comparable sizes of the J values for these compounds and the circumstance that the signal for H-1 moves further upfield than does the signal for H-2 during the change from compound **2** to compound **4** may indicate that the proton is attached to oxygen rather than to nitrogen. Consequently, the location of the proton in the oxazoline ring is not certain, but in the absence of conclusive evidence to the contrary we prefer to use the protonated nitrogen structure.

[6]We are indebted to Prof. R. Y. Moir and Mr. R. S. Reeve, Department of Chemistry, Queen's University, Kingston, Ontario, for performing this analysis.

The i.r. spectra of the oxazoline salt **2** and free base **4** ($n = 2$, R = CH_3) also showed some characteristic features (see Table 2). The salt has a very strong absorption at 1667 cm^{-1} and the base a strong band at 1665 cm^{-1} which are undoubtedly due to the 2-oxazoline N=C—O group (21, 22). The salt also has strong imine salt absorption at 2100–2800 cm^{-1} and a medium intensity salt band at 1810 cm^{-1}, both of which are, of course, absent from the base. The i.r. spectrum of the pure oxazoline salt **2** ($n = 2$, R = CH_3) could be readily observed on samples removed from the reaction solution 5 min after completion of the addition of the amide to the thionyl chloride when they were treated as described in the Experimental to eliminate the excess reagent. The i.r. spectrum of the oxazoline salt is markedly different from that of *trans*-2-acetamidocyclohexanol, the latter containing free and bonded hydroxyl absorptions at 3590 and 3438 cm^{-1}, NH absorption at 3315 cm^{-1}, and amide II absorption at 1500 cm^{-1}, all of which are absent from the spectrum of the oxazoline salt (see Table 2).

The influence of reaction conditions on the yield of oxazoline salt **2** ($n = 2$, R = CH_3) was examined. Control of the reaction temperature at 18–20° caused the yield to fall to 92%, whereas addition of thionyl chloride to a slurry of the amide in chloroform at 5–10° gave a 96% yield. Addition of the amide via a worm-feed addition-tube (23) to a solution of thionyl chloride in chloroform at 0° provided a 98% yield.

The behavior of *trans*-2-acetamidocyclopentanol **1** ($n = 1$, R = CH_3) in the reaction was completely analogous to that of the corresponding cyclohexyl derivative, furnishing D,L-2-methyl-4,5-*cis*-cyclopentanoöxazoline hydrochloride **2** ($n = 1$, R = CH_3) in 95% yield. The latter substance was also readily purified by sublimation *in vacuo* and was hydrolyzed quantitatively to *cis*-2-aminocyclopentanol hydrochloride **3** ($n = 1$) in the usual manner.

The aryloxazoline salts **2** ($n = 2$, R = C_6H_5, C_6H_4-*p*NO_2 and $n = 1$, R = C_6H_4-*p*NO_2) were prepared in yields of 95% or better by the same method.[7] These compounds were not amenable to purification by recrystallization or by sublimation *in vacuo*, but were obtained analytically pure directly from the reaction if proper precautions for the exclusion of moisture were observed. They were also readily convertible to the corresponding free bases **4** ($n = 2$, R = C_6H_5, C_6H_4-*p*NO_2 and $n = 1$, R = C_6H_4-*p*NO_2) in high yield but did not provide yields of *cis*-2-aminocycloalkanol hydrochlorides above 91% by acidic hydrolysis, presumably owing to complications introduced by the formation of the more difficultly separable benzoic and *p*-nitrobenzoic acids as by-products. Consequently, the *trans*-2-acetamidocyclanols are the preferred intermediates for the synthesis of *cis*-2-aminocyclanol derivatives and can provide the latter readily in almost quantitative yield. Nuclear magnetic resonance spectroscopy was not as useful a tool for following the formation of the 2-aryloxazoline salts as it was for the 2-methyloxazoline salts because of the absence of the 2-methyl group, the i.r. spectra of the aryl compounds being more useful in this connection. The chemical shifts of the protons in the 60 MHz n.m.r. spectra of the 2-substituted oxazoline salts and bases examined in this work are given in Table 1 together with those of the *trans*-2-acetamidocyclanols. The principal i.r. absorption frequencies of the *trans*-2-acetamidocyclanols, oxazoline salts, and bases are shown in Table 2.

Experimental[8, 9]

The i.r. spectra were measured as 0.05–0.10 *M* solutions in chloroform on a Perkin–Elmer Model 221 spectrophotometer. When spectra were required of oxazoline salts present in reaction mixtures containing excess thionyl chloride, a sample of the reaction solution (0.1 ml) was distilled to dryness three times at room temperature or below with 1 ml of chloroform or deuterochloroform at water pump pressure, taking precautions to prevent access of water vapor to the sample.

The n.m.r. spectra were measured on a Varian V-4300C spectrometer (60 MHz) using a Varian V-5321 integrator for base-line stabilization. Solutions were 10–20% in chloroform or deuterochloroform and were calibrated with reference to internal tetramethylsilane by the usual side-band technique.

D,L-*trans*-2-Aminocyclohexanol and Derivatives

trans-2-Aminocyclohexanol, m.p. 67.5–68.5°, *trans*-2-aminocyclohexanol hydrochloride, m.p. 180–181°, and *trans*-2-acetamidocyclohexanol, m.p. 126.5–127.5°, were prepared following methods described by Hawkins and Bannard (24), *cf.* McCasland *et al.* (26). *trans*-2-Benzamidocyclohexanol, m.p. 171–172°, was prepared by application of the acylation procedure of Leffler and Adams (25) as reported by Johnson and Schubert (1).

[7]Because of solubility restrictions, these acylaminocyclanols were added *via* a worm-feed addition-tube (23) to thionyl chloride – chloroform solutions at 0°.

[8]All melting points are uncorrected.

[9]Microanalyses by J. G. Helie of these laboratories.

For personal use only.

Anal. Calcd. for $C_{13}H_{17}O_2N$: C, 71.20; H, 7.82; N, 6.39. Found: C, 71.03; H, 7.76; N, 6.56.

trans-2-*p*-Nitrobenzamidocyclohexanol, m.p. 211–211.5°, was prepared similarly (*cf.* McCasland and Smith (2)).

Anal. Calcd. for $C_{13}H_{16}O_4N_2$: C, 59.08; H, 6.10; N, 10.60. Found: C, 59.08; H, 6.00; N, 10.70.

D,L-*2-Methyl-4,5-cis-cyclohexanoöxazoline Hydrochloride (2; n = 2, R = CH_3)*

A solution of *trans*-2-acetamidocyclohexanol (3.92 g, 0.025 mol) in anhydrous chloroform (12 ml, Fisher spectro grade dried over silica gel) was added dropwise with stirring at −5 to 0° over a period of 20 min to thionyl chloride (7.0 ml, *ca.* 0.095 mol) in an apparatus protected against the entry of moisture. The dropping funnel used for the addition was rinsed with an additional 2 ml of chloroform. The temperature of the resultant colorless opalescent solution was allowed to rise to 21° over a period of 30 min while stirring was continued, following which stirring was continued at the same temperature for a further 2 h. The excess thionyl chloride and chloroform were removed from the pale pink solution by distillation at a pressure of 50–60 mm, leaving a viscous pink oil. Chloroform (2 ml) was added and the solution was added dropwise to vigorously stirred anhydrous ether (450 ml) at room temperature. A colorless oil separated and the ether layer became yellow. The mixture was kept overnight at 0° during which the oil crystallized. The ether was decanted and retained and the pale yellow crystals were collected, washed with anhydrous ether (5 × 25 ml), taking care to keep them covered with ether until washing was complete, and then were dried *in vacuo*; wt. 4.17 g, m.p. 98.5–100.5°. A second small crop of crystals, 0.15 g, was recovered by extraction of the residual material in the flask and funnel with chloroform, followed by removal of the solvent *in vacuo*. Evaporation of the ether decanted from the crystals gave 0.289 g of dark evil-smelling oil, which on hydrolysis with 10% hydrochloric acid, furnished 70 mg of *cis*-2-aminocyclohexanol hydrochloride (equivalent to 81 mg of oxazoline salt). Total yield of crude oxazoline hydrochloride, 4.40 g (100%). Sublimation of 200 mg of the crude salt at 50° at 0.001 mm furnished 196 mg (98.0%) of colorless hygroscopic crystals of D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride, m.p. 104–106°.[10]

Anal. Calcd. for $C_8H_{14}ONCl$: C, 54.69; H, 8.03; N, 7.98; Cl, 20.18. Found: C, 54.70; H, 8.20; N, 8.04; Cl, 20.10.

D,L-*cis-1-Acetoxy-2-aminocyclohexane Hydrochloride (5) and* D,L-*trans-1-Chloro-2-acetamidocyclohexane (6)*

Attempted recrystallization of the oxazoline salt (500 mg) from ethanol–ether or chloroform–ether resulted in decomposition and furnished 314 mg (55%) of D,L-*cis*-1-acetoxy-2-aminocyclohexane hydrochloride, as colorless needles, m.p. 213–213.5° (dec.).

Anal. Calcd. for $C_8H_{16}O_2NCl$: C, 49.60; H, 8.33; N, 7.23; Cl, 18.30. Found: C, 49.51; H, 8.61; N, 7.13; Cl, 18.25.

This substance gave a positive ionic halogen test and its i.r. spectrum (0.1 *M* in chloroform) showed prominent bands at 3300–2400 (NH^+), 1728 (ester carbonyl), 1595 (N—H deformation), 1220, and 1013 cm^{-1} (C—O acetate). In addition, 64 mg (12.8%) of D,L-*trans*-1-chloro-2-acetamidocyclohexane[11] was recovered as fine colorless needles, m.p. 130–132°.

Anal. Calcd. for $C_8H_{14}ONCl$: C, 54.69; H, 8.03; N, 7.98; Cl, 20.18. Found: C, 54.55; H, 7.94; N, 7.77; Cl, 20.07.

This substance did not contain ionic halogen and its i.r. spectrum (0.1 *M* in chloroform) had prominent bands at 3445 (N—H, free), 3330 (N—H, bonded) 1665 (amide carbonyl), and 1503 cm^{-1} (amide II).

D,L-*2-Methyl-4,5-cis-cyclohexanoöxazoline (4, n = 2, R = CH_3)*

2-Methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride (2.69 g, 0.0153 mol) was shaken with 15 ml of 5% sodium hydroxide and 30 ml of ether. The ether layer was decanted and the aqueous phase was extracted with ether (4 × 30 ml). The ether solutions were combined, dried over anhydrous magnesium sulfate, decanted, and the ether was removed *in vacuo* The pale brown residue was fractionated in a micro-distillation apparatus at 13 mm pressure and furnished 1.90 g (89.3%) of colorless mobile liquid b.p. 75.5–76.5°, n_D^{25} 1.4698, with a very penetrating odor.

Anal. Calcd. for $C_8H_{13}ON$: C, 69.03; H, 9.41; N, 10.06. Found: C, 69.01; H, 9.17; N, 10.02.

D,L-*cis-2-Aminocyclohexanol Hydrochloride (3, n = 2)*

Hydrolysis of the crude oxazoline hydrochloride (2.00 g) by heating it under reflux for 1 h with 10% hydrochloric acid (35 ml) gave, after evaporation to dryness and recrystallization from ethanol–ether, 1.69 g (97.7%) of D,L-*cis*-2-aminocyclohexanol hydrochloride as colorless platelets, m.p. 190–191.5°, alone, and in admixture with an authentic sample (4).

D,L-*2-Phenyl-4,5-cis-cyclohexanoöxazoline Hydrochloride (2, n = 2, R = C_6H_5)*

A stirred slurry of *trans*-2-benzamidocyclohexanol (2.74 g, 0.0125 mol) and anhydrous chloroform (100 ml) was kept at 0–8° in an apparatus protected against the entry of moisture while thionyl chloride (3.5 ml, 0.0483 mol) was added over a period of 21 min. The temperature of the resultant clear solution was allowed to rise to 21° over a period of 45 min and the solution was stirred at room temperature for an additional 2¾ h. The chloroform and excess thionyl chloride were removed by distillation at a pressure of 50–60 mm, leaving a very viscous pale yellow residue which was transferred quantitatively in 10 ml of chloroform to 250 ml of stirred anhydrous ether. The turbid mixture began to deposit colorless crystals almost immediately and was kept overnight at 0°. The crystals were collected, washed with anhydrous ether, and dried *in vacuo*; wt. 2.96 g (99.3%) m.p. 102–105°. Johnson and Schubert (1) report m.p 96.5–101° but no analytical data on the hydrochloride.

Anal. Calcd. for $C_{13}H_{17}ONCl$: C, 65.40; H, 7.18;

[10]If the crude oxazoline salt is allowed to stand for a prolonged period prior to further purification by sublimation, it slowly decomposes, *e.g.* after standing for 2 months 252 mg of crude oxazoline salt furnished only 222 mg (88.0%) of colorless sublimate.

[11]The structure of this compound was confirmed by measurement of the coupling constant (J = 10 Hz) between the methine protons in $CDCl_3$–C_6H_6 solution. We are indebted to Dr. R. R. Fraser for this measurement.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

N, 5.87; Cl, 14.86. Found: C, 65.28; H, 6.99; N, 5.92; Cl, 14.87.

Hydrolysis of D,L-2-phenyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride with 10% aqueous hydrochloric acid as described for the methyl analogue furnished 91.0% of D,L-*cis*-2-aminocyclohexanol hydrochloride, m.p. 189–190° (4) and 96.5% of benzoic acid, m.p. 121.5–122°.

D,L-*2-p-Nitrophenyl-4,5-cis-cyclohexanoöxazoline Hydrochloride (2, n = 2, R = C_6H_4-pNO_2)*

The procedure was identical with that given above for D,L-2-phenyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride except that *trans*-2-*p*-nitrobenzamidocyclohexanol (3.30 g, 0.0125 mol) was used. The oxazoline salt separated as a solid during the removal of the excess chloroform and thionyl chloride *in vacuo* but was taken up in anhydrous chloroform (10 ml) and precipitated by addition to anhydrous ether as described for the methyl and phenyl analogues. The salt was collected, washed with ether, and dried *in vacuo*; wt. 3.34 g (94.4%), m.p. 144–145°[12] and again at 175–179°, *cf.* McCasland and Smith (2).

Anal. Calcd. for $C_{13}H_{15}O_3N_2Cl$: C, 55.24; H, 5.35; N, 9.91; Cl, 12.54. Found: C, 55.08; H, 5.28; N, 9.64; Cl, 12.50.

Hydrolysis of the oxazoline salt in the usual manner gave a 90% recovery of D,L-*cis*-2-aminocyclohexanol hydrochloride, m.p. 189–190°, and 91% of *p*-nitrobenzoic acid, m.p. 241–242.5°.

D,L-*2-p-Nitrophenyl-4,5-cis-cyclohexanoöxazoline (4, n = 2, R = C_6H_4-pNO_2)*

The oxazoline hydrochloride (731 mg) was shaken with a mixture of 18 ml of 5% sodium hydroxide and 25 ml of ether. The ether layer was decanted and the aqueous phase was extracted with ether (3 × 25 ml). The ether solutions were combined, dried over anhydrous magnesium sulfate, decanted, and taken to dryness *in vacuo* leaving a pale yellow solid, which was recrystallized from absolute ethanol and furnished 460 mg (72.5%) of pale yellow crystals. m.p. 120–121°. McCasland and Smith (2) report m.p. 120–121°.

D,L-*trans-2-Aminocyclopentanol*

D,L-*trans*-2-Aminocyclopentanol was prepared by the ammonolysis of 1,2-epoxycyclopentane (27) following the method used by Hawkins and Bannard (24) for preparation of the cyclohexane analogue, except that it was found necessary to extend the heating period to 4 h. The substance was obtained as a colorless oil, b.p. 65° at 1.5 mm, n_D^{25} 1.4920, in 81.5% yield.

Anal. Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.14; H, 11.21; N, 13.98.

The identity of the compound was confirmed by conversion to the hydrochloride, m.p. 193–194°, after recrystallization from ethanol–ether. McCasland and Smith (2) report m.p. 193–194°.

D,L-*trans-2-Acetamidocyclopentanol*

This substance was prepared according to the method described by Bannard and Hawkins (28) for the preparation of *N*-acetyl derivatives of the alkoxyaminocyclohexanols, and was obtained in 90% yield as a very viscous colorless oil, b.p. 118–120° at 0.02 mm, n_D^{25} 1.4995.

Anal. Calcd. for $C_7H_{13}O_2N$: C, 58.72; H, 9.15; N, 9.78. Found: C, 58.59; H, 9.27; N, 9.96.

D,L-*trans-2-Benzamidocyclopentanol*

This compound was prepared in 77.5% yield in the same manner as its cyclohexyl analogue, and had m.p. 120–121°. McCasland and Smith (2) report m.p. 120–121°.

Anal. Calcd. for $C_{12}H_{15}ON_2$: C. 70.21; H, 7.38; N, 6.83. Found: C, 70.03; H, 7.29; N, 6.82.

D,L-*trans-2-p-Nitrobenzamidocyclopentanol*

This substance was prepared in 75% yield in the same manner as its cyclohexyl analogue as reported by McCasland and Smith (2), m.p. 158–159°.

Anal. Calcd. for $C_{12}H_{14}O_4N_2$: C, 57.58; H, 5.65; N, 11.19. Found: C, 57.50; H, 5.64; N, 11.27.

D,L-*2-Methyl-4,5-cis-cyclopentanoöxazoline Hydrochloride (2, n = 1, R = CH_3)*

The procedure was identical with that given in detail for the preparation of D,L-2-methyl-4,5-*cis*-cyclohexanoöxazoline hydrochloride except that *trans*-2-acetamidocyclopentanol (3.58 g, 0.0250 mol) was used. The crude oxazoline salt (red oil) failed to crystallize on standing in anhydrous ether. The ether was decanted, the oil was taken up in anhydrous chloroform (10 ml), treated with decolorizing charcoal at room temperature, filtered through celite, and the solvent was removed *in vacuo* yielding 4.09 g of brown solid. The latter material was sublimed at 50° at 0.001 mm pressure and furnished 3.87 g (94.7%) of colorless crystals, m.p. 94.5–96.5°.

Anal. Calcd. for $C_7H_{12}ONCl$: C, 52.02; H, 7.49; N, 8.67; Cl, 21.95. Found: C, 51.98; H, 7.26; N, 8.78; Cl, 22.11.

D,L-*2-Methyl-cis-4,5-cyclopentanoöxazoline (4, n = 1, R = CH_3)*

The procedure was identical with that described for the preparation of the cyclohexyl homologue except that D,L-2-methyl-*cis*-4,5-cyclopentanoöxazoline hydrochloride (2.59 g, 0.016 mol) was used. The oxazoline base was obtained as a colorless mobile oil with a very penetrating odor. Yield. 1.75 g (87.7%), b.p. 57.0–57.5° at 13 mm, n_D^{25} 1.4619.

Anal. Calcd. for $C_7H_{11}ON$: C, 67.17; H, 8.86; N, 11.19. Found: C, 66.96; H, 9.06; N, 11.27.

D,L-*cis-2-Aminocyclopentanol Hydrochloride*

2-Methyl-4,5-*cis*-cyclopentanoöxazoline hydrochloride (1.19 g, 0.00617 mol) was hydrolyzed in the usual manner and furnished 1.01 g (100%) of colorless platelets, m.p. 181–183°, after recrystallization from absolute ethanol and ethanol–ether. McCasland and Smith (2) report m.p. 179–180°.

Anal. Calcd. for $C_5H_{12}ONCl$: C, 43.64; H, 8.79; N, 10.18; Cl, 25.77. Found: C, 43.60; H, 8.75; N, 9.92; Cl, 25.56.

D,L-*cis-2-Aminocyclopentanol*

A solution of *cis*-2-aminocyclopentanol hydrochloride (6.88 g, 0.05 mol) and sodium hydroxide (4.0 g, 0.10 mol) in water (90 ml) was continuously extracted with ether for 3 days. The ether was removed *in vacuo* and the colorless residue was recrystallized from ether yielding 4.66 g (92.4%) of colorless needles, m.p. 71.0–73.0°.

[12]If the sample was placed in the capillary m.p. apparatus at a temperature below 135°, only the higher m.p. was observed, *cf.* Fry (13).

Anal. Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.09; H, 10.78; N, 13.64.

D,L-*2-p-Nitrophenyl-4,5-cis-cyclopentanoöxazoline Hydrochloride (2, n = 1, R = C_6H_4-pNO_2)*

trans-2-*p*-Nitrobenzamidocyclopentanol (3.07 g, 0.0123 mol) was added portionwise at −5 to 0° over a period of 8 min via a worm-feed addition tube to a magnetically-stirred solution of thionyl chloride (3.5 ml, 0.0483 mol) in deuterochloroform (9.0 ml) in an apparatus protected against the entry of moisture. The temperature of the clear yellow solution was allowed to rise to 29° over a period of 45 min and two 0.1 ml aliquots were removed for i.r. examination. The solution was stirred at room temperature for a further 2.5 h, following which the solution was transferred quantitatively with deuterochloroform (5 ml) to a round-bottom flask and the excess reagent and solvent were removed at 13 mm pressure, taking precautions to prevent the access of moisture. The crystalline residue 3.04 g (99.1%), had m.p. 153.5–155°. McCasland and Smith (2) report m.p. 150–151°, and Fodor and Kiss (29) report m.p. 159–161° for this compound.

Anal. Calcd. for $C_{12}H_{13}O_3N_2Cl$: C, 53.64; H, 4.88; N, 10.43; Cl, 13.20. Found: C, 53.55; H, 5.11; N, 10.40; Cl, 13.02.

This compound decomposes on attempted recrystallization from ethanol.

D,L-*2-p-Nitrophenyl-4,5-cis-cyclopentanoöxazoline (4, n = 1, R = C_6H_4-pNO_2)*

D,L-2-*p*-Nitrophenyl-4,5-*cis*-cyclopentanoöxazoline hydrochloride (1.05 g, 0.00391 mol) was converted to the free base in the usual manner, and, after removal of the ether *in vacuo*, was obtained as a pale yellow crystalline solid, 882 mg (96.9%), m.p. 138.5–140°. McCasland and Smith (2) report m.p. 139–140° for this compound.

Anal. Calcd. for $C_{12}H_{12}O_3N_2$: C, 62.06; H, 5.21; N, 12.06. Found: C, 62.03; H, 4.88; N, 12.16.

This compound is best purified by recrystallization from ethanol.

Thanks are extended to Dr. M. A. Weinberger and Miss P. M. Lutley for measurement of the majority of the n.m.r. spectra reported herein. We are also indebted to Dr. R. R. Fraser, Mr. F. McClusky, and Mr. A. E. Castagne for n.m.r. spectral measurements made during the final stages of the investigation.

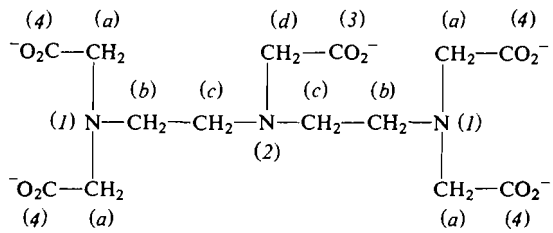
Lead(II) and cadmium(II) each form a 1:1 complex with DTPA. Nuclear magnetic resonance (n.m.r.) spectroscopy was used to show that each complex has three metal–nitrogen bonds and labile metal–oxygen bonds to terminal acetate groups. The latter lead to proton equivalence for the methylene protons of the terminal acetate groups of the lead complex, and near equivalence for those of the cadmium complex. The central carboxylate group is coordinated to the lead but not to the cadmium. Protonation occurs below p*H* 5.5 for the lead complex and occurs predominantly at a terminal nitrogen atom with consequent breaking of the metal–nitrogen bond. In the cadmium complex protonation occurs below p*H* 5 at the terminal nitrogen, breaking the metal–nitrogen bond, and also to almost the same extent at the central, uncoordinated carboxylate group. These differences in behavior of the lead and cadmium complexes are attributed to differences in ionic size. Possible structures are proposed and allowances are made for the possibility of coordination number greater than six. In the protonated complexes, structures and interconversion of protonated forms are discussed in the light of the observed simplification of the n.m.r. spectra.

Le plomb(II) et le cadmium(II) forment chacun un complexe 1:1 avec le DTPA. La spectroscopie r.m.n. a été utilisée pour montrer que chaque complexe possède trois liaisons métal–azote et des liaisons labiles métal–oxygène aux groupes acétates terminaux. Ces dernière rendent équivalent les protons du groupe méthylène situés sur les groupes acétates terminaux dans le complexe avec le plomb. Une quasi-équivalence est obtenue pour le complexe avec le cadmium. Le groupe carboxylate central est coordonné au plomb mais pas au cadmium. Dans le cas d'un complexe avec le plomb, la protonation se fait pour un p*H* inférieur à 5.5 et de préférence sur un atome d'azote terminal avec pour conséquence la rupture de la liaison métal–azote. Avec le complexe du cadmium, la protonation se situe en dessous de p*H* 5 sur l'atome d'azote terminal, provoquant la rupture de la liaison métal–azote, et avec la même importance sur le groupe carboxylate central non coordonné. Ces différences de comportement entre le complexe du plomb et celui du cadmium sont attribuables à des différences de grosseurs ioniques. Des structures possibles sont proposées et il est tenu compte de la possibilité de nombres de coordination supérieurs à six. Dans les complexes protonés, les structures et l'interconversion des formes protonées sont discutées à la lumière de la simplification observée dans les spectres r.m.n.

Canadian Journal of Chemistry, 49, 2073 (1971)

Introduction

The use of proton magnetic resonance (p.m.r.) spectroscopy for the study of aqueous solutions of aminopolycarboxylic acids (1–5) and their diamagnetic complexes with metal ions (5–16) is well-established. In this paper we describe a systematic study of the behavior of the aqueous systems: lead(II)–DTPA and cadmium(II)–DTPA, where DTPA represents diethylenetriaminepentaacetic acid. The pentaanion of DTPA is conveniently represented (1) by



in which there are eight equivalent acetate protons labelled (*a*), two equivalent acetate protons labelled (*d*), four equivalent ethylenic protons labelled (*b*), and four equivalent ethylenic protons labelled (*c*). The equivalent terminal nitrogen

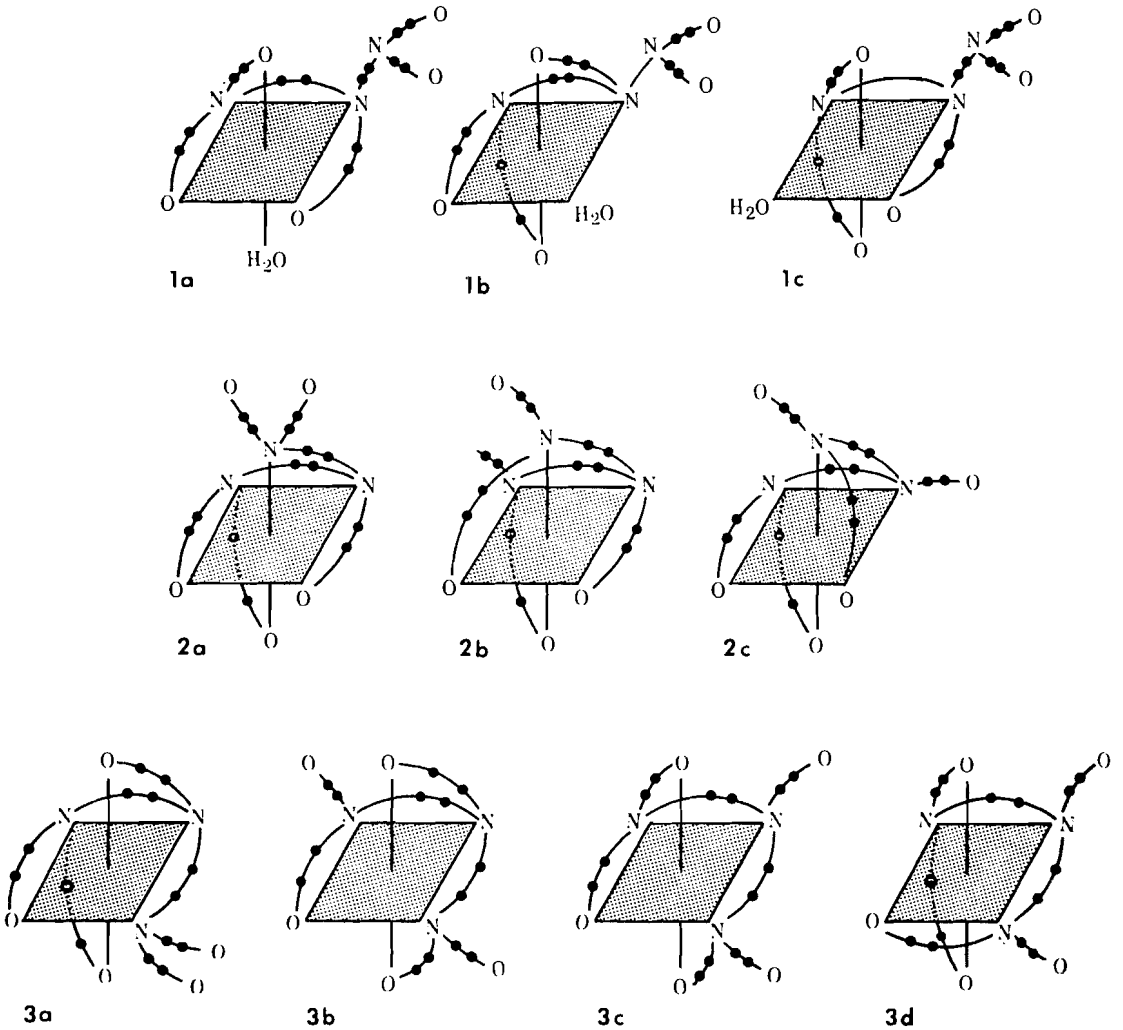

FIG. 1. Possible instantaneous configurations, based on octahedral coordination, for a metal–DTPA complex. In each case, only one of the equivalent forms is shown.

atoms are labelled (*1*) and the unique center nitrogen atom is labelled (*2*). The unique carboxyl group is labelled (*3*) and the four equivalent terminal carboxyl groups are labelled (*4*).

A survey of the coordination chemistry of divalent metal – aminopolycarboxylate complexes revealed evidence for preferred octahedral coordination (17–21) but the X-ray crystallographic studies of Hoard and co-workers (22–30) indicate that this is a simplification and some principles for prediction of coordination number were proposed. DTPA is a potentially octadentate ligand. In this introductory section we have assumed octahedral coordination for the sake of convenience, but as will be shown in the Discussion section, for the most part, the conclusions drawn do not depend upon this assumption. Even assuming octahedral coordination, DTPA can wrap itself around a metal ion in many different ways. The different possible instantaneous configurations, ignoring the consequences of ring strain and steric interference, are shown in Fig. 1. These are also possible configurations for non-labile complexes. It does not seem reasonable to consider configurations in which less than two nitrogen atoms (of which one must be the center nitrogen atom)

For personal use only.

are coordinated, or where carboxylate groups are coordinated but not the associated nitrogen atom. Furthermore, in an instantaneous configuration, different conformations of the ethylenic rings are possible. The different possibilities of optical isomerism are not considered since this will have no bearing on the n.m.r. spectra. Also not shown are configurations in which DTPA acts as less than a sexadentate ligand (except in configurations *1a–1c*) although in labile complexes partially unwrapped structures may make a greater than negligible contribution. For labile complexes the molecule will exist in various stages of unwrapping with the more complete stages of unwrapping being less prevalent. Such unwrapping would be expected to occur from the end of the molecule so that the metal–oxygen (*4*) bonds will form and break more quickly than the metal–nitrogen bonds, *i.e.* all the metal–nitrogen bonds will have longer lifetimes than the metal–oxygen (*4*) bonds. Two characteristic metal–nitrogen bond lifetimes can be distinguished since unwrapped states like *1a, 1b*, and *1c* are possible. The lifetime of the metal–nitrogen (*1*) bond is thus shorter than that of the metal–nitrogen (*2*) bond, which has the longest lifetime of all metal–ligand bonds. The metal–oxygen (*3*) bond lifetime must be shorter than that of the metal–nitrogen (*2*) bond but can be either longer or shorter than those of the other metal–ligand bonds. Thus, the following sequences of relative bond lifetimes are possible:

$$\text{M—N}(2) > \text{M—N}(1) > \text{M—O}(3) > \text{M—O}(4)$$

$$\text{M—N}(2) > \text{M—N}(1) > \text{M—O}(4) > \text{M—O}(3)$$

$$\text{M—N}(2) > \text{M—O}(3) > \text{M—N}(1) > \text{M—O}(4)$$

In a p.m.r. study of metal–DTPA complexes, examples may be encountered in which all metal–ligand bonds have long lifetimes, have short lifetimes, or have some bonds with long lifetimes and others with short lifetimes. Day and Reilley (8) have discussed the effect of the lability of metal–ligand bonds in metal–ethylenediaminetetraacetic acid (EDTA) complexes on their n.m.r. spectra. In the latter part of this paper these discussions have been extended to metal–DTPA complexes.

Experimental

The proton nuclear magnetic resonance spectra were recorded with a Varian A56/60A spectrometer. Most of the spectra were recorded at temperatures (± 1°) of 0, 39, and 70°. The spectral data obtained were average readings of several recordings with a reproducibility of ±0.4 Hz. The values of the chemical shifts were measured with respect to *t*-butyl alcohol (TBA) but reported with respect to DSS (3-trimethylsilylpropanesulfonic acid, sodium salt). The advantage of using TBA is that its signal is independent of p*H* and ionic strength (5) and it has a single resonance close to the region under investigation. One percent by volume of TBA was sufficient to yield a good reference signal at 1.233 p.p.m. downfield from DSS. Prior to recording the spectra of some of the solutions of the metal complexes nitrogen was passed through them, but, as found previously (4) little improvement was achieved by deoxygenation of the solutions.

Stock solutions of DTPA were prepared from the acid (J. T. Baker Chemical Company) after recrystallization from hot water. To 1.000 mol (394.4 g) of the acid suspended in 800 ml of water were added 3 mol of solid potassium hydroxide pellets and the resulting solution was diluted to 1.000 l. Stock solutions (1.000 *M*) of lead(II) and cadmium(II) were prepared from their nitrate salts (reagent grade). From these stock solutions various metal–ligand solutions were prepared in which the ligand concentration was 0.10 to 0.50 *M* since a relatively high concentration of ligand was necessary to obtain a satisfactory n.m.r. signal.

A Radiometer type PH28 p*H* meter, which had been calibrated at p*H* = 6.86, 4.01, and 2.00 (Beckman buffers), was used to determine the p*H* of all the solutions. The p*H* was adjusted by the addition of potassium hydroxide since the metal–DTPA solutions were initially acidic (sometimes the p*H* was as low as 1.5). For the concentrated solutions required to obtain satisfactory n.m.r. spectra no additional buffer was necessary, *i.e.* DTPA served as its own buffer.

Results and Discussion

Our studies on the p.m.r. spectra of aqueous solutions of DTPA as a function of p*H* were in close agreement with those reported previously by other workers (1, 2) and hence are not presented here.

The assignments of the various resonances in the spectra of the metal complexes were made from their relative peak areas, dependence upon p*H*, and from expectations based on earlier work (8).

Lead(II)–DTPA Solutions

Representative n.m.r. spectra obtained for 1:1 ratios of Pb(II):DTPA for a 0.50 *M* concentration over the p*H* range 2–10 and at temperatures of 0, 39, and 72° are presented in Figs. 2–4. In Fig. 2 are recorded the spectra obtained at 39° at p*H* values of 2.0, 5.0, and 7.0. Figure 3 shows the effect of temperature on the spectra at p*H* 8.0. Figure 4 shows a spectrum obtained at p*H* = 9.0 where the spectra are sharper than at lower p*H* values.

The position and form of the resonance due to the (*a*) protons depends upon the p*H* of the solu-

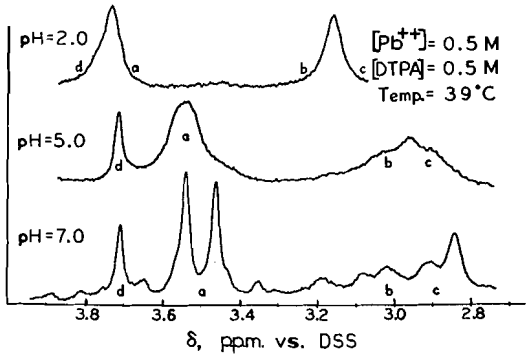

FIG. 2. Nuclear magnetic resonance spectra of Pb–DTPA complex at 39° at selected p*H* values.

tion. All four (*a*)-type carboxyl groups are equivalent throughout the p*H* range. At p*H* values $\geqslant 6$ the (*a*) protons give superimposed *AB* and *ABX* patterns (see Fig. 4) in the approximate ratio required for the relative abundances of lead isotopes having zero spin to one-half spin; ^{207}Pb, the only lead isotope with spin, has a spin of one-half and a relative abundance of 21% (31). From the *AB* spectrum it was found that $\nu_0\delta_{AB} = 12.1$ Hz and the absolute value of $J_{AB} = 16.2$ Hz. The sign of the coupling constant was assumed to be negative since this is close to the value expected for geminal protons adjacent to a keto group (32). Only the inner four peaks of the *AB* part of the *ABX* pattern can be distinguished. Within experimental error (± 0.2 Hz) these are symmetrically displaced with respect to the center of the *AB* multiplet. This is an example of a simple spectrum obtained when $J_{AX} = J_{BX}$ and the coupling constants were calculated from equations derived by Abraham and Bernstein (33, 34). The parameters obtained from the *AB* spectrum were used in the *ABX* spectrum to show that $J_{AX} = J_{BX}$ within 0.5 Hz. The lead-to-acetate proton coupling constant was equal to 12.8 Hz. Metal-to-proton coupling has previously been reported for some EDTA complexes (8) and the coupling constants found were: lead-to-acetate proton = 21.5 Hz, lead-to-ethylenic proton = 19.0 Hz, cadmium-to-acetate proton = 17.2 Hz.

As the p*H* is lowered below 6 the position of the resonance due to the (*a*) protons shifts to lower field and simultaneously the *AB* and *ABX* peaks broaden, then collapse to a common singlet. The p*H* dependence of the chemical shift is shown in Fig. 5, where for values of the p*H* above 6, the chemical shifts shown are for the center of the *AB* multiplet. Above p*H* values of 6 there is little dependence of chemical shifts upon p*H*. Starting from alkaline solution, as the p*H* is lowered, significant protonation of the complex, manifested by movement of chemical shifts towards lower field, does not begin until p*H* values of about 5.5 are reached, the extent of protonation increasing as the p*H* is lowered and reaching a steady value at about 3.5 (see Fig. 5). Allowing for differences in concentration and ionic strength, this is in agreement with studies of the protonation of Pb–DTPA complexes (35) for which it was found that

$$PbA^{3-} + H^+ \rightleftharpoons PbHA^{2-} \qquad \log K = 4.52$$

where A^{5-} represents the pentaanion of DTPA.

The (*d*) protons gave a simple spectrum throughout the entire study. No evidence was found for an *AB* spectrum (expected for unsymmetrical configurations) although broadening of the resonance did occur at $\sim 0°$. Evidence for metal–proton coupling was given by a small peak at a constant displacement of 10.5 Hz on the low field side of the (*d*) proton singlet. This was attributed to one half of an *AX* pattern, the high-field half being lost in resonances due to other protons. A lead-to-acetate proton coupling constant of 21 Hz was obtained, close to the value given above for the EDTA complex. A simple singlet can arise for the (*d*) protons in complexes in which the metal–oxygen(*4*) bonds are labile since rapid interconversion of configurations can give a time-averaged state in which there is a plane of symmetry through the (*d*)-type acetate group. This is consistent with the simplicity of the spectra due to the (*a*) protons which indicates that the lead–oxygen bonds are labile since the four terminal acetate groups show equivalent spectra under all conditions used in this study. Reference to Fig. 1 shows that there is no instantaneous structure in which this is possible so that a rapid exchange between coordinated and non-coordinated acetate groups is occurring. Since an *AB* pattern is observed for these acetate groups for p*H* $\geqslant 6$ the complex has an average configuration based on one or more configurations of type *2a*, *2b*, *3a*, or *3b* with relatively non-labile metal–nitrogen bonds. The contribution of configurations based on *1a*, *1b*, or *1c* to the average configuration must be small for p*H* $\geqslant 6$ since in these configurations inversion at the nitrogen atom is permitted and the (*a*) proton resonance would appear as a singlet. This conclusion is supported by the p*H* de-

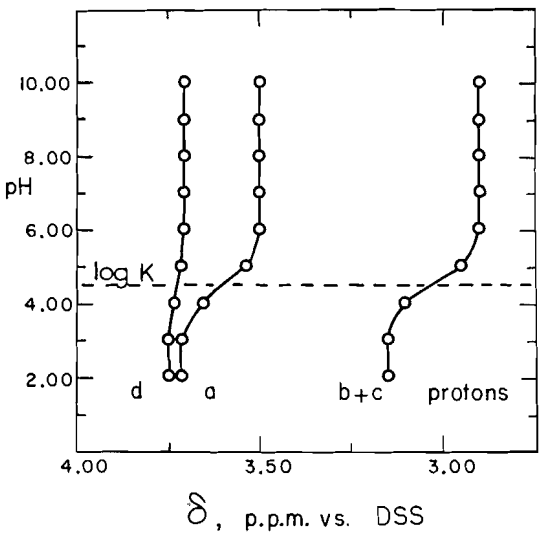

FIG. 5. Variation with pH of chemical shifts of non-labile protons for the Pb–DTPA complex, at 39°. Log K relates to the equilibrium constant for the protonation reaction (35): $PbA^{3-} + H^+ \rightleftharpoons PbHA^{2-}$.

pendence of the chemical shifts. For the free DTPA anion protonation begins when the pH is lowered to ~ 11 and as the pH is further lowered between 10 and 7 the preferred protonation sites are the terminal nitrogen atoms (1, 2). Complexes having average configurations with large contributions from *1a*, *1b*, and *1c* would show evidence (from variation of chemical shifts) of protonation at similar pH values to the free DTPA anion. Since little pH dependence of the chemical shifts is observed between pH = 10 and pH = 6 then contributions to the average configuration from *1a*, *1b*, and *1c* can play no significant part. Thus, all three nitrogen atoms are bonded to the metal atom, but a decision between a planar or non-planar arrangement of the nitrogen atoms cannot be made from the n.m.r. data.

The (*d*) protons show very little change in chemical shift as the pH is lowered from 10 to 3, indicating little change in the extent of protonation at the center nitrogen atom or center carboxylate group. Little protonation at the center nitrogen atom is expected without extensive unwrapping of the complex, but a carboxylate group free for a large fraction of time would surely show some protonation at pH values as low as 2. It seems likely that, irrespective of whether the metal–oxygen bond is labile, the center carboxylate group remains coordinated for an extensive fraction (nearly 100%) of the time throughout the complete range of conditions used in this study.

As the pH is lowered below 5.5, protonation of the complex occurs and the AB pattern of the (*a*) protons collapses to a singlet. This observation, together with the pH dependence of the chemical shifts is consistent with protonation predominantly at a terminal nitrogen atom and rapid interconversion between configurations in which one of the terminal nitrogen atoms is alternately coordinated or non-coordinated as in rapid interchange between one or more configurations of type *1a*, *1b*, *1c* (see Fig. 9). This conclusion is based mainly on the magnitude of the pH dependence of the chemical shift of the (*a*) protons. It is necessary to make the following assumptions: (*i*), in a configuration such as *1a* or *1b* or *1c* the non-coordinated aminodiacetate group shows a similar affinity for protonation both at its nitrogen and carboxylate sites as it does in free DTPA, *i.e.* we are not concerned with the actual extent of protonation at each site, though it is known that the nitrogen site is preferred (1, 2) (this assumption also requires the reasonable condition that proton transfer reactions are very much faster than the making and breaking of the metal–nitrogen bond); (*ii*), the chemical shift of the (*a*) protons is insensitive to whether the center nitrogen atom is protonated, or coordinated to the metal; (*iii*), when one of the terminal nitrogen atoms and its associated acetate groups are not coordinated to the metal the competition for coordination sites by the remaining carboxylate groups is reduced. If the terminal carboxylate groups are now coordinated to the metal ion for a greater percentage of the time that the terminal nitrogen atom is coordinated then a movement of chemical shift toward lower field (higher δ values) will occur. It was assumed that the correction for this effect was negligible; (*iv*), the chemical shift of the (*a*) protons depends directly upon the fraction of time that they spend in a given chemical environment. With these assumptions we can write

$$\delta_a = f\delta_c + (1 - f)\delta_l$$

where δ_a is the chemical shift of the (*a*) protons in the complex at a given pH, δ_l is the chemical shift of the (*a*) protons in free DTPA at the same pH, δ_c is the chemical shift of the (*a*) protons in the unprotonated complex (value at pH 10 used where it is assumed that the nitrogen atoms are co-ordi-

TABLE 1. Estimation of the extent of coordination of a terminal nitrogen atom, as a fraction of time (f) for which the nitrogen atom is coordinated, in lead(II) and cadmium(II) complexes with DTPA at 40°

		Lead(II)		Cadmium(II)	
pH	$\nu_0\delta_l$ (Hz)	$\nu_0\delta_a$ (Hz)	f (%)	$\nu_0\delta_a$ (Hz)	f (%)
10	199.0	209.0	100	197.0	100
7	227.7	209.8	96	196.8	100
6	228.8	210.5	93	196.8	100
5	228.8	212.4	83	197.5	99
4	229.5	219.5	49	199.5	92
3	231.5	223.0	37	204.0	80
2	233.5	223.3	42	217.4	44

nated 100% of the time), f is the fraction of time for which a terminal nitrogen atom is coordinated to the metal. Thus

$$f = (\delta_l - \delta_a)/(\delta_l - \delta_c)$$

Values of f, together with the required data for their calculation are given in Table 1. These values, though approximate, indicate that, on lowering the pH to 3 or 2 a single protonation of the complex occurs, with each terminal nitrogen atom becoming free about 50% of the time, *i.e.* either one or the other of the terminal nitrogen atoms becomes free nearly 100% of the time. A single protonation of the complex is indicated since, in free DTPA in this approximate pH range (p$H \simeq 4$) each aminodiacetate group is associated with one proton (1), and is confirmed by the protonation constant of the complex determined potentiometrically (35) (see above). The approximate nature of the results arises mainly from weaknesses in assumptions (*i*) and (*iii*) above. It has been shown that the extent of protonation of a given site in DTPA and other ligands is not independent of the condition of other sites (1, 2) though the extent of error is difficult to evaluate. The failure to apply a correction for weaknesses in assumption (*iii*) tends to make the f values in Table 1 too low. There can be little doubt that for the pH range 2 to 4 f values close to 50% would be obtained if adequate corrections could be applied and that the f values cited for p$H = 3$ and p$H = 2$ are equal within the accuracy of this approximate treatment.

The (*b*) and (*c*) protons gave a broad unresolved resonance at p$H = 5$. For p$H = 6$ a complex pattern of peaks involving many components resulted. Depending upon the rate of interconversion of configurations of the complex a complicated spectrum of the type $ABCD$ or $AA'BB'$ is to be expected. Lead-to-proton coupling for the ethylenic protons is also to be expected but components attributable to this could not be distinguished in the complex spectrum. No attempt was made to obtain quantitative information from the chemical shifts of the ethylenic protons owing to the complexity of their spectra and their poor resolution. The chemical shifts for the individual (*b*) and (*c*) protons were not obtained but the approximate center of gravity of the chemical shifts of the (*b*) and (*c*) pattern is plotted in Fig. 5. Although it is difficult to evaluate the chemical shifts of the (*b*) and (*c*) protons protonation of a terminal nitrogen atom should cause bigger variations in chemical shift for the (*b*) than for the (*c*) protons. Since protonation causes a narrowing of the width of the (*b*) + (*c*) resonance the (*b*) protons are initially at higher field (lower δ values). For the non-protonated complex, for p$H \geqslant 6$, the high field region of the (*b*) + (*c*) resonances contains higher, less broad peaks, than the low field region. Such asymmetry can be observed for an $ABCD$ type spectrum (36) and can readily be explained for the present case. The (*c*) protons are adjacent to the least labile metal–nitrogen bond in the complex. As far as the (*c*) protons are concerned, this quaternary nitrogen atom has three other substituents which are all different. The (*b*) protons are adjacent to a relatively more labile metal–nitrogen bond. To this quaternary nitrogen atom are bonded two acetate groups which have been shown to become equivalent by rapid exchange of coordination sites in the complex. Thus, the chemical environments of the type (*b*) geminal protons are more similar than those of type (*c*). Consequently the part of the (*b*) + (*c*) spectrum due to the (*b*) protons should be higher and less broad than that due to the (*c*) protons, in agreement with experimental observations.

Temperature changes alter the appearance of some of the spectra of solutions for which conditions are otherwise identical. This is due to alterations in labilities of metal to ligand bonds; these labilities may control the width of some of the resonances. Changes in chemical shift with temperature are small. On reducing the temperature from 70 to 0° the resonances of the (*a*) and (*d*) protons both move to lower field by 2–3 Hz, relative to the internal references, over the p*H* range studied.

Cadmium(II)–DTPA Solutions

The n.m.r. spectra of aqueous solutions of Cd(II) and DTPA were studied from p*H* = 2.0 to p*H* = 10.0. Representative spectra obtained for 1:1 ratios of Cd(II):DTPA are presented in Figs. 6 and 7. Figure 6 shows the spectra obtained at 40° at p*H* = 3.0, 4.5, and 6.0. Figure 7 shows the effect of temperature at p*H* = 10.0.

The position and form of the resonance due to the (*a*) protons depends upon the p*H* of the solution. At p*H* $\leqslant$ 3.0 all four (*a*)-type carboxyl groups are equivalent and give rise to a single n.m.r. peak. As the p*H* is raised, the peak broadens (p*H* $\simeq$ 4.5) and splits into two components (p*H* $\geqslant$ 6). These components are almost, though not quite, symmetrical and identical, and are not as sharp as the resonance for the *d* protons. They were interpreted as the center peaks of the *AB* spectra of chemically very similar, though not identical, (*a*) type, carboxymethyl groups where the outer peaks are lost in the background noise level so that J_{AB} could not be determined. As before metal–proton coupling is to be expected

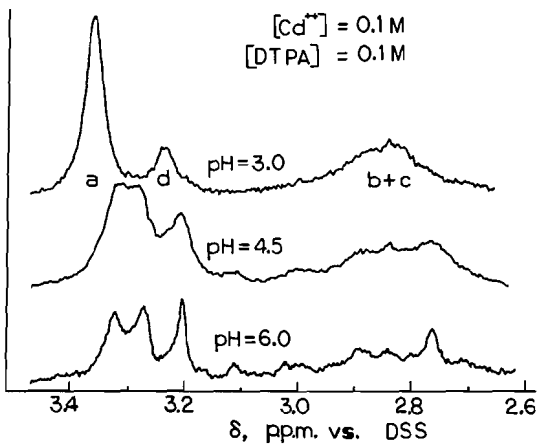

FIG. 6. Nuclear magnetic resonance spectra of Cd–DTPA complex at 40° at selected p*H* values.

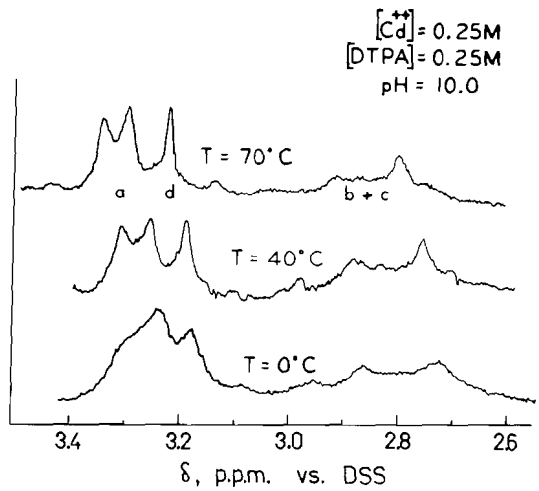

FIG. 7. Nuclear magnetic resonance spectra of Cd–DTPA complex at p*H* = 10 at selected temperatures.

since cadmium isotopes 111 and 113, with spin one-half, have together a relative abundance of approximately 25% (31). We were unable to observe the expected *ABX* pattern, probably because of the broadness of the spectra obtained. At high p*H* (see Fig. 7), as the temperature is lowered, the resonances due to the (*a*) protons broaden and become more unsymmetrical. This may be attributable to decreasing lability of the metal–oxygen bonds as the temperature is lowered, with the result that some of the "instantaneous" configurations of Fig. 1 have lifetimes which are significant in terms of the n.m.r. experiment. The chemical shift of the (*a*) protons as a function of p*H* is shown in Fig. 8. The p*H* region in which the chemical shift changes (p*H* = 2 to p*H* = 5) corresponds to the region in which the resonance changes from a singlet to an *AB* spectrum. For the *AB* spectrum the chemical shift is taken as the center of the twin inner peaks.

The (*d*) protons gave a singlet peak throughout the study. We were unable to detect the expected metal–proton coupling possibly because the small peaks anticipated for an *AX* spectrum overlapped the resonances for the (*a*) or (*b*) + (*c*) protons. An *AB* pattern expected for unsymmetrical configurations was not detected for the (*d*) protons but, at low temperatures, significant broadening of the resonance occurred. This is consistent with the decreasing metal–oxygen(*4*) bond lability suggested by the spectra of the (*a*) protons. The p*H* dependence of the chemical shift of the (*d*) protons is shown in Fig. 8.

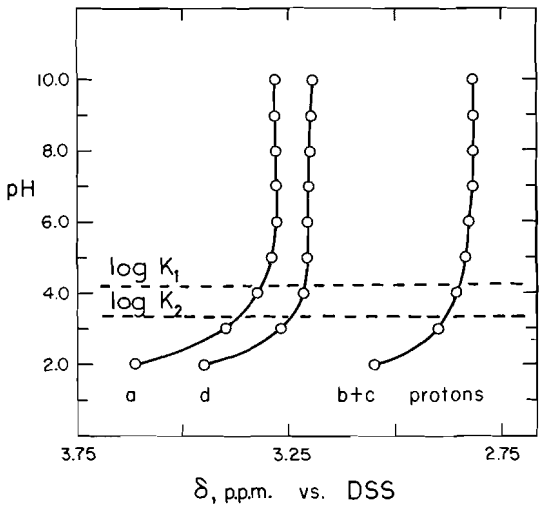

FIG. 8. Variation with pH of chemical shifts of non-labile protons for the Cd–DTPA complex, at 40°. Log K_1 and log K_2 relate to the respective equilibrium constants for the protonation reactions (37): $CdA^{3-} + H^+ \rightleftharpoons CdHA^{2-}$; $CdHA^{2-} + H^+ \rightleftharpoons CdH_2A^-$.

For p$H \geqslant 5$ there is little dependence of the chemical shifts of the (*a*) and (*d*) protons upon pH. Starting from alkaline solution, as the pH is lowered significant protonation of the complex, measured by movement of chemical shifts towards lower field, does not occur until the pH has reached approximately 4.5 (see Fig. 8) and the extent of protonation increases as the pH is lowered to pH = 2.0 and possibly lower. Allowing for differences in concentration and ionic strength, this is in agreement with studies of the protonation of Cd–DTPA complexes, where for the following equilibria the results obtained (37, 38) were

$$CdA^{3-} + H^+ \rightleftharpoons CdHA^{2-} \qquad \log K = 4.17 \text{ or } 4.09$$
$$CdHA^{2-} + H^+ \rightleftharpoons CdH_2A^- \qquad \log K = 3.32$$

where A^{5-} represents the pentaanion of DTPA. These results indicate that double protonation of the Cd(II)–DTPA complex will occur at sufficiently low pH values and will be extensive, *i.e.* greater than 50% of the complexes are doubly protonated, when p$H \leqslant 3.3$.

The (*a*) and (*d*) protons show closely similar dependencies of chemical shift upon the pH of the solution. Closer examination reveals that protonation of the complex causes bigger changes in chemical shift for the (*a*) protons than for the (*d*) protons. Furthermore, the variation in chemical shift on acidifying the solution occurs at slightly higher values of pH for the (*a*) protons than for the (*d*) protons.

When the spectra shown in Fig. 7 are compared with those of Pb–DTPA complexes under similar conditions (see Fig. 3), it is seen that the metal–ligand bonds are less labile for the cadmium than for the lead complexes. (Note the generally broader resonances for the (*a*) and (*d*) protons for the Cd—DTPA complexes than for the Pb–DTPA complexes.) It has also been reported that cadmium–ligand bonds are less labile than lead–ligand bonds in EDTA complexes (2). These observations allow a decision as to whether the (*d*)-type carboxyl group is coordinated to cadmium in the complex with DTPA. Thus, if the (*d*)-type carboxyl group were coordinated to cadmium it would be unlikely to protonate readily, since protonation of the (*d*)-type carboxyl group did not occur for the Pb–DTPA complex (1). In this latter complex, the (*d*)-type carboxyl group was shown to be coordinated to lead and protonation occurred preferentially at the terminal nitrogen atoms. Since the (*d*) protons suffer a significant change in chemical shift as the pH is lowered below 5, protonation of a non-coordinated (*d*)-type carboxyl group is indicated. The magnitude of the change (14.5 Hz between pH = 5.0 and pH = 2.0) is in agreement with that expected for protonation of a carboxyl group adjacent to a methylene group in an aminopolycarboxylic acid (5). Further support for the non-coordination of the (*d*)-type carboxyl group in the Cd complex is given by comparing the chemical shifts of the (*a*) and (*d*) protons in the Cd(II)–DTPA complex with those in the Pb(II)–DTPA complex.

Although the pH dependence of the chemical shift of the (*a*) protons parallels that of the (*d*) protons, a similar interpretation of the cause is not possible. That is, it is not due to protonation of the (*a*)-type carboxyl groups. The four (*a*)-type carboxyl groups are equivalent and even one proton per carboxyl group would be insufficient to produce the observed downfield movement of chemical shift of the (*a*) protons with pH, even assuming that the upfield shift produced by breaking a metal–oxygen bond is small. Furthermore, protonation of the (*a*)-type carboxyl groups would not produce changes in chemical shift of the magnitude observed for the (*b*) + (*c*) protons, nor cause collapse of the *AB* pattern for the spectra of the (*a*) protons. The results, in fact, are consistent with protonation occurring pre-

dominantly at one of the terminal nitrogen atoms and rapid interconversion between complexes in which first one, then the other, terminal nitrogen atom is coordinated to the metal. The breaking of the metal–nitrogen bond permits rapid umbrella inversion at the nitrogen atom and the (*a*) proton spectrum collapses to a singlet (2). Support for this view is given by the magnitude of the p*H* dependence of the chemical shifts of the (*a*) protons. These data were used to calculate *f*, the fraction of time for which a terminal nitrogen atom is coordinated, as described earlier for the Pb(II)–DTPA complex. Values of *f*, together with the data required for their calculation are given in Table 1. These approximate values, subject to the errors described earlier, indicate that as the p*H* is lowered to 2 each terminal atom becomes free about 50% of the time, *i.e.* either one or the other of the terminal nitrogen atoms is free nearly 100% of the time.

The (*b*) and (*c*) protons gave a broad, unresolved resonance at p$H \leqslant 4$ and for p$H \geqslant 5$ a complex pattern of peaks involving many components resulted, consistent with predictions from earlier discussion. The spectrum was asymmetric, the peaks to higher field being higher and less broad than those to lower field. However, the resolution was too poor for us to identify all the components of the assumed *ABCD* type spectrum, or to detect metal–proton coupling. No attempt was made to obtain quantitative information from the chemical shifts of the ethylenic protons but in Fig. 8 the chemical shift dependence of the approximate center of gravity of the resonances due to the (*b*) + (*c*) protons is shown. As with the Pb(II)–DTPA complex the width of the (*b*) + (*c*) resonance pattern decreases upon protonation and a similar interpretation of the spectrum is possible.

As with the lead complexes, temperature changes alter the labilities of metal to ligand bonds with consequent modification of the spectra. Changes in chemical shift with temperature are again small. On reducing the temperature from 70 to 0° the resonances of the (*a*) and (*d*) protons both move to lower field by 3–4 Hz, relative to the internal reference, over the p*H* range studied.

Comparison between the DTPA Complexes of Pb(II) and Cd(II)

The interpretations of the experimental results are summarized in the schemes of Fig, 9.

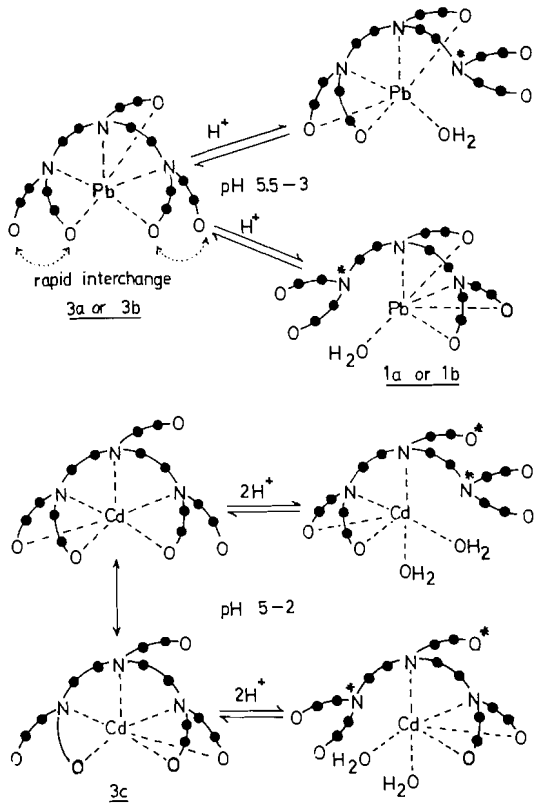

FIG. 9. Schematic representation of equilibria in Pb–DTPA solutions and Cd–DTPA solutions. Six-coordinate complexes are shown though seven or eight-coordinate complexes are considered probable. The more likely octahedral configurations are identified by reference to Fig. 1. (* = preferred protonation site).

The Pb(II)–DTPA complex has labile metal-to-oxygen bonds which permit the terminal carboxyl groups to become equivalent, or at least not detectably different, in the coordination polyhedron. For p$H \geqslant 6$ the complex is not protonated. At lower p*H* values, protonation of the complex occurs predominantly at one of the terminal nitrogen atoms. Rapid interconversion then occurs between protonated complexes in which first one, then the other, terminal nitrogen atom is coordinated to the metal. The center carboxyl group remains coordinated in the p*H* range 2–10.

The Cd(II)–DTPA complex has labile metal-to-oxygen bonds which permit the terminal carboxyl groups to become nearly equivalent in the coordination polyhedron. However, the metal-to-ligand bonds are less labile than those of the lead–DTPA complexes and at low temperatures, at high p*H*, the lability decreases sufficiently to

For personal use only.

show that non-equivalent carboxyl groups are present. For $pH \geqslant 5$ the complex is not protonated. As the pH is lowered, protonation occurs preferentially at two non-equivalent sites, namely, at the non-coordinated center carboxyl group and also at one of the terminal nitrogen atoms. Of these two sites the proton seems to show a slight preference for the nitrogen atom. Since the two pairs of terminal carboxyl groups remain equivalent, interconversion between protonated complexes having first one, then the other, nitrogen atom coordinated, occurs.

The difference in behavior between the lead and cadmium complexes is attributed mainly to the difference in size between the lead(II) and cadmium(II) ions, though the different electronic structures ($d^{10}s^2$ and $d^{10}s^0$, respectively) may be a contributing factor. In both complexes the metal-to-ligand bonds will be predominantly ionic and it is to be expected that the bonds formed by the smaller Cd(II) ion will be less labile than those formed by the larger Pb(II) ion (17, 20), as found experimentally. Further deductions were made from a study of molecular models, with the result that the conclusions drawn will be indicative rather than conclusive.

First, the octahedral configurations of Fig. 1 were considered. Configurations *2a–2c* and *3a–3d* are fundamentally different in that in *2a–2c* the nitrogen atoms occupy adjacent positions in the coordination octahedron whereas in *3a–3d* the three nitrogen atoms and the metal atom lie in the same plane. The models predict that ring strain in the acetate rings is less when the carboxymethyl groups attached to the same nitrogen atom adopt *cis* rather than *trans* positions in the coordination octahedron and thus configurations *1c* and *3d* are considered less probable than other configurations. The models further predict very considerable steric interference between the methylene groups of the terminal carboxymethyl groups in configurations *2a–2c*, even when the central metal ion is very large. Although the center carboxyl group is sterically readily accessible to the metal none of the configurations *2a–2c* seem probable for metal–DTPA complexes. Furthermore, in these configurations, for relatively non-labile metal–nitrogen bonds, it is not possible for the terminal carboxyl groups to become equivalent by rapid exchange of coordination positions. Of the pair of carboxyl groups at either end of the DTPA molecule one can coordinate only at a position *trans* to the center nitrogen atom. The other carboxyl group of this pair can coordinate either at this position or at a position *cis* to the center nitrogen atom. Thus, for the terminal carboxymethyl groups to have nearly equivalent n.m.r. spectra would imply that they were in fact coordinated to the metal ion for a small, nearly equal, fraction of time. This seems unlikely in view of the very high stability constants of metal–DTPA complexes.

When the metal and three nitrogen atoms are coplanar, as in configurations *3a–3d*, steric interference is much less. Even when the metal ion is small, none of the terminal acetate groups interfere with each other. However, the steric accessibility of the center carboxyl group to the metal depends upon the size of the metal ion. For small metal ions, interference between the center and terminal carboxymethyl groups will occur. This interference decreases as the size of the central ion increases. It is to be anticipated that there will be a critical size below which steric interference becomes a major factor in determining the nature of the coordination of metal–DTPA complexes. Possibly this is the main reason why the center carboxyl group is coordinated in the lead–DTPA complex but not in the smaller cadmium–DTPA complex.

When the center carboxyl group is not coordinated, as in configurations *3c* and *3d* then each of the terminal carboxyl groups can coordinate either *cis* or *trans* to the center nitrogen atom. The two *cis* positions (one above, one below, the plane shown in configurations *3c* and *3d*) are not strictly equivalent since only one *cis* position is on the same side of the plane as the uncoordinated center carboxymethyl group. The difference between them is probably very small and in rapidly interconverting structures the four terminal acetate groups can become essentially equivalent. This could be an adequate, though not necessarily correct description of the Cd(II)–DTPA complex. The center carboxyl group can only coordinate at a position *cis* to the center nitrogen atom, as in configurations *3a* and *3b* and in these cases the terminal carboxymethyl groups should not become strictly equivalent by rapid interconversion of structures. Thus, so far, an adequate description of the structure of the Pb(II)–DTPA complex has not been found.

The foregoing discussion has assumed octahedral coordination for the metal ions. The possibility of the trigonal prism as an alternative basis for six-coordination was considered and rejected.

In view of the conclusions of Hoard and coworkers (22–30) the assumption of six-coordination is doubtful. They found the coordination numbers in aminopolycarboxylate complexes of the following ions were: Mn(II), seven (25); Fe(III), seven (26, 30); Zr(IV), eight (27); Ln(III), eight to ten (28, 29). Coordination numbers of seven and eight for Fe(III) in aminopolycarboxylate complexes have also been proposed on the basis of Mössbauer studies (39, 40). For large metal ions the strain in the ethylenic chelate ring increases rapidly with increasing size of the central ion. The stress is expected to be relieved mainly by distortions in the coordinate bonds. Bond angles at the metal may be reduced from the usual 90°. Consequently, the ethylenic chelate rings do not extend as far around the central ion as in a regular octahedral complex. This leaves more room for carboxyl groups to coordinate on the opposite hemisphere of the metal. A coordination number greater than six is therefore to be expected for large ions.

It is difficult to estimate the coordinate bond lengths in the DTPA complexes studied here but the Pauling ionic radii of Cd^{2+} (0.97 Å) and Pb^{2+} (1.21 Å) are larger than those of Mn^{2+}, Fe^{3+}, and Zr^{4+} whereas the radius of La^{3+} is 1.15 Å (17). In comparison with Hoard's results discussed above, and considering the scant tabulated data (41) for the appropriate metal–nitrogen and metal–oxygen coordinate bonds, it is probable that for Cd(II) and Pb(II) complexes (particularly the latter) seven or eight coordination can occur though this conclusion must await experimental confirmation. Configurations in which the metal and the three nitrogen atoms are approximately coplanar are anticipated since these should have minimal steric interference. Even without the restricting assumption of octahedral coordination the equivalence (or apparent equivalence) of the n.m.r. spectra of the four terminal carboxymethyl groups in the Pb–DTPA complex is difficult to explain. The four terminal carboxyl groups cannot coordinate at exactly equivalent positions. Differences between these positions are likely to be smaller than for regular octahedral coordination, however, and in rapidly interconverting structures they may not be large enough to cause noticeable differences in n.m.r. spectra.

The most basic sites in the DTPA molecule are the nitrogen atoms. In a metal complex the nitrogen atoms are free only for a very small fraction of the time and do not protonate extensively until $[H^+]$ becomes relatively high. When one of the terminal nitrogen atoms is not coordinated the stress in the ligand is reduced and the other terminal nitrogen atom is expected to coordinate more strongly. Thus only one terminal nitrogen atom is protonated at one time. The basicity of its associated carboxyl groups is reduced, and the center carboxyl group, if not coordinated, should protonate more readily than these. This is thought to be the case for the Cd(II)–DTPA complex.

Metal – Aminopolycarboxylic Acid Complexes. II. Studies of Triethylenetetraaminehexaacetic Acid and its Lead(II) Complexes in Aqueous Solution by Proton Magnetic Resonance Spectroscopy

P. LETKEMAN

Department of Chemistry, Brandon University, Brandon, Manitoba

AND

J. B. WESTMORE

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received June 29, 1970[1]

Nuclear magnetic resonance (n.m.r.) spectroscopy was used to determine the preferred protonation sites in TTHA. For its 1:1 complex with Pb(II) the following equilibrium constants for protonation were obtained (triethylenetetraaminehexaacetic acid ≡ H_6A)

$$PbA^{4-} + H^+ \rightleftharpoons PbHA^{3-} \qquad \log K = 8.25 \pm 0.2$$
$$PbHA^{3-} + H^+ \rightleftharpoons PbH_2A^{2-} \qquad \log K = 4.25 \pm 0.25$$

The non-protonated complex is considered to have four coplanar (or nearly coplanar) metal–nitrogen bonds with the center carboxylate groups coordinated above and below this plane, and with the terminal carboxylate groups playing only a small part in the coordinate bonding. The first and second protonations of the complex occur preferentially at the terminal and center nitrogen atoms, respectively, on the same side of the complex, accompanied by breaking of the respective metal–nitrogen bonds. This causes partial unwrapping of the complex from one side. Rapid interconversion between configurations in which unwrapping and rewrapping occurs first from one side of the molecule and then from the other leads to simplified n.m.r. spectra.

La spectroscopie r.m.n. a été utilisée pour déterminer les sites préférentiels de protonation dans le TTHA. Dans le cas d'une complexation 1:1 avec le Pb(II) les constantes d'équilibre suivantes ont été obtenues pour la protonation (acide triéthylènetétraaminehéxaacétique ≡ H_6A)

$$PbA^{4-} + H^+ \rightleftharpoons PbHA^{3-} \qquad \log K = 8.25 \pm 0.2$$
$$PbHA^{3-} + H^+ \rightleftharpoons PbH_2A^{2-} \qquad \log K = 4.25 \pm 0.25$$

Dans le complexe non protoné, on considère que les quatre liaisons métal–azote sont coplanaires (ou presque coplanaires), que les groupes carboxylates centraux sont coordonnés au-dessus et en dessous du plan et que les groupes carboxylates terminaux n'interviennent que très peu dans les liaisons coordonnées. La première et la seconde protonation du complexe se font préférentiellement et respectivement sur les atomes d'azote terminaux et centraux et sur le même côté du complexe provoquant ainsi la rupture respective des liaisons métal–azote. Ceci provoque un déroulement du complexe à partir d'un côté. L'interconversion rapide entre les configurations ou l'enroulement et le déroulement se fait d'abord d'un côté de la molécule puis de l'autre, conduit à simplifier les spectres r.m.n.

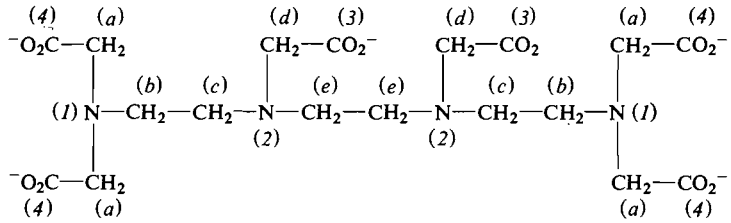
Canadian Journal of Chemistry, 49, 2086 (1971)

Introduction

The application and background of proton magnetic resonance (p.m.r.) in the study of aqueous solutions of aminopolycarboxylic acids and their diamagnetic complexes have been discussed in the first paper in this series (see ref. 1 and references therein). These discussions may be readily extended to aminopolycarboxylic acids and their complexes other than those described in Part I.

In this paper we report the results of a study of aqueous solutions containing triethylenetetraaminehexaacetic acid (TTHA) and Pb(II), using p.m.r. spectroscopy. The hexaanion of TTHA is represented as

[1]Revision received March 12, 1971.



in which donor sites are labelled as (*1*), (*2*), (*3*), and (*4*) and non-labile protons by (*a*), (*b*), (*c*), (*d*), and (*e*). Donor sites or non-labile protons which are equivalent by symmetry have the same label.

Since it was first reported in 1956 (2) TTHA has been used as a titrimetric reagent for metal ions (3) and formation constants of its complexes with a few metal ions have also been determined (4–8). Of particular interest from a theoretical viewpoint is its ability to form 1:1, 2:1, and 3:1 complexes with metal ions (5–7) and also to form mixed complexes (9–11). Its acid dissociation constants have also been determined (2, 4, 5). Infrared (11) and polarographic (12, 13) studies of some of its metal complexes have been reported as well. Since a p.m.r. study of TTHA has not appeared to date this was undertaken by us and since the results are important in the interpretation of the spectra of the 1:1 Pb–TTHA complexes studied here they are also reported in this paper.

Experimental

The proton magnetic resonance spectra were recorded with Varian A56/60A and A-60D spectrometers. The spectra were recorded at temperatures (±1°) of 0, 40, and 72 °C. The spectral data obtained were average readings of three or more recordings with a reproducibility of ±0.4 Hz. Tertiary-butyl alcohol (TBA) was used as an internal reference, though the values of the chemical shifts are reported with respect to sodium trimethylsilylpropane sulfonate (DSS) as previously described (1).

Triethylenetetraaminehexaacetic acid (TTHA) was obtained through the courtesy of the Geigy Chemical Co., Basel, Switzerland. The compound was purified by recrystallization from water. A 0.20 *M* solution of free ligand (TTHA) was prepared by adding 4.945 g of the acid to 40 ml of water, the suspension stirred and potassium hydroxide pellets added until the acid was dissolved. The solution was then diluted to 50.00 ml with the addition of distilled water. Similarly, the Pb–TTHA solutions were prepared by first dissolving the acid (TTHA) in water (made basic with KOH) and later adding the appropriate amount of reagent grade lead nitrate to make a 1:1 mole ratio of metal to ligand at 0.20 *M*. The p*H* of the various solutions was adjusted by the addition of potassium hydroxide or nitric acid and recorded as previously described (1).

Results and Discussion

TTHA

The p.m.r. spectra of TTHA were studied over the p*H* range 1–12. Representative spectra for 0.2 *M* solutions are shown in Figs. 1 and 2. Figure 1 shows the effect of varying p*H* at a temperature of 40° while Fig. 2 shows the effect of varying temperature when the p*H* = 12.0. The assignments of the various resonances in the spectra were made from their relative peak areas, dependence upon p*H* and from expectations based on earlier work (14, 15). Symmetry requires that (*i*) the eight (*a*) protons be equivalent, (*ii*) the four (*d*) protons be equivalent, (*iii*) the four (*e*) protons be equivalent. As anticipated, these groups of protons each give single peaks throughout the entire p*H* range of the study. The (*b*) and (*c*) protons are non-equivalent but their chemical shift difference is likely to be relatively small. This is borne out by the experimental results in which individual (*b*) and (*c*) resonances were not observed. Instead a multi-

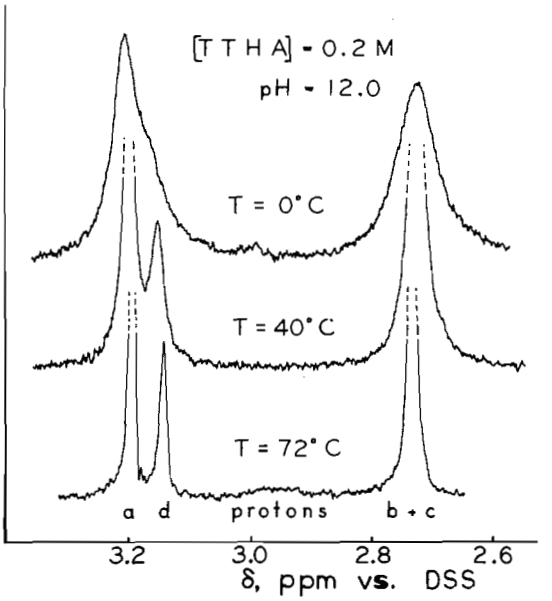

FIG. 2. Proton magnetic resonance spectra of TTHA at pH = 12 at selected temperatures.

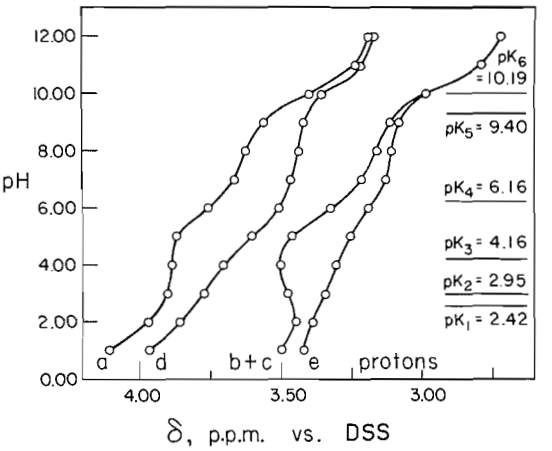

FIG. 3. Variation of chemical shifts of non-labile protons of TTHA with pH.

plet (presumably an unresolved $AA'BB'$ spectrum) is observed, comprising two equivalent sets of four protons. Thus, the only possible source of ambiguity concerns the resonances attributable to the (*d*) and (*e*) protons. Fortunately, it has been shown (14) that, for aminopolycarboxylic acids, resonances due to acetate protons occur at significantly lower field than those due to ethylenic protons. In fact, any other assumption than this is irreconcilable with the pH dependencies of the chemical shifts observed in this work.

The pH dependencies of the chemical shifts of the various resonances are shown in Fig. 3 (for the (*b*) and (*c*) protons the mean chemical shift is given). Also shown are pK values for TTHA (2, 4, 5). At pH = 12, TTHA exists in solution as the hexaanion. As the pH is lowered to *ca.* 8.5 the chemical shifts of all protons move toward lower field. Between pH = 8.5 and pH = 7.0, further movement of chemical shift toward lower field is small indicating that little protonation occurs in this region. This is in agreement with the large difference between pK_4 and pK_5 ($\Delta pK \simeq 3.2$). The pK values indicate that when the pH is lowered from pH = 12 to pH = 8 two protons are added to the TTHA hexaanion. The magnitude of the change in chemical shifts supports this view (see below). When the pH is lowered below pH = 7, further pH regions within which the chemical shifts of all protons remain approximately constant are not apparent. This is to be expected since only small differences exist between successive values of pK_1, pK_2, pK_3, and pK_4 (*i.e.* $pK_n - pK_{n-1} \leq 2$).

It is of importance to the results discussed in the latter part of this paper to determine the preferred protonation sites, and extent of protonation of these sites, in the TTHA anions. This can be done by a method similar to that used by Sudmeier and Reilley (14) if certain rather approximate assumptions are made. In a molecule such as the hexaanion of TTHA, which has several different sites which can accept a proton, the change in chemical shift of a given type of non-labile proton upon varying the pH will depend upon the proximity of the non-labile proton to the site, or sites, at which protonation occurs, and also the fractions of time for which the site or sites, are protonated. It is assumed that the contributions to the chemical shift changes from protonation of different sites are perfectly additive, and linearly related to the fractions of time for which the sites are protonated (14). For TTHA the chemical shifts of the various protons are given by

$$[1] \quad \delta_a = \delta_a^0 + f_1 C_N + f_4 C_0$$
$$[2] \quad \delta_b = \delta_b^0 + f_1 C_N + f_2 C_N'$$
$$[3] \quad \delta_c = \delta_c^0 + f_2 C_N + f_1 C_N'$$

$$[4] \quad \delta_{bc} = \delta_{bc}^{0} + \tfrac{1}{2}(f_1 + f_2)(C_N + C_N')$$

$$[5] \quad \delta_d = \delta_d^{0} + f_2 C_N + f_3 C_0$$

$$[6] \quad \delta_e = \delta_e^{0} + f_2(C_N + C_N')$$

where δ_a, δ_b, δ_c, δ_d, and δ_e are the chemical shifts of the (*a*), (*b*), (*c*), (*d*), and (*e*) protons, respectively, at a given p*H*; δ_a^{0}, δ_b^{0}, δ_c^{0}, δ_d^{0}, and δ_e^{0} are the chemical shifts of the corresponding protons in the TTHA hexaanion (values at p*H* = 12 were used); f_1, f_2, f_3, and f_4 are the fractions of time for which each equivalent site of types (*1*), (*2*), (*3*), and (*4*), respectively, are protonated; C_N is the change in chemical shift produced in the methylene protons, either acetate or ethylenic, upon protonation of the adjacent nitrogen; C_N' is the change in chemical shift produced in an ethylenic proton separated by one CH_2 group from the nitrogen at which protonation occurs; C_0 is the change in chemical shift produced in the acetate protons upon protonation of the carboxylate group; δ_{bc} and δ_{bc}^{0} are the average values of δ_b and δ_c, and δ_b^{0} and δ_c^{0}, respectively, introduced because these values are more readily determined than the individual chemical shifts which are not accurately determinable from the experimental data.

A further important relationship is

$$2f_1 + 2f_2 + 2f_3 + 4f_4 = n$$

where *n* is the number of equivalents of acid added to one mole of TTHA hexaanion and the coefficients arise from the number of equivalent sites of each type.

If C_N, C_N' and C_0 are known then, in principle, f_1, f_2, f_3, and f_4 can be determined since all other quantities are experimentally observable. The first task is to calculate C_N, C_N' and C_0. Values of C_0 and C_N' were obtained by assuming that at p*H* = 7.4 two equivalents of acid have been added to one mole of TTHA hexaanion. Since carboxyl groups are negligibly protonated at such high p*H* values then $f_3 = f_4 = 0$ and therefore $2f_1 + 2f_2 = 2$. Equations 1, 4, 5, and 6 may be used to determine C_N and C_N'. There are more equations than necessary and slight differences in values of C_N and C_N' arise depending upon which equations are used. These variations are not serious and arise because of the simplifying assumptions made. It is apparent that $C_N \simeq 45 \pm 5$ Hz (0.75 p.p.m.) and $C_N' \simeq 15 \pm 5$ Hz (0.25 p.p.m.). Since these values agree favorably with those obtained by Sudmeier and Reilley (C_N = 0.75 p.p.m., C_N' = 0.35 p.p.m.) for similar though different systems (14), they were used for subsequent calculations.

Values of f_1 and f_2 can be calculated as a function of p*H*. The δ_e values can be used to determine values of f_2, using eq. 6. The δ_{bc} values may be used to determine values of $f_1 + f_2$, using eq. 4, and hence f_1. We estimate that the error in the values obtained for f_2 are probably not larger than $\pm 10\%$ and for f_1 not larger than $\pm 20\%$, of the calculated values. Values of f_3 and f_4 are more difficult to calculate. In principle, these can be obtained from δ_d and δ_a, respectively, if f_1, f_2, and C_0 are known. In fact, because C_0 is relatively small (0.2 p.p.m. according to Sudmeier and Reilley (14)), the relatively small errors in f_1, f_2, C_N, or C_N' can cause large errors in f_3 and f_4. Instead, we have assumed (rather arbitrarily, though with probably small error) that at p*H* = 2, *n* = 6; *i.e.* $2f_1 + 2f_2 + 2f_3 + 4f_4 = 6$ and have calculated that C_0 = 17 Hz. Finally f_3 and f_4 were calculated from δ_d and δ_a though the error could be as much as twice as high as those in f_2 and f_1, respectively. The results given in Fig. 4 show that initially all the nitrogen sites are approximately equally basic but when $f_2 \geq 0.3$ the preferred protonation sites are the terminal nitrogen atoms. Somewhat less preferred are the center nitrogen atoms where repulsions between protons would be greater. The center carboxylate groups protonate more readily than the terminal

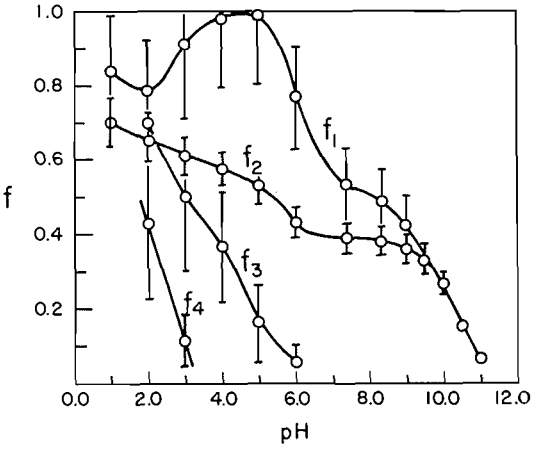

FIG. 4. Extent of protonation of various sites in TTHA as a function of p*H*, expressed as the fraction, *f*, of the time for which a site is protonated.

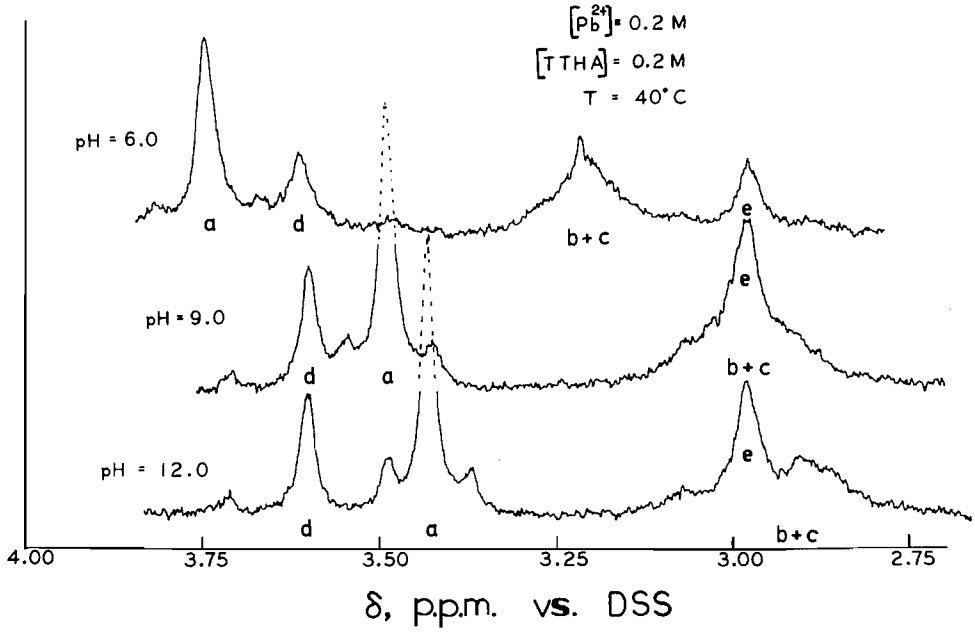

FIG. 5. Proton magnetic resonance spectra of the Pb–TTHA complex at 40° at selected pH values.

carboxylate groups, readily explained by the less extensive protonation of the center nitrogen atoms. Similar behavior has previously been observed for diethylenetriaminepentaacetic acid (DTPA) (3). Interestingly, when the terminal carboxylate groups do eventually protonate there is some deprotonation of the terminal nitrogen atoms. These findings may be compared with earlier discussions, based on potentiometric studies of the species present in aqueous solutions of TTHA (5).

Pb–TTHA

The proton n.m.r. spectra obtained for 1:1 ratios of Pb:TTHA, at a concentration of 0.2 M, were studied over the range pH = 2 to pH = 13. Representative spectra at selected pH values at 40 °C are shown in Fig. 5. Figure 6 gives the pH dependence of the chemical shifts of the various resonances. Assignments of the various resonances in the spectra were made from their relative peak areas, dependence upon pH, and from expectations based on previous discussions (1).

The variations in chemical shift indicate that there are two pH ranges in which protonation of the complex occurs, namely between pH = 10 and pH = 7, and also between pH = 5 and pH = 2.

All four (a)-type carboxyl groups give equivalent spectra throughout the entire pH range of the study, the spectrum of the (a) protons being a simple singlet containing eight protons. At high pH, *i.e.* p$H \geq 9$, the peak is sufficiently far removed from other resonances that two smaller satellite peaks can be distinguished. These are of the approximate intensity required for an AX pattern due to coupling between the (a) protons and the lead isotope 207, which has a spin of one-half and a relative intensity of 21% (15). Lead–proton coupling has been previously reported in EDTA (17) and DTPA (1) complexes. In the TTHA complex the lead–proton coupling constant for the (a) protons is determined to be 3.6 Hz. As the pH is lowered from pH = 9 to pH = 7 the chemical shift of the (a) protons moves to lower field and for p$H \leq 7$ an AX pattern caused by metal–proton coupling is no longer detectable.

The two (d)-type carboxyl groups also give equivalent spectra (simple singlets). For p$H \geq 9$ a satellite peak which can be attributed to one half of an AX pattern due to metal–proton coupling in those molecules containing the ^{207}Pb isotope was detected. The lead–proton coupling constant for the (d) protons was measured to be 6.5 Hz. For both the (a) and (d) protons the lead–proton coupling constants are much smaller than

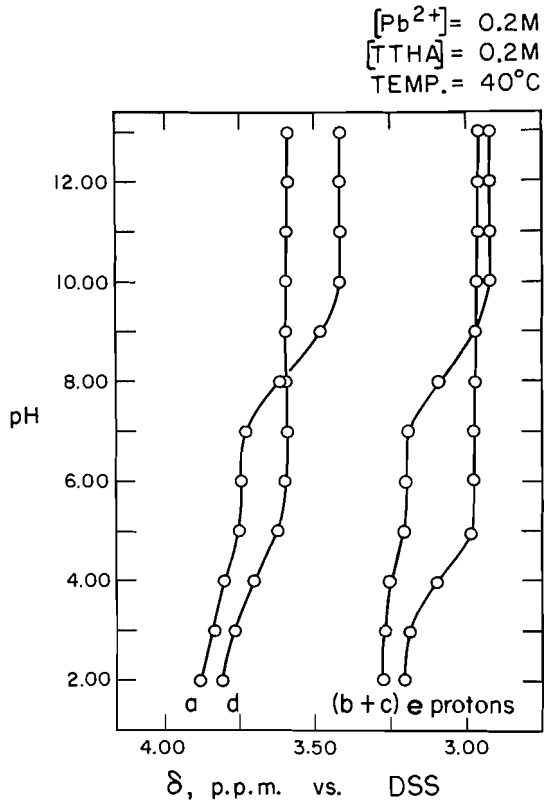

FIG. 6. Variation of chemical shifts of non-labile protons in the Pb–TTHA complex with p*H*.

reported for other lead(II) complexes with aminopolycarboxylic acids (1, 17).

The (*b*) + (*c*) ethylenic protons gave a broad, unresolved resonance throughout the complete p*H* range. Earlier discussions (1) have revealed that a complex spectrum involving many components is to be expected for ethylenic protons in aminopolycarboxylate complexes of this type. Metal–proton coupling could not be detected among the unresolved resonances. The mean chemical shift of the (*b*) + (*c*) protons was taken as the center of the spectral pattern. The results for the (*a*) and (*d*) protons indicate that the two sets of (*b*) + (*c*) protons are equivalent. At p*H* = 12 the (*b*) + (*c*) spectrum appears asymmetric. As the p*H* is lowered to p*H* = 7 the resonance moves downfield and becomes narrower in width, indicating that one end of the ethylenic linkage is more sensitive to protonation changes than the other.

The ethylenic (*e*) protons give a simple singlet throughout the study. Although the (*e*) protons are all equivalent by symmetry in the uncomplexed ligand, there are many instantaneous configurations of a metal–TTHA complex in which they are not. However, the foregoing results indicate that the average configuration of the Pb–TTHA complex is one in which rapid interconversion between non-equivalent configurations produces four equivalent (or not detectably different) (*a*)-type carboxyl groups, and two equivalent (or not detectably different) (*d*)-type carboxyl groups. Thus, the two halves of the TTHA ligand are equivalent in the complex and the four (*e*) protons are also expected to be equivalent.

The n.m.r. spectrum of an aminopolycarboxylate complex will depend upon the labilities of the various metal–ligand bonds, and also upon the fraction of time for which the bond exists, as has been previously shown for EDTA (17) and DTPA (1) complexes. These discussions can be readily extended to diamagnetic metal - TTHA complexes.

In non-labile complexes there are many possible configurations which a metal–TTHA complex can adopt. The p.m.r. spectra of such complexes will be very complicated, as consideration of the various possibilities for the simpler metal - DTPA complexes will show (1). These possibilities will not be discussed here since the comparative simplicity of the Pb(II)–TTHA spectra obtained in aqueous solution shows that the Pb–TTHA complexes are relatively labile in terms of the n.m.r. experiment.

In labile complexes the molecule will exist in various stages of unwrapping with the more complete stages of unwrapping being less prevalent. Such unwrapping would be expected to occur from the ends of the molecule so that the metal–oxygen (*4*) bonds will form and break more quickly than the metal–nitrogen bonds, *i.e.* all the metal–nitrogen bonds will have longer lifetimes than the metal–oxygen (*4*) bonds. Two characteristic metal–nitrogen bond lifetimes can be distinguished since breaking of the metal–nitrogen (*2*) bond corresponds to the formation of a more completely unwrapped complex than does breaking of the metal–nitrogen (*1*) bond. The metal–nitrogen (*2*) bond has the longest lifetime of all metal–ligand bonds in the molecule. The metal–oxygen (*3*) bond lifetime must be shorter than that of the metal–nitrogen (*2*) bond but can be either longer or shorter than those of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the other metal–ligand bonds. Thus the following sequences of relative bond lifetimes are possible

M—N(*2*) > M—N(*1*) > M—O(*3*) > M—O(*4*)

M—N(*2*) > M—N(*1*) > M—O(*4*) > M—O(*3*)

M—N(*2*) > M—O(*3*) > M—N(*1*) > M—O(*4*)

In the following discussion the lifetimes are regarded as "long" or "short" with respect to the n.m.r. experiment.

TTHA is potentially a decadentate ligand and consequently not all donor sites can be coordinated at one time. Even for very large cations with very high coordination numbers steric interference probably prevents complete coordination of all donor sites (1). In fact, the terminal carboxyl groups may be coordinated in the Pb(II)–TTHA complex only a small percentage of the time even though the coordination number is probably greater than six (1). The n.m.r. spectra show the four terminal carboxyl groups to be equivalent and the two center carboxyl groups to be equivalent. Since there is no instantaneous configuration in which this can be true then all metal–oxygen bonds must have short lifetimes so that carboxyl groups can rapidly interchange positions in the coordination polyhedron.

The lifetimes of the metal–nitrogen (*1*) bonds are also relatively short. For a long lifetime an *AB* pattern would be expected for the (*a*) protons, as observed for similar protons in Pb–DTPA complexes (1). However, when the lifetime of the metal–nitrogen (*1*) bond is short then the (*a*) protons can become equivalent by rapid umbrella inversion at the N(*1*) atom, and a singlet rather than an *AB* pattern is expected. Even though a singlet is observed for the (*a*) protons here, for p$H \geq 9$ coupling is still observed between the (*a*) protons and the ^{207}Pb isotope because the metal–nitrogen bond reforms to the same metal ion (17).

The (*d*) protons might be expected to exhibit an *AB* pattern instead of the observed singlet. There are two possibilities why a singlet may be observed; first, the metal–nitrogen (*2*) bond has a short lifetime so that rapid umbrella inversion at the N(2) atom can occur; or second, the (*d*) protons may not see very much difference between the ethylenic bridges connected to the nitrogen (*2*) atoms, irrespective of whether the (*d*)-type carboxyl groups are coordinated, or free to rotate. The first possibility seems unlikely since it requires a high proportion of almost completely unwrapped complexes. The second possibility seems more reasonable; in fact, the magnetic environments of the two protons on a given (*d*)-type acetate group would be expected to be very similar.

When the p$H \geq 10$ the Pb–TTHA complex is non-protonated and the chemical shifts, and their pH dependence at lower pH, indicate that when p$H \geq 10$ all four nitrogen atoms are coordinated to the metal (see below). As the pH is lowered to p$H = 7$ the chemical shifts of the (*a*) and (*b*) + (*c*) protons show significant movement toward lower fields whereas those of the (*d*) and (*e*) protons are hardly affected. Furthermore, the metal–proton coupling exhibited by the (*a*) proton spectra is destroyed.

The magnitudes of the changes of chemical shift of the (*a*) and (*b*) + (*c*) protons indicate that the preferred protonation sites are the terminal nitrogen atoms (carboxyl groups do not protonate in this pH range). The quantitative treatment applied to determine the extent of protonation of Pb–DTPA and Cd–DTPA (1) complexes from the chemical shifts of the non-labile protons does not work well here because (*i*) in the range p$H = 10$ to p$H = 7$ the proton affinity of the terminal nitrogen atom is significantly smaller in free TTHA than a non-coordinated terminal nitrogen atom in the lead complex (the results shown in the earlier part of this paper indicate that, in TTHA, protonation of the center nitrogen atoms reduces the proton affinity of the terminal nitrogen atoms, and vice-versa); (*ii*) study of molecular models suggests that when one of the metal–N(1) bonds breaks some strain in the ligand is relieved and steric interference between terminal carboxyl groups is reduced; the other metal–N(1) bond is expected to gain strength, and as a consequence of this the chemical shifts of the (*a*) and (*b*) protons should move to higher δ values (perhaps approaching those of (*d*) and (*e*), respectively. In spite of these difficulties it is possible to ascertain that only one proton is added to the complex when the pH is lowered from 10 to 7 since the chemical shifts of the (*a*) protons in the complex between p$H = 7$ and p$H = 5$ are close to the value expected for complexes in which a given terminal nitrogen atom is coordinated about 50% of the time, and protonated about 50% of the time, *i.e.* either one or the other terminal nitrogen atoms is co-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ordinated nearly 100% of the time. Double protonation of the complex would correspond to values of $f_1 = 1$ for the uncomplexed ligand; from Figs. 3 and 4 a value of 3.9 p.p.m. is predicted for the value of δ_a in the complex. For single protonation the value predicted for δ_a is the mean of this latter value and the chemical shift expected for acetate protons adjacent to a coordinated nitrogen atom. In the non-protonated complex, Fig. 6 shows the extremes for these chemical shifts are $\simeq$ 3.4 and $\simeq$ 3.6 p.p.m. (in the range pH = 12 to pH = 10). Use of the value 3.6 p.p.m. gives a predicted value for δ_a in the complex of 3.75 p.p.m., close to the observed value between pH = 7 and pH = 5. (This result suggests strengthening of one metal–N(1) bond as the other N(1) atom is protonated.) Though the values of the chemical shifts of the (*b*) + (*c*) protons are less precise they also support single, rather than double, protonation of the complex in this step. From the pH variation of the chemical shifts it is determined that for the reaction

$$PbA^{4-} + H^+ \rightleftharpoons PbHA^{3-}$$

where triethylenetetraaminehexaacetic acid $\equiv H_6A$,

$$\log K = 8.25 \pm 0.2$$

The protonation of the complex thus occurs at approximately 2 pH units lower than does the first protonation of the free TTHA hexaanion, strongly suggesting that all four nitrogen atoms can coordinate to the lead ion at the same time, though the terminal nitrogen atoms will be bound less strongly than the center ones. (A non-coordinated terminal nitrogen atom should have approximately the same proton affinity in the lead complex as in the free ligand. For the terminal nitrogen atoms to be coordinated only 50% of the time would lead to protonation of the complex at pH values only about 0.3 pH unit lower than in the free TTHA hexaanion.)

When the pH is lowered from pH = 5 to pH = 2 all proton chemical shifts move downfield (towards higher δ values) but the movements of the (*a*) and (*b*) + (*c*) protons are relatively small. This is only possible if, in this pH range, the preferred coordination sites are the center nitrogen atoms. The magnitude of the movement of the shifts of the (*e*) protons indicates that the N(2) atoms are coordinated 50% of the time and protonated 50% of the time; *i.e.* at pH = 2 the chemical shift ($\simeq$ 3.2 p.p.m.) of the (*e*) protons is the average of $\simeq$ 2.95 p.p.m. expected when N(2) is coordinated (Fig. 6), and $\simeq$ 3.5 p.p.m. expected when N(2) is fully protonated (Fig. 3). Rapid interconversion between forms in which first one, then the other, center nitrogen atom is coordinated, occurs. Further information about the structure of the complex can be deduced by noting the following considerations: (*i*) Fig. 4 and the earlier Cd(II)–DTPA results (1) indicate that non-coordinated carboxymethyl groups attached to coordinated nitrogen atoms will show increasing protonation as the pH starts to decrease below *ca.* 5, whereas carboxymethyl groups attached to protonated nitrogen atoms have a much smaller tendency to protonate; (*ii*) the movements of the chemical shifts of the (*b*) + (*c*) and (*d*) protons in the range pH = 5 to pH = 3 are smaller than anticipated from 50% protonation at each N(2) atom, though the movement for the (*e*) protons is close to that expected (see above). The following reasoning can be applied. The movement of the (*b*) + (*c*) resonance is small because some deprotonation of the N(1) atoms occurs as the N(2) atoms protonate, a coulombic repulsion effect which has already been observed in aminopolycarboxylate anions (17). The change in position of the (*a*) resonance will be the resultant of that produced by the partial deprotonation at N(1) and that produced by partial protonation of terminal carboxyl groups during the 50% of the time N(1) is coordinated. The second contribution predominates. The smallness of the movement of the (*d*) proton resonance (8.8 Hz compared with 14.0 Hz for the (*e*) protons) indicates that when N(2) is coordinated its attached carboxymethyl group is also coordinated. If this were not so then substantial protonation of the carboxyl group would occur, producing a much larger movement of the (*d*) proton resonance than observed.

In the range pH = 5 to pH = 2 there is more than one type of potential protonation site so that protonation constants determined from variations in chemical shifts will not be precise. However, it is apparent that for the reaction

$$PbHA^{3-} + H^+ \rightleftharpoons PbH_2A^{2-}$$

$$\log K = 4.25 \pm 0.25$$

To summarize, the results can be most readily reconciled in terms of a Pb–TTHA complex having labile bonds. At p$H \geq$ 10, all four

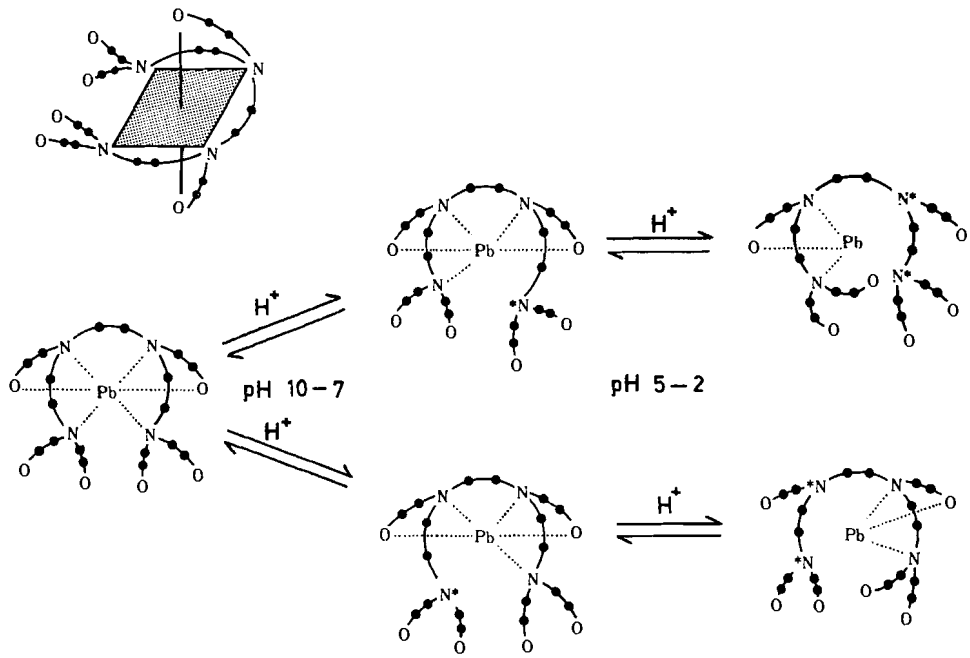

FIG. 7. Schematic representation of the equilibria in 1:1 Pb(II)–TTHA solutions. (* = preferred protonation site).

nitrogen atoms are coordinated to the metal. Since the lifetimes of the terminal oxygen–metal bonds must be shorter than those of the terminal nitrogen–metal bonds the terminal carboxylate groups probably play only a little part in the coordinate bonding in the complex. The remaining places in the coordination polyhedron are taken by the center carboxylate groups. Study of molecular models, using similar considerations to those outlined previously (1), shows that for large ions the least strained and least congested configuration has the four nitrogen atoms and the metal approximately coplanar. Sterically, the center carboxylate groups can then readily coordinate above and below this plane. This is shown diagrammatically in Fig. 7 in which octahedral coordination is assumed. However, the coordination number for lead(II) is probably greater than six, with water molecules or possibly terminal carboxyl groups also participating in the coordinate bonding.

The Pb–TTHA complex protonates in two stages, represented schematically in Fig. 7. In the first stage the Pb–TTHA complex protonates much more readily than the Pb–DTPA complex (1). Two reasons may be advanced for this: first, the proposed small participation in coordinate bonding by the terminal carboxylate groups means that partial unwrapping of the complex at the terminal nitrogen atom can occur more readily in the TTHA complex; second, the TTHA complex is more sterically crowded than the DTPA complex and this crowding can be reduced by breaking the metal–nitrogen bond. The former reason arises possibly because of steric crowding and also because the terminal carboxyl groups are unfavorably situated to compete for the limited number of coordination positions around the metal. The second protonation stage causes further unwrapping of the complex from the same side of the molecule as the first, rather than from the other side. This situation resembles that proposed (5) for the 1:1 Ca(II)–TTHA complex, though for the Pb(II)–TTHA complex the n.m.r. results show that the center nitrogen–metal bond is not broken until the second proton is added (otherwise a downfield shift of the (*d*) proton, resonances would be observed between pH = 10 and pH = 7). It is to be expected that such a complex would readily bind a second metal ion, as, in fact, potentiometric studies have shown (5, 6, 9). This is confirmed also by the n.m.r. spectra of solutions containing Pb(II) and TTHA in the ratio 2:1. At pH = 5 very broad resonances

are obtained indicating exchanging roles of the lead ions in the complexes, and further studies of this system are required.

Metal – Aminopolycarboxylic Acid Complexes. III. Studies of Lead(II) – Tetraethylenepentaaminehеptaacetic Acid in Aqueous Solution by Proton Nuclear Magnetic Resonance Spectroscopy

PETER LETKEMAN[1] AND DONALD T. SAWYER

Department of Chemistry, University of California, Riverside, California 92502

Received August 28, 1970

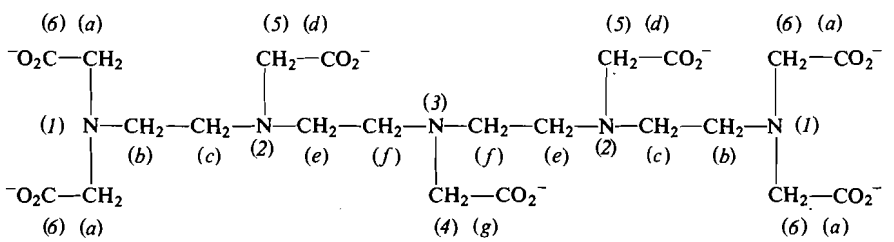
Proton nuclear magnetic resonance (n.m.r.) spectroscopy and the p*H* dependence of the chemical shifts of the nonlabile protons have been used to determine the preferred protonation sites in tetraethylenepentaaminehеptaacetic acid (TPHA). The nitrogen atoms are protonated more readily than the carboxylate groups with the sequence of protonation dependent on electrostatic interactions. The 1:1 Pb(II)–TPHA complex which is not protonated for solution conditions from p*H* 10 to 14, has five metal–nitrogen bonds. The coordinate bonds are labile so that rapid interconversion between nonequivalent configurations produces an average configuration in which the protons of the acetate groups exhibit single n.m.r. peaks. Protonation of the complex probably occurs in three stages. From p*H* 10 to p*H* 8 the preferred protonation sites are the terminal nitrogen atoms with the attendant elimination of the metal–nitrogen bonds. Increasing the acidity to p*H* 4 causes all but the central nitrogen site to be protonated. Below p*H* 4 the central nitrogen atom becomes protonated and causes further unwrapping of the complex.

La spectroscopie r.m.n. et la dépendance du p*H* avec les déplacements chimiques des protons non labiles ont été utilisées pour déterminer les sites de protonation préférentiels dans l'acide tétraéthylénepentaaminehеptaacétique (TPHA). Les atomes d'azote sont protonés plus rapidement que les groupes carboxylates; la séquence de protonation dépendant des interactions électrostatiques. Le complexe 1:1 Pb(II)–TPHA qui n'est pas protoné pour des solutions ayant un p*H* compris entre 10 et 14, possède cinq liaisons métal–azote. Les liaisons coordonnées sont labiles et de ce fait, l'interconversion rapide entre des configurations non équivalente, produit une configuration moyenne dans laquelle les protons des groupes acétates ne montrent que des singulets. La protonation du complexe se fait probablement en trois étapes. Entre p*H* 10 et p*H* 8 les sites de protonation préférentiels sont les atomes d'azote terminaux; ceci se faisant avec rupture subséquente des liaisons métal–azote. L'augmentation de l'acidité jusqu'à p*H* 4 provoque la protonation de tous les sites à l'exception de l'atome d'azote central. En dessous de p*H* 4 l'atome d'azote central se protone et provoque le déroulement ultérieur du complexe.

Canadian Journal of Chemistry, 49, 2096 (1971)

Introduction

The application of proton nuclear magnetic resonance to the study of aqueous solutions of aminopolycarboxylic acids and their diamagnetic complexes have been discussed in the previous papers of this series (1, 2). The heptaanion of tetraethylenepentaaminehеptaacetic acid (TPHA) can be represented as



in which donor sites are labelled as (*1*)–(*6*) and nonlabile protons by (*a*)–(*g*). Donor sites or nonlabile protons which are equivalent by symmetry have the same label.

Unlike triethylenetetraaminehexaacetic acid (TTHA) (2), TPHA is a relatively new complexing agent. It was first prepared in 1960 by the Geigy Chemical Company, Basel, Switzerland, using a modified Strecker synthesis (3). Later a method based on a chloroacetic acid – amine reaction was developed using ion exchange techniques to

For personal use only.

separate the acid from the reaction mixture (4), the latter being similar to Frost's preparation of TTHA (5). The new ligand was first used in the removal of internally deposited radionuclides from rats (6, 7). This study as well as a 1965 review paper (8) conclude the complexing ability of TPHA is slightly weaker than that of TTHA, which in turn was less than diethylenetriaminepentaacetic acid (DTPA). Such a trend has been attributed to the increased steric hindrance and inability to use all of the carboxyl groups when forming metal complexes (8).

A recent spectrophotometric study of Am(III)–TPHA indicates that 2:1, 1:1, and 1:2 complexes are formed (9). The complexes of Mg(II), Ca(II), Sr(II), and Ba(II) have a metal–ligand ratio of 2:1, while those for Co(II), Ni(II), Cu(II), Zn(II), and Pb(II) have ratios of 3:2 (8).

The present paper summarizes the results of a protonation study of TPHA and its Pb(II) complexes in aqueous solutions using proton n.m.r. spectroscopy. The results of the free TPHA study are important in the interpretation of the spectra of Pb–TPHA complexes.

Experimental

The proton nuclear magnetic resonance spectra were recorded with a Varian A-60D spectrometer at temperatures of 40 and 80 °C (±1°). The spectral data obtained were average readings of several recordings with a reproducibility of ±0.4 c.p.s. The values of the chemical shifts were measured with respect to *t*-butyl alcohol (TBA) but reported with respect to sodium trimethylsilylpropane sulfonate (DSS).

A sample of purified TPHA was obtained through the courtesy of the Geigy Chemical Company, Basel, Switzerland, and was used without further purification. A 0.20 *M* stock solution of free ligand was prepared by adding 1.192 g of the acid to 8 ml of D_2O, the suspension stirred with subsequent addition of potassium hydroxide pellets until the acid had dissolved, and finally diluting the solution to 10.00 ml with D_2O. The presence of K^+ ions caused the ligand to be soluble down to p*H* 1.0. The p*H* of the stock solution was adjusted by the addition of potassium hydroxide or nitric acid as needed. The individual n.m.r. samples (p*H* 1.0–13.0) were obtained by adjusting the p*H* of the stock solution to the required value and transferring 0.5 ml of that solution into an n.m.r. tube. Such additions caused dilution of the stock solution, but this could not be avoided due to the limited amount of TPHA available.

Similarly, the metal–ligand (Pb–TPHA) solutions were prepared by first dissolving the acid in D_2O (basic with KOH) and then adding the appropriate amount of reagent grade lead nitrate to make a 1:1 mole ratio of lead to TPHA at 0.20 *M*. Again the concentration of individual Pb–TPHA solutions (p*H* 2.0–12.0) was slightly less than 0.20 *M* due to the dilution caused by adding base or acid in the p*H* adjustments. The p*H* of the various solutions was recorded with a Leeds and Northrup p*H* meter (Cat. #7664) equipped with micro-electrodes and calibrated at p*H* 4.00, 7.00, and 10.00 (Sargent buffers).

Results and Discussion

TPHA

The proton n.m.r. spectra of TPHA have been studied from p*H* 1 to p*H* 13 in D_2O solutions; representative spectra for 0.2 *M* solutions are shown in Fig. 1. Increasing the temperature of the sample solution from 40 to 80 °C at a given p*H* sharpens the spectra in a fashion similar to the TTHA system. The assignments of the various resonances in the spectra have been made from their relative peak areas, dependence on p*H*, and from expectations based on earlier work with DTPA (10, 11) and TTHA (2). Symmetry requires that (*i*) the eight (*a*) protons be equivalent, (*ii*) the four (*d*) protons be equivalent, and (*iii*) the two (*g*) protons be equivalent. These groups of protons each give single peaks throughout the entire p*H* range of the study. The (*b*) and (*c*) protons, as well as the (*e*) and (*f*) protons, are nonequivalent, but their chemical shift differences are likely to be relatively small. This is borne out by the experimental results in which at high p*H* the whole group ((*b*), (*c*), (*e*), and (*f*)) appeared as a single broad peak, and at low p*H* as an unresolved A_2B_2 spectrum (see Fig. 1). The areas of these peaks (at p*H* 10 and p*H* 4) correspond to sixteen protons, which relieves any ambiguity about the proton labelling.

The p*H* dependencies of the chemical shifts of the various resonances are illustrated by Fig. 2 (for the (*b*), (*c*), (*e*), and (*f*) protons the mean chemical shift is given). The reported p*K* values of TPHA (8) are: $pK_1 = —$, $pK_2 = 2.73$, $pK_3 = 3.82$, $pK_4 = 5.56$, $pK_5 = 8.88$, $pK_6 = 9.95$, and $pK_7 = —$; which provide some help in explaining the protonation of the acid. At p*H* 12, TPHA exists in solution as the heptaanion. As the p*H* is lowered to p*H* 9.0, the chemical shifts of all protons move toward lower field with the (*d*) protons showing a pronounced shift. Using the p*K* values ($\frac{1}{2}pK_5 + \frac{1}{2}pK_6 \approx 9.0$), p*H* 9.0 would correspond to the addition of two moles of protons per mole of ligand. Hence, the main sites of protonation are the nitrogen(*2*) positions; *i.e.*, a compromise between basicity of nitrogen atoms and proton–proton repulsion on adjacent nitrogens. Adding another mole of H^+ causes a deprotonation of the nitrogen(*2*) positions as seen from Fig. 2. Hence, the three moles of H^+ mainly occupy positions on nitrogen(*1*), nitro-

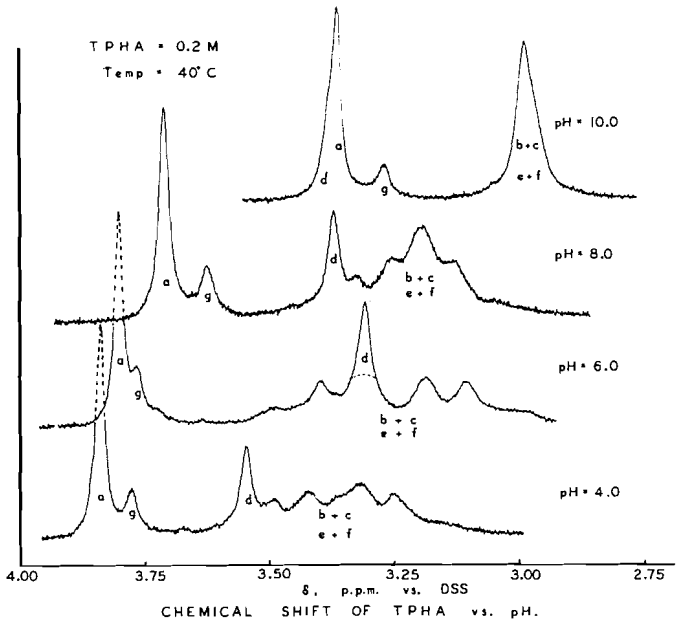

FIG. 1. Proton n.m.r. spectra of TPHA at 40 °C at selected pH values.

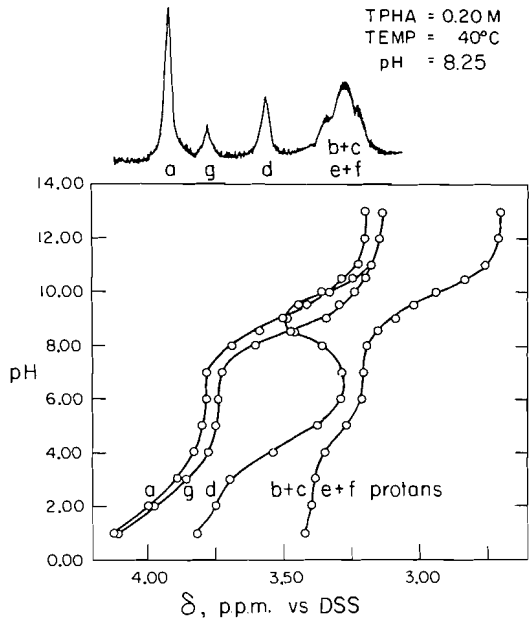

FIG. 2. Variation of the chemical shifts of the nonlabile protons of TPHA with pH.

gen(*3*), and nitrogen(*1*), at approximately pH 6.5. This arrangement of protons is expected because it minimizes proton–proton repulsion on adjacent nitrogen sites. Close inspection of Fig. 2 indicates that little or no protonation occurs between pH 7.5 and pH 5.5. This is in agreement with the large difference between pK_4 and pK_5 ($\Delta pK \cong 3.3$). Upon the addition of a fourth mole of H^+, the (*d*) protons move toward lower field faster than the other protons, indicating the protonation of nitrogen(*2*) sites in preference to protonation of the carboxylate groups.

When the pH is lowered below pH 4.0, the chemical shifts of all protons shift in a constant fashion due to the small differences between successive values of pK_2, pK_3, and pK_4 (*i.e.*, $pK_n - pK_{n-1} \leqslant 2$).

Using a method similar to one described previously (2), the preferred protonation sites and the extent of protonation can be determined quantitatively for the TPHA anion. Again, the contributions to the chemical shift changes from protonation of different sites are assumed to be additive and to be linearly related to the fractions of time for which the sites are protonated (10). For TPHA the chemical shifts, δ, of the various protons are given by

$$[1] \qquad \delta_a = \delta_a^0 + f_1 C_N + f_6 C_0$$

$$[2] \qquad \delta_b = \delta_b^0 + f_1 C_N + f_2 C_N'$$

$$[3] \qquad \delta_c = \delta_c^0 + f_2 C_N + f_1 C_N'$$

$$[4] \qquad \delta_{bc} = \delta_{bc}^0 + 1/2(f_1 + f_2)(C_N + C_N')$$

$$[5] \qquad \delta_d = \delta_d^0 + f_2 C_N + f_5 C_0$$

$$[6] \qquad \delta_e = \delta_e^0 + f_2C_N + f_3C_N'$$

$$[7] \qquad \delta_f = \delta_f^0 + f_3C_N + f_2C_N'$$

$$[8] \qquad \delta_{ef} = \delta_{ef}^0 + 1/2(f_2 + f_3)(C_N + C_N')$$

$$[9] \qquad \delta_g = \delta_g^0 + f_3C_N + f_4C_0$$

where f represents the fraction of a proton on a given nitrogen or carboxylate site and C the chemical shift due to protonation of the adjacent site. The δ^0 values are for the ligand at pH 13.0. A further important relationship is

$$2f_1 + 2f_2 + f_3 + f_4 + 2f_5 + 4f_6 = n$$

where n is the number of equivalents of acid added to one mole of TPHA heptaanion and the coefficients arise from the number of equivalent sites of each type. Values of C_N and C_N' are obtained by assuming that at pH 7.0 three equivalents of acid have been added to one mole of TPHA heptaanion. Because at such high pH values the carboxyl groups are negligibly protonated, $f_4 = f_5 = f_6 = 0$ and therefore $2f_1 + 2f_2 + f_3 = 3$. Equations 1, 2, 5, 6, and 9 have been used to give values for C_N and C_N' of 0.72 and 0.30 p.p.m., respectively. These values agree favorably with those obtained by Sudmeier and Reilley ($C_N = 0.75$ p.p.m. and $C_N' = 0.35$ p.p.m.) (10) and have been used to calculate f_1, f_2, and f_3 from pH 6 to pH 12. Table 1 summarizes the f values as a function of pH and parallels the qualitative protonation sequence presented.

The values of C_0, f_4, f_5, and f_6 are much more difficult to determine. An attempt to calculate C_0 has been made by assuming that at pH 2.0

$$2f_1 + 2f_2 + f_3 + f_4 + 2f_5 + 4f_6 = 7$$

Furthermore, because (*b*), (*c*), (*e*), and (*f*) protons all appear under one broad A_2B_2 spectrum, eqs. 2, 3, 4, 6, 7, and 8 indicate that $f_1 = f_2 = f_3 \approx 2/3$ at pH < 6. This gives an approximate value for C_0 of 0.5 p.p.m., which is high compared to Sudmeier and Reilley's value of 0.2 p.p.m. (10). However, calculation does predict extensive protonation of all nitrogen atoms as well as of the terminal and central carboxyl groups with little protonation for the (*d*) type carboxyl groups. A possible explanation for this is the high congestion of carboxyl groups in the TPHA molecule with an attendant high degree of proton–proton repulsion for neighboring carboxyl groups. No further attempt has been made to determine quantitatively the extent of protonation of the carboxyl groups.

Pb–TPHA

The proton n.m.r. spectra for 1:1 ratios of 0.2 *M* Pb:TPHA have been studied from pH 2.0 to pH 12.0. Representative spectra are illustrated in Fig. 3. Figure 4 summarizes the pH dependence of the chemical shifts for the various resonances. Assignments have been made on the basis of relative peak areas, pH dependence, and expectations based on the behavior of the free ligand.

The variations in chemical shift (see Fig. 4)

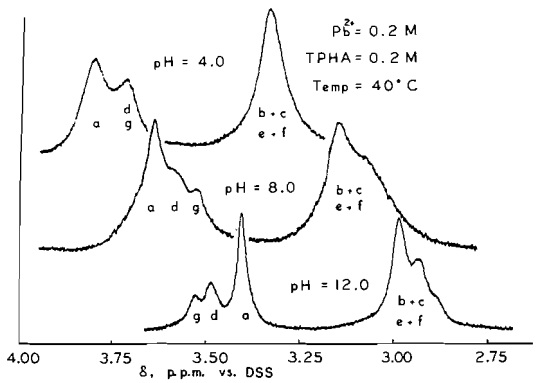

FIG. 3. Proton n.m.r. spectra of the Pb–TPHA complex at 40 °C at selected pH values.

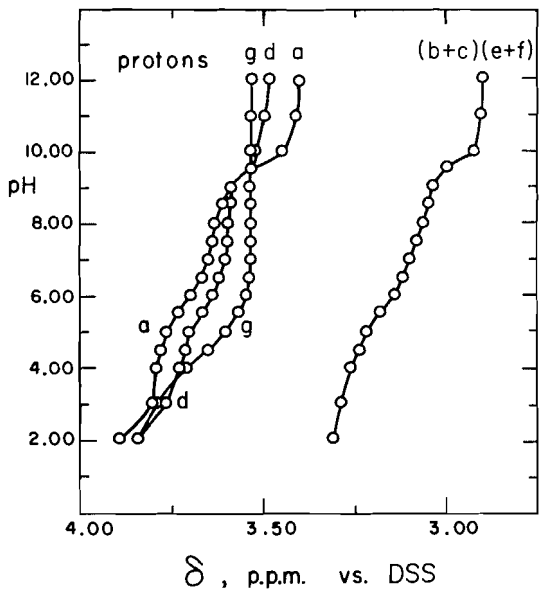

FIG. 4. Variation of the chemical shifts of the nonlabile protons in the Pb–TPHA complex with p*H*.

indicate that there are three p*H* ranges in which protonation of the complex occurs; namely, between p*H* 10–8, p*H* 6–4, and p*H* 4–2. Figure 4 indicates a clear distinction between the first and second stage of protonation with a somewhat less defined distinction between the second and third stage of protonation. This behavior, however, is reasonable when one considers the stability of protonated aminopolycarboxylic acid complexes (12–17); *i.e.*, the stability constants of MH_2Y and MH_3Y differ by approximately one p*K* unit or less, whereas the difference between the stability constants of MHY and MH_2Y is usually five p*K* units or more.

All four (*a*)-type carboxyl groups are equivalent throughout the entire p*H* range of the study; their spectrum is a singlet containing eight protons. The two (*d*)-type carboxyl groups are equivalent and give a singlet as does the (*g*)-type carboxyl group. There is no evidence for any coupling between (*a*), (*d*), or (*g*) protons and the ^{207}Pb isotope, in contrast to earlier studies (1, 2). This probably is due to the lability of Pb–TPHA complex and the resulting poorly resolved spectra. Furthermore, the metal–proton coupling constants follow the sequence Pb–EDTA ≈ Pb–DTPA > Pb–TTHA (1, 2). Thus, metal–proton coupling probably is quite small for Pb–TPHA.

In Fig. 3 the (*b*), (*c*), (*e*), and (*f*) ethylenic protons exhibit a broad, unresolved resonance throughout the complete p*H* range. Earlier discussions (1) have revealed that a complex spectrum is to be expected for ethylenic protons in aminopolycarboxylate complexes of this type. The chemical shift of the (*b*), (*c*), (*e*), and (*f*) protons has been taken as the center of the spectral pattern. At p*H* 12 the (*b*), (*c*), (*e*), and (*f*) spectrum appears asymmetric, which may indicate a slightly different chemical shift for the (*b*) + (*c*) protons compared to the (*e*) + (*f*) protons. Judging from previous work on Pb–TTHA (3) such an explanation is reasonable. As the p*H* is lowered to p*H* 4.0, the resonance moves downfield and becomes a narrower symmetrical peak, indicating that any difference in chemical shifts (between (*b* + *c*) and (*e* + *f*)) has disappeared upon protonation of the complex. The symmetrical peak corresponds to 16 protons.

The n.m.r. spectrum of an aminopolycarboxylate complex will depend upon the labilities of the various metal–ligand bonds, and also upon the fraction of time for which the bond exists, as has been previously shown for EDTA (18), DTPA (1), and TTHA (2) complexes. These discussions can readily be extended to the Pb–TPHA complex, which is relatively labile in terms of the n.m.r. experiment (judging from the simple n.m.r. spectra obtained).

In labile complexes the molecule will exist in various stages of unwrapping with the more complete stages of unwrapping being less prevalent. Such unwrapping is expected to occur from the ends of the molecule so that the metal–oxygen(*6*) bonds will form and break more quickly than the metal–nitrogen bonds, *i.e.*, all metal–nitrogen bonds will have longer lifetimes than the metal–oxygen(*6*) bonds. Three characteristic metal–nitrogen bond lifetimes can be distinguished because breakage of the metal–nitrogen(*3*) bond corresponds to a more completely unwrapped complex than does breakage of the metal–nitrogen(*2*) bond, which in turn is more unwrapped than when the metal–nitrogen(*1*) bond is broken. Thus, the metal–nitrogen(*3*) bond must have the longest lifetime of all of the metal–ligand bonds in the complex. The metal–oxygen(*5*) bond lifetime must be shorter than the metal–nitrogen(*2*) bond.

TPHA is potentially a dodecadentate ligand and consequently not all donor sites can be coordinated at one time in a 1:1 mole ratio solution

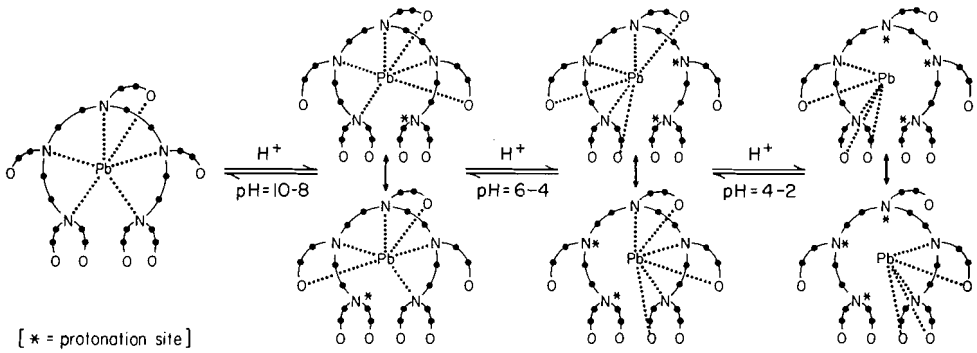

FIG. 5. Possible instantaneous configurations (at various p*H* values) of the Pb–TPHA complex.

of Pb–TPHA. In fact, the terminal carboxylate and nitrogen groups may be coordinated in the Pb(II)–TPHA complex only a small percentage of the time. The n.m.r. spectra indicate that the four terminal carboxyl groups are equivalent and that the two (*d*)-type carboxylate groups also are equivalent. Because there is no instantaneous configuration in which this is possible, all of the metal–oxygen bonds must have short lifetimes so that the carboxylate groups rapidly interchange positions in the coordination polyhedron.

The lifetimes of the metal–nitrogen(*1*) and nitrogen(*2*) bonds also must be relatively short. Otherwise, an *AB* pattern would be expected for the (*a*) and (*d*) protons, as is observed for similar protons in the Pb–DTPA (1) and Pb–TTHA (2) complexes. However, when the lifetime of a metal–nitrogen bond is short, then the (*a*) and (*d*) protons can become equivalent by rapid umbrella inversion at the nitrogen, and a singlet rather than an *AB* pattern is expected. This would involve unwrapping of the complex first from one side of the molecule and then from the other side, with the metal ion continuously attached *via* the central nitrogen(*3*) atom. Experiment indicates that the central nitrogen(*3*) and carboxyl(*4*) groups are coordinated to Pb(II) from p*H* 12 to p*H* 6 (see Fig. 4).

At p*H* > 10 the Pb–TPHA complex is not protonated and all five nitrogen atoms appear to be coordinated to the metal. As the p*H* is lowered to p*H* 8, all protons show significant movement toward lower fields except the (*g*) protons. The magnitudes of the changes of chemical shift of the (*a*), (*b*), (*c*), (*d*), (*e*), and (*f*) protons indicate that the preferred protonation sites are the nitrogen(*1*) and nitrogen(*2*) positions (the carboxylate groups do not protonate in this p*H* range). When the p*H* is lowered from p*H* 6.0 to p*H* 2, all proton chemical shifts move downfield with the (*g*) protons exhibiting the largest change. This is only possible if, in this p*H* range, the preferred protonation site is the central nitrogen(*3*) atom.

In conclusion, the results can be most readily reconciled in terms of a Pb–TPHA complex having labile bonds. At p*H* > 10 all five nitrogen atoms are involved in the coordination of the Pb(II) ion, although the lifetimes of the metal–nitrogen(*1*) and nitrogen(*2*) bonds probably are short. This short lifetime permits these nitrogen atoms to rapidly change positions in the coordination polyhedron, thus producing an averaged configuration which is symmetric through the middle of the complex. The metal–oxygen(*6*) bonds, which have shorter lifetimes than the metal–nitrogen bonds, must play an insignificant role in the coordinate bonding of the Pb–TPHA complex. The central carboxylate groups (types (*4*) and (*5*)) probably occupy the remaining places in the coordination polyhedron when some of the nitrogen atoms are protonated. The Pb–TPHA complex protonates much more readily than the Pb–DTPA complex (1), probably for the same reasons as for the Pb–TTHA complex (2).

The Pb–TPHA complex protonates in three stages, represented schematically in Fig. 5. The second protonation stage causes further unwrapping of the complex from the same side of the molecule as the first, rather than from the other side. The n.m.r. results establish that the central nitrogen–metal bond is not broken until the second and third proton are added (otherwise a downfield shift of the (*g*) proton resonance would be observed between p*H* 10 and p*H* 6). A large ligand such as TPHA should be capable of bond-

For personal use only.

ing two or three metal ions, as recent studies have indicated (8, 9). Hence, a large number of possible metal–TPHA complexes remain to be investigated in the future.

Financial support for this work was provided by the National Research Council of Canada (P.L.) and the National Science Foundation (D.T.S.) under Grant No. GP-16114. One of us (P.L.) would like to thank Brandon University for a sabbatical leave.

Sesquiterpene Lactones from Pyrethrum Flowers

RAYMOND W. DOSKOTCH, FAROUK S. EL-FERALY, AND CHARLES D. HUFFORD
Division of Natural Products Chemistry, College of Pharmacy, The Ohio State University, Columbus, Ohio 43210

Received January 4, 1971

Three new sesquiterpene lactones, dihydro-β-cyclopyrethrosin (**3**), chrysanin (**4**), and chrysanolide (**5**) were isolated from the flowers of *Chrysanthemum cinerariaefolium* and their structures determined by physical and chemical methods. The configuration at C-1 of pyrethrosin (**2**) was established as *R* by its conversion to dihydro-β-cyclopyrethrosin (**3**), a hydrogenation product of β-cyclopyrethrosin (**1**), which had the C-1 hydroxyl group assigned by the Horeau procedure and Brewster's benzoate method. The preparation and properties of the C-11 epimers, **12** and **17**, of dihydropyrethrosin are reported and their stereochemistry established.

L'extraction des fleurs du *Chrysanthemum cinerariaefolium* permet d'isoler trois nouvelles lactones sesquiterpéniques: la dihydro β-cyclopyréthrosine (**3**) la chrysanine (**4**), et la chrysanolide (**5**); leur structure a pu être déduite grâce à des méthodes physiques et chimiques. Grâce à une corrélation avec la dihydro β-cyclopyréthrosine (**3**), un produit d'hydrogénation de la β-cyclopyrethrosine (**1**) pour laquelle la configuration de l'hydroxyle en position 1 a pu être attribuée par les méthodes de Horeau et de Brewster, on a pu établir que la configuration en C-1 de la pyréthrosine (**2**) est *R*. On rapporte aussi la préparation, les propriétés et la façon de déterminer la stéréochimie des épimères **12** et **17** en C-11.

Canadian Journal of Chemistry, 49, 2103 (1971)

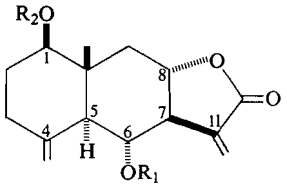
In a previous publication (1), we reported the isolation of β-cyclopyrethrosin (**1**) from the flowers of *Chrysanthemum cinerariaefolium* Visiani. Prior to this, pyrethrosin (**2**), the first recognized germacranolide was the only sesquiterpene lactone obtained from this source (2). By careful chromatography of a fraction of the pyrethrum flower extract, three additional sesquiterpene lactones, dihydro-β-cyclopyrethrosin (**3**), chrysanin (**4**), and chrysanolide (**5**) were isolated.

The isolated dihydro-β-cyclopyrethrosin (**3**) was identical (m.p., i.r., n.m.r., and specific rotation) with the hydrogenation product of β-cyclopyrethrosin (**1**). The stereochemistry at C-11 was determined from the value of the n.m.r. coupling constant between H-7 and -11, and the application of the relationship of Narayanan and Venkatasubramanian (3). The C-11 proton in the 100 MHz spectrum appears as six peaks at δ 2.64, the X of an A_3MX pattern, where $J_{H_7-H_{11}}$ = 12.0 and $J_{H_{11}-H_{13}}$ = 6.8 Hz. The C-11 proton is, therefore, pseudo-axial as shown in the Newman projection **6**. The preparation of desacetyldihydro-β-cycloisopyrethrosin (**7**), a hydrolysis product of dihydro-β-cyclopyrethrosin (**3**), in which the lactone is to C-6 confirmed the assignment. The C-11 proton becomes pseudo-equatorial as in **8** and the pattern[1] changes to five peaks located at δ 2.80, $J_{H_7-H_{11}}$ = 7.7 Hz.

The assignment of stereochemistry at C-1 in β-cyclopyrethrosin (**1**) and its dihydro-derivative **3** has yet to receive unambiguous experimental support. Iriuchijima and Tamura (2*d*) in their study of the α- and β-dihydrocyclopyrethrosin mixture, derived from pyrethrosin by cyclization, utilized the coupling constant values (J = 5 and 10.5 Hz) for the H-1 pattern to assign that proton an axial position, if a chair conformation (**9**) is assumed (4). The boat conformation as shown in **10** (C-2 and -5 being the "flagpole" carbons) in which the hydroxyl is pseudo-equatorial would give similar J values. Consequently, the n.m.r. pattern for H-1 is unable to provide a unique answer for the C-1 configuration.

Utilization of Brewster's benzoate method (5) for this purpose resulted in a large negative shift (−344°) in the molecular rotation between the alcohol **1** and the benzoate ester **11**, signifying an *R* configuration according to the sequence rule

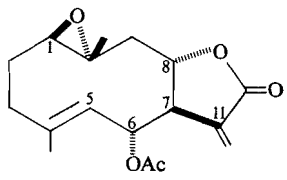
[1]These results are from the n.m.r. spectrum taken in MeOH-d_4, for reasons of solubility. A spectrum in $CDCl_3$ was obtained with aid of a time-averaging computer and after 293 scans a clear five-peak pattern was observed at δ 2.88.



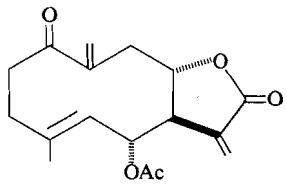
1 $R_1 = Ac$; $R_2 = H$

4 $R_1 = -OC(CH_3)=CHCH_3$ (tiglate); $R_2 = H$

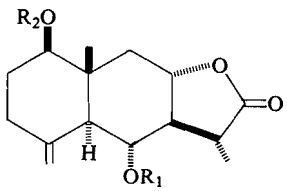
11 $R_1 = Ac$; $R_2 = Benzoyl$



2



5

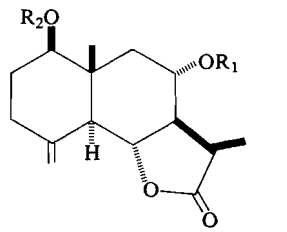


3 $R_1 = Ac$; $R_2 = H$

13 $R_1 = Angeloyl$; $R_2 = H$

14 $R_1 = R_2 = H$

18 $R_1 = R_2 = Ac$



7 $R_1 = R_2 = H$

19 $R_1 = R_2 = Ac$

(6). The Horeau method (7) of "partial resolution" gave the same result[2] since the recovered α-phenylbutyric acid was positive in an optical yield of 46%.

To relate C-1 of pyrethrosin to β-cyclopyrethrosin a mixture of dihydrocyclopyrethrosins was prepared from dihydropyrethrosin (**12**) (*vide infra*) by acid cyclization. Careful chromatography of the mixture on $AgNO_3$-impregnated silica gel yielded dihydro-β-cyclopyrethrosin (**3**) identical with the material isolated from the flowers. The configuration of C-1 in pyrethrosin is, therefore, also *R*.[3]

[2]In assigning the stereochemistry for certain C-8 alcohols of the eudesmanolide sesquiterpene lactones, the two methods gave opposite results (8). Studies on a closely related substance (asperilin) with a C-1 hydroxyl are found in ref. 9.

[3]In a publication on the biosynthesis of santonin, Barton *et al.* (10) mention the results of an X-ray study of pyrethrosin reported to them by Professor C. E. Nordman. The drawing of pyrethrosin as given there can lead to the erroneous conclusion of a *cis* epoxide and an *S* configuration at C-1. Professor Nordman informed us that this work is still unpublished but that both C-1 and -10 have the *R* configuration and our results are in agreement.

Chrysanin, (**4**) m.p. 202–204° (dec.), gave a mass spectrum with a molecular ion peak at 346.1792 (0.26%) which corresponds to the formula $C_{20}H_{26}O_5$. The i.r. spectrum showed peaks for a hydroxyl group, an α,β-unsaturated γ-lactone, an α,β-unsaturated ester, and two double bonds. The u.v. spectrum supported the α,β-unsaturated lactone and ester functions, showing only intense end absorption (log ε_{210} 4.22). The n.m.r. spectrum had many features identical with the spectrum of β-cyclopyrethrosin (see ref. 1 for a reproduction). It differed in that an acetate peak was lacking, but instead two additional olefinic methyl groups were present at δ 1.95 and 1.88. The former appeared as a doublet ($J \sim 8$) that was further weakly split ($J = 1$) into at least four peaks, while the latter appeared as a broadened singlet. Chrysanin was, therefore, formulated as desacetyl-β-cyclopyrethrosin esterified by an unsaturated five-carbon plant acid. The complex one-proton pattern at δ 6.12 was consistent with the olefinic proton of angelic acid (11), which was obtained on hydrolysis of chrysanin (**4**) and characterized as the *p*-phenylphenacyl derivative.

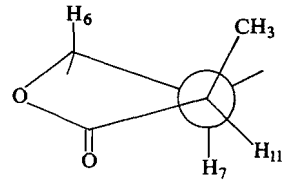
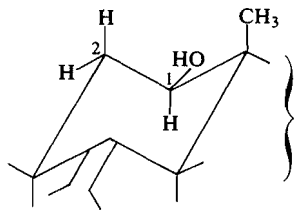
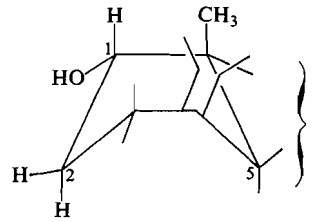
6



8



9



10

The alcohol portion of chrysanin (**4**) was characterized by the hydrolysis products of dihydrochrysanin (**13**); namely desacetyldihydro-β-cyclopyrethrosin (**14**) and its isomer **7**. The hydroxyl group in chrysanin must be located at C-1 since the H-1 pattern (pair of doublets) is found at δ 3.61 and shows a considerable sharpening after D_2O exchange. The lactone must close to C-8 for the six-peak pattern for H-8 shows a smaller chemical shift (δ 4.12) than the three-peak pattern for the proton on the ester bearing carbon (δ 5.64). Additional support for the *trans* lactone structure came from the circular dichroism curve of chrysanin with a maxima for the $n \rightarrow \pi^*$ transition of the α,β-unsaturated lactone at 262 mμ, [θ] +1420 (12). β-Cyclopyrethrosin showed a similar maxima at 253 mμ, [θ] +2340.

Chrysanolide, m.p. 204–205°, $[\alpha]_D^{25}$ −52°, analyzed for $C_{17}H_{20}O_5$, showed a molecular ion at *m/e* 304 in the mass spectrum and exhibited strong i.r. bands for an α,β-unsaturated γ-lactone, an acetate, an α,β-unsaturated ketone, and medium intensity peaks for three olefins, one of which is *trans*. The u.v. spectrum consisted of high intensity end absorption ($\log \varepsilon_{210}$ 4.40) with a weak shoulder at 300 mμ (ε 23). The n.m.r. spectrum showed a pair of one-proton doublets at δ 6.36 (J = 2.9 Hz) and 5.88 (J = 2.4 Hz), that were further weakly split (J = 0.8 Hz), for the H-13 protons; a sharp three-proton singlet at δ 2.07 for an acetate and a slightly split three-proton singlet at δ 1.76 (J = 0.9 Hz) for an olefinic methyl. A two-proton complex between δ 4.8–5.4 was analyzed as a modified AB pattern, δ_A 4.98 and δ_B 5.13 (J = 9.8 Hz, $J_{AB}/\Delta\nu$ = 1.02), where H_B is further split by H_X (J = 8.6 Hz) and H_A is broadened by long-range coupling, a characteristic of the grouping **15** (8). The latter coupling value (J = 8.6 Hz) supports the *trans* arrangement of protons H_B and H_X. A one-proton pattern of eight peaks at δ 4.05 (J = 11.1, 5.3, and 3.1 Hz) is the same as that for the H-8 proton (δ 4.16) of pyrethrosin.

Chrysanolide (**5**) lacks the three-proton singlet for the C-10 methyl group (δ 1.31 in pyrethrosin). Instead a two-proton, partially split and broadened, singlet between δ 5.3–5.9 is present. The 100 MHz spectrum more clearly shows this region to be a pair of doublets at δ 5.83 and 5.87 (J = 2.0 Hz) consistent with an exocyclic methylene. Chrysanolide was, therefore, proposed as a dehydropyrethrosin with the possible structure **5**.

Double irradiation experiments established the partial structure for chrysanolide from C-4 through -8. Irradiation at δ 3.0, the position[4] for H-7, results in the collapse of the split doublets at δ 6.36 and 5.88 to split singlets (C-13 protons), the H-5 and -6 complex (δ 4.98 and 5.13) changed to a simple AB pattern (J = 9.8) with one branch broadened, and the H-8 octet became a broadened doublet (J = 11.2). The latter result establishes the J value for H-7 and -8 as 5.3 Hz, a figure comparable to 6.4 Hz which occurs for pyrethrosin and indicates a *trans* lactone. When the

[4]At 60 MHz this proton pattern is unclear, being obscured by other peaks, but at 100 MHz it is unobstructed and appears at δ 2.95. The spectrum of pyrethrosin at 60 MHz gives a clean pattern at δ 3.06.

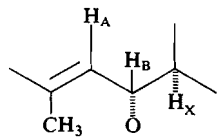
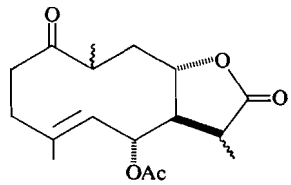
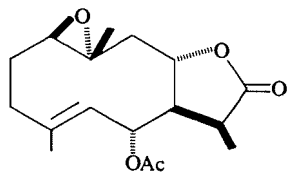
12



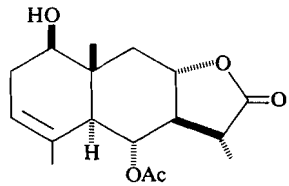
15



16



17



20

olefinic methyl doublet at δ 1.76 (J = 0.8 Hz) was irradiated, the broadened uneven doublet at δ 4.98 (H-5) was considerably sharpened, while the reverse process sharpened the methyl peak.

The c.d. curve of chrysanolide showed a maxima at 246 mμ with [θ] −6170, while pyrethrosin shows a maxima at 249 mμ and [θ] −3620. This is opposite in sign to the general rules as established by W. Stöcklin *et al.* (12) for C-8 *trans* lactones. These lactones are to be added to the few exceptions already known.

The presence of two conjugated exocyclic methylenes in chrysanolide was confirmed by the preparation, with diazomethane, of a crystalline dipyrazoline which in the n.m.r. spectrum lacked the four olefinic methylene protons. Hydrogenation of chrysanolide gave a tetrahydro-product **16** which lacked in the n.m.r. spectrum the methylene protons, but instead showed two three-proton doublets for secondary methyl groups at δ 1.08 (J = 6.8 Hz) and 1.38 (J = 6.9 Hz). Reduction of the remaining olefin group in tetrahydrochrysanolide (**16**) to a substance previously derived from pyrethrosin (*2a*) could not be accomplished under the reported (platinum oxide and ethyl acetate), as well as more drastic (platinum oxide and perchloric acid in ethyl acetate, or glacial acetic acid) conditions. Sodium borohydride reduction of tetrahydrochrysanolide (**16**) gave an alcohol. The scarcity of chrysanolide prevented further study of this product.

Attempts to show a direct relationship between pyrethrosin (**2**) and chrysanolide (**5**) by first opening of the oxirane ring over activated alumina (13) to the corresponding α-methylene allylic alcohol and then oxidation of the hydroxyl group to the ketone failed at the first step. Apparently only cyclization products (judged by n.m.r.) formed. Attempted openings of the epoxide by lithium diethylamide (14) were also unsuccessful.

As an adjunct to our study, we have re-examined the reduction products of pyrethrosin. Barton and de Mayo (*2b*) on hydrogenation over Pd on C obtained two dihydro- derivatives which were separated (but their purity not established) into a major (dihydropyrethrosin), m.p. 156–159°, and a minor (isodihydropyrethrosin) product, m.p. 205–208°. The latter was first reported by Rose and Haller (15) as the hydrogenation product of chrysanthin (pyrethrosin) using Adams' platinum catalyst. A study of the n.m.r. spectrum of the total mixture of dihydro- products from both reductions showed that the palladium catalyst furnished the two isomers in an approximate ratio (dihydro- to isodihydro-) of 4:1, while platinum gave, 1:4. Pure samples of

TABLE 1. Fractions from chromatography of pyrethrum flower extract

Fraction	Weight in g	Constituents
1–72	13.7	Taraxasterol, 4.11 g
73–83	0.98	Green oil
84–88	2.55	(+)-Sesamin, 0.209 g
89–99	2.01	Chrysanolide, 0.031 g
100–113	2.20	Green oil
114–121	1.41	Chrysanin, 0.023 g
122–125	0.50	Oil
126–140	1.06	β-Cyclopyrethrosin, 0.693 g
141–143	0.13	Resin oil
144–148	0.27	Dihydro-β-cyclopyrethrosin, 0.102 g
149–153	0.22	Oil
MeOH wash	11.9	Dark brown gum

both isomers were obtained, as evidenced by their n.m.r. spectra.[5] The major product (m.p. 168–170°) from Pd on C hydrogenation has structure **12** with the C-11 methyl positioned α, since it was possible to isolate dihydro-β-cyclopyrethrosin (**3**) and dihydro-α-cyclopyrethrosin (**20**) from the mixture of cyclization products formed on treatment of **12** with acid. Sodium borohydride reduction of pyrethrosin gives solely epimer **12**. The major product (isodihydropyrethrosin) formed using Adams' platinum catalyst is the C-11 epimer **17**. We prefer to call it epidihydropyrethrosin leaving the prefix iso- for the isomers possessing the reverse lactone closing.

Experimental

Melting points are uncorrected. Elemental analyses were determined by A. Bernhardt, West Germany, or by the Scandinavian Microanalytical Laboratory, Denmark. The i.r. spectra were obtained in chloroform or as KBr pellets on a Perkin–Elmer Infracord 237 or 257 instrument. The u.v. spectra were taken in methanol on a Cary Model 15 spectrophotometer. The n.m.r. spectra were obtained in deuterochloroform or stated otherwise, with tetramethylsilane as internal standard using a Varian A-60A or T-60 spectrometer and signals reported in δ (p.p.m.) units, *J* in Hz and the following abbreviations for spin patterns; s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet and br = broad. Spin decoupling was performed with frequency sweep on the latter instrument. The c.d. curves and optical rotations were taken on a Jasco spectropolarimeter with c.d. attachment. Mass spectra were performed on an A.E.I. MS-9 double-focusing instrument via a direct inlet probe.

Isolation of Constituents

Powdered dried flowers of *Chrysanthemum cinerariaefolium* (2 kg, lot no. LHC-680, S. B. Penick and Co., New York) were percolated to exhaustion at room temperature with ethanol. The residue (457 g), left after evaporation of the solvent at reduced pressure, was partitioned between 1 l of chloroform and three 200-ml portions of water. The chloroform residue (193 g) was partitioned between 600 ml of 10% aqueous methanol and six 200-ml portions of petroleum ether, b.p. 60–68°. The aqueous methanol residue weighed 63 g.

A chromatographic column poured as a slurry in chloroform from 800 g of silicic acid (Mallinckrodt, 100 mesh) was loaded with 45 g of the aqueous methanol fraction. The chloroform effluent was discarded until a positive $KMnO_4$ test was obtained and then 80 ml fractions were collected, evaporated at reduced pressure, and residue weights determined. The results of the column separation are summarized in Table 1.

Taraxasterol, a previously reported common triterpene constituent (2*c*, 16) obtained in the early fractions was not further studied. Results on (+)-sesamin and β-cyclopyrethrosin have already been reported (1). The new compounds have the following properties.

Chrysanolide (5)

The column fraction 89–99 yielded from ethanol – isopropyl ether 31 mg of chrysanolide (**5**) as needles; m.p. 204–205 °C, $[\alpha]_D^{25}$ – 52° (*c*, 0.315 in methanol); u.v. end absorption log ε 4.40 at 210 with a shoulder at 300 mμ (ε 23); i.r. ν_{max} 1765 (γ-lactone), 1737 (acetate), 1680 (α,β-unsaturated ketone), 1665 and 1630 cm^{-1} (olefins); and the mass spectrum showed a parent ion at *m/e* 304.1306 (2%) (calculated for $C_{17}H_{20}O_5$, *m/e* 304.1311). The c.d. curve showed Cotton effect maxima at 310 [θ] −1540; 246, [θ] −6170; and 215 mμ, [θ] +119 000.

Anal. Calcd. for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62. Found: C, 66.94; H, 6.61.

Chrysanin (4)

Column fraction 114–121 when treated with ethanol – isopropyl ether gave 23 mg of chrysanin (**4**); m.p. 202–204° (dec.); $[\alpha]_D^{25}$ +80° (*c*, 0.15 in methanol); u.v. end adsorption log ε 4.22 at 210 mμ; i.r. ν_{max} 3590 and 3450 (hydroxyl), 1770 (γ-lactone), 1710 (ester), 1675 and 1655 cm^{-1} (olefins); and the mass spectrum showed a molecular ion at 346.1792, $C_{20}H_{26}O_5$ requires 346.1780. The c.d. showed $[\theta]_{262}$ +1420, $[\theta]_{224}$ −3530, and $[\theta]_{208}$ +19 300.

Anal. Calcd. for $C_{20}H_{26}O_5$: C, 69.34; H, 7.57. Found: C, 69.20; H, 7.59.

[5]Our experience with these and other sesquiterpenes (8) has been that the n.m.r. spectrum is often the only analytical method that will allow distinguishing of these closely related substances.

Dihydro-β-cyclopyrethrosin (3)

Column fraction 144–148 yielded 102 mg of dihydro-β-cyclopyrethrosin (**3**) on treatment with ethanol – isopropyl ether in the form of needles, m.p. 212–213°. The physical constants were identical with the compound produced by hydrogenation of β-cyclopyrethrosin (**1**) (1) and the i.r. spectra were superimposable.

Dihydro-β-cyclopyrethrosin Acetate (18)

Dihydro-β-cyclopyrethrosin (0.1 g) was dissolved in a mixture of 1 ml of acetic anhydride and 1 ml of pyridine. After 16 h, 2 g of ice were added and the solution extracted with three 50-ml portions of ether. The ether solution was extracted with water, 1 *N* H_2SO_4, 5% $NaHCO_3$, and water. The dried ether (Na_2SO_4) solution left an oily residue (0.11 g) that crystallized from ethanol – isopropyl ether to give 81 mg of acetate **18**; m.p. 191–192°; $[\alpha]_D^{25}$ +69° (*c*, 0.195 in methanol); i.r. ν_{max} 1775 (γ-lactone), 1730 and 1240 cm^{-1} (acetate) with no absorption around 3500 cm^{-1}, and n.m.r. peaks at δ 2.05 and 2.08 (singlets, 3H, acetate methyl).

Anal. Calcd. for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48. Found: C, 65.20; H, 7.42.

Hydrolysis of Dihydro-β-cyclopyrethrosin (3)

A 0.6 g sample of dihydro-β-cyclopyrethrosin (**3**) was dissolved in 6 ml of ethanol and mixed with 40 ml of 0.8 *N* aqueous NaOH. After refluxing for 1 h, the solution was acidified with 1 *N* H_2SO_4 and extracted the following day, first with seven 50-ml portions of ether and then with three 50-ml portions of ethyl acetate. The combined and dried (Na_2SO_4) extracts yielded 214 mg of a heavy oil after evaporation of the solvent. The t.l.c. on silica gel G (Merck) with ether as solvent showed two spots, R_f 0.30 and 0.04 (0.3% $KMnO_4$ as detecting reagent).

The mixture was separated on a column (1.0 × 13.5 cm) of silica gel G (14 g) with 10% chloroform in ether as solvent. The eluting solvent was changed to ether after 30 ml. The colorless oil (71 mg) from fractions (2 ml) 32–60 was crystallized from ethyl acetate – chloroform to give fine needles of desacetyldihydro-β-cyclopyrethrosin (**14**); m.p. 155–156°; $[\alpha]_D^{25}$ +79° (*c*, 0.165 in methanol); i.r. ν_{max} 3580 and 3470 (hydroxyl), 1770 (γ-lactone), and 1648 cm^{-1} (olefin); and lacking the peak in the n.m.r. spectrum at δ 2.03 (s, 3H) for acetate.

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33. Found: C, 67.32; H, 8.28.

Acetylation of this material with acetic anhydride in pyridine gave a diacetate identical with dihydro-β-cyclopyrethrosin acetate (**18**).

The 500 ml of ether effluent, after column fraction 91, left 61 mg of an oily residue that yielded from ethyl acetate – isopropyl ether, 33 mg of desacetyldihydro-β-cycloisopyrethrosin (**7**); m.p. 196–197° with softening at 112°; $[\alpha]_D^{25}$ +184° (*c*, 0.125 in methanol); i.r. ν_{max} (Nujol) 3440 (hydroxyl) and 1750 cm^{-1} (γ-lactone); and the n.m.r. spectrum lacked the peak at δ 2.03 (s, 3H).

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33. Anal. Calcd. for $C_{15}H_{22}O_4 \cdot \frac{1}{2}$ EtOAc: C, 65.78; H, 8.44. Found: C, 65.73; H, 8.47.

Dihydro-β-cycloisopyrethrosin Acetate (19)

A 50 mg sample of dihydro-β-cycloisopyrethrosin (**7**) was treated with 1 ml of pyridine and 1 ml of acetic anhydride. After 24 h the solution was treated with 10 ml of water, extracted with ether, and the extract washed with dilute aqueous acid, $NaHCO_3$, and water. The residue crystallized from isopropyl ether to give prisms; m.p. 148–149°; $[\alpha]_D^{25}$ +270° (*c*, 0.215 in methanol); i.r. ν_{max} 1780 (γ-lactone), 1730 and 1250 cm^{-1} (acetate, double-intensity); and n.m.r. peaks at δ 2.06 (s, 6H, acetate methyl).

Anal. Calcd. for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48. Found: C, 65.02; H, 7.41.

β-Cyclopyrethrosin Benzoate (11)

β-Cyclopyrethrosin (**1**, 50 mg) dissolved in 0.6 ml of dry pyridine was treated with 0.1 ml of benzoyl chloride. After 2 h at room temperature, 5 ml of water was added and the reaction mixture extracted with ether. The ether extract was washed with dilute acid, $NaHCO_3$ solution and water, and the solvent evaporated. The residue (76 mg) crystallized from ethanol, after chromatography on silica gel G (5 g) with $CHCl_3$–ether (1:1) as the solvent. The yield was 35 mg of **11** as needles; m.p. 240° (dec.); i.r. ν_{max} 1725 cm^{-1} (double intensity, acetate and benzoyl); n.m.r. δ 7.2–7.7. (m, 3H) and 7.9–8.2 (m, 2H) for protons of the aromatic ring; and $[\alpha]_D^{25}$ −40.4° (*c*, 0.68 in methanol), $[M]_D$ −166. The alcohol **1** showed $[M]_D$ +178 resulting in $\Delta[M]_D$ (benzoate–alcohol) of −344°.

Anal. Calcd. for $C_{24}H_{26}O_6$: C, 70.23; H, 6.39. Found: C, 70.27; H, 6.49.

Determination of C-1 Configuration in β-Cyclopyrethrosin (1) by Horeau's Method (8)

A 48.9 mg sample of β-cyclopyrethrosin (**1**) and 158.1 mg of α-phenylbutyric anhydride were dissolved in 2.5 ml of dry pyridine. After 18 h at room temperature, 1 ml of water was added, and 6 h later the reaction mixture was extracted with ether and the extract washed with water, 5% $NaHCO_3$, and water. The ether solution residue (68 mg) showed no starting material by t.l.c. The combined aqueous and $NaHCO_3$ solutions left 114 mg of α-phenylbutyric acid, $[\alpha]_D^{25}$ +8.3° (*c*, 1.14 in benzene) corresponding to an optical yield of 46% positive and indicating an *R* configuration.

Dihydrochrysanin (13)

Chrysanin (**4**) (100 mg) was hydrogenated over 60 mg of 5% Pd on C at ambient temperature and pressure. After the rapid uptake of 1 equiv of hydrogen the reaction was stopped. The crude dihydro- derivative crystallized from ethanol – isopropyl ether as needles of **13** (65 mg); m.p. 201–202°; $[\alpha]_D^{25}$ +106° (*c*, 0.1 in methanol); and n.m.r. peak δ 1.10 (d, J = 6.8, 3H, secondary methyl).

Anal. Calcd. for $C_{20}H_{28}O_5$: C, 68.94; H, 8.10. Found: C, 68.52; H, 7.86.

Hydrolysis of Chrysanin (4)

A 70 mg sample of chrysanin was hydrolyzed at room temperature for 3 days in 2.5 ml of 0.3 *N* NaOH in 60% ethanol. The acidified reaction mixture was extracted with ether. The ether extract was back-extracted with 5% $NaHCO_3$ solution which was acidified with 1 *N* H_2SO_4 and extracted with ether. The ether residue (55 mg) was triturated with petroleum ether to remove the crude angelic acid (13 mg).

The sodium salt of the crude acid was treated with 50 mg of *p*-phenylphenacyl bromide in 5 ml of ethanol. After refluxing 1 h, the filtered solution was concentrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and diluted with water to give 27 mg of pale yellow needles, m.p. 86–87°, identical (i.r., mixed m.p.) with authentic *p*-phenylphenacyl ester of angelic acid (11*a*).

Hydrolysis of Dihydrochrysanin (13)

Dihydrochrysanin (**13**) (60 mg) was refluxed for 2 h in about 8 ml of 0.8 *N* NaOH. The reaction solution was acidified with 1 *N* H_2SO_4 and allowed to stand overnight for relactonization and then extracted with ether and ethyl acetate. The combined extract was washed with water, 5% $NaHCO_3$, and water. The residue (45 mg) showed two spots R_f 0.04 and 0.30 (t.l.c. silica gel G, ether) and was separated on a column of silica gel G (7 g) by eluting with ether. The first 23 ml of effluent (fraction I) contained R_f 0.30 material and after a 5 ml fraction with no residue the next 100 ml (fraction II) contained the lower R_f substance. Fraction I gave 18 mg of desacetyldihydro-β-cyclopyrethrosin (**14**), m.p. 155–156°, identical (i.r., mixed m.p., and t.l.c.) with the sample obtained from dihydro-β-cyclopyrethrosin (**3**), while fraction II yielded 14 mg of desacetyldihydro-β-cycloisopyrethrosin (**7**).

Chrysanolide Dipyrazoline

Chrysanolide (**5**, 21 mg) was suspended in 10 ml of ether and mixed with ethereal diazomethane (9 ml) generated from 0.17 g of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide. The solution was kept at 0° for 16 h and on evaporation of the solvent deposited a silky mass of crystals (24 mg). Recrystallization from chloroform–methanol gave the dipyrazoline, m.p. 155–156° (dec.), with gas evolution.

Anal. Calcd. for $C_{19}H_{24}N_4O_5$: N, 14.43. Found: N, 14.30.

Tetrahydrochrysanolide (16)

Chrysanolide (80 mg) was hydrogenated in absolute ethanol over 5% Pd on C at ambient temperature and pressure. Hydrogen uptake was rapid and ceased after 2 equiv. The residue (85 mg) crystallized readily from ethanol – isopropyl ether to give 57 mg of tetrahydrochrysanolide (**16**) as needles; m.p. 159.5–160.0°; $[\alpha]_D^{25}$ +14° (*c*, 0.10 in methanol); u.v. end absorption log ε 4.67 at 210 mμ and λ_{max} 285 mμ (ε 54); i.r. ν_{max} 1765 (γ-lactone), 1730 (acetate), 1710 (ketone), and 1670 cm^{-1} (weak, olefin); n.m.r. δ 1.08 (d, 3H, J = 6.8) and 1.38 (d, 3H, J = 6.7) for two secondary methyl groups and 1.94 (d, 3H, J = 1.3) for olefinic methyl; and the mass spectrum showed a molecular ion at *m/e* 308.1636 ($C_{17}H_{24}O_5$ requires *m/e* 308.1624).

Hexahydrochrysanolide

Tetrahydrochrysanolide (**16**, 40 mg) in 5 ml of absolute ethanol was stirred with 7 mg of $NaBH_4$ for 1.5 h. The mixture was evaporated, two drops of HOAc were added, and the residue was dissolved in 10 ml of chloroform and then extracted with water and dried (Na_2SO_4). Removal of solvent left 39 mg of an oil which on t.l.c. examination (silica gel G, 1% ethanol in ether) showed a major spot at R_f 0.33. Column chromatography on 7 g of the same adsorbent and with the same solvent gave 17 mg of hexahydrochrysanolide as an oil, i.r. ν_{max} 3600 and 3460 (hydroxyl), 1755 (γ-lactone) and 1730 (acetate), and lacking the ketone band at 1710 cm^{-1}. The n.m.r. spectrum indicated a mixture of isomers.

Dihydropyrethrosin (12)

(A) Hydrogenation over Pd on C

Pyrethrosin (**2**, 1.0 g) was hydrogenated over 200 mg of 5% Pd on C in 30 ml of ethanol. Hydrogenation ceased after 1 equiv was absorbed at ambient temperature and pressure. The crude residue crystallized upon addition of ether to give 827 mg of a mixture (4:1 by n.m.r.) of dihydro- and epidihydropyrethrosin,[6] m.p. 152–190°. Recrystallization three times from ethanol gave 263 mg of pure (n.m.r.) dihydropyrethrosin, m.p. 168–170°, $[\alpha]_D^{25}$ −173° (*c*, 0.048 in methanol) which showed in the n.m.r. spectrum a 3H doublet (J = 6.7) at δ 1.38 for the secondary methyl.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85. Found: C, 65.87; H, 7.79.

(B) $NaBH_4$ Reduction

A 1.0 g sample of pyrethrosin was suspended in 50 ml of absolute ethanol and while stirring 200 mg of $NaBH_4$ was added portionwise. After about 30 min, the solution was acidified with 10% acetic acid to p*H* 6.0 and the ethanol removed by evaporation at reduced pressure. The concentrate was diluted with 30 ml of chloroform and extracted with water, 1% $NaHCO_3$, and water. The dried chloroform (Na_2SO_4) residue (1.13 g) contained only one isomer (dihydropyrethrosin) by n.m.r. examination. Chromatography of the residue over 70 g of silica gel G with chloroform–ether as eluant to remove other impurities yielded 686 mg of dihydropyrethrosin (**12**), m.p. 168–170°, identical (i.r., n.m.r., and mixed m.p.) with the major isomer from Pd on C hydrogenation.

Epidihydropyrethrosin (Isodihydropyrethrosin) (17)

Pyrethrosin (**2**, 500 mg) and platinum oxide (45 mg) were suspended in 20 ml of ethanol and hydrogenated under ambient conditions. The reaction was stopped after 1 equiv of hydrogen was absorbed. The residue (516 mg) crystallized when treated with ether. The crystalline product (420 mg), m.p. 169–190°, by n.m.r. analysis was a mixture of dihydro- and epidihydropyrethrosin (1:4).[6] Three recrystallizations from ethanol gave 143 mg of pure epidihydropyrethrosin (**17**) which softens at 195° and melts at 205–207°, $[\alpha]_D^{25}$ −117° (*c*, 0.064 in methanol). The n.m.r. spectrum shows a 3H doublet (J = 7.2) at δ 1.23 for the secondary methyl.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85. Found: C, 66.23; H, 7.84.

Cyclization of Dihydropyrethrosin (12)

To a 500 mg sample of **12** dissolved in 4 ml of chloroform and 2 ml of ether was added three drops of concentrated HCl and the mixture stirred for ½ h. Chromatography of 100 mg of the reaction mixture on 50 g of silica gel G impregnated with 10% $AgNO_3$ and elution with 1 l of benzene followed by 200 ml each of 1, 5, 10, and 40% ether in benzene gave with the last solvent a bell-shaped elution curve (dry-weight analysis of 5-ml fractions) from which pure isomers were obtained at each end. The α-isomer was isolated from fractions 1–4 (37 mg) and the β-isomer from fractions 14–20 (20 mg). The

[6]Although we have not systematically studied the effect of the ratio of catalyst to starting material, it was, however, observed that the product ratio varied when such a change was made.

β-isomer recrystallized from ethanol–pentane was identical with (m.p., mixed m.p., i.r., and n.m.r.) dihydro-β-cyclopyrethrosin (**3**).

Recrystallization of dihydro-α-cyclopyrethrosin (**20**) from ether–pentane gave 24 mg of needles; m.p. 169–170°; $[\alpha]_D^{25}$ +78 (*c*, 0.058 in methanol); i.r. ν_{max} 3620 and 3490 (hydroxyl), 1780 (γ-lactone), 1735 (ester) and 1240 cm^{-1} (acetate); and n.m.r. peaks at δ 5.40 (m, 1H, H-3), 5.27 (t, J = 10.5, 1H, H-6), 4.18 (octet, 3.9, 11.2, 12.1, 1H, H-8), 3.74 (q, 6.8, 9.4, 1H, H-1), 2.11 (s, 3H, acetate), 1.68 (br s, 3H, olefinic methyl), 1.18 (d, 6.8, 3H, secondary methyl), and 0.95 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85. Found: C, 66.22; H, 7.81.

Long-range Spin–Spin Coupling in Pyrimidine Nucleosides

FRANK E. HRUSKA

Departments of Chemistry, The University of Winnipeg and the University of Manitoba,[1] *Winnipeg, Manitoba*

Received December 15, 1970

A study has been made of the 100 MHz p.m.r. spectra of a number of pyrimidine nucleosides in aqueous solution. Long-range five-bond spin–spin coupling interactions between the H-5 and H-1′ hydrogens were noted in uridine, 2′-deoxyuridine, 6-azauridine, and 6-azacytidine and rationalized by a predominantly *anti* conformation for each nucleoside. The absence of a detectable five-bond coupling in orotidine suggested that the *syn* conformation is preferred in this instance. The relative magnitudes of the four-bond and five-bond interactions in uridine and pseudouridine were shown to be consistent with the calculated mobile π-bond orders of the C_6—N_1 and C_6—C_5 bonds of the uracil base.

Les spectres de r.m.n. à 100 MHz d'un certain nombre de nucléosides pyrimidiniques en solution aqueuse, ont été étudiés. Une intéraction de couplage spin–spin à longue distance à travers cinq liaisons entre les hydrogènes H-5 et H-1′ a été mise en évidence dans l'uridine, la 2′-déoxyuridine, la 6-azauridine, et la 6-azacytidine et rationalisée en invoquant une conformation *anti* prédominante pour chacun des nucléosides. L'absence d'un tel couplage dans l'orotidine, suggère que dans ce cas, la conformation *syn* est privilégiée. L'amplitude relative des intéractions sur quatre liaisons et cinq liaisons dans l'uridine est consistante avec les ordres calculés pour les électrons π-mobiles des liaisons C_6—N_1 et C_6—C_5 de l'uracile.

Canadian Journal of Chemistry, 49, 2111 (1971)

Introduction

To facilitate discussion of the orientation of the heterocyclic base relative to the ribose (or deoxyribose) ring in purine and pyrimidine nucleosides Donohue and Trueblood (1) have defined the sugar-base torsion angle about the *N*-glycosyl bond (ϕ) and its *syn* and *anti* ranges. Considerable spectroscopic evidence (1–11) has now been accumulated and indicates that the major nucleoside components of transfer RNA, as well as modified components such as pseudouridine, exist preferentially in their *anti* conformations in the crystalline state as well as in solution. Recent evidence points to a *syn* conformation for orotidine (6-carboxyuridine) in aqueous solution (12) and crystalline 6-thiouridine (13). The p.m.r. studies have been particularly useful for conformational studies in solution. Three-dimensional models have been derived through consideration of the observed base– and ribose – ring proton chemical shifts and via Karplus treatments (14) of the three-bond interactions between hydrogens on bonded carbons. Long-range coupling interactions[2] as well are known to be dependent upon molecular conformation and a number of useful structural correlations have been proposed. These have been considered in a number of reviews (15–18). However, this long-range phenomenon has seldom been observed in nucleosides. Hruska, Grey, and Smith (7, 10) have noted a four-bond benzylic type of interaction in α- and β-pseudouridine and suggested its potential for monitoring perturbations in ϕ. Cushley *et al.* (19) reported a five-bond interaction between fluorine and hydrogen and proposed on this basis the *anti* conformation of 5-fluorouridine.

In this report I wish to present evidence for a five-bond coupling between the H-5 and H-1′ hydrogens of uridine (U), 2′-deoxyuridine (dU), 6-azauridine (6-aU), and 6-azacytidine (6-aC). (Fig. 1). Although p.m.r. spectra of U and dU have appeared on several occasions, these interactions have not been reported. The observed coupling constants are discussed in terms of established correlations of $^5J_{HH'}$,[3] with molecular geometry and their magnitudes are taken as evidence that the *anti* ranges of ϕ are favored in U, dU, 6-aU, and 6-aC. The *syn* range is suggested to be favored in orotidine (O, Fig. 1) since in this instance no $^5J_{51'}$ interaction was detected.

[1]Present address of the author.

[2]Between nuclei separated by more than three bonds.

[3]The coupling constants are henceforth denoted by $^nJ_{HH'}$ where the superscript refers to the number of intervening bonds in the coupling path between the coupled nuclei H and H′.

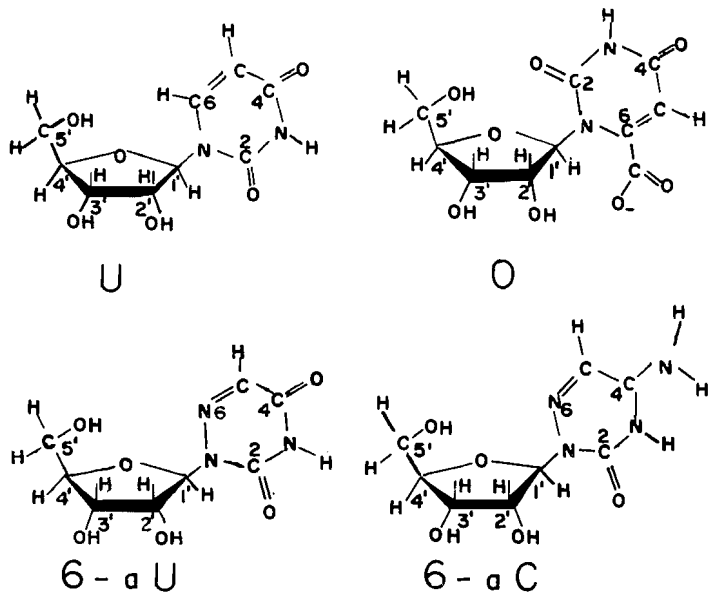

FIG. 1. Structural formulae of uridine (U), 6-azauridine (6-aU), 6-azacytidine (6-aC), and orotine (O).

The absence of any observable four-bond coupling between the H-6 and -1′ hydrogens of U and dU is shown to be consistent with their *anti* conformations and the theoretically calculated mobile π-bond orders of the uracil base. The previously reported (7, 10) four-bond interactions in the pseudouridines are reconsidered in the light of the present study.

Experimental

The nucleosides (A grade) were obtained from Calbiochem and used without further purification. The D_2O solutions containing 0.12 *M* nucleoside and 0.12 *M* DSS (3-trimethylsilylpropanesulfonic acid for internal referencing) were freeze-dried three times to reduce the HDO concentration. The p*D* of the solution[4] was adjusted with DCl and NaOD. Spectra were obtained at 30 °C on a Varian HA-100 spectrometer. Line positions relative to internal DSS were reproducible to within 0.05–0.1 Hz depending on their linewidth. The various bands were assigned by comparison with previously reported data (7–11) of U, dU, and the pseudouridines.

Results

In an earlier report (8) we discussed the spectral analysis of U in neutral solution. Under these conditions there is considerable overlap between the H-5 and -1′ spectral bands and no $^5J_{51'}$ interaction was noted. In this study measurements were carried out in a weakly basic solution such that the nucleoside is in fact present as the monoanion formed by dissociation of the N—H hydrogen at the 3-position of the base (pK_a = 9.4). This dissociation and the associated electronic changes in the uracil moiety produce a shielding of H-5 relative to H-1′ and the two spectral regions become well separated. Data for the other nucleosides were obtained under similar conditions. In Fig. 2 the H-6, -5, and -1′ resonances are shown for U (p*D* 11.2). The doublet centered at 7.660 p.p.m. was assigned to H-6 which is magnetically coupled to H-5 ($^3J_{56}$ = 7.70 Hz). The H-5 resonances are centered at 5.796 p.p.m. and comprise a doublet of doublets with a large splitting ($^3J_{56}$) and a smaller splitting of 0.41 Hz. Centered at 5.906 is a somewhat broader doublet assigned to H-1′ which is coupled to H-2′ ($^3J_{1'2'}$ = 4.4 Hz).

The source of the extra splitting of 0.41 Hz present in the H-5 region was readily established by double-resonance experiments. In Fig. 2 (inverted) is shown the H-5 region obtained with simultaneous irradiation in the H-1′ portion of the spectrum and shows clearly the disappearance of the small spacing. A 0.41 Hz splitting is not, however, apparent in the H-1′ region. That this spacing is present, but unresolved, was demon-

[4]p*D* = p*H* meter reading + 0.4. See Glascoe and Long, ref. 32.

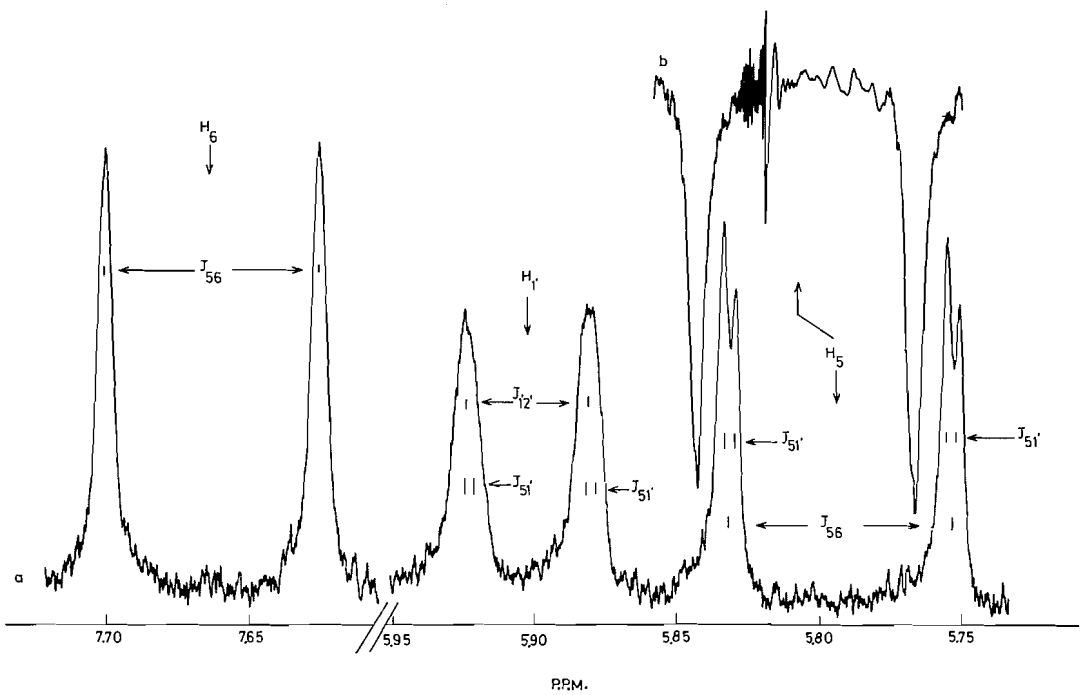

FIG. 2. (*a*) The H-6, -5, and -1′ regions of the 100 MHz p.m.r. spectrum of 0.12 *M* uridine in D_2O (p*D* = 11.2, 30 °C). Chemical shifts in p.p.m. are relative to internal 3-(trimethylsilyl) propanesulfonic acid. (*b*) Inverted H-5 region obtained under double resonance conditions with a second field applied at the frequency of the low-field H-1′ band. Sweep width 50 Hz.

strated by irradiation of the H-5 doublets. Under these double resonance conditions considerable enhancement (15–20%) in peak height as well as line narrowing was observed in the H-1′ lines.[5] No extra splitting is noted in the H-6 region and thus it is safe to conclude that any $^4J_{61'}$ interaction must be less than about 0.2 Hz.

In Fig. 3 are shown the H-5 and -1′ regions of 6-aU (p*D* 10.0). The H-5 region comprises a doublet with a 0.61 Hz splitting; H-1′ appears as a broader doublet at 6.113 p.p.m. ($^3J_{1'2'}$ = 3.6 Hz). Also shown (inverted) is the single H-5 line obtained through irradiation in the H-1′ region. Collapse of H-5 doublet under these decoupling conditions clearly establishes the presence of a 0.61 Hz $^5J_{51'}$ interaction in 6-aU.

Spectra of dU and 6-aC are not shown but in these instances $^5J_{51'}$ interactions of 0.45 and 0.52 Hz respectively were manifest in their H-5 multiplet patterns and confirmed by double resonance experiments.

[5]Other sources of line broadening in the H-1′ region could be unresolved coupling to H-6 and -3′ as well as virtual coupling to H-3′ and nitrogen quadrupolar effects.

In an earlier report (12) a discussion of the p.m.r. data of O was presented but no attention to possible long-range interactions was given at that time. Displayed in Fig. 4 are the H-5 and -1′ regions of this nucleoside (p*D* 12.0). The 3.7 Hz splitting in the latter region was readily attributed to coupling with H-2′ (12). No splitting, however, is evident in the H-5 region. In view of the narrow linewidth of this single resonance (0.35 Hz at half height), any $^5J_{51'}$ interaction, if present, is safely estimated to be less than about 0.1 Hz.

The p.m.r. data of the H-6 and -5 hydrogens are presented in Table 1. The $^5J_{51'}$ couplings are listed as positive numbers although no sign determinations were carried out. However, the signs of the coupling constants between protons separated by five bonds along an extended zig–zag path (*vide infra*) have been shown to be positive in a wide variety of compounds (15–18).

Discussion

(A) Benzylic Coupling

Numerous observations of long-range H–H couplings are now compiled in a number of

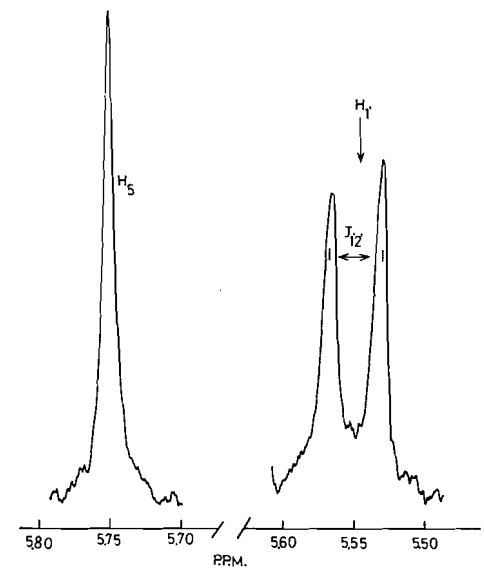

FIG. 4. The H-5 and -1′ regions of the 100 MHz p.m.r. spectrum of 0.12 *M* orotidine in D_2O (p*D* = 12.0, 30 °C). The chemical shifts are in p.p.m. relative to internal DSS. Sweep width 50 Hz.

reviews (15–18). Particularly relevant to the present discussion are the benzylic type of interactions noted in aromatic and heteroaromatic molecules. Three types may be distinguished, the four-, five-, and six-bond interactions of the side chain (α) proton with hydrogens at the ortho (*o*), meta (*m*), and para (*p*) positions of a six-membered ring system. The $^5J_{51'}$ couplings are examples of *m*-benzylic interactions. Although the absolute magnitudes of *m*-benzylic interactions are generally small (<1.0 Hz), a critical dependence on molecular geometry is evident. The dependence is such that coupling is favored when the α- and meta-hydrogens are separated by an extended "zig–zag" path. This steric requirement has been particularly well demonstrated by studies on halogenated toluenes. Schaefer *et al.* (20) for instance, argue that at −40 °C the proton spectrum of α,α,2,6-tetrachlorotoluene (Fig. 5) was consistent with highly-hindered rotation of the side chain and a locked conformation of the molecule with H_α located preferentially in the plane of the benzene ring.

For personal use only.

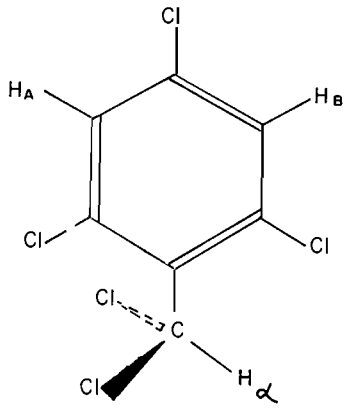

FIG. 5. Structural formula of α,α,2,6-tetrachlorotoluene. The H_α is coplanar with the ring and connected to H_A via a zig–zag route.

The H_α region appeared as a doublet with a splitting of 0.5 Hz attributable to coupling with H_A which is connected to H_α via a zig–zag route. Coupling to the other meta position (H_B) was not detected at this temperature. This zig–zag restriction on $^5J_{HH'}$ interactions is not peculiar to toluene-like molecules but has been noted in heterocyclic, polycyclic, and acyclic systems.

In subsequent paragraphs arguments are presented in support of the zig–zag restriction on the $^5J_{51'}$ interactions. On this basis predictions are made regarding the favored conformations of 6-aU, 6-aC, and O about their respective *N*-glycosyl bonds.

(B) Uridine and 2′-Deoxyuridine

The evidence that the *anti* conformations of U and dU are favored over *syn* in the solid state as well as in solution is not disputed (1–11). That *syn* conformations are not present to any detectable extent is generally agreed to be a consequence of unfavorable steric interactions (between the 2-keto oxygen and the *endo* ribose substituents) not present when the molecules are *anti*. X-Ray data (21) for a number of uridine derivatives indicates a preference for the φ values from −40 to −60° in the *anti* range. Examination of Drieding models shows clearly that when the uracil base is rotated into this range the $C_{1'}$—$H_{1'}$ bond approaches an orientation coplanar with the base plane and that an extended zig–zag path connects H-5 and -1′. Thus in the *anti* conformation of U and dU H-5 and -1′ bear a steric relationship similar to that of H_A and H_α in Fig. 5. Since the magnitudes of their $^5J_{51'}$ are comparable to the observed values in a large number of toluene derivatives, it is reasonable to assume that the electronic and steric factors governing five-bond interactions in pyrimidine nucleosides are similar to those suggested to be operative in toluene-like molecules.

(C) 6-Azauridine and 6-Azacytidine

The 6-azaderivatives have been the center of interest in a number of laboratories because of their potential as chemotherepeutic agents (22). As yet little detailed information regarding their three-dimensional conformations in aqueous solutions is available. The i.r. studies (23, 24) have shown that the diketo and amino forms of 6-aU and 6-aC (*i.e.* those shown in Fig. 1) predominate in nonpolar solvents. I propose as evidence that an extended zig–zag path connects their H-5 and -1′ hydrogens (*i.e.* that their *anti* range is favored over the *syn*) the magnitudes of the observed $^5J_{51'}$. This conclusion is very reasonable on a steric basis since there appear to be no close contacts present in the azaderivatives which could significantly alter their conformations about the *N*-glycosyl bond.

(D) Orotidine

If an extended zig–zag path is a structural requirement for a detectable five-bond interaction in O, then I propose that its absence is evidence that such a path *does not* connect the 5- and 1′-hydrogens and therefore this nucleoside must exist in its *syn* range of torsion angles. In the *syn* range H-5 and -1′ bear a spatial relationship similar to that between H_B and H_α in Fig. 5 where H_B is the meta hydrogen not coupled to the α-position. That the *syn* range should be favored is very reasonable on steric grounds. Locking O into its *anti* range requires placement of the bulky carboxyl group (rather than the 2-keto oxygen) above the sugar in close proximity with its *endo* substituents. In molecular models of O rotation of the 6-substituent is virtually impossible and the torsional freedom of the furanose ring (7–8) severely restricted when the molecule is *anti*. These librational motions are less restricted when the molecule is *syn*.

Thus the present work supports earlier conclusions (12) regarding the conformation of O based on trends in the observed proton chemical shifts and the $^3J_{HH'}$ coupling constants of the ribose ring.

(E) Ortho Benzylic Interactions

Newsoroff and Sternhell (25) have noted that in cases where the α-carbon is sp^3-hybridized the four-bond *o*-benzylic coupling constants are generally larger (in absolute magnitude) than the five-bond *m*-benzylic coupling constants. In toluene itself values of −0.75 and 0.36 Hz have been reported for the *o*-benzylic and *m*-benzylic interactions, respectively (26). It is clear from Fig. 2, however, that any $^4J_{61'}$ interaction, if present in U, is smaller than $^5J_{51'}$ and probably less than about 0.2 Hz. This apparent anomaly in the trends can be readily understood if the (*i*) electronic and (*ii*) steric differences between U and toluene are considered in the light of current theoretical formulations of long-range coupling mechanisms. These have been clearly summarized in the recent review by Barfield and Charabarti (18).

(i) Electronic

Theory suggests that *o*-benzylic couplings may be adequately discussed in terms of σ–π configuration interaction between the benzylic proton (H_α in toluene, H-1′ in U) and the 2pπ orbital on the ring atom to which the benzylic carbon is bonded (C-1 in toluene, N-1 in U).[6] Furthermore, the theoretical treatment predicts a dependence of the four-bond interaction on the square of the mobile π-bond order (P^2) of the C_1—C_{ortho} linkage (N_1—C_6 is the analogous linkage in U). Reasonable correlations between P^2 and *o*-benzylic couplings have appeared in the literature to substantiate these predictions (27, 28). A number of theoretical evaluations of the π-structure of the pyrimidine bases have appeared (29, 30). Pullman and Pullman (29), for instance, list a value of 0.479 for $P(N_1—C_6)$ in uracil which is considerably smaller than the 0.667 value for C_1—C_{ortho} in toluene (26). One factor, therefore, which accounts for the anomalously diminutive $^4J_{61'}$ in U (and dU) must be the attenuated capacity in this nucleoside for σ–π interactions, attributable to the reduced π-density in the N_1—C_6 linkage.

[6]A contribution to the *o*-benzylic coupling from a mechanism involving only the σ network might also be considered in view of the numerous examples of ^4J interactions in saturated systems. It is generally found, however, that such contributions are unimportant unless the bonds form a planar "W". This arrangement between the α- and *o*-hydrogens is not possible since the C_{ortho}—H and C_1—C_α bonds are *cis* across the C_1—C_{ortho} linkage.

(ii) Steric

Theory predicts further that the magnitude of the σ–π interaction between the sp^3 side chain orbital and the adjacent 2pπ orbital bears a $\sin^2\theta$ relationship where θ is the angle between the C_α—H_α bond and the plane of the aromatic ring. The contribution is expected to be maximal when C_α—H_α is perpendicular to the aromatic ring and vanishing small in a coplanar orientation. In toluene free rotation of the methyl group is possible allowing the α-hydrogens to sample coplanar and perpendicular orientations. Since the average value of $\sin^2\theta$ is 0.5 over one complete rotation of the methyl group, the observed magnitude of the four-bond interaction is probably near to 50% of its maximal value at $\theta = 90°$. In U motion about the *N*-glycosyl bond is restricted to a narrower range of θ. The perpendicular orientations ($\theta = \pm 90°$) required for maximal σ–π interactions correspond to sterically unfavorable values of φ (+30 and −15°) and may be discounted. Thus $\sin^2\theta$ averaged over the torsional motion is expected to be less than 0.50. Therefore, insofar as σ–π configuration interaction and *o*-benzylic coupling are concerned the steric as well as electronic properties of U are less favorable than those of toluene.

Contributions to the *m*-benzylic coupling, on the other hand, apparently arise from both the σ–π mechanism as well as from a mechanism involving only the intervening σ-network. The former contribution is maximal for the perpendicular orientation ($\theta = 90°$); the latter is maximal for the planar zig–zag orientation. Thus the observation that in U $^5J_{51'} > {}^4J_{61'}$ whereas in toluene $^5J_{m\alpha} < {}^4J_{o\alpha}$ is readily rationalized on a theoretical basis if the nucleoside is assumed to be *anti* with an essentially planar zig–zag connection between H-5 and -1′.

(F) The Pseudouridines

β-Pseudouridine (β-ψ) is a unique component of all *t*-RNA in that it is a *C*-glycoside (Fig. 6) the point of attachment of the ribose being to the C-5 carbon of the base. At the two meta positions are found N_3—H_3 and N_1—H_1. Thus detection of a $^5J_{51'}$ interaction is precluded in aqueous solution due to rapid exchange of the hydrogens with the solvent. However, we did detect a $^4J_{61'}$ interaction of 0.8 Hz and discussed it briefly (7, 10). In these reports a comparison of the ribose chemical shifts and $^3J_{HH'}$ interaction of U

For personal use only.

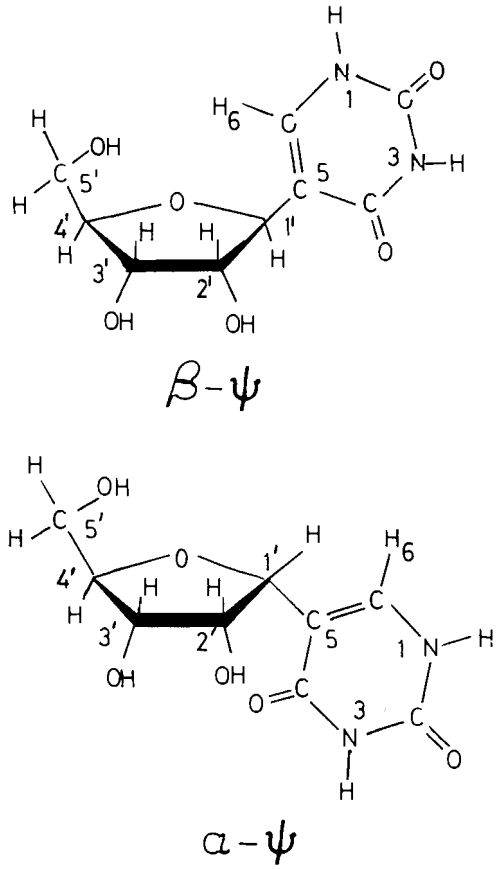

FIG. 6. Structural formula of β-pseudouridine (*anti*) and α-pseudouridine (*syn*).

and β-ψ was made and it was concluded that their three dimensional conformations were similar. In view of the distinctive stereochemical dependence of *o*-benzylic coupling and the absence of a detectable $^4J_{61'}$ in U our conclusions regarding the structural similarity of this isomeric pair may seem invalid. However, the apparent inconsistency is understood if comparison of the coupling paths in U and β-ψ is made.

In U the four-bond coupling proceeds via the segment $H_6—C_6—N_1—C_{1'}—H_{1'}$, whereas in β-ψ the relevant path involves the segment $H_6—C_6—C_5—C_{1'}—H_{1'}$. The σ–π interaction which is thought to be of fundamental importance for *o*-benzylic coupling should be related therefore to the mobile π-bond order of the $C_6—C_5$ and $C_6—N_1$ bonds of β-ψ and U respectively. Pullman and Pullman (29) estimate, however, $P(C_6—C_5)$ to be 0.82 in uracil, considerably larger than their value of 0.48 for $P(C_6—N_1)$. Thus the larger $^4J_{61'}$ interaction in β-ψ is readily interpreted in terms of an enhanced potential (relative to U) for σ–π interaction involving the H-1′ sp^3 orbital, without invoking gross conformational differences for the two nucleosides.

A slightly larger four-bond interaction ($^4J_{61'}$ = 1.2 Hz) was noted for α-ψ, the α-anomer of pseudouridine. This larger coupling is presumably a reflection of larger σ–π contributions in the α-anomer. Since the mobile π-bond order of the uracil base is not expected to be significantly dependent on the anomeric configuration of the molecule their magnitudes must reflect differences in the average values of θ (and therefore φ). Arguments were presented in a previous study (10) supporting a predominantly *anti* conformation for both anomers. However, if it is assumed that the conformations approaching the perpendicular orientation (θ = 90°, φ = 30°) are more favorable in α- than in β-ψ, then the relative magnitudes of their $^4J_{51'}$ couplings can be understood. Recently Rohrer and Sundaralingam (31) have reported a value of +3.2° for φ(θ = 63°) for crystalline α-ψ. The corresponding value is not yet known for β-ψ but if it were to be in the range centered at about −60° which is observed for most β-nucleosides, then the above assumption would be very reasonable.

Conclusions

This study demonstrates the potential usefulness of long-range coupling measurements in the determination of pyrimidine nucleoside conformations. The five-bond couplings in uridine, 2-deoxyuridine, 6-azauridine, and 6-azacytidine were shown to be consistent with their *anti* conformations. The absence of the analogous interaction in orotidine suggested a predominantly *syn* orientation in this case. The relative magnitudes of the *o*- and *m*-benzylic interactions in uridine, 2′-deoxyuridine, and the pseudouridines were shown to be in qualitative agreement with current theoretical formulations of long-range couplings and theoretically determined mobile π-bond orders of the uracil base.

I am grateful to Mr. Rod Wasylishen and Professor T. Schaefer for helpful discussions on the long-range phenomenon and to Drs. H. Dugas, B. Blackburn, R. K. Robins, and I. C. P. Smith for communicating their results on β-CAR prior to publication. This work was made possible through financial aid from The

National Research Council of Canada and The Faculty of Graduate Studies of the University of Manitoba. The work was initiated at The University of Winnipeg and I thank Professor Lawrence Swyers of this institution for his constant encouragement.

Surface Effects in Cationic Polymerizations[1]

V. C. ARMSTRONG,[2] Z. KATOVIC,[2] AND A. M. EASTHAM
National Research Council of Canada, Ottawa, Canada

Received February 11, 1971

β-Methylstyrene dimerizes in the presence of boron fluoride. The rate of dimerization is very erratic under the usual conditions of high vacuum operation but becomes reproducible when reactors are baked out for a few hours at 500 °C under vacuum. In baked reactors reaction still occurs without added cocatalyst, and the rate seems to depend in part on the temperature and length of time of baking. The results suggest the existence of a surface reaction whose rate is of the first order in both monomer and boron fluoride.

Le β-méthylstyrène se dimérise en présence de fluorure de bore. La vitesse de dimérisation est excessivement changeante sous forte pression et dans des conditions standards. Celle-ci devient cependant reproductible lorsque les réacteurs sont calcinés à 500 °C sous vide pendant quelques heures. Dans ces réacteurs calcinés, la réaction se fait encore sans l'adjonction d'un catalyseur et la vitesse semble alors dépendre en partie de la température et de la durée de la calcination. Les résultats suggèrent l'existence d'une réaction de surface dont la vitesse est du premier ordre pour le monomère et le fluorure de bore.

Canadian Journal of Chemistry, 49, 2119 (1971)

In spite of considerable effort, there has been little real progress in our understanding of cationic polymerizations since the classic work of Evans, Polanyi, and coworkers nearly thirty years ago (1). This situation is due, at least in part, to the great difficulty in obtaining precise experimental measurements for the classical cationic systems, so we have sought alternative systems from which accurate kinetic and other data might be obtained. In principle the aliphatic monomers (olefins) should be the simplest and hence most desirable for investigation, but unfortunately they are also the monomers which present the greatest difficulty in analysis, so we have been forced to consider the substituted olefins. The dimerization of β-methylstyrene offers some possibility of serving as a model for the processes occurring in a cationic polymerization and can be followed accurately, at useful concentrations, under rigorous conditions by spectrographic methods. We are aware that results obtained with such a system are not necessarily suitable for direct comparison with our previous data on aliphatic systems, but we do not subscribe to the view that it should be possible to generalize in a simple scheme the reactions of all the monomers and catalysts employed in cationic polymerizations. In this paper we report the results of some studies of the boron fluoride - catalyzed dimerization of β-methylstyrene.

In preliminary experiments the boron fluoride - catalyzed isomerization of allylbenzene to β-methylstyrene was evaluated as a possible model of a protonation (initiation) reaction but was found to be too rapid for satisfactory measurement. It was observed that the isomerization overlapped a consecutive but slower dimerization of the product (β-methylstyrene) so we selected this dimerization as the starting point for our studies. The techniques used were generally similar to those developed earlier in studies of aliphatic systems, but were modified as necessary. Methanol and ethylene dichloride were selected as cocatalyst and solvent respectively.

Despite our most careful efforts the reproducibility of the early experiments was poor, much worse than we had experienced in our studies of aliphatic monomers. Materials were repeatedly purified and dried, vacuum techniques were improved, and analyses refined without improving the quality of the data. Conclusions drawn were necessarily limited but seemed generally similar to those reported in our earlier studies; reaction did not occur in the presence of a 1:1 catalyst–cocatalyst complex but took place immediately if excess boron fluoride were present. Curiously, the initial rates seemed considerably higher if, instead of adding all the boron fluoride at once, the 1:1 complex was left in contact with monomer for a short time before adding the excess boron fluoride. The initial rate of dimerization was found to be dependent on the concentrations of

monomer, free boron fluoride, and catalyst–cocatalyst complex but accurate orders could not be obtained. The temperature dependence was small and negative.

In the presence of boron fluoride alone ('blanks', *i.e.* no added cocatalyst) the initial rates were usually slow but were never zero, and were erratic. The blanks reached their lowest rates when the reactor was pumped and flamed for one or two days, then thoroughly flushed with dry solvent, before filling with reactants; behavior of this kind is, according to conventional views, most probably due to the presence in the reactor of random traces of cocatalytic impurities. It was also observed, however, that the method of cleaning the reactor had a marked effect on the rate of the blanks. Vessels which had been thoroughly cleaned with chromic acid gave consistently higher rates than those cleaned by washing with acetone–water, and a reduced but high rate persisted through a subsequent series of runs in which the reactor was simply washed out after use and pumped out for about a day. Treating the reaction flask with methylsilylchlorides was the only technique which seemed to reduce the rate of the blanks (see below). Because of these observations we are now of the opinion that in our earlier work the walls of the flask may have developed a thin layer of polymeric material during the reactions, which was not removed by washing, and which helped to improve reproducibility. It was our practice at that time to burn out the reaction flask at red heat in a stream of air after a series of experiments; after this treatment it usually took two or three runs, despite prolonged pumping, before the flask returned to its original condition (as judged by the rate data), presumably because polymer had to redeposit on the glass. In the present system, polymer is not formed so perhaps the reaction is less reproducible.

Because of these observations the apparatus was rebuilt so that (*a*) the reaction flask could be pumped out under vacuum at controlled temperature, up to 500 °C, (*b*) bellows-sealed stainless steel valves with Teflon seats replaced all stopcocks, and (*c*) separate lines were provided for evacuating those parts of the system (*e.g.* the reactor) which were occasionally opened to the atmosphere. There was no obvious way in which the whole system could be baked out for each run and still permit us to do a reasonable number of experiments, but on the basis of our previous experience we think that once a system has been well pumped out and flushed with solvent vapor, there is very little mobility of such residual cocatalytic impurities as may be adsorbed on the walls. The reaction vessel itself is thus the primary concern in attempting to obtain rigorous drying of the apparatus.

Rates in the new smaller reactors could not be compared with those from the earlier reactors because, under seemingly identical conditions, they were found to be about three times faster. The source of the difference is not clear since the surface is smaller in the new reactors and furthermore, the difference persists after treatment with silyl chloride.

We were surprised to find that baking-out the reaction vessel actually increased the rate of the blanks (Fig. 1). The rate first fell off, presumably due to drying of the glass surface, then increased again with increase in either time or temperature of baking. Obviously if this is the effect of heating, then the usual techniques of pumping and flaming the reactor can only lead to erratic blanks such as those observed. As an arbitrary reference point for these experiments we carried out reactions in a vessel which had been pumped out under high vacuum for 1 h, then pumped for a further 16 h at liquid nitrogen temperature.

Rate increases in cationic systems always raise a question as to whether they are due to removal of inhibitors or to formation of accelerators, and the present example is no exception. We have concluded, *very* tentatively, that the initial decrease in rate with heating results from removal of cocatalytic material from the glass surface and that the subsequent increase is due to the formation on the glass surface of some sort of active centers which combine with boron fluoride to catalyze reaction. Admission of air to any of these slow reactions causes immediate acceleration (Fig. 2), presumably because of the moisture in the air, but can also stop the reaction if the amount of moisture is in excess of the boron fluoride.

Attempts to clarify and define the surface effect were not very successful but gave some interesting results. Reproducibility in the baked-out systems, though much improved over earlier reactions still left something to be desired. Thus it was found difficult, after major repairs to the vacuum system, to return to the rates obtained prior to the repairs. A mixing problem exists but we have not been able to trace its origin. It is probably due to several factors and leads to a

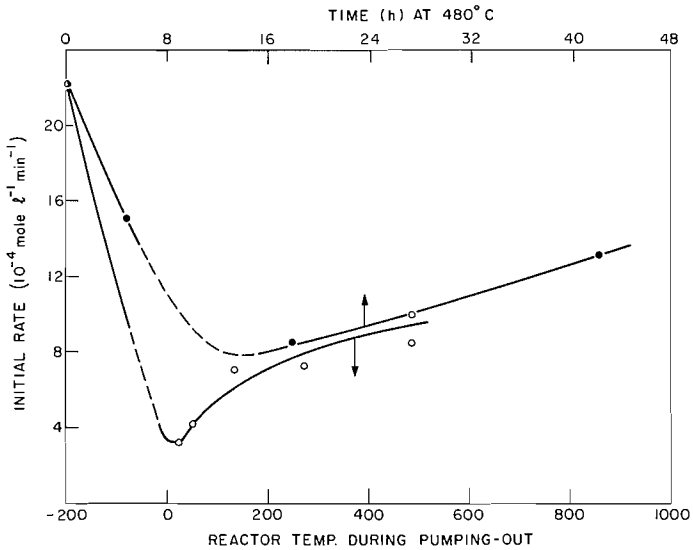

FIG. 1. Effect of time and temperature of bake-out on initial rate: upper curve, bake-out time at 480 °C before filling reactor; lower curve, temperature of bake-out for 22 h prior to filling reactor. ◑ Reference point, cell pumped out at liquid nitrogen temperature (−186°, see text).

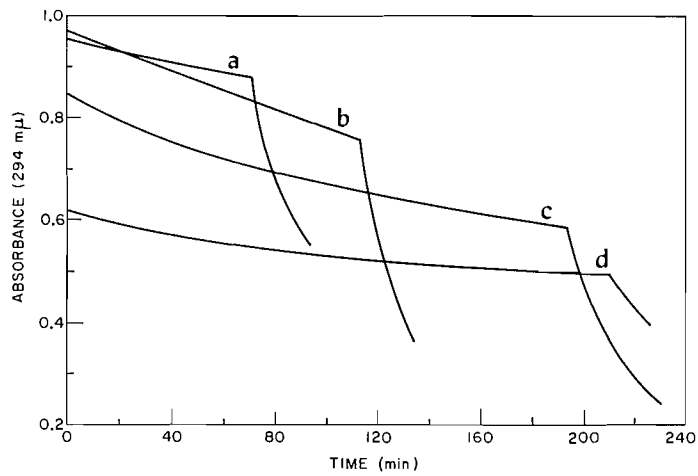

FIG. 2. Effect of admitting air to the reactors. *a*, Reactor (type *a*) treated with dimethylsilyl chloride; *b*, reactor (type *a*) pumped two days at 200 °C; *c*, reactor (type *a*) treated with dimethylsilyl chloride at elevated temperature; *d*, reactor (type *b*) pumped out at 480 °C (initial absorbance = 1.8, curve starts at 200 min).

difference in rates in the optical cell and in the bulk of the solution. We do not think it is due to temperature differences or to variations in the concentration of BF_3. The difference persists when the light is cut off between readings so is not photochemical in origin. It is not due to the difference in composition of the cell and reactor (quartz *vs.* pyrex) since an all-quartz reactor failed to produce marked rate change. One might perhaps expect a higher rate in the cell due to the higher surface/volume ratio and a consequently higher contribution from the surface reaction, but the difference is often in the opposite direction. The effect of this problem on the rate measurements was minimized by frequent mixing (by tipping the contents of the cell into the bulk of the solution) but it is nevertheless disturbing.

The initial rate of reaction in reactors baked out at 500 °C for 18 h was found to be of the first order in both monomer and boron fluoride (Fig.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

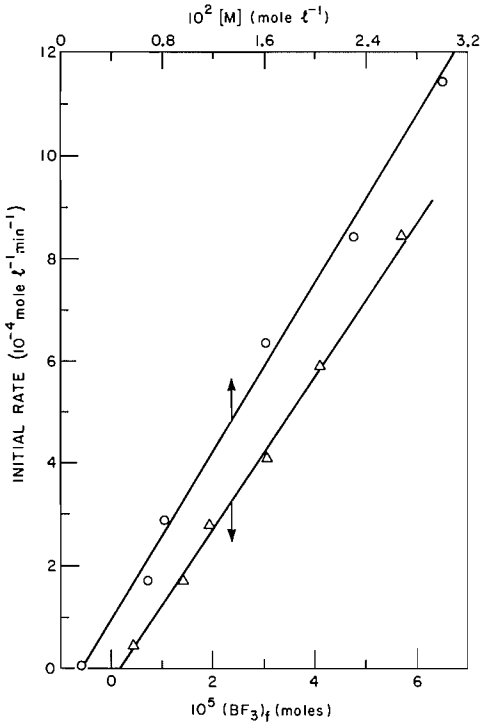

FIG. 3. Variation of initial rate with the concentration of free BF_3 (lower curve, [M] = 2.3×10^{-2} mole l^{-1}), and with the concentration of β-methylstyrene (upper curve, $(BF_3)_f = 5.7 \times 10^{-5}$ moles), in type *b* reactors pumped out for 18 h at 480 °C.

3). The results are generally similar to but more self-consistent than those from unbaked systems, but a small unexplained intercept is to be seen in each plot. The internal rate (the rate at which monomer disappears during the course of the run) does not follow first-order kinetics but falls off much more rapidly, suggesting a consumption of the active centers postulated above. The effect of added cocatalyst has not been examined but admission of air produces a marked rate increase which we attribute to cocatalysis by moisture in the air. All reactions go to completion but the slower ones may take a few days to do so.

Treatment of the unbaked reactors with trimethylsilylchloride or dimethylsilyldichloride causes a marked decrease in the rate of the blanks. The actual rate seems independent of the previous treatment of the cell (annealing, washing with solvent, or cleaning with chromic acid) or of the method of applying the silane (as silylchloride vapor at room temperature or at 200 °C, as the pure liquid, or as a solution in carbon tetrachloride). However, treatment of the vessel with the silylchloride for 4 h at 500 °C, followed by 2 h of pumping, gave no further reduction in rate. Interpretation of these results is not simple. According to the literature two types of reactions at the glass surface must be considered and can be represented by [1] and [2]. Reaction 1 is to be

$$[1] \quad (CH_3)_3SiCl + H_2O \rightarrow (CH_3)_3SiOH + HCl$$

$$[2] \quad (CH_3)_3SiCl + \underset{|}{\overset{|}{SiOH}} \rightarrow \underset{|}{\overset{|}{SiOSi(CH_3)_3}} + HCl$$

regarded as a simple dehydrating process with the products being pumped off, but reaction 2 or some similar process converts surface hydroxyl or siloxy groups to an organic coating on the surface of the glass. It seems to be generally believed that the latter process occurs only at elevated temperatures (*ca.* 400 °C) whereas reaction 1 takes place at ordinary temperatures (2, 3). However, it is also claimed that a dense hydrophobic coating is formed on the glass at ordinary temperatures if the silylchloride is applied in CCl_4 solution (3).

The silane treatment may prove useful but at present we are wary of it. We observed that reactors treated with silane vapors at room temperature were not wetted by solvent–monomer solutions but were wetted completely when the methanol – boron fluoride complex was present. Vessels treated at high temperature were not wetted in either case. These differences may be simple physical phenomena and hence unimportant, but they may indicate reaction between the catalyst and the treated surface in which case they lead to uncertainty concerning the catalytic species.

It is difficult to estimate the importance of this surface effect. The reaction is slow, as is very clear from the marked acceleration which occurs on opening the reactors to the atmosphere (Fig. 2), but it is also true that the product is only a dimer and that we know nothing about the kinetic chain lengths of the reaction. It is therefore conceivable that the surface reaction could be important in the formation of high molecular weight polymer at low cocatalyst concentrations. There seems little doubt that the surface reaction is responsible for the poor reproducibility encountered in the early stages of the present work, and it is possible too, that the strange results reported by Sigwalt and his coworkers (4) may have a similar origin, although their most recent results (7) suggest

otherwise. A surface reaction could also explain the odd shape of the rate curves we observe in the blanks for olefin polymerization; the shape of these curves suggests a two-component rate in which one part falls off rapidly while the other continues steadily to completion. Perhaps the falling off in the initial rate is due to consumption of adventitious cocatalyst leaving the surface reaction to go to completion.

While the slowness of the surface reaction may mean that this process cannot make an important contribution to the overall reaction, nevertheless the mere existence of the heterogeneous reaction is of some interest since it suggests the possibility of an alternative to the classic concept of proton initiation. Our evidence indicates that a catalyst is formed by interaction of boron fluoride with the baked-out glass surface. It has been suggested to us (5) that at temperatures up to about 500 °C, strained, and hence highly reactive silylether groups, may be formed on the glass by reaction 3.

[3] 
At higher temperatures the activity of these ether bonds will tend to disappear because the bond strain is relieved by adjustments in the body of the glass. Reaction of these siloxy groups with boron fluoride might lead to the formation of some sort of silicon–fluoborate compound not unlike the silicon–perchlorate or silicon – acid sulfate catalyst described by Kucera and coworkers (6) and used in the polymerization of trioxane.

Experimental

Materials

β-Methylstyrene (Aldrich) was fractionally distilled, then purified further by preparative g.l.c. on Carbowax 20M. It was dried over silica gel, degassed, and stored on the vacuum line over neutral alumina. When freshly prepared the product contained about 95% *trans*-isomer and very little impurity, but on storage, even though frozen when not in use, the amount of *cis*-isomer increased and some low-boiling impurity appeared.

Purification of solvent ethylene dichloride by our usual treatment with concentrated sulfuric acid was not satisfactory, apparently because of a change in the supply leading to a change in the impurities. The most important contaminant was isolated and identified as trichloroethylene which forms a close-boiling azeotrope with the solvent. We were unable to find a ternary azeotrope which would permit removal of this impurity by distillation, nor could we remove it by treatment with hot H_2SO_4, HCl–$AlCl_3$, ICl, alkali, or adsorption on molecular sieves. The only successful treatments were (*a*) washing with mixtures of concentrated nitric and sulfuric acids or (*b*) treating with a mixture of sulfuryl chloride and aluminum chloride, followed by washing with water; of these, the former method was easier to use. With these methods the major impurity in the solvent could be reduced below 0.01%, other contaminants below the level of detection on a Carbowax g.l.c. column. The purified ethylene dichloride was stored on the vacuum system in a darkened flask over phosphorus pentoxide; for each run, sufficient solvent was transferred to a separate flask and stirred overnight with neutral alumina before use. No difference was observed in the behavior of different batches of solvent.

Boron fluoride was dried by repeated evaporation from freshly prepared sodium mirrors and was stored at liquid nitrogen temperature. Its concentration has been expressed in moles of free boron fluoride; in a type *b* reactor containing 10 ml of solvent, 10^{-5} moles $(BF_3)_f$ is approximately equivalent to 5×10^{-4} mole l^{-1} in solution.

Methanol was used only in the preliminary experiments and was purified and handled as previously described.

Dimethyldichlorosilane and trimethylchlorosilane were purified by distillation, care being taken to exclude atmospheric moisture. The center fractions were stored on the vacuum line at −78 °C, and dispensed as needed through a stopcock lubricated with Kel-F grease.

Apparatus

The usual vacuum system capable of evacuation to a pressure of about 10^{-5} mm Hg was employed. In the later stages of the work most of the glass stopcocks were replaced with Hoke 4251 N6Y bellows-sealed valves attached to the glass system with Kovar seals. These valves proved very satisfactory and eliminated many problems associated with stopcocks and greases.

Reactions were carried out in vessels, shown in Fig. 4, which could be filled under vacuum and then sealed off. For type *a*, a 1 × 1 cm quartz cell containing a quartz spacer block to reduce the light path to a suitable length, usually 0.5 mm, was attached to the body of the pyrex vessel through a graded seal. The spacer could be moved in and out of the cell by means of an attached glass-enclosed magnet to serve as a mixing device. A furnace permitted the reactor to be heated to about 180 °C. Boron fluoride was contained in a separate chamber and was admitted to the reaction zone through a break seal after the remainder of the reactants had been brought to temperature (25 °C) and their initial optical absorbance determined. The temperature of the cell compartment was maintained at 25 °C throughout the run. Volume of the reactor was approximately 60 ml. The decrease in absorbance at 294 mμ was recorded automatically with a Cary Model 14 spectrophotometer and the initial rate obtained directly from the resulting curve since preliminary experiments had shown a good Beer's law dependence. No integrated rate expression was found to fit the curves.

To facilitate baking-out, the reactor was modified as shown at Fig. 4*b*. The 1 × 1 cm cell was replaced with a 1 mm cell and the spacer block was eliminated. The whole assembly, having a volume of about 22 ml, was designed to fit easily into a combustion tube furnace having a 1″ × 12″ heating zone, and was baked-out for every

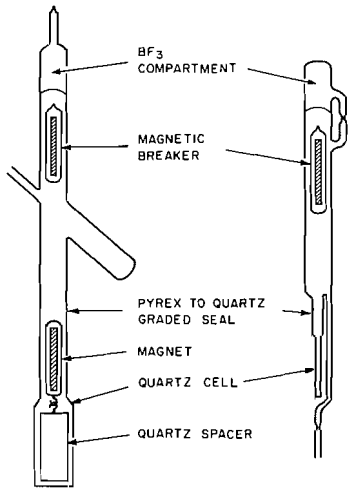

FIG. 4. Reaction vessels; *a*, with spacer block in 1 cm optical cell; *b*, with 1 mm quartz cell for baking-out at 500 °C.

experiment. No difficulty was experienced with the reactors at temperatures up to 500 °C, but as a precaution they were annealed before being attached to the vacuum system. The BF_3 was introduced into the chamber of the baked-out reactor through a by-pass which was then sealed off. A mixing problem (mentioned above) caused difficulty in estimating the initial rates of the faster reactions.

Reaction Products

All experiments showed the same u.v. spectrum at the end of reaction; loss of the long wavelength absorption (*ca.* 300 nm) corresponded to loss of the external conjugated double bond. Reaction products at 15, 50, and 100% reaction were identical according to g.l.c., but attempts to isolate the pure products by this method were unsuccessful. Mass spectrometry showed that the product had a molecular weight of 236, corresponding to a dimer of β-methylstyrene, and further, showed that there were no products of slightly higher weight resulting from incorporation of solvent, catalyst, etc., or from fragmentation of higher molecular weight species. From the mass, n.m.r., and u.v. spectra, it is clear that the product is an indane derivative of the type frequently found in styrene reactions, and is a mixture of approximately equal amounts of two geometric forms of compound **1**.

Mécanisme de la décomposition photosensibilisée au mercure du méthylvinyléther à 2537 Å

J. Castonguay et Y. Rousseau

Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 27 janvier 1971

La décomposition du méthylvinyléther par les atomes Hg6($^3P_1$) a été étudiée dans un système statique à des pressions variant de 10 à 800 Torr. Les résultats obtenus suggèrent que le processus primaire, la rupture de la liaison O—CH_3, procède d'un intermédiaire excité dont la décomposition n'est inhibée qu'à 50% à 800 Torr. L'addition d'oxide nitrique au système a permis de mettre en évidence la formation radicalaire de tous les produits sauf l'éthylène; celle de CH_3SH a permis de confirmer le rendement quantique quasi unitaire des produits primaires.

The study of the mercury 6($^3P_1$) photosensitized decomposition of methyl vinyl ether has been studied in a static system at substrate pressures from 10 to 800 Torr. The excited precursor proposed has a calculated lifetime of 1.18×10^{-10} s and its decomposition proceeds almost exclusively through the rupture of the O—CH_3 bond. A second primary process is the intramolecular formation of ethylene but it accounts only for 2% of the total ether decomposition. The major products are shown to be formed by free radical reactions and the overall reactivity appears to be very similar to that of the olefins. The results obtained with CH_3SH added to the system indicate that the primary radicals are formed with a quantum yield close to unity.

Canadian Journal of Chemistry, **49**, 2125 (1971)

Introduction

La similitude qui existe entre les réactions des atomes Hg6($^3P_1$) avec les éthers et les hydrocarbures saturés était déjà apparente à la suite des travaux de Steacie sur le diméthyléther (1). Les ouvrages plus récents (2–4) ont confirmé cette similarité entre les deux classes de composés, tant du point de vue du processus primaire impliquant dans les deux cas la rupture d'une liaison C—H, que du point de vue de la formation des produits de réaction: hydrogène moléculaire par abstraction d'un atome d'hydrogène et dimère par recombination radicalaire. La différence la plus grande se situe au niveau de l'efficacité de désactivation des atomes de mercure excités; la plus grande efficacité des éthers étant d'ailleurs expliquée en termes d'effet inductif du groupe alkoxy adjacent au radical alkyle (5, 2). D'autre part, les ressemblances qui peuvent exister entre les alcènes et les éthers insaturés ne sont pas connues mais on s'attend à ce que la similarité soit encore plus grande puisque la liaison π est généralement considérée comme le site du transfert d'énergie dans le cas des alcènes (6). De plus, les sections efficaces de désactivation des alcènes et des éthers insaturés sont très voisines (ref. 7, ref. 8 pp. 74–75): $\sigma_q{}^2$MVE = 31.5 Å^2 (7), $\sigma_q{}^2CH_2CHCH_3$ = 29.8 Å^2 (5).

Toutefois, lors d'une étude récente de la décomposition du méthylvinyléther (MVE) photosensibilisé au Hg6($^3P_1$) (7), on n'a pu mettre en évidence la formation d'un intermédiaire excité dans l'étape primaire comme le laisse supposer le parallélisme réactionnel avec les alcènes. Bien que les processus importants aient été établis, les rendements quantiques mesurés sont très faibles et peuvent difficilement être expliqués uniquement en termes d'addition de radicaux sur la double liaison de l'éther (9). Il semble donc désirable d'étudier le système dans des conditions expérimentales qui permettront de mettre en évidence l'intermédiaire excité, s'il existe, et de vérifier les rendements quantiques maxima des produits primaires.

Partie expérimentale

Le méthylvinyléther, obtenu de Matheson, fut purifié par distillation fractionnée "in vacuo" entre −115 et −130 °C et conservé à la température de la pièce dans un ballon noir. Les seules impuretés décelées par analyses au spectromètre de masse et au chromatographe en phase gazeuse sont l'acétaldéhyde (~ 0.035%) et le méthanol (0.015%). Une procédure semblable a servi à purifier et analyser les autres substances utilisées.

La décomposition du MVE fut étudiée en système statique dans une cellule cylindrique de quartz (4.4 cm de diamètre intérieur × 9.1 cm de longueur). L'enceinte réactionnelle contenant la cellule et la source lumineuse

*Pression de MVE = 50 Torr.

était maintenue à 26 ± 0.5 °C par une circulation d'air adéquate. Une lampe à basse pression de mercure Hanovia SC 2537 contenue dans une boîte séparée, a servi de source lumineuse. Cet ensemble était muni d'une fenêtre Vycor et d'une ventillation indépendante. Pour les expériences à 2.0 μE min^{-1}, 10 cm d'air entre la cellule et la source lumineuse servait de filtre pour la lumière de λ = 1849 Å. Les intensités lumineuses absorbées (I_a) furent mesurées par l'actinomètre N_2O–propylène (6, 10), et vérifiées fréquemment.

La photolyse terminée, les produits de réaction furent séparés par distillation simple sur une rampe à vide conventionnelle équipée de valves au Hg. L'analyse proprement dite s'effectuait à l'aide d'une burette à gaz et d'un chromatographe en phase gazeuse. Une colonne de Porapak Q (10 ft × 0.25 in.) utilisée à diverses températures, a servi à séparer tous les produits recueillis au-dessous de −64 °C et a permis leur analyse quantitative.

La nature de tous ces constituants avait auparavant été déterminée par spectrométrie de masse et en chromatographie par l'étude comparative de leur temps de rétention en regard de celui des substances pures. La fraction condensable à −64 °C avait une tension de vapeur trop faible (~ 0.2 Torr) pour en permettre une analyse précise.

Résultats et discussion

Les produits de réaction suivants furent identifiés et dosés: le méthane, le monoxyde de carbone, l'éthylène, l'éthane, l'éthanal et le propanal. Une étude du rendement de chacun de ces produits en fonction du temps d'irradiation permet de différencier, tout au moins partiellement, entre les produits primaires et secondaires. En effet, comme on peut le constater au tableau 1, l'éthylène, l'éthane, le propanal et l'éthanal semblent issus de réactions primaires tandis que le méthane et le monoxyde de carbone semblent surtout formés par des processus secondaires. Les très faibles rendements des aldéhydes n'en permettent pas une mesure quantitative précise à des temps de réaction courts.

Les produits de réaction identifiés sont en accord avec ceux trouvés par Filseth et le mécanisme qu'il propose peut en expliquer la formation (7).

[1] $Hg6(^3P_1) + MVE \rightarrow CH_3: + CH_2CHO\cdot + Hg6(^1S_0)$

[2] $2CH_2CHO\cdot \rightarrow CH_3CHO + CH_2CO$

[3] $CH_2CHO\cdot \rightarrow \cdot CH_2CHO$

[4] $CH_3\cdot + \cdot CH_2CHO \rightarrow CH_3CH_2CHO$

[5] $CH_3\cdot + CH_3\cdot \rightarrow C_2H_6$

[6] $Hg^* + CH_3CH_2CHO \rightarrow CH_3CH_2\cdot + \cdot CHO + Hg$

[7] $CH_3CH_2\cdot + \cdot CH_2CHO \rightarrow n\text{-}C_3H_7CHO$

[8] $CH_3CH_2\cdot + \cdot CH_3 \rightarrow C_3H_8$

[9] $\cdot CHO + \cdot CH_3 \rightarrow CO + CH_4$

[10] $\cdot CH_2CHO + \cdot CHO \rightarrow CO + CH_3CHO$

Les rendements quantiques observés par Filseth à des pressions beaucoup plus faibles que les nôtres (0.82 Torr comparé à 50) sont du même ordre de grandeur que ceux que l'on peut voir au tableau 1. Cependant, nous n'avons pas mesuré quantitativement les rendements du propane et du butanal, ceux-ci étant trop faibles. La présence de cétène n'a pu être mise en évidence qu'indirectement.

Le mécanisme proposé implique la formation dans l'étape primaire de radicaux $CH_3\cdot$ et $CH_2CHO\cdot$. Si tous les produits de réaction sont issus de ces radicaux primaires, l'addition d'oxyde nitrique (au système) devrait inhiber la formation de tous les produits. Au tableau 2, on peut voir que les rendements quantiques de l'éthanal, du propanal et de l'éthane sont considérablement diminués tandis que celui de l'éthylène n'est pas affecté. On peut remarquer aussi que l'oxyde nitrique semble catalyser la décomposition du MVE en acétylène, méthanol, éthylène et éthanal; cette décomposition se fait même sans irradiation.

Afin d'éviter les inconvénients de l'oxyde

‡Trop faible pour être mesuré.

nitrique et pour mieux caractériser les radicaux piégés, le méthanethiol fut utilisé. En présence du mercaptan, le rendement quantique du méthane et de l'éthanal a considérablement augmenté; ceci, en accord avec les réactions suivantes

[11] $CH_3\cdot + CH_3SH \rightarrow CH_4 + CH_3S\cdot$

[12] $(CH_2CHO)\cdot + CH_3SH \rightarrow CH_3CHO + CH_3S\cdot$

La Fig. 1 montre la variation linéaire de $\phi(CH_4)$ en fonction de $[CH_3SH]$. Cependant, il semble qu'à cette intensité lumineuse (4.74 μE min^{-1}), les concentrations radicalaires soient trop grandes pour permettre un piégeage quantitatif; les bilans de $CH_3\cdot$ et $(CH_2CHO)\cdot$ sont moindres qu'en l'absence de méthanethiol. Ceci peut être expliqué par les réactions [13] et [14]. Les produits des trois réactions suivantes ont d'ailleurs été identifiés par spectrométrie de masse.

[13] $CH_3\cdot + CH_3S\cdot \rightarrow CH_3SCH_3$

[14] $(CH_2CHO)\cdot + CH_3S\cdot \rightarrow (CH_3SCH_2CHO)$

[15] $CH_3S\cdot + CH_3S\cdot \rightarrow CH_3SSCH_3$

La diminution de I_a de deux ordres de grandeur a permis un titrage presque complet des radicaux méthyles. Les résultats de ces expériences sont résumés au tableau 3. Ils mettent clairement en évidence le rendement quantique quasi unitaire de la rupture O—CH_3. En effet, on a mesuré des rendements quantiques de radicaux $CH_3\cdot$ atteignant 0.95. Ils suggèrent aussi la formation intramoléculaire d'éthylène comme mode concurrent de la décomposition du MVE. Ce processus n'aurait cependant qu'une probabilité maximale de 2%.

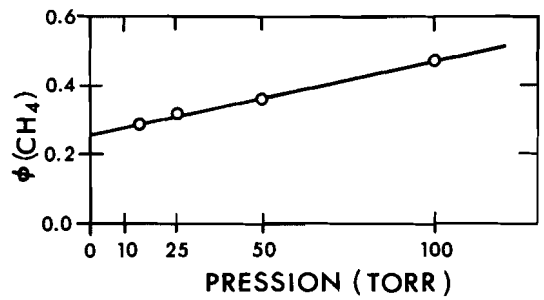

FIG. 1. Variation du rendement quantique de CH_4 en fonction de la concentration de CH_3SH; I_a = 4.74 μE min^{-1}, $[CH_3SH]$ = 5%.

[16] $Hg6(^3P_1) + MVE \rightarrow C_2H_4 + H_2CO + Hg6(^1S_0)$

Le comportement des radicaux $CH_3\cdot$ en présence de méthanethiol est conforme aux observations de Greig et Thynne (11).

Le taux de formation d'éthane est réduit d'un facteur 13 (tableau 3, résultats à 50 Torr) alors que le bilan des radicaux CH_3 recueillis subit une majoration de 25%. Le titrage du radical formylméthyle semble, pour sa part, moins favorisé. Même en profitant d'une augmentation de près de 20%, il demeure qu'environ la moitié de cet espèce manque à l'analyse. La réaction [14] peut être partiellement responsable de cette différence, étant donné la stabilité du radical $(CH_2CHO)\cdot$, [3]. Néanmoins, considérant (*a*) la vitesse de la réaction [15], $k_{15} = 10^{10.3}$ l mol^{-1} s^{-1} (12), (*b*) le fait que la recombinaison des $CH_3\cdot$ est défavorisée, $k_5 \simeq 10^{10.5}$ l mol^{-1} s^{-1} et (*c*) le parallélisme existant entre $\phi(C_2H_6)$ et ϕ(propanal), il semble qui ni [13] ni [14] ne soient très importants dans notre système.

Dans ces conditions, on peut se demander quelles réactions peuvent être responsables du faible rendement quantique observé pour le radical $(C_2H_3O)\cdot$. En effet, la réaction [17] est endothermique de 18 kcal mol^{-1} (13) et enthropiquement défavorisée. De plus, ni l'oxyde d'éthylène ni l'oxyde de propylène n'ont été détectés. On pourrait considérer une isomérisation du radical $(CH_2CHO)\cdot$ en CH_3CO selon [20]. Cependant, le rendement quantique de CO

Les valeurs ci-dessus sont corrigées pour la désactivation du Hg produite par CH_3SH. Le % de conversion n'a jamais excédé 2%.

est très bas, et selon Benson (13) l'isomérisation ne peut qu'être suivie de la décomposition ($\Delta H = 10$ kcal mol^{-1}).

[17] $(CH_2CHO)\cdot \rightarrow CH_2\text{—}CH\cdot$ (O)

[18] $CH_2\text{—}CH\cdot + CH_3SH \rightarrow CH_2\text{—}CH_2 + CH_3S\cdot$ (O) (O)

[19] $(CH_2CHO)\cdot \xrightarrow{\text{parois}}$ polymère

[20] $(CH_2CHO)\cdot \rightarrow (CH_3CO)\cdot$

[21] $(CH_3CO)\cdot \rightarrow CH_3\cdot + CO$

Vu la faible réactivité de $(CH_2CHO)\cdot$, ainsi que l'influence minime de CH_3SH sur la vitesse de formation de CO, la réaction [19] semble être principalement responsable du faible $\phi(CH_2CHO)\cdot$ observé. D'ailleurs, le fait de doubler (CH_3SH) (tableau 3: 25 Torr à 10% de CH_3SH *vs.* 100 Torr à 5% de CH_3SH) ne modifie que peu le rendement quantique d'éthanal, même si l'une ou l'autre des formes de résonnance [3] de $(C_2H_3O)\cdot$ conduit à sa formation.

De ce même tableau 3, on observe qu'une augmentation de la pression totale diminue légèrement le taux des radicaux CH_3 collectés. Ce phénomène peut s'expliquer soit par l'addition de $CH_3\cdot$ sur la double liaison de l'éther [22], soit par la désactivation par collision d'un intermédiaire excité [25].

[22] $CH_3\cdot + MVE \rightarrow R_1\cdot$

[23] $Hg^* + MVE \rightarrow (MVE)^* + Hg$

[24] $(MVE)^* \rightarrow CH_3\cdot + CH_2CHO\cdot$

[25] $(MVE)^* + M \rightarrow MVE + M$

[26] $(MVE)^* \rightarrow C_2H_4 + H_2CO$

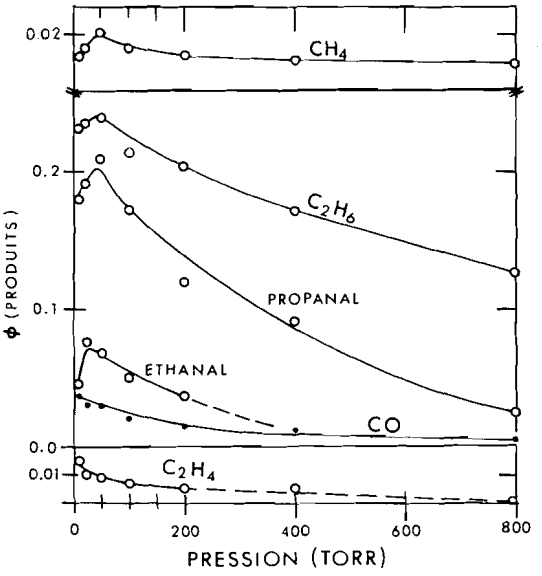

FIG. 2. Variation des rendements quantiques en fonction de la pression totale. C_3F_8 ajouté à 22 Torr de MVE (sauf à 10 Torr); $I_a = 0.037$ μE min^{-1}.

Les résultats obtenus en variant la pression totale et qui sont représentés à la Fig. 2 indiquent la présence d'une molécule d'éther excitée [23]. Au cours de ces expériences, la pression de MVE fut maintenue à 22 Torr et C_3F_8 fut utilisé comme gaz inerte. Dans ces conditions, la réaction [22] peut être négligée, et d'ailleurs, les expériences utilisant le MVE pur (Fig. 4) confirment cette hypothèse. La diminution observée enfin pour les rendements quantiques à des pressions inférieures à 50 Torr est compatible avec celle obtenue par Filseth (7) entre 10 et 0.21 Torr. La raison en est vraisemblablement la désactivation incomplète des atomes $Hg6(^3P_1)$, ou encore une absorption lumineuse différente.

On peut constater, toujours au tableau 3, que le rendement quantique d'éthylène ne varie pas avec l'intensité lumineuse absorbée. Ceci est compatible avec le mécanisme déjà proposé pour sa formation. Sans mercaptan (50 Torr, 0% CH_3SH), cette très faible variation est observée pour les taux de titrage des radicaux primaires. La réaction [27], certainement responsable de cet effet, aurait alors une probabilité de 0.25, calculée de la différence des $\phi(\cdot CH_3)$, avec et sans le thiol.

[27] $CH_3\cdot + CH_2CHO\cdot \rightarrow MVE$

[28] $CH_3\cdot + CH_2CHO\cdot \rightarrow CH_4 + CH_2CO$

[29] $2\cdot CH_2CHO \rightarrow CHOCH_2CH_2CHO$

De plus, seul le rendement quantique de propanal varie dans le même sens que l'intensité lumineuse. Un calcul simple, utilisant ϕ(éthane) et ϕ(propanal), montre ainsi que l'accroissement des concentrations stationnaires de $(CH_3)\cdot$ et $(C_2H_3O)\cdot$ est respectivement de 10 et 18 lorsque leur taux de formation est 130 fois accéléré. Alors, ou les radicaux méthyles sont consommés plus rapidement par d'autres réactions [27], [28] ou encore la disparition de $(CH_2CHO)\cdot$ implique une étape relativement plus lente que les procédés biradicalaires. Ces derniers, [2] et [29], peuvent être négligés devant [19]. L'accumulation de $(CH_2CHO)\cdot$ est aussi un signe de sa stabilité et de sa faible réactivité. Ainsi, à faible I_a, la diffusion de ce radical devient sensiblement plus compétitive vis-à-vis des autres réactions en phase gazeuse.

Enfin, si les réactions [28] et [29] étaient de quelques importance, on devrait observer une augmentation des rendements de méthane et de succénaldéhyde avec une augmentation de I_a. Comme on peut le voir au tableau 3, en l'absence de CH_3SH, $\phi(CH_4)$ qui est très faible de toute façon n'est pas favorisé par une telle augmentation. Quant au succénaldéhyde, même si on a cru le déceler à quelques reprises, au spectromètre de masse, on n'a pu l'identifier d'une façon positive.

Un traitement cinétique basé sur les réactions [2] à [5] et [23] à [29] indique une dépendance linéaire entre l'inverse du rendement quantique d'éthane et la pression totale.

$$[30]\quad \frac{1}{\phi(C_2H_6)} = (1 + ka) + \frac{k_{25}}{k_{24}}(1 + ka)[M]$$

où

$$ka = \frac{k_4 + k_{28} + k_{27}}{\sqrt{k_5(k_2 + k_{29})}}$$

En utilisant l'équation précédente et les paramètres de la droite de la Fig. 3, le rapport k_{25}/k_{24} fut estimé à environ 4.4×10^{-2} mol l^{-1}. En conséquence, à 800 Torr, la désactivation [25] devient aussi importante que la décomposition. On trouve alors: $k_{24} = k_{25}[M] = 8.5 \times 10^9\ s^{-1}$, et de là, $k_{25} = 1.93 \times 10^{11}\ l\ mol^{-1}\ s^{-1}$.

Le temps de vie calculé de (MVE)* apparaît ainsi quelques 50 fois plus court que celui mesuré par Cvetanović et Doyle (14) pour le butène-1. Ces homologues isoélectroniques montrent un parallélisme réactionnel postérieur à la rupture initiale. Ni le MVE, ni le butène-1 ne semblent subir l'addition de $CH_3\cdot$, ni même l'abstraction d'hydrogène de la part de ce radical. La courbe

de la Fig. 4 et le tableau 4 vérifient ces observations pour l'éther.

Discussion

Le présent travail a principalement mis en évidence la grande similitude des systèmes (Hg6($^3P_1$)–éther insaturé) et (Hg6($^3P_1$)–alcène).

(*a*) L'activation initiale produit, semble-t-il, un état triplet vibrationnellement excité. C'est d'ailleurs le propre des alcènes.

(*b*) L'efficacité du MVE à désactiver Hg6($^3P_1$) est identique à celle du propylène (tableau 5). La présence d'oxygène, ou encore le remplacement de CH_3 par CH_3O ne cause pas, à priori, d'activation particulière comme nous l'observons chez les homologues saturés (2, 3).

(*c*) La décomposition dans les deux cas s'effectue presqu'exclusivement par la rupture β, et le radical de type alkyle ainsi créé est stabilisé par résonnance (9, 15). L'énergie du lien C—CH_3, 64 kcal mol^{-1}, suggérée par Lossing, Marsden et Farmer (16) se compare avantageusement à 65 ± 2 kcal mol^{-1}, calculée pour O—CH_3 à l'aide des valeurs suivantes

TABLEAU 5. Réactivité relative du MVE et du propylène en competition avec N_2O*

$\frac{[RH]}{[N_2O]}$	$d[N_2]/dt$	
	C_3H_6	MVE
1	1.39	1.40
3	3.21	3.20
σ_q^2(Å)^2	29.8†	34.0‡

*$I_a = 2.0$ μE min^{-1}, $t = 7.5$ min, $P_{totale} = 200$ Torr.
†Processus I, référence (5).
‡Filseth (7) mesure 31.5 Å^2 en se servant de la valeur "physique" de $\sigma q^2 N_2O$. Cette méthode de calcul conduirait à: σq^2MVE ≃ 47 Å^2.

$$\Delta H_f(\text{MVE}) = -26.2 \text{ kcal mol}^{-1} \quad \text{(ref. 17)}$$

$$\Delta H_f(CH_3\cdot) = 32 \text{ kcal mol}^{-1} \quad \text{(ref. 8, p. 819)}$$

$$\Delta H_f(CH_3O\cdot) = -0.5 \text{ kcal mol}^{-1} \quad \text{(ref. 8, p. 819)}$$

$$\Delta H_f(CH_2{=}CH\cdot) = 65 \text{ kcal mol}^{-1} \quad \text{(ref. 8, p. 819)}$$

$$\text{p.i.}(CH_3\cdot) = 9.83 \text{ eV} \quad \text{(ref. 8)}$$

$$\text{p.a.}(CH_3^+) = 12.7 \text{ eV}^1$$

$$\text{p.a.}(CH_2CHO^+) = 11.6 \text{ eV}^1$$

p.i. = potentiel d'ionisation; p.a. = potentiel d'apparition

(*d*) La très grande majorité des composés stables analysés résultent de réactions radicalaires impliquant uniquement $CH_3\cdot$ et $(CH_2CHO)\cdot$. Les réactions d'abstraction d'hydrogène et d'addition à la double liaison semblent grandement défavorisées.

Il est concevable que ces ressemblances trouvent leur origine dans la similarité de structure de l'état fondamental: cis-planaire (19, 20). Même la barrière de rotation du groupe vinyle a la même hauteur chez l'un et chez l'autre (21).

Néanmoins, il existe chez le MVE une conjugaison interne "$n\pi$" (20) qui ne saurait avoir lieu dans le butène-1. Elle est sûrement responsable de la stabilité inhabituelle de la liaison éther O-vinyl: d'après les données thermodynamiques

[1]Mesuré à l'aide d'un spectromètre de masse CEC 21–104 non modifié, par la méthode d'extrapolation directe. Les gaz suivants, Ne, Xe, Kr ont servi de références internes (18).

précédentes, $\Delta H(CH_2CH—OCH_3) = 90.5$ kcal mol^{-1}.

De ce fait, il est raisonnable d'observer la décomposition de (MVE)* par le procédé quasi exclusif [24], de même que le temps de vie relativement court de cet espèce.

Enfin, un transfert 1,4 d'hydrogène, semblable à celui menant à la formation de méthylcyclopropane (14), conduirait chez le MVE à l'oxyde de propylène. Cependant, faute de désactivation, le (C_3H_6O)* s'isomériserait surtout en propanal (13). Toutefois, la série d'expériences faites en fonction de la pression a montré la formation progressive d'acétone (ϕ à 400 Torr = 0.046, ϕ à 800 Torr = 0.072).

Aucune expérience à plus de 800 Torr ne fut tentée, vu les difficultés d'analyse déjà encourrues: impossibilité de séparer les produits oxygénés du substrat de départ à cause de la grande ressemblance de ces composés dont au moins quatre s'identifient à la formule C_3H_6O.

Finalement, le transfert de H· entre les positions 1 et 3 est suggéré pour la formation intramoléculaire de C_2H_4 et H_2CO.

Les auteurs tiennent à remercier particulièrement le Conseil National de Recherches du Canada pour l'aide financière qu'il leur a accordée. Ils remercient également Monsieur Gabriel Sanchez pour son assistance lors des analyses chromatographiques.

Total Synthesis of Several Monodeoxy and Dideoxy-DL-hexopyranoses from 6,8-Dioxabicyclo[3.2.1]oct-2-ene and 6,8-Dioxabicyclo[3.2.1]oct-3-ene

T. P. MURRAY,[1] U. P. SINGH,[1] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 18, 1971

Reaction of osmic acid with 6,8-dioxabicyclo[3.2.1]oct-3-ene (**1**) gave 1,6-anhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**3**, R = H) which was hydrolyzed to 4-deoxy-α,β-DL-*ribo*-hexopyranose (**4**, R = H). Conversion of **1** to 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**5**) followed by treatment of **5** with lithium aluminum hydride, gave 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hexopyranose (**6**, R = H), and this in turn was hydrolyzed to 3,4-dideoxy-α,β-DL-*erythro*-hexopyranose (**7**, R = H).

Reaction of osmic acid with 6,8-dioxabicyclo[3.2.1]oct-2-ene (**2**) gave 1,6-anhydro-2-deoxy-β-DL-*ribo*-hexopyranose (**8**, R = H), which was hydrolyzed to 2-deoxy-DL-*ribo*-hexopyranose (**9**, R = H). Compound **2** was converted to 1,6:3,4-dianhydro-2-deoxy-β-DL-*ribo*-hexopyranose (**10**) which was hydrolyzed by aqueous base to 1,6-anhydro-2-deoxy-β-DL-*arabino*-hexopyranose (**12**) and this in turn was hydrolyzed by dilute hydrochloric acid to 2-deoxy-α,β-DL-*arabino*-hexopyranose (2-deoxy-DL-glucose) (**13**). The reaction of **10** with lithium aluminum hydride gave 1,6-anhydro-2,3-dideoxy-β-DL-*erythro*-hexopyranose (**14**).

Yields were good to excellent in each of the above reactions.

La réaction de l'acide osmique avec le dioxa-6,8 bicyclo[3.2.1] octène-3 (**1**) conduit à l'anhydro-1,6 désoxy-4 β-DL-*ribo*-hexapyranose (**3**, R = H) qui par hydrolyse fournit le désoxy-4 α,β-DL-*ribo*-hexapyranose (**4**, R = H). Le composé **1** peut être transformé successivement en dianhydro-1,6:2,3 désoxy-4 β-DL-*ribo*-hexapyranose (**5**), puis par traitement par $LiAlH_4$ en anhydro-1,6 didésoxy-3,4 β-DL-*erythro*-hexapyranose (**6**, R = H) et finalement, par hydrolyse, en didésoxy-3,4 α,β-DL-*erythro*-hexapyranose (**7**, R = H).

Par ailleurs l'action de l'acide osmique sur le dioxa-6,8 bicyclo[3.2.1] octène-2 (**2**) fournit l'anhydro-1,6 désoxy-2 β-DL-*ribo*-hexapyranose (**8**, R = H) qui conduit, par hydrolyse, au désoxy-2 DL-*ribo*-hexapyranose (**9**, R = H). On peut aussi transformer le composé **2** pour obtenir successivement le dianhydro-1,6:3,4 désoxy-2 β-DL-*ribo*-hexapyranose (**10**), puis par hydrolyse en milieu basique en anhydro-1,6 désoxy-2 β-DL-*arabino*-hexapyranose (**12**) et finalement par hydrolyse en milieu acide chlorhydrique dilué en désoxy-2 α,β-DL-*arabino*-hexapyranose (désoxy-2 DL-glucose) (**13**). La réaction de **10** avec $LiAlH_4$ fournit l'anhydro-1,6 didésoxy-2,3 β-DL-*erythro*-hexapyranose (**14**).

Dans chacune des réactions décrites ci-haut les rendements sont excellents.

Canadian Journal of Chemistry, 49, 2132 (1971)

Introduction

Recent reports from this laboratory have described the total synthesis of 1,6-anhydro-4-deoxy-β-DL-*xylo*-hexopyranose (1) and α,β-DL-chalcose (2) from 6,8-dioxabicyclo[3.2.1]oct-3-ene (**1**), a compound in turn readily prepared from acrolein dimer (1). We now report the preparation of several monodeoxy and dideoxy-hexopyranoses from the bicyclic olefin **1** and its isomer 6,8-dioxabicyclo[3.2.1]oct-2-ene (**2**), a compound recently described (3).

Results and Discussion

The reactions performed with olefin **1**, and the products so obtained, are shown in Scheme 1. Those involving olefin **2** are portrayed in Scheme 2.

[1]Postdoctoral Fellow.

The reaction of **1** with osmic acid in dioxane or pyridine, following published directions (4–6), gave a nearly quantitative yield of crude material which showed only one spot on a t.l.c. Distillation provided pure 1,6-anhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**3**, R = H) in 96% yield. The elemental analysis and the 100 MHz p.m.r. spectrum of **3** (R = H) as well as those of its diacetate **3** ($R = CH_3CO$) were in complete agreement with the structure shown by **3**. The previous observation (6) that the direction of attack by osmic acid on the double bond of such substituted cyclic olefins is strongly subject to steric influence also provides support for the structure **3**. Acid-catalyzed hydrolysis of **3** (R = H or CH_3CO) in aqueous dioxane gave 4-deoxy-α,β-DL-*ribo*-hexopyranose (**4**) (R = H) as a syrup in 85% yield. The 100 MHz p.m.r. spectrum of **4** (R = H) in D_2O, as well as that

of its tetraacetate (**4**, R = CH_3CO) in $CDCl_3$, showed that this substance possessed the configuration and conformation shown by **4**, and that it was present in D_2O as a mixture of the α and β isomers in the ratio 1:3 respectively.

When 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**5**), prepared from **1** according to published directions (1, 2), was treated with lithium aluminum hydride in diethyl ether, the compound obtained in 91% yield was **6** (R = H). This was the product expected from preferential cleavage of the O—C_3 bond (7) as well as preferential formation of the chair structure obtained by cleavage of the oxirane ring so that the attacking agent and the leaving group are *trans* diaxially disposed (8–10). The 100 MHz p.m.r. spectra of both **6** (R = H) and its acetate **6** (R = CH_3CO) clearly showed that the product of lithium aluminum hydride reduction of **5** was indeed structure **6**. Acid-catalyzed hydrolysis of **6** (R = H) provided 3,4-dideoxy-α,β-DL-*erythro*-hexopyranose (**7**, R = H). The 100 MHz p.m.r. spectrum of **7** (R = H) as well as that of its triacetate (**7**, R = CH_3CO) completely supported the structure and conformation shown by **7**. The integrated areas of the two anomeric proton signals for **7** (R = H) of the spectrum in D_2O, showed that the α and β isomers were present in the ratio 1:4 respectively.

Treatment of olefin **2** with osmic acid in pyridine gave 1,6-anhydro-2-deoxy-β-DL-*ribo*-hexopyranose (**8**, R = H) in 92% yield. Here again most if not all of the reaction with osmic acid had occurred from the least hindered side of the double bond of **2**. The structure was supported by its 100 MHz p.m.r. spectrum, since upon irradiation of the nucleus of the anomeric proton (H-1), a collapsed high field multiplet was obtained for the two protons on C-2 which contained a large coupling of ~10 Hz. A coupling of such magnitude can occur only if the H-3 proton and one of the C-2 protons are *trans* diaxially disposed. The elemental analysis and 100 MHz p.m.r. spectrum of the diacetate **8** (R = CH_3CO) also supported the structure designated by **8**. Hydrolysis of **8** (R = H) or its diacetate with 1 *N* aqueous hydrochloric acid gave 2-deoxy-DL-*ribo*-hexopyranose (**9**, R = H) in 88% yield. The 100 MHz p.m.r. spectrum of **9** (R = H) was identical to that of an authentic sample of 2-deoxy-D-*ribo*-hexopyranose (11, 12) kindly provided by Dr. K. V. Bhat. The elemental analysis and 100 MHz p.m.r. spectrum of the tetraacetate **9** (R = CH_3CO) agreed completely with the assigned structure.

Treatment of **2** with *m*-chloroperoxybenzoic acid gave a 74% yield of an oil whose analysis by g.l.c. showed only two symmetrical peaks in the area ratio of 49:1. The major compound, 1,6:3,4-dianhydro-2-deoxy-β-DL-*ribo*-hexopyranose (**10**), was readily separated in the pure state by g.l.c. The elemental analysis, and the i.r. and 100 MHz p.m.r. spectral data clearly supported structure **10**. The minor component, **11**, could not be obtained free of **10** because of the tailing from **10** during attempted g.l.c. separation. However, the mixture finally isolated was sufficiently enriched in **11** to obtain a 100 MHz p.m.r. spectrum which confirmed that the compound had the structure shown by **11**. The reaction of aqueous potassium hydroxide with **10** gave crystalline 1,6-anhydro-2-deoxy-β-DL-*arabino*-hexopyranose (**12**) in 79% yield. The 100 MHz p.m.r. spectrum agreed completely with the structure assigned and this structure was confirmed by hydrolysis of **12** with 1 *N* aqueous hydrochloric acid to 2-deoxy-α,β-DL-*arabino*-hexopyranose (**13**), whose 100 MHz p.m.r. spectrum in D_2O was identical to that of authentic 2-deoxy-D-glucose.

Lithium aluminum hydride in ether reacted with the oxirane **10** to give, after sublimation, the solid 1,6-anhydro-2,3-dideoxy-β-DL-*erythro*-hexopyranose (**14**) as the only isolable product. Here again cleavage of the oxirane ring gave that product which was the chair form obtainable by opening of the three-membered ring so that the attacking and leaving groups are *trans* diaxially oriented (8–10). The 100 MHz p.m.r. spectrum's pattern of high field signals equivalent to four protons could be accounted for only if these protons were aliphatic and on two adjacent carbon atoms as shown by **14**.

Hydrolysis of **14** with 1 *N* hydrochloric acid gave a viscous syrup whose t.l.c. showed only one spot but the p.m.r. spectrum indicated it to be a mixture, presumably of pyranose and furanose structures. Several attempts to resolve this mixture were unsuccessful.

Experimental

Melting points and boiling points are uncorrected. Elemental analyses were made by Mrs. Darlene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Mahlow and Miss A. Dunn in our microanalytical laboratory.

The i.r. absorption spectra were obtained by Mr. R. Swindlehurst of this Department using a Perkin–Elmer Model 421 spectrometer.

The 60 MHz p.m.r. spectra were made by Mr. R. Swindlehurst using a Varian A-60 instrument. The 100 MHz p.m.r. spectra and spin decoupling experiments were carried out by Mr. Glen Bigam and his associates. Tetramethylsilane was the internal reference. Signal assignments were made with the aid of double irradiation spin decoupling. The coupling constants were estimated from the signal spacings where this was possible, and accordingly are approximate values.

Column and t.l.c. was carried out using Silica Gel G (E. Merck and Co.) as absorbent. Solvents were removed by rotary evaporator under vacuum unless otherwise stated.

*6,8-Dioxabicyclo[3.2.1]oct-3-ene (**1**)*

Compound **1** was prepared according to the modification (2) of the published procedure (1).

*6,8-Dioxabicyclo[3.2.1]oct-2-ene (**2**)*

Compound **2** was prepared in good yield by using directions previously described (3).

*1,6-Anhydro-4-deoxy-β-DL-ribo-hexopyranose (**3**, R = H)*

Osmic acid (1.0 g, 3.93 mmol) in 5 ml of dry pyridine (4–6) was added slowly to a solution of 0.44 g (3.90 mmol) of **1** in 5 ml of pyridine at room temperature. The solution was then kept at room temperature and stirred for 15 h. The reaction mixture was treated with a solution of 1.8 g of sodium bisulfite in 20 ml of pyridine and 30 ml of water and the resulting mixture stirred for 1 h. The orange solution was extracted continuously for 24 h with 250 ml of chloroform. The chloroform extract was dried (Na_2SO_4), filtered, and freed from solvent at 45°. The syrupy residue showed only one spot on t.l.c. (solvent, 2% methanol in dichloromethane). The 60 MHz p.m.r. spectrum in deuteriochloroform showed only one anomeric proton signal and no signals in the olefinic proton region. The syrup was distilled at 120–121° at 0.05 mm to provide a low-melting colorless solid (~ 30°), yield, 0.55 g (96%); lit. m.p. of D isomer 105–107° (108–110° after sublimation) (13).

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90. Found: C, 49.12; H, 7.06.

The i.r. spectrum in chloroform showed a band at 3560 with a shoulder at 3610 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.51 for H-1 (doublet, $J_{1,2} \sim 2.5$ Hz); 5.98–6.40 (multiplet for H-2, -3, -6*exo*, and -6*endo*); 7.8–8.4 (multiplet for H-4*exo* and -4*endo*); 5.47 (broad singlet $w/2 = 10$ Hz for H-5); and 7.82 (singlet for OH). Irradiation of H-5 at τ 5.47 simplified the multiplet at 7.8–8.4 for H-4*exo* and -4*endo* to two quartets showing geminal coupling of ~ 14, $J_{3,4exo} \sim 10$, and $J_{3,4endo} \sim$ 6.5 Hz which can occur only if the C-3 proton is *endo* to the bicyclic structure.

When a mixture of 0.88 g of **1** and 2.0 g of osmic acid in 10 ml of dry dioxane was stirred at room temperature for 24 h as described in published directions (4–6), and then treated with dry hydrogen sulfide, followed by removal of the black precipitate, there was obtained after isolation and distillation as above, 1.0 g (87%) of the low melting (~ 30°) solid boiling at 120–123° at 0.05 mm. This was identical in every respect to **3** (R = H) described immediately above.

*1,6-Anhydro-2,3-di-O-acetyl-4-deoxy-β-DL-ribo-hexopyranose (**3**, R = CH_3CO)*

Compound **3** (R = H) (100 mg) was treated with acetic anhydride (5 ml) in pyridine (5 ml) at 60° for 0.5 h, and gave 130 mg (82.5%) of the crude diacetate **3** (R = CH_3CO). Distillation at 137–139° at 0.1 mm provided a viscous syrup.

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13. Found: C, 52.43; H, 5.93.

The i.r. spectrum in chloroform showed strong absorption at 1750 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.61 for H-1 (doublet, $J_{1,2} \sim 2.5$ Hz); 4.95 for H-2 (quartet showing some long range coupling (< 1.0 Hz) with H-4*endo*, $J_{2,3} \sim 4.5$ Hz); 4.75 for H-3 (multiplet $J_{3,4endo} \sim 6.5$, $J_{3,4exo} \sim 11$ Hz); 8.8 for H-4*exo* and -4*endo* (multiplet masked by acetyl protons); 5.39 for H-5 (multiplet, $J_{5,6endo} \sim 1.5$, $J_{5,6exo} \sim 5.0$ Hz); 6.08 for H-6*endo* (doublet of doublets, $J_{6exo,6endo} \sim$ 7.0 Hz); 6.28 for H-6*exo* (quartet of doublets, $J_{4,6exo} \sim$ 1.7 Hz long range coupling); 7.91 and 8.04 (each a singlet due to two CH_3CO).

*4-Deoxy-α,β-DL-ribo-hexopyranose (**4**, R = H)*

A mixture of 275 mg of **3** (R = H), 5 ml of dioxane, and 10 ml of 1 *N* aqueous hydrochloric acid was heated at ~ 80° for 5 h. The mixture was then cooled, neutralized with Amberlite IRA 400 ($OH^{\ominus}$), and filtered. The solvent was removed and the residue freeze-dried. The yellow syrup obtained was passed twice through a short column of Silica Gel G using a 1:1 mixture of methanol and chloroform as eluent. The solvent was removed and the residue distilled at 110–115° at 0.01 mm and gave 261 mg (85%) of a colorless viscous oil; lit. m.p. of D isomer 89–93° (13).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.75; H, 7.92.

The 100 MHz p.m.r. spectrum in D_2O obtained after the solution had stood for 24 h to permit completion of mutarotation, showed signals at τ 4.06 for H-1 of the α anomer (doublet, $J_{1,2} \sim 3.0$ Hz); 4.64 for H-1 of the β anomer (doublet, $J_{1,2} \sim 8.0$ Hz). Signal area ratio H-1α: H-1β was 1.0:3.0. Other signals were at τ 5.20–6.30 for H-2, -3, -5, and —CH_2— (complex multiplet); 7.40–7.92 for H-4*e* and -4*a* (multiplet); and 4.82 for OH (singlet).

*1,2,3,6-Tetra-O-acetyl-4-deoxy-α,β-DL-ribo-hexopyranose (**4**, R = CH_3CO)*

Treatment of 100 mg of **4** (R = H) with a mixture of 5 ml of acetic anhydride and 5 ml of pyridine at 60° for 0.5 h and then at room temperature overnight gave a syrup from which **4** (R = CH_3CO) was obtained as a colorless oil boiling at 141–143° at 0.1 mm; yield, 165 mg (79%).

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.68; H, 6.17.

The i.r. spectrum in chloroform showed strong absorption at 1755 cm^{-1} (C=O).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 3.80 for H-1 of the α anomer (doublet, $J_{1,2} \sim 4.0$ Hz); 4.01 for H-1 of the β anomer (doublet, $J_{1,2} \sim 8.5$ Hz). Signal area ratio α:$\beta \sim 1.0$:3.0. Other signals were at τ 5.19 for H-2 of the β anomer (quartet, $J_{2,3} \sim 3.0$ Hz); 4.98 for H-2 of the α anomer (triplet, $J_{2,3} \sim J_{1,2} \sim 4.0$ Hz); 4.40–4.70 for H-3 of α and β anomers (multiplet); 7.8–8.3 for H-4*e* and -4*a* masked by the four CH_3—CO (multiplet); 5.60–5.95 for H-5 and —CH_2— (multiplet); 7.90, 7.92, 7.94, and 8.02 (four singlets, each CH_3CO).

*1,6-Anhydro-3,4-dideoxy-*β-DL*-erythro-hexopyranose (**6**, R = H)*

A solution of 1.28 g (0.01 mol) of 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**5**) (1, 2) in 20 ml of dry ether was added slowly, dropwise, to a stirred solution of lithium aluminum hydride (0.88 g, 0.01 mol) in 25 ml of dry ether at room temperature. This was stirred for 12 h at room temperature. The aluminum complex was then decomposed by gradual addition of 15 ml of ether saturated with water, then further addition of 1 ml of 15% aqueous sodium hydroxide. The granular precipitate was separated by gravity filtration and the colorless solid was washed with ether (3 × 20 ml). The combined ether solutions from the washings and filtrate were dried (Na_2SO_4) and freed from solvent at 40° under vacuum (50 mm). The residual solid was sublimed under vacuum (50–55° at 0.01 mm) and provided **6** (R = H) as colorless needles; m.p. 81–82°; yield, 1.18 g (~91%).

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.74. Found: C, 55.25; H, 7.80.

The i.r. spectrum in chloroform showed absorption at 3517 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.67 for H-1 (narrow triplet, $w/2 \sim 4$, $J_{1,2} \sim 1.0$, $J_{1,3} \sim 1.0$ Hz due to long range coupling); 6.40 for H-2 (multiplet, $w/2 \sim 7$; $J_{2,3} \sim 2.0$ Hz); 7.60–8.20 for H-3*exo* and -3*endo* (multiplet); 8.20–8.70 for H-4*exo* and -4*endo* (multiplet $J_{4endo,5} \sim 2.0$; $J_{4exo,6exo} \sim 1.2$ Hz due to long range coupling); 5.50 for H-5 (multiplet, $w/2 \sim 10$, $J_{5,6endo} \sim 1.5$, $J_{5,6exo} \sim 5.0$ Hz); 6.00–6.13 for H-6*endo* (doublet of doublets, $J_{6exo,6endo} \sim 7.0$ Hz); 6.13–6.30 for H-6*exo* (multiplet); τ 7.41 for OH (singlet).

*2-O-Acetyl-1,6-anhydro-3,4-dideoxy-*β-DL*-erythro-hexopyranose (**6**, R = CH_3CO)*

The reaction of 300 mg of **6** (R = H) with acetic anhydride (5 ml) in pyridine (5 ml) for 1 h at 60° gave the crude monoacetate as a pale yellow liquid. Distillation provided a colorless oil boiling at 55–59° at 0.01 mm; yield, 370 mg (93%).

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 7.02. Found: C, 55.66; H, 6.96.

The i.r. spectrum in chloroform showed a strong absorption band at 1725 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.61 for H-1 (narrow quartet, $J_{1,2} \sim 2.0$, $J_{1,3} \sim 1.0$ Hz); 5.30–5.53 for H-2 and -5 (overlapping multiplets, $J_{2,3} \sim 2.0$, $J_{5,6exo} \sim 5.0$, $J_{5,6endo} \sim 1.0$ Hz); τ 8.0–8.35 for H-4*exo* and -4*endo* (multiplet, $J_{4endo,5} \sim 2.0$, $J_{4exo,6exo} \sim 1.2$ Hz long range coupling); 8.35–8.70 for H-3*exo* and -3*endo* (multiplet); 6.07 for H-6*endo* (doublet of doublets, $J_{6exo,6endo} \sim 7.0$ Hz), 6.12–6.30 for H-6*exo* (multiplet); 7.96 for CH_3CO (singlet).

*3,4-Dideoxy-*α,β-DL*-erythro-hexopyranose (**7**, R = H)*

A solution of 500 mg of **6** (R = H) in a mixture of 10 ml of 1 *N* aqueous hydrochloric acid and 5 ml of dioxane was heated at 80° for 5 h in an oil bath. The mixture was cooled and then neutralized with Amberlite IRA 400 ($OH^{\ominus}$) and filtered. The solvent was removed and the residue freeze-dried to give a pale yellow syrup. This was purified by column chromatography using a 3:2 mixture (by volume) of chloroform and methanol as eluent. The first fraction (50 ml) gave a gum which was discarded. The second fraction (150 ml) provided a syrup which was distilled at 130–135° at 0.4 mm to give 7 (R = H) as a viscous colorless oil; yield, 505 mg (89%).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.16. Found: C, 48.46; H, 7.73.

The 100 MHz p.m.r. spectrum in deuterium oxide, obtained after the solution has stood for 24 h to complete mutarotation, showed signals at τ 4.59 for H-1 of the α anomer (doublet, $J_{1,2} \sim 3.5$ Hz); 5.22 for H-1 of the β anomer (doublet, $J_{1,2} \sim 8.0$ Hz). Signal area ratio H-1α:H-1β was 1.0:4.0. Other signals appeared at τ 6.31 for H-2 of β anomer (multiplet); 7.75–8.40 for two H-3 and two -4 (complex multiplet); 5.05 for OH (singlet); 6.15 for —CH_2— and H-5 (multiplet).

*3,4-Dideoxy-*α,β-DL*-erythro-hexopyranose Triacetate (**7**, R = CH_3CO)*

Treatment of 150 mg of 7 (R = H) with a mixture of 5 ml of acetic anhydride and 5 ml of pyridine at 60° for 30 min and then at room temperature overnight gave a syrup which distilled at 95–97° at 0.2 mm to give 7 (R = CH_3CO) as a viscous oil; yield, 265 mg (90%).

Anal. Calcd. for $C_{12}H_{18}O_7$: C, 52.55; H, 6.62. Found: C, 52.81; H, 6.50.

The i.r. spectrum in chloroform showed strong absorption at 1735 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 3.79 for H-1 of α anomer (doublet $J_{1,2} \sim 3.5$ Hz); 4.34 for H-1 of β anomer (doublet, $J_{1,2} \sim 8.0$ Hz). Signal area ratio H-1α:H-1$\beta \sim 1$:3. Other signals appeared at τ 4.90–5.40 for H-2 (broad multiplet); 7.50–8.70 for two H-3 and two -4 (multiplets); 7.87, 7.90, and 7.93 each a singlet for CH_3CO.

*1,6-Anhydro-2-deoxy-*β-DL*-ribo-hexopyranose (**8**, R = H)*

The reaction of osmic acid with **2** (3) was carried out essentially as described above for the reaction of osmic acid with **1** to form **3** (R = H). From 0.44 g (0.0039 mol) of **2**, treated with 1.0 g (0.0039 mol) of osmic acid was obtained a colorless syrup which was sublimed at 80° at 1.0 mm to provide 0.52 g (92%) of **8** (R = H) melting at 28–31°; lit. m.p. for D isomer, 98–99° (14). The t.l.c. analysis (3% methanol in chloroform) showed only one spot. A satisfactory elemental analysis could not be obtained, carbon being generally low. The diacetate **8** (R = CH_3CO) gave satisfactory analysis (see below).

The i.r. spectrum (neat) showed a broad band at 3300–3500 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed signals at τ 4.55 for H-1 (broad singlet $w/2 \sim 5$ Hz); 5.46 for H-5 (multiplet $w/2 \sim 11$ Hz); 5.94–6.50 for H-3,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

-4, -6*exo*, -6*endo* (overlapping multiplets); 6.30 for two OH (singlet); 8.00 for H-2*endo* (quartet $J_{2exo,2endo} \sim 14$, $J_{2endo,3} \sim 6.5$ Hz); 8.42 for H-2*exo* (quartet, $J_{2exo,3} \sim 10$ Hz).

3,4-Di-O-acetyl-1,6-anhydro-2-deoxy-β-DL-*ribo-hexopyranose (**8**, R = CH_3CO)*

A mixture of 12 ml of acetic anhydride, 10 ml of pyridine, and 1.05 g (0.0072 mol) of **8** (R = H) was stirred at room temperature for 72 h. The excess of acetic anhydride and pyridine was removed and the residual brown oil was neutralized with 10 ml of 6 *N* ammonium hydroxide. The mixture was then extracted with chloroform (6 × 15 ml) and the solution dried ($MgSO_4$). Removal of solvent gave a light brown syrup which formed crystals from hexane. Yield of **8** (R = CH_3CO), 1.24 g (93%), m.p. 80–81°.

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13. Found: C, 52.19; H, 5.95.

The i.r. spectrum in chloroform showed a strong band at 1755 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed signals at τ 4.37 for H-1 (narrow multiplet, $w/2 \sim 5$ Hz); 4.50–5.00 for H-3 and -4 (multiplet); 5.30–5.40 for H-5 (multiplet); 6.05 for H-6*endo* (quartet, $J_{6endo,6exo} \sim 7.5$, $J_{5,6endo} \sim 1.5$ Hz); 6.23 for H-6*exo* (quartet, $J_{5,6exo} \sim 5$ Hz); 7.70–8.20 for H-2*exo* and -2*endo* (multiplet); 7.82 and 7.96, each a singlet for CH_3CO.

2-Deoxy-DL-*ribo-hexopyranose (**9**, R = H)*

A solution of 0.3 g (0.0021 mol) of **8** (R = H) in 15 ml of 1 *N* hydrochloric acid was stirred at 55° for 12 h. The solution was then diluted with 100 ml of water and neutralized with Amberlite IRA-400 resin ($OH^{\ominus}$). The resin was removed by filtration and washed with water. The water was removed from the filtrate and washings at reduced pressure to give a colorless syrup. Crystallization from absolute ethanol gave 0.29 g (88%) of solid **9** (R = H), melting at 138–140°; lit. m.p. of 2-deoxy-D-*ribo*-hexopyranose, 140–142° (12).

The 100 MHz p.m.r. spectrum in D_2O was identical to that of authentic 2-deoxy-D-*ribo*-hexopyranose (12). The two quartets for H-1 at τ 4.00 and 4.40 showed that the α and β anomers were present in the approximate ratio of 1:2 as shown by the integrated areas.

2-Deoxy-DL-*ribo-hexopyranose Tetraacetate (**9**, R = CH_3CO)*

Acetylation was accomplished by the same procedure as that used to prepare **8** (R = CH_3CO) above. From 0.1 g (0.0006 mol) of **9** (R = H) there was obtained 0.17 g (88%) of **9** (R = CH_3CO), a syrup, after sublimation of the crude viscous oil at 95° at 0.75 mm. Attempts to crystallize this were unsuccessful. A t.l.c. analysis using 4% methanol in chloroform showed only one spot.

Anal. Calcd. for $C_{14}H_{19}O_9$: C, 50.76; H, 5.78. Found: C, 50.49; H, 6.08.

The i.r. spectrum (neat) showed a strong band at 1775 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed two anomeric proton signals, at τ 3.64 for H-1 of the α anomer (quartet), $J_{1,2e \text{ or } a} \sim 3.0$, $J_{1,2a \text{ or } e} \sim 5.0$ Hz) and at 3.99 for H-1 of the β anomer (quartet, $J_{1,2a} \sim 7.5$, $J_{1,2e} \sim 3.5$ Hz).

2-Deoxy-1,6:3,4-dianhydro-β-DL-*ribo-hexopyranose (**10**)*

To a stirred solution of 11.2 g (0.01 mol) of **2** in 200 ml of methylene chloride kept at room temperature, was added 21.5 g (0.10 mol) of 87% *m*-chloroperoxybenzoic acid. The resulting mixture was stirred at room temperature for an additional 24 h then filtered to remove precipitated *m*-chlorobenzoic acid. The precipitate was washed with 50 ml of methylene chloride. The combined washings and filtrate were washed with water, then with saturated aqueous sodium carbonate (2 × 50 ml). The aqueous washings were extracted with methylene chloride. The combined methylene chloride solutions were dried ($MgSO_4$) and freed from solvent to provide a light amber oil which was distilled at 55–56° at 1.0 mm to give 9.5 g (74%) of 2-deoxy-1,6:3,4-dianhydro-β-DL-*ribo*-hexopyranose (**10**) containing the *lyxo* isomer **11** to the extent of 2%. The g.l.c. analysis of this distillate with a column of 20% butanediol succinate on Gas-Chrom P at 185°, showed two distinct symmetrical peaks in the area ratio 49:1. A 12′ × 1/4″ preparative g.l.c. column of 20% butanediol succinate on Gas-Chrom P, 60–80 mesh, separated the major component **10**. Reinjection of this separated material showed only one peak.

The minor component **11** could not be freed from the isomer **10** because of tailing from the major peak but was obtained as a mixture of **10** and **11** in the ratio 1:2 respectively as measured by the areas of the signals of the H-5 protons in the 100 MHz p.m.r. spectrum and by the g.l.c. analysis.

Anal. Calcd. for $C_6H_8O_3$ for **10**: C, 56.25; H, 6.29. Found: C, 56.38; H, 6.56.

The i.r. spectrum of **10** (neat) showed no absorption band in the double bond region.

The 100 MHz p.m.r. spectrum of **10** in $CDCl_3$ showed signals at τ 4.65 for H-1 (narrow multiplet, $J_{1,2exo} \sim J_{1,2endo} \sim 1$, $J_{1,3} \sim 1.5$ Hz for long range coupling); 5.35 for H-5 (doublet of narrow quartets, $J_{5,6exo} \sim 4.5$, $J_{5,6endo} \sim 1$, $J_{4,5} \sim 1.5$ Hz); 5.95 for H-6*endo* (quartet, $J_{6exo,6endo} \sim 8$ Hz); 6.27 for H-6*exo* (quartet); 6.85–7.05 for H-3 and -4 (narrow multiplet); 7.87 for H-2*exo* (quartet, $J_{2exo,2endo} \sim 16$, $J_{1,2exo} \sim 2.7$ Hz); 8.20 for H-2*endo* (quartet of triplets, $J_{2endo,3} \sim 3.5$, $J_{1,2endo} \sim 1$ Hz).

2-Deoxy-1,6:3,4-dianhydro-β-DL-*lyxo-hexopyranose (**11**)*

The 100 MHz p.m.r. spectrum of this mixture showed the signals found for isomer **10** above. In addition the following signals were perceived. τ 4.60 for H-1 overlapping H-1 of isomer **10** (narrow multiplet $w/2 \sim 6$ Hz); 5.20 for H-5 (triplet $J_{5,6exo} \sim 5$, $J_{4,5} \sim 5$, $J_{5,6endo} < 1$ Hz); 5.97 for H-6*endo* (doublet, $J_{6endo,6exo} \sim 6.5$ Hz); 6.37–6.58 for H-6*exo* and -4 (multiplet); 6.80–7.20 for H-3 overlapping H-3 and -4 of the isomer **10** (multiplet); 7.28–8.23 for H-2*exo* and -2*endo* overlapping the signals for these protons of the isomer **10** (multiplet).

1,6-Anhydro-2-deoxy-β-DL-*arabino-hexopyranose (**12**)*

A mixture of 1.46 g (0.014 mol) of **10** in 5% aqueous potassium hydroxide was stirred and heated under reflux for 24 h. It was then cooled, neutralized with dilute hydrochloric acid to p*H* 8, saturated with sodium chloride, and then extracted continuously for 65 h with chloroform. The chloroform extract was dried ($MgSO_4$), filtered, and freed from solvent to provide a syrup.

This was sublimed at 78–85° at 0.2 mm to give 1.6 g (79%) of the diol **12** as colorless needles melting at 98–101°. The t.l.c. of this material (on silica gel with 20% methanol in chloroform) showed only one spot; lit. m.p. of D isomer 156–153° (14).

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.89. Found: C, 49.38; H, 6.81.

The i.r. spectrum in $CHCl_3$ showed a broad band at 3420 and a narrower band at 3580 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed signals at τ 4.40 for H-1 (narrow multiplet $w/2 \sim 4$ Hz); τ 5.48 for H-5 (multiplet, $J_{5,6exo} \sim 6$ Hz); 5.61 for H-6*endo* (doublet of doublets, $J_{6endo,6exo} \sim 7$, $J_{5,6endo} \sim 1$ Hz); 6.05–6.35 for H-3, -4, and -6*exo* (multiplet); 7.02 for two OH (broad singlet $w/2 \sim 6$ Hz); 7.81 for H-2*exo* (doublet of quartets, $J_{2exo,2endo} \sim 14$; $J_{2exo,3} \sim 5$, $J_{1,2exo} \sim 2$ Hz); 8.17 for H-2*endo* (complicated doublet).

2-Deoxy-α,β-DL-arabino-hexopyranose (13)

A stirred solution of 1.12 g (0.0077 mol) of **12** in 50 ml of 1 *N* hydrochloric acid was heated at 55° for 12 h. The mixture was then diluted to 200 ml with distilled water and neutralized with Amberlite IRA-400 ($OH^{\ominus}$). The resulting water solution was treated with animal charcoal and the excess water removed under reduced pressure to afford 1.06 g (84%) of **13**. The t.l.c. analysis (50% methanol in chloroform) showed a single spot with slight tailing. Therefore, the sugar was chromatographed over a short column of Silica Gel G (eluting with 50% methanol in chloroform) to afford a colorless syrup which crystallized as white needles from methanol–ether (m.p. 125–126°). The p.m.r. is identical with that of an authentic sample of the D isomer.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 44.04; H, 7.32.

1,6-Anhydro-2,3-dideoxy-β-DL-erythro-hexopyranose (14)

A solution of the oxirane **10** (0.73 g, 0.0057 mol) in 25 ml of dry ether was added dropwise with stirring, over a 45 min period, to a slurry of 0.23 g (0.006 mol) of lithium aluminum hydride in 35 ml of dry ether. The resulting mixture was then stirred for 20 h and subsequently treated slowly with 15 ml of ether saturated with water, then with 1 ml of 15% aqueous sodium hydroxide. The colorless precipitate was removed by filtration and washed with ether (3 × 10 ml). The combined ether washings and filtrate were dried ($MgSO_4$). Removal of the drying agent and solvent gave a hygroscopic solid which was sublimed at 60° at 0.3 mm to afford 0.68 g (92%) of **14**, melting at 79–81°.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.75. Found: C, 55.07; H, 7.62.

The i.r. spectrum in chloroform showed a band at 3580 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.48 for H-1 (broad singlet $w/2 \sim 4$ Hz, $J_{1,2endo} \sim 1.5$, $J_{1,6exo} \sim 1$ Hz); 5.53 for H-5 (narrow multiplet $w/2 \sim 10$ Hz); 6.04–6.30 for H-6*exo* and -6*endo* (multiplets); 6.33 for H-4 (narrow multiplet $w/2 \sim 8$ Hz); 6.65 for one OH (singlet); 7.78–8.60 for H-3*exo*, -3*endo*, -2*exo*, -2*endo* (multiplets).

Hydrolysis of 14

A solution of 0.37 g (0.00285 mol) of **14** in a mixture of 10 ml of water and 10 ml of 1 *N* hydrochloric acid was kept at 55° for 24 h and then diluted with 50 ml of water. The acid was neutralized with Amberlite IRA-400 ($OH^{\ominus}$). The water was removed from the filtrate under reduced pressure. The residual syrup was chromatographed through a short column of silica gel (eluent, 20% methanol in chloroform) and gave 0.36 (85%) of a viscous syrup. The t.l.c. analysis (20% methanol in chloroform) showed a single spot.

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.63; H, 8.10. Found: C, 47.90; H, 8.12.

The i.r. spectrum (neat) had a broad band at 3390 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in DMSO-d_6 showed a broad unresolved signal over the range τ 8.00–8.80 for the two methylene aliphatic groups, and broad unresolved multiplets over the range τ 4.90–5.50 in the anomeric proton region.

We thank the National Research Council of Canada for their financial assistance in this work.

We are grateful to Dr. V. K. Bhat, Gulf South Research Institute, P.O. Box 117, New Iberia, Louisiana 70561, for the sample of 2-deoxy-D-*ribo*-hexose.

Reactions of 1-Substituted 5-Tetrazolyllithium Compounds; Preparation of 5-Substituted 1-Methyltetrazoles

R. RAAP

R & L Molecular Research Ltd., 8045 Argyll Road, Edmonton 82, Alberta

Received January 29, 1971

1-Methyl-5-tetrazolyllithium undergoes fragmentation to nitrogen and lithium methylcyanamide at temperatures exceeding −50°. Below −60° it is however fairly stable and a useful reagent for the preparation of various 5-substituted 1-methyltetrazoles. It reacts readily with halogens, cyanogen bromide, sulfur, aldehydes, ketones, and acid chlorides but not appreciably with benzyl bromide and benzonitrile. With methyl benzoate it forms a labile addition compound which can be hydrolyzed to 5-benzoyl-1-methyltetrazole.

1-Phenyl-5-tetrazolyllithium rapidly decomposes to lithium phenylcyanamide at temperatures as low as −65 to −70°.

Le méthyl-1 tétrazolyl-5 de lithium se décompose en azote et en méthylcyanamide de lithium pour une température dépassant −50 °C. En dessous de −60° il demeure peu stable et est un réactif utile pour la préparation de divers méthyl-1 tétrazoles substitués en position-5. Il réagit rapidement avec les halogènes, le bromure de cyanogène, les sulfures, les aldéhydes, les cétones, et chlorures d'acide; il est cependant peu réactif vis-à-vis du bromure de benzyle et du benzonitrile. Avec le benzoate de méthyle il forme un composé d'addition labile qui peut être hydrolysé en benzoyl-5 méthyl-1 tétrazole.

Le phényl-1 tétrazolyl-5 de lithium se décompose rapidement en lithium et phénylcyanamide pour une température aussi basse que −65 à −70 °C.

Canadian Journal of Chemistry, 49, 2139 (1971)

Over the past few years we had the opportunity to investigate the reactions of various five-membered heteroaryllithium compounds (1–4). In the course of this work it was discovered that ring fragmentation occurs with 5-(1,2,3-thiadiazolyl)lithium compounds (at −60°) and 5-(1,2,3-triazolyl)lithium compounds (at or above room temperature) to lithium alkynylthiolates and lithium alkynylamides respectively (1, 4) (eq. 1).

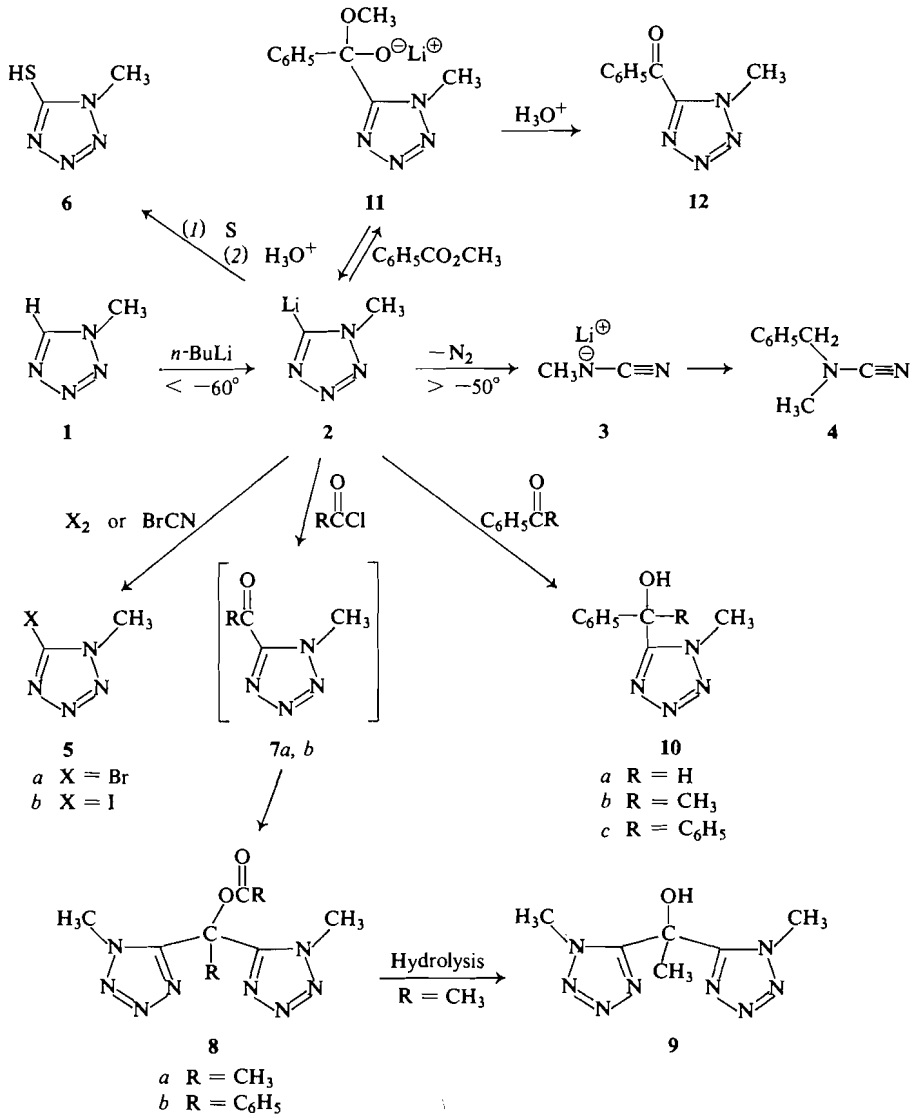
[1]  $\longrightarrow N_2 + R{-}C{\equiv}C{-}X^{\ominus}Li^{\oplus}$

X = S, NR′

1-Substituted tetrazoles constitute another group of compounds where lithiation can result in a ring fragmentation of this type. Kauer and Sheppard (5) have already demonstrated that the reaction of 5-chloro-1-phenyltetrazole with magnesium or *n*-butyllithium results in the formation of phenylcyanamide. An elegant synthesis of carbodiimides, developed by Zimmerman and Olofson (6), involves the ring cleavage of 1,4-disubstituted tetrazolium salts with a weak base. 1-Methyl-5-tetrazolyllithium on the other hand is reportedly stable at −50° (7). In order to gain some insight into their degree of usefulness in organic syntheses we studied the reactions of 1-methyl- and 1-phenyl-5-tetrazolyllithium.

1-Methyl-5-tetrazolyllithium (**2**) was prepared by the careful addition of a solution of 1-methyltetrazole (**1**) in tetrahydrofuran (THF) to *n*-butyllithium at −60 to −65°, conditions similar to the ones employed by Garber and Brubaker (7) for the preparation of di(1-methyl-5-tetrazolyl)-nickel. Although **2** was found to be considerably more prone to ring opening than 1,2,3-triazolyllithium compounds (4) it is sufficiently stable at −60° to permit its use for the preparation of a large variety of 5-substituted 1-methyltetrazoles. The various reactions performed with **2** are outlined in Scheme 1.

When a THF suspension of **2** was left with benzyl bromide at −60° for 1 h, little or no reaction took place. When the temperature was allowed to rise, an exothermic reaction (with gas evolution) started at approximately −50° and the only product isolated was benzylmethylcyanamide (**4**), indicating that **2** had undergone fragmentation to nitrogen and lithium methylcyanamide (**3**). Bromine and iodine however reacted readily with **2** at −60° to give 5-bromo-1-methyltetrazole (**5***a*) and 5-iodo-1-methyltetrazole (**5***b*). In an attempt to prepare the 5-cyano derivative, cyanogen bromide was added to **2**;



SCHEME I

however the attack took place at the bromine as **5***a* was the only product isolated. 5-Mercapto-1-methyltetrazole (**6**) became readily available in good yield by reaction of **2** with sulfur, followed by acidification of the lithium thiolate. The reaction product of **2** with acetyl chloride was 1,1-di(1′-methyl-5′-tetrazolyl)ethyl acetate (**8***a*). The structure of **8***a* was indicated by the i.r. and n.m.r. spectra (see Experimental) and by the formation of 1,1-di(1′-methyl-5′-tetrazolyl)-ethanol (**9**) by reaction with sodium hydroxide. Apparently **2** reacts immediately with the initially formed 5-acetyl-1-methyltetrazole (**7***a*) followed by acylation of the addition product with acetyl chloride. A similar reaction occurred with benzoyl chloride, and **8***b* was obtained. Whereas **2** did not react with benzonitrile at −60°, it reacted readily with benzaldehyde, acetophenone, and benzophenone, thereby providing a good route to the diaryl and triaryl hydroxy compounds **10**.

The affinity of **2** towards carbonyl groups was also indicated by its reaction with methyl benzoate to give **11**, a very labile addition product which rapidly undergoes fragmentation at −50°.

13 14

When a suspension of **11** was quenched with dilute hydrochloric acid 5-benzoyl-1-methyltetrazole (**12**) was obtained in 41% yield.

Analogous to the results obtained in the triazole series (4), 1-phenyl-5-tetrazolyllithium (**13**) decomposed at a lower temperature than **2**. When a solution of 1-phenyltetrazole in THF was added to *n*-butyllithium at −65 to −70° an immediate gas evolution occurred and subsequent addition of acetyl chloride resulted in the formation of *N*-cyanoacetanilide (**14**), which was isolated in 80% yield (eq. 2).

Experimental

All melting points and boiling points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 137 "Infracord" spectrophotometer. The n.m.r. spectra were measured using a Varian Associates Model A-60 spectrometer with tetramethylsilane as a reference. Microanalyses were performed by Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

1-Methyltetrazole (1)

This compound was prepared from hydrazoic acid and methyl isocyanide by a modification of the procedure of Oliveri-Mandalà (8). A solution of methyl isocyanide (23.4 g, 0.57 mol) (9) in 50 ml of benzene was added to a solution of hydrazoic acid, prepared from 71.1 g (1.1 mol) of sodium azide (10), in 450 ml of benzene. The reaction mixture was heated at 75–80° (in pressure bottles) for 30 h. Removal of the solvent followed by crystallization of the residue from *n*-hexane yielded 36.6 g (77%) of pale yellow solid, m.p. 39–41°; reported m.p. 36–37° (8).

1-Methyl-5-tetrazolyllithium Reactions

A solution of 1-methyltetrazole (2.52 g, 0.030 mol) in 10 ml of THF was added dropwise in 15–30 min to a stirred mixture of 15 ml of a 2.0 *M* solution of *n*-butyllithium in *n*-hexane and 25 ml of THF at −60 to −65° in a N_2 atmosphere. An exothermic reaction took place and the lithium compound **2** precipitated as a pale yellow solid. Next a solution of either benzyl bromide, bromine, cyanogen bromide, iodine, acetyl chloride, benzoyl chloride, benzaldehyde, acetophenone, or benzophenone in 10 ml of THF was added dropwise at −60 to −65°. The reaction mixture was maintained at this temperature for an additional 30 min. In the reactions with benzaldehyde, acetophenone, and benzophenone, the temperature was allowed to rise to −30° followed by the addition of 25 ml of 2 *N* hydrochloric acid, drying, and removal of the solvent of the organic layer and recrystallization of the solid residue. In all other instances the temperature was allowed to rise to 0°, followed by removal of the solvent and treatment of the residue with a mixture of ether and water. Compounds **8***a* and **8***b* were isolated by filtration at this stage. For the isolation of **4**, **5***a*, and **5***b* the ether layer was dried, concentrated, and the residue distilled *in vacuo*. The following products were thus prepared.

Benzylmethylcyanamide (**4**) (71%), b.p. 91–95° (0.5 mm); reported b.p. 139–142° (12 mm) (11). At −65° **2** did not react with benzyl bromide. At approximately −50° an exothermic reaction started with concomitant gas evolution. The decomposition of **2** became vigorous at approximately −30° and had to be moderated by cooling. The structure of the product was confirmed by the n.m.r. and i.r. spectra and by the elemental analysis.

5-Bromo-1-methyltetrazole (**5***a*), b.p. 80–82° (0.3 mm), m.p. 72–74° (C_6H_6 – *n*-C_6H_{14}); reported m.p. 72–74° (12); n.m.r. ($CDCl_3$): τ 5.88; yield: 41% (from Br_2), 55% (from BrCN).

5-Mercapto-1-methyltetrazole (6)

A solution of 1-methyltetrazole (15.1 g, 0.18 mol) in 60 ml of THF was dropwise added in 30 min to a stirred mixture of 2 *M* *n*-butyllithium in *n*-hexane (90 ml) and THF (150 ml) at −65 to −70° in a N_2 atmosphere. After 15 min sulfur (6.4 g, 0.20 g at.) was added in one portion at −70°, resulting in a very mildly exothermic reaction. The reaction mixture was stirred at −70° for 1 h and was then allowed to warm to 0° and concentrated to dryness. The residue was treated with 60 ml of water and some sulfur was removed by filtration. The filtrate was cooled, acidified, and extracted with two 60 ml portions of ether. The ether extracts were dried, concentrated, and the solid residue (18 g) recrystallized from $CHCl_3$–CCl_4 (3:1) to give 13.9 g (67%) of white crystals, m.p. 124–126°; reported m.p. 126° (13); n.m.r. (DMSO-d_6): singlet at τ 6.17.

Anal. Calcd. for $C_2H_4N_4S$: C, 20.68; H, 3.47; N, 48.24; S, 27.61. Found: C, 20.34; H, 3.46; N, 48.45; S, 27.27.

5-Benzoyl-1-methyltetrazole (12)

A solution of methyl benzoate (4.1 g, 0.030 mol) in 10 ml of THF was added to a suspension of **2**, prepared in the usual manner from 2.52 g (0.030 mol) of 1-methyltetrazole, in THF at −60 to −70°. The reaction mixture was stirred at this temperature for an additional 30 min and then poured into a stirred mixture of 2 *N* hydrochloric acid (60 ml), ice (40 g), and ether (50 ml). The organic layer was washed with a saturated aqueous sodium chloride solution, dried, and concentrated. The residue, consisting of methyl benzoate and **12**, was treated with 10 ml of ether and cooled. The white crystals, 2.3 g (41%), were collected by filtration and could be recrystallized from a mixture of EtOAc – *n*-C_6H_{14}; m.p. 80–82°; reported m.p. 83–83.5° (14); ν_{max} (Nujol) 1660 cm^{-1} (carbonyl); n.m.r. ($CDCl_3$): phenyl signals at τ 1.4–1.65 (2H) and 2.2–2.5 (3H) and a methyl singlet at 5.63.

Anal. Calcd. for $C_9H_8N_4O$: C, 57.44; H, 4.28; N, 29.77. Found: C, 57.16; H, 4.31; N, 29.64.

1,1-Di(1'-methyl-5'-tetrazolyl)ethanol (9)

A solution of **8***a* (0.76 g, 0.003 mol) was treated with 2 ml of 3 *N* methanolic NaOH. The mixture was left at room temperature for 15 min, then the solvent was removed and the residue dissolved in 5 ml of water. The product was extracted with five 15 ml portions of ethyl acetate. The combined extracts were dried and the solvent removed giving 0.25 g (38%) of solid residue, m.p. 120–123°. When recrystallized from ethyl acetate the material melted at 116–118°, then resolidified and melted at 126–128°. The i.r. spectrum confirmed the presence of a hydroxyl group. The n.m.r. spectrum (DMSO-d_6) consisted of singlets at τ 2.36 (1H), 5.91 (6H), and 7.86 (3H).

Anal. Calcd. for $C_6H_{10}N_8O$: C, 34.29; H, 4.80; N, 53.32. Found: C, 34.29; H, 4.68; N, 53.63.

N-Cyanoacetanilide (14)

A solution of 1-phenyltetrazole (2.92 g, 0.020 mol) (5) in 15 ml of THF was added dropwise in 1 h to a stirred mixture of 10 ml of a 2 *M* solution of *n*-butyllithium in *n*-hexane and 30 ml of THF at −65 to −70° in a N_2 atmosphere. A strongly exothermic reaction (with gas evolution) took place instantaneously. A solution of acetyl chloride (1.73 g, 0.022 mol) in 10 ml of THF was added and the solution was allowed to warm to 0°. The solvent was removed and the residue treated with ether and water. The ether solution was dried, concentrated, and distilled to give 2.6 g (80%) of colorless liquid, b.p. 90–94° (0.1 mm), which solidified and could be recrystallized from CCl_4; m.p. 48–50°; ν_{max} (Nujol) 2240 and 1720 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.56 (s, 5H) and 7.57 (s, 3H).

Anal. Calcd. for $C_9H_8N_2O$: C, 67.48; H, 5.03; N, 17.56. Found: C, 67.46; H, 5.01; N, 17.97.

The author thanks Mr. P. K. Wolfert for his capable technical assistance and Professor R. U. Lemieux, Director of Research, for his interest in this work.

Syntheses of 3,3-Disubstituted 2-Arylacrylic Acids

R. RAAP, C. G. CHIN, AND R. G. MICETICH
R & L Molecular Research Ltd., 8045 Argyll Road, Edmonton 82, Alberta

Received February 1, 1971

The syntheses of several 3,3-disubstituted 2-arylacrylic acids are described. The Wittig reaction between arylglyoxylic esters and isopropylidenetriphenylphosphorane provides an efficient route to 2-aryl-3-methylcrotonic esters. Bromination of these esters with *N*-bromosuccinimide gives a mixture of the 3-bromomethyl-2-arylcrotonic esters and -2-arylisocrotonic esters. The 3-bromomethylcrotonic esters upon heating cyclize to lactones. Also prepared were 2-aryl-3-azidomethylisocrotonic acids and 3-aminomethyl-2-phenylisocrotonic acid. A stereospecific route to 3-azidomethyl-2-phenylisocrotonic acid and *cis*-3-azidomethyl-2-phenyl-2-pentenoic acid has been developed starting from α-methyl- and α-ethylcinnamic esters.

La synthèse de plusieurs acides aryl-2 acryliques disubstitués en position-3,3 est décrite. La réaction de Wittig effectuée entre des esters arylglyoxyliques et l'isopropylidènetriphénylphosphorane conduit avec un bon rendement aux esters de l'acide aryl-2 méthyl-3 crotonique. La bromuration de ces esters avec le *N*-bromosuccinimide conduit à un mélange des esters de l'acide bromoéthyl-3 aryl-2 crotonique et de l'acide aryl-2 isocrotonique. Les esters de l'acide bromoéthyl-3 crotonique se cyclisent en lactones par chauffage. Il a également été préparé les acides aryl-2 azidométhyl-3 isocrotoniques et aminoéthyl-3 phényl-2 isocrotonique. Une synthèse stéréospécifique des acides azidométhyl-3 phényl-2 isocrotonique et azidométhyl-3 *cis* phényl-2 pentenoique-2 a été développée en partant des esters des acides α-méthyl et α-éthylcinnamique.

Canadian Journal of Chemistry, **49**, 2143 (1971)

The syntheses described in the literature for 3,3-disubstituted 2-arylacrylic acids of the general formula **1** include the dehydration of the corresponding saturated β-hydroxy acids (*1*) and the rearrangement of 2,2-dimethyl-3-hydroxy-3-phenylpropionic esters under the influence of P_2O_5 (*2*). In a recent program directed towards the synthesis of penicillins with broad-spectrum activity we synthesized various hindered acids of this type. This paper reports these syntheses and some reactions of these compounds.

The methods employed for the syntheses of the acids **1** are outlined in Scheme 1. The rather curious P_2O_5 rearrangement of 2,2-dimethyl-3-hydroxy-3-phenylpropanoic esters (**2**, R = C_6H_5), first demonstrated by Blaise and Courtot (*2*), could be extended to halogen substituted phenyl derivatives to give the esters **3** in 20–50% yield. The Wittig reaction between an arylglyoxylic ester and isopropylidenetriphenylphosphorane was found to represent a much more versatile method, also applicable to heteroaryl derivatives, to give the esters **3** in fair to good yields. The esters prepared by one of these two methods are listed

in Table 1. The third approach involved the Wittig reaction between the commercially available benzyltriphenylphosphonium chloride and a ketone. The thus obtained β,β-disubstituted styrenes **4** could subsequently be brominated, dehydrobrominated, lithiated, and carboxylated to give the acids **1** in good overall yield. This method, particularly useful for the preparation of 3-methyl-2-phenylcrotonic acid (**1**, R = C_6H_5, $R^1 = R^2 = CH_3$) and 3-ethyl-2-phenyl-2-pentenoic acid (**1**, R = C_6H_5, $R^1 = R^2 = C_2H_5$), has the added advantage of avoiding the hydrolysis step. The Wittig reaction between ethyl phenylglyoxylate and dichloromethylenetriphenylphosphorane provided ethyl 3,3-dichloro-2-phenylacrylate (**1**, R = C_6H_5, $R^1 = R^2$ = Cl) in 36% yield. The latter ylid was prepared *in situ* by heating triphenylphosphine with carbon tetrachloride by the procedure of Rabinowitz and Marcus (3).

The esters **3** were hydrolyzed by heating under reflux in a mixture of 6 *N* hydrochloric acid and acetic acid for 4–16 h except for ethyl 3-methyl-2-thiazolylcrotonate and methyl 3-methyl-2-(1-methyl-2-pyrrolyl)crotonate which could be hydrolyzed in good yield with refluxing methanolic sodium hydroxide, whereas acid hydrolysis resulted in decomposition. In most other instances base hydrolysis led to extensive decomposition. The acids thus prepared are listed in Table 2.

The 2-aryl-3-methylcrotonic esters and acids could readily be brominated with *N*-bromosuccinimide in carbon tetrachloride. Bromination of the esters **3** with an equivalent amount of NBS gave a mixture of the isocrotonic ester **7** and crotonic ester **8** (Scheme 2); the isomer ratio could be determined from the n.m.r. spectra.[1] Upon distillation of a mixture of **7** and **8** only the isocrotonic esters **7** distilled, whereas **8** cyclized to the lactones **9** with the loss of alkyl bromide. The

[1]For the phenyl and phenyl-substituted derivatives **7** and **8**, the chemical shift (in CCl_4) of the allylic methyl protons are in the regions τ 7.65–7.87 and 8.16–8.25 respectively, for the allylic methylene protons in the regions 6.24–6.35 and 5.38–5.65 respectively. When Ar = 5-chloro-2-thienyl the differences in chemical shifts between isomers **7** and **8** are less pronounced, with the methyl signals at τ 7.87 and 7.98 and the methylene signals at 6.03 and 5.74 respectively.

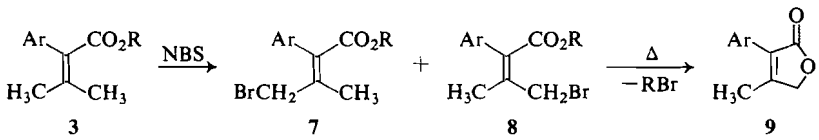
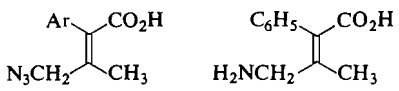
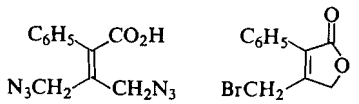


SCHEME 2

lactones **9** could be isolated by distillation and purified by recrystallization from carbon tetrachloride. Table 3 gives the isolated yields and some physical constants of the isocrotonic esters **7** and lactones **9**,[2] that were prepared. The bromine in **7** could be replaced by azide by reaction with sodium azide in aqueous acetone and subsequent acid hydrolysis provided the azido acids **10**. The bromination of 2-aryl-3-methylcro-



10 **11**



12 **13**

tonic acids with 1 equiv of NBS again gave rise to a mixture of the isomeric monobromo acids. When this mixture was treated with sodium azide a mixture of **10** and **9** was obtained, the latter compound arising presumably by cyclization of sodium 2-aryl-3-bromomethylcrotonate. This opened a route to the synthesis of 3-aminomethyl-2-phenylisocrotonic acid (**11**) by treatment of the mixture of isomeric monobromo acids with ammonium hydroxide. The bromination of methyl 3-methyl-2-phenylcrotonate or the acid with 2 equiv of NBS resulted in the formation of a quantitative amount of methyl 4-bromo-3-bromomethyl-2-phenylcrotonate or the dibromo acid. From the dibromo ester, upon reaction with sodium azide, was obtained the diazido ester which could be hydrolyzed, in low yield, to the diazido acid **12**. The dibromo acid upon brief treatment with aqueous sodium bicarbonate cyclized to the lactone **13**.

In order to establish unambiguously the structural assignment for **10** and to obtain homologs of these acids, a synthetic route was devised in which the stereochemistry was controlled throughout and which should lead to only one of the two possible geometrical isomers. Scheme 3 outlines the sequence of reactions that were successfully carried out to synthesize 3-azidomethyl-2-phenylisocrotonic acid (**21***a*) and *cis*-3-azidomethyl-2-phenyl-2-pentenoic acid (**21***b*) starting from the α-methyl and α-ethyl cinnamic esters **14**. When α-methyl-β-bromoisocinnamyl alcohol (**16***a*) was lithiated and then treated with carbon dioxide, only 3-hydroxymethyl-2-phenylcrotonic acid lactone (**9**, Ar = C_6H_5) was isolated after the work-up, indicating that isomerization had taken place in the lithiation step. This isomerization could be avoided by using the tetrahydropyranyl ether **17**. The azido acid **21***a* was identical with the azido acid **10** prepared from 3-methyl-2-phenylcrotonic ester. The hydroxy acid **19***a* was also obtained (in low yield) by acid hydrolysis of methyl 3-bromomethyl-2-phenylisocrotonate. The hydrolysis of these bromo esters however resulted in considerable isomerization as evident from the formation of the lactone.

The various crystalline 3,3-disubstituted 2-arylacrylic acids prepared in this program are listed in Table 2.

Experimental[3]

All melting points and boiling points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 137 "Infrared" spectrophotometer. The n.m.r. spectra were measured using a Varian Associates Model A-60 spectrometer with tetramethylsilane as a reference. Microanalyses[3] were performed by Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

t-Butyl Phenylglyoxylate

To a solution of phenylglyoxylic acid (54.0 g, 0.36 mol) in 300 ml of anhydrous ether, cooled in an ice–salt mixture, was carefully added with stirring 30 ml of concentrated sulfuric acid. The mixture was cooled in Dry

[2]The n.m.r. chemical shifts (in $CDCl_3$) of the allylic methyl and methylene protons of the lactones **9** in Table 3 were in the region τ 7.74–7.99 and 5.17–5.30 respectively.

[3]Elemental analyses were only performed on the 3,3-disubstituted 2-arylacrylic acids (Table 2) and the lactones **9** (Table 3) and **13**, for the elements indicated. They were all within ±0.4% of the calculated values and are filed in the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

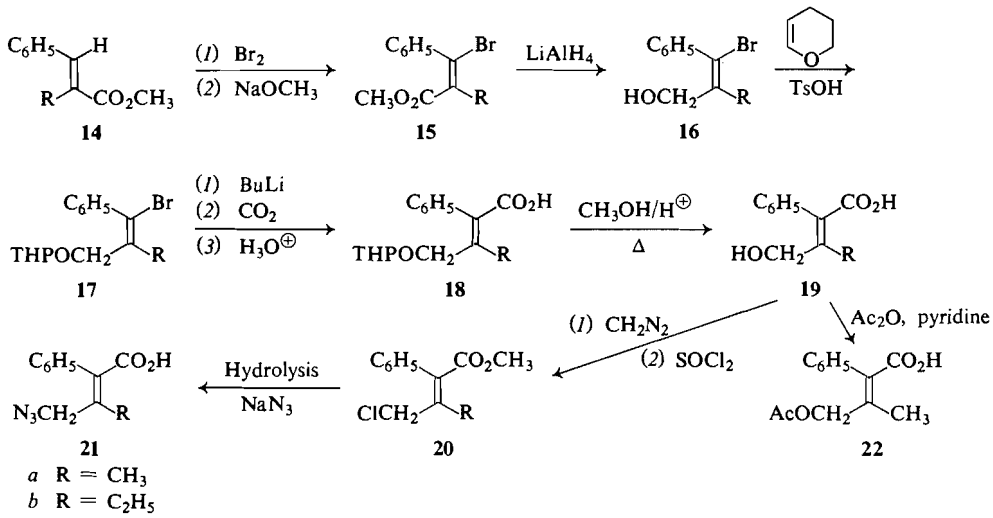

SCHEME 3

Ice – acetone and isobutylene (45.0 g, 0.80 mol) was added. The reaction mixture was allowed to warm slowly to 0° and kept at 0° for 1 day. It was then poured into 200 ml of ice-water. The ether layer, after washing with water and 2 *N* aqueous sodium carbonate, was dried, concentrated, and the residue distilled *in vacuo* to give 51.7 g (70%) of product, b.p. 86–93° (0.5–0.8 mm).

2-Aryl-3-methylcrotonic Esters. General Procedures

(a) From 3-Aryl-3-hydroxy-2,2-dimethylpropanoic Esters with P_2O_5

A solution of the hydroxypropanoic ester (0.10 mol) (2, 4) in 20 ml of benzene was added dropwise in approximately 5 min under vigorous stirring to a suspension of P_2O_5 (0.09 mol) in 40 ml of benzene. The reaction mixture was heated and the benzene distilled off at atmospheric pressure. The last traces of benzene were removed under reduced pressure. The reaction flask was then connected to a vacuum pump and immersed in an oil bath heated at approximately 200°. All volatile material was collected by distillation *in vacuo*. The product was purified by a fractional distillation.

(b) From Arylglyoxylic Esters by a Wittig Reaction

In a N_2 atmosphere a 1.6 *M* solution of *n*-butyllithium in *n*-hexane (64 ml, 0.10 mol of butyllithium) was dropwise added in 15–30 min to a stirred suspension of isopropyltriphenylphosphonium bromide (38.5 g, 0.10 mol) (5) in 200 ml of anhydrous tetrahydrofuran, cooled at 0°. The mixture was stirred at 0° for an additional 30 min, then a solution of the arylglyoxylic ester (0.10 mol) (6–9) in 50 ml of tetrahydrofuran was added in one portion. The cooling bath was removed and the reaction mixture left at room temperature for approximately 3 h (frequently the mixture was left overnight). The solvent was removed, the residue treated with water (100 ml), and the organic material extracted with ether (2 × 100 ml). The ether extract was dried and the ether removed. The residue was treated with *n*-hexane (sometimes a small amount of benzene was added as well) and, after cooling, triphenylphosphine oxide was removed by filtration. Removal of the solvent and distillation of the residue *in vacuo* provided the desired product.

The compounds prepared by either one of the two outlined procedures are listed in Table 1.

Ethyl 3,3-Dichloro-2-phenylacrylate

A mixture of triphenylphosphine (26.2 g, 0.10 mol), ethyl phenylglyoxylate (17.8 g, 0.10 mol), and carbon tetrachloride (75 ml) was heated under reflux for 7 h. To the mixture was added 100 ml of *n*-hexane and the triphenylphosphine oxide removed by filtration. The filtrate was concentrated and the residue distilled *in vacuo* to give 17.7 g of distillate, b.p. 92–102° (1.0 mm), a mixture of product and ethyl phenylglyoxylate. The two components were separated by a fractional distillation using a spinning-band column. Ethyl 3,3-dichloro-2-phenylacrylate, 8.9 g (36%), was obtained as a clear liquid, b.p. 71° (0.1 mm).

2-Aryl-3-methylcrotonic Acids. General Procedure

The ester (1.0 g) was heated under reflux in a mixture of acetic acid (10 ml) and 6 *N* hydrochloric acid (5–10 ml, depending on the solubility of the ester) for the time indicated in Table 2. Generally the acid precipitated by diluting the mixture with 50 ml of water and cooling. In other instances the acetic acid was removed under reduced pressure, the residue diluted with water and the product extracted with ether. The acids are listed in Table 2 together with their melting points and n.m.r. chemical shifts of the methyl groups.

β,β-*Diethylstyrene*

Benzyltriphenylphosphonium chloride (194 g, 0.5 mol) (Carlisle Chemical Works Inc., Reading, Ohio) was added in portions, at room temperature, to a solution of sodium methoxide, prepared from 11.5 g (0.5 g at) of sodium, in 250 ml of methanol in a N_2 atmosphere. An endothermic reaction occurred and an orange color developed. For completion of the reaction the mixture was stirred for an additional 30 min, then 3-pentanone (64.5 g, 0.75 mol) was added and the mixture heated

For personal use only.

under reflux for 6 h. After cooling, the mixture was filtered and the solvent removed from the filtrate. The oily residue was triturated with cold *n*-hexane and the precipitated triphenylphosphine oxide removed by filtration. Removal of the solvent and distillation of the residue *in vacuo* gave 44.8 g (56%) of product, b.p. 92° (9 mm).

β,β-*Dimethylstyrene* (83%) b.p. 64° (9 mm), was prepared in the same manner using acetone instead of 3-pentanone; reported b.p. 76–77° (11 mm) (10).

α-Bromo-β,β-diethylstyrene

A solution of bromine (20.5 g, 0.128 mol) in CCl_4 (25 ml) was added dropwise with stirring to an ice-cooled solution of β,β-diethylstyrene (20.0 g, 0.125 mol) in 25 ml of CCl_4. The resulting dibromo compound (40.0 g, 0.125 mol) was isolated by removal of the solvent and added to a suspension of sodium hydride (3.4 g, 0.14 mol) in 200 ml of benzene. The mixture was stirred and heated under reflux for 12 h with periodic addition of small amounts of methanol (0.5 ml every 30 min). After cooling, the mixture was washed with water and the benzene solution dried. Removal of the solvent, followed by distillation of the residue *in vacuo* gave 18.3 g (64%) of product, b.p. 64–68° (0.3 mm).

α-*Bromo-β,β-dimethylstyrene* (85%), b.p. 52–58° (0.3 mm), was prepared similarly.

3-Ethyl-2-phenyl-2-pentenoic Acid

In a N_2 atmosphere a 1.6 *M* solution of *n*-butyllithium in *n*-hexane (9.4 ml, 0.015 mol of butyllithium) was added dropwise with stirring to a solution of α-bromo-β,β-diethylstyrene (2.9 g, 0.012 mol) in 100 ml anhydrous THF, at −65°. The reaction mixture was cooled at −65° for 1 h, and then poured into a large excess of solid carbon dioxide. When the mixture had reached room temperature, the solvent was removed, the residue dissolved in 30 ml of water, and this solution washed with ether. The aqueous solution was acidified and the product extracted with ether. Drying and removal of the solvent gave 1.9 g (76%) of white solid which could be recrystallized from *n*-hexane; m.p. 104–106°; reported m.p. 105–106° (1). The acid is further described in Table 2.

3-Methyl-2-phenylcrotonic acid (61%), m.p. 151–153°, was prepared in the same manner from α-bromo-β,β-dimethylstyrene; reported m.p. 151° (2).

2-Aryl-3-bromomethylisocrotonic Esters (7) and 2-Aryl-3-hydroxymethylcrotonic Acid Lactones (9). General Procedure

A mixture of 2-aryl-3-methylcrotonic ester (0.10 mol), *N*-bromosuccinimide (17.8 g, 0.10 mol), benzoylperoxide (0.2–0.4 g), and CCl_4 (250 ml) was heated under reflux for 1 h. The succinimide was filtered off and the solvent removed leaving a residue which, according to the n.m.r. spectra, primarily consisted of the two isomeric monobromo compounds but also contained small amounts of the dibromo compound and starting material. The residue was slowly heated *in vacuo*. At approximately 100–120° a decomposition took place as was evident from the increase in pressure. When the decomposition was complete the bath temperature was raised further and the 2-aryl-3-bromomethylisocrotonic ester was distilled. A higher boiling distillation fraction consisted of the lactone which solidified upon cooling and was recrystallized from CCl_4. In the case of ethyl 2-(5-chloro-2-thienyl)-3-methylcrotonate the bromomethylisocrotonic ester decomposed upon distillation and only the lactone could be isolated. The bromomethylisocrotonic esters and lactones prepared in this way are described in Table 3.

Monobromination of 2-Phenyl- and 2-p-Methoxyphenyl-3-methylcrotonic Acid with N-Bromosuccinimide

A mixture of 3-methyl-2-phenylcrotonic acid (36.4 g, 0.206 mol), NBS (36.7 g, 0.206 mol), benzoyl peroxide (0.5 g), and CCl_4 (600 ml) was heated under reflux for 1 h. The mixture was cooled, filtered, and the filtrate concentrated to dryness giving 58 g (100%) of white solid residue, m.p. 92–96°. The n.m.r. spectrum indicated the product to be a mixture of 3-bromomethyl-2-phenylisocrotonic acid, 3-bromomethyl-2-phenylcrotonic acid, 4-bromo-3-bromomethyl-2-phenylcrotonic acid, and starting material in relative amounts of 6:3:1:1 respectively. In the bromination of 2-*p*-methoxyphenyl-3-methylcrotonic acid the ratio of the corresponding products was 6:2:1:1 respectively.

2-Aryl-3-azidomethylisocrotonic Esters

A mixture consisting of 2-aryl-3-bromomethylisocrotonic ester **7** (0.050 mol), sodium azide (3.6 g, 0.055 mol), water (10 ml), and acetone (90 ml) was stirred at room temperature for 3 h. The acetone was removed and water and ether were added to the residue. The ether solution was dried and the solvent removed giving a quantitative amount of the 2-aryl-3-azidomethylcrotonic ester as a liquid residue.

*2-Aryl-3-azidomethylisocrotonic Acids (**10**)*

(a) By Hydrolysis of the Ester

The 2-aryl-3-azidomethylisocrotonic esters (0.050 mol) were heated under reflux in a mixture of acetic acid (100 ml) and 6 *N* hydrochloric acid (50–75 ml) for 2–6 h. The mixture was concentrated to dryness and water and ether added to the residue. The acidic material was extracted from the ether solution with 2 *N* aqueous Na_2CO_3 followed by acidification of the carbonate extract and extraction of the product with ether. Drying and removal of the ether gave the crude azido acid. The recovered neutral material consisted mainly of starting material and was generally subjected again to the same hydrolysis procedure. The azido acids were generally obtained as oils (containing some of the other geometrical isomer resulting from partial isomerization in the hydrolysis) and could be purified by chromatography on silica gel by elution with 10% ether in benzene. The azidomethylisocrotonic acids that were obtained crystalline are described in Table 2.

(b) From 2-Aryl-3-bromomethylisocrotonic Acid

The crude product (38.3 g, 0.15 mol) from the monobromination of 3-methyl-2-phenylcrotonic acid was dissolved in 360 ml of acetone and treated with a solution of sodium azide (9.8 g, 0.15 mol) in 40 ml of water. The mixture was stirred overnight at room temperature, then the acetone was removed and the residue, after dilution with 100 ml of water, extracted with ether. The aqueous solution was cooled and acidified, resulting in a precipitate of 3-azidomethyl-2-phenylisocrotonic acid; 3.2 g, m.p. 96–100°. The ether solution was extracted with two 50 ml portions of 2 *N* aqueous Na_2CO_3. The carbonate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

extract was cooled and acidified to give an additional 12.2 g of the azido acid after recrystallization from 1:2 mixture of CCl_4 and *n*-hexane, m.p. 87–90°; total yield 15.4 g (47%). The low m.p. was due to some contamination with 3-methyl-2-phenylcrotonic acid. The neutral material (9.1 g) obtained by drying and removal of the ether consisted mainly of the lactone.

3-Azidomethyl-2-*p*-methoxyphenylisocrotonic acid was prepared in the same manner from the crude bromo acid and was obtained as a pale yellow oil (50% yield): ν_{max} (Nujol) 2100 and 1685 cm^{-1}; n.m.r. ($CDCl_3$): τ – 1.4 (s, CO_2H), 2.97 (AB quartet, phenyl protons), 6.22 (s, overlapping OCH_3 and N_3CH_2), and 7.81 (s, CH_3).

3-Aminomethyl-2-phenylisocrotonic Acid (11)

The crude product (56.0 g, 0.2 mol) from the monobromination of 3-methyl-2-phenylcrotonic acid was added in portions in 20 min, with stirring, to 600 ml of concentrated ammonium hydroxide cooled in ice. The mixture was kept at 15–20° for an additional 1.5 h, then it was concentrated under reduced pressure to half its original volume and extracted with ether. From the ether extract was obtained, after recrystallization from CCl_4, 5.5 g (16%) of 3-hydroxymethyl-2-phenylcrotonic acid lactone, m.p. 73–82°. The aqueous solution was further concentrated to a volume of approximately 75 ml and cooled at 0° overnight. The white solid was filtered off, washed with ice-water, and dried; 7.2 g (19%), m.p. 222–223° (dec.). An analytical sample, m.p. 213–214° (dec.), prepared by recrystallization from water and drying *in vacuo* at 60° over P_2O_5, still contained some water.

Anal. Calcd. for $C_{11}H_{13}NO_2 \times 0.5\ H_2O$: C, 65.97; H, 7.05; N, 7.00. Found: C, 66.21; H, 7.21; N, 7.32.

The amino acid was further characterized as its *p*-nitrocarbobenzoxy derivative, m.p. 132–133°, prepared by reaction with *p*-nitrobenzyl chloroformate in aqueous THF at p*H* 7–9 (76% yield). More information on these acids is given in Table 2.

Dibromination of 3-Methyl-2-phenylcrotonic Acid with NBS

A mixture of 3-methyl-2-phenylcrotonic acid (14.5 g, 0.0825 mol), NBS (29.4 g, 0.165 mol), benzoyl peroxide (0.2 g), and CCl_4 (400 ml) was heated under reflux for 1.5 h. The mixture was cooled, filtered, and the filtrate concentrated to a volume of approximately 150 ml. Upon cooling *4-bromo-3-bromomethyl-2-phenylcrotonic acid* crystallized from the solution as fine white needles; 23.9 g (87%), m.p. 116–119° (dec.). By recrystallization from CCl_4 the decomposition point could be raised to 127–128°. Although no impurities could be detected in the n.m.r. spectrum (Table 2), the elemental analyses were unsatisfactory and not reproducible. A small sample (2.7 g, 0.008 mol) was added in portions with stirring to 40 ml of 1 *N* aqueous $NaHCO_3$ at room temperature. The white precipitate of *4-bromo-3-hydroxymethyl-2-phenylcrotonic acid lactone* (**13**) (1.2 g, 60%) was collected by filtration and recrystallized from CCl_4; m.p. 94–96°; ν_{max} (Nujol) 1750 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.50 (s, 5H), 5.00 (s, 2H), and 5.70 (s, 2H). Anal. $C_{11}H_9BrO_2$: CHBr.

4-Azido-3-azidomethyl-2-phenylcrotonic Acid (12)

A mixture of methyl 3-methyl-2-phenylcrotonate (19.0 g, 0.104 mol), NBS (37.0 g, 0.208 mol), benzoyl peroxide (0.5 g), and CCl_4 (350 ml) was heated under reflux for 2 h, resulting in the formation of a quantitative amount of methyl 4-bromo-3-bromomethyl-2-phenylcrotonate as a yellow oil; ν_{max} (neat) 1720 cm^{-1}; n.m.r. (CCl_4): sharp singlets at τ 2.67 (phenylprotons), 5.47 (CH_2 *trans* to phenyl), 6.00 (CH_2 *cis* to phenyl), and 6.32 (OCH_3). This dibromo ester (36.0 g, 0.104 mol) was stirred with sodium azide (13.5 g, 0.21 mol) in a mixture of water (40 ml) and acetone (360 ml) for 3 h at room temperature, giving the diazido ester as a yellow oil in quantitative amount (28.5 g); ν_{max} (neat) 2100 and 1730 cm^{-1}. This ester could be hydrolyzed to the diazido acid (ν_{max} (Nujol) 2100 and 1685 cm^{-1}) by heating under reflux with a 2:3 mixture of 6 *N* hydrochloric acid and acetic acid. The acid, which had to be purified by chromatography on silica gel, was obtained in low yield and is further described in Table 2.

Methyl β-Bromo-α-methylisocinnamate (15a) and Methyl β-Bromo-α-ethylisocinnamate (15b)

The methyl ester of α-methylcinnamic acid (300 g, 1.7 mol) (11) in CH_2Cl_2 (300 ml) was treated with bromine (287 g, 1.8 mol) at 25–30°, followed by removal of the solvent. A mixture of the crude dibromo compound, sodium hydride (45.6 g, 1.9 mol), and benzene (300 ml) was treated with methanol, in portions, until the further addition of methanol did not result in any more gas evolution. The mixture was heated under reflux for 5 h, then stirred at room temperature overnight and washed with water. The benzene solution was dried, concentrated, and the residue fractionally distilled *in vacuo* to give 291 g (67%) of product, b.p. 106–111° (1.0 mm).

Compound **15***b* (79%), b.p. 100–110° (0.25–0.5 mm), was prepared in the same manner from the methyl ester of α-ethylcinnamic acid (12).

α-Methyl- and α-Ethyl-β-bromoisocinnamyl Alcohol (16a, b)

A solution of **15***a* (114.8 g, 0.45 mol) in ether was added dropwise to a stirred suspension of lithium aluminum hydride (17.1 g, 0.45 mol) in 200 ml of anhydrous ether, at 0–5°. When the addition was completed the mixture was stirred at this temperature for an additional 1 h, then very carefully water was added, followed by 6 *N* sulfuric acid. The ether solution was dried, concentrated, and distilled *in vacuo* to give 90 g (88%) of **16***a*, b.p. 118–122° (1.5 mm); n.m.r. (CCl_4): τ 2.8 (s, 5H), 6.16 (s, 2H), 6.60 (s, 1H) and 7.98 (s, 3H).

Compound **16***b*, b.p. 112–117° (0.7 mm), was prepared in the same way (88%).

Tetrahydropyranyl Ethers of 16 (17a, b)

To a solution of **16***a* (137.4 g, 0.60 mol) in freshly distilled dihydropyran (94 g, 1.12 mol) at 0°, a few crystals of *p*-toluenesulfonic acid monohydrate were added. The mixture was stirred at 0° for 1 h, at 20° for an additional 1 h and was concentrated under reduced pressure. The residue was dissolved in ether and this solution was washed with an aqueous sodium bicarbonate solution and water, then dried and concentrated to dryness to give a quantitative amount of **17***a*. In the same manner was prepared **17***b*. Attempted distillation of these compounds resulted in decomposition and regeneration of the alcohols.

*Tetrahydropyranyl Ethers of 3-Hydroxymethyl-2-phenylisocrotonic Acid and cis-3-Hydroxymethyl-2-phenyl-2-pentenoic Acid (**18***a*, *b*)*

In a N_2 atmosphere a 1.6 *M* solution of *n*-butyllithium in *n*-hexane (194 ml, 0.31 mol of butyllithium) was dropwise added to a stirred solution of **17***a* (87.1 g, 0.28 mol) in 700 ml of ether at −65 to −70°. Towards the end of the addition some THF was added to redissolve the precipitate. The reaction mixture was stirred at −70° for an additional 1 h, then poured on solid CO_2, and left overnight. The solvent was removed, the residue was dissolved in water, and this solution, after washing with ethyl acetate, acidified. The product was extracted with ethyl acetate. The extract was dried, the solvent removed, and the solid residue washed with *n*-hexane to give 51 g (66%) of off-white solid, m.p. 90–97°, which was not further purified.

Compound **18***b* was prepared by the same procedure (40%).

*3-Hydroxymethyl-2-phenylisocrotonic Acid (**19a**) and cis-3-Hydroxymethyl-2-phenyl-2-pentenoic Acid(**19b**)*

A mixture of **18***a* (2.8 g, 0.010 mol), *p*-toluenesulfonic acid monohydrate (0.10 g), and methanol (40 ml) was heated under reflux for 8 h. The mixture was concentrated, the residue dissolved in ethyl acetate, and this solution extracted with aqueous sodium bicarbonate. A small amount (0.4 g) of a lactone was isolated from the ethyl acetate solution. The bicarbonate extract was cooled, acidified, and the precipitated solid recrystallized from ethyl acetate to give 1.5 g (78%) of **19***a*, m.p. 126–129°. The acid **19***b*, m.p. 160–164°, was prepared analogously (55%). The acids **19** are further described in Table 2.

*3-Acetoxymethyl-2-phenylisocrotonic Acid (**22**)*

The hydroxy acid **19***a* (4.0 g, 0.021 mol), acetic anhydride (8 ml), and pyridine (10 ml) were allowed to stand at room temperature overnight. The mixture was poured into ice-water (25 ml), cooled, and acidified. The product was collected by filtration and recrystallized from ethyl acetate – *n*-hexane to give 3.0 g (61%) of **22**, m.p. 110–111°; neutralization equivalent 232 (calcd. 234); ν_{max} (Nujol) 1740, 1670, 1620, 1210, and 1012 cm^{-1}. See also Table 2.

*3-Azidomethyl-2-phenylisocrotonic Acid (**21a**)*

An excess of ethereal diazomethane was added to a solution of **19***a* (9.4 g, 0.049 mol) in 10 ml of methanol at 0°. The crude hydroxy ester (10 g, 0.049 mol), obtained by removal of the solvent, was treated at 0° with 30 ml of thionyl chloride, resulting in an immediate reaction. The excess of thionyl chloride was removed and the residual chloro ester **20***a* (11.1 g, 0.049 mol) was stirred for 23 h at 25° with sodium azide (3.9 g, 0.06 mol), water (16 ml), and acetone (160 ml), then worked-up in the usual manner to give 11.15 g (99%) of the azido ester as a yellow oil; ν_{max} (neat) 2100, 1720, 1210 and 1060 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.65 (m, 5H), 6.30 (s, 2H) and 7.85 (s, 3H). The hydrolysis of the azido ester has been described. The acid obtained was identical in all respects with the azido acid prepared via bromination of 3-methyl-2-phenylcrotonic acid or methyl 3-methyl-2-phenylcrotonate.

cis-3-Chloromethyl-2-phenyl-2-pentenoic Acid

The chloro ester **20***b* (7.9 g, 0.033 mol), prepared from **19***b* by the same procedure as **20***a*, was treated with 40 ml of concentrated sulfuric acid at 0°. The mixture was stirred at 0° overnight, then poured on ice and the product extracted with ethyl acetate. Drying and removal of the ethyl acetate gave 6.0 g (80%) of acid, m.p. 113–114°, after recrystallization from *n*-hexane (*cf.* Table 2).

*cis-3-Azidomethyl-2-phenyl-2-pentenoic Acid (**21b**)*

This acid, m.p. 80–81°, was prepared by reaction of the chloro acid with sodium azide in aqueous acetone by the procedure described above for the bromo acids; yield, 68%. The material is further described in Table 2.

Nuclear Magnetic Resonance Studies. XXIII. Long-range ^1H–^1H Couplings (J_{HCCOCH}) in some Methyl Bicyclo[2.2.1]heptane-2-carboxylates[1]

H. BROUWER[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London 72, Ontario

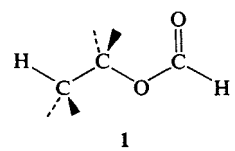
Received February 3, 1971

The methoxyl proton signals of several 3-substituted 2-carbomethoxybicyclo[2.2.1]hept-5-enes and -heptanes appear as doublets because of ^1H–^1H coupling over five σ-bonds (^5J). The dependence of these long-range coupling constants on the nature and orientation of 2- and 3- substituents is discussed in terms of the probable conformations of the 2-carbomethoxyl groups.

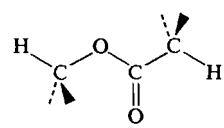
Les signaux des protons du groupe méthoxy de quelques carbométhoxy-2 bicyclo[2.2.1]heptènes-5 et heptanes substitués en position-5 apparaissent sous forme de doublets par suite du couplage ^1H–^1H à travers cinq liaisons σ (^5J). La relation entre ces constantes de couplage à longue distance et la nature et l'orientation des substituants en position-2 et -3 est discutée à la lumière des conformations probables des groupes carbométhoxy-2.

Canadian Journal of Chemistry, 49, 2152 (1971)

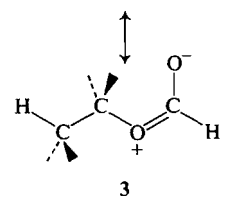
Long-range proton–proton coupling interactions over five bonds, ^5J, have been reported for a variety of systems (1) but the majority of these occur through an unsaturated bonding network. There are relatively few reports of coupling constants between protons separated by five σ-bonds. One of the first reported examples, however, is the long-range coupling observed in the spectra of formic acid esters (2) between the formyl proton and the protons on the β-carbon of the alkyl group, **1**. Other carboxylic acid esters were expected to exhibit similar interactions since the nearest protons are separated by five bonds, **2**, and Hayamizu and Yamamoto (3) subsequently reported measurements of these couplings for a series of 14 saturated aliphatic esters as well as for three unsaturated systems. These compounds exhibit a small, but readily resolved, ^5J splitting either in the methoxyl signals of the methyl esters or in the α-proton absorption of the substituted acetates with values in the range, 0.1–0.25 Hz. Although the signs are not easily determined, the authors assumed these to be positive by analogy with the results for several saturated formic acid esters (4); in the latter series the five-bond couplings are $+0.52 \pm 0.1$ Hz (4). A few additional examples have been reported more recently by Riggs and Verma (5) who ascribed the couplings to transmission through planar "extended-W" σ-bond systems (**1** and **2**) with



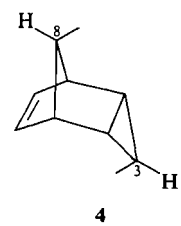
1



2



3



4

the ester group serving to maintain "the necessary degree of planarity". It had been suggested earlier (6), however, that the contribution of resonance forms such as **3** may be a factor although five-bond couplings are known in systems in which such resonance forms cannot contribute. Examples of the latter include $^5J_{14}$ and $^5J_{25}$ for the equatorial protons in pyranose

[1]For Part XXII, see Stothers *et al.* (13).

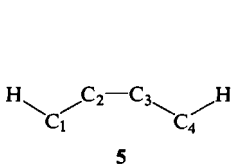
For personal use only.

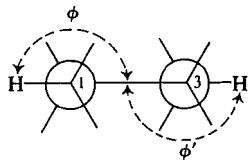
derivatives (7), similarly, $^5J_{25}$ for 1,3-dioxane (8) and $^5J_{3_{x8_s}}$ in **4** (9). According to Barfield and Chakrabarti (1), the indirect mechanism for coupling over five bonds in a fragment of σ-bonds, *e.g.* **5**, leads to a dependence on dihedral angles specified as in eq. 1; where ϕ and ϕ′ are

$$[1]\quad {}^5J_{HH} = (A\cos^2\phi + B\cos\phi + C)(A\cos^2\phi' + B\cos\phi' + C)$$

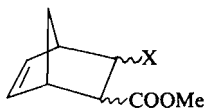
dihedral angles involving the terminal C—H bonds (see **6**); maximum coupling occurs for $\phi = \phi' = 180°$, but $^5J_{HH}$ is independent of the dihedral angle about the central C_2—C_3 bond in **5**. In the course of an investigation of the ^1H and ^{13}C spectra of an extensive series of 3-substituted norbornene- and norbornane-2-carboxylic acid derivatives, **7** and **8**, we have observed five-bond coupling constants in several methyl esters between the methoxyl protons and the C-2 methine proton, *i.e.* J_{HCCOCH}, which we wish to report here.



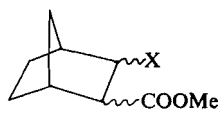
5



6



7



8

The data are listed in Table 1 for a series of 22 norbornene-2-carboxylic methyl esters and 20 methyl norbornane-2-carboxylates. Most of these were obtained by measurements of the wiggle-beat patterns (10) produced by rapid scanning through the methoxyl signals. Although the methoxyl absorption appears as a closely spaced doublet in the normal spectrum, more precise measurements of the spacing are possible with the wiggle-beat technique; the precision of the tabulated data is judged to be ±0.02 Hz.

It is apparent that the long-range coupling in the *exo*-esters is independent of the nature of the *endo*-3-substituents and is slightly attenuated by increasingly bulky *exo*-3-substituents. As expected these ^5J values are independent of the nature of the 5,6 bond; ^5J is essentially the same in both

TABLE 1. Long-range J_{HCCOCH} values* for some 2-carbomethoxynorbornenes **7** and -norbornanes **8**

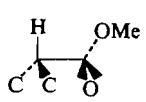
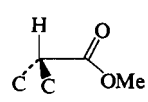
the norbornene and norbornane derivatives. Greater variations in ^5J are found for the *endo*-esters, with the largest values exhibited by the *exo*-3-substituted compounds, averaging 0.27 Hz in the norbornenes. The coupling appears to be slightly smaller in the corresponding norbornanes while ^5J for the *endo*-3-substituted *endo*-2 esters is comparable to that found for the *exo*-esters. There is no marked trend attributable to substituent polarity, but all ^5J values are equal to or smaller than the ^5J for the corresponding unsubstituted esters.

These results may be compared with the previously reported values for various acetates (3, 5) as well as with the data for the methyl *cis*- and *trans*-4-*t*-butylcyclohexanecarboxylates, 0.30 and 0.16 Hz, respectively. The latter value is comparable to ^5J of 0.19 Hz for methyl isobutyrate, an acyclic analog for the cyclic systems. Since the methoxyl group is essentially unhindered in each of the cyclic systems and consequently ϕ can be the same in each, the variation in ^5J must arise from differences in the relative orientation of the carbonyl group with respect to the α-methine proton. There is a general tendency for carbonyl groups to eclipse one of the bonds to the α-carbon (11). Thus the two nonequivalent rotamers available to the cyclohexanecarboxylates may be represented as **9** and **10**, of which **9** will be destabilized in the *cis*-4-*t*-



9



10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

butylcyclohexyl systems because of nonbonded interactions between the carbonyl oxygen and the axial 3-(5-)proton. In **10**, $\phi = 180°$ (*vs.* 60° in **9**); consequently the increase in ^5J for an axial carbomethoxyl relative to that for the equatorial group is readily rationalized. The difference in ^5J values for *exo*- and *endo*-carbomethoxyl groups bonded to the norbornenyl and norbornyl skeletons without 3-substituents may be explained similarly since the rotamer in which the carbonyl bond of an *endo*-COOMe eclipses the C_1—C_2 bond is destabilized by interaction with C-6. The fact that, relative to the unsubstituted cases, ^5J is essentially unaffected by *trans*-vicinal substitution, *i.e.* by *endo*-3 and *exo*-3-substituents in the *exo*- and *endo*-esters, respectively, is consistent with this view. In each series, however, *cis*-vicinal substitution tends to decrease ^5J. This tendency suggests that the decrease results from a steric effect which reduces the relative population in the rotamer corresponding to **10** but dipolar repulsion between electronegative atoms at C-3 and the carbonyl oxygen produces the same effect. In addition, there may be an attractive interaction between the 3-substituents and the ethereal oxygen because of resonance forms corresponding to **3**. In any event the dependence of these five-bond couplings on molecular geometry appears to be qualitatively consistent with eq. 1 as predicted earlier (1).

Experimental

Spectra

All spectra were determined with a Varian HA-100 spectrometer equipped with a Sanborn 151 recorder for the wiggle-beat measurements, using 5 mol % solutions in carbon tetrachloride. The precision of the data is estimated to be ± 0.02 Hz, although repeated measurements showed less scatter for individual cases. The beat frequency of the wiggles produced by rapidly scanning through the methoxyl absorption gives the separation directly. Decoupling experiments confirmed the origins of the observed coupling.

Materials

All of the methyl esters were prepared from the carboxylic acids by reaction with diazomethane in ether. The carboxylic acids are, for the most part, known compounds and were prepared by the Diels–Alder reaction of freshly distilled cyclopentadiene with the appropriate substituted acrylic acid except for the 3-methoxy derivatives (see below). In each case both isomers formed, with the *endo*-acid as the major product; the *exo*-acid was readily separated from the *endo*-isomer using the iodolactone method. Hydrogenation in ethyl acetate over platinum oxide furnished the norbornanecarboxylic acids. Three of the 3-iodo derivatives have not been described previously; their melting points and elemental analyses are as follows.

exo-3-Iodo-*endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid; m.p. 136–138°.

Anal. Calcd. for $C_8H_9O_2I$: C, 36.38; H, 3.44; I, 48.06. Found: C, 36.43; H, 3.44; I, 48.21.

exo-3-Iodo-*endo*-bicyclo[2.2.1]heptane-2-carboxylic acid; m.p. 139–141°.

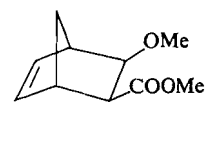
13



14

3-Methoxybicyclo[2.2.1]hept-5-ene-2-carboxylic Acid Esters ***11–14***

These isomers were prepared using a modification of the method described by Miller (12). Propynoic acid (60 g) was added to freshly distilled cyclopentadiene (100 g) at such a rate that the temperature was maintained below 45°, after which the mixture was stirred for 2 h at 40°. Excess cyclopentadiene was removed by evaporation under vacuum and the residue refluxed with methanol (400 ml) containing concentrated H_2SO_4 (2 ml). Polymeric material was removed by filtration and excess methanol evaporated under vacuum. The residue was poured into ice-water and the product (130 g) extracted with methylene chloride which, after removal of solvent, appeared to contain *ca.* 25% of the desired 3-methoxyl substituted esters while the remainder was 2-carbomethoxybicyclo[2.2.1]hepta-2,5-diene. This mixture was dissolved in methanol (250 ml) and benzyltrimethylammonium methoxide (5 g; 40% solution in methanol) was added before the solution was refluxed for 9 h. After removal of methanol, the residue was dissolved in CH_2Cl_2, extracted twice with water, and dried over Na_2SO_4. Fractional distillation of the residue obtained after evaporation of solvent yielded a major fraction containing the *trans* isomers, b.p. 46°/0.4 mm consisting of 94% **11** and 6% **12**. Hydrolysis with 10% Na_2CO_3 solution (200 ml) afforded, by CH_2Cl_2 extraction, a solid residue from which the *endo*-acid (**11**, R = H) was recrystallized from ethyl acetate to yield 22 g, m.p. 109–110°.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 64.32; H, 7.19. Found: C, 64.19; H, 7.13.

Neutralization of the mother liquors with 20% NaOH solution, followed by the reaction with I_2/KI solution permitted isolation of 3.5 g of the minor component (**12**, R = H) *ca.* 95% pure; the contaminant was **11**. Repeated attempts to crystallize **12** failed and the product was esterified to give **12** (R = Me) which was employed for the spectral study. Gas chromatography on a column of diethylene glycol succinate (5% on Chromosorb P, 80/100 mesh) and the proton spectrum showed that **11** (R = Me) was the only contaminant. The higher boiling fractions 48–69°/0.4 mm, shown by gas chromatography to contain varying amounts of **11** and **12** (R = Me) as well as the *cis*-isomers **13** and **14**, were combined and dissolved in pentane. At Dry Ice temperatures, **13** slowly crystallized from solution and, after several recrystallizations, 1.69 g, m.p. 28–30° was obtained. A small sample of **14** (0.1 g) was isolated by preparative gas chromatography on a 15′ × 3/8″ column of diethylene glycol succinate (15% on Chromosorb P, 80/100 mesh) at 180°. The retention times (min) for the four isomers were **11**, 34; **12**, 39.5; **14**, 41.5; **13**, 57.5, at a helium flow rate of 120 ml/min. Analytical g.l.c. indicated that the sample of **14** was at least 97% pure.

We thank the National Research Council of Canada for generous support of this work.

Preparation of 5-Aminomethyl-2-thienylacetic Acid from 1-Methylthio-2-(2′-thienyl)ethyne

R. Raap

R & L Molecular Research Ltd., 8045 Argyll Road, Edmonton, Alberta

Received January 29, 1971

A five-step synthesis of 5-aminomethyl-2-thienylacetic acid is described starting from a 2-thienylethynyl thioether.

On décrit une synthèse qui permet de transformer en cinq étapes le méthylthio-1 (thiényl-2)-2 éthyne en acide aminométhyl-5 thiényl-2 acétique.

Canadian Journal of Chemistry, **49**, 2155 (1971)

In a recent program we required 5-aminomethyl-2-thienylacetic acid. After several unsuccessful attempts to obtain this material via chloromethylation or amidomethylation of 2-thienylacetic acid (or ester) we investigated the use of 1-methylthio-2-(2′-thienyl)ethyne (**1**) as possible starting material. Compound **1** was readily available from 4-(2′-thienyl)-1,2,3-thiadiazole by treatment with *n*-butyllithium at −60° followed by reaction of the resulting lithium 2-thienylethynethiolate with methyl iodide (1).

Lithiation of **1** with *n*-butyllithium at −60° and subsequent reaction with formaldehyde provided the 5-hydroxymethyl thiophene derivative **2** which gave the chloromethyl compound **3** by reaction with thionyl chloride and triethylamine in methylene chloride (Scheme 1). Reaction of **3** with potassium phthalimide in dimethylformamide gave **4**, which could be hydrolyzed to 5-phthalimidomethyl-2-thienylacetic acid (**5**). The hydrolysis was carried out in two stages; **4** was first heated under reflux with dilute sulfuric acid and methanol to give the methylester of **5** which was

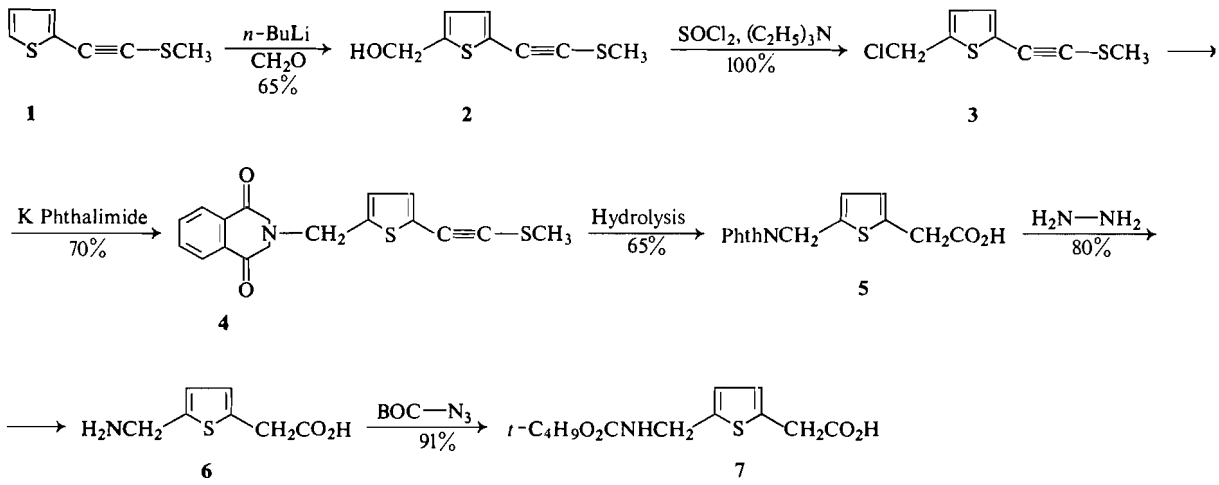


SCHEME 1

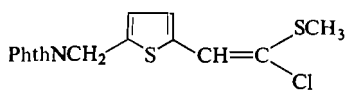
then hydrolyzed at room temperature in a mixture of 6 *N* hydrochloric acid and acetic acid.[1] Hydrazinolysis of **5** in refluxing methanol provided the desired amino acid **6** in good yield. Compound **6** behaved as a normal amino acid and could readily be converted to the BOC-protected amino acid **7** by reaction with *t*-butoxycarbonyl (BOC) azide and triethylamine in aqueous tetrahydrofuran at room temperature.

The successful synthesis of **6** further exemplifies the synthetic value of acetylenic thioethers (3) and indicates that 2-thienylethynyl thioethers may provide useful starting materials for other 5-substituted 2-thienylacetic acids as well.

Experimental

All melting points and boiling points are uncorrected. The i.r. spectra were recorded on a Perkin-Elmer model 137 "Infracord" spectrophotometer. The n.m.r. spectra were measured using a Varian Associates model A-60 spectrometer, with tetramethylsilane as a reference. Microanalyses were performed by Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

[1]When, instead of sulfuric acid, hydrochloric acid was employed in the first stage, the main product was that resulting from the addition of HCl across the triple bond. On the basis of spectral and analytical data and from mechanistic considerations (2) this product was assigned structure **8**.



8

1-Methylthio-2-(2′-thienyl)ethyne (1)

This compound was prepared from 4-(2′-thienyl)-1,2,3-thiadiazole (87.1 g, 0.52 mol) (1), *n*-butyllithium (260 ml of a 2 *M* solution in *n*-hexane), and methyl iodide (110.8 g, 0.78 mol) by the procedure described previously (1). There was obtained 68.7 g (86%) of the product as a pale yellow liquid, b.p. 72–74° (0.2 mm). The i.r. spectrum of the neat liquid contained a weak acetylene band at 2160 cm^{-1}; n.m.r. spectrum (CCl_4): τ 2.7–3.3 (m, 3H), 7.60 (s, 3H).

Anal. Calcd. for $C_7H_6S_2$: C, 54.51; H, 3.92; S, 41.59. Found: C, 54.23; H, 3.87; S, 42.00.

1-Methylthio-2-(5′-hydroxymethyl-2′-thienyl)ethyne (2)

A 2 *M* *n*-butyllithium solution in *n*-hexane (110 ml, 0.22 mol of butyllithium) was added dropwise with stirring, in a nitrogen atmosphere, to a solution of **1** (30.8 g, 0.20 mol) in 200 ml of anhydrous tetrahydrofuran cooled at −60 to −65°. A solution of formaldehyde (8 g, 0.24 mol) in 100 mol of anhydrous THF, prepared immediately before use by thermal depolymerization of paraformaldehyde and collection of the formaldehyde in THF at −60°, was added in one portion at −60°. The reaction mixture was allowed to warm to 0° and treated with 200 ml of 2 *N* hydrochloric acid. The layers were separated and the aqueous layer extracted with ether. The combined organic layers were dried, concentrated, and the residue fractionally distilled *in vacuo* to give 23.7 g (65%) of pale yellow liquid, b.p. 135–140° (0.2 mm). The product solidified upon cooling and could be recrystallized to pale yellow fine needles from a 1:3 mixture of carbon tetrachloride – *n*-hexane; m.p. 34–36°. The i.r. spectrum (Nujol mull) contained a strong OH band at 3100–3500 and a very weak acetylene band at 2150 cm^{-1}. The n.m.r. spectrum (CCl_4) contained two one-proton doublets (J = 3.5 Hz) of an AB quartet at τ 3.01 and 3.27 and singlets at 5.42 (CH_2), 6.64 (OH), and 7.56 (CH_3).

Anal. Calcd. for $C_8H_8OS_2$: C, 52.14; H, 4.38; S, 34.81. Found: C, 51.87; H, 4.19; S, 34.36.

1-Methylthio-2-(5'-chloromethyl-2'-thienyl)ethyne (3)

A solution of thionyl chloride (6.4 g, 0.054 mol) in 35 ml of methylene chloride was added dropwise in 30 min to a stirred solution of **2** (10.0 g, 0.054 mol) and triethylamine (5.5 g, 0.054 mol) in 115 ml of methylene chloride at 0°. The reaction mixture was kept at 0° for an additional 30 min and then treated with 75 ml of water. The methylene chloride solution was dried and the solvent removed giving a quantitative amount (10.9 g) of the chloromethyl compound as a slightly colored liquid residue, which was used for the next step without further purification. In a separate experiment the chloromethyl compound was distilled *in vacuo* (with slight decomposition); b.p. 113–118° (0.4 mm); n.m.r. spectrum (CCl_4): τ 3.04 (q, 2H), 5.33 (s, 2H), and 7.56 (s, 3H).

1-Methylthio-2-(5'-phthalimidomethyl-2'-thienyl)ethyne (4)

A mixture of **3** (10.9 g, 0.054 mol), potassium phthalimide (12.4 g, 0.067 mol), and dimethylformamide (80 ml) was stirred at 40–50° for 5 h, followed by removal of the solvent under reduced pressure. The residue was treated with ethyl acetate (100 ml) and water (50 ml). The ethyl acetate solution was dried, concentrated to a volume of approximately 50 ml and cooled. The pale yellow crystals were collected by filtration; yield 11.8 g (70%), m.p. 131–133°; n.m.r. spectrum (DMSO-d_6): τ 2.06 (s, 4H), 2.85 (AB q, 2H), 5.06 (s, 2H), and 7.53 (s, 3H).

Anal. Calcd. for $C_{16}H_{11}NO_2S_2$: C, 61.32; H, 3.54; S, 20.47. Found: C, 61.42; H, 3.20; S, 20.10.

5-Phthalimidomethyl-2-thienylacetic Acid (5)

A mixture of **4** (17.4 g, 0.0556 mol), methanol (400 ml), and 3 *N* sulfuric acid (60 ml) was heated under reflux for 3 h. The mixture became homogeneous after approximately 2 h. Most of the solvent was removed and the residue treated with ethyl acetate. The ethyl acetate solution was washed with water, dried, and concentrated to dryness, leaving the crude methyl ester as a solid residue (18.5 g, m.p. 77–81°). This was dissolved in 350 ml of acetic acid followed by the addition of 75 ml of 6 *N* hydrochloric acid. The resultant solution was stirred at room temperature for 64 h. After cooling, the white solid precipitate was collected by filtration, washed with water, and taken up in 50 ml of 2 *N* aqueous sodium carbonate. The carbonate solution, after washing with ethyl acetate, was cooled and acidified. The white solid was filtered off, dried, and recrystallized from ethyl acetate to give 8.9 g of white needles, m.p. 180–182°. By concentrating the original filtrate, followed by the same purification procedure, an additional 2.0 g of product, m.p. 180–182°, was obtained. Total yield 10.9 g (65%); ν_{max} (Nujol) 1720 and 1695 cm^{-1}; n.m.r. (DMSO-d_6): τ 2.10 (s, 4H), 3.08 (AB q, 2H), 5.07 (s, 2H), and 6.22 (s, 2H).

Anal. Calcd. for $C_{15}H_{11}NO_4S$: C, 59.79; H, 3.68; N, 4.65; S, 10.64. Found: C, 59.86; H, 3.83; N, 5.02; S, 10.35.

When, instead of 3 *N* sulfuric acid, the same amount of 6 *N* hydrochloric acid was used, yellow crystals of compound **8** precipitated from the reaction mixture in approximately 50% yield; m.p. 135–137° (ethyl acetate); ν_{max} (Nujol) 1700 cm^{-1}; n.m.r. spectrum (DMSO-d_6): τ 2.13 (s, 4H), 2.74 (s, 1H), 2.92 (q, 2H), 5.07 (s, 2H), and 7.55 (s, 3H).

Anal. Calcd. for **8**, $C_{16}H_{12}ClNO_2S_2$: C, 54.93; H, 3.46; Cl, 10.14; S, 18.33. Found: C, 55.05; H, 3.76; Cl, 10.40; S, 18.58.

5-Aminoethyl-2-thienylacetic Acid (6)

5-Phthalimidomethyl-2-thienylacetic acid (7.3 g, 0.0242 mol) was dissolved in 125 ml of refluxing methanol followed by the addition of 97% hydrazine (0.80 g, 0.0242 mol). The reaction mixture was heated under reflux for 16 h, then cooled. The white solid precipitate (6.8 g) was filtered off, treated with 75 ml of water, and this mixture filtered again. The aqueous filtrate was concentrated to dryness and the residue dried to give 3.3 g (80%) of the amino acid, m.p. 228–230° (dec.); n.m.r. spectrum (CF_3CO_2H): τ 2.92 (AB quartet superimposed on broad singlet, 5H), 5.39 (q, 2H), and 5.98 (s, 2H). An elemental analysis was performed on the BOC-amino acid.

5-t-Butoxycarbonylaminomethyl-2-thienylacetic Acid (7)

A solution of *t*-butoxycarbonyl azide (1.43 g, 0.010 mol) in 20 ml of THF was added to a solution of 5-aminomethyl-2-thienylacetic acid (1.38 g, 0.008 mol) and triethylamine (2.0 g, 0.020 mol) in 25 ml of water. The mixture was stirred at room temperature for 16 h, then washed with ether. The aqueous solution was layered with 75 ml of ether and, with ice-cooling and stirring, acidified to p*H* 3. The ether layer was dried and the solvent removed to give 2.0 g (91%) of the BOC-amino acid as a white solid, m.p. 115–117°, which could be recrystallized from an ethylacetate – *n*-hexane mixture; m.p. 116–117°, ν_{max} (Nujol) 3300, 1710, and 1645 cm^{-1}; n.m.r. spectrum ($CDCl_3$): τ 1.53 (s, 1H), 3.21 (s, 2H), 5.59 (d, 2H), 6.19 (s, 2H), and 8.54 (s, 9H).

Anal. Calcd. for $C_{12}H_{17}NO_4S$: C, 53.11; H, 6.32; N, 5.16; S, 11.82. Found: C, 53.30; H, 5.86; N, 5.35; S, 12.17.

Synthesis of β-Poly-α-ethyl-L-aspartate[1]

S. E. MOSCHOPEDIS AND C. MUMFORD[2]
Research Council of Alberta, 11315—87 Avenue, Edmonton, Alberta

Received June 11, 1970[3]

A simple procedure is described for the preparation of *N*-carboxy-L-aspartic anhydride α-esters, and the confirmation of the six-membered ring by i.r. and n.m.r. spectroscopic studies. The polymerization of *N*-carboxy-α-ethyl-L-aspartate to the corresponding β-poly-α-ethyl-L-aspartate is also described.

Un moyen simple de préparation des α-esters de l'anhydride de l'acide *N*-carboxy L-aspartique est décrite. La présence d'un cycle à six chaînons est confirmée par des études i.r. et de r.m.n. La polymérisation du *N*-carboxy L-aspartate d'α-éthyle en β-poly L-aspartate d'α-éthyle correspondant est également décrite.

Canadian Journal of Chemistry, 49, 2158 (1971)

In attempting to synthesize β-poly-α-ethyl-L-aspartate by polymerization of the corresponding *N*-carboxy-L-aspartic anhydride α-ester, we observed that the conventional procedures for the synthesis of the latter (1, 2) are beset with difficulties and lead mainly to unwanted by-products.[4] Furthermore, Birkofer and Modic (3) have shown that β-amino acids do not readily form *N*-carboxy anhydrides by phosgenation.

We have successfully modified the procedure by adding all of the phosgene, as a solution, to the amino acid suspension **1**, since this favors the formation of the carbamyl chloride **2**, and then adding 2 equiv of triethylamine. Addition of triethylamine results in the formation of the triethylammonium salt of the carbamyl chloride **3**, which may promote the nucleophilic attack on the carbonyl group, which subsequently will eliminate the chlorine anion and result in ring closure, as in Scheme 1.

The formation of the six-membered ring anhydride has been confirmed by i.r. and n.m.r. spectroscopic studies. The i.r. spectra of the *N*-carboxy anhydride **4** ($CHCl_3$ and dioxane solutions) showed very prominent absorption bands at 1810 and 1760 cm^{-1}. The five-membered ring Leuch anhydrides exhibit absorptions at 1860 and 1790 cm^{-1} (4). The i.r. spectra failed to show clearly the carbonyl absorption of the esterified α-carboxyl group, which appeared as a shoulder at approximately 1740 cm^{-1}, because it was masked by the strong absorption at 1760 cm^{-1} of the *N*-carboxy anhydride. Therefore, the n.m.r. spectra ($CDCl_3$ solution) of the *N*-carboxy anhydride **4** (R = ethyl) was studied; this further confirmed the presence of the ethyl ester group by exhibiting a quadruplet absorption centered at 5.73 τ and a triplet absorption centered at 8.65 τ, which were assigned to the protons of the ethyl ester group. The presence of the ethyl ester group in the structure of the *N*-carboxy anhydride strongly confirms the formation of a six-membered ring *N*-carboxy anhydride via ring closure by the β-carboxyl group of the α-ethyl aspartate.

Upon heating of the *N*-carboxy-L-aspartic anhydride α-ester above its m.p. at atmospheric and 0.1–0.5 mm pressures for 2 and 5 h, respectively, carbon dioxide was evolved and a polymeric glass-like white material was obtained. The i.r. spectrum of the polymeric product **5** (KBr pellet), besides exhibiting the carbon–hydrogen stretching vibrations at frequencies of 2900 to 3000 cm^{-1}, exhibited absorptions at 3300, 1740, 1650, and 1540 cm^{-1}, which are characteristic of these types of compounds (5). This, combined with the presence of ethoxy groups in the polymer **5**, strongly indicates that the amide bands in the i.r. spectra (absorptions at 1650 and 1540 cm^{-1}) were due to formation of amide bonds from the β-carboxyl group of aspartic acid. Molecular weight determinations have shown that the polymer is a nonamer. Higher molecular weight polymers may be obtained by polymerization of *N*-carboxy-L-aspartic anhydride α-esters in solution (5).

Experimental

Melting points were determined on a Buchi, Dr. Tottoli m.p. apparatus and are uncorrected. The i.r. spectra were recorded on a Beckman IR8 i.r. spectrophotometer. The n.m.r. spectra were taken in deuteriochloroform solutions with a Hitachi Perkin–Elmer R20 high resolution n.m.r. spectrometer using tetramethylsilane as internal standard. Optical rotations were obtained with a Perkin–Elmer polarimeter, Model 141. Elemental analyses were carried out by Alfred Bernhardt Microanalytical Laboratory, West Germany, and Schwarzkopf Microanalytical Laboratory, U.S.A. Molecular weights, determined by the Alfred Bernhardt Microanalytical Laboratory, were measured osmotically in dimethylformamide solution. All apparatus was oven dried at 110 °C for at least 1 h. Solvents were purified and dried by conventional methods.

Preparation of α-Esters of L-*Aspartic Acid (1)*

The method of Kovacs *et al.* (6) was used. For R = ethyl: m.p. 180.5–181° (dec.), $[\alpha]_D^{26}$ +25.5° (*c*, 2.1 water); lit. (6) m.p. 181–183°, $[\alpha]_D^{26}$ +24.2° (*c*, 2.1 water). For R = benzyl: m.p. 168–169.5°, $[\alpha]_D^{26}$ −15.5° (*c*, 5.1 1 *N* hydrochloric acid); lit. (6) m.p. 174–175°.

*Preparation of N-Carboxy-*L-*aspartic Anhydride α-Esters (4)*

Method A

Phosgene (1.18 g, 0.012 mol) dissolved in 10 ml tetrahydrofuran, and triethylamine (2.02 g, 0.02 mol) in 10 ml tetrahydrofuran were added simultaneously, from separate dropping funnels (15 min), to a stirred suspension of dry α-ester of L-aspartic acid (0.01 mol) in 10 ml tetrahydrofuran at 0–5 °C. The resulting slurry was filtered under suction and exclusion of moisture and the precipitate was washed with 10 ml dry ether. The combined filtrates were evaporated at 40° on a rotary evaporator, and further dried under high vacuum. A viscous yellow oil remained which solidified on standing at room temperature. After two crystallizations from chloroform – petroleum ether, the *N*-carboxy anhydride α-ester was obtained in the form of white crystals.

For R = ethyl: yield 0.54 g (≈29%), m.p. 85–86° (dec.), $[\alpha]_D^{26}$ +18.9° (*c*, 1.06 dioxane).

Anal. Calcd. for $C_7H_9N_1O_5$ (mol. wt. 187.15): C, 44.92; H, 4.85; N, 7.48. Found: C, 45.04; H, 4.69; N, 7.66.

For R = benzyl: yield 0.57 g (≈23%), m.p. 101–102° (dec.), $[\alpha]_D^{26}$ +19.8° (*c*, 2.05 dioxane).

Anal. Calcd. for $C_{12}H_{11}N_1O_5$ (mol. wt. 249.21): C, 57.83; H, 4.45; N, 5.62. Found: C, 57.43; H, 4.66; N, 5.41.

Method B

Dry α-ethyl-L-aspartate (3.22 g, 0.02 mol) was suspended in 40 ml tetrahydrofuran. The stirred mixture was cooled to 0–5 °C and 25 ml of tetrahydrofuran containing 1.98 g (0.02 mol) of phosgene was added. The mixture was stirred for 30 min, under cooling, and then 4.05 g (0.04 mol) of triethylamine in 25 ml tetrahydrofuran was added dropwise. The mixture was then filtered and further treated as described in method A. The residue was crystallized from chloroform – petroleum ether. Yield 2.20 g (59%), m.p. 85–86° (dec.), $[\alpha]_D^{26}$ +18.5° (*c*, 1.06 dioxane).

*Preparation of β-Poly-α-ethyl-*L-*aspartate (5)*

(*a*) The *N*-carboxy anhydride of α-ethyl-L-aspartate (0.953 g) obtained under method A or B was slowly heated in a silicone-oil bath at 95 to 100 °C at atmospheric pressure in a flask fitted with a drying tube containing anhydrous calcium chloride. After 2 h, the gas evolution, which had begun at approximately 80°, came to a stop. The white glassy residue (0.624 g), after cooling, could be crushed to a white powder. The substance gave a positive ninhydrin test, and the i.r. spectrum (KBr pellet) showed absorptions centered at 3300, 3080, 2980, 2940, 1740, 1650, and 1540 cm^{-1}. The molecular weight determined osmotically in dimethylformamide was found to be 1247, and the calculated, from the amino-nitrogen (van Slyke) which corresponds to nonapeptide, is 1306; m.p. (dec.) above 240°, melts 253–256°, $[\alpha]_D^{27}$ −2.0° (*c*, 1.0 90% w/w phenol–water).

Anal. Calcd. for $(C_6H_9N_1O_3)_9 \cdot OH_2$ (mol. wt. 1306.27): C, 49.64; H, 6.40; N, 9.65; C_2H_5O, 31.04; H_2N–N, 1.07. Found:[5] C, 49.43; H, 6.55; N, 9.73; C_2H_5O, 30.81; H_2N–N, 1.03.

(*b*) The *N*-carboxy anhydride (2.1 g) was slowly heated in a silicone-oil bath under high vacuum to 95–100 °C and kept at this temperature for 5 h. The white glassy residue (1.48 g), after cooling, was crushed to a fine powder. The polymer gave a positive ninhydrin test and the i.r. spectrum (KBr) pellet was identical to the spectrum of the polymer obtained from section *a*. The molecular weight (osmotically DMF) was found to be 1255, m.p. (dec.) above 240°, 250–253° melts, $[\alpha]_D^{27}$ −2.9° (*c*, 1.0 90% w/w phenol–water).

Anal. Calcd. for $(C_6H_9N_1O_3)_9 \cdot OH_2$ (mol. wt. 1306.27): C, 49.64; H, 6.40; N, 9.65; C_2H_5O, 31.04; H_2N–N, 1.07. Found:[5] C, 49.41; H, 6.19; N, 9.47; C_2H_5O, 30.54; H_2N–N, 1.08.

The authors are indebted to Drs. H. Habgood, S. M. Creighton, and J. G. Speight for commenting on the manuscript, to Miss M. Vetter for valuable assistance, and to Mr. M. Anderson for recording the i.r. and n.m.r. spectra.

A Study of the Pfeiffer Effect in Systems containing Trisoxalatometallate(III) Complexes and Cinchonine Hydrochloride

K. T. KAN AND D. G. BREWER

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received August 4, 1970[1]

The Pfeiffer effect was studied in systems containing cinchonine hydrochloride and trisoxalatometallate(III) complexes of Al, Fe, Cr, Co, and Ir. The Pfeiffer rotatory dispersion curves of the Cr and Co complexes show Cotton effects analogous to that observed in the optical rotatory dispersion (o.r.d.) curves of the respective complexes. The source of the Pfeiffer effect in all these systems is attributed either to an association between the complex ion and the optically active species in solution alone, as in the case of the Ir(III) complex, or to a combination of this association and an "equilibrium shift" between the two enantiomers in solution in favor of one of them, as in the case of the other complexes under investigation.

On a étudié l'effet Pfeiffer dans des systèmes contenant du chlorhydrate de cinchonine et des complexes trisoxalatométallates de Al, Fe, Cr, Co et Ir. On observe que ces courbes de dispersion rotatoire Pfeiffer des complexes du Cr et du Co montrent des effets Cotton analogues à ceux observés dans les courbes de d.c.o. des complexes respectifs. On attribue la source de l'effet Pfeiffer dans tous ces systèmes soit à une association de l'ion complexe avec l'espèce optiquement active seulement en solution (cas du complexe de Ir(III)) ou à une combinaison de cette association et d'un "déplacement d'équilibre" entre les deux énantiomères en solution en faveur de l'un d'eux (cas des autres complexes examinés).

Canadian Journal of Chemistry, 49, 2161 (1971)

Introduction

In 1939, Pfeiffer *et al.* (1–3) observed that the optical rotation of a solution of an optically active compound was altered upon the addition of racemic mixtures of certain optically active complex compounds. A detailed review of the studies of the "Pfeiffer effect" was given by Kirschner, Ahmad, and Magnell (4) and by Kirschner and Ahmad (5).

Early work by Pfeiffer and Nakutsuka (3) proposed that there was a shift in the equilibrium existing between the optical isomers of the compound in solution, resulting in one of the isomers being present in greater quantity. Dwyer *et al.* (6) concluded that the activity coefficients of the optical isomers were different in an asymmetric environment due to "configurational activity" and explained the Pfeiffer effect in terms of this. The controversy was virtually settled when Brasted and his students proved that an association of the enantiomers with the environment compound was the prime source of the Pfeiffer effect in aqueous solution and in methanol, this kind of association being attributed to a combination of van der Waal's force, Debye–Hückel interionic force, and particularly, hydrophobic bonding (7–10).

In this work, we observed that trisoxalatometallate(III) complexes with the formula $K_3M(C_2O_4)_3 \cdot xH_2O$ (M = Al, Fe, Cr, Co, and Ir), exhibit the Pfeiffer effect in cinchonine hydrochloride solution. Since this series of complexes consists of compounds of different lability, the investigation might lead to some further understanding of the Pfeiffer effect.

Experimental

The trisoxalato complexes were prepared by the procedure given in the literature (11, 12). The resolution of the chromium(III), cobalt(III), and iridium(III) complexes was carried out by the method of Dwyer and Sargeson (13).

Cinchonine hydrochloride was obtained from Koch-Light Laboratories, Ltd., and was recrystallized twice from hot water. Analytical grade menthol was used without further purification.

The u.v.–visible spectra were obtained using a Hitachi Ratio Recording spectrophotometer, Model EPS-3T. Optical rotations were determined on a Rudolph Model 200A Photoelectric Polarimeter equipped with a 200 W Mercury Xenon lamp. A Honeywell Electronik 19 Recorder was used to help obtain the polarimeter reading. The optical rotatory dispersion curves were measured with the Rudolph Polarimeter, and subsequently checked with a Durum-Jasco, ORD/UV-5 Recording Spectro-

polarimeter. When using the latter instrument, the large rotation of cinchonine hydrochloride solution under investigation required the expansion of the sensitivity scale and hence reduced the sensitivity. To overcome this, a solution of 1-menthol of suitable concentration in a 1 cm cell was placed in series with the cell containing cinchonine hydrochloride solution. This allowed us to obtain in all the experiments a sensitivity of $\pm 0.002°$. Solutions were studied at a constant temperature of 23 ± 0.5 °C.

Results and Discussion

It was found that the trisoxalato–metal complexes of aluminum(III), iron(III), chromium(III), cobalt(III), and iridium(III) all exhibited the Pfeiffer effect in aqueous solution containing cinchonine hydrochloride. The choice of the concentrations used was a compromise between the strong absorptivity of the chromium and cobalt complexes, and the formation of insoluble diastereoisomers of the complexes and cinchonine hydrochloride at higher concentrations. In all systems studied, the Pfeiffer rotations attain their maximum readings immediately upon the mixing of the complexes with the environment. For the systems containing $Al(C_2O_4)_3^{3-}$ and $Ir(C_2O_4)_3^{3-}$ anion, the rotation remained unchanged for a week. However, the instability of the $Fe(C_2O_4)_3^{3-}$, $Cr(C_2O_4)_3^{3-}$, and $Co(C_2O_4)_3^{3-}$ anions towards heat and light limited our observation to 24 h, during which no change in rotation was noted.

The lability of the tris(oxalato) complexes of trivalent metals follows the trend of Al > Fe > Cr > Co > Ir, which has been established by stability constant, rate of racemization, and ligand exchange measurements (14). The lack of such an analogous trend indicates that the mechanism of the Pfeiffer effect in these systems may be quite complicated. Also, the presence of a magnetic-dipole-allowed d–d transition in complexes of chromium(III) and cobalt(III) contributes greatly to the relatively large Pfeiffer rotations of their complexes at this particular wavelength.

In the systems of trisoxalato complexes with cinchonine hydrochloride, a nearly linear relationship was observed between the Pfeiffer rotation and the concentration of either the complex or the environment compound if the other is held constant, and would suggest that there is no well-defined association (compound formation) between the complex and the environment compound in solution (15, 16). Also, Kirschner and Magnell (16) have used the similar shapes of the o.r.d. curve of the resolved ion and the Pfeiffer rotatory dispersion (P.r.d.) curve of the same cation in the solution of the environment compound to conclude that there was an equilibrium shift between the two enantiomers.

Figures 1 and 2 show the rotatory dispersion curves of solutions containing $M(C_2O_4)_3^{3-}$ ion in cinchonine hydrochloride, and solutions containing the same amount of environment compound alone. The Pfeiffer rotation of $Al(C_2O_4)_3^{3-}$, $Fe(C_2O_4)_3^{3-}$, and $Ir(C_2O_4)_3^{3-}$ shown in Figs. 3 and 4 varies smoothly with respect to the wavelength, whereas a Cotton effect was observed in both the Pfeiffer rotatory dispersion curves of $Cr(C_2O_4)_3^{3-}$ and $Co(C_2O_4)_3^{3-}$ in the wavelength range corresponding to their $^4A_{2g} \rightarrow {}^1T_{2g}$ and $^1A_{1g} \rightarrow {}^1T_{1g}$ magnetic-dipole-allowed d–d transition, respectively. A comparison of the o.r.d. curves of the resolved D(+)-$[Cr(C_2O_4)_3]^{3-}$ and D(−)-$[Co(C_2O_4)_3]^{3-}$ with the Pfeiffer rotatory dispersion curves of the corresponding anions is shown in Figs. 5 and 6. The o.r.d. of the resolved D(+)-$[Ir(C_2O_4)_3]^{3-}$ shows a Cotton effect near 475 mμ. However, the Pfeiffer rotatory dispersion curve of the same ion

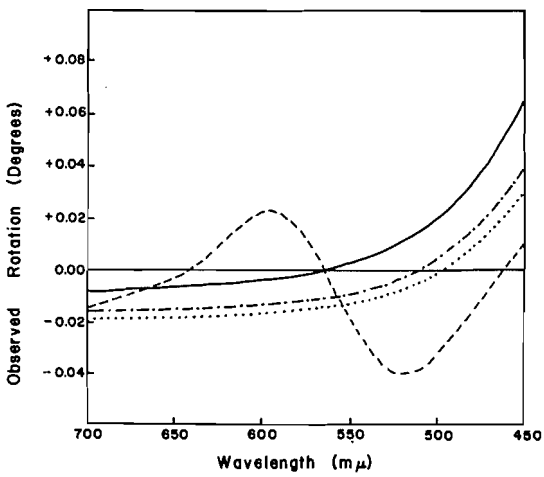

FIG. 1. Comparison of o.r.d. curves of $Al(C_2O_4)_3^{3-}$, $Fe(C_2O_4)_3^{3-}$, and $Cr(C_2O_4)_3^{3-}$ in cinchonine hydrochloride (CH) in a 5 cm cell at 23 °C. does not indicate such an effect, as can be seen in Fig. 4. This is a strong indication that the occurrence of the Pfeiffer effect in systems containing the different trisoxalatometallate(III) complexes does not result from the same source.

In the case of trisoxalatoiridate(III) anion, the inertness of the compound makes the equilibrium shift very unlikely. In view of the stability of the optical isomers of this anion (17), we compared the Pfeiffer rotation of D-, L-, and DL-$[Ir(C_2O_4)_3]^{3-}$ with the same amount of cinchonine hydrochloride and found that the Pfeiffer rotations of all three species were equal within experimental error. This result, together with the absence of a Cotton effect in the Pfeiffer rotatory dispersion curve, rules out any shift in equilibrium between the two enantiomers in solution for the

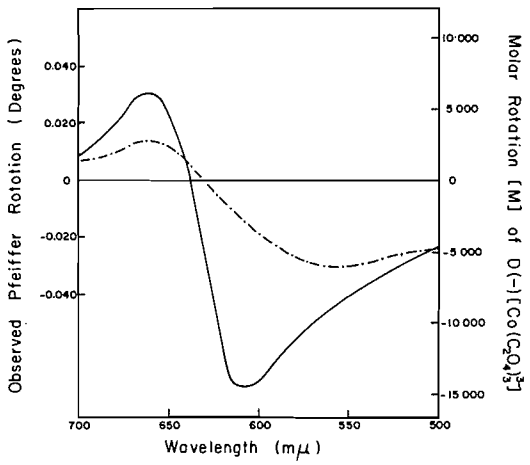

FIG. 6. Comparison of the o.r.d. and the Pfeiffer rotatory dispersion (P.r.d.) curves of $Co(C_2O_4)_3^{3-}$. —, o.r.d. curve of D(−)-$[Co(C_2O_4)_3^{3-}]$. ·····, P.r.d. curve of 2×10^{-3} *M* $Co(C_2O_4)_3^{3-}$ + 3×10^{-2} *M* CH in a 5 cm cell at 23 °C.

iridium system and leaves association as the operative mechanism.

Cinchonine hydrochloride, dissolved in aqueous solution, exists mainly as monoprotonated and diprotonated ions (18). At a p*H* of 6, the monoprotonated cinchonium ion is predominant and it is quite probable that there is an association between this positively charged cinchoninium ion and the negatively charged complex ion in solution (19). In addition, there is also a probability that hydrogen bonding occurs between the cinchoninium ion and the oxalate ligands surrounding the metal.

Experimentally, we found no change in the two d–d transition bands of either the $Co(C_2O_4)_3^{3-}$ or the $Cr(C_2O_4)_3^{3-}$ ion upon the addition of cinchonine hydrochloride. Yet the absorption coefficient of the first charge transfer band of the cinchoninium ion at 315.5 mμ increased from 3.50×10^3 to 3.61×10^3 upon the addition of 1.5×10^{-3} *M* $Al(C_2O_4)_3^{3-}$ to 5×10^{-4} *M* of cinchonine hydrochloride. Therefore, considering association only, the Pfeiffer rotation is likely due to a perturbation of the cinchoninium ion energy levels, not to any distortions of the complex. Unfortunately, the studies on the effect of the d–d transition cannot be extended to the other trisoxalato complexes in the series because they do not have a well-defined absorption band in the visible region. On the other hand, $Al(C_2O_4)_3^{3-}$ is the only choice for the investigation of the variation of the first charge transfer band of the cinchonine hydrochloride, since the other complexes absorb strongly near 135 mμ.

In metal complexes containing optically active ligands, Larsen and Olsen tentatively proposed that an induced Cotton effect in a d–d transition of a transition metal complex will only be of measurable magnitude if the asymmetric ligand is a chelate (20). (Exceptional results of some induced optical activity using monodentate ligands has been reported (21).) Mason and Norman speculated that chelate hydrogen bonding between an optically inactive complex and an optically active ion can induce a Cotton effect (22). It is not very likely, in view of the structure of cinchonine, that this optically active species can act as a chelate. Association alone, therefore, will not likely explain the origin of the induced Cotton effect observed in the trisoxalatochromate(III) ion in aqueous cinchonine hydrochloride solution. In the case of the labile trisoxalatochromate(III) and trisoxalatocobaltate(III) complexes, a first order equilibrium shift between the dextro and levo enantiomers appears to take place through an association of the complex ion with the cinchoninium ion in solution, in agreement with the conclusions reached by Bosnich (23), Kirschner and Ahmad (24), and Brasted *et al.* (10).

Both trisoxalatochromate(III) and trisoxalatocobaltate(III) anion show a positive Pfeiffer rotatory dispersion curve, indicating that the equilibrium shift is in favor of the D-enantiomer. A closer comparison of the resolved o.r.d. curve of the D(+)-$[Cr(C_2O_4)_3]^{3-}$ to the Pfeiffer rotatory dispersion curve of the same anion (Fig. 5) reveals that, besides the striking similarity in shape of these two curves, the ratio of the peak-to-trough for the o.r.d. curve is not the same as that for the P.r.d. curve, so that the whole P.r.d. curve seems to shift down to the negative side. The crossover wavelength (at which the optical rotation is zero) for the P.r.d. curve is higher than that for the o.r.d. curve. Moreover, at shorter wavelengths (below 525 mμ), the P.r.d. curve tends to level off. If an association between the Cr(III) complex anion and the cinchoninium ion does occur in addition to the equilibrium shift, we would expect that the contribution of the association alone will yield a Pfeiffer rotatory dispersion curve

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

similar to the one observed in the iridium(III) case (Fig. 4). When we subtracted this contribution from the observed P.r.d. curve, we were able to obtain a partial P.r.d. curve due to equilibrium shift alone, which was more similar in shape to the resolved o.r.d. curve, and in this way accounted for the differences observed between the o.r.d. and the P.r.d. curve mentioned above.

This similarity between the o.r.d. curve of the resolved D(−)-$[Co(C_2O_4)_3]^{3-}$ and the Pfeiffer rotatory dispersion curve of the same anion is not as good, and the amplitude of the Cotton effect is smaller (Fig. 6), probably because there is a lesser degree of equilibrium shift owing to the greater inertness of the system. This, together with the high absorptivity of the complex, reduces the accuracy of the measurement. Moreover, the two different forms of the trisoxalatocobaltate anion known to exist in aqueous solution (25, 26) may interact differently with the environment. The same arguments may also be applied to the trisoxalatoaluminate(III) and trisoxalatoferrate-(III) systems. However, the lack of a compatibly strong magnetic-dipole-allowed d–d transition in these two complexes minimizes the influence of the equilibrium shift contribution to the Pfeiffer rotatory dispersion curve, so that the P.r.d. curves of the $Al(C_2O_4)_3^{3-}$, $Fe(C_2O_4)_3^{3-}$, and $Ir(C_2O_4)_3^{3-}$ are similar in shape.

In summary, it seems that the combination of an association and an equilibrium shift can successfully be used to account for the observed Pfeiffer rotation in these systems, as concluded by Brasted *et al.* (10), and most recently by Doron *et al.* (27).

The authors wish to thank Dr. D. Idler and Mr. D. Ellis of the Fisheries Research Board in Halifax for the use of their Durum-Jasco Spectropolarimeter and the National Research Council of Canada for financial support.

The Number of Hydride Ions in AlH_2Cl Available for Hydrogenolysis of 1,3-Dioxolanes[1]

H. A. DAVIS AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 22, 1971

2-Methyl-1,3-dioxolane (**1**) in ether is hydrogenolyzed completely to 2-ethoxyethanol by an equimolar proportion of AlH_2Cl, whereas a 1/2 mol of AlH_2Cl hydrogenolyzes 1 mol of **1** only to the extent of 50%. In the latter case, the intermediate compound 2-ethoxyethoxyhydridoaluminum chloride ($C_2H_5OCH_2CH_2OAlHCl$) formed with half of the 2-methyl-1,3-dioxolane, even though it contains a hydride ion, fails to react with the remainder of the dioxolane. This is believed due to the preference of $C_2H_5OCH_2CH_2OAlHCl$ to form an internal Lewis acid–base complex rather than form a similar complex with **1**, a step essential to facilitate the hydrogenolysis of **1**.

La réaction dans l'éther entre le méthyl-2 dioxolane-1,3 (**1**) et une proportion molaire de AlH_2Cl conduit à l'éthoxy-2 éthanol provenant d'une hydrogénolyse complète; par ailleurs l'action d'une demi-mole de AlH_2Cl sur une mole de **1** conduit à une hydrogénolyse de 50% de ce composé. Dans ce cas, le composé intermédiaire ($C_2H_5OCH_2CH_2OAlHCl$) formé avec la moitié du dioxolane **1** contient encore un ion hydrure mais il ne réagit toutefois pas avec le restant du dioxolane. On croit que ce phénomène est dû à la préférence de l'intermédiaire à former un complexe de Lewis interne plutôt que de former avec **1** un complexe semblable qui est essentiel pour faciliter l'hydrogénolyse de **1**.

Canadian Journal of Chemistry, 49, 2166 (1971)

In connection with a study of the $LiAlH_4$–$AlCl_3$ (mixed hydride) reductive cleavage of 1,3-dioxolanes in this laboratory, we have found that 2-methyl-1,3-dioxolane (**1**, Scheme 1) is converted completely to 2-ethoxyethanol **4** in less than 30 min by an *equimolar* proportion of dihydridoaluminum chloride, AlH_2Cl.[2] However, no more than 50% conversion of **1** to **4** could be obtained if a *half molar* proportion of AlH_2Cl was used, even if the reaction time was extended to 48 h. In accordance with the views concerning the course of the reductive cleavage of 1,3-dioxolanes (1, 2), the reaction of AlH_2Cl with **1** first involves formation of a complex **2** due to the Lewis acidity of AlH_2Cl, and this complex subsequently forms an alkoxyhydridoaluminum chloride **3** (Scheme 1).

Although alkoxyaluminum hydrides have been postulated as intermediates in the ring cleavage of epoxides by the mixed hydride (3, 4) and alkoxyaluminum hydrides have been prepared and used to hydrogenolyze epoxides (5), it appears from our work that **3** cannot hydrogenolyze **1**. That this is so has been shown by the failure to observe any reductive cleavage when an ether solution of **1** was treated for as long as 48 h with **3**, prepared separately by the reaction of AlH_2Cl with an equimolar amount of 2-ethoxyethanol according to directions (5) which describe the preparation of alkoxyaluminum hydrides.

The complete conversion of benzaldehyde to benzyl alcohol by **3** in less than 1 h shows that the single hydride unit in **3** is available for reduction of carbonyl compounds and it is not the *bulk* of reagent **3** which causes its failure to react with **1**. Furthermore, we have also shown that **1** is converted to 2-ethoxyethanol **4** in less than 30 min by the reagent ethoxyhydridoaluminum chloride.

It is known that 1,3-dioxolanes are hydrogenolyzed by $LiAlH_4$ much more readily, and in most cases only, if a Lewis acid is present (ref. 1 and references therein, 6). It is clear that both ethoxyhydridoaluminum chloride and **3** are Lewis acids and thus should be able to form a complex with **1** which would initiate the process of reductive cleavage of **1** to **4**. The fact that ethoxyhydridoaluminum chloride rapidly hydrogenolyzes **1** to **4** while **3** apparently fails to do so strongly suggests that the internal structure of **3** is responsible for

[1]Taken from the thesis of H. A. Davis, presented to the Faculty of Graduate Studies at the University of Alberta in partial fulfilment of the requirements for the Ph.D. degree, 1970.

[2]That the reducing species present in the ether solutions obtained by mixing equimolar quantities of $AlCl_3$ and $LiAlH_4$ was AlH_2Cl and not $AlHCl_2$ or AlH_3 was shown by the infrared spectrum of the resulting solution which showed an absorption band only at 5.39 μ characteristic of Al–H_2 stretching frequency. The bands at 5.59 and 5.23 μ characteristic of AlH_3 and $AlHCl_2$ were not detected (3, 6).

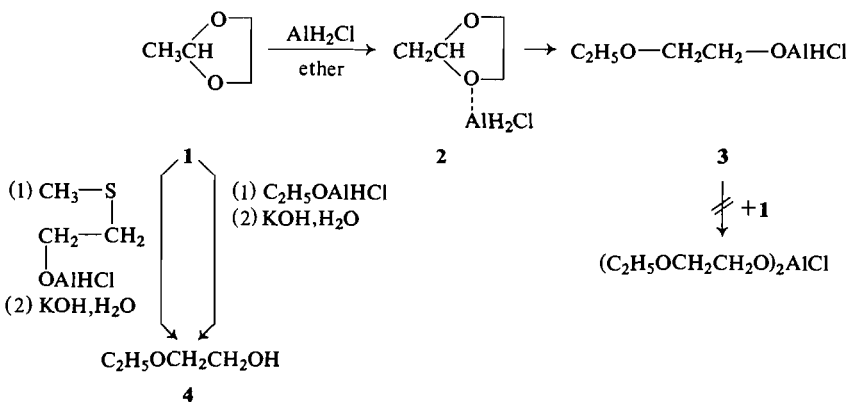
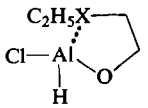


SCHEME 1

the latter's failure to react with **1** and that it is not due to the tendency to form polymeric structures as has been found to occur with alkoxyaluminum hydrides (5). Our view is that **3** forms an internal complex such as **A**(X = O) in preference to the formation of a complex such as **2** with **1**. In support of this proposal, it is found that **1** is converted



to **4** to the extent of 50% in 1 h by reaction with an equimolar proportion of (2-methylthio)ethoxyhydridoaluminum chloride, the homolog and sulfur analog of **3**. On the basis of the finding that 1,3-oxathiolanes are reductively cleaved at the C—O but not the C—S bond by mixed hydrides (7, 8) presumably because of the great preference of the Lewis acid to complex with the oxygen rather than the sulfur atom (8), the reagent (2-methylthio)ethoxyhydridoaluminum chloride is believed to prefer complex formation with the oxygen atom of **1** rather than with its own sulfur atom to form an internal complex such as **A**(X = S).

Experimental

Boiling points are uncorrected.

Elemental analyses were made by Mrs. Darlene Mahlow of this Department.

Infrared spectra were recorded on a Perkin–Elmer Model 21 instrument.

Proton magnetic resonance (p.m.r.) spectra were recorded on a Varian Associates A-60 instrument by Mr. R. Swindlehurst of this Department. All spectra were referred to tetramethylsilane.

Gas liquid chromatographic (g.l.c.) analyses were made with an F and M Model 700 instrument equipped with a 12 ft × 1/8 in. column packed with butanediol succinate, 20% on Gas Chrom P (60–80 mesh) or silicone rubber SE30, 20% on Gas Chrom P (60–80 mesh). Helium was the carrier gas at a flow rate of ~ 40 ml/min. The column temperature depended upon the boiling point of the compounds analyzed. For some cases the temperature was linearly programmed to achieve better resolution, the temperature being increased at the rate of 7.5°/min starting from 80°.

Solvents were removed by rotary evaporator under vacuum. Ether solutions were dried with anhydrous magnesium sulfate.

2-Ethoxyethanol was obtained from Eastman Kodak Co.

2-Methyl-1,3-dioxolane (1) was prepared by the procedure of Hibbert and Timm (9). B.p. 72° at 700 mm; η_D^{25} 1.3962. Lit. b.p., 83–85° at 700 mm (9).

2,Methylthioethanol

To a solution of 39 g (0.5 mol) of 2-mercaptoethanol in 300 ml of dry 1,2-dimethoxyethane (DME) was added 12 g (0.5 mol) of sodium hydride. The resulting mixture was stirred at room temperature for 2 h whereupon methyl iodide (71 g, 0.5 mol) was added slowly. The mixture was stirred overnight at room temperature and then the solids removed by filtration and the filtrate dried and freed from solvent. The residue was dissolved in 200 ml of ether, the solution separated from precipitated solids and the filtrate freed from ether. Distillation of the residue gave 25 g (54%) of colorless liquid, b.p., 78° at 30 mm, η_D^{24} 1.4869. Lit. b.p., 61° at 10 mm, η_D^{20} 1.4930 (10).

Hydrogenolysis of 2-Methyl-1,3-dioxolane (1) with AlH_2Cl

The procedure employed was that described by Diner (11).

Lithium aluminum hydride (0.57 g, 0.015 mol) was dissolved in 15 ml of dry ether and the solution cooled to 5° in an ice bath. To this was added, dropwise, an ether solution of aluminum chloride prepared by adding anhydrous aluminum chloride (1.99 g, 0.015 mol) in small portions to 15 ml of dry ether at 5°. The resulting mixed hydride (AlH_2Cl) solution (3, 6) was stirred at room temperature for 15 min and then 0.03 mol of **1** was added. The reaction mixture was stirred at room tem-

For personal use only.

perature for 30 min and then treated dropwise with a 15% aqueous solution of potassium hydroxide until no further reaction occurred. The colorless solid (lithium aluminate) was separated by filtration under suction, and the ether removed from the filtrate. The residue was analyzed by g.l.c. Only 2-ethoxyethanol was found in the product, in a yield of at least 90%, according to g.l.c. retention time and signal area compared with those of an authentic sample.

Hydrogenolysis of **1** *with Alkoxyhydridoaluminum Chloride*

The same procedure as that above, using AlH_2Cl, was employed except that before the addition of the dioxolane **1**, one molar equivalent of the requisite alcohol was added dropwise to the solution of AlH_2Cl in ether and the mixture then stirred for 15 min. Compound **1** was then added and the remainder of the procedure above was followed.

Hydrogenation of **1** was carried out using the following anhydrous alcohols (*a*) ethanol, (*b*) 2-ethoxyethanol, (*c*) 2-methylthioethanol.

Reaction of Xenon Difluoride with Organosilicon Compounds

J. A. GIBSON[1] AND A. F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received September 22, 1970

The reaction of xenon difluoride in acetonitrile solution with some organosilicon compounds is reported.

On rapporte les résultats obtenus lors de la réaction du difluorure de Xenon en solution dans l'acétonitrile avec quelques composés organiques du silicium.

Canadian Journal of Chemistry, **49**, 2168 (1971)

Xenon difluoride was recently found to be a useful reagent for aromatic substitution reactions in the liquid phase, in the presence of hydrogen fluoride as catalyst (1), as well as in the vapor phase at temperatures 100–200° (2).

We are currently studying the reaction of xenon difluoride with organometallic compounds and wish to report reactions with organosilicon compounds containing Si—Cl, Si—H, Si—C-(allyl), and Si—O bonds. Reactions were carried out with approximately 0.5 *M* solutions of XeF_2 in acetonitrile. These solutions were stable indefinitely at −78° but decomposed slowly at room temperature (see Experimental).

The reaction of xenon difluoride with organosilicon chlorides occurred readily, within 3 to 9 min, to give organosilicon fluorides.

spectrometry, and chlorine by reaction with cyclohexene and styrene.

The products $(CH_3)_3SiF$ and $(C_2H_5)_3SiF$ were formed in quantitative yield and no evidence was found for reaction of XeF_2 with Si—C or C—H bonds.

Lower yields were found for $(CH_3)_2SiF_2$ (70%) and $C_6H_5(CH_3)_2SiF$ (50%) suggesting side reactions and, in each case, chloromethyl derivatives $CH_3(CH_2Cl)SiF_2$ and $C_6H_5(CH_3)(CH_2Cl)$-SiF were formed in about 25% yield. Reaction of chlorine with C—H bonds in organosilicon compounds is well known (3) and the reactivity of chlorine must be taken into account in any reaction of XeF_2 with Si—Cl bonds.

When the reaction of XeF_2 was extended to compounds containing Si—H, Si—C(allyl), and Si—O bonds, no reaction was apparent within about 1 h. After considerably longer reaction times organosilicon fluorides were formed, but additional experiments suggested that XeF_2 was not reacting directly with these bonds.

For example, xenon difluoride did not react appreciably within 1 h when reactions with trimethylsilane, triphenylsilane, allyltrimethylsilane, and dimethyldiethoxysilane were attempted. On the other hand, if a Si—Cl bond was present in similar compounds, reaction occurred within several minutes. Thus reaction of methylphenylchlorosilane, $C_6H_5(CH_3)SiHCl$, and XeF_2 gave $C_6H_5(CH_3)SiF_2$ within 3 min in quantitative yield. It seems reasonable that a stepwise reaction is occurring in which Cl_2, produced as in reaction 1, converts the Si—H to a Si—Cl bond (ref. 3, p. 209) and the Si—Cl bond reacts further with XeF_2.

$$[3]\quad \overset{H}{\underset{|}{R_2Si}}Cl \xrightarrow{XeF_2} \overset{H}{\underset{|}{R_2Si}}F \xrightarrow{Cl_2} \overset{Cl}{\underset{|}{R_2Si}}F \xrightarrow{XeF_2} R_2SiF_2$$

In support of stepwise reaction 3 it is found that increasing the ratio $C_6H_5(CH_3)SiHCl:XeF_2$ to 6:1 permits formation of intermediate C_6H_5-$(CH_3)SiHF$ in 60% yield. In this case any Cl_2 produced could react with excess starting material rather than with the intermediate.

When allyldimethylchlorosilane, $(CH_3)_2Si(Cl)$-$CH_2CH{=}CH_2$, was allowed to react with XeF_2, dimethyldifluorosilane was quantitatively formed within 6 min and at the same time allyl chloride was formed in 60% yield. Reaction again appears to go stepwise, as in eq. 4, since it was found that

$$[4]\quad (CH_3)_2\overset{Cl}{\underset{|}{Si}}CH_2CH{=}CH_2 \xrightarrow{XeF_2} (CH_3)_2\overset{F}{\underset{|}{Si}}CH_2CH{=}CH_2 \xrightarrow{Cl_2} (CH_3)_2\overset{F}{\underset{|}{Si}}Cl \xrightarrow{XeF_2} (CH_3)_2SiF_2$$

allyltrimethylsilane and XeF_2 did not react within 1 h. If chlorine is bubbled through a 10% solution of allyldimethylchlorosilane in acetonitrile, cleavage occurs readily at 0–20° to give allyl chloride and dimethyldichlorosilane. Chlorine may also add to allylsilanes under different conditions (ref. 3, pp. 141, 390).

Xenon difluoride and dimethyldiethoxysilane, $(CH_3)_2Si(OC_2H_5)_2$, did not react within 1 h. After 4 days dimethyldifluorosilane was quantitatively produced, but during this time decomposition of XeF_2 in acetonitrile becomes significant and the decomposition product hydrogen fluoride is known to cleave Si—O bonds and give silicon fluorides (4).

In conclusion, xenon difluoride in acetonitrile solution readily converts Si—Cl to Si—F bonds but does not appear to react directly with Si—H, Si—C(allyl), or Si—O bonds. However, end products or decomposition products such as chlorine, hydrogen fluoride or hydrogen chloride may lead to further reaction.

Experimental

General

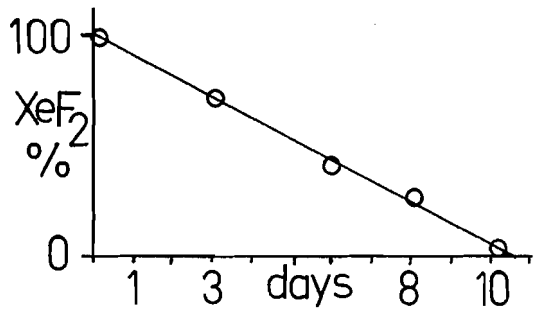
Organosilicon compounds were purchased from Peninsular Chemresearch with the exception of trimethylsilane which was prepared by reduction of trimethylchlorosilane with lithium tetrahydridoaluminate in dioxane (5) and purified by trap-to-trap distillation. Fluorine (Matheson of Canada) was passed over potassium fluoride to remove traces of hydrogen fluoride and handled in a metal vacuum system. Xenon difluoride was prepared photochemically (6) and dissolved in dried (P_2O_5) and distilled acetonitrile to give approximately 0.5 *M* solutions. These solutions were standardized by reacting aliquots with mercury and weighing the xenon gas produced.

Nuclear magnetic resonance spectra were obtained on a Varian A-56/60A spectrometer using 56.4 and 60 MHz for fluorine and proton, respectively. ^{19}F and ^{1}H chemical shifts are relative to internal trichlorofluoromethane and internal tetramethylsilane in dilute acetonitrile. Mass spectra were determined on a Hitachi Perkin–Elmer RMU-6D mass spectrometer.

Stability of Xenon Difluoride in Acetonitrile

Solutions of xenon difluoride in acetonitrile (0.5 *M*) were stored under vacuum at −78° and appeared stable

indefinitely. Slow decomposition occurred at room temperature in daylight and xenon difluoride was consumed within 10 days, as indicated by ^{19}F n.m.r.



Reaction of Xenon Difluoride in Acetonitrile with Trimethylchlorosilane

In a typical reaction xenon difluoride (0.15 mmol) in 0.30 ml acetonitrile solution was syringed into a standard n.m.r. tube and cooled to −10°. Trimethylchlorosilane (80 mg, 0.74 mmol) was added and the reaction mixture allowed to warm to 40° in the sample probe of the n.m.r. spectrometer. The solution turned light brown and reaction was followed by monitoring the disappearance of XeF_2 (and $^{129}XeF_2$) and appearance of product in the ^{19}F n.m.r. spectrum.

After 3 min all XeF_2 had reacted and trimethylfluorosilane, identified by ^{19}F and ^1H n.m.r. (7, 8), was formed in quantitative yield (based on XeF_2).

The other products were xenon, identified by mass spectrometry, and chlorine, identified by reaction with cyclohexene and styrene.

A similar procedure was used in the reactions described below.

Reaction with Triethylchlorosilane

Xenon difluoride (0.12 mmol) and triethylchlorosilane (43 mg, 0.29 mmol) reacted within 9 min to give triethylfluorosilane, identified by ^{19}F and ^1H n.m.r. (7, 9), in 90% yield.

Reaction with Dimethyldichlorosilane

Xenon difluoride (0.15 mmol) and dimethyldichlorosilane (16 mg, 0.13 mmol) reacted within 4 min to give dimethyldifluorosilane, identified by ^{19}F and ^1H n.m.r. (7, 8), in 70% yield.

Another product was formed in 25% yield. The ^{19}F n.m.r. showed a multiplet at +139 p.p.m. which appeared to be a quartet of triplets, assigned to $CH_3(CH_2Cl)SiF_2$.

Reaction with Dimethylphenylchlorosilane

Xenon difluoride (0.12 mmol) and dimethylphenylchlorosilane (49 mg, 0.29 mmol) reacted within 6 min to give dimethylphenylfluorosilane in 50% yield. Nuclear magnetic resonance spectra could not be found in the literature. The ^{19}F n.m.r. showed a septet at +159 p.p.m., $J_{F-CH_3} = 7.5$ Hz and the ^1H n.m.r. showed a doublet at −0.5 p.p.m., $J_{CH_3-F} = 7.5$ Hz, and phenyl peaks, consistent with the assigned structure.

Another product was formed in 30% yield. The ^{19}F n.m.r. showed a multiplet at +164 p.p.m., which appeared to be a quartet of triplets, assigned to $C_6H_5(CH_3)(CH_2Cl)SiF$.

Reaction with Methylphenylchlorosilane

Xenon difluoride (0.15 mmol) and methylphenylchlorosilane (25 mg, 0.16 mmol) reacted within 3 min to give methylphenyldifluorosilane in quantitative yield. Suitable n.m.r. spectra could not be found in the literature (10). ^{19}F n.m.r. showed a quartet at +136 p.p.m., $J_{F-CH_3} = 6$ Hz and the ^1H n.m.r. showed a triplet at −0.70 p.p.m., $J_{CH_3-F} = 6$ Hz, and phenyl peaks, consistent with the assigned structure.

When the reaction was carried out with a 6:1 molar excess of methylphenylchlorosilane, methylphenyldifluorosilane was formed in only 35% yield. Another product, formed in 60% yield, was identified as the intermediate phenylmethylfluorosilane on the basis of its ^{19}F n.m.r. spectrum which showed a doublet of quartets at +170.8 p.p.m., $J_{F-Si-H} = 58$ Hz and $J_{F-CH_3} = 8$ Hz.

Reaction with Trimethylsilane

Xenon difluoride (0.12 mmol) and trimethylsilane (30 mg, 0.41 mmol) were kept in a sealed n.m.r. tube at room temperature. Examination of the ^{19}F n.m.r. spectrum revealed that approximately 30% of XeF_2 had reacted after 1 h, 70% after 4 h, and 100% after 24 h. At the end of this time trimethylfluorosilane (75%) and unreacted trimethylsilane (0.23 mmol) remained.

Reaction with Triphenylsilane

Xenon difluoride (0.12 mmol) and triphenylsilane (60 mg, 0.25 mmol) did not react within 1 h. After 2 days about 50% of XeF_2 had reacted but products could not be positively identified.

Reaction with Allyldimethylchlorosilane

Xenon difluoride (0.15 mmol) and allyldimethylchlorosilane (19 mg, 0.14 mmol) reacted within 6 min to give dimethyldifluorosilane in quantitative yield. Allyl chloride was formed in at least 60% yield and identified by comparing its ^1H n.m.r. spectrum to that of an authentic sample.

When chlorine was bubbled through a 10% solution of allyldimethylchlorosilane in acetonitrile at 0–20° cleavage occurred readily to give allyl chloride and dimethyldichlorosilane, identified by ^1H n.m.r.

Reaction with Allyltrimethylsilane

Xenon difluoride (0.12 mmol) and allyltrimethylsilane (23 mg, 0.20 mmol) did not react within 1 h. After 4 days all XeF_2 had reacted and trimethylfluorosilane (0.10 mmol, 42%) was identified. The yield varied and seemed to be affected by light. Other products could not be identified.

Reaction with Dimethyldiethoxysilane

Xenon difluoride (0.15 mmol) and dimethyldiethoxysilane (27 mg, 0.18 mmol) did not react within 1 h. After 4 days dimethyldifluorosilane was produced in quantitative yield. Ethanol was also identified by ^1H n.m.r.

Reaction with Hexaphenyldisilane

Hexaphenyldisilane (100 mg, 0.19 mmol) is insoluble in acetonitrile and shaking with XeF_2 solution (0.15 mmol) at room temperature for 3 days gave no products containing Si—F bonds.

We wish to thank Dr. L. Stein, Argonne National Laboratories, for valuable advice concerning techniques of handling fluorine compounds. We also thank the

Trimethylgermanium Nitrate

D. POTTS AND A. WALKER

Department of Chemistry, Scarborough College, University of Toronto, 1265 Military Trail, West Hill, Ontario

Received December 21, 1970

The spectroscopic and solution properties of trimethylgermanium nitrate have been determined and compared with those of other known Group IV alkyl nitrates. The vibrational spectra show that the nitrato group is covalently bound to the germanium atom in a unidentate manner. Ultraviolet spectra and conductivity measurements indicate that the compound behaves as a 1:1 electrolyte in water and dimethylsulfoxide, but is a non-electrolyte in methyl cyanide, nitromethane, and ethyl acetate. Attempts to prepare methylgermanium trinitrate are also described.

On a déterminé les propriétés spectroscopiques et celles des solutions du nitrate de triméthylgermanium; on les a ensuite comparé à celles d'autres nitrates connus de dérivés alkylés d'éléments du groupe IV. Le spectre de vibration montre que le groupe nitrate est lié à l'atome de germanium d'une manière covalente et n'impliquant qu'un site de coordination. Le spectre u.v. et les mesures de conductivité indiquent que le composé se comporte comme un électrolyte (1:1) en solution dans l'eau ou le DMSO mais comme un non-électrolyte dans l'acétonitrile, le nitrométhane et l'acétate d'éthyle. On décrit aussi des essais de préparer le trinitrate de méthylgermanium.

Canadian Journal of Chemistry, **49**, 2171 (1971)

The preparation of trimethylgermanium nitrate has been reported previously (1), but as a recent nitrate review points out (2) concerning the compound, more work must be done before it can be said to be adequately characterized. This note describes the solution and spectroscopic properties of the compound and compares them with those reported recently (3) for dimethylgermanium dinitrate. The effects of increased alkylation are compared to similar trends found for analogous tin nitrato complexes (4, 5).

Results and Discussion

In agreement with Schmidt and Ruidisch (1), we found that trimethylgermanium nitrate, a colorless liquid, is soluble in water and in many polar and non-polar organic solvents. These solubility properties are very similar to those found for $Me_2Ge(NO_3)_2$ (3). The lack of reactivity of Me_3GeNO_3 towards diethyl ether, acetone, and Nujol argues against the presence of a symmetrically bound bidentate nitrate group, and in this respect is consistent with the Raman spectroscopic data which indicates a unidentate nitrate group (6).

Vibrational Spectra

The observed infrared and Raman spectra together with suggested assignments are presented in Table 1. The appearance of a medium intensity Raman nitrato band in the 1300 cm^{-1}

region compared to only a weak Raman nitrato band in the 1600 cm^{-1} region is characteristic of the pattern observed for compounds known to contain unidentate nitrato groups, and quite unlike that observed for those compounds containing known symmetrically bidentate nitrato groups (7). Consequently, the nitrate bands are assigned in accordance with Addison and Logan (8) assuming a unidentate nitrato group. The Ge—methyl vibrations are assigned following Griffiths (9).

When the infrared spectrum of trimethylgermanium nitrate is compared to that reported for dimethylgermanium dinitrate (3), it can be seen that the value Δ (the difference in asymmetric and symmetric NO_2 stretching frequencies) is smaller for the mononitrate. Furthermore the symmetric N—O stretching frequency is higher for the mononitrate. Both these observations indicate a less covalently bound unidentate nitrato group in the mononitrate than those in the dinitrate. Thus the effect of increasing alkylation is to produce a less polarizing germanium atom. In support of this conclusion the observed germanium–oxygen stretching frequencies for the mononitrate are some 20 cm^{-1} lower than those seen for the dinitrate (3), indicating weaker germanium–nitrate bonding in the mononitrate. Likewise the degeneracy weighted Ge—C stretching frequencies are lower for the mononitrate.

It should be noted that the structure of Me_3GeNO_3 must be quite different to the analogous tin compound, for which the infrared evidence (10, 11) has been interpreted as containing planar Me_3Sn groups possibly linked together by bridging nitrate groups. The presence of the symmetric Ge—C stretch in the infrared spectrum of Me_3GeNO_3, however, rules out planar Me_3Ge groups and the nitrate group is probably unidentate. The molecule is likely pseudo-tetrahedral.

Nuclear Magnetic Resonance Spectra

The nuclear magnetic resonance spectra of Me_3GeNO_3 and $Me_2Ge(NO_3)_2$ have been determined in chloroform and exhibit single peaks at $\tau = 9.28$ and $\tau = 8.63$, respectively. Under the same conditions, tetramethylgermane shows a peak at $\tau = 9.87$. These results indicate that the germanium atom becomes increasingly electron-deficient (compared to its state in tetramethylgermane) as the number of nitrate groups attached to the germanium atom increases. These conclusions are consistent with the changes in germanium–carbon stretching frequencies observed in the infrared spectra of Me_3GeNO_3 and $Me_2Ge(NO_3)_2$. Similar observations have been made for methyltin nitrato complexes (4) and, as in the case of the tin complexes, the shift to lower field is greater for the nitrato compounds than analogous chloride complexes. (The nuclear magnetic resonance (n.m.r.) spectrum of dimethylgermanium dichloride measured in $CHCl_3$ shows a peak at $\tau = 8.79$.)

208m		

*s = strong, m = medium, w = weak, v = very, sp = sharp, br = broad.

Ultraviolet Spectra

The ultraviolet spectra of solutions of trimethylgermanium nitrate in water and dimethylsulfoxide exhibit peaks at 302.5 mμ ($\varepsilon = 6.90$) and 312.5 mμ ($\varepsilon = 4.41$), respectively, which correspond to dissociation of the molecule yielding one nitrate ion per mol in these solvents (12).

The ultraviolet solution spectra of trimethylgermanium nitrate in methyl cyanide, ethyl acetate, and methanol are typical of those obtained for solutions of many covalent metal nitrates in these solvents (3, 6, 12), indicating considerable metal nitrate interaction (12). In methyl cyanide ε_{max} is 6.38 at 277.5 mμ, in ethyl acetate ε_{max} is 6.14 at 275.0 mμ, and in methanol ε_{max} is 8.40 at 270.0 mμ.

Conductivities

The molar conductivities of trimethylgermanium nitrate in water, dimethylsulfoxide, methanol, methyl cyanide, and nitromethane are listed in Table 2. The low conductivity of methyl cyanide and nitromethane solutions indicate that Me_3GeNO_3 is virtually a non-electrolyte in these solvents (13). The molar conductivities of aqueous solutions exceed the expected value for 1:1 electrolytes (~ 130 ohm^{-1} cm^2), but as these solutions are quite acidic, the high conductivities can be attributed to hydrolysis similar to that encountered with $Me_2Ge(NO_3)_2$ (3). The conductivities of Me_3GeNO_3 in dimethylsulfoxide are typical of values obtained for a 1:1 electrolyte in this solvent (14). The values obtained in methanol show concentration dependence typical of weak electrolyte behavior. Thus, as was found for methanol solutions of $Me_2Ge(NO_3)_2$ (3), while in very dilute solutions (0.001 *M*) the conductivity indicates some degree of ionization ($AgNO_3$ in MeOH has a molar conductivity of 94.20 ohm^{-1} cm^2 at a concentration of 0.00168 *M* (15)), at the concentration used for the u.v. spectrum (0.0730 *M*) considerable association is evident.

Molecular Weight

The molecular weight of Me_3GeNO_3 was determined cryoscopically in nitrobenzene and found to be 179.2 for a 0.195 *M* solution. (Calcd. value for Me_3GeNO_3 is 179.6.)

Reactions of Dinitrogen Pentoxide with Methylgermanium Trichloride

As a result of our work on alkyl nitrato complexes of lead (5), tin (4), and germanium (3), it has become apparent that monomethyl and dimethyl derivatives of these metals may be reacted with dinitrogen pentoxide without removal of methyl groups. Since dinitrogen pentoxide is known to react with chloride complexes of these metals, it was hoped that the reaction between dinitrogen pentoxide and methylgermanium trichloride would yield methylgermanium trinitrate. However, it was found that when $MeGeCl_3$ was reacted with either pure N_2O_5, or solutions of N_2O_5 in carbon tetrachloride, the product was always a viscous unstable oil which liberated NO_2 above 0 °C. The infrared spectrum of the product confirms the presence of a methyl group and two strong bands at 1620 and 1290 cm^{-1} are indicative of covalently bound nitrate. The region between 800–900 cm^{-1} consists of three strong bands suggesting the presence of a Ge—O—Ge species (16). It is probable that the highly polarizing nature of germanium in monomethylgermanium compounds is sufficient to make $MeGe(NO_3)_3$ unstable with respect to nitrogen dioxide and methylgermanium oxide species.

Experimental

Trimethylgermanium nitrate was prepared by the literature method (1). Dinitrogen pentoxide was prepared by a gas phase reaction between dinitrogen tetroxide and ozone.

Infrared spectra were recorded using a Beckman I.R. 12 spectrophotometer. The spectra were taken in carbon tetrachloride and carbon disulfide using variable path length cells with silver chloride windows. Far infrared spectra (200–400 cm^{-1}) were taken in carbon tetrachloride using 0.1 mm polyethylene liquid cells.

Raman spectra of pure liquid Me_3GeNO_3 were obtained on a Spex Raman Instrument using the red line of a Krypton laser.

Nuclear magnetic resonance spectra were run on a Varian T-60 spectrophotometer. Spectra were obtained as 10% solutions in chloroform using either tetramethylsilane or the proton peak of chloroform as standards.

Ultraviolet spectra were recorded on a Cary #14 spectrophotometer using fused silica cells and dried spectroscopic solvents.

Conductivities were recorded with a Beckman model RC-18 bridge system, and a cell following the design of Greiner (17).

We wish to thank the National Research Council of Canada for supporting this work and for a Studentship to D.P.

Nuclear Recoil Reactions in Organo-Manganese Compounds. V. —$Mn(CO)_5$ Target Compounds

H. JAKUBINEK, S. C. SRINIVASAN,[1] AND D. R. WILES
Chemistry Department, Carleton University, Ottawa, Canada

Received January 28, 1971

$HMn(CO)_5$, $DMn(CO)_5$, $CH_3Mn(CO)_5$, and $C_6H_5Mn(CO)_5$ have been irradiated with neutrons and the product spectrum of ^{56}Mn-containing molecules determined. The results show that $H^{56}Mn(CO)_5$ is formed in all cases: 21.0%, 23.6% from $HMn(CO)_5$ and $DMn(CO)_5$ targets, respectively, and 6.9% and 2.1% from $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$, respectively. Thus the yields are not in accord with the number of H atoms per target molecule. Preliminary experiments show that $\cdot{}^*Mn(CO)_5$ exchanges rapidly with $HMn(CO)_5$ and $DMn(CO)_5$ and very slowly with $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$. It is deduced that the very high yield of $H^{56}Mn(CO)_5$ in $HMn(CO)_5$ and $DMn(CO)_5$ targets could arise from the rapid exchange, while the lower yields of $H^{56}Mn(CO)_5$ in other targets must likely come from radical reactions following thermal dissociation of the target molecule.

On a irradié le $HMn(CO)_5$, le $DMn(CO)_5$, le $CH_3Mn(CO)_5$ et le $C_6H_5Mn(CO)_5$ avec des neutrons et l'on a déterminé le spectre des molécules contenant du ^{56}Mn. On observe que le $H^{56}Mn(CO)_5$ se forme dans tous les cas: 21.0% et 23.6% respectivement lorsque le $HMn(CO)_5$ et le $DMn(CO)_5$ sont utilisés comme cibles et 6.9% et 2.1% respectivement à partir du $CH_3Mn(CO)_5$ et $C_6H_5Mn(CO)_5$. Les rendements ne sont donc pas en accord avec le nombre d'atome d'hydrogène par molécule-cible. Des expériences préliminaires ont permis de mettre en évidence que $\cdot{}^*Mn(CO)_5$ s'échange rapidement avec $HMn(CO)_5$ et $DMn(CO)_5$ et très lentement avec $CH_3Mn(CO)_5$ et $C_6H_5Mn(CO)_5$. On en conclut que les rendements élevés de $H^{56}Mn(CO)_5$ obtenus lorsque $HMn(CO)_5$ et $DMn(CO)_5$ sont utilisés proviendraient de l'échange rapide alors que les faibles rendements de $H^{56}Mn(CO)_5$ obtenus lorsque l'on utilise d'autres cibles seraient dus à des réactions radicaliques qui seraient subséquentes à la dissociation thermique de la cible.

Canadian Journal of Chemistry, 49, 2175 (1971)

Introduction

In earlier publications of this series, we have described studies of the chemical behavior of manganese atoms following neutron bombardment of various manganese carbonyl compounds. In particular it has been found (1) that in cyclopentadienylmanganese tricarbonyl ($CpMn(CO)_3$) and its methyl homolog ($CH_3CpMn(CO)_3$), a surprisingly large fraction of the organically bound ^{56}Mn atoms are found as various —$Mn(CO)_5$ compounds. It has also been shown that, in Mn_2CO_{10}, the radioactive free radical $\cdot Mn(CO)_5$ is formed and reacts or decomposes only on dissolution.

It became evident from studies of $CH_3CpMn(CO)_3$ (2) that competitive radical reactions were involved, as in reaction 1.

$$[1] \qquad \left.\begin{matrix}\cdot H \\ \cdot CH_3\end{matrix}\right\} + Mn(CO)_5 \longrightarrow \begin{matrix}HMn(CO)_5 \\ CH_3Mn(CO)_5\end{matrix}$$

While it was not sure whether the hydrogen atoms were abstracted from nearby molecules, or were made available for reaction by radiolysis or local

Nuclear Recoil Reactions in Organo-Manganese Compounds. V. —$Mn(CO)_5$ Target Compounds

H. JAKUBINEK, S. C. SRINIVASAN,[1] AND D. R. WILES
Chemistry Department, Carleton University, Ottawa, Canada

Received January 28, 1971

$HMn(CO)_5$, $DMn(CO)_5$, $CH_3Mn(CO)_5$, and $C_6H_5Mn(CO)_5$ have been irradiated with neutrons and the product spectrum of ^{56}Mn-containing molecules determined. The results show that $H^{56}Mn(CO)_5$ is formed in all cases: 21.0%, 23.6% from $HMn(CO)_5$ and $DMn(CO)_5$ targets, respectively, and 6.9% and 2.1% from $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$, respectively. Thus the yields are not in accord with the number of H atoms per target molecule. Preliminary experiments show that $\cdot{}^*Mn(CO)_5$ exchanges rapidly with $HMn(CO)_5$ and $DMn(CO)_5$ and very slowly with $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$. It is deduced that the very high yield of $H^{56}Mn(CO)_5$ in $HMn(CO)_5$ and $DMn(CO)_5$ targets could arise from the rapid exchange, while the lower yields of $H^{56}Mn(CO)_5$ in other targets must likely come from radical reactions following thermal dissociation of the target molecule.

On a irradié le $HMn(CO)_5$, le $DMn(CO)_5$, le $CH_3Mn(CO)_5$ et le $C_6H_5Mn(CO)_5$ avec des neutrons et l'on a déterminé le spectre des molécules contenant du ^{56}Mn. On observe que le $H^{56}Mn(CO)_5$ se forme dans tous les cas: 21.0% et 23.6% respectivement lorsque le $HMn(CO)_5$ et le $DMn(CO)_5$ sont utilisés comme cibles et 6.9% et 2.1% respectivement à partir du $CH_3Mn(CO)_5$ et $C_6H_5Mn(CO)_5$. Les rendements ne sont donc pas en accord avec le nombre d'atome d'hydrogène par molécule-cible. Des expériences préliminaires ont permis de mettre en évidence que $\cdot{}^*Mn(CO)_5$ s'échange rapidement avec $HMn(CO)_5$ et $DMn(CO)_5$ et très lentement avec $CH_3Mn(CO)_5$ et $C_6H_5Mn(CO)_5$. On en conclut que les rendements élevés de $H^{56}Mn(CO)_5$ obtenus lorsque $HMn(CO)_5$ et $DMn(CO)_5$ sont utilisés proviendraient de l'échange rapide alors que les faibles rendements de $H^{56}Mn(CO)_5$ obtenus lorsque l'on utilise d'autres cibles seraient dus à des réactions radicaliques qui seraient subséquentes à la dissociation thermique de la cible.

Canadian Journal of Chemistry, 49, 2175 (1971)

Introduction

In earlier publications of this series, we have described studies of the chemical behavior of manganese atoms following neutron bombardment of various manganese carbonyl compounds. In particular it has been found (1) that in cyclopentadienylmanganese tricarbonyl ($CpMn(CO)_3$) and its methyl homolog ($CH_3CpMn(CO)_3$), a surprisingly large fraction of the organically bound ^{56}Mn atoms are found as various —$Mn(CO)_5$ compounds. It has also been shown that, in Mn_2CO_{10}, the radioactive free radical $\cdot Mn(CO)_5$ is formed and reacts or decomposes only on dissolution.

It became evident from studies of $CH_3CpMn(CO)_3$ (2) that competitive radical reactions were involved, as in reaction 1.

$$[1] \qquad \left.\begin{matrix}\cdot H \\ \cdot CH_3\end{matrix}\right\} + Mn(CO)_5 \longrightarrow \begin{matrix}HMn(CO)_5 \\ CH_3Mn(CO)_5\end{matrix}$$

While it was not sure whether the hydrogen atoms were abstracted from nearby molecules, or were made available for reaction by radiolysis or local

For personal use only.

thermal effects ("pyrolysis"), it seemed clear that the $-CH_3$ came from the ring substituent, likely by pyrolysis.

A most important question emerging in these studies is that of the origin of the hydrogen atom. There seem to be two extreme possibilities, that of abstraction [2] and that of radiolytic or thermal productions of hydrogen atoms [3]. These would result in reactions such as the following

$$[2] \quad [R, Ar, etc.]H + \cdot Mn(CO)_5 \rightarrow [R, Ar, etc.]\cdot + HMn(CO)_5$$

$$[3a] \quad [R, Ar, etc.]H \rightarrow [R, Ar, etc.]\cdot + H\cdot$$

$$[3b] \quad H\cdot + \cdot Mn(CO)_5 \rightarrow HMn(CO)_5$$

Since in these $-Mn(CO)_3$ systems the formation of the $-Mn(CO)_5$ group is an additional complication, it seemed reasonable to study cases in which $-Mn(CO)_5$ forms part of the initial matrix, so that other differences might perhaps stand out more clearly. (It is not here implied that the $Mn(CO)_5$ group remains intact following nuclear activation; indeed evidence is very strong that activated molecules are largely, if not totally, dissociated.) We are now able to report the results from a study on neutron-irradiated $HMn(CO)_5$, $DMn(CO)_5$, $CH_3Mn(CO)_5$, and $C_6H_5Mn(CO)_5$.

Experimental

The target compounds were made by procedures similar to known methods, starting with $NaMn(CO)_5$, and using the "nitrogen glove" technique (3) for the manipulations.

$HMn(CO)_5$

$NaMn(CO)_5$ was treated with glacial H_3PO_4, and the product purified by vacuum distillation at low temperature (4). $DMn(CO)_5$ was similarly prepared from D_3PO_4.

$CH_3Mn(CO)_5$

$NaMn(CO)_5$ in THF solution was treated with CH_3I. After 2 h at -22 °C, the product was distilled to a cold trap and was subsequently purified by vacuum sublimation (5).

$C_6H_5Mn(CO)_5$

$NaMn(CO)_5$ in THF was treated with benzoyl chloride to produce $C_6H_5COMn(CO)_5$. This intermediate was heated, without purification, at 90 °C for 1 h to remove CO. The product was purified by vacuum sublimation (6).

Separation of Products

Carriers were added for all compounds other than the parent compound.

$HMn(CO)_5$ was converted to $IMn(CO)_5$ by one or more of the following steps

(*a*) Reaction with I_2

$$[4] \quad HMn(CO)_5 + I_2 \rightarrow IMn(CO)_5 + HI$$

(*b*) Exchange with $IMn(CO)_5$

$$[5] \quad H^*Mn(CO)_5 + IMn(CO)_5 \rightleftharpoons I^*Mn(CO)_5 + HMn(CO)_5$$

(*c*) Vacuum distillation followed by (*a*).

Reaction 4 has been shown to be quantitative and fast (7). Reaction 5 has been found to be complete within the time of the experiment (see below). Reactions 4 and 5 have been shown not to occur with $CH_3Mn(CO)_5$ or $C_6H_5Mn(CO)_5$ during the time of the experiment, and since the amount of $IMn(CO)_5$ used in this case was very much larger than the amount of $HMn(CO)_5$, reaction 5 can be considered to go completely to the right. $IMn(CO)_5$ was purified by column chromatography.

$CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$ were separated from the $IMn(CO)_5$ remaining from [4] or [5] by vacuum transfer, and were subsequently purified by further vacuum sublimation. It was assumed that $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$ were not found in the same experiment and thus did not require to be separated from each other.

Neutron Irradiations

Neutron irradiations were done with the Sb–Be neutron sources at Commercial Products Division, A.E.C.L., and at Carleton University. The flux of thermal neutrons was of the order of 10^8 cm^{-2} s^{-1} and the γ-ray dose rate about 1 Mrad h^{-1}. The irradiations were carried out at Dry Ice temperature.

Analytical Measurements

Determination of the chemical recovery of the purified target compounds and carriers was done gravimetrically. $HMn(CO)_5$ was weighed after conversion to $IMn(CO)_5$. Since the quantities recovered were 20 mg or more, the analytical uncertainties are $\leq 1\%$ on individual determinations.

Radioactivity measurements were done using a 3 in. × 3 in. NaI scintillation counter coupled to a 100 channel pulse height analyzer. Numerical integration was done over the 0.84 Mev γ peak from ^{56}Mn. The radioactivity reference was in most cases a sample of crystalline $CpMn(CO)_3$ counted without chemical processing.

Exchange Measurements

Exchange of the $-Mn(CO)_5$ group between $IMn(CO)_5$ and $HMn(CO)_5$, $DMn(CO)_5$, $CH_3Mn(CO)_5$, and $C_6H_5Mn(CO)_5$ has been studied, and a fuller report will be published separately (8). A radioactive species taken to be the radical $\cdot Mn(CO)_5$ (9) is formed by the neutron irradiation of $Mn_2(CO)_{10}$. This species has been found to react rapidly with I_2 in petroleum ether solution or (10) to exchange rapidly with $IMn(CO)_5$ by the assumed reaction

$$[6] \quad \cdot^*Mn(CO)_5 + IMn(CO)_5 \rightleftharpoons \cdot Mn(CO)_5 + I^*Mn(CO)_5$$

Radioactive $I^*Mn(CO)_5$ prepared by direct neutron irradiation of $IMn(CO)_5$ was purified and mixed with either $HMn(CO)_5$, $CH_3Mn(CO)_5$, or $C_6H_5Mn(CO)_5$ in

TABLE 1. Distribution of ^{56}Mn-labelled products

Target	Yield of ^{56}Mn			
	$HMn(CO)_5$	$CH_3Mn(CO)_5$	$C_6H_5Mn(CO)_5$	$Mn_2(CO)_{10}$
$HMn(CO)_5$[a]	21.0	—	—	4.3
$DMn(CO)_5$[b]	23.6	—	—	3.7
$CH_3Mn(CO)_5$[a]	6.9	3.5	—	2.3
$C_6H_5Mn(CO)_5$[b]	2.1	—	2.5	3.6
$CpMn(CO)_3$[c]	7.0	0.0	—	0.9
$CH_3CpMn(CO)_3$[c]	10.0	1.7	—	—

[a]Five irradiations.
[b]Two irradiations.
[c]Taken from ref. 1.

tetrahydrofuran solution. The components of the mixture were separated in vacuo and their specific radioactivity measured. It is found that in the space of 3 min, the exchange with $HMn(CO)_5$ is complete.

[5a] $$HMn(CO)_5 + I^*Mn(CO)_5 \rightleftharpoons H^*Mn(CO)_5 + IMn(CO)_5$$

Exchange with $DMn(CO)_5$ is likewise very fast. With $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$, no exchange is observed after 10 min.

Results and Discussion

The results of the experiments are given in Table 1.

It is clear from the data in Table 1 that the yield of $HMn(CO)_5$ is not related to the number of hydrogen atoms in the target molecules; in fact, quite the reverse.

The value 25.3% for the sum of the yields of radioactive $Mn_2(CO)_{10}$ and $HMn(CO)_5$ gives a lower limit for the radiochemical production of $—^{56}Mn(CO)_5$ in $HMn(CO)_5$ targets. Similar values are to be expected in the other two target compounds.

To identify the reactions occurring and establish their sequence is not easy, although some important indications can be found. It had been concluded before (1) that $\cdot Mn(CO)_5$ does not abstract hydrogen from hydrocarbons, such as those found in petroleum ether. It is apparent then that in $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$ targets, the $HMn(CO)_5$ produced must be constituted from hydrogen atoms formed by collision-induced thermal dissociation.

Regarding the parent yields, it seems from the exchange results given above that $HMn(CO)_5$ can likely be formed in $HMn(CO)_5$ targets by an exchange mechanism, while parallel reactions in the other targets are not possible. The very much higher parent yield in $HMn(CO)_5$ than in the other targets lends support to this exchange as the dominant mechanism for parent reformation in $HMn(CO)_5$. Inertial effects (11) cannot be responsible for this high yield of $HMn(CO)_5$, since the parent yield in $DMn(CO)_5$ is so nearly equal to that in $HMn(CO)_5$.

The inertness of $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$ to exchange with $IMn(CO)_5$ suggests that the $\cdot CH_3$ and $\cdot C_6H_5$ radical may not be transferred by simple chemical reactions. It was observed earlier (1) that in mixed $CH_3CpMn(CO)_3$–isooctane targets the availability of $—CH_3$ appeared to control the amount of $CH_3Mn(CO)_5$ produced. The same must hold for the present case, and likely for the phenyl compound as well.

It thus seems reasonable to conclude that for $CH_3Mn(CO)_5$ and $C_6H_5Mn(CO)_5$ targets, the reformation of the radioactive $RMn(CO)_5$ (where R = H, CH_3, or C_6H_5) is through the recombination of radicals produced from neighboring molecules by the nuclear event. Whether the radicals are produced by direct collision or more diffusely by local thermal effects is not yet known. If the radicals were produced by extensive Auger ionization (12), instead of by thermal dissociation, the methyl and phenyl radicals would themselves not likely have survived (13). In such cases too, the number of hydrogen atoms produced would be in the ratio of 5:3, while our results indicate a ratio of approximately 2:7 for the yields of $H^*Mn(CO)_5$. The general reaction, then, appears to be one of massive radical production followed by a rapid reaction or perhaps more coalescence, reminiscent of the mechanism suggested some years ago by Willard (14) for similar reactions in alkyl halides.

We wish to express our gratitude to Mrs. I. de Jong for experimental assistance, to the Commercial Product, Division, A.E.C.L. for the use of their Sb–Be neutron facility, and to the National Research Council of Canada for financial support.

Absolute Rate Constants for Hydrocarbon Autoxidation. Part XX. Oxidation of Some Organic Sulfides[1]

J. A. HOWARD AND S. KORCEK[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received January 22, 1971

Absolute rate constants for the liquid phase autoxidation of some organic sulfides at 30 °C have been measured. The reactivities of organic sulfides towards *t*-butylperoxy radicals are equal to or somewhat less than the reactivities of structurally analogous ethers. The α-alkylthiylalkylperoxy radicals appear to be about 3–5 times more reactive in hydrogen atom abstraction than the α-alkoxyalkylperoxy radicals.

La constante de vitesse absolue pour l'autoxydation en phase liquide de quelques sulfures organiques a été mesurée à 30 °C. Les réactivités des sulfures organiques vis à vis des radicaux *t*-butylpéroxy sont égales ou un peu inférieures aux réactivités des éthers de structure analogue. Les radicaux α-alkylthiylalkylpéroxy semblent 3 à 5 fois plus réactifs pour l'abstraction d'atome d'hydrogène que les radicaux α-alkoxyalkylpéroxy.

Canadian Journal of Chemistry, 49, 2178 (1971)

Introduction

Previous publications in this series have reported absolute propagation and termination rate constants for liquid-phase autoxidations of hydrocarbons, aldehydes, ethers, and α-monosubstituted toluenes at atmospheric pressure and 30 °C (1). An attempt has been made to extend this work to the autoxidation of organic sulfides.

Saturated alkyl, aralkyl, and aryl mono- and disulfides do not react spontaneously with molecular oxygen at temperatures below about 100 °C. Unsaturated sulfides, however, absorb oxygen autocatalytically at first and faster than comparable mono-olefins but the rate soon begins to slow down and may cease before 0.1 mol of oxygen per mole of sulfide has been absorbed. This autoretardation is a feature of sulfide autoxidation and is indicative of the formation of oxidation inhibitors.

The reaction of many sulfides with molecular oxygen can be accelerated by the addition of typical free radical initiators, *e.g.* α,α′-azobisisobutyronitrile, upon irradiation with near ultraviolet light and can be retarded by the addition of free-radical inhibitors.

Unlike hydrocarbons and their oxygenated derivatives, organic sulfides give little or no hydroperoxidic material upon autoxidation. The principal reaction products appear to be a sulfoxide, water, and products resulting from scission of the weaker C—S bond. The reaction of organic sulfides with molecular oxygen at ambient temperatures has been described by the following reaction scheme (2)

Concentration (M)	Oxygen pressure (mm Hg)	$R_i \times 10^7$ ($M\,s^{-1}$)	$R_s \times 10^6$ ($M\,s^{-1}$)	$k_p/(2k_t)^{1/2} \times 10^3$ ($M^{-1/2}\,s^{-1/2}$)
11.3	95	0.97	4.8	1.4
11.3	150	0.97	4.8	1.4
11.3	396	0.97	4.3	1.2
11.3	700	0.97	4.5	1.3
4.54	700	0.40	1.04	1.2
11.3	700	0.18	1.85	1.2
11.3	700	0.88	3.5	1.1
11.3	700	2.75	7.5	1.3

Initiation

[1] Production of free radicals

Propagation

[2] $R\dot{C}HSR' + O_2 \rightarrow RCH(OO^{\cdot})SR'$

[3] $RCH(OO^{\cdot})SR' + RCH_2SR' \xrightarrow{k_p} RCH(OOH)SR' + R\dot{C}HSR'$

Hydroperoxide decomposition

[4] $RCH(OOH)SR' + RCH_2SR' \rightarrow RCH(OH)SR' + RCH_2SOR'$

[5] $RCH(OOH)SR' + RCHSOR' \rightarrow R_2'S_2 + H_2O +$ other products

Monothioacetal decomposition

[6] $RCH(OH)SR' \rightarrow RCHO + R'SH$

[7] $RCH(OH)SR' + R'SH \rightarrow H_2O +$ complex sulfides

where RCH_2SR' represents the organic sulfide, $R\dot{C}HSR'$ the carbon radical formed by abstraction of an α-hydrogen atom, and $RCH(OO^{\cdot})SR'$ the corresponding peroxy radical. Reactions 1, 2, and 3 are the initiation and propagation steps usually used to describe the autoxidation of other organic compounds. Reaction 4 accounts for the absence of hydroperoxides and the high yields of sulfoxides at low conversions. Reactions 5, 6, and 7 represent secondary reactions which are believed to be responsible for the complex nature of the autoxidation of organic sulfides. Although a termination step was not included in this reaction scheme it can be assumed that the chain reaction would be terminated (at least initially), at oxygen pressures above about 100 mm Hg, by the self-reaction of two peroxy radicals to give non-radical products.

[8] $RCH(OO^{\cdot})SR' + RCH(OO^{\cdot})SR' \rightarrow$ non-radical products

We have attempted to measure absolute rate constants for reactions 3 and 8, the rate controlling propagation and termination steps, for the autoxidation of some cyclic and acyclic organic sulfides and the results are reported below.

Experimental

Materials

Tetrahydrothiopyran, tetrahydrothiophene, α-toluenethiol, and cyclohexene were dried and distilled before use. Dibenzyl sulfide, dibenzyl disulfide, and benzyl phenyl sulfide were purified by recrystallization. Benzyl *t*-butyl sulfide was prepared from isobutylene and α-toluenethiol (3). Isopropyl sulfide was purified to better than 99.9% by preparative gas–liquid chromatography using a F & M Prepmaster Jr. 776 instrument, equipped with a 3/4 in. column packed with silicone gum rubber on Chromosorb W at 70°. Nitrogen was used as the carrier gas at a flow rate of 200 cc/min. Tetrahydrothiophene-α-d_4 and cyclohexene-d_{10} were obtained from Merck, Sharpe and Dohme of Canada Limited.

Kinetic Procedure

Measurement of rates of oxidation and chain initiation have been described previously (4). Absolute rate constants were measured at 30° using the rotating sector method. Autoxidations were initiated with either α,α′-azobisisobutyronitrile or α,α′-azobiscyclohexylnitrile and inhibited by 2,6-di-*t*-butyl-4-methoxyphenol.

Results and Discussion

Cyclic Sulfides

Rates of oxidation of tetrahydrothiophene at various partial pressures of oxygen, rates of chain initiation, and substrate concentrations are summarized in Table 1. These results imply that the overall rate of oxidation of this organic sulfide is given by

[9] $$R_s = k_p[RH]R_i^{1/2}/(2k_t)^{1/2}$$

which is the kinetic expression used to describe the autoxidation of many hydrocarbons and their oxygenated derivatives. In this expression R_s represents the rate of oxidation, R_i the rate of chain initiation, [RH] the concentration of tetrahydrothiophene, and k_p and $2k_t$ the rate

controlling propagation and termination rate constants.

Photochemically initiated rates of oxidation of tetrahydrothiophene were found to be reasonably constant over the length of time necessary to measure the following four rates of oxidation: (*i*) the rate of an oxidation illuminated continuously, R_s; (*ii*) the rate at a very high speed of sector rotation, R_∞; (*iii*) the rate at a sector speed where the rate was most sensitive to the length of the dark period; and (*iv*) a second value of R_s. The ratio of R_∞/R_s for tetrahydrothiophene was found to equal 0.5. Absolute propagation and termination rate constants were determined at three different rates of chain initiation and are summarized in Table 2.

The average propagation and termination rate constants for the oxidation of tetrahydrothiophene are $k_p = 6.4\ M^{-1}\ s^{-1}$ and $2k_t = 3.0 \times 10^7\ M^{-1}\ s^{-1}$. These rate constants are very similar to the propagation and termination rate constants we have previously obtained for the oxidation of the structurally analogous ether, tetrahydrofuran (see Table 4).

Tetrahydrothiophene-α-d_4 oxidizes about one tenth as fast as tetrahydrothiophene, *i.e.* $(k_p/(2k_t)^{1/2})_H/(k_p/(2k_t)^{1/2})_D = 10$. We have previously reported a deuterium isotope effect for the rate constants for the self reaction of secondary alkylperoxy radicals, $(2k_t)_H/(2k_t)_D$ equal to 1.37 (5). Using this isotope effect and the relative rates of oxidation of the deuterated and undeuterated tetrahydrothiophenes, a value of k_p equal to $0.58\ M^{-1}\ s^{-1}$ has been calculated for tetrahydrothiophene-α-d_4 and a propagation deuterium isotope effect equal to about 11. This isotope effect can be compared with the relative reactivities of tetralin and perdeuterotetralin towards *t*-butylperoxy radicals, $(k_p)_H/(k_p)_D = 16$ (6) and diphenylmethane and diphenylmethane-α-d_2 towards the diphenylmethylperoxy radical, $(k_p)_H/(k_p)_D = 5.1$ (7). While the work on the oxidation of organic sulfides was in progress we carefully checked the reactivities of cyclohexene and perdeuterocyclohexene towards *t*-butylperoxy radicals. Cyclohexene gave a value of $k_p = 1.5\ M^{-1}\ s^{-1}$ and perdeuterocyclohexene gave a value of $k_p = 0.13\ M^{-1}\ s^{-1}$ and an isotope effect of 11.5, in excellent agreement with the value for tetrahydrothiophene.

Tetrahydrothiopyran oxidizes about one fifth as fast as tetrahydrothiophene since the ratio $k_p/(2k_t)^{1/2}$ is equal to $2.7 \times 10^{-4}\ M^{-1}\ s^{-1}$. Because of the similarity between termination rate constants for the oxidation of tetrahydrothiophene, tetrahydrofuran, and tetrahydropyran a value of $2k_t$ equal to $3.0 \times 10^7\ M^{-1}\ s^{-1}$ has been assumed for tetrahydrothiopyran. This means that k_p for this six-membered cyclic sulfide is about $1.5\ M^{-1}\ s^{-1}$.

Acyclic Sulfides

The rate constant ratio, $k_p/(2k_t)^{1/2}$, and individual values of k_p and $2k_t$ could not be measured for the autoxidation of diisopropyl sulfide, dibenzyl sulfide, dibenzyl disulfide, benzyl *t*-butyl sulfide or α-toluenethiol. This was because the overall rates of oxidation of these sulfides were close to first order in light intensity and hence close to first order in the rate of chain initiation. For example, oxidation rates for the photochemically initiated autoxidation of diisopropyl sulfide gave a value of 0.25 for the ratio R_∞/R_s.

Benzyl phenyl sulfide was the only acyclic sulfide which gave a ratio of R_∞/R_s close to 0.5 and the individual rate constants for this compound were found to be $k_p/(2k_t)^{1/2} = 1.2 \times 10^{-3}\ M^{-1/2}\ s^{-1/2}$, $k_p = 9.5\ M^{-1}\ s^{-1}$, and $2k_t = 5.6 \times 10^7\ M^{-1}\ s^{-1}$. This sulfide appears to oxidize about four times faster than benzyl phenyl ether because of a larger propagation rate constant (see Table 4).

Autoxidation of Organic Sulfides in the Presence of t-Butyl Hydroperoxide

Previous publications in this series have reported rate constants for the reaction of organic compounds with *t*-butylperoxy radicals

*Reference 8.
†Values in parentheses are estimated rate constants.

determined from oxidations in the presence of *t*-butyl hydroperoxide (usually > 1.0 M). Hydroperoxides are, however, believed to be unstable in the presence of organic sulfides. For example, no titratable hydroperoxide is formed during the oxidation of tetrahydrothiophene or the co-oxidation of tetrahydrothiophene and tetralin at 30°. *t*-Butyl hydroperoxide is, however, stable enough in the presence of some organic sulfides for rate constants to be measured for their reaction with the *t*-butylperoxy radical, k_p^{br}

$$[10]\quad BOO\cdot + RCH_2SR' \xrightarrow{k_p^{br}} BOOH + R\dot{C}HSR'$$

where BOO· represents the *t*-butylperoxy radical.

Table 3 summarizes rate and rate constant data for the oxidation of benzyl *t*-butyl sulfide, tetrahydrothiophene, dibenzyl disulfide, benzyl phenyl sulfide and dibenzyl sulfide in the presence of *t*-butylhydroperoxide (2–4 M). In all cases R_∞/R_s was close to or equal to 0.5 and the termination rate constant was about $1.2 \times 10^3\ M^{-1}\,s^{-1}$, our best value of the termination rate constant for *t*-butylperoxy radicals (8).[3]

Rates of oxidation of α-toluenethiol in the presence of *t*-butyl hydroperoxide were too autoretarding to give a meaningful value of $k_p/(2k_t)^{1/2}$ while the ratio R_∞/R_s for the oxidation of diisopropyl sulfide in the presence of *t*-butyl hydroperoxide was less than 0.3.

Tetrahydrothiophene-α-d_4 ($k_p^{br} = 0.015\ M^{-1}\,s^{-1}$) is less reactive towards *t*-butylperoxy radicals than tetrahydrothiophene and the deuterium isotope effect, $(k_p^{br})_H/(k_p^{br})_D$, is about 7, close to the value obtained from the oxidation of the pure sulfides.

In conclusion, propagation and termination rate constants for the oxidation of organic

[3]The oxidation of most sulfides in the presence of *t*-butyl hydroperoxide developed a large thermal rate of chain initiation after the absorption of a small quantity of oxygen. This implies that an oxidation product may be inducing the decomposition of *t*-butyl hydroperoxide by a free-radical process.

sulfides are summarized in Table 4 and are compared with the rate constants for the oxidation of structurally analogous ethers. It can be seen that towards the *t*-butylperoxy radical the sulfides are of equal or lower reactivity than the corresponding ethers. Furthermore, all three of the sulfides for which absolute rate constants have been determined are more reactive towards their own peroxy radical than the corresponding ethers are towards their own peroxy radical. Tetrahydrothiophene and tetrahydrofuran exhibit the mildest difference in k_p values, but for this pair the k_p^{br} values indicate a 3-fold higher reactivity for tetrahydrofuran. If allowance is made for this factor the measured rate constants suggest that α-alkylthiylalkylperoxy radicals are about 3–5 times more reactive in hydrogen atom abstractions than α-alkoxyalkylperoxy radicals.

The Acetone – Acetic Anhydride – Carbon Disulfide System: Surface Tension, Viscosity, and Total and Partial Vapor Pressures

A. N. CAMPBELL, E. M. KARTZMARK, AND S. C. ANAND

Department of Chemistry, University of Manitoba, Winnipeg

Received February 5, 1971

The surface tensions, viscosities, and vapor pressures, total and partial, have been determined as functions of concentration for the following systems: (*a*) acetone – acetic anhydride; (*b*) acetone – carbon disulfide; (*c*) acetic anhydride – carbon disulfide; and (*d*) pseudo-binary mixtures of (*a*) and (*b*), whose compositions lie on a straight line tangential to the plait point of the ternary system.

The general behavior of ideal and non-ideal systems, in regard to surface tension and viscosity is discussed. For the system acetone – carbon disulfide, whose vapor phase can be considered ideal, the activities, activity coefficients, excess free energies, enthalpies and entropies of mixing have been obtained from the vapor pressures. The vapor phase of the other three systems contains acetic anhydride which is associated in the vapor state, and for these systems the experimental data are reported without further calculation.

Les tensions superficielles, les viscosités et les pressions de vapeur, totales et partielles, ont été déterminées en fonction de la concentration pour les systèmes suivants: (*a*) acétone – anhydride acétique; (*b*) acétone – disulfure de carbone; (*c*) anhydride acétique – disulfure de carbone; et (*d*) des pseudo-mélanges binaires de (*a*) et (*b*), dont les compositions se trouvent sur une droite tangente au point de plissement du système ternaire.

Le comportement général des systèmes idéaux et non idéaux est discuté en fonction de la tension superficielle et de la viscosité. Pour le système acétone – disulfure de carbone, dont la phase vapeur peut être considérée comme idéale, les activités, les coéfficients d'activité, l'excès d'énergie libre, les enthalpies et les entropies de mélanges ont été obtenus des pressions de vapeur. La phase vapeur des trois autres systèmes contient de l'anhydride acétique qui existe à l'état associé en phase vapeur; pour ces systèmes les données expérimentales sont rapportées sans calculs ultérieurs

Canadian Journal of Chemistry, **49**, 2183 (1971)

Introduction

The acetone – acetic anhydride – carbon disulfide system has been the subject of extended research in this laboratory because the acetic anhydride – carbon disulfide binary system forms two layers over a composition range of about 35 mol% at 25°, the critical solution temperature being 52.8° (1–4), but the heterogeneity is destroyed by the addition of about 4 mol% acetone. It is therefore possible, by studying the properties of mixtures whose compositions lie on a straight line tangential to the plait point, to examine isothermally the behavior of solutions just outside the critical condition. The line tangential to the plait point was obtained by drawing a straight line through the plait point, parallel to the tie-lines in the heterogeneous region. The compositions corresponding to the intersection of this line with the two binary systems acetic anhydride – acetone and carbon disulfide – acetone were described as solutions *A* and *B*. Large volumes of these solutions were made up. Mixtures in various proportions of these two solutions gave solutions lying on this straight line. The properties we have previously studied both for the ternary system and its component binary systems are: congruent compositions, excess volumes, and dielectric constants (1) and heats of mixing (2). In the present paper, we report on the surface tensions, viscosities, and total and partial vapor pressures, all at 25°.

Experimental

The purification of materials and experimental methods have all been described before (1–4 and particularly ref.

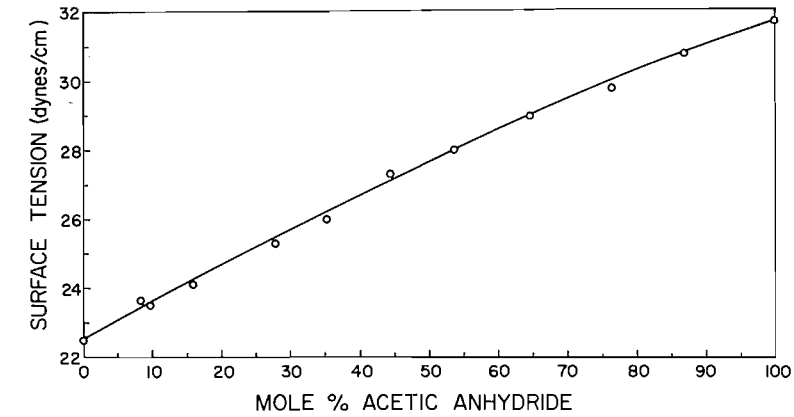

FIG. 1. Surface tension of the acetone – acetic anhydride system at 25°.

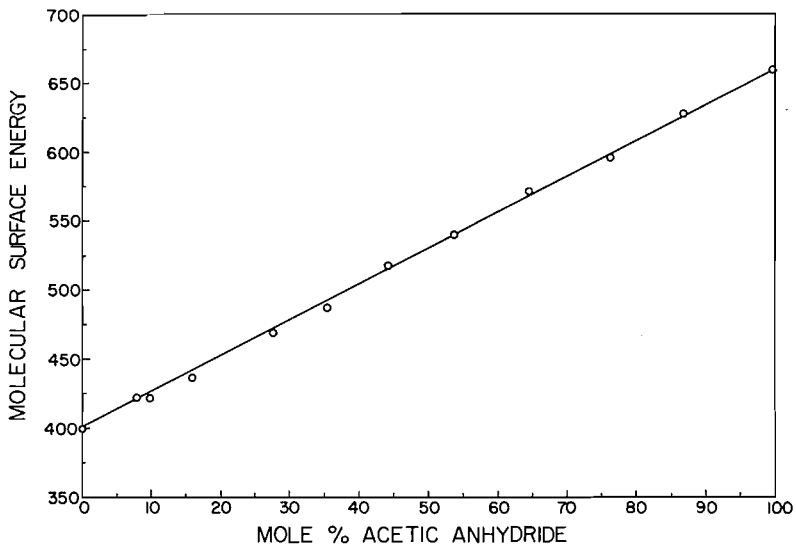

FIG. 2. Molecular surface energy of the acetone – acetic anhydride system at 25°.

5), with the exception of total and partial vapor pressures. The total pressure was determined using a wide bore manometer containing mercury. Solutions were repeatedly frozen in liquid nitrogen and exhausted for several hours, before establishing communication with the manometer. With solutions rich in carbon disulfide, a peculiar phenomenon was observed. Such solutions frequently exploded on warming up, after cooling to liquid nitrogen temperatures. Experiment in an open vessel with pure carbon disulfide showed that the warming up is accompanied by a pronounced crackling sound, which seems to indicate a phase change in the solidified carbon disulfide, with consequent rupture of the containing vessel. This problem was solved by using vessels with very thick walls containing short lengths of sealed Teflon tubing to take up the expansion. Composition of the equilibrium liquid was checked refractometrically. The compositions of the vapors in equilibrium with liquid mixtures of given composition were determined by the air-saturation method, using what was essentially the apparatus of Bichowsky and Storch (6). For the one system whose vapor may be said to behave ideally, *viz.* acetone – carbon disulfide, partial pressures were calculated.

Results

Surface Tension

All numerical results are to be found in the Depository of Unpublished Data of the National Research Council of Canada, but for the benefit of the general reader we express our results

graphically.[1] Although the old-fashioned molecular surface energy ($\gamma(Mv)^{2/3}$) no longer has any exact meaning, it still serves as a method of comparison and we have also represented this graphically. Figure 1 expresses the surface tension and Fig. 2 the molecular surface energy (m.s.e.) of the acetone – acetic anhydride system, *vs.* mol% acetic anhydride. Figures 3 and 4 represent the same data for acetone – carbon disulfide. There seem to be some discrepancies in the literature as to the surface tension of pure carbon disulfide. Our own figure for 25° is 31.78 dyn/cm. Figures 5 and 6 show the surface tensions and m.s.e.'s of the acetic anhydride – carbon disulfide system on both sides of the miscibility gap.

The same data were obtained for the pseudo-binary system and are represented graphically in Figs. 7 and 8, where the compositions are calculated to absence of acetone.

Viscosity

The viscosities (water = 1) of all systems are represented graphically in Figs. 9, 10, 11, and 12.

Vapor Pressure

Tables 1, 2, 3, and 4 give the total pressures and vapor compositions of all four systems. For the acetone – carbon disulfide system, the partial pressures and derived thermodynamic quantities have also been calculated and are given in Table 1. The partial pressures yield the activities directly and from these and the concentrations, the activity coefficients. The excess free energy of mixing is then obtained from

$$G^E = X_1 RT \ln \gamma_1 + X_2 RT \ln \gamma_2$$

A previous paper (3) enabled us to calculate H^E ($= \Delta H_m$), using the constants of the Redlich and Kister equation given in that paper. From these

data, S^E or TS^E results in the usual manner. The results are expressed graphically as Fig. 13. The vapor pressures of the system, carbon disulfide – acetone were first determined by Zawidsky (7) at 35.17° and later by Hirschberg (8) at 29.2°.

Thermodynamic quantities have not been derived for the remaining systems, because the vapor of acetic anhydride is associated (11) and it is therefore not possible to obtain the true partial pressures or activities by any simple method, although no great error would be made in making the calculations for the more volatile constituents, since the vapor pressure of acetic

*The liquid phase lies on the pseudo-binary line but this, of course, is not true of the vapor composition.

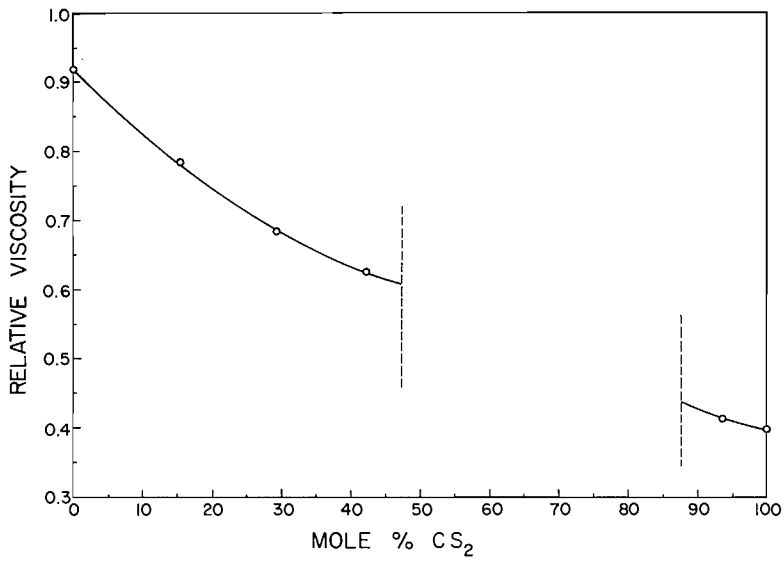

FIG. 11. Viscosity of the acetic anhydride – carbon disulfide system at 25°.

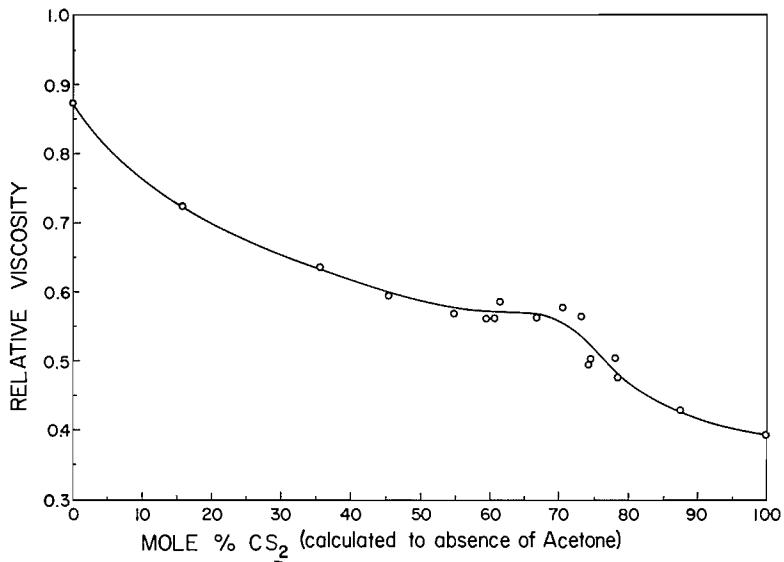

FIG. 12. Viscosity of the acetone – acetic anhydride – carbon disulfide system at 25°.

anhydride is quite low (= 7 mm at 25°). If it is desired to take into account the dimerization of one component in the vapor phase, this can be done, if, as in the present paper, the equilibrium compositions of liquid and vapor are known (10–12).

Discussion

In Fig. 1 the surface tensions of acetone – acetic anhydride mixtures show slight positive deviation from linearity. The m.s.e., however (Fig. 2), gives a practically straight line plot. We have previously pointed out (1, 2) that the acetone – acetic anhydride system is practically ideal. The acetone – carbon disulfide system shows very strong negative deviation from straight line behavior of the surface tension and m.s.e. plots, and it is well known that this system is very non-ideal. Indeed, at a sufficiently low temperature

For personal use only.

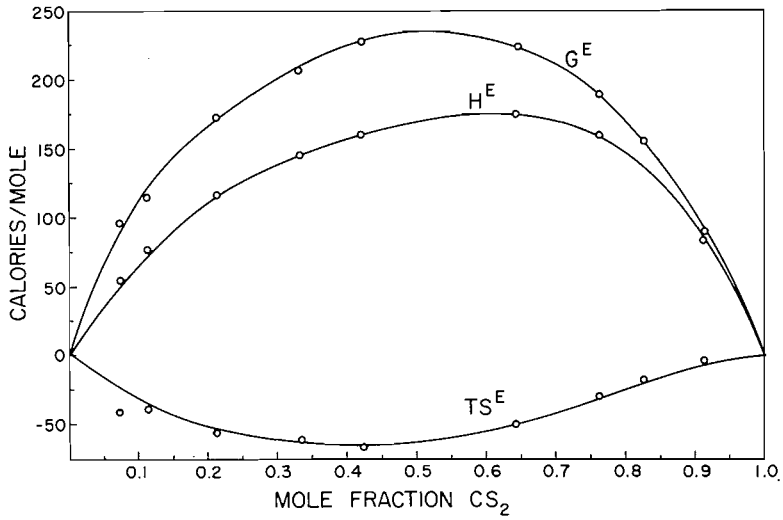

FIG. 13. Thermodynamic quantities *vs.* mole fraction of the acetone – carbon disulfide system at 25°.

(−73 °C), the system forms two layers (2). Figures 5 and 6 show similar non-ideal behavior for the acetic anhydride – carbon disulfide system, as of course is to be expected, since this system forms two layers at 25°. The pseudo-binary system, *A–B*, while also showing negative deviation from ideality, is not so markedly non-ideal as the two other non-ideal systems. The application of the Gibbs adsorption equation to this is obvious.

A general scrutiny of these non-ideal systems indicates that the surface tension of the non-polar substance (carbon disulfide) is rapidly reduced by small additions of the polar substance (acetic anhydride or acetone). On the other hand, the surface tension of the polar substance, though also reduced, follows an almost linear relation for small additions of the non-polar substance. It is not necessary, where partial miscibility occurs, that the congruent layers should have the same surface tension (9).

The behavior of these systems with respect to viscosity seems not unlike that with respect to surface tension. The viscosities of the acetic anhydride – acetone system show almost straight line behavior, as a function of molar composition. The other three (non-ideal) systems show pronounced negative deviation from additivity. Concerning the system showing a gap at 25° (acetic anhydride – carbon disulfide), it is noteworthy that the viscosities of the congruent layers are far from being the same. The pseudo-binary system, however, seems to show a region of roughly constant viscosity in the neighborhood of the plait point. This region of constant viscosity is a manifestation of the "anomalous viscosity", commonly observed in the neighborhood of critical points, *i.e.*, the viscosity is greater than what would correspond to the smooth curve. This again is a manifestation of the colloidal, or semi colloidal, nature of solutions close to the critical state.

An extended discussion of the vapor pressure and thermodynamic measurements seems to us out of place. We have applied the equations of Margulese and of van Laar and obtained the usual 5% discrepancy between calculated and observed activity coefficients of acetone and of carbon disulfide.

Table 4, which gives total pressures and liquid and vapor compositions in the pseudo-binary system, is of particular interest. If total pressure is plotted against mol% carbon disulfide (calculated to absence of acetone), it is seen to be practically constant over the range 23 to 51 mol% acetic anhydride. The same must be true of the partial pressures, since the vapor composition changes hardly at all. Since all compositions of the pseudo-binary system lie on a straight line tangential to the curve of congruent compositions at the plait point, it appears that the (isothermal) thermodynamic requirement that two liquid layers in equilibrium must possess the same total and partial pressures persists in the homogeneous region in the immediate neighborhood of the plait point.

Production of $O(^1D_2)$ Atoms in the Photolysis of CO_2 at close to 1600 Å[1]

L. M. QUICK[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 4, 1971

Photolysis of CO_2/neopentane mixtures with a bromine lamp was studied at room temperature to obtain chemical evidence for primary formation of $O(^1D_2)$ atoms in the photolysis of CO_2 at close to 1600 Å. The trends in the effects of various added gases on the yield of neopentanol agreed well with those reported in the literature for the rates of deactivation of $O(^1D_2)$ atoms. This agreement demonstrated $O(^1D_2)$ formation in the photolysis of CO_2 at the wavelength used.

On a étudié la photolyse de mélanges CO_2/neopentane à la température de la pièce et à l'aide d'une lampe à brome afin de détecter des preuves chimiques concernant la formation primaire d'atomes $O(^1D_2)$ lors de la photolyse du CO_2 autour de 1600 Å. Les effets produits par l'addition de divers gaz sur le rendement de néopentanol sont en accord avec ceux rapportés dans la littérature pour les taux de désactivation des atomes $O(^1D_2)$. Cette concordance démontre que des atomes $O(^1D_2)$ sont formés lors de la photolyse du CO_2 à la longueur d'onde utilisée.

Canadian Journal of Chemistry, **49**, 2193 (1971)

Introduction

Photolysis of carbon dioxide takes place in the vacuum ultraviolet spectral region at wavelengths shorter than about 1700 Å. It is a process of importance for understanding of the photochemical balances of some planetary atmospheres and although it has been studied extensively in recent years (1–9), some aspects of its detailed mechanism are still quite controversial and uncertain. Primary formation of the excited oxygen atoms $O(^1D_2)$ is generally postulated but their direct observation by spectroscopic methods is difficult because of their great reactivity and quite long radiative life time. On the other hand, their indirect observation by chemical methods is now well established and is responsible for much of the current knowledge of their chemical and physical behavior.

In the present work an attempt is made to use the relatively simple reaction of $O(^1D_2)$ atoms with neopentane (10, 11) as a chemical probe for the production of $O(^1D_2)$ atoms in the photolysis of CO_2 at about 1600 Å. In this reaction neopentanol is formed by insertion of $O(^1D_2)$ into the CH bonds of neopentane with an efficiency of about 65% and the "hot" alcohol is completely stabilized at moderate pressures (100–200 Torr). The known effects (10, 12–16) of various additive gases are used in conjunction with the yield of neopentanol as qualitative evidence for the presence of $O(^1D_2)$ atoms. The quantum yield of neopentanol provides a quantitative indication of the primary quantum yield of $O(^1D_2)$ atoms. The present study is a continuation of an earlier investigation (17) of CO_2 photolysis at close to 1600 Å.

Experimental

Photolyses were carried out at room temperature (25 ± 1 °C) in a semispherical reaction vessel of about 250 ml in volume, incorporated in a circulating system containing a piston type circulating pump and connected to a bromine lamp through a thin semispherical Suprasil window. A lamp and reactor of the same construction were designed and used in the earlier study of CO_2 photolysis and are described in greater detail elsewhere (17). The lamp itself was an adaptation of the bromine lamp of Harteck and co-workers (18). The main output is at 1633 Å and also there are two smaller lines at around 1575 Å and some low background continuum extending to the 2100 Å region. The circulating pump was used to achieve efficient mixing of the reactants before the photolysis and to assure after the photolysis complete condensation at −196 °C of the condensable products in a U-bend of the reaction system immersed in liquid nitrogen. The non-condensable gases were collected through a liquid nitrogen trap into a combined Toepler pump-gas burette. The condensables were warmed up and the above procedure repeated to collect any residual non-condensables trapped in the frozen products. The non-condensables were analyzed on a 20 ft 13X molecular sieve column at room temperature, using helium as the carrier gas and a thermistor detector.

A known amount of toluene was added as an internal standard to the condensable products in a vessel provided with a magnetically operated stirrer. After thorough mixing, these products were analyzed at room temperature on a 300 ft 0.015 in. i.d. stainless steel capillary column coated with β,β′thiodipropionitrile, using helium as the

[1]NRCC No. 11934.

For personal use only.

carrier gas and a hydrogen flame detector. Mass spectrometric identification of the individual gas chromatographic peaks was carried out on a fast scanning CH4 Atlas mass spectrometer connected so to scan directly the column eluents. Hydrocarbon products were analyzed on a 300 ft squalane capillary column at 25 °C and a 300 ft dinonyl phthalate capillary column at 0 °C.

The main emphasis was on a quantitative analysis of the neopentanol/CO ratios. These ratios were time dependent at larger conversions, decreasing at longer irradiation times, and the initial values were then obtained by extrapolation to zero time. In later work, analyses were carried out at small conversions and extrapolations to zero time were found to be unnecessary.

Matheson Research Grade carbon dioxide was used after degassing at −196 °C and several bulb-to-bulb distillations from −78 to −196 °C with retention of the middle cut. Phillips Research Grade neopentane was treated with concentrated H_2SO_4 and then passed over KOH pellets to remove traces of olefins. This was followed by several bulb-to-bulb distillations from −78 to −196 °C, with degassing. However, a sample of neopentane not treated with H_2SO_4 and KOH gave results similar to those obtained with a treated sample.

Matheson Research Grade xenon was degassed from solid nitrogen. Matheson carbon monoxide (stated purity 99.5%) was passed through a trap at −78 °C to remove iron carbonyl. Matheson Research Grade nitrogen was used without further purification and Matheson Ultra High Purity hydrogen was expanded into its vacuum reservoir through a liquid nitrogen trap. Matheson sulfur hexafluoride was degassed at −140 °C to remove carbon tetrafluoride and subjected to two bulb-to-bulb distillations with retention of the middle cut. Phillips Research grade ethane and propane were used after degassing and several bulb-to-bulb distillations from −78 to −196 °C.

At the wave lengths of 1633 and 1575 Å from the bromine lamp used no photolysis of sulfur hexafluoride was observed, in agreement with the fact that SF_6 begins to absorb at 1520 Å and peaks at 1050 Å.

Results

Chemical evidence for $O(^1D)$ atom formation in the photolysis of CO_2 was sought in the present work in the type of products formed in the photolysis of CO_2/neopentane mixtures. An obvious complication arises from the fact that the bromine lamp used photolyzes not only CO_2 but also neopentane and some of the primary reaction products. However, although this complication was troublesome it did not interfere with the primary objective of the work to obtain evidence for the presence of $O(^1D)$ atoms. Photolysis of neopentane at about 1600 Å was found to produce H_2, CH_4, C_2H_6 and various higher paraffins and olefins (hexamethylethane, 2,2,4-trimethylpentane, and 2,4,4-trimethylpentene-1 were identified). Some of these products were also found in the photolysis of CO_2/neopentane mixtures but they did not interfere with the study of the yields of oxygen-containing products, notably of neopentanol, the major product of reaction of $O(^1D)$ with neopentane. Hydrocarbons higher than C_2H_6 were therefore not measured quantitatively. Photolysis of neopentanol alone at about 1600 Å formed a variety of products, including pivalaldehyde, acetone, tert-butanol, methanol, and isobutyraldehyde. Pivalaldehyde was the main product. These products were formed also in the neopentane/CO_2 system but were not measured quantitatively. Initial yield of neopentanol was determined by extrapolation to zero reaction time, as will be described below.

Photolysis of CO_2 alone at pressures up to about 1 atm has been recently investigated in some detail in this laboratory (17). Our experiments at 100, 220, and 600 Torr CO_2 show similar O_2/CO values and do not require further discussion.

With CO_2/neopentane mixtures the main attention was focused on the neopentanol/CO ratio. As already indicated, this ratio was time dependent mainly as a result of the secondary photolysis of neopentanol. Figure 1 shows examples of decreasing neopentanol/CO ratios at longer reaction times. Steeper decrease is observed at larger

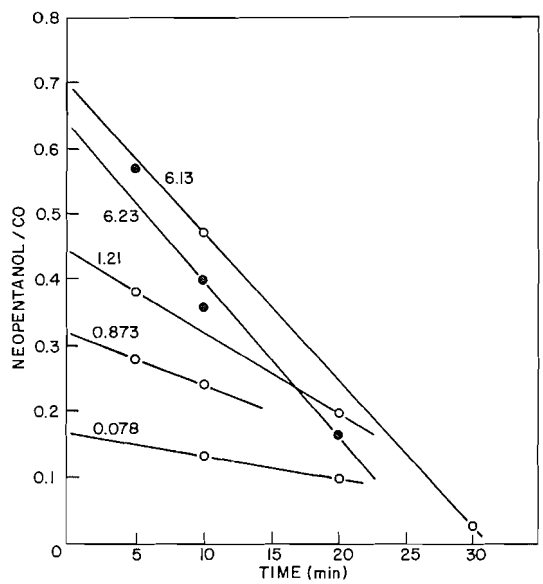

FIG. 1. Variation of the neopentanol/CO yields as a function of time at different [neopentane]/[CO_2] ratios (indicated on the lines).

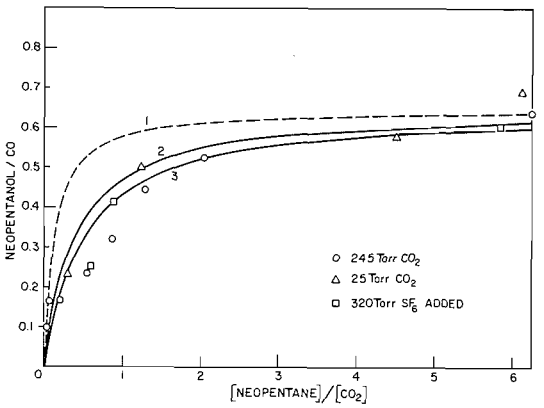

FIG. 2. Variation of the neopentanol/CO yields as a function of the [neopentane]/[CO_2] ratio. (The meaning of the broken and solid curves is explained in the text).

neopentane/CO_2 ratios (indicated by the numbers on the lines). Linear extrapolations to zero time were used to determine approximately the initial values of the neopentanol/CO ratios and these are plotted in Fig. 2 for a number of experiments. The ratios increase with increasing neopentane/CO_2, tending to a plateau value between 0.6 and 0.7. Because of errors in extrapolations to zero time and possible slight changes in the character of lamp emission, there is considerable scatter of points, but within this uncertainty there does not seem to be a difference between experiments with 25 and 245 Torr CO_2. Furthermore, as shown in Fig. 2, addition of approximately 320 Torr SF_6 in some of these experiments had no effect on the neopentanol/CO ratios. The significance of the solid and the interrupted curves in Fig. 2 will be discussed later.

In order to test directly whether O(^{1}D) atoms are involved in the process, the effect of various added gases on the relative yield of neopentanol has been investigated. Since Fig. 2 shows that for neopentane/$CO_2 \geqslant 6.5$ the neopentanol yield was at the plateau value, such mixtures were used (with about 11 Torr CO_2) in the presence of different pressures of added gases (SF_6, Xe, C_2H_6, C_3H_8, CO, N_2, and H_2). The ratios of the initial rates of formation of CO and neopentanol (r_{CO}/r_{ROH}) were determined and plotted as a function of the ratio of concentrations of the added gas (A) and neopentane (RH). At the very small conversions used in some of the systems studied extrapolations to zero time were found to be unnecessary and were not made. Slope to intercept ratios of the linear r_{CO}/r_{ROH} plots gave ratios of rate constants for the over-all (chemical plus physical) reaction of O($^1D_2$) atoms with the added gas (k_A) and with neopentane (k_{np}), since, as will be shown later, under conditions of these experiments

$$[1] \qquad \frac{r_{CO}}{r_{ROH}} = \frac{1}{\alpha}\left(1 + \frac{k_A}{k_{np}}\frac{[A]}{[RH]}\right)$$

The constant α is the fraction of O($^1D_2$) atoms interacting with neopentane which insert into the CH bonds to form neopentanol.

Plots of eq. 1 for SF_6, Xe, C_2H_6, and C_3H_8 are shown in Fig. 3. There is an appreciable scatter of points but the expected pronounced increase in reactivity in going from SF_6 to Xe, C_2H_6, and C_3H_8 is clearly shown. Least-square values and the corresponding standard deviations of k_A/k_{np} are given in Table 1 and are compared with the literature values obtained in vastly different systems.

The values of k_A/k_{np} for CO, N_2, and H_2 have been obtained in somewhat similar manner and are also included in Table 1. However, in the presence of large amounts of these non-condensable gases it was not feasible to measure directly the yield of CO and it was assumed that the lamp intensity remained approximately constant. Under such conditions and at constant concentrations of CO_2 and neopentane, plots of $1/r_{ROH}$ against [A]/[RH] would be expected to be

linear and the intercept to be independent of the gas added. The lamp intensity was kept constant by (*a*) using the same current in the microwave generator and (*b*) by adjusting the visible output of the lamp so that it just filled the Suprasil window between the lamp and the reactor. Scatter of points showed that the u.v. output of the lamp remained constant to better than ±20%. Moreover, the least squares intercepts for the three gases were the same within ±10%. The least squares k_A/k_{np} values compare again quite well with the corresponding literature values although the standard deviations are appreciably larger.

Discussion

Discussion of the results of this work may be based on the following reaction scheme

[2]	$CO_2 + h\nu$	$\rightarrow CO_2^*$
[2*a*]	CO_2^*	$\rightarrow CO + O(^1D_2)$
[2*b*]		$\rightarrow CO + O(^3P)$
[3]	$O(^1D_2) + CO_2$	$\rightarrow O(^3P) + CO_2$
[4*a*]	$O(^1D_2) + RH$	$\rightarrow ROH^*$
[4*b*]		$\rightarrow R + OH$
[4*c*]		$\rightarrow RH + O(^3P)$
[5*a*]	$O(^1D_2) + A$	$\rightarrow A + O(^3P)$
[5*b*]		$\rightarrow$ Products
[6]	ROH^*	$\rightarrow$ Fragmentation
[7]	$ROH^* + M$	$\rightarrow ROH + M$

Some other reactions will be mentioned later. RH stands for neopentane, ROH for neopentanol, A is a "quencher" of $O(^1D_2)$ atoms, and M stands for any molecules present which can collisionally deactivate the "hot" neopentanol (ROH^*). Steady state treatment gives

$$[8]\quad \frac{r_{ROH}}{r_{CO}} = \frac{k_{2a}}{k_{2a}+k_{2b}} \cdot \frac{1}{1+\dfrac{k_6}{k_7[M]}} \cdot \frac{k_{4a}/k_4}{1+\dfrac{k_3[CO_2]}{k_4[RH]}+\dfrac{k_5[A]}{k_4[RH]}}$$

The constant k_4 stands for $(k_{4a} + k_{4b} + k_{4c})$, *i.e.* for $(k_{4a} + k_{4b})$ since k_{4c} has been shown (10) to be very small or zero. Similarly, k_5 stands for $(k_{5a} + k_{5b})$.

At pressures higher than about 100 to 200 Torr $k_7[M] \gg k_6$ and when also $[CO_2]/[RH]$ is small enough so that $k_3[CO_2]/k_4[RH] \ll (1 + k_5[A]/k_4[RH])$, eq. 8 reduces to eq. 1, with $\alpha = \{k_{2a}/(k_{2a}+k_{2b})\}\{k_{4a}/k_4\}$, $k_{np} = k_4$, and $k_A = (k_{5a} + k_{5b})$. The present values of k_A listed in Table 1 are based on the use of eq. 1 derived in this manner. Their good agreement with the corresponding literature values clearly shows the presence of $O(^1D_2)$ atoms in the reaction system studied. The primary objective of the present work has been to obtain such information and the experimental accuracy is evidently adequate for this purpose in spite of the considerable scatter of experimental points. At the same time, the overall experimental uncertainty of present determinations is appreciable and we therefore feel that they should not be used to refine the corresponding k_A values in the literature.

The neopentanol/CO trend in Fig. 2 is qualitatively predicted by eq. 8 with [A] = 0. However, it is now known (10, 14) that $k_3/k_4 = 0.127$ and the expected trend calculated using this value is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

shown by curve *1* (interrupted curve) in Fig. 2. In these calculations it was assumed that $k_6/k_7[M] \ll 1$ and $\alpha = 0.65$. The latter figure is identical with the experimental value of k_{4a}/k_4 for neopentane determined recently in this laboratory (10) and is also approximately equal to the "plateau" value of r_{ROH}/r_{CO} in Fig. 2. The approximate validity of the assumption that $k_6/k_7[M] \ll 1$ is shown by the insensitivity of the data in Fig. 2 to variation in CO_2 pressure and addition of 320 Torr SF_6.

The exact reasons for the deviations in Fig. 2 of the observed $r_{neopentanol}/r_{CO}$ values from those expected (curve *1*) are not known. It is important to note that deviations become negligible at higher neopentane/CO_2, where also $r_{neopentanol}/r_{CO}$ coincides with the experimental k_{4a}/k_4 value of 0.65. It could be argued that the deviations are only due to an error in the value $k_3/k_4 = 0.127$ used to compute curve *1*. Alternative curves (curves *2* and *3* in Fig. 2) have been computed with k_3/k_4 values which are, respectively, 3 and 4 times larger than 0.127 and they are indeed reasonably close to the experimental points. Nevertheless, such an explanation of the deviations must be rejected, in particular because it would also lead to a k_{CO_2}/k_{Xe} value 3 to 4 times larger than the well established literature values of close to unity (10, 12–14).

The deviations in $r_{neopentanol}/r_{CO}$ at lower neopentane/CO_2 in Fig. 2 appear therefore to be real. No doubt they are at least partly due to inaccurate extrapolations to zero time and it is in fact possible that such extrapolations may be inadequate in some cases. Such would be the case, for example, if in the very early stages of the reaction a preferential attack on neopentanol occurred by some reactive intermediates which are scavenged efficiently later in the reaction by other reaction products (olefins, free radicals), especially so at higher neopentane/CO_2 ratios. Alternatively, at larger CO_2/neopentane there could be some attack on CO_2 to form extra CO (in addition to the CO formed in reaction 2) by some active intermediates, as for example "hot" hydrogen atoms formed in the photolysis of neopentane. Additional assumptions would then be required to explain the trend with neopentane/CO_2. However, it would not be feasible at present to obtain a direct experimental evidence for or against such hypotheses and further discussion is not warranted. An attack of OH* ("hot" OH radicals formed in reaction 4*b*) on CO_2 to produce excess CO seems to be ruled out by the experiments with N_2O/CO_2/neopentane mixtures at 2139 Å (10) in which a substantial increase in CO was not observed under conditions conducive to an appreciable interaction of OH* with CO_2.[3] An interaction of CO_2* formed in reaction 2 with CO_2 to produce CO

$$CO_2^* + CO_2 \rightarrow CO + O(^3P) + CO_2$$

may appear at first sight to provide a feasible explanation of the deviations (excess CO) in Fig. 2 at larger CO_2/neopentane. However, since $r_{neopentanol}/r_{CO}$ is not a function of $[CO_2]$ but of $[CO_2]/[neopentane]$, it would be necessary to postulate also that

$$[CO_2^*] + RH \rightarrow CO + O(^1D_2) + RH$$

while other gases, such as SF_6 etc., should have no effect on CO_2*. Such a behavior would be difficult to understand.

While these various possible explanations of the deviations at lower $[neopentane]/[CO_2]$ ratios cannot be resolved at this time, the overall agreement in the quenching rates (Table 1) with the corresponding literature values shows that under conditions used in their determinations, *i.e.* at $[neopentane]/[CO_2] \geqslant 6.5$, such complications are negligible.

The overall agreement in the trends found in the present and the literature determinations of k_A in Table 1 shows clearly that $O(^1D_2)$ atoms are generated in the photolysis of CO_2 at close to 1600 Å and are responsible for the formation of neopentanol when neopentane is added. Furthermore, the observation in this work of a plateau value for $r_{neopentanol}/r_{CO}$ of about 0.65, which is the same as observed in N_2O photolysis (10), suggests that the quantum yield of $O(^1D_2)$ atom production in the photolysis of CO_2 is close to unity. However, the appreciable experimental scatter weakens the quantitative aspect of this conclusion.

Mechanism of the Pyrolysis of Acetylene

M. H. BACK
Chemistry Department, The University of Ottawa, Ottawa, Canada

Received January 28, 1971

A free radical chain mechanism is presented to describe the kinetics of the pyrolysis of acetylene over the temperature range 700–2400 °K. The mechanism is based on the following initiation reaction

$$2\,C_2H_2 \rightarrow {}^{\bullet}C_2H + {}^{\bullet}C_2H_3$$

and subsequent addition, abstraction, and decomposition reactions of the radicals involved are shown to account for the products observed and for the kinetic characteristics of the reaction.

Pour décrire la cinétique de la pyrolyse de l'acétylène entre 700 et 2400 °K, on propose un mécanisme en chaîne impliquant des radicaux libres et qui serait basé sur la réaction d'initiation suivante

$$2\,C_2H_2 \rightarrow {}^{\bullet}C_2H + {}^{\bullet}C_2H_3$$

des réactions subséquentes d'addition, d'abstraction et de décomposition des radicaux impliqués permettent de rendre compte des produits obtenus et de la cinétique caractéristique de la réaction.

Canadian Journal of Chemistry, 49, 2199 (1971)

Introduction

The mechanism of the pyrolysis of acetylene is not well established, partly because of the analytical difficulties involved in obtaining reliable data with highly reactive products and also because of the variable effects of heterogeneous reactions. Modern analysis has largely overcome many of these problems and in particular the work of Cullis and Franklin (1) over the range 700–1200 °K and of Gay *et al.* (2) in the range 1600–2400 °K has clearly distinguished the primary from the secondary products. In the lower temperature region, below about 1200 °K, vinyl acetylene, C_4H_4, is the sole initial product, while in the high temperature region diacetylene, C_4H_2, is the primary molecular product. Benzene is an important secondary product, particularly in the lower temperature range, and methane, hydrogen, ethylene, and butadiene are also formed in varying yields depending on temperature and conversion.

A remarkable feature of the acetylene system is that the second-order rate constants for the reaction of acetylene obtained by many different workers covering the temperature range 620–2450 °K apparently lie on a single linear plot of $\log k$ against $1/T$ (3) and may be represented by the Arrhenius expression (2)

$$\log k\ (\text{l mol}^{-1}\text{s}^{-1}) = 10.8 - 41\,600/2.3RT$$

This suggests that the mechanism involves the same rate-controlling steps over the entire temperature range.

In several respects the kinetics of the acetylene pyrolysis bear a strong resemblance to those observed in the pyrolysis of ethylene (4). The activation energy of the reaction is low, between 40 and 45 kcal/mol, and induction periods are observed. Both the initial rates and the maximum rates after the induction period are second order in acetylene (5). The activation energy is too low to allow initiation by unimolecular fission of bonds in the acetylene molecule and many authors have favored a bimolecular reaction of acetylene to give an excited molecule of acetylene in the triplet state (6, 7) or a triplet or biradical species C_4H_4* (8, 9). The rate of formation of excited molecules in thermal systems is, however, somewhat uncertain; the frequency factor may be very low. In the ethylene system initiation was suggested to occur by the bimolecular disproportionation reaction of two ethylene molecules to form an ethyl and a vinyl radical. Such a reaction appeared reasonable in the acetylene system also, and had been suggested (8), but was not followed up with a complete mechanism. With this initiation a series of radical addition, abstraction and decomposition reactions may occur which will lead to the formation of the observed products over a wide temperature range.

The Mechanism

Reactions 1–17 represent an outline of the most probable reactions and may be considered a framework for the building of a complete mechanism.

The products formed depend on the tempera-

[17]	${}^{\bullet}C_nH_{n+1} + C_2H_2 \rightarrow {}^{\bullet}C_{n+2}H_{n+3}$	

ture region where the reaction occurs. At high temperatures, as found in shock tubes, the vinyl radical will be largely dissociated and the chain will be carried by hydrogen atoms and C_2H radicals. Decomposition of the C_4H_3 radical will compete with addition and C_4H_2 will be the primary product. This region is illustrated by the work of Gay *et al.* (2). At lower temperatures reactions of the vinyl radical will become important and vinyl acetylene, ethylene, and butadiene are products. At still lower temperatures further addition reactions will build up higher molecular weight products.

Rate Expressions

Assuming a long chain reaction with a steady state concentration of radicals, the rates of formation of the products may be expressed as follows:

(a) High Temperature Region

$$\text{Rate } C_4H_2 = k_3(k_1/k_6)^{\frac{1}{2}}(C_2H_2)^2$$

(b) Intermediate Temperature Region

Vinyl acetylene may be formed by either of the sequences [3] followed by [10] or [7] followed by [8], depending on the relative concentration of C_2H_3 and C_2H radicals. If C_2H radicals are dominant the rate may be expressed as

$$\text{Rate } C_4H_4 = k_3(k_1/k_6)^{\frac{1}{2}}(C_2H_2)^2$$

while if C_2H_3 radicals are dominant the rate becomes

$$\text{Rate } C_4H_4 = k_7(k_1/k_{13})^{\frac{1}{2}}(C_2H_2)^2$$

The relative concentration of C_2H_3 and C_2H radicals is a complex function of a number of competing reactions. High temperatures favor the formation of C_2H, which is formed by abstraction from acetylene, while the addition reaction to form C_2H_3, either of hydrogen atoms or of larger radicals followed by decomposition, having a lower activation energy, will make an increasing contribution as the temperature is lowered. It is possible that the changes in the product distribution with temperature follow the change in the relative concentration of C_2H and C_2H_3, but this cannot be ascertained without a more exact knowledge of the rate constants for the elementary reactions involved.

(c) Low Temperature Region

The primary products in this region are somewhat more uncertain but a general expression similar to those for the other regions may be written,

$$\text{Rate polymer} = k_a(k_1/k_t)^{\frac{1}{2}}(C_2H_2)^2$$

where k_a is an average rate constant for addition and k_t represents the termination rate constant for the radicals involved.

TABLE 1. Thermodynamic quantities used in the estimation of rate constants

Radical	$\Delta H_f°$(298 °K) kcal/mol	Reference	$S°$(298 °K)* Gibbs/mol	Reference
C_2H_2	54.3	31	48.0	31
C_2H_3	64	16	56.3	32

‡Estimated.

Thus the rate expressions covering a wide temperature range differ only insofar as the rate constants for addition of radicals to acetylene and for combination of radicals vary with the size of the radical. Neither of these rate constants would be expected to change very much as the size of the radical is increased, keeping in mind that because of the ease of C—C bond fission in larger radicals, the chain is probably carried by low molecular weight radicals even in the lower temperature region. An Arrhenius plot linear within the error limits involved in the measurements of the acetylene pyrolysis would therefore be consistent with the radical mechanism.

A quantitative comparison between these rate expressions and the experimental rate measurements may be made by making reasonable estimates of the rate constants involved. The equilibrium constant for the initiation reaction may be estimated using the thermodynamic quantities listed in Table 1. The rate constant for reaction 1 may then be calculated by making some assumptions about the reverse disproportionation reaction of vinyl and ethynyl radicals. Holroyd and Klein (10) have shown that the relation proposed by Bradley (11) between the ratio of the rate constants for disproportionation and combination and the difference in entropy of the products of the disproportionation and combination reactions is applicable for a large number of alkyl radicals. On this basis k_d/k_c for ethynyl and vinyl radicals would have the low value of 0.03. Measurements of the ratio k_d/k_c for methyl and vinyl radicals and for vinyl radicals themselves, however, gave values of 2.3 and 1.1 respectively (12), although from the relation with the entropy difference the value should also be low in both cases. It seems that the transfer of the hydrogen atom from the vinyl radical may be very facile, leading to a larger ratio for k_d/k_c than would be predicted from the corresponding entropy difference between the disproportionation and combination products of alkyl radicals. A reasonable estimate for k_d/k_c for the ethynyl–vinyl radical pair may be 1.0 and if the rate constant for combination of these radicals is assumed equal to that for two ethyl radicals (13) then

$$\log k_{-1}(\text{l mol}^{-1}\text{s}^{-1}) = 10.04$$

The rate constant for reaction 1 may then be written as

$$\log k_1(\text{l mol}^{-1}\text{s}^{-1}) = 12.7 \pm 0.5 - (70\,000 \pm 3000)/2.3RT$$

An average rate constant for addition of low molecular weight radicals to acetylene may be estimated by comparison of values for addition of radicals to olefins (14) and from values reported by Dominguez and Trotman–Dickenson (15) for the addition of saturated radicals to acetylene. The rate constant for addition of unsaturated radicals to acetylene is probably somewhat faster than the corresponding value for the saturated radicals and the following value is suggested,

$$\log k_a(\text{l mol}^{-1}\text{s}^{-1}) = 8.8 \pm 0.5 - (6500 \pm 1000)/2.3RT$$

Very few rate constants have been reported for reactions of radicals with alkynes and the experimental difficulties involved make the wide error limits necessary. The rate constant for termination may be taken equal to that for two ethyl radicals (13),

$$\log k_t(\text{l mol}^{-1}\text{s}^{-1}) = 10.3$$

The composite rate constant may therefore be expressed as

$$\log k(\text{l mol}^{-1}\text{s}^{-1}) = 10.0 - 41\,500/2.3RT$$

This expression is shown as the dashed line in

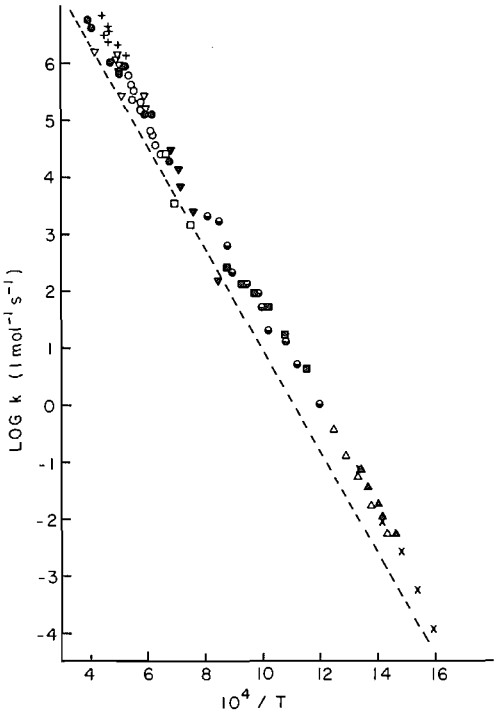

FIG. 1. Arrhenius plot of the second-order rate constants for the pyrolysis of acetylene: ○, ref. 27; △, ref. 26; ▼, ref. 28; ▲, ref. 5; ▽, ref. 29; ×, ref. 30; ●, ref. 3; □, ref. 9; ■, ref. 22; ◒, ref. 1; +, ref. 2; broken line, calculated from the rate expressions derived from the mechanism.

Fig. 1 together with rate constants obtained by 11 different investigators. The uncertainties in these estimated rate constants could easily allow for an uncertainty of a factor of 10 and perhaps as much as 50 in the composite rate constant. The correspondence of the calculated rate with the measurements is therefore as close as may be reasonably expected.

The mechanism depends on the assumption that the addition of radicals is the rate-controlling step in the chain propagation. The rate of addition of C_4H_3 radicals to acetylene may be compared to their rate of decomposition taking the value for k_a used in the preceding calculation and assuming the following value for k_4,

$$\log k_4(s^{-1}) = 14 - (40\,000 \pm 4000)/2.3RT$$

The activation energy for dissociation of the C—H bond in the C_4H_3 radical would be expected to be very similar to that for dissociation of the C—H bond in the vinyl radical (16). Although the substitution of the C_2H radical for the hydrogen atom in the vinyl radical would act to increase the strength of the C—H bond through conjugation, the stability of the molecule formed by the loss of the hydrogen atom would be correspondingly increased and the two effects would probably cancel. Thus a value of 40 kcal/mol is a reasonable estimate. This value is lower than the endothermicity of 61 kcal/mol suggested by Cowperthwaite and Bauer (17) from a consideration of the heats of formation of various C_4H_3 and C_4H_2 species. Their C_4H_3 radical, however, did not have the same structure as the radical formed by addition of C_2H to acetylene.

$$\frac{\text{Rate (4)}}{\text{Rate (a)}} = \frac{k_4}{k_a(C_2H_2)}$$

Thus at 1200 °K and a pressure of 100 Torr of acetylene,

$$\frac{\text{Rate (4)}}{\text{Rate (a)}} \sim 100$$

Thus at temperatures above 1200 °K, C_4H_2 may be the main primary product with addition being the rate-determining step. If vinyl radicals are somewhat more stable than the C_4H_3 radicals, C_4H_5 radicals may be formed in appreciable amounts below 1200 °K and vinyl acetylene may become the main initial product. Dissociation of C_4H_5 to vinyl acetylene may still compete successfully with addition down to about 1000 °K. Palmer and Dormish (9) observed that the more prominent C_4 product at 1333 °K was vinyl acetylene while at 1528 °K it was diacetylene. These regions are essentially in agreement with the present rough estimate.

As addition of radicals to acetylene becomes important at lower temperatures, radicals of molecular weight C_6 or C_8 may be formed. From these radicals lower molecular weight products may be formed by C—C fission and this process, having a lower activation energy than that for C—H dissociation, will remain faster than addition down to fairly low temperatures. Vinyl acetylene could be formed by such a route at lower temperatures, for example as follows,

$$\dot{C}H{=}CH{-}CH{=}CH_2 + C_2H_2 \rightarrow \dot{C}H{=}CH{-}CH{=}CH{-}CH{=}CH_2$$

$$\dot{C}H{=}CH{-}CH{=}CH{-}CH{=}CH_2 \rightarrow CH_2{=}CH{-}CH{=}\dot{C}{-}CH{=}CH_2$$

$$CH_2{=}CH{-}CH{=}\dot{C}{-}CH{=}CH_2 \rightarrow CH_2{=}\dot{C}H + CH{\equiv}C{-}CH{=}CH_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

There is some evidence (18) that in the addition of radicals to ethylene, low molecular weight molecules are formed by C—C dissociation of larger radicals rather than by C—H fission of a parent radical. Formation of vinyl acetylene by this route would not affect the kinetics as long as addition is the rate-controlling process.

Over small ranges of temperature, deviation from the simple mechanism, where addition is rate-controlling, may occur as different decomposition mechanisms become important. This may account for the fact that certain sets of data obtained over a narrow temperature range give Arrhenius parameters rather different from the average. Palmer and Dormish (9) in fact suggested that the Arrhenius plot of the data showed a transition region in the neighborhood of 1000 °K where a change in mechanism must occur. The errors involved in obtaining rate constants from the acetylene system are, however, probably sufficiently large to account for the scatter observed and it is probably not possible to fix with any certainty the region of temperature where a change in mechanism occurs. Indeed several changes in mechanism must occur over such a wide temperature range and the radical chain mechanism allows such changes without altering the main kinetic characteristics.

An alternative initiation step, kinetically indistinguishable from reaction 1 was suggested by Gay *et al.* (2) and by Cullis and Read (19).

$$2C_2H_2 \rightarrow C_4H_3 + H$$

It seems more probable however, that this reaction would occur by the series of reactions 1, 2, and 3 of the present mechanism.

Other Features of the Acetylene System

The mechanism as outlined thus accounts for the major kinetic characteristics of the acetylene pyrolysis, in particular the second order rate dependence and the low activation energy. In addition several other features of the acetylene system are explained by this type of radical chain reaction. The rather erratic effects of surfaces observed (20) may be expected in a long chain reaction where the propagation reactions of radicals may occur following adsorption on surface sites. Because the over-all rate is second order the initiation step is probably homogeneous. The formation of methane and of compounds containing an odd number of carbon atoms may be most easily accounted for by isomerization and dissociation of radicals. For example, a 1,5 hydrogen shift may occur in the C_6H_7 radical in a similar way to that shown to occur in the hexyl radical (21):

$$C_4H_5 + C_2H_2 \rightarrow CH_2{=}CH{-}CH{=}CH{-}CH{=}\dot{C}H$$

$$CH_2{=}CH{-}CH{=}CH{-}CH{=}\dot{C}H \rightarrow CH_3{-}\dot{C}H{-}CH{=}CH{-}C{\equiv}CH$$

The terminal methyl radical may split off and form methane by abstraction. Similar isomerizations may occur with larger radicals, and other radicals containing an odd number of carbon atoms may be formed. The radical mechanism also accounts adequately for the products formed when halogens are added to the reacting acetylene (22). The isotope exchange observed at very high temperatures (2) would occur rapidly by the dissociation and formation of vinyl radicals by reactions 2 and -2. Cyclization processes giving benzene and higher molecular weight aromatic ring compounds are important reactions in the acetylene system (23). Such processes may occur through biradical intermediates (5, 24) or from monoradicals, or, as has been suggested recently, through a Diels–Alder condensation (25). The kinetics of formation of the higher products has not been sufficiently well established to favor one particular mode.

The Induction Period

Induction periods have been observed in the acetylene pyrolysis by most investigators. The kinetics are second order both in the initial stages and in the region of maximum rate (5). The bimolecular reaction of acetylene is therefore very likely the main initiation step in both regions. The increase in rate after a period of time may be the result of an increase in the rate of the propagation steps which may occur if the rate of addition of radicals to the products is faster than to acetylene itself. This is possible because the maximum rate is only 2–4 times the initial rate (5, 26) and a large factor is not involved. If the increase in rate were due to secondary initiation caused by dissociation of the products, the kinetic characteristics would be expected to alter more drastically.

In summary, the radical chain process outlined here is intended to show that there is no need to suggest the formation of excited molecules of acetylene as a kinetically important step in the reaction. The rates of such processes are difficult

to assess particularly when a change of multiplicity is involved. On the other hand the rate of the simple bimolecular disproportionation reaction of two molecules of acetylene may be estimated with fair accuracy and together with the addition, abstraction, and decomposition reactions of the resulting radicals may account for the main features of the acetylene pyrolysis.

Nuclear Charge Dispersion in the Fission of ^{235}U by Protons of Energy 20–85 MeV[1]

G. B. SAHA,[2] I. TOMITA,[3] AND L. YAFFE

Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received January 14, 1971

Independent formation cross sections of ^{129}Cs, ^{130}Cs, ^{131}Cs, $^{134}Cs^{m}$, $^{134}Cs^{m+g}$, ^{136}Cs, ^{139}Ce, and cumulative formation cross sections of ^{141}Ce and ^{143}Ce were obtained when ^{235}U was caused to fission with protons of energies varying between 20 and 85 MeV. The energies at which the excitation functions reached their maxima were related to the neutron-to-proton ratio of the fission products. These were compared with other fissioning systems. Charge dispersion curves were obtained from the cross section data. The variation of $(Z_A - Z_p)$ with energy, both in magnitude and in trend, agrees extremely well with predictions made by Saha and Yaffe for nuclides in this mass range. Calculations for Z_p show that good agreement is obtained with the unchanged charge division hypothesis. An estimate has been made of the total number of neutrons emitted in fission at these energies.

On a obtenu des sections efficaces de formation indépendante de ^{129}Cs, ^{130}Cs, ^{131}Cs, $^{134}Cs^{m}$, $^{134}Cs^{m+g}$, ^{136}Cs, ^{139}Ce, et des sections efficaces de formation cumulative de ^{141}Ce et de ^{143}Ce, par la réaction de fission de ^{235}U sous l'action de protons d'énergie variant de 20 à 85 MeV. Les énergies auxquelles les fonctions d'excitation atteignent leur maxima ont été reliées au rapport neutron-à-proton des produits de fission. Celles-ci ont été comparées à d'autres systèmes où il y a réaction de fission. Des courbes de dispersion de charge ont été obtenues d'après les valeurs des sections efficaces. L'allure et la grandeur de la variation de $(Z_A - Z_p)$ avec l'énergie sont tout à fait conformes aux prédictions de Saha et Yaffe pour les nucléides de masse comparable. Des calculs de Z_p sont tout à fait en accord avec l'hypothèse de la division de la charge inchangée. On a fait un estimé du nombre total de neutrons émis lors de la fission se passant à ces énergies.

Canadian Journal of Chemistry, 49, 2205 (1971)

Introduction

A number of studies on nuclear charge dispersion in the fission of heavy-mass targets by protons of energies 20–85 MeV have been reported (1–10). In all these studies the displacement of the most probable charge, Z_p, from the charge, Z_A, corresponding to stability for mass A has been measured. In addition the full-widths at half-maximum (FWHM) of the charge dispersion curves have been determined. All the above-mentioned studies (with the exception of refs. 2, 6, and 10) have dealt with fission products with masses A in the range 129–144. The others have concerned themselves with the lighter fragment.

In all cases, as the bombarding energy is increased, the most probable charge, Z_p, shifts towards stability. It has been shown by Tomita and Yaffe (8) and Saha and Yaffe (9) that the values of $(Z_A - Z_p)$ can be correlated with the neutron-to-proton ratio, N/Z, of the target. Thus, for fission products in the mass range A = 129–144, and in the energy range 20–85 MeV the most probable charge, Z_p, can be predicted from the nuclear composition (protons and neutrons) of the target. A recent summary (11) correlates the information obtained from the various targets. This summary, for completeness, included some preliminary information about ^{235}U which had not yet been published. Since some of these data are being used by others (particularly those who use mass spectrometry as a measuring device and thus obtain only relative yields) as calibration and reference points, and because of the intrinsic interest in this area of research, the original and amended data on ^{235}U are now being published.

In the present work we report the study of the nuclear charge dispersion of fission products in the mass range A = 129–143 formed in the fission of ^{235}U by protons of energies 20–85 MeV.

Experimental

(1) Targets and Irradiations

The targets were foils of ^{235}U (94% enrichment) having a superficial density of about 122 mg/cm^2. Prior

to irradiation the foils were cleaned with nitric acid, washed with water, then acetone, dried and the superficial density of each foil determined by obtaining the weight of a measured area. The $^{65}Cu(p,pn)^{64}Cu$ reaction was used to monitor the proton beam. The monitor copper foil had a superficial density of 21.4 mg/cm^2. The target foil was sandwiched between two aluminum foils (20 μm thick) which served as guard foils for fission products recoiling out of the target. The copper foil, guarded in a similar manner by two other copper foils, was placed upstream to the protons with respect to the target. The target and monitor foils were properly aligned and wrapped with a thin aluminum cover foil. The entire stack was then fastened to the target holder which was in turn attached to the cyclotron probe. The target assembly was then placed inside the cyclotron at a fixed radius corresponding to the desired energy.

All irradiations were performed in the internal circulating beam of the McGill proton synchrocyclotron. Irradiations, for a period of about 10 min, at a beam current of about 1 μA, were made at 10-MeV intervals in the energy range 20–70 MeV, at 77, and 85 MeV. The energy spread was ±2 MeV and the degradation of the beam in the target was calculated to be negligible compared to this.

(2) Chemical Separations

After irradiation the respective foils were dissolved in suitable acids and the different elements separated. The uranium and its aluminum guard foils were dissolved together in concentrated hydrochloric acid, to which a few drops of nitric acid had been added, in the presence of cesium, cerium, lanthanum, barium, strontium, yttrium, and rubidium carriers. The solution was made up to a standard volume and aliquots were taken for the chemical separation of cesium and cerium. The copper monitor foil was dissolved in concentrated hydrochloric acid and a few drops of hydrogen peroxide.

(i) Cesium

The details of the purification of cesium have been given elsewhere (9). These consisted of precipitation of cesium as silicotungstate, as bismuth iodide, and finally as chloroplatinate. The final precipitate was filtered on a glass-fiber disc, dried, weighed, and mounted for activity measurements.

(ii) Cerium

The procedure for chemical separation of the cerium was adapted from those of Glendenin *et al.* (12) and Barnes (13). The aliquot for cerium separation was evaporated to near dryness. Four ml of concentrated nitric acid and 2 ml of 2.5 *M* sodium bromate were added to make the solution 9–10 molar in nitric acid. The solution was heated for about 1 min to complete the oxidation of Ce^{3+} to Ce^{4+}, cooled, and extracted into 50 ml of methyl isobutyl ketone. The organic phase was washed three times with 1 ml of 9 *M* nitric acid containing a few drops of 2.5 *M* sodium bromate, and cerium was back-extracted into 5 ml water containing a few drops of 30% hydrogen peroxide. Cerium oxalate was precipitated with saturated oxalic acid, washed with water, alcohol, and ignited to CeO_2 at 800 °C for about 30 min. The oxide was powdered, slurried with alcohol, filtered on a small glass-fiber disc, dried at 110 °C, weighed, and mounted for activity measurements.

(iii) Copper

The copper was chemically separated by using the procedure of Kraus and Moore (14). The copper solution was adsorbed on a Dowex-1 anion exchange column and copper was eluted with 1.5 *M* hydrochloric acid. The copper was reduced to Cu^+ by heating with sodium bisulfite, and cuprous thiocyanate was precipitated with ammonium thiocyanate. The precipitate was filtered, washed with alcohol and ether, dried, weighed, and mounted for activity measurements.

(3) Activity Measurements

The pertinent decay characteristics of the nuclides of interest are shown in Table 1. They have been taken from the compilation by Lederer *et al.* (15).

Three instruments were used for the activity measurements. A 7.6 cm × 7.6 cm NaI(Tl) crystal coupled to a 400-channel pulse-height analyzer was used to measure the γ-radiations and K X-rays emitted by the different nuclides. An end-window gas-flow proportional counter was used to measure the β-radiation from ^{136}Cs. The annihilation radiation from the decay by positron emission of ^{130}Cs was measured by two NaI(Tl) crystals at 180 °C to each other coupled to a γ–γ coincidence unit gated to receive the 511-keV photopeak. The details of this unit and the determination of its operating characteristics have been described elsewhere (9).

The decay of 2.9-h $^{134}Cs^m$ and 2.05-year $^{134}Cs^g$ was followed by measuring the activity due to the 127-keV and 796-keV photopeaks, respectively. In order to reduce the background due to Compton scattering of the high-energy γ-rays, $^{134}Cs^m$ was measured after the complete decay of 32.2 min ^{138}Cs, and $^{134}Cs^g$ after the essentially complete decay of 12.9-day ^{136}Cs.

The activities of 32-h ^{129}Cs, 9.7-day ^{131}Cs, 6.5-day ^{132}Cs were measured by detecting their characteristic X-rays. The composite curve resulting from the X-ray activities was resolved by the CLSQ least-squares computer program of Cumming (16). The K X-ray emission rates were converted to K electron-capture decay rates using a fluorescence yield of 0.87 (17) and a value of 0.12 (18) for the L/K capture ratio. The activity due to the 2.05-year $^{134}Cs^g$ was resolved from that of the 12.9-day ^{136}Cs in the gross β^--decay by the CLSQ program. However, the uncertainty in the $^{134}Cs^g$ component was too large to enable the β^--activity to be used in the cross-

TABLE 1. Decay characteristics (15) of nuclides

Nuclides	Half-life	Radiation measured	Abundance
^{129}Cs	32.2 h	K X-ray	1.0
^{130}Cs	30.0 min	β^+	0.46
^{131}Cs	9.7 day	K X-ray	1.0
^{132}Cs	6.5 day	K X-ray	1.0
$^{134}Cs^m$	2.9 h	127-keV γ	0.14
$^{134}Cs^g$	2.05 year	796-keV γ	0.99

section calculation and this was done from the γ-ray data as indicated above. A small correction for the self-absorption in the source of the β^--radiations from ^{136}Cs was made.

The ^{64}Cu activity was measured by detecting the 511-keV annihilation radiation with the NaI spectrometer. The activity of ^{143}Ce was measured by following the decay of the photopeak due to the 293-keV γ-ray on the NaI spectrometer. The resolution of the NaI crystal was not good enough to resolve completely the 145-keV and 166-keV γ-rays due to 32.5-day ^{141}Ce and 138-day ^{139}Ce, respectively. These were measured as a composite photopeak and the activities resolved by the CLSQ program.

The efficiency of the annihilation radiation coincidence counter was determined with a standard source of ^{22}Na. The efficiency of the NaI(Tl) detector was determined with the aid of several γ-ray standards, while the end-window proportional counter was calibrated against a 4πβ-counter (9).

The counting rates of the different nuclides at the end of bombardment were converted to disintegration rates by correcting for chemical yields, branching ratios, and counter efficiencies. Disintegration rates were then used to calculate the formation cross sections of the different nuclides using well-known equations (19). The cross sections for the $^{65}Cu(p,pn)^{64}Cu$ reaction at different energies were those of Meghir (20) and are given in Table 2.

Results

The measured formation cross sections of the nuclides are given in Table 3 and the excitation functions are shown in Figs. 1–4. The errors shown in the table and the figures were estimated from the uncertainties in activity measurements, chemical yields, counting efficiencies, and target thicknesses. The energy spread (±2 MeV) in the proton beam is not shown in the diagrams.

The formation cross section of 2.2-h ^{129}Ba, even at a proton energy of 85 MeV, is very small, as evidenced from the charge dispersion curves and the low yield of ^{129}Cs. The separation time from end of bombardment was only 30 min and so the contribution from the decay of ^{129}Ba to the formation of ^{129}Cs can be considered to be negligible. The yields of ^{129}Cs were thus considered to be independent. Similarly the rapid separation time precluded a large contribution to the yield of ^{131}Cs from its relatively long-lived parent, 11.6-day ^{131}Ba, and the yields of the former could be considered as independent.

It can be noted from Table 3 and Fig. 3 that the cross sections for formation of $^{134}Cs^m$ are greater than those for $^{134}Cs^g$ and that the isomer ratios

are insensitive to energy. Interpretation of the relative formation probabilities of these isomers in terms of the average spins of the primary fragments has been presented in a separate publication (21). The cross sections for ^{133}Cs, ^{135}Cs, and ^{137}Cs have been interpolated from the charge dispersion curves (see section 2 of Discussion). The excitation functions are shown in Fig. 5 without error bars.

In Fig. 4 are shown the cumulative yields of ^{141}Ce and ^{143}Ce, and the independent yields of ^{139}Ce. The formation cross sections of the latter are judged to be independent because the yields of ^{139}Pr in this energy region are very small. When the formation yields of ^{141}Ce and ^{143}Ce were being determined, the chemical separations were made after complete decay of the precursors to ensure that the yields determined would indeed be cumulative.

Discussion

(1) Excitation Functions

The excitation functions shown in Figs. 1–5 exhibit the trends expected at these bombarding energies. The excitation functions of the relatively neutron-deficient nuclides increase with increasing bombarding energy, while those of the neutron-rich products show maxima in this energy region. Also the formation cross sections of the neutron-deficient nuclides are relatively smaller than those of the neutron-richer products. Qualitatively these results can be explained in terms of increasing energy deposition leading to increasing neutron evaporation, either prior to or after fission, as the bombarding energy is increased. Because of this one would expect the charge dispersion curves to broaden with increasing energy as the contribution from the neutron-deficient components becomes larger. Thus the independent yield of any member of a chain will increase with increasing excitation energy, pass through a maximum and then decrease. The initial increase in the cumulative yields of ^{141}Ce and ^{143}Ce thus results from the increasing contribution of the various members of the chain. The nuclides contributing to these products are produced in good yield early in the

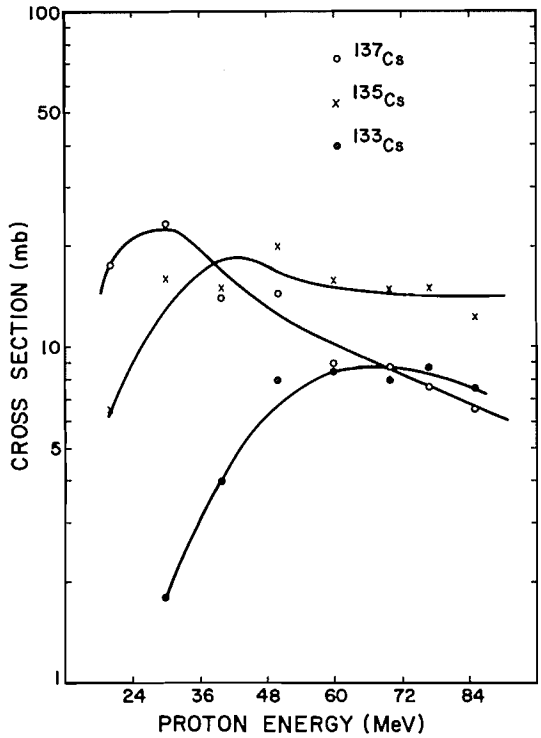

FIG. 5. Excitation functions of independent yields of ^{133}Cs, ^{135}Cs, and ^{137}Cs interpolated from charge dispersion curves.

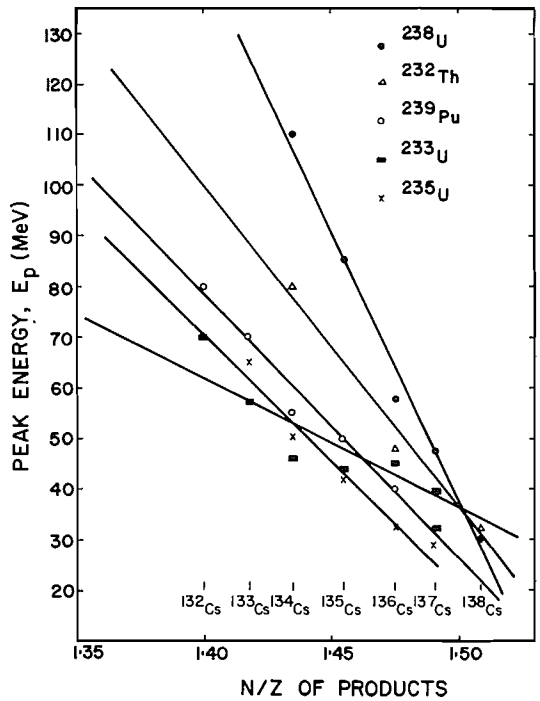

FIG. 6. Energies at which excitation functions in the fission of ^{238}U, ^{232}Th, ^{239}Pu, ^{233}U, and ^{235}U reach their maxima as a function of N/Z of the fission product.

chain at low excitation energies and lower yield at higher energies. This is confirmed from the charge dispersion curves, their broadening and shift of Z_p towards Z_A with increasing bombardment energy.

The excitation functions of ^{134}Cs and ^{136}Cs (experimentally determined) and of ^{133}Cs, ^{135}Cs, and ^{137}Cs (interpolated from charge dispersion curves) show well-defined maxima. As was first done by Friedlander *et al.* (19), the energies at which these excitation functions reach their peak are plotted against the neutron-to-proton (N/Z) ratio of the fission product and are shown in Fig. 6. Also included for comparison are data for ^{238}U (3), ^{232}Th (7), ^{239}Pu (9), and ^{233}U (8) by other workers. The determination of the peak energy may, as is evident from many of the excitation functions, involve an error of anywhere between 10 and 20 MeV, depending on the prominence of the maximum of the excitation function. It is also obvious that the ^{233}U data are very sparse and more data are obviously needed. However, all the data show an approximately linear decrease of the energy at which the fission product has its greatest probability of occurrence with an increase in N/Z of the products, although the slopes of the lines are different for different targets and some curvature may be occurring. It is obvious from the data that the same fission product has its greatest probability of occurrence at a relatively lower energy in the fission of a target of lower N/Z. This is shown graphically in Fig. 7 for ^{129}Cs, ^{132}Cs, ^{134}Cs, and ^{136}Cs. This conclusion lends support to the earlier observation made by Tomita and Yaffe (8) and Saha and Yaffe (9), who pointed out the importance of the role of the neutron-to-proton ratio of the target in the fission process. The lines in Fig. 6, despite the uncertainty of the slopes, converge on the N/Z axis at a value of about 1.55. This means that such a fission product, *e.g.* ^{140}Cs, would have a maximum formation probability with very low energy expenditure in all of these fissioning systems.

(2) Charge Dispersion

The cross sections were used to construct charge dispersion curves, according to the

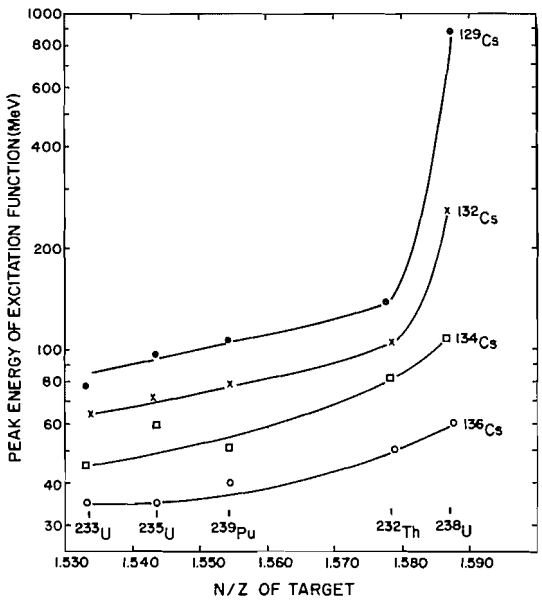

FIG. 7. Energies at which various cesium isotopes have their greatest probability of production as a function of N/Z of the target.

method suggested by Friedlander *et al.* (19) and since then used by many other workers. The independent formation cross sections were plotted against the neutron-to-proton ratio (N/Z) of the products. The dotted portion of the curve was so drawn that the sum of the independent yields read from the curve of the individual members of chains giving ^{141}Ce and ^{143}Ce equalled the experimentally-determined cumulative yields of ^{141}Ce and ^{143}Ce. It has been shown (1, 19) that this restriction uniquely determines the shape of the curve, provided that there are no discontinuities. Underlying the above is the assumption that, in the energy range 20–85 MeV, the mass–yield curve is flat in the region A = 129–143. This enables one to plot cross sections rather than fractional yields. The charge dispersion curve at 70 MeV is shown in Fig. 8 as a typical example of the curves obtained in this fashion.

The most probable charge, Z_p, was calculated for each curve from the value of N/Z corresponding to the maximum of the curve for the mass number nearest the peak. The full-widths at half-maximum (FWHM) of the curves were also calculated, in Z units for the same mass number, from the values of N/Z at half-maximum.[4] These parameters of the charge dispersion curves are given in Table 4. Values of Z_A used are those of Coryell (23). The variations of the FWHM and of $Z_A - Z_p$ with proton bombarding energy are given in Figs. 9 and 10, respectively, along with data obtained by other workers.

From Fig. 9 it can be seen that the FWHM of the charge dispersion curves increases with increasing bombarding energy for all the systems shown. In the case of ^{238}U (3) and ^{232}Th (7) the values of FWHM are almost constant up to 40–45 MeV and then increase at higher energies. This is not the case with the targets of lower values of N/Z, where there is a regular increase with energy. In Fig. 10 the variation of $(Z_A - Z_p)$ for the same fissioning systems is shown. The dotted line gives the prediction made by Saha and Yaffe (9) for the variation of $(Z_A - Z_p)$ with bombarding energy for fission products with A = 129–140 in the fission of ^{235}U. The agreement

[4]Hogan and Sugarman (22) have shown that such an analysis for the FWHM values in Z units is valid only if Z_p is constant with A. Work in this laboratory (unpublished) has shown that while this is important at higher bombarding energies, the correction for this effect in this energy region is small, of the order of 0.2 Z units.

between prediction and experiment is excellent. It should be emphasized that these predictions, made in the mass region $A = 129$–140, only hold for this region. Khan *et al.* (10) have shown that the behavior of the light-mass region, in the

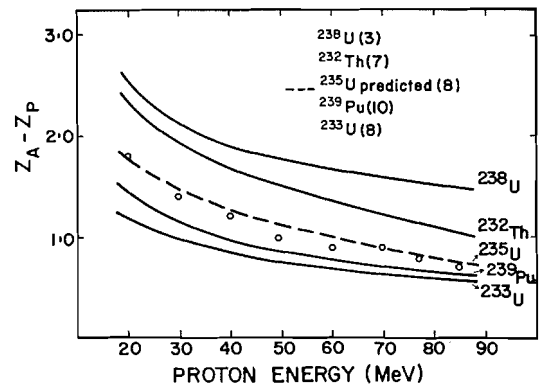

FIG. 10. Variation of $Z_A - Z_p$ as a function of energy in the fission of ^{238}U, ^{232}Th, ^{235}U, ^{239}Pu, and ^{233}U.

vicinity of $A = 96$, is totally different. One cannot, for example, differentiate $(Z_A - Z_p)$ as a function of energy between ^{235}U and ^{238}U as one can easily do in the present study. Thus one cannot regard the light-mass fragment merely as the accompanying partner of the heavy-mass fragment, but the different neutron-emission characteristics of the two fragments must be considered.

The above predictions were made on the basis of plots of $(Z_A - Z_p)$ *vs.* N/Z of the *target* by Tomita and Yaffe (8) and Saha and Yaffe (9). The data of the other workers have been supplemented in Fig. 11 by the present data. It is rather interesting to note that the values, for example, of $(Z_A - Z_p)$ for fission of ^{233}U at 25 MeV (interpolated) are the same as those at 80 MeV for ^{238}U, leading one to suspect that the average fissioning nucleus is the same in both cases.

As can be seen from Figs. 10 and 11 the values of $(Z_A - Z_p)$ remain almost constant for each system at higher energies. As pointed out by Saha and Yaffe (9), this indicates a direct interaction where only part of the bombarding energy is transferred to the fissioning nucleus and thus the fission process takes place as though induced at lower energies.

It would indeed have been more rigorous not to use N/Z of the target, but to consider the variation of $(Z_A - Z_p)$ as a function of N/Z of the *average* fissioning nucleus for each target at each energy. This has been done, as shown in Fig. 12, using the calculated values of N/Z of the average fissioning nucleus. This calculation is outlined in the following section. It is apparent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

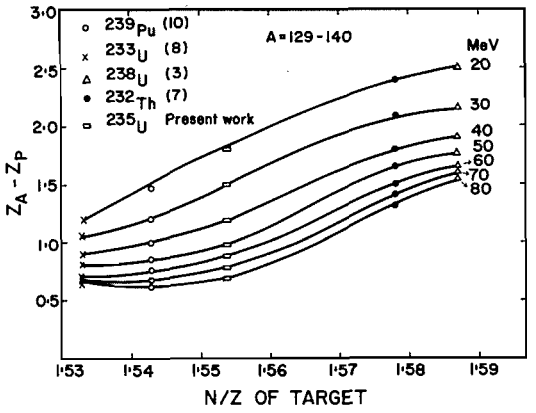

FIG. 11. Variation of $Z_A - Z_p$ as a function of N/Z of the target for various bombarding energies.

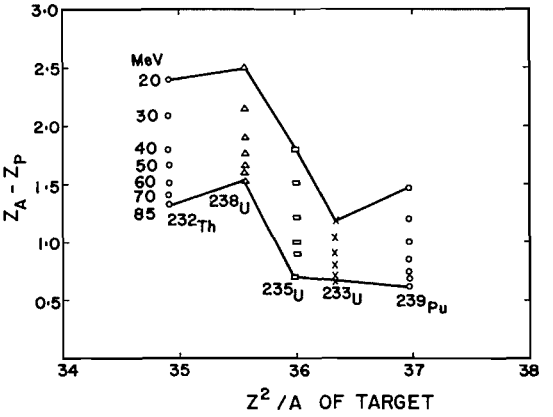

FIG. 13. Variation of $Z_A - Z_p$ as a function of the fissionability parameter, Z^2/A, of the target.

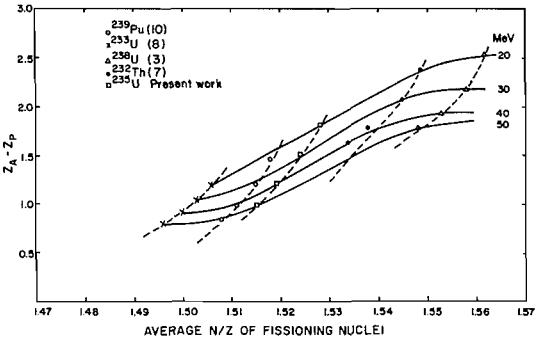

FIG. 12. Variation of $Z_A - Z_p$ as a function of N/Z of the average fissioning nucleus for various bombarding energies.

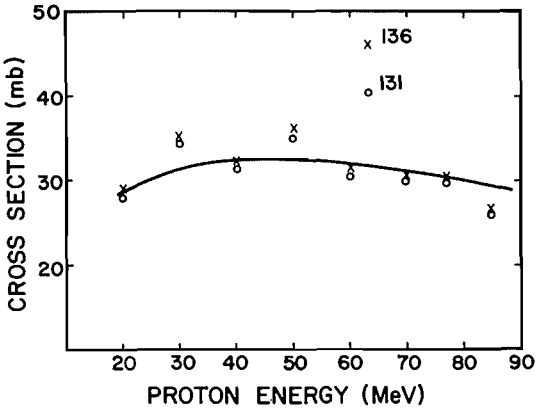

FIG. 14. Excitation function of the isobaric yields of masses 131 and 136 in the fission of ^{235}U.

that, at these energies, this gives no better correlation than with N/Z of the original target.

An attempt was made to correlate $(Z_A - Z_p)$ with the fissionability parameter Z^2/A of the target. As can be seen from Fig. 13 no ready correlation exists, although here again the *average* fissioning target might be a more useful parameter. However, it is questionable whether Z^2/A is itself a very meaningful parameter at these energies. The parameter owes its origin to the liquid-drop model, a model which has proved to be very useful at much lower energies.

The total isobaric yields of chains $A = 131$ and $A = 136$ were obtained from the charge dispersion curves and are plotted as a function of energy in Fig. 14. The excitation functions are almost energy-invariant in this region and are indistinguishable. The latter confirms the assumption that the mass–yield curve is sensibly flat in this energy region in the narrow mass range studied.

(3) Comparison of Experimental Z_p Values with Those Calculated

Unfortunately no reasonable theory for the distribution of nuclear charge in fission has yet been proposed. The experimental values for Z_p have been compared with those calculated on the basis of equal charge displacement (e.c.d.) and unchanged charge division (u.c.d.) postulates. The details of the calculation have been given elsewhere (8, 9). Compound nucleus formation was assumed at bombarding energies, of 30, 40, and 50 MeV and calculations made at these energies for $A = 136$.

The compound nucleus was considered to undergo fission or neutron evaporation. The

40	236, 235, 234, 233, 232	140, 139, 139, 138, 137	54.2	55.0	55.0
50	236, 235, 234, 233, 232, 231	141, 140, 139, 139, 138, 137	54.6	55.4	55.2

neutrons were assumed to carry off energy equal to $B_n + 2T$ where B_n is the binding energy of the neutron, and $2T$ is the average kinetic energy of the emitted neutron. T, the nuclear temperature, is calculated from $U = aT^2 - 4T$ (24), where U is the excitation energy of the residual nucleus and a, the level-density parameter, was taken to be 10.5 MeV^{-1} (25). Corresponding to each fissioning nucleus a number of primary fragments were obtained with values of $A = 136$–142. The total excitation energy was assumed to be shared between the two complementary fragments in the ratio of their masses. Each fragment was then allowed to evaporate neutrons, once again assuming that each neutron carries away energy equal to $B_n + 2T$. Only those final fragments were chosen which gave rise to products of mass 136. Values of Z_p were then calculated according to the e.c.d. and u.c.d. postulates for each fragment corresponding to each fissioning nucleus. Finally the average value of Z_p was obtained by weighting each calculated Z_p value with the fission branching ratio of each fissioning nucleus $G = \Gamma_f/(\Gamma_f + \Gamma_n)$, obtained from Huizenga and Vandenbosch (25). These data are summarized in Table 5. The u.c.d. values are in excellent agreement with the experimental results, whereas the e.c.d. values are 0.6–0.9 Z units lower than the experimental values. Similar results have been found in the fission of ^{233}U (8) and ^{239}Pu (9).

(4) Total Number of Neutrons Emitted

McHugh and Michel (26) have shown that the total number of neutrons, ν_T, emitted in fission can be calculated from the variation of Z_p with excitation energy. The relevant equation is

$$[1] \qquad d\nu/dE = (dZ_p/dE)/0.38$$

where dZ_p/dE, the variation of the most probable charge with excitation energy, is available from the present data. These are shown in Fig. 15 along with the data for ^{238}U (3) for $A = 136$. Compound nucleus formation has been assumed up to a bombarding energy of 50 MeV in the calculation of excitation energy. Table 6 shows the values for $d\nu_h/dE$, where h refers to the heavy fragments in fission, derived in this fashion. Khan *et al.* (10) have determined Z_p values in the mass range $A = 96$ in the fission of ^{235}U and ^{238}U and these, as a function of excitation energy

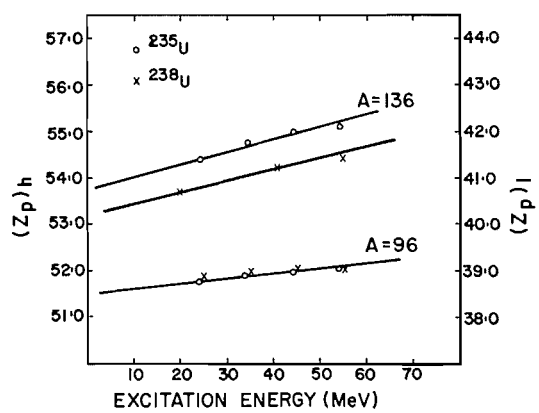

FIG. 15. dZ_p/dE for masses 96 and 136 in the fission of ^{235}U and ^{238}U.

TABLE 6. Neutron emission during fission

Parameter	Value (MeV^{-1})				
	^{235}U	^{238}U	^{232}Th	^{239}Pu	^{233}U
$(dZ_p/dE)_h$	0.0274	0.0250	0.030	0.024	0.013
$(dZ_p/dE)_l$	0.0111	0.0111	—	—	—
$d\nu_h/dE$	0.072	0.066	0.080	0.063	0.034
$d\nu_l/dE$	0.029	0.029	0.040	0.031	0.017
$d\nu_T/dE$	0.101	0.095	0.120	0.094	0.051

for the light fragments, l, are also shown in Fig. 15. The values for $d\nu_l/dE$ are also given in Table 6. Since

$$[2] \qquad d\nu_l/dE + d\nu_h/dE = d\nu_T/dE$$

the summation yields the total number of neutrons emitted both prior to and after fission for two fragments in these mass ranges. It may of course be that $A = 136$ and $A = 96$ may not arise from complementary fragments, but there is no reason to expect great variation in a very narrow mass region for either $d\nu_l/dE$ or $d\nu_h/dE$.

Saha and Yaffe (9) have made a similar calculation, but lacking the data of Khan *et al.* (10), they had assumed that $d\nu_l/dE = d\nu_h/dE$. The present treatment is of course more reliable. McHugh and Michel (26) and Nethaway and Levy (27) also concluded that the heavy fragments emit more neutrons than the light fragments. The data for fissioning systems other than ^{235}U and ^{238}U have been recalculated on the basis of $d\nu_h/dE = 2d\nu_l/dE$, although this is obviously an assumption, and the data are also given in Table 6.

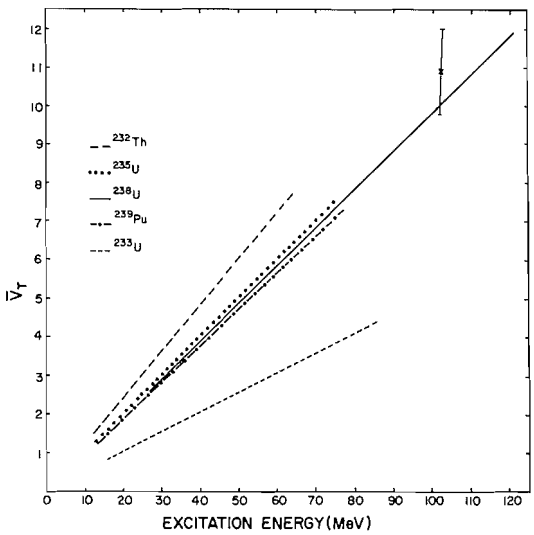

FIG. 16. Variation of the average number of neutrons, $\bar{\nu}_T$, emitted during fission from ^{232}Th, ^{235}U, ^{238}U, ^{239}Pu, and ^{233}U.

The total number of neutrons, ν_T, has been obtained by multiplying $d\nu_T/dE$ with excitation energy and is shown as a function of excitation energy in Fig. 16. These data are of course representative of these two mass regions only. Cheifetz *et al.* (28) have studied the emission of both pre-fission and post-fission neutrons in the fission of ^{238}U by 155-MeV protons. Their value, $\nu_T = 10.9 \pm 1.1$, has been plotted at the appropriate average excitation energy, 102 MeV.[5] The results are in very good agreement with the present data.

Ion–Molecule Reactions in Methyl Fluoride and Methyl Chloride

A. A. HEROD,[1] A. G. HARRISON,[2] AND N. A. MCASKILL[3]
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received January 22, 1971

The reactions of the molecular ion have been studied as a function of the ion kinetic energy for methyl fluoride and methyl chloride. The following reactions are observed

[*a*] $CH_3X^+ + CH_3X \rightarrow C_2H_4X^+ + (H_2X)$

[*b*] $\rightarrow CH_4X^+ + CH_2X$

[*c*] $\rightarrow CH_2X^+ + (CH_4X)$

[*d*] $\rightarrow CH_3^+ + (CH_3X_2)$

For methyl fluoride (X = F) reactions *c* and *d* have kinetic energy thresholds and become significant at high ion energies. For CH_3Cl (X = Cl) reaction *a* is not observed and reactions *c* and *d* are of only minor importance at high ion energies. Rate coefficients for the molecular ions and a number of fragment ions as well as rate coefficients for further reaction of CH_4X^+ are reported.

On a étudié les réactions de l'ion moléculaire des fluorure et chlorure de méthyle en fonction de l'énergie cinétique de l'ion. On a observé les réactions suivantes

[*a*] $CH_3X^+ + CH_3X \rightarrow C_2H_4X^+ + (H_2X)$

[*b*] $\rightarrow CH_4X^+ + CH_2X$

[*c*] $\rightarrow CH_2X^+ + (CH_4X)$

[*d*] $\rightarrow CH_3^+ + (CH_3X_2)$

Les réactions *c* et *d*, dans le cas du fluorure de méthyle (X = F), ont des énergies cinétiques minima et ne deviennent importantes qu'à hautes énergies des ions. Dans le cas du chlorure de méthyl (X = Cl) on n'observe pas la réaction *a* et l'importance des réactions *c* et *d* est négligeable à hautes énergies des ions. On rapporte les coefficients de vitesse des ions moléculaires et d'un certain nombre d'ions fragmentés ainsi que les coefficients de vitesse d'autres réactions de l'ion CH_4X^+.

Canadian Journal of Chemistry, 49, 2217 (1971)

Introduction

The ion–molecule reactions forming CH_4Cl^+ in CH_3Cl have been studied previously at low electron energies both by the zero-field pulsing technique (1) and by pressure variation (2). More recently McAskill (3) has reported a detailed study of the ionic reactions in methyl chloride at 70–85 eV ionizing energy and ion exit energies ranging from 0.2 to 2.0 eV. In this pressure study the major reactions occurring have been elucidated and the energy dependence of the reactions investigated. A similar, but briefer, study of the methyl fluoride system also has been reported by McAskill (4), while the reactions of the molecular ion have been studied at thermal ion energies using ion cyclotron resonance techniques by Marshall and Buttrill (5).

The present study of the ionic reactions in methyl fluoride and methyl chloride can be divided into three parts. Pressure studies at 50–70 eV electron energy have been carried out; the results from these studies confirm the earlier results of McAskill (3, 4). In each system the reactions of the molecular ion have been studied in detail at low electron energies and the product distribution determined as a function of ion energy. Finally, the ionic reactions have been investigated using the ion-trapping technique reported recently (6).

Experimental

The pressure studies, both at low and high electron energies, were carried out using the medium pressure instrument described previously (2, 7). The ionizing electron beam was pulsed and ion source residence times were measured directly by the deflection technique (2).

For personal use only.

At low electron energies, pressure studies were made at various repeller voltages covering the range of ion exit energies detailed in the following. In each run the electron energy was adjusted to give the maximum possible fractional yield of the molecular ion at low pressures. For methyl chloride CH_3Cl^+ was >95% of the total ionization at low pressures, however, for methyl fluoride the CH_2F^+ fragment ion amounted to ~20% of the total ionization at low pressures since a.p.(CH_2F^+) = 13.25 eV (8) is relatively close to i.p.(CH_3F) = 12.85 eV (9) (where a.p. = appearance potential, i.p. = ionization potential). The remaining pressure studies were carried out at 50 or 70 eV electron energy and ion exit energies as detailed in the following. Source pressures were measured directly using an MKS Baratron micromanometer.

The ion-trapping studies were carried out using the instrument and techniques previously described (6) and source concentrations in the region of 1×10^{13} molecule cm^{-3}. The source pressure was not measured directly but was related to the measured sample system inlet pressure through a study of the reaction $CH_4^+ + CH_4$ in methane. Consequently the rate coefficients reported for the ion-trapping experiments are relative to the value of 1.20×10^{-9} cm^3 $molecule^{-1}$ s^{-1} (2) for the methane reaction.

Methyl chloride was obtained from Matheson and Co. while methyl fluoride was obtained from Columbia Organic Chemical Co. In each case samples were distilled bulb-to-bulb *in vacuo* and a middle fraction retained for use. The mass spectra showed no detectable impurities.

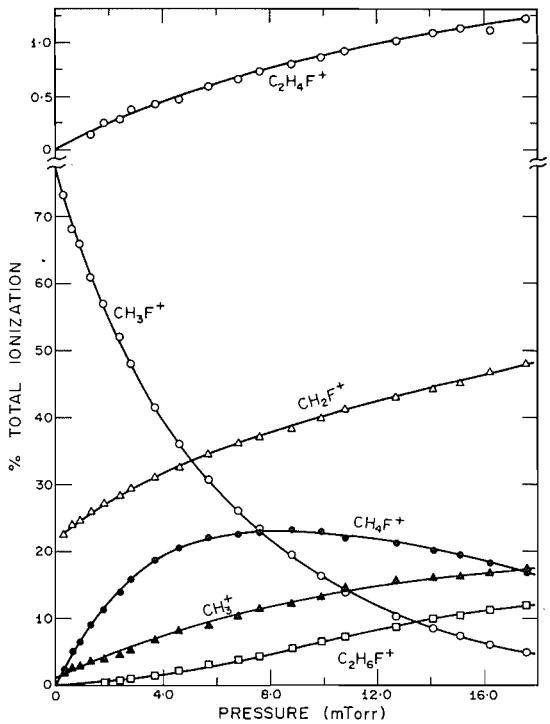

FIG. 1. Pressure plot for CH_3F at low electron energy.

Results and Discussion

Methyl Fluoride

A typical pressure plot obtained at 3.3 eV ion exit energy and low electron energy is shown in Fig. 1. It is evident that at this ion energy CH_3^+, CH_2F^+, CH_4F^+, and $C_2H_4F^+$ are products of the reaction of CH_3F^+ while $C_2H_6F^+$ is a higher-order product originating from the reaction

[1] $$CH_4F^+ + CH_3F \rightarrow C_2H_6F^+ + HF$$

The reaction of CH_3F^+ to produce both $C_2H_4F^+$ and CH_4F^+ as well as the subsequent reaction of CH_4F^+ by reaction 1 have been reported previously (4, 5). At higher conversions some of the CH_2F^+ also may originate from reaction of CH_4F^+ as suggested previously (4).

From Δ plots (7, 10) we have obtained the initial fractional yields at ion exit energies ranging from 0.73 to 3.3 eV. These fractional yields are plotted in Fig. 2 as a function of the average ion energy $\bar{E} = E_{e/3}$ (11) where E_e is the ion exit energy. Also shown in Fig. 2 are the fractional yields at thermal energies reported by Marshall and Buttrill (5) and the yields obtained from the ion-trapping studies at low electron energies (see below).

The yields of CH_4F^+ and $C_2H_4F^+$, both formed in presumably exothermic reactions, decrease with increasing ion energy while the yields of CH_2F^+ and CH_3^+ increase with ion energy and have an apparent kinetic energy threshold (ill-defined for CH_2F^+) consistent with formation of these products by endothermic reactions. Reactions 2 to 4 are possible reactions for formation of CH_2F^+.

[2] $$CH_3F^+ + CH_3F \rightarrow CH_2F^+ + H + CH_3F \qquad \Delta H = +15 \text{ kcal/mol}$$

[3] $$\rightarrow CH_2F^+ + H_2 + CH_2F \qquad \Delta H = +3 \text{ kcal/mol}$$

[4] $$\rightarrow CH_2F^+ + HF + CH_3 \qquad \Delta H = -9 \text{ kcal/mol}$$

Although the energy threshold for formation of CH_2F^+ is low this product is not observed at thermal ion energies indicating that the reaction must have a significant energy barrier and suggesting reaction 2 as the most probable reaction. This reaction is analogous to the collision-induced decomposition of CH_4^+ responsible for CH_3^+ formation in methane at higher ion kinetic energies (12).

TABLE 1. Rate coefficients in methyl fluoride system

Average ion energy (eV)	Rate coefficient (cm^3 $molecule^{-1}$ s^{-1}) × 10^9							Reference

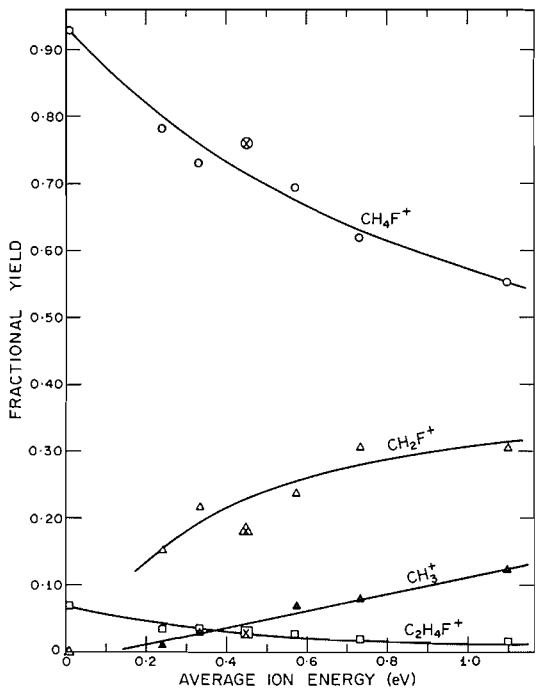

FIG. 2. Fractional yield *vs.* ion energy for CH_3F system.

Reactions 5 to 7 are possible reactions leading to CH_3^+ formation. Although reaction 7 is essentially thermoneutral, the threshold behavior

[5] $CH_3F^+ + CH_3F \rightarrow CH_3^+ + F + CH_3F$
$\Delta H = +45$ kcal/mol

[6] $\rightarrow CH_3^+ + F_2 + CH_3$
$\Delta H = +119$ kcal/mol

[7] $\rightarrow CH_3^+ + HF + CH_2F$
$\Delta H = +1$ kcal/mol

indicates that there is a significant energy barrier in the reaction forming CH_3^+. No clear decision concerning the reaction occurring can be made.

The rate coefficients for disappearance of the CH_3F^+ primary ion obtained from the pressure studies at low electron energy are recorded as the first five entries in Table 1. Pressure studies were also carried out at 70 eV electron energy and ion exit energies of 0.78 and 1.9_5 eV. The results obtained with respect to the reactions occurring were in agreement with the conclusions reached by McAskill (4). The disappearance rate coefficients for the molecular ion and several fragment ions are listed in Table 1.

Figure 3 shows typical results obtained in the study of the methyl fluoride system at low electron energies using the ion-trapping technique. The fractional yields of the products, with the exception of CH_3^+, are shown in Fig. 2 as the data points at 0.45 eV ion energy. Because of mass discrimination effects the low yield of CH_3^+ could not be determined with any accuracy. The CH_4F^+ ion reacts quite rapidly, primarily to produce $C_2H_6F^+$ but may also produce CH_2F^+ as suggested by McAskill (4). Both $C_2H_6F^+$ and $C_2H_4F^+$ are unreactive with CH_3F at the pressures used while CH_2F^+ reacts only very slowly to produce CHF_2^+ and $C_2H_5F_2^+$.

Difficulties were encountered in studying the reactions of fragment ions by the trapping technique because it was observed that several of the fragment ions (C^+, CH^+, CH_2^+, CH_3^+) were not completely trapped, presumably because they are formed with initial kinetic energy. Consistent with this reasoning was the observation that these ions also had broad shallow ion source residence time profiles on the medium pressure instrument. The kinetic data which could be obtained reliably from the trapping experiments is summarized as entry 8 in Table 1.

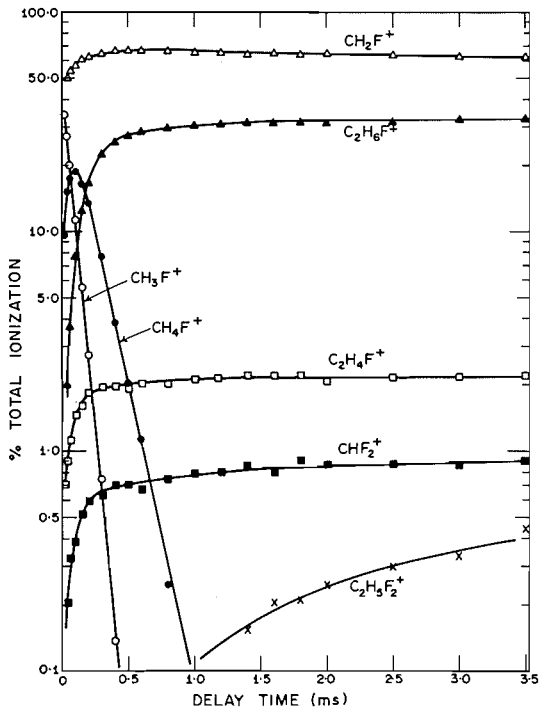

FIG. 3. Normalized ion intensities *vs.* reaction time for CH_3F system.

The final two entries in Table 1 present the kinetic data obtained by McAskill (4) from pressure studies at 70 eV electron energy and the thermal energy results of Marshall and Buttrill (5). The agreement between the present results and the earlier data is quite satisfactory; it is particularly encouraging to note the excellent agreement between the trapped-ion results and the i.c.r. results for reaction of CH_4F^+.

The rate coefficient for disappearance of CH_3F^+ clearly increases with increasing ion energy in contrast to the results for many simple systems (2) where the rate coefficient is independent of energy and in contrast to theoretical predictions. For an ion-induced dipole interaction as for an ion-averaged dipole interaction the collision rate coefficient should be independent of ion energy, while for an ion "locked-in" dipole interaction the collision rate coefficient should decrease with increasing ion energy (2). It should be noted that the experimental rate coefficient is considerably less than the calculated rate constant of 3.3×10^{-9} cm^3 molecule^{-1} s^{-1} (4) based on ion-averaged dipole interaction model (3), indicating that an appreciable fraction of the collisions lead to no detectable chemical change (*i.e.* no reaction or charge transfer). The increase of the disappearance rate coefficient undoubtedly reflects the effect of the ion kinetic energy on the competition between the reactive and the non-reactive or charge-transfer reaction channels. Several of the fragment ions, notably C^+, CH^+, and CH_2^+, also appear to have rate coefficients which are energy dependent.

Methyl Chloride

Figure 4 shows a typical pressure plot obtained at low electron energy and 3.3 eV ion exit energy. The major reaction of CH_3Cl^+ results in formation of CH_4Cl^+ which subsequently reacts to form $C_2H_6Cl^+$. CH_2Cl^+ and CH_3^+ are formed in low yield only in contrast to the methyl fluoride system at the same ion exit energy (*cf.* Fig. 1) where the analogous products are formed in substantial yield. No $C_2H_4Cl^+$ product, comparable to $C_2H_4F^+$ in methyl fluoride, was observed.

Table 2 records the fractional yields obtained from Δ plots as a function of the average reactant ion energy. Comparison of the results with those obtained for methyl fluoride (Fig. 2) clearly shows the much lower yield of the CH_2X^+ and CH_3^+ products. This undoubtedly results from the fact that the possible reactions producing these species in the methyl chloride system, reactions 8 to 13, are much more endothermic than the analogous reactions 2 to 7 in the methyl fluoride system.

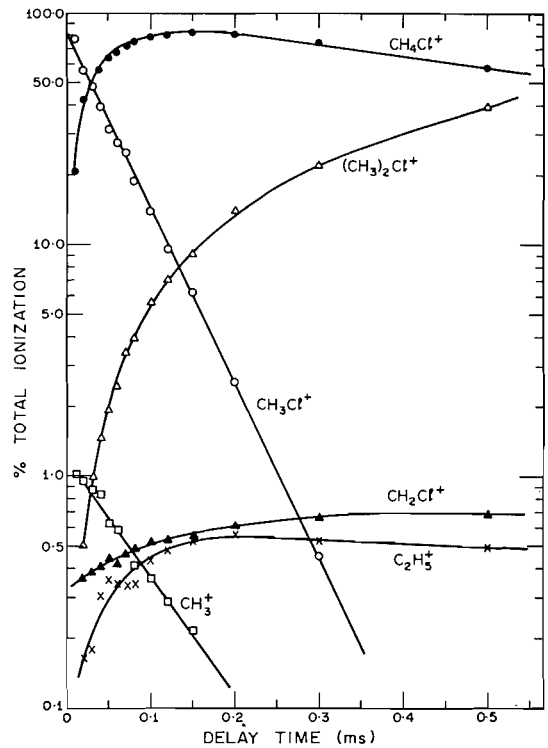

FIG. 5. Normalized ion intensities *vs.* reaction time for CH_3Cl system.

[12] $\rightarrow CH_3^+ + Cl_2 + CH_3$
$\Delta H = +73$ kcal/mol

[13] $\rightarrow CH_3^+ + HCl + CH_2Cl$
$\Delta H = +49$ kcal/mol

Pressure plots were also carried out at 50 eV electron energy and ion exit energies in the range 0.63 to 3.3 eV. The general features of these plots and the reaction assignments are in agreement with those reported earlier by McAskill (3). The disappearance rate coefficients obtained for a number of ions are summarized in Table 3. The rate coefficient for disappearance of CH_3Cl^+ was found to be independent of ion energy, in contrast to the CH_3F results, and yielded an average value of $1.5_3 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} in good agreement with the CH_3Cl^+ decay rate of 1.66×10^{-9} cm^3 $molecule^{-1}$ s^{-1} obtained by McAskill (3). The low electron energy pressure plots yielded rate constants in agreement with the high electron energy data.

As in the methyl fluoride system we observed that several of the low mass ions were formed with initial kinetic energy and were not completely trapped in the electron space charge. Consequently rate coefficients for disappearance of only a few ions could be determined. Figure 5 shows a typical plot obtained at 12 eV nominal electron energy, while the rate coefficients obtained from the trapping experiments are shown as the final entry in Table 3.

Several points should be noted concerning the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

methyl chloride results. At the ion energies of the trapping experiments the yield of CH_2Cl^+ is very low and can be accounted for almost entirely by reaction of CH_3^+. This indicates that the reaction

[14] $CH_4Cl^+ + CH_3Cl \rightarrow CH_2Cl^+ + HCl + CH_4$

suggested by McAskill (3) is not significant at these energies. McAskill has presented evidence that reaction 14 is endothermic with the rate increasing with ion energy. Our Δ plots at high ion energies indicated a tertiary formation of CH_2Cl^+ which supports this conclusion. Neither in the pressure studies nor the trapped-ion studies was there any evidence that CH_2Cl^+ reacted to form CH_4Cl^+. This result is in agreement with McAskill but in disagreement with earlier ratio plot studies (1) in this laboratory which must be considered erroneous.

Reactions of Norbornen-7-one with Organolithium Reagents

F. R. S. CLARK AND J. WARKENTIN[1]
Chemistry Department, McMaster University, Hamilton, Ontario

Received December 15, 1970

Alkyllithium reagents (RLi: R = methyl, *n*-butyl, *t*-butyl) add to norbornen-7-one either without stereochemical preference (R = *n*-butyl) or with *syn* attack favored. This addition selectivity is qualitatively the same as that shown by corresponding alkylmagnesium reagents but competition from reduction is much less important in the case of alkyllithium reagents.

Phenyllithium and vinyllithium add preferentially from the *anti* face, although the corresponding Grignard reagents add selectively from the *syn* face. Possible causes of the stereoselectivities are considered. Solvent effects on the stereochemistry of addition are small.

L'addition des alkyl-lithium (RLi ou R = Me, *n*-Bu, *t*-Bu) à la norbornèn-7 one se fait soit sans préférence stéréochimique (R = *n*-Bu) soit avec une attaque *syn* favorisée. La sélectivité de cette addition est qualitativement la même que celle observée lors de l'action des organomagnésiens correspondants mais la compétition des réactions de réduction est beaucoup moins importante avec les organo-lithiens.

Quoique les organomagnésiens correspondants s'additionnent sélectivement par la face *syn*, le phényllithium et le vinyl-lithium s'additionnent préférentiellement par la face *anti*. On considère les causes possibles de ces stéréosélectivités. Les effets de solvants sur la stéréochimie de ces additions sont faibles.

Canadian Journal of Chemistry, 49, 2223 (1971)

Introduction

The treatment of norbornen-7-one (1) (**1**), with alkyl Grignard reagents gives mainly the corresponding 7-alkylnorbornen-7-*anti*-ols (2). Reduction of the ketone to *syn*- and *anti*-norbornen-7-ol accompanies the addition and in cases where the number of β-hydrogens of the Grignard reagent is large, reduction dominates.

The alternative synthesis of 7-R-norbornen-7-ols (R = alkyl, aryl), from organolithium reagents, has been used to prepare 7-methylnorbornen-7-ol of both *syn* and *anti* configurations (3). At 0–5 °C, in diethyl ether as solvent, *syn* attack was favored by a factor of 1.5:1. Similarly, Gassman and coworkers (4) have prepared a series of 7-arylnorbornen-7-ols by the reaction of **1** with aryllithium compounds.

In view of the marked difference in stereoselectivity of reactions of organolithium reagents and Grignard reagents with **1** (3, 5) and also the lesser importance of reduction by the former (6), a more systematic study of the reactions of organolithium compounds with **1** was undertaken.

Results and Discussion

Norbornen-7-one was reacted with three alkyllithium reagents in which the extent of β-branching varied (RLi: R = methyl, *n*-butyl, *t*-butyl), and with two unsaturated organolithium reagents, phenyllithium and vinyllithium. To a mimimum of 81% of a material balance, the only products obtained, in general, were the two isomeric 7-R-norbornen-7-ols. *t*-Butyllithium, which has the maximum number of β-hydrogens, gave a maximum of 20% reduction. In all other cases, reduction was not detectable.

The assignment of stereochemistry at C-7 of the alcohols has been approached in several ways. Relative retention times in g.l.p.c. and intramolecular hydrogen bonding in *syn*-ols (3, 4, 7) have served as criteria of configuration. Warkentin (2) used the g.l.p.c. criterion, backed by conversion to the isomer of a known bromide. The bromide from material thought to be 7-methylnorbornen-7-*anti*-ol was shown (p.m.r.) to be isomeric with 7-methyl-7-*syn*-bromonorbornene, the structure of which had been assigned on the basis of its slow solvolysis (8).

In the present work, analogy with the known members of the series was used; the p.m.r. spectra and, in particular, the chemical shifts of the vinyl protons and the bridgehead protons provided good evidence for stereochemistry at C-7 (Table 1). Relative g.l.p.c. retention times on Carbowax were also consistent with those previously established, "*syn*-ols" eluting before "*anti*-ols" (2, 3, 7). A further criterion of

stereochemistry is the O—H stretching pattern in the i.r. spectrum. Intramolecular hydrogen bonding to the etheno bridge leads to absorption near 3575 cm^{-1} in the spectra of "*syn*-ols" (3, 5). All "*syn*-ols" reported in this paper showed such absorption while "*anti*-ols" showed a free O—H stretching band above 3600 cm^{-1}. These criteria were sufficient for all alkylnorbornenols studied.

The products from phenyllithium were not separable on the Carbowax g.l.p.c. column used for the alkylnorbornenols. On a SE-30 column, the isomer assigned "*anti*-ol" by p.m.r. had the shorter, rather than the longer, retention time. To confirm the structures, the two 7-phenylnorbornen-7-ols were separated (g.l.p.c.) and each was partially acetylated in conditions unlikely to cause isomerization (acetyl chloride in excess pyridine). Changes in the bridgehead and vinyl proton resonances resulting from acetylation could then be studied with the best possible internal references. Erman (3) has prepared 7-*syn*- and 7-*anti*-acetoxy-7-methylnorbornene and these, together with the corresponding alcohols, were used as model compounds. The results are summarized in Table 2. Acetylation of 7-methylnorbornen-7-*anti*-ol causes a downfield shift of the bridgehead resonance but leaves the chemical shift of the vinyl hydrogens unchanged. A comparable shift of the bridgehead resonance occurs on acetylation of 7-methylnorbornen-7-*syn*-ol, but here the vinyl proton resonance moves upfield by 0.12 δ. Similar effects are observed for the phenyl compounds. In both isomers, bridgehead resonances move downfield, while in one isomer the vinyl resonance remains constant on acetylation and in the other it moves upfield by 0.17 δ. The former was therefore assigned the "*anti*-ol" structure and the latter the "*syn*-ol" structure. Thus, as with the 7-alkylnorbornen-7-ols, the phenyl compound with the vinyl proton resonance at lower field is that with the "*syn*-ol" stereochemistry.

The 7-vinylnorbornenols, like the 7-alkylnor-

¶*t*-Butyl addition was observed in variable yield and ratio in these cases.

bornenols, were separable on the Carbowax column. Elution order and i.r. and p.m.r. spectra were consistent criteria of configuration. Moreover these criteria pointed to the solid isomer, m.p. 56–56.5°, as 7-vinylnorbornen-7-*anti*-ol, in agreement with a previous assignment, lit. (9), m.p. 58.2–59.8°.[2]

With the C-7 configuration of the products established the sense of attack of organolithium compounds on **1** could be investigated. In a series of experiments the solvents of both ketone and organolithium reagent were varied from diethyl ether to saturated hydrocarbon. Thus, for example, methyllithium, which is commercially available in diethyl ether solution, was added to the ketone, itself dissolved in diethyl ether or *n*-hexane. A similar pair of results was obtained by adding a large excess of *n*-hexane to the sample of methyllithium in diethyl ether; this was also reacted with the ketone in the two solvents. Phenyllithium is supplied commercially in benzene – diethyl ether (70:30). The reagent is insoluble in *n*-hexane and was used undiluted (in benzene – diethyl ether 70:30) and also with excess diethyl ether. *t*-Butyllithium was used in *n*-pentane and in *n*-pentane – ether solutions. *n*-Butyllithium was used in hexane and in ether–hexane solutions. Vinyllithium in tetrahydrofuran was added to the ketone in diethyl ether. A summary of the results of the solvent dependence of addition ratio appears in Table 3, together with results of experiments in which BF_3 and LiOEt were also present.

t-Butyllithium reacted to form expected addition products in *n*-hexane, but when diethyl ether was present, other alcohols were formed, assigned by p.m.r. and by relative retention time (g.l.p.c.) as 7-(3′,3′-dimethylbutyl)-norbornen-7-ols. In a series of experiments in which the mole ratio of *t*-butyllithium, relative to **1**, was varied from 1 to 10, only 3,3-dimethylbutyl addition products were observed until the ratio exceeded 8:1; at 10:1, *t*-butyl addition was also observed. The stereochemistry of attack at C-7 of **1**, in both *t*-butyl and 3,3-dimethylbutyl addition varied considerably over a number of runs. Unreacted ketone **1** was always present in product mixtures containing 7-(3′,3′-dimethyl-

[4] 
butyl)-norbornen-7-ols. A rationale for these observations is illustrated with eqs. 1–4. There is precedent for addition of *t*-butyllithium to ethylene (10). Evidently some of the norbornen-7-one is protected as the hemiketal anion.

Of particular note is the *anti* addition preference shown by phenyllithium and vinyllithium. In view of the pronounced *syn* preference shown by Grignard reagents (2, 5, 9), phenyl Grignard reagent was added to the ketone in diethyl ether. A 2.8:1 preference for *syn* attack was observed. Vinyl Grignard reagent shows a still higher (4:1) preference for *syn* attack (9). Thus, either isomer of the 7-phenylnorbornen-7-ols and 7-vinylnorbornen-7-ols can be prepared in excess of the other isomer simply by choosing the appropriate reagent.

The stereochemical preferences shown by the different organolithium reagents are not likely to be caused by impurities. Two equivalents of BF_3, for example, altered the *syn*:*anti* attack ratio of methyllithium from 2.9 to 1.9. In the presence of 10 equiv of LiOEt, addition of *n*-butyllithium to **1** gave a product ratio of 1.3, in favor of *syn* attack, as compared to 1.0 without LiOEt. Phenyllithium from a new bottle gave the same product ratio as that which had been stored for 3 years. In view of the fact that neither an electrophilic reagent nor a nucleophilic impurity present in copious amount changed the ratios drastically it is unlikely that unknown impurities in the reagents are responsible for observed differences.

Although the reasons for the dependence of product stereochemistry on reagent structure or solvent composition are not clear, some potential factors are worthy of brief discussion. A change in the sense of the stereochemical preference indicates that there are at least two opposing factors involved and that they are nearly balanced. Which side, *syn* or *anti*, is the more hindered has not been rigorously established. Two studies of equilibrated systems indicate that the larger of two substituents at C-7 prefers the *syn* position (4, 11), suggesting that the *syn* face is less hindered. Preliminary studies of equilibria involving mixed ketals of **1** lend support to that conclusion (12).

The preferred course of alkyllithium addition may therefore be the result of a dominating steric factor and the magnitude of the selectivity may be related to the effective steric requirements of the alkyllithium. Alkyllithium reagents tend to be associated in solution (13, 14); methyllithium, for example, being tetrameric in ether, tetrahydrofuran, and triethylamine (13). This means that the effective steric requirement of such a reagent is not easily predicted from the formula of the monomer.

In the case of phenyllithium and vinyllithium, both of which are more polar than alkyllithium reagents (15), a polar factor may be dominant. A possible destabilizing polar interaction in transition states for *syn*-addition is that between carbanion-like reagent and the double bond (**2**).

A similar interaction may be responsible for the lower acidity of norbornene-*syn*-7-carboxylic acid ($pK_a = 4.66$) relative to that of the *anti* acid ($pK_a = 4.50$) (16).[3] Qualitatively, this picture can accommodate the *syn* preference of the Grignard reagents which, being less polar than corresponding organolithium reagents (15) would be controlled primarily by the steric factor.

The alternative that must be considered is a factor stabilizing transition states for *anti* addition. A well-known process in which *anti* attack is greatly favored is capture of nonclassical 7-norbornenyl cations (18). However, such an analogy would require that phenyllithium and vinyllithium can behave primarily as electrophiles capable of inducing nonclassical cation character into the ketone, as in **3**. Such behavior is quite unlikely, especially in view of the fact that BF_3 did not overcome the *syn* preference of methyllithium.

Small variations in attack ratio with solvent are readily accommodated in the general scheme. Both the steric factor and the polar factor can be expected to depend on structural detail, which includes solvation.

Experimental

Chemicals

Methyllithium, *t*-butyllithium, vinyllithium, and phenyllithium were supplied by Alpha Inorganics Inc. *n*-Butyllithium was a product of Foote Mineral Co. Limited.

Product Analyses

Crude product mixtures were analyzed by g.l.p.c. using a 10′ × 3/8″ column packed with 15% Carbowax 20M on 60–80 mesh Chromosorb W (7-alkyl-norbornen-7-ols) and a 5′ × 1/4″ column packed with 20% SE30 on the same support (7-phenyl-norbornen-7-ols). Analytical samples were obtained by preparative g.l.p.c. employing a freshly prepared 10′ × 1/4″ column packed with 15% Carbowax 20M on the same support. An Aerograph 90P-3 instrument, with thermal conductivity detector, was used throughout.

Product ratios were determined both by measuring areas under peaks from the g.l.p.c. traces by triangulation[4] and by repeated integration of the vinyl proton absorptions in the p.m.r. spectra. All p.m.r. data were obtained with a Varian T60 instrument.

Organolithium Reagents

The concentration of the reagents was obtained by titration against hydrochloric acid (2.44 *M*) using phenolphthalein as indicator. This analysis relies on the insolubility of lithium hydroxide in the solvents present.

The following description is typical of all experiments. *n*-Butyllithium (1.6 *M* in *n*-hexane, 2.0 ml, 3.2 mmol) was dissolved in *n*-hexane (5.0 ml) and stirred magnetically. The *n*-butyllithium solution was added dropwise to the ketone solution, at −75°, over 2 min and the resulting mixture was stirred for a further 15 min at −75°. The reaction was quenched by pouring onto water at room temperature (approximately 75 ml). The ether layer was separated, washed twice with water (2 × 75 ml) and dried over $MgSO_4$ before concentrating with a rotary evaporator. Product ratios were accepted only if the last traces of ether were not removed, as the products are quite volatile.

In a similar experiment employing methyllithium in ether (the products of which were the most volatile encountered) and norbornen-7-one (1.06 g, 9.82 mmol) in *n*-hexane the yield of ether-free 7-methylnorbornen-7-ols was 0.98 g (81%). In all other cases the yields were higher.

Effect of Boron Trifluoride

To norbornen-7-one (50 mg, 0.46 mmol) in dry diethyl ether (10 ml) was added freshly-distilled boron trifluoride etherate (144 mg, 1.01 mmol) and the solution was stirred for 5 min at 22° before it was cooled to −70°. Methyllithium (1.83 *M* in ether, 2.6 ml, 4.6 mmol) was added during 3 min. Work-up analogous to that described above gave a colorless oil which crystallized on standing (60 mg). Analysis by g.l.p.c. showed that the ratio, *anti*-ol : *syn*-ol, of 7-methylnorbornen-7-ols was 1.9.

Effect of Sodium Ethoxide

n-Butyllithium (1.78 *M* in hexane, 5.2 ml, 9.3 mmol) was added to ethanol (0.43 g, 9.3 mmol) in diethyl ether (10 ml) at −78°. The mixture was stirred for 5 min before norbornen-7-one (100 mg, 0.93 mmol) was added, followed, after 5 min, by *n*-butyllithium (5.2 ml, 9.3 mmol). After 15 min of stirring at −78° the mixture was worked-up, resulting in a colorless oil (0.090 g). Analysis by g.l.p.c. showed this to consist of norbornen-7-one (7%) and 7-*n*-butylnorbornen-7-ols in the ratio 1.3 (*anti*-ol : *syn*-ol) compared to about 1.0 (Table 3) without lithium ethoxide.

Phenyl Grignard Reagent

Dry bromobenzene (7.60 g, 46.0 mmol) was added through a serum cap to a stirred mixture of heat-dried, Grignard-grade magnesium turnings (2.0 g, 0.082 g-atom) in sodium-dried diethyl ether (25 ml) under a N_2 atmosphere. The reaction was initiated with gentle heating, and after 1 h reflux the solution was brown in color. Norbornen-7-one (0.50 g, 4.6 mmol) was added dropwise and the mixture was held at reflux temperature for 1 h. The reaction was quenched by pouring onto saturated aqueous NH_4Cl solution. This hydrolysis was highly exothermic, indicating the presence of excess Grignard reagent. Drying the ether layer over K_2CO_3 and evaporation of ether left a yellow oil (1.0 g). This was shown to contain 7-phenylnorbornen-7-*anti*-ol (44 parts) and 7-phenylnorbornen-7-*syn*-ol (16 parts) (70% yield) by spectral and g.l.p.c. comparison with authentic samples. The third product, biphenyl, was identified from its p.m.r. spectrum and m.p. (70–71°, lit (19) 70°).

[3]The order of these acidities has been confirmed (17).

[4]Thermal conductivities of products were assumed to be the same.

Normal Coordinate Calculations of the Vibrations of Methylene Cyclopropane-h_6 and -d_6

J. E. BERTIE AND M. G. NORTON
Department of Chemistry, The University of Alberta, Edmonton, Alberta

Received March 1, 1971

Normal coordinate calculations for methylene cyclopropane-h_6 and -d_6 have been carried out using two models. In the first model 31 internal coordinates were used, and in the second model 25 internal coordinates were used. The force constants were, in each case, refined to the 40 frequencies observed for the two molecules. Using the first model 26 force constants, of which four were constrained, fitted the frequencies with an average error of 1.2% for C_4H_6 and 2.8% for C_4D_6. Using the second model 24 force constants, of which two were constrained, fitted the frequencies with an average error of 1.4% for C_4H_6 and 2.8% for C_4D_6.

The very low isotopic shift of the C═C stretching mode can be explained by an interaction with the ethylenic CH_2 deformation, which is best assigned at 1047 cm^{-1}, rather than at 1139 cm^{-1}, in C_4D_6. The calculations indicate that the experimental assignment for the A_1 ring breathing mode and the A_1 methylenic wag in C_4H_6 should probably be reversed. For the A_1 and the B_1 modes with frequencies between 500 and 1300 cm^{-1}, the normal coordinates change considerably on deuteration. The symmetry coordinates are mixed in the normal modes of C_4D_6 to a much greater extent than in those of C_4H_6.

Des calculs en coordonnées normales ont été effectués pour le méthylène cyclopropane-h_6 et -d_6 utilisant deux modèles. Dans le premier modèle 31 coordonnées internes ont été utilisées et dans le second modèle 25 coordonnées internes ont été utilisées. Les constantes de force ont été, dans chaque cas, raffinées aux 40 fréquences observées pour les deux molécules. En utilisant le premier modèle comprenant 26 constantes de force, parmi lesquelles quatre étaient contraintes, les fréquences coincidèrent avec une erreur moyenne de 1.2% pour C_4H_6 et 2.8% pour C_4D_6. En utilisant le second modèle comprenant 24 constantes de force, parmi lesquelles deux étaient contraintes, les fréquences coincidèrent avec une erreur moyenne de 1.4% pour C_4H_6 et 2.8% pour C_4D_6.

Le déplacement isotopique très faible du mode de valence C═C peut être expliqué par une interaction avec la déformation CH_2 éthylénique, qui est mieux attribuée à 1047 cm^{-1}, plutôt qu'à 1139 cm^{-1}, dans C_4D_6. Les calculs indiquent que l'attribution expérimentale pour le mode A_1 de pulsation du cycle et le balancement (wag) A_1 méthylénique dans C_4H_6 devrait probablement être inversée. Pour les modes A_1 et B_1 de fréquences entre 500 et 1300 cm^{-1}, les coordonnées normales changent considérablement avec la deutération. Les coordonnées de symétrie sont mélangées dans les modes normaux de C_4D_6 de façon beaucoup plus importante que ceux du C_4H_6.

Canadian Journal of Chemistry, 49, 2229 (1971)

I. Introduction

The vibrational assignments reported in an earlier paper (1) imply surprisingly small isotopic shifts of certain vibrations. In particular, the C═C stretching mode, ν_3, appears to shift from 1742.2 to 1727.7 cm^{-1} on deuteration, instead of to about 1650 cm^{-1} as would be expected on simple grounds. The frequency shift on deuteration of the ethylenic CH_2 deformation, ν_5, is uncertain between 1411.0 to 1139 cm^{-1}, (assignment I) and 1411.0 to 1047 cm^{-1} (assignment II). The former appears to be more reasonable in relation to the shifts of the methylenic CH_2 deformations, but the latter is required to fit the product rule reasonably. Further, the B_1 methylenic wag, ν_{17}, shifts on deuteration from 1125 to 1017 cm^{-1}, yielding an isotopic frequency ratio of only 1.11, compared to 1.27 found for the A_1 wag, ν_7. On the other hand, the B_1 ring deformation, ν_{18}, shifts on deuteration from 895 to 735 cm^{-1}, yielding a surprisingly high isotopic frequency ratio of 1.22. Without normal coordinate calculations one would ascribe these peculiarities to the different modes coupling to a different extent in the different isotopic molecules. It is desirable to carry out the calculations and determine which of these peculiarities can be accounted for by the mass changes and the geometry of the molecule alone, *i.e.* by kinetic coupling, and which of them require specific force constants to account for interactions between certain internal coordinates for their explanation, *i.e.* potential energy coupling. And further, to determine whether a harmonic force field can account for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the observed frequencies in both molecules at all. These calculations were undertaken, also, to see if the apparently high frequency, 1354.4 cm^{-1} in C_4H_6 and 1073 cm^{-1} in C_4D_6 of the ethylenic rock, ν_{16}, could arise from interaction with other modes of vibration, or merely from a high force constant. Further, the force field of cyclopropane has been investigated by several authors (2–4) and it is of interest to extend this work to include methylene cyclopropane, in which the C_3 ring is thought to be under greater strain due to the presence of the ethylenic group.

Blau (5) and Loewenstein (6) solved the secular equation for C_4H_6 to assist in the assignment of the normal modes, but did not attempt a convergent solution to the problem. No calculations have been reported for C_4D_6.

We have therefore used the results of the vibrational assignment of C_4H_6 and C_4D_6 described in a previous paper (1) to carry out normal coordinate analyses of these molecules. In the calculations we have used two sets of coordinates: (*a*) the 31 internal valence coordinates which introduce 7 redundancies and (*b*) a set of 25 internal coordinates which do not require consideration of redundancy in the ring, but which do include one redundancy by the use of the two C—C=C angles. Set *b* is directly comparable with those used in the previous work on cyclopropane (2–4). Modified valence force fields were used for each case.

These two treatments will be discussed in Sections III and IV, respectively.

II. Computer Programs

The calculations were carried out on the I.B.M. model 360/67 computer at the University of Alberta. The **G** matrices were calculated from the **X** matrix via the **B** matrix using Schachtschneider's (7) GMAT program. The **X** matrix was constructed from the microwave data of Laurie and Stigliani (8).

Two programs were used to calculate the normal modes and their frequencies, and to refine the force constants. A program originally written by Smith (9), and translated into PL/1 for the University of Alberta computer by M. G. Norton, was used for the majority of the work, including the development of the force-field. This program is similar in method to Schachtschneider's program FPERT (7), but allows greater flexibility in input. Towards the end of the work all of the results of the PL/1 program were checked using the widely-used FPERT, to confirm the results obtained.

Both programs were checked out using the methyl fluoride data of Schachtschneider (7). Our implementation of FPERT reproduced Schachtschneider's solutions exactly, and has satisfactorily reproduced other published data. The PL/1 program reproduced Schachtschneider's frequencies for normal and heavy methyl fluoride to better than 1 cm^{-1}, and reproduced his force constants well, the worst disagreement being about 2% on an interaction constant. Because the two programs converged to slightly different solutions, and because FPERT converged at times when the PL/1 program led to a slightly oscillatory solution, the final force constants and frequencies presented are those obtained with FPERT. The potential energy distribution was obtained, using the force constants presented, from the PL/1 program, without allowing it to refine the force constants further, because this program yields the potential energy distribution in a rather more convenient form for our purpose than does FPERT. The PL/1 program also yields the potential energy distribution in the same form as FPERT, and these agreed very closely when the same force constants were used in both programs.

The criteria for accepting a solution were the following. The calculation must converge to a repeatedly consistent solution. The singularity test ratio (10) must be examined, because when this is very near to zero false potential energy minima may be entered. Solutions for which the potential energy distribution among the symmetry coordinates was consistent with the original assignments (1) were sought.

III. Calculation Including all Internal Coordinates

This calculation was carried out because it seemed to be a more rigorous approach to the problem than the method described in Section IV, which is the more usual one (2–4). After constructing the symmetry coordinates, we proceeded in two stages. First the best solution for C_4H_6 alone was sought. Then this force field was applied to C_4D_6, without refinement, to see how serious the discrepancies were. They were serious, and so the force field was re-refined, and modified

(2) $\delta\alpha_{78} + \delta\alpha_{79} + \delta\alpha_{89} = 0$

(3) $\delta\alpha_{89} + \delta\alpha_{810} + \delta\alpha_{910} = 0$

(4) $0.46538\delta R_{10} - 0.24615(\delta R_8 + \delta R_9) + 0.57544(\delta\alpha_{810} + \delta\alpha_{910}) = 0$

(5) $0.16043(\delta\alpha_{810} + \delta\alpha_{910}) + 0.44081(\delta\alpha_{34} + \delta\alpha_{56}) + 0.26455(\delta\alpha_{38} + \delta\alpha_{310} + \delta\alpha_{48} + \delta\alpha_{410} + \delta\alpha_{59} + \delta\alpha_{510} + \delta\alpha_{69} + \delta\alpha_{610}) = 0$

(6) $0.52348(\delta R_8 - \delta R_9) + 0.47536(\delta\alpha_{810} - \delta\alpha_{910}) = 0$

(7) $0.16043(\delta\alpha_{810} - \delta\alpha_{910}) + 0.44081(\delta\alpha_{34} - \delta\alpha_{56}) + 0.26455(\delta\alpha_{38} + \delta\alpha_{310} + \delta\alpha_{48} + \delta\alpha_{410} - \delta\alpha_{59} - \delta\alpha_{69} - \delta\alpha_{510} - \delta\alpha_{610}) = 0$

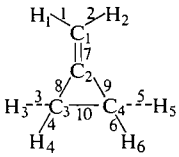

FIG. 1. The bond numbering scheme upon which the definition of the internal coordinates is based.

by the inclusion of new force constants, using the data for C_4H_6 and C_4D_6 together.

The 31 internal coordinates are defined with reference to Fig. 1. The bond stretching coordinates are δR_i, using the i appropriate to each bond as shown in Fig. 1, *e.g.* $\delta R_{C_1H_1}$ is δR_1 etc. The angle deformation coordinates are $\delta\alpha_{ij}$, where i and j are the numbers assigned in Fig. 1 to the bonds forming the angle, *e.g.* $\delta\alpha_{410}$ is the change in the angle H_4—C_3—C_4. The torsional coordinate τ is the dihedral angle between the planes $H_1C_1H_2$ and $C_3C_2C_4$. β_{712} is the angle between the double bond and the $H_1C_1H_2$ plane, and β_{789} is the angle between the double bond and the $C_3C_2C_4$ plane.

(a) Construction of Symmetry Coordinates

Seven relationships between these internal displacement coordinates arise from the geometry of the molecule, and are given in Table 1. Conditions *1* and *2* relate the coplanar angles about C_1 and about C_2, conditions *3*, *4*, and *6* represent the *3* ring redundancy conditions, and conditions *5* and *7* are symmetric and asymmetric combinations, respectively, of the relation between the six angles about C_3 with that between the angles about C_4. The relation between the six angles about a point through which one symmetry plane passes that we used is

$$\delta\alpha_{12} + \frac{\tan(\alpha_{34}/2)}{\tan(\alpha_{12}/2)} \cdot \delta\alpha_{34} + \frac{\sin\alpha_{13}}{2\sin(\alpha_{12}/2)\cos(\alpha_{34}/2)}(\delta\alpha_{13} + \delta\alpha_{14} + \delta\alpha_{23} + \delta\alpha_{24}) = 0$$

where R_i, $i = 1$ to 4, designate the 4 bonds, and α_{ik} designates the angle between bond i and bond k.

The redundancy conditions, *1*, *2*, *3*, *4*, and *5* transform according to representation A_1 of C_{2v}, while *6* and *7* transform according to the B_1 representation. The redundancy relations belonging to a given representation were made orthonormal to each other by the Schmidt method (11). The remainder of the symmetry coordinates were then made orthonormal to the redundant set and to each other. The final set of 31 symmetry coordinates is given in Table 2. The seven redundant or "null" coordinates were found to give zero roots upon solving the secular equation and were removed from the **U** matrix to give a 24 × 31 **U** matrix.

(b) Calculation and Results for C_4H_6 Alone

In order to simplify the development of a force field which would serve as a starting approximation for the whole, two molecule, problem, we first considered the C_4H_6 molecule alone. Before even the simplest force field is used, two diagonal force constants must be constrained. The ethylenic torsional mode has not been observed, and the torsional force constant was given the value 0.15 mdyn Å which gives a calculated frequency for this mode of around 740 cm^{-1}, close to the torsional frequency in asymmetrically disubstituted ethylenes (12). With our present set of internal coordinates, the C_3 ring has 4 diagonal force constants, $F(R_8) = F(R_9)$, $F(R_{10})$, $F(\alpha_{89})$, $F(\alpha_{810}) = F(\alpha_{910})$, to contribute to 3 degrees of

freedom. $F(\alpha_{89})$ was, therefore, arbitrarily constrained to 0.9 mdyn Å. The two methylenic H—C—C force constants were assumed to be equal, *e.g.* $F(\alpha_{38}) = F(\alpha_{310})$.

This diagonal force field allowed only two modes to converge to the correct frequencies, the ethylenic wag at 890.5 cm^{-1} and the C—C=C out-of-plane bend at 279.6 cm^{-1}. These two modes are uniquely determined, *i.e.*, they interact very little with other modes. The other frequencies did not converge to their observed values, and even the order of the methylenic deformation frequencies was calculated incorrectly. In particular the methylenic twist was calculated to low frequency of the methylenic rock.

The following interaction constants were then introduced:

(*1*) To improve the fit of the C—H stretching modes the constants F(CH,CH')(eth), *i.e.*, $F(R_1,R_2)$, and F(CH,CH')(meth), *i.e.*, $F(R_3,R_4) = F(R_5,R_6)$, were introduced.

(*2*) To improve the calculated frequencies for the methylenic deformation modes the following constants were introduced: $F^a(\alpha,\alpha)$, H—C—C H—C—C angle interaction, with bonds R_3, R_4, R_5 or R_6 common, *e.g.* $F(\alpha_{38},\alpha_{310})$; $F^b(\alpha,\alpha)$, H—C—C H—C—C angle interaction, with bonds R_8, R_9 or R_{10} common, *i.e.* $F(\alpha_{38},\alpha_{48}) = F(\alpha_{59},\alpha_{69})$ and $F(\alpha_{310},\alpha_{410}) = F(\alpha_{510},\alpha_{610})$. For simplicity $F(\alpha_{38},\alpha_{48})$ was assumed equal to $F(\alpha_{310},\alpha_{410})$, thus introducing only one parameter.

(*3*) To improve upon the agreement in the ring modes F(C—C,C—C) interactions were used. $F(R_9,R_{10})$ equals $F(R_8,R_{10})$ by symmetry, and we assumed for simplicity that these two also equal $F(R_8,R_9)$, and used these three constants, set equal to each other. The introduction of this extra parameter again overdetermines the ring frequencies, and $F(\alpha_{810})$ and $F(\alpha_{910})$ were constrained to 0.5 mdyn Å to overcome this.

This force field allowed complete convergence of the C—H stretches and gave a more accurate description of the methylenic deformations. The methylenic twist converged to 1073 cm^{-1} and the methylenic rock converged to 748 cm^{-1}. However, the three ring frequencies were still poorly determined, and an oscillatory solution involving F(C—C) and F(C=C) resulted.

Because of the ring redundancies, no unique solution can be obtained for the ring force constants. Therefore we tried three different approximations to seek the best fit.

(*1*) The F(C—C,C—C) interaction constants were all constrained at the value −0.15 mdyn/Å found in cyclopropane (3). No further constants were introduced and no constraints were released, and thus $F(R_8) = F(R_9)$, and $F(R_{10})$ were the only ring constants allowed to vary. This did not improve the frequency fit and gave an oscillatory solution involving F(C=C) and F(C—C).

(*2*) An interaction constant of the type F(C—C,C=C) was introduced, with the constraints above maintained, thus leaving three parameters varying to fit the three ring frequencies. There are two constants of this type, $F(R_7,R_8) = F(R_7,R_9)$, and $F(R_7,R_{10})$. The latter was found to be more helpful than the former, with the PL/1 program, and was used. Including $F(R_7,R_{10})$ then, an oscillatory solution resulted with the value of F(C=C) around 8 mdyn/Å and $F(R_7,R_{10})$ around 1 mdyn/Å. In order to allow further experiments with the ring force constants, $F(R_7,R_{10})$ was constrained at this value, 1 mdyn/Å.

(*3*) Because the F(C—C,C—C) interaction constants $F(R_9,R_{10}) = F(R_8,R_{10})$ might be expected to approximate more closely to the value found in cyclopropane for this type of constant than would $F(R_8,R_9)$, $F(R_9,R_{10}) = F(R_8,R_{10})$ were kept constrained at −0.15 mdyn/Å, while $F(R_8,R_9)$ was released to seek its preferred value. At this stage the ring constants $F(\alpha_{89})$, $F(\alpha_{810})$, $F(\alpha_{910})$, and the F(C—C,C=C) interaction constant, were still constrained, leaving $F(R_8) = F(R_9)$, $F(R_{10})$, and $F(R_8,R_9)$ as the only ring constants allowed to adjust to their optimum values. This improved the ring frequency fit, the best being obtained with $F(R_8,R_9) = 0.2$ mdyn/Å. However, this did not represent a stable solution, and $F(R_8,R_9)$ converged to a value more consistent with $F(R_8,R_{10})$, even though this gave a poorer fit to the ring frequencies. This arose because of interactions between the ring modes and the methylenic deformations, in particular, between the A_1 ring stretch and the A_1 methylenic deformation, and between the A_1 ring deformation and the A_1 methylenic wag.

The convergent solution obtained from approximation *3* just described gave the most satisfactory description of the ring modes, but the calculated frequency difference between the A_1 and B_1 methylenic wags was still smaller than that required by the assignment, being calculated at 1065 and 1097 cm^{-1} and assigned at 1003 and 1125 cm^{-1}, respectively. To correct this a further H—C—C, H—C—C angle interaction constant

‡The force constant was constrained at the value shown.

was introduced $F(\alpha_{310},\alpha_{510}) = F(\alpha_{410},\alpha_{610})$, and a more acceptable frequency difference for the wags was obtained.

At this stage no further development was possible using C_4H_6 frequencies only, and the force-field developed above was used as a starting approximation for calculations using C_4H_6 and C_4D_6 frequencies together.

(c) *Calculation and Results for C_4H_6 and C_4D_6 Combined*

The force field described above, when allowed to refine to fit the combined C_4H_6 and C_4D_6 data, was unable to calculate an isotopic shift near to that observed (1) for the C=C stretching mode, ν_3. The smallest shift calculated was 105 cm^{-1} compared to the observed shift of 14.5 cm^{-1}. This force field also failed to explain the small shift of the B_1 methylenic wag, which was assigned as 1125.3 to 1017 cm^{-1} and calculated as 1135 to 950 cm^{-1}.

The additional data allowed further experimenting with the force field. In an attempt to improve the fit of the ring frequencies, $F(R_7,R_{10})$ and $F(R_8,R_{10}) = F(R_9,R_{10})$ were released from constraint, but this field failed to converge. Reconstraint of $F(R_8,R_{10}) = F(R_9,R_{10})$ at −0.15 mdyn/Å did not improve the calculation, and a convergent solution could only be obtained with all of the F(C—C,C—C) constants constrained at

*The frequencies are in cm^{-1} units.
†The force constants are in units of mdyn $Å^{-1}$, mdyn, or mdyn Å, for constants of the type $F(R)$ and $F(RR')$, $F(R\alpha)$, or $F(\alpha)$ and $F(\alpha\alpha')$, respectively.
‡The force constants were constrained at the value shown.

−0.15 mdyn/Å, and $F(R_7,R_{10})$ varying. In a successful attempt to improve the fit of the A_1 and B_1 methylenic deformations, an interaction constant of the type F(H—C—H,H—C′—H) was also introduced, $F(\alpha_{34},\alpha_{56})$. To improve the isotopic shift for the C=C stretching mode, the constant $F(R_7,\alpha_{17}) = F(R_7,\alpha_{27})$ was introduced. In order to help further to account for the interactions between the ring modes and the methylenic deformations (including wag, rock, and twist), two further bond-angle interaction constants were introduced: F^a(C—C,α) *i.e.*, $F(R_8,\alpha_{38}) = F(R_8,\alpha_{48}) = F(R_9,\alpha_{59}) = F(R_9,\alpha_{69})$; F^b(C—C,α) *i.e.*, $F(R_{10},\alpha_{310}) = F(R_{10},\alpha_{410}) = F(R_{10},\alpha_{510}) = F(R_{10},\alpha_{610})$.

The results of this force-field are given in Tables 3 and 4, and represent the best agreement with the observed frequencies that we have been able to obtain. The assignment of ν_5 was uncertain between 1139 and 1047 cm^{-1} (or 1043 cm^{-1}) from experimental data (1). Table 3 shows the results obtained by refining ν_5 to 1139 cm^{-1} (assignment I), and Table 4 presents the results obtained by refining ν_5 to 1047 cm^{-1} (assignment II).

It is apparent that this force field has improved the fit of the C=C stretching mode by reducing the isotopic shift to about 60 cm^{-1} in Table 3 and about 50 cm^{-1} in Table 4. This is accomplished primarily by $F(R_7,\alpha_{17}) = F(R_7,\alpha_{27})$ and is neces-

sarily accompanied by an increase in the shift of the ethylenic deformation, ν_5.

It is seen that the larger isotopic shift required for ν_5 in assignment II is more consistent with the calculations. The overall agreement between calculated and observed frequencies is better for assignment II than for assignment I. This suggests that ν_5 in C_4D_6 should be assigned to 1047 cm^{-1}, not 1139 cm^{-1}, if the other A_1 modes are correctly assigned. The combination of the reasonably good agreement obtained by calculation for the A_1 frequencies and assignments, plus the lack of viable alternative assignments, leads us to believe that assignment II is correct for methylene cyclopropane. We have therefore only given the calculated assignments, as potential energy distributions (p.e.d.), for assignment II. The potential energy distribution of the normal modes among the symmetry coordinates was calculated from the expression

$$\text{p.e.d.}\ (i,j) = \frac{100 \times \mathbf{L}_s^2(i,j) \times \mathbf{F}_s(i,i)}{\lambda_j}$$

where $\mathbf{L}_s$ is the symmetrized eigenvector matrix, $\mathbf{F}_s$ is the symmetrized force constant matrix, and λ_j is the eigenvalue for mode j, and is given for assignment II in Table 5.

The omission of the potential energy distribution for assignment I makes it necessary to point out one further argument against assignment I. In Table 3, ν_4 and ν_5 are shown to be calculated for C_4H_6 at 1465.5 and 1416.2 cm^{-1}, respectively. But the potential energy distribution shows that it is the ethylenic deformation that is calculated at 1465.5 cm^{-1} and the methylenic deformation at 1416.2 cm^{-1}. This is the reverse of the assignment, and the evidence presented for the assignment in ref. 1 makes it extremely unlikely that the ethylenic deformation can be to high frequency of the methylenic deformation in the molecule. In assignment II the ethylenic deformation is calculated at 1414.3 cm^{-1} and the methylenic deformation at 1446.8 cm^{-1}, both for C_4H_6, in agreement with the assignment.

The results in Table 4 show that the calculations have reproduced the observed frequencies for both molecules reasonably well, and the data in Table 5 show that the calculated assignments are consistent with the assignments made in ref. 1.

It is perhaps worth briefly stating that various attempts to improve the frequency fit were made,

unsuccessfully. These included: (*a*) releasing the approximation $F(\alpha_{38}) = F(\alpha_{310})$; (*b*) setting $F(R_8,\alpha_{38}) = F(R_{10},\alpha_{310})$ to be consistent with the assumption that $F(\alpha_{38}) = F(\alpha_{310})$; (*c*) raising the value of $F(\alpha_{89})$ relative to that of $F(\alpha_{810})$. Attempt *c* was intended to improve the fit of the symmetric ring deformation, ν_8, and it did raise ν_8, but not by far enough to be useful. To raise it to the observed frequency by this method would require $F(\alpha_{89})$ to be about 10 times, or more, $F(\alpha_{810})$ which is unreasonable. Any other attempt to raise ν_8 harmed the fit of the other ring modes.

IV. Calculations Using a Set of Coordinates Ignoring Redundancy of the Ring

In order to make meaningful comparisons with the work reported on cyclopropane (2, 3), we also carried out a normal coordinate analysis using a set of 25 internal coordinates involving no redundancy in the ring and using group coordinates to describe the methylenic deformational modes. The 25 internal coordinates were obtained by ignoring α_{34}, α_{56}, α_{89}, α_{810}, α_{910}, and α_{12}, in the original set of 31 (Section III). The methylenic group coordinates are as follows:

Deformation on C_3

$$\zeta_1 = \tfrac{1}{2}(\delta\alpha_{38} + \delta\alpha_{48} + \delta\alpha_{310} + \delta\alpha_{410})$$

Deformation on C_4

$$\zeta_2 = \tfrac{1}{2}(\delta\alpha_{59} + \delta\alpha_{69} + \delta\alpha_{510} + \delta\alpha_{610})$$

Wag on C_3

$$\eta_1 = \tfrac{1}{2}(\delta\alpha_{38} + \delta\alpha_{48} - \delta\alpha_{310} - \delta\alpha_{410})$$

Wag on C_4

$$\eta_2 = \tfrac{1}{2}(\delta\alpha_{59} + \delta\alpha_{69} - \delta\alpha_{510} - \delta\alpha_{610})$$

Twist on C_3

$$\theta_1 = \tfrac{1}{2}(\delta\alpha_{38} - \delta\alpha_{48} - \delta\alpha_{310} + \delta\alpha_{410})$$

Twist on C_4

$$\theta_2 = \tfrac{1}{2}(\delta\alpha_{59} - \delta\alpha_{69} - \delta\alpha_{510} + \delta\alpha_{610})$$

Rock on C_3

$$\xi_1 = \tfrac{1}{2}(\delta\alpha_{38} - \delta\alpha_{48} + \delta\alpha_{310} - \delta\alpha_{410})$$

Rock on C_4

$$\xi_2 = \tfrac{1}{2}(\delta\alpha_{59} - \delta\alpha_{69} + \delta\alpha_{510} - \delta\alpha_{610})$$

The 24 non-trivial symmetry coordinates used are shown in Table 6. The twenty-fifth symmetry coordinate, $(1/\sqrt{2})(\alpha_{78} + \alpha_{79})$, was carried through the calculation and yielded a zero frequency.

The most successful force field was found to be analogous to that given in Table 4, and it was possible to obtain good frequency agreement in all modes for assignment II. As with the first force field model, reduction in the ν_3 isotopic shift was accompanied by an increase in ν_5's isotopic shift, supporting assignment II. The results of this calculation are given in Table 7 for assignment II. The force constants equivalent to the bond-angle interaction constants F^a(C—C,α) and F^b(C—C,α) of Section III were F(C—C,ζ) and F(C—C,η), using the approximations $F(R_8,\zeta_1) = F(R_9,\zeta_2) = F(R_{10},\zeta_1) = F(R_{10},\zeta_2)$ and $F(R_8,\eta_1) = F(R_9,\eta_2) = F(R_{10},\eta_1) = F(R_{10},\eta_2)$.

$S_{23} = \delta\beta_{712}$
$S_{24} = \delta\beta_{789}$

V. Discussion

Arguments have been presented in Section III *c* that favor assignment II over assignment I. In this section the discussion is restricted to the results obtained for assignment II by the two force fields. Model I refers to the calculation using 31 internal coordinates, and model II to that using 25 internal coordinates. The potential energy distribution for model II is not presented in a table. For C_4H_6 it gives essentially the same assignments as indicated by Table 5, except that it assigns ν_4 to the ethylenic CH_2 deformation and ν_5 to the methylenic CH_2

‡The force constant was constrained at the value shown.

deformation. As discussed above, this is unlikely on experimental grounds and must be considered a defect of model II. For C_4D_6 model II provides essentially the same assignments as model I. The calculations indicate a large degree of mixing of the symmetry coordinates in the normal vibrations of A_1 and B_1 symmetry. This mixing is greater in C_4D_6 than in C_4H_6, as expected from the smaller frequency separations in C_4D_6, and this explains some of the rather unusual isotopic shifts found for this molecule.

The calculations have been partly successful in explaining the low isotopic shift of ν_3 and, as has been pointed out, in doing so have strongly indicated that ν_5 in C_4D_6 should be assigned at 1047 cm^{-1} rather than at 1139 cm^{-1}. An examination of the potential energy distribution for both models shows that there is no major difference in the normal coordinate for ν_3 between C_4H_6 and C_4D_6, ν_3 involving interactions between C=C stretch and ring stretch in both molecules, with slight interaction with the ethylenic C—D stretch in C_4D_6. Thus the low isotopic shift is not a product of major changes in the form of the ν_3 vibration between C_4H_6 and C_4D_6. As discussed above, the isotopic shift of ν_3 was reduced by the introduction of the interaction between the C=C stretch and the HC=C angles, leading to a 1 to 2% admixture of the ethylenic deformation in ν_3.

In our experimental assignment (1) we postu-

lated that ν_4, the symmetric methylenic deformation, gains Raman intensity in C_4D_6 by coupling with the ring modes. The calculations support this suggestion, and further indicate some mixing with the A_1 ethylenic deformation in both molecules. ν_5 is clearly indicated as the ethylenic deformation, with about 12% of the methylenic deformation in both molecules. ν_6 was assigned as the ring stretching mode because of its high Raman intensity. The calculations assign it as predominantly methylenic wag plus some ring stretch in C_4H_6, and a fairly even mixture of the methylenic wag plus ring stretch, plus some methylenic deformation, in C_4D_6. ν_7, assigned previously (1) as the methylenic wag, is calculated to be mainly ring stretch in C_4H_6, and a mixture of ring stretch plus methylenic wag plus methylenic deformation in C_4D_6. Similarly the contribution of the methylenic wagging motion to ν_8 increases drastically on deuteration. In C_4D_6, ν_6, ν_7, and ν_8 cannot be usefully classified by a single symmetry coordinate at all, but are all heavy mixtures of ring motion and methylenic wag, with the methylenic deformation contributing significantly to ν_6 and ν_7.

Similar changes in the normal coordinates upon deuteration are indicated by the calculations for the B_1 modes, ν_{15} to ν_{18}. In C_4H_6 they are calculated to be as assigned experimentally, rather pure methylenic deformation, ethylenic rock, methylenic wag, and the ring deformation, respectively. In C_4D_6, ν_{15} is calculated as an even mixture of ethylenic rock and ring deformation, with some methylenic deformation involved, ν_{16} as mainly methylenic deformation with some ethylenic rock, ν_{17} as mainly the methylenic wag with some ring deformation and ethylenic rock included, and ν_{18} as a fairly even mixture of the ring deformation, the ethylenic rock and the methylenic wag, with some methylenic deformation included. It is clear that in C_4D_6 no one symmetry coordinate is an adequate description of ν_{15} to ν_{18}.

The calculations from both models reverse the experimental assignment for ν_6 and ν_7 in C_4H_6. One must consider whether the calculated assignment is to be preferred. It is clear that the calculation of the modes involving the ring must be subject to a certain amount of arbitrariness because of the large number of redundancies and the correspondingly large number of force constants, some of which must be constrained. However, the two models gave the same assignment in spite of the force fields being quite different. In each model the interactions in the ring are accounted for by use of interaction constants that undoubtedly cannot truly represent the forces acting in the ring but which combine to achieve much the same effect. But the way in which this is achieved differs in the two models. This is perhaps most clearly indicated by the interaction constant between the ring basal bond and the C=C stretch, $F(R_7,R_{10})$ which is of different sign in the two models. It seems clear that the observed frequencies have been reasonably well reproduced by each model, yet the way in which the ring interactions achieve this result differs significantly between the two models. Yet the calculated assignments are the same in the two models, except for ν_4 and ν_5. This makes us conclude that the calculated assignments for ν_6 and ν_7 are likely correct.

The calculations have reproduced the frequencies reasonably well. The average errors are: model I, for C_4H_6 1.2%, for C_4D_6 2.8%; model II, for C_4H_6 1.4%, for C_4D_6 2.8%. For model I the worst agreement is for ν_8, which is calculated 37.4 cm^{-1} low for C_4H_6 and 63.8 cm^{-1} low for C_4D_6. As discussed in Section III no reasonable change in the force field would raise these values. The observed isotope shift of ν_{17} could not be reproduced by model I, the calculation being 30.8 cm^{-1} high for C_4H_6 and 44.8 cm^{-1} low for C_4D_6. ν_{15} and ν_{16} were calculated reasonably well for C_4H_6 but were 36.1 cm^{-1} high and 31.7 cm^{-1} low, respectively, for C_4D_6. This appears to indicate errors in the degree of mixing of the motions involved, but no improvement could be found. Model II had its greatest errors in the frequencies of the same modes, being worse than model I for ν_8, ν_{15}, and ν_{17}, and better for ν_{16}. Bearing in mind the somewhat different force fields of the two models, one is tempted to assign these considerable errors, found in the same modes in both models, to the influence of anharmonicity.

A few observations can be made from the magnitudes of the force constants. Both models show that the high C=C stretching frequency is due entirely to the kinetic effects of the $\sim 60°$ $C_3C_2C_4$ angle. Indeed, comparison with F(C=C) in ethylene (13) (9.57 mdyn/Å) shows that the distortion in the sp^2 hybridization needed to accommodate the ring structure has resulted in weakening the C=C stretching force constant by 0.3 to 0.6 mdyn/Å depending on the model employed. In model II (Section IV), which is more com-

*Using the observed frequencies of assignment II and the A_2 mode frequencies of model 1; units are cal mol^{-1} deg^{-1}.

parable to work on cyclopropane, the C—C stretching force constants are 4.25 and 4.03 mdyn/Å. In Duncan and Burn's (3) work the primary force constant was 4.29 mdyn/Å and in Cyvin's work (2) 4.22 mdyn/Å. As the latter used frequencies that were supposedly corrected for anharmonicity, we consider Duncan and Burn's value more useful from our point of view. It is seen that no significant change has occurred in the strength of the two C—C bonds adjacent to the C=C bond, but that, in keeping with its greater length, the third C—C bond is slightly weaker.

The frequencies of the A_2 modes were calculated, using both models, and the A_2 modes, if they could be located, would be extremely helpful for deciding between these two force fields. For C_4H_6 the A_2 modes were calculated at 3086.1, 1176.3, 908.1, and 790.5 cm^{-1} using model I, and at 3081.6, 1013.4, 860.6, and 751.1 cm^{-1} using model II. For C_4D_6 they were at 2318.8, 938.7, 646.3, and 561.1 using model I, and at 2307.7, 785.0, 631.3, and 534.7 using model II. For each model the assignment was C—H stretch, methylenic twist, methylenic rock, and ethylenic torsion, respectively, with some mixing of motions, particularly in C_4D_6. The main difference between the two models is the frequency of the A_2 methylenic twist, and its experimental location would indicate which, if either, of these two models is correct.

It is difficult to predict the relative order of the A_2 and B_2 twists and rocks using data from other molecules. Cyclopropane is the only molecule which is reasonably similar and for which reasonably definitive data exist, yet cyclopropane is not similar enough to methylene cyclopropane for one to be sure of one's analogy. The A_1'' twist in cyclopropane is expected to relate to the A_2 twist in methylene cyclopropane while the E'' twist relates to the B_2 twist. The A_2'' rock in cyclopropane relates to the B_2 rock in methylene cyclopropane while the E'' rock relates to the A_2 rock. But the relation is not as straightforward as is desirable. In cyclopropane the E'' twist is 62 cm^{-1} higher in frequency than the A_1'' twist, suggesting that the B_2 twist in methylene cyclopropane should be higher in frequency than the A_2 twist. This favors the result of model II. The A_2'' rock in cyclopropane is 115 cm^{-1} higher than the E'' rock, suggesting that the B_2 rock in methylene cyclopropane should be higher than the A_2 rock. Neither model predicts this result. The picture is, thus, confused, and no strong indication of the correct relative frequencies of the A_2 and B_2 twists can be obtained. We distrust the suggestion obtained by the analogy with cyclopropane, and believe that the best indication of the frequencies of the A_2 modes in methylene cyclopropane is the result calculated by model I. The force field used for the motions of the methylenic group in model I is quite general and has reasonably well reproduced all of the observed frequencies and can therefore be reasonably expected to yield the unobserved frequencies correctly. The corresponding force field for model II is far more specific, and is, we believe, less likely to correctly yield the unobserved frequencies. However, it is clear that a good deal of uncertainty exists as to the correct A_2 mode frequencies.

C_4H_6 and C_4D_6 were calculated twice. In each case the observed frequencies for assignment II were used, and in one case the A_2 mode frequencies from model I were used, and in the second case the A_2 mode frequencies from model II were used. In Table 8 the results obtained with the A_2 mode frequencies from model I are tabulated. Some uncertainty is associated with these values because of the uncertainty in the A_2 mode frequencies. An indication of this uncertainty can be obtained by comparing Table 8 with the results obtained when the A_2 mode frequencies obtained from model II are used. In the latter case we find for C_4H_6 and C_4D_6 (in parentheses) that: $(H_0 - E_0^0)/T$ is the same at 150 °K, is greater by 0.1 (0.13) at 300 °K, and by 0.17 (0.20) at 500 °K; $-(G_0 - E_0^0)/T$ is the same at 150 °K, is greater by 0.02 (0.06) at 300 °K, and by 0.09 (0.14) at 500 °K; S_0 is the same at 150 °K, is greater by 0.1 (0.18) at 300 °K, and by 0.26 (0.33) at 500 °K; C_p is the same at 150 °K (greater by 0.1), is greater by 0.2 (0.3) at 300 °K, and by 0.3 (0.2) at 500 °K.

Studies on Hydrogen–Oxygen Systems in the Electrical Discharge. V. Raman Spectra of the Trapped Products

XAVIER DEGLISE[1] AND PAUL A. GIGUÈRE

Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec, Québec

Received February 12, 1971

The condensed products (at −180 °C) of electrically dissociated water vapor and other related systems were examined by means of laser Raman spectroscopy. A new type of total reflection cell had to be developed for the study of metastable species trapped in an amorphous matrix. Besides the characteristic O—O stretching band of hydrogen peroxide at 878 cm^{-1}, always the strongest, another fairly strong band at 500 cm^{-1}, and a third one at about 760 cm^{-1} were present in all cases. A couple of weaker bands around 820–830 cm^{-1} and 430–440 cm^{-1} occurred only in oxygen-rich system (H_2O_2 vapor or H_2O–O_2 mixtures). In the latter, the presence of condensed ozone was confirmed by a band at 1025 cm^{-1}, and occasionally another faint one around 1120 cm^{-1}. The relative intensities of the bands varied locally in a given sample, indicating uneven composition.

Isotopic shifts with ^{18}O confirmed that these Raman bands arise from vibrations of oxygen atoms. Essentially the same results were obtained in hydrogen as in deuterium systems, except that in the latter case the new bands were appreciably stronger and sharper. The present results support the assignment of previous infrared spectra to hydrogen polyoxides, H_2O_3 and H_2O_4.

On a étudié par spectroscopie Raman à laser les produits piégés à −180 °C de la vapeur d'eau et autres systèmes connexes dissociés dans une décharge électrique. La préparation des échantillons a nécessité la construction d'un nouveau type de cellule spécialement adapté à l'examen de molécules instables piégées dans une matrice amorphe. Outre la bande caractéristique du peroxyde à 878 cm^{-1}, de beaucoup la plus forte, on a observé dans tous les cas une seconde bande assez forte à 500 cm^{-1} ainsi qu'une troisième, vers 760 cm^{-1}. Une couple de bandes plus faibles vers 820–830 cm^{-1} et 430–440 cm^{-1} apparaissaient seulement dans les systèmes riches en oxygène (vapeur de H_2O_2 ou mélanges de H_2O et O_2). Dans ces derniers, également, la présence d'ozone condensé se manifestait par une bande à 1025 cm^{-1}, et parfois une seconde, très faible, vers 1120 cm^{-1}. Les intensités relatives des bandes semblaient varier d'un point à l'autre dans le même échantillon dû, sans doute, à des gradients de composition.

Grâce au décalage isotopique avec ^{18}O on a vérifié que toutes ces bandes proviennent de vibrations des atomes d'oxygène dans le matériau piégé. Les systèmes deutériés ont donné essentiellement les mêmes résultats que les systèmes hydrogénés, sauf que dans ces derniers les nouvelles bandes étaient sensiblement moins fortes et moins nettes. Ces résultats renforcent notre interprétation récente des spectres infrarouges des polyoxydes H_2O_3 et H_2O_4.

Canadian Journal of Chemistry, 49, 2242 (1971)

Introduction

Following our recent identification (1) by infrared spectroscopy of the polyoxide molecules H_2O_3 and H_2O_4 (more exactly D_2O_3 and D_2O_4) trapped in a frozen ice–peroxide matrix, it was felt desirable to secure further direct evidence from another source. Now, diffraction techniques did not seem suitable because the preparation method of that material (by trapping electrically dissociated vapors) yields a vitreous, nonhomogeneous deposit with relatively low concentrations (less than 10% mol) of the new molecular species. For the same reason conventional Raman spectroscopy is not easily applicable. In fact we have made, without success, a number of preliminary attempts using combined Raman cells – liquid nitrogen traps of various designs in a mercury arc spectrometer (Cary, Model 81). However, the advent of laser excitation has made possible the Raman study of such optically imperfect material. A considerable advantage of Raman spectroscopy in the present case comes from the fact that the region where the characteristic bands of the polyoxide molecules occur is virtually free, in contrast with the infrared.

Experimental

The design and construction of the low temperature Raman cell presented a difficult problem. The multiple reflection technique described by Devlin (2) for investiga-

[1]Postdoctorate Research Fellow, 1968–1970. Present address: Faculté des Sciences, Université de Nancy, Nancy, France.

For personal use only.

tion of thin films deposited on a metal strip was later found unsuitable. Likewise, it was not possible to get any spectra by condensing the dissociated gas stream on a Pyrex flat sealed at the bottom of a liquid nitrogen trap. The only arrangement that gave satisfactory results incorporated the device described by Levin (3). Basically the cell (Fig. 1) resembled that used for the infrared (1), except that the inlet and outlet tubes entered through the top part. Condensation of the deposit took place, not on a salt window, but on a stainless steel mirror at the bottom of the coolant well. It was found by trial that fairly thick deposits (0.2 to 0.4 mm) were needed for a good spectrum. This meant rather long deposition times (3 to 8 h) with input rates of the order of 0.5 g/h. Because of the low trapping efficiency of the Raman cell at least 20% of the input was evacuated as permanent gases.

For recording the spectra the whole cell assembly was disconnected from the vacuum system and mounted in the sample compartment of the spectrometer. The laser beam entered the cell vertically through a glass flat at the bottom. After reflection at 90° on the cold mirror it was focussed *directly onto* the entrance slit of the monochromator. Only with such an arrangement was it possible to get any spectra. The optical lining-up, a rather delicate operation, required positioning the whole cell, both vertically and laterally, by means of micrometer screws. A suitable spot on the sample was located using the strong 878 cm^{-1} band of hydrogen peroxide as a monitor. Only the significant region, from 400 to 1500 cm^{-1}, was scanned.

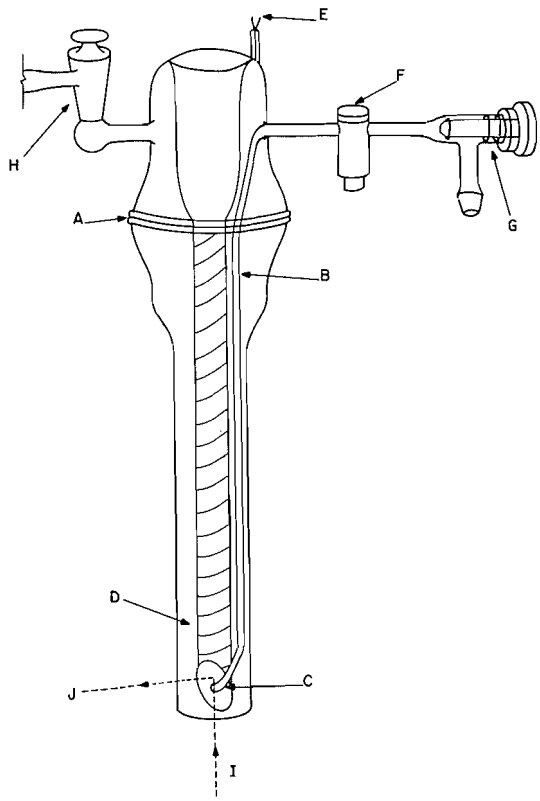

FIG. 1. Combined low temperature Raman cell and discharge tube. *A*, Large size (10 cm diam.) O-ring joint; *B*, injector tube, 8 mm o.d., 40 cm long; *C*, oval shaped stainless steel mirror silver soldered to Kovar seal, *D*; *E*, outlet for the copper–constantan thermocouple located at *D*; *F*, microwave discharge cavity; *G*, greaseless vacuum stopcock with Teflon plug and Viton O-rings; *H*, large stopcock leading to the vacuum line; *I*, *J*, incident and reflected laser beam.

The Raman spectrometer comprised a Spex, Model 14-II monochromator, and a Coherent Radiation, He–Ne laser. The other components have been described elsewhere (4). The samples of heavy water and concentrated hydrogen peroxide were the same as for the infrared work. The deuterium peroxide was prepared by the electrical discharge process (5). By repeated fractional distillations the peroxide concentration of the end product (about 60%) was brought up to near 99%. As for the mixed isotopic water sample (Bio-Rad Laboratories), the ^{18}O content was stated to be 66.4% and the deuterium content, 19.7%.

Results

Due to the poor optical quality of the condensed films and the low power (50 mW max.) of the laser source it was necessary to work with rather wide slits (0.1 to 0.3 mm), and a high amplifier gain. This reduced the signal-to-noise ratio and, consequently, the accuracy in evaluating the band contour as well as the location of the maximum; specially for the weaker bands (Fig. 2). For clarity the original tracings were smoothed out in drawing Fig. 3.

The New Bands

The most conspicuous among the new features of the present spectra (Table 1) is the band at exactly 500 cm^{-1} found in all cases, and with an intensity about one tenth that of the peroxide band at 878 cm^{-1}. Blank runs made by condensing water–peroxide vapor mixtures of roughly equimolar composition in the same cell, but without electrical dissociation, confirmed that the new band was genuine of the discharge products. Since the infrared spectra gave no indication of a corresponding band, albeit the conditions there are not at all favorable, a number of tests were carried out to insure that it was not spurious. For instance, it remained unaltered whether the microwave discharge was located before or after the vacuum stopcock and ring seal, in the case of the long discharge tube; also whether the latter was made of some different material, *e.g.* quartz, or coated with phosphoric acid as described before (6). Incidentally, the

presence of nitrogen oxides resulting from minute leaks in the vacuum system could be readily monitored from a few sharp peaks in the 1270–1290 cm^{-1} region. Another band, generally less intense than that at 500 cm^{-1}, was also found in all systems at about 760 cm^{-1}, the same frequency as the main infrared band of the polyoxides. Lastly, two other weaker bands could be seen, also at frequencies corresponding to those in infrared, namely 430 and 820 cm^{-1}. They were barely detectable, especially the latter, in the products from dissociated water alone. In some spectra there were indications of a third low-frequency component bridging the gap between the main bands at 500 and 430 cm^{-1}.

The Isotope Effects

Since identification of the polyoxides by infrared rested almost exclusively on the study of deuterated systems, it was desirable to confirm that the corresponding hydrogen species are also produced under the same conditions. As may be judged from spectra *A* and *B* in Fig. 3, there was no essential difference between the spectra of the two systems as far as the frequency of the new bands is concerned. In particular the lower frequency band in the region of 430 cm^{-1}, which is badly obscured in infrared by libration and lattice modes, in both the hydrogen and deuterium systems, is hereby confirmed definitely as an oxygen atom vibration. On the other hand it was observed consistently that the new bands were weaker and more diffuse in the hydrogen than in the deuterium compounds. Accordingly thicker deposits were required (*e.g.* 15 h for *B*, Fig. 3), or else wider slits, for recording the spectra. This implies that the hydrogen polyoxides are somewhat less stable, and therefore less readily produced than their deuterium counterparts. A similar, although very much larger (about 6 times), isotope effect was reported

recently (7) in the half-life of a metastable intermediate, presumably the trioxide, produced in the radiolysis of aqueous acid solutions.

As for the ^{18}O experiments, only two were carried out to confirm qualitatively that all the new bands, and specially that at 500 cm^{-1}, involve oxygen atom vibrations. Since ^{18}O content of the sample was only of the order of two thirds the resulting spectra were somewhat complex. Exceptionally the O—O band of the peroxide gave rise to three distinct peaks as in infrared. The 760 cm^{-1} band evolved into a broad group with maximum at 730 cm^{-1} and a couple of minor components; that at 500 cm^{-1} was mostly shifted to 470 cm^{-1}. Unfortunately, it was not possible to confirm the shift of the weak band around 430 cm^{-1}, expected to occur near 400 cm^{-1}. This was below the lower limit of our observations set by the excessive width of the exciting line in our unusual optical line-up.

The Band Intensities

For obvious reasons the experimental conditions did not allow accurate intensity measurements, even on a relative basis. From the results of some 20 different runs the following generalizations emerge: (*a*) The strongest of the new bands, at 500 cm^{-1}, was in all cases, and within narrow limits, about one tenth as intense as the peroxide band. (*b*) The other bands showed much wider intensity variations depending, among others, on the chemical composition of the system. (*c*) The new bands tended to grow weaker away from the impact point of the dissociated gas stream. This fractionation follows from the very fast recombination reactions. Also, since the latter are exothermic, thermal conductivity of the cold surface is an important factor. (*d*) Slow diffusion of the trapped species at $-180°$ was noticeable. For instance, the yellow color visible in freshly condensed samples, and generally ascribed to trapped free radicals, faded away and was completely bleached after 10–12 h.

The Bands of Condensed Ozone

In the glassy deposits from oxygen-rich systems the dark blue color characteristic of liquid ozone was usually noticeable. Accordingly the Raman spectra revealed a medium intensity band at 1020–1030 cm^{-1} and, in two instances, a weaker one near 1120 cm^{-1}. As in the case of infrared (1) the trapping was certainly a matrix effect. Indeed, at the temperature of our cold surface ($-180°$) the vapor pressure of ozone (1 Torr) is greater, by about an order of magnitude, than the operating pressure in our plasma. In view of the close agreement with the frequencies of the infrared bands (8), which could hardly be a coincidence, the present bands are therefore ascribed to condensed ozone. However, this interpretation meets with a serious difficulty because the intensities are in the same order as in infrared, instead of the normal reversed order. It is also at variance with the Raman spectrum of gaseous ozone (9) which shows only two highly polarized bands; $\nu_1 = 1103.3$ cm^{-1}, $\nu_2 = 702.1$ cm^{-1}. *A priori* it is not clear why the antisymmetric stretching mode should be stronger than the symmetric one in the Raman effect of condensed ozone. On the other hand there is no other obvious explanation for the band at 1030 cm^{-1}. It must belong to an oxygen vibration as it appears both in hydrogen and deuterium systems. Other species, such as $(O_2)_2$, seem much less probable than O_3. We intend to investigate this question further, in particular by means of isotopically pure ^{18}O compounds.

Conclusion

The present study adds substantial evidence to the infrared detection of metastable intermediates in the hydrogen–oxygen reactions. In addition to confirming three of the four oxygen vibrations of the polyoxide species already discovered, it has revealed a fifth mode apparently inactive in infrared. Except for the latter, the intensity pattern of the new bands resembles that in infrared. This must arise from overlapping of different bands from two distinct species; namely H_2O_3 and H_2O_4, as in the case of the analogous hydrogen polysulfides (10). Likewise, all the O—O stretching frequencies of the polyoxides are seen to lie *lower* than that of the peroxide. This is contrary to recent calculations (11) which yielded values ranging from 900 up to 1250 cm^{-1} for various models of the H_2O_4 molecule. Lastly, a frequency of 500 cm^{-1} seems a little high for the bending of single-bonded oxygen atoms. Hydrogen bonds in the matrix may be partly responsible for this. Also in agreement are the results of a recent *a priori* calculation of the electronic structure of the H_2O_3 molecule (12) which indicate a slightly shorter O—O distance (1.438 Å) than in H_2O_2 (1.48 Å). Clearly, there is a great need for more experimental data on the structure of these molecules.

The authors would like to thank the National Research Council of Canada for financial assistance. They are also grateful to Messers. F. Bouchard and G. Robert, glassblowers, and G. Marier, mechanic, for their skillful assistance in constructing the laser Raman cell. The junior author (X.D.) benefited from a teaching assistantship in the Department of Chemistry while carrying out this research work.

Free-ion Yield in the Radiolysis of Dimethylsulfoxide

T. K. Cooper and D. C. Walker

Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received January 27, 1971

Dimethylsulfoxide is a dipolar aprotic solvent of high basicity having a large dielectric constant ($\varepsilon = 48$) but very low solvating power for negative ions. The radiation yield of "free ions" in this liquid is in accord with the dielectric constant, G(free ions) $= 1.8 \pm 0.2$, but these "free ions" do not resemble the strongly solvated electrons found in other polar media such as water and aliphatic alcohols. Evidence for this conclusion is based principally on competitive reactions involving a wide range of scavengers in competition with nitrous oxide. The radiation yields of gaseous products from pure liquid dimethylsulfoxide are $G(H_2) = 0.20 \pm 0.01$, $G(CH_4) = 3.3 \pm 0.1$, and $G(C_2H_6) = 0.49 \pm 0.03$.

Le diméthylsulfonyle est un solvant dipolaire aprotique de haute basicité, ayant une constante diélectrique élevée ($\varepsilon = 48$) mais un pouvoir de solvatation très faible pour les ions négatifs. Le rendement d"ions libres" obtenus par radiation dans ce liquide, G(ions libres) $= 1.8 \pm 0.2$, est en accord avec la constante diélectrique mais ces ions libres ne ressemblent pas du tout aux électrons hautement solvatés trouvés dans des milieux polaires comme l'eau ou les alcools aliphatiques. Les preuves supportant cette conclusion sont basées principalement sur les réactions compétitives impliquant un grand nombre de scavangers en compétition avec l'oxyde nitreux. Les rendements de produits gazeux obtenus par radiation de DMSO pur à l'état liquide sont $G(H_2) = 0.20 \pm 0.01$, $G(CH_4) = 3.3 \pm 0.1$ et $G(C_2H_6) = 0.49 \pm 0.03$.

Canadian Journal of Chemistry, 49, 2248 (1971)

Introduction

The yield of solvated electrons in the radiolysis of a pure liquid has implications for chemistry in general because it gives some indication of the ability of the solvent to stabilize these species and thus permit their involvement in certain reactions, such as Birch reductions. There is little doubt that the yield of solvated electrons in general increases systematically with increasing static dielectric constant (1–4), but one might expect the solvating power of the solvent also to be a crucial factor.

Dimethylsulfoxide $(CH_3)_2SO$, referred to as DMSO for brevity, is an aprotic polar solvent that is widely used in organic and inorganic chemistry because of its inability to solvate negative ions; consequently bases appear exceptionally strong in this medium. We have endeavored to establish the radiation yield of "free ions" in DMSO and to determine whether or not solvated electrons are formed. It is evident from a recent study on liquid formamide (3) that some systems may show "free ion" yields which are consistent with a high dielectric constant, but that the chemical species formed, although strongly reducing, are neither solvated electrons nor hydrogen atoms and are too long-lived to be quasi-free electrons.

Some recent studies on aspects of the radiolysis of DMSO have been reported including pulse radiolysis absorption spectroscopy using various solutes to scavenge electrons and cations produced (4, 5). The only other report (6) on the radiolysis of DMSO concerns a study of DMSO containing 0.4 M H_2SO_4 where the chemistry seems to be rather different, since neither solvated electrons nor solvent anions can be involved in secondary reactions.

Experimental

The dimethylsulfoxide (Matheson, Coleman and Bell, spectroscopic grade) was stirred in a closed vessel over calcium hydride for at least 2 days and then distilled under reduced pressure (~1 Torr at 48–50 °C). Only the middle 50% was collected and stored over a layer of Linde 4 A molecular sieve and sealed in an atmosphere of pure nitrogen. Prior to use it was redistilled and the samples immediately prepared. Nitrous oxide was purified by trap-to-trap distillation and other chemicals used were reagent grade or better and not purified further.

Irradiations were performed in a 4000 curie ^{60}Co Gammacell at a dose rate of approximately 5.0×10^3 rads min^{-1} with total doses up to 1.7×10^6 rads. The experiments were performed using a sample cell similar to the one described previously (3) but containing an additional side-arm with a standard tapered joint. Dosimetry was established using the Fricke solution, taking for Fe^{3+} ions $\varepsilon(304) = 2174$ M^{-1} cm^{-1} and $G(Fe^{3+}) = 15.5$. The dose rate in DMSO was then obtained by multiplying by 0.971, the ratio of the electron densities of the DMSO and Fricke solution.

DMSO samples were prepared by adding the liquid

through the B10 cone and then deoxygenated by bubbling high purity argon through the sintered disk for 30 min prior to the irradiation which was conducted at 23 ± 2 °C. After irradiation, the cell was attached to the gas chromatograph (Varian Aerograph Series 1700) and the volatile gaseous products flushed directly into the chromatograph. A Poropak-Q pre-column at 23 °C was used to prevent DMSO vapor from saturating the 20 ft × 1/4 in. stainless steel 13X molecular sieve chromatograph column. Argon was used as the carrier gas, detection was made using WX thermal conductivity detectors and the detector and column temperatures used were 125 and 55 °C, respectively. Ethane was measured by temperature programming, after the other gas products were detected, by heating the column to 130 °C at a rate of 20 °C per min. With a flow rate of 30 ml a minute, it was found that over 95% of the volatile gases (CH_4, N_2, H_2, and C_2H_6) were extracted in the first 3 min so that tailing of the peaks was very small. However, the bubbling was continued throughout the analysis (except for ethane) to avoid a pressure change during analysis. Under such conditions the response factors ($cm^2/\mu mol$ gas) for hydrogen, nitrogen, methane, and ethane were 59.5, 4.85, 15.2, and 12.7, respectively. Non-volatile products were not analyzed for. For the DMSO – nitrous oxide solutions, the DMSO was deoxygenated by flushing the sample with argon, degassed on a vacuum line, and equilibrated with nitrous oxide. The solubility of nitrous oxide in DMSO was found to be $1.10 \pm 0.05 \times 10^{-4}$ M $Torr^{-1}$ at 23 °C.

Results

The gaseous products obtained under γ-radiolysis of pure DMSO were hydrogen, methane, and ethane. Hydrogen and ethane were formed with yields of $G(H_2) = 0.20 \pm 0.01$ and $G(C_2H_6) = 0.49 \pm 0.03$, which were independent of dose up to at least 1.3×10^6 rads. However, methane formation was not linear with dose, in contrast to some previously reported results (6), and the data suggest that some non-volatile radiation product was being built up which scavenges the precursor of part of the methane. This can be seen in Fig. 1 in which the volatile gases were removed after each irradiation and the total accumulated yield plotted as a function of dose. Three different series were carried out; one in which all the doses were the same, another in which each dose was different, and a third in which a small dose was followed by a large dose and then followed by the same small dose. As can be seen, all the points fall on a smooth curve but the methane yield is only linear up to about 1.8×10^5 rads. Consequently, all scavenging studies with various added solutes were carried out with doses less than 1.8×10^5 rads so that the real effect of these on the methane yield could be seen. By taking the slope at various portions of the curve, it was found that $G(CH_4)$ falls from 3.3 ± 0.1 to 2.1 ± 0.1 over the dose range studied.

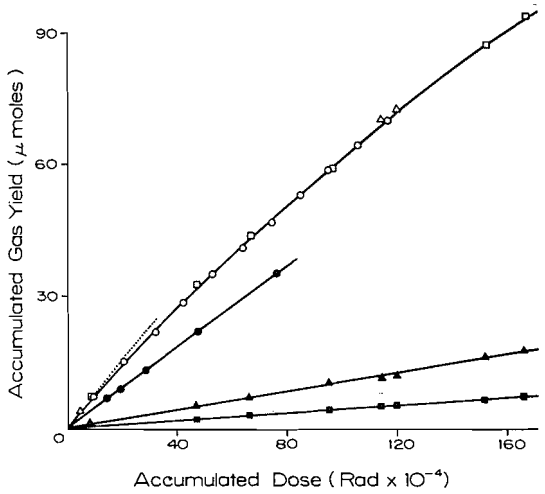

FIG. 1. Accumulated gas yields as a function of accumulated dose: ○, □, △, CH_4 at various doses; ▲, C_2H_6; ■, H_2; and ●, N_2 yield when 0.054 M N_2O added.

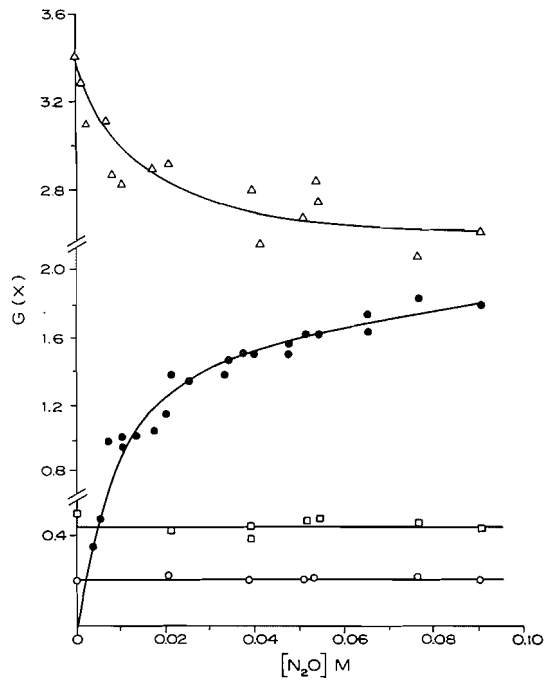

FIG. 2. Radiation yields as a function of N_2O concentration: △, CH_4; □, C_2H_6; ○, H_2 and ●, N_2. In the case of CH_4, all doses were $< 1.8 \times 10^5$ rads.

The addition to DMSO of various concentrations of nitrous oxide affects these gas yields in the manner shown in Fig. 2. Methane was found

†0.5 M methanol added.

to decrease by about 20% (from 3.3 to 2.6) while hydrogen and ethane were unaffected. At $[N_2O] = 0.054$ M, the nitrogen yield was independent of dose up to at least 7.5×10^5 rads (Fig. 1) suggesting that whatever the non-volatile product is which inhibits the methane, it does not affect the nitrogen yield. From the slope of Fig. 1, $G(N_2) = 1.6 \pm 0.1$ at this concentration. Figure 2 shows the steady increase in $G(N_2)$ as the nitrous oxide concentration is increased up to 0.09 M. No simple plateau is evident and $G(N_2)$ increases from 1.4 to 1.8 over the range 0.03 to 0.09 M.

In order to test the nature of the chemical species with which the nitrous oxide was reacting, various second scavengers were added to compete with it. Several of the scavengers, such as carbon tetrachloride, hydrogen ions, silver nitrate, chloroform, acetone, and iodine are known to react rapidly with solvated electrons in various polar liquids whereas methanol and isopropanol react rapidly only with hydrogen atoms. Data on the effect of these scavengers in competition with 0.05 M N_2O are given in Table 1.

The effect of iodine and hydrogen ions on the gaseous products is shown in Figs. 3 and 4. The addition of water was also tested because DMSO is quite hygroscopic and there could have been a trace of water in the sample despite the precau-

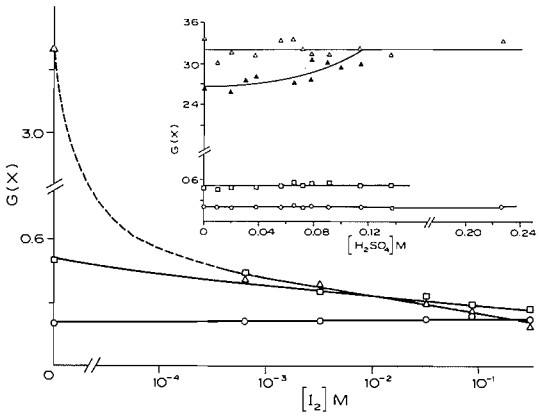

FIG. 3. Radiation yields of CH_4, C_2H_6, and H_2 as a function of I_2 and H^+ concentration: △, CH_4; □, C_2H_6 and ○, H_2; ▲ corresponds to the yield of CH_4 when 0.05 *M* N_2O is added to the corresponding acid solution of DMSO. In the case of CH_4 yields, all doses were $< 1.8 \times 10^5$ rads. For the I_2 solutions, the doses were $< 5 \times 10^4$ rads.

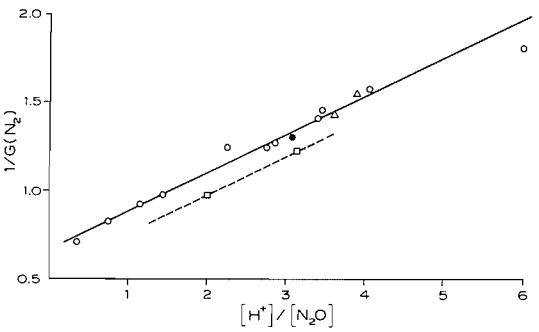

FIG. 4. Plot of $1/G(N_2)$ as a function of $[H^+]/[N_2O]$ in which ○, □, and △ correspond to different N_2O concentrations; ○, 0.05 *M* N_2O; △, 0.04 *M* N_2O and □, 0.07 *M* N_2O. ● corresponds to 0.5 *M* methanol added to acid solution containing 0.05 *M* N_2O.

tions taken to eliminate it. As can be seen from Table 1 the added water had no appreciable effect on any of the gas yields, so that either all samples contained enough adventitious water for its effect to be fully felt or water cannot compete with the precursors of the gaseous products, including nitrogen.

Discussion

Since the original work with nitrous oxide in aqueous solutions by Dainton and Peterson (7), nitrous oxide has been widely used as a specific scavenger for solvated electrons in many liquids. However, this solute may give nitrogen by reactions with other types of strongly reducing species formed in the radiolysis and strong inferences have to be drawn from competition studies with other scavengers. In DMSO solvated electrons, hydrogen atoms, free radicals (R), and solvent anions could yield nitrogen in reactions 1, 2, 3, and 4 if their alternate fates were comparatively slow.

[1] $$e_s^- + N_2O \rightarrow N_2 + O_s^-$$

[2] $$H\cdot + N_2O \rightarrow N_2 + \cdot OH$$

[3] $$R\cdot + N_2O \rightarrow N_2 + RO\cdot$$

[4] $$DMSO^- + N_2O \rightarrow N_2 + DMSO_2^-$$

In this scheme $DMSO^-$ is to be regarded as a solvent anion formed by electron attachment or solvent decomposition from free or solvated electrons.

It is evident from Table 1 that addition of methanol or isopropanol to a nitrous oxide solution did not alter the nitrogen yield. Since these alcohols are generally much better scavengers of hydrogen atoms than is nitrous oxide these results imply that reaction 2 is not contributing significantly to the nitrogen yield. Furthermore $G(H_2)$ changes only from 0.21 to 0.25 by the addition of alcohols to DMSO in both the presence and absence of nitrous oxide suggesting that hydrogen atoms are produced in only low yield. Involvement of reaction 3 can likewise be disregarded by analogy with similar competition studies and because iodine, which in other systems is a much better radical scavenger than nitrous oxide, competed almost on an equal basis with nitrous oxide for the precursor of nitrogen in DMSO. This inference is supported by the data in Fig. 3 where it is evident that iodine, even at 0.006 *M*, virtually eliminates the methane. This suggests that methane arises from methyl radicals which abstract a hydrogen atom from DMSO. Nevertheless, N_2O decreases the CH_4 yield somewhat and evidently can interfere with a minor reaction leading to the formation of methane. Iodine also cuts down the ethane yield somewhat indicating that it too is partly formed by radical reactions. On the other hand iodine does not affect the hydrogen yield implying that all the hydrogen is formed in "molecular processes" or by a fast reaction of thermal hydrogen atoms with DMSO. About half of the ethane

and 10% of the methane may also originate from direct or non-thermal radical reactions.

With regard to the formation of N_2 from N_2O solutions, there are several reasons for believing that any solvated electrons formed in DMSO do not resemble in reactivity the strongly-solvated electrons found in other highly polar solvents such as water. Firstly, although H^+, Ag^+, $CHCl_3$, CCl_4, and I_2 compete effectively with N_2O, acetone does not. Secondly, when these competitions are analyzed the relative rate constants obtained differ markedly from the relative rates of these scavengers with hydrated electrons. The following relationship was applied to the competitions between nitrous oxide and the second scavenger (S) for the precursor (P) of nitrogen

$$\frac{1}{G(N_2)} = \frac{1}{G(P)}[1 + k_s[S]/k_{N_2O}[N_2O]]$$

where k_s is the rate constant of P with S and k_{N_2O} is the rate constant for the reaction of P with N_2O. The data is plotted in Figs. 4 and 5 and appear to follow the simple competition relationship. The slopes of these plots give values for k_s/k_{N_2O} which are recorded in Table 2 and compared with the published values of this ratio for reaction with e_{aq}^-. It should be noted that the intercept of these plots gives the value of $G(P) = 1.6 \pm 0.2$ but because $G(N_2)$ does not show a plateau value at high nitrous oxide concentrations (see Fig. 2), the yield of $G(P)$ depends on the nitrous oxide concentrations used above 0.03 M. This is evident in Fig. 4, the H^+ competition, in which two lines having the same slope but different intercepts were obtained from two different but high values of nitrous oxide. Therefore, in the competitions in Fig. 5, the nitrous oxide concentration was held constant at 0.05 M and the concentration of the second scavenger varied.

The third argument against involvement of a solvated electron stems from the competition between H^+ and N_2O with 0.5 M methanol also added to the solution (Table 1). If the reaction 1 was in competition with [5] then the hydrogen

[5] $$e_s^- + H_s^+ \rightarrow H\cdot$$

yield would be increased by the presence of methanol in an acidic solution of DMSO. No such increase was found. In fact hydrogen ions do not affect the gaseous yields of pure DMSO at all (Fig. 3), in agreement with the results of Pujo and Berthou (6), and counteract the slight effect nitrous oxide has on the methane yield. However, it is possible that hydrogen atoms

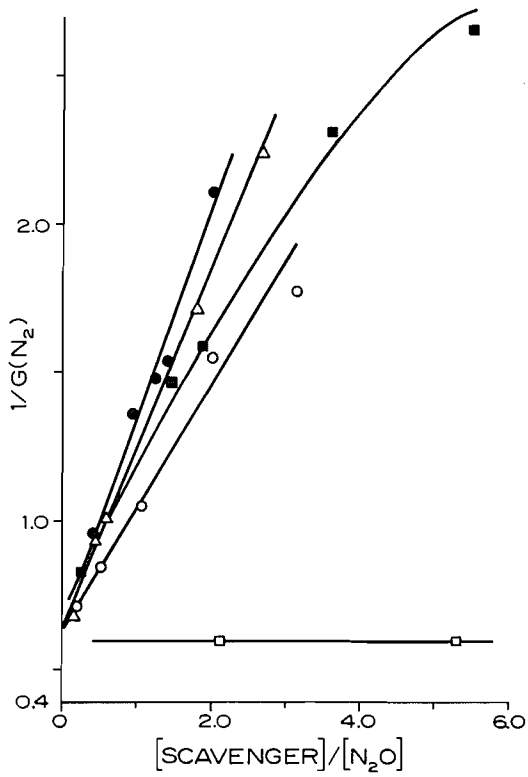

FIG. 5. Plot of $1/G(N_2)$ as a function of [scavenger]/[N_2O]. The N_2O concentration was 0.05 M and the second scavenger concentration was varied. The data were taken from Table 1. ● CCl_4, △ I_2, ■ $CHCl_3$, ○ Ag^+, and □ acetone.

react rapidly with DMSO to give non-gaseous products.

Additional evidence against thermodynamically stable solvated electrons in DMSO comes from the fact that irradiated polycrystalline DMSO at 77 °K (only partially transparent) does not show any coloration nor does it yield an electron spin resonance (e.s.r.) signal corresponding to a trapped electron (8), despite the fact that it has a high dipole moment (3.9 D). Furthermore metallic sodium does not dissolve to generate hydrogen gas but rather decomposes DMSO, producing a mixture of sodium mesityl, methane sulfenate, dimethyl sulfide, and methane (9).

In a recent pulse radiolysis study of pure liquid DMSO (10), there are strong indications of very short-lived (τ = 10–20 ns) solvated electrons having an optical absorption band maximum at $\lambda > 1500$ nm and produced in low yield ($G < 1$). These species are incompletely scavenged by 0.08 M N_2O. Such data suggest that the solvation energy is very small (comparable to hydrocarbons) and that these weakly-solvated electrons react with the solvent or very rapidly with trace impurities. These observations corroborate the notion that the solvating power of the solvent is more important than the dielectric constant in stabilizing electrons in liquids (10).

The curvature of $G(N_2)$ at $[N_2O] > 0.03$ is difficult to interpret without knowledge of the absolute rates of the reactions involved and the alternative fates of the N_2 precursor(s). Perhaps some solvated electrons may be scavenged by N_2O at high concentrations but that the major part of $G(N_2) = 1.8$ (the total free-ion yield) corresponds to another reducing species such as a solvent anion or decomposition product formed therefrom.

Pulse radiolysis studies on DMSO have yielded similar values for the free ion yield. Kemp *et al.* (5) obtained $G = 1.7$ for the yield of radical cations of TMPD in DMSO which they attribute to the "free ion" yield. Hayon (4) has also recently reported $G = 1.62$ as the yield of anthracene anions produced from solvated electrons in DMSO. However, as with H^+, I_2, $CHCl_3$, CCl_4, and Ag^+ in this study, perhaps anthracene can undergo charge transfer with a solvent anion just as easily as it scavenges a solvated electron. The available d orbital on the sulfur atom of DMSO perhaps favors electron attachment there but the product may well be quite reactive towards these other "electron" scavengers. Meissner *et al.* (11) have studied the absorption spectra of species produced during the pulse radiolysis of a dilute solution of DMSO in water and have assigned an absorption band centered at 350 nm to a DMSO radical anion.

The authors wish to acknowledge the generous financial support of the National Research Council of Canada. T.K.C. wishes to thank the F. J. Nicholson Family and the National Research Council for graduate scholarships during part of this work.

ET

JEAN-CLAUDE POITE ET JEAN ROGGERO

Laboratoire de Chimie Organique, C.S.U., 33 rue Louis Pasteur, 84 Avignon, France

Reçu le 14 décembre, 1970

Les deutério-4, deutério-5, et dideutério-4,5 isothiazoles ont été synthétisés et leurs spectres i.r. enregistrés sous différents états, vapeur notamment.

L'étude du spectre Raman de l'isothiazole a permis de rectifier l'attribution de deux modes fondamentaux de cet hétérocycle. Une interprétation des spectres i.r. des trois deutério isothiazoles est discutée.

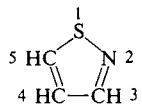
The 4- and 5-monodeuterio and 4,5-dideuterio isothiazoles were prepared and their i.r. spectra recorded in different states, vapor particularly.

The Raman spectrum of isothiazole was also measured; its analysis leads to the modification of the assignment of two of the fundamental modes previously described for this compound. The analysis of the i.r. spectra of the three deuterio isothiazoles is discussed.

Canadian Journal of Chemistry, **49**, 2254 (1971)

Introduction

Dans le cadre de recherches d'ensemble sur la structure et la réactivité de composés hétérocycliques, nous avons été amenés à examiner les spectres i.r. et Raman de l'isothiazole ainsi que



les spectres i.r., sous différents états (vapeur en particulier), des dérivés mono et dideutériés de l'isothiazole en positions -4, -5, et -4,5.

Une étude du spectre i.r. de l'isothiazole a déjà été publiée par Califano *et al.* (1), mais l'analyse du spectre Raman de cette molécule apportant de nouvelles données, il nous a paru intéressant de rediscuter les attributions. Celles-ci ont été étendues aux dérivés deutériés et leur validité confirmée à l'aide des structures de vibration rotation i.r. à l'état vapeur et des règles isotopiques.

Nous donnerons d'abord nos conditions expérimentales. Après un court chapitre consacré au dénombrement des vibrations dans l'isothiazole et ses dérivés deutériés, nous indiquerons nos résultats expérimentaux qui seront suivis de l'analyse des spectres.

Conditions expérimentales

La synthèse de l'isothiazole C_3H_3NS étudié dans ce travail a été exécutée par la méthode de Wille *et al.* (2), modifiée par Raap (3); celle du deutério-4 isothiazole a nécessité l'emploi de D_2O, CH_3CO_2D, et $S_2O_3Na_2$ anhydre.

Les deutério-5 et dideutério-4,5 isothiazoles ont été obtenus à partir, respectivement, d'isothiazole et de deutério-4 isothiazole, par réaction d'échange dans un mélange D_2O, CH_3OD, en présence de NaOD à température ambiante, la position 3 étant, dans ces conditions, très peu affectée (4, 5).

L'isothiazole a été purifié par formation du complexe mercurique C_3H_3NS, $HgCl_2$, dont la décomposition a été effectuée à 80 °C, sous un vide de 10^{-4} mm Hg.

Les impuretés isotopiques décelées par spectroscopie i.r. dans les échantillons d'isothiazoles deutériés sont indiquées dans les tableaux 3 à 5. Leurs pourcentages, quand ils ont pu être évalués par r.m.n. ou spectroscopie i.r. sont les suivants: dans le deutério-4 isothiazole, D-4,5 isothiazole ~0.8–1.5% (i.r.), isothiazole, moins de 3% (r.m.n.); dans le deutério-5 isothiazole, isothiazole ~0.6% (r.m.n.); dans le dideutério-4,5 isothiazole, D-4 isothiazole ~4.5% (r.m.n.),

TABLEAU 1. Moments principaux d'inertie et paramètres moléculaires*

	I_x (uma Å^2)	I_y (uma Å^2)	I_z (uma Å^2)
(7) Isothiazole	61.087	86.471	147.634
Isothiazole	59.8	87.6	147.4
D-4 Isothiazole	61	92.9	153.9
D-5 Isothiazole	65.2	87.7	152.9
D-4,5 Isothiazole	66.2	92.9	159.1

Longueurs (Å): $C_3H = C_4H = 1.079$ (9); $C_5H = 1.083$ (10)
[SN = 1.631; $NC_3 = 1.327$; $C_3C_4 = 1.420$] (8, 9); [$C_4C_5 = 1.355$; $C_5S = 1.719$] (10)
Angles (d°): [$C_3C_4C_5 = 111.7$; $C_3C_4H = 123.5$] (11)
[$SNC_3 = 106.5$; $NC_3C_4 = 113.7$; $C_4C_3H = 126.2$] (9);
[$C_4C_5S = 119.6$; $SC_5H = 128$] (10)

*Les différents paramètres sont accompagnés, entre parenthèses, de la référence bibliographique du travail dont ils sont tirés.

~1.1–2.3% (i.r.), D-5 isothiazole ~1.4% (r.m.n.), ~1–2.2% (i.r.). Les deux taux d'impuretés calculés à partir des spectres i.r. correspondent, respectivement, à des mesures de densité optique effectuées avec et sans correction d'ailes.

L'étude des spectres de masse des deutério isothiazoles n'a pu être faite à des énergies suffisamment proches du potentiel d'ionisation pour que les puretés isotopiques des différents échantillons puissent être déterminées par cette méthode. Il semblerait, cependant, que la proportion d'isothiazole non deutérié soit deux fois plus élevée dans le deutério-5 que dans le deutério-4 isothiazole, d'après leurs spectres de masse. L'existence d'un pic $M = 76$ susceptible d'être dû à CS_2 dans le spectre de masse des quatre isothiazoles (5), permet de penser que les bandes d'absorption faibles et sensibles à la température observées, vers 1515 cm^{-1}, dans les spectres i.r. de ces hétérocycles, proviennent de traces de sulfure de carbone.

Les conditions d'enregistrement des spectres i.r. et Raman sont identiques à celles indiquées dans un précédent mémoire (6).

Dénombrement des vibrations

Les moments principaux d'inertie de l'isothiazole, déduits des constantes rotationnelles (7), vérifient très sensiblement la planéité de cet hétérocycle (*cf.* tableau 1). Ils sont en assez bon accord avec les valeurs calculées en adoptant certains des paramètres moléculaires du -1,2,5 thiadiazole (8, 9), du thiazole (10), et du thiophène (11) (*cf.* tableau 1).

L'isothiazole et ses dérivés deutériés admettant la symétrie C_s, leurs 18 vibrations normales se décomposent en 13 modes de classe A′ et cinq modes de classe A″ (12).

Dans l'approximation des vibrations de groupe, on attend neuf oscillations (6A′ + 3A″) des liaisons CX (X = H ou D) et neuf mouvements (7A′ + 2A″) du squelette.

Il est possible de distinguer les vibrations de classe A″ et A′ qui doivent, le grand axe d'inertie de ces molécules étant normal au plan du noyau, donner lieu, respectivement, à des bandes de vibration rotation de type C d'une part, et A, B, ou hybride A + B d'autre part, dans les spectres i.r. des composés à l'état vapeur (13, 14).

Dans le spectre Raman on s'attend, en outre, à ce que les oscillations de symétrie A″ se manifestent par des raies Raman faibles et dépolarisées (15), celles de symétrie A′, par des raies plus intenses et polarisées (12).

Dans une même classe de symétrie, l'exactitude des attributions peut être vérifiée, pour chacune des molécules isotopiques, à l'aide de la règle du produit des fréquences de Teller–Redlich (16, 17) et, pour l'ensemble des quatre molécules, en appliquant la règle de la somme des carrés des fréquences expérimentales (16).

Résultats expérimentaux

Les spectres i.r. des deutério-4, deutério-5, et dideutério-4,5 isothiazoles à l'état liquide sont reproduits dans la fig. 1. Les fréquences i.r. observées dans les spectres de ces composés et dans celui de l'isothiazole en solution dans des solvants inertes et à l'état vapeur, sont, ainsi que les coefficients d'extinction molaire apparents et les structures des bandes de vibration rotation, indiqués dans les tableaux 2 à 5. Le tableau 2 comporte également les fréquences, intensités relatives et les facteurs de dépolarisation, des raies de diffusion du spectre Raman de l'isothiazole.

Analyse des spectres

Nous examinerons, en premier lieu, les vibrations de symétrie A′, puis celles de symétrie A″. Nous dirons ensuite quelques mots sur les vibrations de combinaison.

Les attributions relatives aux vibrations fondamentales des quatre hétérocycles sont réunies dans le tableau 6, et sont aussi mentionnées, ainsi qu'une interprétation possible des principales bandes de combinaison, dans les tableaux 2 à 5.

*it, Isothiazole; π, produit de Teller–Redlich.
†Produit et somme calculés avec la fréquence 858 cm^{-1}.
‡Avec la fréquence 826 cm^{-1}.

affectées aux vibrations de valence ν(CH) (1); les raies Raman correspondantes sont faibles (*cf.* tableau 2).

Des bandes i.r. qui, en raison de leurs positions proches de celles des fréquences précédentes, peuvent également être rattachées à des mouvements ν(CH) sont observées, vers 3060 cm^{-1}, dans les spectres des trois dérivés deutériés et vers 3095 ± 10 cm^{-1}, dans ceux des composés monodeutériés (*cf.* tableaux 3 à 5 et fig. 1).

Les résultats expérimentaux sembleraient indiquer que les vibrateurs CH ne sont que faiblement couplés dans les oscillations de valence ν(CH). En effet, le maximum vers 3060 cm^{-1} qui subsiste lors d'une double substitution sur les carbones 4 et 5, paraît appartenir à la vibration mettant plus particulièrement en jeu la liaison CH en 3. Par ailleurs, les mouvements de valence des vibrateurs CH en 4 et en 5 paraissent, respectivement, donner lieu aux sommets vers 3090 et 3110 cm^{-1}, que l'on retrouve dans les spectres des dérivés monodeutériés en position 5 ou 4 (*cf.* tableau 6 et fig. 1).

Ceci n'est, cependant, qu'une première approximation qui devra être vérifiée lorsque, la géométrie de l'isothiazole étant parfaitement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

connue, il sera possible de comparer les structures prévues et observées des bandes de vibration rotation dues aux oscillations ν(CH). On doit, du reste, remarquer que l'ordre expérimental des fréquences: $\nu(C_5H) > \nu(C_4H) > \nu(C_3H)$, ne coïncide pas avec celui: $\nu(C_3H) > \nu(C_5H) > \nu(C_4H)$, que laisseraient prévoir les valeurs calculées des charges π des atomes de carbone (18).

Oscillations ν(CD)

Dans les spectres i.r. des deutério-4 et dideutério-4,5 isothiazoles à l'état liquide, on peut affecter une bande d'absorption vers 2300 cm^{-1} à la vibration $\nu(C_4D)$, tandis qu'un maximum vers 2320 cm^{-1}, existant à la fois dans les spectres des deutério-5 et dideutério-4,5 isothiazoles, paraît attribuable au mouvement $\nu(C_5D)$ (*cf.* tableau 6).

(2) Vibrations de déformation δ(CX)

Vibrations δ(CH)

Califano *et al.* (1) assignent les vibrations de déformation δ(CH) à 1236, 1066, et 1040 cm^{-1}, dans l'isothiazole. L'intensité et les facteurs de dépolarisation des raies Raman correspondantes, confirment qu'il s'agit bien de modes fondamentaux de symétrie A′ (*cf.* tableau 2). L'interprétation des deux maximums vers 1050 cm^{-1} se trouve justifiée par l'examen des spectres i.r. des trois isothiazoles deutériés. Le spectre du dérivé dideutérié ne présente, en effet, aucune bande i.r. au voisinage de cette fréquence (*cf.* tableau 5 et fig. 1) tandis que celui de chacun des dérivés monodeutériés en comporte une seulement, de type AB à l'état vapeur, qui peut, par conséquent, être rattachée à un mouvement δ(CH) (*cf.* tableaux 3 et 4).

Soulignons, en faveur de l'attribution de la fréquence 1236 cm^{-1} à une vibration de déformation δ(CH), dans le spectre de l'isothiazole, que l'oscillation δ(CH) la plus élevée de nombreux dérivés hétérocycliques pentagonaux, est observée vers 1250 ± 20 cm^{-1} (19–31). Par analogie, nous relions aussi à un mouvement δ(CH), la suite vers 1200 cm^{-1}, composée de bandes i.r. présentant, dans les spectres des deutério isothiazoles à l'état vapeur, des enveloppes de type B (*cf.* tableaux 3 à 5).

Vibrations δ(CD)

Nous affectons à des vibrations de déformation δ(CD), une absorption vers 780 cm^{-1}, dans les spectres des deutério-4 et dideutério-4,5 isothiazoles et vers 750 cm^{-1}, dans ceux de ce dernier composé et du deutério-5 isothiazole (*cf.* tableau 6 et fig. 1). Les contours de type A ou AB de ces bandes, dans les spectres i.r. des dérivés à l'état vapeur, indiquent qu'elles sont bien dues à des vibrations de symétrie A′.

(3) Vibrations de noyau

Isothiazole

Les sept vibrations de noyau dans le plan ont, pour l'isothiazole, été situées par Califano *et al.* (1) à 1484, 1390, 1335, 1056, 869, 815, et 758 cm^{-1} (*cf.* tableau 2).

Or, le spectre Raman de l'isothiazole montre encore, outre des raies plus ou moins intenses, correspondant aux sept fréquences précédentes, deux autres raies de diffusion, fortes et polarisées, à 1296 et 639 cm^{-1}. Celles-ci appartenant incontestablement à des mouvements de noyau dans le plan, l'attribution de Califano *et al.* (1) est incorrecte pour deux des oscillations de noyau de symétrie A′.

Le choix des maximums à 1390, 815, et 758 cm^{-1} doit être maintenu, en raison de leur structure de vibration rotation, dans les spectres i.r. des composés à l'état vapeur et de leur forte activité en i.r. et en Raman. De plus, par comparaison avec le thiazole (19, 20) et le thiophène (21), on peut rattacher les enveloppes de type A, plus faibles, et les deux raies Raman peu intenses, à 1484 et 869 cm^{-1}, aux deux vibrations de noyau de classe A′ restantes.

Quant aux fréquences 1335 et 1056 cm^{-1}, elles doivent être reliées à des oscillations de combinaison (*cf.* tableau 2). La plus élevée n'apparaît, en effet, que très faiblement à la fois en Raman et en i.r. La plus basse se manifeste par une raie Raman faible et par une bande i.r. assez forte, mais dont l'intensité pourrait s'expliquer par un phénomène de résonance de Fermi avec le niveau δ(CH) adjacent à 1040 cm^{-1}.

Deutério isothiazoles

Des suites de bandes i.r. ayant des positions assez voisines de celles des vibrations ω_1 à ω_7 de l'isothiazole, dont on peut, pour cette raison, les rapprocher, peuvent être constituées pour les trois isothiazoles deutériés (*cf.* tableau 6).

Du fait de recouvrements, ou de leur faible intensité, les enveloppes des bandes à 849, 731, et 629 cm^{-1}, à 1268, 737, et 626 cm^{-1} et à 728 et 624 cm^{-1}, ne sont pas bien observées dans les spectres respectifs des deutério-4, deutério-5, et dideutério-4,5 isothiazoles. Par contre, la symétrie A′ de toutes les autres vibrations faisant l'objet des suites ω_1 à ω_7 est bien vérifiée par les structures de type A, B, ou AB des bandes de vibration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rotation i.r. correspondantes, dans les spectres des composés à l'état vapeur (*cf.* tableaux 3 à 5).

Soulignons que les fréquences rattachées à des oscillations de mode A′ (*cf.* tableau 6), vérifient, de façon satisfaisante, à la fois la règle du produit de Teller–Redlich et celle de la somme des carrés des fréquences expérimentales (*cf.* tableau 7), ce qui justifie l'ensemble des attributions, dans cette classe de symétrie.

Vibrations de symétrie A″

Nous envisagerons d'abord les vibrations de noyau hors du plan, dans l'isothiazole et ses dérivés deutériés, successivement, puis les mouvements de déformation γ(CX).

(1) Vibrations de noyau

Les vibrations de noyau hors du plan sont observées, dans l'isothiazole, à 587 et 474 cm^{-1} (1), nous les avons notées, respectivement, Γ_1 et Γ_2: la plus basse, seule, donne lieu, dans le spectre Raman, à une faible raie dépolarisée (*cf.* tableau 2).

Une suite, formée de bandes de vibration rotation i.r. de type C peut être reliée, dans les spectres des trois dérivés deutériés à l'état vapeur, à une vibration analogue au mouvement Γ_2. Les spectres des trois composés à l'état vapeur montrant deux bandes de type C entre 610 et 540 cm^{-1}, l'oscillation Γ_1 ne peut pas être assignée avec certitude, particulièrement dans le deutério-5 isothiazole, où elle doit être responsable de l'une des deux fréquences 606 ou 576 cm^{-1}. Toutefois, dans les spectres du dideutério-4,5 isothiazole, pour les raisons qui seront discutées par la suite, l'un des mouvements γ(CD) pouvant, vraisemblablement, être situé à 578 cm^{-1}, nous préférons affecter à la vibration de noyau Γ_1 la bande de type C à 541 cm^{-1}.

Dans le cas du deutério-4 isothiazole, la difficulté vient de ce que les deux enveloppes de type C à 577 et 541 cm^{-1} ont des positions identiques à celles observées dans le spectre du dideutério-4,5 isothiazole. Or ce composé constitue, précisément, l'une des impuretés contenues dans l'échantillon de deutério-4 isothiazole examiné (*cf.* tableau 3). Mais, tandis que les intensités relatives des autres bandes i.r. dues au dideutério-4,5 isothiazole d'une part, et du maximum à 541 cm^{-1}, d'autre part, indiquent que dans le spectre du deutério-4 isothiazole, ce dernier sommet provient uniquement de l'impureté, il ne semble pas en être de même pour l'absorption à 576 cm^{-1} dont le coefficient d'extinction molaire est trop important. Comme, par ailleurs, les deux bandes à 576 cm^{-1} n'ont, dans les spectres i.r. du deutério-4 et du dideutério-4,5 isothiazole, ni même profil à l'état liquide (*cf.* fig. 1), ni même structure de vibration rotation à l'état vapeur, on peut envisager que l'absorption à 576 cm^{-1} recouvre, dans le spectre du deutério-4 isothiazole, la vibration γ(CD) du dideutério-4,5 isothiazole et l'oscillation de noyau Γ_1 du deutério-4 isothiazole.

(2) Vibrations de déformation hors du plan γ(CX)

Les vibrations γ(CH) ont été attribuées par Califano *et al.* (1) à 908, 858, et 728 cm^{-1}, dans l'isothiazole; elles ne se manifestent pas dans le spectre de diffusion.

Les spectres i.r. de tous les dérivés deutériés de l'isothiazole, montrent une forte branche Q vers 900 cm^{-1}, appartenant certainement à une bande de vibration–rotation de type C, et pouvant donc être rapprochée de la vibration γ(CH) la plus élevée de l'isothiazole (*cf.* tableau 6).

Dans le spectre i.r. du deutério-4 isothiazole en phase vapeur, on observe deux fortes branches Q à 806 et 726 cm^{-1}, caractéristiques de bandes de type C et une enveloppe de type C, de contour nettement défini, à 644 cm^{-1}. Tandis que ce dernier sommet peut être relié à une oscillation hors du plan γ(CD), la branche Q à 726 cm^{-1}, dont la position est semblable à celle de l'un des mouvements γ(CH) de l'isothiazole, est certainement due à la présence de ce composé à l'état d'impureté. C'est donc l'absorption à 806 cm^{-1} qui doit être affectée à la deuxième vibration hors du plan γ(CH) du deutério-4 isothiazole. Cette interprétation est confirmée par le bon accord entre le produit de Teller–Redlich expérimental, faisant intervenir cette fréquence, et le produit théorique (*cf.* tableau 7).

En ce qui concerne le dideutério-4,5 isothiazole, le spectre i.r. de cet hétérocycle à l'état gazeux montre deux branches Q à 709 et 645 cm^{-1} et une bande de type C à 578 cm^{-1}, résultant de mouvements de symétrie A″. Le maximum à 645 cm^{-1} étant manifestement dû à la présence de deutério-4 isothiazole (*cf.* tableaux 3 et 5), nous affectons les deux autres aux vibrations γ(CD). La bonne concordance entre le produit de Teller–Redlich théorique et celui, calculé avec ces valeurs, justifie cette attribution (*cf.* tableau 7). On note que la bande vers 580 cm^{-1}, assignée à la vibration γ(CD), est large et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dissymétrique dans le spectre du composé à l'état liquide, (*cf.* fig. 1) et devient fine, symétrique et beaucoup plus intense, dans celui du dideutério-4,5 isothiazole à l'état dissous dans un solvant neutre. C'est ce comportement, analogue à celui de certaines absorptions γ(CH) dans les hétérocycles thiazoliques (19–20), qui nous a incités à choisir, pour la vibration γ(CD), cette fréquence plutôt que celle, plus basse, à 541 cm^{-1}, qui a été rattachée à l'oscillation de noyau Γ_1.

La méthode précédente ne peut servir à reconnaître si la vibration γ(CD) du deutério-5 isothiazole doit être située à 606 ou 576 cm^{-1}, en raison de la trop grande intensité et de la forme mal définie de ces deux bandes i.r. dans le spectre du composé à l'état liquide (*cf.* fig. 1). Par ailleurs, aucune autre enveloppe de type C, susceptible de correspondre au deuxième mouvement γ(CH), n'est observée dans le spectre du deutério-5 isothiazole à l'état vapeur. Toutefois, la position de quatre vibrations de symétrie A'' étant connue, celle de la cinquième peut être déterminée, approximativement, en appliquant les règles isotopiques qui fournissent les fréquences 813 et 830 cm^{-1} (*cf.* tableau 7). On peut, par suite, envisager de relier au deuxième mouvement γ(CH) du deutério-5 isothiazole, soit un fort épaulement à 858 cm^{-1}, vu seulement dans le spectre du composé à l'état vapeur, soit la très forte bande de vibration rotation de type A à 826 cm^{-1}, qui résulterait alors de la superposition de deux mouvements (*cf.* tableau 6).

Vibrations de combinaison

Califano *et al.* (1) ont assigné quelques unes des vibrations de combinaison de l'isothiazole: certaines de ces attributions, principalement en ce qui concerne les combinaisons mettant en jeu les mouvements γ(CH), ne concordent pas avec celles que nous indiquons dans le tableau 2. D'une manière générale, lorsque les bandes i.r., dues aux combinaisons des mouvements γ(CX) ont été mesurées à l'état liquide et à l'état dissous dans un solvant neutre, on constate un glissement de fréquence de même sens que celui observé pour les oscillations γ(CX) (32), ce qui est en faveur de notre interprétation.

Solubility of Bromine in Molten Silver Bromide

A. Block-Bolten and S. N. Flengas
Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario

Received March 8, 1971

The solubility of bromine vapor in molten silver bromide has been measured gravimetrically. At 950 °K the solubility is about 0.4×10^{-4} g-mol of Br_2 per ml of salt, or 14.6×10^{-4} g-mol of bromine per g-mol of salt. At 760 °K the solubility of bromine is about 1.1×10^{-4} mol per ml of salt, or 36.6×10^{-4} g-mol per g-mol of salt.

The solutions were also investigated spectrophotometrically and absorption spectra were compared with the gravimetric results to provide calibration curves. The results indicate that bromine vapor dissolves in the molten AgBr predominantly in the form of Br_3^- anions. Possible molecular solubility is small and cannot be detected by the gravimetric technique. The thermodynamic properties of the solutions are reported, and indicate an exothermic partial molar heat of mixing and negative excess entropies.

On a mesuré gravimétiquement la solubilité des vapeurs de brome dans le bromure d'argent fondu. A 950 °K, la solubilité est approximativement de 0.4×10^{-4} g-mol de Br_2 par ml de sel ou 14.6×10^{-4} g-mol par g-mol de sel. A 760 °K la solubilité du brome est approximativement de 1.1×10^{-4} mol par ml de sel ou 36.6×10^{-4} g-mol par g-mol de sel.

On a aussi étudié les solutions par des méthodes spectrophotométriques et les spectres d'absorption ont été comparés aux résultats gravimétriques afin d'obtenir des courbes de calibration. Les résultats indiquent que le brome à l'état vapeur se dissout dans le bromure d'argent fondu principalement sous forme d'anions Br_3^-. La solubilité moléculaire possible est faible et ne peut être mise en évidence par la technique gravimétrique. Les propriétés thermodynamiques des solutions rapportées indiquent que la chaleur de mélange molaire partielle est endothermique et que les entropies d'excès sont négatives.

Canadian Journal of Chemistry, 49, 2266 (1971)

Introduction

In spite of the large amount of work which is now available on the physical chemical properties of molten salt systems, information regarding the solubility and behavior of reacting gases in molten salts is still scarce. This information is important from the theoretical point of view, and also for the practical purpose of understanding metal–salt corrosion reactions in high temperature electrochemical systems, gas–melt chemical reactions, and also for understanding the limits of purification of salts by degassing techniques.

Previous work in this field includes the work of Flengas and associates on the solubility of the reactive gases $TiCl_4$, $ZrCl_4$, and $HfCl_4$ in molten salts (1–4), and of Morozov and Sun-In-Chzu (5) on the solubility of hafnium and zirconium tetrachlorides in molten alkali chlorides. Other papers on reactive gases in the molten salts are those of Wartenberg (6) on the halogen gases in their alkali and alkaline earth-halides, of Winsor and Cady (7) on HF solubility in CsF, of Burkhardt and Corbett (8) on water vapor solubility in alkali chlorides, of Greenberg and Sundheim (9) on halogen gases in halide eutectic melts, of Shaffer, Grimes, and Watson (10) on HF solubility in molten fluoride mixtures, of Pearce (11) on CO_2 in sodium borate melts, Sachetto, Bombi, and Fiorani (12) on the iodine–iodide system in molten (Li,K) nitrate, of Van Norman and Tivers (13) on chlorine and bromine solubility in lithium, potassium, lead, and silver halides, and that of Ryabuchin (14) on chlorine solubility in alkali chlorides.

In the present work the solubilities of gaseous bromine in molten AgBr have been investigated by both gravimetric and spectrophotometric methods.

Experimental

The solubility of bromine in molten silver bromide was investigated gravimetrically. For the measurements a quartz spring thermobalance, and the Ruska-Worden torsion quartz-fiber type microbalance were used. The experimental apparatuses are shown in Fig. 1. Both designs included a sliding resistance furnace, and an all glass reaction cell which was connected to a liquid bromine reservoir by means of a side-arm glass tube. As the wax in the ground glass joints could not stand the bromine vapors a completely sealed system was used in all the experiments. For measurements the temperature in the reaction cell in the sliding furnace was varied between 742 and 952 °K. To start an experiment a disc of silver metal of known weight of about 5 mm diameter

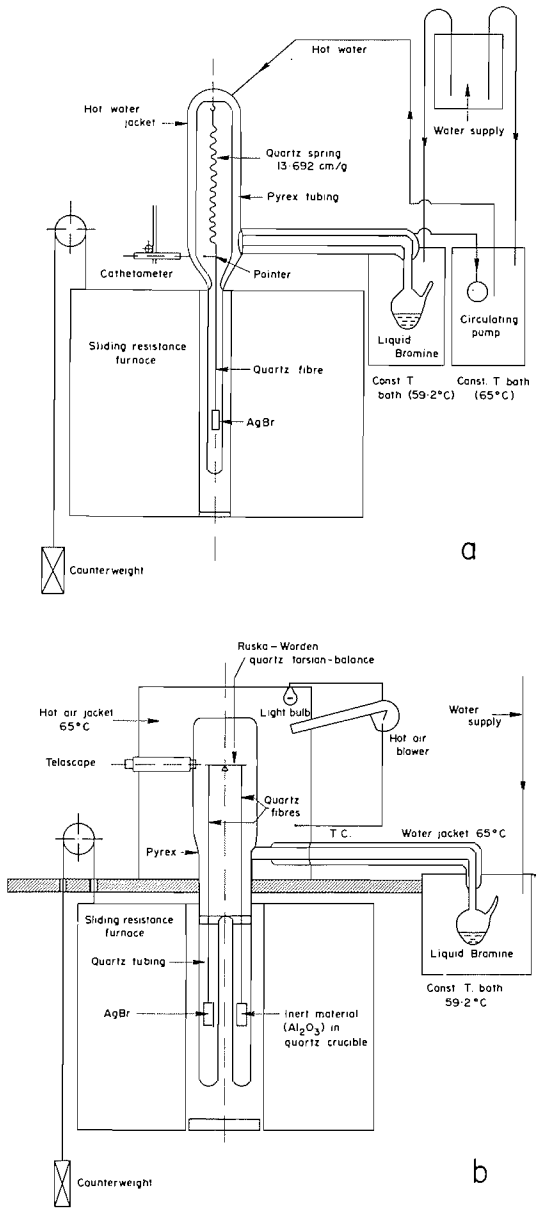

FIG. 1. (*a*) Spring balance apparatus, (*b*) torsion balance apparatus.

was placed at the bottom of the crucible containing the silver bromide, and the apparatus was assembled as shown in Fig. 1. To evacuate the system liquid bromine in its container was frozen using liquid nitrogen. The filling side arm was then flame-sealed under vacuum. The part of the balance containing the crucible was then heated and when temperature equilibrium had been established the temperature of the bromine bath was raised to 59 °C, at which temperature a Br_2 pressure of 1 atm was created throughout the entire system. To prevent the condensation of liquid bromine on the exposed cooler parts of the glass apparatus the double-jacket glass tube shown in the diagram was connected to a recirculating hot water pump, its water temperature being about 65 °C. In the case of the torsion balance a hot air bath replaced the hot water jacket to serve the same purpose. The disc of silver metal was placed inside the AgBr melt used for the solubility measurements for the purpose of promoting the diffusion of bromine into the melt through counter-diffusion of dissolved silver and dissolved bromine. Thus, the overall solubility process may be described by two stages. In the first stage, bromine dissolves in the AgBr melt and then it reacts with the silver metal in solution to produce more silver bromide. When all the silver has been consumed in this manner, excess bromine will dissolve until its solubility limit in the melt is reached. In the actual weight-gain measurement the true solubility was calculated from the total weight gain after subtracting the weight of bromine required to react with all the metallic silver present. In the case of the quartz spring balance, buoyancy corrections were made whilst the Ruska torsion balance did not require any corrections.

Each experimental point was accepted as an equilibrium value after a rest period of at least 24 h, during which numerous intermediate readings were also taken.

The visible spectra of the AgBr–Br_2 system were measured using a Hitachi–Perkin–Elmer 139, u.v.–visible light spectrophotometer modified for high temperature work, as described by Brookes and Flengas (15). The design of the spectrophotometric cell and its attachments was based on the same principle as that for the gravimetric work described above. The quartz optical cell had its optical path reduced through the insertion of precision quartz inserts of 10 mm thickness, and was placed into the furnace of the modified Hitachi–Perkin–Elmer spectrophotometer. The cell was connected by a quartz tube to a heart shaped bromine reservoir, immersed in a controlled-temperature bath. The side-arm tube connecting the spectrophotometric cell to the bromine reservoir was always kept at a temperature higher than the dew point of bromine, as during the gravimetric measurements. Absorption spectra were measured at various cell temperatures and bromine pressures.

Prior to use, the spectrophotometric cells filled with the silver bromide salt were kept under vacuum for several hours at temperatures above the melting point of AgBr, and then the system was sealed under vacuum.

For purposes of comparison the spectra of aqueous solutions of bromine were also obtained. The saturated solutions of Br_2 in aqueous KBr were created directly in an optical cell sealed at the top. The Br_2 pressure inside this system and the bromine solubility was directly dependent upon the temperature of the furnace which was controlled between 15 and 75 °C. This low temperature cell was not supplied with quartz inserts and its light path was 10 mm.

All values of $\ln \tau$, where τ is the transmittance, are given only corrected to a constant sensitivity. For all measurements the spectrophotometer slit was set at 0.5 mm. In the case of the solution of bromine in molten silver bromide the light path was only 0.0425 mm. The wavelength scale of the spectrophotometer was calibrated by means of the 656.1 mμ line of the deuterium u.v. lamp

provided with the instrument. For all other measurements the visible-light tungsten lamp was used. The absorption band for quartz limited the range of those measurements, as below the wavelength of 620 mμ there was considerable interference, and the measured absorptivities had to be corrected for this effect.

Results and Discussion

(a) Solubility Measurements

The results of the solubility measurements are given in Table 1, and plotted in Fig. 2. It may be seen that at 950 °K bromine dissolves in AgBr to the extent of 1.46×10^{-3} g per g-mol of molten silver bromide, and that at 760 °K the solubility increases to 3.66×10^{-3}.

The corresponding concentrations in g-mol/ml salt are 0.414×10^{-4} and 1.076×10^{-4}, respectively.

For the reaction

$$[1] \qquad |Br_2|_{\substack{\text{gas phase}\\ \text{at 1 atm, } T}} = |Br_2|_{\substack{\text{liquid phase}\\ \text{at 1 atm, } T}}$$

the reference states are chosen as follows. For gaseous bromine its standard state represents the state of gaseous Br_2 at 1 atm pressure and any temperature T. For bromine in solution the standard state is taken as the state of pure liquid Br_2 under a pressure of 1 atm and all temperatures.

For reaction 1,

$$\Delta G_R = 0$$

and

$$G^0_{\substack{Br_2,\ \text{gas}\\ 1\ \text{atm},\ T}} = G^0_{\substack{Br_2,\ \text{liquid}\\ 1\ \text{atm},\ T}} + RT \ln a_{Br_2}$$

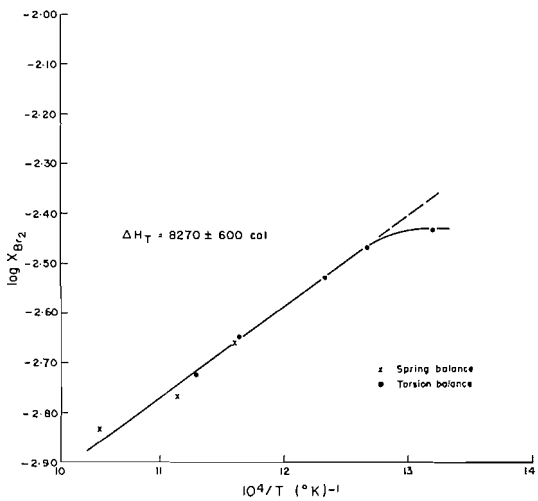

FIG. 2. Plot of log X_{Br_2} *vs.* $1/T$.

where

$$\Delta G^0_{Br_2} = -\Delta G_V{}^0$$

Accordingly

$$[2] \qquad \left[\frac{d \ln a_{Br_2}}{d\left(\frac{1}{T}\right)}\right]_P = \frac{\Delta H_V{}^0}{R}$$

where $\Delta H_V{}^0$ and $\Delta G_V{}^0$ are the heat and the free energy of vaporization of liquid bromine at any temperature. If it assumed that for dilute solutions the activity coefficients are independent of composition and depend only on temperature (Henrian behavior), then this equation may be written as

$$[3] \qquad \left[\frac{d \ln X}{d\left(\frac{1}{T}\right)}\right]_P = \frac{\Delta H_T}{R}$$

where

$$[4] \qquad \Delta H_T = \Delta H_V{}^0 - \overline{\Delta H}_{Br_2}$$

and $\overline{\Delta H}_{Br_2}$ is the limiting heat of mixing of liquid bromine in molten AgBr. Hence, the plot of log x *vs.* $1/T$ should yield a curve having a slope equal to $\Delta H_T/R$.

The plot is presented in Fig. 2. It may be seen that it is linear over the temperature range 950 to 790 °K. Excluding the point at 760 °K, the calculated least-squares slope represent a heat term equal to 8270 ± 600 cal/mol. This uncertainty includes the effect of uncertainty of ±2 °K in the temperature measurements. The solubility measurement at 760 °K, which is close to the melting point of silver bromide, lies outside the least-square curve.

To calculate the partial molar heats of mixing $\overline{\Delta H}_{Br_2}$, the heat of vaporization at each temperature was calculated from tabulated data given in JANAF thermodynamic tables (16). These calculations are included in Table 1. The partial molar heats of mixing which are obtained from eq. 4 are also given in Table 1. It is readily seen that the limiting heats of mixing are exothermic and indicate a slight temperature dependence.

All measurements presented in Table 1 refer to a pressure of 1 atm. Solubilities were also measured at lower pressures, and indicated a pronounced decrease in solubility. Because of the large relative error of these measurements at low solubilities, those values were not too conclusive and shall not be reported. It appears,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

however, that the apparent heat of mixing is independent of pressure.

Considering the mixing reaction to proceed in two steps, *e.g.*

(*a*) $Br_{2\ \underset{1atm,\ T}{gas}} \rightarrow Br_{2\ \underset{1\ atm,\ T}{Pure\ liquid}}$ $\quad \Delta S_1 = -\Delta S_V$

(*b*) $Br_{2\ \underset{1\ atm,\ T}{Pure\ liquid}} \rightarrow (Br_2)_{\ In\ solution}$ $\quad \Delta S_2 = \overline{\Delta S}_{Br_2}$

the total entropy for the solubility process (reaction 1) may be described as

$$[5] \qquad \Delta S_{mix} = -\Delta S_V + \overline{\Delta S}_{Br_2}$$

when ΔS_V is the entropy of vaporization of Br_2 at a temperature T, and $\overline{\Delta S}_{Br_2}$ is the partial molar entropy of mixing of liquid bromine. The excess partial molar entropy of mixing is given as

$$\overline{\Delta S}_{Br_2}{}^{XS} = \overline{\Delta S}_{Br_2} - \overline{\Delta S}_{ideal}$$

where, $\overline{\Delta S}_{ideal}$ is the configurational component of the entropy of mixing based on the mole fraction concentration scale.

The excess partial molar entropy of mixing may be calculated directly from the expression

$$[6] \qquad \overline{\Delta S}_{Br_2}{}^{XS} = (\overline{\Delta H}_{Br_2} - RT \ln \gamma_{Br_2})/T$$

and may be taken to represent vibrational contributions. Values for the excess entropies and for the total entropy of mixing for reaction 1, as calculated from eqs. 5 and 6, are also listed in Table 1.

From these calculations, the partial molar heats of mixing between 760 and 950 °K, are exothermic and change from about $-5\,500$ to $-7\,200$ cal/mol, respectively. The corresponding excess entropies of mixing are also negative and also vary from -8.4 to -10.1 e.u.

The exothermic heats and the negative excess entropies of solution indicate that the solution process involves strong interactions between Br_2 and bromide ions in the melt. The magnitude of solubility of bromine found in the present study is in agreement with the predictions by Greenberg and Sundheim (9), and by Wartenberg (6). By analogy with the mechanism of solubility in the other reactive halogen gases, the solubility of bromine may be described by the reaction

$$[7] \qquad Br_{2\ (gas)} + Ag^+Br^-{}_{liquid} \rightarrow Ag^+Br_3^-{}_{liquid}$$

where the Br_3^- anion is thought (9, 18) to represent a triplet resulting from an ion–dipole type interaction of the structure $Br^-(Br^+ \ldots Br^-)$

(b) Spectrophotometric Measurements

The observed absorption spectra are limited by the absorption band for quartz. The wavelength range below 620 mμ is dominated by the absorption of the quartz cells. Above this range the spectra characteristic of the solutions are evident and may be described by a single peak, the position of which depends upon temperature and the concentration of the bromine species which is taken to be pressure dependent. The transition between transmission and absorption is rather abrupt as it occurs over a wavelength change of less than 50 to 60 mμ. As quartz still shows some absorbance in this range, all observed spectrograms had to be corrected for the corresponding quartz absorbance at each wavelength. In fused salt spectra of this type the reported characteristic wavelengths are usually those representing the transition between absorption and transmission. In this paper, because of the observed short range for this transition, only maximum transmittance wavelengths shall be reported.

The absorption spectrum of pure molten AgBr has been reported by Sundheim and Greenberg (19). At 454 °C, it is characterized by a single peak which rises rather abruptly. The wavelength λ_0, representing the mid-point between peak absorption and peak transmission, depends on temperature and at 454 °C, it is given as 600 mμ. Spectra of this kind have been interpreted as due to a change transfer between Br^- anions and the surrounding cations. The spectra of the solutions of bromine in molten AgBr are similar and the maximum transmission occurs at slightly higher wavelengths: λ_0 as well as peak transmittance are shifted towards higher wavelengths as the temperature is increased. In the present system the shift of λ_0 with temperature is about 55 mμ per 200 °C. The pressure effect is less consistent. As the pressure is increased the concentration of bromine in the liquid increases. However, at temperatures between 760 and 820 °K, an increase in pressure shifts the peak transmittance towards shorter wavelengths. At higher temperatures, between 820 and 950 °K, an increase in pressure has no significant influence on the wavelength of peak transmittance. The pressure–temperature dependence of peak transmittance for those solutions is given in Fig. 3. The curve at $P = 1$ atm in this figure corresponds to the solubility measurements de-

scribed earlier. The detailed data are summarized in Table 2.

Figure 3 also contains the shift in peak transmittance for aqueous solutions of bromine in 1 and 2 *N*, KBr, respectively. The temperature behavior is similar as in the fused salt systems. However, peak transmittances for the aqueous solutions are shifted towards slightly shorter wavelengths. The increase of concentration of KBr from 1 to 2 *N*, which is expected to increase the solubility of bromine as Br_3^-, shifts further the peak transmittance to longer wavelengths and higher transmittances. However, it is significant that in both systems transmittance occurs in a wavelength range which varies only between 640 and 720 mμ, indicating the similarity of the two processes.

It should be noted that u.v. spectra in aqueous solutions (20) have indicated that a very small proportion of the total solubility may be attributed to the presence of molecularly dissolved Br_2. However, this amount is usually three to four orders of magnitude lower than the ionic solubility as Br_3^- and cannot be detected in macroscopic gravimetric measurements. In a molten bromide salt where the activity of Br^- is higher than in any possible aqueous solutions, the equilibrium favors the formation of Br_3^- ions, particularly at low temperatures, and the molecular solubility should be expected to decrease further.

It appears, therefore, that the shift in the transmittance curves in the present system, as compared to that occurring in pure molten silver bromide, indicates that the charge transfer between the Br_3^- triplet and the surrounding Ag^+ is requiring lower energies at higher temperatures.

At low temperature, between 740 and 800 °K, the solubilities are high and the solutions have an orange-reddish color. This color changes to deep red at the higher temperatures up to 950 °K, for which the total solubilities of bromine have decreased considerably. The transmittance isobars appear to indicate differences in the absorption mechanisms at temperatures below and above about 820 °K. At a given bromine pressure the shift in transmittance peaks with temperature indicates that the solution becomes more opaque as the temperature is increased. The two possible absorption mechanisms indicated by the change in slope in the transmittance curves, could be attributed to the existence of two kinds of soluble Br_2 in these melts. At low temperatures the higher energy charge transfer type transition should correspond to bromine dissolved in its ionic form as Br_3^-.

At temperatures higher than 820 °K where the solubilities are lower, the higher absorptivity could indicate the presence of some molecularly dissolved bromine.

The molecular and ionic mechanism for the solubility of halogens in molten salts is also supported by recent electrochemical measurements on an iodine–iodide electrode in molten salts by Sachetto, Bombi, and Fiorani (12).

However, it should be understood that the thermodynamic evidence from the gravimetric measurements indicates that the Br_3^- type inter-

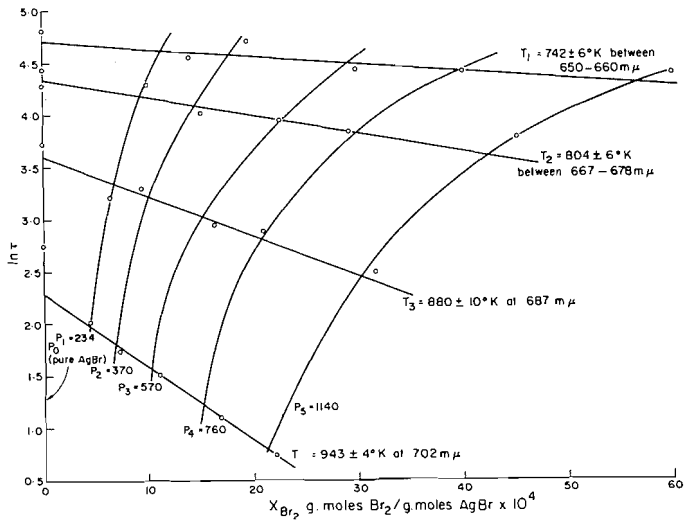

FIG. 4. Calibration curves based on peak transmittance for bromine solubility at various temperatures and bromine pressures.

action is probably the main effect determining the solubility in this system.

The transmittance curves in Fig. 3 may be used as a calibration method for the purpose of calculating the solubility of bromine in molten AgBr at various pressures of bromine.

Thus from the transmittance isobar at P_{Br_2} = 1 atm and various temperatures, Henry's law may be written as

$$X_{Br_2} = KP$$

where, X_{Br_2} is the mole fraction of soluble bromine and K is Henry's law solubility constant which is only temperature dependent. From the measured solubility at P = 1 atm pressure and various temperatures, the solubility at other pressures may be calculated as

$$(X_{Br_2})_{P,T} = (X_{Br_2})_{1\ atm,\ T}P$$

The calibration plot of ln τ *vs.* mole fraction of soluble bromine at various pressures for four isotherms is given in Fig. 4. It may be seen that ln τ is a linear relation of X, as expected, and the isotherms intercept zero solubility at transmittance values close to those representing pure silver bromide. In a sense this limiting value represents the solubility of bromine in silver bromide at a pressure P_0 equal to the bromine decomposition pressure of the salt.

In conclusion, the combined solubility and spectrophotometric measurements support the existence of Br_3^- species in these solutions and that the solubility reaction is exothermic and accompanied by a decrease in entropy. It is obvious that when a gaseous molecule dissolves in a liquid it must loose its vibrational and translational degrees of freedom and by necessity acquire the vibrational characteristics of the form in which it appears in the liquid phase.

However, the calculation of excess entropies is based on the assumption that the configurational component of the entropy of mixing is totally random. If the species in solutions are not randomly distributed then the excess entropy cannot be identified entirely with vibrational contributions.

We express our gratitude to Mr. R. H. Chappell for his considerable effort and time in preparing the glass components of our apparatus.

Production of Electrons by Reaction of Sodium with Methanol and Ethanol: Kinetics of their Formation and Subsequent Reactions[1]

J. W. FLETCHER AND P. J. RICHARDS

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received December 3, 1970

In the reaction of sodium with alcohols an electron is generated without the formation of other reactive products. This, therefore, provides an excellent system to study the reactions of the electrons with themselves, with the solvent, and with added scavengers. A mathematical treatment for such formation and reaction has been derived.

Evidence for a bimolecular electron reaction was investigated by observing the formation of D_2 in the reaction of sodium with ethanol-d_1 or methanol-d_1, via reaction

$$e_{ROD}^- + e_{ROD}^- \rightarrow D_2 + 2RO^-$$

A calculated rate constant for this reaction in ethanol at 25 °C, $k = (5 \pm 4) \times 10^9\ M^{-1}\ s^{-1}$, similar to that observed for the equivalent reaction in water, is obtained. An isotope effect ($\alpha = 2$) for the above reaction in both ethanol and methanol is observed. This would indicate the formation of an electron dimer $(e^-)_2$ as an intermediate in the formation of hydrogen as has been suggested for the equivalent reaction in water.

Lors de la réaction entre le sodium et des alcools, un électron est engendré sans formation d'autres produits réactifs. Ceci fournit ainsi un excellent système pour étudier les réactions des électrons entre eux, avec le solvant et avec des agents capteurs ajoutés. Un traitement mathématique pour de telles formations et réactions en a été déduit.

La preuve d'une réaction des électrons bimoléculaire a été recherchée en observant la formation de D_2 dans la réaction entre le sodium et l'éthanol-d_1, ou le méthanol-d_1, au moyen de la réaction

$$e_{ROD}^- + e_{ROD}^- \rightarrow D_2 + 2RO^-$$

Une constante de vitesse calculée est obtenue pour cette réaction dans l'éthanol à 25 °C $k = (5 \pm 4) \times 10^9\ M^{-1}\ s^{-1}$, et il apparaît que celle-ci est très semblable à celle observée pour la même réaction dans l'eau. Un effet isotopique ($\alpha = 2$) pour la réaction ci-dessus est observé à la fois dans l'éthanol et le méthanol; ceci prouverait la formation d'un électron dimère $(e^-)_2$ en tant qu'intermédiaire dans la formation d'hydrogène, comme cela a été suggéré pour la même réaction dans l'eau.

Canadian Journal of Chemistry, 49, 2275 (1971)

Introduction

Bennett *et al.* (1) have observed the electron as an intermediate in the reaction of sodium with solid alcohol, both optically and by electron spin resonance (e.s.r.) in a rotating cryostat experiment. Shaede and Walker (2) have obtained chemical evidence that the electron is an intermediate in the reaction of sodium with liquid water. Therefore it would be expected that the electron would also be formed in liquid alcohols

[1] $$Na + ROD \rightarrow e_{ROD}^- + Na^+$$

where ROD represents an alcohol deuterated in the oxy position.

The formation of the electron is demonstrated by the addition of an electron scavenger such as N_2O with the resultant formation of N_2, as has been observed in the aqueous system (2). In the absence of electron scavengers two modes of electron decay are possible, *i.e.* either pseudo first order decay or bimolecular recombination. Using pure alcohol deuterated in the oxy position the former can be represented by reaction 2 to produce HD.

[2*a*] $$e_{ROD}^- + ROD \rightarrow RO^- + D$$

[2*b*] $$D + ROD \rightarrow (R - 1)CHOD + HD$$

A bimolecular electron decay reaction has been shown to occur in aqueous solutions (3, 4). Formation of deuterium in isotopic studies (4) has been used as evidence for the occurrence of the bimolecular reaction in the aqueous system and by analogy it can be assumed that in oxy deuterated alcohol the deuterium would be

[1]AECL No. 3896.

TABLE 1. Reaction of sodium with alcohol: production of hydrogen

Alcohol	Temperature (°C)	Products (%) D_2	Products (%) HD	N_A (mol s^{-1} cm^{-2})
CH_3CH_2OD	25	96±1	4±1	4×10^{-6}
	−78	82±2	18±2	4×10^{-8}
CH_3OD	25	96±1	4±1	10×10^{-6}

formed by the bimolecular electron reaction 3.

[3] $$e_{ROD}^- + e_{ROD}^- \rightarrow 2RO^- + D_2$$

The assumption is consistent with the results given in the paper. In this work the relative importance of reactions 2 and 3 have been investigated by measurement of the ratio of HD to D_2.

In the sodium alcohol system the sodium ion produced does not react with the electron whereas the radiolytically produced acetaldehyde and positive ion (ROH_2^+) do.

[4] $$e_{ROD}^- + ROD_2^+ \rightarrow D + ROD$$

Thus the electron disappears only by the pseudo first order reaction 2 and the bimolecular reaction 3, in competition with each other. The relative importance of reaction 2 can be increased by dilution with ether, which is unreactive towards sodium in alcohol, to decrease the rate of electron formation and hence the electron concentration. Electron scavengers can also be added to compete with reactions 2 and 3.

It is observed that the reactions involved in this system do not obey simple homogeneous kinetics as a result of high electron concentration gradients originating at the surface of the sodium. In this paper a mathematical treatment of the system using a combination of homogeneous and diffusion kinetics has been developed to explain the experimental results.

Experimental

The sodium was handled in an inert atmosphere dry box. A clean piece of sodium was placed in a sodium press and extruded in wire form as required. In most experiments a 1 cm length of 0.006 in. diameter sodium wire was used. It was placed in a double valved side arm of a reaction vessel to which 5 ml of alcohol had previously been added and degassed. The side arm was evacuated and the measured amount of sodium added to the alcohol and allowed to completely react. The resulting hydrogen was pumped off, after freezing the alcohol, and analyzed by a CEC 21-130 mass spectrometer. The rate of dissolution of sodium was obtained from the rate of weight loss from a flat piece of sodium of known surface area.

Reagents

The anhydrous ethanol was obtained from Commercial Alcohols and purified by distillation through a spinning band column (5). Shawinigan Chemical Reagent grade methanol was vacuum distilled with only the middle fraction being used. The ethanol-d_1 and methanol-d_1 were used as received from Merck, Sharpe and Dohme and were stated to be better than 99% deuterium. Nuclear magnetic resonance (n.m.r.) analysis of one lot of ethanol gave >99.5%. Fisher anhydrous ether was dried with and stored over sodium. J. T. Baker Analyzed Reagent dry sodium was used as received.

Results

In pure ethanol-d_1 and methanol-d_1, the reaction of sodium with the alcohol at room temperature leads to the formation of hydrogen which is mainly D_2 (Table 1). When the reaction temperature is lowered to −78 °C the percentage D_2 is lowered (Table 1). The lowering of the reaction temperature to Dry Ice temperature also decreases the rate of dissolution (N_A) of the sodium and hence the rate of formation of the electron in ethanol from 4×10^{-6} to 4×10^{-8} mol s^{-1} cm^{-2} as shown in Table 1.

Dilution of the alcohol-d_1 with undeuterated alcohol increases the relative proportion of HD and H_2 in the hydrogen produced as shown in Fig. 1.

The addition of N_2O to the pure ethanol-d_1 before reaction with the sodium results in N_2 being formed. The amount of N_2 formed is a function of the N_2O concentration as is given in Table 2. The total gas yield was 0.7 ± 0.3 mol of gas per mol of sodium added and remained relatively constant over the N_2O concentration studied. The large errors in the absolute yield arise from the difficulty in determining the exact amount of sodium added, however, the relative amounts of hydrogen and nitrogen can be accurately determined. The addition of electron scavengers which compete with the N_2O for the electrons, leads to a reduction in the percentage N_2 yield. For example a solution of 0.2 *M* hydrogen chloride and 0.2 *M* N_2O leads to an

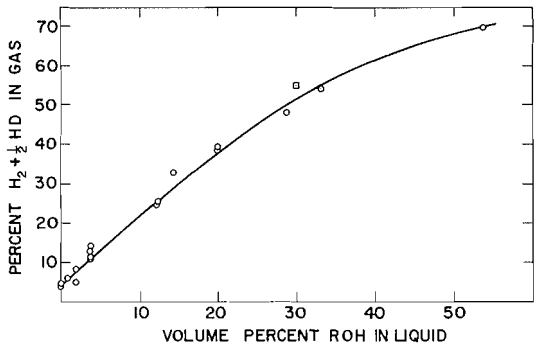

FIG. 1. Atom percent hydrogen as a function of added alcohol-OH: ○, methanol, individual experimental observations; □, ethanol, individual experimental observations. The curve is calculated by first subtracting the hydrogen yield from the competing 1st order decay, then using a value of $\alpha = 2$. In pure alcohol-d_1 the hydrogen formed is $<1\%$ H_2.

experimental yield of 2% nitrogen and 98% hydrogen, while a solution of 0.2 M N_2O yields 45% nitrogen. The addition of C_6F_{12} to an ethanolic N_2O solution also reduces the nitrogen yield. The percentage nitrogen yield at a given N_2O concentration is increased by the addition of an inert solvent (diethyl ether) to the ethanol. In 90% ether solution N_2O is $\geqslant 10^3$ times as effective in scavenging the electron as it is in pure ethanol (Table 2).

Discussion

The results obtained using N_2O as an electron scavenger, both by itself and in competition with a second electron scavenger (Table 2), indicate that the electron is formed as an intermediate in the reaction of sodium with alcohols to give hydrogen.

In pure alcohol the yield of hydrogen from reaction 3 should be one half mole per mole of sodium reacted, while in N_2O solutions the yield of N_2 from reaction 5 should tend towards unity with increasing N_2O concentration

$$[5] \qquad N_2O + e_{ROD}^- \rightarrow N_2 + O^-$$

However, due to the large errors in the absolute yield measurements noted in the Results section this could not be quantitatively demonstrated.

(1) Bimolecular Reaction

The large percentage of D_2 obtained in pure ethanol-d_1 (Table 1) can by analogy with the aqueous system (4) be assumed to be due to the bimolecular decay of the electron (reaction 3), and indicates that this reaction is more important than the pseudo first order decay (reaction 2) which produces HD.

$$[2] \qquad e_{ROD}^- + ROD \xrightarrow{k_2} HD + (R-1)CHOD$$

$$[3] \qquad e_{ROD}^- + e_{ROD}^- \xrightarrow{k_3} D_2 + 2RO^-$$

Knowing the rate of reaction 2 an estimate can be made of k_3, the rate constant for reaction 3.

The formation and decay reactions 1, 2, and 3 involve spacial inhomogeneity, since they occur at or near the surface of the sodium. Hence calculation of the reaction rate must include the diffusion of the electron from the surface. Before this can be done a mathematical model must be developed. It is postulated that the electron is formed at the surface of the sodium which for purposes of calculation is assumed to be flat. The electron subsequently diffuses away and ultimately reacts. Since the reaction distances are very small (Fig. 2), thermally induced convection currents can be neglected. The use of elementary

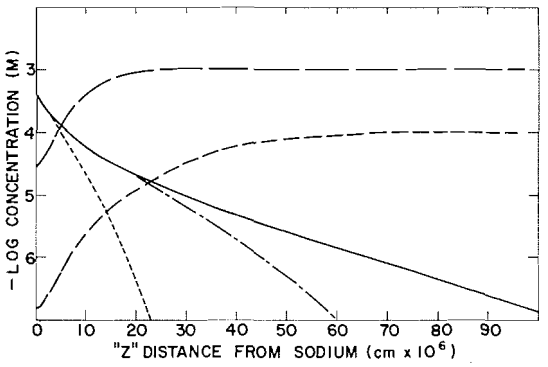

FIG. 2. Electron and N_2O concentration as a function of distance from the sodium surface. Electron concentration profile: ——, $[N_2O] = 0$; ----, $[N_2O] = 10^{-4}$; ------, $[N_2O] = 10^{-3}$. N_2O concentration profile: – –, $[N_2O] = 10^{-4}$; — —, $[N_2O] = 10^{-3}$.

diffusion theory combined with homogeneous chemical reaction kinetics (6), leads to eqs. 6 and 7 at steady state.

$$[6] \quad (dN_A/dZ) \times 10^3 + k_2C_A + (2k_3)C_A^2 = 0$$

The concentration gradient established by diffusion is related to a molar flux (N_A) as follows

$$[7] \quad N_A = -D_A(dC_A/dZ) \times 10^{-3}$$

where N_A = molar flux for electrons produced from Na reaction (mol s^{-1} cm^{-2}), D_A = diffusion constant (cm^2 s^{-1}), C_A = electron concentration (M), k_2 = rate constant for reaction 2 (s^{-1}), k_3 = rate constant for reaction 3 (M^{-1} s^{-1}), Z = distance from sodium surface (cm).

Combining eqs. 6 and 7 gives

$$[8a] \quad -D_A \frac{d^2C_A}{-dZ^2} + k_2C_A + (2k_3)C_A^2 = 0$$

and solving for the first differential gives

$$[8b] \quad \frac{dC_A}{dZ} = -\left(\frac{k_2}{D_A} C_A^2 + \frac{(2k_3)}{D_A}\frac{2}{3} C_A^3\right)^{\frac{1}{2}}$$

The experimentally observed HD-to-D_2 ratio can be expressed in terms of the electron concentration as follows

$$[9a] \quad \frac{[HD]}{[D_2]} = \frac{\int_0^\infty k_2C_A\,dZ}{\int_0^\infty (2k_3)C_A^2\,dZ}.$$

Substituting dZ from eq. 8b in eq. 9a and integrating gives

$$[9b] \quad \frac{[HD]}{[D_2]} = \frac{\frac{3k_1^{3/2}D_A^{1/2}}{(2k_2)}[(b+1)^{\frac{1}{2}} - 1]}{\frac{1}{2}\frac{3k_1^{3/2}D_A^{1/2}}{(2k_2)}[2 - (2-b)(1+b)^{\frac{1}{2}}]} = \frac{2((b+1)^{\frac{1}{2}} - 1)}{2 - (2-b)(1+b)^{\frac{1}{2}}}$$

where

$$[9c] \quad b \text{ (dimensionless parameter)} = \frac{2}{3}\frac{(2k_3)}{k_2} C_{A_0}$$

C_{A_0} represents the electron concentration at the surface of the sodium. A second independent eq. 10 is obtained by combining eqs. 8 and 7 as $Z \to 0$

$$[10] \quad \frac{2}{3}(2k_3)C_{A_0}^3 + k_2C_{A_0}^2 = \frac{N_A^2}{D_A} \times 10^6$$

At 25 °C the empirical "b" value (Table 3) was calculated to be 30 from eq. 9b using the experimental HD to D_2 ratio in Table 1.

b	30	3	30
$C_{A_0}(M)$	4.2×10^{-4} 3.8×10^{-4}	5.1×10^{-4}	7.7×10^{-4}
$k_2(s^{-1})$	9×10^{4c} 1.2×10^{5b}	1.2×10^{3d}	1.1×10^{5c}
$k_3(M^{-1}\ s^{-1})$	$(5\pm4)\times10^9$ $(7\pm3)\times10^9$	$(5.3\pm2)\times10^6$	$(3.3\pm2)\times10^9$
$k_{3\ aq}(M^{-1}\ s^{-1})$	6.3×10^{9e}		
$D_{N_2O}(cm^2\ s^{-1})$	1×10^{-5f}		
$k_5(M^{-1}\ s^{-1})$	8×10^{9g}		

[a]Calculated from the value obtained in water 4.7×10^{-5} cm^2 s^{-1} (ref. 3 using the Wilke Stoke Einstein eq. ref. 6 which is the same as a value by Russell and Freeman (9)).
[b]Reference 5.
[c]In alkaline solution ref. 10. This independent value at room temperature makes a useful comparison.
[d]Value calculated using E_a = 4.8 kcal/mol for [2] (10) which is similar to a value of 4.6 ± 1 estimated by Freeman (12) and 4.5 ± 1 obtained for the aqueous system (11).
[e]Aqueous system ref. 7.
[f]Estimated from data in ref. 6.
[g]J. W. Fletcher, unpublished data; obtained by steady state γ-radiolysis relative to $k_{(e^-+H^+)} = 2\times10^{10}\ M^{-1}\ s^{-1}$. This value is similar to that obtained by other authors $7\times10^9\ M^{-1}\ s^{-1}$ ref. 12.

The values of k_3 and C_{A_0} given in Table 3 are calculated from eqs. 9*c* and 10 using the values of b, N_A, D_A, and k_2 given in Tables 1 and 3. The value of $k_3 = (5 \pm 4) \times 10^9\ M^{-1}\ s^{-1}$ is similar to the value obtained $k_{3\ aq} = 6.3 \times 10^9\ M^{-1}\ s^{-1}$ obtained in radiolysis of aqueous solutions (7).

The results obtained at −78 °C were calculated in the same way using the experimental numbers in Table 1 and the constants in Table 3. The derived values for $k_3 = (5 \pm 2) \times 10^6\ M^{-1}\ s^{-1}$ at −78 °C and $(5 \pm 4) \times 10^9\ M^{-1}\ s^{-1}$ at 25 °C lead to an activation energy $E_A = 7.6 \pm 2$ kcal/mol for the bimolecular reaction in ethanol which is slightly higher than the value of 5.2 ± 0.3 kcal/mol obtained for water (7).

(2) Isotope Effects Arising from the Bimolecular Decay of the Electron

Similar results were obtained for the isotopic composition of the gas evolved in both methanol and ethanol, shown in Fig. 1. The isotope effect α is defined as the ratio of the (H/D) in the hydrogen product to the oxy (H/D) in the solvent mixture. A comparison of the uncorrected values of α (Table 4), for alcohol with results obtained in aqueous solutions (8), show a similar trend as a function of %D, but the value of α is one half that in water. When a correction is made for the HD formed in pure alcohol-d_1 due to the first order decay, the value of α is decreased slightly and becomes a constant value $\alpha = 2 \pm 0.1$. The curve in Fig. 1 is calculated using this correction and assuming $\alpha = 2$.

The rates of the aqueous analogue of reaction 3 in H_2O and D_2O are comparable (3)

$$e_{H_2O}^- + e_{H_2O}^- \rightarrow H_2 + 2OH^-$$

$$e_{D_2O}^- + e_{D_2O}^- \rightarrow D_2 + 2OD^-$$

Since they are comparable no isotope effect would be expected from these reactions in H_2O–D_2O solutions. We have estimated in this paper that the rate of reaction 3 in alcohol is similar to that in water. It can therefore be assumed that the rate of reaction 3 in oxy-deuterium and oxy-hydrogen alcohol would also be similar and that no isotope effect would arise from reaction 3 in ROD–ROH solutions.

It has been suggested (8) that the relatively large isotope effect found in water could arise from the decomposition of the dimer intermediate $(e_{aq}^-)_2$, formed by the diffusion controlled reaction 11

[11] $$e_{aq}^- + e_{aq}^- \rightarrow (e_{aq}^-)_2$$

where aq can represent both deuterated and undeuterated water in the solvent shell. The dimer intermediate would have to have a lifetime long enough to allow preferential cleavage of the OH over the OD bonds of the molecules in the solvation shell to take place. The isotope effect arising from the direct decomposition of the solvated dimer should be similar in alcohol and water.

Since the isotope effect in alcohol is observed to be less than in water there must be a second source of the isotope effect in the aqueous system.

TABLE 4. Reaction of sodium with alcohol: H/D isotope effects

Atom % oxy-hydrogen	"α" aqueous (8)[a]	"α" alcoholic[a]	
		Uncorrected	Corrected
25	5.5±0.2	2.4±0.4	2.0±0.2
50	4.7±0.2	2.0±0.3	2.0±0.2

[a] $\alpha = (H/D)_{\text{hydrogen product}}/(H/D)_{\text{solvent oxy-hydrogen}}$.

This second isotope effect could arise from each electron within the dimer (reaction 12) becoming associated with a specific molecule $(H_2O^-)_2$ before the formation of hydrogen (reaction 13),

[12] $$(e_{aq}^-)_2 \rightarrow (H_2O^-)_2$$

[13] $$(H_2O^-)_2 \rightarrow H_2 + 2OH^-$$

where H_2O represents both deuterated and undeuterated water. If this occurred, then no further isotope effect would arise from the decomposition of the desolvated dimer by a reaction analogous to reaction 13 in the ROH–ROD alcohol system since there are only two available hydrogens per dimer. However, in the aqueous H_2O–D_2O system an isotope effect in addition to that in reaction 12 would be observed from reaction 13 since there are four available hydrogens per dimer. This additional isotope effect in water could account for the larger value of α in the aqueous system than in alcohol.

The desolvation process [12] would require time and this could account for the finite lifetime of the solvated dimer $(e_{aq}^-)_2$ as an intermediate and thus the observed isotope effect. The lifetime and the concentration of the dimer is still small in comparison with that of the electron and would not affect the mathematical treatment in this paper.

(3) Scavenger Kinetics

The electron formed in reaction 1

[1] $$Na + ROD \rightarrow e_{ROD}^- + Na^+$$

can react with N_2O to give N_2 by reaction 5

[5] $$N_2O + e_{ROD}^- \xrightarrow{k_5} N_2 + O^-$$

in competition mainly with reaction 3

[3] $$e_{ROD}^- + e_{ROD}^- \rightarrow D_2 + 2RO^-$$

Calculations based on the assumption that reactions 3 and 5 obey simple homogeneous reaction kinetics, give much higher N_2 yields than the experimental values (Table 2). A more exact solution is required, which takes into account the rates of diffusion and concentration gradients of both the electron and the scavenger.

An exact solution of the equations is not possible so an iterative solution has been developed using a computer for the calculations. This solution makes use of the diffusion and reaction terms of the electron and nitrous oxide in eqs. 14 and 15, respectively.

[14] $$-D_A \frac{d^2C_A}{dZ^2} + k_2C_A + (2k_3)C_A^2 + k_5[N_2O]C_A = 0$$

[15] $$-D_{N_2O} \frac{d^2[N_2O]}{dY^2} + k_5[N_2O]C_A = 0$$

The solution is a mixed boundary value problem in which Z is a measure of the distance the electron has diffused away from the sodium surface and Y is a measure of the distance the N_2O has diffused toward the surface from a point Y_0 where the N_2O has a constant concentration. The first step is to calculate an electron concentration gradient equation assuming no nitrous oxide has been added and for this case the differential eq. 7*b* can be solved in the form

[16] $$Z = \left(\frac{D_A}{K}\right)^{\frac{1}{2}}\left[\ln\left(\frac{(1 + B_0)^{\frac{1}{2}} - 1}{(1 + B_0)^{\frac{1}{2}} + 1}\right) - \ln\left(\frac{(1 + B)^{\frac{1}{2}} - 1}{(1 + B)^{\frac{1}{2}} + 1}\right)\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where

$$B_0 = \frac{4}{3}\left(\frac{k_3 C_{A_0}}{K}\right)$$

$$B = \frac{4}{3}\left(\frac{k_3 C_A}{K}\right)$$

$$K = k_2$$

The calculated electron concentration as a function of distance from the sodium surface is shown in Fig. 2 for $[N_2O] = 0$.

A first estimate of the N_2O concentration profile can then be made using the electron concentration obtained from the profile calculated above. This is done using eq. 17 which is a solution of eq. 15 assuming a constant electron concentration in an interval ΔY.

$$[17] \qquad [N_2O]_n = [N_2O]_{n-1} \frac{\cosh(BA(1 - \Delta Y/L))}{\cosh(BA)}$$

where ΔY = the distance interval, $Y_1 - Y_0, \cdots, Y_n - Y_{n-1}$ etc., $BA = (k_5 E/D_{N_2O})^{1/2} L$, k_5 = rate of reaction of electron with N_2O, E = average electron concentration over ΔY, D_{N_2O} = rate of diffusion of N_2O, L = effective distance from Y_n to the surface of the sodium.[2]

Equation 17 is used to calculate the N_2O concentration $[N_2O]_1$ a distance ΔY from Y_0, the point where the N_2O concentration $[N_2O]_0$ is the same as the bulk concentration. The value ΔY is chosen such that the electron concentration is relatively constant over the interval. Taking $Y_1 = Y_0 + \Delta Y$ as a new starting point this process is repeated until the concentration profile of the N_2O has been calculated to the surface of the sodium. The equation for the N_2O profile can then be obtained.

The first approximation of the N_2O concentration as a function of distance from the sodium surface can be used to calculate a better estimate of the electron concentration gradient from the solution of the electron diffusion eq. 14. Equation 14 can be solved only for constant N_2O concentration. The solution obtained is the same as eq. 16 except that

$$K = k_2 + k_5[N_2O]$$

The distance Z must be small enough that the N_2O concentration does not vary within the interval. Therefore a step-by-step process is again used to calculate a distance for each decreasing electron concentration. The N_2O concentration used is that calculated from the N_2O concentration gradient equation.

The electron concentration profile above is used to obtain a better estimate of the N_2O concentration, which in turn is used to calculate a more accurate electron concentration profile. The process is repeated until convergence to a constant value is obtained. The calculated N_2O and electron concentrations (in the presence of N_2O) are also shown in Fig. 2. From these values the percentage N_2 is calculated. The calculated values (Table 2) do not give an exact fit with the experimental values but are in much better agreement than that obtained by simple competitive kinetic calculations. No attempt was made to vary the rate or diffusion constants in order to obtain a better fit. It was felt that the mathematical treatment was not exact enough to merit this fitting procedure.

(4) Scavenger Kinetics with Added Inert Solvent

The addition of ether, which reacts at a negligible rate with sodium, decreased the rate of formation and thus the concentration of the electron; this made it easier for the N_2O to scavenge electrons, reaction 5, in competition with reaction 3. The expected N_2 yields can be calculated using the same equations as in

[2]The parameter L arises from the boundary conditions that there is no diffusion of N_2O through the sodium surface. At a constant electron concentration, L is equivalent to the distance from Y_0 to the surface of the sodium. Since the electron concentration is greater near the sodium surface, more N_2O will be removed than if the electron concentration were constant. Parameter L takes this into consideration and hence has a value larger than the actual distance from Y_0 to the surface of the sodium. Hence, the larger value of L is related to the concentration gradient and to a first approximation

$$L = \left(\int_{Y_0}^{\text{Na surface}} C_A \, dY\right)/C_A.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

section 3 and are given in Table 2. These calculations indicate that N_2O should be greater than 10^3 times as effective in scavenging the electron when an inert solvent has been added, which confirms the effect observed experimentally (Table 2).

Conclusions

The reaction of sodium with alcohol to produce hydrogen involves the electron as an intermediate. The electron in pure alcohol reacts mainly bimolecularly with another electron to produce hydrogen. It is suggested that an electron dimer is formed prior to the production of hydrogen. A comparison of the isotope effect in alcohol ($\alpha = 2$) and water suggests that this dimer is desolvated before the formation of hydrogen and this desolvation contributes to the finite lifetime of the dimer.

A Re-examination of the Yields in the High Dose Rate Radiolysis of Gaseous Ammonia[1]

A. W. BOYD, C. WILLIS, AND O. A. MILLER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received January 14, 1971

Eyre and Smithies have recently obtained radical yields of $G_{NH_2} = G_H = 10.4$ in the radiolysis of gaseous ammonia. The consistency of these with N_2, H_2, and N_2H_4 yields obtained in the high dose rate radiolysis of NH_3 and NH_3–C_3H_6 mixtures has been shown by numerical integration of the rate expressions in a simple radical mechanism. These calculations give a value of $2.1 \pm 0.5 \times 10^{10}\ M^{-1}\ s^{-1}$ for the reaction of H atoms and NH_2 radicals and a ratio of recombination to disproportionation of 6:1.

Eyre et Smithies ont récemment obtenu les rendements radicalaires de $G_{NH_2} = G_H = 10.4$ lors de la radiolyse d'ammoniaque gazeux. Ces résultats sont consistants avec les rendements de N_2, H_2 et N_2H_4 obtenus lors de la radiolyse de NH_3 et de mélanges NH_3–C_3H_6 aux débits de dose trés éleves; ceci a pu être mis en évidence par intégration numérique des expression de vitesse dans un mécanisme radicalaire simple. Ces calculs conduisent à une valeur de $2.1 \pm 0.5 \times 10^{10}\ M^{-1}\ s^{-1}$ pour la réaction d'atomes d'hydrogène et de radicaux NH_2, et à un rapport recombinaison sur disproportionation de 6:1.

Canadian Journal of Chemistry, 49, 2283 (1971)

Introduction

In a recent paper (1) we gave values for the yields of H_2, N_2, and N_2H_4 in the radiolysis of gaseous ammonia and ammonia–propene mixtures with intense electron pulses at a dose rate of 2×10^{27} eV g^{-1} s^{-1}. Minimum primary radical yields of $G_{NH_2} = G_H = 4.8$ were derived from the yields in NH_3–C_3H_6 mixtures by extrapolating to zero C_3H_6 concentration and assuming for these extrapolated values that reactions of NH_2 with propene, propyl radicals, and residual H atoms could be neglected.

Nishikawa *et al.* (2) using NH_3–C_3H_8 mixtures at low dose rates reported a value of $G_H = 5.1$. This is lower than the yield of $G_H = 7.2$ obtained by Johnson and Simic (3) from the same system. Jones and Sworski (4) using both NH_3–N_2H_4 and NH_3–D_2 mixtures obtained a value of $G_H = 12.5$. A paper just published by Eyre and Smithies (5) reports $G_{NH_2} = G_H = 10.4$ from a very careful study using a variety of additives. They suggest that the low values reported in refs. 2 and 3 are due to the build-up of propene in NH_3–C_3H_8 mixtures.

It is clearly of interest to determine, then, if our product yields at high dose rates are consistent with the higher and apparently most reliable primary yields of Eyre and Smithies. To do this we have assumed the simplest mechanism, taken experimentally measured values for the rate constants of some of the reactions and derived the values of the other rate constants by numerical integration of the rate expression (using the computer program of Schmidt (6)). We have also measured the yield of propylamine in NH_3–C_3H_6 mixtures at 2×10^{27} eV g^{-1} s^{-1} at room temperature and the yields of N_2, H_2, and N_2H_4 from room temperature to 460 °C in pure NH_3 at one tenth this dose rate and determined the consistency of these new data.

Experimental

Irradiation Procedure and Analysis

The irradiations of NH_3 and NH_3–C_3H_6 mixtures and the analyses for H_2, N_2, and N_2H_4 were as described in (1).

Propylamine was analyzed by gas chromatography using Chromasorb 103. To obtain consistent results with the propylamine it was found necessary to use Teflon plug stopcocks as both neoprene O-ring or greased stopcocks gave irreproducible results.

The pyrolysis corrections in the irradiation of pure NH_3 above 400 °C were 10–20%. These are less than would be inferred from the corrections at the higher dose rate in ref. 1. This reduction in the magnitude of the corrections was obtained by reducing the time the sample was in the furnace before irradiation. It was found that the sample gas reached thermal equilibrium within 5 min.

Dosimetry

In the previous work (1) and in the irradiations of NH_3–C_3H_6 mixtures in the present work the window of the quartz cell was placed ~3 cm from the Febetron

[1]AECL No. 3894.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tube window. In this position the dose in the gas is 1.6 Mrads per pulse. A dose rate one tenth of this was obtained by putting a 0.005 cm Ta scattering foil 2 cm from the tube window and placing the cell window 5 cm from the foil. The irradiations of pure NH_3 at temperatures from room temperature to 450 °C in ref. 1 were repeated with this lower dose rate.

The dosimetry at both dose rates is based on the yield of nitrogen of $G(N_2) = 12.4$ in N_2O radiolysis (7, 8). This value was established by calorimetry at the higher dose rate. It is expected to be the same at the lower dose rate (8) and this has been confirmed by measurement of the ozone yield in oxygen radiolysis. At both dose rates $G(O_3) = 12.8 \pm 0.6$ relative to $G(N_2) = 12.4 \pm 0.4$. The value of the ozone yield in single pulse irradiations should be constant down to at least 10^{25} eV g^{-1} s^{-1} (9).

Results

(a) Propylamine in the Radiolysis of NH_3–C_3H_6 Mixtures

The yields of propylamine in NH_3–C_3H_6 mixtures at room temperature and a pressure of 760 Torr are compared with the hydrazine yields in these mixtures in Fig. 1. These yields were obtained at a dose rate of 2×10^{27} eV g^{-1} s^{-1}.

(b) Hydrazine, Hydrogen, and Nitrogen in Pure Ammonia

The yields of N_2H_4, H_2, and N_2 in pure NH_3 at 760 Torr at temperatures to 460 °C and a dose rate of 2×10^{26} eV g^{-1} s^{-1} are compared with the yields reported in ref. 1 at 2×10^{27} eV g^{-1} s^{-1} in Fig. 2.

In ref. 1 we reported an increase in yields with decreasing pressure below 700 Torr at room temperature. We have since determined the effect of decreasing pressure at 300 °C and 2×10^{27} eV g^{-1} s^{-1}. The relative increase is not noticeably different at this higher temperature from that observed at 25 °C.

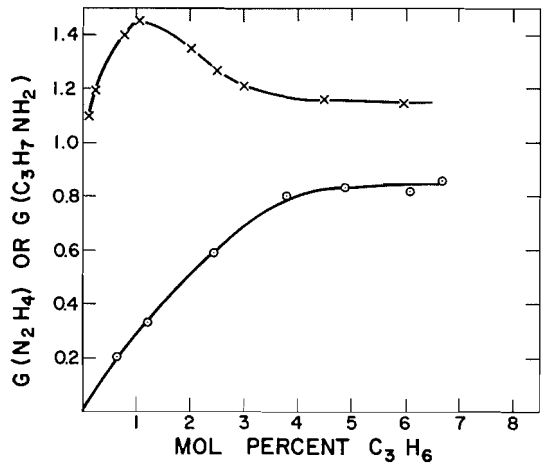

FIG. 1. Yields of $C_3H_7NH_2$ and N_2H_4 from the radiolysis of NH_3–C_3H_6 mixtures at 700 Torr, 25 °C at 2×10^{27} eV g^{-1} s^{-1}. ○, $C_3H_7NH_2$; ×, N_2H_4.

Discussion

The consistency of our data with the yields of Eyre and Smithies will be discussed under three headings: NH_3 at room temperature, NH_3–C_3H_6 mixtures at room temperature, and NH_3 at high temperatures.

As discussed in ref. 1 the reactions producing radicals should not be different at $\sim 10^{27}$ eV g^{-1} s^{-1} from those at low dose rates. These are assumed to be

[1] $NH_3 \rightsquigarrow NH_3^*$

[2] $NH_3^* \rightarrow NH_2 + H$

[3] $NH_3^* \rightarrow NH + H_2$

[4] $NH_3 \rightsquigarrow NH_3^+ + e$

[5] $NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$

[6] $NH_4^+ + e \rightarrow NH_3 + H$

The yield of reaction 3 is taken to be 0.74 G units (2–5).

The radical yields, then, at our dose rates should be those measured by Eyre and Smithies. The subsequent mechanism for high dose rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

radiolysis, as discussed below, will be simpler than the low dose rate mechanism due to the absence of back reactions of the radicals with the products (1).

NH_3 at 25 °C

At 2×10^{27} eV g^{-1} s^{-1} in pure NH_3 from 1 to 5 atm and for doses from 1×10^{20} to 5×10^{20} eV g^{-1}, $G(H_2) = 3.6 \pm 0.1$, $G(N_2) = 1.0 \pm 0.05$, and $G(N_2H_4) = 0.58 \pm 0.05$ (1).

In order to satisfactorily explain these yields we must assume the following set of reactions, 7–12.

[7] $NH_2 + NH_2 \rightarrow N_2H_4$

[8] $NH_2 + NH_2 \rightarrow NH + NH_3$

[9] $NH_2 + H \rightarrow NH_3$

[10] $NH_2 + H \rightarrow NH + H_2$

[11] $H + H \rightarrow H_2$

[12] $NH + NH \rightarrow N_2 + H_2$

As well as recombination of NH_2 radicals to form hydrazine, reaction 7, it is known (10) that these radicals can also disproportionate to give NH and NH_3, reaction 8. The difference between our product yields and the high primary radical yields can only be explained by a back reaction, reaction 9, and this must be accompanied by reaction 10 to explain the relatively high hydrogen yield we observe. Reaction 11 is well known and removes the residual hydrogen atoms and reaction 12 has been observed directly by Meaburn and Gordon (11) and may account for the removal of NH radicals from the system.

Another possible reaction is 13 presumably (12) followed by reaction 14.

[13] $NH + NH_2 \rightarrow N_2H_3$

[14] $N_2H_3 + N_2H_3 \rightarrow N_2 + 2NH_3$

On the basis of the value of 7×10^{11} M^{-1} s^{-1} reported (11) for k_{12} NH radicals should disappear by reaction 12 provided k_{13} is much smaller, of the order of k_7. In any event the primary yield of NH is less than 10% that of NH_2 and the mode of NH disappearance will not greatly affect reactions 7 to 11.

Hanes and Bair (13) from work with discharges in NH_3 at low pressures give a value of 2.3×10^9 M^{-1} s^{-1} for the second order disappearance of NH_2 at the high pressure limit (above 0.85 Torr) and this can be equated to $k_7 + k_8$. The value of k_{11} is 1.6×10^8 M^{-1} s^{-1} (at 1 atm) (14).

Experimental values for reactions 9 and 10 have not been reported though Hanes and Bair (13) have calculated a value of $\sim 1.3 \times 10^{10}$ M^{-1} s^{-1} for the high pressure limit above 1000 Torr.

In our calculations we have taken the yields of Eyre and Smithies, set $k_7 + k_8 \approx 2.3 \times 10^9$ M^{-1} s^{-1} and then determined, using a computer program based on that of Schmidt (6), $G(N_2H_4)$, $G(H_2)$, and $G(N_2)$ for various values of k_7/k_8 and k_9, k_{10}, k_{11}, and k_{12}. The results for these calculations are given in Table 1.

It is evident from Table 1 that the yield of N_2H_4 is mainly dependent on k_7 and k_9 as changes in the other rate constants have little effect on this yield. Similarly the yield of hydrogen for fixed values of k_7 and k_9 is largely dependent on k_{10}. Assuming the mechanism given in the table and taking $k_7 = 1.8 \times 10^9$ M^{-1} s^{-1} and $G_{NH_2} = G_H = 10.4$, k_9 must be equal to 1.8×10^{10} M^{-1} s^{-1} and k_{10} to 2.9×10^9 M^{-1} s^{-1} within $\pm 20\%$. Since the rate constants of the other reactions can be changed by a factor of 2 or more without any significant change in the yields our results give little information as to their values.

The calculated values for the concentrations of NH_2, H, NH, N_2H_4, H_2, and NH_3 formed by recombination of $NH_2 + H$ as a function of time following a Febetron pulse are shown in Fig. 3. The initial rapid decrease in the H atom

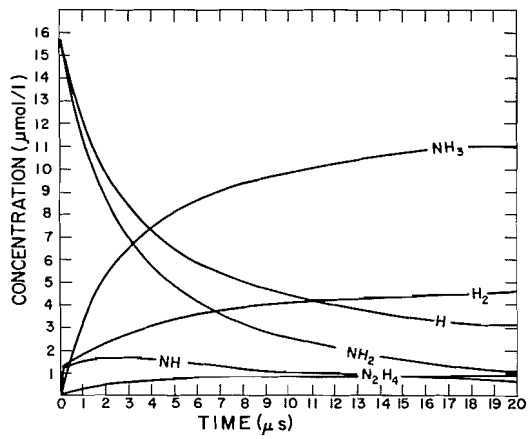

FIG. 3. Calculated concentrations of NH_2, H, NH, N_2H_4, and H_2 *vs.* time following 1.6 Mrads 60 ns electron pulse in NH_3 at 700 Torr and 25 °C at a maximum dose rate of 1.5×10^{27} eV g^{-1} s^{-1}. The calculated concentration of NH_3 formed by reaction 9 is also shown. The shape of the curve for NH is dependent largely on the value assumed for reaction 12.

$= 4 \times 10^8$		0.60	3.70	1.07
†$k_{12} = 5 \times 10^9$		0.59	3.57	1.07
$= 1 \times 10^{11}$		0.59	3.57	1.07

*Assumed primary radical yields: $G_{NH_2} = G_H = 10.4$; $G_{NH} = G_{H_2} = 0.74$.
†In each of these cases the other rate constant values are as listed in the first section of the table.

concentration is due mainly to reaction with NH_2 radicals, reaction 9. As NH_2 radicals are also disappearing by reactions 7 and 8, there is an excess of H atoms which disappear relatively slowly by reaction 11. It is obvious from the figure that the major reaction is reformation of NH_3.

NH_3–C_3H_6 Mixtures

The increase in the N_2H_4 yield with the addition of C_3H_6 shown in Fig. 1 is primarily due to the removal of H atoms by reaction 15

[15] $$H + C_3H_6 \rightarrow C_3H_7$$

thus reducing the occurrence of reactions 9 and 10, and favoring reactions 7 and 8. The calculated fit to our experimental results for these mixtures using the yields in ref. 5 will be largely dependent on the value of the ratio k_{15}/k_8 at low propene concentrations. Reported values of k_{15} range from 10^7 M^{-1} s^{-1} to 6×10^8 M^{-1} s^{-1} (15) and we have calculated yields using values of k_{15} in this range.

Propylamine will be formed by reaction 16

[16] $$NH_2 + C_3H_7 \rightarrow C_3H_7NH_2$$

The calculations predicted that the amount of $C_3H_7NH_2$ from this reaction would reach a plateau value at ~1 mol% C_3H_6. To account for the increase observed at higher C_3H_6 concentrations in Fig. 1*a*, reaction of the form

[17] $$NH_2 + C_3H_6 \rightarrow X \rightarrow C_3H_7NH_2$$

must be occurring. This will give a linear dependence of the $C_3H_7NH_2$ yield on C_3H_6 concentration. The reduction in N_2H_4 at propene concentrations above 1% is presumably due to reaction of NH_2 with propene as in reaction 17 or to form other products as in reaction 18.

[18] $$NH_2 + C_3H_6 \rightarrow P$$

The rate constant for reaction 18 will also have a marked effect on the calculated yields as is shown in Table 2.

The calculated values for the yields of N_2H_4, H_2, N_2, and $C_3H_7NH_2$ for the range of C_3H_6 concentrations used are compared with the experimental values in Fig. 4. The overall fit is satisfactory. The rise and fall in the N_2H_4 yields are predicted quite well by the mechanism and the fit to both the N_2 and $C_3H_7NH_2$ is probably within the experimental error. The experimental hydrogen yields above 2% propene are considerably higher than the calculated curve. This is to be expected as contributions from direct radiolysis of propene and from disproportionation reactions of H atoms with hydrocarbon radicals were neglected. As well as

†In each of these cases the other rate constant values are as listed in the first part of the table.

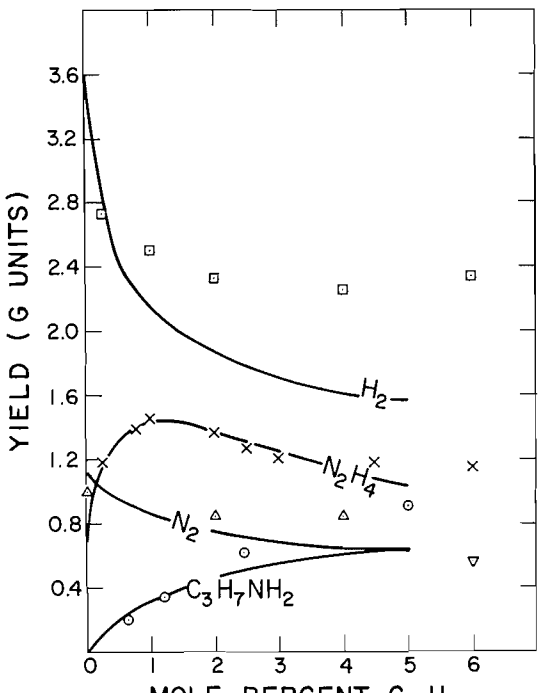

FIG. 4. Calculated and experimental yields from the radiolysis of NH_3–C_3H_6 mixtures at 700 Torr, 25 °C at a dose rate of 2×10^{27} eV g^{-1} s^{-1}. Solid lines, calculated values.

the product yields, the contributions of each of the reactions of NH_2 and H have been calculated. The importance of these various reactions as a function of C_3H_6 concentration is shown in Table 3. It is evident that at any propene concentration, less than 30% of the NH_2 radicals form N_2H_4. As the reaction of these with H atoms is suppressed their reaction with C_3H_6 increases. The simple extrapolation made in ref. 1 could then give only minimum values for the primary radical yields.

The value of $k_{15} = 8.5 \times 10^8$ M^{-1} s^{-1} used in these calculations is necessary to give the observed dependence of the N_2H_4 yield on the propene concentration. The decrease in $G(N_2H_4)$ above 1 mol% C_3H_6 must be due to removal of NH_2 by propene and this in turn requires a high value of k_{15}. This value of k_{15} is at the high end of the reported values (15) but is consistent with the value of 5.5×10^8 M^{-1} s^{-1} reported recently for the high pressure limit of $H + C_2H_4$ (16).

NH_3 at High Temperatures

It was proposed in ref. 1 that the increase in the yields with temperature shown in Fig. 2 is due to reaction 20.

[20] $H + NH_3 \rightarrow H_2 + NH_2$

A value of $k_{20} = 4 \pm 2 \times 10^9 \exp(-10\,000 \pm$

1500 cal/RT) M^{-1} s^{-1} was derived from the observed increases in product yields assuming the primary yields of $G_{NH_2} = G_H = 4.8$. The relative rates of k_{20} were estimated from the total NH_2 formed at the different temperatures. To find the absolute value it was assumed that at ~380 °C, k_{20} [NH_3] = ($k_9 + k_{10}$) [NH_2] *i.e.* k_{20} [4×10^{-2} M] = 1.1×10^{10} [$\sim 5 \times 10^{-6}$ M], see Fig. 3.

Using the values for the rate constants of reactions 6 to 12 in the first part of Table 1, values for k_{20} to give the experimental yields at the higher dose rate were calculated with the computer program. These values give an activation energy of 10.5 kcal mol^{-1} and a pre-exponential factor of 3.6×10^9 M^{-1} s^{-1} in good agreement with the rate constant in ref. 1 However, treating the experimental yields at the lower dose rate in the same way gives an activation energy of 7.2 kcal mol^{-1} and a pre-exponential factor of 8×10^7 M^{-1} s^{-1}. For both dose rates the derived rate expression gave a very good fit to the experimental values. This inconsistency in values for k_{20} indicates that the rate constants for some or all of reactions 6 to 12 change with temperature and that a precise value of k_{20} cannot be estimated. The most probable changes in these reactions are in the ratios of disproportionation to combination for $NH_2 + NH_2$ and $H + NH_2$. Figure 5 compares the experimental N_2H_4 yields for both dose rates with values calculated setting k_{20} equal to the intermediate value of 4×10^8 exp (−8500/cal/RT) M^{-1} s^{-1}. This clearly shows the effect of the uncertainty in k_{20} and further, that no single value can give agreement with both dose rates.

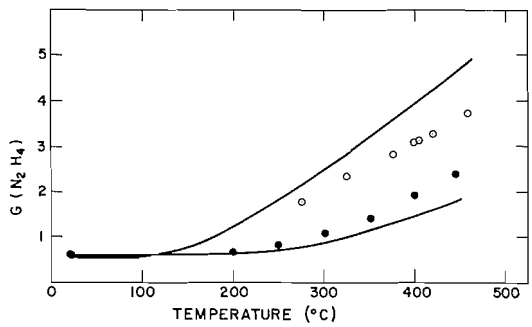

FIG. 5. Calculated and experimental yields of N_2H_4 from the radiolysis of NH_3 at 700 Torr *vs.* temperature. Upper solid line, calculated values at 2×10^{26} eV g^{-1} s^{-1}; lower solid line, calculated values at 2×10^{27} eV g^{-1} s^{-1}. ○, experimental yields at 2×10^{26} eV g^{-1} s^{-1}; ●, experimental yields at 2×10^{27} eV g^{-1} s^{-1}.

Conclusions

The yields of N_2H_4, H_2, and N_2 obtained in irradiations of NH_3 and NH_3–C_3H_6 mixtures at 2×10^{27} eV g^{-1} s^{-1} are consistent with the primary radical yields of $G_{NH_2} = G_H = 10.4$ reported by Eyre and Smithies (5). Assuming that reactions of NH with NH_2 or H are not significant at these dose rates and that the rate constant for NH_2 recombination is 1.8×10^9 M^{-1} s^{-1}, the rate

For personal use only.

constants for recombination and disproportionation of H with NH_2, k_9 and k_{10} are $1.8 \pm 0.4 \times 10^{10}$ and $2.9 \pm 0.7 \times 10^9$ M^{-1} s^{-1}, respectively. The results in NH_3–C_3H_6 mixtures are consistent with $k_{NH_2 + C_3H_6} = 3 \times 10^7$ M^{-1} s^{-1}.

Comparison of the product yields from 200–450° at 2×10^{27} and 2×10^{26} eV g^{-1} s^{-1} indicates that a precise derivation for the rate expression for reaction 20 cannot be obtained from our data.

[20] $$H + NH_3 \rightarrow H_2 + NH_2$$

The rate constants we have derived are clearly dependent upon the mechanism we have assumed. Although it is difficult to assess the uniqueness of this mechanism, it seems clear that the back reaction must be an order of magnitude faster than the reaction between NH_2 radicals.

Thermal Decomposition of di-*tert*-Butyl Peroxide in Binary Mixtures near the Critical Point

C. K. YIP AND H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received December 24, 1970

The thermal decomposition of di-*tert*-butyl peroxide has been studied in the presence of high pressures of cyclopropane; the rate constant for the decomposition was determined from the sum of the rates of formation of *tert*-butanol and acetone. In the temperature range 125–160 °C, *i.e.* above the critical point of cyclopropane, concentrations of cyclopropane of between 2.6 and 3.6 mol/l (60–80 amagats) were used; in the temperature range 100–124 °C, *i.e.* below the critical point of cyclopropane, an equivalent mean (liquid + gas) cyclopropane concentration was used. An Arrhenius plot of the rate constants for the peroxide decomposition is continuous through the critical point of the cyclopropane, and is indistinguishable from the best Arrhenius line representing all previous work on the reaction.

However, an Arrhenius plot of the ratio of the rates of formation of *tert*-butanol and acetone shows a marked discontinuity at the critical point, but further investigation shows that this results from the unequal distribution of the reactant peroxide between the two phases which are present below the critical point of the cyclopropane.

Less extensive series of experiments using propane, isobutane, cyanogen, and carbon dioxide as pressurizing gases confirm the pressure-independence of the rate of decomposition of di-*tert*-butyl peroxide: the experiments with propane and isobutane confirm the phase-independence of the rate; the propane experiments also exhibit the same apparent kinetic discontinuity at the critical point. Finally, rate-constant data are obtained for the reactions of the *tert*-butoxy radical with cyclopropane and isobutane, and for the addition of methyl radicals to cyanogen.

La décomposition thermique du péroxyde di-*tert*-butylique a été étudiée en présence de fortes pressions de cyclopropane; la constante de vitesse de décomposition a été déterminée à partir de la somme des vitesses de formation du *tert*-butanol et de l'acétone. Dans un intervalle de température de 125–160 °C, *i.e.* au-dessus du point critique du cyclopropane, des concentrations de cyclopropane entre 2.6 et 3.6 mol/l (60–80 amagate) ont été utilisées; dans l'intervalle de température 100–124 °C, *i.e.* en-dessous du point critique du cyclopropane, une moyenne équivalente (liquide + gaz) de concentration de cyclopropane a été utilisée. Un graphe d'Arrhénius des constantes de vitesse pour la décomposition du péroxyde est continu en passant par le point critique du cyclopropane, et est indiscernable de la meilleure ligne d'Arrhénius représentant tous les travaux antécédents sur la réaction.

Cependant, un graphe d'Arrhénius du rapport des vitesses de formation du *tert*-butanol et de l'acétone montre une discontinuité marquée au point critique, mais des recherches ultérieures montrent que ceci résulte d'une distribution inégale du réactif péroxyde entre les deux phases qui sont présentes au-dessous du point critique du cyclopropane.

Des séries d'expériences moins étendues utilisant le propane, l'isobutane, le cyanogène et le dioxyde de carbone comme gas pour pressuriser confirment que la vitesse de décomposition du péroxyde di-*tert*-butylique est indépendante de la pression. Les expériences avec le propane et l'isobutane confirment que la vitesse est indépendante de la phase; les expériences avec le propane montrent également la même discontinuité cinétique apparente au point critique. Enfin, les données de constante de vitesse sont obtenues pour les réactions du radical *tert*-butoxyle avec le cyclopropane et l'isobutane et pour l'addition des radicaux méthyles au cyanogène.

Canadian Journal of Chemistry, 49, 2290 (1971)

The purpose of the work described in this paper is two-fold, (*i*) to extend the study of the thermal decomposition of di-*tert*-butyl peroxide (DTBP) to higher pressures of added gases than have been used before, with a view to eliminating the concept of "induced decomposition" from the terminology of unimolecular reaction theory; and (*ii*) to study the decomposition in both liquid and gaseous phases, keeping as far as possible all other system parameters constant, possibly to throw light on the apparent difference between the rate of this reaction in the gas phase and in solution.

(*i*) We have already emphasized the importance of studying this thermal decomposition in the presence of high pressures of added gases, but in our earlier study, we were only able to perform satisfactory experiments using, at most, 10–15

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

atm of pressurizing gas (1). Improvements in our analytical procedures (2) now enable us to use ten times as much of certain pressurizing gases, in particular propane, cyclopropane, and carbon dioxide. Much of the preliminary work was done using propane, but for reasons explained below, the most extensive series of experiments was performed with cyclopropane as the pressurizing gas. Because the hydrocarbons used have high compressibility factors in the experimental temperature range, the absolute pressure is, however, much less than that of an ideal gas at the same molar concentration; it is therefore convenient to use the amagat unit of density where 1 amagat is equivalent to 0.0446 mol l^{-1}. These experiments still reside in the concentration range where normal unimolecular reaction theories remain adequate and volume effects which have been observed in this reaction (3) and other first order reactions (4) at still higher pressures are not in question.

(*ii*) The thermal decomposition of di-*tert*-butyl peroxide has been studied in both the gaseous and liquid phases by Raley, Rust, and Vaughan (5). They found that in each of the three solvents they used, the rate of decomposition was about 50% greater than it was in the gas phase, throughout their experimental temperature range. We (2) have recently studied some aspects of this reaction in the gas phase using high pressures of added propane, and we decided to extend these measurements down below the critical temperature of propane to see if any change in kinetic behavior could be detected; the liquid-phase results of Raley, Rust, and Vaughan (5) would indicate that we might find a discontinuity or a curvature in the Arrhenius plot of the rate constant for the decomposition of the peroxide, at or near the critical point of the solvent.

Experimental

The preparation and/or purification of di-*tert*-butyl peroxide, carbon dioxide, and propane have been described previously (1, 2). Cyclopropane was supplied by Matheson of Canada Ltd: the principal impurities were stated to be air and cyclopropyl chloride; the latter would be expected to have a marked catalytic effect on the peroxide decomposition (1). After conventional degassing procedures with rejection of tail-fractions, the material was found to be free of any impurity that could be detected by mass-spectrographic or gas-chromatographic techniques, and can safely be assumed to have been cyclopropane, perhaps containing traces of other C_3 hydrocarbons. Isobutane was of research grade, supplied by Phillips Petroleum Company, and was similarly treated; cyanogen was supplied by Matheson of Canada Ltd.

Two stainless-steel reaction vessels were used, and their volumes were both determined to be in the range 11.90 ± 0.05 cc. The remainder of the experimental procedures have been described in detail (1, 2): in each of the main series of experiments, a total of 10^{-4} mol of peroxide was used, together with a propane or cyclopropane concentration of 3.1 ± 0.5 mol l^{-1}; departures from these standard conditions are noted below as they arise.

Results and Discussion

(a) Exploratory Experiments using Propane

The accepted reaction scheme (see refs. 1 and 2 for further discussion) for the thermal decomposition of di-*tert*-butyl peroxide is

[1] $$\text{DTBP} \rightarrow 2t\text{-BuO}$$

[2] $$t\text{-BuO} \rightarrow \text{CH}_3 + \text{CH}_3\text{COCH}_3$$

[3] $$t\text{-BuO} + \text{RH} \rightarrow t\text{-BuOH} + \text{R etc.}$$

The decomposition of the peroxide was studied between 90 and 104 °C at propane densities of about 70–75 amagats. Rate constants k_1 were established by measuring the rate of formation of acetone + *tert*-butanol as described previously (2), and when plotted in Arrhenius form, whether obtained at temperatures above or below the critical point, were consistent with those obtained previously (1). Since the critical temperature of propane (6) is 96.7 °C, and the reaction becomes too slow (1) for convenient study below 90 °C, the accessible liquid range is somewhat limited; in fact, at our propane concentrations, the gas density is such (7) that two phases would only be present in pure propane below about 93 °C. At the same time, whilst the sum of acetone + *tert*-butanol formation did not appear to show anomalies at 90 °C, the ratio of acetone/*tert*-butanol was only about 50% of that expected by extrapolating the previous gas-phase data (2); unfortunately, at 90 °C, these ratios are quite small, and probably not very reliable. On both counts, therefore, the decisive experiment would need an added hydrocarbon having a higher critical temperature. The next hydrocarbon in the series is isobutane, with a critical temperature (6) of 135 °C, but this is a little too near the top of the accessible temperature range (1) for a reliable Arrhenius plot to be established in gas-phase experiments carried out above the critical temperature; also, the analytical problems are more severe because the boiling point of isobutane

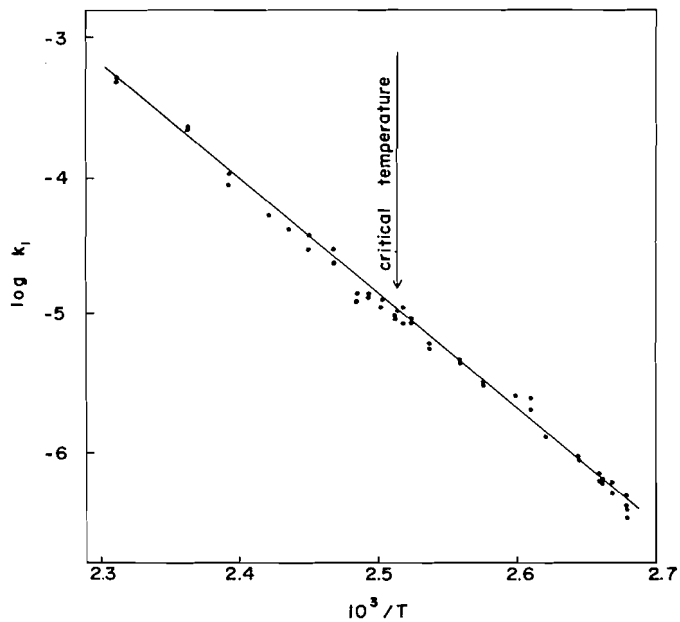

FIG. 1. Thermal decomposition of di-*tert*-butyl peroxide in the presence of 60–80 amagats of cyclopropane; the line shown in the diagram is not fitted to the points, but is the line selected for k_1 in our earlier review of the published data (1).

is too close to that of acetone. Two choices remain. One is to use suitable mixtures of propane and isobutane (or indeed other pairs of gases) tailored to a chosen critical temperature (8); the disadvantages of this approach are an increase in the complexity of the analytical procedure and the continual need to make up gas mixtures reliably conforming to the chosen critical temperature. The other is to use cyclopropane, which has a more convenient critical temperature (6) of 124.6 °C: the principal disadvantage of using cyclopropane was that its liquid and gas densities have not been measured near the critical point, so that one could not calculate reliably whether liquid should be present under any given conditions; it turned out subsequently that the presence of liquid could be inferred from the acetone/*tert*-butanol ratio.

(b) Experiments using Cyclopropane

Forty-seven experiments were carried out at cyclopropane densities between 60 and 80 amagats in the temperature range 100–160 °C. The results of these experiments are shown in Arrhenius form in Fig. 1: note that the line shown is *not* the best line drawn through these points, but is the "best" line (1) representing all previous work on this reaction, almost all of which was carried out at sub-atmospheric pressures. This, in our view, establishes[1] much more convincingly than our earlier work (1, 2) the absence of any pressure dependence in reaction 1; thus our previous comments about induced decomposition (1) are strongly reinforced.

Comparison between the Arrhenius parameters for the previously selected line (1) and the present results is[2]: for the selected line, log A_1 (s^{-1}) = 15.80 ± 0.03, E_1 (kcal/mol) = 37.78 ± 0.06; Fig. 1 (47 points), log A_1 (s^{-1}) = 15.62 ± 0.23, E_1 (kcal/mol) = 37.51 ± 0.42. The coincidence of our high-pressure experiments with earlier work is very satisfactory.

[1]Incidentally, using an analytical method somewhat different to any used previously: a slight variant of this method would be to use the methyl radical balance, *i.e.*, *tert*-butanol + methane + 2(ethane) as a measure of the extent of reaction; this proved to be more time-consuming and less reproducible, and was abandoned.

[2]Least-squares treatments of results reported in this paper use the method of York as noted previously (1) with the following assumed uncertainties in the temperature and rate constant, respectively: cyclopropane data: ±0.2 °C and ±10%; other data: ±0.2 °C and ±20%; data from refs. 13 to 15: ±0.1 °C and ±5% (for sake of consistency with other values quoted in ref. 1); errors quoted for the calculated A and E are standard deviations.

Further inspection of Fig. 1 shows that 26 of the 47 experiments were conducted below the critical temperature of cyclopropane. In the absence of gas and liquid density for cyclopropane[3] and of dew- and bubble-point data for peroxide–cyclopropane mixtures, it is impossible to predict whether liquid is present in any experiment, and if so, how much. However, by comparison with other hydrocarbons, it seems likely that at our cyclopropane concentrations, phase separation in pure cyclopropane would occur below about 119 °C; thus, in 20 of the 26 experiments carried out below T_c, liquid must have been present to a greater or lesser extent, and in all probability, at the lowest temperature (100 °C) the distribution would be of the order of half liquid – half gas. However, from evidence presented in Appendices 1 and 2, it is clear that liquid onset occurs in our binary mixtures at, or very close to, the critical temperature of the hydrocarbon. Thus, our evidence is that the rate of reaction 1 is completely independent of phase in light hydrocarbon substrates. The cause of the acceleration observed by Raley, Rust, and Vaughan (5) is not obvious, but the possibility that each of the three solvents they used could have contained *traces* of halogenated impurity, which would catalyze (1) reaction 1, should not be overlooked.

The main conclusions, therefore, in respect of the two objectives defined at the beginning of this paper are (*i*) that there is no anomalous pressure dependence at high pressures in the thermal decomposition of di-*tert*-butyl peroxide; and (*ii*) that the rate of decomposition of the peroxide is the same in light hydrocarbon solutions as it is in the gas phase. Appendices 1 to 3 below describe other features of these binary systems containing di-*tert*-butyl peroxide, and Appendix 4 brings up to date our earlier review of the work on the thermal decomposition of this molecule.

The authors are indebted to Professor J. S. Rowlinson, F.R.S., for helpful correspondence.

Appendix 1

The Reaction of tert-BuO with Cyclopropane

In Fig. 2 we show, in Arrhenius form, a plot of the ratio

$$\frac{k_2}{k_3} = \frac{[\mathrm{RH}]R_{\text{acetone}}}{R_{\textit{tert}\text{-butanol}}}$$

and it is clear that there is a marked break at the critical point of cyclopropane, similar to that indicated by the preliminary propane experiments; in this expression [RH] is simply the total number of moles of cyclopropane present in the vessel divided by the volume of the vessel. Hence, above T_c, the activation energy difference $(E_2 - E_3)$ is about 11 kcal/mol, but below T_c, there is an apparent difference of about 17 kcal/mol between E_2 and E_3; the figure of 11 kcal is consistent with previous data on the reaction of the *tert*-butoxy radical with toluene (2), propane (2), butane (10), and isobutane (10). A change in slope of this magnitude is much too large, in our view, to be caused by any cage or diffusion effects which may be present (3). We believe the explanation to be the following, and in the Appendix 2 below, we describe experiments which support this contention. The (approximately 400 to 1) cyclopropane–peroxide mixtures we use are such that two phases appear whenever the temperature is below T_c of the hydrocarbon, the liquid/gas ratio of course increasing as the temperature decreases. The concentrations of both hydrocarbon and peroxide will be different in each phase, each giving rise to its own characteristic acetone and *tert*-butanol production rates. It is a simple matter to write down expressions for the rates of formation of each product in either phase, and to show that the ratio of acetone/*tert*-butanol is different in the two phases; it is not quite so simple to show that the overall (*i.e.* gas + liquid) rate ratio is *less* than the gas-phase rate ratio would be at *the same mean* hydrocarbon concentration.

A least-squares treatment of the 21 points in Fig. 2, corresponding to experiments carried out above the critical point of cyclopropane gives

$$E_2 - E_3 = 10.96 \pm 0.47 \text{ kcal/mol}$$

$$\log \frac{A_2}{A_3} = 7.06 \pm 0.25 \text{ (mol/l)}$$

the rate of attack of the *tert*-butoxy radical on cyclopropane is just about a factor of ten slower than on propane (for example, at 124 °C, the values of k_2/k_3 are 12 and 1.2, respectively), although the activation energies are very similar (2).

Appendix 2

Attempts to Detect the Dew Point

If only one phase is present, a plot of the ratio of acetone/*tert*-butanol formation against $[\mathrm{RH}]^{-1}$, at fixed temperature, is a straight line of slope k_2/k_3 passing through the origin (2). Thus, starting at low hydrocarbon concentrations, one should find acetone/*tert*-butanol ratios lying on a straight line when plotted against $[\mathrm{RH}]^{-1}$: the straight line should point toward the origin, and should have a slope equal to the value of k_2/k_3 which can be determined by extrapolation of the gas-phase data in Fig. 2; as soon as phase separation occurs, the acetone/*tert*-butanol ratios should fall below the line. With this in mind, a series of 33 experiments was carried out at 115 °C, at cyclopropane densities ranging from 1 to 64 amagats. That these experiments were reliable was judged from the acetone + *tert*-butanol formation, which of

[3]Since this paper was written, these data have become available (9) and our estimate of liquid onset is confirmed: 119 °C for the highest and 116 °C for the lowest densities used in the subcritical temperature range.

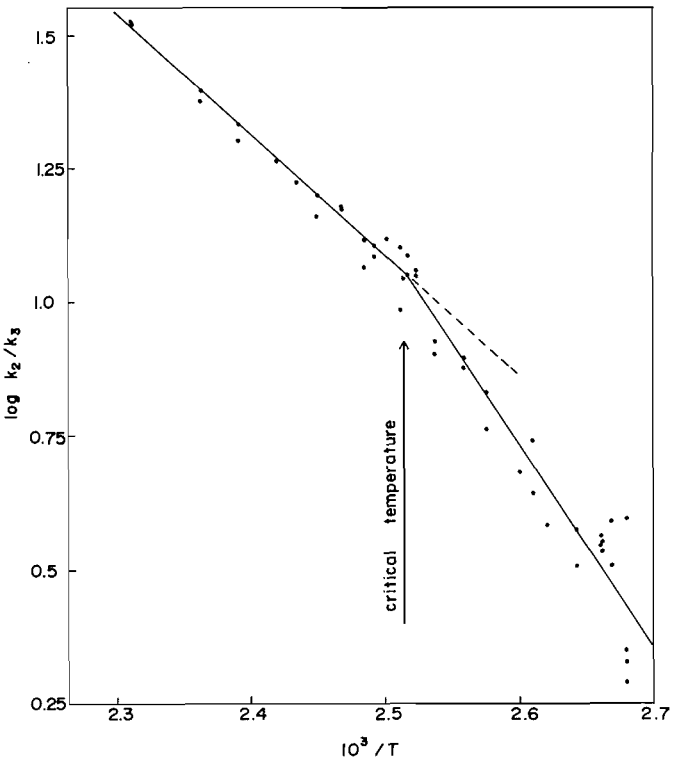

FIG. 2. Arrhenius plot of k_2/k_3 in the presence of 60–80 amagats of cyclopropane.

course gives k_1, and the mean of the 33 values of k_1 is shown in Fig. 4. At high pressures, the acetone/*tert*-butanol ratio was below the theoretical line as expected, but as the cyclopropane concentration was reduced, the ratios, instead of coming up to the predicted line, fell further and further below it! It was found, however, that if the vessel was packed with steel balls, lower acetone/*tert*-butanol ratios were obtained than at the same gas density in an unpacked vessel. It appears that reaction 3 has a heterogeneous component, which shows up because the reaction of *tert*-butoxy radicals with cyclopropane is so slow that some of the radicals scavenge hydrogen atoms from the metal surface to form *tert*-butanol; thus, a demonstration of the effect of liquid onset would need a much more reactive hydrocarbon, and preferably also a higher temperature.

Consequently, a similar series of experiments was performed using isobutane as the hydrocarbon; these experiments were carried out at 118.3 °C, the highest temperature at which accurate density data is available for isobutane (11). The results are shown in Fig. 3 for the acetone/*tert*-butanol formation ratio, and the values of k_1 derived from acetone + *tert*-butanol, used as a reliability check, are shown in Fig. 4. The low-pressure data in Fig. 3 do lie on a reasonable straight line having zero intercept and a slope k_2/k_3 of about 0.40 mol/l, indicating that the rate of reaction of the *tert*-butoxy radical with isobutane is about twice as fast as with propane at 118 °C. The high-pressure data in Fig. 3 do seem to fall below this line, and would suggest that the dew

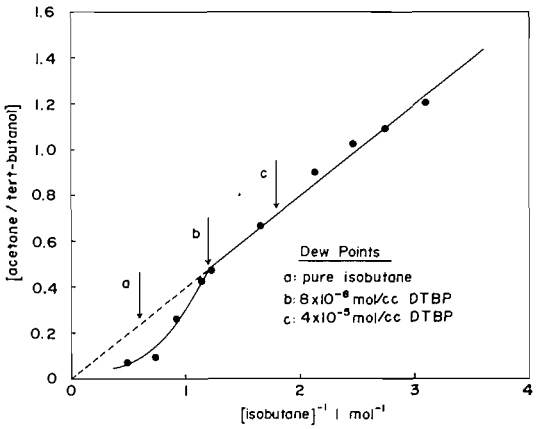

FIG. 3. Illustration of liquid onset in isobutane/di-*tert*-butyl peroxide mixtures at 118.3 °C.

point occurs near [isobutane]$^{-1} \approx 1.2$ l/mol, *i.e.* [isobutane] ≈ 0.8 mol/l ≈ 18.5 amagats; the dew point in *pure* isobutane (11) is at much higher densities (1.6 mol/l ≈ 36.6 amagats), also shown on Fig. 3. All the measurements plotted in Fig. 3 were made in the same reaction vessel. A second set, made in the other reaction vessel were distinguishable from them, having a slightly higher slope of 0.43 mol/l, but with the break at about the same

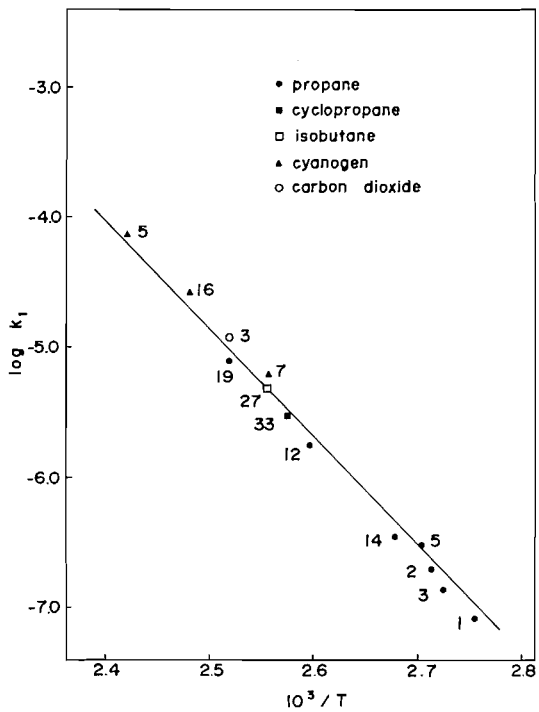

FIG. 4. Thermal decomposition of di-*tert*-butyl peroxide in the presence of high pressures of propane, cyclopropane, isobutane, cyanogen, and carbon dioxide: the line shown in the diagram is not fitted to the points, but is the line selected for k_1 in our earlier review of the published data (1); the integer adjacent to each point indicates the number of experiments the point represents.

density; presumably this slight difference in behavior is due to the heterogeneous effects already described above.

In a further attempt to confirm our hypothesis, this series of experiments was repeated in one reaction vessel using five times as much peroxide per filling (*i.e.* 5×10^{-4} mol). The dew point should now occur at even lower isobutane concentrations (8), and in fact a break similar to that shown in Fig. 3 occurred at about 0.55 mol/l (12.5 amagats). Unfortunately, this latter experiment is not absolutely conclusive because at low density, a falling-off in the acetone/*tert*-butanol ratio was observed, presumably as the result of abstraction from the wall; at the same time, the limiting high pressure gas phase rate-constant ratio k_2/k_3 appeared to be a little low, 0.35 mol/l, presumably for the same reason. Thus, we feel that our explanation of the break which occurs in Fig. 2 at the critical point of cyclopropane (and the similar one found for propane) is moderately well substantiated; hence, one has the possibility that in some system uncomplicated by wall effects and given somewhat more reproducible analytical procedures, dew-point curves could be deduced from kinetic observations.

Appendix 3

Experiments with Carbon Dioxide and Cyanogen

A few experiments were performed with carbon dioxide and with cyanogen as pressurizing gases. Virtually no *tert*-butanol was formed in these cases, and in this sense the values of k_1 shown in Fig. 4 more nearly resemble those determined previously (1) in experiments where only the rate of formation of acetone was measured.

The cyanogen experiments are interesting in several respects. In the first place, there is a very rapid removal of methyl radicals by cyanogen, to the extent that ethane could be detected only at sub-atmospheric pressures; on the other hand, no volatile nitrogen-containing products were found, only a brown coloration on the (glass) vessel walls, which was not paracyanogen. We postulate the reaction

$$[4] \qquad CH_3 + C_2N_2 \rightarrow [?] \rightarrow \text{solid products}$$

and will proceed to deduce its rate. Apart from forming ethane

$$[5] \qquad CH_3 + CH_3 \rightarrow C_2H_6$$

all the methyl radicals formed by reaction 2 must abstract from DTBP or acetone to form methane, or react with cyanogen. Thus, the rate of reaction 4 can be obtained from the methyl-radical balance *i.e.*

$$R_4 = R_{\text{acetone}} - R_{\text{methane}} - 2R_{\text{ethane}}$$

and in Fig. 5 we show a plot of $R_4/R_{\text{ethane}}^{1/2}$ against $[C_2N_2]$, the slope of which gives $k_4/k_5^{1/2} \approx 20$ mol$^{-1/2}$ cm$^{3/2}$ s$^{-1/2}$ at 130 °C; similar values of $k_4/k_5^{1/2}$ were obtained at 118 and at 140 °C, suggesting that reaction 4 has virtually zero activation energy, but rather a low frequency factor.

Second, the consistency of k_1 with the other data for reaction 1 means that even at the highest cyanogen concentrations (34 amagats), the *tert*-butoxy radical does not react with cyanogen to any detectable extent. And third, that at high cyanogen pressures, some methyl cyanide is formed: it can be detected in all experiments using more than 5 amagats of cyanogen; it is rather

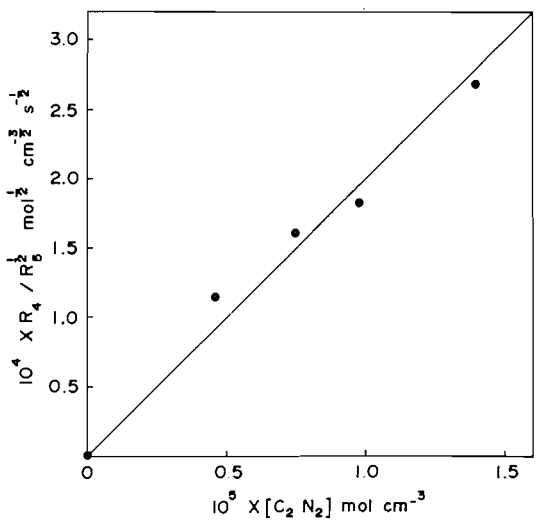

FIG. 5. The reaction of methyl radicals with cyanogen at 130 °C.

variable, but accounts for about 5% of the methyl radicals at these pressures, rising to more than 50% of the methyl radicals above 30 amagats. The reaction

[6] $$R + C_2N_2 \rightarrow RCN + CN$$

has been postulated in the liquid phase (12), and clearly reaction 4 as written is an oversimplification.

Appendix 4

Tabulated Data

In our previous review of the thermal decomposition of di-*tert*-butyl peroxide (1), we lodged a list of 272 values of k_1 with the National Science Library in Ottawa. One set of data obtained by Brinton and Volman (13) was inadvertently omitted from this list, and two new sets of data have been published (14, 15) since, as follows:

Temperature range (°C)	Number of points	E (kcal/mol)	log A (s^{-1})	Reference
130–167	7	37.44±1.05	15.56±0.55	13
231–254	8	39.46±0.41	16.59±0.17	14
140–165	6	37.77±0.48	15.82±0.25	15

Whilst the Arrhenius slopes of two of these sets of data differ somewhat from our selected value, the points lie very close to our selected line, and their inclusion would not alter perceptibly our selected values (1) of the Arrhenius parameters for k_1. As part of this paper, we now lodge a further list of 219 values of k_1, the 21 mentioned above, and 198 values obtained in this work,[4] and in ref. 2. Only one point merits comment here, a caveat on the use of least squares with inconsistent sets of data. We have separated the data in Fig. 1 and Fig. 4 on the basis of reproducibility[2]: the cyclopropane analyses were the cleanest of the whole set; the propane experiments were performed at a much earlier date and relatively poor for that reason; in the isobutane experiments, the closeness of the boiling point to that of acetone is a problem; the cyanogen and carbon dioxide experiments were only exploratory in nature, and the analytical procedure was not optimized. The following data illustrate our point.

Data set	Temperature range (°C)	Number of points	E (kcal/mol)	log A (s^{-1})
Cyclopropane	100–160	80	38.12±0.53	15.94±0.29
Propane	90–124	56	38.31±0.59	15.99±0.34
Cyanogen	118–140	28	36.37±0.71	15.14±0.38
All three sets	90–160	164	40.31±0.41	17.17±0.23

In our view, the importance of this kind of averaging on the discussion of anomalous Arrhenius parameters needs to be well appreciated, for it can arise not only, as in this case, when data having different systematic errors in different temperature ranges are combined (see Fig. 4), but when there is a variation of reliability with temperature within one set of data; we refer again to footnote 2 of ref. 1, and to the recent discussions by Thorn of this problem in another context (16).

New Syntheses of Demethylsuberosin, Xanthyletin, (±)-Decursinol, (+)-Marmesin, (−)-Nodakenetin, (±)-Decursin, and (±)-Prantschimgin[1]

WARREN STECK

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received February 25, 1971

The title compounds, natural coumarins or their racemic modifications, were synthesized via malonic acid condensations with appropriate salicylaldehydes. Oxidation of 2,4-dihydroxy-5-(3-methyl-2-butenyl)benzaldehyde with DDQ, peracid, and acid–peracid gave the aldehydes for xanthyletin, marmesin, and decursinol, respectively. Some ^{14}C-labelled coumarins were prepared similarly. The n.m.r. spectral data for the products are presented.

Les produits mentionnés dans le titre qui sont des coumarines naturelles ou des modifications racémiques ont été synthétisées en faisant appel à la condensation malonique sur les salicaldéhydes appropriés. Les aldéhydes nécessaires pour la préparation de la xanthylétine, de la marmésine et du décursinol ont respectivement été obtenus par oxydation du dihydroxy-2,4 (méthyl-3 butén-2 yl)-5 benzaldéhyde à l'aide du DDQ, de péracide et d'acide péracide. On a préparé de la même manière quelques coumarines contenant du ^{14}C. On rapporte les spectres de r.m.n. des produits.

Canadian Journal of Chemistry, 49, 2297 (1971)

Introduction

The synthesis of coumarins can be achieved in several ways, of which the most widely used are the Pechmann reaction (1), the Perkin reaction (2), and condensation with malonic acid derivatives. The latter reactions require salicylaldehydes as starting materials, and encounter difficulties when applied to the synthesis of natural coumarins: for example, the malonate route has as the final step decarboxylation of the 3-carboxycoumarin, which may affect other functional groups present; the severe conditions of the Perkin reaction may be similarly deleterious. But in practice the most immediate problem in most cases lies in obtaining the suitably substituted salicylaldehydes to begin with, especially when isoprenoid coumarins are desired.

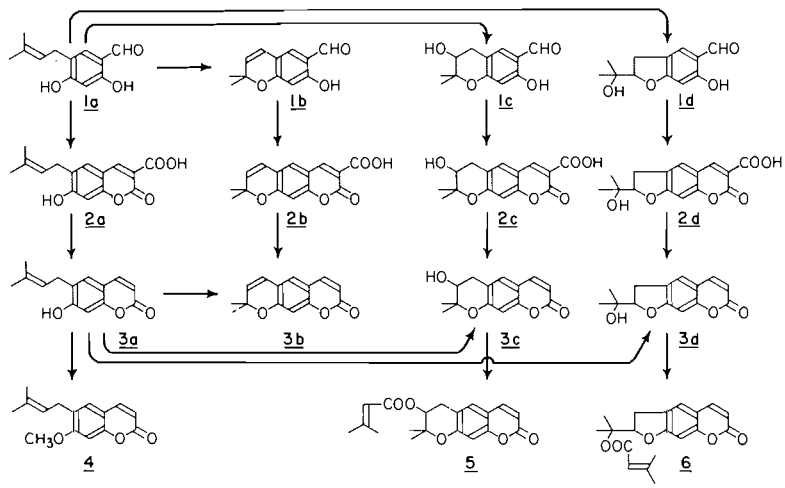
I have solved this problem for a number of natural products by chemical manipulation of 2,4-dihydroxy-5-(3-methyl-2-butenyl)benzaldehyde, have converted the aldehydes to coumarins, and have demonstrated the application of these sequences to radiochemical labelling. Some biogenetic-type syntheses of natural coumarins have been carried out similarly.

Results and Discussion

2,4-Dihydroxy-5-(3-methyl-2-butenyl)benzaldehyde (**1***a* in Scheme 1) was prepared from 2,4-dihydroxybenzaldehyde and 3-hydroxy-3-methyl-1-butene as previously reported (3). It was condensed with malonic acid under a variety of conditions, producing a number of products. Under vigorous reaction conditions cyclization of the initially formed product (3-carboxy-6-[3-methyl-2-butenyl]-7-hydroxycoumarin, **2***a*) usually occurred, affording 3-carboxydihydroxanthyletin (4). Only under very mild conditions of condensation was **2***a* obtained, but in such cases the yields were excellent, and the product could be decarboxylated satisfactorily to **3***a* (demethylsuberosin) by controlled heating in copper–quinoline. The final product was compared directly with natural material isolated from *Chloroxylon swietenia* wood. This is a more convenient synthetic method for this coumarin than that involving the Perkin reaction (5).

The aldehyde **1***a* was oxidatively cyclized in three ways to provide salicylaldehyde derivatives for the synthesis of marmesin, decursinol, and xanthyletin. With 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) as oxidant, the chromene **1***b* was obtained in good yield, m.p. 95–96°. Its conversion to 3-carboxyxanthyletin and xanthyletin (**3***b*) was straightforward. With *m*-chloroperoxybenzoic acid/*p*-toluenesulfonic acid as an oxidant system the chromanol **1***c* was obtained in good yield, m.p. 97.5–99°; from it was prepared (±)-decursinol (**3***c*). With neutral *m*-chloroperoxybenzoic acid, **1***a* gave a mixture of **1***c* and **1***d* which was most easily separated by column chromatography on silicic acid. In

[1]NRCC No. 11943.



SCHEME 1. Transformations of 2,4-dihydroxy-5-(3-methyl-2-butenyl)-benzaldehyde (**1***a*).

chloroform **1***d* always predominated in at least a 2:1 ratio, and the formation of **1***c* could be suppressed entirely by using a trace of triethylamine in the reaction or by using acetone as the solvent. (±)-Marmesin (**3***d*) was synthesized from **1***d*; the intermediate acid has been optically resolved, and the isomers decarboxylated, previously (6). In my hands the reported alkaline bisulfite decarboxylation method was unsatisfactory, so that here again, copper–quinoline proved a better method. Condensations of **1***d* with [2-^{14}C]malonic acid were also successful, leading to (+)-, (−)-, and (±)-[3-^{14}C]marmesin.

Demethylsuberosin (**3***a*), oxidized in the same ways as **1***a*, gave directly xanthyletin (**3***b*) with DDQ, and (±)-decursinol (**3***c*) and (±)-marmesin with peracid. This last reaction is a biogenetic-type synthesis which undoubtedly proceeds through an epoxide intermediate, as suggested for the *in vivo* formation of the products (7). Both (+)- and (−)-marmesin as well as (+)- and (−)-decursinol occur naturally and many of their esters have also been isolated from plants. For example (−)-marmesin angelate (8), (−)-prantschimgin (**6**) (9), and (−)-marmesin benzoate (10) have been isolated from umbellifers, and (+)-decursinol angelate (11) and (+)-decursin (**5**) (12) are also known. Warming 5 mg each of (±)-marmesin and senecioyl chloride in a few drops of pyridine gave an excellent yield of (±)-prantschimgin, m.p. 145–147°, readily identified by its n.m.r. spectrum. Similar reaction of (±)-decursinol and senecioyl chloride gave (±)-decursin as a glassy substance, its n.m.r. spectrum superimposable on that of natural decursin.

Aldehydes **1***a* and *d* were used as starting materials for the preparation of ^{14}C-labelled coumarins. From **1***a* about 30% [3-^{14}C]demethylsuberosin was obtained. From **1***d* both (+)-[3-^{14}C]marmesin and (−)-[3-^{14}C]nodakenetin (= (−)-[3-^{14}C]marmesin) were prepared by resolving the intermediate ^{14}C-carboxylic acid with brucine (6) and thermally decarboxylating each isomer. Besides the yield of each pure isomer (24 and 32%) a further 20% of racemic (±)-[3-^{14}C]marmesin also resulted from work-up of combined mother liquors.

The difficulty of introducing a 3-methyl-2-butenyl type group into the 6-position of preformed 7-hydroxycoumarins is well known (13, 14); consequently the synthesis of linear three-ring coumarins has usually been launched from natural coumarins in which the necessary substituents are already in place (11). Rearrangements of 7-alkoxycoumarins favor 8-alkylation (15). The methods described above give linear compounds readily and in generally good yields, and seem to represent an improvement over existing methods of synthesis.

Experimental

All melting points are uncorrected. The n.m.r. spectra were obtained with a Varian HA-100 instrument using tetramethylsilane as an internal reference standard and are summarized for nine coumarins in Table 1.

Authentic 7-demethylsuberosin and xanthyletin were obtained by extraction of ground *Chloroxylon swietenia* wood (16).

3-Carboxy-6-(3-methyl-2-butenyl)-7-hydroxycoumarin (2a)

Malonic acid and **1***a* (1.0 g each) were dissolved in 5.5 ml pyridine containing 0.5 ml aniline, and the solution, after 24 h at 22°, was poured into 80 ml ice-cold 10% HCl. The yellow precipitate was washed with cold water to remove mineral acid, then air dried. Yield 1.3 g (100%), m.p. 205–215°, raised to 218–224° on recrystallization from EtOAc–MeOH–hexane [2:1:2]. λ_{max} (EtOH) 261, 363 nm. For n.m.r. data see Table 1.

6-(3-Methyl-2-butenyl)-7-hydroxycoumarin (Demethylsuberosin, 3a)

Crude **2***a* (0.23 g) in 2 ml quinoline containing 0.4 g Cu powder was held 3 min at 215–220° in an oil bath, cooled and diluted with 30 ml chloroform. The decanted solution was shaken with 2 × 30 ml 10% HCl then with 30 ml water. The dried chloroform solution was evaporated, leaving a tacky orange solid which was chromatographed on a small amount of silicic acid (developed with 50 up to 100% EtOAc–hexane) to afford 0.12 g (62%) cream crystals of **3***a*, m.p. 129–133° (lit. m.p. 133–134° (16)). The product co-chromatographed (paper chromatography, t.l.c., g.l.c.) with authentic material and had identical u.v. and n.m.r. spectra. λ_{max} (EtOH) 247, 257, 333 nm.

2H-2,2-Dimethyl-7-hydroxychromen-6-aldehyde (1b)

Compound **1***a* (0.60 g) was oxidized with 0.6 g DDQ (2,3-dichloro-5,6-dicyanobenzoquinone) in 15 ml benzene (5 min boiling). The filtrate was freed of solvent and the residue chromatographed on silicic acid (ether–hexane, 1:1), giving 0.44 g (75%) colorless crystals of **1***b*, m.p. 95–96° from hexane.

Anal. Calcd. for $C_{12}H_{12}O_3$: C, 70.6; H, 5.9. Found: C, 70.4; H, 6.0.

The n.m.r. signals ($DCCl_3$) at δ 1.46 (singlet, CH_3's); 5.58 and 6.26 (doublets, J = 9.5 Hz, H-3 and -4); 7.10 and 6.33 (singlets, H-5 and -8); 9.67 (singlet, CHO), and 11.4 (singlet, 7-OH).

Xanthyletin (3b)

The procedure for **2***a* gave, from 0.40 g **1***b* and 0.7 g malonic acid, 0.4 g crude and 0.21 g (40%) purified **2***b*, m.p. 193–195° from alcohol. λ_{max} (EtOH) 263, 280, 374 nm. Decarboxylation in copper–quinoline (235–240° for 5 min) gave, after work-up, 50% yield of **3***b*, m.p. 128–130° (lit. m.p. 128–131° (16)).

(±)-2,2-Dimethyl-3,7-dihydroxychroman-6-aldehyde (1c)

A mixture of 0.50 g **1***a*, 0.50 g *m*-chloroperoxybenzoic acid, 0.02 g *p*-toluenesulfonic acid, and 60 ml chloroform were kept overnight at room temperature, then the solution was washed with dilute aqueous $NaHCO_3$ and H_2O. Evaporation of the chloroform left crystals, m.p. 97.5–99°, from benzene–hexane. Yield 0.4 g (75%).

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.8; H, 6.3. Found: C, 64.5; H, 6.5.

The n.m.r. signals ($DCCl_3$) at δ 1.36 and 1.38 (CH_3's), 6.36 (H-8), 7.21 (H-5), 9.65 (CHO), and 11.0 (7-OH), all singlets; 2.05 (broad, 3-OH). The presence of a six-membered ring was indicated by a —CH_2CH— ABX system, δ 2.73 and 3.02 (doublets of doublets, J_{AB} = 16 Hz, CH_2), 3.82 (doublet of doublet, J_{AX} = 5, J_{BX} = 6 Hz, CH).

(±)-Decursinol (3c)

The procedure for **2***a* gave, from 1.6 g **1***c* and 2.5 g malonic acid, 1.5 g (72%) **2***c*, m.p. 191.5–193° from methanol. λ_{max} (EtOH) 358 nm.

Anal. Calcd. for $C_{15}H_{14}O_6$: C, 62.0; H, 4.9. Found: C, 61.7; H, 5.0.

This product (0.10 g) was decarboxylated in copper–quinoline (230° for 10 min) to give about 0.05 g **3***c*, m.p. 166–168° from benzene (lit. m.p. 167.5–168.5° (11)). λ_{max} (EtOH) 248, 258, 329 nm.

(±)-2,3-Dihydro-2-(1-hydroxy-1-methylethyl)-6-hydroxybenzofuran-5-aldehyde (1d)

Aldehyde **1***a* was oxidized as in the preparation of **1***c* above but omitting *p*-toluenesulfonic acid. The crude product was chromatographed on a small column of silicic acid (developed with 1:1 ether–hexane) to obtain first a small amount of **1***c*, then **1***d* (65–85% yield), m.p. 116–118° from benzene:hexane (lit. m.p. 117–118°) (6)). The n.m.r. signals ($DCCl_3$) at δ 1.23 and 1.35 (CH_3's), 1.75 (*t*-OH), 6.36 (H-7), 7.26 (H-5), 9.65 (CHO) and 11.7 (6-OH), all singlets. A five-membered ring was indicated by the coupled signals at δ 3.11 (doublet, CH_2) and 4.71 (triplet, CH, J = 8.5 Hz).

(±)-Marmesin (3d)

This was made from **1***d* by the reported method (6). From 0.20 g malonic acid and 0.12 g aldehyde kept 24 h in 2 ml pyridine containing a drop of aniline was obtained 0.15 g (95%) **2***d*, m.p. 217–222° (lit. 222–223°). The decarboxylation with bisulfite and alkali (6) gave poor yields and was replaced by the copper–quinoline method (50–80% yields).

[3-^{14}C]Demethylsuberosin

A solution of 100 mg **1***a* and 52 mg [2-^{14}C]malonic acid in 0.5 ml 9:1 pyridine:aniline was kept 4 h, then a further 50 mg non-labelled malonic acid was added. After yet another 18 h the solution was acidified with ice – 3 *N* HCl and the precipitated yellow solid was filtered, washed thoroughly with cold water, and air-dried to give 140 mg (107%) crude [3-^{14}C]-**1***b*. It was decarboxylated by heating 3.5 min at 214–218° in 1.5 ml quinoline containing 0.3 g copper powder. Work-up as described above gave a tacky orange product which was purified by chromatography on silicic acid followed by chromatography on Polyclar AT powder (development with 2:1 methanol–water). Yield of [3-^{14}C]demethylsuberosin was 38 mg (33%) after recrystallization from ethyl acetate – hexane. A further 6 mg (5%) was recovered from the mother liquors. The material was radiochemically pure and melted at 131.5–133° (lit. m.p. 133–134° (16)).

(+)-[3-^{14}C]Marmesin and (−)-[3-^{14}C]Nodakenetin

A solution of 0.45 g **1***d* and 0.21 g [2-^{14}C]malonic acid in 3 ml pyridine and 0.2 ml aniline was kept overnight at room temperature, then 0.40 g non-labelled malonic acid was added. After a further 24 h the solidified reaction mixture was stirred with 30 ml ice – 3 *N* HCl and the yellow solid was filtered, washed with water, and air

For personal use only.

dried. The yield of (±)-3-carboxy[3-^{14}C]marmesin was 0.49 g (84% based on aldehyde). This was boiled 2 min with 0.70 g (−)-brucine in 10 ml methanol, then the solvent was evaporated and the residue crystallized overnight from 30 ml water. Hydrolysis (6) of crystals and mother liquors gave, respectively, 0.23 g crude (+)-3-carboxy[3-^{14}C]marmesin and 0.20 g crude (−)-3-carboxy[3-^{14}C]nodakenetin. Recrystallization from methanol (150 ml per g acid) gave 0.18 and 0.12 g of pure materials, both m.p. 240–244° (lit. m.p. 241,° 236–237° (6)). Each isomer was decarboxylated in 2 ml quinoline containing 0.2 g Cu powder (7 min at 230–232°), and the products, isolated in the way described above, were recrystallized from benzene (about 100 ml/g coumarin). Overall yield of (+)-[3-^{14}C]marmesin, m.p. 178–186° (lit. m.p. 186.5–187° (6)), was 0.08 g (32% of theoretical); yield of (−)-[3-^{14}C]nodakenetin, m.p. 186–189° (lit. m.p. 188–189° (6)) was 0.06 g (24%). Both products gave only one radioactive spot on paper chromatograms.

(±)-[3-^{14}C]Marmesin

All the mother liquors from the above crystallizations were combined and concentrated to give a crystalline mixture of labelled marmesin and 3-carboxymarmesin which was decarboxylated to provide 0.10 g (20% based on aldehyde) (±)-[3-^{14}C]marmesin, m.p. 150–152° (lit. m.p. 153–154° (6)).

Derivatives of 3a

(±)-Marmesin and (±)-Decursinol

Oxidation of **3a** with 1 equiv of *m*-chloroperoxybenzoic acid gave (±)-marmesin and a small amount of (±)-decursinol, which were separated by column chromatography on silicic acid (development with 1:3 EtOAc–hexane). (±)-Decursinol was eluted first, m.p. 166–168° from CH_2Cl_2–ether (lit. m.p. 167.5–168.5° (11)), and was identified by g.l.c., n.m.r. spectrum, and by comparison with **3c** prepared as described above. (±)-Marmesin was eluted next, m.p. 152–154° from benzene (lit. m.p. 153–154° (6)), and was identified similarly.

Xanthyletin

Oxidation of **3a** with DDQ in boiling benzene gave a 50% yield of xanthyletin, m.p. 128–130° (lit. m.p. 128–131° (16)) which was identical with xanthyletin as prepared earlier and with xanthyletin isolated from *Chloroxylon swietenia*.

Suberosin (4)

A solution of 0.1 g **3a** in 3 ml 1:1 methanol–methylene chloride was treated with 3 ml fresh diazomethane solution. Evaporation of the solvent left a viscous yellow syrup which on chromatography gave mostly suberosin, m.p. 84–86° (lit. m.p. 86–87° (5)), whose identity was confirmed by n.m.r.

(±)-Prantschimgin (6)

A solution of about 5 mg (±)-marmesin in 0.1 ml pyridine was treated with 1 drop of senecioyl chloride (3-methyl-2-butenoyl chloride) and warmed a few minutes. After dilution with CH_2Cl_2 and work-up as for decarboxylation reactions, 6 mg yellow syrup was obtained. Gas chromatography showed one major peak. The product from a five-fold reaction was crystallized from ethyl acetate – hexane to needles, m.p. 145–147°, and identified by n.m.r. spectroscopy. Besides appropriate signals for the marmesin nucleus, senecioate peaks were seen at δ 5.53 (quartet $J \sim 1$ Hz, = CH), 2.09 (doublet, $J \sim 1$ Hz, *trans*-CH_3) and 1.85 (doublet, $J \sim 1$ Hz, *cis*-CH_3).

(±)-Decursin (5)

This was prepared from (±)-decursinol and senecioyl chloride in the same manner as (±)-prantschimgin, and was isolated pure by gas chromatography. It was obtained as a glassy product and was characterized by n.m.r. (signals, assigned as above, at δ 5.67, 2.14, and 1.88). The same spectrum and gas chromatographic behavior was exhibited by a specimen of natural decursin.

I thank Mr. B. K. Bailey for skillful technical assistance, Mr. W. Haid for microanalyses, and Mr. M. Mazurek for measurement of n.m.r. spectra. A specimen of natural decursin was kindly supplied by Prof. K. Hata (Osaka College of Pharmacy, Osaka, Japan); *Chloroxylon swietenia* wood was the generous gift of Robert Bury & Co., Toronto, Ontario. I am also indebted to Drs. D. J. Austin and S. A. Brown for their interest and assistance in problems of synthesis.

Further Investigations on the Chemistry of Fulvic Acid, a Soil Humic Fraction[1]

S. U. KHAN[2] AND M. SCHNITZER
Soil Research Institute, Canada Department of Agriculture, Ottawa, Canada

Received March 1, 1971

The fractionation scheme described in this and in an earlier paper resulted in the isolation and identification of about 2.0 g of pure components from 100 g of fulvic acid. About 28% of these compounds were phenolic acids, 19% benzenecarboxylic acids, 13% alkanes and fatty acids, and 40% dialkyl phthalates. The isolation of appreciable amounts of dialkyl phthalates was somewhat surprising but their presence was shown not be an artifact. The $KMnO_4$ oxidation of the same fractions increased the yields of methylated phenolic and benzenecarboxylic acids by between 3 and 11 times.

Following $KMnO_4$ oxidation of methylated but unfractioned fulvic acid, the yield of phenolic and benzenecarboxylic acids increased substantially. The increased yields, after oxidation, of the same compounds as those that were separated without oxidation indicate that either these compounds originated from more complex structures or that they came from a structure of the type proposed earlier, which consists of phenolic and benzenecarboxylic acids joined by hydrogen-bonds, on which alkanes, fatty acids, and dialkyl phthalates are adsorbed.

Le schéma de fractionnement dans cette note et dans une note précédente résulte de la séparation et de l'identification d'à peu près 2.0 g de constituants purs à partir de 100 g d'acide fulvique. Environ 28% de ces composés sont des acides phénoliques, 19% des acides benzènecarboxyliques, 13% des alcanes et des acides gras, et 40% de dialkylphtalates. L'isolement de quantités appréciables de dialkylphtalates avait quelque chose de surprenant mais il a été montré que leur présence était due à la réaction. L'oxydation par $KMnO_4$ des mêmes fractions a accru entre 3 et 11 fois les rendements d'acides phénoliques et benzènecarboxyliques méthylés.

Après une oxydation par $KMnO_4$ d'acide fulvique méthylé mais non fractionné, le rendement en acides phénoliques et benzènecarboxyliques est accru de façon notable. Les rendements accrus, après oxydation, des mêmes composés que ceux qui avaient été séparés sans l'oxydation indiquent soit que ces composés proviennent de structures plus complexes ou qu'ils sont issus d'une structure du type proposé précédemment. Cette structure est faite d'acides phénoliques et benzènecarboxyliques reliés par des liaisons hydrogène au sein desquelles les alcanes, les acides gras et les phtalates dialkylés sont adsorbés.

Canadian Journal of Chemistry, 49, 2302 (1971)

Introduction

In 1963, Barton and Schnitzer (1) proposed a new approach to unravelling the chemical structure of fulvic acid, a water-soluble, relatively low-molecular weight humic fraction. The fulvic acid was first exhaustively methylated so as to make it soluble in benzene. The benzene-soluble methyl esters and ethers were then separated over Al_2O_3 with the aid of solvents of increasing polarity into chromatographically homogeneous fractions which differed in molecular weights, oxygen-containing functional groups, and spectroscopic properties. In a recent communication (2) from this laboratory, an extension and modification of this approach was reported. Following preliminary separation over Al_2O_3, each fraction was further separated by t.l.c. and preparative gas-chromatography into relatively pure components which were identified by matching their mass and micro-i.r. spectra and gas chromatographic retention times with those of standards of known structures. Using this approach, over 20 phenolic and benzenecarboxylic acids were isolated as methyl ethers and esters from two fractions eluted from the Al_2O_3 column with mixtures of benzene and ethyl acetate.

The present report deals with the isolation from the same fulvic acid of major components from fractions of greater molecular complexity, that is, fractions that were eluted from the Al_2O_3 column with more polar solvents such as ethyl acetate and methanol. The major components of the fractions were identified by the same techniques that had been used in the previous investigation (2). We were especially interested

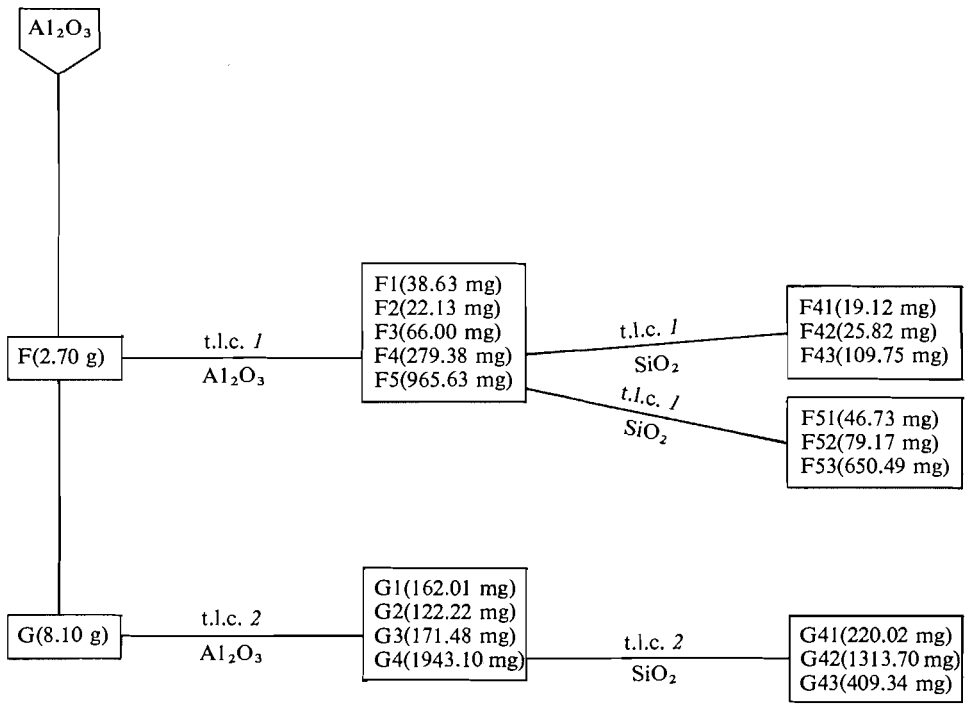

FIG. 1. Fractionation scheme (t.l.c. 1: toluene – ethyl acetate (1:1); t.l.c. 2: toluene – ethyl acetate (2:1)).

in finding out how our approach, which does not involve any chemical degradation, would work with the chemically more complex fractions. To obtain additional information on the main components of the two fractions, we oxidized each fraction with alkaline $KMnO_4$ and identified the oxidation products.

Experimental

Extraction, Purification, Methylation, and Separation of Fulvic Acid

The origin of the fulvic acid, methods of extraction, purification, methylation, and separation over Al_2O_3 were identical to those described previously (2).

Briefly, 100 g of fulvic acid yielded 75.0 g of methylated fulvic acid. Of the latter, 41.3 g was soluble in benzene. Chromatography of the benzene-soluble material over neutral Al_2O_3 (2000 g) with 3 l of each of the following solvents: hexane, benzene, benzene – ethyl acetate (9:1), benzene – ethyl acetate (1:1), and an additional 3 l of benzene – ethyl acetate (1:1) yielded fractions A, B, C, D, and E, weighing 0.07, 0.02, 0.04, 0.50, and 0.61 g, respectively. Fraction A contained only alkanes (3), whereas fractions B and C were found to contain both alkanes and fatty acid methyl esters in addition to small amounts of dialkyl phthalates (4). Fractions D and E consisted mainly of phenolic and benzenecarboxylic acid methyl ethers and esters (2). Elution with 3 l of ethyl acetate and 3 l of methanol afforded fractions F and G, weighing 2.70 and 8.10 g, respectively. Fraction F contained 60.8% C, 5.4% H, and 33.0% OCH_3; fraction G analyzed 60.1% C, 5.2% H, and 29.6% OCH_3. This paper deals with the separation of fractions F and G, which were quantitatively the major fractions that we were able to separate from the fulvic acid.

Analytical Methods

Following chromatography over the Al_2O_3 column, fraction F was further separated by preparative t.l.c. on Al_2O_3 (activated at 150 °C for 18 h, thickness of sorbent coating, 0.5 mm) with toluene – ethyl acetate (1:1) as solvent. The t.l.c. plate was inspected under a u.v. lamp and five subfractions (F1 to F5) were marked out, scraped off the plate, and extracted with ethyl acetate. Subfractions F4 to F5 were further separated by t.l.c. on SiO_2 (activated at 150 °C for 18 h, thickness of sorbent coating, 0.5 mm) with toluene – ethyl acetate (1:1) to afford additional subfractions F41 to F43 and F51 to F53. Fraction G was separated first by t.l.c. on Al_2O_3 with toluene – ethyl acetate (2:1) to yield the four subfractions G1 to G4. Subfraction G4 was further separated by t.l.c. on SiO_2 with toluene – ethyl acetate (2:1) into subfractions G41 to G43. The fractionation scheme, including the yield of each fraction and subfraction, is shown in Fig. 1. The R_f values for the main fractions separated by t.l.c. are given in Table 1.

Each subfraction was then separated by preparative

gas chromatography and the material in each major peak was analyzed by i.r. spectrophotometry and mass spectrometry. The gas chromatographic conditions (except that the support was coated with 5% SE-30 instead of 3% OV-17), methods of collection of gas chromatographic peaks, of preparation of micro-i.r. pellets, as well as of mass spectrometric analysis were the same as those employed in the earlier investigation (2). The gas chromatographic separation of subfraction G1 is illustrated in Fig. 2.

The origins and preparations of the known compounds used as standards for the mass spectrometric and i.r. spectrophotometric identification of the unknowns were identical to those described previously (2).

Alkaline $KMnO_4$ Oxidation

Samples (1.0 g) of fractions F and G were refluxed for 8 h with 250 ml of 4% (w/v) aqueous $KMnO_4$ solution. Following oxidation, the excess $KMnO_4$ was destroyed by careful addition of small volumes of CH_3OH. The insoluble MnO_2 was removed by filtration and washed with small aliquots of hot water. The filtrate (p*H* 9.9) plus washings were acidified to p*H* 2 with 6 *N* H_2SO_4 solution, transferred to a liquid–liquid extractor, and extracted with 500 ml of ethyl acetate for 48 h. The extract was dried and dissolved in a small volume of CH_3OH and methylated with an ether solution of diazomethane, generated from Diazald. The methylated oxidation product was first analyzed by analytical gas

chromatography (Fig. 3). The major peaks were then collected by preparative gas-chromatography and identified by comparing their chromatographic retention times, mass and micro-i.r. spectra with those of authentic specimens, and by co-chromatography with the latter.

Results and Discussion

Compounds Isolated from Fractions G and F

Three types of compounds were found (Table 2): (*a*) fully methylated phenolic acids; (*b*) benzenecarboxylic acid methyl esters, and (*c*) dialkyl phthalates. The chemical structures of all compounds identified are shown in Fig. 4. In view of the low OCH_3-content of the unmethylated fulvic acid (2), it is likely that most of the phenolic and benzenecarboxylic acids were methylated in the laboratory and that they occurred as phenols and acids in the untreated fulvic acid.

The most prominent component isolated from fraction F was **13**. Next in abundance were **18**, **19**, and **11**.

After oxidation (Table 2), the yields of all compounds except that of **13** and of the dialkyl phthalates increased substantially. Also, a number of additional benzenecarboxylic acid methyl

FIG. 4. Chemical structures of compounds isolated.

esters (**1–5** and **7–9**) were isolated. Since more than 90% of **13** was isolated without degradation, it is likely that most of this compound occurred in this fulvic acid fraction as the free acid.

From fraction G we were able to isolate only small amounts of methylated phenolic and benzenecarboxylic acids; most of the components that could be identified were dialkyl phthalates. While the identifiable components in fraction F consisted of about 65% fully methylated phenolic and benzenecarboxylic acids and of 35% dialkyl phthalates, those in fraction G consisted of only 10% phenolic and benzenecarboxylic acid esters but of 90% dialkyl phthalates (Table 2).

The alkaline $KMnO_4$ oxidation of fraction G yielded increased amounts of **5**, **6**, and **12** aside from substantial quantities of **10**, **11** and **13**. For fractions F and G the yields of fully methylated phenolic and benzenecarboxylic acids after oxidation were between 3 and 11 times higher than those obtained without degradation.

Most of the fully methylated phenolic and benzenecarboxylic acids listed in Table 2 were the same as those isolated from fractions D and E in the earlier investigation (2). Small amounts of dialkyl phthalates were also found in fractions B and C (4). The occurrence in fractions F and G of significant amounts of dialkyl phthalates, especially *bis*(2-ethylhexyl)phthalate, was quite unexpected. Dialkyl phthalates are used in industry as plasticizers, lubricants, and in the manufacture of alkyd resins and dyes (4). We first suspected that the phthalates were contaminants that had interacted with the fulvic acid during the extraction and purification procedure. Hot toluene washings of a polyethylene bottle, used for the extraction of fulvic acid from the soil, did not contain any dialkyl phthalates. Prolonged extraction of 50 g of ovendry Rexyn-101 H-resin, used for lowering the ash content of the fulvic acid, with 300 ml of hot toluene yielded no dialkyl phthalates. A hot toluene extract of silicone grease, used occasionally to grease the ground-glass joint of the inlet tube of the rotary evaporator, was free of phthalates. To check on possible air contamination, we exposed 250 ml of toluene in a 20 l glass flask, with the mouth loosely covered with aluminum foil, to air in the laboratory for 24 h. Gas chromatographic analysis of the exposed toluene failed to show any dialkyl phthalates. Similarly, repeated checks for column-bleeding indicated that the liquid phase (SE-30) in our gas chromatographic columns was not the source of any measureable amounts of dialkyl phthalates. In view of all these checks, and considering the fact that small amounts of dialkyl phthalates were found earlier (4), we believe that the dialkyl phthalates are components of the fulvic acid. In connection with this, it is noteworthy that Cifrulak (5) reported the occurrence of unidentified phthalates in organic extracts of soil samples.

Dehydrodiveratric acid dimethyl esters	10.5	546.0
Benzenedicarboxylic acid dimethyl esters	6.0	256.0
Benzenetricarboxylic acid trimethyl esters	10.5	330.0
Benzenetetracarboxylic acid tetramethyl esters	25.9	3170.0
Benzenepentacarboxylic acid pentamethyl esters	34.7	4465.0
Benzenehexacarboxylic acid hexamethyl esters	117.3	3268.0
Dibutyl phthalate	6.1	—
Dicyclohexyl phthalate	15.4	—
Bis(2-Ethylhexyl) phthalate	315.9	—
Dioctyl phthalate	25.9	—
Dialkyl phthalates (not identified)	46.7	—
C_{14}–C_{36} Alkanes	78.0	—
C_{14}–C_{36} Fatty acids	50.0	—
Total	1030.3	20436.0

Dialkyl phthalates have also been found to occur in plants, petroleum and in fungal metabolites (4), so that a biosynthetic origin cannot be excluded.

Recent work in our laboratory showed that aqueous fulvic acid solutions reacted readily with dialkyl phthalates. One number-average molecular weight (951 g) of fulvic acid was found to solubilize 4 mol of **18** (1560 g) but only 1 mol of **16** (278 g), whereas two number-average molecular weights of fulvic acid (1902 g) were found to solubilize 3 mol of **17** (990 g). The i.r. spectra of untreated fulvic acid, dialkyl phthalates, and fulvic acid – dialkyl phthalate complexes failed to provide evidence for the occurrence of chemical reactions between fulvic acid and the phthalates. The latter appeared to be solubilized by the fulvic acid molecule. We also found that while the $KMnO_4$ oxidation of 600 mg of **18** in the absence of fulvic acid yielded no *o*-phthalic acid, that of the same amount of **18** in the presence of 366 mg of fulvic acid produced 12.0 mg of *o*-phthalic acid (or 14.0 mg of **1**). Since 100 g of fulvic acid contained approximately 300 mg of **18** plus about 90 mg of the other phthalates (see Table 3), one would expect the $KMnO_4$ oxidation of these compounds to yield about 9.0 mg of **1**. We found that the $KMnO_4$ oxidation of 100 g of fulvic acid produced 159.0 mg of **1**, which is ample to account for any *o*-phthalic acid that may have originated from the dialkyl phthalates.

Summary of Compounds Isolated from All Fractions

Table 3 lists the compounds that were isolated from all fractions of the fractionation scheme including those reported in the earlier investigation (2). *In toto*, the compounds isolated from 100 g of fulvic acid weighed 1.03 g. Since preliminary experiments with known fully methylated phenolic and benzenecarboxylic acids showed that at least 50% of the starting material was lost during the fractionation and purification procedure, it is likely that the compounds listed in Table 3 may account for up to 2.0% of the original fulvic acid.

It should be borne in mind that these compounds were isolated from the fulvic acid without degradation by chemical methods in the laboratory. About 28% of the material identified consisted of fully methylated phenolic acids, 19% of benzenecarboxylic acid methyl esters, 40% of dialkyl phthalates, and 13% of alkanes and fatty

acid methyl esters. Compounds **12** and **13** accounted for about 45% of the fully methylated phenolic- and benzene-carboxylic acids, respectively. Following $KMnO_4$ oxidation of methylated but unfractionated fulvic acid, the yields of phenolic and benzenecarboxylic acids increased by between 20 and 125 times (Table 3). Many of the compounds listed in Table 3 have been reported to arise from the $KMnO_4$ oxidation of lignin (6), thus indicating a lignin origin for the fulvic acid.

It was suggested earlier (2) on the basis of i.r. studies that in fulvic acid, benzenecarboxylic and phenolic acids were joined by hydrogen-bonding to form a polymeric structure of considerable stability on which alkanes, fatty acids and dialkyl phthalates were adsorbed. This structure could be weakened by methylation which is known to reduce hydrogen-bonding (2). Thus, the increased release of the same phenolic and benzenecarboxylic acids after oxidation as those that were isolated without oxidation indicates that either these compounds originated from more complex structures or that they came from a structure of the type mentioned above, in which the components are held together relatively loosely. Additional work is needed to shed light on this point.

We thank S. I. M. Skinner for mass spectrometric analyses and J. G. Desjardins for technical assistance.

Metal Oxide Trialkylsilyloxide Polymers. Part VI. Aluminum Oxide Trimethylsilyloxides[1]

D. C. Bradley,[2] J. W. Lorimer,[3] and C. Prevedorou-Demas

Department of Chemistry, The University of Western Ontario, London 72, Ontario

Received February 19, 1971

Tris(trimethylsilyloxy)aluminum, $[Al(OSiMe_3)_3]_2$, was hydrolyzed under controlled conditions in dioxane at 25 °C. The soluble initial products $[AlO_x(OH)_z(OSiMe_3)_{3-2x-z}]_n$, with $x = 0.03$–0.65, underwent disproportionation when heated at 120–150 °C under vacuum to give final products with $x = 0.8$–1.1. Molecular weights were determined by cryoscopy in cyclohexane, and the linear dependence of $1/n$ on x was combined with an extension of the theory of regular polymer series to show that the number of OH groups, z, was small compared to the number of bridging oxygen atoms, x, per Al atom. The initial products consist of dimeric units, each linked to an adjacent unit by one or two oxygen bridges between aluminum atoms. The degree of polymerization is 1 to 4, based on the dimer unit. The final products have much higher degrees of polymerization (10–40, based on the dimer), and appear to contain a higher proportion of Al—O—Al bridges.

Le tris(triméthylsilyloxy)aluminium, $[Al(OSiMe_3)_3]_2$, a été hydrolysé dans le dioxane à 25 °C et dans des conditions définies. Les produits initiaux solubles $[AlO_x(OH)_z(OSiMe_3)_{3-2x-z}]_n$, avec $x = 0.03$–0.65, subissent une disproportionation lorsqu'ils sont chauffés à 120–150 °C sous vide, pour donner des produits finaux avec $x = 0.8$–1.1. Les masses moléculaires ont été déterminées par cryoscopie dans le cyclohexane, et la dépendance linéaire de $1/n$ sur x a été combinée avec une extension de la théorie des séries des polymères réguliers, afin de montrer que le nombre de groupes OH, z, était petit comparé au nombre d'atomes d'oxygène servant de pont, x, par atome d'Al. Les produits initiaux sont des unités dimériques, chacune étant liée à une unité adjacente par un ou deux ponts oxygène entre les atomes d'aluminium. Le degré de polymérisation, fondé sur l'unité dimérique, est de 1 à 4. Les produits finaux ont des degrés de polymérisation bien plus élevés (10–40, fondé sur le dimère) et semblent contenir une plus grande proportion de ponts Al—O—Al.

Canadian Journal of Chemistry, 49, 2310 (1971)

Introduction

Previous papers in this series (1–5) have described the hydrolysis of the trialkylsilyloxides of some group IV B and V B metals to form the metal oxide trialkylsilyloxides, or poly(trialkylsiloxanometalloxanes). Of these, the titanium oxide triethylsilyloxides (4, 5), the tantalum oxide trimethylsilyloxides (3, 6), and the zirconium oxide trimethylsilyloxides (before disproportionation) (2, 6) could be described with the aid of the theory of regular polymer series (6) as simple repeating units containing one or two metal atoms joined through metal–oxygen–metal bridges. By contrast, the oxide trimethylsilyloxides of titanium (1, 6) and zirconium (after disproportionation) (2, 6) could be described successfully only in terms of octameric repeating units, each containing twelve metal–oxygen–metal bridges, and linked together by one or two such bridges.

It is of interest to extend these observations to compounds containing metal atoms with different possibilities of coordination. This paper describes the products of the hydrolysis of tris(trimethylsilyloxy)aluminum (III) (aluminum trimethylsilyloxide, $[Al(OSiMe_3)_3]_2$), the thermal disproportionation of these products, and the interpretation of the data according to the theory of regular polymer series (6).

Experimental

Aluminum trimethylsilyloxide has been prepared by the reaction of anhydrous aluminum chloride with sodium trimethylsilanolate in ether solution (7). Here, the general method of Bradley and Thomas (8) was used, in which trimethylsilanol was added slowly to a refluxing solution of aluminum isopropoxide in benzene, and the alcohol liberated was distilled off as an azeotrope with benzene as the reaction proceeded. The solid product was purified by sublimation under vacuum. Analysis by general methods (8) gave Al 9.16%, Si 28.6%; calcd. for

$Al(OSiMe_3)_3$, Al 9.16%, Si 28.6%. Molecular weight 587 (by cryoscopy in cyclohexane); calcd. molecular weight for dimer (7), 589.1.

Hydrolysis was carried out in dioxane which had been refluxed over sodium for several hours and fractionally distilled. A weighed amount of the silyloxide (2.0–2.5 g) was dissolved in dioxane (30 g) at room temperature, and a weighed amount of water (h mole per mole metal atoms) was added to the stirred solution. After 1 h of further stirring, the volatile products and solvent were evaporated under vacuum at room temperature. Analysis of these volatile products by gas chromatography showed the presence of dioxane and trimethylsilanol, and quantitative determination of trimethylsilanol indicated that hydrolysis was complete. The residues from this procedure constitute the initial hydrolysis products (I). These were heated under vacuum at 120–150 °C to give the final hydrolysis products (II). $[Al(OSiMe_3)_3]_2$ was identified as a volatile product on heating.

All hydrolysis products were analyzed for aluminum and silicon (8) and their molecular weights were determined by cryoscopy in cyclohexane. Infrared spectra were recorded for several products at concentrations of 3.0, 4.0, 5.0, and 6.0 wt.% in cyclohexane, using KBr cells of path length 0.1 mm and a Beckman IR-7 spectrophotometer. Comparative analyses for hydroxyl groups were obtained from spectra showing absorbance as a function of frequency. A baseline was interpolated from the strong background absorption adjoining the band between 3450 and 3800 cm^{-1}, and the area under this band was measured by planimeter.

Results and Discussion

Tables 1 and 2 give the number of moles of water added per mole of aluminum, the percentages by weight of aluminum and silicon, and the number average molecular weight, $\bar{M}_n$, for the initial (I) and final (II) polymers, respectively. Above $h = 1.50$, the hydrolysis products are not completely soluble. The products remaining after removal of the insoluble portion by filtration gave the same analyses for Al and Si as before filtration. Analyses of the insoluble portions were impracticable because of their small volumes. For a given mass concentration of polymer (3, 4, 5, or 6 wt.%), the OH infrared bands could be superposed for all the initial products (I) that were examined (h = 0.4, 1.15, 1.75 mole H_2O per mole Al). This was also true for the final products (II) (h = 0.3, 0.8) but the band intensities were higher. For products I, the ratio of band area (cm^{-1}) to concentration (wt.%) was 0.10, standard error 0.02, while for products II this ratio was 0.15, standard error 0.02. No correlation between these ratios and percent Si (see Tables 1, 2), degree of hydrolysis $\bar{x}_n$ (see below) or degree of polymerization (related to $\bar{M}_n$) is found. From Tables 1 and 2, the percent Al varies from 10.4 to 13.5 (average 12.0) for products I with h = 0.4, 1.14, 1.75, and has the value 22.8 for products II. The ratio of these values lies between 1.7 and 2.2, which is equal to the ratios of the band areas per unit concentration for the two products, within experimental error. A consistent interpretation

of these data is that the ratio of OH groups to Al atoms is roughly constant for all hydrolysis products. No satisfactory standard is available for estimation of the actual concentration of OH groups, but the band intensities are very small compared to the intensity of the neighboring aliphatic C—H band centered at 2980 cm^{-1}.

The effect of OH groups on the general relations of the theory of regular polymer series (6) will not be examined. The hydrolysis reaction may be written

$$[1]\quad n\mathrm{Al(OSiMe_3)_3} + n(x+z)\mathrm{H_2O} \rightarrow [\mathrm{AlO}_x(\mathrm{OH})_z(\mathrm{OSiMe_3})_{3-2x-z}]_n + n(2x+z)\mathrm{Me_3SiOH}$$

where x is the ratio of bridging oxygen atoms to metal atoms, z is the ratio of hydroxyl groups to metal atoms, and n is the number of metal atoms per mole, or the degree of polymerization. In general n, x, and z are not integral, and are written as the number averages $\bar{n}_n$, $\bar{x}_n$, and $\bar{z}_n$.

Consider a polymer chain i of degree of polymerization n_i, with x_i bridging oxygens and z_i OH groups per metal atom, and containing q metal–oxygen–metal bridges between successive repeating units. If r is an integer, the basic equations for the chain are, according to eq. 1,

$$[2]\qquad n_i = pr, \quad r = 1,2,\cdots$$

for the degree of polymerization, where p is the number of metal atoms per repeating unit, and

$$[3]\qquad n_i(x_i + z_i) = q(r-1) + n_i z_i$$

or

$$[4]\qquad n_i x_i = q(r-1)$$

for the degree of hydrolysis. Equations 2 and 4 are identical with the usual case $z_i = 0$ (6), if calculations of n_i and the degree of hydrolysis $x_i + z_i$ are carried out properly. The equations for the four general models of the theory of regular polymer series (6) are, therefore, unchanged by the presence of hydroxyl groups.

From eq. 1, the mole ratios of Si to Al and of OH to Al are, respectively,

$$[5]\quad N_{\mathrm{Si}}/N_{\mathrm{Al}} = 3 - 2\bar{x}_n - \bar{z}_n, \quad N_{\mathrm{OH}}/N_{\mathrm{Al}} = \bar{z}_n$$

from which the average degree of hydrolysis is

$$[6]\quad \bar{x}_n + \bar{z}_n = (3 - N_{\mathrm{Si}}/N_{\mathrm{Al}} + N_{\mathrm{OH}}/N_{\mathrm{Al}})/2$$

As an approximation $\bar{x}'_n$ to the true value of $\bar{x}_n$, set $\bar{z}_n = 0$ in eq. 5 to give $N_{\mathrm{Si}}/N_{\mathrm{Al}} = 3 - 2\bar{x}'_n$. Substitute this value and $N_{\mathrm{OH}}/N_{\mathrm{Al}} = \bar{z}_n$ in eq. 6 to give

$$[7]\qquad \bar{x}'_n = \bar{x}_n + \bar{z}_n/2$$

If P_{Al}, P'_{Al} and $\bar{n}_n$, $\bar{n}'_n$ are the true values and approximate values (with $\bar{z}_n = 0$) for the percent Al and the degree of polymerization, respectively,

$$[8]\quad P'_{\mathrm{Al}}/P_{\mathrm{Al}} = (1/\bar{n}'_n)/(1/\bar{n}_n) = [\mathrm{Al(OX)_3} - (\mathrm{O}+2\mathrm{X})\bar{x}_n - (\mathrm{X}-\mathrm{H})\bar{z}_n]/[\mathrm{Al(OX)_3} - (\mathrm{O}+2\mathrm{X})\bar{x}_n] = 1 + \bar{z}_n/(A - B\bar{x}'_n)$$

where each chemical symbol represents 1 mole, X is $SiMe_3$, and the constants have the values $A = \mathrm{Al(OX)_3}/(\mathrm{O}/2 + \mathrm{H}) = 32.70$, $B = (\mathrm{O}+2\mathrm{X})/(\mathrm{O}/2 + \mathrm{H}) = 18.02$. Equation 8 may also be written

$$[9]\quad (P'_{\mathrm{Al}} - P_{\mathrm{Al}})/P'_{\mathrm{Al}} = \bar{z}_n/(A - B\bar{x}'_n + \bar{z}_n)$$

The approximate value of the percent Al will always be greater than the true value, since $A > B\bar{x}'_n$ in general.

For personal use only.

Values of $\bar{x}'_n$ can be calculated from eq. 5 and the analytical data, and calculated values of P'_{Al} can then be found from the formula weights. The degrees of polymerization $\bar{n}'_n$ (approximate) can then be found from the formula weights and the number average molecular weights. These values are also given in Tables 1 and 2. As predicted by eq. 9, the calculated values of the percent Al for products I are greater than the observed values, although any solvent or trimethylsilanol not removed from the products would give a similar effect. The percentage difference between the calculated and observed values of the percent Al may be used, with eq. 9, to give a rough estimate of $\bar{z}_n \sim 1$. In view of the very small infrared OH intensity and the analysis given below, this value is almost certainly much too high. For products II, the calculated percent Al is smaller than the observed value, possibly because of a systematic error in analysis. For this reason, it is believed that the small differences in the observed and calculated values of the percent Al are not significant in terms of eq. 9.

The theory of regular polymer series (6) yields the general relation $1/\bar{n}_n = a + b\bar{x}_n$ for many metal oxide trialkylsilyloxides over a large range of $\bar{x}_n$. If this equation holds for the present case, eqs. 7 and 8 give

$$[10] \quad 1/\bar{n}'_n = [a - b\bar{z}_n/2 + b\bar{x}'_n]/[1 + \bar{z}_n/(A - B\bar{x}'_n)]$$

Figure 1 is a plot of $1/\bar{n}'_n$ against $\bar{x}'_n$ for both sets of hydrolysis products, and Table 3 contains the results of a least-square analysis (6). The slope and intercept in the general relation $y = 1/\bar{n}'_n = a' + b'\bar{x}'_n$ are given, together with the ratio $a'/|b'|$, the corresponding standard errors in a' and b', the standard error $\sigma(y)$ and the correlation coefficients $\rho(x,y)$ for the variables and $\rho(a',b')$ for the parameters.

TABLE 3. Hydrolysis products of $[Al(OSiMe_3)_3]_2$

$\sigma(y)$	0.013	0.011	0.009

For products I, the first 17 entries in Table 1 yield a good straight line. The intercept is equal to the reciprocal degree of polymerization of the dimer to within experimental error, and the theory of regular polymer series indicates that the polymers are made up of dimeric repeating units, presumably containing 4-coordinated Al atoms as in the pure dimer $[Al(OSiMe_3)_3]_2$. With the help of eq. 10, the data for products I indicate that $\bar{z}_n$ must be considerably smaller than 0.01; *i.e.*, the effect of OH groups on the properties of the polymers can be disregarded.

Since the degree of polymerization is $p = 2$ for products I, the four general models which result from a systematic application of the theory of regular polymer series (6) can be simplified considerably. Cyclic species are improbable, since the reciprocal of the slope b' is neither integral nor infinite (6). Only one of the general equations applies

$$[11] \quad 1/\bar{n}_n = 1/p - \bar{x}_n/\bar{q}$$

where $\bar{n}_n = \bar{n}'_n$, $\bar{x}_n = \bar{x}'_n$, $p = 2$, and $\bar{q} = \alpha q_A + (1 - \alpha)q_B$; q_A, q_B are the bridge multiplicities (numbers of metal–oxygen–metal bridges between adjacent repeating units). The parameter α is either the fraction of metal atoms in homo-

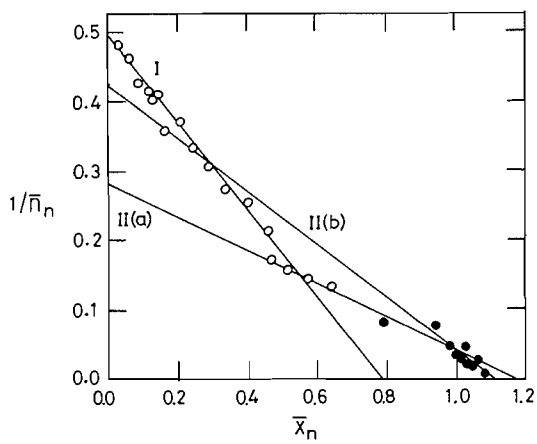

FIG. 1. Dependence of reciprocal degree of polymerization on degree of hydrolysis for aluminum oxide trimethylsilyloxides: ○, before thermal disproportionation; ●, after thermal disproportionation. The lines are the least-square equations with parameters given in Table 3.

geneous chains with bridge multiplicity α, or the fraction of bridges of multiplicity q_A within a single heterogeneous chain. No distinction can be made between these two cases on the basis of the available experimental evidence. The values $q_A = 1$, $q_B = 2$, $\alpha = 0.43$, standard error in $\alpha = 0.05$, fit the data, indicating that the polymers may be considered to be dimeric units linked by one or two metal–oxygen–metal bridges. This mixture could arise by disproportionation, as outlined previously for the titanium oxide triethylsilyloxides (5). The first member of either a p_2q_1 or a p_2q_2 series is the unhydrolyzed dimer, and a mixture of this dimer (p_2q_0) and p_2q_2 chains, with $\alpha = 0.43$, will also satisfy the data, as will a mixture $p_2q_0 + p_2q_1 + p_2q_2$. The polymer thus may contain the unhydrolyzed dimer. A mixture of p_2q_1 and p_2q_3 chains will also satisfy the data, but the combination p_2q_3 is highly improbable. Figure 2 indicates the nature of chains of the p_2q_1 and p_2q_2 types.

Table 3 gives two sets of parameters for the final products II. In the second set, the point with $\bar{x}'_n = 0.79$ has been omitted (see also Fig. 1). Clearly, the range of $\bar{x}'_n$ for the products II is too narrow and the errors are too large to justify a systematic application of theory. However, it will be noted that products I contain only a few dimer units at low values of $\bar{x}'_n$. At higher values, the points appear to lie on a curved extension to the line for products I that includes the points for products II. This suggests that high values of the apparent degree of hydrolysis and thermal disproportionation have similar effects, namely, to increase the degree of polymerization and to increase the degree of hydrolysis. Thermal disproportionation is a more rapid process, however, and may occur by the mechanism suggested for the disproportionation of the titanium oxide triethylsilyloxides (5). Since the number of OH groups per Al atom appears to be more or less constant, deviations from the linear plot at higher values of $\bar{x}'_n$ can be attributed to increases in the average bridge multiplicity, and possible decomposition of the dimeric repeating units. This would increase both the intercept and slope, which, despite the values in Table 3, could account for the data at high values of $\bar{x}'_n$. For example, a p_2q_2 series will fit products II within 95% confidence levels based on the standard errors given in column (*b*) of Table 3. The values of $\bar{x}_n$ show a small but significant variation with $\bar{n}_n$, so that a mixture of cyclic species, or a pure cyclic species, is improbable (6). A mixture of a linear and a cyclic species will not give a reasonable value of α for the values $p = 3$ or 4 suggested by the experimental data and the appropriate model (6). A more precise description of products II would require preparation of samples with a wider range of $\bar{x}_n$, but this has not been possible using the present techniques.

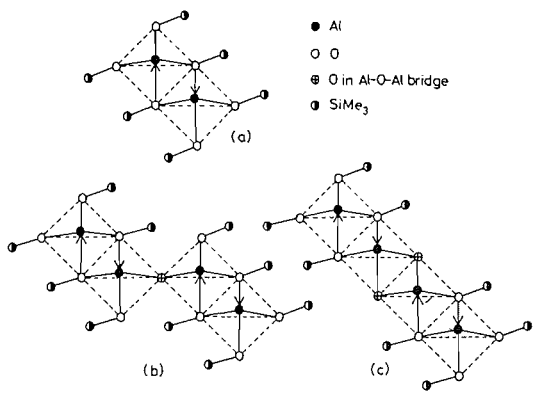

FIG. 2. (*a*) $[Al(OSiMe_3)_3]_2$ dimer, (*b*) $Al_4O(OSiMe_3)_{10}$, a p_2q_1 polymer, (*c*) $Al_4O_2(OSiMe_3)_8$, a p_2q_2 polymer.

Reaction of Phenyllithium with Some *N,N*-Disubstituted Cyanamides

HUGH J. ANDERSON, NAM-CHIANG WANG, AND (IN PART) E. T. P. JWILI
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received February 15, 1971

Phenyllithium adds to *N,N*-dialkylcyanamides **1** to form, successively, the metal salts of the amidines **3** and the guanidinylamidines **5** followed by further addition and ring closure to give the phenyl-1,3,5-triazines **8**. This proposed course of the reaction is supported by the isolation of intermediates, and compounds derived from them, as well as by determination of product yields with varying ratio of reactants. It appears that 2-thienyllithium reacts similarly with dimethylcyanamide. The reaction of phenyllithium with *N*-methyl-*N*-phenylcyanamide gives mostly the tetrasubstituted cyanoguanidine **10**.

Le phényl-lithium s'additionne aux *N,N*-dialkylcyanamides **1** pour former successivement les sels métalliques des amidines **3** et les guanidinylamidines **5**; des additions supplémentaires peuvent se produire pour conduire, après cyclisation aux phényltriazines-1,3,5 **8**. Cette séquence de réaction est supportée (*a*) par le fait que les intermédiaires ont pu être isolés et transformés en produits et (*b*) en se basant sur les rendements en produits obtenus à partir de diverses quantités de réactifs. Il semble que le thiényl-2 lithium réagit de la même manière avec la diméthyl-cyanamide. La réaction du phényl-lithium avec la *N*-méthyl *N*-phénylcyanamide fournit principalement la cyanoguanidine tétrasubstituée **10**.

Canadian Journal of Chemistry, **49**, 2315 (1971)

Some organometallics, such as phenyllithium, are known to react with *N*-methyl-*N*-phenylcyanamide to give nitriles (1). It was found however that when 2-thienyllithium reacted with dimethylcyanamide a solid was obtained instead of the desired nitrile. Microanalysis and spectral properties suggested the product to be 2,4-bis-(dimethylamino)-6-(2-thienyl)-1,3,5-triazine. To support this identification the reaction was repeated using phenyllithium and the expected 2,4-bis(dimethylamino)-6-phenyl-1,3,5-triazine (2) obtained. In addition, a second solid precipitated from the aqueous layer overnight. Subsequently it was identified as 1,1-dimethyl-2-benzoylguanidine (3).

As these results differed from those using the other cyanamide (1) and from the reaction of dimethylcyanamide with phenylmagnesium halide (4) it was decided to examine the reaction of phenyllithium with several disubstituted cyanamides varying the concentrations and solvent.

Scheme 1 shows the types of compounds obtained from the reactions of phenyllithium with dimethylcyanamide (**1***a*) and with tetramethylenecyanamide (*N*-cyanopyrrolidine) (**1***b*). It will be seen that additions of successive organometallic reagents to molecules of the cyanamide formed the salt of the amidine **2**, the salt of the guanidinylamidine **4**, and then, probably, the intermediate **7** which cyclized to the triazine **8**.

The amidine **3***a* and the triazine **8***a* obtained from dimethylcyanamide and phenyllithium were known compounds. The liquid amidine **3***a* (4) was characterized as its *p*-toluenesulfonyl derivative (5). The 2,4-bis(dimethylamino)-6-phenyl-1,3,5-triazine (**8***a*) (2) was separated from a small amount of 2,4,6-tris(dimethylamino)-1,3,5-triazine (**9***a*) (hexamethylmelamine) (6) by chromatography on silica gel.

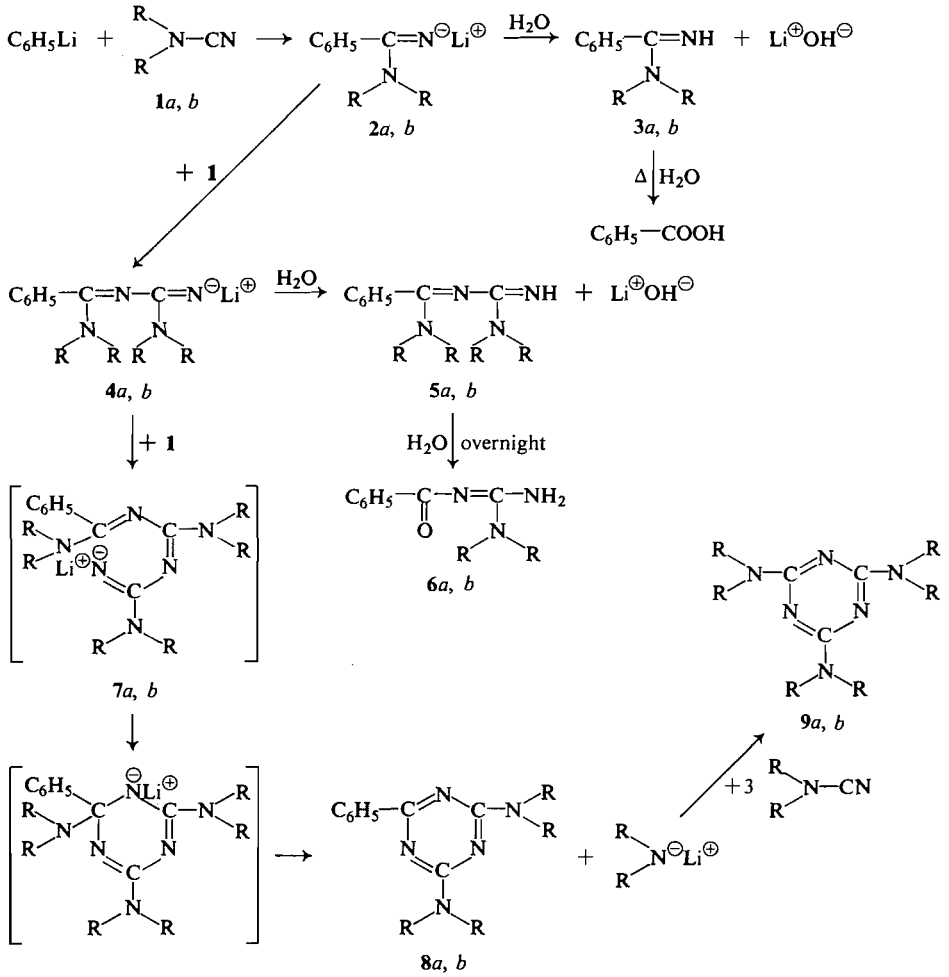
The triazine **9** probably arose from the addition of the eliminated dialkylamide ion to further molecules of dialkylcyanamide. When lithium dimethylamide was mixed with an excess of dimethylcyanamide in ether the symmetrical triazine **9***a* was obtained in poor yield.

The guanidinylamidine type compounds **5** were characterized as their *p*-toluenesulfonyl derivatives. On the basis of analysis, spectral properties, and the conversion by base solution to the corresponding benzoylguanidine **6**, structure **5** was assigned to these compounds. The known benzoylguanidine **6***a* (3) was synthesized and was identical to the hydrolysis product from **5***a*.

The structures of the "*b*" series of compounds were assigned on the basis of analysis, spectral data, and by analogy to the "*a*" series of products. Only **9***b* had been reported before (7).

It was observed that a small phenyllithium/dialkylcyanamide ratio gave more triazine while a higher ratio gave more amidine. When the solvent was a hydrocarbon, where phenyllithium has a very low solubility, triazine **9** was the major product with phenyltriazine **8** an impurity.

Observing that Lettré *et al.* had obtained a very low yield of benzonitrile when phenyllithium re-



SCHEME 1

acted with *N*-methyl-*N*-phenylcyanamide at room temperature (1) we decided to examine the residues of this reaction. A small amount of benzonitrile was obtained, together with some methylaniline. The rather insoluble substance **10** was formed in about 60% yield, based on the cyanamide. The i.r. indicated a C≡N at 2170 cm^{-1}, while the parent cyanamide value is 2225 cm^{-1}. Substance **10** was gently hydrolyzed in acid to an amide **11**, while prolonged acid hydrolysis gave 1,3-dimethyl-1,3-diphenylguanidine (**12**). The i.r. spectrum of the latter compound was identical to that recorded by Meek *et al.* (8).[1]

The 1,3-dimethyl-1,3-diphenylguanidine **12** was then hydrolyzed in base to the corresponding urea **13** which was identical to an authentic specimen (9). These reactions showed that **10** was 1,3-dimethyl-1,3-diphenyl-2-cyanoguanidine.[2] The probable mode of formation of **10** is shown in Scheme 2. To support it, lithium methyl-

[1]We thank Dr. P. M. Daugherty, Director, Chemicals Research of Scripto, Inc., for further experimental details and physical constants.

[2]The known 1,1,3,3-tetramethyl-2-cyanoguanidine (10) shows a similar C≡N peak at 2173 cm^{-1}, and in the C=N region it had two peaks at 1564 and 1546 cm^{-1}. The first was assigned to C=N stretch and the second to asymmetric CN_2 stretch. McCarty *et al.* (11) prepared *N*-substituted-*N'*-cyano-*S*-methylisothioureas. These showed the C≡N at 2160–2180 and the C=N at 1520–1550 cm^{-1}. In our cyanoguanidine the aromatic bands overlap the C=N region. There is a broad band with strong maximum at 1535, a shoulder about 1555, as well as a weak peak at 1580 cm^{-1}.

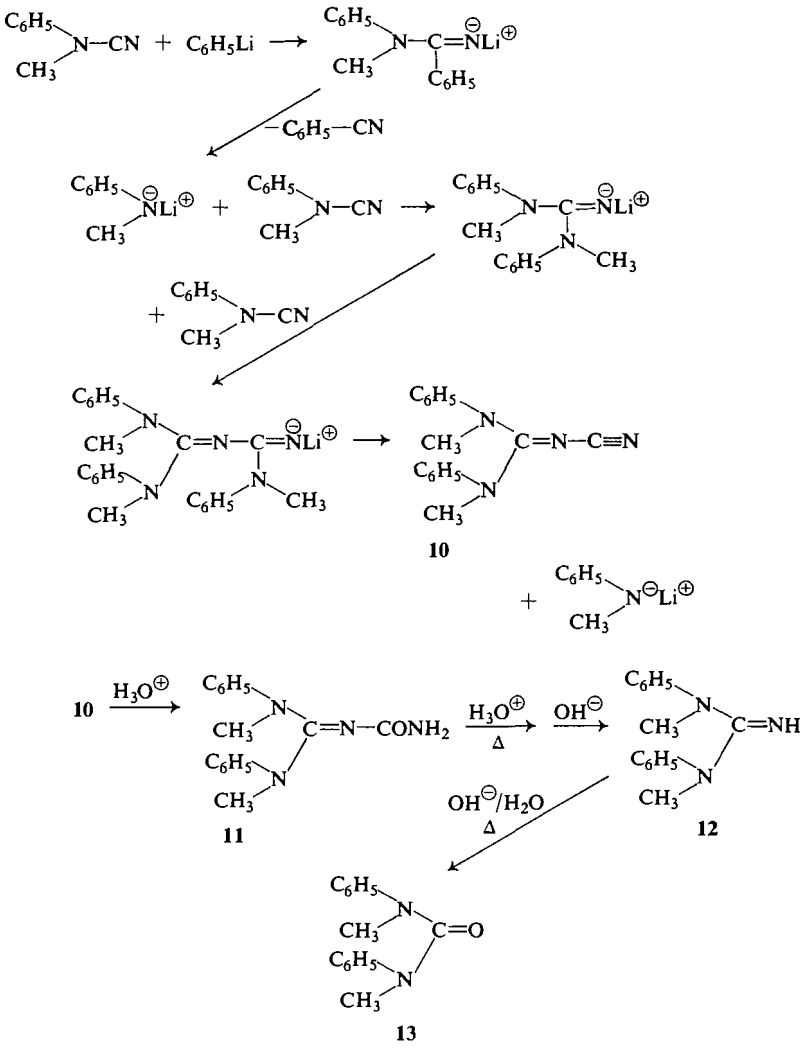

SCHEME 2

phenylamide was reacted with methylphenylcyanamide to give an 80% yield of the cyanoguanidine **10**. It will be seen that the significant difference in Scheme 2 is the splitting out of the methylphenylamide ion.

These results led to us to consider the reaction of phenyllithium with diphenylcyanamide. However, the yield of benzonitrile was small and most of the cyanamide was recovered unchanged.

The mass spectra of the triazines are consistent with those observed previously for triazines which possess the alkylamino group (12). All the triazines showed a strong molecular ion. For the bis- and tris-pyrrolidinyltriazines the base peak was M-28, representing the loss of ethylene. In the dimethylamino series loss of CH_3 was important as was loss of 43(CH_3—N=CH_2). There were strong peaks at 71($(CH_3)_2$N—$\overset{+}{C}$NH) and 96($(CH_3)_2$N—$\overset{+}{C}$N—CN). Corresponding peaks occurred in the pyrrolidinyl series. Mechanisms may be drawn for the formation of these ions in the manner of Ross and Tweedy (12).

Experimental

Melting points (uncorrected) were determined on a Fisher–Johns apparatus. Elemental analyses were by Alfred Bernhardt, West Germany. The i.r. spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer using potassium chloride discs, while u.v. spectra were recorded on a Perkin–Elmer 202 spectrophotometer. The p.m.r. spectra were determined using a Varian A-60 or HA100 instrument. Values are given using the τ scale

with tetramethylsilane as internal reference. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6E spectrometer using the direct inlet system. Spectra were normalized when the variation of total ion current was less than 6%. Peak intensities are given as a percentage of the base peak.

Reaction of Phenyllithium with Dimethylcyanamide

Phenyllithium (2.1 g, 0.025 mol) in 40 ml dry ether (13) was transferred under dry nitrogen into a 1-l three-necked flask equipped with dropping funnel, stirrer, and condenser. A solution of dimethylcyanamide (7 g, 0.1 mol) (14) in 40 ml dry ether was added, under nitrogen and with stirring, at a rate to maintain gentle reflux. After 15 min reflux the solution was cooled and cold water (80 ml) was added. Some solid separated, but redissolved. The layers were separated and the aqueous one extracted twice again with ether. After drying ($MgSO_4$) the combined ether layer was flashed down and the residue distilled in vacuum to remove unreacted materials. The remaining solid was extracted with isopropyl alcohol and chromatographed on silica gel using chloroform as eluant to give two pure products.

2,4-Bis(dimethylamino)-6-phenyl-1,3,5-triazine (**8***a*), 2.29 g (38%) m.p. 103–103.5° from isopropyl alcohol, lit. (2) m.p. 105–106°; λ_{max} (ethanol) 235 nm (ε 40 500); ν_{max} 1595s, 1550s, 1520s, 1460w, 1385s, and 1215m cm^{-1}; n.m.r. τ 1.50 (m, 2H), 2.58 (m, 3H), 6.78 (s, 12H); mass spectrum M^+ 243 (100%), major fragments at *m/e*, 228(62), 214(28), 200(53), 96(26), and 71(34).

2,4,6-Tris(dimethylamino)-1,3,5-triazine (**9***a*), 1.02 g (14%) m.p. 172.5–173° from dimethylformamide, lit. (6) m.p. 172–174°; λ_{max} (ethanol) 226 nm (ε 49 400); ν_{max} 1625m, 1545s, 1525s, 1450m, 1385s, and 1215m cm^{-1}; n.m.r. τ 6.90(s); mass spectrum M^+ 210(100%) major fragments at *m/e* 195(62), 167(37), 152(30), 96(57), and 71(19).

The distillate from an experiment where the ratio of reactants was 1:1 was dissolved in ether (80 ml) and extracted with an equal volume of 3 *N* hydrochloric acid. The extract was cooled and made basic. An ether extract of the basic solution was washed with water and dried ($MgSO_4$). After removal of the solvent vacuum distillation gave *N,N*-dimethylbenzamidine (**3***a*) b.p. 76–78°/1 mm (yield about 28%), lit. b.p. 118°/11 mm (4). The i.r. spectrum was identical to that of an authentic specimen. *p*-Toluenesulfonyl derivative, m.p. 161–162° lit. (5) m.p. 161–162°.

The aqueous layer from the original separation was then treated in one of two ways:

(*a*) From a reaction where the ratio of dimethylcyanamide to phenyllithium was 1.5:1 the aqueous layer was immediately extracted twice with chloroform and dried ($MgSO_4$). After removal of the chloroform the residue, **5***a*, was dissolved in acetone and a solution of *p*-toluenesulfonyl chloride was added followed by 50% sodium hydroxide solution and, after stirring, ice-water (100 ml). The precipitate was 1-(α-dimethylaminobenzylidene)-3,3-dimethyl-2-*p*-toluenesulfonylguanidine, m.p. 168–170° from isopropyl alcohol; λ_{max} (methanol) 239 nm (ε 20 800); ν_{max} 1585s, 1570s; n.m.r. τ 2.50 (m, 9H), 7.02 (s, 6H), 7.22 (s, 6H), 7.65 (s, 3H); mass spectrum M^+ 372(9%).

Anal. Calcd. for $C_{19}H_{24}N_4O_2S$: C, 61.27; H, 6.49; N, 15.04; S, 8.61. Found: C, 61.40; H, 6.35; N, 15.26; S, 8.41.

(*b*) The aqueous layer from a reaction where the ratio of reactants was 2:1 was allowed to stand overnight. 1,1-Dimethyl-2-benzoylguanidine (**6***a*) precipitated, m.p. 163–164°, from benzene (yield 17%). Identical to an authentic sample prepared by the method of Bredereck and Richter (3), as determined by comparison of i.r. spectra and mixture m.p.

Reaction of Lithium Dimethylamide with Dimethylcyanamide

A solution of lithium dimethylamide (0.05 mol) was prepared in 100 ml absolute ether (15). Dimethylcyanamide (14 g, 0.20 mol) in 20 ml ether was then added at a rate which kept the mixture at reflux. After a further 30 min reflux, it was cooled and an equal volume of cold water added. The layers were separated and the aqueous layer extracted twice with ether. From the residue of the dried ether extract about 8% of 2,4,6-tris(dimethylamino)-1,3,5-triazine (**9***a*) was obtained, m.p. 172.5–173°. Most of the cyanamide was recovered unreacted. No crystals precipitated from the aqueous layer overnight.

Reaction of Phenyllithium with Tetramethylenecyanamide

The procedures used were identical to those described above but using a 2.5:1 mol ratio of tetramethylenecyanamide (*N*-cyanopyrrolidine) (16) to phenyllithium. Evaporation of the combined, dried ether extracts produced a solid which was chromatographed on silica gel, eluting with a 15:1 mixture of chloroform and acetone. This gave 2,4-bis(1-pyrrolidinyl)-6-phenyl-1,3,5-triazine (**8***b*), m.p. 179–180°, from dimethylformamide; λ_{max} (methanol) 237 nm (ε 46 500); ν_{max} 1590m, 1580m, 1550s, 1520s, 1490m, 1475s, 1460s, 1385m, 1350m cm^{-1}; n.m.r. τ 1.55 (m, 2H), 2.58 (m, 3H), 6.34 (t, 8H), 8.08 (m, 8H); mass spectrum M^+ 295(94%) major fragments at *m/e* 268(62), 267(100), 266(33), 239(31), 226(43), 70(30), 55(26).

Anal. Calcd. for $C_{17}H_{21}N_5$: C, 69.12; H, 7.17; N, 23.71. Found: C, 69.02; H, 7.37; N, 23.54.

Also eluted was 2,4,6-tris(1-pyrrolidinyl)-1,3,5-triazine (**9***b*), m.p. 184.5–187°, from dimethoxyethane and a little water, lit. (7) m.p. 186.6–189.8°; λ_{max} (ethanol) 230 nm (ε 58 000); ν_{max} 1525s, 1490m, 1475m, 1450s, 1350m, 1330m, 810m cm^{-1}; n.m.r. τ 6.45 (t, 12H), 8.10 (m, 12H); mass spectrum M^+ 288(78%) major fragments at *m/e* 260(100), 232(40), 219(41), 122(28), 55(28).

After standing overnight, the aqueous layer precipitated 1,1-tetramethylene-2-benzoylguanidine (**6***b*), m.p. 167–168°, from benzene; λ_{max} (methanol) 246 (sh ε 9200) 271 nm (ε 17 000); ν_{max} 3290m, 1625m, 1590s, 1560s, 1525s, 1445s, 1425m, 1340s, 1325s cm^{-1}; n.m.r. τ 1.75 (m, 2H), 2.35 (s, broad, 2H), 2.62 (m, 3H), 6.48 (m, 4H), 8.08 (m, 4H); mass spectrum M^+ 217(31%) major fragments at 140(26), 105(27), 77(32), 70(100).

Anal. Calcd. for $C_{12}H_{15}N_3O$: C, 66.34; H, 6.96; N, 19.34. Found: C, 66.21; H, 6.89; N, 19.51.

From an experiment where the mole ratio of tetramethylenecyanamide to phenyllithium was 1:1 the corresponding amidine **3***b* and guanidinylamidine **5***b* were obtained from the ether and aqueous layers by the procedures described earlier and isolated as their *p*-toluenesulfonyl derivatives.

N,N - Tetramethylene - *N'* - *p* - toluenesulfonylbenzamidine, m.p. 150–151° from ethyl acetate; λ_{max} (methanol) 248 nm (ε 19 000); ν_{max} 1575w, 1525s, 1450s, 1440s,

Anal. Calcd. for $C_{23}H_{28}N_4O_2S$: C, 65.07; H, 6.65; N, 13.20; S, 7.55. Found: C, 65.03; H, 6.52; N, 13.25; S, 7.45.

Reaction of 2-Thienyllithium with Dimethylcyanamide

2-Thienyllithium (17) (0.1 mol) was prepared in ether (100 ml), and was added to dimethylcyanamide (0.1 mol) in ether (50 ml) with stirring and cooling. After stirring a further 2 h at room temperature the solution was poured onto ice, acidified with 3 *N* hydrochloric acid, and the layers separated. The combined dried ether extract of the aqueous layer was removed and some low boiling material distilled off under vacuum. The black crystalline residue was crystallized from isopropyl alcohol. 2,4-Bis(dimethylamino)-6-(2-thienyl)-1,3,5-triazine, m.p. 95–96°; λ_{max} (ethanol) 233 (ε 30 400), 285 nm (16 800); ν_{max} 1595m, 1550s, 1535s, 1505s, 1395s; n.m.r. (CCl_4) τ 2.12 (q, 1H), 2.71 (q, 1H), 3.03 (q, 1H), 6.88 (s, 12H); mass spectrum M^+ 249(100%) major fragments at *m/e* 234(47), 220(25), 206(35), 96(24), 71(23).

Anal. Calcd. for $C_{11}H_{15}N_5S$: C, 52.99; H, 6.06; N, 28.09; S, 12.86. Found: C, 52.98; H, 6.54; N, 27.91; S, 12.85.

Reaction of Phenyllithium with Phenylmethylcyanamide

Following the method of Lettré *et al.* (1) a solution of phenyllithium (0.1 mol) in 100 ml absolute ether was added to *N*-phenyl-*N*-methylcyanamide (32.5 g, 0.24 mol) in 35 ml absolute ether. A white solid separated which persisted during a 30 min reflux and appeared at the interface when an equal volume of water was added to the reaction mixture. It was filtered and the two layers separated. After two extractions the combined ether extract was washed with dilute hydrochloric acid, water, and dried. Following evaporation of ether the benzonitrile and unreacted material were distilled under reduced pressure. A pure sample of benzonitrile was obtained by passing the mixture through a column of neutral alumina, eluting with 5 parts petroleum (60–80°) to 3 parts benzene; yield 4%. Recrystallization of the residue from distillation yielded more of the insoluble material above (yield 58%). 1,3-Dimethyl-1,3-diphenyl-2-cyanoguanidine (**10**), m.p. 126–126.5°, from carbon tetrachloride; λ_{max} (methanol) 258 nm (ε 21 000); ν_{max} 2170s, 1535s, 1480s; n.m.r. τ 2.92 (m, 6H), 3.25 (m, 4H), 6.64 (m, 6H); mass spectrum M^+ 264(30%) major fragments at *m/e* 158(23), 147(100), 132(24), 117(24), 106(30), 77(57).

Anal. Calcd. for $C_{16}H_{16}N_4$: C, 72.70; H, 6.10; N, 21.20. Found: C, 72.60; H, 6.08; N, 21.30.

The dilute hydrochloric acid wash solution was allowed to stand overnight, cooled, and made basic with 6 *N* sodium hydroxide solution. It was extracted and the ether layer was washed with water, dried ($MgSO_4$), and removed. A thick liquid, 1,3-dimethyl-1,3-diphenylguanidine, distilled at 105–110°/0.05 mm, lit. (8) 124°/0.07 mm. The i.r. spectrum was identical to that reported by these authors for 1,3-dimethyl-1,3-diphenylguanidine (**12**).

The hydrogen halide salts were prepared by bubbling the appropriate dried gas into an ether solution of the guanidine **12**. 1,3-Dimethyl-1,3-diphenylguanidinium chloride, sintered 238° (blue color), m.p. 242–243° (dec.) from methanol/ether, lit. (8) m.p. 238°. 1,3-Dimethyl-1,3-diphenylguanidinium bromide, sintered 237°, m.p. 243–244° (dec.), lit. (8) m.p. 244–245°.

Reaction of Methylphenylcyanamide with Lithium Methylphenylamide

A solution of lithium methylphenylamide was prepared from *N*-methylaniline (16 g, 0.15 mol) and phenyllithium (0.1 mol) in about 80 ml absolute ether. The solution was refluxed 30 min, cooled, and a solution of methylphenylcyanamide (26.4 g, 0.2 mol) in 20 ml absolute ether was added slowly. After a further 30 min reflux the white solid was filtered and a second crop was recovered from the ether layer. After recrystallization the solid was proved to be 1,3-dimethyl-1,3-diphenyl-2-cyanoguanidine (**10**) (75%) by comparison of i.r. spectra and mixture m.p.

Hydrolyses of 1,3-Dimethyl-1,3-diphenyl-2-cyanoguanidine

(*a*) 1,3-Dimethyl-1,3-diphenyl-2-cyanoguanidine (2.0 g, 0.0076 mol) was warmed with 60 ml 6 *N* hydrochloric acid until clear, was cooled in ice, neutralized with 6 *N* sodium hydroxide, and the solid filtered. 1,3-Dimethyl-1,3-diphenyl-2-carbamylguanidine (**11**), m.p. 154–155°, from pyridine, yield 80%; λ_{max} (methanol) 256 nm (ε 19 100); ν_{max} 3300m (broad), 1675m, 1600m, 1585w, 1560s, 1495m, 1365s; n.m.r. (d_6DMSO) τ 3.00 (m, 10H), 3.82 (s, broad, 2H), 6.90 (s, 6H); mass spectrum M^+ 282(3%), major fragments at *m/e* 238(41), 133(30), 107(100), 106(77), 77(34), 43(41).

Anal. Calcd. for $C_{16}H_{18}N_4O$: C, 68.06; H, 6.43; N, 19.85. Found: C, 68.19; H, 6.39; N, 20.01.

(*b*) The cyanoguanidine (4 g, 0.015 mol) was refluxed in 6 *N* hydrochloric acid for 24 h. The solution was cooled, made strongly basic with 6 *N* sodium hydroxide, and extracted with ether. The ether layer was washed with water, dried ($MgSO_4$), and flashed down in vacuum. A thick liquid distilled at 105–110°/0.05 mm identical with 1,3-dimethyl-1,3-diphenylguanidine (**12**) (80%) above.

(*c*) The cyanoguanidine was refluxed in 3 *N* sodium hydroxide solution for 48 h, cooled, and extracted with chloroform. The extract was washed with water and dried ($MgSO_4$). After distillation the residue was recrystallized from ether to give *N,N'*-dimethyl-*N,N'*-diphenylurea (**13**) m.p. 118–119°, lit. (9) m.p. 121°. Shown by i.r. spectra and mixture m.p. to be identical to an authentic specimen (9).

Reaction of Phenyllithium and Diphenylcyanamide

Following the procedure for the reaction with phenylmethylcyanamide the reaction of phenyllithium and

N,N-diphenylcyanamide was found to give about a 10% yield of benzonitrile and unreacted starting material.

Base-catalyzed Dehydrobromination of Several α-Bromoacetals[1]

H. A. Davis and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received February 18, 1971

Base-catalyzed dehydrohalogenation with potassium *t*-butoxide in *t*-butyl alcohol of the acetals obtained from homologues of α-bromoacetaldehyde and ethylene glycol[2-(α-bromoalkyl)-1,3-dioxolanes] or 1,3-propanediol[2-(α-bromoalkyl)-1,3-dioxane] provides the corresponding ketene acetal, in some cases exclusively and in others as the major product along with a smaller proportion of the α,β-unsaturated acetal. In contrast, similar dehydrohalogenation conditions convert the acetals obtained from homologues of α-bromoacetaldehyde and monohydroxy alcohols, to the α,β-unsaturated acetals, in some cases exclusively, and in others as the major product accompanied by a smaller proportion of the corresponding ketene acetal.

The preference for the ketene acetal formation from the 2-(α-bromoalkyl)-1,3-dioxolanes (the ethyleneacetals) is believed due to greater ease of approach by base to the methine proton as a result of the restricted shape of the 1,3-dioxolane ring. Approach by base to the methine proton of the α-bromoalkyl dialkylacetals is more hindered by the two alkoxy groups, which cause preferred attack by base at the β proton to provide the α,β-unsaturated acetal.

The proportion of α,β-unsaturated acetal obtained from base-catalyzed dehydrohalogenation of 2-(α-bromoalkyl)-1,3-dioxolanes can be greatly increased if the reaction is carried out in dimethyl sulfoxide. This marked change in proportion of products is thought to be due to a change in mechanism occasioned by the dimethyl sulfoxide.

La déhydrohalogénation baso-catalysée avec le *t*-butoxyde de potassium dans l'alcool *t*-butylique, des acétals obtenus à partir des homologues de l'α-bromoacétaldéhyde et des [(α-bromoalkyl)-2 dioxolanes-1,3] éthylène glycol ou [(α-bromoalkyl)-2 dioxanes-1,3] propanediol-1,3, conduit aux acétals cétène correspondants; et ceci exclusivement dans certains cas et dans d'autres cas en tant que produits majoritaires avec une plus petite proportion d'acétal α–β insaturé. Au contraire, les mêmes conditions de déhydrohalogénation transforment les acétals obtenus à partir des homologues de l'α-bromoacétaldéhyde et des alcools monohydroxy, en acétals α–β insaturés, exclusivement dans certains cas, et en tant que produits majoritaires dans d'autres cas, accompagnés par une petite proportion de l'acétal cétène correspondant.

La formation préférentielle de l'acétal cétène à partir des (α-bromoalkyl)-2 dioxolanes-1,3 (les éthylèneacétals) est probablement due à une plus grande facilité d'approche du proton méthyne par la base et ceci probablement par suite de la forme restreinte du cycle du dioxolane-1,3. L'approche par une base du proton méthyne des α-bromoalkyl dialkylacétals est plus empêchée par les deux groupes alkoxy qui provoquent l'attaque préférentielle par une base sur le proton β pour conduire à un acétal α–β insaturé.

Le proportion d'acétal α–β insaturé obtenu par déhydrohalogénation baso-catalysée des (α-bromoalkyl)-2 dioxolanes-1,3 peut être de beaucoup augmentée si la réaction est effectuée dans le diméthyl sulfoxyde. Cette modification importante dans la proportion des produits obtenus est probablement due à un mecanisme différent provoqué par le diméthyl sulfoxyde.

Canadian Journal of Chemistry, 49, 2321 (1971)

Introduction

For a part of our general study of the hydrogenolysis of acetals and ketals, several α,β-unsaturated ethyleneacetals were required. The preparation of a few α,β-unsaturated dialkylacetals has been described by McElvain *et al.* (1–4) in reports of their extensive investigations of ketene acetals. They found that base-catalyzed dehydrohalogenation of α-haloacetals containing only hydrogen, aryl, or halogen substituents on the α carbon, gave only ketene acetals (**1** in eq. *a*, Scheme 1). However, if the α carbon had attached to it a carbon atom bearing one or more hydrogen atoms, then only the α,β-unsaturated acetal was produced (**2** in eq. *b*, Scheme 1). They also showed that authentic alkylketene acetals (*e.g.* **3**, R, R′ = H or alkyl in eq. *b*, Scheme 1) were not converted to α,β-unsaturated acetals under the dehydrobromination conditions. They did pre-

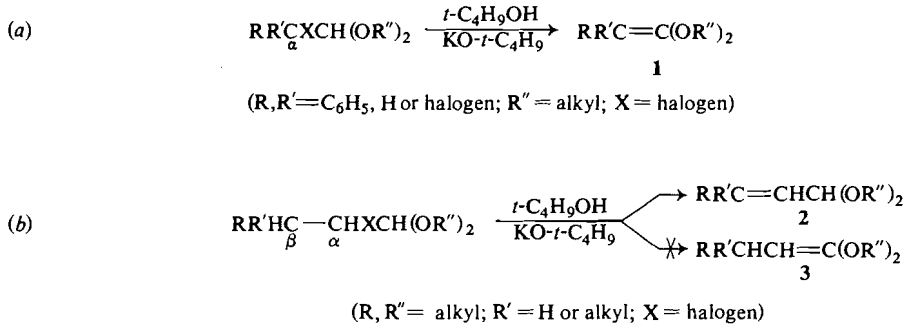

SCHEME 1

pare some α-bromo acetals from diols, but none of these had an alkyl group attached to the α carbon, hence on dehydrohalogenation these could produce only the ketene acetals (4).

This paper describes the results of our experiments concerning the base-catalyzed dehydrobromination of several α-bromoacetals derived from the combination of some higher homologues of α-bromoacetaldehyde with dihydroxy alcohols as well as with some monohydroxy alcohols.

Results and Discussion

When α-bromo-*n*-valeraldehyde ethyleneacetal was dehydrohalogenated with potassium *t*-butoxide in *t*-butyl alcohol and the product isolated and purified by the procedure of McElvain *et al.* (3) (procedure IIIA, Experimental), only the ketene acetal was produced. There was no evidence whatsoever, either by g.l.c., t.l.c., or the p.m.r. spectrum of the crude product obtained by distillation, that the α,β-unsaturated acetal had been formed even in small amount (experiment 3, Table 1). Similar treatment of α-bromo-*iso*-valeraldehyde ethyleneacetal provided primarily the ketene acetal, but in this case the α,β-unsaturated acetal was also formed, though only to the extent of 14% of the product (experiment 7, Table 1). These results are contrary to those expected on the basis of the previous work (1–4). Accordingly, the dehydrohalogenation of several homologues of these α-bromoaldehyde ethyleneacetals (experiments 1, 2, 4, 8, 11) and of the acetal obtained from α-bromo-*n*-valeraldehyde and 1,3-propanediol (experiment 12) was investigated. As well, a number of α-bromoaldehyde dialkylacetals were also dehydrohalogenated (experiments 13–17) and the products examined by modern techniques.

Since we had found in several cases that the α,β-unsaturated acetal and ketene acetal products of an experiment had nearly the same g.l.c. retention time and also that some of the ketenes decomposed on the g.l.c. column, the isolation procedure was modified by treating the reaction mixture, after the heating period was completed, with water followed by extraction of the products and subsequent purification (procedure IIIB, Experimental). This addition of water trapped the ketene product by quantitative conversion to an ester (4) which was stable on the g.l.c. column. Because the g.l.c. retention time was considerably greater than that of the α,β-unsaturated acetal, the relative quantity of the ester, and hence of the ketene acetal precursor, could be estimated by g.l.c. The results are shown in Table 1.

It is seen that base-catalyzed dehydrohalogenation of our 2-(α-bromoalkyl)-1,3-*dioxolanes* (the ethyleneacetals) and of 2-(α-bromoalkyl)-1,3-*dioxane* generally provides the ketene acetal in greater proportion, and in several cases exclusively (experiments 1–4, 7, 8, 12). The only one which does not follow this general course is the tetramethylated 1,3-dioxolane of experiment 11, and this goes to the other extreme in giving only the α,β-unsaturated acetal. In contrast, the dehydrohalogenation of our di*alkyl*acetals provides the α,β-unsaturated acetals, in some cases exclusively (experiments 13, 16) and in other cases as the major product along with a smaller proportion (6–26%) of the ketene acetal (experiments 14, 15, 17).

The reduction of the percentage of ketene acetal obtained from the α-bromo-*n*-valeraldehyde dialkylacetals from 26 to 12 to 0% when the alkyl group is changed from methyl to ethyl, to isopropyl respectively (experiments 14–16) could be

due to either an electronic effect following the views of McElvain *et al.* (2) or to an increasing steric opposition to approach of the methine hydrogen by the base as the alkyl group becomes larger. The exclusive formation of the ketene acetal from 2-(α-bromo-*n*-butyl)-1,3-dioxolane (experiment 4) strongly supports the view that it is the steric approach to the methine hydrogen rather than the difference in electronic properties of the alkyl groups, which is the feature which determines the proportion of ketene acetal obtained, since the small difference in electron donor properties of the methyl groups (experiment 14) and the ethylene group (experiment 4) would not account for the marked change in the proportion of ketene acetal obtained in these two cases. Models of the dialkylacetals of α-bromo-*n*-valeraldehyde show that the freely rotating alkoxy groups offer much steric opposition to approach to the methine hydrogen. On the other hand, models of the ethyleneacetals show that the restricted shape and position of the 1,3-dioxolane ring permits easy access by base to the methine hydrogen. When this approach is blocked, as in the case of 2-(α-bromo-*n*-butyl)-4,4,5,5-tetramethyl-1,3-dioxolane (experiment 11), then the α,β-unsaturated acetal rather than the ketene acetal is produced. The chair conformation of the 2-(α-bromo-*n*-butyl)-1,3-dioxane ring (5) provides some steric opposition to approach of the base to the methine hydrogen due to interaction of the two remaining axial protons (1,3-diaxial interaction) and hence the proportion of ketene to α,β-unsaturated acetal obtained in this case is as low as 60:40 (experiment 12).

The results described above clearly show that the methine hydrogen of acetals (the "anomeric" hydrogen) can be removed by base if an halogen atom is attached to the α carbon, and that this appears to occur more readily than does the alternate path of dehydrohalogenation involving removal of hydrogen from the β carbon of α-halogenated acetals, providing that the methine hydrogen is readily accessible to the base. The formation of only the ketene acetal from both α-bromopropionaldehyde ethyleneacetal (experiment 1) and α-bromo-*iso*-butyraldehyde ethyleneacetal (experiment 2) also supports this view. We have found that *n*-valeraldehyde ethyleneacetal, when subjected to the dehydrohalogenation conditions with potassium *t*-butoxide in *t*-butyl alcohol-OD (procedure IIIA, Experimental), was unchanged, containing no deuterium on the methine carbon. Furthermore, α-bromo-*n*-valeraldehyde ethyleneacetal, heated in *t*-butyl alcohol-OD with a half-molar equivalent of potassium *t*-butoxide (procedure IIIA, Experimental), provided the ketene acetal along with recovered α-bromo-*n*-valeraldehyde ethyleneacetal which contained no deuterium. These results strongly suggest that the elimination of the halogen acid to form the ketene acetal does not involve initial removal of the methine hydrogen as a proton by an ElcB process, but rather that the loss of the proton and the halogen occurs by a concerted process under the conditions employed.

The observation that as much as 15% of α,β-unsaturated acetal is obtained from the dehydrohalogenation of α-bromo-*iso*-valeraldehyde ethyleneacetal (experiment 8), while only the ketene acetal is obtained by similar dehydrohalogenation of α-bromo-*n*-valeraldehyde ethyleneacetal (experiment 4) suggests that the transition state leading to the formation of the α,β-unsaturated acetal in experiment 8 is stabilized by the two methyl groups (6), and this counteracts to some extent the ease of access to and removal of the methine hydrogen by base to cause preferential formation of the ketene acetal. The same phenomenon could explain the greater proportion (94%) of α,β-unsaturated acetal formed from α-bromo-*iso*-valeraldehyde diethylacetal (experiment 17) than from α-bromo-*n*-valeraldehyde diethylacetal (88%, experiment 15).

It has been possible to increase markedly the proportion of α,β-unsaturated acetals obtained from the α-bromoaldehyde ethyleneacetals by changing the solvent from *t*-butyl alcohol to dimethyl sulfoxide (DMSO). Dehydrohalogenation of α-bromo-*n*-valeraldehyde ethyleneacetal (experiment 5) and α-bromo-*iso*-valeraldehyde ethyleneacetal (experiment 9) with sodium methoxide in DMSO (procedure IIIC, Experimental) provides the corresponding α,β-unsaturated acetals to the extent of 70 and 98% respectively. If the base employed in DMSO is potassium *t*-butoxide (procedure IIID, Experimental), the proportion of α,β-unsaturated acetal obtained is decreased to 33 and 72% respectively (experiments 6 and 10), but this is still much more than is obtained by using *t*-butyl alcohol as solvent (0 and 14% respectively, experiments 3 and 7). The difference in results obtained by the two bases in DMSO may be due to their differences in size.

The pronounced increase in proportion of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

α,β-unsaturated ethyleneacetal to ketene acetal obtained by changing the solvent from *t*-butyl alcohol to DMSO is believed due to a change in mechanism. It is known that the basicity of metal alkoxides is enhanced in DMSO and this is thought to result in a greater degree of C—H bond stretching as compared with C—Br bond stretching in the transition state (7, 8). The following explanation is suggested to account for the results obtained.

In *t*-butyl alcohol, association of the solvent with the bromine atom as well as with the oxygen atom(s) of the 1,3-dioxolane ring would encourage C—Br bond stretching in the former situation, while in the latter, the methine hydrogen would tend to become more acidic. If one assumes a considerable extent of both C—Br and C—H bond breaking along with a substantial degree of double bond formation in the transition state, then steric or "*cis*" effects become important (9 and references therein). Because of the shape of the 1,3-dioxolane ring, one would expect these steric effects to be much less important in the transition state leading to the ketene acetal than in the transition state leading to the α,β-unsaturated acetal. On this basis the preference for the formation of the ketene acetal (100% from α-bromo-*n*-valeraldehyde ethyleneacetal, experiment 3; 85% from α-bromo-*iso*-valeraldehyde ethyleneacetal, experiment 8) becomes understandable. The formation of the α,β-unsaturated acetal to the extent of 15% from α-bromo-*iso*-valeraldehyde ethyleneacetal may be a reflection of electronic effects due to the two methyl groups.

In DMSO, such association of the solvent with the bromine and oxygen atoms does not occur. In this situation, C—H bond breaking is considered to be much more important than is C—Br breaking (7, 8). Accordingly, the transition state does not involve substantial double bond formation and hence the "*cis*" effects noted above would not hinder the attainment of the transition state. Of importance is the ease of C—H bond stretching with consequent development of carbanion character. Development of a negative charge on the methine ("anomeric") carbon of the ring would be opposed by the partial negative charge on the adjacent oxygen atom(s), a charge which is not reduced by solvation, as was suggested above for the solvent *t*-butyl alcohol. Hence attainment of the transition state leading to the ketene acetal becomes more difficult. The greater extent of α,β-unsaturated acetal formation from the α-bromo-*iso*-valeraldehyde ethyleneacetal than from the α-bromo-*n*-valeraldehyde ethyleneacetal (experiments 10 and 6 respectively) may be the result of electronic effects due to the alkyl substituents, while the greater effectiveness of sodium methoxide (experiments 5 and 9) over that of potassium *t*-butoxide (experiments 6 and 10) may be due to steric requirements of the base.

In agreement with the findings of McElvain *et al.* (1–4) we have found that ketene acetals were not converted to the corresponding α,β-unsaturated acetals either in *t*-butyl alcohol containing sodium methoxide or potassium *t*-butoxide, or in DMSO containing either of these two bases. In addition it was established that α,β-unsaturated acetals were not converted to ketene acetals under the conditions of dehydrohalogenation noted immediately above. However, the α,β-unsaturated acetals are slowly converted, at least in part, to the β,γ-unsaturated acetals. For example, when 2-pentenal ethyleneacetal was heated in refluxing *t*-butyl alcohol containing potassium *t*-butoxide, very little isomerization to the β,γ-unsaturated acetal was observed. Extension of the reflux period to ~25 h resulted in 25% conversion. Dehydrohalogenation reactions in DMSO, however, had to be carried out at temperatures no greater than 40°, since at higher temperatures, the conversion of the α,β- to the β,γ-unsaturated acetal was much more readily achieved. Table 2 shows the results of isomerization experiments carried out with several unsaturated acetals in DMSO at 80°, and containing either sodium methoxide or potassium *t*-butoxide. These support the statements above, and show also that the β,γ-unsaturated acetals under these conditions are also converted in part to the α,β-isomer. But neither is isomerized to the ketene acetal. The proportion of α,β- to β,γ-unsaturated acetal obtained apparently depends upon the relative stability of these two isomers under the reaction conditions. Experiments 5 and 9 in Table 1 also illustrate the stability of the ketene acetals and as well that the α,β-unsaturated acetals are not converted to the ketene acetals.

Experimental

Boiling points and melting points are uncorrected. The g.l.c. analyses were made with an F and M Model 700 instrument, equipped with 12′ × 1/8″ columns packed with either (*a*) butanediol succinate, 20% on Gas Chrom P (60–80 mesh), (*b*) silicone rubber SE30, 20% on Gas Chrom P (60–80 mesh) or, (*c*) Carbowax 20M, 20% on Gas Chrom P (60–80 mesh). Helium was the

carrier gas at a flow rate of ~40 ml/min. For preparative g.l.c., an Aerograph Autoprep Model A-700 was employed and this was equipped with a column 12′ × 1/4″ packed with butanediol succinate, 20% on Gas Chrom P (60–80 mesh). The column temperature and type of column used was dependent on the boiling points of the compounds. For some analytical work on the F and M Model 700, the temperature was linearly programmed to achieve better resolution. The temperature was increased at the rate of 7.5°/min starting from 80–100°, while the terminal temperature depended on the column stability. Quantitative analyses were made by measuring the areas of the peaks. In many cases, these areas were compared with those obtained from known artificial mixtures. It was found that equimolar mixtures of the products obtained from dehydrohalogenation gave peaks that were very nearly equal, if not equal in area, the difference being well within 10%.

The i.r. spectra were recorded with a Perkin–Elmer Model 21 instrument.

The p.m.r. spectra were recorded on either a Varian Associates A-60 instrument or Varian Associates A-56/60A instrument operated by Mr. R. Swindlehurst and assistants. All spectra were referred to tetramethylsilane and carried out in carbon tetrachloride solution. Signal positions were located in many cases by spin decoupling, using a 100 MHz Varian instrument. These were carried out by Mr. Glen Bigham and his associates of this Department.

The p.m.r. and i.r. spectra were obtained for all compounds, and found to be consistent with the assigned structure.

Elemental analyses were made by Mrs. Darlene Mahlow of this Department.

The drying agent for solutions was anhydrous magnesium sulfate unless otherwise stated. Solvents were removed by rotary evaporator under vacuum unless otherwise stated.

(I) Preparation of Saturated Acetals

n-Valeraldehyde Dimethylacetal

This compound was prepared by the following modification of the procedure used by Bachman for the preparation of hexanal diethylacetal (10).

To a stirred suspension of magnesium turnings (22.6 g, 0.94 mol) in 100 ml of anhydrous ether, was added dropwise 20 ml of a solution of 129 g (0.94 mol) of *n*-butyl bromide in 100 ml of anhydrous ether. The addition was carried out cautiously at first until the Grignard reaction was well started, then at such a rate as to maintain the ether at gentle reflux. After the 20 ml of the solution of *n*-butyl bromide had been added, the reaction mixture was diluted with a further quantity (400 ml) of anhydrous ether, and then the remainder of the *n*-butyl bromide solution was added dropwise. After the addition was completed, the ether solution was heated under gentle reflux for 4 h, then cooled to room temperature and 100 g (0.94 mol) of trimethyl orthoformate added dropwise and then the solution was heated under reflux overnight.

The solution, cooled to room temperature, was poured onto 500 ml of a stirred ice-water mixture. The ether layer was separated and the aqueous layer extracted with ether (2 × 200 ml). The combined ether solutions were washed first with 100 ml of water, then with 100 ml of saturated aqueous sodium chloride solution. The ether layer was dried, filtered free of solid, and the filtrate freed from ether. The residue was distilled to give a colorless liquid (45 g, 36%) boiling at 51–53° at 30 mm; η_D^{24} 1.3969 (lit. b.p. 120–129° at 760 mm (11)).

The Following Three Acetals were Prepared by the Method Used to Prepare n-Valeraldehyde Dimethylacetal Described Above

n-Valeraldehyde diethylacetal from *n*-butyl bromide and triethyl orthoformate in 80% yield. Colorless liquid, b.p. 60° at 11 mm; η_D^{23} 1.4019 (lit. b.p. 162.5–163.5°; η_D^{20} 1.4021 (12)).

iso-Valeraldehyde diethylacetal from 1-bromo-2-methylpropane and triethyl orthoformate in 75% yield. The b.p. 71° at 50 mm; η_D^{24} 1.3974 (lit. b.p. 156–158° (2)).

Propionaldehyde diethylacetal from ethyl bromide and triethyl orthoformate in 73% yield. The b.p. 121–124° at 704 mm; η_D^{26} 1.3861 (lit. b.p. 123° at 760 mm; η_D^{20} 1.3897 (13)).

(II) Preparation of α-Bromoacetals

α-Bromo-n-valeraldehyde Dimethylacetal

This compound was prepared by the following modification of the literature procedure (14).

To a stirred solution of *n*-valeraldehyde dimethylacetal (42 g, 0.32 mol) in 300 ml of dry chloroform was added, dropwise, 51 g (0.32 mol) of bromine at such a rate as to maintain the temperature of the reaction mixture at 30–35°. When the addition was complete, the solution was stirred at room temperature for 2 h and then cooled to −10°. Potassium hydroxide (18 g, 0.32 mol) in 150 ml of methanol was then added dropwise and the resulting solution then stirred while it reached room temperature. The precipitated potassium bromide was separated and the solvents removed from the filtrate by fractional distillation at atmospheric pressure through a 4-in Vigreux column. An ether (400 ml) solution of the residue was washed first with saturated aqueous sodium carbonate solution (4 × 100 ml) and then with 100 ml of saturated aqueous sodium chloride solution. The ether layer was dried, filtered, and freed from ether. The residue when distilled gave 40 g (59%) of colorless liquid, b.p. 78–80° at 12 mm; η_D^{23} 1.4559.

Anal. Calcd. for $C_7H_{15}BrO_2$: C, 39.80; H, 7.12; Br, 37.90. Found: C, 39.58; H, 7.04; Br, 38.08.

The 60 MHz p.m.r. spectrum showed a doublet centered at τ 5.70 (1H, $J \sim 6$ Hz for the methine hydrogen); a multiplet between 6.0–6.32 (1H); two singlets at 6.66 and 6.68 (6H); and a multiplet between 8.0–9.25 (7H).

The Following Three α-Bromoaldehyde Acetals were Prepared by the Same Method Used to Make α-Bromo-n-valeraldehyde dimethylacetal Above

α-Bromo-n-valeraldehyde diethylacetal from *n*-valeraldehyde diethylacetal in 70% yield. Colorless liquid, b.p. 80° at 7 mm; η_D^{23} 1.4453 (lit. b.p. 92–96° at 12 mm (15)).

α-Bromo-iso-valeraldehyde diethylacetal from *iso*-valeraldehyde diethylacetal in 60% yield, b.p. 90° at 15 mm; η_D^{23} 1.4426 (lit. b.p. 92–93° at 14 mm; η_D^{25} 1.4438 (2)).

α-Bromopropionaldehyde diethylacetal from propionaldehyde diethylacetal in 65% yield, b.p. 76–79° at 19 mm; η_D^{23} 1.4375 (lit. b.p. 82–85° at 30 mm; η_D^{20} 1.4371 (16)).

α-Bromo-n-valeraldehyde ethyleneacetal

This compound was prepared by the *trans*-acetalization of α-bromo-*n*-valeraldehyde diethylacetal with ethylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

glycol by the following modification of the procedure of McElvain and Curry (4).

α-Bromo-*n*-valeraldehyde diethylacetal (41 g, 0.17 mol) was added to a solution of ethylene glycol (11 g, 0.17 mol) in 200 ml of dry toluene. The flask was set up for fractional distillation through a 4-in. Vigreux column. *p*-Toluene sulfonic acid (0.1 g) was added to the reaction mixture which was then heated. A mixture of toluene and ethanol distilled between 75–110°. The distillation was continued until the temperature reached 110° at which only toluene was collected. The solution was cooled, washed with saturated aqueous sodium carbonate solution (2 × 100 ml), and then with 100 ml of saturated aqueous sodium chloride solution. The toluene layer was dried, filtered, and freed from solvent. The residue distilled to give 30 g (85%) of liquid, b.p. 81° at 5 mm; η_D^{24} 1.4734.

Anal. Calcd. for $C_7H_{13}BrO_2$: C, 40.02; H, 6.23; Br, 38.25. Found: C, 40.13; H, 6.10; Br, 38.15.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.15 (1H, $J \sim 4$ Hz for the methine proton); a multiplet centered at 6.1 (5H); a multiplet between 8.0–8.75 (4H); and a multiplet between 8.91–9.25 (3H).

The Following Four α-Bromoaldehyde Acetals were Prepared by the Same Method Used Above to Synthesize α-Bromo-n-valeraldehyde Ethyleneacetal

α-Bromo-iso-valeraldehyde ethyleneacetal from α-bromo-*iso*-valeraldehyde diethylacetal and ethylene glycol in 75% yield, b.p. 75° at 4.5 mm; η_D^{24} 1.4747.

Anal. Calcd. for $C_7H_{13}BrO_2$: C, 40.02; H, 6.23; Br, 38.25. Found: C, 40.09; H, 6.22; Br, 38.39.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.08 (1H, $J \sim 5$ Hz for the methine proton); a multiplet centered at 6.10 (5H); a broad multiplet between 7.70 and 8.24 (1H); and two doublets centered at 8.98 and 9.00 (6H, $J \sim 2.5$ Hz).

α-Bromopropionaldehyde ethyleneacetal from α-bromopropionaldehyde diethylacetal and ethylene glycol in 67% yield, b.p. 72° at 10 mm; η_D^{22} 1.4769.

Anal. Calcd. for $C_5H_9BrO_2$: C, 33.15; H, 4.97; Br, 44.10. Found: C, 33.49; H, 5.03; Br, 43.87.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.18 (1H, $J \sim 4$ Hz for the methine proton); a multiplet centered at 6.1 (5H); and a doublet at 8.38 (3H, $J \sim 7$ Hz).

α-Bromo-n-valeraldehyde tetramethylethyleneacetal from α-bromo-*n*-valeraldehyde diethylacetal and dry pinacol. The pinacol was prepared from pinacol hydrate (17) which was dried by the method described by Vogel (18). Yield of acetal, 75%, b.p. 84–88° at 2 mm; η_D^{24} 1.4626.

Anal. Calcd. for $C_{11}H_{21}BrO_2$: C, 49.80; H, 7.93: Br, 30.07. Found: C, 49.94; H, 7.52; Br, 30.02.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.08 (1H, $J \sim 6.5$ Hz for the methine proton); a multiplet at 6.37 (1H); a multiplet between 8.08 and 9.17 (7H); and two closely spaced singlets (12H).

2-(α-Bromo-n-butyl)-1,3-dioxane from α-bromo-*n*-valeraldehyde diethylacetal and 1,3-propanediol in 90% yield, b.p. 89–91° at 4.5 mm; η_D^{23} 1.4770.

Anal. Calcd. for $C_8H_{15}BrO_2$: C, 43.09; H, 6.73; Br, 35.83. Found: C, 43.06; H, 7.15; Br, 35.75.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.43 (1H, $J \sim 4$ Hz for the methine proton); a multiplet between 5.68 and 6.53 (5H); a multiplet between 7.52 and 9.24 (9H).

α-Bromo-n-valeraldehyde Diisopropylacetal

α-Bromo-n-valeraldehyde was made by the following modification of the procedure of Erlenmeyer and Yung (19). To a stirred solution of *n*-valeraldehyde (86 g, 1 mol) in 300 ml of chloroform, kept at −15° by means of a Dry Ice – acetone bath, was added dropwise 160 g (1 mol) of bromine. After addition of the bromine, the stirred solution was allowed to come to room temperature and then left overnight, by which time the solution's color had changed from red to yellow. Sodium bicarbonate (90 g, 1.07 mol) was added in 10 g portions so as to control the evolution of carbon dioxide. The solution was then stirred for 1 h and filtered. The chloroform was removed from the filtrate by fractional distillation at atmospheric pressure, and the residue was then distilled under vacuum from 10 g of solid sodium carbonate. Yield of colorless liquid which yellowed on standing, 49.5 g (30%), b.p. 52–56° at 15 mm; η_D^{24} 1.4702 (lit. b.p. 53–54° at 13 mm (19); η_D^{20} 1.4640 (20)).

To a stirred solution of α-bromo-*n*-valeraldehyde (66 g, 0.4 mol) in 200 ml of *iso*-propyl alcohol was added 100 g of anhydrous magnesium sulfate and 0.5 g of *p*-toluenesulfonic acid. The mixture was heated under reflux for 24 h and then cooled to room temperature and filtered free of solid. The excess *iso*-propyl alcohol was removed by fractional distillation at atmospheric pressure and the residue was distilled to give 35 g (34%) of colorless α-bromo-*n*-valeraldehyde di-*iso*-propylacetal, b.p. 85° at 8 mm; η_D^{23} 1.4398.

Anal. Calcd. for $C_{11}H_{23}BrO_2$: C, 49.44; H, 8.61; Br, 29.96. Found: C, 49.23; H, 8.31; Br, 29.67.

The 60 MHz p.m.r. spectrum showed a doublet at τ 5.40 (1 H, $J \sim 3.5$ Hz for the methine proton); a multiplet between 5.94 and 6.44 (3H), and a multiplet between 8.00 and 9.15 (19H).

α-Bromo-iso-butyraldehyde Ethyleneacetal

To a stirred solution of *iso*-butyraldehyde (43 g, 0.5 mol) in 400 ml of dry chloroform, maintained at 0° by means of an ice bath, was added dropwise 80 g (0.5 mol) of bromine. After complete addition, the solution was stirred for 1 h at room temperature whereupon sodium bicarbonate (42 g, 0.5 mol) was added to the reaction mixture in 5 g portions to control the evolution of carbon dioxide. The resulting mixture was stirred overnight and then filtered free of solid. The filtrate was washed with saturated aqueous sodium bicarbonate solution (2 × 100 ml) and then with 100 ml of saturated aqueous sodium chloride solution. The chloroform layer was dried, filtered, and freed from solvent.

To a dry benzene solution (200 ml) of the residue, was added 31 g (0.5 mol) of ethylene glycol and 0.5 g of *p*-toluenesulfonic acid. The mixture was heated under reflux for 16 h in an apparatus equipped with a water trap. The solution, cooled to room temperature, was washed with saturated aqueous sodium carbonate solution (2 × 100 ml), and then with 100 ml of saturated aqueous sodium chloride solution. The benzene layer was dried, filtered, and freed from solvent. The residue distilled to give 35 g (36%) of colorless liquid, b.p. 66° at 8 mm; η_D^{23} 1.4731.

Anal. Calcd. for $C_6H_{11}BrO_2$: C, 36.90; H, 5.74; Br, 41.00. Found: C, 36.52; H, 5.95; Br, 41.00.

The 60 MHz p.m.r. spectrum showed a singlet at τ 5.18 (1H, for the methine proton); a multiplet at 6.0 (4H); and a singlet at 8.35 (6H).

(III) Dehydrobrominations of α-Bromoaldehyde Acetals

Procedure A

This followed in detail the published procedure (3).

Procedure B

Dehydrobromination followed by addition of water to trap the ketene acetal. This is illustrated as follows for the dehydrohalogenation of *α-bromo-iso-butyraldehyde ethyleneacetal.*

To a stirred solution of potassium *t*-butoxide (2.87 g, 0.0256 mol) in 25 ml of dry *t*-butyl alcohol was added 5 g (0.0256 mol) of α-bromo-*iso*-butyraldehyde ethyleneace-

tal. The mixture was heated at 80° for 5 h (or for the time indicated in Table 1) then cooled to 50° and 50 ml of water added. This mixture was stirred for a short time, then extracted continuously for 12 h with ether. The ether layer was dried, filtered and the filtrate freed from ether and *t*-butyl alcohol by fractional distillation through a 4-in. Vigreux column. A g.l.c. analysis of the residue showed only two peaks, one due to the unreacted starting material and the other due to β-hydroxyethyl *iso*-butyrate. Comparison of the retention time of authentic methacrolein ethyleneacetal with the g.l.c. spectrum of the crude residue showed no evidence that this α,β-unsaturated acetal had been produced.

The residue was then distilled to provide unreacted α-bromo-*iso*-butyraldehyde ethyleneacetal and a 40% yield of β-hydroxyethyl-*iso*-butyrate, b.p. 78–79° at 8 mm; η_D^{20} 1.4224.

Anal. Calcd. for $C_6H_{12}O_2$: C, 54.53; H, 9.15. Found: C, 54.13; H, 9.17.

Procedure B was used in all dehydrobromination reactions involving the use of water during the work-up procedure. Products were identified either by comparison of the retention times of authentic samples with those of the peaks obtained from a g.l.c. analysis of the crude residue, or by isolation of the products and their characterization by means of their p.m.r. and i.r. spectra as well as their elemental analysis. Physical constants and elemental analysis of the products isolated from these reactions are given in Table 3. Their spectral data are shown in Table 4.

Procedure C

Dehydrobromination in DMSO followed by addition of water to trap the ketene acetal.

The procedure used was the same as that of procedure *B* except that (*a*) the solvent was DMSO and the base was sodium methoxide; (*b*) the bromoacetal was added slowly and the temperature was kept at ~40° for the requisite time (1 or 20 h); (*c*) the water was added as a saturated aqueous solution of sodium chloride to decrease the solubility of the products in the DMSO–water mixture. Products were identified by comparison of their g.l.c. retention times with those of authentic materials.

Procedure D

This was identical to procedure C except that the base was potassium *t*-butoxide.

(IV) Preparation of Some Authentic Dehydrobromination Products

Methyl n-Valerate

To a stirred solution of *n*-valeric acid (25 g, 0.245 mol) in 100 ml of anhydrous methanol was added 1 ml of concentrated sulfuric acid, and the solution heated under reflux for 2 h and then left overnight. The mixture was poured into 200 ml of saturated aqueous sodium chloride solution and this was extracted with ether (2 × 100 ml). The ether extract was washed with saturated aqueous sodium carbonate solution (3 × 50 ml) and then with 100 ml of saturated aqueous sodium chloride solution. The ether layer was dried, filtered, and the filtrate freed of solvent by fractional distillation at atmospheric pressure. The residue when distilled gave 20 g (70%) of colorless liquid, b.p. 122–123° at 705 mm; η_D^{24} 1.3952 (lit. b.p. 130° at 760 mm; η_D^{20} 1.4003 (21)).

The Following Two Esters were Prepared by the Procedure Used for the Synthesis of Methyl n-Valerate Above

Ethyl iso-valerate from *iso*-valeric acid and ethanol. Yield, 50%, b.p. 120–121° at 700 mm; η_D^{25} 1.3939 (lit. b.p. 134.7° at 760 mm; $\eta_D^{18.35}$ 1.39738 (21)).

Isopropyl n-valerate from *iso*-propyl alcohol and *n*-valeric acid. Yield, 57%, b.p. 60° at 20 mm; η_D^{24} 1.3988 (lit. b.p. 153.5° at 760 mm; η_D^{20} 1.4009 (22)).

Acrolein Ethyleneacetal

This compound was prepared by the following modification of the procedure of Fischer and Smith (23).

To a mixture of 300 ml of pentane and 100 ml of anhydrous ether was added 123.3 g (2.2 mol) of acrolein, 126 g (2.0 mol) of ethylene glycol, and 1 g of *p*-toluenesulfonic acid. The mixture was then heated under reflux in an apparatus equipped with a water trap. Vigorous stirring was required to ensure mixing of the two phases. After a 50-h reflux period, 29 ml of water was collected whereupon the mixture was allowed to cool, and then was treated with 20 g of anhydrous sodium carbonate and stirred for 1 h. Solid material was removed by suction filtration, and the filtrate freed of solvent. The residue was distilled to give 45 g (23%) of colorless oil, b.p. 62° at 110 mm; η_D^{28} 1.4260 (lit. b.p. 114–116° at 760 mm; η_D^{20} 1.4327 (23)).

Methacrolein Ethyleneacetal

This compound was prepared by published general directions (24).

From 70 g (1.0 mol) of methacrolein and 62 g (1.0 mol) of ethylene glycol there was obtained 18 g (15%) of colorless oil, b.p. 61° at 50 mm; η_D^{26} 1.4338.

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.14; H, 8.83. Found: C, 63.34; H, 9.04.

The 60 MHz p.m.r. spectrum showed a multiplet centered at τ 4.92 (2H, olefinic); a triplet at 5.10 (1H, $J \sim 1.5$ Hz methine proton); a multiplet centered at 6.17 (4H); and a doublet at 8.31 (3H, $J \sim 1.5$ Hz).

Electronic Raman Spectra. VII. Raman Spectra of the Lanthanides[1]

J. A. KONINGSTEIN[2] AND P. GRUNBERG[3]
Chemistry Department, Carleton University, Ottawa, Canada

Received November 16, 1970

Additional experimental data are reported on electronic Raman scattering of trivalent lanthanides, making the observation of this effect of the series nearly complete. The bulk of the information now available points to the fact that the intensity of electronic Raman transition is strongest for the rare earth ions in the middle of the series. The most profound differences of polarization features of electronic transitions and phonons is observed in the situation where the lanthanide ions have an odd number of 4f electrons. Antisymmetric scattering tensors play a less important role.

Des données expérimentales supplémentaires sont rapportées sur la dispersion électronique Raman des lanthanides trivalents. Ceci rend l'observation de cet effet dans les séries à peu prés complète. Le volume de l'information maintenant disponible met en évidence le fait que l'intensité de la transition électronique Raman est très importante pour les ions des terres rares dans le milieu des séries. Les différences très grandes de traits de polarisation des transitions électroniques et de phonons sont observées quand les ions lanthanidiques ont un nombre impair d'électrons 4f. Les tenseurs de dispersion antisymétriques jouent un rôle moins important.

Canadian Journal of Chemistry, 49, 2336 (1971)

Introduction

The interest in exciting the electronic Raman effect of trivalent lanthanide ions mainly stems from the fact that it can be used as a technique to determine the position and symmetry species of low lying electronic levels. Only in a few isolated cases in the pre-laser period was Raman scattering detected in which electronic levels were involved (4–6) but experimental data now available suggest that the intensity of the electronic effect of lanthanide ions in crystals is in some cases comparable to the intensity of phonons of those crystals. In this regard it may be remarked that direct transitions between the electronic states of the same configuration are parity forbidden, but they become weakly allowed as a result of crystal field or vibronic coupling effects. The intensity of these direct electronic transitions is, however, much weaker than the intensity of the phonons of the host lattice and as we shall see later this situation is sometimes reversed in the Raman spectra.

In this paper scattering of some of the ions is reported for the first time making the observation of this effect almost complete throughout the series. In other cases results of new rare earth compounds are given. Some previous results will also be mentioned where it helps to enlighten the discussion. All new results are collected in Table 1.

Up to now the following rare earth compounds have been investigated; rare earth aluminum and gallium garnets (ref. 1 and other papers of this series), chlorides (2, 7) and fluorides (3), ethyl sulfates and oxides (8), and rare earth aluminates (25).[4] One has not always been successful in exciting the electronic Raman effects. For instance, the rare earth ethyl sulfate crystals have a rather complicated phonon spectrum and the position of phonon and electronic transitions may coincide, but also the percentage of lanthanide ions in this compound is much smaller than for the rare earth aluminates and garnets. Apart from the concentration effects there is the width of the transitions. For chlorides and ethylsulfates it is necessary to study the spectra at low temperature of the samples but even then, as a result of local heating effects, due to the laser radiation, the widths of the transitions are so large that they have escaped detection (7).

The most pronounced differences of the polarization properties of phonon and electronic transitions of the same rare earth doped crystal occurs in the situation of lanthanide ions having an odd number of electrons. Examples are given

*The electronic nature is uncertain.

in Experimental section. These differences are related to the fact that extended groups (double groups) have to be employed to determine the selection rules and thus the polarization features.

Experimental Procedure

Good quality Raman spectra of single crystals of rare earth compounds were photo-electrically recorded. The apparatus has been described elsewhere (1). Some Raman spectra are shown in Figs. 1–8. The spectra were obtained from polished single crystals (4 × 2 × 4 mm) and the orientation of the crystals was in most cases known. They were cooled to 4.2 or 77 °K and several excitation frequencies were used. This was sometimes necessary to distinguish fluorescence lines from Raman bands but the routine was normally adopted to make sure that the observed spectrum was a Raman spectrum. At low temperatures of the sample the intensity of the anti-Stokes lines is very weak and a comparison of Stokes and anti-Stokes lines cannot be made.

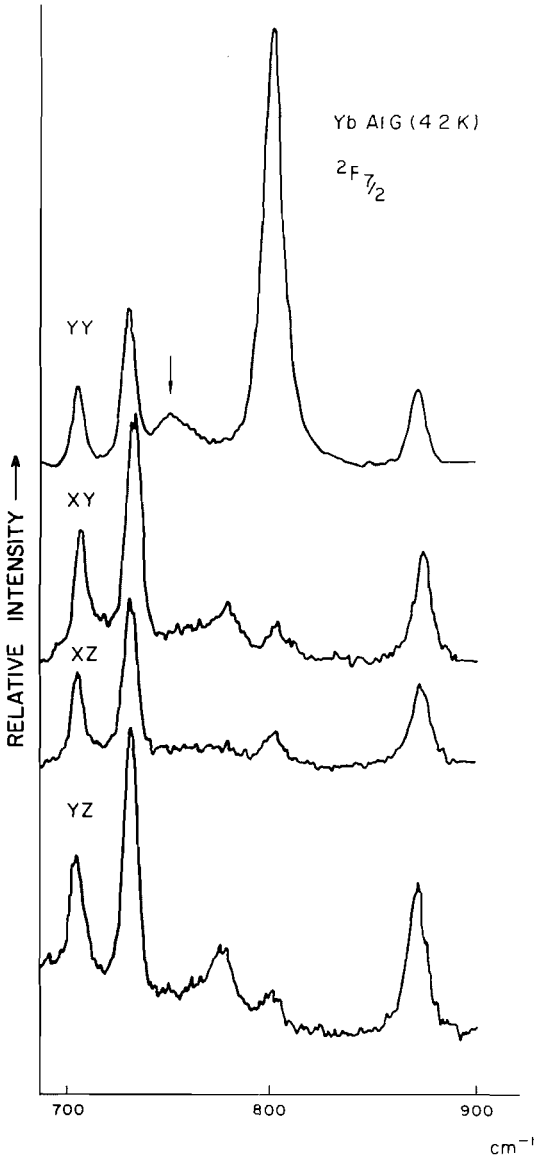

FIG. 1. Phonons and electronic (↓) Raman effects of the compound YbAlG. Temperature of the sample was 4.2 °K, slit width of 4 cm^{-1}. Indicated are the tensor components of the various Raman transitions. λ_0 = 4880 Å.

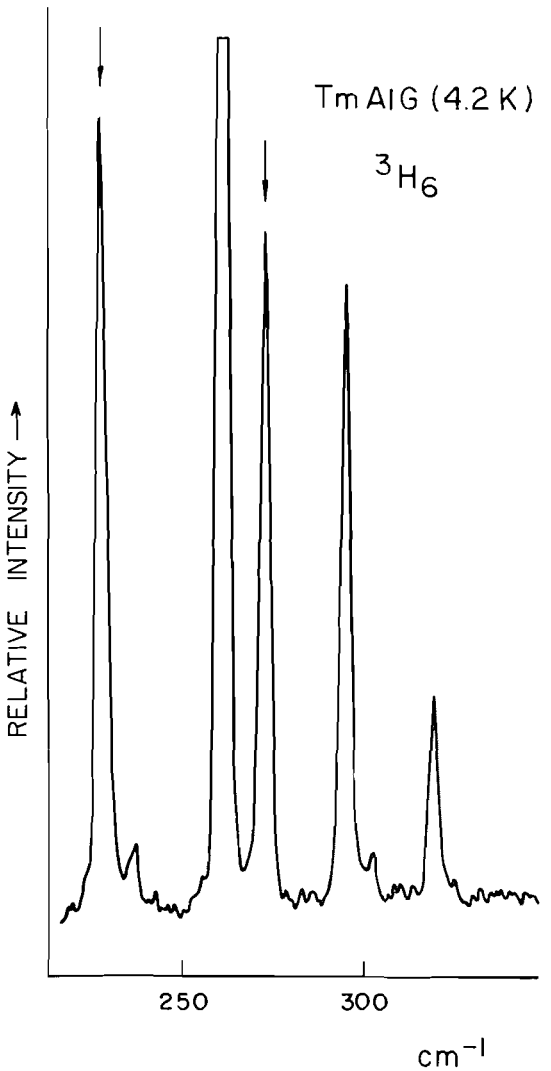

FIG. 2. Part of the low temperature Raman spectrum of an oriented crystal of TmAlG. The electronic effects are indicated. The symmetry of the Raman lines of 274 (electronic) and 296 cm^{-1} (phonon) is T_{2g}. Slit width 3 cm^{-1}, λ_0 = 5154 Å.

Discussion of the Experimental Data

(a) Scattering of Yb^{3+}

The ground state $^2F_{7/2}$ of the Yb^{3+} ion contains a maximum of 4 Kramers degenerate crystal field levels. The crystal field components of the other 4f state $^2F_{5/2}$ are at about 10 000 cm^{-1}. The case of Yb (and also Tm) in the aluminum garnet crystals may serve as an example that electron Raman spectroscopy can be employed as a tool to find low lying electronic states. Although the selection rules do not forbid the observation of the $^2F_{7/2} \rightarrow {}^2F_{5/2}$ transitions, Raman lines with shifts of 10 000 cm^{-1} are weaker by a factor of eight if compared to the intensities of transition with shifts of $\Delta\tilde{\nu} \approx 1000$ cm^{-1}, assuming $\tilde{\nu}_0 = 20\,000$ cm^{-1}. The sensitivity of detectors is

For personal use only.

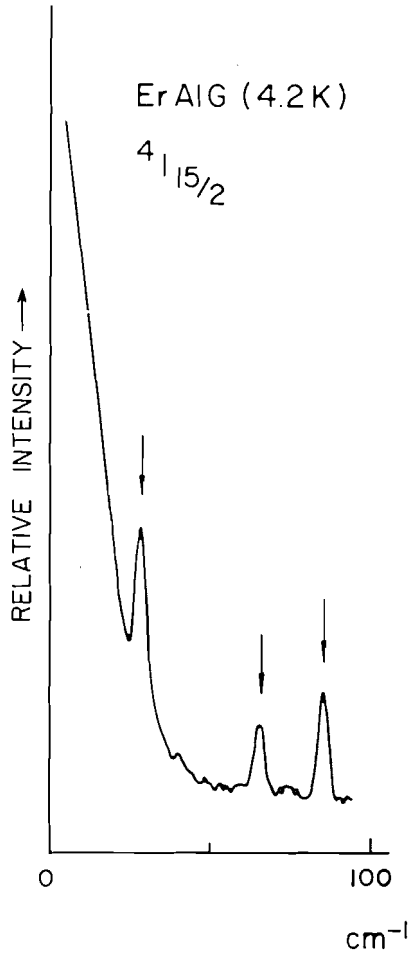

FIG. 3. Electronic Raman scattering of Er in ErAlG. All the elements of the scattering tensor for the electronic transitions are different from zero and independent of the orientation of the crystal, all three transitions are observed.

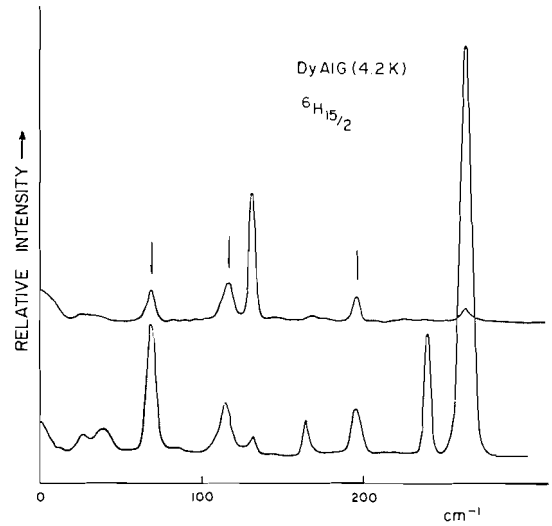

FIG. 4. Polarized Raman spectrum of cubic DyAlG (arbitrarily oriented in space). The intensity of T_{2g} phonons modes in the upper trace is about 1/30 of the intensity of the modes in the lower trace, for an E_g mode this ratio is 7/1 (compare lines at 260 and 135 cm^{-1}). The electronic transitions (↓) have different polarization features because the Dy^{3+} ion has 4f electrons and all levels and parts of the tensor belong to representatives of a double group.

also lower in the region of 1 μ and consequently from an experimental point of view it is more convenient to try to find scattering to crystal field states of the $^2F_{7/2}$ ground manifold. For YbAlG there are four Kramers pairs (9) because the site symmetry for the rare earth ion is D_2.

Fluorescence, absorption, and Raman measurement all point to the existence of a state at ~610 cm^{-1} above the ground state. Due to the occurrence of strong vibronic coupling in the fluorescence and absorption spectrum (9) a clear way to pin down the pure electronic transitions does not exist. It has been shown that such vibronic coupling effects are very weak in electronic Raman scattering (10) and that the intensity of pure electronic transition is at least one order of magnitude stronger than the intensity of vibroelectronic Raman bands. The position of phonon bands of the cubic aluminum, gallium, and also ytterbium iron garnet crystals is known in great detail (11–15). Vibrational and electronic Raman transitions differ in their polarization features (14) and usually in their line width and this allowed the assignment of Raman lines of YbAlG with shifts of 586 and 610 cm^{-1} as due to electronic transitions of the Yb^{3+} ion. The third transition was found in a similar way but due to the presence of close lying phonons its position was more difficult to locate. In Fig. 1 the Raman spectrum with shifts of 700 to 900 cm^{-1} is shown. The symmetry of the phonons are as follows: 710, 735, and 870 cm^{-1} belong to the species T_{2g}, 775 cm^{-1} is of species E_g, and the shift on 806 cm^{-1} is of type A_{1g} of the group O_h. The position of the third electronic transition is indicated in Fig. 1 and it is seen that the polarization features are different from those of the phonons.

The case of Yb in YbAlG may serve as a good

For personal use only.

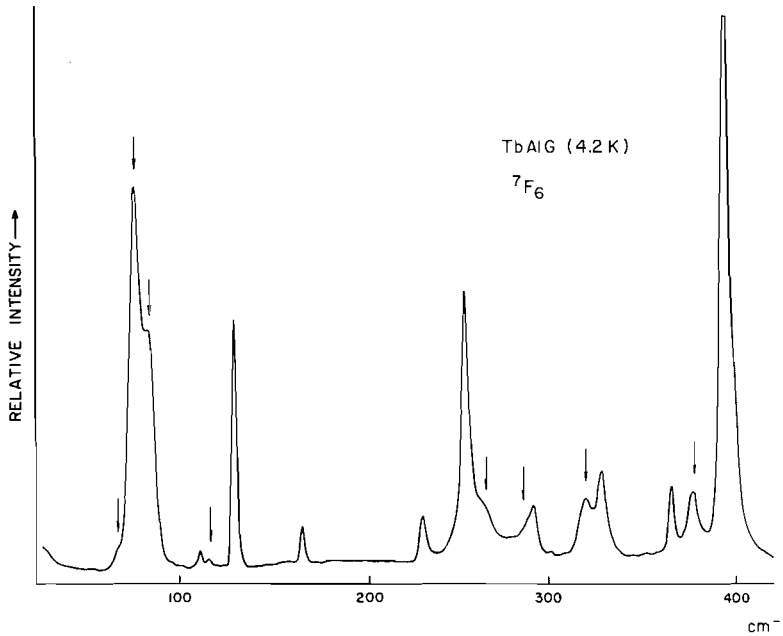

FIG. 5. Electronic effects (↓) of Tb^{3+} in TbAlG. Slit width 3 cm^{-1}. The tensor components are $\alpha_{xx} + \alpha_{xz}$. The electronic Raman line at 373 cm^{-1} is a case of pure isotropic scattering.

example if a comparison is made of the results of electronic Raman scattering and fluorescence and absorption spectra. The electronic levels of the $^2F_{7/2}$ manifold of Yb^{3+} in YbAlG could be determined from the polarization measurement of the Raman lines. Apart from the occurrence of vibronic bands it was not possible to find all the electronic levels from the fluorescence or absorption spectra because direct-electric dipole transitions do not show polarization features in the cubic garnet crystals but the Raman lines of such a crystal do have definite polarization features. The results of recent work on the Yb^{3+} ion are collected in Table 1.

(b) Scattering between Levels of the Tm^{3+} Ion

The excited states $^3H_4$ and $^3H_5$ of the free Tm^{3+} ion are ~6000 and ~8000 cm^{-1} above the ground state ($^3H_6$), respectively. Only Raman transitions from the lowest to higher crystal field components of $^3H_6$ have been observed.

In the garnets the crystal field states of the Tm^{3+} ion belong to the representations A, B_1, B_2, B_3 of the single group D_2. Raman tensors of transitions at the site belong necessarily to these representations. The effect of all rare earth sites in the primitive cell should be considered to explain the polarization properties of Raman transitions of the whole crystal (16). In the cubic symmetry of the crystal, space group O_h^{10}, a transition of type A at the sites is observed as $A_{1g} + E_g + T_{2g}$. B_1 goes to $E_g + T_{1g}$, B_2 and B_3 go to $T_{2g} + T_{1g}$.

Strong vibronic coupling has been observed in the absorption or phonon spectrum of TmAlG or Tm in YAlG and therefore again the electronic Raman effect has been used successfully in finding new electronic levels. In Fig. 2 part of the 4.2 °K Raman spectrum of TmAlG is shown and from a knowledge of the position of phonons the electronic effects could be assigned. Additional electronic Raman transitions were observed in other parts of the spectrum and all data are brought together in Table 1. Although twelve electronic Raman transitions can in principle be expected from the lowest to other crystal field states of the $^3H_6$ ground manifold a maximum of only four transitions have been observed for TmAlG and only one of TmGaG. Two of the four transitions of the former crystal are, however, very strong (see Fig. 2). The tensor could be determined and the electronic Raman transition with a shift of 228 cm^{-1} is of species $A_{1g} + E_g + T_{2g}$ and the transition at 274 cm^{-1} belongs to

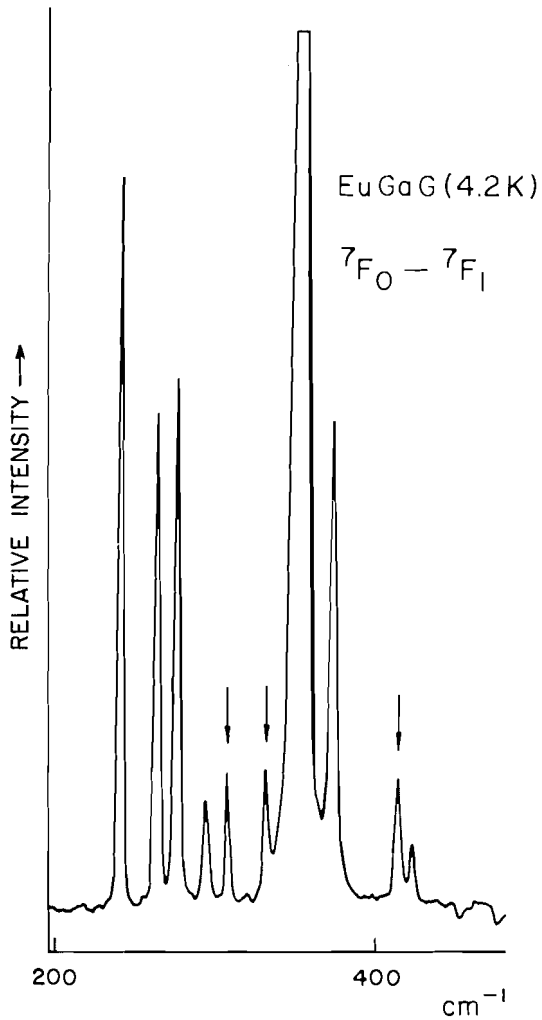

FIG. 6. Electronic Raman effects of EuGaG. The asymmetry of the transition is believed to be present, although part of the intensity is the result of crystal field mixing effects of wave functions of $^7F_1$ and $^7F_2$ states.

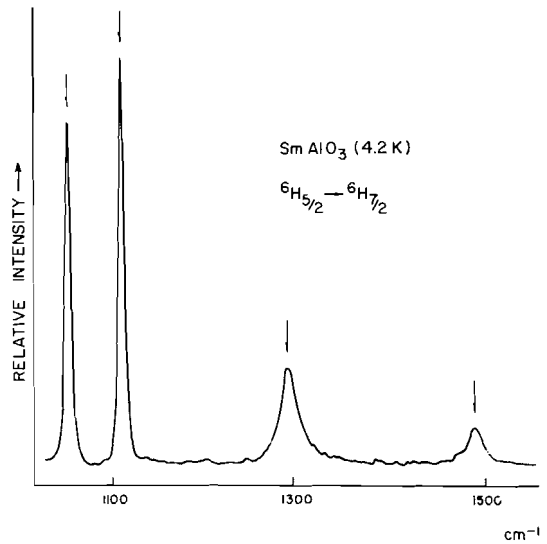

FIG. 7. Low temperature electronic Raman transitions of a small crystal of $SmAlO_3$. $\lambda_0 = 5154$ Å, slit width 2 cm^{-1}. The position of all four Kramers pairs of $^6H_{7/2}$ can be directly obtained from the spectrum.

the species T_{2g}. Thus, the former Raman line is associated with a transition between states of the same symmetry and the latter is one of $A \rightarrow B_3$; $B_1 \rightarrow B_2$; $B_2 \rightarrow B_3$ or $B_1 \rightarrow B_3$. The amount of T_{2g} character of the Raman line at 228 cm^{-1} is larger than the amount of $A_{1g} + E_g$ combined. This is an indication that the components α_{xx}, α_{yy}, and α_{zz} for the tensor at one site are quite different. If the symmetry of the surrounding of the Tm^{3+} ion would be described by the point group D_{4h} then $\alpha_{xx} = \alpha_{yy} \neq \alpha_{zz}$. It can therefore be concluded that the local symmetry of Tm^{3+} in TmAlG cannot be approximated by D_{4h}. Evidence of an electronic transition of TmGaG has already been presented (16) but the search for electronic effects of this lanthanide ion in other crystals was negative.

(c) Scattering of Er^{3+} Levels

Electronic transitions of Er^{3+} were detected in ErAlG and ErGaG crystals but the main difference with the data of Yb^{3+} and Tm^{3+} in garnets is that the position of the crystal field states of the ground manifold and excited manifolds have already been determined from low temperature absorption and fluorescence spectra (17–19). To a certain degree the position of these excited states interfere with the excitation of the Raman spectrum in that near resonance occurs of some of the states and the energy of the radiation of either the He–Ne or Argon ion laser. As a result of this resonance, for some exciting lines, fluorescence is excited in the same spectral region where Raman transitions occur and the intensity of the fluorescence transitions being much more intense than the electronic Raman transitions makes it difficult to observe the latter. Electronic Raman scattering was, however, observed at 4.2 °K in ErAlG and ErGaG employing the 4965 Å line of argon ion laser. The transitions are shown in Fig. 3 and the frequency shifts are given in Table 1. The width of higher lying

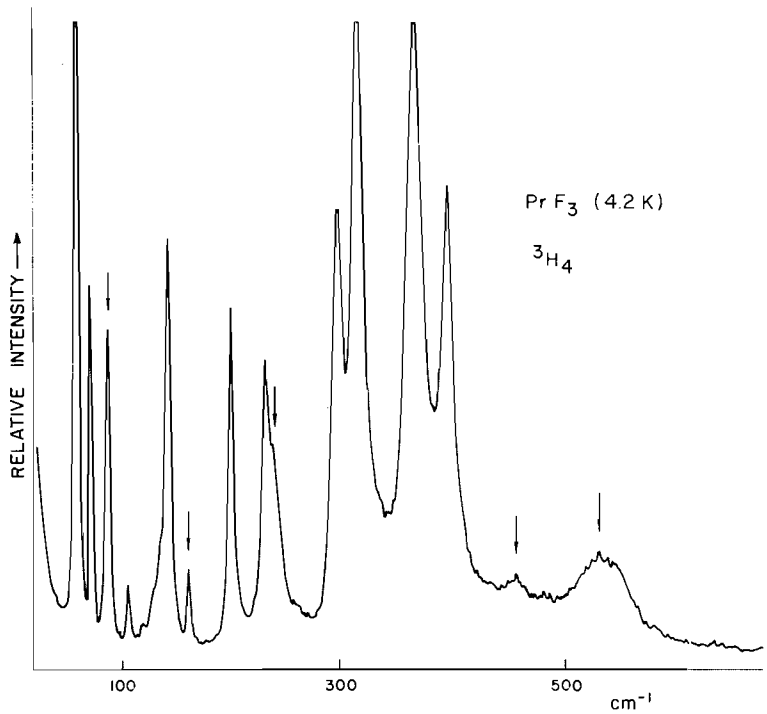

FIG. 8. Low temperature Raman spectrum of PrF_3. The tensor is α_{xx} and all electronic Raman effects are indicated. $\lambda_0 = 5154$ Å and the slit width is 2 cm^{-1}.

crystal field levels of the $^4I_{15/2}$ manifold of Er^{3+} is considerably more than the width of the ground state and as a result, the Raman lines representing a transition from the ground state to such higher lying states are rather broad. On the other hand, the peak height of transitions with small shifts is large and this allows the detection of the Raman transitions to very low lying electronic states in a straightforward way. Figure 3 suggests that it is quite easy to detect levels with a shift of >25 cm^{-1}.

Raman spectra of other erbium compounds have also been investigated but electronic transitions there escaped detection, partly due to sample size or due to the excitation of strong fluorescence which obscured electronic Raman effects. In the course of the experiments we have been unable to detect electronic effects of the Holmium ion.

(d) Scattering of the Dy^{3+} Ion

The levels of the $^6H_{13/2}$ manifold are approximately 3600 cm^{-1} above the ground state. $^6H_{15/2}$, and other electronic states are at energies >6000 cm^{-1}. Transitions within $^6H_{15/2}$ and to the components of $^6H_{13/2}$ have been observed. Some of the electronic Raman transitions of DyAlG are shown in Fig. 4. They could be assigned because of (*i*) their temperature dependence and (*ii*) their polarization features. The data obtained from the Raman measurements of DyAlG are of interest in that the positions of the levels of $^6H_{13/2}$ could not be determined (20) from either absorption of fluorescence measurements of this compound.

All frequency shifts are given in Table 1. Due to increasing widths of electronic states several electronic Raman transitions escaped detection. It is perhaps worthwhile to note that the percentage of rare earth ions in garnet structures is smaller than in rare earth aluminate compounds and experimental data are available which show that the electronic effect of rare earth aluminates is much stronger than those of garnet crystals. On the other hand, the transitions of DyAlG which were observed were so strong that detailed polarization studies could be made and in Fig. 4 is shown an example of the fact that electronic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

transitions between Kramers pairs differ very much in their polarization properties if compared to the phonons of the crystal.

Although only scattering to the lower lying states of $^6H_{15/2}$ and $^6H_{13/2}$ manifolds could be detected, the intensity of the transitions is comparable to the intensity of the phonon modes of the garnet crystal. Many hot bands were also observed while studying the 77 °K Raman spectrum of this crystal. The population of the lower lying levels at 77 °K is apparently large enough so that transitions originating in levels situated at 69 and 112 cm^{-1} appear in the spectrum.

Other rare earth compounds containing the Dy ion have not been studied yet but in view of the fact that the Dy ion scatters more intensely than Er, Tm, and Yb ions, there is no reason to assume that the observation of electronic transitions should be limited to DyAlG only.

(e) Scattering of the Tb^{3+} and Eu^{3+} Ion

The low lying states of the Tb^{3+} and Eu^{3+} ion are the almost pure Russell–Saunders multiplet components of ^7F, in reversed order for Tb^{3+} and Eu^{3+}. The splitting of the levels by the crystal field can in most cases not be considered to be small compared to the distances between the free ion levels and strong *J*-mixings of the states occurs. This has a strong influence on the intensities and polarization features of the electronic Raman transitions. For TbAlG very strong electronic effects have been observed from the ground state to the crystal field levels of the $^7F_6$ split manifold. Some of the electronic transitions are shown in Fig. 5. Detailed measurements have been made of the polarization properties and magnetic field dependence of the Raman shifts (21) and at least one of the Raman transitions is related to a tensor which contains asymmetry. The case of TbAlG is of importance in that many of the electronic transitions have a larger intensity than the phonons and it thus appears that the Tb ion is an excellent example for strong electronic Raman spectroscopy, the reader is referred to other publications for details (22). This, to a certain degree, is also true for the europium ion. Transitions between $^7F_0$ and the components of $^7F_1$ have been observed in the spectral range of $250\ cm^{-1} < \Delta\nu < 450\ cm^{-1}$ for Eu^{3+} in YAlG, YGaG, and YVO_4 (1, 23, 24). For Eu in EuGaG transitions of medium intensity have now also been observed (1). Some are shown in Fig. 6. The tensors have been measured and in agreement with theory (1), the antisymmetric tensors do contribute to these intensities.

(f) Scattering of Sm^{3+}

The low lying energy levels of Sm^{3+} are the multiplet components of ^6H. We succeeded in exciting Raman transitions between the lowest crystal field components of $^6H_{5/2}$ and the components of $^6H_{7/2}$ and $^6H_{9/2}$. The Raman shifts are given in Table 1. They agreed with the level positions obtained from fluorescence spectra, only the highest component of $^6H_{9/2}$ was not found in the Raman spectrum. The absorption spectrum of $SmAlO_3$ contains a great number of lines in the area between 4600 and 5050 Å, the occurrence of a resonance Raman effect has some probability. In particular the laser line at 4965 sits in the wing of a broad absorption line and some indication of resonance was found in the Raman spectrum excited with the 4965 line. Like Dy^{3+} also, Sm^{3+} seems to be a fairly good scatterer.

(g) Scattering of Pr^{3+} and Ce^{3+}

Low lying manifolds of Pr^{3+} in crystals are the components of $^3H_{4,5,6}$. Electronic scattering in $PrCl_3$ was already reported before the advent of the laser. Hougen and Singh (26) found scattering from the ground state to other crystal field levels of $^3H_4$, and also $^3H_4 \rightarrow {}^3H_5$ and $^3H_4$–$^3F_2$ transitions. We have repeated the experiments with an argon ion laser and could only detect $^3H_4$ intermanifold transitions. Bauman and Porto (3) studied the Raman spectrum of PrF_3. Electronic effects were observed with shifts of 66, 94, and 537 cm^{-1} whilst the temperature of the sample was 20 °K (see Table 1). In Fig. 9 the 4.2 °K Raman spectrum of PrF_3 is shown and the electronic effects at 68, 243, and 539 cm^{-1} are indicated. Apparently there is a drastic change in the positions of the $^3H_4$ states of PrF_3 and Pr^{3+} in LaF_3. (Note also the ten-fold increase in line width of the 539 cm^{-1} band compared to the Raman line shift of 68 cm^{-1}.) Other weak electronic effects were observed with shifts $>2000\ cm^{-1}$. They have been assigned to $^3H_4$–$^3H_5$ transitions. Only one electronic Raman transition of $CeMg(NO_3)_6H_2O$ could be observed. The transition terminates on the lowest level of the split $^2F_{5/2}$ state situated at 27 cm^{-1}

but due to strong phonon bands the search for electronic effects in the 150–200 cm^{-1} region was negative. Good spectra were, however, recorded by Kiel *et al.* (2) of a single crystal of $CeCl_3$. Asymmetry in some of the tensors which was predicted (27) was verified experimentally.

Conclusions

Comparing the electronic Raman spectra of the lanthanide ions in different crystals some general considerations can be made. It is for instance obvious that the strongest spectra have been obtained from the ions in the middle of a series, *i.e.*, Eu and Tb. Ce at the beginning and Yb at the end of the series show the weakest effects.

The width of the first excited state configuration (that is the energy difference of highest and lowest electronic level of this configuration) is larger for the ions in the middle than for the ions at the beginning and end of the series (28). It may very well be that this change in width is related to the observed intensity pattern. Unfortunately, such large widths are responsible for the fact that the theory to compute the intensities is not valid anymore. More experimental data are required to arrive at a better understanding of the intensity problem.

The authors wish to thank Drs. L. G. Van Uitert and J. Scott of the Bell Telephone Laboratories, Inc. for supplying rare earth garnet and rare earth aluminate crystals. Thanks are also due to Dr. G. Schaack of the T. H. Darmstadt, Germany for information on the rare earth ethyl sulfates, rare earth chlorides, and rare earth oxides crystals and their suitability for exciting the electronic spectra.

Orientation of Solute Molecules in Nematic Liquid Crystal Solvents

J. C. ROBERTSON, C. T. YIM,[1] AND D. F. R. GILSON
Department of Chemistry, McGill University, Montreal 110, Quebec

Received February 1, 1971

The tendency of solute molecules to align with their longest dimension parallel to the optic axis of a nematic liquid crystal solvent can be explained by a simple model, based on dispersion force interactions, relating *S*-values obtained from nuclear magnetic resonance measurements, to molecular dimensions.

Les molécules de soluté ont tendance à s'aligner suivant leur plus grande dimension parallèlement à l'axe optique du solvant constitué de cristaux liquides nématiques. Ceci peut être expliqué par un modèle simple en invoquant des interactions de forces de dispersion, qui relient les valeurs de *S* obtenues des mesures de résonance magnétique nucléaire, aux dimensions moléculaires.

Canadian Journal of Chemistry, 49, 2345 (1971)

Nematic liquid crystals provide a means of partially orienting solute molecules in nuclear magnetic resonance experiments (1–4). The degree of solute alignment can be described either by the order matrix {**S**} due to Saupe (5), or in terms of the motional constants given by Snyder (6); the two approaches are simply related (6). The number of elements of the **S**-matrix required to describe the degree of orientation depends upon the symmetry of the molecule and can be minimized by a proper choice of axes. If the molecule has two perpendicular planes of symmetry, but a less than three-fold symmetry axis, two elements suffice. The *S*-value of a given axis lies between -0.5 and $+1.0$ for alignment ranging between perpendicular and parallel to the applied magnetic field and, unless a high degree of parallel alignment occurs, *i.e.* $S > 0.5$, the sign of *S* is not immediately determined. It is generally observed, however, that a solute molecule is preferentially oriented with the longest molecular dimension parallel to the optic axis of the liquid crystal.

Saupe has shown that, except in the case of specific interactions such as hydrogen bonding, dispersion forces are primarily responsible for the alignment of solute molecules and permanent electric dipole moments are of minor importance. Using a statistical treatment, the interaction potential energy has been correlated with localized contributions from substituent bonds in chloro- and fluoro-substituted benzene derivatives (7, 8). Since dispersion forces are involved, a dependence on polarizability anisotropies and thus on molecular size is not unexpected. In the present work, a simple treatment relating *S*-values to molecular dimensions is developed.

The average potential energy of a solute molecule is, as a function of its orientation (8),

$$[1]\quad \bar{V}(\theta,\phi) = -a_1 \sin^2\theta\cos^2\phi - a_2 \sin^2\theta\sin^2\phi - a_3\cos^2\theta$$

where θ and ϕ are the usual polar angles relating the molecule-fixed *1*, *2*, *3* axial system to the optic axis of the solvent and a_i is the potential energy of interaction along the *i*th molecular axis. It is assumed in the subsequent discussion that the longest molecular feature lies along the *2*-direction with the shortest along the *3*-direction. Equation 1 is conveniently rewritten as

$$[2]\quad \bar{V}(\theta,\phi) = -a_3 - (a_1 - a_3)\sin^2\theta\cos^2\phi - (a_2 - a_3)\sin^2\theta\sin^2\phi$$

Saupe (7) has shown that according to classical Boltzmann statistics, the two *S*-values required for molecules possessing two perpendicular planes of symmetry but a less than three-fold symmetry axis can be described by

$$[3a]\quad S_{11} = \frac{3}{2}\frac{\int_0^{\pi/2}\int_0^{\pi/2}\sin^2\theta\cos^2\phi\exp\{-\bar{V}(\theta,\phi)/kT\}\sin\theta\,d\theta\,d\phi}{\int_0^{\pi/2}\int_0^{\pi/2}\exp\{-\bar{V}(\theta,\phi)/kT\}\sin\theta\,d\theta\,d\phi} - \frac{1}{2}$$

[1]Present address: Department of Chemistry, Dawson College, Westmount 215, Quebec.

and

$$[3b] \qquad S_{22} = \frac{3}{2} \frac{\int_0^{\pi/2} \int_0^{\pi/2} \sin^2\theta \sin^2\phi \exp\{-\bar{V}(\theta, \phi)/kT\} \sin\theta \, d\theta \, d\phi}{\int_0^{\pi/2} \int_0^{\pi/2} \exp\{-\bar{V}(\theta, \phi)/kT\} \sin\theta \, d\theta \, d\phi} - \frac{1}{2}$$

Clearly, the term $-a_3$ in eq. 2 cancels in the exponentials of eqs. 3. Thus the two elements of the S-matrix are dependent only on the differences $(a_1 - a_3)$ and $(a_2 - a_3)$.

If only the dispersion forces are considered and a dipole–dipole approximation used, the orientational potential energy may be expressed in terms of polarizability anisotropies (9). For certain specific orientations of the molecular axial system with respect to the optic axis of the liquid crystal, it is found that

$$[4a] \qquad \bar{V}\left(\frac{\pi}{2}, 0\right) = -a_1 \propto (\alpha_1\alpha_\parallel + \alpha_2\alpha_\perp + \alpha_3\alpha_\perp)$$

$$[4b] \qquad \bar{V}\left(\frac{\pi}{2}, \frac{\pi}{2}\right) = -a_2 \propto (\alpha_1\alpha_\perp + \alpha_2\alpha_\parallel + \alpha_3\alpha_\perp)$$

$$[4c] \qquad \bar{V}\left(0, \frac{\pi}{2}\right) = -a_3 \propto (\alpha_1\alpha_\perp + \alpha_2\alpha_\perp + \alpha_3\alpha_\parallel)$$

where α_1, α_2, and α_3 are the semi-axes of the solute molecule polarizability ellipsoid while $\alpha_\parallel$ and $\alpha_\perp$ are the polarizabilities of the liquid crystal solvent parallel and perpendicular to the optic axis (it is assumed that the optic axis has C_∞ symmetry). Defining the ratio of differences between interaction energies,

$$[5] \qquad R = \frac{a_2 - a_3}{a_1 - a_3}$$

then substitution of eqs. 4 leads to

$$[6] \qquad R = \frac{\alpha_2 - \alpha_3}{\alpha_1 - \alpha_3}$$

This ratio is a function of the properties of the solute molecule only and is independent of the mesophase properties and of temperature. Anisotropic polarizability ellipsoids are known for relatively few molecules of interest in the present context. However, Le Fèvre and Le Fèvre (10) have noted that the ratio of the semi-axes $\alpha_1:\alpha_2:\alpha_3$ approximates the ratio of the corresponding molecular dimensions $L_1:L_2:L_3$ and thus eq. 6 can be replaced by

$$[7] \qquad R = \frac{L_2 - L_3}{L_1 - L_3}$$

The dependence of S_{11} and S_{22} on the ratio R as computed from eqs. 3 is shown for a range of values $(a_1 - a_3)/kT$ in Fig. 1 (*a*) and (*b*), respectively. Clearly it is not possible to predict S-values unambiguously from molecular dimensions alone. An estimate of $(a_1 - a_3)/kT \propto (\alpha_1 - \alpha_3)$-$(\alpha_\parallel - \alpha_\perp)/kT$ is required. In Fig. 2, the curves demonstrate the calculated dependence of the ratio S_{11}/S_{22} on R for the same range in $(a_1 - a_3)/kT$. It is observed that for a given R, S_{11}/S_{22} should fall within rather narrow limits irrespective of the value of $(a_1 - a_3)/kT$. S_{11}/S_{22} is a measure of the extent to which a solute molecule is aligned and it is expected that a plot of the observed S_{11}/S_{22} ratio against R, calculated from molecular dimensions (eq. 7), should exhibit the same trend. For $S_{11}/S_{22} = 1.0$, there is no alignment, while for $S_{11}/S_{22} = -0.5$, alignment is complete.

For a number of solute molecules possessing C_{2v} or D_{2h} symmetry, Table 1 compares the observed S_{11}/S_{22} ratio with R. In Table 2, the nematic liquid crystals used are listed. The molecular dimensions L_1 and L_2 are calculated by superposition of Stuart's "Wirkungsradien" (11) upon nuclear positions (12) as suggested by Le Fèvre and Le Fèvre (10). The "thickness", L_3, of the ethylenic and aromatic molecules is taken to be 3.70 Å (13); in no case would the "Wirkungsradius" of a substituent atom lead to a larger L_3.

The data of Table 1 are plotted on Fig. 2. The

general trend of the theoretical curves is followed but with considerable scatter, particularly at low R values. A part of the deviation can be attributed to errors in the values of R due to uncertainties in the "Wirkungsradien" and the molecular thickness which may be accurate only to 0.05 to 0.10 Å, leading to errors in R of up to 10%. The more serious errors in this treatment result from the assumed independence from solvent properties and from solute concentration. The potential energy function, eq. 1, should properly include dependence on the molar volume and solvent order (14). Such an enlarged function can be employed with relative facility in electron paramagnetic resonance studies where solute mole fractions of less than 10^{-3} can be used; thus the molar volume and solute order are essentially the same for the dilute solution and the pure liquid crystal. The high solution concentrations required in n.m.r. studies preclude an exactly analogous treatment. The variation in the ratio S_{11}/S_{22} for the same solute molecule in different nematic solvents is shown in Table 1 for *p*-difluorobenzene. The range of values of S_{11}/S_{22} clearly indicates the involvement of a solvent-dependent term in the potential energy function.

Compounds which have been examined in the most commonly used solvent VI (triangles, Fig. 2) show much better agreement with the theoretical curves, the notable exceptions being 1,2,4,5-tetrafluorobenzene and 2,6-dibromopyridine. The latter molecule is almost triangular in shape making it difficult to approximate the length-to-width ratio. The reason for the poor agreement for tetrafluorobenzene is difficult to rationalize. Molecules which possess large dipole moments do not appear to show large deviations, supporting the assumption that dipole interactions are relatively unimportant (7).

The authors thank Dr. B. C. Eu for helpful discussions. This work was supported by grants from the National Research Council of Canada.

The Electron Spin Resonance Spectra of the Photochemically Produced Perfluorobenzophenone Ketyl and Anion Radicals[1]

F. P. SARGENT AND M. G. BAILEY

Materials Science Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba

Received February 25, 1971

The electron spin resonance spectra of the ketyl and radical anion of perfluorobenzophenone were generated in alcoholic solution by means of a photochemical method. The radical anion was prepared in alkaline solutions by means of a flow system to prevent nucleophillic degradation of the perfluorobenzophenone prior to photolysis. A comparison is made of the fluorine nuclear hyperfine coupling constants to those reported for partially fluorinated radical anions.

Grâce à une méthode photochimique, on a généré en solution alcoolique le spectre r.p.e. du cétyle et de l'anion-radical de la perfluorobenzophénone. L'anion-radical a été préparé dans un système continu pour éviter la dégradation nucléophile de la perfluorobenzophénone avant sa photolyse. On a établi une comparaison entre les constantes de couplage hyperfines du fluor et celles rapportées pour les anion-radicaux partiellement fluorés.

Canadian Journal of Chemistry, 49, 2350 (1971)

In recent years there has been much interest in the electron spin resonance (e.s.r.) spectra of fluorinated radicals (for example, see ref. 1). In the case of benzophenone, only partly fluorinated radicals have been reported. There have been several attempts to prepare the radical ion of perfluorobenzophenone (PFB) but each has led to partly fluorinated species usually via removal of the para fluorines. Brown and Williams (2) attempted to prepare the PFB radical anion by means of a photochemical method (3) in a basic alcohol solution but found that their spectra were due to the *pp'*-dialkoxy PFB anion. Attempts by both Fischer and Zimmermann (4) and by Kulkarni and Trapp (5) to produce the PFB anion electrochemically were not successful and in the former case removal of the two para fluorines was postulated. We believe that we have been successful in producing both the ketyl, $(C_6F_5)_2\dot{C}OH$, and the radical anion of PFB in alcohol solution by a photochemical method. These species have recently been detected in a pulse radiolysis and flash photolysis study (6).

Solutions of PFB in various alcohols were photolyzed *in situ* in a Varian V4500 e.s.r. spectrometer by a medium pressure mercury arc lamp. The e.s.r. spectra were calibrated by means of a dual cavity and the standard aqueous solutions of Fremy's salt, taking $\alpha_N = 13.0$ G. The e.s.r. spectra were simulated by means of a computer together with a plotter. The spectra obtained at room temperature during continuous photolysis were often poorly resolved but on raising the temperature the resolution improved considerably. The spectrum from PFB in isopropanol at 80 °C is shown in Fig. 1(*a*). This was interpreted in terms of hyperfine interaction with two sets of four equivalent fluorine nuclei of 4.66 and 1.77 G, two equivalent fluorines of 8.23 G, and a doublet splitting of 2.42 G. The simulated spectrum based on these values together with a linewidth of 0.25 G and a Lorentzian line shape is shown in Fig. 1(*b*). From expanded charts we were able to obtain an almost perfect fit of the experimental and computed spectra. From additional studies such as the variation of these values with temperature and solvent, molecular orbital calculations, and the absence of the doublet in deuterated alcohols, we feel confident that this species is the ketyl radical of PFB with fluorine coupling constants assigned as in Table 1,

[1]AECL No. 3889.

TABLE 1. Fluorine coupling constants in various fluorinated benzophenone radicals

Radical	Position			Reference
	Ortho	Meta	Para	
Perfluorobenzophenone ketyl	4.66	1.77	8.23	This work
Perfluorobenzophenone anion	4.80	1.06	8.36	This work
4,4′-Difluorobenzophenone anion			7.42	5
			7.50	4
4-Fluorobenzophenone anion			7.27	5
2-Fluorobenzophenone anion	4.63			4
2,2′,6,6′-Tetrafluorobenzophenone anion	4.12			5
2,3,4,5,6-Pentafluorobenzophenone anion	4.08	1.14	5.88	5
4,4′-Dimethoxy-perfluorobenzophenone anion	4.60	1.14		2

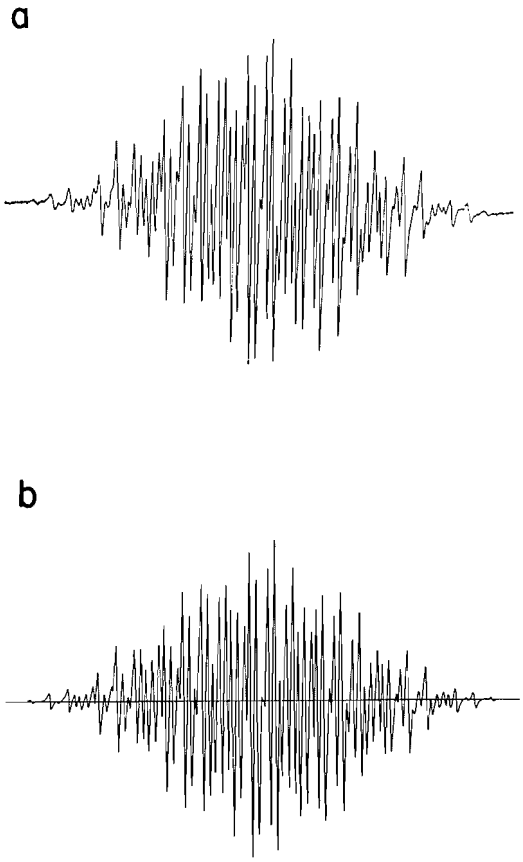

FIG. 1. The e.s.r. of the perfluorobenzophenone ketyl radical in 2-propanol at 80 °C. (*a*) The experimental spectrum, (*b*) the computer simulated spectrum.

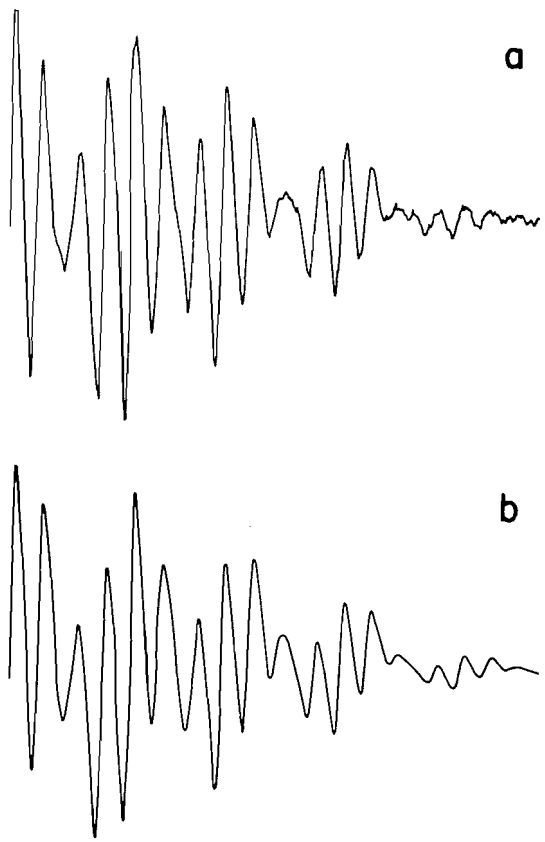

FIG. 2. One half of the e.s.r. spectrum of the perfluorobenzophenone radical anion observed in basic methanol at room temperature: (*a*) the experimental spectrum (*b*) the computer simulated spectrum.

together with a proton coupling of 2.42 G due to the ketyl OH group.

When two solutions, one of PFB in methanol and the other of 0.05 *M* sodium methoxide in methanol, were flowed together and mixed just prior to entering the e.s.r. cavity, *i.e.* the photolysis zone, quite different spectra were observed. These spectra were a function of the absolute and relative flow rates of the two components. With no base flow the ketyl radical was observed but as the base flow was increased this was replaced by the spectrum shown in Fig. 2(*a*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This was interpreted in terms of nuclear hyperfine interaction with two sets of four equivalent fluorines of 4.80 and 1.06 G and two equivalent fluorines of 8.36 G. The simulated spectrum based on these values together with a linewidth of 0.58 G and a Lorentzian line shape is shown in Fig. 2(*b*). From expanded charts a good fit of the computed and experimental spectra was possible. We attribute this spectrum to the radical anion of PFB and on the basis of molecular orbital calculations, make the positional assignments of Table 1.

We wish to draw attention to the magnitude of the fluorine splitting in the perfluorinated ketyl and the anion. From Table 1 it is seen that these are substantially larger than those observed for the partly fluorinated species. We are at present attempting to explain these differences by means of molecular orbital calculations. From preliminary calculations it has become obvious that a general revision of the usual parameters is required.

We thank Dr. R. E. D. McClung of the University of Alberta and K. H. Witzke of W.N.R.E. for assistance with the development of the computer simulation program. Dr. A. Singh of W.N.R.E. is gratefully acknowledged for constructive discussions and for suggesting the problem.

Compressibilities of Porous Glass

W. B. Kipkie[1] and R. McIntosh
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 18, 1971

Partial extension isotherms have confirmed earlier results that polar adsorbates cause greater extensions than non-polar adsorbates. Data now found for ethyl chloride are in disagreement with those reported by Quinn and McIntosh (3) which are presumed to be in error. Support of this view is provided by consistent values of β', the compressibility of the glass–adsorbate system, based upon studies with four adsorbates. The consistency now revealed suggests that the mechanism postulated by Quinn and McIntosh is valid for the reversible adsorption along the top of a desorption loop.

Les extensions partielles isothermes ont confirmé les résultats précédents d'après lesquels les produits polaires adsorbés provoquent une extension plus grande que les produits non polaires adsorbés. Les données actuellement trouvées pour le chlorure d'éthyle sont en désaccord avec celles rapportées par Quinn et McIntosh (3), ces dernières étant probablement fausses. Les valeurs consistantes obtenues pour β', la compressibilité du système verre–adsorbé, provenant des études effectuées avec quatre produits adsorbés, sont en accord avec le point de vue proposé. Ces résultats suggèrent que le mécanisme postulé par Quinn et McIntosh est valable pour l'adsorption réversible le long du sommet d'une boucle de désorption.

Canadian Journal of Chemistry, 49, 2352 (1971)

In the past there have been numerous studies of adsorption and the hysteresis phenomenon utilizing the measurement of dimensional changes of the adsorbent on adsorption to aid in the analysis of the findings (1–5). In ref. 1 the authors used a linear variable differential transducer, incorporated into a cell of a dead space of 25.9 ml, for their investigations into the influence of meniscus curvature on the detection of solidification of adsorbates in porous glass (1).

Several partial extention isotherms were

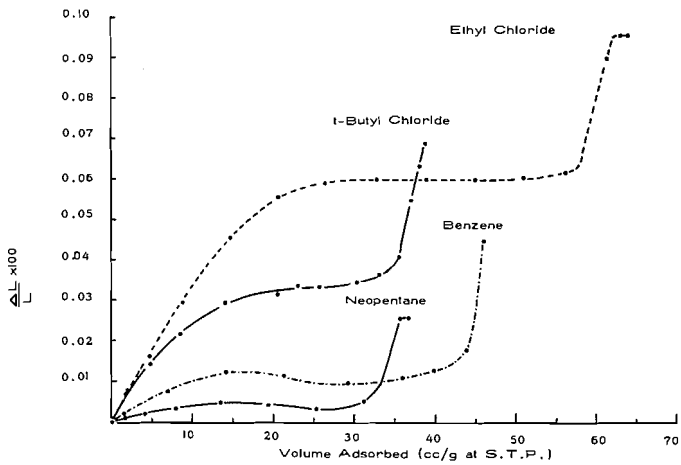

FIG. 1. Extension isotherms of ethyl chloride, *t*-butyl chloride, benzene, and neopentane.

obtained for neopentane, *t*-butyl chloride, benzene, and ethyl chloride in order to compare the performance of this extensometer with others of the parallel-plate version (2–5). It was found that ethyl chloride exhibited the largest extension followed by *t*-butyl chloride, benzene, and neopentane (Fig. 1). These results were consistent with the results of Quinn and McIntosh (2) for ethyl chloride and butane. In general, polar adsorbates tended to exhibit greater expansions than non-polar adsorbates.

However, the magnitude of the dimensional changes for ethyl chloride in this study over the whole extension isotherm was approximately one-third of that found by Quinn and McIntosh (3). In fact, Quinn and McIntosh found extensions for ethyl chloride that were considerably greater than those for water. On the other hand, the magnitude of the dimensional changes for benzene in the present work were almost identical to those observed by Hodgson and McIntosh (4).

In an effort to clarify this discrepancy, it was considered worthwhile to calculate the compressibility coefficient β' of the porous glass – adsorbate system, using the steep desorption branch of both the ethyl chloride and neopentane isotherms, to compare them with those obtained by Quinn and McIntosh (3), Amberg and McIntosh (5), and Hodgson and McIntosh (4). The procedure has been outlined previously by Quinn and McIntosh and the results are seen in Table 1.

It is immediately obvious that results of Quinn and McIntosh on ethyl chloride are approximately four times greater than the present ones. Also, there is reasonably close agreement among all values of β', except for that of Quinn and McIntosh even though the adsorbate molecules are all very dissimilar. The results obtained by Quinn and McIntosh cannot be due to a difference in adsorbents, as the porous glass used, and its treatment before use, were identical in all respects to that used in this study, so far as is known. It would appear that they may be in error although it is impossible to determine the cause, other than a possible error in calibration.

On the basis of the data available at that time, Sereda and Feldman (6) suggested that the discrepancy in the values obtained by Quinn and McIntosh may have been due to the difficulty in evaluating correctly such quantities as wetting angles, capillary radius, and molar volume, or more seriously, that the concept of changing radius of curvature of meniscus was invalid. The relatively close agreement now found for all the

Selected Catalytic Decompositions of Indole-2-diazoketone[1]

KULDIP S. BHANDARI AND VICTOR SNIECKUS
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received February 15, 1971

Whereas Wolff rearrangement of indole-2-diazoketone (**1**) in the presence of silver benzoate led to the indolyl-2-acetic esters **2***a* and *b* in low yields, the reaction of **1** in methanol with copper powder or with acidic resin gave methoxymethyl-2-indolyl ketone (**3**) in 65–80% yields. Chloromethyl 2-indolyl ketone (**4**) was prepared and converted to the α-aminoketone hydrochloride salts **5***a* and *b*. Treatment of **1** with cuprous iodide in acetonitrile–methanol gave **2***a*, iodomethyl 2-indolyl ketone (**6**), and methyl 2-indolylglyoxalate (**7**). Compound **6** was converted to *N*-(2-(2-indolyl)-2-oxoethyl)pyridinium iodide (**8**) and to 2-acetylindole (**9**) while **7** was degraded *via* indole-2-glyoxylic acid (**10**) to indole-2-carboxylic acid (**11**). Compound **7** represents a type of product not previously observed in diazoketone chemistry. The mechanism of its formation is discussed.

Alors que le réarrangement de Wolff de l'indole diazocétone-2 (**1**) en présence de benzoate d'argent conduit avec de mauvais rendements aux esters **2***a* et *b* de l'acide indolyl-2 acetique, on observe que la réaction de **1**, en solution dans le méthanol, avec de la poudre de cuivre ou une résine acide, forment la méthoxyméthyl indolyl-2 cétone (**3**) avec des rendements de 65 à 80%. On a préparé la chlorométhyl indolyl-2 cétone (**4**) qui par transformation conduit aux chlorhydrates **5***a* et *b* de l'α-amino-cétone. Le traitement de **1** par de l'iodure cuivreux dans un mélange d'acétonitrile/méthanol fourni l'ester **2***a*, l'iodométhyl indolyl-2 cétone (**6**) et l'indolyl-2 glyoxylate de méthyle (**7**). Le composé **6** peut être transformé en iodure de *N*-[(indolyl-(2)-2 oxo-2 éthyl] pyridinium (**8**) et en acétyl-2 indole (**9**) alors que **7** peut être dégradé pour conduire successivement à l'acide indole-2 glyoxylique (**10**) et à l'acide indole-2 carboxylique (**11**). Le composé **7** représente un type de composés qui n'avait pas été observé anterieurement en chimie des diazocétones; on discute de son mécanisme de formation.

Canadian Journal of Chemistry, 49, 2354 (1971)

As an outgrowth of our interest in the synthesis of the relatively unexplored 2-substituted indole derivatives (1), we studied some metal and acid-promoted decompositions of indole-2-diazoketone (**1**).[2] This study has led to the preparation of new indole derivatives (**3**, **4**, **5**, **6**, **7**, and **10**) and a type of reaction (**1** → **7**) not previously observed in diazoketone chemistry. These results may have synthetic utility and mechanistic interest.

Matell's lack of success (3) in effecting the Wolff rearrangement (4) of diazoketone **1** by the use of silver oxide led us to attempt the reaction in the presence of silver benzoate, a prescribed superior reagent for such a transformation (4). In the event, no reaction was observed at room temperature in methanol or ethanol solution but at reflux the indole-2-acetic esters, **2***a* and *b* respectively, were isolated in low yields. In view of the high yields of **2***a* and *b* obtained by the photochemical method (2), further study of these conditions was not warranted.

In harmony with the general observation that α-diazoketones undergo insertion reactions in the presence of copper powder (5, 6), diazoketone

[1]This work represents part of the Ph.D. Thesis of K.S.B. presented to the University Graduate Council of the University of Waterloo, Waterloo, Ontario, 1971.

1 gave **3** in 65% yield using this catalyst in methanol solution under reflux. However, contrary to previous results (6), **1** did not give the corresponding α-aminoketones **5** when treated with secondary amines. This failure may be largely attributed to the instability of the expected products (*vide infra*).

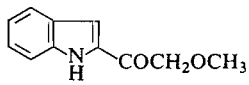
b R = C_2H_5
c R = $CH_2C_6H_5$



3

Numerous examples of acid-catalyzed decompositions of α-diazoketones to α-alkoxy-, and α-haloketones are known (7). Thus, not surprisingly, **1** furnished **3** in 70–80% yields when treated with hydrogen chloride gas or Dowex-50 acidic resin in methanol. The reaction of **1** in anhydrous ether in the presence of hydrogen chloride gas gave the α-chloroketone **4** in 89% yield. Compound **4** was readily converted into the α-aminoketones **5***a* (42%) and *b* (40%) by treatment with piperidine and pyrrolidine respectively. These new 2-substituted indole derivatives were unstable but were isolated and characterized as the corresponding hydrochloride salts.

a *n* = 5
b *n* = 4

Among the copper salts, cuprous iodide is the only one reported to be an efficient catalyst for the Wolff rearrangement (6, 8) and, for the sake of a complete study, it became of interest to test this reagent in reaction with the diazoketone **1**.[3] When the reaction was carried out in acetonitrile–methanol solution there were isolated, in addition to the expected ester **2***a*, two other compounds which are assigned structures **6** and **7** on the basis of spectral and chemical evidence. Compound **6** exhibited a u.v. spectrum characteristic of a 2-acyl indole chromophore and i.r. absorption at 3400 (NH) and 1665 (C=O) cm^{-1}. The n.m.r. spectrum showed, in addition to the indole-NH and four aromatic protons, a two-proton singlet at τ 5.65, typical of a $COCH_2X$ (X = halogen) function (9). Chemical confirmation was obtained by conversion of **6** to the known pyridinium iodide salt **8** (10) and by its reduction to 2-acetylindole (**9**) which was prepared from diazoketone **1** (Scheme 1).

On the basis of the 2-acyl indole u.v. spectrum and i.r. absorption at 1740 (ester C=O) and 1650 (C=O) cm^{-1}, the third product from the reaction of **1** with cuprous iodide was formulated as **7**. In agreement with this structure, the n.m.r. spectrum showed a three-proton singlet at τ 6.05 (CO_2CH_3). Mild hydrolysis of **7** gave the glyoxylic acid **10** which could be reesterified to **7**. Finally, basic hydrogen peroxide treatment of **7** gave the known indole-2-carboxylic acid (**11**) (11) thus fully confirming the assigned structure.

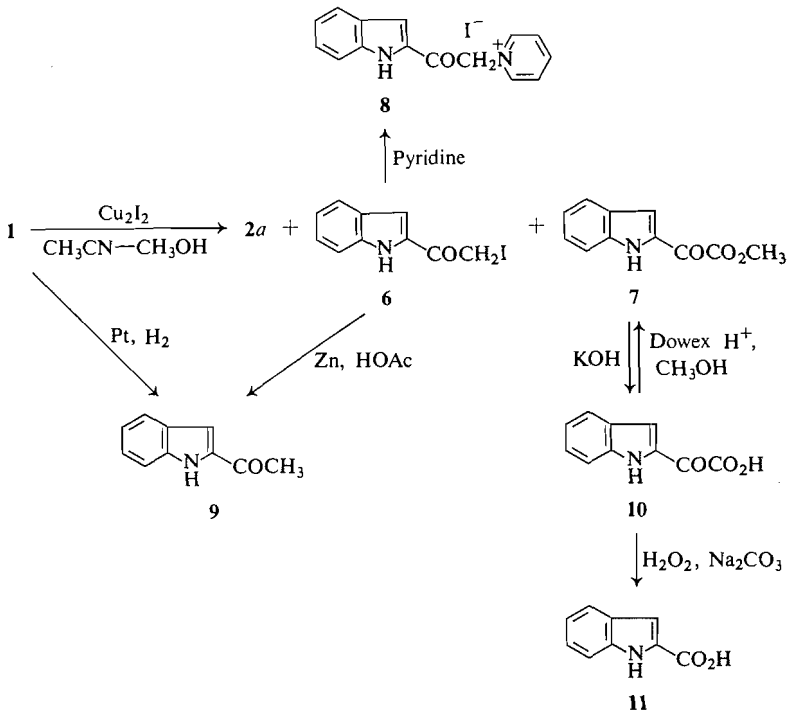
A search of the literature revealed that Russian workers have claimed the synthesis of **7** by reaction of indolyl magnesium bromide with methyl glyoxalate (12).[4] However, the reported physical and spectral data are identical with those observed for the isomeric methyl indole-3-glyoxalate (**12**) (14). These experimental facts, theoretical considerations (15), and now our chemical evidence for **7** leave no doubt that the Russian workers had in fact prepared compound **12** by their method.

Mechanistically, the formation of **6** may be explained by an insertion of iodide ion into the ketocarbene–copper complex (6, 16) resulting from **1**. Since compound **7** represents a type of product not previously encountered in diazoketone chemistry, brief examination of the mode of its formation was undertaken. *A priori*, any one of the compounds **2***a*, **3**, and **6** could act as a precursor for **7**. However, when each of these was subjected to the identical reaction conditions, no **7** was formed. Alternatively, by analogy with previous observation (17), the ketocarbene–copper complex could undergo oxygen insertion to give **13** which, in turn, could yield the product (**7**) via oxidation of its methyl hemiacetal derivative.[5] That **7** was produced as a result of aerial

[3]Cupric acetate failed to promote decomposition of **1** (6).

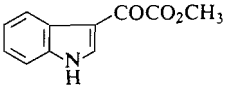
[4]Recently, the *N*-methyl analogue of **7** has been synthesized, see ref. 13.

[5]For an analogous oxidation with chromium trioxide, see ref. 18.

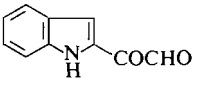


SCHEME 1

oxidation was shown by the following experiments. When the reaction was carried out at room temperature under nitrogen, only **2***a* (10–15%) and **6** (8–10%) were obtained and **7** was not detected. In contrast, in the presence of an atmosphere of oxygen but otherwise identical conditions, **7** was produced in 8–12% yield in addition to **6** (8–12%) and only a trace of **2***a* was obtained. Unfortunately, the proposal that **13** is an intermediate in the reaction could not be tested since it could not be prepared from **4** under the standard conditions for α-ketoaldehyde synthesis (19).



12



13

It may be expected that the presumed ketocarbene–copper complex would tend to be unstable with respect to Wolff rearrangement at higher reaction temperatures. The observed product distribution (**2***a* (25%), very low yields of **3** and **6**, and no **7**) when diazoketone **1** was treated with cuprous idide in acetonitrile–methanol at reflux temperature was in agreement with this expectation. Compound **7** was found to be stable to these reaction conditions. Similarly, the decomposition of **1** in acetonitrile–ethanol and acetonitrile – benzyl alcohol solutions in the presence of cuprous iodide at reflux temperatures gave the ethyl and benzyl esters **2***b* and *c* respectively together with trace amounts of **3** and **6** but no ethyl or benzyl glyoxalate ester corresponding to **7** was detected in each case.

The mechanism of the reaction may subtly involve the (**1**) + $Cu^+ \leftrightarrows Cu^{2+}$ + (products) redox system (20) but no further mechanistic information is presently available.

Experimental

Analyses were performed by Micro-Tech Laboratories, Inc., Skokie, Illinois, Chemalytics, Inc., Tempe, Arizona, and A. B. Gygli, Toronto, Ontario. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Beckman IR-5 spectrophotometer in chloroform solution unless otherwise stated. The u.v. spectra were measured on Beckman DB-G and Coleman EPS-3T spectrophotometers in methanol solution. The n.m.r. spectra were recorded on JEOL-C60 and Varian T-60 spectrometers in deuteriochloroform solution unless otherwise indicated with tetramethylsilane (TMS) as internal standard. Spectra

listed follow the order: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet), number of protons, coupling constant (Hz), and assignment. Mass spectra were determined with a Hitachi–Perkin Elmer RMU-6E single focussing mass spectrometer. Column chromatography was performed with silical gel (0.05–0.20 mm) obtained from Brinkmann (Canada) Ltd. Acetonitrile was reagent grade as supplied by Allied Chemical Co. and cuprous iodide was obtained from Fisher Scientific Co.

*Reaction of Indole-2-diazoketone (**1**) with Silver Benzoate – Triethylamine*

(a) In Methanol Solution

To a solution of 100 mg (0.54 mmol) of **1** in 20 ml of absolute methanol at reflux was added dropwise a solution of 124 mg (0.56 mmol) of freshly prepared dry silver benzoate (**4**) in 5 ml of dry triethylamine. The mixture was refluxed and stirred under nitrogen in the dark for 15 h. After removal of the solvent *in vacuo*, the resulting residue was thoroughly shaken with ether (30 ml). The solid was removed by filtration and the filtrate was evaporated to yield a brown oil which was purified by chromatography (benzene) to give 9.5 mg (9%) of *methyl 2-indolylacetate* (**2***a*) as pale yellow crystals, m.p. 71–73°; i.r. ν_{max} 3405 (NH), 1736 (C=O) cm^{-1}; n.m.r. τ 1.48 (s, 1, NH), 2.28–3.11 (m, 4, aromatics), 3.68 (s, 1, indole-3H), 6.19 (s, 2, CH_2), 6.30 (s, 3, OCH_3).

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.83; H, 5.86; N, 7.40. Found: C, 69.99; H, 5.80; N, 7.25.

(b) In Ethanol Solution

Using the procedure described above, 100 mg (0.54 mmol) of **1** in ethanol at reflux afforded 11 mg (10%) of *ethyl 2-indolylacetate* (**2***b*) as a colorless oil, b.p. 119–122°/0.003 mm (lit. (21): b.p. 118–120°/0.003 mm); i.r. ν_{max} (neat) 3390 (NH), 1734 (C=O) cm^{-1}; n.m.r. τ 1.34 (s, 1, NH), 2.31–3.33 (m, 4, aromatics), 3.69 (s, 1, indole-3H), 5.58 (q, 2, J = 6, $CO_2C\underline{H}_2CH_3$), 6.30 (s, 2, CH_2), 8.59 (t, 3, J = 6, $CO_2CH_2C\underline{H}_3$).

*Preparation of Methoxymethyl 2-Indolyl Ketone (**3**)*

(a) Copper Powder

To a solution of 200 mg (1.08 mmol) of indole-2-diazoketone (**1**) in 40 ml of absolute methanol at reflux there was added 68 mg (1.08 mmol) of copper powder in small portions. After refluxing for 8 h, a precipitate was removed by filtration and the filtrate was treated with activated carbon. Evaporation to dryness *in vacuo* yielded 133 mg (65%) of **3** which was recrystallized from cyclohexane – methylene chloride to give colorless needles, m.p. 92–93°; i.r. ν_{max} 3250 (NH), 1650 (C=O) cm^{-1}; u.v. λ_{max} 310 (13 000), 235 (8240) mμ; n.m.r. τ 0.40 (s, 1, NH), 2.22–2.81 (m, 4, aromatics), 5.35 (s, 2, $COCH_2$), 6.45 (s, 3, OCH_3).

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.83; H, 5.86; N, 7.40. Found: C, 69.87; H, 5.83; N, 7.33.

(b) Hydrogen Chloride

Hydrogen chloride gas was bubbled through a solution of 200 mg (1.08 mmol) of **1** in 60 ml of absolute methanol at room temperature for 5–7 s and the reaction mixture was stirred for 10 min. It was then basified with excess of solid sodium carbonate and subjected to filtration. The filtrate was treated with activated carbon and evaporated to dryness *in vacuo* to yield 147 mg (72%) of crystalline **3**.

(c) Dowex Resin

A solution of 100 mg (0.54 mmol) of **1** in 30 ml of absolute methanol was stirred at room temperature with 250 mg of Dowex 50 W-X2 resin (200–400 mesh, H^+ Form) for about 10 min. Some solid was removed by filtration and the filtrate was evaporated to dryness *in vacuo* to leave a solid which was crystallized from cyclohexane – methylene chloride to yield 85 mg (83%) of ketone **3**.

*Preparation of Chloromethyl 2-Indolyl Ketone (**4**)*

A slow stream of dry hydrogen chloride gas was passed for 15–20 s through a suspension of 300 mg (1.62 mmol) of **1** in 30 ml of anhydrous ether at room temperature. After 15 min, gas evolution ceased and some solid was removed by filtration. The filtrate was evaporated to dryness *in vacuo* at room temperature to leave 280 mg (89%) of **4** which was characterized as its pyridinium chloride salt, m.p. 208–210° (lit. (10): m.p. 210°).

*N-Piperidinomethyl 2-Indolyl Ketone (**5***a*)

The freshly prepared chloro ketone **4** (316 mg, 1.63 mmol) was immediately dissolved in 15 ml of anhydrous ether and mixed with a solution of 275 mg (3.24 mmol) of piperidine in 10 ml of anhydrous ether. The reaction mixture was set aside under nitrogen for 24 h at room temperature. Evaporation to dryness under reduced pressure in a cold water bath left a crude residue which was washed twice with 10 ml portions of petroleum ether (35–60°) to remove traces of piperidine. The hydrochloride salt of **5***a* was prepared by the standard procedure and crystallized from ethanol – ethyl acetate to yield 190 mg (42%) of colorless crystals, m.p. 250–255° (dec.); i.r. ν_{max} (Nujol) 3100 (indole-N*H*), 2540 ($\overset{+}{N}H$), 1665 (C=O) cm^{-1}; u.v. λ_{max} 314 (14 560), 235 (9320) mμ; n.m.r. (D_2O) τ 2.00–2.84 (m, 5, aromatics), 5.30 (s, 2, $COCH_2$), 6.62 (broad s, 4, α-CH_2 of piperidine ring), 8.11 (broad s, 6, β- and γ-CH_2 of piperidine ring).

Anal. Calcd. for $C_{15}H_{19}N_2OCl$: C, 64.62; H, 6.82; N, 10.05. Found: C, 64.44; H, 6.74; N, 9.96.

*N-Pyrrolidinomethyl 2-Indolyl Ketone (**5***b*)

The hydrochloride salt of **5***b* was prepared in the same manner as described for compound **5***a*. From 300 mg (1.54 mmol) of **4** and 230 mg (3.24 mmol) of pyrrolidine there was obtained 172 mg (40%) of **5***b* hydrochloride as colorless crystals, m.p. 245–250° (dec.); i.r. ν_{max} (Nujol) 3200 (indole-NH), 2550 ($\overset{+}{N}H$) and 1666 (C=O) cm^{-1}; n.m.r. (D_2O) τ 2.04–2.92 (m, 5, aromatics), 5.15 (s, 2, $COCH_2$), 6.02–6.91 (m, 4, α-CH_2 of pyrrolidine ring), and 7.60–8.00 (m, 4, β-CH_2 of pyrrolidine ring).

Anal. Calcd. for $C_{14}H_{17}N_2OCl$: C, 63.51; H, 6.42; N, 10.58; Cl, 13.42. Found: C, 63.38; H, 6.74; N, 10.80; Cl, 13.59.

*Reaction of Indole-2-diazoketone (**1**) with Cuprous Iodide in Acetonitrile–Methanol Solution*

(a) At Room Temperature

A mixture of 500 mg (2.7 mmol) of **1**, 1.0 g (2.7 mmol) of cuprous iodide, 50 ml of acetonitrile, and 40 ml of absolute methanol was stirred at room temperature for 15 h. Evaporation to dryness *in vacuo* gave a reddish

brown residue which was triturated with 50 ml of ether. A precipitate was removed by filtration and washed thoroughly with ether until the filtrate remained colorless. Evaporation of the combined filtrates left a brown gum which was chromatographed (benzene) to give three products in the following order of elution which were purified and characterized individually:

Iodomethyl 2-indolyl ketone (**6**) was crystallized from cyclohexane – methylene chloride to give 60 mg (8%) of pale yellow crystals, m.p. 160°; mass spectrum: M^+ 285; i.r. ν_{max} 1645 (C=O) cm^{-1}; u.v. λ_{max} 312 (12 740) and 235 (8000) mμ; n.m.r. τ 0.45 (s, 1, NH), 2.21–2.83 (m, 5, aromatics), and 5.65 (s, 2, $COCH_2I$). The pyridinium iodide salt (**8**) was prepared in benzene and showed m.p. 245–246° (dec.) [lit. (10): m.p. 245–246° (dec.)].

Methyl 2-indolylacetate (**2***a*) was crystallized from petroleum ether (35–60°) to give 85 mg (17%) of pale yellow crystals identical by m.p. and mixture m.p. determinations with an authentic sample as prepared above.

Methyl 2-indolylglyoxylate (**7**) was crystallized from cyclohexane – methylene chloride to give 55 mg (10%) of orange–yellow crystals, m.p. 132–133°; mass spectrum: M^+ 203; i.r. ν_{max} 3400 (NH), 1740 (ester C=O), 1650 (C=O) cm^{-1}; u.v. λ_{max} 327 (13 850), and 240 (9000) mμ; n.m.r. τ 0.75 (s, 1, NH), 2.31–2.82 (m, 5, aromatics) and 6.05 (s, 3, OCH_3).

Anal. Calcd. for $C_{11}H_9NO_3$: C, 65.02; H, 4.43; N, 6.89. Found: C, 64.77; H, 4.44; N, 6.75.

(b) At Reflux Temperature

The above reaction was carried out using identical quantities of reactants at reflux for 13 h and the following compounds were isolated after chromatography: **2***a* (25%), **3** (7%), and **6** (4%).

*Conversion of Iodomethyl 2-Indolyl Ketone (**6**) to 2-Acetylindole (**9**)*

A mixture of compound **6** (57 mg, 0.2 mmol) and zinc dust (65 mg, 1 mmol) was refluxed in 15 ml of ethanol for 24 h. The inorganic precipitate was removed by filtration and the filtrate was evaporated to leave a gummy residue which was crystallized from cyclohexane – methylene chloride to give 25 mg (79%) of 9 as colorless needles, m.p. 147–148°, shown to be identical to authentic material by m.p. and mixture m.p. determinations as prepared below.

*Preparation of 2-Acetylindole (**9**)*

A solution of indole-2-diazoketone (**1**) (185 mg, 1 mmol) in 50 ml of ethanol was hydrogenated in the presence of 30 mg of platinum oxide under standard conditions. Normal isolation procedure gave a gummy material which was crystallized from cyclohexane – methylene chloride to yield 121 mg (76%) of colorless needles of 9, m.p. 147–148° [lit. (22): m.p. 148–149°].

*Indole-2-glyoxylic Acid (**10**)*

Compound 7 (120 mg, 0.59 mmol) was suspended in 10 ml of 1.0 *N* aqueous potassium hydroxide and the mixture was stirred at room temperature for 20 min. A small amount of solid was removed by filtration. The filtrate was cooled to 0° and acidified with 2 ml of concentrated hydrochloric acid. The resulting orange–yellow precipitate was collected, washed with minimum of cold water, and dried to yield 102 mg (92%) of **10**. Recrystallization from acetone–water furnished orange–yellow feathery needles, m.p. 160–161°; i.r. ν_{max} (CH_2Cl_2) 3400 (NH), 2900–3100 (OH), 1780 (acid C=O), and 1640 (C=O) cm^{-1}; u.v. λ_{max} 315 (14 000), 235 (9100) mμ; n.m.r. (polysol-*d*) τ −1.40 (s, 1, COOH), 0.51 (s, 1, NH), and 2.21–3.18 (m, 5, aromatics).

Anal. Calcd. for $C_{10}H_7NO_3$: C, 63.49; H, 3.73. Found: C, 63.50; H, 3.88.

*Esterification of Indole-2-glyoxylic Acid (**10**)*

A solution of 100 mg (0.53 mmol) of **10** in methanol was stirred in contact with 200 mg of Dowex 50 W-X2 resin (200–400 mesh, H^+ Form) at room temperature for 15.h. The resin was removed by filtration and the filtrate was evaporated to dryness *in vacuo*. The residue was crystallized from cyclohexane – methylene chloride to give 93 mg (86%) of orange–yellow needles, identical with 7 as shown by n.m.r. spectral, m.p., and mixture m.p. determinations.

*Conversion of Indole-2-glyoxylic Acid (**10**) to Indole-2-carboxylic Acid (**11**)*

To a solution of 15 mg (0.08 mmol) of **10** in 5 ml of 10% aqueous sodium carbonate solution, was added 5 drops of hydrogen peroxide and the reaction mixture was left overnight at room temperature. Acidification with hydrochloric acid followed by extraction with ether provided 9 mg (70%) of a solid which was recrystallized from acetone–water to give colorless needles of **11**, identical with an authentic sample (m.p. and mixture m.p. determinations) prepared by a literature method (11).

*Reaction of Indole-2-diazoketone (**1**) with Cuprous Iodide*

(a) In Acetonitrile–Ethanol Solution at Reflux

The procedure was essentially that described for the reaction of **1** in acetonitrile–methanol solution except that the mixture was refluxed for 1 h. From 100 mg of **1** there was obtained 28.5 mg (28%) of *ethyl 2-indolylacetate* (**2***b*) which was shown to be identical to a sample prepared as above.

(b) In Acetonitrile – Benzyl Alcohol Solution at Reflux

The above procedure was used. From 100 mg of **1** there was obtained 35 mg (24%) of *benzyl 2-indolylacetate* (**2***c*), m.p. 85–86° [lit. (23): m.p. 86°]; i.r. ν_{max} 3385 (NH), 1733 (C=O) cm^{-1}; n.m.r. τ 0.42 (s, 1, NH), 2.62–3.20 (m, 9, aromatics), 3.78 (s, 1, indole-3H), 4.85 (s, 2, $CO_2C\underline{H}_2C_6H_5$), and 6.25 (s, 2, CH_2).

Financial support of this work by the National Research Council of Canada and by Bristol Laboratories is gratefully acknowledged. We are indebted to Professor D. B. MacLean for the mass spectra and to Professor Potts for an authentic sample of compound **8**. We also thank Professor S. McLean for discussion and Dr. F. X. Garneau for correspondence regarding the mechanism of formation of 7.

Calcium(II) and Magnesium(II) Binding by L-Serine Orthophosphate in Aqueous Solutions

C. W. CHILDS[1]

Department of Medical Chemistry, Institute of Advanced Studies, Australian National University, Canberra, Australia

Received February 3, 1971

The dissociation of L-serine orthophosphate (H_3L) and its complexation reactions with calcium(II) and magnesium(II) have been studied by potentiometric titration at 37 °C in the 0.15 mol l^{-1} potassium nitrate medium and (with the exception of calcium(II) complexation) in the 0.15 mol l^{-1} tetraethylammonium bromide medium. A least squares interpretation of the data has yielded dissociation constants for H_3L and equilibrium constants for the formation of the 1:1 metal–ion complexes MH_2L^+, MHL, and ML^-. In addition the dimeric species $H_5L_2^-$, $MH_3L_2^-$, and $M_2H_2L_2$ are consistent with the data and equilibrium constants for their formation have been determined.

On a étudié, par titrage potentiométrique à 37 °C dans des milieux contenant 0.15 mol l^{-1} de nitrate de potassium et (à l'exception de la complexation du Ca(II)) 0.15 mol l^{-1} de bromure de tétraéthylammonium, la dissociation de l'orthophosphate de L-sérine (H_3L) et ses réactions de complexation avec le calcium(II) et le magnésium(II). Utilisant la méthode des moindres carrés, il est possible d'évaluer les constantes de dissociation de H_3L et les constantes d'équilibre pour la formation des complexes 1:1 ion–métal $MH_2L^{\oplus}$, MHL, et ML^-. De plus les données sont en accord avec les quantités d'espèces dimériques $H_5L_2^-$, $MH_3L_2^-$, et $M_2H_2L_2$ présentes et les constantes d'équilibre pour leur formation ont été déterminées.

Canadian Journal of Chemistry, **49**, 2359 (1971)

Introduction

Knowledge of the properties of serine orthophosphate (H_2O_3P—O—CH_2—$CH(NH_2)$—$COOH \equiv H_3L$) possibly offers insight into the metabolic role of phosphoproteins in physiological systems. One property, that of metal–ion binding in solution, has been studied once before by Österburg (1), who reported the dissociation constants of the ligand and the stability constants

Calcium(II) and Magnesium(II) Binding by L-Serine Orthophosphate in Aqueous Solutions

C. W. CHILDS[1]

Department of Medical Chemistry, Institute of Advanced Studies, Australian National University, Canberra, Australia

Received February 3, 1971

The dissociation of L-serine orthophosphate (H_3L) and its complexation reactions with calcium(II) and magnesium(II) have been studied by potentiometric titration at 37 °C in the 0.15 mol l^{-1} potassium nitrate medium and (with the exception of calcium(II) complexation) in the 0.15 mol l^{-1} tetraethylammonium bromide medium. A least squares interpretation of the data has yielded dissociation constants for H_3L and equilibrium constants for the formation of the 1:1 metal–ion complexes MH_2L^+, MHL, and ML^-. In addition the dimeric species $H_5L_2^-$, $MH_3L_2^-$, and $M_2H_2L_2$ are consistent with the data and equilibrium constants for their formation have been determined.

On a étudié, par titrage potentiométrique à 37 °C dans des milieux contenant 0.15 mol l^{-1} de nitrate de potassium et (à l'exception de la complexation du Ca(II)) 0.15 mol l^{-1} de bromure de tétraéthylammonium, la dissociation de l'orthophosphate de L-sérine (H_3L) et ses réactions de complexation avec le calcium(II) et le magnésium(II). Utilisant la méthode des moindres carrés, il est possible d'évaluer les constantes de dissociation de H_3L et les constantes d'équilibre pour la formation des complexes 1:1 ion–métal $MH_2L^{\oplus}$, MHL, et ML^-. De plus les données sont en accord avec les quantités d'espèces dimériques $H_5L_2^-$, $MH_3L_2^-$, et $M_2H_2L_2$ présentes et les constantes d'équilibre pour leur formation ont été déterminées.

Canadian Journal of Chemistry, **49**, 2359 (1971)

Introduction

Knowledge of the properties of serine orthophosphate (H_2O_3P—O—CH_2—$CH(NH_2)$—$COOH \equiv H_3L$) possibly offers insight into the metabolic role of phosphoproteins in physiological systems. One property, that of metal–ion binding in solution, has been studied once before by Österburg (1), who reported the dissociation constants of the ligand and the stability constants

of the metal–ion complexes MHL and ML (where M represents calcium(II), magnesium(II), manganese(II), copper(II), and iron(III)) and, in addition, ML_2, (for copper(II) and iron(III)) at 25 °C for the 0.15 mol l^{-1} potassium chloride medium.

It is likely that H_3L in solution is mostly in the zwitterionic form with one proton removed from the phosphate segment and an extra one located on the amino nitrogen (1). Correlation with the dissociation constants of orthophosphate and serine (2) then suggests that the successive dissociations of H_3L would yield a ligand with metal–ion binding properties derived from the following combinations:

H_3L : —O—PO_3H^-

H_2L^- : —O—PO_3H^- and —COO^-

HL^{2-} : —O—PO_3^{2-} and —COO^-

L^{3-} : —O—PO_3^{2-} and —$HC(\dot{N}H_2)$—COO^-

Previous work on orthophosphate solution equilibria (3) and metal–ion orthophosphate complexes (4) indicated the possibility of dimeric species existing in solutions of serine orthophosphate.

All of these possibilities have been considered in deriving the equilibrium constants in the present paper for the dissociation of L-serine orthophosphate and the complexation reactions with calcium(II) and magnesium(II) in 0.15 mol l^{-1} potassium nitrate, and (calcium(II) complexation excepted) in 0.15 mol l^{-1} tetraethylammonium bromide at 37 °C. The results have been derived from potentiometric titration data in the pH range 3 to 10, where the species H_4L^+ can safely be neglected.

Experimental

L-Serine orthophosphate (Calbiochem A grade) was dried at 20 °C over anhydrous magnesium perchlorate and was used without purification as analysis for C, H, N, and P indicated close to 100% purity.[2] Freshly prepared solutions were always used in the experiments. Tetraethylammonium bromide (BDH Laboratory Reagent) was recrystallized from a chloroform–ether mixture and dried at 20 °C under reduced pressure for several weeks. The other materials and solutions were obtained as described previously (4).

AnalaR potassium hydrogen phthalate and sodium tetraborate were used without further purification for the preparation of 0.05 mol l^{-1} standard buffer solutions (pH values 4.029 and 9.082 respectively (5) at 37 °C). The potentiometric measurements were made at 37 ± 0.05 °C with the apparatus and procedure described previously (4). The precision of all of the pH measurements was estimated from duplicate titrations to be about ±0.005 pH unit. In all cases the standard buffer readings after a titration agreed within 0.005 pH unit with the initial settings.

The complete pH titration data are on file with the Depository of Unpublished Data.[3] There were five sets of three titrations; in each set the L-serine orthophosphate concentrations were close to 3×10^{-3}, 6×10^{-3}, and 9×10^{-3} mol l^{-1}. In three sets calcium(II) nitrate or magnesium(II) nitrate were included at concentrations close to 2×10^{-3}, 7×10^{-3}, and 5×10^{-3} mol l^{-1} respectively. The average number of readings in a titration was 33, the minimum number was 27, and each titration covered the pH range 3 to 10. The titrant was always potassium hydroxide solution close to 1.0 mol l^{-1}. In three sets of titrations (H_3L, Ca(II)–H_3L, and Mg(II)–H_3L) the medium was 0.15 mol l^{-1} potassium nitrate, and in two (H_3L and Mg(II)–H_3L) it was 0.15 mole l^{-1} tetraethylammonium bromide.

Interpretation of Data

The data were interpreted with the aid of the computer program SCOGS (6) as previously described (3, 4, 7). This program uses an iterative least squares method to find the best match between the observed and calculated volumes of titrant by refining the estimated values of the equilibrium constants for a postulated set of equilibria.

For the solution of mass balance equations the hydrogen ion concentrations were estimated from the pH values by eq. 1 (4). For the 0.15 mol

$$[1] \qquad p[H^+] = pH + \log F$$

l^{-1} potassium nitrate medium and the apparatus used in this work F has been shown (4) to lie in the range 0.80–0.85. For the 0.15 mol l^{-1} tetraethylammonium bromide medium the same range of F was used and this was consistent with the best least squares fit obtained as F was varied, a criterion which has proved useful before (3, 4, 7).

The ionic activity product of water was taken to be $10^{-13.62}$ at 37 °C (8).

The equilibrium constants are defined in eqs.

[2] I am grateful to Dr. J. E. Fildes of the Microanalytical Laboratory, John Curtin School of Medical Research, Canberra, Australia, for these analyses.

2–11 in forms which involve $(H^+) = 10^{-pH}$, and the concentrations (denoted by square brackets) of all other species.

$$[2] \quad K_{a1} = [H_2L^-](H^+)/[H_3L]$$

$$[3] \quad K_{a2} = [HL^{2-}](H^+)/[H_2L^-]$$

$$[4] \quad K_{a3} = [L^{3-}](H^+)/[HL^{2-}]$$

$$[5] \quad K(H_5L_2^-) = [H_5L_2^-]/[H_3L][H_2L^-]$$

$$[6] \quad {}^*K_1 = [MOH^+](H^+)/[M^{2+}]$$

$$[7] \quad K_{m,1} = [MH_2L^+]/[M^{2+}][H_2L^-]$$

$$[8] \quad K_{m,2} = [MHL]/[M^{2+}][HL^{2-}]$$

$$[9] \quad K_{m,3} = [ML^-]/[M^{2+}][L^{3-}]$$

$$[10] \quad K_{m1,2} = [MH_3L_2^-]/[MH_2L^+][HL^{2-}]$$

$$[11] \quad K_{m2.m2} = [M_2H_2L_2]/[MHL]^2$$

Values for the equilibrium constants [2] to [5] were determined in the first two sets of experiments. By analogy with results obtained earlier from similar measurements on orthophosphate (3) the dimeric species $H_4L_2^{2-}$, $H_3L_2^{3-}$, and H_6L_2 were also tried in the interpretation, but their inclusion (individually or together) failed to produce an improvement in least squares fit to the data and the estimated values of the equilibrium constants were progressively decreased in the iteration process until the calculated concentrations of the species became negligible. The values obtained for equilibrium constants [2] to [5] are given in Table 1. The limits shown in Tables 1 and 2 for this work are the sums of the standard deviations of the cumulative equilibrium constants (as refined by the computer) used in obtaining the values. The standard deviation in volume of titrant (SDT) is a measure of the ability of the refined values to reproduce the experimental data.

The small amount of metal–ion hydrolysis occurring in the solutions was accounted for by the use of ${}^*K_1$ values given previously (4) with the exception of the formation of $MgOH^+$ in the 0.15 mol l^{-1} tetraethylammonium bromide medium; in this case the value of ${}^*K_1$ was determined simultaneously with the equilibrium constants for the magnesium(II) – L-serine orthophosphate species, and was found to be $10^{-10.5\pm0.1}$ for both $F = 0.80$ and 0.85.

The last three sets of experiments, when calcium(II) or magnesium(II) ions were included, were used to determine the values for equilibrium constants [7] to [11]. Initially MH_3L^{2+}, MH_2L^+, MHL, and ML^- were the metal–ion complexes included in the interpretations, but MH_3L^{2+} proved inconsistent with the data and was omitted from further calculations. Subsequently all of the possible 1:2 and 2:1 metal–ion – L-serine orthophosphate species were added successively to the interpretations, but of these only $MH_3L_2^-$ and $M_2H_2L_2$ were consistent with the data for each system, the inclusion of each of these species produced an improvement in the least squares fit to the data and the estimates of the corresponding equilibrium constants converged to apparently reasonable values. Table 2 lists the refined values of the equilibrium constants for species involving calcium(II) or magnesium(II). The same results were obtained with $F = 0.80$ as with $F = 0.85$.

Discussion

It should be noted that in this work the medium (0.15 mol l^{-1} potassium nitrate or tetraethylammonium bromide) has been treated as a 'solvent' in the sense that Rossotti and Rossotti

(9) and Sillén (10) have enunciated. Hence the formulas for the various species include an unknown number of water molecules and medium ions, and it is necessary to specify with the results both the nature and the ionic strength of the medium. It is not assumed that the medium ions do not form complexes with the reactants of interest. The results determined with this approach are sometimes referred to as 'apparent' equilibrium constants. The necessity for specifying the nature of the medium can be seen by comparing the results for the potassium nitrate medium with those for the tetraethylammonium bromide medium in Tables 1 and 2.

The agreement between the values of $K_{m,2}$ and $K_{m,3}$ obtained in this work for the potassium nitrate medium and those obtained by Österburg for the potassium chloride medium (see Table 2) is surprisingly close considering that the measurements were made at different temperatures and that the data have been interpreted in somewhat different ways. The differences between the results for the potassium nitrate medium and those for the tetraethylammonium bromide medium (see Tables 1 and 2) tend to be greater, probably due to the relative inertness of tetraethylammonium bromide in the systems studied.

The evidence for the dimeric species $H_5L_2^-$, $MH_3L_2^-$, and $M_2H_2L_2$ is partly dependent upon the decrease of a least squares parameter when each species is included in the interpretation. Such evidence is always open to question on the basis that the improvement in fit may be fortuitous. On the other hand, several other species tried did not improve the fit, and the values obtained for the equilibrium constants are of the same order as those obtained earlier for dimeric phosphates in solution (3, 4). Possible structures for $H_5L_2^-$, $MH_3L_2^-$, and $M_2H_2L_2$ in solution are shown in **1**, **2**, and **3** respectively. These are similar to those described earlier for orthophosphate complexes (3, 4). Note that if H_3L is zwitterionic in solution as $^-HO_3P—O—CH_2—CH(NH_3^+)—COOH$ then in $H_5L_2^-$ only two hydrogen bonds may exist between the two phosphate segments as against three in the corresponding orthophosphate dimer. With L-serine orthophosphate there is also the possibility of the existence of inter- or intra-molecular hydrogen bonds which involve the carboxylate and amino groups (11).

Table 3 lists the calculated compositions of solution containing 0.006 mol l^{-1} magnesium(II) and 0.009 mol l^{-1} L-serine orthophosphate as the p*H* varies from 3 to 10. The values in Tables 1 and 2 for the potassium nitrate medium have been

Alkylammonium Ions: Chemical Shifts and Interactions with Solvent in Aqueous Acid Solutions

J. T. Edward

Department of Chemistry, McGill University, Montreal, Quebec

Received January 19, 1971

The difference between the chemical shifts of the α and β hydrogens of the mono-, di-, tri-, and tetraethylammonium ions changes as the concentration of the solvent sulfuric acid is increased from 0 to 94%. A tentative explanation based on hydration of the ions is presented.

La différence entre les déplacements chimiques des hydrogènes α et β des ions mono-, di-, tri-, et tetraéthylammonium change par rapport à la concentration de l'acide sulfurique employé comme solvant. On propose une explication basée sur l'hydratation des ions.

Canadian Journal of Chemistry, **49**, 2364 (1971)

In the past nine years several investigators (cited in ref. 1) have followed the protonation of organic molecules in increasing concentrations of sulfuric acid by observing changes in their n.m.r. chemical shifts. It accordingly becomes important to know how the chemical shift varies with acid concentration when the degree of protonation of the molecule is not changing. For this reason we have measured the difference Δδ (previously symbolized by δ_i (2)) between the chemical shifts of the α and β hydrogens of the ethyl groups in the mono-, di-, tri-, and tetraethylammonium ions in 0–80% sulfuric acid. The results are shown in Fig. 1 and are included in Table 1.

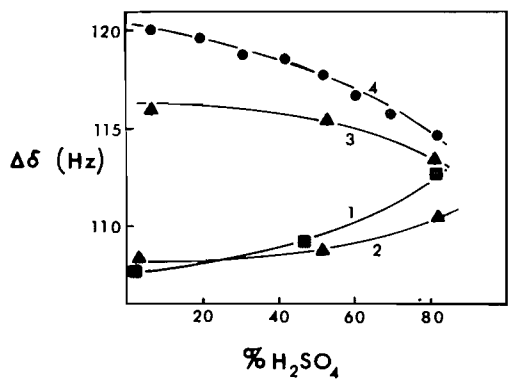

FIG. 1. Effect of acid concentration on Δδ of (*1*) monoethylammonium; (*2*) diethylammonium; (*3*) triethylammonium; and (*4*) tetraethylammonium ions.

The Δδ of the ethyl group is known to be proportional to the electronegativity of the group attached to it (3), so that it is evident (Fig. 1) that in aqueous solution the positive nitrogen of the tetraethylammonium ion attracts electrons more strongly than the positive nitrogen of the ethylammonium ion. This may be plausibly attributed to hydrogen-bonding of water molecules to the $-NH_3^+$ group, as shown in **1** (see ref. 4 for documentation). The negative ends of

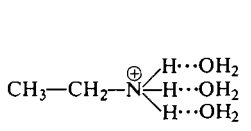
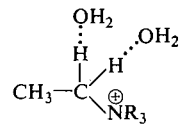
the bonded water dipoles neutralize slightly the partial positive charges of the hydrogen atoms attached to N^+, and so effectively decrease the positive charge of the $—NH_3^+$ group. The $—NEt_3^+$ group, where this effect is absent, should accordingly be expected to be more strongly electron-pulling. Fraenkel and Kim (5) observed a similar difference for primary and quaternary anilinium ions dissolved in methanol.



1



2

The $—NH_3^+$ may be expected progressively to lose its bonded water molecules as the concentration of sulfuric acid increases from 0 to 80%, and the activity of water decreases from 1.00 to 0.005 (6). This explains satisfactorily the increase in Δδ of the ethylammonium ion with acid concentration, as shown in Fig. 1; similar increases have been noted in Δδ of other protonated species (1, 2). However, it does not explain the *decrease* of Δδ of the tetraethylammonium ion as the acid concentration is increased (Table 1 and Fig. 1); it might have been expected that Δδ of this ion would remain constant. Any explanation of this result must be highly tentative: shifts of ionic species are poorly understood, and may be due to many factors. A possible explanation may be weak hydrogen-bonding of the methylenic protons, known to be slightly acidic (7), to water molecules as pictured in **2**.[1] Such hydrogen bonding would shift the resonance of the methylenic hydrogens downfield (9), and increase Δδ; the effect would diminish with the decreasing water activity accompanying increase of acid concentration. Deno and co-workers (10) have noted that the chemical shift of the methyl protons of the tetramethylammonium ion (referred to the methyl protons of $(CH_3)_3Si(CH_2)_3SO_3H$) moves downfield as the concentration of sulfuric acid is increased from 0 to 96%, and a similar explanation would apply.

Some support for this interpretation comes from the fact that Δδ of the tetraethylammonium ion in water decreases from 120.1 ± 0.3 Hz at 31° to 118.6 ± 0.2 Hz at 86.5 ± 2°; hydrogen bonding would be expected to diminish at higher temperatures.

Other explanations, based on a specific interaction between tetraethylammonium and bisulfate ions, are made less likely by the fact that a wide variety of other solutes (*e.g.* calcium chloride and sodium hydroxide) lower Δδ, the extent of the lowering depending on the solute concentration. The general similarity of the behavior of the ion in different strong acids is shown in Fig. 2: Δδ is roughly linear with $-H_0$ (11) between 0 and +8 for solutions in aqueous sulfuric, perchloric, nitric and hydrochloric acids. The increase in $-H_0$ with acid concentration is known to be related to the decreasing water activity in different acid solutions (12).

In summary, chemical shift data seem to indicate that even the tetraethylammonium ion (regarded as the "ideal" cation (13)) shows some interaction with solvent.

Experimental

Measurements were made with a Varian HR-60 spectrometer at a probe temperature of about 39°

[1]Ko and Leffek (8) have recently reported a variation of isotope effect with solvent in the decomposition of benzyl-α-d_2-phenyldimethylammonium bromide and have given a similar rationalization in terms of a specific solvent interaction with methylenic protons or deuterons.

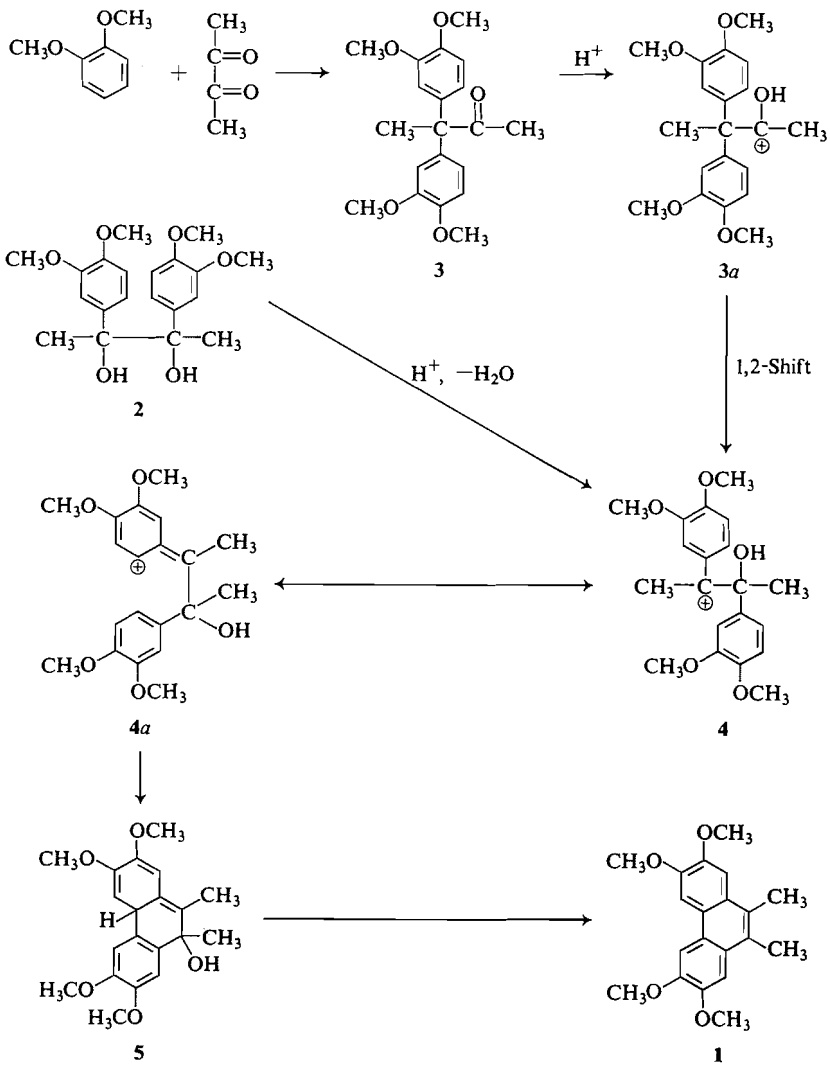

SCHEME 1

future, we wish to present some observations made, in the hope that they may be of interest for synthetic approaches to biologically active phenanthrene derivatives (*e.g.* the alkaloids of the tylophorine and cryptopleurine types).

The reaction of veratrole with biacetyl in 70% v/v aqueous sulfuric acid at room temperature to give the phenanthrene **1** has been reported by Manson and Musgrave (1), who suggested that the reaction proceeds through 2,3-bis-(3,4-dimethoxyphenyl)butane-2,3-diol (**2**), since this diol gave **1** in 75% v/v aqueous sulfuric acid. It was later claimed (2) that 3,3-bis-(3,4-dimethoxyphenyl)butane-2-one (**3**) was not converted to **1** in this medium.

Attempting to define the conditions for formation of **1** more clearly, we have monitored the reaction by t.l.c.[2] The results show that veratrole and biacetyl react very rapidly to give an intermediate which is slowly (2–4 days) converted to **1**.[3] By quenching the reaction with water within 20 min of mixing the reactants, and extracting with chloroform, the intermediate was isolated in 75% yield; m.p. 88.5–90 °C from methanol. Spectral data are completely consistent with 3,3-bis-(3,4-dimethoxyphenyl)butane-2-

[2]Silica gel, Merck, developed with 2% methanol in chloroform.

[3]The aqueous sulfuric acid was prepared by adding 700 ml of 97.9% sulfuric acid to 300 ml of water.

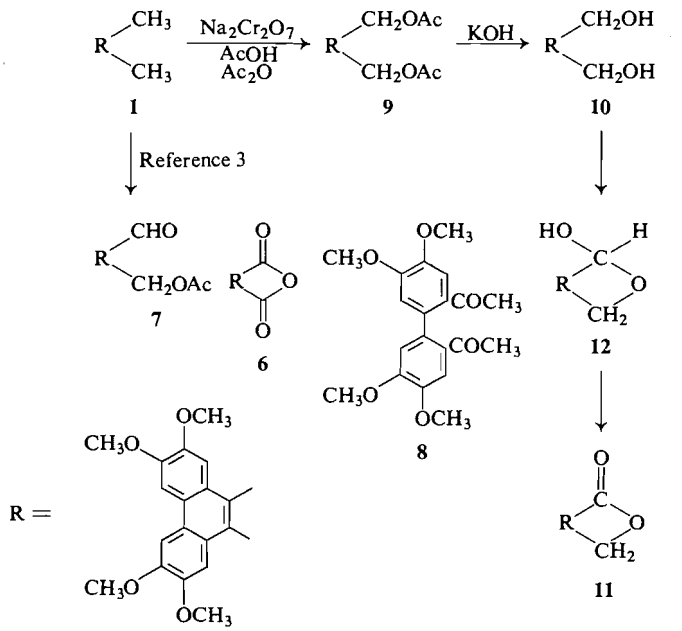

SCHEME 2

one (**3**) (2). Contrary to earlier results (2), this ketone was converted in 50% yield to **1** in aqueous sulfuric acid.

In view of the many possible equilibria involving the pinacol–pinacolone pair **2** and **3**, no definite statement about the actual reaction sequence leading to **1** can be made. However, the observed rapid appearance of **3**, and its further conversion to **2**, suggest the sequence shown in Scheme 1 as the most straightforward interpretation of the formation of **1**.

The oxidation of **1** has been examined by Edwards and Weiss (3), who obtained, depending upon conditions, the phenanthrene dicarboxanhydride **6**, the monoacetoxy aldehyde **7**, and the diacetyl-tetramethoxybiphenyl **8**. In extension of this work, we have now found that oxidation of **1** with $Na_2Cr_2O_7$ in Ac_2O–AcOH directly gives the diacetate **9** which had previously (3) been obtained on hydride reduction of **7**, followed by acetylation (see Scheme 2). Attempts to convert the parent diol **10** (3) to the dialdehyde with pyridine–CrO_3 were unsuccessful; the only product isolable was the phthalide **11** which was presumably formed through the hemiacetal **12**, a well-known side reaction in this type of oxidation (4). The structure of **11** rests on chemical and spectroscopic evidence. Compound **11**, $C_{20}H_{18}O_6$, does not form a dinitrophenylhydrazone; the i.r. absorption at 1735 cm^{-1} is indicative of an ester carbonyl rather than an aromatic aldehyde. The n.m.r. did not reveal any aldehydic protons and from its pattern, the compound is clearly not symmetrical (see Experimental). In view of this non-symmetrical structure, and of the versatile reactivity of phthalides in general, **11** may be a useful intermediate in the synthesis of a variety of polycyclic compounds.

Experimental

Melting points, determined on a Reichert hot-stage microscope, are uncorrected. The i.r. spectra were recorded in $CHCl_3$ on an Perkin–Elmer 257 instrument; u.v. spectra in absolute methanol or chloroform were recorded on a Cary 14 spectrophotometer; and n.m.r. spectra in deuteriochloroform or deuteriodimethyl sulfoxide on a Varian Associates A-60 instrument. Mass spectra were obtained on an L.K.B. 7000 mass spectrometer through the courtesy of Mr. W. E. Comstock.

3,3-Bis-(3,4-dimethoxyphenyl)butane-2-one (3)

To a stirred solution of veratrole (3.2 g, 23.2 mmol) in 40 ml 70% aqueous H_2SO_4, biacetyl (1 g, 11.6 mmol) was added dropwise. After 20 min the mixture was poured into water, (300 ml), and extracted with $CHCl_3$. The extracts were washed with water, dried ($MgSO_4$), and concentrated. The residue was crystallized from methanol to give **3** in 74% yield; m.p. 85–87° (lit. (2) 83.5–84.5°); ν_{max} 1725 cm^{-1} (ketone); δ ($CDCl_3$) 6.82 (multiplet, 6H),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

aromatic protons, 3.90 (singlet, 6H), and 3.82 (singlet, 6H), OCH_3, 2.12 (singlet, 3H), CH_3—C=O, 1.86 (singlet, 3H), CH_3—C; λ_{max} (ethanol) 282 nm (log ε 3.80); mol. wt. 344 (mass spectrometry) (calcd. 344).

2,3,6,7-Tetramethoxy-9,10-dimethylphenanthrene (1)

(*a*) Compound **1** was prepared in 50% yield by the method of Manson and Musgrave (1); m.p. 226.5–227° (lit. (1) 222–223°).

(*b*) The intermediate **3** (1 g) was dissolved in 12 ml 70% H_2SO_4 and kept at room temperature for 4 days. The mixture was filtered, the solid dissolved in ethanol, treated with charcoal, and crystallized to give **1** in 50% yield; m.p. 226.5–227°. The m.p. was not depressed on admixture with a sample prepared by method *a*, and the i.r. spectra of the two samples were identical.

2,3,6,7-Tetramethoxy-9,10-diacetoxymethylphenanthrene (9)

A solution of $Na_2Cr_2O_7 \cdot 2H_2O$ (9.4 g, 31 mmol) in acetic acid (75 ml) was added dropwise over a period of 20 min to a refluxing solution of **1** (10 g, 31 mmol) in 150 ml acetic anhydride – acetic acid (1:1). The hot solution was poured into ice water (750 ml) and kept overnight. Crude **9** was obtained in 65% yield by filtration; m.p. 224–226°, after recrystallization from MeOH–$CHCl_3$; (lit. (3) 226–228°). This compound was spectroscopically identical with **9** prepared earlier in this laboratory.

Compound **10** was prepared by a saponification of **9** with KOH; m.p. 223–225° (lit. (3) 225–227°). Again this compound was identical with the **10** previously prepared.

2′,3′,6′,7′-Tetramethoxyphenanthro-[3,10-c]-(5H)-furan-2-one (11)

CrO_3 (6 g, 60 mmol) was slowly added to stirred pyridine (60 ml) cooled in an ice bath. After the addition was complete, a solution of **10** (3.58 g, 10 mmol) in pyridine (25 ml) was added. The mixture was stirred for 30 min and allowed to stand overnight. It was next poured into water (200 ml) and extracted with $CHCl_3$. The extracts were washed with 10% HCl, water, 10% $NaHCO_3$, and water, dried ($MgSO_4$), and evaporated. The residue was crystallized from $CHCl_3$ to give **11** in 63% yield; yellow crystals of m.p. 254–256°; ν 1735 cm^{-1} (phthalide C=O); δ (DMSO) 7.94, (1H), 7.43, (1H) 7.39, (1H), and 6.66 (1H), singlets, aromatic protons, 5.13 (singlet, 2H), benzylic protons, and 4.09, (3H), 4.06, (3H), 3.98 (3H), and 3.92 (3H), singlets, OCH_3; λ_{max} ($CHCl_3$) 372, 352, 333, 325 sh, 288 and 280 sh. nm (log ε 3.72, 3.74, 4.15, 4.09, 4.46, and 4.43).

Anal. Calcd. for $C_{20}H_{18}O_6$ (mol. wt. 354): C, 67.79; H, 5.12. Found (354 (mass spectrometry)): C, 67.68; H, 5.24.

Synthesis of (RS)-Abscisic Acid

J. A. Findlay and W. D. MacKay
Chemistry Department, University of New Brunswick, Fredericton, New Brunswick

Received February 18, 1971

New approaches to the abscisic acid synthetic precursor **4** and the abscisic acid analog **6** are reported.

On rapporte de nouvelles approches pouvant conduire au composé **4** et **6** qui sont respectivement un précurseur synthétique et un analogue de l'acide absicique.

Canadian Journal of Chemistry, **49**, 2369 (1971)

Syntheses of the plant hormone abscisic acid **1** have been reported previously (1–3). The three-step synthesis of Roberts *et al.* (3) involves the conversion of α-ionone into 1-hydroxy-4-keto-α-ionone (**4**) in 23–27% yield by the agency of *t*-butyl chromate. The compound **4** is subsequently converted into (RS)-abscisic acid and its *trans,trans* isomer in two steps by routine methods.

We have now prepared the key intermediate **4** from β-ionone in 43% yield, thus providing an alternate synthetic approach to (RS)-abscisic acid. Tungsten lamp irradiation of a carbon tetrachloride solution containing β-ionone and *N*-bromosuccinimide afforded 3,4-dehydro-β-ionone (**2**) in 91% yield (4). This material was oxidized with *m*-chloroperbenzoic acid to the known (5) epoxide **3** which was treated directly with Jones' reagent, yielding the crystalline abscisic acid precursor **4** (m.p. 109–112°) in 48% yield from **2**.

aromatic protons, 3.90 (singlet, 6H), and 3.82 (singlet, 6H), OCH_3, 2.12 (singlet, 3H), CH_3—C=O, 1.86 (singlet, 3H), CH_3—C; λ_{max} (ethanol) 282 nm (log ε 3.80); mol. wt. 344 (mass spectrometry) (calcd. 344).

2,3,6,7-Tetramethoxy-9,10-dimethylphenanthrene (1)

(*a*) Compound **1** was prepared in 50% yield by the method of Manson and Musgrave (1); m.p. 226.5–227° (lit. (1) 222–223°).

(*b*) The intermediate **3** (1 g) was dissolved in 12 ml 70% H_2SO_4 and kept at room temperature for 4 days. The mixture was filtered, the solid dissolved in ethanol, treated with charcoal, and crystallized to give **1** in 50% yield; m.p. 226.5–227°. The m.p. was not depressed on admixture with a sample prepared by method *a*, and the i.r. spectra of the two samples were identical.

2,3,6,7-Tetramethoxy-9,10-diacetoxymethylphenanthrene (9)

A solution of $Na_2Cr_2O_7 \cdot 2H_2O$ (9.4 g, 31 mmol) in acetic acid (75 ml) was added dropwise over a period of 20 min to a refluxing solution of **1** (10 g, 31 mmol) in 150 ml acetic anhydride – acetic acid (1:1). The hot solution was poured into ice water (750 ml) and kept overnight. Crude **9** was obtained in 65% yield by filtration; m.p. 224–226°, after recrystallization from MeOH–$CHCl_3$; (lit. (3) 226–228°). This compound was spectroscopically identical with **9** prepared earlier in this laboratory.

Compound **10** was prepared by a saponification of **9** with KOH; m.p. 223–225° (lit. (3) 225–227°). Again this compound was identical with the **10** previously prepared.

2′,3′,6′,7′-Tetramethoxyphenanthro-[3,10-c]-(5H)-furan-2-one (11)

CrO_3 (6 g, 60 mmol) was slowly added to stirred pyridine (60 ml) cooled in an ice bath. After the addition was complete, a solution of **10** (3.58 g, 10 mmol) in pyridine (25 ml) was added. The mixture was stirred for 30 min and allowed to stand overnight. It was next poured into water (200 ml) and extracted with $CHCl_3$. The extracts were washed with 10% HCl, water, 10% $NaHCO_3$, and water, dried ($MgSO_4$), and evaporated. The residue was crystallized from $CHCl_3$ to give **11** in 63% yield; yellow crystals of m.p. 254–256°; ν 1735 cm^{-1} (phthalide C=O); δ (DMSO) 7.94, (1H), 7.43, (1H) 7.39, (1H), and 6.66 (1H), singlets, aromatic protons, 5.13 (singlet, 2H), benzylic protons, and 4.09, (3H), 4.06, (3H), 3.98 (3H), and 3.92 (3H), singlets, OCH_3; λ_{max} ($CHCl_3$) 372, 352, 333, 325 sh, 288 and 280 sh. nm (log ε 3.72, 3.74, 4.15, 4.09, 4.46, and 4.43).

Synthesis of (RS)-Abscisic Acid

J. A. Findlay and W. D. MacKay
Chemistry Department, University of New Brunswick, Fredericton, New Brunswick

Received February 18, 1971

New approaches to the abscisic acid synthetic precursor **4** and the abscisic acid analog **6** are reported.

On rapporte de nouvelles approches pouvant conduire au composé **4** et **6** qui sont respectivement un précurseur synthétique et un analogue de l'acide absicique.

Canadian Journal of Chemistry, **49**, 2369 (1971)

Syntheses of the plant hormone abscisic acid **1** have been reported previously (1–3). The three-step synthesis of Roberts *et al.* (3) involves the conversion of α-ionone into 1-hydroxy-4-keto-α-ionone (**4**) in 23–27% yield by the agency of *t*-butyl chromate. The compound **4** is subsequently converted into (RS)-abscisic acid and its *trans,trans* isomer in two steps by routine methods.

We have now prepared the key intermediate **4** from β-ionone in 43% yield, thus providing an alternate synthetic approach to (RS)-abscisic acid. Tungsten lamp irradiation of a carbon tetrachloride solution containing β-ionone and *N*-bromosuccinimide afforded 3,4-dehydro-β-ionone (**2**) in 91% yield (4). This material was oxidized with *m*-chloroperbenzoic acid to the known (5) epoxide **3** which was treated directly with Jones' reagent, yielding the crystalline abscisic acid precursor **4** (m.p. 109–112°) in 48% yield from **2**.

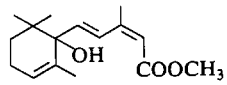
5*a* R = OH



6

The spectral and physical characteristics of **4** were in agreement with the reported data (3).

The location of the oxide bridge in **3** was readily ascertained from its n.m.r. spectrum which shows no signal corresponding to a vinylic methyl group but an appropriate sharp singlet at τ 8.72 assigned to the C-2 methyl. The vinylic protons of the side chain display a simple AB pattern, hence the ether linkage must span C-1 and -2. The oxidation of **3** to **4** probably proceeds via the intermediate **5***a*, a hydration product of the epoxide **3**.

The racemic ester **6**, made via **5** by Tamura and Nagao (6), was found to be a biologically potent analog of abscisic acid. In preparing the synthetic precursor **5** these authors employed the two-step procedure of Roberts (2) which gives it in less than 5% yield from β-ionone. We have recently prepared the key intermediate 1-hydroxy-α-ionone (m.p. 89–90°) in 31% yield by direct oxidation of α-ionone with selenium dioxide in refluxing ethanol. The mass spectrum of this product displays a prominent molecular ion (*m/e* 208) corresponding to $C_{13}H_{20}O_8$ and appropriate hydroxylic absorption (3600, 3450 cm^{-1}) in the i.r. Its n.m.r. spectrum confirms formulation **5** by displaying a simple AB pattern for the signals of the vinyl protons of the side chain and a doublet for the C-2 vinylic methyl group, completely parallel with features of the n.m.r. spectrum of **4**. Hence the tertiary hydroxyl group is located at C-1.

Experimental

The i.r. spectra were recorded on a Perkin–Elmer model 237B spectrophotometer. The mass spectra were determined with an Hitachi Perkin–Elmer model RMU-6D spectrometer. The n.m.r. were recorded with a Varian T-60 instrument and using tetramethylsilane as internal standard. A Kofler hot stage apparatus was employed to determine melting points which are uncorrected. All compounds described proved homogeneous on a variety of t.l.c. systems and their n.m.r. spectra showed them to be devoid of detectable amounts of impurities.

3,4-Dehydro-β-ionone (2)

A refluxing solution of β-ionone (1.92 g) and *N*-bromosuccinimide (2.30 g) in dry carbon tetrachloride (100 ml) contained in a Pyrex vessel was irradiated with a tungsten lamp (100 W) for 30 min. After cooling to room temperature and filtering, anhydrous sodium carbonate (2.5 g) and dimethylformamide (25 ml) were added and the bulk of the carbon tetrachloride was distilled off. The mixture was cooled to room temperature, diluted with ether (200 ml), filtered, washed with 5% aqueous HCl (2 × 50 ml), washed with a dilute solution of sodium chloride, dried ($MgSO_4$), and evaporated yielding a brown liquid (2.9 g) which was chromatographed on a silica gel column giving 3,4-dehydro-β-ionone (1.73 g, 91%) as a yellow liquid; ν_{max} ($CHCl_3$) 1665, 1660 cm^{-1}; λ_{max} (EtOH) 226 (ε, 8500), 233 (ε, 6800); τ ($CDCl_3$) 2.66 (1H, broad d, *J* 16 Hz), 3.80 (1H, d, *J* 16 Hz), 6.12 (2H, m), 7.68 (3H, s), 7.88 (2H, m), 8.08 (3H, s), 8.90 (6H, s); M (mass spectrometry) 190.

3,4-Dehydro-1,2-epoxy-β-ionone (3)

A solution of 3,4-dehydro-β-ionone (**2**) (1.7 g) and *m*-chloroperbenzoic acid (2.0 g) in anhydrous ether (35 ml) was stirred at room temperature for 5 h. Excess acid was decomposed with sodium bisulfite solution (10%) and the mixture diluted to 100 ml with ether, washed with 5% aqueous sodium bicarbonate (2 × 20 ml), washed with saturated sodium chloride solution (2 × 20 ml), dried ($MgSO_4$), filtered, and evaporated yielding the crude 3,4-dehydro-1,2-epoxy-β-ionone (**3**) (1.78 g) which was used without further purification to prepare **4**. A sample of compound **3** was chromatographed on silica gel for spectral characterization; ν_{max} ($CHCl_3$) 1680, 1640 cm^{-1}; λ_{max} 242 (ε, 7700); τ ($CDCl_3$) 2.88 (1H, d, *J* 16 Hz), 3.68 (1H, d, *J* 16 Hz), 4.18 (2H, m), 7.69 (3H, s), 7.8–8.5 (2H, m), 8.72 (3H, s), 8.87 (3H, s), 8.97 (3H, s); M (mass spectrometry) 206.

1-Hydroxy-4-keto-α-ionone (4)

The crude epoxide **3** (1.78 g) prepared as above, was dissolved in 95% aqueous acetone (35 ml) and cooled to 0°. Jones' reagent was added dropwise until an orange color persisted and the mixture was allowed to come to room temperature slowly and was stirred overnight. The bulk of the acetone was evaporated, water (100 ml) was added and the mixture extracted with ether (4 × 20 ml). The ether layer was dried ($MgSO_4$) and evaporated yielding a light orange oil (1.59 g) which was chromatographed on a silica gel column using benzene as eluant yielding white crystalline 1-hydroxy-4-keto-α-ionone (**4**), m.p. 109–112° (lit. 112–113°) (0.961 g, 48% from **2**); ν_{max} ($CHCl_3$) 3560 (broad), 1670, 1620 cm^{-1}; ν_{max} (KBr) 3509, 1661, 1629, 1429, 1366, 1292, 1266, 1178, 1122, 1025, 994, 978, 918, 883 cm^{-1}; λ_{max} 237 (ε, 13 500); τ ($CDCl_3$) 3.08 (1H, d, *J* 16 Hz), 3.53 (1H, d, *J* 16 Hz), 4.02 (1H, s, broad), 7.25 (s, broad, exchanges with D_2O), 7.58 (2H, s, broad), 7.64 (3H, s), 8.08 (3H, d, *J* 2 Hz), 8.86 (3H, s), 8.95 (3H, s); M (mass spectrometry) 222.

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16. Found: C, 70.38; H, 8.21.

1-Hydroxy-α-ionone (5)

Selenium dioxide (1.11 g) in 95% ethanol (400 ml) was added dropwise over 5 h to a refluxing solution of α-ionone (2.5 g) in 95% ethanol (100 ml). After allowing the mixture to reflux for a further 16 h, it was filtered and evaporated yielding a dark brown oil (3.4 g) which was chromatographed on silica gel using ether/petroleum ether (1:1) as eluant. A light brown oil (1.64 g) was thus obtained which after two recrystallizations from petroleum ether furnished pure 1-hydroxy-α-ionone (**5**) (0.65 g, 31%), m.p. 89–90° (lit. 82–83°); ν_{max} ($CHCl_3$) 3600, 3450, 1675, 1625 cm^{-1}; τ ($CDCl_3$) 3.13 (1H, d, *J* 16 Hz), 3.67 (1H, d, *J* 16 Hz), 4.43 (1H, broad), 7.70 (3H, s), 7.98 (2H, m), 8.40 (3H, d, *J* 2 Hz) superimposed on 8.45 (2H, m), 9.00 (3H, s), 9.33 (3H, s); M (mass spectrometry) 208.

Reaction of Trialkylboranes with Cyclic α-Diazo Ketones. A New Synthesis of α-Alkyl Cycloalkanones

John Hooz, Donald M. Gunn,[1] and Hiromichi Kono[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 9, 1971

An efficient procedure has been developed for the alkylation of cyclic ketones, based on the reaction of trialkylboranes with cyclic α-diazo ketones. The reaction proceeds under mild conditions, affords high yields of α-alkylated cycloalkanones, and circumvents certain difficulties inherent in previous alkylation methods.

On a développé une procédure efficace pour alkyler des cétones cycliques; cette méthode fait appel à la réaction de trialkylboranes avec des α-diazocétones cycliques. La réaction se fait dans des conditions douces et conduit à des rendements élevés de cycloalcanones α-alkylées et permet d'éviter certaines difficultés inhérentes aux méthodes d'alkylation précédentes.

Canadian Journal of Chemistry, **49**, 2371 (1971)

Two general schemes have previously been designed to offset the traditional problems (polyalkylation, self-condensation) encountered in typical base-catalyzed ketone alkylation procedures, involving prior modification of the α-methylene group: (*i*) activation (path *a*, A = activating group, eq. 1), and (*ii*) the use of blocking groups (path *b*, B = blocking group, eq. 1) the latter being employed particularly for alkylation at angular positions. However, either former approach necessitates the discrete removal (occasionally requiring several independent steps) of the activating/protecting group, and the pursuant problems frequently lead to but modest yields of the desired alkylate (1).

It was previously observed that trialkylboranes react with a variety of functional diazo compounds to provide numerous synthetically useful derivatives (aldehydes (2), ketones (3, 4), diketones (5), nitriles (6), esters (6)). Moreover, these transformations usually occurred in high yields and under mild conditions, and of special consideration is the fact that the homologated functionalized organoborane intermediate[3]

[1]University of Alberta Postdoctoral Research Fellow, 1967–1969.

[2]University of Alberta Postdoctoral Research Fellow, 1969–Present.

[3]The initial suggestions regarding mechanism (3) have been of considerable value for exploratory synthetic studies. Subsequent work (2, 4) has suggested the intermediacy of enol borinates, and this additional subtlety is in accord with the recent isolation of vinyloxyboranes (7). However, the presence of transient B—C bonded species cannot at present be rigorously eliminated.

[1] 
underwent rapid *in situ* hydrolysis when the reaction was conducted in the presence of water (2, 4, 6).

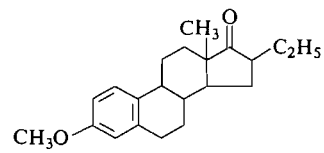
Since such processes may be regarded as conceptually analogous[4] to the previous "activating- or blocking-group approach" toward constructing 2-alkylcycloalkanones (eq. 1), it was of interest to explore some reactions of representative cyclic α-diazo ketones with trialkylboranes (eq. 2) in the hope that this method could circumvent the aforementioned difficulties.

[2] 
In the event, we employed (for convenience) triethylborane[5] as alkylating agent and observed that in the presence of water, a variety of cyclic α-diazo ketones reacted with smooth evolution of nitrogen to furnish excellent yields (82–100%) of the corresponding 2-ethylcycloalkanones.

Equations 3–9 summarize the scope and yields[6] of the transformations accomplished using triethylborane; in a single experiment 2-diazocyclohexanone was alkylated with tripentylborane and provided a 96% yield of 2-*n*-pentylcyclohexanone. In all instances the products were analyzed by g.l.p.c., isolated, and characterized by i.r., p.m.r., and mass spectroscopy, and (in the case of new products), corroborative combustion analyses.

Since neither the organoborane nor diazo substrate react with water appreciably under the experimental conditions, the reactions are conveniently performed by adding water to a solution of the organoborane in tetrahydrofuran at *ca.* 25°; subsequent addition of the diazo ketone results in smooth liberation of nitrogen and the concurrent alkylation, *in situ* hydrolysis

[3] 
[4] 
[5] 
[6] 
[7] 
[8] 
[9] 



[4]The diazo function serves the interesting dual purpose (in terms of previous methodology) of acting as both an activating group (eq. 1, path *a*, A = N_2), as well as a blocking group (eq. 1, path *b*, B = N_2).

[5]Obtained from Alfa Inorganics Inc.

[6]By g.l.p.c. analysis. Yields of isolated product (with no special attention to avoid handling losses) were *ca.* 15–20% lower.

of the functionalized organoboron intermediate. The results for a variety of structural types (eqs. 3–9) indicate the method to be general for ring sizes 5 through 8. Interestingly, this procedure may also be employed for the concurrent α,α′-dialkylation of *bis*-diazo ketones, as exemplified by the high yield of 2,6-diethylcyclohexanone (eq. 5). However, it is to be anticipated that concurrent dialkylations are of preparative value for the exclusive introduction of two identical alkyl groups (9).

There has been considerable effort devoted to devising and improving synthetic routes to cyclic α-diazo ketones (8). The present development illustrates that in instances where the diazo substrate is readily accessible, this method provides a useful and unique, high-yield abridgment of prior approaches (1) by obviating the necessity of multi-step, yield-lowering removal of activating/protecting groups. Owing to the structural stringencies imposed on the requisite diazo ketone, however, this process is obviously intrinsically inapplicable to angular alkylations.

Experimental

General Considerations

All boiling points and melting points are uncorrected. Microanalyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta. Mass spectra were measured by Dr. A. M. Hogg and his associates using an A.E.I. MS-9 spectrometer at an ionization potential of 70 eV; n.m.r. spectra were recorded on a Varian A-60 spectrometer using TMS as internal standard and $CDCl_3$ as solvent.

In all cases the molar ratio of diazo ketone:trialkylborane:water was 1:1.5:10, although it was not established that this stoichiometry is optimal. In cases where products were isolated, the yields (based on diazo ketone) were *ca.* 15–20% lower than the quoted g.l.p.c. yields; since no special precautions were observed to minimize handling losses, however, this yield could doubtless be improved. The stereochemistry of the products derived from eqs. 4, 5, and 9 were not established.

The procedure described in detail for the preparation of 2-ethyl-1-indanone (eq. 8) is representative, except that the reactions with 2-diazocyclooctanone and 16-diazoestrone methyl ether require a brief reflux period before nitrogen evolution ceases.

2-Ethyl-1-indanone

In a 100-ml three-necked flask fitted with a dropping funnel, a thermometer, a reflux condenser connected to an azotometer, and a magnetic stirring bar, were placed triethylborane[5] (30 mmol), 20 ml of tetrahydrofuran, and water (200 mmol). To this stirred mixture was added (2 h) a solution of 2-diazo-1-indanone (19.5 mmol) (8*a*) in 30 ml THF at 27°. After stirring an additional hour at 27° nitrogen evolution was quantitative. At this stage g.l.p.c. analysis indicated a 100% yield of 2-ethyl-1-indanone. The mixture was treated with 15 ml of 3 *N* sodium acetate solution and 15 ml of 30% hydrogen peroxide, maintaining the temperature below 60°. The organic layer was poured into water and extracted with ether (three 30-ml portions). The yellow oil which remained after removal of solvent from the combined, dried (Na_2SO_4) extracts was distilled to afford 2-ethyl-1-indanone (78%), b.p. 65.5–67.0° (0.05 mm); n_D^{25} 1.5449; i.r. (liquid film) 1714 cm^{-1}; n.m.r. ($CDCl_3$) 2.58 (4H, multiplet, aromatic protons), 6.97 (2H, multiplet, benzylic protons), 7.48 (1H, multiplet, methine), 8.30 (2H, multiplet, methylene), 9.03 τ (3H, triplet methyl); mass spectrum (70 eV) M^+ 160.0886 (calcd. 160.0888).

Anal. Calcd. for $C_{10}H_{20}O$: C, 82.46; H, 7.55. Found: C, 82.66; H, 7.67.

Other new compounds prepared in this study were:

2-Ethylcycloheptanone, n_D^{25} 1.4610; mass spectrum (70 eV), M^+ 140.1194 (calcd. 140.1201).

Cyclic Alkoxyoxosulfonium Ions in the Chlorination of Hydroxy Sulfoxides

T. DURST AND K.-C. TIN

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

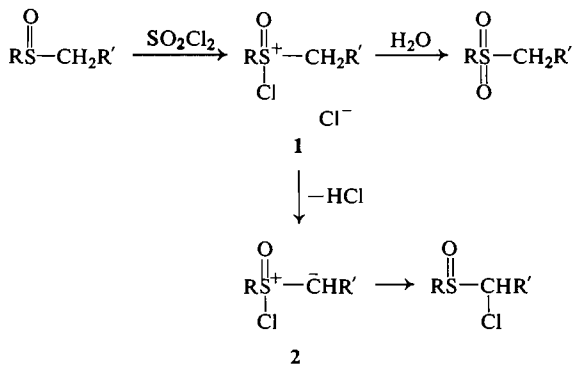
Received March 5, 1971

Chlorination of β-, γ-, and δ-hydroxy sulfoxides with SO_2Cl_2 in CH_2Cl_2 at −78° resulted in the formation of the corresponding β-, γ-, and δ-chloro sulfones. Stereochemical evidence is presented that cyclic alkoxyoxosulfonium salts (*O*-alkylated sulfones) are intermediates in these transformations.

La chloration des β-, γ-, et δ-hydroxy sulfoxydes avec SO_2Cl_2 dans CH_2Cl_2 a −78° conduit aux β-, γ-, et δ-chloro sulfones correspondantes. Des preuves stéréochimiques permettent de montrer que des sels d'alcoxyoxosulfonium cycliques (sulfones *O*-alcoylées) sont des intermédiaires dans ces réactions.

Canadian Journal of Chemistry, 49, 2374 (1971)

Recently we reported the α-chlorination of sulfoxides with sulfuryl chloride in CH_2Cl_2 at −78 or 0° (1). In addition to α-chloro sulfoxides we generally observed the formation of sulfones as by-product. We now propose Scheme 1 to explain the formation of both types of products and present evidence supporting various intermediates.



SCHEME 1

Chlorination of sulfoxides could occur either at carbon or at sulfur (2, 3), the latter pathway leading to chloro-oxosulfonium ions, *e.g.* **1**. α-Chloro sulfoxides can be obtained from **1** via the ylid **2** (3) either by a concerted rearrangement (3) or by an elimination–addition sequence.[1] Displacement of chloride from **1** by H_2O results, after proton transfer, in sulfone formation. In agreement with this, the presence of water in the reaction mixture greatly increased the ratio of sulfone to α-chloro sulfoxide.

In order to obtain further evidence regarding **1** and to examine some of its chemistry we have carried out the chlorination of a number of sulfoxides bearing hydroxyl functions β, γ, or δ to the sulfoxide grouping. In all of these reactions we obtained, in high yield, products in which the sulfur had been oxidized from sulfoxide to sulfone and the remote hydroxyl group replaced by chlorine; the production of α-chlorosulfoxide was completely suppressed. The formation of the chloro sulfones **6** is rationalized as involving intramolecular displacement of chloride ion from **4**, forming cyclic alkoxyoxosulfonium ions (oxygen-alkylated sulfones), *e.g.* **5**, followed by ring cleavage, Scheme 2. Bromination of **3** ($n = 2$) in the presence of pyridine (required) gave the bromo sulfone **7** and the pyridinium salt **8**,[2] both of which are readily explained as the products of the ring opening

[1]The rearrangement **1** to α-chloro sulfoxides can be considered analogous to Pummerer-type rearrangement, T. Durst, ref. 4.

[2]All new compounds had the expected spectroscopic properties (i.r. and n.m.r.) and satisfactory analysis.

SCHEME 3

of **5** ($n = 2$) by bromide ion and pyridine respectively.

Alkoxyoxosulfonium derivatives such as **5** have previously not been considered as potential intermediates in the oxidation of sulfoxides to sulfones. The closely related aryloxosulfonium salts have recently been isolated from the thermal decomposition of aryldiazonium salts in the presence of sulfones (5). Other species which have a structural similarity to **5** are the (dialkylamino)oxosulfonium salts (6) and, more distantly, the trialkyloxosulfonium salts (2, 7).

Chlorination of hydroxy sulfides, *e.g.* **9** at −78°, in contrast to the hydroxy sulfoxides, gave an intermediate formulated as **10** (8) which is stable enough to be observed by n.m.r. at room temperature. Addition of water resulted in hydrolysis and formation of the hydroxy sulfoxide **3** ($n = 2$). With 2 equiv of sulfuryl chloride, **9** is converted to the chloro sulfone **6** ($n = 2$), presumably via **10** and **3** ($n = 2$), Scheme 3.

Stereochemical evidence supporting the intermediacy of species such as **5** was provided from a study of the sulfoxides **11** and **14** (Scheme 4). Chlorination of **11**, prepared from cyclohexene oxide and $PhS(O)CH_2Li$, proceeded rapidly in CH_2Cl_2 at −78° and gave the chloro sulfone **13** in 77% yield. The *cis* stereochemistry in **13** was established by n.m.r. The hydrogen on carbon bearing chlorine which occurred at $\delta = 4.53$ with a width at half-height of less than 7 Hz is consistent with the equatorial assignment in **13**. The formation of the *cis*-sulfone **13** from the *trans*-hydroxy sulfoxide **11** requires inversion at the carbon initially bearing the hydroxyl group, in agreement with the intermediacy of the alkoxyoxosulfonium ion **12**. In contrast, chlorination of the *trans*-hydroxy sulfoxide **14** gave a complex mixture containing at least five components which we have not been able to separate. The n.m.r. inspection of the total mixture indicated the absence of significant amounts of the chloro sulfone **16**. The failure to obtain **16** is not unexpected since its formation requires the intermediacy of **15** which contains the highly strained 6,4-*trans* fused ring system.

Extension of these results to systems involving

Structure and Nuclear Magnetic Resonance Spectrum of *N*-Nitrosocamphidine

J. W. APSIMON AND J. D. COONEY[1]

Department of Chemistry, Carleton University, Ottawa, Canada

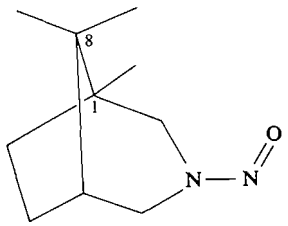
Received March 11, 1971

The 220 MHz n.m.r. spectrum of *N*-nitrosocamphidine is interpreted in terms of a 1:1 *syn–anti* isomer mixture. Benzene solvent-induced shifts and the spectrum of the tris(dipivalomethanato)europium(III) – nitrosocamphidine complex are used to assign the methyl resonances.

On interprète le spectre à 220 MHz de la *N*-nitrosocamphidine en termes d'un mélange 1:1 d'isomères *syn–anti*. On a utilisé les déplacements chimiques induits par le butène ainsi que le spectre du complexe *N*-nitrosocamphidine – Eu $(DPM)_3$ pour attribuer les résonances des groupes méthyles.

Canadian Journal of Chemistry, 49, 2377 (1971)

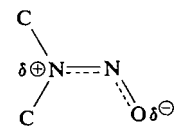
The three methyl groups of *N*-nitrosocamphidine **1** (*N*-nitroso-1,8,8-trimethyl-3-azabicyclo-[3.2.1] octane) were reported (1) to exhibit a 60 MHz n.m.r. spectrum with four unsplit peaks in



1

the methyl region at 1.09, 1.01, 0.96, and 0.91 δ from TMS with intensity ratios 3.0:2.0:2.7:1.4, respectively. Marburg (1) suggested the presence of either a *syn–anti* isomerism of the nitroso group or a chair–boat equilibrium of the ring system as an explanation for the four methyl peaks since one of the methyl groups would experience different shielding in the two forms. In this paper the *N*-nitrosocamphidine 220 MHz n.m.r. spectrum is analyzed for the CH_2—N region and an argument in favor of *syn–anti* isomerism is presented. Specific assignments of the methyl peaks are also included.

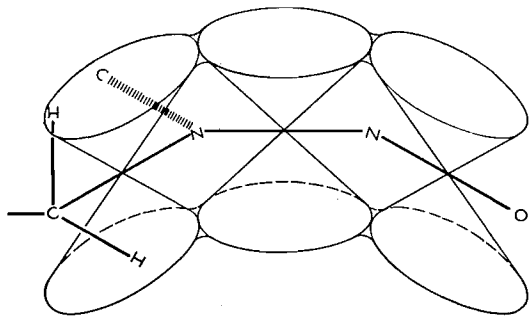
Before analyzing the *N*-α-methylene n.m.r. splitting pattern it is necessary to know both the geometry and the long-range shielding effects of the *N*-nitroso group. A large ionic resonance contribution to the *N*-nitroso group is well supported by i.r. spectroscopy (2); a large barrier to N—NO bond rotation (20–25 kcal/mol) (3); a large dipole moment (4.01 D) (4); electron diffraction studies (5); and molecular orbital theory (6). The best depiction of this group should therefore show a planar CCNNO unit as in **2**.



2

The long range n.m.r. diamagnetic shielding effect of the *N*-nitroso group was described by Harris and Spragg (7) and illustrated by Chow and Colón (8) as shown in **3**. The shielding cones derived from the C_α—N single bond and the N===N===O partial double bond are regarded as

[1]Taken in part from the M.Sc. thesis of J. D. Cooney, Carleton University, Ottawa, Canada, April, 1970. Present Address: Textile Chemistry Section, Division of Chemistry, National Research Council of Canada, Ottawa, Canada.



3

being fused together to form a semicircular shielding zone curved towards the *cis* side. The shielding zone extends perpendicularly above and below the C_α—N=N=O plane. This results in a greater shielding environment on the *cis* side than on the *trans* side. The deshielding zone is located in the C_α—N=N=O plane and studies on conformationally "frozen" 4-substituted *N*-nitrosopiperidines (9) indicated a slightly stronger deshielding zone on the *cis* side.

The possibility of a *syn–anti* isomerism of the *N*-nitroso group and a chair–boat equilibrium of the nitrogen containing ring could give a mixture of the four structures **4–7**.

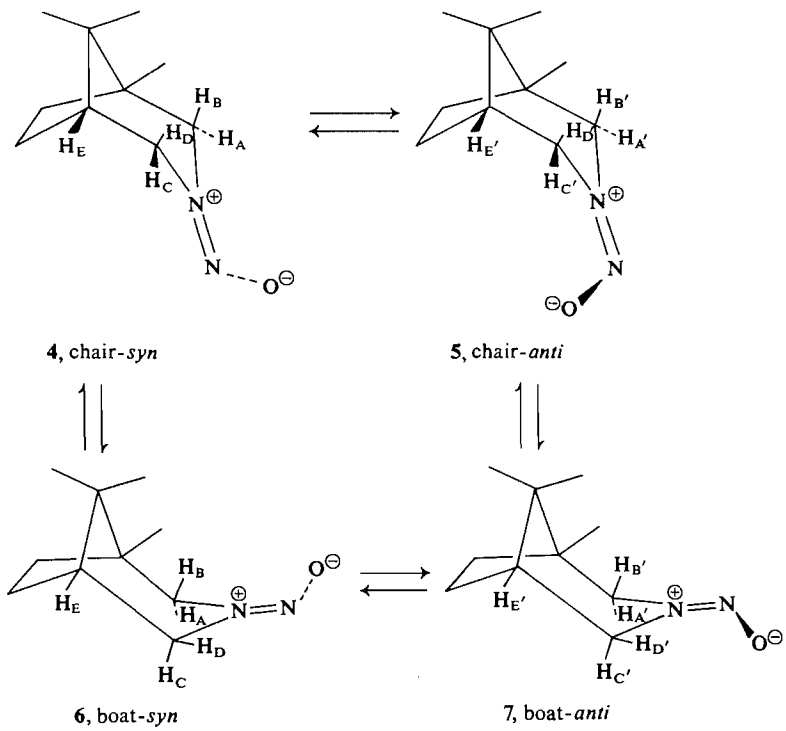
Application of the Karplus expression (10) to the vicinal coupling constants J_{CE} and J_{DE} immediately eliminates the possibility of a boat conformation since the n.m.r. spectrum of **1** (Fig. 1) shows values of 1.3 and 2.5 Hz, respectively. Examination of molecular models would suggest approximate values of J_{DE} 1.2, J_{CE} 2.5 Hz for **4** or **5** and J_{DE} 6.8, J_{CE} 0.2 Hz for **6** or **7**. Presumably the 8-methyl to N—N bond interaction aids in destabilization of the boat conformations (**6** and **7**).

The 220 MHz spectrum of **1** is shown in Fig. 1, together with the assignments given to the *N*-α-methylene resonances based on the following reasons (using the proton designations in **4** and **5**):

(*i*) The spectrum is a composite of the spectra of **4** and **5**, showing normal coupling for AB, A′B′, CD, C′D′, DE, D′E′.

(*ii*) The *cis*-α-equatorial hydrogens, H_A and $H_{C'}$ are furthest downfield since they are *cis* and lie almost in the NNO plane.

(*iii*) The *trans*-α-equatorial hydrogens $H_{A'}$ and H_C should resonate approximately 0.4 p.p.m.



4, chair-*syn* **5**, chair-*anti*

Relative Eu to Me distances	1.00	1.12	1.25	1.03	

*Average of *syn* and *anti* resonances.

upfield (9) from H_A and $H_{C'}$ since they are *trans* to, and almost in the plane of, the NNO group.

(*iv*) The *trans*-α-axial hydrogens H_D and $H_{B'}$ should be upfield from the H_A and H_C resonances since they are outside the deshielded region.

(*v*) The *cis*-α-axial hydrogens, H_B and $H_{D'}$ should be in the shielding cones of the *N*-nitroso group (see **3**) and will therefore resonate at higher fields.

Spin decoupling (100 MHz) confirmed the coupling $J_{AB}, J_{C'D'}$. Only partial spin decouplings of $J_{A'B'}$ and J_{CD} were observed because of the promixity of the resonances. Integration suggests a *syn–anti* isomer ratio of 1:1.

The 100 MHz n.m.r. spectra of *N*-nitrosocamphidine exhibited the expected four methyl resonances (see Table 1). The use of benzene-induced shifts in the n.m.r. spectrum of *N*-nitrosoamines (11) enabled assignment of the methyl resonances. Thus, in the case of the chair-*syn* isomer, **4**, a benzene molecule would be oriented close to C-4 and would induce an upfield shift in the *cis*-8-methyl[2] resonance by comparison to its resonance in carbon tetrachloride. In the case of the chair-*anti* isomer, **5**, a benzene molecule would be oriented close to C-2 and both the 1-methyl and the *cis*-8-methyl groups would experience a shielding effect. The *trans*-8-methyl[3] group in both isomers and the 1-methyl group in the *syn* isomer experience much smaller solvent upfield shifts since the associated benzene molecule is further away. This rationale suggested the methyl assignments presented in Table 1. The

[2]*cis*-8-Methyl ≡ 8-methyl closest to the ring nitrogen.
[3]*trans*-8-Methyl ≡ 8-methyl furthest from the ring nitrogen.

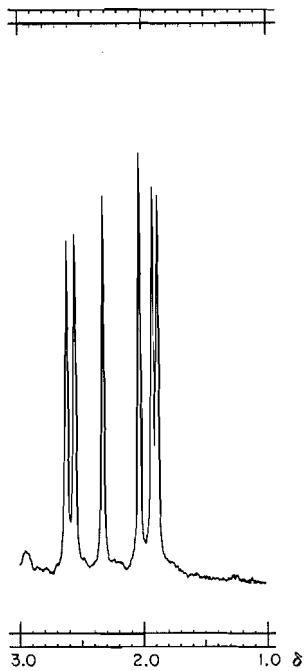

FIG. 2. The 100 MHz n.m.r. spectrum of the methyl resonances of *N*-nitrosocamphidine-tris(dipivalomethanato)-europium(III) complex (2:1 molar mixture) in CCl_4 solution.

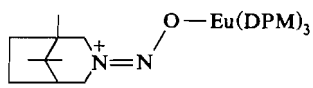
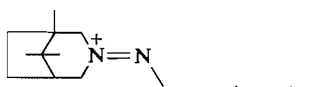
1-methyl group experiences slightly different environments in the *syn* and *anti* isomers and is responsible for the appearance of a fourth methyl resonance.

The 100 MHz n.m.r. spectrum of the *N*-nitrosocamphidine - tris(dipivalomethanato)europium-(III) complex (12) shows six *N*-nitrosocamphidine methyl peaks (Fig. 2) *i.e.* one for each methyl in the *syn* and *anti* isomers, **8** and **9**, respectively. The $Eu(DPM)_3$ induced pseudocontact methyl shifts listed in Table 1 support the methyl assignments deduced from benzene solvent shift data. The methyl shifts increased with decreasing methyl to europium distances (R) and an approximate $1/R^3$ relationship was observed.[4]

Addition of $Eu(DPM)_3$ shifted the *N*-nitrosocamphidine α-methylene resonances 2 p.p.m. downfield but line broadening prevented unambiguous assignment.



8



9

Experimental

The n.m.r. spectra were recorded at 220 and 100 MHz on Varian HR-220 and HR-100 spectrometers using TMS as an internal standard.

N-Nitrosocamphidine

N-Nitrosocamphidine was prepared by a three step synthesis. Camphoric anhydride was converted to camphorimide by heating with concentrated ammonium hydroxide (13). Camphorimide was reduced to camphidine by $LiAlH_4$ (14). The *N*-nitrosocamphidine, formed by nitrosation of camphidine (1), showed all requisite spectral and analytical properties (15).

Eu(DPM)$_3$

The $Eu(DPM)_3$ was synthesized according to the procedure of Eisentraut and Sievers (16).

J. D. C. thanks the National Research Council of Canada for study leave. We thank Dr. A. A. Grey, Canadian 220 MHz NMR Centre for his free introductory offer of a spectrum and Mr. J. Bornais, Division of Chemistry, National Research Council of Canada, for the 100 MHz n.m.r. spectra.

Radiation-induced Rearrangement of Ethylene Glycol in Aqueous Solution[1]

C. E. BURCHILL AND K. M. PERRON
Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received March 8, 1971

Under γ-irradiation, aqueous solutions of ethylene glycol containing hydrogen peroxide form acetaldehyde as a major product via a free-radical chain rearrangement. The yield of acetaldehyde is essentially unchanged when hydrogen peroxide is replaced by N_2O or $HClO_4$. A mechanism is proposed in which the glycol radical, $\dot{C}HOHCH_2OH$, rearranges to the acetaldehyde precursor, $\dot{C}H_2CHO$, followed by the hydrogen atom transfer reaction;

$$\dot{C}H_2CHO + (CH_2OH)_2 \rightarrow CH_3CHO + \dot{C}HOHCH_2OH$$

thus propagating a chain reaction.[2]

The rearrangement is also induced by the photo-dissociation of H_2O_2 in aqueous solutions of ethylene glycol.

Sous une γ-irradiation, des solutions aqueuses d'éthylène glycol contenant du peroxyde d'hydrogène produisent de l'acétaldéhyde comme produit principal par une transposition radicalaire en chaîne. Le rendement en acétaldéhyde n'est pas modifié lorsque le peroxyde d'hydrogène est remplacé par N_2O ou $HClO_4$. Un mécanisme est proposé ou le radical glycol, $\dot{C}HOHCH_2OH$, se transpose en un précurseur, $\dot{C}H_2CHO$, de l'acétaldéhyde suivi par une réaction de transfert d'atome d'hydrogène;

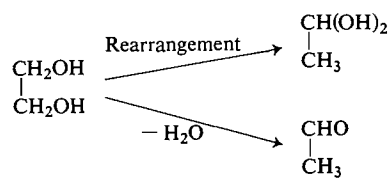
$$\dot{C}H_2CHO + (CH_2OH)_2 \rightarrow CH_3CHO + \dot{C}HOHCH_2OH$$

il en résulte une réaction de propagation en chaîne.[2]

Dans des solutions aqueuses d'éthylène glycol, la transposition peut également être induite par la photo-dissociation de H_2O_2.

Canadian Journal of Chemistry, 49, 2382 (1971)

During a recent investigation of the radiation-induced oxidation of aliphatic alcohols by hydrogen peroxide (1) it was observed that irradiation of deaerated aqueous solutions of ethylene glycol (2.0 *M*) containing hydrogen peroxide resulted in the formation of acetaldehyde as a major product. The yield of acetaldehyde ($G \sim 15$) suggested that a chain reaction was involved but it was the nature of this product which evoked our curiosity. Acetaldehyde cannot be represented as a product of the oxidation of ethylene glycol. If acetaldehyde is written as the hydrate, $CH_3CH(OH)_2$, its formation from ethylene glycol may be represented as a rearrangement or, alternatively, the reaction may be considered as a dehydration. By analogy with the pinacol–pinacolone reaction we have chosen to refer to the formation of acetaldehyde from ethylene glycol as a rearrangement.



The study reported here was undertaken in an attempt to establish a plausible mechanism for the rearrangement. Shortly after this work was begun Seidler and von Sonntag (2) reported the formation of acetaldehyde on irradiation of dilute aqueous solutions of ethylene glycol saturated with nitrous oxide. More recently Scherz (3) has reported the formation of deoxy products (perhaps better termed *dehydro* products) in the radiolysis of dilute aqueous solutions of carbohydrates and polyalcohols. In neither case was the effect of varying the concentration of the organic substrate investigated and a chain mechanism for the rearrangement of ethylene glycol was inferred only at high temperature (100 °C).

[1]This work was supported in part by the Defence Research Board of Canada, Grant No. 9530-78, and in part by the National Research Council of Canada.

[2]After this paper was submitted for publication a note appeared by von Sonntag and Thoms (26) in which a similar conclusion was reached regarding the nature of the chain process for the formation of acetaldehyde by γ-irradiation of N_2O-saturated aqueous solutions of ethylene glycol.

Experimental

The general techniques of sample preparation and irradiation were identical to those previously employed in the study of the radiation-induced oxidation of alcohols (4). Samples, of 10-ml volume, were degassed under vacuum by the freeze–pump–thaw technique and irradiated in a Gammacell 220 ^{60}Co radiation facility. The average dose-rate was 1.45×10^{19} eV l^{-1} s^{-1} estimated by ferrous sulfate dosimetry, assuming $G(Fe^{3+}) = 15.6$ (5). Lower dose rates were achieved by the use of a cylindrical lead attenuator in the sample chamber. Irradiations were carried out at the ambient temperature of the Gammacell (35 without and 40 °C with the attenuator).

Photo-initiation of the reaction employed a Hanovia Z 1500-108 low pressure mercury arc with a Vycor envelope. The reaction cells and experimental assembly were the same as those used by Burchill and Wolodarsky (6). The intensity of the 2537 Å light at the cell face was estimated by ferri-oxalate actinometry (7, 6) and the fraction of the incident light absorbed by H_2O_2 in the solution was calculated from its measured concentration and a molar absorbancy of 19.6 l mol^{-1} cm^{-1} at 2537 Å (8).

Acetaldehyde was determined by vapor-phase chromatography using a 6 ft column of Chromosorb 102 with flame-ionization detection. Hydrogen peroxide was determined by the tri-iodide method (9). Glycolic acid was measured by reaction with chromotropic acid (10).

Ethylene glycol (Fisher Certified Reagent) and hydrogen peroxide (Fisher Certified Reagent, 30%, unstabilized) were used to prepare solutions in triply-distilled water. Acid solutions were prepared with $HClO_4$ (Baker and Adamson, 70% A.C.S.). Nitrous oxide (Matheson, anaesthetic grade) was passed through a column of KOH pellets and freed of permanent gases by freezing, pumping, and thawing on a vacuum line. Aqueous solutions were equilibrated with this gas at a particular pressure and its concentration in the solution was calculated from the data of Markham and Kobe (11).

Results

Under γ-irradiation, deaerated aqueous solutions of ethylene glycol containing H_2O_2 formed acetaldehyde in a dose-independent yield, as shown in Fig. 1. The G(acetaldehyde) value, determined from similar linear yield–dose plots, increased linearly with increasing glycol concentration, as shown in Fig. 2. The reduction of H_2O_2 under irradiation was approximately first-order in H_2O_2 (see Fig. 3) and the apparent first-order rate constant for this reduction increased with increasing glycol concentration although the apparent linear relationship did not extrapolate to the origin (see Fig. 4).

That the yield of acetaldehyde is independent of H_2O_2 concentration was demonstrated by the fact that the acetaldehyde formation yield remained independent of dose, as in Fig. 1, despite the reduction of more than one-half the initial hydrogen peroxide. This is further demonstrated by the data of Table 1. For solutions whose concentration of ethylene glycol was 1.78 M, varying the initial concentration of H_2O_2 from 0.02 to

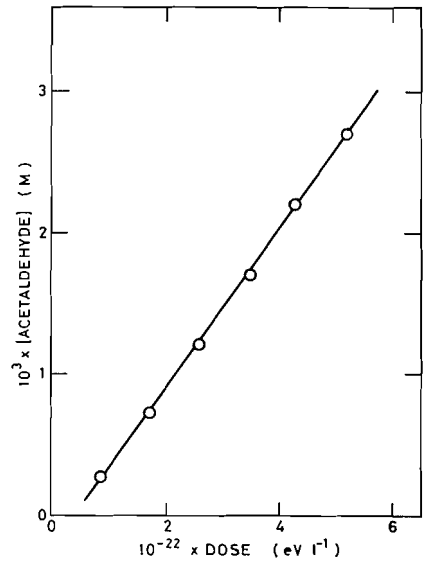

FIG. 1. Yield–dose plot for a deaerated aqueous solution 0.54 M in ethylene glycol and 0.01 M in H_2O_2; dose-rate = 1.45×10^{19} eV l^{-1} s^{-1}.

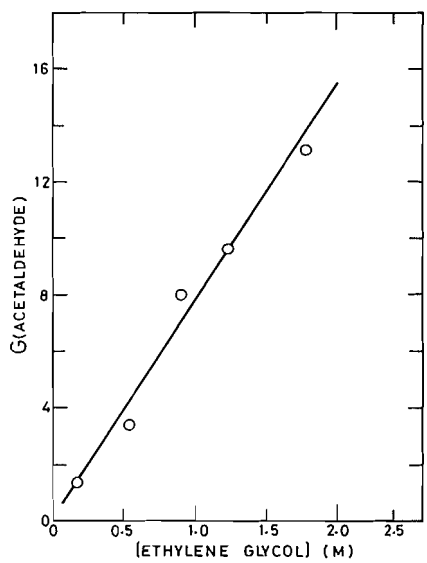

FIG. 2. Variation of G(acetaldehyde) with [ethylene glycol] for solutions 0.01 M in H_2O_2; dose-rate = 1.44×10^{19} eV l^{-1} s^{-1}.

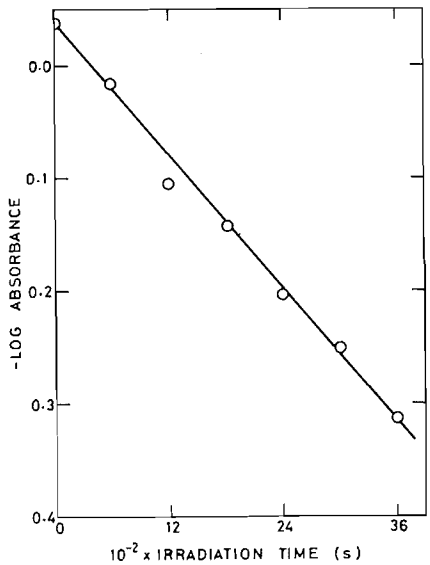

FIG. 3. First-order plot for H_2O_2 reduction in an aqueous solution 0.54 M in ethylene glycol. $[H_2O_2]_0$ = 0.01 M; dose rate = 1.45×10^{19} eV l^{-1} s^{-1}.

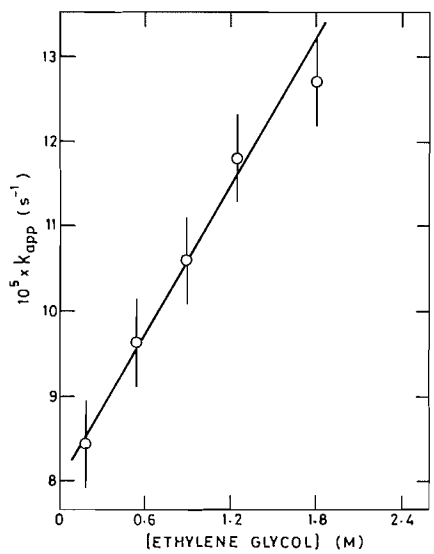

FIG. 4. Variation of the apparent first-order rate constant for peroxide reduction with glycol concentration. $[H_2O_2]_0$ = 0.01 M; dose-rate = 1.44×10^{19} eV l^{-1} s^{-1}.

1.5×10^{-4} M did not markedly affect G(acetaldehyde).

When solutions containing 0.01 M H_2O_2 and 1.78 M ethylene glycol were acidified with $HClO_4$, the yield of acetaldehyde was only slightly affected whereas the consumption of H_2O_2 was reduced almost to zero in 0.1 M acid. When H_2O_2 was omitted from a solution 0.1 M in acid the yield of acetaldehyde was somewhat greater than that with H_2O_2 present. This information is presented in Table 2.

When neutral solutions of ethylene glycol containing nitrous oxide were irradiated, acetaldehyde was formed in a yield which increased with increasing glycol concentration. The reproducibility of the results was somewhat poorer than when H_2O_2 was present, but for solutions containing 0.01 M N_2O the yields of acetaldehyde were similar to those obtained from solutions with 0.01 M H_2O_2 at the same glycol concentrations. The yields are tabulated for comparison in Table 3.

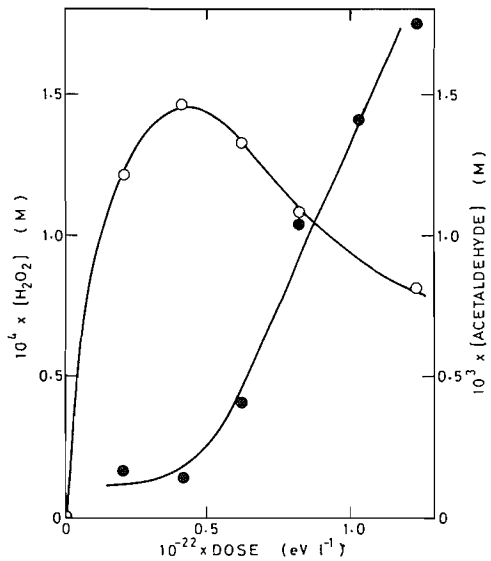

FIG. 5. Yield–dose profile for an aerated solution 1.78 M in ethylene glycol. ○, H_2O_2; ●, acetaldehyde.

The effect of dose-rate on the yield of acetaldehyde was investigated for a variety of initial conditions. In all cases G(acetaldehyde) increased considerably with a decrease in dose-rate as shown in Table 4.

Air saturation, of aqueous solutions containing only ethylene glycol, initially inhibited the formation of acetaldehyde. As shown in Fig. 5, H_2O_2 was formed as a net product at low dose, reaching a maximum concentration of 1.5×10^{-4} M after a dose of 5×10^{21} eV l^{-1}, after which its concentration decreased. The formation of acetaldehyde was inhibited until this same dose had been delivered, after which G(acetaldehyde) was essentially equal to that from a deaerated solution containing H_2O_2 initially. Saturation with O_2 increased the induction dose and the maximum concentration of H_2O_2 formed.

To demonstrate that the formation of acetaldehyde from ethylene glycol was not merely an artifact of γ-irradiation the rearrangement was initiated by photo-dissociation of H_2O_2. With a light path length of 1.0 cm the absorption by 0.01 M H_2O_2 of 2537 Å light was approximately 35%, giving reasonably homogeneous initiation. For neutral solutions 1.78 M in ethylene glycol ϕ(acetaldehyde) was 8.0 ± 0.5 with $I_a = 1.41 \times 10^{-7}$ einstein l^{-1} s^{-1}. When such a solution was made 0.1 M in $HClO_4$ the yield of acetaldehyde increased slightly, although probably not significantly, to $\phi = 9.6 \pm 0.6$.

In neutral solutions containing ethylene glycol and H_2O_2, the peroxide is reduced in a chain reaction initiated by γ-irradiation or photodissociation of the peroxide. This reductive process must necessarily be accompanied by an equivalent oxidation but the nature of the oxidized product was not established unequivocally. When hydrogen peroxide is reduced under γ-irradiation in the presence of aliphatic primary or secondary alcohols the major oxidized product is the corresponding aldehyde or ketone (4, 12). The analogous product from ethylene glycol would be glycolaldehyde but attempts to find this product in the irradiated solutions were unsuccessful. If glycolaldehyde were formed it is possible that it could undergo a further thermal oxidation by H_2O_2 to glycolic acid. Reaction with chromotropic acid gave a violet color (10) but this test is not specific for glycolic acid, being a test for formaldehyde, and gives the same reaction with any other species decomposing to formaldehyde (13). Vasudeva and Wasif (14) have reported glycolic acid and oxalic acid as products of the oxidation of ethylene glycol by peroxydisulfate. In that study no glycolaldehyde was found as a product, nor was acetaldehyde reported, although the authors did not specifically mention having looked for it. In this work the yield of the product reacting with chromotropic acid, and assumed to be glycolic acid, was less than half that required by the stoichiometry $2H_2O_2 + (CH_2OH)_2 \rightarrow 3H_2O + CH_2OHCOOH$.

Discussion

The major features of the formation of acetaldehyde from ethylene glycol under γ-irradiation may be summarized as follows:

(*a*) It is a chain reaction, as demonstrated by the large *G* values (up to 50 in one case).

(*b*) The *G*(acetaldehyde) value is linearly dependent upon glycol concentration in solutions containing H_2O_2 but it is independent of the concentration of H_2O_2.

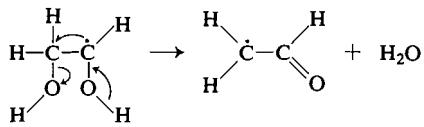
(*c*) The concurrent reduction of H_2O_2 occurs by an independent chain reaction since it is apparently first-order in H_2O_2.

(*d*) H_2O_2 may be replaced by N_2O or H_3O^+ without a major effect on *G*(acetaldehyde) but if none of these is present initially the yield of acetaldehyde is significantly reduced.

Seidler and von Sonntag (2) attributed the formation of acetaldehyde from ethylene glycol to the disproportionation of a radical produced by the rearrangement of the primary ethylene glycol radical (eq. 1).

[1] $$\dot{C}HOHCH_2OH \xrightarrow{-H_2O} \dot{C}H_2CHO$$

A similar mechanism was proposed by Scherz (3) to account for the formation of deoxy products from sugars and polyalcohols. The rearrangement, or dehydration, of the radical was observed by Buley *et al.* (15) using e.s.r. detection of intermediates in a flowing system of Ti(III) – H_2O_2 – ethylene glycol. The rearrangement was represented as



and was said to be acid-catalyzed since the broad triplet spectrum of the rearranged radical was observed only at high acid concentrations while with a minimum acid concentration a 24 line spectrum was observed, characteristic of the primary radical. Livingston and Zeldes (16) also observed this transformation by e.s.r. in a flow system with initiation by photolysis of H_2O_2. In pure ethylene glycol only the spectrum of the primary glycol radical, $\dot{C}HOHCH_2OH$, was observed but as the glycol was diluted with water the intensity of the 24 line spectrum was reduced and broader lines were observed. When acid was added, only the broad triplet spectrum of the rearranged radical was observed, again suggesting that the rearrangement was acid-catalyzed.

We propose that this rearrangement occurs and is acid-catalyzed but that it also occurs at a significant rate in neutral solution. The rearranged radical was not observed at higher p*H* in the e.s.r. flow systems because of a relatively high rate of initiation. If the radicals in these systems undergo bimolecular termination their average lifetime before termination is a function of their steady-state concentration and hence the rate of initiation. At the higher rates of initiation typical of the e.s.r. experiments described there may be insufficient time for the primary glycol radicals to undergo a first-order rearrangement before termination. With acid present to increase the rate of rearrangement, or at the lower rates of initiation such as those of the radiation–chemical experiments described here, the situation may be reversed and the rearranged radical may be the dominant form.

If the primary radical from ethylene glycol can rearrange in neutral solution to $\dot{C}H_2CHO$, the rearranged radical may be considered as a substituted methyl radical. As such it may be expected to be capable of abstracting an α hydrogen from an alcohol or glycol as has been demonstrated for similar radicals with 2-propanol and ethanol (4, 12), eq. 2. This would provide the propagating step for a chain rearrangement of the glycol.

[2] $$\dot{C}H_2CHO + (CH_2OH)_2 \rightarrow CH_3CHO + \dot{C}HOHCH_2OH$$

At the same time the primary glycol radical, being an α-hydroxyalkyl radical, would be expected to be capable of reducing H_2O_2 to propagate an oxidative chain reaction, eq. 3.

[3] $$\dot{C}HOHCH_2OH + H_2O_2 \rightarrow CHOCH_2OH + H_2O + \dot{O}H$$

This oxidative chain reaction need not, however, affect the rearrangement chain reaction since $\dot{C}HOHCH_2OH$ is immediately replaced via reaction 4. Glycolaldehyde was not found in the

[4] $$\dot{O}H + (CH_2OH)_2 \rightarrow H_2O + \dot{C}HOHCH_2OH$$

irradiated solutions containing H_2O_2 but it may undergo further oxidation in such solutions.

The overall reaction mechanism proposed for the irradiation of aqueous solutions of ethylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

glycol and H_2O_2 is summarized in the following equations:

$$H_2O \rightsquigarrow e_{aq}^-,\ H,\ OH,\ H_2O_2,\ H_2,\ H_3O^+$$

[5] $$e_{aq}^- + H_2O_2 \rightarrow OH^- + \dot{O}H$$

[6] $$H + (CH_2OH)_2 \rightarrow H_2 + \dot{C}HOHCH_2OH \qquad \dot{C}HOHCH_2OH = \mathbf{1}$$

[4] $$\dot{O}H + (CH_2OH)_2 \rightarrow H_2O + \mathbf{1}$$

[1] $$\mathbf{1} \rightarrow H_2O + \dot{C}H_2CHO \qquad \dot{C}H_2CHO = \mathbf{2}$$

[1c] $$\mathbf{1} + H^+ \rightarrow H_3O^+ + \mathbf{2}$$

[2] $$\mathbf{2} + (CH_2OH)_2 \rightarrow CH_3CHO + \mathbf{1}$$

[3] $$\mathbf{1} + H_2O_2 \rightarrow CHOCH_2OH + H_2O + \dot{O}H$$

[7] $$CHOCH_2OH + n\,H_2O_2 \rightarrow \text{Other oxidized products}$$

[8] $$\mathbf{2} + \mathbf{2} \rightarrow \text{Termination}$$

On the basis of this mechanism and the usual steady-state assumptions, expressions for the radiation chemical yields, eqs. 9 and 10, may be derived; D is the dose-rate in units of 6.023×10^{25} eV l^{-1} s^{-1}.

[9] $$G(\text{acetaldehyde}) = k_2\left(\frac{G_{e_{aq}^-} + G_{OH} + G_H}{2k_8 D}\right)^{1/2}[\text{glycol}]$$

[10] $$\frac{-d[H_2O_2]}{dt} = (G_{e_{aq}^-} - G_{H_2O_2})D + A[H_2O_2]$$

$$A = \frac{(n+1)k_3}{k_1 + k_{1c}[H^+]} \times \left[k_2\left\{\frac{(G_{e_{aq}^-} + G_{OH} + G_H)D}{2k_8}\right\}^{1/2} \times [\text{glycol}] + (G_{e_{aq}^-} + G_{OH} + G_H)D\right]$$

The yield of acetaldehyde predicted by this mechanism is seen to be directly proportional to the glycol concentration and independent of peroxide concentration, as observed experimentally. Extrapolation of the straight line in Fig. 2 gives an intercept of very nearly zero which suggests that acetaldehyde is not a significant product of the termination step. Termination by processes other than reaction 8, such as combination of radicals **1** or cross-combination of **1** and **2**, would lead to some dependence of the acetaldehyde yield on $[H_2O_2]$, which was not observed. This supports the suggestion made earlier that, at the dose rates used here, the rearranged radical, **2**, is the predominant radical intermediate species. Equation 9 predicts a reciprocal square-root dependence of the acetaldehyde yield on the dose rate. As shown in Table 4 the acetaldehyde yield increased by more than the predicted amount on attenuation of the dose rate to ~25%. This excess increase in the acetaldehyde yield on attenuation may perhaps be accounted for by the higher temperature in the Gammacell with the attenuators in place. Seidler and von Sonntag (2) noted that the acetaldehyde yield increased with increasing temperature.

If this mechanism is accepted it is possible to estimate the magnitude of k_2 for the hydrogen atom transfer from ethylene glycol to the rearranged radical. It may be seen that the coefficient of [glycol] in eq. 9 is the slope of the line in Fig. 2. Taking $G_{e_{aq}^-} + G_H = 3.18$ and $G_{OH} = 2.72$ (17), and $2k_8 = 2 \times 10^9$ l mol^{-1} s^{-1} as representative of the rate of bimolecular reaction of simple organic radicals in aqueous solution (18), leads to a value of $k_2 = 75 \pm 5$ l mol^{-1} s^{-1}. This is of the same order as the rate constants for similar reactions with 2-propanol and ethanol (4, 12).

Equation 10, derived from the above mechanism, is in fair agreement with the observed kinetics of the reduction of H_2O_2 under irradiation in the presence of ethylene glycol. If the first term, $(G_{e_{aq}^-} - G_{H_2O_2})D$, is small compared to the rest, eq. 10 is seen to represent a process first order in H_2O_2, with the whole coefficient of $[H_2O_2]$, A, being $k_{app}(-H_2O_2)$. The k_{app} value may be seen to be linearly dependent on the concentration of glycol (as observed experimentally) and also to involve a term independent of glycol concentration (corresponding to the extrapolated non-zero intercept of Fig. 4). The increase in $k_{app}(-H_2O_2)$ at low peroxide concentrations (Table 1) is a consequence of the failure of the approximation above, $(G_{e_{aq}^-} - G_{H_2O_2})D$ being of the same order as the chain term for peroxide reduction at these low concentrations. Without a better knowledge of the stoichiometry of the peroxide reduction any attempt to estimate the values of the individual rate constants is highly speculative. However, the extrapolated intercept of Fig. 4 is $\sim 8 \times 10^{-5}$ s^{-1} and this may be equated with $(n+1)k_3/k_1(G_{e_{aq}^-} + G_H + G_{OH})D$ for neutral

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solutions. Assuming $n = 1$, and $(G_{e_{aq}^-} + G_H + G_{OH}) = 5.9$ (17) gives $k_3/k_1 = 28 \pm 2$ mol^{-1} for the dose rate involved. If k_3 is of the same order as the rate constant for the reduction of H_2O_2 by the hydroxymethyl radical (4×10^4 l mol^{-1} s^{-1} (12)) this suggests that the rate constant for reaction 1 is of the order of 10^3 s^{-1}. Such a value for this rate constant is consistent with the unrearranged radical being the dominant species at high rates of initiation, as in the e.s.r. experiments (15, 16), but the rearranged radical being dominant at low rates of initiation.

If the rearrangement is also acid-catalyzed, [1*c*], eq. 10 predicts a decrease in $k_{app}(-H_2O_2)$ with increasing acid concentration. Such a decrease was observed (Table 2).

When H_2O_2 is replaced by N_2O, reaction 5 is replaced by reaction 11, and no oxidative chain would be anticipated since α-hydroxyalkyl radicals from simple alcohols do not reduce N_2O (19).

[11] $$e_{aq}^- + N_2O + H_2O \rightarrow N_2 + OH^- + \dot{O}H$$

The remaining reactions are unchanged and the yield of acetaldehyde should be given by eq. 9, and unchanged from that with H_2O_2 present.

With neither N_2O nor H_2O_2 in solution, but in the presence of a mineral acid, e_{aq}^- will be converted to H by reaction 12 and, via reaction 6, give the same initial radical from ethylene glycol.

[12] $$e_{aq}^- + H^+ \rightarrow H$$

The yield of acetaldehyde should again be unchanged from that with N_2O or H_2O_2 present, except as it reflects any change in the primary radical yields.

Under the experimental conditions used here the yield of acetaldehyde was generally somewhat smaller when N_2O was used in place of H_2O_2 and somewhat greater when replaced with $HClO_4$ (Tables 3 and 4). However the continuance of the chain reaction and the similarity of the yield under these changed conditions lead us to believe that the proposed mechanism is a reasonable representation of the overall reaction.

With none of H_2O_2, N_2O, or $HClO_4$ present in the solution the yield of acetaldehyde was significantly less (Table 1). Under these circumstances the only scavenger for e_{aq}^- is the acetaldehyde formed as a product.

[13] $$e_{aq}^- + CH_3CHO + H_2O \rightarrow OH^- + CH_3\dot{C}HOH$$

The hydroxyethyl radical so formed would not enter into the rearrangement chain reaction nor is there sufficient H_2O_2 formed as a primary product to oxidize it to generate ȮH as in the chain oxidation of ethanol (12). Thus the number of free radicals initiating the rearrangement chain is reduced and a portion of the product acetaldehyde is consumed as an electron scavenger.

When a deaerated aqueous solution of ethylene glycol and H_2O_2 is subjected to irradiation by 2537 Å light the peroxide dissociates into ȮH radicals, eq. 14 (8) (Φ_a represents the primary

[14] $$H_2O_2 \xrightarrow{h\nu} 2\Phi_a\dot{O}H$$

quantum yield for peroxide homolysis). The remaining reactions would be the same as for the radiation initiation, and the quantum yield of acetaldehyde formation would be given by eq. 15.

[15] $$\Phi(\text{acetaldehyde}) = k_2(\Phi_a/k_8\, I_a)^{1/2}[\text{glycol}]$$

The effects of light intensity and glycol concentration on the acetaldehyde yield were not investigated but the addition of 0.1 *M* $HClO_4$ did not significantly affect the yield. The photochemical and radiation chemical yields may be compared by taking the ratio of eqs. 15 and 9 for identical glycol concentrations.

[16] $$\frac{\Phi(\text{acetaldehyde})}{G(\text{acetaldehyde})} = \left(\frac{2\Phi_a D}{(G_{e_{aq}^-} + G_H + G_{OH})I_a}\right)^{1/2}$$

Using the results for solutions 1.78 *M* in glycol and 0.01 *M* in H_2O_2, $I_a = 1.41 \times 10^{-7}$ einstein l^{-1} s^{-1}, $D = 1.45 \times 10^{19}$ eV l^{-1} s^{-1}

$$\frac{\Phi(\text{acetaldehyde})}{G(\text{acetaldehyde})} = \frac{8.0 \pm 0.5}{13.2 \pm 0.7} = 0.60 \pm 0.05$$

Assuming $2\Phi_a = 1.0$ for peroxide photolysis (8) and $(G_{e_{aq}^-} + G_H + G_{OH}) = 5.9$ (17) a value of 0.54 is predicted for this ratio for the dose rate and light intensity involved. The yield of acetaldehyde is thus somewhat greater in the photochemical experiment than would be predicted from the radiation chemical results. This may, in part, be a result of the uncertainty in the appropriate values for the primary free-radical yields in these systems. Once again the fair correlation of the radiation-induced with the photochemical initiation serves to confirm the major features of the proposed mechanism.

For personal use only.

The inhibition of the rearrangement by oxygen may be explained by the very fast reaction of radical **1** with O_2 and the net yield of H_2O_2 by the disproportionation of the product peroxy radicals (20).

[17] $\mathbf{1} + O_2 \rightarrow CH_2OHCHO + HO_2$

[18] $2HO_2 \rightarrow O_2 + H_2O_2$

The rate of reaction of α-hydroxyalkyl radicals with O_2 is sufficiently rapid (21) to scavenge all of **1** prior to rearrangement or oxidation by H_2O_2 until essentially all O_2 is consumed, whereupon the chain rearrangement, as previously described, follows and with it the chain reduction of H_2O_2. (A similar concentration-dose profile is observed for H_2O_2 with a wide variety of organic solutes in aerated aqueous solution (22).)

A number of observations suggest that the rearrangement of vicinal glycols to the corresponding carbonyl compound via a free-radical mechanism is a general phenomenon. Preliminary experiments in this laboratory demonstrated the formation of acetone from 1,2-propanediol and methyl ethyl ketone from 2,3-butanediol on γ-irradiation of their aqueous solutions saturated with N_2O (23). The formation of deoxy products on irradiation of aqueous solutions of sugars and polyalcohols (3) suggests a similar mechanism. The rearrangement of the intermediate free radicals has been observed by Norman and co-workers (15, 24) using the flow-e.s.r. technique for a number of vicinal glycols, including one cyclic glycol, chlorhydrins, sugars, and for mesoinositol. Livingston and Zeldes (25) have suggested a similar rearrangement for the fragment ĊHOHCHOHCOOH formed in the photolysis of tartaric acid.

The rearrangement or dehydration of polyhydroxy compounds may be of considerable significance in systems containing high concentrations of carbohydrates or carbohydrate residues, particularly under anoxic conditions. The fact that the overall rearrangement may proceed by a chain mechanism would make it particularly important at low dose rates. The implications of such processes in biological systems may be considerable.

Nucleophilic Reactivity of 4,4′-Disubstituted Diphenyl Sulfides Towards *trans*-Dichlorobis(pyridine)platinum(II)

J. R. GAYLOR AND C. V. SENOFF
Department of Chemistry, University of Guelph, Guelph, Ontario

Received March 12, 1971

The kinetics of the reaction of *trans*-$[PtCl_2py_2]$ with a series of 4,4′-disubstituted diphenyl sulfides, $XC_6H_4SC_6H_4Y$, have been studied at 30° in methanol. A linear free energy correlation has been obtained between the logarithm of the second order rate constant and the sum of the Hammett substituent parameters for X and Y. This result is consistent with the notion that bond making is the driving force when divalent sulfur functions as a nucleophile towards platinum(II) substrates and is consistent with the inability of 4,4′-dinitrodiphenyl sulfide to coordinate to platinum(II).

Les cinétiques des réactions entre le $[PtCl_2py_2]$-*trans* et une série de diphénylsulfures disubstitués en -4,4′, $XC_6H_4SC_6H_4Y$, ont été étudiées à 30 °C dans le méthanol. Une corrélation linéaire de l'énergie libre a été obtenue entre le logarithme de la constante de vitesse du second ordre et la somme des paramètres de Hammett pour les substituants X et Y. Ce résultat est consistant avec la notion d'après laquelle l'établissement d'une liaison est la force directive lorsqu'un soufre divalent fonctionne en tant que nucléophile envers le platine(II); ce résultat est également cohérent avec le fait que le dinitro-4,4′ diphénylsulfure ne se coordonne pas avec le platine(II).

Canadian Journal of Chemistry, 49, 2390 (1971)

Substitution reactions of square planar d^8 metal complexes, especially those of platinum(II) have been well documented (1–3). Previous investigations have utilized *trans*-$[PtCl_2py_2]$ as a representative substrate in order to investigate the reactivity of a variety of nucleophiles towards platinum(II) complexes (4, 5). As part of a general interest in the donor properties of ligands containing a sulfur donor atom, we have undertaken a kinetic study of reaction 1 where Ar_2S = a 4,4′-disubstituted diphenyl sulfide and py = pyridine. It was also anticipated that this study

[1] *trans*-$[PtCl_2py_2] + 2Ar_2S \rightarrow$ *trans*-$[Pt(Ar_2S)_2py_2]^{2+} + 2Cl^-$

would provide a quantitative indication of the ability of divalent sulfur in a diaryl sulfide to transmit the electronic effect of a para-substituent. The results of this study are reported at this time.

Results and Discussion

The rates of reaction between *trans*-$[PtCl_2py_2]$ and $XC_6H_4SC_6H_4Y$ (= Ar_2S) follow the usual two term rate law which is common to substitution reactions of square planar platinum(II) complexes, *viz.* eq. 2, where k_1 is a first order rate constant associated with solvolysis of the complex and k_2 is a second order rate constant associated with direct nucleophilic displacement at the complex (1). The two term rate law is consistent with the reaction scheme, [3] and [4].

[2] $\text{Rate} = k_1[\text{Complex}] + k_2[\text{Complex}][XC_6H_4SC_6H_4Y]$

[3] *trans*-$[PtCl_2py_2] + Ar_2S \xrightarrow[\text{slow}]{k_2}$ *trans*-$[PtCl(Ar_2S)py_2]^+ + Cl^-$

[4] *trans*-$[PtCl(Ar_2S)py_2]^+ + Ar_2S \xrightarrow{\text{fast}}$ *trans*-$[Pt(Ar_2S)_2py_2]^{2+} + Cl^-$

The experimental pseudo first order rate constants, k_{obs}, are related to k_1 and k_2 by [5].

[5] $$k_{obs} = k_1 + k_2[XC_6H_4SC_6H_4Y]$$

Typical plots of k_{obs} *vs.* $[XC_6H_4SC_6H_4Y]$ are shown in Fig. 1. The slopes of these linear plots correspond to the various k_2's and the common intercept to k_1. The kinetic data are tabulated in Table 1 together with the calculated values of the nucleophilic reactivity constant, n_{Pt}^0, and the sum of the Hammett substituent parameters for each nucleophile. The nucleophilic reactivity constant has been defined by eq. 6. In order to

[6] $$n_{Pt}^0 = \log(k_2/k_1)$$

render n_{Pt}^0 a dimensionless quantity, k_1 has been divided by 26, the molar concentration of methanol (4). A fairly good linear free energy

*Values obtained from ref. (18).
†Extrapolated from Fig. 2.

relation is obtained when log k_2 is plotted *vs.* $\Sigma(\sigma_p)$ where σ_p is the Hammett substituent parameter for X and Y (see Fig. 2). This linear correlation indicates that the para-substituents make a significant contribution to the nucleophilic reactivity of the diaryl sulfide towards the substrate. This may be readily attributed to a change in "basicity" (σ donor capability) of the sulfur donor atom as a direct consequence of the inductive and mesomeric effects of the substituents, X and Y. Hence, nucleophilic reactivity is lessened when electron withdrawing substituents are present and vice versa for electron releasing substituents. The kinetic results reported herein also lend further support to the suggestion that bond making is the driving force in the intimate mechanism when divalent sulfur functions as a nucleophile towards a platinum(II) substrate (6).

From a synthetic point of view, the kinetic data given in Table 2 are of some interest since it has been observed that 4,4′-dinitrodiphenyl sulfide will not readily react with K_2PtCl_4 to form *trans*-$[PtCl_2(Ar_2S)_2]$ as does diphenyl sulfide and other 4,4′-disubstituted diphenyl sulfides (7–9). The data plotted in Fig. 2 are consistent with this observation. Extrapolation of this linear plot to $\Sigma(\sigma_p) = 1.54$ (X = Y = NO_2) gives $k_2 = 9.6 \times 10^{-5} M^{-1} s^{-1}$ and a value of 2.4 for the nucleophilic reactivity constant. This small value of n_{Pt}^0 catalogues 4,4′-dinitrodiphenyl sulfide as a very poor nucleophile for platinum(II). Hence it is not surprising that this particular sulfide does not readily coordinate to platinum(II).

The calculated values of n_{Pt}^0 listed in Table 2 may be taken as an overall relative measure of the "nucleophilicity" of organic sulfides of the type, $XC_6H_4SC_6H_4Y$ towards *trans*-$[PtCl_2py_2]$. Presumably, this order of reactivity applies to other square planar complexes of platinum(II) as well.

Experimental

(1) Materials

trans-Dichlorobis(pyridine)platinum(II)

This complex was prepared according to the procedure of Kauffman (10).

4,4′-Dihydroxydiphenyl Sulfide

A generous sample of this nucleophile was provided by Dr. Karl H. Heller, Farbenfabriken Bayer A-G, West Germany.

4,4′-Dimethoxydiphenyl Sulfide

This was prepared by the methylation of 4,4′-dihydroxydiphenyl sulfide with dimethyl sulfate (11), m.p. 41–43° (lit. (11), m.p. 42–45°).

4,4′-Dimethyldiphenyl Sulfide

This nucleophile was prepared by reacting the Grignard reagent formed from 4-methyl-4′-bromobenzene in tetrahydrofuran with sulfur monochloride (12), m.p. 55–57° (lit. (13), m.p. 56.6–56.9°).

4-Methoxydiphenyl Sulfide

This was prepared according to the method outlined in the literature (14).

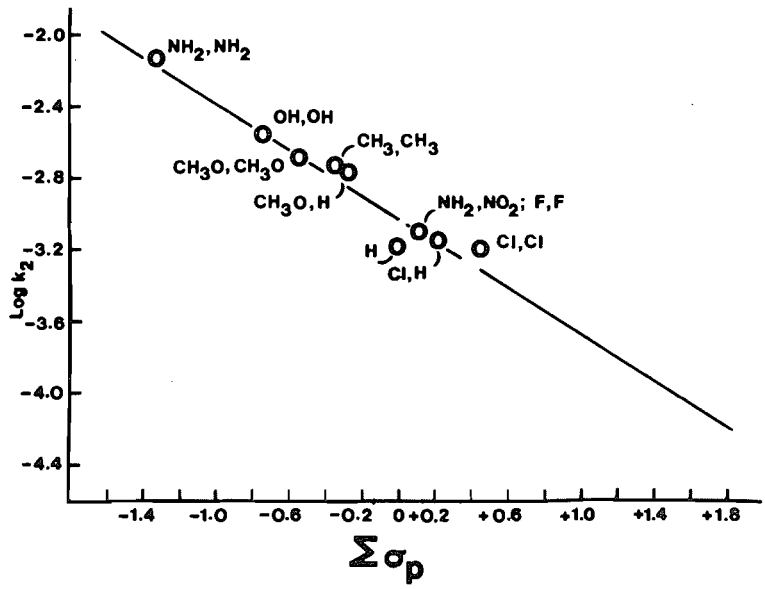

FIG. 2. Hammett plot of $\log k_2$ *vs.* $\Sigma\sigma_p$.

Anal. Calcd. for $C_{13}H_{12}OS$: C, 72.22; H, 5.55. Found: C, 71.42; H, 5.46.

4,4′-Difluorodiphenyl Sulfide

This was prepared by following the procedure of Leonard and Sutton (15), b.p. 134–138° (10 mm) (lit. (15), b.p. 136–137° (9 mm)).

4,4′-Dichlorodiphenyl Sulfide

This was prepared by reduction of the corresponding sulfoxide with zinc in acetic acid (16).

4-Chlorodiphenyl Sulfide

This nucleophile was isolated from the reaction of sodium thiophenolate with *para*-dichlorobenzene in DMF (17), b.p. 156–160° (2 mm) (lit. (17), b.p. 155–158° (2.5 mm)).

The following nucleophiles were obtained from Eastman Organic Chemicals, Inc. or Aldrich Organic Chemicals, Inc. and were purified by fractional distillation or recrystallization from ethanol: 4,4′-diaminodiphenyl sulfide, diphenyl sulfide, and 4-amino-4′-dinitrodiphenyl sulfide.

(2) Kinetic Measurements

The rates of reaction of the diaryl sulfides with *trans*-$[PtCl_2py_2]$ were determined at 30 ± 0.1° in methanol by monitoring the change in electrical conductivity with a Beckman Model RC16B1 conductivity meter at 1000 Hz. The platinum electrodes of the conductivity cell were coated with platinum black. Pseudo first order kinetics were maintained during the course of a kinetic run where the concentration of the substrate, *trans*-$[PtCl_2py_2]$, was 5.0×10^{-5} *M* and the concentration of the nucleophile was varied from 4.5×10^{-3} to 2.5×10^{-1} *M* (at least a 90-fold excess). Pseudo first order rate plots of $\ln R_t/R_t - R_\infty$ *vs.* time, where R_t, R_∞ are the electrical resistances at time, *t*, and at infinite time respectively, were linear for at least 50–60% reaction. The pseudo first order rate constants (k_{obs}) were calculated from the slopes of these linear plots using a least squares analysis. The pseudo first order rate constants were reproducible to within ± 5%.

(3) Isolation of Reaction Products

The following general procedure based on the outline of Pearson *et al.* (5) was used to obtain several of the reaction products. Stoichiometric amounts of *trans*-$[PtCl_2py_2]$, the appropriate nucleophile, and silver para-toluenesulfonate (silver tosylate) were allowed to react in methanol at 25° for approximately 24 h with the exclusion of light. The AgCl which precipitated from the reaction mixture was filtered off and the filtrate evaporated to dryness. The product was washed with water, ether, and recrystallized from methanol.

Anal. Calcd. for $[Ptpy_2(Ph_2S)_2](tosylate)_2$: C, 53.96; H, 4.12; Pt, 18.26. Found: C, 51.64; H, 4.57, Pt, 17.62.

Anal. Calcd. for $[Ptpy_2(CH_3OC_6H_4SC_6H_4OCH_3)_2](tosylate)_2$: C, 52.57; H, 4.38; Pt, 16.42. Found: C, 51.45; H, 4.53; Pt, 15.36.

Anal. Calcd. for $[Ptpy_2(CH_3OC_6H_4SC_6H_5)_2](tosylate)_2$: C, 53.23; H, 4.25; Pt, 17.29. Found: C, 51.23; H, 4.20; Pt, 16.85.

Anal. Calcd. for $[Ptpy_2(CH_3C_6H_4SC_6H_4CH_3)_2](tosylate)_2$: C, 55.57; H, 4.63; Pt, 17.35. Found: C, 53.54; H, 4.38; Pt, 17.02.

Microanalyses were determined by A. B. Gygli, Toronto, Ontario. Platinum was determined by reduction to the metal in an atmosphere of hydrogen at *ca.* 700°.

The Pseudo Thermodynamics of Solvolysis. A Detailed Study of the Pressure and Temperature Dependence of Benzyl Chloride Solvolysis in *t*-Butyl Alcohol – Water Mixtures

S. J. DICKSON AND J. B. HYNE

Department of Chemistry, University of Calgary, Calgary, Alberta

Received March 15, 1971

The pseudo first order rate constants for the solvolysis of benzyl chloride in aqueous *t*-butyl alcohol (*t*-BuOH) are reported at 40.00, 50.25, and 60.50 °C at various pressures up to 4084 atm. From these data the first temperature derivatives (ΔH^* and ΔS^*), the first (ΔV^*) and second pressure derivatives, $\partial\Delta V^*/\partial P$, and the mixed second derivative, $\partial\Delta V_0^*/\partial T$, of the rate are evaluated. These activation parameters exhibit extremum behavior in the highly aqueous solvent region. This behavior is discussed in terms of solvent structure variation. The signs of the pressure dependence of ΔH^* and ΔS^* are shown to be consistent with those required by the Maxwell type relationships for classical thermodynamic systems.

Les constantes de vitesse du pseudo premier ordre pour la solvolyse du chlorure de benzyle dans l'alcool tertiobutyllique (*t*-BuOH) sont rapportées à 40.00, 50.25, et 60.50 °C pour différentes pressions supérieures à 4084 atm. A partir de ces données, les dérivées premières de la vitesse par rapport à la température (ΔH^* et ΔS^*), ses dérivées première (ΔV^*) et seconde par rapport à la pression, $\partial V^*/\partial P$, et sa dérivée seconde $\partial\Delta V_0^*/\partial T$ sont calculées. Ces paramètres d'activation montrent un comportement extrême dans la région des solvants fortement aqueux. Ce comportement est analysé en fonction de la variation de structure du solvant. On montre que les signes de ΔH^* et ΔS^* dépendant de la pression sont compatibles avec ceux requis par les relations du type relations de Maxwell pour des systèmes thermodynamiques classiques.

Canadian Journal of Chemistry, 49, 2394 (1971)

Introduction

In recent years a number of researchers (1–3) have investigated the behavior of the first derivative pseudo thermodynamic activation parameters. Their efforts have demonstrated that many interesting phenomena are concealed in free energy parameters by the compensatory behavior of enthalpy and entropy. More recently the extremum behavior exhibited by ΔH^* and ΔS^* in aqueous binary solvent mixtures has been observed for the volume, ΔV^*, (4–6) and the heat capacity, ΔC_p^*, (7) of activation. The particular sensitivity of ΔC_p^*, the second derivative of the rate with respect to temperature, to variation of the binary solvent composition suggests that the parameter may be even more valuable than ΔH^* or ΔS^* for the investigation of solvent effects on reaction rates. This increased sensitivity of a second derivative parameter also prompts investigation of the second *pressure* derivative of the rate, $\partial\Delta V^*/\partial P$.

A major difficulty in understanding the solvent dependence of the various pseudo thermodynamic parameters has arisen because no single system has been examined exhaustively to obtain values for all of the accessible activation parameters. Accordingly, it was decided to examine the solvolysis of benzyl chloride in *t*-butyl alcohol – water binary solvent mixtures with a view to determining ΔH^*, ΔS^*, ΔV^*, $\partial\Delta V^*/\partial P$, $\partial\Delta V^*/\partial T$, $\partial\Delta H^*/\partial P$, and $\partial\Delta S^*/\partial P$. A summary of the relationship between the various derivatives is demonstrated in Fig. 1. The ΔC_p^* value was not included in this study since the accurate determination of this parameter requires that the rate be measured at many more than the three temperatures used in this work.

The technique of dissecting the differential pseudo thermodynamic parameters of activation into their component initial and transition state parts has been previously employed (4, 8). In this study the enthalpy and volume of activation were so dissected by determining the partial molal enthalpies and volumes of solution of the initial state benzyl chloride as a function of binary solvent composition. Such dissections establish whether the initial state or transition state is primarily responsible for the observed behavior of the differential activation parameter.

The Maxwell relationships shown in eqs. 1 and

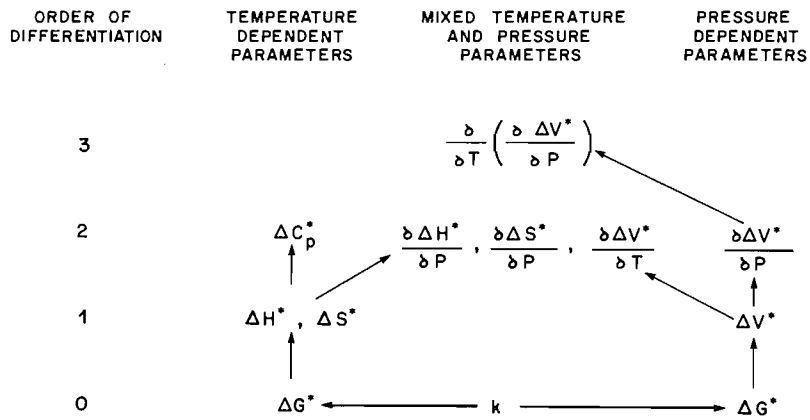

FIG. 1. Inter-relationship of pseudo thermodynamic parameters of activation.

2 can also be tested for a pseudo thermodynamic

$$[1] \qquad (\partial \Delta S/\partial P)_T = -(\partial \Delta V/\partial T)_P$$

$$[2] \qquad (\partial \Delta H/\partial P)_T = \Delta V - T(\partial \Delta V/\partial T)_P$$

system since the parameters $\partial \Delta S^*/\partial P$, $\partial \Delta V^*/\partial T$, $\partial \Delta H^*/\partial P$, and ΔV^* are available from the rate–pressure–temperature data.

The solvolysis of benzyl chloride in aqueous *t*-butyl alcohol solvent mixtures was chosen for this investigation for the following reasons. The solvolysis of benzyl chloride has been extensively investigated (4–6, 9–11) in other solvent media and a wide range of other activation parameters are available. The solvolysis reaction velocity is also convenient for the precision rate determinations required in second derivative rate studies. In addition, aqueous *t*-butyl alcohol solvent mixtures are known to display the most marked extremum behavior of any aqueous binary mixture both in activation parameters and other physical properties (12). Consequently, it was hoped that large changes in the parameters studied might be observed with variation of the composition of this aqueous binary.

Experimental

Kinetics

All rate constants were determined by following the change of conductance of the reaction mixture due to HCl formation as a function of time. With the exception of the conductivity cells, the high pressure apparatus and techniques employed in this work have been described previously (13). Some comments on the types of conductance cell employed are, however, justified. The three different types of conductivity cells which were used to determine the reaction rates are illustrated in Fig. 2. For the majority of the slower reactions studied the cell shown in Fig. 2A was used. This cell had a capacity of about 10 ml. Occasionally during the course of a slow reaction the teflon rods moved to the end of the precision bore glass tubing and into the electrode compartment changing the cell characteristics and producing discontinuities in the rate data plots. In order to reduce the risk of this happening the cells shown in Fig. 2B were employed for the slowest reactions. These cells had the advantage of having a longer length of precision bore tubing and removed the danger of the pistons dropping into the cell compartment between the electrodes.

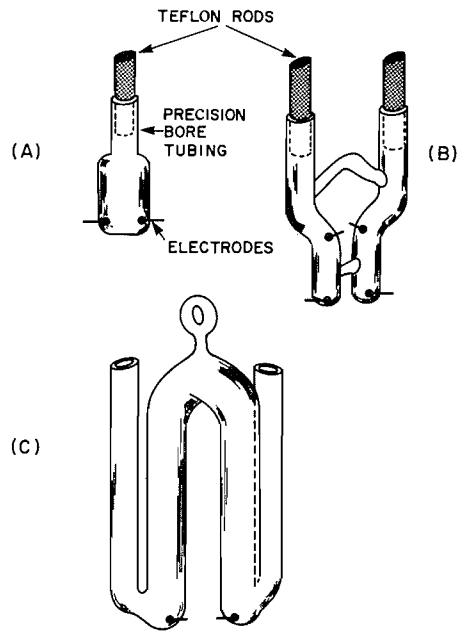

FIG. 2. Conductivity reaction cells.

*Temperature recorded for rates in pure water was 50.10 not 50.25 °C.
†Data taken from ref. 4.

The cell used for the fastest ($k = 10^{-3}$ to 10^{-4} s^{-1}) solvolysis reactions in pure water had a capacity of 25 ml and is shown in Fig. 2C. It was found that if the small cells were employed to measure the fast reaction rates, the differences in successive resistance values were close to zero after thermal and pressure equilibration had been attained. The larger cells, having a path length about 20 times greater than the smaller cells, were preferred because of the increased differences in successive resistance values and hence increased experimental sensitivity.

Duplicate kinetic runs carried out in the three different types of conductivity cells yielded rates which agreed within the maximum experimental uncertainty of ±1%.

Enthalpy and Volume of Solution

The modified dilatometric technique employed in this study for the measurement of the partial molal volume ($\bar{V}^s$) of the benzyl chloride as a function of solvent composition has been discussed previously (4). The partial molal heat of solution of the initial state, $\Delta\bar{H}_s^s$, was determined using the method described by Arnett and coworkers (8). As reported by Arnett, limited solubility of benzyl chloride in highly aqueous solvent systems precluded enthalpy determinations in this composition region.

Results

Rates

The pseudo first order rate constants for the solvolysis of the benzyl chloride (10^{-3} *M* maximum concentration) under various conditions of temperature, pressure, and solvent composition were obtained by analyzing the conductance–time data by the method of Guggenheim (14) using a computerized least mean squares calculation (13). Rate constants and associated uncertainties are presented in Tables 1–3. In all cases the rate constants are the average of a minimum of three duplicate runs. The deviations listed are the average deviations of the individual rate determinations from the mean value and in general represent an uncertainty of less than ±1%. In some instances the rate *vs.* pressure data are incomplete; although it was desirable, it was not always possible to record rate data over the entire pressure range (1–4084 atm). The rate of reaction increased as the temperature and

pressure increased, and consequently at the higher temperatures and pressures the rate could not always be measured with the conventional apparatus employed. For each system studied the rate was determined at a minimum of six pressures.

Golinkin *et al.* (4) have reported rate constants for the solvolysis of benzyl chloride in aqueous *t*-butyl alcohol mixtures at 50.25 °C. It will be noted that some of the data used here have been measured by Golinkin (5). The general effects studied by Golinkin *et al.* required less accurate data than was considered essential for this study. Consequently, if the uncertainty in Golinkin's rate constants was greater than ±1%, or if the data did not lie on a smooth ln *k vs.* pressure curve, it was redetermined in this study. In the majority of instances in which repetition was deemed necessary the data lay within the limits of uncertainty claimed by the earlier workers.

The solvolysis of benzyl chloride in 0.10 mol fraction of *t*-butyl alcohol at 60.50 °C was examined in considerable detail as a specific test of the adequacy of the rate–pressure relationship used in this work. The ln *k vs.* pressure plot for this system is shown in Figure 3A. Two important points should be noted. Firstly, this plot indicates that ln *k* is a smooth monotonic function of pressure. Secondly, because the uncertainties in

the rate determinations are extremely small, it is possible to establish with confidence the magnitude of the curvature in these plots, *i.e.* $\partial \Delta V^*/\partial P$.

The Enthalpy and Entropy of Activation

The enthalpies of activation used in this work were all calculated using eq. 3.

$$[3] \qquad \Delta H^* = -R\left(\frac{\ln k_2/T_2 - \ln k_1/T_1}{1/T_2 - 1/T_1}\right)$$

The temperatures, T_2 and T_1, in this case are 60.50 and 40.00 °C respectively. The extracted enthalpies of activation can then be associated with the mean temperature of 50.25 °C (15). The values obtained for ΔH^* in pure water are in excellent agreement with the results of other researchers (15–17). The uncertainties associated with each ΔH^* value listed in Table 4 are shown.

The entropies of activation used in this work were calculated by substituting the rate constant k at 50.25 °C, and the corresponding ΔH^* value into eq. 4, where k_b is Boltzmann's constant, and

$$[4] \qquad \Delta S^* = R \ln k - R \ln k_b T/h + \Delta H^*/T$$

h is Planck's constant.

It should be noted that the hydrolyses in water were carried out at 40.00, 50.10 (not 50.25), and 60.50 °C. The difference between this intermediate temperature, 50.10 °C, and that at which ΔH^* was calculated, 50.25 °C, is sufficiently small to render any correction insignificant compared with the experimental uncertainty.

The Volume of Activation

According to the transition state theory (18) the volume of activation, ΔV^*, for a reaction is related to the pressure dependence of the rate constant by eq. 5.

$$[5] \qquad \Delta V^* = -RT(\partial \ln k/\partial P)_T$$

Before the evaluation of ΔV^* from a set of rate constants is possible, the functional dependence of ln k on pressure must be established. The four main algebraic expressions that have been employed are given by eqs. 6–9 (19).

$$[6] \qquad \text{Linear: } \ln k = A + BP$$

$$[7] \qquad \text{Quadratic: } \ln k = A + BP + CP^2$$

$$[8] \qquad \text{Benson–Berson: } \frac{\ln k/k_0}{P} = A + BP^{0.523}$$

$$[9] \qquad \text{Incremental: } \frac{\ln k_{n+1}/k_n}{P_{n+1} - P_n} = A + B\left(\frac{P_{n+1} + P_n}{2}\right)$$

Golinkin *et al.* (19) have examined the relative merits of these empirical equations, and con-

0.3000	3.7 ±0.3	3.15±0.07	3.70±0.02

cluded that for the solvolysis of benzyl chloride in aqueous alcohol mixtures the quadratic (eq. 7) gives the best representation of the data. Nevertheless, it was considered necessary to recheck these expressions to determine which one gave a best fit for the present data. The linear eq. 6 was eliminated because of the obvious non-linear pressure dependence of ln k (see Fig. 3A). The constants A, B, and C in the other three equations were evaluated by fitting the 0.1 mol fraction alcohol rate data to each expression in turn using a computer programmed least mean squares technique. The deviations between ln $k_{(\text{observed})}$ and ln $k_{(\text{calculated})}$ for each equation were determined as previously reported (13). These deviations are shown in Fig. 3B as a function of experimental pressure for each of the three equations tested. Similar analyses were performed on all the rates at the several temperatures and solvent compositions employed. The deviations for the quadratic equation, when taken for all mol fractions of solvent, at all temperatures, were considered to be more random functions of pressure than those obtained by using the other two expressions. The standard deviations were smaller for the quadratic equation than for the other functions. On this basis the quadratic form was preferred to the other relationships.

A possibility which deserves consideration is whether or not the data could be better represented by a polynomial of higher than second order (see ref. 20). In view of the fact that most of the deviations shown in Fig. 3B are of the same order of magnitude as the experimental uncertainty (±1%), the extension of the polynomial to powers higher than two seems unjustified in this particular instance.

Substitution of the quadratic expression (eq. 7) into eq. 5 produces eq. 10 and enables ΔV^* to be evaluated.

$$[5] \qquad \Delta V^* = -RT(\partial \ln k/\partial P)_T$$

$$[10] \qquad = -RT\,\partial(A + BP + CP^2)/\partial P$$

$$[11] \qquad = -RT(B + 2CP)$$

The volume of activation at atmospheric pressure (zero applied pressure) is therefore given by eq. 12.

$$[12] \qquad \Delta V_0^* = -RTB$$

The pressure dependence of ΔV^* is given by differentiation of eq. 11 with respect to pressure.

$$[13] \qquad \partial\Delta V^*/\partial P = -2RTC$$

The uncertainties in ΔV_0^* and $\partial\Delta V^*/\partial P$ were calculated using eqs. 14 and 15 respectively,

$$[14] \qquad \delta\Delta V_0^* = -RT\delta B$$

$$[15] \qquad \delta\partial\Delta V^*/\partial P = -2RT\delta C$$

where δB and δC are the uncertainties in the B and C coefficients of eq. 7 given by the least squares analysis. The values of ΔV_0^* and $\partial\Delta V^*/\partial P$ and their limits of uncertainty are shown in Table 5.

Enthalpies and Volumes of the Initial State

The partial molal volumes, $\bar{V}^g$, and the partial molal heats of solution, $\Delta\bar{H}_s^g$, of benzyl chloride in aqueous *t*-butyl alcohol mixtures are listed in Table 6. The values of $\Delta\bar{H}_s^g$ were determined at 25.0 °C (not 50.25 °C) to minimize solvolysis of the reacting solute. The determination of the solvent dependence of the partial molal heat of solution of the benzyl chloride transition state in the following section is therefore based on the difference between two enthalpies determined at two different temperatures. While this may have a small effect on absolute magnitude of the transition state enthalpies, it is unlikely to effect the general form of the solvent dependence.

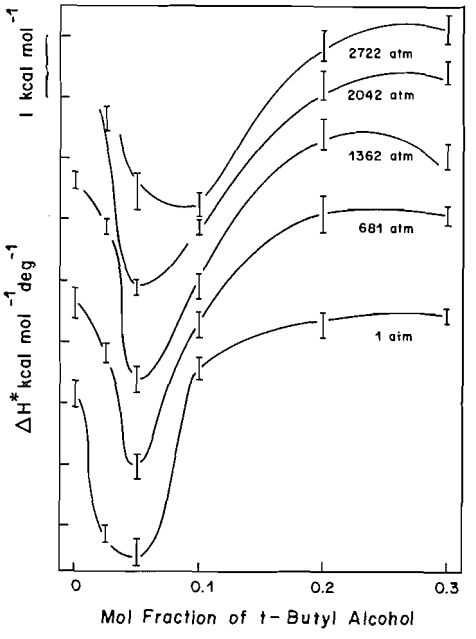

FIG. 4. Solvent dependence of activation enthalpy at various pressures.

Discussion

The Temperature Derivatives of the Rate, ΔH^* and ΔS^*

The enthalpies and entropies of activation are plotted against binary solvent composition in Figs. 4 and 5 respectively. The main feature of both plots is the appearance of deep minima in the range 0.05–0.10 mol fraction *t*-butyl alcohol.

Arnett (21) has offered the most comprehensive explanation of this extremum behavior. For the solvolysis of *t*-butyl chloride in aqueous ethyl alcohol, Arnett was able to demonstrate that the minimum in ΔH^* was due, in large part, to the variation of the partial molal heat of solution of the *initial state* with solvent composition.

In Fig. 6 the solvent dependences of ΔH^*, at atmospheric pressure, and the partial molal heat of solution of the initial state ($\Delta\bar{H}_s^g$) across the same solvent composition range are compared for the solvolysis of benzyl chloride in aqueous *t*-butyl alcohol. This data permits the extraction of the solvent dependence of the enthalpy of the transition state, $\delta\Delta\bar{H}_s^t$, using eq. 16.

$$[16] \qquad \delta\Delta\bar{H}_s^t = \delta(\Delta H^* + \Delta\bar{H}_s^g)$$

The solubility of benzyl chloride in highly aqueous *t*-butyl alcohol was insufficient to permit measurement of $\Delta\bar{H}_s^g$ at compositions containing

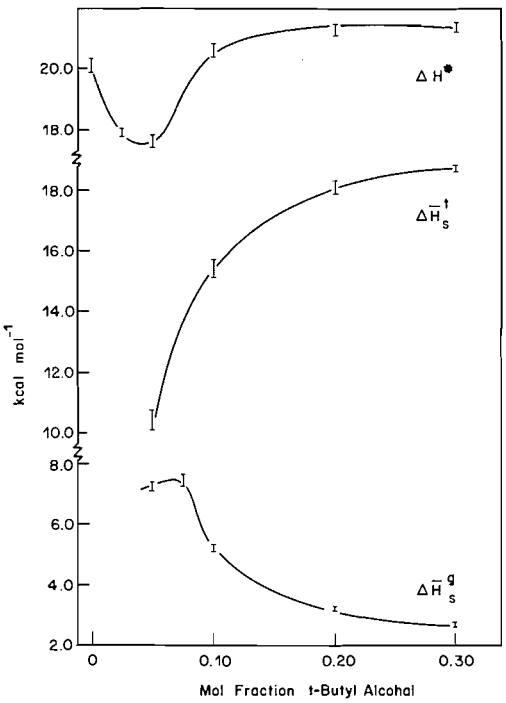

FIG. 6. Dissection of activation enthalpy. Solvent dependence of activation (ΔH^*) and initial ($\Delta \bar{H}_s^g$) and transition state ($\Delta \bar{H}_s^t$) enthalpies at 50.25 °C.

less than 0.05 mol fraction alcohol. For this reason one cannot be dogmatic about concluding that the extremum in ΔH^* is due to a corresponding extremum in the enthalpy behavior of the initial state $\Delta \bar{H}_s^g$. However, there is every indication in the limited data available at 0.05 and 0.075 mol fraction *t*-butyl alcohol that this may indeed be so.

In Figs. 4 and 5 the positions of minima in ΔH^* and ΔS^* appear to be pressure dependent and move to higher alcohol compositions as the pressure is increased. If the extremum in ΔH^* is due to the difference in the structure making and breaking abilities of the initial and transition states, as Arnett has suggested (21), then this observation is not surprising. The application of pressure itself is known to influence the structure of aqueous binary solutions (22) and hence presumably the additional structural influence of solute molecules, such as benzyl chloride, would be expected to vary with pressure.

The concurrent shift of the position of the extremum in ΔS^* is in keeping with the generally observed compensatory behavior of enthalpy and entropy changes, but also suggests that the order–disorder phenomena which produce the observed extrema have their optimum effect at higher alcohol compositions at higher pressures.

The Pressure Derivatives of the Rate, ΔV^* and $\partial \Delta V^*/\partial P$

The volumes of activation obtained in this work are plotted against solvent composition in Fig. 7. The negative values of ΔV_0^* are characteristic for solvolyses of alkyl halides in aqueous binary solvents (4–6). The negative sign corresponds to increased electrostriction of the kinetically important immediate solvent environment around the more polar transition state compared with the initial state (23–25).

The volume of activation is defined by eq. 17 and thus can be "dissected" in a similar manner to enthalpy. Values of $\bar{V}^t$ were calculated from

$$\Delta V_0^* = \bar{V}^t - \bar{V}^g \qquad [17]$$

the measured values of ΔV_0^* and $\bar{V}^g$. The solvent dependences of these three parameters at 50.25 °C are shown in Fig. 8. It is apparent that the minimum in the behavior of the activation parameter, ΔV_0^*, is primarily, but not exclusively, the result of a maximum in $\bar{V}^g$ rather than in the extremum behavior of the transition state volume, $\bar{V}^t$, as a function of solvent composition.

The extremum behavior of $\bar{V}^t$ of benzyl chlo-

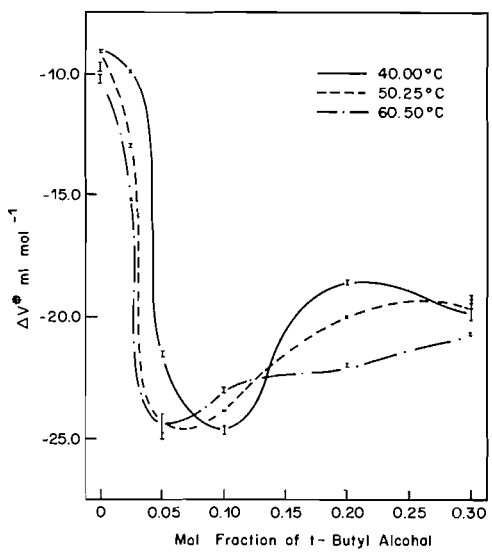

FIG. 7. Solvent dependence of activation volume at three temperatures.

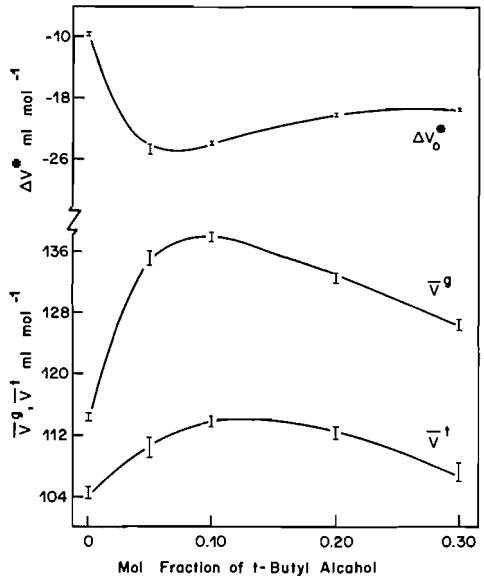

FIG. 8. Dissection of activation volume. Solvent dependence of activation (ΔV_0^*) and initial ($\overline{V}^g$) and transition state ($\overline{V}^t$) volumes at 50.25 °C.

ride in aqueous *t*-butyl alcohol is actually typical of several other non-electrolytes in aqueous alcohol mixtures. In aqueous ethyl alcohol, for example, benzyl fluoride, benzyl chloride and *p*-chloro benzyl chloride all pass through a maximum in $\overline{V}^g$ near 0.3 mol fraction alcohol (26). These maxima occur at a solvent composition which has been suggested to possess minimum structuredness (27). *If* it is valid to draw an analogy between the behavior of the benzyl chloride initial state in aqueous ethyl alcohol and in aqueous *t*-butyl alcohol, then the maximum in $\overline{V}^g$ in the latter solvent may indicate that the solvent possesses a minimum of structuredness at 0.1 mol fraction of alcohol. The observed minima in ΔV_0^* in the 0.05–0.10 mol fraction alcohol region would then be largely attributed to solvent structural changes.

Since 0.1 mol fraction *t*-butyl alcohol corresponds to 30% alcohol by volume it is hardly surprising that relatively little water-like open structuredness remains in such a binary and hence non-electrostricting solutes such as benzyl chloride must *displace* solvent molecules on dissolution resulting in a maximization of partial molal volume of solution.

In Fig. 7 it is apparent that an increase in temperature from 40.00 to 50.25 °C causes the minimum in ΔV_0^* to move to a less alcoholic composition. Whether the further increase in temperature from 50.25 to 60.50 °C produces any further shift in the extremum is not conclusive. An increase in temperature also causes the minimum in the partial molal volume of *t*-butyl alcohol in aqueous *t*-butyl alcohol mixtures, $\overline{V}_{t\text{-BuOH}}$, to move to lower alcohol compositions (12). Since $\overline{V}_{t\text{-BuOH}}$ presumably reflects the solvent structure, the parallel effect of temperature on the extremum in ΔV_0^* and $\overline{V}_{t\text{-BuOH}}$ strengthens the argument that this activation parameter reflects solvent structural changes.

Figure 9 illustrates the effect of solvent and temperature variation on $\partial\Delta V^*/\partial P$ the second pressure derivative of the rate. The values of $\partial\Delta V^*/\partial P$ are generally positive and exhibit a pronounced maximum at about 0.05 mol fraction of *t*-butyl alcohol.

The pressure dependence of ΔV^* is defined by eq. 18. This dissection is analogous to the Arnett

$$[18] \qquad \partial\Delta V^*/\partial P = \partial\overline{V}^t/\partial P - \partial\overline{V}^g/\partial P$$

et. al. (8) and Golinkin *et al.* (4) dissections of ΔH^* and ΔV_0^* respectively.

In pure water $\partial\Delta V^*/\partial P$ is approximately zero indicating that the partial molal volumes of the initial and transition states responded similarly to pressure, *i.e.* $\partial\overline{V}^t/\partial P \doteqdot \partial\overline{V}^g/\partial P$. This appar-

		Maxwell relationship		Maxwell relationship	

ently equal "compressibility" of the transition state and initial state solvent shells is particularly interesting since it implies that the *electrostricted* solvent shell around the strongly dipolar transition state is no "harder" than the solvation shell around the initial state which presumably is primarily the result of *hydrophobic* type interactions.

Until experimental techniques are developed to enable the transition and initial state contributions to $\partial\Delta V^*/\partial P$ to be determined, any interpretation of the solvent dependence of this parameter is perhaps premature. It is nonetheless interesting to note that the compression of aqueous *t*-butyl alcohol passes through a minimum at 0.03 mol fraction alcohol (28), close to the composition possessing a maximum in $\partial\Delta V^*/\partial P$. This must surely be yet a further indication that the extremum behavior of these activation parameters primarily reflects changes in solvent structure.

The sharp extremum behavior of $\partial\Delta V^*/\partial P$, a *second pressure derivative* of the rate, for the solvolysis of benzyl chloride in aqueous *t*-butyl alcohol, is remarkably similar to the solvent dependence of the second temperature derivative of the rate, ΔC_p^*, for the solvolysis of *t*-butyl chloride in the same solvent mixtures as reported by Robertson and Sugamori (7). It would appear that the extremum behavior of such second derivative pseudo thermodynamic parameters of activation is both more pronounced and more complex than is the case for the corresponding first derivative parameters (ΔH^*, ΔS^*, ΔV^*) where single extrema of modest amplitude are more characteristic.

Mixed Temperature and Pressure Derivatives, $\partial\Delta S^*/\partial P$, $\partial\Delta H^*/\partial P$, and $\partial\Delta V_0^*/\partial T$

It should be recognized at once that the parameters under consideration in this section are second derivatives of the measured rate and are subject to the accumulated errors of rate, pressure, and temperature measurements. It is, therefore, hardly surprising that the errors associated with such mixed second derivatives are sizeable. The values shown in Table 7 should therefore be viewed primarily as indications of the sign of the parameter (*i.e.* the slope, positive or negative, of the plots in Figs. 10 and 11) with little significance being attached to the numerical values where these are shown.

The entropy and enthalpy of activation are plotted against pressure in Figs. 10 and 11. The plots indicate that both these activation parameters are pressure dependent and at some compositions the dependence is non-linear. This non-linearity presents difficulties in obtaining numerical values of the pressure dependence of the entropy, $\partial\Delta S^*/\partial P$, and the enthalpy, $\partial\Delta H^*/\partial P$. Because of these difficulties the signs, as obtained from the *initial* slopes of Figs. 10 and 11, but not the magnitudes of $\partial\Delta S^*/\partial P$ and $\partial\Delta H^*/\partial P$ are reported in Table 7.

Examination of Figs. 10 and 11 and also the signs in Table 7 reveals that the solvent dependence of $\partial\Delta S^*/\partial P$ and $\partial\Delta H^*/\partial P$ are very similar. This would tend to suggest that the well known compensatory behavior of ΔH^* and ΔS^* (27) is still in evidence when the second derivatives are compared. This is in fact to be expected. The differences in the intermolecular interactions, of the initial state and the transition state with the solvent environment, that resulted in the compensatory behavior of the first derivative parameters are still operative in the second derivatives.

The volumes of activation for the solvolysis of benzyl chloride in aqueous *t*-butyl alcohol mixtures were determined at 40.00, 50.25, and

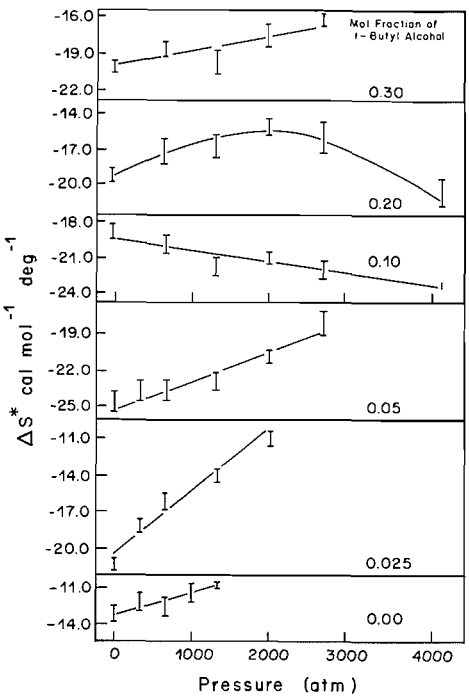

FIG. 11. Pressure dependence of activation entropy at various *t*-butyl alcohol mol fractions.

60.50 °C (Table 5). The temperature dependence, $\partial\Delta V_0^*/\partial T$, can thus be evaluated. Values of $\partial\Delta V_0^*/\partial T$ are not reported for 0.05 or 0.30 mol fraction of *t*-butyl alcohol since it appears that at these solvent compositions the dependence of ΔV_0^* on temperature is markedly non-linear. The values of $\partial\Delta V_0^*/\partial T$ obtained at other solvent compositions are listed in Table 7, and it is apparent that this second derivative of the rate is extremely sensitive to solvent composition changes.

The solvent dependence of $\partial\Delta V_0^*/\partial T$ is due to the different responses of the temperature dependence of the volume of the component initial and transition states to solvent changes. The solvent dependence of the initial and transition state contributions, and hence of the activation parameter itself, may well be a reflection of the changing structural stability of the solvent medium as cosolvent is added to water.

Maxwell Type Pseudo Thermodynamic Relationships

The availability of a large number of temperature and pressure derived pseudo thermodynamic parameters of activation for the single system examined in this work permits the application of classical thermodynamic identity tests to these "kinetic" parameters. In particular the following well established thermodynamic relationships may be tested using the pseudo thermodynamic parameters obtained in this work.

$$[19] \qquad (\partial\Delta S^*/\partial P)_T = -(\partial\Delta V^*/\partial T)_P$$

$$[20] \qquad (\partial\Delta H^*/\partial P)_T = \Delta V^* - T(\partial\Delta V^*/\partial T)_P$$

The high experimental accuracy required to obtain meaningful values of the mixed second derivative parameters in eq. 19 has limited the testing of this identity to establishing that the parameters have indeed opposite signs in the case of the Menshutkin reaction (29) and some hydrolyses (30).

The present work offers the opportunity of examining this Maxwell relationship as a function of solvent composition. Unfortunately, as was noted above, the determination of a numerical value of $\partial\Delta S^*/\partial P$ was not possible. It was possible, however, to determine the sign of $\partial\Delta S^*/\partial P$. The signs of both $\partial\Delta S^*/\partial P$ and $\partial\Delta V_0^*/\partial T$ are shown in Table 7 and demonstrate again that these parameters have opposite signs as required by eq. 19.

The present data also enables eq. 20 to be tested. The numerical evaluation of $\Delta V_0^* - T\partial\Delta V_0^*/\partial T$ is shown in Table 7. Numerical values of $\partial\Delta H^*/\partial P$ could not be obtained but again its

sign could be determined. It is apparent, from the results listed in Table 7, that the signs of $\partial\Delta H^*/\partial P$ and $\Delta V_0^* - T\partial\Delta V_0^*/\partial T$ are in agreement with eq. 20.

Although it is not presently justifiable to extract numerical values which would permit rigorous checks of the validity of eqs. 19 and 20 for pseudo thermodynamic parameters, the agreement of signs obtained in these complex second derivative relationships serves to establish further the credibility and reality of the mixed second derivative parameters obtained from exhaustive examination of the temperature and pressure dependence of the rate of this solvolytic reaction.

Conclusion

(*1*) The extremum behavior exhibited by the activation parameters, as a function of solvent composition, holds clues to our understanding of kinetic solvent effects. Explanation of these extrema requires knowledge of both the initial and transition state solvent dependences.

(*2*) The extrema observed in ΔH^*, ΔS^*, and ΔV^* are also present in the second derivative parameters. These latter exhibit more pronounced extremum behavior and, as in the study of ΔH^* and ΔS^* behavior, may further aid our comprehension of these systems.

(*3*) The analogous behavior of the activation parameters and non-kinetic properties of the solvent itself indicate that the extrema in the former are related to solvent structure.

(*4*) The validity of Maxwellian type relationships in this pseudo thermodynamic system supports the application of real state thermodynamics to kinetic systems.

(*5*) The evaluation of a third derivative of the rate, the temperature dependence of $\partial\Delta V^*/\partial P$ is at present premature. Figure 9 suggests that $\partial\Delta V^*/\partial P$ is temperature dependent, but this dependence is small. This demonstrates that, in spite of the extreme accuracy of the data, still greater reproducibility will be necessary to permit the determination of third derivative pseudo thermodynamic parameters.

The authors would like to acknowledge the assistance of Dr. Moyra Mackinnon and Mrs. Margaret Estep who determined the partial molal volumes and the partial molal heats of solution respectively. Financial assistance for this research was provided by the National Research Council of Canada.

Permeation of Electrolytically Generated Hydrogen and Tritium Atoms through Lead[1]

BANSI L. MUJU AND FRANK R. SMITH[2]
Chemistry Department, Memorial University, St. John's, Newfoundland

Received February 26, 1971

Radiochemical and electrochemical evidence is presented that electrochemically generated tritium and hydrogen atoms permeate through lead foil at measureable rates at room temperature. The permeation process is controlled by diffusion through the metal lattice, Fick's First Law being obeyed by both H and ^{3}H atoms. Using earlier measurements of the diffusivity of H in Pb, H and ^{3}H concentrations of 4×10^{-7} and 9×10^{-13} g-atom cm^{-3} are computed for a current density of 53 mA cm^{-2} at the Pb cathode surface.

The overall hydrogen–tritium separation factor, S_T is apparently 0.3 ± 0.15, in contrast to Bockris and Srinivasan's 6.7 and 7.2 for cathodic gas evolution from acidic and alkaline media, respectively. Reasons are suggested for this large difference.

Une preuve radiochimique et électrochimique est donnée pour montrer que des atomes d'hydrogène et de tritium, engendrés d'une façon électrochimique, traversent à la température de la pièce et à vitesse mesurable un feuille de plomb. Le processus de passage est contrôlé par la diffusion à travers le réseau métallique; la première loi de Fick étant observée à la fois pour les atomes H et ^{3}H En se servant des mesures antérieures sur la diffusion de H dans le Pb, les concentrations de 4.10^{-7} et 9.10^{-13} pour H et ^{3}H sont calculées dans le but d'avoir une densité de courant de 53 mA cm^{-2} à la surface de la cathode en Pb.

Le facteur de séparation global, S_T, hydrogène–tritium semble être de 0.3 ± 0.15; valeur très différente de celles de Bockris et Srinivasan (6.7 et 7.2) pour le dégagement de gaz à la cathode à partir d'un milieu respectivement acide et basique. Des raisons pour cette grande différence sont suggérées.

Canadian Journal of Chemistry, **49**, 2406 (1971)

In earlier work, Ives and Smith (1) presented evidence of long-term overpotential changes in electrolytic hydrogen evolution at lead electrodes under conditions of high purity. During periods of electrolysis of several days, overpotential decreases of hundreds of mV were observed and attributed to activation of the lead by continuous accumulation in the lattice of electro-generated H atoms. The possibility that the effects were caused by impurities was discounted (*i*) by the observation that little change of overpotential occurred when experimental conditions were not optimal and (*ii*) because of the use in the work of proven methods of attaining high surface cleanliness, namely anodic polishing, cathodic preelectrolysis, and continuous adsorptive cleaning with activated carbon.

The argument for hydrogen entry into the lead lattice was based largely on grounds of plausibility, although some earlier (2) and some more recent work (3, 4) was unfavorable to this hypothesis. However, the atomic H uptake experiments of Wells and Roberts (5) in 1964 with evaporated and sintered Pb films were encouraging. The H uptake was far more than could be accounted for by *adsorption* on the measured surface. This work, recently extended by Roberts and Young (6), led to a proposal that a solid lead hydride exists, and is of composition $PbH_{0.19}$ at 0 °C. This hydride has considerably more stability than such transient entities as Paneth's assumed gaseous PbH_4 (7).

Recently, we have shown by an electrochemical method (8) that electrolytic permeation of hydrogen through lead foils of 0.15 mm thickness does indeed occur (9), in contrast to earlier negative findings (3, 4), and that the diffusivity at 25 °C lies between 10^{-7} and 10^{-6} cm^2 s^{-1}. We now present radiochemical and electrochemical evidence that the electrolytic permeation rate of tritium and of hydrogen is governed by diffusion in the solid phase. The radiochemical method has

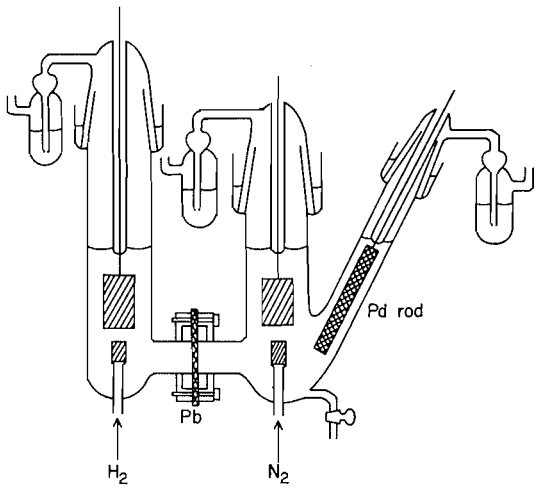

FIG. 1. Electrolysis permeation cells. Left hand side, cathodization cell with Ptized Pt anode and cathode side of Pb in H_2-saturated 1 *M* $HClO_4$; right hand side, diffusion side cell with Ptized Pt cathode, Pd hydride reference and diffusion side of Pb in N_2-saturated 0.2 *M* KOH.

not previously been reported. It is likely to have wide applicability to metals having low hydrogen solubilities, hitherto little studied.

Experimental

Goodfellow Metals Ltd. 99.9% pure lead foils were degreased in refluxing benzene (4 h), washed with ethanol and with 3× distilled water. They were chemically polished in 60% $HClO_4$ in contact with Pt, washed in 3× distilled water and mounted in the cell (Fig. 1) with thin polyethylene gaskets between the flat flanges. Thicknesses were determined with a micrometer.

The cathode side had a 3 cm^2 platinized platinum counter electrode, supplied with H_2 from an Elhygen generator. This H_2 passed through copper and Pyrex tubing, a liquid N_2-cooled trap and a 3× distilled water-filled presaturator. $HClO_4$ (7 ml of 1.0 *M*, 70% double vacuum distilled $HClO_4$ from G. F. Smith and Co., diluted with 3× distilled water) with a ^{3}H concentration of 2 mCi ml^{-1} (diluted from 100 mCi ml^{-1} Tracerlab tritiated water) was used as catholyte.

The diffusion side had a similar counter electrode supplied with Matheson prepurified N_2, passing through a similar gas train, except that the trap was cooled with solid CO_2 and ethanol. N_2 was deoxygenated by prereduced BTS catalyst Badische Anilin- und Soda-Fabrik maintained in a furnace at 140 °C. The reference electrode was a 3 mm diameter × 4 cm long palladium rod, first palladized in 2% aqueous $PdCl_2$ in 1 *M* HCl for 5 min (10) and then potentiostatically hydrogen-charged during 16 h at +50 mV *vs.* H_2 reference, both in H_2 saturated 0.2 *M* KOH. Charging was accomplished in the absence of the lead foil. As diffusion side electrolyte, 15 ml of 0.2 *M* KOH in 3 × distilled water was normally used.

The diffusion side of the Pb foil was potentiostatted at +136 to +140 mV *vs.* PdH with the inexpensive circuit of Fig. 2. Floating current measurements were made with a Keithley 150B Microvolt-Ammeter, the output of which was attenuated and recorded by a Heath EUW20A Servo Recorder, isolated from the ammeter by a Fluke A88 amplifier.

A Heath EUW15 Power Supply used at 300 V, a Simpson ammeter and make-before-break switchable resistors enabled cathodic currents of 30 μA up to tens of mA to be applied to the cathode side of the foil. With a protection current of 30 μA, the diffusion side background current was 1 to 2 μA anodic, apparently Pb dissolution.

Preliminary work by Cadersky *et al.*[3] established that H atom oxidation occurs on lead with high efficiency at potentials ⩾ 190 mV *vs.* H_2 in 0.2 *M* KOH. This potential is close to +136 mV *vs.* α/β PdH since the steady state plateau potential of the Pd–H system was found to lie in the range +50 to +60 mV, the potential being more positive during ionization of the absorbed H, in agreement with Barton and Lewis (11). Stability of reference potential was established experimentally to be ±1 mV over a 40 h period with continuous N_2 stirring.

After 4 h electrolysis at the desired current density, a cathodic protection current was reapplied and the diffusion side electrolyte run out via the 1 mm bore tap into a flask, from which twenty 0.25 ml samples were pipetted out. Fifteen ml of a scintillation cocktail of composition (12): naphthalene (80 g l^{-1}), 2,5-diphenyloxazole (5 g l^{-1}), and 1,4-bis-[2-(5-phenyloxazolyl)]benzene (50 mg l^{-1}) in xylene (38.5%), 1,4-dioxane (38.5%) and ethanol (23.1%), was used at −15 °C for each sample in a polyethylene vial. Fresh cocktail was prepared for each experiment and its efficiency (21.0 to 27.3%) determined with a standard 20 000 disintegrations per minute ^{3}H sample together with 0.25 ml 0.2 *M* KOH. A counting time of 40 min in a Nuclear Chicago Model 6860 Mark I liquid scintillation computer refrigerated to 0–5 °C was adopted as standard, the background count rate of 13 to 39 counts per minute being deducted or discriminated in the measurements. Sample count rates of 80 to 490 counts per minute were observed in the experiments reported.

Thorough cleaning and testing of the diffusion side glassware was essential for the success of this work. Initial cleaning was with hot concentrated HNO_3, followed by water washing, steaming and drying in an oven. Since glassware was blown onto the gas lines, subsequent cleaning was effected *in situ*. This always included steaming. The palladium hydride electrode was allowed to degas in 0.2 *M* KOH after each experiment. This also freed it of possible ^{3}H contamination.

Experiments were conducted at 25 ± 3 °C in a thermostatted room.

Results

In Figs. 3 and 4 are presented steady state permeation rates of H and ^{3}H atoms, respectively, as

[3]I. Cadersky, B. L. Muju, and F. R. Smith, unpublished work.

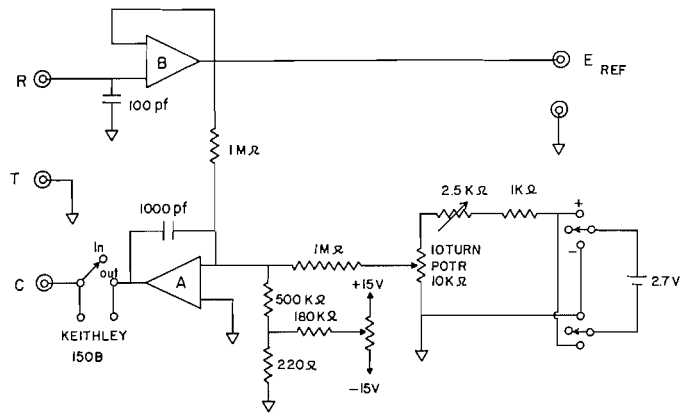

FIG. 2. Potentiostat circuit for diffusion side of Pb. R, T, and C are reference, test (Pb), and counter electrode inputs. Amplifiers A and B are Analog Devices Inc. Models 183K and 146K, respectively, powered from a ±15 V power supply (Model 904). Features are high common mode rejection, low drift and noise, and a 5 mA output capability at ±10 V. Potentials measured at E_{ref} equal R–T electromotive force within ±0.7 mV; input impedance of B is 10^{11} ohm.

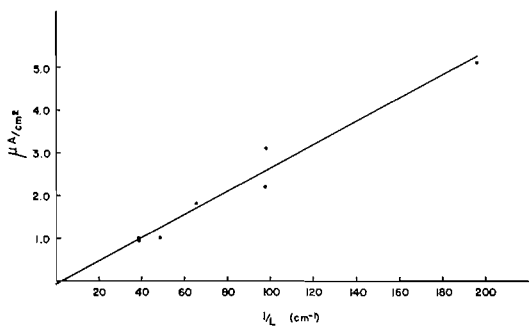

FIG. 3. Steady state H atom permeation current density (ordinate) *vs.* reciprocal thickness (abscissa) of chemically polished Pb foil.

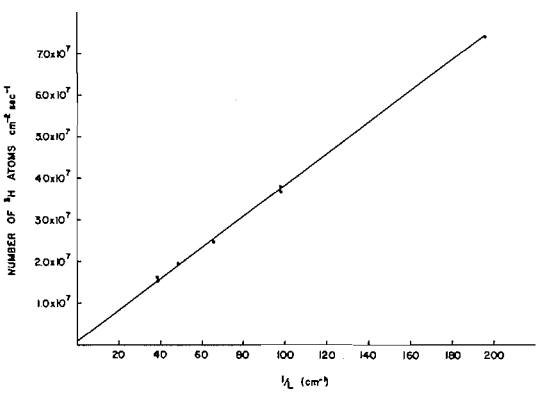

FIG. 4. Mean permeation rate of tritium (ordinate) *vs.* reciprocal thickness (abscissa) of chemically polished Pb foil.

functions of the reciprocal thickness ($1/L$) of the lead foils for L values 0.05 to 0.25 mm. These permeation rates apply to an assumed constant cathodic H atom surface coverage (^{3}H coverage) maintained for 4 h by cathodic polarization of 53 mA cm^{-2} in 1 M $HClO_4$ of 2 mCi ml^{-1} ^{3}H activity. The relatively short duration of the transient (*ca.* 0.1 h) is included in the 4 h electrolysis period.

The linearity of the plots and their zero intercepts indicate that Fick's First Law is obeyed

$$[1] \qquad J_H = D_H \frac{(C_H)_{cath} - (C_H)_{diff}}{L}$$

and

$$[1a] \qquad J_T = D_T \frac{(C_T)_{cath} - (C_T)_{diff}}{L}$$

where J_H and J_T are H and ^{3}H fluxes, respectively, and the C's are the H and ^{3}H atom concentrations *within* the metal on the cathode and diffusion sides, as indicated by the subscripts. It is assumed that the atom concentrations are determined solely by the prevailing electrochemical conditions: constant cathodic current density on the cathode side of the foil and constant potential on the diffusion side, sufficiently positive to ensure rapid ionization of diffusing atoms as they arrive. This last condition implies

$$[2] \qquad (C_H)_{diff} = (C_T)_{diff} = 0$$

and enables estimates to be made of $(C_H)_{cath}$ and $(C_T)_{cath}$ if D_H and D_T, respectively, are known.

Least squares values of the slopes of Figs. 3 and 4 are 0.027 μA cm^{-1} and 3.73 × 10^5 ^{3}H atoms cm^{-1} s^{-1}. Corresponding intercepts at $1/L = 0$ are −0.036 μA cm^{-2} and +1.01 × 10^6 ^{3}H atoms cm^{-2} s^{-1}, *i.e.* zero, within experimental error.

Consideration of errors is appropriate at this point. From the number of sample counts and background counts, assuming a Poisson distribution, the relative standard deviation calculated is in no case greater than 1.8%. Relative standard deviations of the sampling (20 samples of 0.25 ml) were between 5.3 and 9.05%, probably because a graduated 0.5 ml pipette was used. Disintegration rates of ^{3}H for the entire diffusion side electrolyte were calculated from the mean count rates, excluding in one experiment an extremely deviant count, and from the scintillation cocktail efficiency. Knowledge of the decay constant λ for tritium (13) enabled calculation of the ^{3}H concentration in the diffusion side electrolyte at the end of the electrolysis period and hence the average permeation rate (J_T).

The electrochemical permeation rates are the measured currents, the overall ammeter/recorder system accuracy being about ±2%.

Foil thicknesses were precise to ±5% or better.

It is evident from the very satisfactory linear plot of Fig. 4, in particular, that the above assessment of errors is probably pessimistic. The special difficulties of the electrochemical permeation measurements will be considered later.

Assuming that $D_H \approx 7 \times 10^{-7}$ cm^2 s^{-1}, from our previous work (9), an H atom concentration of 4 × 10^{-7} g-atom cm^{-3} just inside the cathode surface is calculated from eq. 1 and the slope of Fig. 3. This compares favorably with our earlier result (9) of 10^{-6} g-atom cm^{-3}, again at *ca.* 50 mA cm^{-2} in 1 *M* $HClO_4$.

In the absence of a measured diffusivity for tritium in lead, the value for hydrogen must be considered a fair approximation, judging by deuterium isotope effects on diffusivities of hydrogen in Pd and its alloys (14). From eq. 1*a* and the slope of Fig. 4, $(C_T)_{cath}$ is calculated to be 9 × 10^{-13} g-atom ^{3}H cm^{-3} for the present experimental conditions (^{3}H catholyte concentration of 6.85 × 10^{-8} g-atom cm^{-3}).

The data permit calculation of an overall separation factor for hydrogen and tritium originating in the catholyte, entering the metal and being ionized into the diffusion side electrolyte

$$[3] \qquad S_T = \frac{(J_H/J_T)_{diff\ side}}{(N_H/N_T)_{catholyte}}$$

where N_H and N_T are the H and ^{3}H atomic concentrations, respectively, in the cathode side electrolyte and J_H and J_T are the measured atom fluxes (expressed in the same units). S_T values range from 0.20 to 0.44, the mean of seven experiments being 0.28. S_T values less than unity have not previously been reported for electrolytic isotope separation. Thus, Bockris and Srinivasan (15) using Pb wires in 0.25 *M* H_2SO_4 and 0.5 *M* NaOH, each containing only 6 μCi ml^{-1} of tritium, obtained $S_T = 6.7 \pm 0.7$ and 7.2 ± 0.8, respectively, from the H_2 and HT evolved at the cathode.

Discussion

Hydrogen Diffusion and Hydrogen Overpotential

Ives and Smith (1) estimated the upper and lower limits for the diffusivity of hydrogen atoms in lead as 10^{-6} and 2.5 × 10^{-11} cm^2 s^{-1} (the value for interstitial Au diffusion in Pb) at 300 °K. Cadersky, Muju, and Smith (9) obtained values of 1.2 to 8.7 × 10^{-7} cm^2 s^{-1} from electrochemical permeation measurements at cathode current densities of 10 to 50 mA cm^{-2}, *i.e.* close to Ives and Smith's upper estimate.

The present work conclusively proves that H transport through Pb with these diffusivities is a bulk phenomenon, the rate of which is controlled by lattice diffusion for all foil thicknesses so far examined. This is to be expected for the chosen conditions of electrochemical generation of H atoms at the cathode side and ionization of H atoms at the diffusion side of the foil. Nothing can be said about H atom recombination at lead as a result of this work; processes of this type have occupied the attention of Roberts and Young (6).

The question arises whether the hypothesis of Ives and Smith (1) concerning the mechanism of the long term fall of hydrogen overpotential and of overshoot hysteresis effects upon step changes of current density is correct. It was assumed that both types of observation were manifestations of the same phenomenon, *i.e.* the accumulation of H atoms in the bulk of the metal during cathodic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

electrolysis and its redistribution when the current was changed. The present observations may be used to comment on the velocity of the redistribution process.

If the radiochemical observations are taken as correct, the electrochemical ones being set aside for reasons to be given below, it is possible to calculate a more reasonable upper limit for the hydrogen concentration in the cathode surface layer of lead based on the more realistic separation factor ($S_T = 7$) of Bockris and Srinivasan (15). This would have a composition of $PbH_{0.0002}$ in contrast to the $PbH_{0.00002}$ of Cadersky, Muju, and Smith (9) and the $PbH_{0.2}$ of Roberts and Young (6). For a 2 mm diameter cylinder of lead, assuming a central core 1 mm deep free of hydrogen, the mean hydrogen gradient of 0.0001 g-atom cm^{-3} cm^{-1} and diffusivity of 7×10^{-5} cm^2 s^{-1} would result in a flux density of 7×10^{-11} g-atom cm^{-2} s^{-1} or a current of 7 μA cm^{-2}, which is appreciable. Correspondingly, with the thinnest foils examined (0.005 cm) in the work now reported the hydrogen permeation current should have been about 140 μA on this basis, whereas only 5.1 μA was observed. It must be emphasized that these calculations refer to a cathodic current density of *ca.* 50 mA cm^{-2}, at least five times larger than the largest steady current in Ives and Smith's investigation!

The evidence of the present work is therefore favorable to the views expressed by Ives and Smith, but it remains to clarify this matter further. Recent capacity measurements by Cadersky *et al.*[4] seem likely to provide the needed breakthrough; hydrogen adsorption pseudocapacities indicating $\theta_H \approx 0.05$ have been observed using Pb in $HClO_4$.

Hydrogen–Tritium Separation Factors

In discussing our abnormally low S_T results it may be helpful to indicate that the separation of H from ^3H according to eq. 3 is believed to involve the following stages

[4] $H_2O + H_{aq}^+ \rightleftharpoons H_3O_{aq}^+$

[4*a*] $HTO + H_{aq}^+ \rightleftharpoons H_2TO_{aq}^+$

[5] $H_3O_{aq}^+ + Pb + e_{metal}^- = H_2O + Pb\text{–}H_{ads}$

[5*a*] $H_2TO_{aq}^+ + Pb + e_{metal}^- = H_2O + Pb\text{–}T_{ads}$

[6] Diffusion of H atoms from cathode to diffusion side of Pb

[6*a*] Diffusion of ^3H atoms from cathode to diffusion side of Pb

[7] $Pb\text{–}H_{ads} + OH_{aq}^- = Pb + H_2O + e_{metal}^-$

[7*a*] $Pb\text{–}T_{ads} + OH_{aq}^- = Pb + HTO + e_{metal}^-$

Steps 4 and 5 occur in the catholyte and on the cathode side of the Pb foil, respectively, while step 7 occurs on the diffusion side. The S_T data of Bockris and Srinivasan (15) refer to steps 4 and 5, followed by H_{ads} and T_{ads} desorption as H_2 and HT, respectively. Their S_T value of 7 in acidic solution is consistent with cathodic H–D separation factors obtained on Pb, and on Hg, which is generally held to have a similar electrolytic hydrogen evolution mechanism to that of Pb (16).

In considering expected S_T values for steps 4 to 7 inclusive, it is necessary to estimate the additional separation attributable to steps 6 and 7, the values of ref. 15 being thought to be due to the equilibria of steps 4 and 4*a*, and the H_2- and HT-evolution rate-controlling steps 5 and 5*a*.

Recent work on H–D separation on cathode and diffusion sides of Ag–Pd alloy foils (17) suggests that additional separation by steps 6 and 7 is *unlikely* to result in $S_T > 15$. Under the chosen potentiostatic conditions, steps 7 and 7*a* should have rates determined solely by the diffusion steps 6 and 6*a*. The diffusivities of D and H in other metals and alloys (14, 17) are not markedly different from one another. Appreciable separation of H from ^3H is, therefore, not expected from steps 6 and 6*a* and it is extremely improbable that $D_T \approx 25\ D_H$, the relationship needed to bring our S_T's into conformity with those of ref. 15.

It is thought that our low S_T's arise from experimental difficulties associated with the complete elimination of O_2 from the system. The results of Cadersky and Smith,[5] who observed considerable sensitivity of electrochemical permeation currents to the experimental conditions, are in accord with this view. It is suggested that the H atom concentrations and permeation rates reported here and earlier (9) may be low by several orders of magnitude. To account for low S_T values, however, requires not merely that H and ^3H atoms be removed by a scavenger such as O_2 in proportion to their concentrations, but that

[4] I. Cadersky, G. M. Rao, and F. R. Smith, in preparation.

[5] I. Cadersky and F. R. Smith, unpublished work.

H atoms be removed *preferentially*. It can be argued that weakly adsorbed H and ^{3}H atoms on the cathode surface are both likely to react rapidly with O_2 and that these processes may well be diffusion-controlled. But preferential removal of H atoms would be likely only if the nature of the adsorbed species were fundamentally different in the two cases, an improbable hypothesis.

A possible explanation is that H and ^{3}H atoms, diffusing through the foil (steps 6 and 6*a*) to the diffusion side, may interact as above with O_2 and enter the solution without undergoing steps 7 and 7*a*. No error would result in the radiochemical counting method but the electrochemically measured permeation current would be diminished, since *only* those H atoms undergoing ionization (step 7) would be counted in this manner.

It is obvious that the water-sealed apparatus with its flanges and the tap on the diffusion side cannot be as gas-tight as, for instance, the high vacuum system used by Wells, Roberts, and Young (5, 6) in their gas phase adsorption studies with H atoms. This highlights one of the main difficulties of electrochemical studies of the adsorption of air-sensitive atoms and molecules.

. Finally, it may be commented that a surface phase composition of $PbH_{0.00001}$ seems very dilute for a current density of 50 mA cm^{-2}. When it is recalled that cathodic disintegration of lead in acid solution has been observed by Salzberg *et al.* (18) at 100 mA cm^{-2} and attributed by them to PbH_2 gas formation and decomposition, it is difficult to accept that even the more concentrated $PbH_{0.0002}$ is realistic. According to Bockris and Devanathan (19), surface H coverages are calculable from electrolytic permeation measurements but it is our view that this can be done only if the electrolyte composition is the same on both sides of the metal membrane. This prevents such a calculation being validly made here and is unfortunate since it is anticipated that a surface coverage approaching 100% would be found at current densities in the cathodic disintegration range.

We must emphasize, however, that we do not accept the view of the Russian (20) and Polish (21) schools that cathodic disintegration of lead and other metals is caused *solely* by alkali metal penetration into the cathode and subsequent decomposition of the alkali alloy. Experiments by Salzberg *et al.* (18) and Ives and Smith (1) have clearly shown that alkali ions are not essential in such disintegration processes.

We wish to thank Dr. W. H. Marshall and other members of the Memorial University Medical School for the use of the liquid scintillation facilities, Dr. I. Cadersky for his initial investigations of this problem and Mr. D. Seymour for glassware construction. The support of the Defence Research Board and the National Research Council of Canada is gratefully acknowledged.

An Electron Spin Resonance Investigation of the Mechanism of the Intramolecular Cation Migration of Alkali Metal Semiquinone Ion-pairs

T. E. GOUGH[1] AND P. R. HINDLE

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 11, 1971

A systematic survey of the kinetic characteristics of the intramolecular cation exchange reactions of semiquinone ion-pairs is described. A linear correlation exists between the free energy of activation for the exchange and the strength of the ionic interaction within the ion pair; however, this correlation does not extend to the enthalpy of activation. The significance of the kinetic parameters is discussed in terms of the role solvation plays in determining the course of the exchange process.

Une analyse systématique des caractéristiques cinétiques des réactions d'échange par cation intramoléculaire des paires d'ions de la sémiquinone est faite. Il existe une corrélation linéaire entre l'énergie libre d'activation de l'échange et la force de l'interaction ionique dans une paire d'ions; toutefois, cette corrélation ne s'étend pas à l'enthalpie d'activation. La signification de paramètres cinétiques est discutée en fonction du rôle que la solvatation joue dans la détermination de l'évolution du procédé d'échange.

Canadian Journal of Chemistry, 49, 2412 (1971)

Introduction

The phenomenon of line-width alternation in an electron spin resonance spectrum is now well understood; a recent review article indicates the necessary conditions for its occurrence and the variety of systems which can exhibit the effect (1). Line-width alternation in the electron spin resonance spectra of semiquinone ion-pairs has been reported by a number of workers; the majority of these results have been collated by Oakes and Symons (2) and thus are not given separate reference here. It is now generally agreed that, for these systems, the alternation in line-widths is the result of an intramolecular migration of the cation of the ion-pair between the oxygens of the semiquinone. However, the mechanistic details remain uncertain because of the lack of quantitative data concerning the rates of cation exchange. Three previous papers (3–5) have reported E_a and $\log_{10} A$ values for a number of semiquinone ion-pairs but at least one of these (3) should no longer be regarded as more than an exploratory semi-quantitative series of measurements. Thus the literature contains insufficient data from which to draw general conclusions concerning the quantitative aspects of the exchange. Accordingly, we have performed kinetic studies on a series of semiquinone ion-pairs in ethereal solvents in order to generate consistent data with which to evaluate and interpret trends in the measured kinetic parameters.

[1]To whom all correspondence should be addressed.

Experimental

Experimental procedures for the purification of reagents and the production of the ion-pairs have been described (3). Cesium mirrors were prepared by heating cesium chloride/calcium mixtures *in vacuo* and driving the resultant cesium vapor through a sintered disc and onto a cool glass surface within the reduction vessel. The spectra were recorded on a Varian E-3 spectrometer equipped with a Varian E4540 variable temperature unit. The sample temperature for each spectrum was recorded using a copper–constantan thermocouple in conjunction with a Hewlett–Packard 3420 A voltmeter. Simulations of the experimental spectra, using the Bloch equations appropriately modified to include the 2-site cation exchange (6) were performed on an IBM 360/75 computer in conjunction with a Calcomp plotter.

Results

Electron spin resonance spectra of each system studied were recorded at 10° intervals over as wide a range of temperatures as possible. The spectra were fully in accord with expectation showing static configurations of the ion-pairs at low temperatures, and the effects of intramolecular cation migration at higher temperatures.

Sodium Durosemiquinone, NaD

Satisfactory concentrations of NaD were obtained in 1:2 dimethoxyethane, DME, and in tetrahydrofuran, THF, but not in 2-methyltetrahydrofuran, MeTHF. The methyl hyperfine splitting constants of NaD in DME and THF were found to be temperature dependent; Δa_{Me}, the difference between the two observed methyl splittings of the static configuration, increased as the temperature was increased, but the mean of

the two splittings remained constant (1.94 ± 0.03 G). In Fig. 1, Δa_{Me} is plotted as a function of temperature from -80 to $+20$ °C above which temperature exchange effects preclude measurement of the individual splitting constants. It is important when evaluating the kinetics of the exchange reaction to include the temperature dependence of Δa_{Me}. If this effect is neglected, as was done previously (3), then the Arrhenius plots become S shaped. Arrhenius plots for the intramolecular exchange of sodium for NaD in DME and THF are given in Fig. 2; values of E_a and A are given in Table 1. The Arrhenius plot for NaD in THF covered slow, intermediate, and fast exchange regions, while that for DME covered slow and intermediate regions.

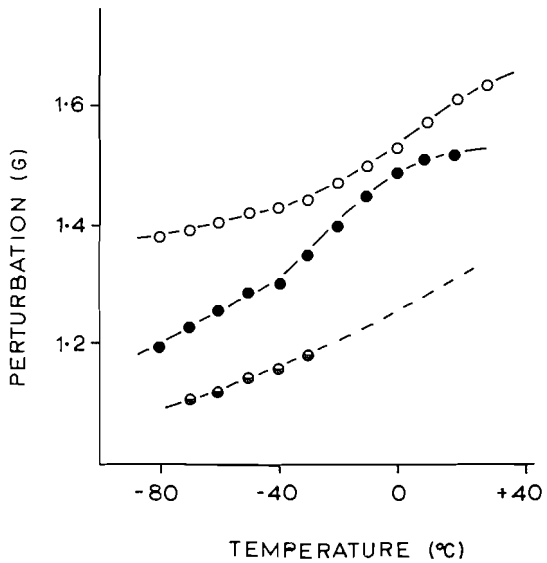

FIG. 1. Δa_{Me}, the perturbation of the hyperfine splitting constants of durosemiquinone produced by ionic association plotted as a function of temperature for ○, NaD in THF; ●, NaD in DME; ◒, KD in THF.

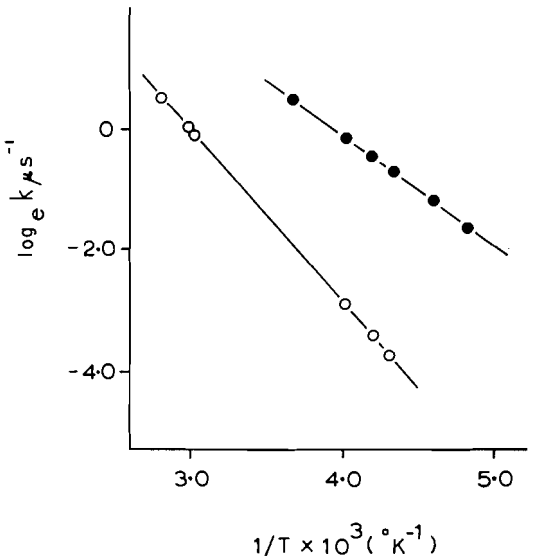

FIG. 2. Arrhenius plots for the intramolecular migration of sodium within the ion pair NaD in ○, THF; ●, DME.

Potassium Durosemiquinone, KD

KD was prepared in THF, and studied through the slow, intermediate, and fast exchange regions. The temperature dependence of Δa_{Me} could only be measured from -80 to -30 °C, exchange effects becoming too severe above this temperature range; as shown in Fig. 1, the results for NaD were used to guide the extrapolation of Δa_{Me} values for KD to $+20$ °C. Values of E_a and A for KD in THF are given in Table 1. Das and co-workers (5) have published an excellent linear Arrhenius plot for KD in DME and their results for E_a and A are incorporated into Table 1.

Cesium Durosemiquinone, CsD

CsD spectra were detectable in THF and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

MeTHF only after 8 h reduction, though the ion-pair formed quite readily in DME. The initial solutions were light brown (DME) and wine-red (THF and MeTHF) but these colorations gradually settled out leaving pale green solutions having strong electron spin resonance spectra. Locked-in configurations of the ion-pairs were not observable over a sufficient temperature range to evaluate the temperature dependence of Δa_{Me} for CsD and so temperature independent values of 0.98 G in DME, 0.88 G in THF, and 1.12 G in MeTHF were used when evaluating E_a and A. Larger amounts of free D^- were present in the CsD solutions than in the NaD and KD solutions; the relative amount of free ion decreased in the series DME > THF > MeTHF. The spectrum of the ion-pair occurred to high field of the free ion, the separation being 0.15 G in DME, 0.13 G in THF, and 0.18 G in MeTHF. Figure 3 shows the variation with temperature of the cesium hyperfine interaction expressed as a percentage of the atomic interaction.

Potassium p-Benzosemiquinone, KB

The intramolecular exchange of potassium within the KB ion-pair was examined in DME and THF over the temperature range −30 to +40 °C,

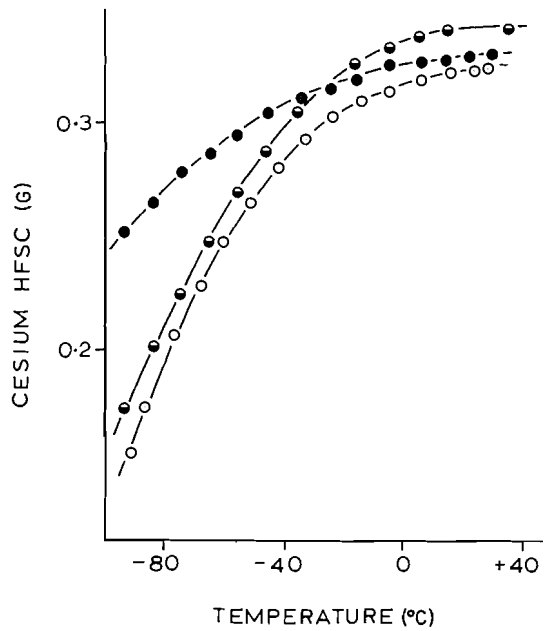

FIG. 3. Cesium hyperfine splitting constant of CsD plotted as a function of temperature in ○, THF; ●, DME; ◒, MeTHF.

including the slow intermediate, and fast exchange regions. Arrhenius parameters are listed in Table 1.

Discussion

Analysis of the line-widths of magnetic resonance spectra in terms of kinetic parameters has been attempted much more frequently for nuclear than for electronic resonances; hence the problems inherent in the analysis have been realized and discussed more fully by nuclear magnetic resonance (n.m.r.) spectroscopists (7, 8). Systematic errors have been shown to be particularly important when determining E_a and A, or in terms of the thermodynamic formulation of reaction rates, when determining $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ the enthalpy and entropy of activation. The principle systematic errors considered have been in the measurement of temperature and in the limitations of any approximations involved in the formulation of the spectra. It has been observed that, where several workers have studied a system, although the values reported for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ vary considerably, they may be combined to give consistent values for $\Delta G^{\ddagger}$, the free energy of activation. The reason for this compensation of errors is readily seen from the Arrhenius formulation: a too high value of the slope necessarily leads to a too high value of the intercept. The electron spin resonance (e.s.r.) experiment offers some advantages over the n.m.r. experiment when determining kinetic parameters; because the E_a values of processes typically studied *via* e.s.r. are lower than those studied *via* n.m.r., meaningful measurements can be made over wider temperature ranges, thereby reducing the effects of systematic errors in the measurement of temperature; magnet homogeneity does not play a critical role in determining line-shape and so need not be frequently readjusted; the spectra are normally (*i*) first order, so that a complete and simple description is readily available, and (*ii*) contain many lines, so that many cross checks on the results are available. The most important sources of potential error in the present work are temperature measurement, contributions to the spectrum from small amounts of unassociated semiquinone anion, assignment of a value for the electronic transverse relaxation time, and correction for anisotropic broadening mechanisms. The last three factors were treated in subjective fashion,

TABLE 2. Kinetic parameters for the intramolecular migration of cations within semiquinone ion-pairs. System number code as for Table 1

System number	Temperature (°K)	Δa (G)	$\Delta G^{\ddagger}$ (kcal)	$\Delta H^{\ddagger}$ (kcal)	$\Delta S^{\ddagger}$ (e.u.)

9	200	1.16	6.37	5.80	−2.9

input parameters to the simulation programme being varied until it was judged that optimum agreement between experimental and computed spectra had been obtained. The decision as to when optimum agreement was reached was made by measuring the amplitudes of all lines having satisfactory signal-to-noise ratios, relative to the amplitude of the central line. When the r.m.s. difference between the relative amplitudes of the experimental and computed lines was a minimum, it was taken that optimum agreement had been obtained.

The measured rate constants were fitted to the Arrhenius equation, partly to extract E_a and $\log_{10} A$ values and partly to check the internal consistency of each temperature run. From the optimum least squares fit straight line through the data values of k_{200} and k_{300}, the rate constant at 200 and 300 °K were determined from which $\Delta G^{\ddagger}_{200}$ and $\Delta G^{\ddagger}_{300}$ were obtained *via* the relationship.

$$k_T = \frac{kT}{h} \exp(-\Delta G^{\ddagger}/RT)$$

The enthalpy of activation is most readily obtained (9) for a unimolecular reaction from

$$E_a = \Delta H^{\ddagger} + RT$$

and may be combined with the free energy of activation to give the entropy of activation. Results of these computations are given in Table 2.

A number of systematic trends within the data are noticeable and worthy of comment. Previous empirical calculations have shown (3, 10) that Δa_{Me}, the difference between the methyl hyperfine splitting constants of a durosemiquinone ion-pair, locked into a "static" configuration, is a direct measure of the strength of the perturbation applied to the anion. In Fig. 4, Δa_{Me} measured at 200 °K is plotted against $1/r$, the reciprocal of the radius of the cation incorporated into the ion-pair. Except for the Cs/DME point, a system which Swarc and co-workers have already demonstrated to be exceptional with respect to cation solvation (11) and which also appears anomalous in Fig. 3, an excellent correlation exists between Δa_{Me} and $1/r$ indicating, as intuitively expected, that the perturbation of durosemiquinone produced by a cation is proportional to the polarizing

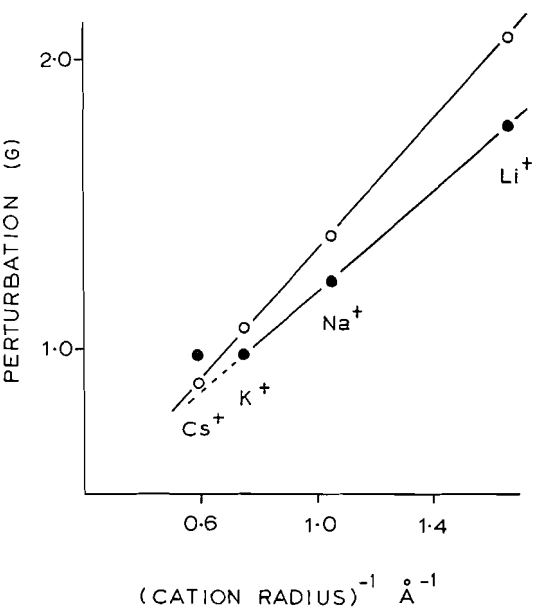

FIG. 4. Δa_{Me}, the perturbation of the hyperfine splitting constants of durosemiquinone produced by ionic association plotted as a function of inverse cation radius for ○ THF and ● DME. Sample temperature 200 °K; Li^+ data taken from (2).

power of the cation, and that Δa_{Me} may be used as a linear experimental parameter with which to estimate the strengths of the ionic interactions within the various ion-pairs examined.

In Fig. 5, $\Delta G^{\ddagger}$ measured as described above is plotted as a function of Δa; the data are for a temperature of 200 °K, with the exception of points *1'* and *2'* which are for 300 °K, only these sodium ion-pairs allowing a measurement of Δa_{Me} at 200 and 300 °K. Bearing in mind that the data in Fig. 5 cover three solvents, three cations, and two anions, the correlation between $\Delta G^{\ddagger}$ and Δa is very satisfactory, the r.m.s. error to the line drawn (0.63 kcal/mol) being comparable to those involved in fitting the raw data to the Arrhenius equation. The solid line in Fig. 5 has been drawn through the origin indicating that a hypothetical cation too large to perturb the anion will have a zero $\Delta G^{\ddagger}$ for the intramolecular exchange process. An increase in the strength of the ionic interaction, as measured by Δa, is accompanied by a linear increase in the free energy necessary to remove the cation from its equilibrium position close to one of the oxygens, and place it into the configuration of the activated complex, which must be symmetrical with respect to the two oxygens of the semiquinone.

Using the literature values (2) of Δa_{Me} for LiD in DME and THF, Fig. 5 may be used to estimate $\Delta G^{\ddagger}_{300}$ for LiD $\simeq$ 14 kcal mol^{-1}, corresponding to $k_{300} \simeq 10^3$ s^{-1}, a value compatible with the reported "static" geometry of the lithium ion-pair in these solvents.

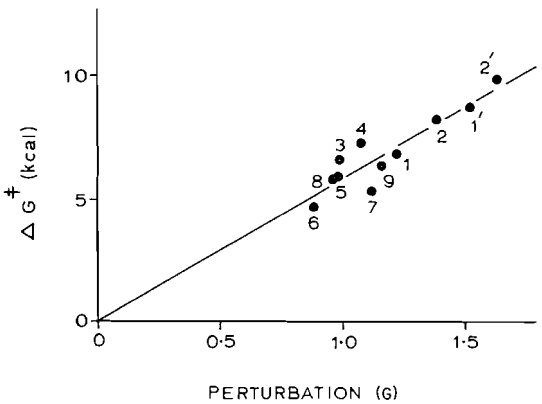

FIG. 5. Free energy of activation for intramolecular cation migration plotted as a function of the perturbation of the anion. Sample temperature 200 °K except *1'* and *2'* at 300 °K; numerals correspond to system numbers of Table 1.

The correlation found between $\Delta G^{\ddagger}$ and Δa indicates that the present measurements of the rates of intramolecular migration are at least internally consistent, and permits further speculation concerning the significance of E_a and A or, equivalently, of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Inspection of Table 2 shows that no correlation equivalent to Fig. 5 exists between $\Delta H^{\ddagger}$ and Δa. For example, in a given solvent $\Delta H^{\ddagger}$ for NaD is smaller than for KD even though Δa_{Me} is larger for the former species, but, for each of these ion-pairs, if Δa_{Me} is increased by changing the solvent from DME to THF then $\Delta H^{\ddagger}$ also increases. Conversely, the reverse trend is shown by the CsD ion-pair, $\Delta H^{\ddagger}$ being larger in the solvents where Δa_{Me} is smaller. Evidently, $\Delta H^{\ddagger}$ is not solely determined by the strength of the ionic interaction.

In Fig. 6 $\Delta H^{\ddagger}_{200}$ is plotted as a function of $\Delta S^{\ddagger}_{200}$ for all the systems studied; lines have been drawn to emphasize the relationship between data points for each of the ion-pairs. For any ion-pair, changing the solvent so as to increase $\Delta H^{\ddagger}$ also increases $\Delta S^{\ddagger}$ providing an example of the isokinetic principle discussed by Leffler (12). When $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are combined to form $\Delta G^{\ddagger}$ the contributions common to $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are cancelled out.

Some of the negative $\Delta S^{\ddagger}$ values observed are remarkably large when it is remembered that they apply to an elementary first order reaction, and can only mean that solvation plays an important role in determining the kinetics of these intramolecular migrations. In support of this statement there appears to be a rough correlation between the size of $\Delta S^{\ddagger}$ and the anticipated

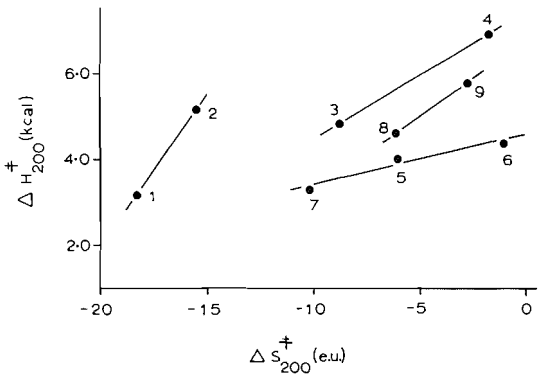

FIG. 6. Enthalpy of activation plotted as a function of entropy of activation for the intramolecular cation migration within semiquinone ion pairs at 200 °K: numerals correspond to system numbers of Table 1.

amount of cationic solvation in a system, the more negative values of $\Delta S^{\ddagger}$ being found for smaller cations and more polar solvents, though the cesium results are perhaps not as anticipated.

A negative entropy of activation indicates that there is a higher degree of order in the activated complex than in the reactants, which for the present systems must mean that the activated complex is more solvated than the reactant ion-pair. The higher degree of solvation postulated for the activated complex is in keeping with the greater charge separation in the symmetrical activated complex. Concurrent with the entropy change due to differential solvation of the reactant and the activated complex there will be an enthalpy change. The greater degree of solvation of the activated complex will decrease the value of $\Delta H^{\ddagger}$ and so, when discussing $\Delta H^{\ddagger}$, two factors must be considered; the difference in the enthalpy of ionic association between activated complex and reactant (positive) and the corresponding difference in solvation enthalpy (negative). Thus $\Delta H^{\ddagger}$ is not expected to be a linear function of Δa for a series of ion-pairs in differing environments because it is determined by the difference between larger terms of opposite sign, which, although related are not expected to be linearly dependent on one another. However, when $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are combined to form $\Delta G^{\ddagger}$, the effects of the differential solvation are cancelled out leaving only the effects of the ionic association.

The above interpretation of the kinetic parameters allows further speculation concerning the details of the mechanism of the migration, particularly for systems where $\Delta S^{\ddagger}$ is very negative and $\Delta H^{\ddagger}$ correspondingly smaller than expected, *e.g.* NaD in DME. Solvation of the activated complex provides a lower energy path for the reaction to follow; however, in order for this solvation to facilitate the reaction, because of the rapidity of the actual transfer it is necessary that the reaction proceeds only when the solvent adopts, by chance, a favorable configuration. The more developed and organized the solvation shell of the activated complex the less likely is this configuration to occur, hence the more negative is $\Delta S^{\ddagger}$. It should be noted that this description of the migration is in conflict with that of Claxton who treats the solvent as a time-independent continuum (13).

The quantitative agreement between the data in Table 1 and the available literature data is not impressive as far as the Arrhenius parameters are concerned. For KD in THF Das and co-workers (5) report $E_A = 5.96$ kcal $A = 4.3 \times 10^{11}$ s^{-1}; for KB in DME values of $E_A = 3.40$ kcal $A = 3.2 \times 10^{9}$ s^{-1} have been given (4). However, these parameters when converted to $\Delta G^{\ddagger}_{200}$ produce values of 6.87 and 6.72 kcal, respectively, each within 0.5 kcal of the appropriate number in Table 2.

This work was supported by an operating grant from the National Research Council of Canada and by a Province of Ontario Graduate Fellowship to P.R.H.

The anodic oxidation of cholesterol yields 3β,3′β-(methylenedioxy)-dicholest-5-ene. A new method for the preparation of methoxymethyl ethers of steroids is described. The n.m.r. and mass spectra of these compounds is reported.

L'oxydation anodique du cholestérol conduit au (méthylènedioxy)-3β,3′β dicholestene-5. On décrit une nouvelle méthode pour la préparation des éthers méthoxyméthylés des stéroides. On rapporte les spectres de r.m.n. et de masse de ces composés.

Canadian Journal of Chemistry, 49, 2418 (1971)

In order to confirm the identity of the main anodic oxidation product of cholesterol in aqueous acidic methanol as 3β,3′β-(methylenedioxy)-dicholest-5-ene (**1**) direct comparison with an authentic specimen was necessary.

Compound **1** was prepared by reaction of cholesterol and chloromethyl methyl ether in the presence of sodium hydride (1) and shown to be identical in all respects with the anodic oxidation product. Reaction of 5α-cholestan-3β-ol under the same conditions however gave a mixture of 3β,3′β-(methylenedioxy)-5α-cholestane (**2**) and 3β-(methoxymethoxy)-5α-cholestane (**3**) in poor yield.

As an alternative method for preparing compound **1**, the reaction of cholesterol and dimethoxymethane in the presence of acidic catalysts was investigated. The product thus obtained was 3β-(methoxymethoxy)-cholest-5-ene (**4**), the structure of which was confirmed by its n.m.r. (Table 1) and mass spectra (see below). This method was also used to prepare compound **3** and seems of general applicability. Methoxymethyl ethers have also been prepared by Kupchan *et al.* (1) by a modification of the method employing chloromethyl methyl ether.

The mass spectrum of compound **1** differs from that of cholesterol only in the greater abundance of the ions *m/e* 368 and 353 relative to 386 (the molecular ion of cholesterol). Higher mass ions cannot be detected and no metastable transition can be found in the first field-free region of the spectrometer (2) for the decomposition of the parent molecular ion (M^+, *m/e* 784) to either 386 or 368. Evidently a very ready fragmentation, either thermal or electron impact induced, results in the formation of the molecular ions of cholesterol and cholestadiene. The mass spectrum of 3β-(methoxymethoxy)-cholest-5-ene (**4**) is also very similar to that of cholesterol and shows no parent molecular ion (*m/e* 430). Higher mass ions are very weak in the spectrum of compound **2** but the decomposition 788 (M^+) → 402 can be detected in the first field-free region. The latter together with a fairly intense ion at *m/e* 386 suggests a fragmentation producing (nominally) the molecular ion of methoxycholestane and of cholestanone. The mass spectrum of 3β-(methoxymethoxy)-5α-cholestane is remarkable. The molecular ion (*m/e* 432) is one of the strongest in the spectrum while another (370) is derived from it by loss of methoxymethanol. Such an intense molecular ion appears to be without precedent for an acetal (3).

Experimental

The n.m.r. spectra were determined for deuteriochloroform solutions with tetramethylsilane as an internal reference using a Varian A-60 spectrometer. Mass spectra were determined using an A.E.I. MS9 instrument, samples being inserted directly into the ion source at the lowest possible temperature.

Anodic Oxidation of Cholesterol

Cholesterol (1 g) was partially dissolved in methanol (40 ml), water (40 ml), and 20% sulfuric acid (5 ml), and electrolyzed (4) for 5 h on a lead dioxide electrode (30 V, 2 A) with agitation and external cooling (ice–water). The mixture was extracted with methylene chloride and the extract washed free of acid. The residue on evaporation was crystallized several times from methylene chloride – acetone giving 3β,3′β-(methylenedioxy)-dicholest-5-ene, m.p. 191°, $[\alpha]_D$ −36° (lit. (1) m.p. 190.5°, $[\alpha]_D$ −30.8°).

Anal. Calcd. for $C_{55}H_{92}O_2$ (mol. wt. 785): C, 84.12; H, 11.81. Found (770 (Rast)): C, 83.93; H, 12.01.

Reaction of 5α-Cholestan-3β-ol with Chloromethyl Methyl Ether

5α-Cholestan-3β-ol (3.14 g) was added to a suspension of 50% sodium hydride (0.24 g NaH) in dry benzene (50 ml) and the mixture refluxed for 30 min. Chloromethyl methyl ether (1.1 g) was added dropwise to the cooled mixture which was then agitated for 18 h. Water was added and the organic layer separated and evaporated to dryness. The residue was separated on a dry silica gel column using methylene chloride as a solvent giving 3β-(methoxymethoxy)-5α-cholestane (243 mg), m.p. 61°, after crystallization from ethyl acetate – methanol, $[\alpha]_D$ +17° ($CHCl_3$).

Anal. Calcd. for $C_{29}H_{52}O_2$: C, 80.49; H, 12.11. Found: C, 80.64; H, 12.21.

Later fractions yielded 3β,3′β-(methylenedioxy)-di-5α-cholestane (100 mg), m.p. 206–207°, after crystallization from ethyl acetate, $[\alpha]_D$ +1° ($CHCl_3$).

Anal. Calcd. for $C_{55}H_{96}O_2$: C, 83.69; H, 12.36. Found: C, 83.47; H, 12.19.

3β-(Methoxymethoxy)-cholest-5-ene

To cholesterol (1 g), dimethoxymethane (10 ml), and dry tetrahydrofuran (10 ml) was added perchloric acid (70%, 5 drops). After agitation for 24 h at room temperature, solid Na_2CO_3 was added, the solids removed by filtration, and the filtrate evaporated to dryness. Chromatography of the residue on neutral alumina in hexane gave the title compound (265 mg), m.p. 76–78°, after crystallization from methylene chloride – methanol, $[\alpha]_D$ −23° (in $CHCl_3$) (lit. (1) m.p. 85–86°).

Anal. Calcd. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70. Found: C, 80.94; H, 11.70.

3β-(Methoxymethoxy)-5α-cholestane

This was prepared from 5α-cholestan-3β-ol and dimethoxymethane as described above. It was purified by chromatography on basic alumina (Bio Rad A 10) and crystallization from ethyl acetate – methanol, yield 41%, m.p. 62°, $[\alpha]_D$ +20° (in $CHCl_3$).

One of us (J.E.H.) thanks the Royal Society of Great Britain for a travel grant. We thank Mr. J. N. Bilton for assistance in measuring the mass spectra.

Steroids and Steroidases. XI.[1] Synthetic Approaches to C-17 Bis(2-hydroxyethyl)-amino Compounds as Potential Precursors of 17-Hydroxyandrostane Nitrogen Mustards[2]

J. Bryan Jones and Jeffrey D. Leman

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 1, 1971

The synthesis of some potential nitrogen mustard precursor 17α-bis(2-hydroxyethyl)aminomethyl androst-17β-ol derivatives has been achieved by two routes. During the investigation, unequivocal proof was obtained that addition of cyanide to 17-keto steroids gives predominantly 17β-hydroxy-17α-cyano epimers.

On rapporte la synthèse par deux voies différentes de quelques dérivés de bis(hydroxy-2 éthyl) aminométhyl-17α-androstol-17β qui sont possiblement actifs comme moutardes azotés. Au cours de ces travaux, on a pu obtenir des preuves sans équivoques que l'addition du cyanure sur les 17-cétastéroïdes conduit principalement aux épimères hydroxy-17β cyano-17α.

Canadian Journal of Chemistry, 49, 2420 (1971)

In the search for anti-tumor effective nitrogen mustards many compounds in which a steroid molecule has been used as a carrier for the bis(2-chloroethyl)amino group have been examined.[3] We have previously synthesized and evaluated some androstane C-17 mustard compounds in which hormonally important ring A functional groups were present (2) and this communication describes our attempts to extend the investigation to androstane mustards in which *both* the ring A Δ^4-3-keto and ring D 17β-hydroxyl functions of 17β-hydroxyandrost-4-en-3-one (testosterone) were retained.

The compound selected as the initial target was the 17α-bis(2-chloroethyl)aminomethyl testosterone (**1***a*). The reservations expressed (2) regarding the usefulness of aliphatic nitrogen mustards in cancer chemotherapy owing to their high reactivity potential do not necessarily apply to hydroxy mustards of this type since for such compounds formation of a five-membered hydrogen bonded ring (3) should prolong the physiological activity by retarding the formation of the active ethylenimmonium ion species (4, 7–9).[4]

Our earlier studies (2) had indicated syntheses involving chlorination of bis(2-hydroxyethyl)-amino precursors in the final step to be the most satisfactory for the preparation of steroid mustards. Similar pathways to **2***a* were therefore examined and, as summarized in Schemes 1 and 3, two routes to the precursor triol **2***b* proved satisfactory. In the cyanohydrin approach (Scheme 1), 5α-androstan-17-one (**3**) was found to react smoothly with potassium cyanide in acetic acid to give in 87% yield a mixture of the C-17 cyanohydrin epimers in which the 17β-hydroxy compound **4** predominated to a large extent.[5] Reduction of **4** with lithium aluminum hydride followed by reaction with ethylene oxide gave the 2-hydroxyethylamino compound **2***b* in 38% overall yield.

The synthesis of the analogous bis(2-hydroxyethyl)amino precursor **1***b* of androst-4-en-3-one was also achievable via cyanohydrin routes and the two pathways followed are outlined in Scheme 2. The sequence **6** → **7** → **8** → **9** was explored first and although ketalization of testosterone (**6**) followed by Sarett oxidation of the C-17 hydroxyl group proceeded smoothly to give the 17-keto-3-ketal **8** in good yield, the presence of the ketal function posed problems with regard to the subsequent C-17 cyanohydrination reaction. The use of the acidic potassium

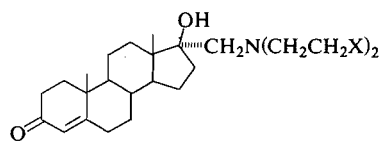
[1]For Part X see ref. 2.

[2]Abstracted from ref. 1. First presented in part at the C.I.C. Conferences, Montreal, Quebec, May 1969 and Toronto, Ontario, May 1970.

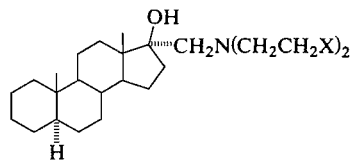
[3]A comprehensive review of nitrogen mustards is included in ref. 1 and the most relevant steroid literature is cited and discussed in ref. 2.

[4]It has been pointed out by Ross (4) and others (5, 6) that competition with chlorine for the lone pair of electrons on nitrogen produces modifications of biological actions of nitrogen mustards.

[5]That the desired 17β-hydroxy-17α-cyano compound would be the major product was expected from a consideration of the known preference for α-attack of the 17-carbonyl group by the cyanide ion in closely related steroids (10).



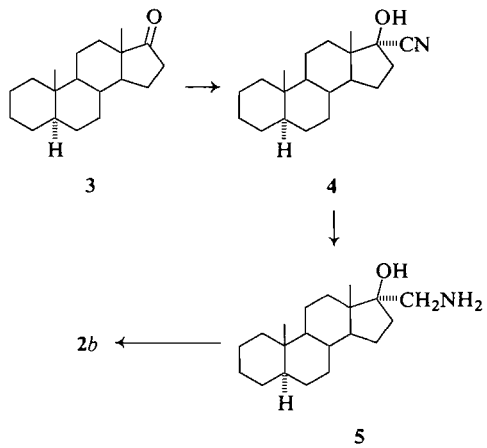
1



2

a X = Cl
b X = OH

cyanide conditions found to be satisfactory in the case of the model compound **3** was precluded by the acid sensitivity of the 3-ketal of **8** and it was found necessary to employ *trans*-cyanohydrination with acetone cyanohydrin. Again one epimer predominated in the mixture produced and this was assigned the 17β-hydroxy configuration shown in **9** for the reasons cited above for the 5α-androstane analogue.



SCHEME I

Since the yields obtained of **9** in the last step of the above sequence were influenced quite markedly by minor variations in the *trans*-cyanohydrination reaction conditions, the alternative route to **9** via intermediates **10** and **11** was also investigated. On treatment of **10** with acetone cyanohydrin, selective reaction (11) at C-17 was achieved to give the 17β-hydroxy epimer **11** in 74% yield. Its subsequent ketalization was readily accomplished to give samples of **9** of superior purity and in higher overall yield (53% as opposed to 38%) than obtained by the initial route.

The subsequent transformations of **9** into the bis(2-hydroxyethyl)amino ketal **12** by lithium aluminum hydride reduction followed by ethylene oxide alkylation were accomplished in 46 and 73% yields respectively and preliminary experiments showed that acid-catalyzed deketalization of **12** to give the Δ^4-3-keto compound **1***b* could be readily achieved when required.

The cyanohydrin routes discussed above suffer from the disadvantage that the final yields obtained of the desired mustard precursors are rather low owing to the problems encountered in the cyanohydrin reduction steps where partial dissociation of the hydroxynitriles to the corresponding ketones during reduction could not be prevented even when the cyanohydrin acetates were used (12). A further cause for dissatisfaction with the cyanohydrin routes was that although the C-17 configurational assignments made were felt to be fairly secure on the basis of their analogy with earlier work in similar steroidal systems (10) no physical or chemical data had been obtained which would permit the C-17 stereochemistries of the cyanohydrins and their derivatives to be accepted unequivocally. Therefore, in an attempt to improve the yields of **1***b* and **2***b* and in order to remove all ambiguity from the assignment of their C-17 geometries, the alternative approaches involving the oxiranes **13** and **17** outlined in Schemes 3 and 4 were investigated.

5α-Androstan-17-one (**3**) was converted stereospecifically[6] by reaction with dimethylsulfonium methylide to give spiro-17β-oxiranyl-5α-androstane (**13**) in 84% yield. The 17β-configuration of the epoxide group was verified by reduction of **13** with lithium aluminum hydride to 17α-methyl-5α-androstan-17β-ol (**14**, 70% yield) which showed peaks in the p.m.r. spectrum for the C-17 proton, and C-18 and -19 methyl groups at chemical shifts characteristic of 17β-hydroxy-17α-methyl steroids (13, 14) and which was identical in all respects with an authentic sample prepared unambiguously from 17α-methyltestos-

[6]That a single C-17 epimer only was formed was confirmed by the p.m.r. spectrum which showed the C-18 methyl protons as a sharp *singlet* at δ 0.86 p.p.m. only.

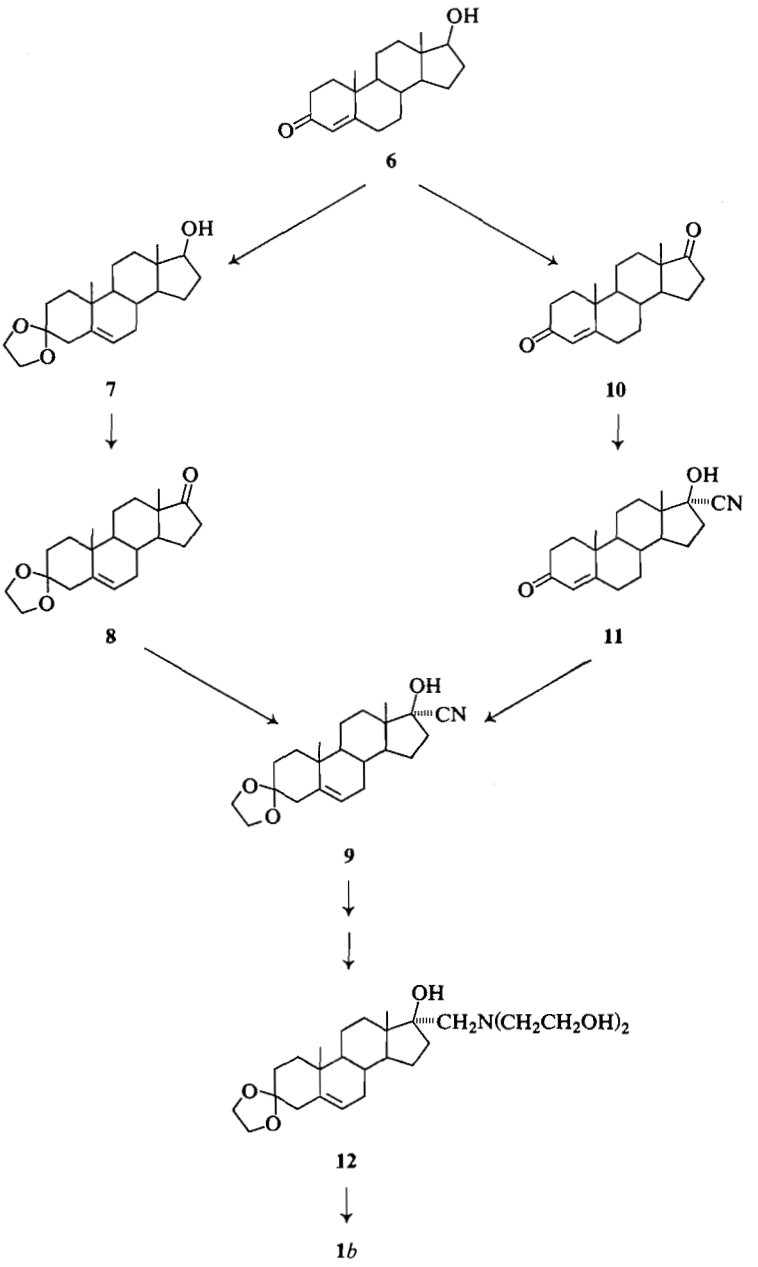

SCHEME 2

terone (**15**). The oxirane **13** was condensed with bis(2-hydroxyethyl)amine in ethylene glycol at 160° (15) and 92% of the mustard precursor triol **2***b* was obtained directly as the sole product.[7] A comparison of this sample of **2***b* of chemically verified C-17 stereochemistry with that obtained by the cyanohydrin route of Scheme 1 showed both to be identical in all respects. This therefore established unambiguously that the major products of cyanide ion addition to the C-17 carbonyl group of **3**, and by analogy to those of **8** and **10**,

[7]When water was used as a catalyst (16), a 42% yield only was obtained.

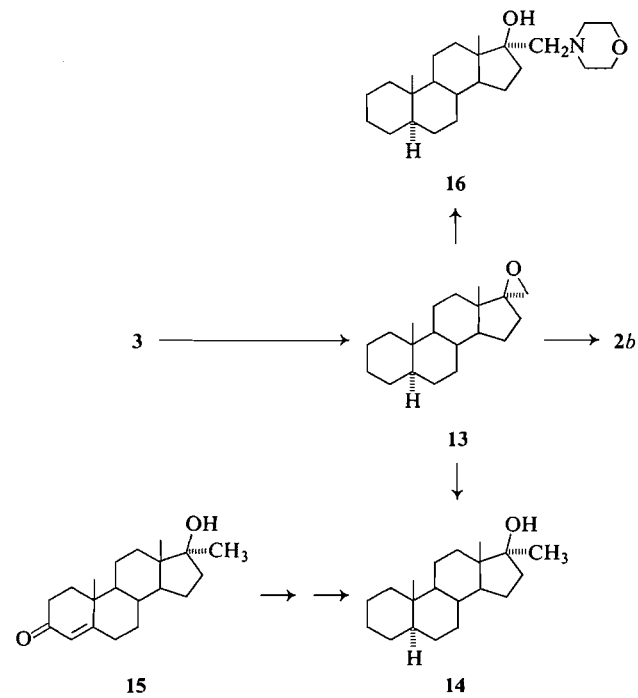
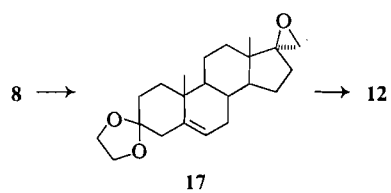


SCHEME 3

were the cyanohydrins **4**, **9**, and **11** respectively as had been predicted from steric considerations.[5] The overall yield (80%) of the triol **2*b*** from the starting ketone **3** by the oxirane route was much higher than that obtained via the cyanohydrin intermediates (38%) and thus was much the preferred synthetic method. Unfortunately, the preparation of the Δ^4-3-keto mustard precursor **1*b*** via reaction of the oxirane **17** with bis(2-hydroxyethylamine to give the ketal **12** (Scheme 4), followed by mild hydrolysis, turned out to be less satisfactory than for the analogous route described above for the model series (Scheme 3) the overall yield of **12** from testosterone (**6**) being only 15%.

Disappointingly, all attempts to effect the conversion of the mustard precursors **1*b***, **2*b***, and **12** into the corresponding bis(2-chloroethyl)amino derivatives were unsuccessful. Application of such reagents as thionyl chloride, phosphoryl chloride, and methane sulfonyl chloride under the conditions delineated previously (2) for other sensitive androstane compounds afforded extensively decomposed, complex, reaction mixtures in which none of the desired or related mustards could be detected even by the sensitive p.m.r. and mass spectral diagnostic methods (2). Major difficulties in achieving the desired selective chlorinations had, of course, been anticipated but surprisingly the products of the expected competitive reactions, such as $\Delta^{16,17}$, perhydrooxazino, and morpholino[8] derivatives, were not formed in isolable quantities either. Direct conversion of the oxiranes **13** and **17** to the corresponding nitrogen mustards by condensation with bis(2-chloroethyl)amine (17) was also attempted under a variety of conditions but in most cases the starting oxiranes were recovered quantitatively. Under forcing conditions (130° in alcoholic solvents in sealed tubes) multiple reactions occurred but in no instance was any steroid mustard detectable. The marked instability of nitrogen mustard itself to elevated tempera-



SCHEME 4

[8]For reference purposes a sample of one such possible product, **16**, was prepared by the phenol-catalyzed reaction of the oxirane **12** with morpholine.

tures (18) was presumably a major factor in the failure of this approach.

In view of the discouraging results encountered in the final stages it is considered unlikely that the approaches described above can be modified sufficiently to provide satisfactory syntheses of the mustards **1***a* and **2***a* and alternative routes to these latter compounds are now being explored.

Experimental

Melting points were determined on a Fisher–Johns block and are corrected. The i.r. spectra were recorded on a Perkin–Elmer 237 B or 257 spectrometer. The p.m.r. spectra were determined in deuteriochloroform with tetramethylsilane as the internal standard on a Varian A-60 or HA-100 instrument. Column chromatographic separations were effected with Fisher Scientific Co. Florisil or neutral alumina deactivated with 2% w/w of water. The t.l.c. and preparative layer chromatography was performed on silica gel G and the compounds were visualized with iodine vapor or under u.v. light. Unless otherwise stated, all compounds described were purified until they were homogeneous to t.l.c. analysis.

17α-Bis(2-hydroxyethyl)aminomethyl-5α-androstane (2b)

(a) Cyanohydrin Route

A solution of 5α-androstan-17-one (1 g, 3.7 mmol) in absolute ethanol (125 ml) was added to a solution of potassium cyanide (11 g) in water (50 ml). The mixture was cooled in an ice bath and glacial acetic acid (15 ml) was added dropwise with stirring. The resulting solution was stirred for 1 h, and was then diluted with water (200 ml) and filtered to give the *17α-cyano-5α-androstan-17β-ol* (**4**, 0.96 g, 87%), m.p. 120–124°; i.r. (KBr) 3448, 2232, and 1730 cm^{-1} (C-17 carbonyl impurity).[9]

A solution of the above cyanohydrin (2.50 g, 8.3 mmol) in anhydrous benzene–ether (1:1, 500 ml) was added dropwise during 1 h at 0° to a well-stirred slurry of lithium aluminum hydride (0.48 g, 12.5 mmol) in anhydrous ether (250 ml). The mixture was then refluxed 18 h, and water (50 ml) followed by 10% aqueous sodium hydroxide (50 ml) were added dropwise in the presence of Celite. The resulting mixture was filtered, and the filtrate dried ($MgSO_4$) and evaporated. The residual solid (1.3 g) was combined with the material (0.95 g) obtained by Soxhlet extraction[10] of the filter cake with chloroform–methanol (1:1). The product so obtained was shown by g.l.c., t.l.c., and p.m.r. analyses to contain 18% of 5α-androstan-17β-ol[11] and 82% of the desired *17α-aminomethyl-5α-androstan-17β-ol* (**5**) which was used without further purification.

A solution containing the aminomethyl alcohol **5** (0.5 g, 1.27 mmol) in the minimum amount of chloroform (*ca.* 15 ml) was added rapidly to a stirred solution of ethylene oxide (10 ml) in methanol (20 ml), at 0°. The reaction flask was tightly stoppered and stirring was continued for a further 1 h at 0°. The solution was then kept at 20° for a further 2 days and was then refluxed for 8 h using an acetone – Dry Ice coating system to condense the remaining ethylene oxide. The solvent was removed by rotary evaporation at 20° and the yellow residue obtained (0.45 g) was purified by chromatography on Florisil. Elution with chloroform removed the 5α-androstan-17β-ol (35 mg) impurity and subsequent elution with chloroform–methanol–ammonia (90:15:1) afforded a colorless solid (0.39 g) which was recrystallized from methylene chloride to give *17α-bis(2-hydroxyethyl)-aminomethyl-5α-androstan-17β-ol* (**2***b*) (0.37 g, 58%),[12] m.p. 182–183°; i.r. ($CHCl_3$) 3448 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.78 (3H, s, C-19 CH_3), 0.85 (3H, s, C-18 CH_3), 2.68 (2H, midpoint of AB quartet superimposed on signal centered at 2.78 p.p.m., C-17 CH_2N), 2.78 (4H, 't', J = 4.8 Hz, NCH_2CH_2OH), 3.35 (3H, m, partially exchangeable with D_2O, OH), and 3.62 p.p.m. (4H, 't', J = 4.8 Hz, $NCHCH_2OH$).

(b) Oxirane Route

A mixture of spiro-17β-oxiranyl-5α-androstane (**13**, 60 mg, 0.21 mmol), bis(2-hydroxyethyl)amine (1 ml), and ethylene glycol (2 ml) was heated in a sealed tube at 160° for 5 h. The mixture was then poured into water and filtered. The solid obtained was dissolved in the minimum amount of anhydrous ether (20 ml) and hydrogen chloride was bubbled into the solution. The precipitate produced was filtered, washed with anhydrous ether, and dried *in vacuo* to give the hydrochloride (76 mg) which was resuspended in ether (50 ml) and then stirred with saturated aqueous sodium hydrogen carbonate (50 ml) for 1 h. The ether layer was then separated, washed with water (2 × 15 ml), and dried ($MgSO_4$). Evaporation of the solvent and recrystallization of the residue from methylene chloride gave the bis(2-hydroxyethyl)amino alcohol **2***b* (75 mg, 92%) which was identical in all respects to the material obtained above from the cyanohydrin route.

The analogous preparation of **2***b* using water as a solvent gave a 42% yield only.

Spiro-17β-oxiranyl-5α-androstane (13)

A 53.8% suspension of sodium hydride in mineral oil (0.65 g, 14.6 mmol) was washed with tetrahydrofuran by

[9]Recrystallization of this material from methanol did not remove the trace of the starting ketone **3** and attempted purification via column chromatography on alumina afforded 5α-androstan-17-one only. Accordingly the cyanohydrin **4** was used in its initially isolated form for the subsequent reaction.

[10]Several groups have observed that the filter cakes obtained during metal hydride reduction of cyanohydrins retain a considerable proportion of the desired amines (10, 19).

[11]The formation of the relatively large amount of this compound arises from the significant disproportionation which occurs during reduction of the cyanohydrin to the original C-17 ketone and cyanide ion (12).

[12]In spite of the application of various purification procedures satisfactory analytical data could not be obtained for this compound, nor for its hydrochloride. Analytical difficulties with steroid mustard compounds and intermediates have also been encountered previously (2, 20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

decantation. Dry dimethyl sulfoxide (10 ml) was added and the mixture was stirred for 45 min at 70° under nitrogen. Tetrahydrofuran (10 ml) was then added, the mixture cooled to −5°, and solution of trimethylsulfonium iodide (30 g, 14.6 mmol) in dimethyl sulfoxide (23 ml) added rapidly with stirring (13). During this addition the reaction mixture solidified and the addition of further tetrahydrofuran (14 ml) became necessary. 5α-Androstan-17-one (**3**) (1.0 g, 3.65 mmol) in tetrahydrofuran (30 ml) was then added to the mixture and after being kept at 20° for 15 h the whole was poured into water (150 ml) and extracted with ether (4 × 75 ml). The combined ether extracts were washed with water (2 × 25 ml), dried ($MgSO_4$), and evaporated. The residue (0.93 g) was purified by chromatography on alumina and elution with petroleum ether (60–70°). Recrystallization from acetone gave *spiro-17β-oxiranyl-5α-androstane* (**13**) as feathery plates (0.88 g, 84%), m.p. 160–161°; p.m.r. ($CDCl_3$) δ 0.78 (3H, s, C-19 CH_3), 0.86 (3H, s, C-18 CH_3), and 2.71 p.p.m. (2H, midpoint of AB quartet, δ_A 2.82, δ_B 2.52, J_{AB} = 5.0 Hz, C-17 CH_2).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 83.22; H, 11.31.

17α-Methyl-5α-androstan-17β-ol (**14**)

(a) From the Oxirane (**13**)

Spiro-17β-oxiranyl-5α-androstane (**13**) (300 mg, 1.04 mmol) was refluxed for 4 h with lithium aluminum hydride (0.30 g, 7.8 mmol) in tetrahydrofuran (50 ml). Ethyl acetate (50 ml) was then carefully added to the cooled reaction mixture following which it was poured into aqueous hydrochloric acid (5%, 150 ml). The mixture was extracted with benzene (3 × 40 ml) and the combined extracts were washed with water and dried ($MgSO_4$). Evaporation gave a colorless solid (225 mg) which recrystallized from acetone to produce *17α-methyl-5α-androstan-17β-ol* (**14**) as plates (210 mg, 70%), m.p. 165–166°; i.r. ($CHCl_3$) 3597 and 3472 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.79 (3H, s, C-19 CH_3), 0.82 (3H, s, C-18 CH_3), and 1.18 p.p.m. (3H, s, C-17 CH_3).

Anal. Calcd. for $C_{20}H_{34}O$: C, 82.69; H, 11.80. Found: C, 82.45; H, 11.95.

(b) From 17β-Hydroxy-17α-methylandrost-4-en-3-one (**15**)

17β-Hydroxy-17α-methylandrost-4-en-3-one (**15**, 4 g, 13.2 mmol) was converted, via lithium in liquid ammonia, followed by Wolff–Kishner reductions (21) into authentic 17α-methyl-5α-androstan-17β-ol (**14**, 1.95 g, 50%) which was identical in all respects with the material obtained above.

17α-Bis(2-hydroxyethyl)aminomethyl-3,3′-ethylenedioxyandrost-5-en-17β-ol (**12**)

(a) Cyanohydrin Routes

3,3′-Ethylenedioxy-17β-hydroxyandrost-5-ene (**7**) m.p. 183–184° (lit. (22) m.p. 182–184°) was obtained from testosterone (**6**) in 46% yield (22). Oxidation of **7** with chromium trioxide in pyridine (22) proceeded smoothly to give 3,3′-ethylenedioxyandrost-5-en-17-one (**8**) m.p. 196–197° (lit. (22) m.p. 197–198°) in 80% yield. Freshly prepared (23) acetone cyanohydrin (1 ml) was added to the ketal **8** (200 mg, 0.61 mmol) dissolved in the minimum quantity of warm methanol. The resulting solution was heated on a steam bath for 3 min and a few drops of a methanolic solution containing 2% w/w of potassium cyanide were added. After keeping for 4 h at 20° the crystalline precipitate was filtered off, washed with water, and then dried *in vacuo* to give 3,3′-ethylenedioxyandrost-5-ene-17-cyanohydrin (**9**, 180 mg, 83%), m.p. 205–209° (lit. (11) m.p. 185°); i.r. (KBr) 3390 and 1739 cm^{-1} (C-17 carbonyl impurity). This material was not further purified but was used directly in subsequent experiments (*cf.* footnote 9).

Alternatively, the cyanohydrin **9** could be prepared from androst-4-ene-3,17-dione (**10**).

Androst-4-ene-3,17-dione (2 g, 7.0 mmol) was dissolved by gentle warming and swirling in freshly prepared (23) acetone cyanohydrin (3 ml). The solution was allowed to stand for 2 h at 20° and was then diluted with water (15 ml) and extracted with ether (4 × 40 ml). The combined ether extracts were washed with water and the ether solution was then cooled in an ice bath. The precipitated crystalline mass was filtered and dried *in vacuo* to give crude androst-4-en-3-one-17-cyanohydrin (**11**) (1.62 g, 74%), m.p. 174–180° (lit. (11) m.p. 176–178°); i.r. (KBr) 2279, 2237, 1656, and 1739 cm^{-1} (C-17 C=O impurity). No attempt was made to further purify this material (*cf.* footnote 9).

A suspension of the above cyanohydrin **11** (1.0 g, 3.2 mmol) in benzene (65 ml) and ethylene glycol (1.30 ml) with toluene-*p*-sulfonic acid (0.1 g) was refluxed for 16 h in a Soxhlet extractor with the water formed during the reaction being removed with molecular sieves. Evaporation of the solvent and recrystallization of the residue from methanol containing a few drops of pyridine produced the cyanohydrin ketal **9** (0.91 g, 80%), m.p. 205–208°. The i.r. spectrum of this material indicated that less C-17 carbonyl impurity was present than in the previous material, m.p. 205–209°, obtained above.

3,3′-Ethylenedioxyandrost-5-ene-17-cyanohydrin (**9**) (1.20 g, 34 mmol) was treated with lithium aluminum hydride (0.19 g, 5.1 mmol) and the reaction mixture worked-up as described for the synthesis of the 5α-androstane analogue **5**. The product obtained by extraction of the filter cake[10] (0.51 g) was combined with the material obtained by evaporation of the supernatant (0.66 g) and the whole chromatographed on Florisil. Elution with chloroform gave 3,3′-ethylenedioxyandrost-5-en-17β-ol[9] (0.30 g) and elution with chloroform – methanol – ammonium hydroxide (90:15:1) produced the amino-carbinol **12** (0.56 g, 46%) which was recrystallized from benzene as prisms, m.p. 240°; i.r. (KBr) 3778, 3300, 3175, 1107, and 1093 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.90 (3H, s, C-18 CH_3), 1.02 (3H, s, C-19 CH_3), 2.70 (2H, midpoint of AB quartet superimposed on other H signals, δ_A 2.90, δ_B 7.50, J_{AB} = 12.8 Hz, C-17 CH_2N), 3.90 (4H, s, OCH_2CH_2O), and 5.31 p.p.m. (1H, m, vinyl H). Mass spectrum (70 eV) *m/e* 361 (parent ion).

3,3′-Ethylenedioxy-17β-hydroxy-17α-aminomethylandrost-5-ene (**12**) (0.30 g, 0.83 mmol) and ethylene oxide (6 ml) were reacted and worked-up as described above for the synthesis of the model compound **2***b*. Recrystallization of the product from methylene chloride gave *17α-bis(2-hydroxyethyl)aminomethyl-3,3′-ethylenedioxyandrost-5-en-17β-ol* (**12**) as plates (270 mg, 72%), m.p. 199–201°; i.r. ($CHCl_3$) 3425, 1663, and 1096 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.90 (3H, s, C-18 CH_3), 1.03 (3H, s,

C-19 CH_3), 2.69 (2H, m, superimposed on signal centered at 2.77 p.p.m., C-17 CH_2N), 3.40 (3H, m, partially exchangeable with D_2O, OH), 3.61 (4H, 't', $J = 5.5$ Hz, NCH_2CH_2OH), 3.90 (4H, s, OCH_2CH_2O), and 5.29 p.p.m. (1H, m, vinyl H). Mass spectrum (70 eV) *m/e* 449 (parent ion).

Anal. Calcd. for $C_{26}H_{43}NO_5$: C, 69.45; H, 9.64; N, 3.11. Found: C, 69.13; H, 9.48; N, 3.47.

(b) Oxirane Route

3,3′-Ethylenedioxyandrost-5-en-17-one (**8**, 1 g, 3 mmol) was reacted with dimethylsulfonium methylide as described above in the preparation of the oxirane **13**. 3,3′-Ethylenedioxy-spiro-17β-oxiranylandrost-5-ene (**17**) was obtained as feathery plates (0.88 g, 88%) from acetone, m.p. 185–190°; i.r. ($CHCl_3$) 1096 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.94 (3H, s, C-18 CH_3), 1.09 (3H, s, C-19 CH_3), 2.78 (2H, midpoint of AB quartet, δ_A 2.78, δ_B 2.63, $J_{AB} = 4.9$ Hz, oxiranyl CH_2), 3.97 (4H, s, OCH_2CH_2O) and 5.40 p.p.m. (1H, m, vinyl H).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.65; H, 9.36. Found: C, 76.75; H, 9.43.

A mixture of the spiro-17β-oxiranyl-3-ketal **17** (0.50 g, 1.45 mmol), bis(2-hydroxyethyl)amine (25 ml), and water (6 ml) was reacted and worked-up by the procedure described above for the conversion of the oxirane **13** into **2***b*. Recrystallization of the product from methylene chloride yielded 0.31 g (48%) of the aminotriol **12** identical in all respects with the material obtained via the cyanohydrin route.

17α-(N-Morpholinomethyl)-5α-androstan-17β-ol (16)

A solution of spiro-17β-oxiranyl-5α-androstane (**13**, 125 mg, 0.44 mmol) in morpholine (5 ml) containing phenol (55 mg) was refluxed for 24 h. The solution was then poured into water (25 ml) and extracted with ether (3 × 20 ml). The combined ether extracts were washed with aqueous sodium hydroxide (10%, 3 × 10 ml), then with water (2 × 15 ml), and dried ($MgSO_4$). Evaporation of the solvent and recrystallization of the residue (130 mg) from methanol gave *17α-(N-morpholinomethyl)-5α-androstan-17β-ol* (**16**, 108 mg, 66%), m.p. 160–161.5°; i.r. ($CHCl_3$) 3425 cm^{-1}; p.m.r. ($CDCl_3$) δ 0.78 (3H, s, C-19 CH_3), 0.87 (3H, s, C-18 CH_3), 2.24–2.68 (6H, m, NCH_2CH_2O and C-17 CH_2N), 3.48 (1H, s, OH), and 3.71 p.p.m. (4H, 't', NCH_2CH_2O, $J = 4.4$ Hz).

Anal. Calcd. for $C_{24}H_{41}NO_2 \cdot \frac{1}{2}H_2O$: C, 74.95; H, 11.07; N, 3.64. Found: C, 75.27; H, 10.98; N, 3.78.

Pyrrole Chemistry. Part XIII. New Syntheses of 3-Alkylpyrroles

J. K. GROVES, HUGH J. ANDERSON, AND (IN PART) H. NAGY
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received March 22, 1971

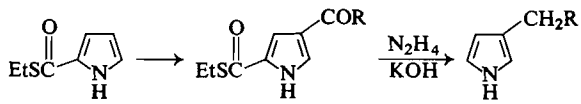
3-*n*-Alkylpyrroles are prepared in good yield by a combined Wolff–Kishner reduction and hydrolysis and decarboxylation of 4-acyl-2-pyrrolethiolcarboxylates. Methyl 4-isopropyl-2-pyrrolecarboxylate and 4-*t*-butyl-2-pyrrolecarbonitrile are prepared by alkylation of methyl 2-pyrrolecarboxylate and 2-pyrrolecarbonitrile respectively. Hydrolysis and decarboxylation of these disubstituted compounds afford the corresponding 3-alkylpyrroles. Mass spectral data for some 1-, 2-, and 3-alkylpyrroles are reported.

Les alkyl-3-*n* pyrroles sont préparés avec un bon rendement par réduction de Wolff–Kishner, hydrolyse et décarboxylation des acyl-4 pyrrolethiolcarboxylates-2. L'isopropyl-4 pyrrolecarboxylate-2 de méthyle et le *t*-butyl-4 pyrrolecarbonitrile-2 sont préparés par alkylation respectivement du pyrrolecarboxylate-2 de méthyle et du pyrrolecarbonitrile-2. L'hydrolyse et la décarboxylation de ces composés disubstitués conduit aux alkyl-3 pyrroles correspondants. On rapporte les données de spectrométrie de masse pour des alkyl-1, -2, et -3 pyrroles.

Canadian Journal of Chemistry, 49, 2427 (1971)

Although numerous monoalkylpyrroles are known good synthetic routes to the 3-alkylpyrroles, with the possible exception of 3-methylpyrrole (1–6), are notably absent. Skell and Bean (7) have prepared numerous 3-alkylpyrroles by the alkylation of pyrrylmagnesium bromide. The low yields of 3-isomer so obtained (5–18%) together with the necessity of effecting separation from relatively large amounts (10–32%) of 2-alkylpyrrole have prompted us to devise new synthetic routes to the former compounds.

We have previously shown (8) that a 2-ethylthiolcarboxylate substituent at the pyrrole nucleus directs Friedel–Crafts acylation and formylation almost exclusively to the 4-position. We now report that the resulting 2,4-substituted pyrroles are readily converted to the corresponding 3-alkylpyrroles by a combined Wolff–Kishner reduction of the acyl substituent and hydrolysis and decarboxylation of the thiolester group (Scheme 1). Yields for the reaction were



SCHEME 1

in the range 44–91% representing yields of 15–31% from pyrrole itself. The preparations of 3-methyl-, 3-ethyl-, and 3-benzylpyrrole are described but the method should prove to be quite general for the synthesis of 3-*n*-alkylpyrroles. A 2-methylcarboxylate substituent appears equally satisfactory in directing substitution to the 4-position thus methyl 2-pyrrolecarboxylate readily afforded 4-benzoyl-2-pyrrolecarboxylate which was subsequently converted to 3-benzylpyrrole by reduction and decarboxylation.

The aluminum chloride - catalyzed isopropylation (9) and *t*-butylation (10) of methyl 2-pyrrolecarboxylate afford the corresponding 4-alkyl-2-esters as the major kinetically controlled alkylation product. However these compounds exhibit a pronounced tendency to isomerize to the 5-alkyl-2-esters under these conditions preventing the use of these reactions as a convenient route to the corresponding 3-alkylpyrroles. Such rearrangement is largely avoided in the gallium trichloride - catalyzed isopropylation of the 2-ester (11) and by this method an 80% yield of methyl 4-isopropyl-2-pyrrolecarboxylate is obtained. This is readily separated from the small amount (*ca.* 8%) of 5-isopropyl-2-ester and hydrolysis and decarboxylation of the former affords 3-isopropylpyrrole in high yield (78%).

Rearrangement of the *t*-butyl group from the 4- to the 5-position of the alkylated 2-ester is more facile than for the corresponding isopropylated compound, thus the aluminum chloride - catalyzed *t*-butylation of methyl 2-pyrrolecarboxylate affords a 95:5 mixture of the 5- and 4-*t*-butyl-2-esters respectively (10). We find that the use of gallium trichloride as catalyst markedly increases the proportion of 4-*t*-butyl-2-ester (62% of the alkylation product) but still does not provide a sufficiently specific method

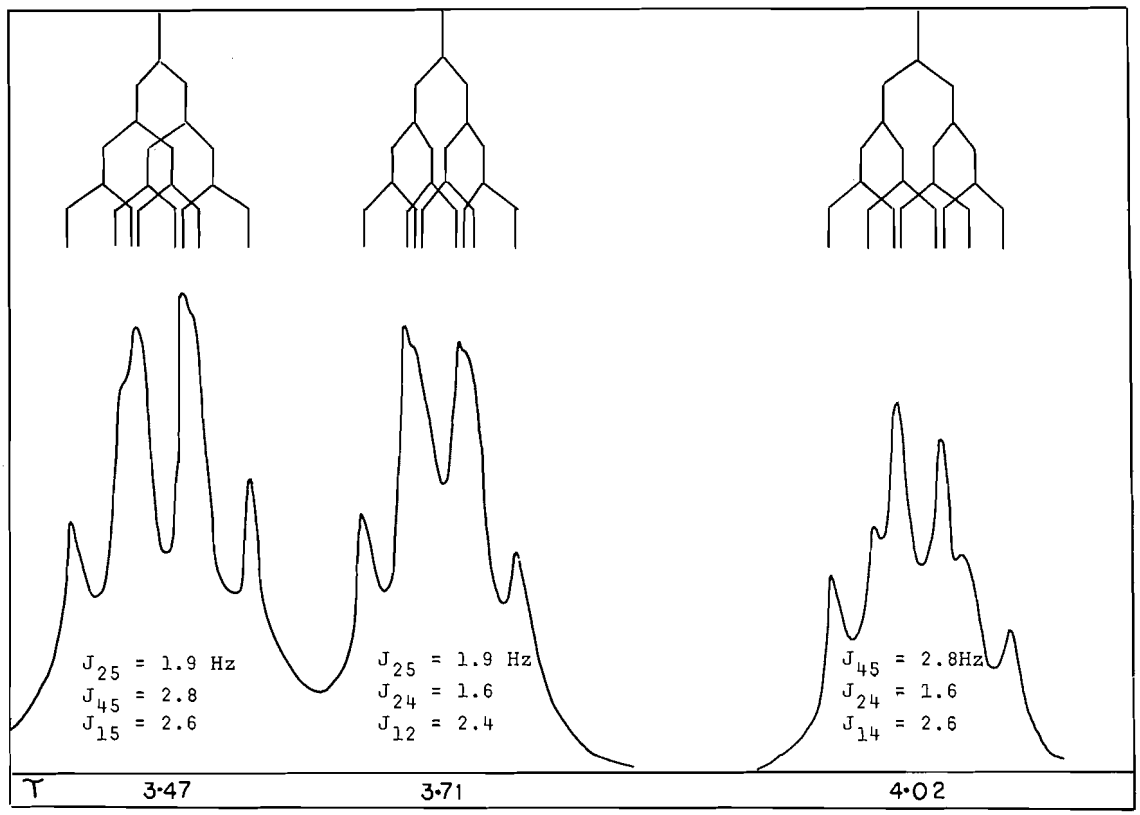


FIG. 1. Ring proton absorptions in the n.m.r. spectrum of 3-*t*-butylpyrrole.

of introducing a β-*t*-butyl substituent. A more strongly electron-withdrawing substituent at the 2-position should not only direct electrophilic attack more exclusively to the 4-position but should also suppress protonation of the product so obtained, hence reducing the extent of rearrangement. The cyano group might be expected to act in this way and should also permit a single stage hydrolysis and decarboxylation of the 4-*t*-butyl-2-pyrrolecarbonitrile to 3-*t*-butylpyrrole. Aluminum chloride - catalyzed *t*-butylation of 2-pyrrolecarbonitrile afforded a 13:87 mixture of the 5- and 4-alkylated products and the use of gallium trichloride as catalyst improved this ratio to 2:98. Purification and subsequent hydrolysis and decarboxylation of the 4-*t*-butylated product afforded pure 3-*t*-butylpyrrole (64%).

The structures of the alkylpyrroles were confirmed by their n.m.r. spectra. In all cases a separate signal was observed in the aromatic region for each of the three ring protons. Chemical shift data are given in Table 1. An analysis of the spectrum of 3-*t*-butylpyrrole is shown in Fig. 1. The various coupling constants were determined by deuteration and subsequent double irradiation. The spectra of the other 3-alkylpyrroles are further complicated by coupling between the ring protons and those of the alkyl substituent.

TABLE 1. The n.m.r. chemical shifts of 3-alkylpyrroles*

Substituent	H-2	H-4	H-5	3-Substituent
Me	3.71	4.12	3.57	8.93
Et	3.68	4.09	3.55	7.55 8.84
CH_2Ph	3.70	3.96	3.51	2.78 6.20
$CHMe_2$	3.65	4.05	3.53	7.21 8.82
CMe_3	3.71	4.02	3.47	8.79

*Values refer to *ca.* 10% solutions in CCl_4 and are quoted on the τ scale using TMS as an internal standard.

Mass spectral data for the 3-alkylpyrroles are reported in Table 2 along with those of some

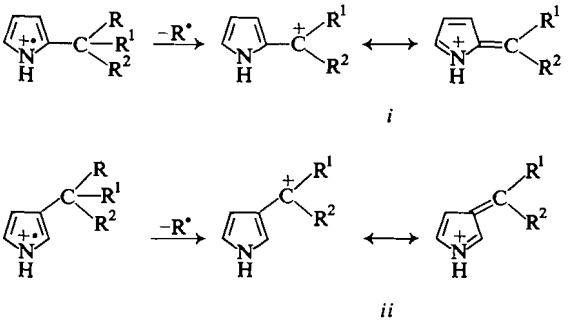
1- and 2-alkylpyrroles. High resolution mass spectrometry was not available and hence assignments of the fragment structures are tentative.

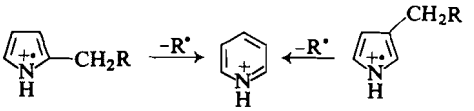
The base peak for all the *C*-alkylpyrroles involves loss of a hydrogen or methyl radical to afford the azafulvene ions (*i* or *ii*) or their rearrangement products (Scheme 2). Such fragmentation might proceed with concurrent rearrangement to a pyridinium ion (12, 13). The very marked similarity of the spectra of the *C*-methylpyrroles both with each other and with those of the *C*-ethylpyrroles are consistent with the involvement of a mutual stable ion of $m/e = 80$ (Scheme 3). In the formation of *i*, *ii*, or their rearrangement products from *C*-alkylpyrroles loss of methyl is preferred to loss of hydrogen. The *C*-benzylpyrroles differ in that loss of phenyl and hydrogen are about equally favorable, doubtless because of the extensive charge delocalization that can occur in the ions *iii* or *iv* or their rearrangement products.



i

ii

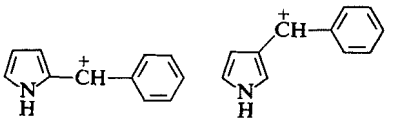
SCHEME 2



m/e 80

SCHEME 3

The mass spectra of the *C*-*t*-butylpyrroles also exhibit an ion of $m/e = 80$ of appreciable abundance (10%). Involvement of a cyclopropane intermediate, such as occurs in the fragmentation of *t*-butylbenzene (14), provides one possible explanation (Scheme 4).



iii *iv*

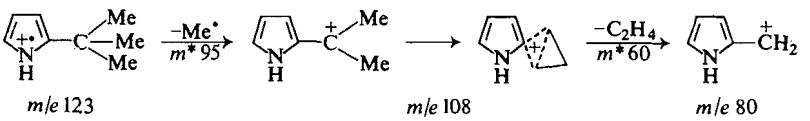
Whilst the mass spectra of the isomeric 2- and 3-substituted pyrroles are very similar those of the 1-substituted pyrroles differ substantially. The base peak in the spectrum of 1-benzylpyrrole arises by decomposition of the parent ion to a pyrrolyl radical and tropylium ion. Analogous but less abundant fragmentation occurs for the branched alkylpyrroles, however the major fragmentation for these compounds involves loss of a molecule of alkene with concurrent hydrogen transfer (*cf.* refs. 15 and 16) (Scheme 5). The extent of formation of immonium ions or their rearrangement products (*cf.* ref. 17) varies from being the major fragmentation process for 1-methylpyrrole to being relatively insignificant for 1-*t*-butylpyrrole.

Experimental

Melting points were determined on a Fisher–Johns m.p. block and are uncorrected. The n.m.r. spectra were determined on a Varian HA 100 spectrometer at 100 MHz and i.r. spectra were determined on a Perkin–Elmer 237B spectrophotometer. Mass spectra were determined on a Hitachi Perkin–Elmer RMU 6E instrument using an ionization energy of 70 eV. An indirect inlet system maintained at 60° was used throughout and total ion current variation was maintained at $< 5\%$. The g.l.c. analyses of 2,4-substituted pyrroles were carried out on a Beckman GC 2A chromatograph fitted with a 30″ column (no. 70007) packed with Carbowax 4000 dioleate on firebrick and operating at 190°. The 3-alkylpyrroles were purified by preparative g.l.c. on a Wilkens Aerograph 1520 fitted with an 8 ft column packed with OV17 (methyl phenyl silicone) on Chromosorb G and operating between 80–130°.

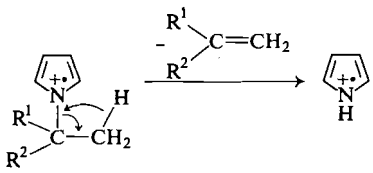
Benzoylation of Ethyl 2-Pyrrolethiolcarboxylate

Ethyl 2-pyrrolethiolcarboxylate (465 mg), aluminum chloride (800 mg), and dichloromethane (20 ml) were stirred and heated under reflux during the dropwise addition of benzoyl chloride (420 mg) in dichloromethane



m/e 123 *m/e* 108 *m/e* 80

SCHEME 4



SCHEME 5

(5 ml). After 3 h the mixture was poured onto ice–HCl and extracted with chloroform. The extracts were washed with $NaHCO_3$ solution, dried ($MgSO_4$), and the solvents removed to afford an oily solid. Recrystallization from CCl_4 afforded ethyl 4-benzoyl-2-pyrrolethiolcarboxylate (435 mg, 56%); m.p. 103.5°; n.m.r. bands at τ 1.9–2.7 (complex, Ar—H), 6.90 (q, CH_2CH_3, *J* 7Hz), 8.64 (t, CH_2CH_3, *J* 7Hz).

Anal. Calcd. for $C_{14}H_{13}NO_2S$: C, 64.9; H, 5.1. Found: C, 65.1; H, 5.2.

Benzoylation of Methyl 2-Pyrrolecarboxylate

Analogous reaction of methyl 2-pyrrolecarboxylate (500 mg) with aluminum chloride (1.68 g) and benzoyl chloride (843 mg) afforded methyl 4-benzoyl-2-pyrrolecarboxylate (430 mg, 48%), m.p. 145–146° (from aqueous 2-propanol); n.m.r. bands at τ 2.05–2.73 (complex, Ar—H) and 6.14 (s, CO_2CH_3).

Anal. Calcd. for $C_{13}H_{11}NO_3$: C, 68.1; H, 4.8. Found: C, 68.4; H, 4.8.

Hydrolysis in methanolic KOH gave the corresponding acid m.p. 223.5–224° (dec.) (lit. (18) 224–225° (dec.)).

General Procedure for Alkylations

The 2-substituted pyrrole, catalyst (1.1 equiv), and carbon disulfide (40 ml) were stirred and heated at 40° for 30 min prior to the rapid addition of alkyl halide (1.1 equiv). After further stirring at 40° for the set time the reaction mixture was poured onto ice–HCl and extracted with chloroform. The extracts were washed with $NaHCO_3$ solution, dried ($MgSO_4$), and the solvent removed.

The t-Butylation of Methyl 2-Pyrrolecarboxylate

Methyl 2-pyrrolecarboxylate (1.50 g), gallium chloride, and *t*-butyl chloride were allowed to react for 40 min prior to isolation of the product (2.18 g, 91%) which was shown (g.l.c.) to contain two components in 38:62 ratio. Chromatography on neutral activity I alumina using 1:1 petroleum – diethyl ether effected separation and the major component was shown to be methyl 4-*t*-butyl-2-pyrrolecarboxylate, m.p. and mixture m.p. 121–122°; n.m.r. bands ($CDCl_3$) at τ 7.10 (m, 3H and 5H), 6.10 (s, CO_2CH_3), and 8.72 (s, *t*-Bu). The minor component was methyl 5-*t*-butyl-2-pyrrolecarboxylate, m.p. and mixture m.p. 127–128°; n.m.r. bands ($CDCl_3$) at τ 3.08 (q, 3H, J_{34} 3.8, J_{13} 2.5 Hz), 3.90 (q, 4H, J_{34} 3.8, J_{14}, 2.5 Hz), 6.10 (s, CO_2CH_3), and 8.65 (s, *t*-Bu).

The t-Butylation of 2-Pyrrolecarbonitrile

(*A*) 2-Pyrrolecarbonitrile (19) (950 mg), aluminum chloride, and *t*-butyl chloride were allowed to react for 30 min prior to isolation of the product (1.407 g, 95%) which was shown (g.l.c.) to contain two components in 13:87 ratio. These were shown to be 5-*t*-butyl-2-pyrrolecarbonitrile and 4-*t*-butyl-2-pyrrolecarbonitrile respectively since hydrolysis and subsequent methylation (CH_2N_2) of the mixture afforded the corresponding alkylated 2-esters which were identified by g.l.c. comparison with the authentic esters.

(*B*) 2-Pyrrolecarbonitrile (1.12 g), gallium chloride, and *t*-butyl chloride were allowed to react for 30 min whilst the reaction mixture was flushed with nitrogen. Isolation gave a product (1.62 g, 93%) shown by g.l.c. to contain 4-*t*-butyl-2-pyrrolecarbonitrile contaminated by < 2% of the 5-*t*-butyl isomer. Distillation, b.p. 125–128°/0.05 mm and subsequent crystallization from petroleum afforded pure 4-*t*-butyl-2-pyrrolecarbonitrile m.p. 56–57°; n.m.r. bands (CCl_4) at τ 3.2 (d, 3H and 5H, $J_{13} \approx J_{15} = 2.6$), ν_{CN} (Nujol) 2220 cm^{-1}.

Anal. Calcd. for $C_9H_{12}N_2$: C, 73.0; H, 8.1; N, 18.9. Found: C, 72.9; H, 8.0; N 19.0.

3-Methylpyrrole

Ethyl 4-formyl-2-pyrrolethiolcarboxylate (8) (500 mg), potassium hydroxide (500 mg), hydrazine (500 mg of 64%), and triethylene glycol (5 ml) were stirred at 125° for 90 min. The temperature was then raised to 220° for 4 h prior to pouring into ice–water and extracting with ether. The extract was washed with water, dried ($MgSO_4$), and chromatographed on neutral activity I alumina to remove tarry material. Subsequent distillation afforded 3-methylpyrrole (122 mg, 44%), b.p. 142–144° (lit. (1) b.p. 143–143.5°).

3-Ethylpyrrole

Ethyl 4-acetyl-2-pyrrolethiolcarboxylate (8) (500 mg) was similarly converted into 3-ethylpyrrole (20) (135 mg, 53%), b.p. 86–88°/20 mm.

3-Benzylpyrrole

(*A*) Ethyl 4-benzoyl-2-pyrrolethiolcarboxylate (330 mg) was similarly converted to 3-benzylpyrrole (182 mg, 91%).

Anal. Calcd. for $C_{11}H_{11}N$: C, 84.0; H, 7.1. Found: C, 84.1; H, 7.2.

(*B*) Methyl 4-benzoyl-2-pyrrolecarboxylate (425 mg) similarly afforded 3-benzylpyrrole (270 mg, 92%).

3-Isopropylpyrrole

Methyl 4-isopropyl-2-pyrrolecarboxylate (200 mg), prepared by the gallium chloride - catalyzed isopropylation of methyl 2-pyrrolecarboxylate (11), was heated at 230° for 5 h with KOH (250 mg), water (250 mg), and triethylene glycol (3 ml). The mixture was then poured onto ice–HOAc, extracted with ether, washed with $NaHCO_3$ solution, and dried ($MgSO_4$). Removal of the solvent afforded 3-isopropylpyrrole (7) (101 mg, 78%).

3-t-Butylpyrrole

4-*t*-Butyl-2-pyrrolecarbonitrile (200 mg) was similarly hydrolyzed and decarboxylated to afford 3-*t*-butylpyrrole (7) (126 mg, 64%).

1-Alkylpyrroles

The 1-alkylpyrroles were prepared from 2,5-dimethoxytetrahydrofuran and the appropriate amine according to the method of Elming and Clauson–Kaas (21, 22).

2-Alkylpyrroles

The 2-*n*-alkylpyrroles (23) and 2-benzylpyrrole (24) were prepared by Wolff–Kishner reduction of the corresponding 2-acylpyrrole. 2-Isopropylpyrrole (7) and 2-*t*-

Received December 22, 1970

The hydrothermal deposition of CrO(OH) from aqueous chromium(III) chloride, nitrate, and perchlorate, and of $Cr_3(SO_4)_2(OH)_5.H_2O$ and $Cr(OH)SO_4.2H_2O$(?) from aqueous chromium(III) sulfate, has been investigated. Aqueous chromium(III) is oxidized to chromium(VI) by 0.4 *M* perchloric acid above 225 °C, and by molecular oxygen above 250 °C. Aqueous chromium(III) can react at 300 °C with iron or steel, cobalt, and copper to produce $FeCr_2O_4$, $CoCr_2O_4$, and $Cu_2Cr_2O_4$, respectively. CrO(OH) reacts with type 316 stainless steel at 440 °C in supercritical water of density 0.7 g cm^{-3} to yield (Fe,Ni)-Cr_2O_4, which is the "cubic Cr_2O_3" of Laubengayer and McCune. The spinels MCr_2O_4 (M = Mg, Mn, Fe, Co) can be made hydrothermally at *ca.* 300 °C from $Cr(OH)_3$ and $M(OH)_2$. This information is relevant to corrosion phenomena, and the possible hydrothermal origin of chromite deposits in serpentinized rocks.

Le dépot hydrothermique de CrO(OH) à partir d'une solution aqueuse de chlorure, nitrate et perchlorate de chrome(III) ainsi que le dépot de $Cr_3(SO_4)_2(OH)_5.H_2O$ et $Cr(OH)SO_4.2H_2O$(?) à partir d'une solution aqueuse de sulfate de chrome(III), ont été étudiés. Une solution aqueuse de chrome(III) est oxydée en chrome(VI) au-dessus de 225 °C par l'acide perchlorique 0.4 *M* et par de l'oxygène moléculaire au-dessus de 250 °C. Une solution aqueuse de chrome(III) peut réagir à 300 °C avec du fer ou de l'acier, du cobalt, et du cuivre pour donner respectivement du $FeCr_2O_4$, $CoCr_2O_4$ et $Cu_2Cr_2O_4$. Le CrO(OH) réagit à 440 °C avec l'acier inoxydable du type 316, dans de l'eau supracritique de densité 0.7 g cm^{-3} pour donner le (Fe,Ni)Cr_2O_4, qui est le "Cr_2O_3 cubique" de Laubengayer et McCune. Les spinelles MCr_2O_4 (M = Mg, Mn, Fe, Co) peuvent être formés d'une façon hydrothermique à 300 °C à partir de $Cr(OH)_3$ et $M(OH)_2$. Cette information correspond au phénomène de la corrosion et à l'origine hydrothermique possible de dépots de chromites dans les roches serpentinisées.

Canadian Journal of Chemistry, **49**, 2433 (1971)

Introduction

Chromium(III) offers several advantages as a model ion for studies intended to elucidate aqueous metal–ion chemistry at high temperatures. Much information is now available on its aqueous chemistry below 100 °C (1); the ion is not easily oxidized or reduced; and its complexes and hydrolytic polymers undergo substitution reactions sufficiently slowly at room temperature that it may be possible to characterize individual solute species formed at high temperatures after rapid quenching. Therefore a preliminary study of the qualitative solution chemistry of chromium(III) was undertaken; as it pertains to future experiments where the spectroscopic properties, hydrolysis, and complex formation of chromium(III) may be investigated quantitatively.

Experimental

Materials

The chemicals used were Fisher Certified reagents. Distilled water was passed through both Barnstead organic removal and de-ionizer cartridges before use. Chromium(III) hydroxide was prepared by precipitation from 1 *M* $CrCl_3$ solution with 0.1 *M* aqueous ammonia, followed by centrifugation and re-suspension in fresh ammonia; this process was repeated until no detectable chloride ion remained; then the product was dried under vacuum at 20 °C. Chromium(III) perchlorate was prepared by reducing chromium(VI) oxide in aqueous perchloric acid with hydrogen peroxide; the produce was recrystallized from 0.1 *M* perchloric acid.

Equipment

The pressure vessels used are of four types as follows: (*a*) a small vessel of capacity 87 cm^3 (Fig. 1) constructed from ATL-40 titanium with 0.2% palladium (Atlas Titanium, Welland, Ontario) for service up to 180 bars at 350 °C; the sealing gasket is Teflon contained between two rings constructed from titanium with 0.2% palladium

as recommended by Gill and Marshall (2). (*b*) Similar to the above vessel (type *a*) but with a smaller diameter to reduce the capacity to 62 cm^3. (*c*) A vessel constructed from type 316 stainless steel for service up to 420 °C at 150 bars; the sealing gasket is a commercial asbestos gasket shod with type 304 stainless steel rings (Flexitallic Type R3-25D, Canadian Gasket Co. Ltd., Fort Erie, Ontario). (*d*) A high-pressure vessel of capacity 50 cm^3 constructed from 316 stainless steel from the design by H.L.Barnes; the seal is a 90° delta-ring seated in 60° countersinks in the body and cap. A silica liner with a loose-fitting cap for the low-pressure vessels (types *a*, *b*, and *c*) or a mild steel liner (AISI C1020) for a low-pressure stainless steel vessel (type *c*) was used in some experiments.

The vessels were heated in either a Blue M Conwate CW-160HF-1 forced-convection oven, or a Thermolyne type 1700 electric furnace with a Barber–Coleman Capacitrol Model 292 temperature controller. The temperatures recorded are accurate to within ±5 °C.

Concentrations throughout this article are expressed as molarities valid at 20 °C. The atmospheres within the vessel prior to reaction unless otherwise specified were pure nitrogen at 1 bar pressure, and in no case did the pressure of nitrogen at higher temperatures exceed 3 bars.

Analyses

Aqueous chromium was estimated spectrophotometrically as CrO_4^{2-} after oxidation with alkaline H_2O_2; other chemical analyses followed standard practice (3). Solids were identified from X-ray diffraction powder patterns obtained from an X-ray diffractometer with Cu–Kα radiation. The letters ASTM followed by numbers in the following text refer to the data in the X-Ray Diffraction Powder File.

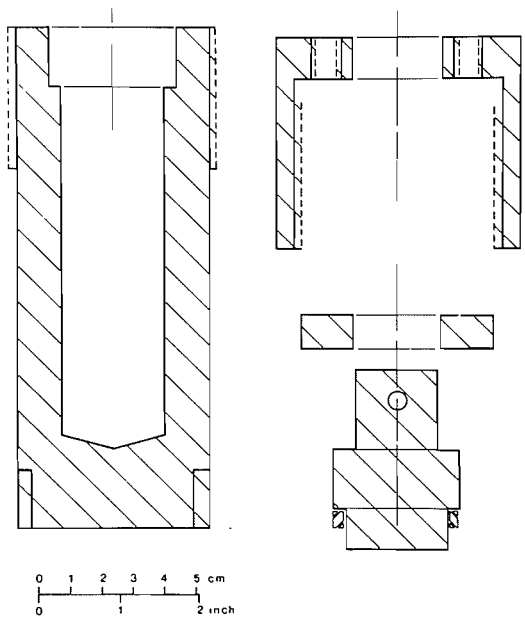

FIG. 1. Pressure vessel. The cap (top right) and the bearing ring (center right) are type 316 stainless steel, and the sealing ring is Teflon; the remaining parts are titanium with 0.2% palladium.

Results

Precipitation Reactions

Chromium(III) Nitrate

At 300 °C, $Cr(NO_3)_3$ solutions (0.05 *M*) deposited well-crystallized rhombohedral CrO(OH) (4) (ASTM 9-331) quantitatively in 24 h with the evolution of heavy nitrogen(IV) oxide fumes. These results are the same whatever the vessel type, although the final p*H* was 1.5 in a titanium vessel and 5 in a stainless steel vessel with a mild steel liner. Partial deposition of CrO(OH) from 1.05 *M* $Cr(NO_3)_3$ occurs below 150 °C. Table 1 summarizes the percentage of CrO(OH) deposited in a titanium vessel after 24 h as a function of temperature. At 200 °C, 1.05 *M* $Cr(NO_3)_3$ deposited a similar amount of CrO(OH) in 4 days as in 24 h, so these data in Table 1 represents equilibrium conditions. Nitrogen(IV) oxide fumes were only observed as a reaction product at 300 °C. None of the products contained $Cr(OH)_3$.

Chromium(III) Chloride

Chromium(III) chloride solutions were less extensively decomposed than their nitrate analogues when heated in an inert vessel. Thus 0.8 *M* $CrCl_3$ deposited in 24 h 86% of well-crystallized CrO(OH) (ASTM 9–331) at 300 °C, only 4% amorphous material at 250 °C, and none at 200 °C, in a titanium vessel. A 250 °C, 49% CrO(OH) was deposited in 48 h in a titanium vessel with silica liner, and 59% in 4 days in a stainless steel vessel with silica liner. Therefore the precipitation process is slow at 250 °C and is favored by silica surfaces. At 300 °C in an unlined stainless steel vessel, 0.05 *M* $CrCl_3$ reacted with the vessel walls to produce a near quantitative precipitate of $FeCr_2O_4$ and ferrous iron in solution.

Chromium(III) Sulfate

At a low acidity and above 250 °C, chromium-

(III) sulfate solutions deposited a green, well-crystallized solid with an X-ray diffraction powder pattern similar to carphosiderite, $Fe_3(SO_4)_2(OH)_5.H_2O$ (ASTM 18-644 and ref. 5). The conditions of precipitation are summarized in Table 2. The solid is almost insoluble in water or mineral acids including aqua regia even on heating, but it dissolved in water after fusion with NaOH. The alkaline solution was heated with excess H_2O_2 and the chromium content estimated as CrO_4^{2-}. Then the sulfate content was determined gravimetrically as $BaSO_4$ following acidification and reduction of the chromium(VI) to chromium(III) with further H_2O_2.

Anal. Calcd. for $Cr_3(SO_4)_2(OH)_5.H_2O$: Cr, 34.6; SO_4, 42.6. Found: Cr, 33.5; SO_4, 42.5.

This compound is the same as that obtained by Lecerf *et al.* (6) from chromium(III) sulfate solutions at 300 °C under somewhat different conditions. Its X-ray diffraction powder pattern agrees with that of Lecerf *et al.* (ASTM 18–381), but its observed chemical composition is in better accordance than theirs with the formula $Cr_3(SO_4)_2(OH)_5.H_2O$.

In all the experiments listed in Table 2, the sole crystalline product is $Cr_3(SO_4)_2(OH)_5.H_2O$; ion-exchange chromatography of the quenched supernatant solutions indicated the presence of $Cr(H_2O)_5SO_4^+$ and $Cr(H_2O)_2(SO_4)_2^-$. However, at 300 °C, a solution 0.13 M in chromium(III) and 0.88 M in H_2SO_4 yielded no precipitate in 24 h, but after 5 days yielded 18% of a green powder, which was mainly $Cr_3(SO_4)_2(OH)_5.H_2O$. It also showed additional X-ray diffraction reflections at the d-spacings and relative intensities as follows: 5.76 Å (30), 5.06 Å (50), and 3.15 Å (100). Analogy with $Fe(OH)SO_4.2H_2O$ (parabutlerite, ASTM 16–939) suggests it is $Cr(OH)SO_4.2H_2O$.

When a high concentration (2.31 M) of $Cr_2(SO_4)_3$ was heated at 300 °C, a considerable amount of sulfur dioxide was produced. A similar effect was noted with 1.25 M H_2SO_4 in the absence of chromium(III); after 4 days at 300 °C in a titanium vessel with silica liner, 1.4% of the sulfur appeared as SO_2 as measured by iodometric titration. Even more SO_2 (4.8%) was produced in 3 days when an unlined titanium vessel was used. Aqueous Na_2SO_4 was not significantly changed by similar treatment.

Chromium(III) Perchlorate

A dilute (0.0167 M) chromium(III) perchlorate solution was examined for both hydrolytic precipitation and oxidation of chromium(III) in the presence of various concentrations of excess $HClO_4$ and $NaClO_4$ (total $[H^+] + [Na^+] = 0.4$ M) on heating for 24 h in a titanium vessel with silica liner. At 200 °C a small quantity of CrO(OH) (ASTM 9–331) was precipitated from solutions containing initially 0.02 M $HClO_4$ and also 0.05 M $HClO_4$, whereas all the chromium was precipitated as CrO(OH) when no $HClO_4$ was originally present, but no precipitation occurred with 0.4 M $HClO_4$. Each solution was passed through a Dowex 50W-X8 ion-exchange column to remove chromium(III) species; the issuing solution was tested for chromium(VI) both spectrophotometrically and with diphenyl-

carbazide solution with a negative result. Above 225 °C oxidation of chromium(III) by 0.4 *M* $HClO_4$ to chromium(VI) was essentially complete in 24 h, with the concomitant formation of 0.39 mol of chloride ion per mole chromium(III) originally present.

Chromium(III) Sulfate with Oxygen

In hydrothermal experiments at 300 °C, some chromium(VI) was often produced from chromium(III), if the original atmosphere in the vessel was air rather than nitrogen. This phenomenon was investigated using a silica-lined titanium vessel in which an oxygen atmosphere was generated by thermal decomposition of a measured amount of 8 *M* H_2O_2 placed in the vessel *outside* the silica liner; the chromium(III) sulfate solution was kept inside the capped liner. Any chromium(VI) in the products was detected as described under the previous section *Chromium(III) Perchlorate.*

At 250 °C after 24 h, 0.23 *M* chromium(III) as sulfate yielded approximately 40% $Cr_3(SO_4)_2(OH)_5.H_2O$ (ASTM 18–381) in a nitrogen atmosphere. In the presence of excess oxygen at 4.2 bars pressure, 3.7% aqueous chromium(VI) was also formed, but both precipitation and oxidation were completely suppressed by the addition of 0.63 *M* H_2SO_4 prior to heating. At 300 °C under 16 bars of excess oxygen pressure, 0.23 *M* chromium(III) sulfate yielded 13% chromium(VI), while the remainder was precipitated as $Cr_3(SO_4)_2(OH)_5.H_2O$. When 1.5 *M* H_2SO_4 was present initially, there was no precipitate, but 4.2% chromium(VI) was still produced. Similar results were obtained when the H_2O_2 was placed in the chromium(III) solution rather than outside the liner prior to heating.

Chromium(III) Solutions with Metals

Aqueous chromium(III) sulfate (0.111 *M* in chromium(III)) was heated for 24 h at 300 °C in a new unlined type 316 stainless steel vessel. It reacted completely with the vessel walls to yield a brown-black, feebly-magnetic spinel of unit cell $a_0 = 8.36$ Å; the remaining solution was found by dichromate titration to be 0.084 *M* in iron(II), *i.e.*, 3 mol of aqueous iron(II) were produced for every 4 mol chromium(III) originally present. The brown-black solid was identified as chromite, $FeCr_2O_4$ (ASTM 4–0759), however this X-ray diffraction powder pattern and those of other spinels did not include the strong 331 reflection reported in ASTM 4–0759. Similar results were obtained when 0.04 to 0.06 *M* chromium(III) sulfate solutions were heated for 24 h at 300 °C in a stainless steel vessel with a mild steel liner or with iron strips inside a titanium vessel except that in this last case the spinel formed was shown by X-ray fluorescence analysis to have the composition $(Fe(II)_{0.6}\ Fe(III)_{0.4})\ (Cr(III)_{1.6}\ Fe(II)_{0.4})O_4$. On the other hand, relatively concentrated chromium(III) sulfate solutions of 1 *M* in chromium(III) yielded mainly $Cr_3(SO_4)_2(OH)_5.H_2O$ (ASTM 18–381) after 24 h at 300 °C in a stainless steel vessel with mild steel liner; after 4 days at 250 °C, some $FeSO_4.H_2O$ (szomolnokite, ASTM 12–226) was also formed. Reaction of dilute $Cr_2(SO_4)_3$ solutions at 300 °C with small excesses of fine iron wire in a stainless steel vessel with silica liner produced green $Cr_3(SO_4)_2(OH)_5.H_2O$ and a red-brown solid of composition $Fe_{0.95}Cr_{1.05}O_3$ (X-ray fluorescence analysis), with an X-ray diffraction powder pattern similar to that of $FeCrO_3$ (ASTM 2–1357), *i.e.*, it is essentially a solid solution of α-Fe_2O_3 in α-Cr_2O_3.

Chromium chloride solutions (0.05 *M*) also produced $FeCr_2O_4$ after 24 h at 300 °C in a stainless steel vessel with mild steel liner, but CrO(OH) (ASTM 9-331) was also present and accounted for 30% of the total chromium content as determined by X-ray fluorescence analysis; CrO(OH) became the major product under the same conditions when the solution was heated in an unlined stainless steel vessel. At 235 °C, 0.73 *M* $CrCl_3$ precipitated only poorly-crystalline CrO(OH) in 4 days, whether in contact with mild steel or stainless steel. Chromium(III) nitrate solutions deposited CrO(OH) in all circumstances at temperatures above 150 °C.

Solid CrO(OH) did not react with a mild steel liner in water at 300 °C over a 24 h period. When $Cr(OH)_3$ (5 mmol) was heated for 11 days at 440 °C with 35.2 g water under nitrogen in a stainless steel Barnes high-pressure vessel, the product was a brown spinel with a unit cell of 8.37_4 Å and approximate composition $(Fe_{0.5}Ni_{0.4}Cu_{0.06})Cr_2O_4$ as determined by X-ray fluorescence analysis. The water vapor pressure at 440 °C is approximately 1.4 kbars in this experiment (7). This experiment was repeated several times with similar results; however, in one case all of the water was lost through malfunction of the sealing ring, and the product was then

α-Cr_2O_3 (ASTM 6-504). When α-Cr_2O_3 was exposed to supercritical water in a stainless steel vessel at 440 °C and 1.4 kbars for 10 days, no change was observed.

Chromium(III) sulfate solutions (0.042 *M*) in chromium(III) were heated for 24 h at 300 °C in a titanium vessel with a polished strip or sphere of a selected metal in excess. Cobalt yielded dark-green $CoCr_2O_4$ (ASTM 1-1122) and aqueous cobalt(II); no $Cr_3(SO_4)_2(OH)_5.H_2O$, α-$Co(OH)_2$, β-$Co(OH)_2$, or rhombohedral CrO(OH) was detected by X-ray diffraction, although a weak reflection at 3.29 Å may indicate the less familiar orthorhombic CrO(OH) (8) (ASTM 17-268). Nickel yielded well-crystallized $NiSO_4.H_2O$ (ASTM 1-659) but no spinel; weak reflections in the X-ray diffraction powder pattern match those of γ-NiO(OH) (ASTM 6-75), but this is unlikely to have been a reaction product. Copper yielded the olive-green cuprous compound, $Cu_2Cr_2O_4$ (ASTM 5-668), which is not a spinel (9). In the above cases, most of the metal was recovered. However, manganese reacted almost completely with the water to yield Mn_3O_4 (hausmannite, ASTM 16-154), and zinc to yield ZnO (zincite, ASTM 5-664); magnesium reacts quantitatively with water to yield $Mg(OH)_2$ (brucite, ASTM 7-239).

Hydrothermal Synthesis of Chromium Spinels

Magnesium oxide (4.25 mmol) and $Cr(OH)_3$ (8.5 mmol) in 60 g water reacted at 250 °C in 24 h to give $Mg(OH)_2$ (brucite, ASTM 7-239) and CrO(OH) (ASTM 9-331) only. The product after 24 h at 300 °C showed no $Mg(OH)_2$ or MgO reflections in its X-ray diffraction powder pattern, and the CrO(OH) reflections were much more diffuse and less intense than in similar experiments where MgO was omitted. In addition a new diffuse reflection appeared at 2.5 Å to indicate formation of $MgCr_2O_4$ (picrochromite, ASTM 10-351). On repeating the experiment at 300 °C for 12 days, a brown powder was produced with all the reported X-ray diffraction reflections greater than intensity 10 of $MgCr_2O_4$. In addition a reflection at 1.49 Å indicates MgO (periclase, ASTM 4-829; the principal MgO reflection at 2.11 Å is obscured by the 400 reflection of $MgCr_2O_4$), and also weak reflections due to CrO(OH) persisted.

Nickel hydroxide which was made by precipitation with NaOH from aqueous $Ni(NO_3)_2$ did not react with $Cr(OH)_3$ at 250 °C in 24 h, and the products recovered were $Ni(OH)_2$ (ASTM 14-117) and CrO(OH); at 300 °C the products were only well-crystallized NiO (bunsenite, ASTM 4-835) and CrO(OH) even after 12 days.

$MnCl_2.4H_2O$ (12.7 mmol) and NaOH (25.0 mmol) reacted with 25 mmol $Cr(OH)_3$ in 40 g water at 300 °C over 10 days to yield a brown spinel, $MnCr_2O_4$ with the typical 111, 220, 331 (strongest), 400, 333 and/or 511, and 440 X-ray diffraction reflections. The unit cell is 8.42 ± 0.02 Å, *cf.* 8.437 Å reported (10) for authentic $MnCr_2O_4$. Similarly when $CoCl_2.6H_2O$ replaced $MnCl_2.4H_2O$, a bottle-green spinel, $CoCr_2O_4$ (ASTM 1-1122), was produced with a unit cell of 8.34 ± 0.02 Å, *cf.* 8.319 Å reported (11) for $CoCr_2O_4$; all the X-ray diffraction reflections reported with intensities greater than 20 were observed, although the reflections were diffuse.

Iron(II) hydroxide oxidized water slowly to give hydrogen and magnetite, Fe_3O_4 (ASTM 19-629). Thus stoichiometric amounts of aqueous $FeSO_4$ and NaOH in the absence of oxygen were heated for 5 days at 200 °C to produce yellow-green particles, which were observed under the microscope to have a pale-colored center encased by a black, rhombic dodecahedral shell of magnetite, Fe_3O_4. The hand-picked yellow-green center had X-ray diffraction reflections at 7.4 Å (strong, diffuse), 3.8 Å (strong, diffuse), 2.82 Å (strong, sharp), 2.52 Å (weak, coincident with the 311 reflection of Fe_3O_4), and 1.63 Å (weak); these match the pattern (ASTM 13-90) cited for a "green rust" of composition $Fe(II)_{3.6}Fe(III)_{0.9}(OH,O,SO_4)_9$, but sulfate was present only in trace amounts in this product. Therefore the oxidation to Fe_3O_4 was much less than half complete in this experiment.

In contrast when 10 mmol aqueous $FeSO_4$ and 20 mmol chromium(III) sulfate were treated with 80 mmol aqueous NaOH to give a total liquid volume of 30 ml (20 °C) and then heated for 3 days at 200 °C; the sole product was 2.2 g of a brown-black, feebly magnetic, poorly crystalline powder with rather diffuse X-ray diffraction reflections at 2.97 Å (30), 2.53 Å (100), and 2.09 Å (40). No reflections due to CrO(OH) and so forth could be detected. These facts indicate that the product was $FeCr_2O_4$ (ASTM 4-0759) in essentially quantitative yield; the alternative possibility, that the solid was Fe_3O_4 intimately mixed with amorphous

CrO(OH) or $Cr(OH)_3$, cannot be ruled out, but this would require that CrO(OH) or $Cr(OH)_3$ catalyze the reaction of $Fe(OH)_2$ with water.

A similar experiment of only 24 h duration yielded a seemingly homogeneous but amorphous brown-black powder, and another experiment at 300 °C yielded once again a poorly crystalline brown-black spinel of unit cell 8.30 Å. However, at 150 and 175 °C mixtures of green and black powders resulted, and substantial pressures of gas (evidently H_2) were created. The p*H* of the solution (20 °C) rose from 7 to 12; a spinel was present in the products, but this may be Fe_3O_4. The chromium-containing products were CrO(OH) and some $Cr(OH)_3$ (ASTM 12-241). Experiments in which 4 *M* NaCl was present produced mixtures of insoluble, amorphous green and black solids. Other experiments using a deficiency of NaOH at various temperatures from 150 to 300 °C produced only amorphous or poorly-crystalline powders, or brown powders in which CrO(OH) was the only identifiable component.

Attempts to make $MgAl_2O_4$ from MgO and $Al(OH)_3$ under hydrothermal conditions in a titanium vessel at 300 °C were unsuccessful, the aluminium-containing products being mainly boehmite, AlO(OH) (ASTM 17-940) and tucanite $Al_2(OH)_6.H_2O$ (ASTM 18-32); when a silica liner was used, the main products were serpentine, $Mg_6Si_4O_{10}(OH)_8$ (ASTM 9-444) and boehmite.

Discussion

Hydrolytic Precipitation Reactions

Many of the phenomena reported may be explained with the sequential aqueous reactions 1 through 4.

[1] $$Cr(H_2O)_6^{3+} \rightleftarrows Cr(H_2O)_5OH^{2+} + H^+$$

[2] $$Cr(H_2O)_5OH^{2+} \rightleftarrows Cr(H_2O)_4(OH)_2^{+} + H^+$$

[3] $$Cr(H_2O)_4(OH)_2^{+} \rightleftarrows Cr(OH)_3(s) + H^+$$

[4] $$Cr(OH)_3(s) \rightleftarrows CrO(OH)(s)$$

Reaction 4 occurs above 55 °C in aqueous systems (12); CrO(OH) can exist in a grey-brown rhombohedral form (4) or a green orthorhombic form (8), but with one possible exception, the CrO(OH) in these experiments has the rhombohedral form. Reaction 1 and also presumably reactions 2 and 3 are markedly endothermic and slightly favored by pressure (13), so that these equilibria will lie increasingly to the right as the temperature is increased; the equilibrium constant for reaction 1 is probably about 0.14 *m* at 200 °C and near 1.0 *m* at 300 °C (14).

Furthermore nitric acid, which may not be completely dissociated in its more concentrated aqueous solutions even at room temperature, becomes an increasingly weak acid as the temperature is increased (15). This will force the equilibria even further to the right in chromium(III) nitrate solutions, so that CrO(OH) precipitates at temperatures as low as 150 °C. However, this precipitation occurs at higher temperatures than in the analogous iron(III) nitrate system (16), because hexaaquochromium(III) ion is a markedly weaker acid than hexaaquoiron(III).

In contrast, $CrCl_3$ solutions precipitated CrO(OH) only at temperatures above 200 °C. This shift of the equilibria to the left is ascribed partly to the greater acid strength of HCl (15), and partly to the greater ability of chloride (as compared with nitrate) to complex chromium(III) (17). The importance of this complex formation factor is stressed by the observation that CrO(OH) precipitates from unacidified $Cr(ClO_4)_3$ solutions at 200 °C; $HClO_4$ is a stronger acid than either HCl or HNO_3, but ClO_4^- is a weaker complexing agent than either Cl^- or NO_3^-. On the basis of the Bjerrum theory of ion pairing (18), complex formation between aqueous anions and cations will become increasingly important at high temperatures, because the product of the absolute temperature and the dielectric constant of water decreases as the temperature increases. The greater precipitation of CrO(OH) in a stainless steel vessel with silica liner as compared with a titanium vessel with silica liner can be ascribed to loss of molecular HCl in the vapor phase, either through reaction with the steel or by leakage through the relatively inefficient asbestos gaskets.

Aqueous HSO_4^- ion becomes progressively less acidic up to 300 °C, and it is neither appreciably acidic nor basic between 300 and 400 °C (19). Thus hydrolysis of chromium(III) sulfate at high temperatures is aided by protonation of SO_4^{2-} only as far as HSO_4^-, and the observed complexing of chromium(III) by SO_4^{2-} will suppress further hydrolysis. The limiting factor in the high-temperature solubility of chromium(III) sulfate is the precipitation of $Cr_3(SO_4)_2(OH)_5.H_2O$, which like the isomorphous iron(III)

compound (5), has a favorable crystal structure (6).

Data in Table 2 verify that $Cr_3(SO_4)_2(OH)_5.H_2O$ precipitates at temperatures above 250 °C and it is suppressed by the addition of H_2SO_4. The more concentrated chromium(III) sulfate solutions are markedly less susceptible to the precipitation of $Cr_3(SO_4)_2(OH)_5.H_2O$, presumably because of the extensive formation of di- and perhaps tri-sulfato complexes. This precipitation may not have reached equilibrium in some of the cases listed in Table 2. The evolution of SO_2 from a very concentrated solution, where extensive precipitation had occurred, evidently originated in the thermal decomposition of the H_2SO_4 generated by hydrolytic precipitation.

The precipitation of a new compound along with $Cr_3(SO_4)_2(OH)_5.H_2O$, from a relatively acidic solution near the borderline of solubility at 300 °C, is consistent with its tentative identification as $Cr(OH)SO_4.2H_2O$, which is more acidic than $Cr_3(SO_4)_2(OH)_5.H_2O$. The Cr_2O_3–H_2O–SO_3 system is similar to its iron(III) analogue (5), except that once again the lower acidity of aqueous chromium(III) *vis-à-vis* iron(III) leads to precipitation at significantly higher temperatures in the chromium system.

Oxidation of Aqueous Chromium(III)

The oxidation of chromium(III) to chromium(VI) by 0.4 *M* aqueous perchloric acid above 225 °C must occur by the direct interaction of $HClO_4$ and chromium(III), since the rate of spontaneous decomposition of 0.04 *M* aqueous $HClO_4$ is negligible at 250 °C (20). The yield of chloride ion and the absence of chlorine gas in the reaction products are consistent with the stoichiometry

$$[5] \quad 8Cr^{3+} + 3ClO_4^- + 2OH_2O \rightleftarrows 8HCrO_4^- + 3Cl^- + 32H^+$$

It is apparent that physical measurements on chromium(III) species in perchlorate media are feasible up to 200 °C.

The oxidation of chromium(III) to chromium(VI) by oxygen in acidic solution is not quite thermodynamically favored under standard state conditions at 25 °C; the standard potential for reaction 6 is −0.10 V.

$$[6] \quad 3O_2 + 4Cr^{3+} + 8H_2O \rightleftharpoons 2Cr_2O_7^{2-} + 16H^+$$

However, at high temperatures, with departures from standard conditions, changes in the nature of the chromium(III) species, and the breakdown of kinetic barriers, reaction 6 apparently becomes important enough to require the exclusion of oxygen from chromium(III) solutions. Reaction 6 indicates suppression of the oxidation by O_2 with the addition of substantial excess acid, at least at 250 °C.

Reaction of Aqueous Chromium(III) with Metals

The precipitation of $FeCr_2O_4$ when a chromium(III) solution reacts with a steel is explained by the hydrolytic reactions 1 to 3. The liberated hydrogen ion probably reacts with the metal to produce $Fe^{2+}(aq)$ and maintains the relatively high p*H*; then at about 300 °C, hydrolyzed iron(II) and chromium(III) species precipitate together as $FeCr_2O_4$ or a related compound. This sequence of events is most well-defined with chromium(III) sulfate solutions, because they retain relatively high concentrations of chromium(III) at high temperatures and deposit $Cr_3(SO_4)_2(OH)_5.H_2O$ only slowly. Recalling that 3 mol of iron(II) were found in solution after total precipitation of 4 mol of chromium(III) as $FeCr_2O_4$, and that aqueous HSO_4^- is neither acidic nor basic at 300 °C (19), reaction 7 is conceived as

$$[7] \quad 5Fe(s) + 2Cr_2(SO_4)_3(aq) + 8H_2O(l) \rightleftharpoons 2FeCr_2O_4(s) + 3Fe(HSO_4)_2(aq) + 5H_2(g)$$

The occurrence of iron(III) in some products suggests the reduction of either water or H^+ by Fe^{2+} in high-temperature water; certainly $Fe(OH)_2$ reduces water at a significant rate even at 150 °C. Aqueous $CrCl_3$ tends to deposit CrO(OH) by reactions 1 to 4 concomitantly with $FeCr_2O_4$ production. CrO(OH) does not react with steels in aqueous media or with aqueous Fe^{2+} in 24 h at 300 °C, so the formation of $FeCr_2O_4$ from chromium(III) solutions and steels evidently involves reactions 1 to 3 directly.

In supercritical water of density 0.7 g cm^{-3} at 440 °C, CrO(OH) reacts with stainless steel to produce a spinel $(Fe,Ni)Cr_2O_4$ (a trace of copper was also present in this spinel, because the strongly adhesive copper–graphite lubricant used on the threaded parts apparently accidentally contaminated the internal vessel walls). This experiment suggests that the "cubic Cr_2O_3" of Laubengayer and McCune (21), which was produced in the same way except that the CrO(OH) was contained in a platinum thimble, is probably $FeCr_2O_4$ or $(Fe,Ni)Cr_2O_4$. Certainly

their X-ray diffraction pattern (21) agrees closely with our pattern. Their failure to detect much iron in their "cubic Cr_2O_3" may result from the difficulty of dissolving $(Fe,Ni)Cr_2O_4$, which in any event contains only *ca.* 10% iron and furthermore the Laubengayer–McCune sample was contaminated with CrO(OH). The incomplete reaction of CrO(OH) in the Laubengayer–McCune (21) and Shafer–Roy (12) experiments is ascribed to its limited chemical contact with the stainless steel vessel walls, via the supercritical aqueous fluid through leaks or openings in the platinum container. The reported conversion of the "cubic Cr_2O_3" to α-Cr_2O_3 by heating in air at 800 °C (21) may result from aerial oxidation of $FeCr_2O_4$ to a solid solution of α-Fe_2O_3 in α-Cr_2O_3 (22), whose X-ray diffraction pattern is similar to that of α-Cr_2O_3.

Corrosion of Stainless Steel by High-Temperature Water

The chief corrosion product of stainless steel by water in the temperature range 200–350 °C is the mixed spinel $(Fe,Ni)(Cr,Fe)_2O_4$, in which the chromium content increases with the reaction temperature (23). This suggests that the metal surface reacts with water to produce $Fe(OH)_2$, which can react slowly with liquid water at 200 °C to produce Fe_3O_4. However, the concomitant aqueous oxidation of the chromium and nickel components in the stainless steel to produce CrO(OH) and $Ni(OH)_2$ will be followed (especially at the higher temperatures) by reaction with $Fe(OH)_2$ to produce $FeCr_2O_4$, and above 300 °C to produce $(Fe,Ni)Cr_2O_4$.

This insoluble chromite may be largely responsible for the passivity of stainless steel in contact with water above 200 °C. However, the oxidation of aqueous chromium(III) by molecular oxygen, at low acidities and above 250 °C, to soluble chromium(VI) suggests that the passivity of stainless steel in high-temperature aqueous environments may be destroyed by the presence of molecular oxygen in the system; the iron(II) content would yield iron(III) oxides which may be non-protective.

Hydrothermal Synthesis of Chromium Spinels

The results indicate that chromium spinels can form hydrothermally from the appropriate hydrolyzed metal species (*i.e.*, $M(OH)_2$ and $Cr(OH)_3$ or CrO(OH)) above 300 °C. The reaction of $Fe(OH)_2$ with CrO(OH) may be complicated by the slower reaction of $Fe(OH)_2$ with liquid water to produce Fe_3O_4 and hydrogen, but the main product is $FeCr_2O_4$ above 200 °C. This complication is avoided when the unstable $Fe(OH)_2$ is replaced by $Mn(OH)_2$, $Co(OH)_2$, $Mg(OH)_2$, and $Ni(OH)_2$. The manganese, cobalt and magnesium hydroxides produced a spinel after several days at 300 °C. The order of entry into the M(II) sites of MCr_2O_4 is $Fe^{2+} > Mn^{2+}$, $Co^{2+} > Mg^{2+} \gg Ni^{2+}$. This sequence is generally consistent with the thermodynamic data (24) for the formation of MCr_2O_4 from Cr_2O_3 and MO.

The failure to produce $NiCr_2O_4$ hydrothermally may be due to the conversion of $Ni(OH)_2$ into NiO between 250 and 300 °C. Ligand field theory predicts that Ni^{2+} will not readily leave the octahedral site in NiO, which has the NaCl structure, for a tetrahedral site in $NiCr_2O_4$; and it is unlikely to compete with Cr^{3+} for the octahedral sites. On the other hand, Mn^{2+} (d^5, high spin) and especially Co^{2+} (d^7, high spin) should enter tetrahedral sites readily.

Possible Hydrothermal Origin of Certain Chromite Mineral Deposits

Most major deposits of the mineral chromite, $(Fe,Mg)(Cr,Al,Fe)_2O_4$, were formed by magmatic segregation in ultrabasic rocks. Indeed chromite is one of the first minerals to separate from a cooling rock magma. However, several authors (25) have argued that chromite grains, which occur in hydrothermally altered ultrabasic rocks such as serpentinites, may have been deposited by the hydrothermal solutions themselves.

These views have not gone unchallenged (26), and it is not intended to review critically the mineralogical evidence for and against a hydrothermal origin of chromite in serpentinized rocks. The results in this paper show that $FeCr_2O_4$ and $MgCr_2O_4$, and therefore presumably $(Fe,Mg)Cr_2O_4$, may be deposited from aqueous solutions at near-neutral p*H* values, even in geologically short times and at temperatures of 300 °C and probably less. The few attempts to produce spinel ($MgAl_2O_4$) hydrothermally were unsuccessful, but it is expected that Al^{3+} like Fe^{3+} could be incorporated into the octahedral sites of a hydrothermally formed chromite in serpentinized rocks.

It is apparent that complexing of chromium(III)

by sulfate or chloride is necessary to effect large-scale transport of chromium(III) by aqueous solutions at temperatures about 300 °C into the regions where serpentinization occurs. It is noted that high concentrations of alkali metal chlorides and perhaps less commonly sulfates are evidently present in typical hydrothermal ore-forming fluids (27).

We thank Atomic Energy of Canada, Ltd., for financial support of this work through Whiteshell Nuclear Research Establishment, and Mr. D. Harvey for the X-ray fluorescence analyses.

Received December 22, 1970

The stabilities of aqueous solutions of typical salts of manganese(II), iron(II), cobalt(II), cobalt(III), nickel(II), and copper(II) at temperatures up to 300 °C have been investigated. At 200 to 300 °C, hydrolysis of the metal ions can lead to the partial precipitation of metal oxides, or silicates in the cases of nickel(II) and cobalt(II) when a silica vessel is used; except for the M(II) sulfates, which precipitate as $MSO_4.H_2O$ (M = Mn, Fe, Co, and Ni) and $Cu_3SO_4(OH)_4$. Manganese(II), iron(II), and cobalt(II) tend to be oxidized at 250 to 300 °C in neutral or acidic solutions, while cobalt(III) in aqueous ammonia is reduced. Aqueous $CuCl_2$ is in equilibrium with CuCl and Cl_2 at 300 °C. Hydrolytic precipitation is suppressed by the addition of small concentrations of hydrogen ion or larger concentrations of chloride ion, if oxidation–reduction processes do not interfere.

Les stabilités des solutions aqueuses de quelques sels caractéristiques de manganèse(II), fer(II), cobalt(II), cobalt(III), nickel(II) et cuivre(II) ont été étudiées jusqu'à des températures de 300 °C. Entre 200 et 300 °C, l'hydrolyse des ions métalliques peut provoquer une précipitation partielle d'oxydes métalliques, ou de silicates dans le cas du nickel(II) et cobalt(II) et ceci lorsque des récipients en silice sont utilisés; exception faite pour les sulfates de M(II) qui précipitent en tant que $MSO_4.H_2O$ (M = Mn, Fe, Co et Ni) et $Cu_3SO_4(OH)_4$. Le manganèse(II), le fer(II) et le cobalt(II) ont tendance à être oxydés entre 250 et 300 °C dans des solutions neutres ou acides, alors que le cobalt(III) est réduit dans l'ammoniaque aqueux. Une solution aqueuse de $CuCl_2$ est en équilibre à 300 °C avec du CuCl et du Cl_2. La précipitation hydrolytique peut être supprimée par l'addition d'ions hydrogène en petite concentration ou d'ions chlorure en concentration plus élevée, à condition que le processus d'oxydo-réduction n'interfère pas.

Canadian Journal of Chemistry, 49, 2442 (1971)

Introduction

The experiments reported herein were undertaken primarily to determine the feasibility of spectroscopic and other physicochemical studies of aqueous ions of the more common transition elements (manganese, iron, cobalt, nickel, and copper) at temperatures in the 100 to 300 °C range. Such studies are relevant to the corrosion processes and the transport of radioactive material in boiling or pressurized-water nuclear power reactors, and also the geochemistry of certain mineral deposits which have a hydrothermal origin. In any event the extension of our knowledge of the chemistry of aqueous solutions to temperatures beyond their normal boiling points is highly desirable (1).

Experimental

The chemicals used were Fisher Certified reagents with the exceptions of perchloric acid (Baker Analyzed) and $Co(ClO_4)_2.6H_2O$ (Alfa Inorganics). Perchlorate salts were prepared by precipitation of the corresponding metal hydroxide from a solution of the nitrate or chloride, followed by dissolution in dilute perchloric acid; precipitation and redissolution were repeated until the original anion could not be detected in the solution. Some of the $Co(ClO_4)_2.6H_2O$ used was also prepared in this manner with identical results as the commercial chemical.

The equipment and techniques have been described previously (2). The vessels are type 316 stainless steel, or titanium with 0.2% palladium. The solutions were contained in loosely-capped silica liners within the pressure vessels in all cases, to facilitate observation of small amounts of precipitate and to prevent interaction of the solutions with the metal of the vessel walls. In all experiments, the atmosphere in the vessels prior to heating was nitrogen at 1 bar pressure, and in no case did the partial pressure of nitrogen at high temperatures exceed 3 bars. Most experiments were duplicated to ensure reproducibility of the observations.

Concentrations are expressed in molar units valid at 20 °C, and the percentage decompositions quoted are the decreases in metal ion concentration in the solutions, measured spectrophotometrically. The letters ASTM followed by numbers refer to the data in the X-Ray Diffraction Powder File.

Results

Manganese

Manganese(II) perchlorate (0.05 *M*) maintained at 300 °C for 24 h in either a titanium or stainless steel vessel deposited 4% of a brown–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

black solid (probably MnO(OH) or MnO_2). The same result was obtained after repeating the experiment with the addition of 0.012 *M* $HClO_4$. Manganese(II) nitrate (0.2 *M*) decomposed completely in 24 h at 300 °C in a titanium vessel to yield well-crystallized MnO_2 (pyrolusite, ASTM 12-716). At 250 °C, 0.2 *M* manganese(II) nitrate in a stainless steel vessel again decomposed completely in 24 h, but the products were mainly β-MnO(OH) (teitknechtite, ASTM 18-804) and γ-MnO(OH) (manganite, ASTM 18-805) and some MnO_2.

Manganese(II) chloride solution (0.05 *M*) in a stainless steel vessel lost about 9% of its manganese content (as determined by EDTA titration) at 300 °C in 24 h as a brown precipitate and suspension; the addition of 0.75 *M* NaCl prior to heating reduced this loss of manganese content to 4%. More concentrated $MnCl_2$ (0.2 *M*) similarly yielded a black precipitate (probably MnO(OH) or MnO_2) at 300 °C in 24 h; and at 250 °C a small quantity of a brown precipitate appeared as a light suspension, whether the solution was heated for either 1 day or 6 days. Manganese(II) sulfate (0.2 *M*) at 300 °C for 24 h yielded a well-crystallized white solid, $MnSO_4.H_2O$ (szmikite, ASTM 14-166).

Iron

Iron(II) chloride (0.05 *M*) at 300 °C for 24 h in a titanium vessel yielded well-crystallized α-Fe_2O_3 (hematite, ASTM 13-534) and a substance with a strong reflection at 4.92 Å and a weak reflection at 1.60 Å; the solution was colorless. No precipitate other than a slight turbidity is observed when 0.2 *M* $FeCl_2$ is heated with 0.1 *M* HCl at 300 °C for 24 h, although this iron(II) solution is slightly cloudy at the outset, presumably because of failure to remove the last traces of oxygen. Iron(II) sulfate solution (0.2 *M*) in H_2SO_4(0.1 *M*) at 300 °C in a stainless steel vessel for 24 h yielded $FeSO_4.H_2O$ (szomolnokite, ASTM 12-226) and a small amount of α-Fe_2O_3.

Cobalt

At 300 °C for 24 h in a stainless steel vessel 1.17 *M* cobalt(II) perchlorate yielded Co_3O_4 (ASTM 9-418) whether $NaClO_4$ is present or not, but 0.05 *M* $Co(ClO_4)_2$ in 0.01 *M* $HClO_4$ yielded 25% of black, highly-crystalline solid, whose X-ray diffraction pattern is similar to that of CoO(OH) (heterogenite, ASTM 7-169). At 250 °C for 24 h, the brown product obtained in absence of $HClO_4$ contained both cobalt and silicon in approximately a 2:5 atomic ratio as determined by X-ray fluorescence analysis; its X-ray diffraction pattern was diffuse, but the main reflections coincided with those of synthetic cobalt talc, $Co_3Si_4O_{10}(OH)_2$ (ASTM 15-187). This cobalt silicate is evidently the synthetic cobalt talc of Pistorius (3) intermixed with amorphous silica. At 200 °C for 24 h in a stainless steel vessel only a trace of a black precipitate (probably Co_3O_4) formed from 1.17 *M* $Co(ClO_4)_2$.

Cobalt(II) nitrate (0.025 to 0.01 *M*) at 300 °C for 24 h yielded black Co_3O_4 in major quantities. The Co_3O_4 yield is slightly greater when 1.0 *M* $NaNO_3$ is present. Approximately 8% of a similar black precipitate was obtained at 250 °C in 24 h with a titanium vessel, but the yield was 40% with a stainless steel vessel; the discrepancy probably originated through loss of HNO_3 in the vapor phase, either by leakage through the asbestos gasket or by reaction with the stainless steel.

Cobalt(II) chloride solutions (0.05 *M*) at 300 °C in either a titanium or stainless steel vessel yielded a black precipitate (probably Co_3O_4); the yield was only 10% after 7 days. This precipitation was suppressed completely by the addition of 0.01 *M* HCl or 0.25 *M* (or more) NaCl for cobalt concentrations from 0.045 to 0.18 *M* at least. At 250 °C in a titanium vessel $CoCl_2$ solutions without either HCl or NaCl added deposited a black precipitate (probably Co_3O_4) of less than 1% in 24 h and 5% in 6 days. Even at 200 °C a trace of a black residue was noticed. Cobalt(II) bromide solution (0.05 *M*) in a stainless steel vessel at 300 °C deposited a similar quantity of a black solid (probably Co_3O_4), and this precipitation was entirely suppressed by the addition of 0.01 *M* HBr but not by 1.0 *M* NaBr, which yielded 3% insoluble cobalt compounds.

Cobalt(II) sulfate solutions (0.09 *M*) in either a titanium or stainless steel vessel yielded in 24 h a trace of a black precipitate (probably Co_3O_4) even at 150 °C; but at 200, 250, and 300 °C, 0.05 to 0.4 *M* $CoSO_4$ solutions yielded a pink solid which is mainly $CoSO_4.H_2O$ (ASTM 15-701). It could be dissolved on prolonged contact with fresh water to give a red solution of Co^{2+} (aq) and a blue residue which is mainly poorly-crystalline α-$Co(OH)_2$ (ASTM 2-925). Thus typically a 0.4 *M* $CoSO_4$ solution deposited 42% of the pink solid at 300 °C in 24 h; the soluble component was shown spectroscopically to con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tain 32% cobalt (*cf.* 33% for authentic $CoSO_4.H_2O$), and the residue after 24 h contact with water at 20 °C contained α-$Co(OH)_2$ and 6% sulfur, *i.e.* it contained 4 mol $Co(OH)_2$ to 1 mol of $CoSO_4.H_2O$. Addition of H_2SO_4 to the $CoSO_4$ solution prior to heating prevented deposition of $Co(OH)_2$, so that $CoSO_4$ (0.1 *M*) in H_2SO_4 (0.09 *M*) produced a 25% yield of pure $CoSO_4.H_2O$ at 300 °C in 24 h.

Hexaaminecobalt(III) chloride (0.128 *M*) in water and 1.4 *M* ammonia or 2.7 *M* ammonia decomposed completely at 300 °C in 24 h to yield mainly black Co_3O_4 and blue α-$Co(OH)_2$. A pink solid (probably $CoSO_4.H_2O$) was also present in the product from water at 300 °C.

Nickel

Nickel(II) perchlorate (0.05 *M*) at 300 °C in a titanium vessel for 24 h yielded 5% of a fibrous green precipitate, synthetic nickel talc ($Ni_3Si_4O_{10}(OH)_2$, ASTM 15-384) with some poorly crystalline synthetic nickel serpentine ($Ni_3Si_2O_5(OH)_4$, ASTM 11-98) (3). However, in the presence of 0.012 *M* $HClO_4$ at 300 °C for 24 h, no precipitate formed and the solution remained clear. Similarly nickel(II) nitrate (0.05 *M*) at 300 °C for 24 h yielded $Ni_3Si_4O_{10}(OH)_2$ with some $Ni_3Si_2O_5(OH)_4$, but these yields were greater than with the perchlorate salt at 70% for 0.025 *M* Ni(II), and 14% for 0.2 *M* Ni(II); the same products were obtained in lesser yields at 250 °C for 24 h. Again nickel(II) chloride (0.05 *M*) in 24 h gave the same silicates at 300 °C in yields of 10%. This occurred even in the presence of 0.5 *M* NaCl, and also to a minor extent at 200 °C. Nickel(II) sulfate solutions (0.05 *M*) in 24 h yielded 72% at 300 °C and 32% at 250 °C of the green solid, $NiSO_4.H_2O$ (ASTM 1-659).

Copper

Copper(II) perchlorate solutions (0.05 *M*) to 0.2 *M* yielded 4 to 6% of black CuO (tenorite, ASTM 5-661) at 300 °C in 24 h in a stainless steel vessel but this precipitation was prevented completely by the presence of 0.012 *M* $HClO_4$. A more dilute 0.02 *M* $Cu(ClO_4)_2$ solution remained homogeneous at 300 °C after 24 h even in the absence of $HClO_4$, so that the copper(II) concentration is an important variable. Copper(II) nitrate (0.05 *M*) produced well-crystallized CuO at 300 °C in a stainless steel vessel with a 5% yield in 24 h and a 10% yield after 5 days.

Copper(II) chloride (0.05 *M*) at 300 °C for 24 h in a stainless steel vessel yielded 22% of white, highly-crystalline CuCl (nantokite, ASTM 6-344), but no precipitate formed and the solution remained clear when the experiment was repeated at 300 or 250 °C in a titanium vessel. However, when the experiment was repeated at 300 °C using a titanium vessel in which the silica liner was wound on the outside with iron wire, CuCl was again precipitated and the wire was severely corroded. Copper sulfate solution (0.02 *M*) produced a large yield of well-crystallized $Cu_3SO_4(OH)_4$ (antlerite, ASTM 7-407) at 300 °C in 24 h.

Discussion

Many of the above results can be understood if it is recognized that the "hydrolysis" (acid dissociation) reactions 1 and 2 of divalent metal aquo ions is significant at 200 °C and of major importance at 300 °C.

$$[1] \quad M(H_2O)_6^{2+} \overset{K_1}{\rightleftharpoons} M(H_2O)_5OH^+ + H^+$$

$$[2] \quad M(H_2O)_5OH^{2+} \overset{K_2}{\rightleftharpoons} M(OH)_2(s) + H^+ + 4H_2O$$

Criss (4) has predicted that when M is manganese, pK_1 should fall sharply with temperature from 10.6 at 25 °C to 5.3 at 200 °C; further extrapolation suggests that pK_1 is less than 4 at 300 °C. It is expected that the other metal ions considered in this article (M = Fe, Co, Ni, and Cu) will be more acidic than Mn^{2+}(aq) (5).

M(II) Perchlorates

The deposition of CuO from aqueous $Cu(ClO_4)_2$ at 300 °C involves the dehydration of $Cu(OH)_2$, as this is known to occur in the presence of water above 77 °C (6). Similarly $Ni(ClO_4)_2$ at 300 °C probably formed some $Ni(OH)_2$, which would react with the silica dissolved from the liner to form $Ni_3Si_4O_{10}(OH)_2$ and $Ni_3Si_2O_5(OH)_4$; addition of a small amount of perchloric acid prevented this, just as it prevented deposition of CuO from aqueous $Cu(ClO_4)_2$. Therefore silica equipment is not inert with these aqueous solutions at 200–300 °C. Silica is quite soluble in superheated water (7) with solubilities of 900 p.p.m. at 200 °C and 1400–1500 p.p.m. at 300 °C (8). Cobalt(II) perchlorate solutions at 250 °C reacted similarly to their nickel analogues to form $Co_3Si_4O_{10}(OH)_2$, but at 300 °C partial oxidation of cobalt(II) occurred with the pre-

For personal use only.

cipitation of Co_3O_4. In the presence of added $HClO_4$ but not $NaClO_4$, the precipitate was entirely cobalt(III) in the form of CoO(OH), which is also obtained from aqueous suspensions of $Co(OH)_2$ by boiling in air or by aerial oxidation at 20 °C (9).

Only a small concentration of added acid will suppress hydrolytic precipitation at 300 °C. This is consistent with Criss' predicted K_1 values (4) which show that reaction 1 though important at high temperatures favors the unhydrolyzed aquo-ion at 300 °C unless other factors intervene.

M(II) Nitrates

Whereas perchlorate ion is probably not appreciably basic at 300 °C, nitric acid is incompletely dissociated in aqueous solutions at high temperatures (10), so that hydrolytic precipitation from nitrate solutions is significantly greater than that from the perchlorate analogues, *cf.* chromium(III) nitrate (2). Cobalt(II) nitrate like the perchlorate precipitated Co_3O_4 at 300 °C. The formation of β-MnO(OH), γ-MnO(OH), and MnO_2 from $Mn(NO_3)_2$ solutions at 250 °C may involve oxidation by HNO_3 or its decomposition products. The mixture, hydrohausmannite, has been made (11) by aerial oxidation of an aqueous suspension of $Mn(OH)_2$ at 25 °C, but at 350 °C a reducing environment (hydrogen gas) is apparently necessary to prevent the oxidation of $Mn(OH)_2$ by liquid water (12). Criss (4) predicted that potential reducing agents are unstable in water at high temperatures, and this agrees with the observed oxidation of $Fe(OH)_2$ (2) and the formation of cobalt(III) from cobalt(II) in hydrothermal experiments. Aqueous nitric acid decomposes to oxygen and nitrogen(IV) oxide above 250 °C (2, 13), and at 300 °C a manganese(II) nitrate solution yields manganese(IV) oxide exclusively in accordance with the development of more strongly oxidizing conditions.

M(II) Chlorides

The precipitation of small quantities of various metal oxides or silicates from manganese(II), iron(II), cobalt(II), and nickel(II) solutions is suppressed by the addition of a little HCl, and also by a large concentration of NaCl. Chloride ion has been shown (14) to complex the metal ion at high temperatures and so displaces the reactions 1 and 2 further toward the left. This is particularly effective with cobalt(II), which gives comparatively stable tetrahedral halo-complexes. Bromide is markedly less effective than chloride in the suppression of precipitation, despite its lower basicity towards protons, and this reflects the lower ligand-field strength of bromide. The increasing importance of anion–cation complexing in aqueous solutions as one goes to higher temperatures is a consequence of the decreasing numerical value of the product of the solvent dielectric constant and the absolute temperature (2, 14).

Aqueous $CuCl_2$ at 300 °C yielded crystalline CuCl if the vapor phase was in contact with iron or stainless steel, which was then heavily corroded. This phenomenon suggests that the reaction

$$[3] \quad Cu^{2+}(aq) + 2Cl^{-}(aq) = CuCl(s) + \tfrac{1}{2}Cl_2(g)$$

which is very unlikely at 25 °C ($E^0 = -0.82$ V (15)), may become sufficiently favored at 300 °C that continuous removal of chlorine from the gas phase by reaction with iron would reduce significant amounts of copper(II) to CuCl. Indeed the available thermodynamic data (16) enable one to calculate $\Delta H^0 = +11$ kcal for reaction 3 at 25 °C, *i.e.*, it is favored by high temperatures.

Hydrothermal precipitation from solutions of $CrCl_3$, $MnCl_2$, $FeCl_2$, $CoCl_2$, $NiCl_2$, $CuCl_2$, $ZnCl_2$, and $AlCl_3$ has been reported by Fischer (17) to occur at 210 °C in ordinary sealed glass tubes, but these reactions would certainly be influenced by the presence of silicates and alkali leached from the glass. Katsurai and Sone (18) on the other hand found that solutions of several cobalt(II), nickel(II), and copper(II) salts remained visibly homogeneous up to at least 200 °C.

M(II) Sulfates

Solutions of manganese(II), iron(II), cobalt(II), and nickel(II) sulfates all yielded the monohydrates, $MSO_4.H_2O$, which are isomorphous with kieserite, $MgSO_4.H_2O$, which has a known structure (19). The insolubility of these and certain other basic sulfates (2, 20) under hydrothermal conditions may reflect the fact that sulfate ion exists almost exclusively as HSO_4^- in water between 300 and 400 °C (21), so that aqueous MSO_4 at 300 °C exists as MOH^+ and HSO_4^-. These components form $MSO_4.H_2O$ in the solid state.

The $NiO–SO_3–H_2O$ system at high temperatures has received detailed attention by previous workers (22), as has the $CuO–SO_3–H_2O$ system

(23). Our results with these solutions agree with the published data.

M(III) Salts

The total decomposition of aqueous $Co(NH_3)_6^{3+}$ to Co_3O_4 and α-$Co(OH)_2$ at 300 °C, even in the presence of large excesses of ammonia, was predictable; since at 20 °C the $Co(H_2O)_6^{3+}$ ion is slowly but completely reduced by water to cobalt(II), reaction 4, and the kinetic barriers which prevent aquation of $Co(NH_3)_6^{3+}$ at 20 °C would be overcome at high temperatures.

[4] $$4Co^{3+} + 2H_2O = 4Co^{2+} + 4H^+ + O_2$$

On the other hand, the partial reduction of cobalt(III) to cobalt(II) in these basic solutions contrasts with the tendency of cobalt(II) to be oxidized to cobalt(III) in acidic environments at high temperatures. These facts are reconciled by supposing that reaction 4 is freely reversible at high temperatures; oxygen may have been present in our experimental systems in small amounts as a contaminant, or in greater quantity as a decomposition product of HNO_3 or $HClO_4$.

The high-temperature aqueous chemistry of chromium(III) and iron(III) has been dealt with elsewhere(2, 20, 24).

NOTES

Oxidation of 1,4-Cyclohexadiene Dioxide with Dimethyl Sulfoxide

B. McKAGUE

Orchem Research, 3650 Wesbrook Crescent, Vancouver 167, British Columbia

Received March 17, 1971

The oxidation of 1,4-cyclohexadiene dioxide with dimethyl sulfoxide and boron trifluoride etherate catalysis yields catechol in 70–75% yield.

L'oxydation du dioxyde du cyclohexanediène-1,4 par le diméthyl sulfoxyde, catalysée par l'éthérate de trifluorure de bore, conduit au cathécol avec un rendement de 70–75%.

Canadian Journal of Chemistry, **49**, 2447 (1971)

The use of dimethyl sulfoxide as an oxidizing agent in organic chemistry has recently been reviewed (1). The boron trifluoride etherate catalyzed oxidation of epoxides with dimethyl sulfoxide provides a useful synthesis of α-hydroxyaldehydes and α-hydroxyketones and the oxidation of cyclohexene oxide gives 2-hydroxycyclohexanone in good yield (2, 3). The reaction has been demonstrated as proceeding through an intermediate alkoxysulfonium salt which decomposes to the hydroxyketone and dimethyl sulfide (4).

The boron trifluoride etherate catalyzed oxidation of 1,4-cyclohexadiene dioxide (5, 6) with dimethyl sulfoxide yields catechol in 70–75% yield. Presumably after the oxidation of one epoxide ring the reaction intermediates decompose as shown in Scheme 1, dimethyl sulfide being a readily identifiable product.

The decomposition of the intermediate epoxyketol to catechol rather than resorcinol or hydroquinone would appear reasonable on the basis of the known severity of conditions usually required to eliminate hydroxyl groups next to ketone functions (7, 8) and the expected ease of epoxide opening due to the adjacent active methylene group (9).

The reaction was carried out using dimethyl sulfoxide as solvent, 0.025 to 0.1 mol of boron trifluoride etherate per mol of diepoxide, and a temperature of 90 to 130 °C. Under these conditions the time required for reaction was 3 to 12 h depending on the aforementioned variables. The reaction was also performed with tetramethylene sulfoxide, tetramethylene sulfide being isolated and identified.

The reaction was generally performed on the *trans*-diepoxide (5, 6) since the favored method of preparation was the *t*-butyl hydroperoxide – molybdenum trioxide method (10) which gave nearly exclusively the highly crystalline *trans*-isomer. However, when the diepoxide is prepared by an extension of the halohydrin method for cyclohexene oxide (11) a nearly equal mixture of both isomers is obtained which can also be used. Separation of the *cis*-isomer (6) by column chromatography on alumina and reaction separately also gave catechol in similar yield. Various

For personal use only.

per-acids may also be used to prepare the diepoxides (6).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were run on a Perkin–Elmer Model 521 Grating Infrared Spectrophotometer. Gas chromatography was carried out on a Varian Aerograph Model 1200. The n.m.r. spectra were determined in deuteriochloroform at 60 MHz on a Varian T-60 spectrometer. Column chromatography was performed on standard silica gel and neutral activity II alumina.

Mixture of cis- and trans-1,4-Cyclohexadiene Dioxide

Calcium hypochlorite (19.0 g, 0.13 mol) was added to water (250 ml), and treated with glacial acetic acid (15.8 g, 0.26 mol). The resultant solution was added dropwise with stirring to 1,4-cyclohexadiene (8.4 g, 0.105 mol) over 45 min maintaining the temperature at 15–20 °C by cooling in a cold water bath. After the addition was complete the solution was stirred 10 min, then saturated with salt, and extracted with five 50-ml portions of ether. The combined extracts were washed with saturated salt solution, dried over anhydrous sodium sulfate, and evaporated to give a crude mixture of colorless solid chlorohydrins (17.3 g). This mixture was crushed and suspended in water (20 ml) then added to a solution of sodium hydroxide (8.0 g, 0.2 mol) in water (30 ml). The resultant mixture was stirred for 1½ h then saturated with salt and extracted with five 50-ml portions of dichloromethane. The combined extracts were washed with saturated salt solution and dried over anhydrous sodium sulfate. The solvent removed by distillation through a 40-cm Vigreux column at slightly reduced pressure to yield a crude residual mixture of *trans*- and *cis*-1,4-cyclohexadiene dioxides (10.9 g, 93% yield). Gas chromatography on 5% SE 30, 1/8″ × 5′, at 90 °C indicated the *trans*:*cis* ratio was about 6:4. This procedure could easily be scaled up to large quantities.

Column chromatography of a small amount of this mixture on alumina allowed an easy separation of the two isomers. Elution with benzene gave the pure *trans*-isomer, recrystallized from ether–hexane, m.p. 107.5–108.5 °C (lit. (6) 106.5–107.5 °C) and elution with benzene–ether (9:1) gave the *cis*-isomer, recrystallized from ether–hexane, m.p. 58–60 °C (lit. (6) 60–61 °C). The n.m.r. spectra of each isomer agreed with the reported data (6).

trans-1,4-Cyclohexadiene Dioxide

A solution of 1,4-cyclohexadiene (10 g, 0.125 mol) in benzene (20 ml) was refluxed with 90% *t*-butyl hydroperoxide (37.5 g, 0.375 mol) and molybdenum trioxide (1.0 g) for 12 h. The catalyst was filtered and the solution concentrated to a small volume by vacuum distillation through a 10-cm Vigreux column. The semi-solid crude diepoxide was triturated with hexane, filtered, and crystallized from ether–hexane to give long needles of the pure *trans*-diepoxide (7.5 g) m.p. 107.5–108.5 °C. This procedure could also be scaled up to larger quantities.

Oxidation of trans-1,4-Cyclohexadiene Dioxide with Dimethyl Sulfoxide

A solution of *trans*-1,4-cyclohexadiene dioxide (1.0 g, 8.93 mmol) in dry dimethyl sulfoxide (10 ml) containing boron trifluoride etherate (0.028 ml) was heated in an oil bath at 125 °C for 3 h. Dimethyl sulfide and most of the excess dimethyl sulfoxide were distilled under reduced pressure, the dimethyl sulfide being collected in a Dry Ice – acetone trap and identified by i.r. comparison with an authentic sample. The dark residue was extracted with five 10-ml portions of ether. The combined extracts were washed twice with a small amount of water, then the washes were back-extracted twice with ether. The combined ether extracts were dried over anhydrous sodium sulfate and evaporated to give crude yellow crystalline catechol (920 mg). This was chromatographed on silica gel (20 g) and elution with chloroform – ethyl acetate (5:1) gave pure catechol (740 mg, 75% yield) identical in all respects with an authentic sample.

A number of variations in quantities of the reactants were tried and a similar yield obtained. For example heating the *trans*-diepoxide (1.0 g), dimethyl sulfoxide (15 ml), and boron trifluoride etherate (0.057 ml) at 100–105 °C for 7 h gave catechol in 73% yield. Temperatures lower than 90 °C or smaller amounts of catalyst lowered the yield or made the reaction time unduly long. A mixture of *cis*- and *trans*-diepoxides, as obtained by the chlorohydrin route, or the pure *cis*-isomers could also be used with similar results.

Oxidation of trans-1,4-Cyclohexadiene Dioxide with Tetramethylene Sulfoxide

A solution of the *trans*-diepoxide (1.0 g, 8.93 mmol) in dry tetramethylene sulfoxide (15 ml) containing boron trifluoride etherate (0.028 ml) was heated at 125 °C for 5½ h. Work-up as described above gave tetramethylene sulfide identified by i.r. comparison with an authentic sample and catechol in 50–60% yield.

Molecular Conformation of 4-Thiouridine in Aqueous Solution

F. E. HRUSKA, K. K. OGILVIE, A. A. SMITH,[1] AND H. WAYBORN
Department of Chemistry, The University of Manitoba, Winnipeg 19, Manitoba

Received February 18, 1971

β-4-Thiouridine is a component of several tRNA molecules. A recent X-ray study has shown that this pyrimidine nucleoside favors the *syn* conformation in the crystalline state. The 100 and 220 MHz p.m.r. data and a comparison with those of uridine are presented here. A long-range five-bond spin–spin coupling interaction between the H-5 and -1′ hydrogens is noted. The results are consistent with an *anti* conformation for 4-thiouridine in an aqueous solution.

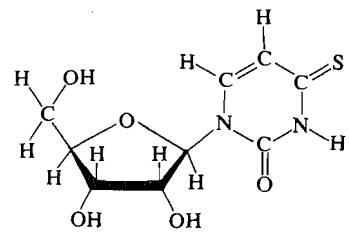
La β-thiouridine-4 est un composant de plusieurs molécules de tRNA. Il a été démontré récemment à l'aide d'une étude par rayons-X que ce nucléoside pyrimidinique existe préférentiellement, à l'état cristallin, dans la conformation *syn*. On a présenté les spectres de r.m.n. à 100 et 220 MHz et une comparaison de ces résultats avec ceux de l'uridine. On note un couplage à longue distance répartie sur cinq liens entre les protons H-5 et -1′. Les résultats sont consistants avec une conformation *anti* pour la thiouridine-4 en solution aqueuse.

Canadian Journal of Chemistry, 49, 2449 (1971)

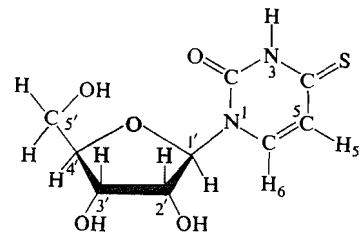
We report here complete analyses of the 100 and 220 MHz spectra of β-4-thiouridine (4-SU). 4-SU is a sulfur analog of β-uridine (U) and is known to occur in a number of *E. coli* tRNA molecules (1). A recent X-ray study (2) has shown 4-SU to be the first pyrimidine nucleoside to favor the *syn* conformation in the crystalline state. The o.r.d. (3) and n.m.r. (4–7) studies, however, argue for a predominantly *anti* conformation for U and its phosphate derivatives in aqueous solution. Green *et al.* (8) have reported an *anti* conformation for U in the solid state as well. In view of the experimental evidence that the *anti* conformation for pyrimidine (and purine) nucleoside di- and triphosphates is required for enzymic incorporation into polynucleotides (9), we have carried out this study to determine the conformation of 4-SU in solution.

The n.m.r. spectra were obtained on Varian HA100 and 220 MHz spectrometers. Samples were freeze-dried three times using 99.8% D_2O. DSS was used as an internal reference. Spectra were analyzed using LAOCOON III (10).

The H-6, -5, and -1′ resonances of 4-SU (obtained at 100 MHz) are shown in Fig. 1. The H-6 doublet ($^3J_{56}$ = 7.7 Hz)[2] is centered at



4-SU *anti*



4-SU *syn*

7.75 p.p.m. from internal DSS. The H-5 region centered at 6.56 p.p.m. is a quartet with a $^3J_{56}$ splitting and a small splitting of 0.35 Hz. Double resonance experiments demonstrated that the 0.35 Hz separation was a consequence of a five-bond long-range spin–spin coupling interaction between the H-5 and -1′ hydrogens. The H-1′ portion of the spectrum consists of a broad doublet ($^3J_{1'2'}$ = 3.9 Hz) at 5.86 p.p.m. No 0.35 Hz splitting is evident in this region, presumably a consequence of the line broadening effect of unresolved long range interactions

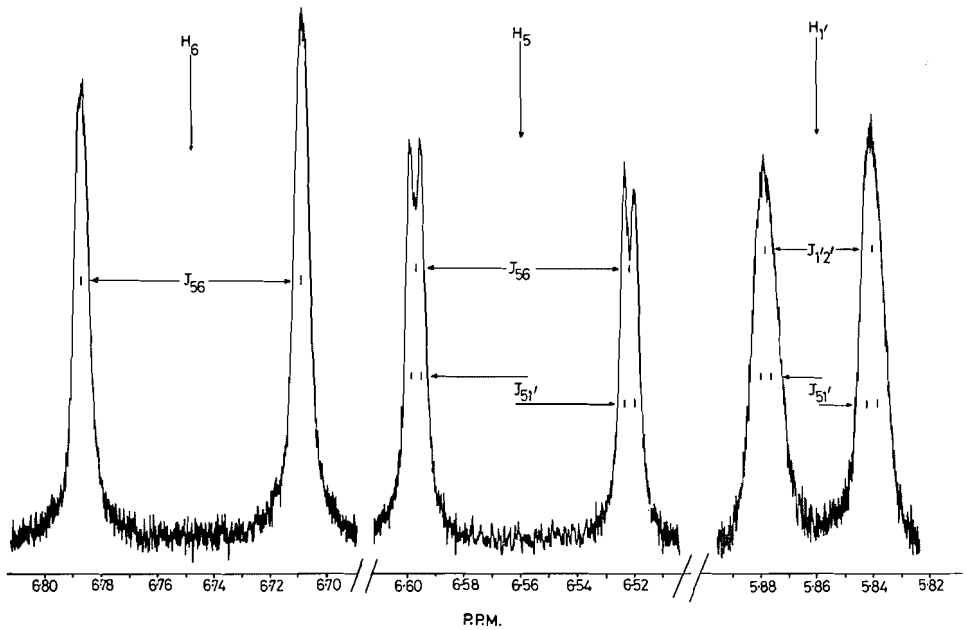

FIG. 1. The H-6, -5, and -1′ portions of the 100 MHz p.m.r. spectrum of a 0.12 *M* aqueous solution of 4-thiouridine (D_2O, p*D* = 6.9, 30 °C). In p.p.m. from internal DSS.

between H-1′ and the H-3′, -4′, and -5′ hydrogens of the ribose ring (11).[3]

The 220 MHz spectrum of the 2′ to 5′ regions is shown in Fig. 2. The assignment of the bands was carried out by comparison with published data for U(4) and confirmed by computer analysis. The calculated spectrum is also shown in Fig. 2.

The chemical shift and coupling constant data are presented in Table 1. For comparison, the 220 MHz data of U taken from ref. 4 are included.

Comparison of the tabulated ribose data reveals a striking similarity for the two nucleosides which is consistent with the existence of 4-SU in the *anti* conformation. First, all the corresponding ^3J and ^2J values differ by 0.1 Hz or less (except for the $^3J_{1'2'}$ values which differ by 0.5 Hz). Furthermore all corresponding ribose chemical shifts are identical to within 0.04 p.p.m. Recent studies, particularly on 1-β-D-ribofuranylcyanuric acid, by Schweizer *et al.* (12) and Dugas *et al.* (5) are relevant in this regard. In this nucleoside a keto group is found at both positions *ortho* to the *N*-glycosyl linkage and hence one keto oxygen must be located above the furanose ring. In this manner the authors have demonstrated that the magnetic anisotropy and steric effects of such a keto group lead to large and specific changes in the chemical shift and coupling constants of the ring. Thus, the similarity in the ribose data must be taken as evidence that 4-SU assumes the *anti* conformation in which the C_6—H_6 (rather than the C_2=O_2) moiety is located above the ribose.

Further evidence for the *anti* conformation of 4-SU is afforded by the long range $^5J_{51'}$ interactions. These interactions are examples of meta benzylic spin–spin coupling (13). Theory (substantiated by considerable experimental data) predicts a critical stereochemical dependence of ^5J couplings. The dependence is such that coupling is favored when the side-chain (H-1′) hydrogen and the meta substituent on the ring are connected by an "extended zig–zag" coupling path (14). Such a path connects the H-1′ and -5 hydrogens of a pyrimidine nucleoside and H-1′ and F-5 of 5-fluoropyrimidine nucleosides in the *anti* (but not the *syn*) conformation. The question of the $^5J_{HF}$ coupling and its relationship to the *syn–anti* structural problem in the latter group of molecules has been thoroughly discussed by Cushley *et al.* (15). Recently Hruska (16) has correlated observed $^5J_{51'}$ H–H couplings in a

[3]Another source of broadening of the H-1′ resonances could be N-1 quadrupolar relaxation.

number of nucleosides with their *anti* forms. No such coupling was detected for orotidine (6-carboxyuridine) which is known to prefer the *syn* form in aqueous solution (17). The interactions of 0.41 and 0.35 Hz for U and 4-SU respectively are, therefore, taken as evidence that a zig–zag path connects the H-5 and -1′ hydrogens in each instance, and, therefore, that 4-SU is *anti* in aqueous solution.

A more detailed consideration of the ribose conformation can be made via a Karplus equation of the vicinal ^3J coupling constant in the manner discussed in earlier reports (4, 18). In view of the similarity in the ^3J values for 4-SU

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and U we may conclude that the conformation of the ribose ring of 4-SU is best described by a rapid equilibrium between various puckered forms (2′-*endo*, etc.). Furthermore, both U and 4-SU exhibit a preference for the *gauche–gauche*[4] rotamer about the $C_{4'}$—$C_{5'}$ bond, the conformation preferred by crystalline β-nucleosides in the *anti* conformation (19).

During the course of our work that of Schweizer *et al.* (12) appeared. The emphasis of their work was on the anisotropy effect of the 2-keto group on the ribose chemical shifts. By comparison of the shifts for a number of molecules the authors concluded that 4-SU existed mostly *anti* in solution. Our present study which involves comparison of the shift and coupling data of U and 4-SU is in agreement with their conclusion.

On the Triplet Energies of the Trifluorobenzenes and of *cis*-Butene-2

G. P. Semeluk and R. D. S. Stevens
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received October 19, 1970

Evans' method of high pressure oxygen induced singlet–triplet absorption spectra were used to estimate the triplet energies of the title compounds. Phosphorescent emission spectra from EPA glassy matrix at 77 °K were taken for the trifluorobenzenes. The 0–0 bands of the T ← S absorption indicate that the triplet energy of *cis*-butene-2 is lower than that of all three trifluorobenzenes.

La méthode d'induction des spectres d'absorption singulet–triplet par l'oxygène sous pression décrite par Evans a été utilisée pour estimer l'énergie des niveaux triplets des composés mentionnés dans le titre. Les spectres d'émission de phosphorescence des trifluorobenzènes en solution dans une matrice de EPA à 77 °K ont été enregistrés. Les bandes 0–0 obtenues du spectre d'absorption T ← S indiquent que l'énergie de l'état triplet du *cis*-butène-2 est inférieure à celles des trois trifluorobenzènes.

Canadian Journal of Chemistry, 49, 2452 (1971)

Introduction

The methods of sensitized biacetyl emission (1) and of butene-2 *cis–trans* isomerization (2) in the detection of triplet states are commonly used techniques. A method which combines the two approaches (3) has been in use in this laboratory for some time. The success of these diagnostics depends primarily on three factors: (*i*) The triplet state energy of the donor relative to that of the acceptor. In solution for example, it appears that

Introduction

The methods of sensitized biacetyl emission (1) and of butene-2 *cis–trans* isomerization (2) in the detection of triplet states are commonly used techniques. A method which combines the two approaches (3) has been in use in this laboratory for some time. The success of these diagnostics depends primarily on three factors: (*i*) The triplet state energy of the donor relative to that of the acceptor. In solution for example, it appears that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the donor triplet energy must exceed that of the acceptor by up to 3 kcal (4). (*ii*) The lifetime of the donor triplet state relative to the mean period between collisions with the acceptor. If processes competitive with the rate of collisions are very fast, then energy transfer may be difficult to observe in a conveniently accessible pressure range. (*iii*) The efficiency of energy transfer from triplet donor to acceptor during a collision. A useful and illuminating discussion of this factor has been given recently by Schmidt and Lee (5).

In a previous study (6), it was speculated that the triplet energy of 1,2,4-trifluorobenzene (1,2,4-F_3B) was lower than that of *cis*-butene-2 (*c*-B-2), based on the result that the addition of up to 50 Torr *c*-B-2 failed to noticeably decrease the biacetyl phosphorescent yield sensitized by triplet 1,2,4-F_3B. Recent work (7) with a number of fluorinated benzenes indicates that pressures of *c*-B-2 as high as 1000 Torr may not completely quench the donor triplet, even though energy considerations ((*i*) above) appear to be favorable. In this respect, triplet energy transfer from these compounds to biacetyl appears to be more efficient than to *c*-B-2. In view of these considerations, we felt it would be useful to determine the triplet state energies by the relatively straightforward method of Evans (8), and to obtain confirmation by examining phosphorescent emission from low temperature matrices, in an attempt to clarify these energy relationships.

Experimental

1,3,5-F_3B and 1,2,4-F_3B were obtained from Peninsular Chemresearch Inc., with a second sample of 1,2,4-F_3B being obtained from Bristol Organics Ltd. 1,2,3-Trifluorobenzene (1,2,3-F_3B) was a gift from Donald R. Dickerson of the Illinois State Geological Survey, Urbana. *c*-B-2 was Philips Research grade and was used without further purification. Chloroform solvent was A.C.S. reagent grade from Allied Chemical Company and was found to be transparent in the spectral region of interest.

The trifluorobenzenes were purified by temperature programmed preparative chromatography using carbowax 20M and di-isodecylphthalate columns with helium carrier.

Two Research and Industrial Instruments Company high pressure u.v. cells (number F-076) were used; one for reference which contained chloroform solvent alone, and one for sample, which contained an optimum concentration of the compound of interest in chloroform solution. Both cells contained equal pressures, typically 50 to 150 atm of oxygen. In the case of gas phase measurements the reference cell contained only oxygen at the same pressure as the sample cell, which in addition contained an optimum partial pressure of the compound. The absorption spectra were recorded on a Hitachi-Colemen model EPS-3T spectrophotometer.

EPA glassy matrix studies at 77 °K were carried out with a modified Aminco-Bowman spectrophotofluorometer. The modifications include a light condensing system and adjustable slits at the entrance to the excitation monochromator, provision for nitrogen flushing of the monochromator cases, for cooling of the emission monochromator photomultiplier housing, and for voltages up to 2500 V across photomultiplier dynode resistor networks.

Results and Discussion

($T \leftarrow S$) absorption spectra were obtained by the ingenious method developed by Evans (8). The (0–0) bands observed in this study, along with that previously reported for benzene (8*c*), are given in Table 1. Also included are the short wavelength limits of the phosphorescent emission from EPA glassy matrices at 77 °K. Not included in Table 1 are the several additional vibrational bands, having no greater diffuseness than observed for benzene, which were clearly evident for all three trifluorobenzenes. The highest of these were 5.9, 5.9, and 6.4 kcal mol^{-1} above the 0–0 bands for 1,3,5-F_3B, 1,2,3-F_3B, and 1,2,4-F_3B, respectively.

The value of 78.2 kcal mol^{-1} for the gas phase triplet energy of *c*-B-2 is higher than the value 76 kcal mol^{-1} obtained by the electron scattering method, but within the stated uncertainty of ± 0.2 eV (9). The data indicate the triplet energy of 1,2,4-F_3B to be greater than that of *c*-B-2 apparently by more than 5 kcal mol^{-1} in the gas phase, and to be only slightly smaller than that of benzene. Triplet–triplet energy transfer ought, therefore, to be energetically possible. Since *c*-B-2 readily quenches the triplet of benzene (2), the apparent "non-effect" of *c*-B-2 on the triplet 1,2,4-F_3B sensitized BiA emission yield may be due to a shorter triplet lifetime, an inefficient energy transfer on collision, to a combination of these factors, or to the experimental limitation noted in the previous article (6). A brief discussion of these considerations is therefore in order.

There is no direct evidence regarding transfer efficiency or triplet lifetimes, but there are reasons to suspect that the lifetimes of fluorinated benzenes may be considerably shorter than the lifetime of triplet benzene (10). As one example we may cite the data already reported (6), which show that 15 and 10 (estimated) Torr of BiA must be used for 1,2,4-F_3B and 1,3,5-F_3B triplets, respectively, to obtain a maximum sensitized

TABLE 1. Triplet energies of trifluorobenzenes and *cis*-butene-2

	From (T ← S) spectra				From (T → S) spectra	
	Vapor		$CHCl_3$ solution		EPA glassy matrix*	
Compound	cm^{-1}	kcal mol^{-1}	cm^{-1}	kcal mol^{-1}	cm^{-1}	kcal mol^{-1}
1,3,5-F_3B	30 120	86.12	30 080	85.99	29 890	85.47
1,2,3-F_3B	29 590	84.59	29 500	84.34	29 150	83.35
1,2,4-F_3B	29 320	83.84	29 280	83.72	29 450	84.21
c-B-2	27 360	78.22	~ 27 800†	79.4†		
Benzene	29 510‡	84.37‡	29 440	84.17	29 400	84.0

*The experimental arrangement did not allow the location of the (0–0) bands in (T → S) emission. The wave numbers noted are the shor wavelength limit of the observed phosphorescent emission.
†It was not possible to locate the (0–0) band precisely since the vibrational structure was very weak and diffuse.
‡Reference 8*c*. Confirmed in this laboratory.

emission yield compared with only 0.12 Torr of BiA for the case of benzene sensitized emission (1). These data suggest that the lifetime of triplet 1,3,5-F_3B is 1.2×10^{-2} times shorter than that of triplet benzene, and that the lifetime of triplet 1,2,4-F_3B is 1.5 times shorter than that of triplet 1,3,5-F_3B, if we assume that triplet energy transfer efficiency from the triplets of these molecules to biacetyl is the same as that from benzene triplet to biacetyl. This assumption is justified in part by two considerations, both supported by experimental observations. Thus, in spite of the wide differences in constitution, symmetry, and polarity between benzene and acetone, the rate of triplet energy transfer from acetone to biacetyl is not much different (less than a factor of two) from that of benzene to biacetyl (Table III, ref. 5). Because of the closer similarity of the trifluorobenzenes to benzene than of acetone to benzene (experimentally supported by a comparison of phosphorescent emission spectra), it may be expected that the triplet transfer efficiency of the substituted benzenes will be closer to that of benzene than to acetone.

Triplet energy transfer efficiency is most conveniently discussed in terms of an "exchange integral" used by Dexter (11) to discuss sensitized luminescence in solid phosphors. This integral may be approximated by the expression

$$K^2 \exp(-2R/L) \int_0^\infty F_d(\bar{\nu}) F_a(\bar{\nu})\, d\bar{\nu}$$

where the "spectral overlap integral" contains $F_d(\bar{\nu})$, the *normalized* donor luminescence (the shape of the phosphorescent emission spectrum), $F_a(\bar{\nu})$, the *normalized* acceptor absorption (the shape of the T ← S spectrum). $\bar{\nu}$ is the wave number, L is an effective average radius of the excited donor and unexcited acceptor molecules, R is the distance between excited donor and acceptor molecules which may be thought of as the donor–acceptor distance in the collision complex, and K^2 is a constant made up of the fundamental quantities relating to the energy transfer process.

Using *c*-B-2 as the acceptor common to 1,2,4-F_3B and 1,3,5-F_3B triplets as donors, we estimate

$$\frac{\int F_{1,2,4\text{-}F_3B} F_{c\text{-}B\text{-}2}\, d\bar{\nu}}{\int F_{1,3,5\text{-}F_3B} F_{c\text{-}B\text{-}2}\, d\bar{\nu}} = 0.93$$

Thus, the spectral overlap difference and the triplet lifetime difference indicate that a *c*-B-2 pressure 1.6 times as great would be required to produce the same extent of quenching of 1,2,4-F_3B triplet as for 1,3,5-F_3B triplet. Qualitatively, then, both factors predict a lesser triplet quenching efficiency of *c*-B-2 with 1,2,4-F_3B. We may therefore conclude tentatively, that the limited pressure range which was experimentally accessible to us in the previous study (6) probably prevented us from observing a *c*-B-2 quenching effect.

A final comment may be useful. It may be suggested that the triplet state which is detected in the spectrofluorometric studies is not the same as is observed in the (T ← S) studies: that there is a rapid crossover from the optically accessible triplet to another not optically accessible *lower* energy $n\pi^*$ triplet. This possibility seems unlikely in view of the existence of a potential well at least 5 kcal in depth in these triplet states, and the apparent absence of diffuseness in the (T ← S) spectra.

Financial support of this work by the National Research Council of Canada is gratefully acknowledged. We wish to acknowledge our indebtedness to Mr. Donald Dickerson, who kindly provided us with a sample of

Acid-catalyzed Solvolysis of Isonitriles. I

Y. Y. LIM AND A. R. STEIN[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received February 16, 1971

The acid-catalyzed hydrolysis of methyl isonitrile has been examined. The initial hydrolysis product is *N*-methylformamide which is further hydrolyzed to methyl amine and formic acid at a much slower rate. The hydrolysis to *N*-methylformamide is pseudo-first order in methyl isonitrile and shows a linear rate dependence on concentration of general (buffer) acid at fixed p*H*. The significance of general acid-catalysis in terms of the mechanism of the hydrolysis is considered and taken as evidence for carbon protonation rather than nitrogen protonation as the initiating step.

L'hydrolyse acido-catalysée du méthylisonitrile a été examinée. Le produit initial de l'hydrolyse est la *N*-méthylformamide qui est hydrolysée ultérieurement en méthylamine et en acide formique selon une vitesse beaucoup plus lente. L'hydrolyse en *N*-méthylformamide est du pseudo-premier ordre en méthylisonitrile et montre une relation linéaire entre la vitesse et la concentration en acide général (tampon) à p*H* déterminé. La signification d'une catalyse acide générale en terme de mécanisme d'hydrolyse est envisagée et constitue la preuve d'une protonation sur le carbone plutôt que sur l'azote, dans l'étape initiale.

Canadian Journal of Chemistry, **49**, 2455 (1971)

There have been numerous studies of the thermal rearrangement of isonitriles to nitriles, especially of methyl isonitrile in the vapor phase (1) and of the more complex reactions of isonitriles, most of which permit the synthesis of otherwise difficultly accessible nitrogen heterocyclic compounds (2). There is, however, a dearth of studies of the simpler chemistry of this fascinating if odoriferous class of compounds, the acid-catalyzed solvolysis being a case in point. Consequently, we have commenced such a study with an examination of the acid-catalyzed hydrolysis of methyl isonitrile to *N*-methylformamide.

Two mechanisms for the hydrolysis of isonitriles have on occasion been suggested, the first involving initial protonation on nitrogen, the other on carbon (3), eqs. 1 and 2 respectively.

Isonitriles are well known to give stable coordination compounds, especially with the softer metal cations (4) and to form strong hydrogen bonds with, for example, chloroform, alcohols, phenols, and water (5). Bonding in both cases is to the carbon of the isonitrile group. Consequently, the initial reversible formation of a hydrogen

bond to carbon might be expected if the second mechanistic sequence were followed. Such hydrogen bonding – proton transfer should show general acid-catalysis since any acidic species present could take part.

For initial protonation on nitrogen (eq. 1), protonation would be much more difficult, requiring a stronger acid and might be expected to show little reversibility in aqueous medium. Here specific acid-catalysis should be observed. This mechanism would be somewhat analogous to the hydration of alkenes, for example isobutylene, where general acid-catalysis is absent and specific acid-catalysis alone is observed (6).

Experimental

Methyl isonitrile was prepared by a procedure slightly modified from that of Ugi *et al.* (7) and redistilled through an 8-in. Vigreux column, b.p. 58.5–59.5 °C, until no impurities were detectable by i.r. or gas chromatography. The product was stored in the dark in a refrigerator, with aliquots being removed as required.

The reaction solutions were made with doubly distilled deionized water. Aqueous stock solutions of reagent grade citric acid and potassium hydroxide were mixed to give the desired p*H* (Radiometer p*H* meter 4d, glass electrode) and concentration and potassium chloride added to give the constant ionic strength (1.333 *M* in potassium ion). After 5 ml of the solution in a thin-walled 10-ml flask fitted with a gum rubber septum had equilibrated in a water bath controlled to 30.00 °C by a Sargent Thermonitor, Model ST, 10 μl of methyl isonitrile was injected, the flask shaken, and the timer started. At time intervals such that 12–20 points could be obtained, 2-μl aliquots were removed with a Hamilton 10-μl syringe and injected directly onto the column of an Aerograph Model 1520B Gas Chromatograph equipped with an all glass system and a flame ionization detector. The column was a 5 ft × $\frac{1}{8}$ in. glass column packed with 0.2% OV-17 on 100–120 mesh glass beads operated at approximately 60 °C.

The area of the methyl isonitrile peak varied linearly with concentration and was used directly as a measure of the relative methyl isonitrile concentration. The p*H* of the reaction solution was the same prior to and after reaction.

Additional experimental detail will appear in a later paper.

Results

The hydrolysis of isonitriles is a two step process:

$$RNC + H_2O \xrightarrow{H^\oplus} RNHCOH$$

$$RNHCOH + H_3O^\oplus \longrightarrow \overset{\oplus}{R}NH_3 + HCO_2H$$

Both reactions or stages are acid-catalyzed but in acidic media, a proton is incorporated in the product of the second. Despite the fact that the first reaction is several orders of magnitude faster than the second and that in following the rate of disappearance of methyl isonitrile, only the first reaction need be considered, the fact that the second reaction incorporates a proton necessitated the use of a rather high buffer concentration to ensure that no detectable change in p*H* occurred, especially in the later stages of the reaction.

In Table 1 are presented the results of a study of the rate constant for the acid-catalyzed hydrolysis of methyl isonitrile as a function of the p*H* and

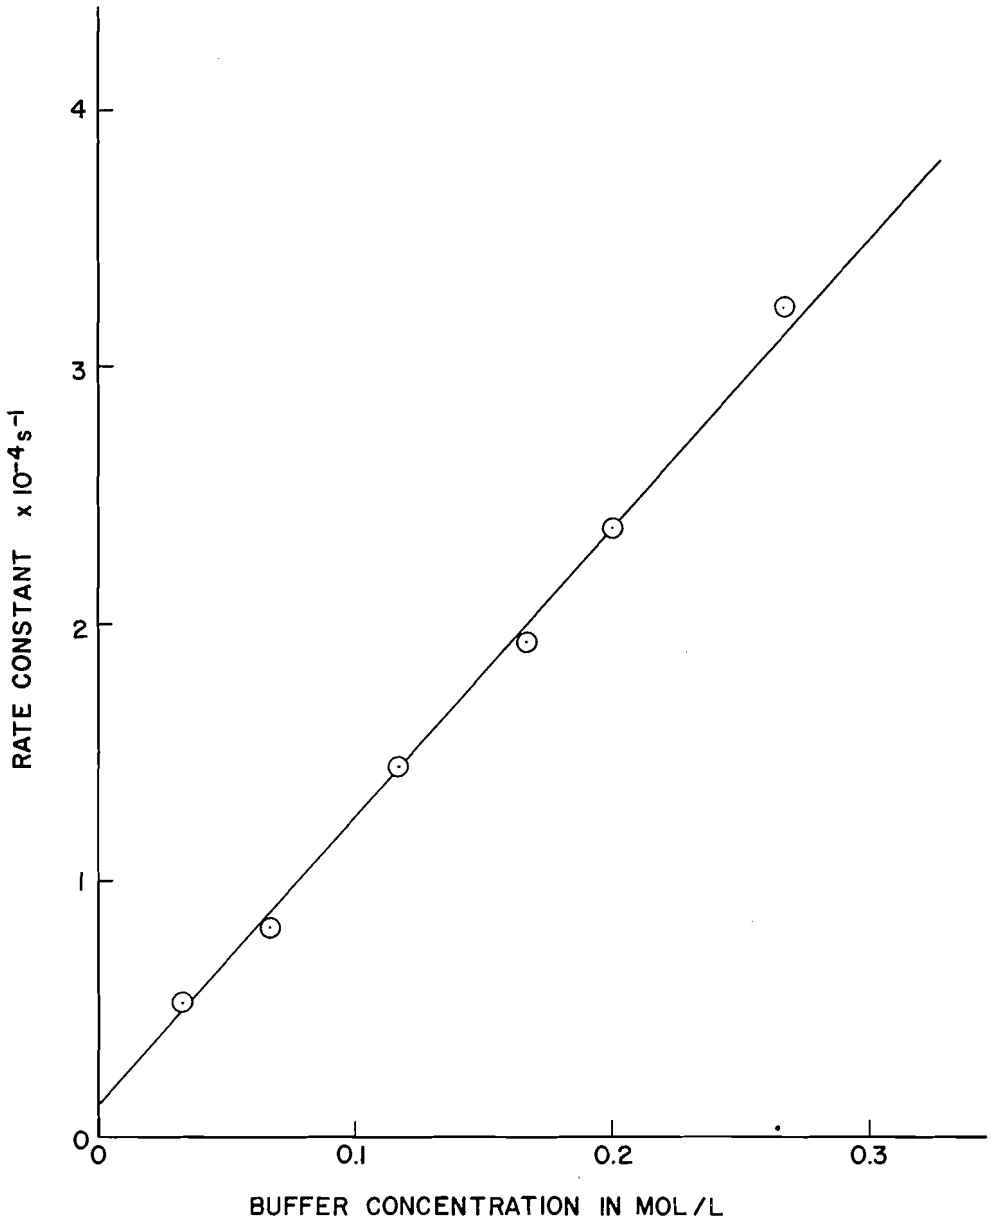

FIG. 1. Effect of citrate buffer concentration on the rate constant for the acid-catalyzed hydrolysis of methyl isonitrile; pH = 4.18; T = 30 °C; ionic strength = 1.33 M.

hydronium ion activity. Throughout this study, the ionic strength was maintained at 1.33 M in potassium ion, the buffer concentration at 0.167 M, and the temperature at 30.00 °C. When plotted as a function of pH, the catalytic rate constant approaches zero asymptotically at high pH and below a pH of 4.5 or 5, increases rapidly with decreasing pH.

Plotting the catalytic rate constant as a function of hydronium ion activity as determined with a glass electrode also gives a curve. Extrapolation to zero hydronium ion activity gives an intercept of zero or slightly greater but the rate of increase in the catalytic rate constant falls off with increasing hydronium ion activity. The acid-catalyzed hydrolysis of methyl isonitrile is then clearly not a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

specific acid-catalyzed process. That the reaction is general acid-catalyzed was confirmed by varying the buffer concentration at constant p*H*.

The results of a study of the rate constant as a function of citrate buffer concentration are presented in Fig. 1. The p*H* was adjusted to 4.18 at each buffer concentration and the ionic strength and temperature were as before. Only at the lowest concentration was any change noted in the p*H* after the reaction period and this was only 0.01–0.02 p*H* unit. Taking the slope of the rate constant *vs.* p*H* curve at p*H* = 4.18, such a change would represent a maximum error in the rate constant of approximately 10%. The actual error from this source, however, should be much less since only in the later stages of the reaction would the concentration of *N*-methylformamide and hence its hydrolysis be significant and so affect the activity of the hydronium ion appreciably. Also no consistent curvature of the plots of the log of methyl isonitrile concentration *vs.* time for two and one half to three half lives was noted and the standard deviation in the least squares treatment of the data was not excessive, being about ±3.5% on the average of six runs at the lowest buffer concentration.

Discussion

The observation that the reaction shows general acid-catalysis means that the observed or experimental rate of disappearance of methyl isonitrile, equating activity and concentration, will be given by eq. 3.

$$[3] \qquad \frac{d[RNC]}{dt} = \{k_{H_3O^\oplus}[H_3O^\oplus] + k_{H_2O}[H_2O] + k_{HA}[HA] + k_{HA'}[HA'] + k_{HA''}[HA''] + \ldots\}[RNC]$$

By the Brønsted catalysis relationship, the log of the individual rate constants will be proportional to the log of the K_a of the acid in question. The values of the appropriate rate constants then will be:

$$k_{H_3O^\oplus} \gg k_{\text{citric I}} > k_{\text{citric II}} > k_{\text{citric III}} > k_{H_2O}$$

Since the study of $k_{obs.}$ *vs.* p*H* was done with fixed total buffer concentration, that is a constant initial amount of citric acid was used and potassium hydroxide solution added to give the desired p*H*, the concentration of citric acid is not constant at the different p*H*'s. Hence the contribution to the observed rate from the acid-catalysis by citric acid and the "bicitrates" would decrease as the activity of the hydronium ion decreased. At "zero" hydronium ion activity, the activities of the various citric acids would also be "zero" so that extrapolation of the $a_{H_3O^\oplus}$ *vs.* $k_{obs.}$ curve to zero hydronium ion activity should give an intercept of zero or, more accurately, at the catalytic rate constant for the only remaining acid, water. (The actual intercept is zero or slightly above but the extrapolation is not sufficiently accurate to assign a value to the water catalytic rate constant.)

The experimental observations are consistent with an acid-catalyzed hydrolysis in which there is a reversible initial hydrogen bonding between a general acid and the isonitrile carbon followed by a rate determining nucleophilic attack, also at carbon, by water. The mechanistic Scheme 1 is

$$RNC + HA \underset{}{\overset{K}{\rightleftharpoons}} RNC\cdots HA$$

$$RNC\cdots HA + H_2O \overset{k}{\rightleftharpoons} RN{=}C\begin{matrix}H\\OH\end{matrix} + HA$$

$$RN{=}C\begin{matrix}H\\OH\end{matrix} \overset{K}{\rightleftharpoons} RNHCOH$$

SCHEME 1

proposed. It must be emphasized that the alternate mechanism with initial protonation at nitrogen has not yet been ruled out but is unlikely in light of the present work. Subsequent papers will report additional results and elaborate upon the mechanistic conclusions presented here.

Far-infrared and Raman Spectra of Crystalline ICN

R. SAVOIE AND M. PÉZOLET

Centre de recherches sur les atomes et les molécules et Département de Chimie, Université Laval, Québec, Québec

Received March 25, 1971

The Raman and far-infrared spectra of crystalline cyanogen iodide have been recorded. High-frequency shoulders alongside the Raman bands confirm the piezoelectric nature of this solid and allow an estimate to be made of the frequencies of the longitudinal modes associated to the fundamental vibrations. Dipole derivatives calculated from these frequencies agree qualitatively with those obtained from infrared band intensity measurements.

Les spectres Raman et infrarouge lointain de l'iodure de cyanogène ont été enregistrés. Des épaulements à plus haute fréquence sur certaines bandes en Raman indiquent que le cristal est piézoélectrique et permettent d'estimer les fréquences des modes longitudinaux associés aux vibrations fondamentales. Les variations du moment dipolaire calculées à partir de ces fréquences sont qualitativement en accord avec les valeurs déduites de la mesure des intensités des bandes infrarouges.

Canadian Journal of Chemistry, **49**, 2459 (1971)

Introduction

The cyanogen iodide molecule, ICN, is known from electron diffraction (1) and microwave studies (2, 3) to be linear, with C—I and C—N bond lengths of 1.995 and 1.159 Å, respectively. The infrared spectra of the crystal reported by Freitag and Nixon (4), and the recent infrared intensity measurements by Bandy *et al.* (5), were found to be consistent with the reported crystal structure of this compound. An X-ray diffraction study (6) of crystalline cyanogen iodide has shown this solid to be built of parallel linear chains, the molecules being located on sites of C_{3v} symmetry. The crystal belongs to the trigonal system (space group C_{3v}^5-$R3m$), with one molecule per primitive cell.

Although ICN exists as a colorless solid at room temperature and seems well suited for Raman investigations, no such study has hitherto been reported. The only available Raman spectrum of cyanogen iodide was obtained with a photographic instrument, from a solution of ICN in methanol (7). Our main interest in this solid stemmed from the fact that it has a crystal structure somewhat similar to that of HCN, the Raman spectrum of which revealed anomalous dispersion on the high-frequency side of the fundamental bands (8). It has already been pointed out that such anomalies should occur in Raman spectra of non centro-symmetric crystals only (9). It was therefore expected that the fundamental bands in the Raman spectrum of crystalline ICN would be complicated by high-frequency shoulders, whereas such an effect was not detected in the spectra of ClCN and BrCN because of their centro-symmetric crystal structure (10).

Experimental

The cyanogen iodide used in our experiments was obtained by the reaction of an aqueous solution of NaCN with solid iodine, as described by Bak and Hillebert (11). The ICN thus produced was extracted with ether and recrystallized several times, first with cold water, and then with cold chloroform until a completely colorless solid was obtained. Purification was also accomplished by vacuum sublimation, but the final product then consisted of silky needles which proved very difficult to handle and gave poorer spectra.

The Raman spectrum was recorded on both a Cary 81 spectrometer with Toronto arc source and on a Spex

Introduction

The cyanogen iodide molecule, ICN, is known from electron diffraction (1) and microwave studies (2, 3) to be linear, with C—I and C—N bond lengths of 1.995 and 1.159 Å, respectively. The infrared spectra of the crystal reported by Freitag and Nixon (4), and the recent infrared intensity measurements by Bandy *et al.* (5), were found to be consistent with the reported crystal structure of this compound. An X-ray diffraction study (6) of crystalline cyanogen iodide has shown this solid to be built of parallel linear chains, the molecules being located on sites of C_{3v} symmetry. The crystal belongs to the trigonal system (space group C_{3v}^5-$R3m$), with one molecule per primitive cell.

Although ICN exists as a colorless solid at room temperature and seems well suited for Raman investigations, no such study has hitherto been reported. The only available Raman spectrum of cyanogen iodide was obtained with a photographic instrument, from a solution of ICN in methanol (7). Our main interest in this solid stemmed from the fact that it has a crystal structure somewhat similar to that of HCN, the Raman spectrum of which revealed anomalous dispersion on the high-frequency side of the fundamental bands (8). It has already been pointed out that such anomalies should occur in Raman spectra of non centro-symmetric crystals only (9). It was therefore expected that the fundamental bands in the Raman spectrum of crystalline ICN would be complicated by high-frequency shoulders, whereas such an effect was not detected in the spectra of ClCN and BrCN because of their centro-symmetric crystal structure (10).

Experimental

The cyanogen iodide used in our experiments was obtained by the reaction of an aqueous solution of NaCN with solid iodine, as described by Bak and Hillebert (11). The ICN thus produced was extracted with ether and recrystallized several times, first with cold water, and then with cold chloroform until a completely colorless solid was obtained. Purification was also accomplished by vacuum sublimation, but the final product then consisted of silky needles which proved very difficult to handle and gave poorer spectra.

The Raman spectrum was recorded on both a Cary 81 spectrometer with Toronto arc source and on a Spex

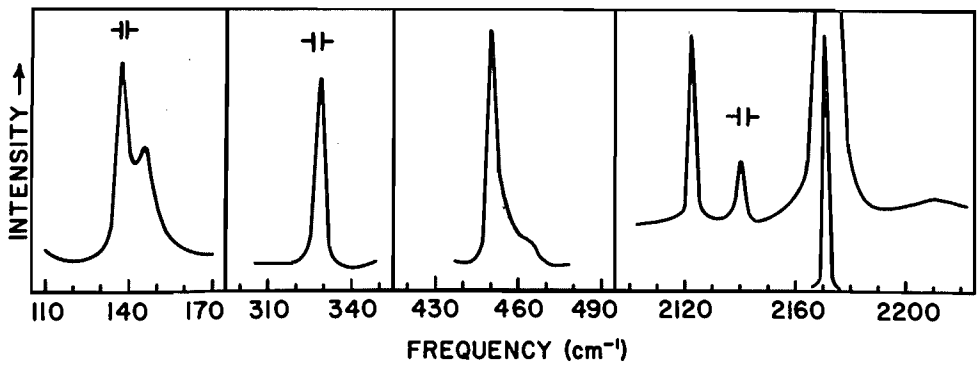

FIG. 1. Raman spectrum of crystalline ICN at −195 °C. Spectral slit widths in the 450 and 2170 cm^{-1} regions are 0.7 and 0.5 cm^{-1}, respectively.

(model 1400) monochromator with He–Ne laser source (Spectra Physics, model 125). These instruments were calibrated with a neon discharge lamp and the frequencies cited later are believed to be accurate to ± 1 cm^{-1}. Best results on the Cary spectrometer were obtained by using a conical cell (12) filled with very small crystals. With the laser instrument, a large polycrystalline needle, obtained by slow evaporation of a chloroform solution, was studied in a sealed capillary tube. The low-temperature spectra were recorded with the sample cells placed inside flat-end Dewar and cooled by a flow of cold nitrogen gas.

The far-infrared spectrum was recorded on a model FS-720 RIIC interferometer coupled to a Fourier transform computer (RIIC, model FTC-100/7). The theoretical resolution of this instrument in the 20–200 cm^{-1} region is 1.25 cm^{-1} and the frequency accuracy is estimated at 1 cm^{-1}. A conventional cryostat with polyethylene external windows was used to obtain the low-temperature spectrum. Samples were deposited from the vapor onto a wedge-shaped silicon plate cooled to −100 °C. Annealing, which in most cases resulted in partial loss of the deposited film, was done by raising the temperature to about −30 °C.

Results and Discussion

The Raman spectrum of crystalline ICN at liquid nitrogen temperature is reproduced in Fig. 1 and observed frequencies are given in Table 1. The far-infrared spectrum is not reproduced here since it contains a single band, with a half-width of about 15 cm^{-1}, located at 136 cm^{-1}.

Using standard group-theoretical procedures (13), it can be predicted that both the infrared and Raman spectra of crystalline ICN should be extremely simple. The correlation diagram (Table 2) indicates no splitting of the bands from either the site or coupling effect. As for the lattice vibrations, only one doubly degenerate (R_{xy}) librational mode is predicted, the three translations becoming acoustic modes with zero limiting frequency in the crystal. Coincidence of the Raman and infrared frequencies is also expected, the same vibrations being active in both types of spectra.

Although the main features of the Raman spectrum of crystalline ICN are in agreement with the above predictions, it is clear that many of the fundamental bands are complicated by anomalous high-frequency shoulders, as was the case in HCN (8). The effect is slight in the C—N stretching (ν_3) region where only an asymmetry of the band is seen. In the C—I stretching (ν_1) region however, a shoulder extending about 20 cm^{-1} from the main peak is clearly visible. In the region of the librational mode, this shoulder is of such proportion as to make the band appear as a well defined doublet.

We have already pointed out (9) that such features, related to the splitting of vibrations into transverse and longitudinal components, are likely to occur in Raman spectra of piezoelectric molecular crystals whenever a large variation of the electric dipole moment results from a particular vibration. To verify this interpretation in the present case, we have estimated the dipole derivatives for the fundamental vibrations using the formula of Haas and Hornig (14). In this calculation, the crystal density was taken as 3.1 g/cm^3 (6) and the refractive index as 1.64 (15). Calculated values for the $\partial\mu/\partial Q$ (see Table 1) agree qualitatively with those obtained from infrared band intensity measurements (5), which indicates that our explanation for the shoulders alongside the Raman fundamentals is most likely correct.

(ν_2, R_{xy}, T_{xy})	E_1	E	E	Raman, i.r.

There is an apparent discrepancy between the reported infrared frequencies (4) of the fundamentals of crystalline ICN and the measured Raman frequencies. The difference in the ν_1 and ν_2 regions is not serious since it is within the probable combined experimental error on frequency measurements ($\pm 2\ cm^{-1}$). The reported ν_3 infrared frequency ($2176\ cm^{-1}$), however, differs significantly from that in the Raman spectrum ($2172\ cm^{-1}$). In order to clarify this point, we have reinvestigated the infrared spectrum in this region. (Experiments were performed on a Perkin–Elmer model 621 spectrometer.) We found that the ν_3 peak frequency was located at 2172–2173 cm^{-1}, which means that there is indeed coincidence of the Raman and infrared frequencies. A somewhat different behavior was observed in our far-infrared study, the frequency of the librational mode taking different values ranging from 136 to 141 cm^{-1}. When well-annealed very thin films were studied, however, peak frequencies were in most cases almost identical to the corresponding Raman frequency. It seems that as the film thickness is increased reflection, which should extend approximately to the longitudinal frequency (16), causes an apparent blue shift of this band maximum.

An interesting feature in the Raman spectrum of crystalline ICN is the weak band at 2200 cm^{-1}, which we tentatively assign to a combination of ν_3 and a lattice vibration. It is clear that this transition then has to occur at $\boldsymbol{k} \neq 0$, which is rather uncommon, although it is not theoretically forbidden (17). A similar phenomenon has been found to occur in solid OCS (18).

The Removal of Oxide Impurities from Alkali Metal Fluoride Melts by Additions of Silver Halide

SYDNEY H. WHITE

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

Received September 2, 1970[1]

Electrochemical and chemical studies have shown that AgF and AgCl react quantitatively with oxide ions and hydroxide ions present as residual impurities in molten FLiNaK. This reaction offers a method for the simultaneous determination and removal of oxide containing impurities in fluoride melts.

Les études chimiques et électrochimiques ont montré que AgF et AgCl réagissent quantitativement avec les ions oxydes et les ions hydroxydes qui se trouvent à l'état d'impuretés résiduelles dans le FLiNaK fondu. Cette réaction permet d'avoir une méthode simultanée de détermination et d'élimination des impuretés contenant des oxydes dans des fluorures fondus.

Canadian Journal of Chemistry, 49, 2462 (1971)

The necessity of high purity, oxide-free, alkali metal fluoride melts for electrochemical studies has been emphasized (ref. 1, p. 529). Pizzini *et al.* (2) estimated that melts purified by conventional molten salt techniques (ref. 1, p. 532) contain oxygen impurities in the form of hydroxide at 10^{-2} to 10^{-1} formal concentration. In this note, a reaction is reported which leads to a method by which oxide impurities may be determined and removed simultaneously from alkali metal fluoride melts.

A chronopotentiometric study of silver halide dissolved in molten FLiNaK (lithium fluoride–sodium fluoride–potassium fluoride eutectic mixture) at 500 °C showed that small additions say 50–100 mg of AgCl or AgF gave transition times which were time dependent (Fig. 1). The con-

TABLE 1. Calculated thermodynamic data relating to reaction 4 at 1000 °K*

	Fluorides			Chlorides		
Oxide	$(\Delta G_R°)^{1000}$ (kcal/mol)	K oxide	a_{M_2O}	$(\Delta G_R°)^{1000}$ (kcal/mol)	K oxide	a_{M_2O}
Li_2O	−57.9	4.6×10^{12}	5.4×10^{-17}	+4.5	0.96×10^{1}	2.6×10^{-5}
Na_2O	−77.4	8.9×10^{16}	2.8×10^{-21}	−44.6	5.5×10^{9}	4.5×10^{-14}
K_2O	−86.0	6.5×10^{18}	3.9×10^{-23}	−68.6	1.0×10^{15}	2.5×10^{-19}

*Thermodynamic data on which the calculations are based were taken from ref. 5. It was assumed that $a_{Ag} = 1$, $a_{MX} = 0.5$, $a_{AgX} = 0.001$, and $p_{O2} = 10^{-18}$ atm, which might be typical values encountered under experimental conditions.

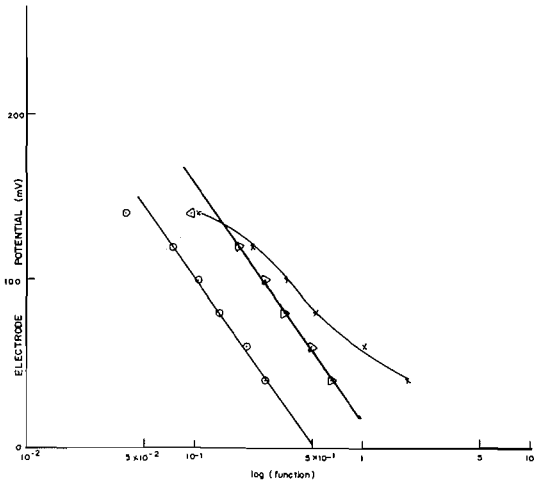

FIG. 2. Electrode potential *vs.* (*a*) $\log(\tau^{1/2} - t^{1/2})$ ○, (*b*) $\log 1 - (t/\tau)^{1/2}$ ▽, (*c*) $\log(\tau/t)^{1/2} - 1$ ×. Slope (*a*) = 143 mV (n = 1.08).

tinued addition of the silver halide finally resulted in a stable time independent transition time for silver ions. The transition time τ was determined, using a silver wire microelectrode, as a function of applied current i for the stabilized solution of silver ions. The product $i\tau^{1/2}$ was found to be a constant in accord with the Sand's equation

$$[1] \qquad i\tau^{1/2} = \frac{nF\pi^{1/2}D^{1/2}CA}{2}$$

for a diffusion controlled process (3) where the symbols have their usual meaning. A potential time analysis is shown in Fig. 2. The best fit is obtained using the equation for a reversible reduction process involving the formation of a solid product (4). This is supported by current reversal experiments (see Fig. 1 (*1*)). The number of electrons, n, involved in the overall reduction process was found from the slope in Fig. 2 to be equal to unity, *i.e.*

$$[2] \qquad Ag^+ + e \rightarrow Ag \text{ (solid)}$$

These observations suggest that the silver ions initially added to the FLiNaK melt were removed quantitatively by a reaction with oxygen containing impurities in the melt, *e.g.*

$$[3] \quad 2AgF(soln) + Li_2O(soln) \rightleftharpoons 2Ag(solid) + 2LiF(soln) + \tfrac{1}{2}O_2(gas)$$

Small beads of a silvery metal, determined chemically to be silver, were found in the base of a solidified ingot of FLiNaK in which time dependent transition times had been observed. This reaction between silver ions and oxide impurities is supported by the following experiment. A small pellet (24.5 mg) of sodium hydroxide was added to a stabilized solution of silver ions in FLiNaK melt. Transition time measurements before and after the addition of NaOH show that silver ions were removed quantitatively from the melt (Fig. 3).

Further confirmation for the proposed reaction 3 can be obtained from thermodynamic data calculated for the reaction

$$[4] \quad 2AgX(liq) + M_2O(solid) \rightleftharpoons 2Ag(solid) + 2MX(solid) + \tfrac{1}{2}O_2(gas)$$

where $X^- = F^-$, Cl^- and $M^+ = Li^+$, Na^+,

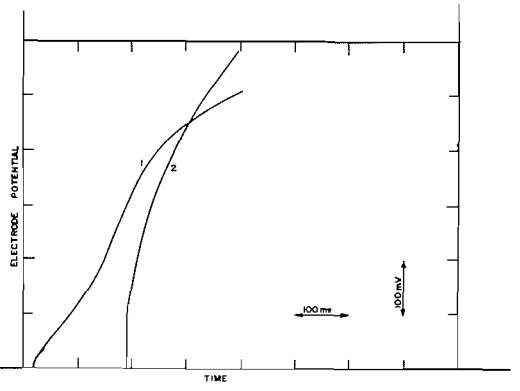

FIG. 3. Chronopotentiograms (*1*) before (*2*) after addition of NaOH to FLiNaK containing Ag^+ ions. mV/cm = 100, ms/cm = 100, i = 0.8 mA.

K^+. The results of these calculations are summarized in Table 1. The equilibrium activity of oxide a_{M_2O} is found to be very small in the case of the fluorides. The calculations although based on thermodynamic data for the pure substances (5), indicate that reactions such as [3] should be quantitative for dilute solutions in molten alkali metal fluorides and their mixtures. These predictions for fluoride melts are contrasted with those for chloride melts in Table 1.

The oxide ion impurity was found to be between 2 and 3×10^{-2} M in the melts used in this work.

Ozone reacts very smoothly with acetals to give the corresponding esters. Tetrahydropyranyl ethers, β-glycopyranosides, ethylidene, or benzylidene derivatives are also oxidized whereas the α-glycopyranosides are inert.

Les acétals se transforment facilement en esters correspondants sous l'action de l'ozone. Les éthers de tétrahydropyrannyle, les β-glucopyrannosides, les dérivés éthylidéniques et benzylidéniques sont facilement oxydés tandis que les α-glucopyrannosides résistent à l'ozone.

Canadian Journal of Chemistry, 49, 2465 (1971)

We wish to report the discovery that ozone reacts in essentially quantitative yield and in a complete specific manner with the acetal function to give the corresponding ester.

For example, acetal **1** dissolved in dichloromethane or ethyl acetate reacts quantitatively within 10 min at −78 °C with ozone to give the ester **2**.[3] Similarly, acetal **3** gives the methyl ester **4**[4] (90% yield) but the rate of this reaction is considerably slower (15 h at −78 °C or more conveniently 1.5 h at room temperature).

The generality of this reaction has been confirmed by obtaining similar results with acetals made from different aldehydes (*n*-heptanal, cyclohexanecarboxaldehyde, and benzaldehyde) and different types of alcohol (methanol, ethanol, ethylene glycol, 1,3-propanediol, and 2,2-dimethyl-1,3-propanediol). The cyclic acetals react readily at −78 °C within 2 h while the acyclic ones require approximately the same period of time, but at room temperature.

This new reaction constitutes a novel method for converting an aldehyde into an ester.

It is assumed that this reaction proceeds via insertion of ozone in the C—H bond of the acetal to give a hydrotrioxide intermediate such as **5** which then gives the corresponding ester and alcohol functions. Such an insertion reaction has been shown to be operative in the reaction of ozone with simple ether (1).

Ozone reacts with **6** (ethyl acetate, −78 °C, 1.5 h, 97% yield) in a complete specific manner to give exclusively **7**.[3] No trace of lactone **8** could be detected. A similar result was obtained with **9**. Thus, this reaction constitutes also a new highly efficient method for the cleavage of the tetrahydropyranyl protecting group.

Some conformationally rigid tetrahydropyranyl ethers were also investigated. Methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**10**) dissolved in acetic anhydride – sodium acetate[5] reacts with ozone (room temperature, 15 h) to give methyl 2,3,4,5,6-penta-*O*-acetyl-gluconate (**11***b*, 95% yield, (2)). *The corresponding α anomer*

[3]The corresponding acetate derivative gave satisfactory analytical data.

[4]This compound was identified by comparison with an authentic sample.

[5]The reaction proceeds at a similar rate in CH_2Cl_2 or ethyl acetate. The Ac_2O–AcONa system is used to trap **11***a* *in situ* (**11***a* being a secondary alcohol, it slowly reacts with ozone at room temperature).

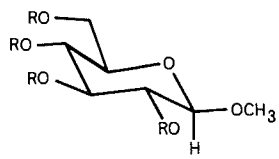
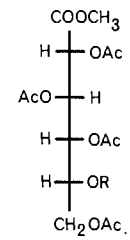
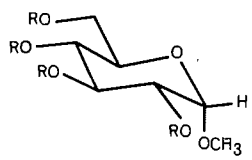
6 R = Methyl
9 R = Cyclohexyl 7 8



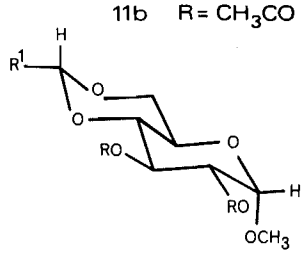
10 R = CH_3CO



11a R = H
11b R = CH_3CO



12 R = CH_3CO



13 R = CH_3CO $R^1 = CH_3$
14 R = CH_3CO $R^1 = C_6H_5$

12, however, was shown to be completely unaffected under the same condition.[6,7]

Furthermore, methyl 4,6-*O*-ethylidene-2,3-di-*O*-acetyl-α-D-glucopyranoside (**13**) (5), dissolved in acetic anhydride – sodium acetate, was treated with an excess of ozone during 1 h at room temperature. The resulting mixture was then heated to reflux for 1 h to complete the acetylation and gave after usual work-up a quantitative yield of **12**.[4] Ozonolysis of methyl 4,6-*O*-benzylidene-2,3-di-*O*-acetyl-α-D-glucopyranoside (**14**) (6) gave **12**[4] (acetic acid, 1 h) after hydrolysis (triethylamine in 70% aqueous methanol (7)) and acetylation (Ac_2O–AcONa, reflux, 1 h). Ozone can therefore be used for the removal of ethylidene and benzylidene protecting group.[8,9]

The preceding results clearly indicate that this new ozonolysis reaction should find many important applications in the carbohydrate field. Ozone could in principle be used as a method of purification of α anomer from an α and β anomeric mixture by selective chemical transformation of the β isomer. These results also suggest that this ozonolysis reaction works only if the acetal function can assume a conformation in which both oxygens of the acetal can have one of their lone-pair orbitals oriented *trans*-antiparallel to the C—H bond. Such arrangement is impossible for the α-glycosides.

An investigation of the mechanism as well as the scope and limitation of this new reaction is under active study.

[6]Similarly, methyl 3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (3) was rapidly ozonized (1 h, room temperature), while the corresponding α anomer (3) was completely inert.

[7]It should be noted that Angyal and James (4) have recently shown that **10** and **12** are oxidized with chromium trioxide in glacial acetic acid. The β anomer (**10**) gave a keto ester while the α anomer (**12**) suffered oxidation of the methoxyl group.

[8]The regioselectivity for the oxidation cleavage of **13**, **14** (8, 9), and related compounds are being studied.

[9]It should be noted that Marvel and Joncich (10) have reported the oxidation of benzaldehyde diethyl acetal into ethyl benzoate by *N*-bromosuccinimide (NBS). The oxidation of benzylidene derivatives of cyclohexane-1,2-diols with molecular oxygen and NBS has also been reported (11). The NBS oxidation reaction has also been carried out on various types of acetals (12) and extended to benzylidene derivatives of the carbohydrates (8 and 9).

Thermal Conductivity, Anomaly in Temperature-dependence for Liquids[1]

J. E. S. VENART[2] AND N. MANI
Department of Mechanical Engineering, The University of Calgary, Calgary 44, Alberta

Received December 30, 1970

Most empirical equations express the thermal conductivity of normal simple liquids as linear functions of temperature. The majority of measurements to date, except water, support such a description. Very precise new measurements on toluene over the complete liquid range at 1 atm ($0.299 < T_r < 0.645$) show a substantial pre-freezing anomaly. At the freezing point (t_f) there is a depression of the expected conductivity of 7.9×10^{-3} W/m °K. This t_f behavior is attributed to cluster formation.

La plupart des équations empiriques expriment la conductivité thermique de liquides simples et normaux comme des fonctions linéaires de la température. Jusqu'à présent la majorité des mesures, excepté pour l'eau, sont en accord avec ce point de vue. De nouvelles mesures très précises avec le toluène, sur tout l'intervalle liquide et à une atmosphère ($0.299 < T_r < 0.645$), montrent un certain degré d'anomalie au point de précongélation. Au point de congélation (t_f) il y a une dépression par rapport à la conductivité attendue de 7.9×10^{-3} W/m °K. Ce comportement à la t_f est attribué à la formation d'agrégat.

Canadian Journal of Chemistry, 49, 2468 (1971)

Introduction

It is well known in viscometry that deviations from the usual Arrhenius type expression can occur as the freezing point is approached. This behavior is explained on the basis of the formation of multi-molecular clusters in the liquid state (1). Since it seems likely (2) that liquids conduct heat mainly through vibrational transfers, other methods of transfer such as molecular convection and radiation contribute on a small scale. It could thus be expected that for liquids formed of complex molecules, the formation of clusters near the freezing point would appreciably increase the scattering of phonons and hence decrease the conductivity over that normally expected (3).

Experimental difficulties, to date, have precluded any completely definitive attribution to this effect and for most simple normal liquids the thermal conductivity is generally characterized as decreasing linearly with increasing temperature;

$$[1] \qquad \lambda = A' - B't$$

Attempts to interpret the coefficients A' and B' are few (2) and it can only be stated that this type of behavior has been experimentally confirmed for simple liquids (Ar, Kr, Xe) (4) and other fluids. Even for some complex liquids at *sufficiently high temperature* the linear law seems to follow over a portion of the liquid range. Experimental evidence for the above mentioned anomaly and linear behavior is reported here for toluene.

Experimental

A modification of the absolute transient line source apparatus (5) was employed using A.R. grade toluene (99.96% pure conforming to ACS specifications: S < 0.003%, H_2O < 0.03%, residue after evaporation < 0.001%).[3] The measurements shown in Fig. 1 are

obtained with a precision of about 4000 p.p.m. by measuring the voltage–time behavior of a 25 μm platinum line source immersed in the fluid and pulsed with a constant current sufficient to produce temperature rises of 1 to 2 °C in 5 s. Experimental procedure is such that convection and radiation effects can be minimized.

Discussion

For toluene *sufficiently high temperature*, that is, the temperature range wherein conduction can be treated as consisting of the contributions of single molecules, was observed to occur between −25 and 101 °C; over this range a value of $A' = (136.7_7 \pm 0.25_3)$ mW/m °K and $B' = (0.295_2 \pm 0.7_4 \times 10^{-3})$ mW/m °K^2 were found. Letting this expression yield the *normal* or expected value λ_i by extrapolation to t_f, we can now consider the experimental deviations of the actual values λ_a. If the deviations near t_f were due to cluster formation, it would be expected that these deviations might follow a rate process and thus be governed by the Arrhenius type expression

$$\lambda_a/\lambda_i = 1 - A \exp(B/\sqrt{T^*})$$

where

$$T^* = (T - T')/(T_f - T)$$

Analysis of the data by the above expression yields the establishment of a t_f depression of 7.9×10^{-3} W/m °K with $A = 0.07144$ and $B = -1.74936$. The temperature T' at which the anomaly has been observed to vanish is numerically estimated as 148 °K. The data analysis further suggests that the pre-freezing anomalous behavior is dependent more upon $B/\sqrt{T^*}$ rather than B/T^*. This latter implication may thus advocate a scaling of the property (6).

Conclusion

A substantial pre-freezing anomaly has been shown to exist in the thermal conductivity of toluene. It is postulated that this pre-freezing behavior is due to cluster formation. This behavior emphasizes the need for further study with a great variety of liquids of more complex molecular structure and for exhaustive study on liquids suggested for thermal conductivity standards.

Kinetics and Thermodynamic Data for the Hydrogen Fluoride Addition to Vinyl Fluoride

LEONARD O. MOORE

Research and Development Department, Chemicals and Plastics, Union Carbide Corporation, South Charleston, West Virginia 25303

Received February 22, 1971

The kinetics of the addition of hydrogen fluoride to vinyl fluoride have been measured in the vapor phase at temperatures of 100 and 150 °C and under pressures of 170, 308, and 446 N/m². The rate equation was found to be a typical second order expression, $-dx/dt = k\,[CHF{=}CH_2]\,[HF]$. The energy of activation was calculated to be 17 ± 2 kcal/mol, and the frequency factor, log A (l/mol s) was 6 ± 1. Based on reaction data from the literature, equilibrium constants and a value for ΔH_{298} were calculated. For this reaction, ΔH_{298} is about −12 kcal/mol.

Les cinétiques de l'addition du fluorure d'hydrogène au fluorure de vinyle ont été mesurées en phase vapeur à des températures de 100 et 150 °C et sous des pressions de 170, 308 et 446 N/m². L'équation de vitesse est une expression typique du second ordre, $-dx/dt = k[CHF{=}CH_2][HF]$. L'énergie d'activation calculée est de 17 ± 2 kcal/mol, et le facteur fréquence, log A (1 mol^{-1} s^{-1}), est de 6 ± 1. A partir des données de la littérature, les constantes d'équilibre et une valeur pour ΔH_{298} ont été calculées. Pour cette réaction, ΔH_{298} est environ de −12 kcal/mol.

Canadian Journal of Chemistry, 49, 2471 (1971)

Introduction

Although the patent literature is replete with examples of the addition of hydrogen fluoride to olefins, there is little experimental information on the kinetics of this reaction (1). In lieu of this, data have been compiled based on the R.R.K. and R.R.K.M. calculations starting from data of dehydrohalogenations of chemically activated molecules.

Sun and Sze (2) estimated the activation energy for the addition of hydrogen fluoride to ethylene from Morse curves and predicted that the reaction would not take place. Benson and Haugen (3), in discussion of the reactions of "hot" fluorinated ethanes, stated that calculations indicated the addition of hydrogen fluoride to ethylene or vinyl fluoride would have an activation energy of 54 ± 3 kcal/mol. Recent measurements using the shock-tube method have indicated that the activation energy for the elimination of hydrogen fluoride from 1,1-difluoroethane is 61.9 ± 1.8 kcal/mol, and that the earlier estimation of the energy of activation for the reverse reaction may be high by 8 to 13 kcal/mol (4).

In an attempt to study this reaction we have measured the rate of heterogeneous addition of hydrogen fluoride to vinyl fluoride.

Experimental

The equipment used is shown schematically in Fig. 1. Vinyl fluoride was fed through a Watts regulator to provide a constant pressure, a rotameter, and a Moore regulator with a needle valve to control the feed rate. Hydrogen fluoride was fed as a vapor from a heated cylinder through a Moore regulator with a needle valve. Check valves before the mixing tee prevented back flow into the feed lines. A portion of each of the feed lines was in the constant temperature bath to bring the reactants to temperature before mixing. Feed rates were sufficient to provide turbulent flow through the reactor. The reactor was a nickel pipe coil of 500 cc volume, ending at a motor valve mounted just after the pipe emerged from the bath. The water quench followed immediately and was backed by a calcium chloride drying tower and Dry Ice-cooled traps to collect the products.

Unreacted hydrogen fluoride was determined by titra-

Results and Discussion

Kinetics

The results from the kinetic runs fit a second order equation, $-d[CHF{=}CH_2]/dt = k[CHF{=}CH_2][HF]$. The numerical values are given in Table 1, and use of the Arrhenius equation, $\log k = \log A - E_{act}/2.303RT$, provides an energy of activation of 17 ± 2 kcal/mol and a frequency factor, log A (l/mol s) of 6 ± 1. This value for the activation energy is considerably lower than the 54 ± 3 kcal/mol predicted by Benson and Haugen (3) or even that predicted based on the results of Tschuikow-Roux *et al.* (4).

These results represent the kinetic expression for a surface catalyzed reaction since the data available for hydrogen fluoride elimination reactions from "hot" fluorinated ethanes (3–5) can be used in the R.R.K.M. calculation to predict the approximate energetics of the addition reactions (6, 7). It is known, for example, that the dehydrochlorination of ethyl chloride follows first order kinetics with either an activation energy of 24 or 56 kcal/mol depending on whether the system is surface catalyzed or not.

In our system, early experiments were erratic until the reactor wall was conditioned at 150 to 200 °C with vinyl fluoride. It was hoped that the conditioning would eliminate the surface catalyzed reaction, but it apparently did not.

In an experiment air was fed with the vinyl fluoride to detect radical mechanism (8). No acceleration was noted. The reaction is believed to be ionic or polar, probably a four-center reaction, rather than radical and the transition state therefore involves some degree of charge separation. This inductive effect of the fluorine (9) in vinyl fluoride is the major influence for the direction of addition, but, to what extent it affects the transition state cannot yet be stated. Tschuikow-Roux *et al.* (4), Pritchard and Perona (10), and Carlton *et al.* (11) have pointed out the pitfalls in trying to apply the point-dipole model of Benson *et al.* (12–14) to olefins with polar ground states. It will be of interest to compare the results reported here with similar ones for the reaction of hydrogen fluoride with ethylene and vinylidene fluoride when they are available.

It is also hoped that a system can be designed for the measurement of the homogeneous rates of addition of hydrogen fluoride to olefins.

Hydrogen fluoride posed certain problems not normally encountered in the type of study described here. Glass, because of its reactivity with hydrogen fluoride, had to be kept completely out of the system and the metal surfaces had to be conditioned.

Another possible problem was that hydrogen fluoride exists as an equilibrium mixture of

*Values used in calculation.

monomeric and polymeric forms (15). Consideration of this equilibrium under the conditions used in this study, however, indicated that the error in hydrogen fluoride monomer concentration would be less than 0.5% in the worst case. Erratic results at 100 °C and 446 N/m^2 apparently were due to partial condensation of hydrogen fluoride in the feed line preventing constant feed to the reactor.

Equilibrium Constant and Heat of Reaction

A discrepancy was noted when equilibrium constants for the reaction of hydrogen fluoride and vinyl fluoride were calculated using the thermodynamic values for the compounds involved and compared with the equilibrium constants estimated from experimental results in the literature. The values based on the thermodynamic functions are too large.

The thermodynamic values reported in the literature vary over a considerable range as indicated in Table 2. Use of $-\Delta H^0_{f\,298}$ values for vinyl fluoride and 1,1-difluoroethane from Vitvitskii (16) with the available values for S^0_{298} (17, 18) and C_p (18, 19) and the values of $-\Delta F_{f\,298}$ for hydrogen fluoride from the JANAF tables (20) led to values for log K_{eq} of 3.7 at 600 °K and 7.6 at 298 °K. These are compared with values of 0.9 at 600 °K based on experimental data from the literature and a derived value of 6.0 at 298 °K assuming that the values of C_p for the compounds involved are valid. The plots of these values are presented in Fig. 2.

The heat of reaction is derived from the values

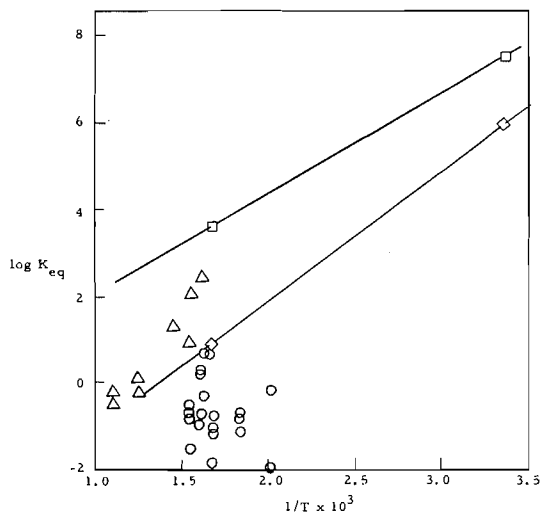

FIG. 2. Arrhenius plot. △, reaction data, maxima; ○, reaction data, minima; □, calculated constant, see text; ◇, corrected constants, $\Delta H_{298} = -12$ kcal/mol.

of the equilibrium constants by standard thermodynamic calculations assuming that the values of both S^0_{298} and C_p are valid. The heat of reaction is

$$\log K_{eq} = -\Delta F/2.303RT$$

$$\Delta F = \Delta H - T\Delta S$$

-12 kcal/mol. This compares to -14.6 kcal/mol based on the reported thermodynamic functions.

Benson *et al.* (23) have developed a method of estimating thermodynamic properties based on group contributions. Use of this method gives a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

heat of reaction of -23.3 kcal/mol. These authors point out, however, that there are certain contradictions because of the differences of polarity and suggest that caution should be used in combining groups with large differences in polarity. The source of the group contribution of =CHF is CF_2=CHF. Further, Benson and Haugen (3) have estimated the heat of reaction for $HF + C_2FH_3 \rightarrow C_2F_2H_4$ to be -8 kcal/mol.

The literature data available for the reaction of vinyl fluoride and hydrogen fluoride are of two types. The formation of vinyl fluoride from thermal dehydrofluorination of 1,1-difluoroethane (24, 25) approaches the equilibrium from the high side and the formation of 1,1-difluoroethane from the addition of hydrogen fluoride to vinyl fluoride (24, 26–28) approaches it from the low side. The correct value should lie between these sets of values. The results of calculating equilibrium constants from the literature reaction data are plotted in Fig. 2.

The error in the thermodynamic functions could not be further defined, but the values of $-\Delta H^0_f$ for the organic compounds are most suspect because of the lack of good values for comparison and the major influence on the values of $-\Delta F^0_f$ and K_{eq}.

The Hydrocarbon-induced Fluorescence of Atoms in Flames[1]

A. T. BLADES
Research Council of Alberta, Edmonton, Alberta

Received February 8, 1971

The phenomenon of chemiluminescent emission from atoms introduced into hydrocarbon flames has been studied in a basic hydrogen–oxygen diffusion flame at low hydrocarbon concentrations. Emissions from several atoms are first order in methane concentration and examination of the relative populations of the excited states of arsenic suggests a single excitation mechanism with available energy in excess of 8.5 eV. Previously proposed mechanisms are discussed and the available evidence favors the process

$$CH + O \rightarrow CHO$$

as the origin of the energy of excitation.

Le phénomène de l'émission par chimioluminescence à partir d'atomes introduits dans une flamme d'hydrocarbure a été étudié dans une flamme de diffusion hydrogène–oxygène à faible concentration en hydrocarbure. Les émissions de différents atomes sont du premier ordre par rapport à la concentration en méthane et l'examen des populations relatives dans les états excités de l'arsenic, suggère un mécanisme d'excitation unique avec un excès d'énergie disponible de 8.5 eV. On discute des mécanismes proposés antérieurement ainsi que de la preuve qui existe en faveur du processus:

$$CH + O \rightarrow CHO$$

qui est à l'origine de l'énergie d'excitation.

Canadian Journal of Chemistry, 49, 2476 (1971)

Atomic emissions may be observed from both the primary reaction zone and the outer combustion zone of hydrocarbon–oxygen flames seeded with compounds of some of the elements. In the outer zone the emission arises from atoms previously excited either thermally or by the reactions (1)

$$H + H + M \rightarrow M^* + H_2$$

and

$$H + OH + M \rightarrow M^* + H_2O$$

the energy limit of excitation being determined by the exothermicity of the latter process, 5.2 eV. The spectrum observed in the primary reaction zone is commonly more extensive, including emissions from much higher energy levels, the extreme case being a zinc level at 9.0 eV (2). Since these emissions arise from the region of the flame defined by the blue and green emissions from CH and C_2, it may be assumed that the energy for the atomic excitation arises in the oxidation of these, or similar, hydrocarbon species. Thus, while the excitation of the atoms is probably of little consequence in itself, its occurrence provides a further source of information on the mechanism of hydrocarbon combustion. Unfortunately, although a number of mechanisms for the atom excitations have been proposed (1, 3–7), no clear preference exists for any one process. We have recently found that it is possible to observe chemi-ionization and CH emission when low concentrations of hydrocarbons are present in a hydrogen-in-oxygen diffusion flame on a commercial flame spectrophotometry burner. This same technique has now been applied to a study of the atomic emissions which arise when volatile inorganic compounds are added to the system.

Experimental

The apparatus consisted of a Beckman DU-2 spectrophotometer wherein the IP 28 photomultiplier was replaced by an RCA 7200 to facilitate measurements at short wavelength. The burner mount of the flame emission attachment was replaced with a Teflon holder and a spiral electrode was mounted above the primary reaction zone of the flame for rate of ion formation determination. The burner was modified by removing the axial aspirator capillary. Hydrogen (1 l/min) containing the gaseous additive and the hydrocarbon entered through the axial hole while oxygen (4 l/min) was supplied through the annular orifice. The luminous primary reaction zone so formed was about 1 mm in diameter and 4 mm high, and did not change appreciably with hydrocarbon concentrations up to 1%. The additive compounds, arsine, stibine, germanium hydride, tin tetramethyl, silicon tri-*n*-propyl and chromium, iron, nickel, and molybdenum carbonyl were diluted with hydrogen for convenient introduction to the hydrogen stream. The gaseous hydrocarbon additives, better than 99% pure grades, were introduced continuously into the hydrogen stream and their concentrations monitored by thermal conductivity.

[1]Contribution No. 535 from the Research Council of Alberta, Edmonton, Alberta.

Results

Chemiluminescence was observed from arsenic, antimony, tin, iron, nickel, chromium, molybdenum, germanium, and silicon. Some previously unrecorded emissions from high energy levels were observed, notably from (*a*) the $4p^4\ ^2D$ level of arsenic (8.5 eV), (*b*) the $7d\ ^3D^0$ level of tin (6.7 eV), (*c*) the $4d\ ^1F^0$ level of germanium (6.5 eV), and (*d*) the $3d\ ^1F^0$ level of silicon (6.6 eV). An attempt was made to correlate the population of excited states of arsenic with the excitation energies, as has been described by Brennen and Kistiakowsky (8). These data are plotted in Fig. 1, where the line drawn through the points corresponds to a flame "temperature" of 4500 °K. The emissions from the levels at 53 156 K (6.6 eV) and 54 605 K (6.8 eV) do not fit the line at all well, but similar population anomalies were observed in the emission from an arsenic hollow cathode lamp, and it would seem most probable that this arises from incorrect "*gA*" values, as have been observed by Brennen and Kistiakowsky (8).

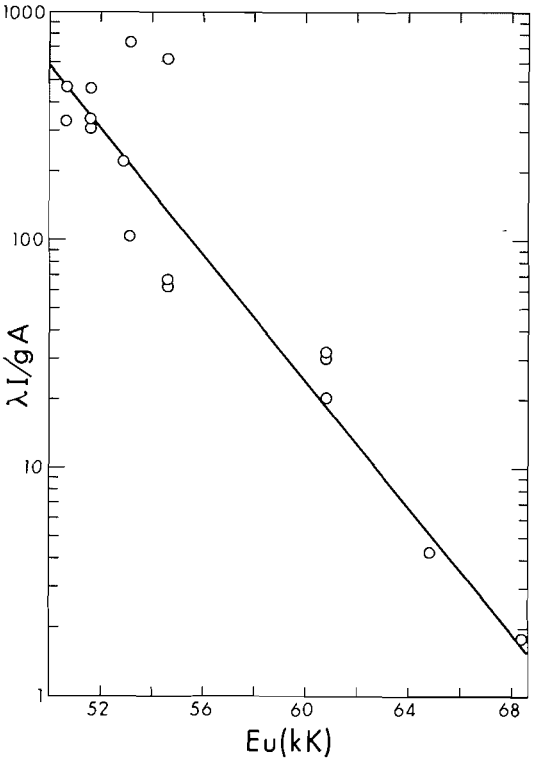

FIG. 1. Apparent relative populations ($\lambda I/gA$) of arsenic levels in the flame *vs.* excitation energy (1 kK = 0.124 eV).

The effect of the additive concentration in the flame was examined for arsenic emission at 197.2 nm and was found to be linear up to 0.01% arsenic in hydrogen, but exhibited some self-absorption at higher concentrations. The effect of hydrocarbon concentration on the atomic emission was determined for chromium, molybdenum, tin, antimony, and arsenic emissions, and was invariably found to be linearly dependent at low concentration. Some typical data are shown in Fig. 2 *a*, *b*, *c*. The maximum energy of excitation for which this relationship was established was 6.8 eV (As 228.8 nm).

Molecular emission of an additive compound was observed only for SnO; the intensity was linearly dependent on the tin concentration in the flame, and was independent of the presence of hydrocarbon. An electric field had no effect on the atomic emission intensities. It was, however, possible to observe the chemi-ionization due to hydrocarbons in the flame; this shows a similar behavior to the atomic emissions (Fig. 2 *e*). The CH emission at 431.5 nm (Fig. 2 *d*), while paralleling the atomic emission and chemi-ion formation at low concentrations, shows a declining

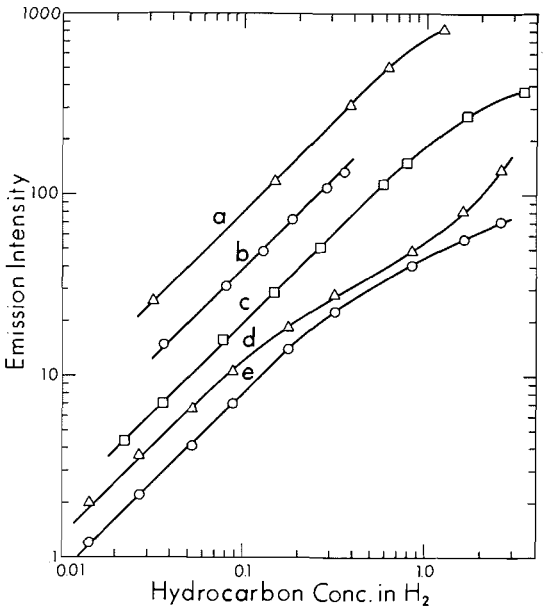

FIG. 2. Emission intensity (*a*, *b*, *c*, *d*) and rate of ion formation (*e*) variation with hydrocarbon concentration in the flame. (*a*), arsenic emission at 197.2 nm with C_2H_4; (*b*), antimony emission at 231.1 nm with C_2H_6; (*c*), arsenic emission at 228.8 nm with CH_4; (*d*), CH emission at 431.5 nm with CH_4; (*e*), ion formation with CH_4.

dependence below 1% hydrocarbon but an increasing dependence above this concentration.

Discussion

A major aspect of this research is the observation of a unit order dependence of the rate of ion formation, CH emission, and some atomic emissions on the concentration of hydrocarbon in a hydrogen–oxygen diffusion flame. Concern has been expressed (9) that even at very low concentrations, hydrocarbons may so alter the flame chemistry that apparent kinetic orders would be meaningless. Chemi-ion formation in such flames has been found proportional to the hydrocarbon concentration over several decades of concentration (10). Ions are formed from the interaction of CH and oxygen atoms (11), and their first order dependence may therefore be interpreted as evidence that CH arises by a series of processes first order in hydrocarbon fragments. But it also implies that the presence of the hydrocarbon has a negligible effect on the oxygen atom concentration in that region of the flame where ions are formed. Chemi-ionization is first order in hydrocarbon in the spectrophotometer flame where CH emission is also observed to be first order. If the electronically excited CH arises from the process

$$CH + H + OH \rightarrow CH^* + H_2O$$

as has recently been suggested for low concentration conditions (12), this order in emission must also be kinetically significant. Similar conclusions follow from the observation of second order dependence of the emission from C_2 (12) and S_2 (13) in this and other flame systems when methane and hydrogen sulfide are added to the flame.

On this basis, it seems reasonable to assume that the kinetic orders of the atomic emissions also have relevance to the mode of formation of the electronically excited emitter and discussion is based on this premise. The proportionality between the AsH_3 concentration in the flame and the arsenic emission at 197.2 nm at low concentrations is in keeping with similar observations in conventional flame photometry (3) and confirms that the mechanism involves a species with one arsenic or other additive atom. Similarly, the first order dependence of the atomic emission intensity on the methane concentration implies the participation of a single carbon species or a derivative. The parallel behavior of the rate of ion formation, the CH emission and the atomic emissions at low concentrations suggests that both $CH(X^2\Pi)$ and $CH(A^2\Delta)$ may be involved in the atomic excitation reaction. The discrepancy between the atomic emission and the CH emission, Fig. 2, at higher concentrations tends to exclude $CH(A^2\Delta)$ as a reactant, but it is uncertain whether the enhanced $CH(A^2\Delta)$ formation, presumably by (14)

$$C_2 + OH \rightarrow CH^* + CO$$

arises in the same zone of the flame as that excited by energy transfer. Further evidence against the involvement of this species is provided by studies of an acetylene–oxygen flame by Dean and Carnes (15) where the CH and atomic emission reach maxima in different regions of the flame.

The other feature of the excitation mechanism of major consequence is the maximum available energy. Buell (2) has reported emission from zinc at 9.0 and 8.5 eV, and a value of 8.5 eV is reported herein for arsenic. Unfortunately it was not possible to determine the order in methane concentration for the emission from this high energy state and hence it has not been proven that the order and energy conditions apply to the same process. The arsenic emission intensity data in Fig. 1, however, indicate a monotonous decline of the population of excited states with energy up to the energy limit of 8.5 eV. This is to be contrasted with the behavior of mercury excited by active nitrogen (8) where the population of the excited species declines more rapidly as the maximum energy is approached. It would therefore seem reasonable to assume that in hydrocarbon flames, a single atomic excitation reaction is operative, which is more exothermic than 8.5 eV.

The recombination of ions and electrons has been suggested as a potential source of the excitation energy of atoms in hydrocarbon flames (1, 2). Ions (and electrons) are formed in the flame by a process first order in hydrocarbon concentration; their recombination on the other hand is first order in the concentration of each, or second order in either, and hence the atomic emission would be expected to be second order in hydrocarbon concentration. The rigorous first order observed hence provides strong kinetic evidence against this type of excitation. This conclusion is

further justified by the failure of the electric field to influence the emission, and by previous objections on energetic grounds (1).

Mechanisms of excitation involving additive monoxides have been criticized on chemical and energetic grounds. The process

$$C + MO \rightarrow M^* + CO$$

was found to release insufficient energy to excite certain tin lines (1), and similar observations can be cited in the present studies on germanium, arsenic, and silicon, where energy deficiencies of 2.3, 2.3 and 3.8 eV exist. Uncertainty in the concentration of carbon atoms is an additional concern (1). The reaction

$$CO^* + MO \rightarrow M^* + CO_2$$

satisfies the energy requirements if the CO is in the $A^1\Pi$ or $a^3\Pi$ electronic states which have minimum energies of 8.0 and 6.0 eV. Nevertheless, for the maximum excitation energies herein observed for tin, germanium, arsenic, and silicon, energies of excitation of the CO of 7.0, 7.9, 7.9, and 9.5 eV would be required. While CO excitation up to 9.1 eV is known to occur in flames, it is attributed to the reaction (16)

$$C_2O + O \rightarrow 2CO$$

and this process is excluded from consideration by the "first order in methane" observation. Other processes for CO excitation

$$CH + O \rightarrow CO + H$$

or

$$CH_2 + O \rightarrow CO + H_2$$

are exothermic to the extent of 7.7 eV and hence fall far short of the energy requirement for silicon excitation.

Direct energy transfer from excited molecules to the atom has most frequently been suggested as the source of excitation. Prime consideration has been given to CO, particularly in the $a^3\pi$ state (4, 7, 17) as the excited molecule, since it might reasonably be expected to arise in the above reactions with energies of 7.7 eV plus a thermal contribution and yet satisfy the "first order in methane" requirement. While it is difficult to judge with certainty from the present data, indications are that the thermal contribution is not adequate to explain the intensity of the highest energy arsenic emission, or the observation of zinc emission from an upper state at 9.0 eV (2).

Energy transfer from CHO* formed in the process

$$CH + O \rightarrow CHO^*$$

has been proposed by Sugden (1) as the source of excitation energies up to 8.9 eV. While little is known of the energy states of this molecule, it is known from its emission to be formed in hydrocarbon flames (18). Cummings and Hutton (5) have discredited this mechanism on the grounds that the CHO* would have a lifetime too short for energy transfer, but this decision is premature in the absence of extensive knowledge of the excited states of CHO. As an alternative, Cummings and Hutton propose excitation by OH* formed in the process (14)

$$CH + O_2 \rightarrow CO + OH$$

which is exothermic by 7.0 eV and they attribute iron excitations above this energy to thermal contributions. There are, however, no known stable states of OH in the energy interval from 6.35 to 8.65 eV, and hence the thermal contribution for excitation to 7.6 eV is 1.25 eV rather than the superficially expected 0.6 eV. This mechanism is therefore extremely improbable as described; the basic oxidation process could, however, be a source of CO with excitation up to 7.0 eV.

Mechanistic difficulties associated with the existence and lifetime of vibronic states of the energy transferring molecule are obviated if the atom is excited in a termolecular reaction, *e.g.*

$$CH + O + M \rightarrow CHO + M^*$$

Broida and Shuler (17) pointed out that the low additive atom concentration made it an unlikely participant in a termolecular reaction, and they suggested the intermediacy of a major flame constituent such as H_2O or CO_2 as an energy transfer agent. A simple steady state treatment for such a process reveals that an intermediate is of consequence with regard to the atom concentration only under the circumstance that the energy transfer agent is quenched exclusively by the atom. This requires the emission to be zero order in additive atoms, which is not true. In any case, the distinction between a termolecular and two consecutive bimolecular reactions loses significance in the present context if there is almost complete energy retention between the occurrence of the first and second bimolecular

reactions. This fact, and the observation of SnO and other monoxide emissions (4) in flames, suggest an alternative mechanism to the termolecular reaction above, which may be generalized as

$$M + O \rightarrow MO^*$$

$$MO^* + CH \rightarrow CHO + M^*$$

where MO* is the electronically and (or) vibrationally excited additive monoxide.

Thus, while the available kinetic and energetic evidence favors the interaction of CH, O, and the additive atom as the source of atomic emissions from the primary reaction zone of hydrocarbon flames, the sequence of reactions leading to the excitation is still uncertain. Recent studies of the quenching of these emissions (7), however, suggest that resolution of the mechanism is possible and further studies are projected along these lines.

Excess Thermodynamic Properties of Cyclopentane – Isomeric Decalin Systems at 25 °C[1]

D. E. G. Jones,[2] I. A. Weeks,[3] and G. C. Benson

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 17, 1971

Molar excess enthalpies and volumes of the systems cyclopentane – *cis*-decalin and cyclopentane – *trans*-decalin at 25 °C were determined by direct calorimetric and dilatometric measurements. Excess Gibbs free energies, also at 25 °C, were obtained from a study of the vapor–liquid equilibria. The excess properties of these cyclopentane systems are compared with those of their cyclohexane counterparts, and are interpreted in terms of the theory of Flory.

On a mesuré par calorimétrie et par dilatométrie les enthalpies et les volumes molaires d'excés des systèmes cyclopentane-*cis*-décaline et cyclopentane – *trans*-décaline, à 25 °C. Les énergies libres d'excès de Gibbs furent tirées d'une étude des équilibres liquide–vapeur. Les propriétés d'excès de ces systèmes cyclopentaniques sont comparées à celles des systèmes cyclohexaniques équivalents et l'interprétation en est faite en termes de la théorie de Flory.

Canadian Journal of Chemistry, **49**, 2481 (1971)

Introduction

Comparisons of the excess properties of binary systems formed by mixing *cis*-decalin and *trans*-decalin with a common second component are of interest since they must reflect the structural and energetic differences between the isomeric decalins. Measurements of the excess enthalpies and volumes of cyclohexane – isomeric decalin mixtures at 25 °C were described recently (1). The results of similar calorimetric and dilatometric studies of the systems cyclopentane – *cis*-decalin and cyclopentane – *trans*-decalin are reported in the present paper, along with their vapor–liquid equilibria determined by the static method.

Experimental

The methods used in our laboratory for studying the excess thermodynamic properties of binary mixtures have been described previously (2–4). Reference should be made to these earlier publications for details of the equipment and operating techniques.

Calorimetric Measurements

The isothermally-jacketed calorimeter described by Murakami and Benson (2) was used to determine the change in enthalpy when cyclopentane was mixed with *cis*-decalin and with *trans*-decalin. All measurements were made at 25.00 ± 0.01 °C and the accuracy of the results is believed to be better than ±0.5% over most of the concentration range.

Volumetric Measurements

The volume changes associated with the formation of cyclopentane – isomeric decalin mixtures at 25.00 ± 0.01 °C were derived from direct dilatometric measurements (3). The uncertainty of the results for equimolar mixtures is estimated to be ±0.0015 $cm^3\ mol^{-1}$.

Vapor–Liquid Studies

Static vapor pressures of mixtures of known total composition and known total volume (*i.e.* liquid + vapor phases) were measured in a cell and vacuum system similar to that used by Singh and Benson (4). The equilibrium cell and sample manifold were thermostated at 25.000 ± 0.003 °C; pressures were measured to ±0.005 mm Hg with a calibrated quartz spiral gauge (Texas Instruments).

Materials

The component liquids were obtained by chromatographic purification of commercial reagents. Cyclopentane (pure grade reagent from Phillips Petroleum Co.) was pas ed through a column packed with Chromosorb W (30/60 mesh) containing 20% squalane. The *cis* and *trans* isomers of decalin were separated from a practical grade decalin mixture as described in ref. 1.

During the course of the investigation, samples from several preparations of each component were employed. In general, values of the densities, refractive indices, and vapor pressures of material from different preparations agreed well, and were in reasonable agreement with data from the literature (5, 6). This is shown in Table 1, where average values of the physical properties at 25 °C are listed, along with indications of the range of variation encountered.

All samples of the component liquids used in the vapor–liquid studies were thoroughly degassed. A vacuum sublimation technique (7) was used to degas initial charges

for the equilibrium cell; other samples, prepared in small ampuls, were repeatedly frozen and thawed while about half the sample was pumped away.

Results

The experimental results for the molar excess enthalpies, H^E, and molar excess volumes, V^E, of the two cyclopentane – isomeric decalin systems at 25.00 °C are summarized in Table 2. In both cases, x_1 indicates the mole fraction of cyclopentane. Figures 1 and 2 provide graphical presentations of these data.

Each set of results was fitted with a Redlich–Kister form of the type

$$[1] \quad X^E = x_1(1 - x_1)\sum_j^n a_j(1 - 2x_1)^{j-1}$$

where X^E represents the excess property under consideration. The method of least-squares was used to determine the values of the coefficients a_j. In each case, the optimum number of coefficients was ascertained from an examination of the variation with n, of the standard error of estimate

$$[2] \quad \sigma_x = [\sum(X_{obs.}^E - X_{calcd.}^E)^2/(n_{obs.} - n)]^{\frac{1}{2}}$$

where the sum was taken over the $n_{obs.}$ results.

The resulting values of the coefficients are given in Table 3 along with the corresponding standard errors of estimate for the representations. The continuous curves for H^E and V^E, in Figs. 1 and 2 were calculated from eq. 1, using these values for the coefficients.

Molar excess energies at constant volume were obtained from the relation

$$[3] \qquad U_V^E = H^E - T(\alpha/\beta)V^E$$

using the smoothed representations of the excess enthalpies and volumes. Values of α, the coefficient of thermal expansion, and of β, the isothermal compressibility, were estimated for the mixture, from data for the pure components (1, 8) by assuming both properties to be additive on a volume fraction basis. Coefficients for the Redlich–Kister forms representing the results for U_V^E are included in Table 3.

A modified form of Barker's analysis (9) was used to calculate the distribution of material between the vapor and liquid phases from a series of observations of the equilibrium pressure p for known amounts of the two components contained in a known total volume. The molar excess Gibbs free energy of the liquid phase is related to the vapor–liquid equilibrium by the equation

$$[4] \quad G^E = \sum_i^2 x_i[RT\ln(y_i p/x_i p_i^0) + (B_{ii} - V_i^0)(p - p_i^0) + (2B_{12} - B_{11} - B_{22})(1 - y_i)^2 p]$$

where R is the gas constant, T is the absolute temperature, x_i and y_i are the mole fractions of component i in the liquid and vapor phases, respectively, and p_i^0 and V_i^0 are the vapor pressure and molar volume of pure liquid i. It is implicit in eq. 4 that the imperfection of the vapor phase can be described adequately for the present purpose by the equation of state

$$[5] \quad V^g = RT/p + y_1{}^2B_{11} + 2y_1y_2B_{12} + y_2{}^2B_{22}$$

where V^g is the molar volume of the vapor and the quantities B_{ij} are the second virial coefficients.

The Barker treatment assumes that at constant temperature G^E can also be represented by a Redlich–Kister form similar to eq. 1. The values of the coefficients a_γ are determined by an iterative calculation which minimizes the sum of the squares of the deviations between observed and calculated values of the pressure. In the present application, the composition of the liquid phase was computed for each iteration from the total amounts of the components by using eq. 5 to correct for the material present in the vapor phase. A value of $B_{11} = -1054$ cm^3 mol^{-1} (10) was adopted for cyclopentane. The empirical correlation developed by O'Connell and Prausnitz (11) was used to estimate B_{12} and B_{22} from critical point data (12–14). The values obtained were $B_{12} = -2825$ and $B_{22} = -8322$ cm^3 mol^{-1} for the *cis*-decalin system, and $B_{12} = -2599$ and $B_{22} = -6826$ cm^3 mol^{-1} for the *trans*-decalin system; these estimates are subject to fairly large uncertainties, not only because of the empirical nature of the correlation, but also due to the meager (and somewhat inconsistent) critical point data available for the decalins. Fortunately, the effects of these uncertainties are negligible since the terms in B_{12} and B_{22} make relatively minor contributions to G^E for the present systems.

The results of the vapor–liquid equilibrium studies at 25.000 °C are summarized in Table 4, where the experimental pressures and the corresponding values of x_1, y_1, and G^E calculated from the Barker analysis are given. Coefficients for the Redlich–Kister representation of G^E are included in Table 3. The experimental values of G^E and their representations by eq. 1, are plotted in Fig. 3.

The contribution of the molar excess entropy S^E to G^E is

$$[6] \quad TS^E = H^E - G^E$$

Curves for TS^E computed from this relation,

Discussion

Comparison with Cyclohexane – Isomeric Decalin Systems

A direct comparison of our results with independent data from the literature is not possible since the excess properties of cyclopentane – isomeric decalin systems do not appear to have been studied previously. However, a qualitative comparison with the properties of cyclohexane – isomeric decalin systems (1, 15, 16) reveals some interesting differences.

At 25 °C, the excess enthalpies of cyclopentane – isomeric decalin systems are negative over the whole concentration range and the H^E curve for *trans*-decalin lies below that for *cis*-decalin. The excess enthalpies of cyclohexane – isomeric decalin systems (1) exhibit changes of sign at 25 °C but again the curve for *trans*-decalin is always lower than that for *cis*-decalin. Assuming the variations of H^E in these systems are qualitatively similar to those found in binary *n*-alkane systems (17, 18) it appears for both pairs of isomeric decalin systems that replacement of the *cis*-isomer by the *trans* is roughly equivalent to an increase in temperature or to an enhancement of the dissimilarity between the component molecules.

The volume changes for the four cycloalkane – isomeric decalin systems are all negative and the contractions for those formed from cyclopentane are considerably larger than for their cyclohexane counterparts (1). Qualitatively, this is in line with the greater disparity in the size of the component molecules in the cyclopentane systems. On the same basis, the relative positions of the V^E curves for *cis*-decalin and *trans*-decalin appear to be normal for the cyclopentane mixtures and reversed for the cyclohexane mixtures. Thus it is evident that other factors, apart from molecular size, are of importance in determining the volume behavior of these systems.

It was pointed out for the cyclohexane systems (1) that the volume correction needed to obtain U_V^E from H^E was relatively large. This is also true for the present cyclopentane systems. However, the values of U_V^E are positive for cyclopentane – *cis*-decalin and negative for

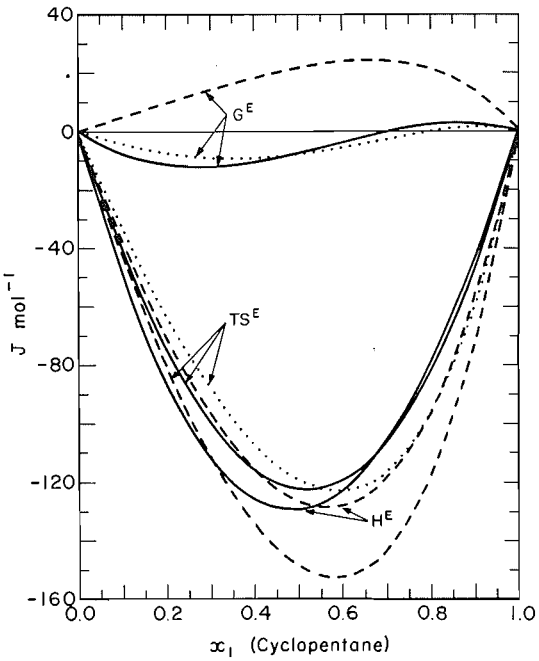

FIG. 4. Molar excess thermodynamic properties of cyclopentane – *cis*-decalin mixtures at 25 °C. Solid curves are least-squares representations of experimental results. Broken and dotted curves were calculated from the theory of Flory with $Q_{12} = 0$ and 0.00464 J cm^{-3} K^{-1}, respectively.

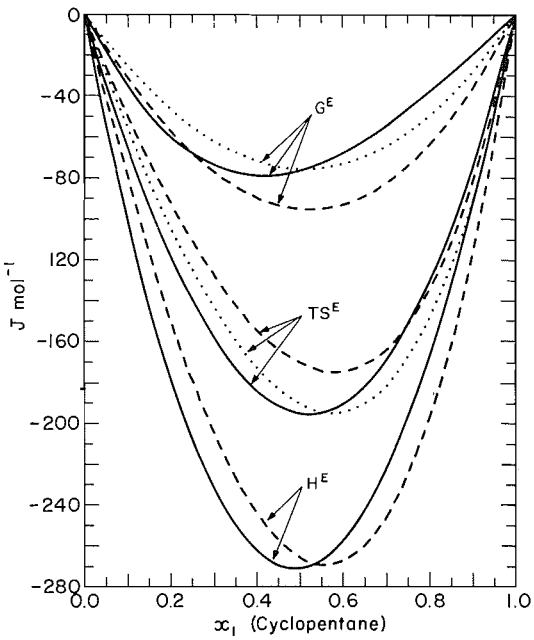

FIG. 5. Molar excess thermodynamic properties of cyclopentane – *trans*-decalin mixtures at 25 °C. Solid curves are least-squares representations of experimental results. Broken and dotted curves were calculated from the theory of Flory with $Q_{12} = 0$ and -0.00306 J cm^{-3} K^{-1}, respectively.

cyclopentane – *trans*-decalin, in contrast to the positive values found for both of the cyclohexane systems.

The excess Gibbs free energies of cyclopentane – isomeric decalin systems are relatively small at 25 °C and indicate a cancellation between the enthalpic and entropic contributions. The values of G^E for the *trans*-decalin systems are negative over the whole concentration range; those for the *cis*-decalin system change sign but the positive values observed are of the same magnitude as the experimental uncertainty. Unpublished vapor–liquid equilibria for the system cyclohexane – *cis*-decalin (15) indicate that the Gibbs free energy is small and positive at 25 °C. At higher temperatures (in the range 80–120 °C) Dutta (16) has reported G^E curves for cyclohexane with *cis*-decalin and with *trans*-decalin; both systems exhibit changes in the sign of G^E and a rather complicated variation with temperature.

Flory Theory of Mixtures

The theory of Flory (19) provided a fairly reasonable correlation (1) between the excess enthalpies and volumes of the cyclohexane – isomeric decalin mixtures and the properties of their pure components. It is therefore of interest to consider a similar treatment of the present results.

The Flory theory leads to the following formulae for the molar excess enthalpy, volume, and Gibbs free energy.

$$[7]\quad H^E = \sum_1^2 x_i p_i^* v_i^* (\tilde{v}_i^{-1} - \tilde{v}^{-1}) + x_1 v_1^* \theta_2 X_{12} \tilde{v}^{-1}$$

$$[8]\quad V^E = (x_1 v_1^* + x_2 v_2^*)(\tilde{v} - \phi_1 \tilde{v}_1 - \phi_2 \tilde{v}_2)$$

and

$$[9]\quad G^E = \sum_i^2 x_i p_i^* v_i^* \left[(\tilde{v}_i^{-1} - \tilde{v}^{-1}) + \tilde{T}_i \ln \left(\frac{\tilde{v}_i^{1/3} - 1}{\tilde{v}^{1/3} - 1} \right) \right] + x_1 v_1^* \theta_2 (X_{12} \tilde{v}^{-1} - Q_{12} T)$$

Derivations of these relations can be found in the original works of Flory and co-workers (19–21). The notation employed above is the same as in

our previous publications (1, 8) and will not be described in detail. It will suffice to note that the superscript asterisk and tilde are used, respectively, to label characteristic values and reduced values of the temperature, pressure, and volume. The reduced temperature of a mixture is

$$[10]\quad \tilde{T} = (\phi_1 p_1^* \tilde{T}_1 + \phi_2 p_2^* \tilde{T}_2)/(\phi_1 p_1^* + \phi_2 p_2^* - \phi_1 \theta_2 X_{12})$$

At low pressures, the reduced temperature and volume satisfy the equation of state

$$[11]\quad \tilde{T}\tilde{v}^{4/3} - \tilde{v}^{1/3} + 1 = 0$$

By hypothesis each molecule consists of a number of segments (isometric portions) and each segment carries a number of sites which may interact with sites on adjacent molecules. Segment fractions ϕ_i and site fractions θ_i are defined by the expressions

$$[12]\quad \phi_2 = 1 - \phi_1 = x_2/(x_2 + x_1 v_1^*/v_2^*)$$

and

$$[13]\quad \theta_2 = 1 - \theta_1 = \phi_2/(\phi_2 + \phi_1 s_1/s_2)$$

where s_1/s_2 is the ratio of the numbers of intermolecular contact sites per segment for the two species. Abe and Flory (20) showed that

$$[14]\quad s_1/s_2 = (v_2^*/v_1^*)^{1/3}$$

on the assumption that the number of sites on each molecule is proportional to the surface area of a sphere having a volume equal to the characteristic volume.

The quantity X_{12} in eq. 7 is treated as an empirical parameter and its value is usually adjusted to give the best fit between theoretical and experimental values of the excess enthalpy. It is assumed in eq. 9 that the combinatorial entropy is ideal; this is reasonable for molecules not differing excessively in size. The term with Q_{12} did not appear in the original formulation of the excess Gibbs free energy (19) but was added later (21). Q_{12}, like X_{12}, is treated as an adjustable parameter and its value is selected to give the best fit between theoretical and experimental values of G^E.

The characteristic temperatures, pressures, and volumes estimated previously for cyclopentane (8) and *cis*- and *trans*-decalin (1) were used in applying the Flory theory to the present systems. For convenience, the former estimates are listed again in Table 5. Assuming the validity of eq. 7, values of $X_{12} = -3.618$ and -9.949 J cm^{-3} gave least-squares fits of the smoothed excess enthalpies for the *cis*-decalin and *trans*-decalin systems, respectively. The broken curves for H^E in Figs. 4 and 5 were calculated with these values of X_{12}; the corresponding predictions for V^E, calculated from eq. 8, are plotted in Fig. 2.

TABLE 5. Characteristic values for the pure liquids at 25 °C

Component	T^* (°K)	p^* (J cm^{-3})	v^* (cm^3 mol^{-1})
Cyclopentane	4531	509.0	72.28
cis-Decalin	5739	542.6	127.30
trans-Decalin	5683	504.6	130.93

Two calculations of G^E and TS^E were carried out for each system. The first assumed $Q_{12} = 0$ for both systems; the second used the values of Q_{12} determined to give a least-squares fit of G^E for each system. The results of the calculations are shown as broken and dotted curves in Figs. 4 and 5.

Theoretical values of the excess functions for equimolar mixtures are compared with experimental results in Table 6. Also listed in this table are the standard deviations between the calculated and smooth experimental curves over the whole concentration range.

It can be seen from Figs. 2, 4, and 5, and from Table 6 that the Flory theory is fairly successful in correlating the excess properties of the cyclopentane – isomeric decalin systems. In some respects the correlation is better than that achieved previously for the cyclohexane – isomeric decalin systems (1). In order to approximate the sigmoid-shaped H^E curves of the latter systems, it was necessary to adjust not only X_{12}, but also the ratio s_1/s_2, and to use values of s_1/s_2 which were physically unrealistic.

The minima of H^E calculated for the cyclopentane – isomeric decalin systems are of the correct depth, but the curves are skewed to slightly larger mole fractions of cyclopentane than found experimentally. In contrast to the cyclohexane – isomeric decalin systems, the values of X_{12} are negative for the present systems. This is unusual for non-polar components, and it appears that the contributions to H^E arising from volume effects (1) are insufficient to account for the negative excess enthalpies observed experimentally. It is evident from Fig. 2 that the theory underestimates the contractions

	−3.618	4.64					−7.9 (2.3)	−7.4	−118.4 (9.5)	−121.6
Cyclopentane – *trans*-decalin	−9.949	0.0	−265.8 (20.6)	−270.6	−0.4221 (0.1937)	−0.6925	−95.6 (17.0)	−76.4	−170.2 (18.7)	−194.2
	−9.949	−3.06					−75.9 (9.0)	−76.4	−189.9 (11.8)	−194.2

*Entries in parentheses are standard deviations between theoretical and experimental values over the whole concentration range *i.e.* $[\int_0^1 (X_{\text{Flory}}{}^E(x_1) - X_{\text{Expt}}{}^E(x_1))^2 dx_1]^{1/2}$.

associated with the mixing process and that the relative positions of the *cis* and *trans* curves are reversed from those found experimentally. Whether this is due to inadequacies of the theoretical treatment or to uncertainties in the primary data for the component liquids is not clear.

The values of G^E and TS^E calculated for $Q_{12} = 0$ are of the right magnitude, however, there is a significant improvement in the agreement between theoretical and experimental values when Q_{12} is adjusted. The difference in sign of the least squares values of Q_{12} for the two systems follows directly from the calculations for $Q_{12} = 0$, which led to excess Gibbs free energies which were too positive for the *cis*-decalin system and too negative for the *trans*-decalin system.

We are indebted to Mr. P. J. D'Arcy and Mr. C. J. Halpin for their capable assistance in all phases of the experimental work.

Kinetic and Equilibrium Studies of σ-Complex Formation Reactions Between 1,3,5-Trinitrobenzene and the Lyate Ions of Water, Methanol, Ethanol, *n*- and *i*-Propanol, and *n*-, *i*-, and *t*-Butanol in their Respective Solvents

L. H. GAN AND A. R. NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 16, 1971

Kinetic and thermodynamic parameters have been determined for the σ-complex formation reactions between 1,3,5-trinitrobenzene and the lyate ions of water, methanol, ethanol, *n*- and *i*-propanol and *n*-, *i*-, and *t*-butanol in their respective solvents. Trends in these values are interpreted in terms of specific solvation effects associated with both the base and the σ-complex. Solvent and kinetic isotope effects associated with the σ-complex formation reactions of ethoxide with 1,3,5-trinitrobenzene and 1,3,5-trinitrobenzene-d_3 in ethanol and ethanol-*O*-*d* have also been evaluated.

On a déterminé les paramètres cinétiques et thermodynamiques pour les réactions de formation de σ-complexes entre le trinitro-1,3,5 benzène et les ions lyates de l'eau, du méthanol, de l'éthanol, des propanols-1 et -2 et des *n*-, *i*-, et *t*-butanol dans leurs solvants respectifs. On interprête les tendances dans ces valeurs internes d'effets spécifiques de solvatation associés et avec la base et avec le σ-complexe. On a évalué les effets de solvant et les effets isotopiques cinétiques associés avec les réactions de formation de σ-complexe de l'éthylate avec le trinitro-1,3,5 benzène et le trinitro-1,3,5 benzène-d_3 dans l'éthanol et l'éthanol-*O*-*d*.

Canadian Journal of Chemistry, 49, 2490 (1971)

Introduction

As part of a comprehensive study of the effects of solvent and base in the reactions of bases with nitroaromatics we have looked at the reactions of a range of alkoxide ions with 1,3,5-trinitrobenzene (TNB) and 2,4,6-trinitrotoluene (TNT). Initially we determined at 25.0 °C specific rate constants only for the reactions of these two substrates with a wide range of alkoxide ions in the corresponding alcohols.[1] While the collection of rate data at a number of different temperatures was still in progress, but before studies had been extended to include the lower alcohols, Bernasconi (1) reported full kinetic data for the reactions of TNB with hydroxide ion in water, methoxide ion in methanol, and ethoxide ion in ethanol. We wish to report here kinetic and thermodynamic data for the reactions of TNB with a series of lyate ions derived from the higher alcohols together with some observations on the kinetics of the reactions of TNB and TNB-d_3 with ethoxide ion in ethanol and ethanol-*O*-*d*.

[1]The results of these studies were presented, in part, at the International Conference on the Mechanisms of Reactions in Solution held in Canterbury, England July 20–24, 1970. Paper B-11.

Experimental

Materials

Eastman 1,3,5-trinitrobenzene was recrystallized several times from an ethanol–water mixture and dried *in vacuo* over silica gel, m.p. 122 °C (uncorrected). 1,3,5-Trinitrobenzene-d_3 was prepared as described by Buncel and Symons (2), recrystallized from ethanol–water, and dried to constant weight *in vacuo*, m.p. 120.5–121.5° (uncorrected). Analysis of the compound using an i.r. technique described by Symons (3) indicated 91 ± 2% deuteration.

Reagent grade methanol, absolute ethanol, ethanol-*O*-*d* (Merck, Sharp, and Dohme) and *n*-propanol were distilled from magnesium and iodine according to the procedure described by Vogel (4). The higher alcohols, which were reagent grade or better, were refluxed over Linde Molecular Sieve 4 Å for several hours then distilled under nitrogen. Normally only the middle third of the distillate was retained. All solvents were stored under dry nitrogen prior to use.

Standardized stock solutions of sodium hydroxide (Fisher Scientific 0.10 and 1.0 *N*) were used as received. Stock solutions of the sodium alkoxides were prepared by adding freshly cut sodium metal, pre-washed in the solvent in question, to pure solvent maintained in an atmosphere of dry nitrogen. Solutions thus prepared were stored under nitrogen and standardized immediately before use by titration with 0.10 *N* HCl to the phenolphthalein-endpoint. Stock solutions of the sodium alkoxides were usually 0.05 to 0.10 *M* in concentration. Solutions of lower concentration were prepared by dilution.

Eastman 1-(*p*-hydroxyphenyl)-2,4,6-triphenylpyridin-

ium betaine was converted to the perchlorate salt as described by Dimroth *et al.* (5) and recrystallized from anhydrous methanol. After drying *in vacuo* over silica gel the pale yellow, needle-shaped crystals had m.p. 250 °C (uncorrected).

All other chemicals were reagent grade or better and were used without further purification.

Procedure

Kinetic measurements were carried out by means of a Durrum–Gibson stopped-flow spectrophotometer. Water from a constant temperature water bath was circulated through the cell compartment and drive syringe chamber to maintain the reacting solutions at a constant temperature.

All kinetic runs were carried out with base in large excess over TNB. Concentrations of TNB varied from 0.4×10^{-5} to 2.0×10^{-5} *M*. Concentrations of RO^- varied from 1.0×10^{-4} to 70×10^{-4} *M* except for the case R = H where HO^- varied from 2.5×10^{-2} to 25.0×10^{-2} *M*. The ionic strength of the reactant mixtures was not maintained constant except in reactions involving HO^- where μ was kept at 0.25 *M* using NaCl. At the low concentrations of base employed, even very low levels of absorbed CO_2 may well alter the actual base concentrations in an uncontrolled manner thereby rendering the experimental data inaccurate. To preclude CO_2 absorption all manipulations, such as preparation of the sodium alkoxide stock solutions, titration of these solutions with 0.10 *N* HCl, dilution of the stock solutions, and transfer of the base solutions to the "reservoir" syringes of the stopped-flow spectrophotometer, were performed under an atmosphere of dry nitrogen. Consistently reproducible kinetic results, the absence of any gentle rise in the infinity line as reported by Bernasconi (1), and linear absorbance *vs.* concentration of TNB plots passing through (0, 0), for solutions of constant base but variable TNB concentration suggest that errors due to CO_2 absorption have been largely eliminated.

Changes in concentration of the complex were normally followed by means of the absorbance at the long wavelength maximum. Pseudo-first-order rate constants (k_{obs}) were obtained from the slopes of the $\ln(A_\infty - A_t)$ *vs.* time plots where A_∞ and A_t refer to absorbances at times infinity and t respectively. Plots were normally linear to approximately 80% completion of the reaction. Individual k_{obs} values were reproducible to $\pm 3\%$ except for the reactions of TNB with isopropoxide at high temperature where the reproducibility was generally $\pm 5\%$.

Equilibrium constants for complex formation were determined by a spectrophotometric method using data obtained on a Cary 14 spectrophotometer. Since solutions used to determine equilibrium constants had approximately the same concentrations of base and TNB as those solutions used in the kinetic experiments, the precautions used to preclude CO_2 absorption in the kinetic experiments were also applied in all studies involving the determination of equilibrium constants.

In the E_t (5) measurements 3 to 5 mg of pure betaine perchlorate was weighed into a 25.0 ml volumetric flask, 0.10 ml of a 1% methanolic solution of sodium methoxide was added, and the flask filled to the mark with the solvent whose E_t was to be determined. Although the final solution always contained approximately 0.4% methanol and some sodium perchlorate, the presence of these species at the concentrations stated has little effect on the magnitude of the measured E_t (5). The absorption spectrum of the betaine was recorded on a Cary 14 spectrophotometer and the E_t of the solvent calculated from eq. 1, where $\bar{\nu}$ is the wavenumber (cm^{-1}) of the absorption maximum of betaine in the solvent (5).

$$[1] \qquad E_t \text{ (kcal mol}^{-1}) = 2.859 \times 10^{-3} \bar{\nu}$$

Results and Discussion

The reaction of TNB and RO^- under the conditions employed in our studies leads to the reversible formation of 1:1 σ-complexes **1** according to eq. 2. The 1:1 stoichiometry of the

[2] TNB + RO^- (in ROH) $\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$

R = H, CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, and *t*-C_4H_9

TNB–OR^- complexes where R = H, CH_3, and C_2H_5 has previously been established (1, 6–9). The 1:1 stoichiometry of each of the remaining complexes has been confirmed by the results obtained in the course of the kinetics and equilibrium studies of these systems and, in the case of the complex in which R = *n*-C_3H_7, through the use of the method of continuous variations (10) to establish the composition.

The spectral properties of the reaction products studied (Table 1) are fully in accord with the formulation of these species as σ-complexes (6, 11).

In all the systems studied k_{obs} was linearly related to the concentration of RO^- over the entire range of RO^- concentrations at all the temperatures studied. Typical data are shown in Fig. 1 for the reactions of TNB and *n*-propoxide ion at 4.0, 16.5, 25.0, 30.0, and 35.0 °C. The linearity of the k_{obs} *vs.* [RO^-] plots strongly suggests that ion-pairing effects are not a problem at the concentrations of base employed in these studies. Further support for this suggestion comes from the observation that, over the range of base concentrations studied, solutions of potassium *t*-butoxide yielded the same values of k_{obs} as did solutions of equal concentration of sodium *t*-butoxide. Of all the systems studied ion-pairing

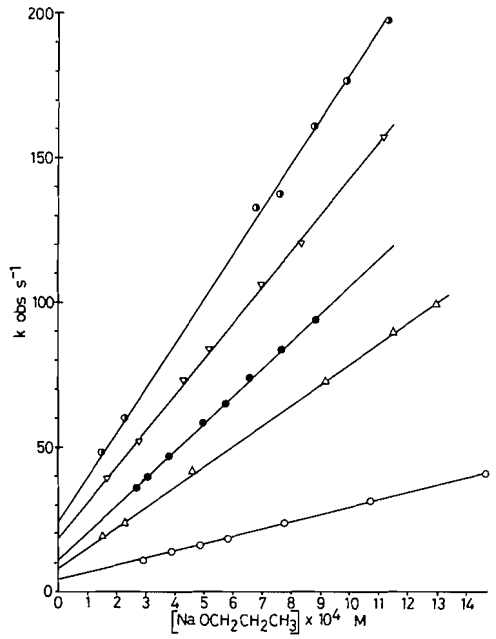

FIG. 1. Plot of k_{obs} *vs.* concentration of *n*-propoxide ion for the σ-complex formation reactions between 1,3,5-trinitrobenzene and *n*-propoxide in *n*-propanol at 4.0 (0), 16.5 (△), 25.0 (●), 30.0 (▽), and 35.0 °C (◑).

effects would be expected to be most pronounced in the *t*-butoxide – *t*-butanol system (12).

Since $[RO^-] \gg [TNB]$ in all runs

$$[3] \qquad k_{obs} = k_1[RO^-] + k_{-1}$$

Values of k_1 and k_{-1} were obtained in all cases from the "least squares" slopes and intercepts of plots of k_{obs} *vs.* $[RO^-]$. Because k_{-1} values are obtained from the intercepts of such plots the error associated with k_{-1} is always considerably larger than the error associated with k_1. When in addition the magnitude of k_{-1} is very small, as it is in the reactions of TNB with the lyate ions of the higher alcohols, the actual value of k_{-1} becomes very uncertain.

In Table 2 are listed specific rate constants (k_1 and k_{-1}), equilibrium constants determined spectrophotometrically (K), and kinetic and thermodynamic parameters associated with σ-complex formation between TNB and the various lyate ions according to eq. 1.

A substantial variation is found for the rate coefficients of complex formation with the various lyate ions. These are found to be in the ratio 1:304:1900:3660:3740:4960:3820:1500 for HO^-, CH_3O^-, $C_2H_5O^-$, n-$C_3H_7O^-$, n-$C_4H_9O^-$, i-$C_4H_9O^-$, i-$C_3H_7O^-$, and t-$C_4H_9O^-$.

Our value of k_1 (at 25.0 °C) for the TNB-CH_3O^- reaction agrees well with Bernasconi's (1) value for this reaction despite the fact that systems of different ionic strength were used in the studies and that we used the stopped-flow technique while Bernasconi used the temperature-jump technique to obtain rate constants. Agreement is much less satisfactory in the case of the TNB–HO^- and TNB–$C_2H_5O^-$ reactions. Exact comparisons in the case of the TNB–HO^- system are rendered difficult because reaction media of quite different ionic strengths (μ) were used in the two studies.[2]

In studies of the TNB–$C_2H_5O^-$ reaction we made no attempt to control μ ($\mu_{max} = 7.2 \times 10^{-3}$ *M*) and studied the reaction under conditions $[RO^-] \gg [TNB]$. Bernasconi (1) chose reaction conditions $[TNB] \gg [RO^-]$. In principle both modes of study should lead to the same values of k_1 and k_{-1}. While Bernasconi's and Ainscough and Caldin's values of k_1 for the TNB–$C_2H_5O^-$ at 25.0 °C apparently show reasonable agreement, it should be noted that

[2]Although results from other systems studied (13) suggest that ionic strength effects in the formation of 1:1 complexes should be negligible, no detailed information is available regarding ionic strength effects in the formation of 1:1 σ-complexes between nitroaromatics and uninegative bases.

Ainscough and Caldin (9) did not obtain k_1 at 25 °C directly but through the use of k_1 and E_a values determined at lower temperatures. As Bernasconi (1) points out the value of E_a reported by Ainscough and Caldin is probably in error (*vide infra*).

The trend in k_1 values is intelligible in terms of decreasing solvation of the lyate ion in passing from HO^- through to $i\text{-}C_4H_9O^-$. The lower values of k_1 recorded for $i\text{-}C_3H_7O^-$ and $t\text{-}C_4H_9O^-$ are seen to arise largely because low ΔH_1^+ values (in the range of ΔH_1^+ for R = $n\text{-}C_3H_7$ and $n\text{-}C_4H_9$) are offset by the significantly more negative values of ΔS_1^+ for these alkoxides as compared to the ΔS_1^+ values for R = $n\text{-}C_3H_7$ and $n\text{-}C_4H_9$. Both steric effects associated with formation of a carbon–oxygen bond in **1** and less efficient solvation of the $i\text{-}C_3H_7O^-$ and $t\text{-}C_4H_9O^-$ ions in their ground states would be expected to contribute to the more negative values of ΔS_1^+ in these systems. That steric effects are important in determining the magnitude of k_1 can be seen by comparing the ΔH_1^+ and ΔS_1^+ values for the systems R = $i\text{-}C_4H_9$ and $i\text{-}C_3H_7$.[3]

Our kinetic parameters ΔH_1^+ and ΔS_1^+ are in agreement with Bernasconi's results where R = H, CH_3, and C_2H_5. In the light of all the thermodynamic values reported it seems probable that Ainscough and Caldin's values of ΔH_1^+ and ΔS_1^+ for the TNB–$C_2H_5O^-$ reaction are in error.

Rate coefficients for reversion of complex to reactants (k_{-1}) show a less pronounced variation than do k_1 values in going from HO^- to $t\text{-}C_4H_9O^-$. Values of k_{-1} are in the ratio 1:26.6:1.15:0.89:0.39:0.12 < 0.12: ⩽ 0.07 for the same sequence of bases discussed above. Again, our value of k_{-1} for the TNB–CH_3O^- reaction agrees well with that reported by Bernasconi (1) while agreement in the TNB–HO^- and TNB–$C_2H_5O^-$ systems is less satisfactory. The surprisingly low value of k_{-1} for the TNB–HO^- system has been attributed by Bernasconi (1) to intramolecular hydrogen bonding to an ortho nitro group in complex **1**. Comparison of the ΔH_{-1}^+ and ΔS_{-1}^+ values for the TNB–HO^- system to the corresponding values in the remaining TNB–RO^- systems (where R = alkyl) indicates the major difference arises in the ΔS_{-1}^+ term since the ΔH_1^+ values do not change appreciably. The value of ΔH_{-1}^+ is unexpectedly high while the value of ΔS_{-1}^+ is unexpectedly low for the TNB – $i\text{-}C_3H_7O^-$ system. Both effects may be related to a much greater solvation of the σ-complex by $i\text{-}C_3H_7OH$. Detailed information regarding the heats of solution of TNB, sodium alkoxide and the sodium salt of the 1:1 σ-complex would be required to test this suggestion. Calorimetric studies of the type indicated have been reported by Larsen *et al.* (15) in connection with the reaction of sodium methoxide and 2,4,6-trinitroanisole in a wide range of methanol–dimethylsulfoxide mixtures. In this system, in passing from methanol to 95% dimethylsulfoxide–methanol, the heat of solution of sodium methoxide decreased by 10.6 kcal mol^{-1} while the heat of solution of the adduct increased by 7.0 kcal mol^{-1}.

In most cases in which equilibrium constants for complex formation (K) can be measured independently by a spectrophotometric technique the agreement between K and k_1/k_{-1} is reasonable. In general, because of uncertainties in k_{-1}, particularly at low values of k_{-1}, the ratios k_1/k_{-1} are best regarded as approximations only to the true values of K. For all the systems studied equilibrium constants determined spectrophotometrically are considered to be the more reliable except where K exceeds 5×10^5 l mol^{-1}.

Equilibrium constants for complex formation are in the ratio 1:9:1100:3900:7900:24,400:113,000 for HO^-, CH_3O^-, $C_2H_5O^-$, $n\text{-}C_3H_7O^-$, $n\text{-}C_4H_9O^-$, $i\text{-}C_4H_9O^-$, and $i\text{-}C_3H_7O^-$.

In the systems under study both solvent effects and base effects must necessarily play a role in determining the values of ΔH_1^+, ΔS_1^+, ΔH_{-1}^+, ΔS_{-1}^+, and ΔG^0. It is of interest to see what relationships, if any, exist between the observed thermodynamic and kinetic parameters and known solvent and base parameters.

For the cases R = CH_3, C_2H_5, $n\text{-}C_3H_7$, $i\text{-}C_3H_7$, $n\text{-}C_4H_9$, and $i\text{-}C_4H_9$ the log K *vs.* solvent parameter E_t (5, 16) is linear with a slope −0.57 (Fig. 2). The linear relationship between log K and the E_t of the solvents suggests that solvent effects play a major role in determining the equilibrium constants for reactions of the type under investigation

[3]A study of the replacement of halogens from 6-halogenobenzothiazoles by mercaptide ions in a common solvent (methanol) revealed that branching at the position α to the nucleophilic atom in the nucleophile resulted in a rate retardation whose magnitude was nearly independent of the size of the halogen displaced (14).

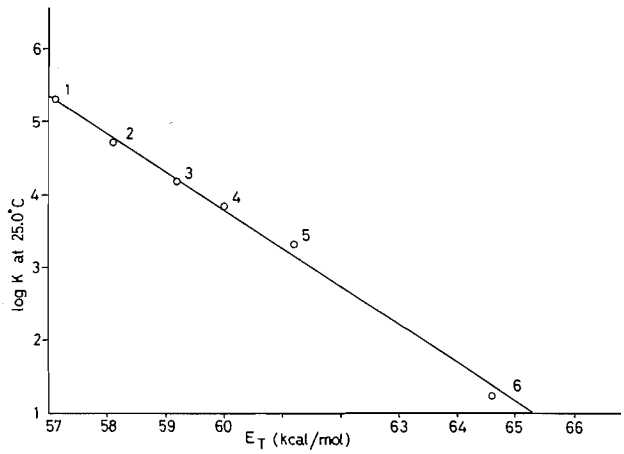

FIG. 2. Plot of log K at 25.0° for σ-complex formation according to eq. 2 *vs.* the solvent parameter E_t of the corresponding ROH. Points: 1, *i*-propanol; 2, *i*-butanol; 3, *n*-butanol; 4, *n*-propanol; 5, ethanol; 6, methanol.

(17). For σ-complex formation between cyanide ion and TNB in the alcohols a linear log K *vs.* E_t plot with slope −0.35 was found over the range R = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, and *t*-C_4H_9 (17). The more negative slope observed in the reactions of TNB with RO^- undoubtedly reflects the combined effect of changing solvent and changing base strength as one proceeds from R = CH_3 to R = *n*-C_4H_9 in the RO^- series. For dilute alcoholic solutions (*e.g.*, 0.1 *M* alkali metal alkoxide in the corresponding alcohol) the order of basicity rises in passing from methanol (H_- = 12.66) to ethanol (H_- = 14.57) to *i*-propyl alcohol (H_- = 16.95) to *t*-butyl alcohol (H_- = 19.14) (18).

Log k_1 and log k_{-1} *vs.* E_t plots are also approximately linear for the cases R = CH_3, C_2H_5, *n*-C_3H_7, and *n*- and *i*-C_4H_9 with slopes −0.23 and 0.31 respectively. Employing the E_t values of *i*-C_3H_7OH and *t*-C_4H_9OH as bases, lower than expected values of log k_1 and higher than expected values of log k_{-1} are obtained for R = *i*-C_3H_7 and *t*-C_4H_9. When R = H both log k_1 and k_{-1} values are smaller than expected on the basis of the E_t for H_2O with log k_{-1} showing the most marked deviation from the expected value. This suggests that K for the case R = H is higher than expected on the basis of the E_t value for H_2O largely because of the abnormally small value of k_{-1}. A possible reason for the small value of k_{-1} in this system has already been advanced (1).

TABLE 3. Pseudo-first-order rate constants for σ-complex formation between 1,3,5-trinitrobenzene and 1,3,5-trinitrobenzene-d_3 with ethoxide ion in ethanol at 25.0 °C

$[NaOC_2H_5]$ ($M \times 10^{-4}$)	k_{obs}[a] (s^{-1})	
	TNB	TNB-d_3
3.6	13.4	13.3
6.7	21.8	21.6
12.2	34.7	34.6
21.6	51.6	51.5
25.4	59.4	59.6
29.0	70.0	70.5

[a] From plots of ln ($A_\infty - A_t$) *vs.* time; A measured at 426.5 nm; $[TNB]_0 = 0.82 \times 10^{-5} - 1.15 \times 10^{-5} M$.

As part of this study we also investigated the reaction of TNB-d_3 with ethoxide ion in ethanol. The data in Table 3 show that at the same concentration of ethoxide ion k_{obs} is, within experimental error, the same for the two substrates. We can discern no kinetic isotope effect associated with this σ-complex formation reaction. If a kinetic isotope effect $\{k_1(TNB)/k_1(TNB\text{-}d_3)\}$ exists, we estimate it is less than 1.03. Negligible kinetic isotope effects are to be expected for σ-complex formation reactions (19).

A solvent isotope effect is associated with σ-complex formation in the TNB–$C_2H_5O^-$ reaction as exemplified by the data in Table 4. At every base concentration k_{obs} for σ-complex formation is substantially larger in ethanol-*O*-*d*

Crystal and Molecular Structure of 2-Bromo-11-ethyl-5,9-dimethoxytetracyclo[5.4.1.1^{4,12}.1^{8,11}]tetradecan-3-one, $C_{18}H_{27}BrO_3$

R. F. DUNPHY AND H. LYNTON

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 11, 1971

The molecular structure of 2-bromo-11-ethyl-5,9-dimethoxytetracyclo[5.4.1.1^{4,12}.1^{8,11}]tetradecan-3-one, $C_{18}H_{27}BrO_3$, synthesized in an attempt to develop a method of conversion from an advanced relay compound to the alkaloid delphinine, has been determined by the heavy atom method. The compound crystallizes in the monoclinic system, space group $P2_1/c$, with unit cell dimensions $a = 9.684(9)$, $b = 13.481(15)$, $c = 12.988(14)$ Å, $\beta = 99.47(7)°$, and four molecules in the unit cell. The atomic parameters were refined by block-diagonal least squares using anisotropic thermal parameters. The hydrogen atom positions were established but the parameters were not refined. The final agreement residual for 816 observed reflections is $R = 0.044$.

The stereochemistry of the compound was found to be unsuitable for the delphinine synthesis.

La structure moléculaire du 2-bromo-11-ethyl-5,9-diméthoxytétracyclo[5.4.1.1^{4,12}.1^{8,11}]tétradecan-3-one, $C_{18}H_{27}O_3Br$, synthétisé dans l'espoir d'obtenir l'alcaloide delphinine à partir d'une étape intermédiaire avancée, a été déterminée par la méthode de l'atome lourd. Ce composé cristallise dans le système monoclinique, groupe d'espace $P2_1/c$. La maille élémentaire, contenant quatre molécules, a pour dimensions: $a = 9.684(9)$, $b = 13.481(15)$, $c = 12.988(14)$ Å, et $\beta = 99.47(7)°$. Les paramètres atomiques ont été affinés par moindres carrés (diagonalisation par blocs) en utilisant des facteurs thermiques anisotropes. Les positions des atomes d'hydrogène ont été établies mais n'ont pas été affinées. L'indice d'accord final est $R = 0.044$ pour 816 reflexions observées.

La stéréochimie de ce composé ne convient pas à la synthèse de la delphinine.

Canadian Journal of Chemistry, 49, 2497 (1971)

Introduction

In 1970, Wiesner *et al.* (1) reported the synthesis of an advanced relay compound and showed it to be indistinguishable from the product obtained by degradation of delphinine. A conversion of this relay compound to delphinine, if successful, will accomplish the total synthesis of this interesting alkaloid.

The model compound **1** (Fig. 1) has been synthesized by Wiesner and Tsai to develop the methods of conversion. Compound **2** (Fig. 1) has been prepared from the model compound and, if the new alicyclic *cisoid* ring system has the necessary *cis–exo* stereochemistry, ring contraction would yield the complete skeleton and stereochemistry of the delphinine C/D ring system (2). The method could then be applied to the relay compound to produce delphinine with some substituents missing, the addition of which would pose no fundamental problem. A sample of the compound **2** was submitted for X-ray investigation to determine whether the desired stereochemistry had been obtained.

squares evaluation of the positions of 12 independent reflections. The space group is $P2_1/c$ (C_{2h}^5) No. 14 in ref. 3.

Intensity data were collected on a Picker computer-controlled four-angle diffractometer using a $\theta/2\theta$ scan with β-filtered Mo Kα radiation and a scintillation detector. The two octants hkl and $\bar{h}kl$ were explored to a maximum of 2θ of 35°. There were 1142 accessible reflections in this region of which 816 were considered observed. The threshold was taken as 0.10 times the background count or 70 counts, whichever was greater. The specimen was an elongated crystal with dimensions 0.54 × 0.32 × 0.22 mm, the long direction being parallel to the b axis. The b axis of the crystal was mounted parallel to the ϕ direction of the diffractometer. The linear absorption coefficient for Mo Kα radiation is $\mu = 26.14$ cm^{-1}. No absorption or extinction corrections were applied.

The position of the bromine atom was established from a three-dimensional Patterson synthesis. All of the carbon and oxygen atoms were then located from a three-dimensional Fourier synthesis based on the phases determined by the bromine atom alone. All atoms were found to be in general positions. The method of refinement was by successive cycles of block-diagonal least squares, using 3 × 3 matrices for the positional parameters and 6 × 6 matrices for the anisotropic thermal parameters of each atom. The quantity minimized was

$$R_2 = \Sigma\omega(|F_o| - |F_c|)^2$$

for observed reflections only, using weighting function

$$\omega = \frac{1}{1 + [(|F_o| - P_2)/P_1]^4}$$

with $P_1 = 30$, $P_2 = 40$. Scattering factor curves used were those for Br, O, C, and H given in ref. 4. The bromine scattering curve was corrected for anomalous dispersion (5).

The final agreement residual

$$R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$$

for all atoms except hydrogen was 0.069. A difference synthesis at this point showed the positions of all hydrogens as peaks with electron density between 0.4–0.5 eÅ^{-3} and no other electron density greater than 0.25 eÅ^{-3}. The hydrogens were assigned isotropic thermal parameters by the following scheme: for hydrogens on terminal methyl groups, $B = 5.00$; for those on the secondary side chain carbon, $B = 4.75$; for those on other secondary (bridging) carbons, $B = 4.50$; and for those attached to tertiary carbons, $B = 4.00$ Å^2. The positional and thermal parameters for the hydrogens were not refined during subsequent least squares

cycles. In the last cycle no parameter shift exceeded 0.3 times the estimated standard deviation. The final agreement residual for the observed reflections, for all atoms, was $R = 0.044$. A set of structure factors for the final parameters given in Tables 1 and 2 has been placed in the depository of Unpublished Data.[1]

Discussion

The intramolecular bond distances and angles are given in Table 3. The general stereochemistry of the molecule and the numbering scheme used in this paper are shown in Fig. 2.

The general structure indicated in Fig. 1 is seen to be correct but the ring in question does not have the desired *exo* configuration. Hence, another method of conversion must be found for the formation of delphinine from the relay compound. The *endo* configuration of the ring gives the molecule a cage-like structure with the bromine, carboxyl, methoxy, and ethyl substituents pointing outward from the ring system. The new ring adopts the chair configuration while the other two six-membered rings are in the boat form, giving the molecule a fairly rigid structure.

Most of the bond lengths and angles shown in Table 3 are comparable with those for organic structures found in the literature, although there are several which are significantly different from the expected values. In particular, there is a very short bond C(15)—C(16) 1.490(14) Å. A "riding-

Oxidative Degradation of a Podocarpic Acid Derivative

TSE-LOK HO[1]

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 29, 1971

The dichromate oxidation of methyl-7-methyl-6,8,11,13-podocarpatetraen-19-oate, (**5**), is reported.

L'oxydation par le dichromate du méthyl-7 podocarpatétraène-6,8,11,13 oate-19 (**5**) de méthyle est rapportée.

Canadian Journal of Chemistry, 49, 2501 (1971)

During the study of ring B expansion of methyl *O*-methylpodocarpate (**1**) which served as a model in a projected synthesis of aconitine-type diterpene alkaloids (1), we discovered a novel oxidative degradation.

It was intended to prepare the exocyclic olefin **2**, a useful intermediate for our purpose (2), from the well-known 7-keto derivative **3** of **1**.

We first attempted the Reformatsky reaction on **3**, hoping that further transformations of the product **4** by dehydration, saponification and pyrolysis would yield the desired olefin. Surprisingly, direct acid treatment of the crude product gave only the styrene **5**, whose structure followed from spectroscopic data.

Wittig olefination (3), when applied to ketone **3**, also led to the isomerized product **5**. The definite structure of **5** was settled on a firm basis by its preparation by dehydration of the methyl Grignard product of **3**.

Dichromate oxidation of the styrene **5** gave, unexpectedly, methyl *O*-methyl-5,6-dehydro-7-ketopodocarpate (**6**). The physical properties of this substance are consistent with those reported by Wenkert *et al.* (4), who prepared it by a different route. Hydrogenation of **6** yielded methyl *O*-methylpodocarpate.

The mechanistic pathway of the oxidation may be envisaged as outlined in Scheme 1. It is noteworthy that a close analogy of the initial steps may be found in the cleavage of cycloalkenes to dialdehydes by chromyl trichloroacetate (5).

Experimental

Melting points were determined on a Kofler microscope hot-stage and are uncorrected. The i.r. spectra were

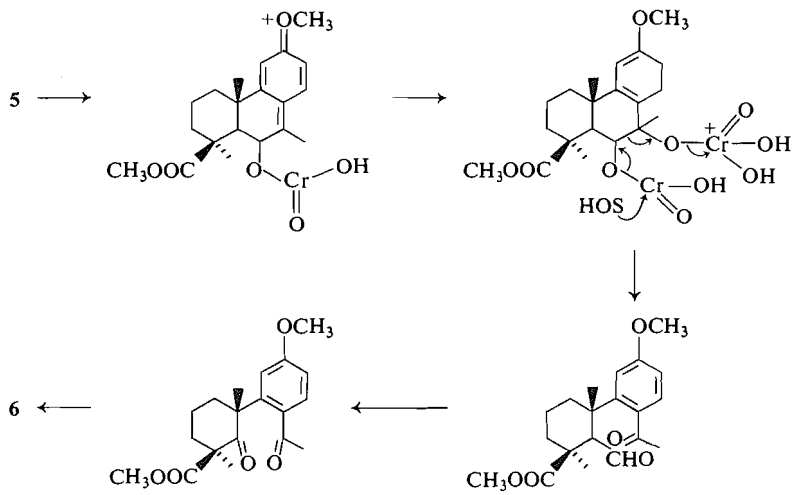

SCHEME I

recorded on a Perkin–Elmer model 21 spectrophotometer. The u.v. spectra were taken on a Beckman DK-2 spectrophotometer. The n.m.r. spectra were measured in $CDCl_3$ on a Varian HR-60 spectrometer operated at 56.4 MHz, with TMS as internal standard.

Reformatsky Reaction, Dehydration of 3

To a stirred, refluxing suspension of 0.65 g of activated zinc dust and a crystal of iodine in 10 ml of anhydrous benzene was introduced from a dropping funnel of a solution of 0.95 g of methyl *O*-methyl-7-ketopodocarpate (**3**) and 1.7 g of ethyl bromoacetate. An additional 0.20 g of zinc dust and 0.50 g of ethyl bromoacetate were added after 1 and 1.5 h, respectively. The reaction was allowed to proceed overnight, the mixture was cooled and poured into 10% aqueous sulfuric acid. The layers were separated and the aqueous phase was further extracted with chloroform. An orange brown oil was obtained from the dried organic extracts.

The crude product (2.71 g, combined from two identical runs) was dissolved in 50 ml of benzene containing 1.0 g of *p*-toluenesulfonic acid monohydrate, and was brought to reflux under a Dean–Stark water separator for 24 h. The contents were poured into ice-cold sodium bicarbonate solution, extracted with chloroform. The dried organic phase was evaporated to dryness and the residue (1.8 g) was chromatographed on 50 g of neutral alumina (Woelm, activity II) to furnish 1.099 g of pure styrene **5**, m.p. 84–86°, and 0.20 g of **3**. An analytical sample of **5** was prepared by sublimation under high vacuum. The i.r.: ν_{max} (CCl_4) 1732 (ester), 1615 cm^{-1}; u.v.: λ_{max} (log ε) 271.5 (4.10), 218.5 (4.21); n.m.r.: τ ($CDCl_3$) 9.16 (3H, s, CH_3), 8.73 (3H, s, CH_3), 7.94 (3H, br, s, CH_3), 6.32 (3H, s, $COOCH_3$), 6.19 (3H, s, $ArOCH_3$), 3.86 (1H, br, $=CH$), 3.42, 3.25, 2.91 (3H, ArH).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.50; H, 8.35; O, 15.29. Found: C, 76.57, 76.38; H, 8.30, 8.41; O, 14.81.

Wittig Reaction on 3

To a solution of phenyllithium prepared from 0.14 g of lithium and 1.57 g of bromobenzene in 100 ml of ether was added 4.35 g of methyl triphenylphosphonium bromide. After 2 h stirring at 25° under nitrogen, the ylid solution was cooled in an ice-bath, and a solution of 1.05 g of methyl *O*-methyl-7-ketopodocarpate in 30 ml of dry tetrahydrofuran was introduced. The reaction mixture was allowed to warm up to room temperature and left aside overnight, then finally heated under reflux for 5 h. After removal of the solvents, the residue was triturated several times with ether and filtered through an alumina column. Further chromatography of the product over 50 g of neutral alumina (Woelm, activity II) yielded 0.49 g of the styrene **5**, identical with the compound obtained from the Reformatsky-dehydration reactions (i.r., n.m.r., t.l.c., m.p., mixture m.p. 84–86°).

From later fractions of the chromatogram, 0.336 g of unreacted **3** was recovered.

Grignard Reaction, Dehydration of 3

To the Grignard reagent prepared from 0.38 g of magnesium turnings and 1 ml of methyl iodide, diluted to 100 ml with anhydrous ether, was added 1.0 g of finely pulverized ketone **3** with vigorous magnetic stirring. The reaction mixture was then refluxed overnight, cooled, and destroyed with aqueous ammonium chloride. The aqueous layer after separation was extracted with benzene. Evaporation of the dried organic solution gave 1.0 g of a crude product.

Direct dehydration with 1.0 g of *p*-toluenesulfonic acid monohydrate in 50 ml of benzene at reflux yielded 0.9 g of material. Pure styrene **5** (0.602 g) was isolated by chromatography on alumina. Some unreacted ketone (0.246 g) contaminated with a small amount of **5** was collected from later fractions.

Dichromate Oxidation of 5

Sodium dichromate dihydrate (80 mg) was added to a solution of 75 mg of styrene **5** in 5 ml of glacial acetic acid. After heating in a boiling water bath for 3 h, the reaction mixture was cooled, poured into crushed ice,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

neutralized with sodium carbonate, and extracted with chloroform. Evaporation of the dried extracts *in vacuo* afforded 80 mg of material. Purification of the product by column chromatography (neutral alumina, Woelm, activity II) yielded 40 mg of the cross-conjugated ketone **6**, m.p. 175–178.5°, after crystallization from methanol (lit. (5) m.p. 173–175°). The i.r.: ν_{max} ($CHCl_3$) 1730 (ester), 1652 (ketone), 1602 (Ar) cm^{-1}; u.v.: λ_{max} (log ε) (C_2H_5OH) 302.5 (4.10), 242.5 nm (4.22); n.m.r.: τ ($CDCl_3$) 8.65 (3H, s, CH_3), 8.47 (3H, s, CH_3), 6.35 (3H, s, $COOCH_3$), 6.15 (3H, s, $ArOCH_3$), 3.43 (1H, s, H-6), 3.05 (2H, m, ArH), 1.87 (1H, d, $J \simeq 10$ Hz, ArH).

Hydrogenation of Ketone 6

The ketone **6** (0.109 g) was hydrogenated in 10 ml of ethanol with 12 mg of 10% Pd–C for 20 h. The catalyst was removed by filtration (Celite) and the filtrate was evaporated to dryness. The product (0.105 g) obtained crystallized on standing and was recrystallized from methanol, m.p. 126–129°. This specimen was found to be identical with methyl *O*-methylpodocarpate (i.r., n.m.r., t.l.c., mixture m.p. 128–129.5°).

Lewis Acid – Base Interactions Between Bis-π-cyclopentadienyl Tungsten and Molybdenum Dihydrides, Cp_2MH_2, and some Main Group III Moieties

A. STORR AND B. S. THOMAS

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received January 14, 1971

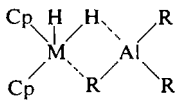
Combination of the Lewis bases Cp_2MH_2 (where M = W or Mo) with the Group III Lewis acids AlR_3 (where R = Me, Et, or Ph) and $AlMe_2H$ has yielded a series of 1:1 complexes of the type $Cp_2MH_2.AlR_3$. A number of the complexes undergoes a slow elimination of hydrogen or alkane in benzene solution. Attempts to isolate mixed hydride adducts of the type, $Cp_2MH_2.M'H_3$ (where M' = Al or Ga), were unsuccessful.

La combinaison des bases de Lewis Cp_2MH_2 (M = W ou Mo) avec les acides de Lewis du groupe III, AlR_3 (R = Me, Et ou Ph) et $AlMe_2H$, conduit à une des séries de complexes 1:1 du type $Cp_2MH_2.AlR_3$. Un certain nombre de ces complexes perdent de l'hydrogène ou un alkane, en solution dans le benzène. Les tentatives en vue d'isoler des hydrures doubles du type, $Cp_2MH_2.M'H_3$ (M' = Al ou Ga) sont demeurées vaines.

Canadian Journal of Chemistry, **49**, 2504 (1971)

The transition metal hydrides, Cp_2MH_2 (where M = W or Mo), have been shown to act as Lewis bases (1, 2). In the present study we were interested in extending the range of transition metal – Group III derivative compounds by investigating reactions between these two hydrides and a number of potential Group III acceptor moieties. It was found that organo aluminum derivatives AlR_3 (where R = Me, Et, or Ph) and $AlMe_2H$ all form 1:1 complexes with the tungsten and molybdenum hydrides. The compounds are, in general, yellow crystalline solids which are monomeric in benzene solution. However, with dimethyl aluminum hydride as the acceptor moiety only the tungsten compound could be isolated from solution, the molybdenum adduct decomposing on removal of solvent.

The infrared spectra of the complexes in benzene solution in the region 4000–250 cm^{-1} show all the characteristic bands individually displayed by the separate components with no noteworthy changes due to complex formation. These observations effectively rule out bridge structures of the type



and indicate in all probability the presence of a direct metal–metal bond in the complexes. A similar conclusion was reached by Brunner *et al.* (3) for the complex $Cp_2WH_2.AlMe_3$ on the basis of their infrared (i.r.) data and low temperature nuclear magnetic resonance (n.m.r.) measurements.

Proton n.m.r. data collected on benzene solutions of the complexes are summarized in Table 1. The cyclopentadienyl-hydrogen signals show fine splittings due to coupling to the M—H protons but only at high field strengths and small sweep widths ($J_{Cp-W-H} \simeq 0.5$–0.7 c.p.s.). In general the M—H signals are fairly broad and couplings to cyclopentadienyl ring protons were not resolved. On standing the appearance of additional signals to those listed in Table 1 indicate the slow decomposition, with alkane elimination, of some of the complexes in benzene solution. Thus, $Cp_2MoH_2.AlMe_3$, $Cp_2MoH_2.AlEt_3$, and $Cp_2WH_2.AlEt_3$ all decompose slowly at room temperature with evolution of alkane, and on long standing, the deposition of solid material from the benzene solutions. In the typical case of $Cp_2WH_2.AlEt_3$, the proton n.m.r. spectrum of a freshly prepared sample is illustrated in Fig. 1(*a*). After several days the spectrum of the solution appears as shown in Fig. 1(*b*) with a sharp new signal (τ = 9.2 p.p.m.) appearing in addition to the signals observed initially. The new signal is assigned to the presence of ethane in the sample, an assignment initially suggested by the pressure build-up within the n.m.r. tube and confirmed by previous measurements on the chemical shift of ethane (4). Initially even with the presence of ethane indicated by the spectrum, the solution in the n.m.r. tube remained clear,

but on long standing a dark brown solid of uncertain composition was deposited. The appearance of the ethane signal coincided with a more complicated signal for the cyclopentadienyl rings and a reduction in the relative intensity of the M—H signal. These observations suggest that although soluble low molecular weight species are initially formed following ethane elimination, these gradually polymerize to yield insoluble, cross-linked, materials containing a network of tungsten and aluminum atoms. In the case of dimethyl aluminum hydride adducts hydrogen is eliminated in preference to methane, possibly because of the greater polarity of the aluminum hydrogen bond. With the trimethyl aluminum complexes, methane was evolved only from the molybdenum compound at room temperature in benzene solution. (A signal due to methane appeared in the n.m.r. spectrum at $\tau = 9.9$ p.p.m.) Even after prolonged periods at room temperature, benzene solutions of $Cp_2WH_2.AlMe_3$ gave no evidence of methane elimination. This observation is in agreement with the generality (2) that transition metal basicity increases down a group of the *d* block elements in contrast to the trend usually observed for main group bases.

Our inability to prepare stable mixed hydride derivatives of the type $Cp_2MH_2AlH_3$ demonstrates the reduced Lewis acidity of the "AlH_3" unit over the AlR_3 moieties. The reaction of lithium aluminum hydride with the tungsten base and hydrogen chloride did indicate the formation of an unstable complex which deposited polymeric $(AlH_3)_x$ from benzene solution.

$$Cp_2WH_2AlH_3 \xrightarrow[\text{room temperature}]{C_6H_6} Cp_2WH_2 + \frac{1}{x}(AlH_3)_x$$

The i.r. spectrum of the initially clear solution displayed both W—H and Al—H absorptions. On standing, a white solid was deposited slowly from the solution and the intensity of the Al—H absorption decreased until finally the spectrum was that of pure Cp_2WH_2 in benzene solution. The white solid was characterized as $(AlH_3)_x$ which is known to be insoluble in benzene solution (5). The corresponding gallane reaction gave no indication of complex formation to yield $Cp_2WH_2.GaH_3$, and the "GaH_3" unit released by the action of hydrogen chloride on the lithium gallium hydride promptly decomposed to give hydrogen and gallium metal in characteristic fashion (6).

Experimental

Materials were handled in a conventional high vacuum line or in a glove box under an atmosphere of oxygen-free dry nitrogen. All solvents were thoroughly dried and redistilled before use.

Starting Materials

Bis-π-cyclopentadienyl molybdenum and tungsten dihydrides were prepared by the method of Green *et al.* (7). Trimethyl aluminum and triethyl aluminum (Alfa Inorganics) were purified by reduced pressure distillation. Triphenyl aluminum was prepared by the reaction of diphenyl mercury with a slight excess of aluminum foil in refluxing toluene. Lithium aluminum hydride was purified by extracting the crude material (Alfa Inorganics) with diethyl ether, and an ether solution of lithium gallium hydride was obtained by the standard procedure (8). Hydrogen chloride gas (Matheson Co., Inc.) was carefully dried by repeated passage over phosphorus pentoxide before use. Dimethyl aluminum hydride was prepared by the reaction of trimethyl boron (K and K Laboratories, Inc.) on lithium aluminum hydride in a sealed bulb, and purified by vacuum transfer (9).

Spectra

Definitive infrared spectra were recorded on a Perkin–Elmer Model 457 spectrometer (4000–250 cm^{-1}). The samples were run as benzene solutions, the cells being loaded in the glove box.

Proton n.m.r. spectra were obtained on Varian HA-100 and T-60 instruments. The benzene solutions were prepared in the glove box and the sample tubes sealed off to prevent oxidation and hydrolysis. All τ values are referred to benzene as $\tau_{C_6H_6} = 2.84$ p.p.m. Concentrations of all the solutions were kept roughly the same (~0.3 *M*) to minimize any possible concentration dependence of the signals.

Molecular Weights

Cryoscopic molecular weight determinations were conducted using benzene as solvent. The apparatus was designed to provide a nitrogen blanket over the solution to prevent atmospheric interference.

Analyses

The active hydrogen and alkyl group contents of the complexes were determined gas volumetrically after hydrolysis with a methanol–water mixture. All gas volumes are quoted at standard temperature and pressure. The aluminum content of the hydrolysate was determined gravimetrically as the 8-hydroxyquinolate (10).

Preparative Details

(a) Preparation of Aluminum Alkyl (Aryl) Derivatives

The complexes $Cp_2MH_2.AlR_3$ and $Cp_2MH_2.AlMe_2H$ were all prepared by the same general procedure which can be illustrated by the preparation of $Cp_2WH_2.AlEt_3$:

TABLE 2. Analytical data

Complex	Mol. wt. data		Analysis			
			Found		Calcd.	
	Found	Calcd.	Al	R(hydrolysable)	Al	R(hydrolysable)
$Cp_2WH_2.AlMe_3$	400	388	6.90	11.4	6.95	11.6
$Cp_2WH_2.AlEt_3$	405	430	6.25	20.0	6.30	20.2
$Cp_2WH_2.AlMe_2H$	404	374	7.24	—	7.22	—
$Cp_2WH_2.AlPh_3$	620	574	4.66	—	4.70	—
$Cp_2MoH_2.AlMe_3$	306	300	9.10	15.2	9.00	15.0
$Cp_2MoH_2.AlEt_3$	361	342	7.95	25.9	7.90	25.4
$Cp_2MoH_2.AlMe_2H$	290	286	—	—	—	—
$Cp_2MoH_2.AlPh_3$	477	486	5.60	—	5.55	—

Bis-π-cyclopentadienyl tungsten dihydride (0.4486 g, 1.42 mmol) was dissolved in benzene (20 ml) and triethyl aluminum (0.1620 g, 1.42 mmol) was added dropwise. The solvent was pumped away to leave the yellow, crystalline complex, $Cp_2WH_2.AlEt_3$. Analytical data for the complexes are listed in Table 2.

(b) Attempted Preparation of Mixed Hydride Species

Hydrogen chloride (21.6 ml, 0.96 mmol) was condensed onto a mixture of bis-π-cyclopentadienyl tungsten dihydride (0.2806 g, 0.96 mmol) and excess lithium

$$Cp_2WH_2 + HCl + LiAlH_4 \rightarrow Cp_2WH_2.AlH_3 + H_2 + LiCl$$

aluminum hydride (0.1 g, 2.6 mmol) in diethyl ether (20 ml). The mixture was warmed to room temperature with stirring and the volume of hydrogen evolved measured (23.0 ml, 1.02 mmol). The ether was removed at −80° and the product extracted with benzene. The solution displayed both W—H and Al—H stretching frequencies in its infrared spectrum but on standing deposited a white solid. Similar results were obtained using bis-π-cyclopentadienyl molybdenum dihydride as the Lewis base. However, in similar reactions employing lithium gallium hydride, no evidence of even transient complex formation was obtained.

We thank the National Research Council of Canada for financial support.

^{35}Cl Nuclear Quadrupole Resonance of Alkyl Chloroformates, Alkyl Acid Chlorides, and Carbamyl Chlorides

R. M. HART AND M. A. WHITEHEAD[1]

Radiofrequency Spectroscopy Laboratory, Chemistry Department, McGill University, The Royal Institution for the Advancement of Learning, Montreal 110, Quebec

Received February 22, 1971

The ^{35}Cl nuclear quadrupole resonance (n.q.r.) frequencies at 77 °K of twenty-two chloroformates, twenty-eight acid chlorides, two thiocarbonyl molecules, and five carbamyl chlorides are reported.

On rapporte les fréquences de résonance nucléaire quadrupolaire du ^{35}Cl à 77 °K de vingt-deux chloroformates, vingt-huit chlorures d'acides, deux molécules thiocarbonylées et cinq chlorures de carbamoyle.

Canadian Journal of Chemistry, 49, 2508 (1971)

Introduction

The planarity (1, 2) of the —X—COCl unit suggests π-bonding, and the difference in π-bonding when X is R, O, S, or N could be measured by comparing the ^{35}Cl n.q.r. in equivalent molecules. Unfortunately, no resonances were detected in —SCOCl molecules nor in —NCSCl molecules. Frequencies were obtained for thirteen pairs of molecules, RCOCl and ROCOCl, and the frequency variation within each series was small. The frequency variation is qualitatively discussed.

Experimental

Commercial samples were used and purified by distillation and sublimation.

A modified Dean type externally quenched superregenerative oscillator with phase-sensitive detection and strip chart recording was used to measure the ^{35}Cl n.q.r. frequencies, as previously described (3).

1. The Chloroformate Molecules (Table 1)

The frequencies of the *n*-alkyl chloroformates are approximately constant for R greater than *n*-C_3H_7, in agreement with the behavior of the frequencies in the RCl series (4) and with the normal σ-inductive effects of organic chemistry in such alkyl molecules (5–7).

A comparison of the frequencies from the RCl, RCH_2Cl, RCOCl, and ROCOCl series shows that the frequencies are roughly correlated when R is a saturated organic group such as CH_3 and XCH_2 (where X is halogen), or when an unsaturated group, such as Ph is separated from the chlorine by a saturated linkage. The frequency variation is most pronounced in the RCl system and least pronounced in the RCOCl series. When the group R is unsaturated and capable of conjugation, the RCl and RCOCl frequencies roughly correlate, and the ROCOCl and RCH_2Cl frequencies roughly correlate; since in RCl π-conjugation to the chlorine is possible while in RCH_2Cl it is impossible, these correlations suggest that ROCOCl shows no π-conjugation to the chlorine while RCOCl does show π-conjugation to the chlorine. There is, however, no linear correlation between the frequencies of the RCl and RCOCl or the RCH_2Cl and ROCOCl series. Table 2 gives the results for CNDO/2 calculations on four chloroformate molecules with R equal to CH_3, CH_2F, CHF_2, and CF_3. The calculations use Santry and Segal parameters (8) and the Townes and Dailey formula (9). They show that there is little or no π-bonding to the chlorine from the carbon (4) and that it does not change with increased fluorine substitution. The frequency changes are, consequently, σ-induced. Thus $C_6H_5CH_2$— has a frequency within the *n*-alkyl range, as do $CH_2{=}CHCH_2$ and $Cl(CH_2)_3$; the other fluorine or chlorine substituted *n*-alkyl groups fall in the normal σ-inductive order (10–12). The similarity of the frequencies for C_6H_5— and *p*-$CH_3OC_6H_4$— support such a σ-inductive view, but it must always be remembered that any large change in the σ-bond between the carbon and chlorine will always cause a change in the π-bond between the carbon and chlorine (13), however, the specific amount of π-character in each molecule must be calculated (16). The changes, although small,

TABLE 1. ^{35}Cl n.q.r. frequencies of chloroformates at 77 °K[a]

Molecule	Frequency (MHz)	
	Acyl chlorine	Carbon chlorine
CH_3OCOCl	34.257	
C_2H_5OCOCl	34.270, 34.364 (33.858)[c]	
n-C_3H_7OCOCl	33.823	
n-C_4H_9OCOCl	33.746	
n-$C_5H_{11}OCOCl$	33.770	
n-$C_6H_{13}OCOCl$	33.749	
n-$C_7H_{15}OCOCl$	33.806	
n-$C_8H_{17}OCOCl$	33.873	
$(CH_3)_2CHOCOCl$	33.798, 33.701	
$(CH_3)_2CHCH_2OCOCl$	34.030, 34.082	
O-$(CH_2CH_2OCOCl)_2$	34.102, 34.848	
$CH_2{=}CHCH_2OCOCl$	34.282	
C_6H_5OCOCl	34.818	
p-$CH_3OC_6H_4OCOCl$	34.943	
$C_6H_5CH_2OCOCl$	33.772	
$(CF_3)_3COCOCl$	36.737	
C_2F_5OCOCl	36.563, 36.731	
i-C_3F_7OCOCl	36.258	
$F_5SOCOCl$	36.604	
Cl_3CCH_2OCOCl	35.691	38.746, 38.918, 39.141
$ClCH_2CH_2OCOCl$	34.436[b]	34.319[b]
$ClCH_2CH_2CH_2OCOCl$	34.194, 33.968	33.370, 33.069

[a]Attempts to crystallize samples of $(CH_2OCOCl)_2$ were unsuccessful. No frequencies were detected in CF_3OCOCl or $CH_3(CF_3)_2COCOCl$. All multiple interactions are of equal intensity.
[b]These assignments are arbitrary.
[c]Reference 24.

account for the lack of linearity in the correlation of RCl and ROCOCl frequencies. Furthermore Table 2 demonstrates that small changes in σ and π can cause large frequency differences. In the calculations the —OCOCl group was assumed to have the same geometry in all four molecules, and the rough correlation between the ROCOCl and RCH_2Cl frequencies supports such an assumption: some chloroformates have been postulated to have dioxan structures such as $ClCO_2CCl_3$ being  but this has been disproved by i.r. measurements on similar compounds in CCl_4, and there is no evidence for such structures in the solid state (14). Dipole moments have favored the R to be *cis* to Cl in RXCOCl (15) and electron diffraction (1) has shown *cis* for the methyl chloroformate only. The ^{35}Cl n.q.r. frequencies do not give any evidence on these points, except that the regularity of the frequency change with R suggests similar structures for all molecules.

The similarity of the frequencies of $F_5SOCOCl$ and C_2F_5OCOCl shows that the sulfur, although capable of d_π–p_π conjugation with the —OCOCl group, nevertheless affects the chlorine by σ induction.

2. The Acid Chloride Molecules (Table 3)

The frequencies for the *n*-alkyl acid chlorides are approximately constant for R greater than C_3H_7, with less variation than in the chloroformates, and in the expected σ-inductive sequence (4, 16, 17).

The low frequencies of the RCOCl molecules is due to large π-bonding to the chlorine (4); consequently the C_6H_5— and *p*-$CH_3OC_6H_4$— groups are conjugated to the Cl in RCOCl, but σ-inductive in ROCOCl. The $(CH_3)_3$— group of pivaloylchloride results in this molecule $(CH_3)_3$-CCOCl having the *lowest* ^{35}Cl—C n.q.r. frequency observed (17).

The chloro, fluoro, and bromo substituted molecules show acyl chlorine frequencies in agreement with inductive effects due to the high electronegativity of the halogen bonding orbitals (18). The F_3C— molecule has a lower frequency than the Cl_3F— molecule; similar trends occur in the chloroalkanes and α-chloro ethers (4), where they have been explained as hyperconjugation between the C—Cl bond and the fluorine lone

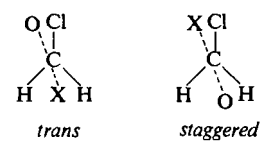
[i]β-C—Cl bond.
[j]No quadrupolar interactions were detected in methylchloro-oxylate; valeryl, cinnamoyl, or itaconyl chloride.

pairs (19). In the present case hyperconjugation is between the fluorine lone pairs and the CO antibonding molecular orbital. Inductive effects cease beyond C_3 as in the *n*-alkyl series.

C_6H_5— raises the frequency of the RCOCl above that of the R equal to *n*-alkyl by 1 MHz (compared to 0.6 MHz in ROCOCl) while *p*-$CH_3OC_6H_4$ raises the frequency by 1.16 MHz (compared to 0.73 MHz in ROCOCl). Consequently the π-bonding to the chlorine enhances the σ-bond effect, shown by these groups in ROCOCl, by approximately 0.4 MHz.

The reported ^{35}Cl frequencies in $COCl_2$ seem too high in view of the other frequencies in Table 3. Substitution of a single chlorine in place of a perhalo group should not raise the frequency by 2.5 MHz; it may, however, be isomeric (20). The possible isomers are the *trans* and *staggered* forms.



trans *staggered*

For the chloroacetyl chlorides these have been shown to exist in the liquid; however, in the solid

Diphenylcarbamylchloride	$(C_6H_5)_2NCOCl$	33.202
Methylphenylcarbamylchloride	$(CH_3)(C_6H_5)NCOCl$	32.664
Ethylphenylcarbamylchloride	$(C_2H_5)(C_6H_5)NCOCl$	32.951

[a]2 kHz above frequency in ref. 19.

only the *trans* isomer exists for CH_3COF, $ClCH_2COF$, CH_3COCl, $ClCH_2COCl$, $ClCH_2COBr$, and CH_3COBr (20*a*). For $COCl_2$ the solid state has been shown to have an ordered structure but with unexplained residual entropy, which may be due to both isomers existing in the solid, but there is no evidence to establish this (20*b*).

3. The Thiocarbonyl Molecules (Table 4)

On σ-orbital electronegativity arguments the phenoxythiocarbonyl chloride frequency should be lower than that of phenylchloroformate. However, the π-orbital to chlorine could be affected by the stronger CS π bond (18).

4. The Carbamyl Molecules (Table 5)

The unsymmetrically substituted molecules both had intense resonances which exhibited normal temperature dependence, with no break in frequency dependence and no line width peculiarities (21) between 77 °K and room temperature. This suggests that CN bond reorientation (22, 23) does not occur in this range of temperature. The diphenylcarbamylchloride resonance is very weak.

The frequencies are in accord with σ-bond inductive effects from electronegativity considerations (10–13, 18) with the unsymmetrically substituted molecules between the symmetrical parent molecule frequencies. The high frequencies in the thiocarbamyl and carbamyl molecules suggest that like the chloroformates there is little π-bonding to the chlorine.

This research was supported by the National Research Council of Canada, to whom R.M.H. is grateful for a Bursary, 1969–1970. The McGill Committee on Research is thanked for finance of a frequency meter, and summer support for R.M.H., 1970. The McGill Computing Centre provided facilities on their IBM 360/75 computer. Mr. J. Grabenstetter did the CNDO calculations. Dr. D. E. Young of Allied Chemicals, Morristown, New Jersey, is thanked for providing samples of the fluorochloroformates prior to publication of their preparation.

Electron Spin Resonance of γ-Irradiated Dicyandiamide

G. LIND AND R. KEWLEY
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 9, 1971

The X-band e.s.r. spectra of single crystal and powder samples of γ-irradiated dicyandiamide, $(H_2N)_2CNCN$, have been observed. The results show that three radical species are formed on irradiation at room temperature. One of these radicals, which gives a single broad line spectrum of width 8.5 G and $g = 2.0040$, has not been identified. The other two species are considered both to have the same chemical formula $NH_2\dot{C}(NH)NCN$ but one is a π-electron radical whereas the other is a σ-electron radical with a very large proton hyperfine splitting in the range of 73–81 G. The production of two types of radicals by radiation damage to the same $—NH_2$ group of dicyandiamide is explained in terms of the ease of formation of π- and σ-electron radicals as influenced by geometrical considerations stemming from the hydrogen bonding in the dicyandiamide crystal.

On observe la bande X du spectre de e.s.r. d'un cristal unique et d'échantillons en poudre de dicyandiamide, $(H_2N)_2CNCN$, irradiés par des rayons γ. Les résultats indiquent que trois espèces radicalaires se forment sous irradiation à température de la pièce. L'un de ces radicaux, donnant un spectre constitué d'un signal large et unique de largeur 8.5 G et $g = 2.0040$, n'a pas été identifié. On suppose que les deux autres espèces ont la même formule chimique $NH_2\dot{C}(NH)NCN$ mais que l'un d'eux est un radical π-électronique et que l'autre est un radical σ-électronique donnant lieu à un important dédoublement hyperfin de proton dans la région de 73–81 G. La formation de deux espèces de radicaux, obtenus par suite des dommages causés par les radiations sur le même groupe $—NH_2$ du dicyandiamide, est expliquée en terme de facilité de formation des radicaux π- et σ-électroniques; ceci par suite de considérations géométriques provenant des liaisons hydrogène dans le cristal de dicyandiamide.

Canadian Journal of Chemistry, 49, 2514 (1971)

Introduction

In e.s.r. studies of radiation damage to carboxylic acids a frequent occurrence has been the observation of radicals containing the grouping $—\dot{C}HCOOH$, in which the unpaired electron occupies a π molecular orbital (1). On the other hand, an e.s.r. study of the formyl radical $H\dot{C}O$ (2) showed that this species has an unusually large proton hyperfine splitting of 137 G, which is inconsistent with the magnitude expected for a π-electron radical. Flow system experiments in which hydrogen was abstracted by OH radicals from acetamide and formamide yielded radicals identified as $\dot{C}H_2CONH_2$ and $HCO\dot{N}H$ (3). The former radical is a normal π-radical having closely equivalent methylene protons with $a_H = 21.28$ G. The latter radical has fairly large nitrogen hyperfine coupling, $a_N = 21.65$ G, and one proton with $a_H = 30.55$ G. Later, by means of deuteration, studies of temperature variation of hyperfine coupling constants and line width dependence on p*H*, this species was shown in fact to be not $HCO\dot{N}H$ but $O\dot{C}NH_2$ (4). It was described as a "non-π" radical analogous to the formyl radical, the small proton hyperfine coupling, relative to that in $H\dot{C}O$, being attributed to the substantial spin density at the nitrogen atom.

Recently e.s.r. studies following irradiation of malonamide (5, 6) and cyanoacetylurea (7) have shown that two types of radicals, designated π-electron and σ-electron, can be produced from a particular substance by radiation damage. The π-electron radicals are characterized primarily by CH proton hyperfine coupling constants in the range 7 to 33 G with $a_{iso} \sim 20$ G (in $H_2NCO\dot{C}HCONH_2$ (6) and $NC\dot{C}HCONH$-$CONH_2$ (7)). The latter value is similar to the hyperfine splitting constant a_H of the methyl radical and to values of Q_H found in aromatic radical ions (8). The σ-electron radicals, $H_2NCOCH_2CO\dot{N}H$ and $NCCH_2CONHCO\dot{N}H$, have much larger proton hyperfine coupling constants which are in the range 79 to 87 G, with $a_{iso} \sim 80$ G. In contrast to these results an e.s.r. investigation of γ-irradiated pentafluoropropionamide (9) showed the presence of the two species $CF_3\dot{C}FCONH_2$ and $CF_3CF_2CO\dot{N}H$, both of which are considered to be π-electron radicals, although it may be noted that a detailed study of the latter radical was not feasible under the conditions of the experiment. X-Irradiation

of hydroxyurea produces a radical first thought to be H_2NCONH but later identified as NH_2CONHO· which is a π-radical with the unpaired electron centered on oxygen (10, 11). The same radical can also be produced by oxidation in aqueous solution, see (12) for example, and has been shown to have $a_H^{NH} = 12.5$ G and $a_N^{NH} = 8.2$ G (10, 13).

The present work was undertaken in order to concentrate attention on the effects of radiation on the $-NH_2$ group. Dicyandiamide (1-cyanoguanidine), $(H_2N)_2C{=}N{-}C{\equiv}N$, offers the possibilities of formation of both π- and σ-electron radicals centered on nitrogen without complications in the e.s.r. signal due to a π-electron radical centered on carbon or oxygen. Another interesting feature of the substance is the extensive hydrogen bonding in the crystal, which causes inequivalence of the two protons of each of the two amino groups in the molecule, with the anticipated result that more than one radical may be produced by damage to an NH_2 group by high energy radiation.

Experimental

The powder and single crystal studies were carried out using reagent grade samples supplied by Eastman Organic Chemicals and the Aldrich Chemical Company, Inc. Both gave the same e.s.r. spectrum following 1.5 h of γ-irradiation of powder samples. The γ-ray dosage used throughout both the powder and single crystal investigations was 8×10^{17} eV/g/min, irradiation being carried out in a ^{60}Co Gamma cell (A.E.C.L.) at room temperature.

The crystal structure parameters and atom positions for dicyandiamide are well known from previous investigations (14–17). The space group is *C2/c*. The unit cell contains eight molecules of $C_2H_4N_4$ and has the parameters: $a = 15.00$, $b = 4.44$, $c = 13.12$ Å, and $\beta = 115°$ 20′ (15). The neutron diffraction study (17) proved that the correct structural formula of the molecule in the crystal is the diamino form. Of considerable importance to the present work is the fact that in the crystal the molecule is almost entirely planar and that hydrogen bonding joins the molecules together in "infinite" layers which are closely parallel to the (310) and (3$\bar{1}$0) planes.

The single crystal used in this work was of dimensions 1 mm × 1.5 mm × 4 mm and was grown by the hydrothermal process (18) at 30 °C. The faces of the crystal were identified and its initial orientation was found, using X-ray diffraction. A smaller crystal, having a similar but sharper diffraction pattern, was used with a precession camera to redetermine the unit cell parameters as $a = 15.0$, $b = 4.49$, $c = 13.2$ Å, and $\beta = 115°$ 5′, which are in good agreement with the results of Hughes (15) given above. The 1 mm × 1.5 mm × 4 mm crystal was found to be elongated along the *c*-axis with the (001), (310), and (3$\bar{1}$0) faces well developed. The (310) and (3$\bar{1}$0) faces are

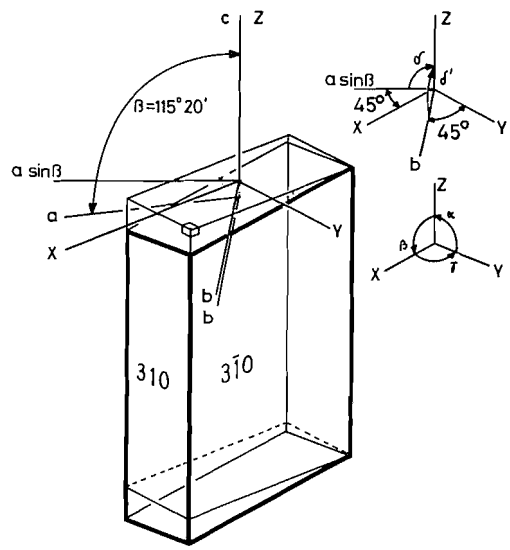

FIG. 1. The form of the single crystal showing the choice of the reference axes. The angles α, β, γ, δ, and δ′ are defined at the upper right.

very nearly at right angles (89° 36′). The orthogonal axes of rotation chosen initially for the single crystal study are designated *X*, *Y*, and *Z*. Rotations were also carried out about the axes $a \sin \beta$ and *b*. The *Z*-axis is the same as the crystal *c*-axis, the *X*-axis is at right angles to the (310) plane, and the *Y*-axis is at right angles to *X* and *Z* and lies very closely along the (3$\bar{1}$0) axis, see Fig. 1, and is indistinguishable from it within experimental error. After 24 h exposure to γ radiation the crystal was mounted by means of silicone grease on plexiglass plates which could be inserted into a holder, allowing rotation about the chosen directions. The silicone grease gave no e.s.r. signal. However, the holder and plate were found to have an e.s.r. spectrum consisting of a very broad line, width ~500 G, centered at a field of 2900 G and a second broad line of 250 G width at a field of 1300 G. Neither of these signals interfered with the study of the e.s.r. spectra from the crystal. The orientation of the mounted crystal could be read to ±0.5°. The error in mounting the crystal on the plate is, however, somewhat larger, approximately 3–5°. For the powder measurements irradiation was carried out for periods up to 24 h. After irradiation samples were transferred to 3 mm quartz tubes. The e.s.r. spectra were recorded with a Varian 4502 X-band spectrometer equipped with a 9 in. magnet and a V-4532 dual cavity. The standard used was an aqueous solution containing peroxylamine disulfonate which was taken to have a g value of 2.00550 and a hyperfine separation of 13.00 G between the low field and center line of the ^{14}N three line hyperfine pattern (19). Most of the e.s.r. spectra, including those of the single crystal, were taken at room temperature. For work at low and high temperatures the V-4557 variable temperature accessory together with a V-4540 temperature controller were used, temperature being measured with a resistance type temperature sensor to an accuracy of ±5 °C.

Results

(i) Powder

The powder, when subjected to γ radiation for periods up to about 7 h, gave an e.s.r. signal at room temperature which is the superposition of two overlapping spectra, which we call spectra A and B. For irradiation periods above 7 h an additional spectrum, C, could be observed so the complete e.s.r. signal is made up of the three overlapping spectra A, B, and C. Intensity comparisons for spectrum B at various times during the first 16 h of irradiation showed that the radical species concerned increases in amount in a linear manner with time. This observation furnishes good evidence that the radicals responsible for spectra B and C are produced simultaneously from dicyandiamide, not by consecutive processes. The lack of observation of spectrum C during the first 7 h can be attributed to its overlapping with the more intense spectrum B. For all irradiation periods up to 24 h spectrum B disappeared irreversibly when the irradiated powder was heated to 150 °C, the e.s.r. signal being observed after returing the sample to room temperature. Having available the experimental spectra A + B, A, A + B + C, and A + C it was possible by subtraction to separate out the individual spectra B and C, see Fig. 2. The species giving rise to spectra A, B, and C are all stable at room temperature over a period of several months.

Spectrum A is a single line with its center at $\mathbf{g} = 2.0040 \pm 0.0004$ and a line width of about 8.5 G. The radical giving this signal has not been identified. Spectrum C is due to an unpaired electron interacting with one proton and one nitrogen nucleus. From the powder spectrum one principal value of each of the nitrogen and proton hyperfine tensors could be determined and these values are consistent with a π-electron radical, see Table 1. Spectrum C is similar to an e.s.r. spectrum reported by Morton (20) which he obtained by γ-irradiation of a single crystal of $(NH_4)_2HPO_4$. This spectrum was explained as being that of a π-electron radical centered on nitrogen, a fragment of the form $H—\overset{+}{N}\diagdown\!\diagup$. Later, however, Symons and Atkins (21) doubted this and considered alternative explanations to be either (*i*) the species NH_3^+, with two protons not exhibiting interaction with the unpaired electron due to hydrogen bonding to a phosphate group or (*ii*) a species of the form X—N—H where X is a phosphate oxygen. The spectrum B, which disappears on heating, may be seen to consist of two well-separated three-line groups each having two shoulders, one on each side, as shown in Fig. 2. The pair of strong triplets show the presence of one proton and one nitrogen nucleus. The shoulders indicate that interaction of the unpaired electron with a second nitrogen could be taking place. Applying the theory of e.s.r. spectra of polycrystalline matrices (ref. 1, pp. 323–332), to the powder spectrum allows for this radical the determination of two of the **g**-tensor elements and also two of the elements of the proton hyperfine tensor, see Fig. 2. The nature of the spectrum does not allow a clear distinction to be drawn between an axially symmetric **g**-tensor with elements $g_\parallel$ and $g_\perp$ and a tensor with three unequal elements, in which case one of the **g**-values has not been determined. Also from the powder spectrum alone it is difficult to distinguish between the coupling of one nitrogen nucleus with two different tensor elements in its hyperfine tensor and two nitrogen nuclei interacting with the unpaired electron. However, the width of the shoulders does indicate that there are two nitrogen nuclei interacting. This indeed is proved by the single crystal results.

The values of the proton hyperfine coupling constants of spectrum B, see Table 1, are not consistent with the presence of a π-electron

TABLE 1. Observed values for elements of the g-tensors, the proton hyperfine coupling tensors and the nitrogen hyperfine coupling tensors for spectra B and C of γ-irradiated dicyandiamide powder*

Spectrum B	g_1	= 2.0028 (0.0004)
	g_2	= 2.0040 (0.0004)
	g_3	= ?
	A_1(H)	= 80.4 (4) G
	A_2(H)	= 73.2 (1.0) G
	A_3(H)	= ?
	$A_1(N_1)$	= 25.5 (3.0) G
	$A_2(N_1)$	= 0 (2.0) G
	$A_3(N_1)$	= ?
	$A_1(N_2)$	< 5 G
	$A_2(N_2)$	= 6.5 (1.0) G
	$A_3(N_2)$	= ?
Spectrum C†	g_2	= 2.0031 (0.0004)
	A_2(H)	= 29.4 (1.0) G
	A_2(N)	= 15.8 (1.0) G

*Tensor elements not given in the table could not be found either from the powder or single crystal measurements.

†Only one element of each of the g-tensor and the nitrogen and proton hyperfine coupling tensors is determined.

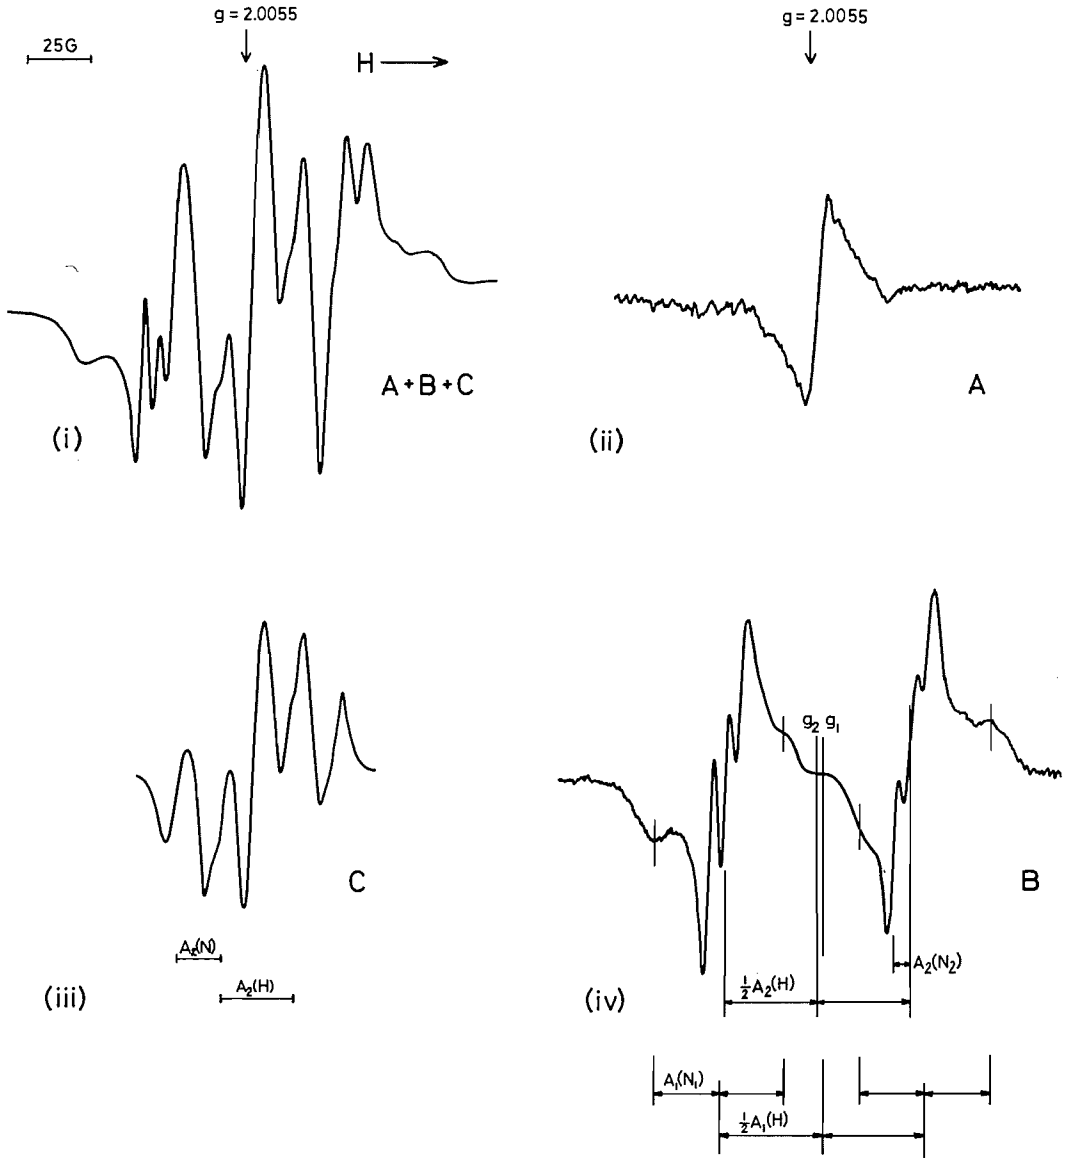

FIG. 2: Spectra from the powder experiments, taken at a klystron frequency of 9.5 GHz. (*i*) Trace of the X-band e.s.r. spectrum of dicyandiamide after 20 h of γ-irradiation at room temperature. (*ii*) Spectrum of unidentified species (A) observed following 3 h of irradiation followed by heating to 150 °C. (*iii*) Spectrum of the π-radical (C), obtained by subtracting the spectrum of the unidentified radical (A) from the residual spectrum (A + C), observed after γ-irradiating for 20 h and then heating to 150 °C to remove spectrum B. (*iv*) Spectrum of the σ-radical (B), also obtained by subtraction. The figure shows how the values of the derived g and hyperfine tensor elements were deduced.

radical but do allow the possibility of a σ-electron radical with $\rho_H^\sigma \approx 0.14$, Two of the principal values, $A_1(H)$ and $A_2(H)$, of the proton hyperfine splitting tensor were arrived at by measuring the positions of the weaker shoulders and stronger triplets, respectively. The same measurements also gave the values of g_1 and g_2 and also $A_1(N_1)$ and $A_2(N_2)$ in Table 1.

(ii) Single Crystal

The e.s.r. spectra of the dicyandiamide single crystal, irradiated and studied at room tempera-

ture, were recorded at 10° intervals for rotation about the *X*, *Y*, *Z*, *a* sin β, and *b* axes (angles α, β, γ, δ′, and δ, respectively) and in addition at 2° intervals for $0° \leqslant \gamma \leqslant 45°$ and 1° intervals for γ near 135°. These smaller intervals were chosen in an attempt to gain additional information concerning the nitrogen hyperfine splitting, particularly to study the movement of the outermost weak satellites described below. The spectra observed for the single crystal can again be understood as due to superposition of the three spectra A, B, and C, taking into account the possibility of magnetically non-equivalent sites, particularly for the spectrum B. Because of the overlapping of spectra it was not possible to carry out complete determinations of the magnitudes and direction cosines of principal values of g, $A(N_1)$, $A(N_2)$, and A(H) tensors. Even so, the results allow some interesting deductions to be made concerning the nature and orientation of the radicals responsible for spectrum B.

The e.s.r. spectra with the magnetic field in the *YZ* and *XZ* planes are not well resolved and show only a slight dependence on the angles α and β. At most angles α and β the spectrum consists of three broad lines similar to those shown in Fig. 3 but at a few orientations of the field in the *YZ* and *XZ* planes each of the outermost lines showed a further splitting into a strong 1:1:1 triplet with some weaker satellite peaks on both sides. There is a significant improvement in the resolution of the hyperfine structure when the magnetic field is in the *XY* plane, with the triplet structure and satellites becoming most obvious at $\gamma = 45°$, and also at $\gamma = 135°$, compare Figs. 3 and 4. In addition to the angular variation in the spectra required by the symmetry of the host crystal, the spectra also repeat exactly after 90°, *i.e.* e.s.r. (γ) = e.s.r. (90° + γ). The best resolution was found at $\gamma = 45$ and 135°, indicating probable equivalence of different magnetic sites at these orientations. For rotation about the *b* axis $\delta = 0$ corresponded to $\gamma = 135°$ and about the *a* sin β axis $\delta' = 0$ was the same as $\gamma = 45°$. The e.s.r. spectra with the magnetic field in the *bc* plane (angle δ′) showed the expected symmetry with respect to the *c*(*Z*) axis, *i.e.* e.s.r. (90° − δ′) ≡ e.s.r. (90° + δ′). The spectra with the magnetic field in the *ac* plane (angle δ) did not show this symmetry with respect to the *c* axis and differed from those in the *bc* plane in having very good resolution over a fairly wide range of values of δ, with two well-resolved nine-line groups being observed near $\delta = 30°$, see Fig. 5.

The observed behavior is interpreted as follows. The e.s.r. spectra for $\gamma = 45$ and 135° are due to overlapping of spectra from radicals in two inequivalent magnetic sites, see Fig. 4. The large doublet splitting is caused by interaction of the unpaired electron with one proton. A fairly large and anisotropic hyperfine interaction occurs with one nitrogen, hyperfine coupling tensor $A(N_1)$, and a smaller and more isotropic coupling takes place with a second nitrogen, hyperfine coupling tensor $A(N_2)$. At $\gamma = 45$ and 135° the two overlapping spectra give rise to two 1:1:1:4:4:4:1:1:1 groups. The unusually large proton splitting shows the presence of a σ-radical which is produced by loss of one of the hydrogens from either of the two $-NH_2$ groups. This is dealt with in greater detail in the discussion

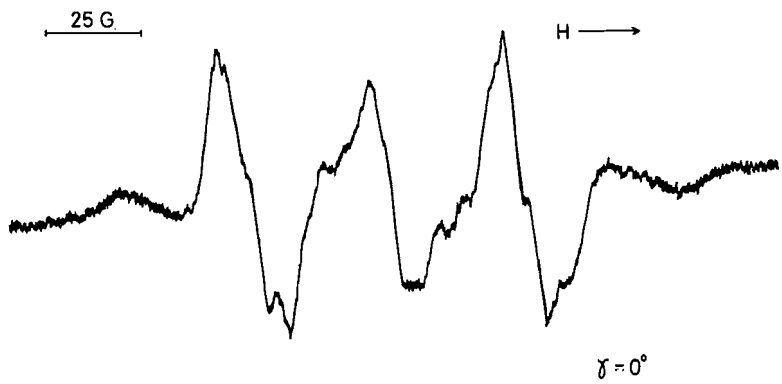

FIG. 3. The 9.5 GHz e.s.r. spectrum of the γ-irradiated dicyandiamide crystal with the magnetic field along the (310) or *X* direction.

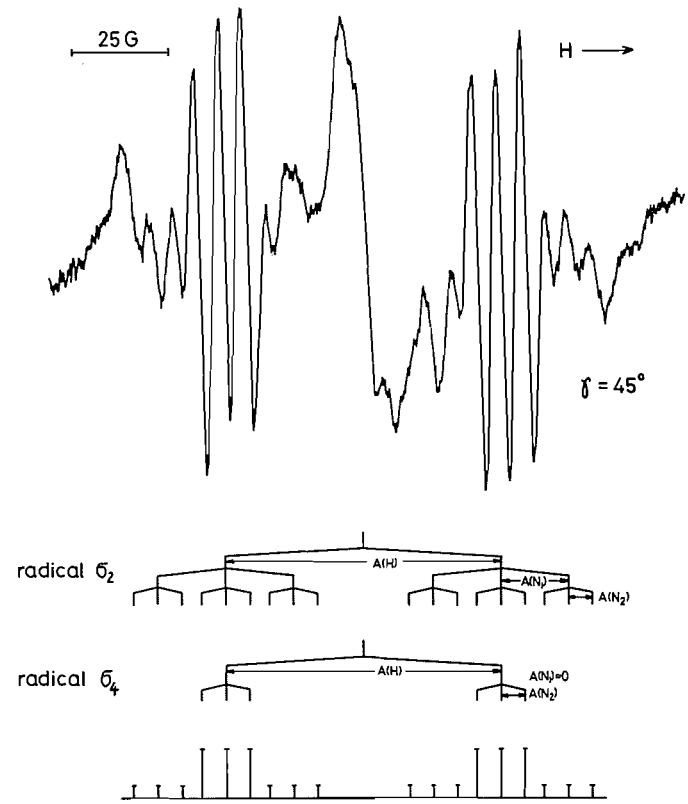

FIG. 4. The 9.5 GHz e.s.r. spectrum of the γ-irradiated single crystal with the magnetic field along the *b* axis. At this orientation the two lattice sites of radical formed by loss of H_2 are magnetically equivalent as are those for the radical formed by loss of H_4.

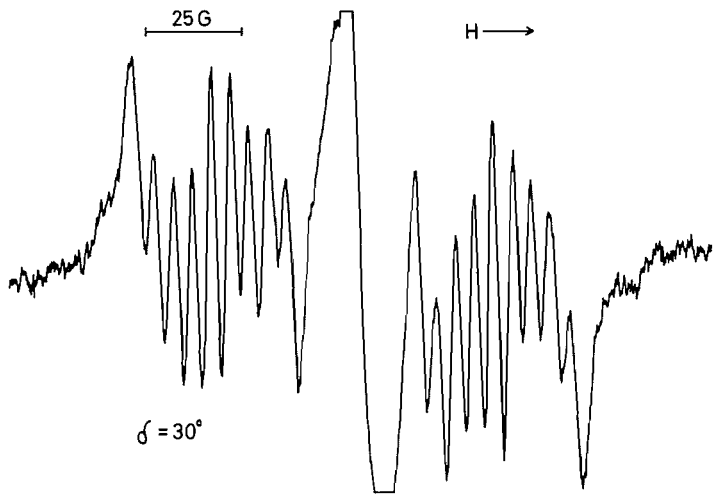

FIG. 5. The 9.5 GHz e.s.r. spectrum of the γ-irradiated dicyandiamide single crystal for the magnetic field orientation $\delta = 30°$ in the *ac* plane.

below. The large coupling, tensor A(H), can then be attributed to the remaining hydrogen in the —ṄH fragment and the tensor $A(N_1)$ to this nitrogen. The further and quite isotropic splitting may belong to the nitrogen of the undamaged $-\dot{N}H_2$ group or possibly to one of the two CN nitrogens. The results for rotation about the *b* and *a* sin β axes confirm that the *ac* plane is a mirror plane for the crystal, an important fact which is utilized below in the discussion section.

When the γ-irradiated single crystal was heated to 150 °C for 5 min and then cooled to room temperature the strong outer triplets and weaker satellites (spectrum B, $\gamma = 45°$) disappeared leaving behind a broad line of width approximately 13 G and having two shoulders. This residual spectrum is similar to the spectrum A + C obtained from the powder. However, the resolution for this spectrum was not sufficiently good to allow the determination of any further information beyond that already found from the powder study.

The single crystal spectra thus confirm the main conclusions of the powder work showing, in addition to the single line spectrum A, spectra B and C from two different types of radicals, one in which the unpaired electron interacts with one proton and two N nuclei (B) and one in which the unpaired electron appears to interact with one proton and only one N nucleus (C).

Discussion

In order to understand the nature of the radicals observed in this study it is necessary first to consider in some detail the dicyandiamide molecule and its crystal structure. Arguing from the observed internuclear distances Hughes (15) concluded that the cyanimino group, NCN, could be represented in terms of the resonance structures

$:N\equiv C-\ddot{N}\diagdown$ (25%) $\qquad :\bar{\ddot{N}}=C=\ddot{N}\diagdown$ (75%)

and that in the guanidine group, $NC(NH_2)_2$, the C—N distances indicate considerable delocalization of the carbon–nitrogen double bond. The heavy atoms in the guanidine group should thus be planar. The most recent studies of the crystal structure (16, 17) show that all the atoms of a particular molecule lie nearly in the same plane with the exception of H_3 and N_1, see Fig. 6. The molecular planes, held together by interplanar hydrogen bonding, are very close to the crystal $(3\bar{1}0)$ and (310) planes.

In the undamaged crystal the $-NH_2$ group angles are as shown in Fig. 6. They were calculated using the data of Rannev and Ozerov (17). The angle $C_2N_4H_4$ is 124° so that after the removal of H_3 formation of a π-electron radical could take place with very little disturbance in the position of the hydrogen bonded atom H_4, which lies in the plane of the molecule. The nitrogen N_4 would thus achieve an approximately sp^2 hybridization state. The same argument may be applied to the group $C_2N_3H_2$. The angle $C_2N_4H_3$ is 108° so that after the loss of H_4 formation of a so-called σ-electron radical (2, 5, 7, 22) can occur, again with only small readjustments of the atom positions. The nitrogen N_4 would now reach a state of approximately sp^3 hybridization. We consider that in this case π-electron radical formation does not occur because of the constraint placed upon H_3 by hydrogen bonding to N_1 of an adjacent molecule. Again we can apply the argument to the residual atoms $C_2N_3H_1$ after loss of H_2. This model thus leads to the four possibilities, shown in Chart 1, for radical formation after the loss of one of the four hydrogen atoms in the molecule, assuming that all four N—H bonds may be broken. The notation here is that for example π_3 means a π-electron radical formed by loss of H_3.

Chart 1

The dicyandiamide crystal belongs to the space group *C2/c*. Although there are eight molecules per unit cell, their positions are related by inversion and translation in such a way that for a given

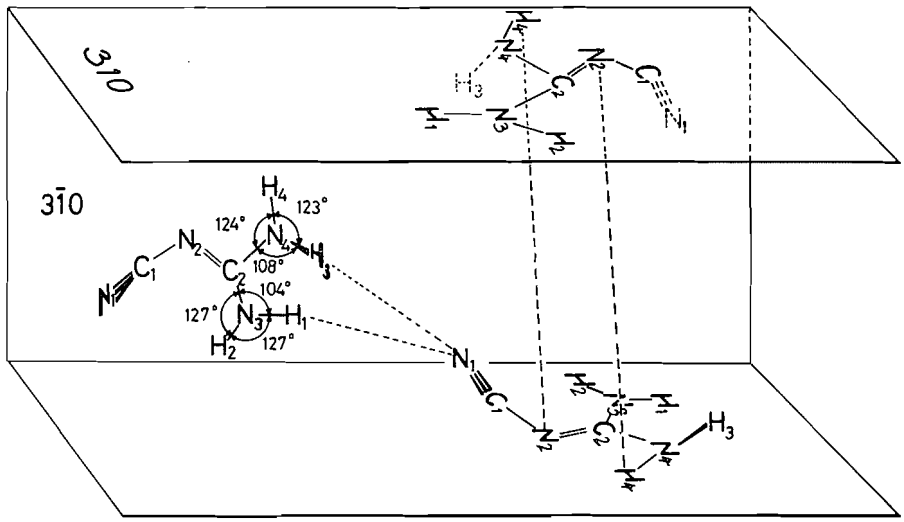

FIG. 6. Schematic diagram showing the arrangement of atoms in the dicyandiamide crystal structure. For each molecule all atoms are coplanar except H_3 and N_1. Hydrogen bonding to molecules in other planes is indicated by dashed lines. The bond lengths are not to scale.

radical there can be only two inequivalent magnetic sites. These must be related to each other by reflection in the *ac* plane. We refer to these two positions as I and II, respectively. It is then possible to have four π-radicals in magnetically non-equivalent positions: π_1(I), π_1(II), π_3(I), and π_3(II) and also four σ-radicals σ_2(I), σ_2(II), σ_4(I), and σ_4(II). The four π-radical positions could give rise to the e.s.r. spectrum C, observed in both powder and single crystal and found to be less well resolved in the latter case. The four σ-radical positions produce spectrum B. This assumes that when either the N_4H_4 or N_3H_2 bond is broken the orbital in which the now unpaired electron is located is able to take up a position consistent with sp^3 hybridization. This reorientation appears to be more likely than a change in the position of either H_3 or H_1, which are both constrained by hydrogen bonding. Assuming that the orbital containing the unpaired electron points along a direction which makes angles of 109° 28′ with the adjacent NH and CN bonds and from the two resulting solutions choosing the direction closest to the direction of the original unbroken N_4H_4 or N_3H_2 bond, then the directions shown in Fig. 7 were obtained. These directions should be the ones in which the largest value of the $A(N_1)$ tensor is found for the four σ-radical positions. It may be seen from Fig. 7 that the projections of these directions on the XY plane lie close to $a \sin \beta$ or $\gamma = 135°$ for σ_4(I) and σ_4(II) and close to b or $\gamma = 45°$ for σ_2(I) and σ_2(II). For the field in the XY plane we should therefore find maxima in $A(N_1)$ for these four directions. These four maxima may be taken in two sets of two, one pair near $\gamma = 45°$ and one near $\gamma = 135°$. At $\gamma = 45$ and 135°, crossing of each pair of $A(N_1)$ curves takes place giving only two distinguishable e.s.r. patterns, or two different values of $A(N_1)$. At most of the other values of γ four signals should be present. The condition that only two distinguishable patterns can be observed also holds for the field anywhere in the *ac* plane, the mirror plane. This is not generally true for the field in the *bc* plane. However, for the *bc* plane the condition e.s.r. $(90° + \delta') \equiv$ e.s.r. $(90° - \delta')$ must hold which is found experimentally to be the case. Although experimental points could only be obtained near $\gamma = 45$ and 135° for the field in the XY plane the measured values of $A(N_1)$ in these regions and the general features of the variation of the spectra for rotation of the crystal about the b, Z, and $a \sin \beta$ axes give strong support to the proposed model.

The following considerations can be made to give a better understanding of the reason for the large proton hyperfine coupling in the σ-electron radical. The interaction between the magnetic moments of an electron and a nucleus can be

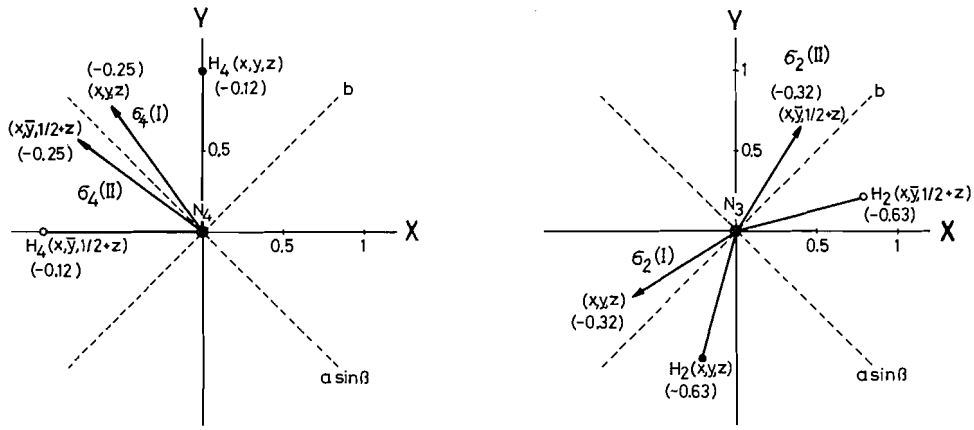

FIG. 7. Calculated directions of the orbital containing the unpaired electron for each of the four different magnetic sites of the σ-radical: σ_2(I), σ_2(II), σ_4(I), and σ_4(II). The Z coordinates are given in brackets. The orbital directions are taken to be unit vectors (1 Å). For each pair of sites the nitrogen atoms have been superimposed at the origin.

expressed in the usual way as the sum of the isotropic Fermi contact and anisotropic dipole–dipole terms: $H_{hf} = H_F + H_D$. If the unpaired electron is in a $p_z(\pi)$ orbital the probability density in the p-orbital nodal plane is zero. Even so protons in the planar methyl radical and in the rings of aromatic radicals do show some non-zero isotropic hyperfine coupling (8). This happens because of σπ spin polarization, brought about through exchange interaction coupling together the spins of the σ-electrons in the C—H bond with the $p_z(\pi)$ electron of the carbon. The isotropic term H_F in such a case can be written

$$[1] \quad H_F = \frac{8\pi}{3} g_e\beta_e g_N\beta_N\rho(r_N)(\hat{I}\cdot\hat{S}) = K\rho(r_N)(\hat{I}\cdot\hat{S}) = a(\hat{I}\cdot\hat{S})$$

where $\rho(r_N)$ is the unpaired electron density at the nucleus. Also

$$[2] \quad \rho(r_N) = \pi^2(r_N) - \frac{4}{\sqrt{6}}\lambda\sigma(r_N)\sigma^*(r_N) \quad (\lambda^2 \ll 1)$$

where λ is the coefficient which determines the magnitude of the configurational admixture of one of the two excited doublet states with the ground doublet (23, 24). $\pi^2(r_N)$ is the π-type spin density of the electron at the proton. σ and σ* refer to bonding and antibonding orbitals, respectively.

Without the admixture of the excited doublet term to the ground doublet term the unpaired electron density would be

$$[3] \quad \rho(r_N) = \pi^2(r_N)$$

In the case of an aromatic ring proton

$$[4] \quad \pi^2(r_N) = 0$$

Equations 1 and 2 then lead to

$$[5] \quad a_{H\mu} = Q_{CH}\rho_\mu^\pi \qquad Q_{CH} < 0$$

for the hyperfine coupling of the proton H_μ, which is the McConnell relation. ρ_μ^π is the π-electron density at the carbon atom, C_μ, to which the proton is bound. It should be noted that ρ_μ^π is the integrated spin density, obtained by integration of $\rho(r_N)$ over the π-orbital located at the carbon atom. It is easily seen that the McConnell relation [5] holds only for a nucleus which lies in the nodal plane of the π-orbital, in other words when the condition [4] is fulfilled. If [4] does not hold then

$$[6] \quad a_{H\mu} = K_H\pi^2(r_H) + Q_{CH}\rho_\mu^\pi$$

($K_H = 2.3626 \times 10^{-22}$ G cm^3) and the isotropic proton hyperfine splitting, $a_{H\mu}$, now depends very strongly on the position of the proton as defined by r_H.

In 1959 Karplus (25) carried out a valence bond calculation for the methyl radical of the dependence of the proton hyperfine splitting on the angle θ between the symmetry axis and each C—H bond. The calculation was made in terms of a seven electron – seven orbital model for CH_3 as well as for a three electron – three orbital model. These calculations show that a_H is

strongly dependent on the magnitude of θ. For example with θ = 90°, 109° 28′, and 144° 45′, corresponding to planar (sp^2), tetrahedral (sp^3), and pyramidal (p^3) hybridization, respectively, the following results were obtained: θ = 90° (sp^2), $23.4 < a_H < 34.6$ G; θ = 109° 28′ (sp^3), $34.5 < a_H < 44.1$ G; θ = 144° 45′ (p^3), $145.3 < a_H < 179.3$ G.

Although the corresponding angle between the N—H bond and the orbital containing the unpaired electron in the σ-electron radical of the present study is not known precisely it is probably near the tetrahedral angle which could lead to the large observed proton hyperfine coupling.

We should like to thank Mrs. J. D. Savage for growing single crystals of dicyandiamide and also Professor R. D. Heyding for identifying crystal faces and axes. We acknowledge the generous support given to this work by the National Research Council of Canada.

Trimethylstannylarsines

J. W. ANDERSON AND J. E. DRAKE
Department of Chemistry, University of Windsor, Windsor, Ontario

Received February 15, 1971

Tin arsines which contain an As—H bond, namely trimethylstannylarsine, bis-trimethylstannylarsine, and phenyl(trimethylstannyl)arsine, have been prepared and characterized. Alternative preparations of other trimethylstannylarsines are also discussed.

Des arsines d'étain contenant une liaison As—H, la triméthylstannylarsine, la bis-triméthylstannylarsine, et la phényl (triméthylstannyl) arsine, ont été préparés et caractérisés. D'autres modes de préparation de triméthylstannylarsines sont discutés.

Canadian Journal of Chemistry, 49, 2524 (1971)

Introduction

Several routes have been established for the formation of silyl- and germyl-arsines in which there are no organo-substituents on arsenic. Lithium tetra-arsinoaluminate has been used in the preparation of mono- and bis-arsino substituted silanes and mono-arsino substituted germanes by reaction with the appropriate bromides (1). Trisilylarsine and mono-, di-, and tri-germylarsines were prepared from the reaction of arsino-potassium with bromosilane (2) or bromogermane (3). Under carefully controlled conditions followed by acidification with hydrogen sulfide, this route has been used for the synthesis of mono- and di-silylarsine (4). Exchange reactions between silylarsines and halogeno-germanes have also been used to produce germylarsines (1, 3, 5).

Methods for the preparation of tertiary arsines containing an Sn—As bond include amine cleavage (6) and removal of hydrogen chloride from arsine and a tin chloride using a tertiary amine (7).

We have attempted the preparation of primary and secondary (*i.e.*, As—H containing) tin arsines by related methods. Compounds of this type have not been prepared previously (8).

Experimental

Apparatus

The experiments were carried out in conventional Pyrex glass vacuum systems. The i.r. spectra were recorded on a Beckman IR 12 spectrometer in a gas cell (5 cm path length) or in an air-tight cell-holder between KBr plates for liquid samples; the values given are cm^{-1}. The ^1H n.m.r. spectra were recorded in sealed n.m.r. tubes (*ca.* 2 mm o.d.) on a JEOL C-60 HL spectrometer, and molecular weights were determined by freezing-point depression of benzene.
