The information from H-1 and -4 taken in conjunction therefore confirms the above speculation that compound **2** exists in one of the conformations **7** and **8**. Arrangement **7** is clearly preferred on stereochemical grounds and accordingly, the values for J_{45} and J_{45}' observed in **2***b* (1.7 and 2.5 Hz respectively), are very close to those observed by Lemieux and Stevens (1.6 and 2.3) for 2-deoxy-β-D-ribopyranose triacetate, of known *1C* conformation (10). This observation implies incidentally that **2** must exist predominantly in the conformation **7**. Thus on this basis the axial C-5 proton deshielded by the C-1 oxygen is ascribed the low field quartet (Table 1).

Compound 1

Having assigned **2** as the β-D anomer in (conformation **7**) compound **1** must be the α-D alcohol, and it remained only to assign a suitable conformation from among the four possibilities **8**–**11**. The n.m.r. spectrum for **1***a* (Fig. 1*a*) was more complex than that for **2***a*, particularly for the H-1 signal. However by double irradiation experiments the couplings J_{12} and J_{24} were determined to be 2.5, and 1.3 Hz respectively. In view of the criteria outlined above (7–9) the large value for J_{12} indicates pseudoequatorial orientation for H-1, thereby eliminating **9** and **11**. The large values for the three- and four-bond vinyl–allylic couplings (J_{34} = 2.5 and J_{24} = 1.3 Hz) indicates pseudoaxial orientation for H-4, which therefore now eliminates **8** leaving only **10**.

The dinitrobenzoate ester **1***b* was also examined, and as with the β-D anomer **2***b*, esterifi-

cation had reduced the chemical shift for the olefinic protons making an AA'X system for H-2, -3, and -4 in the 100 MHz spectrum (Fig. 2*a*). As an added complication here, the C-5 protons were also unresolved (*vide infra*) thereby making H-4 the X-proton of *another* AA'X system. H-2, -3, -4, -5, and H'-5 of **1***b* therefore constituted an AA'MXX' system and the signal at τ 4.36 for H-4 (the M-proton) was understandably complex. To further compound the matter, double irradiation revealed a long-range coupling constant, J_{14}, of 2.0 Hz. In spite of these complications the major spacings (J') in H-4 should be derived from the largest couplings contributed to it, which are J_{45} and $J_{45'}$. Using typical values[4] of 8.9 and 4.7 Hz for these couplings, H-4 should appear as a broadened triplet with a calculated value for J' being the average of these, 6.8 Hz. The measured value in the 100 MHz spectrum (Fig. 1*a*) is 7.0 Hz.

The foregoing information would appear to imply that **1** must exist predominantly in conformation **10**. However it was impossible to obtain affirmation of this by studying the signals for the C-5 protons of the dinitrobenzoate **1***b* or acetate **1***c* since they were unresolved at 60 and 100 MHz. They therefore appeared as a doublet with J = 7.0 Hz (*e.g.* Fig. 2*a*). The 220 MHz spectrometer resolved these protons into two distinct AB quartets (Fig. 2*b*). The spacings observed (7.5 and 6.0 Hz) are in the acceptable range for *trans*-diaxial and equatorial–axial parameters for the system represented by **10** (12).

The presence of a homoallylic coupling (J_{14}) in the esters **1***b* and *c* but not in **2***b* and *c* is now readily explained since couplings of this type, which are thought to be transmitted through the intervening π-bond, follow the order 1,4-diaxial > 1,4-axial–equatorial > 1,4-equatorial-equatorial (13).

While this manuscript was being prepared a pertinent publication by Lemieux *et al.* appeared in which conformations of the methyl 2,3-dideoxy α-L and β-L-*glycero*-pent-2-enopyranosides were discussed (14). We prepared the methyl α-D (**12**) and β-D (**13**) enantiomers from D-xylal (or D-arabinal) diacetate and methanol as previously described for ethanol (1, 2). The n.m.r. spectra of these substances in DMSO-d_6 were identical in all respects with those kindly supplied by Professor Lemieux (14). Furthermore the spectra agreed in the expected manner with those of the ethyl analogues. Here again, difference in oxidizability of the anomers was observed *i.e.* **12** was smoothly oxidized while **13** was not.

These olefins (**1**, **2**, **12**, **13**) are expected to prefer the half-chair conformations (15) and since there are no serious non-bonded interactions to affect the outcome, the anomeric effect should have over-riding control and it is therefore not surprising that the half-chair forms chosen by these four substances, are those having the benefit of the anomeric effect (16, 17*a*). The result is that these substances appear to exist in much greater conformational purity than do most pentopyranose derivatives (10, 17).

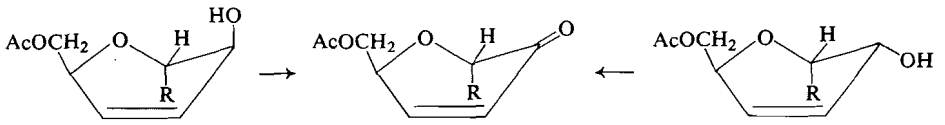
The foregoing indicates that the hydroxyl groups in **1**, **2**, **12**, **13** are in different orientations, equatorial in the oxidizable substances (**1**, **12**) and axial in the unoxidizable, (**2**, **13**). However, this difference is not sufficient to account for the anomaly since steroidal allylic alcohols of either orientation are known to be oxidized (18). Another possible explanation is that hydrogen bonding of the hydroxyl group to the ring oxygen, possible only in the β-D anomers **2** and **13**, might prevent these alcohols from being oxidized. However, the allylic hydroxyl groups in epimers **14** and **15** are both oxidized to ketone **16** (19), although **14** should be as capable of hydrogen bonding to the ring oxygen as **2** or **13**.[5] In any event there is evidently a question as to the possible effects of stereochemistry on the oxidation of allylic alcohols. Experiments designed to clarify this issue are currently underway.

ABX_3 Spectra for some Ethoxy Groups

Magnetic non-equivalence for diastereotopic methylene protons of an ethoxy residue have been reported in several instances (20–22). Therefore the ABX 220 MHz spectra for the ethoxy aglycon of these substances (Fig. 2) would go unmentioned were it not for the unusually large magnitude of $|\nu_A - \nu_B|$. The value observed here, 0.28 p.p.m, is twice as large as that reported for ethoxy attached to carbon

[4]These values are the average of those reported by Lemieux and Stevens (10) in their Table II.

[5]A referee has suggested the possibility of a complex between the *cis* groupings of the α-D isomers (**1** and **12**) and manganese dioxide.



14
R = OEt

15

(21) although still much smaller than that for ethoxy attached to a hetero-atom (22). Thus in the 60 MHz spectrum, the ethoxy methylene protons appeared as a jumble of lines which could be reduced to two singlets at τ 6.09 and 6.37 by double irradiation of the τ 8.50 triplet.

The 16-line simulated spectrum for the AB portion (Fig. 2*e*) is shown along with the observed spectrum (Fig. 2*b*).

The phenomenon also occurs in the hexopyranoside analogues of **1** and **2**, and the large value $|\nu_A - \nu_B|$ is not associated with the double bond in these molecules, since their saturated derivatives also show the same effect.

The readiness with which these substances can be prepared allow for much easier access to these five-spin systems than the substituted propenes used elsewhere (23).

Experimental

The α- and β-anomers of ethyl 2,3-dideoxy-D-*glycero*-pent-2-enopyranoside (**1***a* and **2***a* respectively) were prepared from D-xylal diacetate as previously described (3) and separated by silica column chromatography using petroleum ether (35–60) – ethyl acetate (1:1) mixture as eluent. The acetates (**1***c*, **2***c*) and 3,5-dinitrobenzoates (**1***b*, **2***b*) were prepared by standard acylation methods.

The methyl analogues of **1** and **2** (**12** and **13** respectively) were also prepared in a similar way (3) from methanol and D-xylal diacetate or D-arabinal diacetate, the latter being obtained commercially from Raylo Chemicals Ltd., Edmonton, Alberta.

The alcohols **1**, **2**, **12**, and **13** were oxidized with manganese dioxide as previously described (1).

The n.m.r. spectra were determined on a Varian T60, a Varian HA 100 and/or a Varian 220 MHz spectrometer.

The simulated spectra were prepared using a modified version of LACOON III run on the IBM 360-75 belonging to the Faculty of Mathematics, University of Waterloo. The following data for the computations were derived from the 220 MHz spectra: $J_{AX} = J_{BX} = 7.0$, $J_{AB} = 9.5$ Hz; $\delta_A = 797.1$, $\delta_B = 860.5$, $\delta_X = 300.0$ Hz from TMS.

Financial support from the National Research Council of Canada is gratefully acknowledged. We express our gratitude to the staff of the Canadian 220 MHz NMR Centre for their help and to Professor L. W. Reeves for making available to us (1) his 100 MHz n.m.r. spectrometer and to Mr. R. Shaddick for operating it, and (2) a modified LACOON III program and to Dr. K. Shaw for assistance with the computation. We are grateful to Professor R. U. Lemieux and Dr. T. L. Nagabhushan for providing us with n.m.r. spectra of the α- and β-anomers of methyl 2,3-dideoxy-L-*glycero*-pent-2-enopyranoside.

Reaction of Iodine Azide with Cyclopentenone and Cyclohexenone

JOHN M. MCINTOSH
Department of Chemistry, University of Windsor, Windsor, Ontario

Received April 21, 1971

The addition of iodine azide to 2-cyclopentenone led to the formation of 2-iodo-2-cyclopentenone. A similar reaction with 2-cyclohexenone afforded the expected addition products in addition to 2-iodo-2-cyclohexenone.

L'addition d'azoture d'iode sur la cyclopentène-2 one conduit à l'iodo-2 cyclopentène-2 one. Une réaction similaire avec la cyclohexène-2 one conduit au produit d'addition attendu et à l'iodo-2 cyclohexène-2 one.

Canadian Journal of Chemistry, **49**, 3045 (1971)

In connection with other work, a sample of 3-aminocyclopentanone was required. From among many possible syntheses, the addition of iodine azide (1) to 2-cyclopentenone was selected. While this reaction was not expected to be regiospecific (2), separation of the reduction products 2-amino- and 3-aminocyclopentanone was not envisaged to be a problem of major proportions.

When 2-cyclopentenone (**1**) was treated with a solution of iodine azide in acetonitrile containing excess sodium azide according to the published procedure (1), the n.m.r. spectrum of the crude reaction mixture showed none of the expected absorptions for the addition products **3** (Scheme 1), but showed the product to be of the 2-substituted-2-cyclopentenone type. The i.r. spectrum showed strong azide and conjugated carbonyl absorptions (2120 and 1712 cm^{-1} respectively). Chromatography afforded 2-iodo-2-cyclopentenone (**4**) and a compound **A** whose stability precluded identification. When a solution of **4** was treated under the reaction conditions with iodine azide, t.l.c. of the product indicated a partial conversion into **A** had occurred. When the reaction was carried out in an n.m.r. tube, a very weak and broad absorption appeared at *ca.* 5 p.p.m. which remained constant throughout the reaction. Whether this absorption is due to the addition products **3** which are subsequently converted into **4**, or whether it is due to some small impurity is unclear. However, if the former is the case, the concentration of **3** cannot be more than 2% of the mixture at any time.

When the same reaction was applied to 2-cyclohexenone (**5**) (Scheme 2), the crude reaction mixture showed n.m.r. absorptions characteristic (2) of both of the two expected addition products **7***a* and *b* as well as of a 2-substituted-2-cyclohexenone in the ratio of 7:7:9 respectively. Chromatography afforded a mixture of **7***a* and *b* in the ratio of 1:1 (n.m.r.), and pure 2-iodo-2-cyclohexenone (**8***a*). Treatment of the crude mixture with triethyl amine in ether resulted in the disappearance of the n.m.r. signals between δ 4 and 7. The i.r. spectrum showed conjugated carbonyl and azide absorptions indicating the presence of **8***b*, but chromatography afforded only **8***a* in slightly increased yield.

Comparison of the base-catalyzed rate of exchange of cyclopentanone and cyclohexanone (7:1) (4) provides a rationale for the relative amounts of **3** and **7** in the two reaction mixtures. If these relative acidities also apply to **2** and **6** or

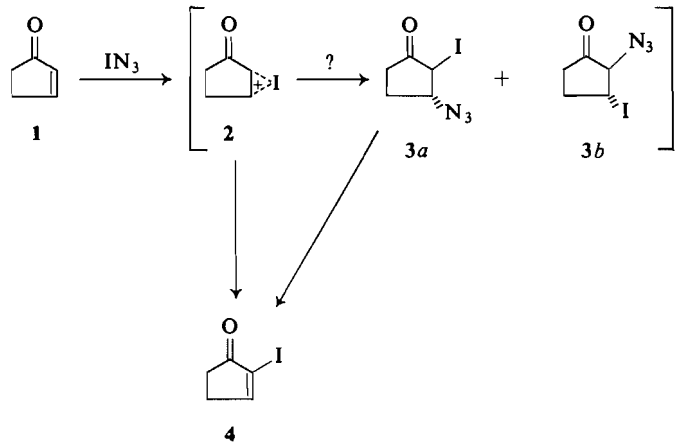
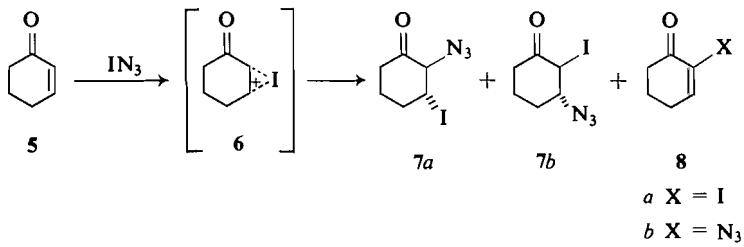


SCHEME 1



SCHEME 2

to **3** and **7**, it is clear that loss of a proton from **2** or **3** will be more favorable than a similar deprotonation of **6** or **7**.

The formation of 2-iodovinyl ketones from this reaction has not been reported previously. While Hassner *et al.* has reported (2, 3) the preparation of 2-azidovinyl ketones, either from the iodine azide adducts of conjugated ketones with sodium azide or from 2-bromovinyl ketones with sodium azide and hydrazoic acid in DMF, no mention of the presence of 2-iodovinyl ketones has been made. The reaction reported here, while not a general synthetic route, does provide a source of two members of this unusual class of compounds.

Experimental

The i.r. spectra were recorded on a Beckman IR 12 spectrometer in chloroform solution; n.m.r. spectra were obtained on a JEOLCO C6OHL spectrometer in deuteriochloroform and are reported in p.p.m. from an internal standard (TMS 0). Melting points are corrected. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

2-Iodo-2-cyclopentenone

To a slurry of 12.0 g (0.185 mol) of sodium azide in 45 ml of acetonitrile which had been cooled to −20°, was added 4.5 g (0.027 mol) of iodine monochloride in 10 ml of the same solvent over a period of 30 min. 2-Cyclopentenone (2.0 g, 0.026 mol) was added all at once and the reaction mixture was stirred for 24 h and allowed to rise to ambient temperature. The dark brown mixture was poured into 100 ml of water and the aqueous solution was extracted with three 60 ml portions of ether. The combined ethereal extracts were washed with two 50 ml portions of 10% sodium thiosulfate solution and two 50 ml portions of water and were dried over sodium sulfate. Evaporation gave 3.4 g of a brown oil which showed no n.m.r. absorptions between 4 and 8 p.p.m., but did show a triplet at δ 8.15. The i.r. spectrum showed a very weak shoulder at 1745 cm^{-1} and strong absorptions at 1720 and 2110 cm^{-1}. The t.l.c. (alumina, 50% petroleum ether, 48% benzene, 2% ethanol) showed the presence of two components with R_f values of 0.73 and 0.64.

Chromatography on silica gel using benzene – petroleum ether as eluent gave 1.53 g (30%) of **4**, m.p. 70.5–71.0° from petroleum ether: i.r. 3030, 2925, 1718, 1685 cm^{-1}; n.m.r. δ 8.15 (1H, t, J = 3 Hz), 3.00–2.37 (4H, mult); R_f 0.73.

Anal. Calcd. for C_5H_5IO: C, 28.86; H, 2.24; I, 61.03. Found: C, 28.87; H, 2.46; I, 61.23.

Further elution gave 0.7 g of a very unstable yellow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

oil (A) which exhibited strong azide and conjugated carbonyl absorptions in the i.r. spectrum (2100, 1719, 1590 cm^{-1}) but no signals below δ 3.00 in the n.m.r. spectrum. This material decomposed to a black tar within minutes when solvent was removed. The t.l.c. indicated the presence of only the material with R_f 0.64.

2-Iodo-2-cyclohexenone

The reaction was run in exactly the same manner using the same molar quantities of reactants. Evaporation of the dried solution gave 5.6 g of a dark brown oil; n.m.r. δ 7.90 (t, J = 6 Hz), 4.83 (br), 4.60 (br d), 4.24 (mult), 3.7–1.5 (mult); i.r. 3030, 2960, 2880, 2110, 1715, 1690, 1590, 1575 cm^{-1}.

Assignment of the first three n.m.r. absorptions to **8***a*, 7*b*, and 7*a* (2) respectively gives a product distribution by n.m.r. integration of 9:7:7

Chromatography of the mixture on silica gel using benzene – petroleum ether as eluent gave a mixture of 7*a* and 7*b* in 20% yield

Anal. Calcd. for $C_6H_8N_3IO$: C, 27.17; H, 3.02. Found: C, 27.31; H, 2.93.

Further elution of the column with benzene and benzene–ethanol afforded **8***a* (2.53 g, 44%) as white crystals from petroleum ether, m.p. 46.0–47.0°: i.r. 3030, 2960, 2940, 2890, 2870, 1690, 1593 cm^{-1}; n.m.r. δ 7.90 (1H, t) 2.87–1.82 (6H, mult).

Anal. Calcd. for C_6H_7IO: C, 32.46; H, 3.18; I, 57.16. Found: C, 32.76; H, 3.46; I, 56.76.

Crude adduct (3.0 g) was dissolved in 100 ml ether and 5 ml of triethyl amine was added. The mixture was stirred at room temperature for 18 h, filtered, washed with two 50 ml portions of water, dried, and evaporated to give a dark oil; n.m.r. blank between δ 4.0 and 7.5; i.r. 2110, 1695 cm^{-1}. Purification as previously outlined afforded 1.65 g (55%) of **8***a*. A dark immobile band on the column may have been **8***b* or its decomposition products.

Ozonation of Naphthalene with Water as Participating Solvent. Preparation of *o*-Phthalaldehyde

MURRAY G. STURROCK, BETTY J. CRAVY, AND VIRGINIA ALLEN WING
Department of Chemistry, Texas Woman's University, T.W.U. Station, Denton, Texas 76204

Received April 14, 1971

The water in aqueous acetone solutions acts as a participating solvent in the reaction of naphthalene with ozone forming hydroperoxy intermediates which are reduced to *o*-phthalaldehyde by conventional agents. The results are markedly different from those obtained in anhydrous solvents. Yields of product requiring no purification are 63%.

Dans des solutions aqueuses d'acétone, l'eau agit comme solvant de participation dans la réaction de l'ozone avec le naphtalène. Il se forme des hydropéroxy intermédiaires que sont réduits en *o*-phthaladéhyde par les agents conventionnels. Les résultats sont très différents de ceux obtenus dans des solvants anhydres. Les rendements en produit (ne demandant aucune purification) sont de 63%.

Canadian Journal of Chemistry, 49, 3047 (1971)

The profound effect that the presence of water in the solvent can have on the course of the reaction of a polycyclic aromatic hydrocarbon with ozone was first demonstrated some ten years ago (1) when yields of anthraquinone obtained directly from anthracene without the aid of reducing agents were improved from 28% in glacial acetic acid (2) to 73% in aqueous *t*-butanol (1). The anthracene reaction gave no useful isolable intermediate products and the mechanism of the ozonation reaction in aqueous media was studied first with phenanthrene (3) and later with pyrene (4). This is therefore the third in a series of reports devoted to the subject of ozonation in aqueous solvents.

The results of the work with anthracene,

oil (A) which exhibited strong azide and conjugated carbonyl absorptions in the i.r. spectrum (2100, 1719, 1590 cm^{-1}) but no signals below δ 3.00 in the n.m.r. spectrum. This material decomposed to a black tar within minutes when solvent was removed. The t.l.c. indicated the presence of only the material with R_f 0.64.

2-Iodo-2-cyclohexenone

The reaction was run in exactly the same manner using the same molar quantities of reactants. Evaporation of the dried solution gave 5.6 g of a dark brown oil; n.m.r. δ 7.90 (t, J = 6 Hz), 4.83 (br), 4.60 (br d), 4.24 (mult), 3.7–1.5 (mult); i.r. 3030, 2960, 2880, 2110, 1715, 1690, 1590, 1575 cm^{-1}.

Assignment of the first three n.m.r. absorptions to **8***a*, 7*b*, and 7*a* (2) respectively gives a product distribution by n.m.r. integration of 9:7:7

Chromatography of the mixture on silica gel using benzene – petroleum ether as eluent gave a mixture of 7*a* and 7*b* in 20% yield

Anal. Calcd. for $C_6H_8N_3IO$: C, 27.17; H, 3.02. Found: C, 27.31; H, 2.93.

Further elution of the column with benzene and benzene–ethanol afforded **8***a* (2.53 g, 44%) as white crystals from petroleum ether, m.p. 46.0–47.0°: i.r. 3030, 2960, 2940, 2890, 2870, 1690, 1593 cm^{-1}; n.m.r. δ 7.90 (1H, t) 2.87–1.82 (6H, mult).

Anal. Calcd. for C_6H_7IO: C, 32.46; H, 3.18; I, 57.16. Found: C, 32.76; H, 3.46; I, 56.76.

Crude adduct (3.0 g) was dissolved in 100 ml ether and 5 ml of triethyl amine was added. The mixture was stirred at room temperature for 18 h, filtered, washed with two 50 ml portions of water, dried, and evaporated to give a dark oil; n.m.r. blank between δ 4.0 and 7.5; i.r. 2110, 1695 cm^{-1}. Purification as previously outlined afforded 1.65 g (55%) of **8***a*. A dark immobile band on the column may have been **8***b* or its decomposition products.

The financial assistance of the National Research Council of Canada and the technical assistance of Mr. D. Hill are gratefully acknowledged.

phenanthrene, and pyrene suggested that the effect of the presence of water during the ozonation of naphthalene would be to promote the formation of *o*-phthalaldehyde. This interesting but expensive dialdehyde has not been prepared heretofore in reasonable yield by the ozonation of naphthalene followed by conventional sodium iodide in acetic acid reduction of the ozonation products.

The reaction of ozone with naphthalene has been investigated by a number of workers (5–9). After some uncertainty (9), Bailey and co-workers concluded (10) that the explosive ozonation product isolated from the inert solvents used in all these studies was indeed the diozonide of naphthalene as originally reported by Harries (5). This group also made an extensive study of the reaction in anhydrous aliphatic alcohols, particularly anhydrous methanol, and isolated intermediate cyclic alkoxyhydroxyperoxides. They found, however, that the intermediates were completely resistant to reduction by sodium iodide in acetic acid (10). Only *o*-phthalaldehydic acid, or derivatives of it depending on the nature of the alcohol used as solvent and the type of work-up procedure, was recovered. Pappas and co-workers (11, 12) confirmed the surprising resistance of the cyclic hydroxymethoxyperoxide intermediate to reduction by sodium iodide. He was successful in obtaining a 40–50% yield of *o*-phthalaldehyde (as the bis[(2,4-dinitrophenyl)-hydrazone] derivative) by treating the cold methanolic ozonation product with dimethyl sulfide (11) and a 57% yield using triphenylphosphine (12).

The work with phenanthrene in aqueous *t*-butanol (3) had shown that water, like the aliphatic alcohols, acts as a participating solvent in the ozonation reaction and that the analogous cyclic dihydroxyperoxide decomposes quantitatively to biphenaldehyde on heating in aqueous solution. On the other hand, the cyclic methoxyhydroxyperoxide from phenanthrene yielded biphenaldehydic acid (13). The dihydroxyperoxide intermediate had not been isolated from the ozonation of phenanthrene in this earlier work (3) but had been prepared from biphenaldehyde and 30% hydrogen peroxide. Later it was prepared by the ozonation of phenanthrene in aqueous acetone (M. G. Sturrock, unpublished results). A series of equilibria including the open chain hydroxyhydroperoxide had been postulated to explain the results (3).

Considered in the light of the difference in the course of the reactions of ozone with phenanthrene and with anthracene in anhydrous and in aqueous solvents, it seemed probable that *o*-phthalaldehyde would result if the ozonation conditions were such that the formation of the intermediate hydroxyhydroperoxide would be favored, or better, that the formation of the cyclic alkoxyhydroxyperoxide would be precluded. Further support for the belief that *o*-phthalaldehyde could be prepared in this way was to be found in the process which had been patented for the removal of thionaphthene from crude coal tar naphthalene by the selective reaction of the thionaphthene using a deficiency of ozone and aqueous *t*-butanol as solvent (14). *o*-Phthalaldehyde had been detected qualitatively in these ozonation products (15).[1]

Accordingly, naphthalene was treated with two molar equivalents of ozone using aqueous acetone solutions as solvents. After conventional reduction with potassium iodide in acetic acid, removal of the acetone by evaporation, reduction of the liberated iodine with sodium thiosulfate solution, extracted with chloroform, and sublimation of the chloroform residue, pure *o*-phthalaldehyde was recovered. Yields of 63% were obtained consistently by this procedure. The principal product recovered when aqueous methanol was used as solvent was methyl-*o*-phthalaldehydate although *o*-phthalaldehyde could be detected qualitatively (15).[1] Yields of *o*-phthalaldehyde from ozonations made in aqueous *t*-butanol were slightly less than those in aqueous acetone, averaging 58% in a series of several experiments.

The conditions outlined in the Experimental evidently represent the optimum for this reaction in acetone–water solutions. Changes made in the ratio of acetone to water, in the quantity of naphthalene charged and, rather surprisingly, in the temperature of the ozonation step, had no significant effect on the yield. The results of typical experiments are given in Table 1.

It was evident at an early point in this work that the critical operation was the extraction of the *o*-phthalaldehyde from the aqueous solution after the reduction and evaporation of the acetone. Substitution of ethyl acetate or ethyl ether for chloroform made little difference in the

[1] *o*-Phthalaldehyde gives an intense blue–black coloration when treated with ammonia followed by acetic acid. The same color is developed when *o*-phthalaldehyde comes into contact with the skin.

TABLE 1. Ozonation of naphthalene in acetone–water mixtures

Naphthalene (g charged)	Ozone (*M* equiv)	Solvent (ml)		Temperature (°C) ozonation	*o*-Phthalaldehyde (% Yield)
		Acetone	Water		
5.0	2.1	105	45	27	61.6
5.0	2.1	105	45	27	63.9
5.0	2.1	105	45	26	60.1
5.0	2.1	75	75	27	57.5
2.5	2.1	62	22	26	61.5
5.0	2.1	105	45	−20	62.0
2.5	2.1	62	22	−20	59.0

yields obtained on sublimation. Steam distillation of the reduced product prior to extraction markedly reduced the efficiency of extraction probably as the result of increased hydration of the *o*-phthalaldehyde. The possibility of multipoint attack by ozone on the naphthalene molecule was discounted because unreacted naphthalene was not recovered when the amount of ozone absorbed was in the 2.1–2.2 *M* equiv range. A reddish gummy substance always remained at the end of the sublimation. This is believed to be a polymer of *o*-phthalaldehyde. A positive "Thiele test" (15) was obtained with it by treatment with ammonium hydroxide followed by acidification with acetic acid but the product could not be decomposed to any identifiable material. *o*-Phthalaldehydic acid formation was not a problem since the purity of the sublimed product remained high (m.p. 54–56°; lit. (16) 55.5–56°) regardless of the yield and of the final temperature used in sublimation. Undoubtedly some product was lost in the atmospheric temperature and pressure evaporation of the acetone after the reduction step. When the acetone was removed with a Rinco evaporator, the distillate gave positive "Thiele" tests. In a single experiment performed in acetone–water followed by a non-reductive work-up procedure, *o*-phthalaldehydic acid (m.p. 96–99°) was recovered in 62.5% yield. The literature (10) reports 88% yield of *o*-phthalaldehydic acid (m.p. 99°) from the low temperature ozonation of naphthalene in anhydrous methanol. Although the difference is believed to lie in incomplete extraction, the matter was not further investigated.

Aqueous methanol and aqueous ethanol proved to be unsuitable solvents for the preparation of *o*-phthalaldehyde. After treatment of the ozonation product with potassium iodide and acetic acid, the materials extracted with chloroform were esters of *o*-phthalaldehydic acid. This observation serves to illustrate the tendency of ethyl and methyl alcohols to form cyclic alkoxyhydroxyperoxides. In the case of phenanthrene these alkoxyhydroxyperoxides were found to decompose in a manner which retained the three atoms of oxygen of the original ozone molecule forming acidic products. The analogous hydroxyperoxides yield carbonyl derivatives (1, 3).

The results of this work have again demonstrated that water can act as a participating solvent in the ozonation of aromatic compounds and that its use is advantageous, particularly when aldehydic rather than acidic products are desired. *o*-Phthalaldehyde requiring no further purification is obtained by the ozonation of naphthalene in aqueous acetone solutions in yields which compare favorably with or exceed those reported by any procedure.

Experimental

The equipment and procedures used were those previously described (4). The naphthalene was reagent grade, m.p. 79–80°.[2] It was established that purification to m.p. 80.2° (14) had no discernable effect on the yields of *o*-phthalaldehyde. All other chemicals employed were also of reagent grade.

o-Phthalaldehyde by the Ozonation of Naphthalene

(A) Ozonation in Acetone–Water with Potassium Iodide Reduction

A stream of ozonized oxygen containing 1.73 g/ft³ of ozone was passed into a solution 5.0 g (0.039 mol) of naphthalene in 105 ml of acetone and 45 ml of water at a rate of 0.010 ft³/min. Under these conditions 98–99% of the ozone being introduced was absorbed. After 4 h the ozone absorption decreased to about 95% of that being introduced. A total of 4.1 g of ozone was passed into the reaction mixture of which 4.0 g (0.0834 mol) was absorbed. Immediately after completion of the ozonation, the product was treated with excess potassium iodide (13 g) and 5 ml of glacial acetic acid. The iodine released was reduced with 10% aqueous sodium thiosulfate solution and the acetone removed under reduced pressure at room temperature using a Rinco evaporator. The aqueous solution was extracted several times with

25 ml portions of chloroform. It was then saturated with sodium bicarbonate and again extracted several times with chloroform until the extract gave a negative test for *o*-phthalaldehyde (15). The chloroform was allowed to evaporate by overnight standing in an open beaker under mild magnetic stirrer agitation. The residue remaining, a light red or pinkish solid, was sublimed at a temperature of 45–60° under reduced pressure using ice-water in the cold finger of the sublimation apparatus. The sublimed product (3.33 g) light yellowish well formed crystals of *o*-phthalaldehyde, melted at 55–56°; lit. (16) 55.5–56°. The yield, 63.6% of theory, was typical of runs made in this manner.

Anal.[3] Calcd. for $C_8H_6O_2$: C, 71.65; H, 4.53. Found: C, 71.58; H, 4.50.

The n.m.r. spectrum obtained in $CDCl_3$ showed a singlet at -0.7 τ equivalent to two hydrogens and a multiplet from 1.8–2.2 τ equivalent to four hydrogens.[4]

After the sublimations were completed, that is to say when no further material was condensed on raising the temperature of the bath to 80–90°, a small quantity of red glass-like substance remained. The n.m.r. spectra, run on several different samples of the glass dissolved in acetone, invariably showed a singlet at -0.7 τ indicative of the aldehyde protons on *o*-phthalaldehyde and peaks at 1.7 τ to 2.7 τ corresponding to aromatic ring hydrogens. It is believed to be a polymeric phthalaldehyde.

(B) Ozonation in t-Butanol–Water with Potassium Iodide Reduction

A solution of 5.0 g of naphthalene in 105 ml of *t*-butanol and 45 ml of water was treated with a stream of ozonized oxygen containing 1.56 g/ft^3 of ozone at a rate of 0.0125 ft^3/min. Under these conditions 99% of the ozone introduced was absorbed. A total of 4.1 g of ozone was passed through the reaction mixture. Upon completion of the ozonation the product was treated in the manner described under section *A*. The yield of *o*-phthalaldehyde (m.p. 54–56°) was 3.05 g (58.3%).

(C) Ozonation in Acetone–Water with Dimethyl Sulfide Reduction

The ozonation was carried out using 5.0 g of naphthalene in a mixture of acetone and water as described under section *A*. Dimethyl sulfide (4 ml) was immediately added and the acetone allowed to evaporate at room temperature under gentle agitation. An additional 6 ml of reducing agent was added over the course of the next 3 h. Tests for active oxygen (potassium iodide) were made periodically until, after 4 h, a negative test was obtained. The solution was allowed to stand overnight to assure complete evaporation of the acetone. It was then extracted several times with chloroform and the extract allowed to evaporate. The yellow oil remaining was sublimed as previously described. The sublimed product gave a heavy "Thiele Test" (15) but was pasty and smelled strongly of dimethyl sulfoxide. An unsuccessful attempt was made to avoid the dimethyl sulfoxide difficulty by steam distillation prior to extraction. It is possible that this problem using dimethyl sulfide in the preparation of *o*-phthalaldehyde was encountered by Pappas *et al.* (12) since yields of this particular aldehyde were reported as the bis[(2,4-dinitrophenyl)hydrazone] derivative.

(D) Ozonation in Aqueous Methanol

A solution of 5.0 g of naphthalene in 105 ml of methanol and 45 ml of water was treated with 4.1 g of ozone as described in section *A*. After removal of the alcohol (Rinco, reduced pressure, bath temperature 34°), a brown oil separated. The aqueous solution was decanted and extracted with chloroform. The oil and the chloroform extract, were combined and the solvent removed by evaporation. The product remaining was crude methyl-*o*-phthalaldehydate. An n.m.r. spectrum of the oil in acetone showed a singlet at -0.7, a multiplet from 1.8 to 2.5, a broad singlet at 2.9, a broad singlet at 4.9, a singlet at 6.0, and several small peaks from 6.3 to 6.8 τ as well as a very small peak at about 9 τ. The peaks can be given the following assignments according to their chemical shifts: -0.7, aromatic aldehyde; 1.8 to 2.5, phenyl hydrogens; 4.9, hydroxyl proton; and 6.0 τ $C_6H_5COOCH_3$. On hydrolysis with sodium hydroxide solution followed by acidification, the oil yielded crude *o*-phthalaldehydic acid.

(E) Ozonation in Aqueous Ethanol

In a similar experiment using aqueous ethanol as solvent, the orange oil recovered was crude ethyl-*o*-phthalaldehydate. An n.m.r. spectrum of the oil in acetone showed a singlet at -0.7, a multiplet from 1.7 to 2.5, a quartet from 5.3 to 5.7 (centered at 5.5), a triplet from 8.5 to 8.7 τ (centered at 8.6), and a small impurity peak due to ethanol. The peaks can be given the following assignments according to their chemical shifts: -0.7, aromatic aldehyde; 1.7 to 2.5, phenyl hydrogens; quartet from 5.3 to 5.7, $C_6H_5COOCH_2CH_3$; and the triplet from 8.5 to 8.7 τ, $C_6H_5COOCH_2CH_3$.

3,6-Dihydroxy-4,5-benzo-1,2-dioxane (the Cyclic Dihydroxyperoxide)

(A) From o-Phthalaldehyde

o-Phthalaldehyde (1 g) was covered with 30% hydrogen peroxide and allowed to stand overnight in a refrigerator. White crystals, 0.39 g, (31 2%) m.p. 108–111° crude product separated. Recrystallization from ethyl acetate and petroleum ether gave 0.20 g of product m.p. 127–128°; lit. (18) 127–128°.

Anal. Calcd. for $C_8H_8O_4$: C, 57.15; H, 4.76. Found: C, 57.06; H, 4.72.

Three attempts were made to determine the active oxygen content of the product using the room temperature procedure (17) which had been used successfully in previous work (3, 4). The results were 26.7, 25.9, and 21.8% respectively, of the theoretical. The procedure of Rieche and Schmitz (18) which involves the use of higher temperatures during the reduction gave only 66.6% of theory.

(B) From the Ozonation of Naphthalene in Acetone–Water

A solution of 5.0 g of naphthalene in 105 ml of acetone and 45 ml of water was treated with 4.1 g of ozone in the manner described for the preparation of *o*-phthalaldehyde, section *A*. Removal of the acetone formed a cloudy solution which could not be induced to yield a crystalline product after standing several hours in an ice bath. The solution was extracted twice with 25 ml portions of ethyl

[3]Microanalyses were carried out using a Perkin–Elmer 240 Elemental Analyser.

[4]All n.m.r. spectra were obtained using a Varian A-60A Analytical Nuclear Magnetic Resonance Spectrometer.

acetate. The white crystals which formed as the ethyl acetate evaporated melted 99–150°. Recrystallization from ethyl acetate – petroleum ether (3:2), gave a product m.p. 129.5–131°, not depressed by an authentic sample of the cyclic dihydroxyperoxide m.p. 127–128°. The yield was low, 0.39 g, 6.0%. A quantity of crystals, 1.4 g, meanwhile had separated from the solution which had been extracted. The m.p. 107–115° was narrowed to 99–100° on recrystallization from water. Identification as *o*-phthalaldehydic acid was confirmed by elemental analysis.

Anal. Calcd. for $C_8H_6O_3$: C, 64.0; H, 4.0. Found: C, 64.12; H, 3.89.

o-Phthalaldehydic Acid by Ozonation in Aqueous Acetone, Alkaline Work-up

A solution of 2.5 g of naphthalene in 105 ml of acetone and 45 ml of water was treated with 2.05 g of ozone in the manner previously described. The product was refluxed with 25 ml of 15% sodium hydroxide solution for 30 min, cooled, acidified with hydrochloric acid and extracted five times with 25-ml portions of ethyl ether. The combined extracts were allowed to evaporate by overnight standing. The oil which remained was treated with a few drops of water and placed in the ice-bath. After several hours 1.83 g (62.4%) of *o*-phthalaldehydic acid, m.p. 96–99° separated, no depression with an authentic sample.

Ouverture normale d'époxydes aromatiques para-substitués par des α-mercapto esters

CASIMIR BERSE ET RONALD COULOMBE[1]

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 19 février 1971

Les α-mercaptoesters peuvent ouvrir le cycle oxirannique des époxydes aromatiques. Les produits formés résultent en grande majorité d'une ouverture normale du cycle et l'influence du substituant sur le noyau aromatique est de peu d'importance.

The three-membered ring of aromatic epoxides can be opened by α-mercaptoesters. The reaction products arise to a great extent by a normal opening of the ring and the substituent effect of the aromatic epoxide is of little importance.

Canadian Journal of Chemistry, 49, 3051 (1971)

Beaucoup de travaux (1–4) ont été effectués sur l'ouverture des époxydes par des acides aminés et nous avons été amenés à étudier cette réaction d'ouverture par des α-mercaptoesters aliphatiques. Même si le comportement des époxydes a déjà été étudié (5) en présence de thiols légers, aucun travail n'a été effectué avec des mercaptoesters.

Le schéma 1 résume les réactions effectuées dans la pyridine à reflux.

acetate. The white crystals which formed as the ethyl acetate evaporated melted 99–150°. Recrystallization from ethyl acetate – petroleum ether (3:2), gave a product m.p. 129.5–131°, not depressed by an authentic sample of the cyclic dihydroxyperoxide m.p. 127–128°. The yield was low, 0.39 g, 6.0%. A quantity of crystals, 1.4 g, meanwhile had separated from the solution which had been extracted. The m.p. 107–115° was narrowed to 99–100° on recrystallization from water. Identification as *o*-phthalaldehydic acid was confirmed by elemental analysis.

Anal. Calcd. for $C_8H_6O_3$: C, 64.0; H, 4.0. Found: C, 64.12; H, 3.89.

o-Phthalaldehydic Acid by Ozonation in Aqueous Acetone, Alkaline Work-up

A solution of 2.5 g of naphthalene in 105 ml of acetone and 45 ml of water was treated with 2.05 g of ozone in the manner previously described. The product was refluxed with 25 ml of 15% sodium hydroxide solution for 30 min, cooled, acidified with hydrochloric acid and extracted five times with 25-ml portions of ethyl ether. The combined extracts were allowed to evaporate by overnight standing. The oil which remained was treated with a few drops of water and placed in the ice-bath. After several hours 1.83 g (62.4%) of *o*-phthalaldehydic acid, m.p. 96–99° separated, no depression with an authentic sample.

The authors are grateful to The Robert A. Welch Foundation, Houston, Texas, for the financial support of this work.

Ouverture normale d'époxydes aromatiques para-substitués par des α-mercapto esters

CASIMIR BERSE ET RONALD COULOMBE[1]

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 19 février 1971

Les α-mercaptoesters peuvent ouvrir le cycle oxirannique des époxydes aromatiques. Les produits formés résultent en grande majorité d'une ouverture normale du cycle et l'influence du substituant sur le noyau aromatique est de peu d'importance.

The three-membered ring of aromatic epoxides can be opened by α-mercaptoesters. The reaction products arise to a great extent by a normal opening of the ring and the substituent effect of the aromatic epoxide is of little importance.

Canadian Journal of Chemistry, 49, 3051 (1971)

Beaucoup de travaux (1–4) ont été effectués sur l'ouverture des époxydes par des acides aminés et nous avons été amenés à étudier cette réaction d'ouverture par des α-mercaptoesters aliphatiques. Même si le comportement des époxydes a déjà été étudié (5) en présence de thiols légers, aucun travail n'a été effectué avec des mercaptoesters.

Le schéma 1 résume les réactions effectuées dans la pyridine à reflux.

TABLEAU 2. Analyses

Produit	Formule	Calculé (%) C	Calculé (%) H	Trouvé (%) C	Trouvé (%) H
7	$C_{12}H_{16}O_3S$	59.97	6.71	59.69	6.80
8	$C_{12}H_{15}BrO_3S$	45.21	4.73	44.87	4.68
9	$C_{13}H_{18}O_4S$	56.62	6.23	56.17	6.21
10	$C_{12}H_{15}NO_5S$	50.51	5.29	50.77	5.42
11	$C_{16}H_{22}O_3S$	65.29	7.53	65.07	7.35
12	$C_{16}H_{21}BrO_3S$	51.48	5.67	51.42	5.85
13	$C_{17}H_{24}O_4S$	62.90	7.45	63.17	7.36
14	$C_{16}H_{21}NO_5S$	57.75	6.71	57.52	6.93

des résultats (tableau 1). Chacun des produits **7–14** présente en r.m.n. un système ABX, la partie X représentant le proton benzylique. Tous les spectres sont pris dans le CCl_4 sauf pour le produit **10** où on ajoute une trace de $CDCl_3$ pour des raisons de solubilité. Certains spectres ont également été pris dans le DMSO-d_6 (6).

Les spectres i.r. des produits **7–14** montrèrent en solution dans CCl_4 les caractéristiques attendues pour ces produits, soit OH de type alcoolique et carbonyle à 1720 (± 5) cm^{-1}.

Il ne fait donc aucun doute quant à la structure de ces dérivés et à l'orientation de la réaction. Aucun mécanisme n'est proposé ici pour expliquer tant la sélectivité de l'ouverture que l'influence pratiquement indécelable du groupement attaché au noyau aromatique, contrairement à ce qui fut observé dans d'autres conditions expérimentales (7–9).

L'étude de la réactivité de ces composés **7–14** est en cours et fera l'objet d'une communication indépendante.

Partie expérimentale

Les spectres i.r. ont été pris sur un spectrophotomètre Beckman IR-8. Les spectres r.m.n. ont été pris sur un appareil JNM-4H-100 de Jeol et un appareil Varian T-60 avec le TMS comme référence interne.

Les analyses élémentaires ont été effectuées par Midwest Microlab Inc., à Indianapolis, Indiana.

Les points de fusion et d'ébullition ne sont pas corrigés.

Le mercaptocyclohexane carboxylate de méthyle (p.é. 60°/1.5 mm) a été préparé par la méthode de Jones *et al.* (10) à partir de l'acide α-bromocyclohexane carboxylique suivi d'estérification dans le méthanol. Les époxydes ont été préparés par la méthode de Shevchuk et Dombrovskii (11) et Fuchs et Vanderwerf (7) à partir des acétophénones correspondantes.

Toutes les ouvertures furent effectuées de la même façon. Le mercaptan et l'époxyde (mole à mole) furent dissous dans la pyridine (solution environ 10%) et portés à reflux environ trois heures. On constata la disparition du mercaptan par chromatographie sur couche mince. Le solvant fut retiré *in vacuo* et le résidu fut d'abord filtré sur une colonne de gel de silice pour éliminer les fractions polymériques avant d'être chromatographié dans l'hexane enrichi graduellement en éther. Les produits **7–14** n'ont en aucun cas été distillés car toute tentative entraîna la décomposition des produits. Ce sont tous des liquides jaunâtres à l'exception du composé **11** (p.f. sublimé: 54°).

Les produits ont été repurifiés par chromatographie sur colonne de gel de silice pour les microanalyses (voir tableau 2).

Nous remercions le Conseil National de Recherches du Canada de l'aide financière qui a rendu ce travail possible.

Thermodynamics of Ionization of Fluoroalcohols in Aqueous Solution: Hexafluoropropan-2-ol and Hexafluoropropan-2,2-diol

EARL M. WOOLLEY[1] AND LOREN G. HEPLER
Department of Chemistry, The University of Lethbridge, Lethbridge, Alberta

AND

RODNEY S. ROCHE
Department of Chemistry, The University of Calgary, Calgary, Alberta

Received May 13, 1971

Calorimetric measurements have led to $\Delta H^0 = 6.37$ kcal mol^{-1} for ionization of aqueous hexafluoropropan-2-ol (HFIP) and to $\Delta H^0 = 6.00$ kcal mol^{-1} for ionization of aqueous hexafluoropropan-2,2-diol (HFPD). We have combined these values with our ΔG^0 values from p$K = 9.42$ for HFIP and p$K = 6.65$ for HFPD to obtain $\Delta S^0 = -21.7$ cal deg^{-1} mol^{-1} for ionization of aqueous HFIP and $\Delta S^0 = -10.3$ cal deg^{-1} mol^{-1} for ionization of aqueous HFPD. These results (all for 298 °K) show that most of the difference in pK values is due to the large difference in entropy of ionization. The ΔS^0 values can be explained largely in terms of solute–solvent interactions.

Les mesures calorimétriques conduisent à $\Delta H° = 6.37$ kcal mol^{-1} pour l'ionisation d'hexafluoropropanol-2 aqueux (HFIP) et à $\Delta H° = 6.00$ kcal mol^{-1} pour l'ionisation d'hexafluoropropanediol-2,2 aqueux (HFPD). En associant ces valeurs avec les valeurs de $\Delta G°$ obtenues à partir de p$K = 9.42$ pour HFIP et p$K = 6.65$ pour HFPD, on obtient $\Delta S° = -21.7$ cal deg^{-1} mol^{-1} pour l'ionisation de HFIP aqueux et $\Delta S° = -10.3$ cal deg^{-1} mol^{-1} pour l'ionisation de HFPD aqueux. Ces résultats (pour 298 °K) indiquent que la différence dans les valeurs de pK est principalement due aux différences importantes dans l'entropie d'ionisation. Les valeurs de $\Delta S°$ peuvent être rationalisées, en grande partie en invoquant des interactions soluté–solvant.

Canadian Journal of Chemistry, 49, 3054 (1971)

Introduction

Middleton and Lindsey (1) have reported p$K_a = 9.30$ for hexafluoropropan-2-ol (hexafluoroisopropanol, HFIP) and p$K_a = 6.58$ for hexafluoropropan-2,2-diol (hexafluoropropanediol, HFPD), presumably at about 25 °C, and have commented on the "abnormal acidity" of HFPD in terms of hydrogen bonding. Since earlier investigations (2) of thermodynamics of ionization of aqueous acids have shown that solute–solvent interactions and entropy effects can be as important as "internal energies" in relation to acid strengths and intramolecular hydrogen bonding, we have undertaken the calorimetric and e.m.f. measurements reported here. Also, it should be noted that there are no enthalpy and entropy data for ionization of other highly fluorinated acids or for any gem-diols.

Experimental

HFPD was prepared by stoichiometric addition of hexafluoroacetone (Mathieson) to water as described previously (3). The resulting HFPD was a stable gem-diol with melting point 44–46 °C. A solution of HFPD in CCl_4 (0.01 M) showed strong absorption at 3580 cm^{-1}, but no absorption in the 1800 cm^{-1} region (gaseous hexafluoroacetone has a carbonyl band at 1810 cm^{-1}) in this solution or in 1.0 M aqueous solution. No n–π^* or π–π^* transitions were observed in the u.v. spectrum.

HFIP was prepared by catalytic hydrogenation of hexafluoroacetone (PtO_2, 120 °C, maximum pressure 6000 p.s.i.) and purified by column fractionation at a reflux ratio of 10:1. The resulting HFIP was a colorless liquid, $n_D^{25\,°C} = 1.2748$, b.p. (760 mm Hg) = 59 °C.

Standard solutions were prepared by weighing HFIP and HFPD in a N_2 blanketed dry box, followed by addition of water to give known volumes of solutions of known concentrations, which were confirmed by titration with standard NaOH solution.

Calorimetric measurements were made with an LKB Precision Calorimetry System, used as a titration calorimeter. The titrant was supplied to the calorimeter by a Metrohm automatic titrator. Results refer to 25.0 °C and are reported in terms of the defined calorie (1 cal = 4.184 J).

Calorimetric titrations were carried out by adding known amounts of 0.2925 M NaOH to 95.5$_4$ ml of 0.01995 M HFIP or 0.01994 M HFPD. Heat effects associated with addition of three portions of NaOH solution were measured. Each of the first two portions neutralized about 45% of the acid originally present. The third portion contained enough NaOH to neutralize about 30% of the original acid. Molar heats of neutralization calculated from the heats associated with the first two additions of NaOH agreed with each other and also

TABLE 1. Thermodynamics of ionization of HFIP (aq) and HFPD (aq) at 298 °K

Compound	pK	K	ΔG^0 (kcal mol^{-1})	ΔH^0 (kcal mol^{-1})	ΔS^0 (cal deg^{-1} mol^{-1})
HFIP	9.42 ± 0.04	$3.8(\pm 0.3) \times 10^{-10}$	12.85 ± 0.05	6.37 ± 0.06	-21.7 ± 0.03
HFPD	6.65 ± 0.02	$2.2(\pm 0.1) \times 10^{-7}$	9.07 ± 0.03	6.00 ± 0.04	-10.3 ± 0.2

with the heat of ionization calculated from the total heat associated with all three additions, thus demonstrating the absence of impurities with pK much different from the pK of the acid under investigation. Results of duplicate runs were in good agreement. In each case there were small corrections for heats of dilution, which were evaluated from results of separate measurements.

Ionization constants were determined by potentiometric titration at 25.0 °C with an Orion 801 pH meter with Beckman electrode pH 0–14. Initial concentrations of acid were 0.09974 M for HFIP and 0.08969 M for HFPD. Calculations, including activity coefficients, were carried out as described by King (4).

Results and Discussion

Results of our measurements are given in Table 1. Although our pH titrations were carried out with concentrations expressed as molarities, we report our results in terms of K, pK, ΔG^0, and ΔS^0 values based on the usual hypothetical one molal standard state (4). The reported ΔH^0 values are derived by combination of our heats of neutralization with $\Delta H^0 = 13.34$ kcal mol^{-1} for ionization of water (2, 5). The $\pm$ values given are our estimates of *total* uncertainties.

The results in Table 1 show that ~10% of the difference in ΔG^0 values is due to the difference in enthalpies of ionization, with the remaining ~90% of the ΔG^0 difference due to the difference in ΔS^0 of ionization. Since the ΔH^0 values can be regarded (2, 4, 6) as a sum of contributions from "internal" and "environmental" effects, we shall not try to interpret the small difference between the enthalpies of ionization of these compounds. On the other hand, the difference between the entropies of ionization can be interpreted (2, 4, 6, 7) largely in terms of solute–solvent interaction.

We begin by emphasizing that all available evidence shows that the equilibrium between hexafluoroacetone and water is such that it is appropriate to represent HFPD as a gem-diol rather than as a hydrated ketone. Next we note that the statistical effect of having two —OH groups on HFPD amounts to only 1.4 cal deg^{-1} mol^{-1} in ΔS^0, which is small compared to the observed 11.4 cal deg^{-1} mol^{-1} difference between ΔS^0 values for ionization of aqueous HFPD and HFIP.

Since our $\Delta S^0 = -21.7$ cal deg^{-1} mol^{-1} for ionization of aqueous HFIP is typical of many uncharged acids (2), we turn to consideration of either un-ionized HFPD or its anion as having an unusual partial molal entropy. In order for the ΔS^0 for ionization of aqueous HFPD to be less negative than usual, it is necessary that the partial molal entropy of un-ionized HFPD be unusually small or that the partial molal entropy of the HFPD anion be unusually large. We tentatively assume that the difference in entropies of ionization of aqueous HFPD and HFIP is due to an unusually large partial molal entropy for the anion of HFPD. This unusually large partial molal entropy for the anion of HFPD could result from an unusually small amount of "ordering" of water molecules around this ion.

The ordering of polar solvent molecules near anions of the type we are concerned with can be expressed in terms of the effective electrostatic field about the —O^- group. In the case of the HFPD anion the effective field near the —O^- group is diminished (compared to the field near the anion of HFIP) by the presence of the geminal —OH group that is oriented by intramolecular charge–dipole interaction. In molecules with appropriate geometry, this interaction leads to intramolecular hydrogen bonds.

In the absence of appropriate thermodynamic data for other acids of the gem-diol type, we turn to consideration of data in Table 2 for ionization of acids in which there may be intramolecular hydrogen bonding.

The ΔS^0 of ionization of *o*-hydroxybenzoic

TABLE 2. Entropies of ionization of aqueous acids at 298 °K (all ΔS^0 values from ref. 2)

Acid	ΔS^0 (cal deg^{-1} mol^{-1})
o-Hydroxybenzoic	−11.2
m-Hydroxybenzoic	−18.1
p-Hydroxybenzoic	−19.6
Maleic	−8.5
Fumaric	−13.8
Malic	−13.4
Succinic	−16.7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

acid is larger (less negative) than ΔS^0 values for the *meta* or the *para* isomer. Similarly, ΔS^0 values for maleic acid and malic acid are greater than for fumaric and succinic acids. Thus we see that entropies of ionization for those acids in which we expect to find intramolecular hydrogen bonding in the anion are larger (less negative) than for "similar" acids in which the anion can have no intramolecular hydrogen bonding. It is reasonable to infer in these cases that the electrostatic field about the $-O^-$ group is diminished by hydrogen bonding, thus reducing "ordering" of solvent (as compared to similar anions without such intramolecular hydrogen bonding) in much the same way as the intramolecular charge–dipole interaction postulated above for the anion of HFPD.

We are grateful to the National Research Council of Canada for support of this research and to Douglas Dolman for his advice.

Crystal Structure of α-$Zn_3(VO_4)_2$

R. GOPAL AND C. CALVO
Institute for Materials Research, McMaster University, Hamilton, Ontario

Received January 25, 1971

α-$Zn_3(VO_4)_2$, the low temperature form of this compound, crystallizes in the orthorhombic space group *Cmca* with $a = 6.088(3)$, $b = 11.489(3)$, and $c = 8.280(3)$ Å and $Z = 4$. A total of 726 unique reflections were recorded from integrated precession photographs or with a manually set scintillation counter and used in a full matrix least squares refinement to a final R value of 0.089. The Zn ions lie in two types of octahedral sites while the V ions lie in sites showing tetrahedral coordination to oxygen atoms. The mean V—O bond length is 1.71 Å but one of the V—O bond lengths, involving an oxygen atom bonded to three Zn^{2+}, is 1.78(1) Å long. The average Zn—O bond lengths are 2.13 and 2.10 Å for the Zn ion with site symmetry $2/m$ and m site symmetry, respectively. α-$Zn_3(VO_4)_2$ is isostructural with $Mg_3(VO_4)_2$ and thus has a structure based upon a closest packing of oxygen atoms much like that found in spinel.

A basse température, le composé α-$Zn_3(VO_4)_2$, cristallise dans le système orthorhombique, groupe d'espace *Cmca* avec $a = 6.088(3)$, $b = 11.489(3)$ et $c = 8.280(3)$ Å et $Z = 4.726$ réflexions uniques ont été enregistrées soit à partir de photographies de précession intégrées soit au moyen d'un compteur de scintillement manuel et les résultats ont été affinés par moindre carrés jusqu'à une valeur finale $R = 0.089$. Les ions Zn se trouvent dans deux types de sites octahédriques alors que les ions V se trouvent dans des sites qui montrent une coordination tétrahédrique avec des atomes d'oxygène. La moyenne de la longueur de la liaison V—O est de 1.71 Å mais l'une des liaisons V—O, impliquant un atome d'oxygène lié à trois Zn^{2+}, a une longueur de 1.78(1) Å. Les moyennes des longueurs des liaisons Zn—O sont de 2.13 et 2.10 Å respectivement pour l'ion Zn ayant un site de symétrie $2/m$ et celui ayant un site de symétrie m. α-$Zn_3(VO_4)_2$ a la même structure que $Mg_3(VO_4)_2$ et de ce fait possède une structure fondée sur le tassement maximum des atomes d'oxygène un peu comme celle de la spinelle.

Canadian Journal of Chemistry, **49**, 3056 (1971)

The structures of $Mg_3(VO_4)_2$ (1), $Ni_3(VO_4)_2$ and the high temperature form of $Co_3(VO_4)_2$ (2) and the low temperature form of $Zn_3(VO_4)_2$, called α, are basically the same. The crystal structure of the first of these compounds has been refined by least squares methods using data obtained from a single crystal and the results indicate that three of the four V—O bond lengths about the VO_4 group are normal while the fourth is unusually long. The oxygen atom involved in this latter bond is shared with three Mg^{2+} ions, in addition to the vanadium, while the remaining

acid is larger (less negative) than ΔS^0 values for the *meta* or the *para* isomer. Similarly, ΔS^0 values for maleic acid and malic acid are greater than for fumaric and succinic acids. Thus we see that entropies of ionization for those acids in which we expect to find intramolecular hydrogen bonding in the anion are larger (less negative) than for "similar" acids in which the anion can have no intramolecular hydrogen bonding. It is reasonable to infer in these cases that the electrostatic field about the $-O^-$ group is diminished by hydrogen bonding, thus reducing "ordering" of solvent (as compared to similar anions without such intramolecular hydrogen bonding) in much the same way as the intramolecular charge–dipole interaction postulated above for the anion of HFPD.

We are grateful to the National Research Council of Canada for support of this research and to Douglas Dolman for his advice.

Crystal Structure of α-$Zn_3(VO_4)_2$

R. GOPAL AND C. CALVO
Institute for Materials Research, McMaster University, Hamilton, Ontario

Received January 25, 1971

α-$Zn_3(VO_4)_2$, the low temperature form of this compound, crystallizes in the orthorhombic space group *Cmca* with $a = 6.088(3)$, $b = 11.489(3)$, and $c = 8.280(3)$ Å and $Z = 4$. A total of 726 unique reflections were recorded from integrated precession photographs or with a manually set scintillation counter and used in a full matrix least squares refinement to a final R value of 0.089. The Zn ions lie in two types of octahedral sites while the V ions lie in sites showing tetrahedral coordination to oxygen atoms. The mean V—O bond length is 1.71 Å but one of the V—O bond lengths, involving an oxygen atom bonded to three Zn^{2+}, is 1.78(1) Å long. The average Zn—O bond lengths are 2.13 and 2.10 Å for the Zn ion with site symmetry $2/m$ and m site symmetry, respectively. α-$Zn_3(VO_4)_2$ is isostructural with $Mg_3(VO_4)_2$ and thus has a structure based upon a closest packing of oxygen atoms much like that found in spinel.

A basse température, le composé α-$Zn_3(VO_4)_2$, cristallise dans le système orthorhombique, groupe d'espace *Cmca* avec $a = 6.088(3)$, $b = 11.489(3)$ et $c = 8.280(3)$ Å et $Z = 4.726$ réflexions uniques ont été enregistrées soit à partir de photographies de précession intégrées soit au moyen d'un compteur de scintillement manuel et les résultats ont été affinés par moindre carrés jusqu'à une valeur finale $R = 0.089$. Les ions Zn se trouvent dans deux types de sites octahédriques alors que les ions V se trouvent dans des sites qui montrent une coordination tétrahédrique avec des atomes d'oxygène. La moyenne de la longueur de la liaison V—O est de 1.71 Å mais l'une des liaisons V—O, impliquant un atome d'oxygène lié à trois Zn^{2+}, a une longueur de 1.78(1) Å. Les moyennes des longueurs des liaisons Zn—O sont de 2.13 et 2.10 Å respectivement pour l'ion Zn ayant un site de symétrie $2/m$ et celui ayant un site de symétrie m. α-$Zn_3(VO_4)_2$ a la même structure que $Mg_3(VO_4)_2$ et de ce fait possède une structure fondée sur le tassement maximum des atomes d'oxygène un peu comme celle de la spinelle.

Canadian Journal of Chemistry, **49**, 3056 (1971)

The structures of $Mg_3(VO_4)_2$ (1), $Ni_3(VO_4)_2$ and the high temperature form of $Co_3(VO_4)_2$ (2) and the low temperature form of $Zn_3(VO_4)_2$, called α, are basically the same. The crystal structure of the first of these compounds has been refined by least squares methods using data obtained from a single crystal and the results indicate that three of the four V—O bond lengths about the VO_4 group are normal while the fourth is unusually long. The oxygen atom involved in this latter bond is shared with three Mg^{2+} ions, in addition to the vanadium, while the remaining

oxygen atoms are shared by only two magnesium atoms and the vanadium atom. The results of a recent refinement of X-ray and neutron powder data from $Co_3(VO_4)_2$ and $Ni_3(VO_4)_2$ are dissimilar in this detail (2). An environmental effect has been noted in α-$Mg_2P_2O_7$ (3), α-$Zn_2P_2O_7$ (4), and α-$Co_2P_2O_7$ (5) where bond length changes of the order of 0.05 Å in the diphosphate group have been noted as compared to 0.1 Å in $Mg_3(VO_4)_2$ (1). The structure of α-$Zn_3(VO_4)_2$ has been refined, in part, to determine whether a similar effect occurs in this material since there is a substantial difference in the electronegativity of the two cations, $Mg^{2+} = 1.2$ and $Zn^{2+} = 1.6$, as compared to 1.9 for V^{5+} (6).

α-$Zn_3(VO_4)_2$ undergoes two phase transformations upon increasing the temperature. The transition at 795 °C is sluggish but reversible while the one at 815 °C is rapid and reversible (7). An understanding of the driving forces for these transformations will require a detailed knowledge of the structure of each of the phases.

Crystals of α-$Zn_3(VO_4)_2$ were prepared from a slowly cooled melt containing stoichiometric amounts of ZnO and V_2O_5 in a platinum crucible. Unit cell parameters were determined by least squares refinement of single crystal photographs calibrated with the single crystal pattern of TiO_2 whose lattice parameters were taken to be $a = 4.5929$, $c = 2.9591$ Å (8). The values obtained are $a = 6.088(3)$, $b = 11.489(3)$, and $c = 8.280(3)$ Å using MoKα radiation ($\lambda_\alpha = 0.71069$ Å). A density of 5.0 g/cm^3 was measured with a pycnometer while the calculated density for $Z = 4$ is 4.88 g/cm^3. The assigned space group, *Cmca*, is the same as that of $Mg_3(VO_4)_2$ since the extinctions are $h + k$ odd for all reflections, l odd for $h0l$ and h and/or k odd for $hk0$. Intensities were measured from integrated precession photographs or with a manually set scintillation counter attached to a Supper Weissenberg camera using an ω scan. MoKα radiation was diffracted from a crystal whose size was 0.14 × 0.14 × 0.07 mm. The data set, consisting of nkl, $n = 0$ to 5; hkm, $m = 0$ and 1; and hpl, $p = 0$ to 4 were corrected for Lorentz and polarization effects and absorption.

The structure was refined by full matrix least squares procedures using 726 unique reflections. The final parameters of $Mg_3(VO_4)_2$ were used as trial coordinates and weights determined from the function $\omega = (30 + 0.2F_o + 0.012F_o^2)^{-1}$. The coefficients were chosen so that $\omega||F_o| - |F_c||^2$, the square of the difference between the observed and calculated structure factors would be independent of the local average of $|F_o|$. The weight was set to zero if the calculated intensity was less than the local minimum intensity. Common reflections were used to place all the data on a common scale. The atomic scattering curves were taken from the International Tables for X-Ray Diffraction and those for zinc and vanadium were corrected for dispersion (9). Refinement terminated when the calculated shifts in the varied parameters were all less than 1/3 of the calculated standard deviations. A full matrix least squares program written by J. S. Stephens for the CDC 6400 was used. The final R value was 0.089 while the weighted value is 0.116. The final atomic coordinates can be found in Table 1 while the observed and calculated structure factors are compared in Table 2.[1]

The bond lengths and angles are tabulated in Table 3 and, as with $Mg_3(VO_4)_2$, the three V—O bond lengths differ significantly. The V—O(2) bond length, involving that oxygen atom shared with three Zn^{2+}, is 1.79(1) Å long compared with 1.809(1) Å in $Mg_3(VO_4)_2$. In both structures the V—O(1) bond lengths are longer than the V—O(3) lengths. These values are 1.73(1) and 1.67(1) Å in the present case and 1.716(1) and 1.695(1) Å in $Mg_3(VO_4)_2$. The mean V—O bond length of 1.71 Å compares with the mean values of 1.70 and 1.71 Å found in $Ba_3(VO_4)_2$ (10). As a result of the larger errors in $\alpha Zn_3(VO_4)_2$ it cannot be concluded whether the individual V—O bond lengths between Mg and Zn orthovanadate differ significantly. On the other hand these results are completely reversed from those reported by Fuess *et al.* (2) on $Co_3(VO_4)_2$ and $Ni_3(VO_4)_2$ where the long V—O bond length corresponds to the V—O(1) bond. The O—V—O angles in the VO_4 tetrahedron do not deviate significantly from regularity and therefore the major distortion involves a radial displacement of O(2) from its ideal position, as is the case in $Mg_3(VO_4)_2$. The average ZnO bond lengths about Zn(1), lying in a site of $2/m$ symmetry, is 2.13 Å while the average Zn(2)—O bond length is 2.10 Å. This latter cation lies on the mirror plane. Both cations show substantially irregular octahedral coordination.

The crystal packing and the relationship between this structure and that of spinel have been discussed previously (1). One new feature concerns the phase transformations in this compound. A single crystal was heated and photographed *in situ*. The phase transformation is indeed sluggish and all attempts to convert a single crystal to the high temperature phase resulted in diffraction rings. It is thus curious that single crystals of the low temperature form survived the cooling process.

Studies on Horseradish Peroxidase. VII. A Kinetic Study of the Oxidation of Iodide by Horseradish Peroxidase Compound II

R. ROMAN, H. B. DUNFORD, AND M. EVETT
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 1, 1971

The kinetics of the oxidation of iodide ion by horseradish peroxidase compound II have been studied as a function of p*H* at 25° and ionic strength of 0.11. The logarithm of the second-order rate constant decreases linearly from 2.3×10^5 to 0.1 M^{-1} s^{-1} with increasing p*H* over the p*H* range 2.7 to 9.0. The p*H* dependence of the reaction is explained in terms of an acid dissociation outside the p*H* range of the study.

Les cinétiques de l'oxydation d'ions iodure par le composé II (raifort peroxydase) ont été étudiées en fonction du p*H*, à 25 °C et avec une force ionique de 0.11. Le logarithm de la constante de vitesse du second ordre décroît linéairement de 2.3×10^5 jusqu'à 0.1 M^{-1} s^{-1} lorsque le p*H* augmente de 2.7 à 9.0. La dépendence du p*H* de la réaction est expliquée en fonction d'une dissociation acide, extérieure à la zone de p*H* étudiée.

Canadian Journal of Chemistry, **49**, 3059 (1971)

This work is part of a continuing series of studies the object of which is to elucidate the mechanism of the reactions of horseradish peroxidase (HRP). Previous studies have dealt with the effect of p*H* on the structure and kinetics of native HRP (1–4). More recently, we studied the kinetics of the reactions of two oxidized forms of HRP with ferrocyanide as a function of p*H*

(5, 6). The present work describes a p*H* study of the reaction of compound II of HRP with iodide. It is generally accepted that compound II (HRP-II) is an intermediate in the peroxidase-catalyzed reactions between hydrogen peroxide and a variety of reducing agents (7). It is possible to prepare HRP-II, which has one more oxidizing equivalent than native HRP, and to study its reactions in isolation from the other steps in the HRP cyclic reaction sequence. By studying one of its reactions over a p*H* range, it is possible to gain information concerning the ionizations which affect the active site of HRP-II for this reaction. Iodide was chosen as a substrate partly because its single ionization is outside the measurable p*H* range for the enzyme, thus simplifying the interpretation of the kinetic p*H* dependence.

The biological functions of most peroxidases are uncertain. However, it has been proposed that thyroid peroxidase functions in mammalian thyroid glands by oxidizing iodide in the synthesis of thyroxine (8). We thought that the readily available HRP might serve as a model for thyroid peroxidase, which at present can only be isolated in small quantities (9).

Experimental

Horseradish peroxidase was obtained from Boehringer-Mannheim either as a purified, lyophilized powder or as a highly purified ammonium sulfate suspension. The suspension, which had a p.n.[1] of 3.0 was dialyzed and passed through a millipore filter prior to use. The lyophilized powder (p.n. about 0.6) was purified by the method of Shannon *et al.* (10). From 0.1 to 0.5 g of the powder was dissolved in a sodium acetate buffer (p*H* 4.4 and ionic strength 0.005) and transferred to a Sephadex C50-(CM) column. The eluent was that of Shannon *et al.* The major peak was collected in 5 ml fractions and those of p.n. 2.8 or greater were combined and precipitated with ammonium sulfate (53 g/100 ml of solution) at −10 °C. The precipitate was dissolved, dialyzed, and passed through a millipore filter prior to use. Both enzyme preparations exhibited the same kinetic behavior and were sufficiently free from reducing impurities to give HRP-II a half-life of about 20 min. The fact that the observed reactions were first-order in HRP-II indicates that if more than one isozyme was present in detectable concentrations, these isozymes must react with similar rates. The concentration of HRP was determined spectrophotometrically at 403 nm using a molar absorptivity of $9.1 \times 10^4\ M^{-1}\ cm^{-1}$ (11).

All solutions were prepared from water that had been distilled from alkaline permanganate and then redistilled. Reagent grade inorganic chemicals were used without further purification. The ionic strength of all reaction mixtures was kept constant at 0.11 with 0.01 contributed by the buffer and the remainder by potassium nitrate and potassium iodide. Fresh solutions of potassium iodide were prepared weekly and were protected from light during storage. The concentrations of these iodide solutions were checked by titration with silver nitrate or with an Orion specific ion iodide electrode (84-53A); no change was detected during the storage period (12). The concentrations of the hydrogen peroxide solutions were determined spectrophotometrically by the molybdate-catalyzed oxidation of iodide (13, 14).

An Orion model 801 digital p*H* meter in conjunction with a Fisher combination electrode was used for p*H* measurements. A Beckman DU spectrophotometer was used for routine absorption measurements and a Cary 14 spectrophotometer was employed for recording spectra.

Kinetic measurements on solutions with p*H* lower than 6.5 were performed on a stopped flow apparatus; measurements on solutions with higher p*H* were performed on the Cary 14. The reaction was monitored by following the decrease in absorbance at 425 nm. All measurements were made with the solutions thermostatted at 25.0 °C. The stopped flow data were obtained as voltage *vs.* time measurements from oscilloscope traces. The observed first-order rate constants were determined by a nonlinear least squares fit to the equation

$$V_t = (V_0 - V_\infty)e^{-k_{obs}t} + V_\infty$$

where V_t, V_0, and V_∞ are the voltages observed at time t, at t equal to 0, and at t equal to ∞, respectively, and k_{obs} is the first-order rate constant. At the low absorbance changes used (0.04), voltage changes were taken to be proportional to changes in absorbance. For the analysis 20–30 points were taken per trace, and 4–8 traces were analyzed to give an average rate constant. The absorbance *vs.* time data from the Cary 14 experiments were analyzed in the same manner as the stopped flow data.

The preparation of HRP-II was similar to that described previously (5). It was found that the addition of an equimolar amount of hydrogen peroxide to HRP produced compound I, which could be converted to compound II by the addition of one-half of a molar equivalent of *p*-cresol. The absence of any compound I in the resulting mixture of HRP and HRP-II was verified spectrophotometrically (5). Care was taken in the preparation of HRP-II to avoid adding an excess of hydrogen peroxide, which would recycle part of the enzyme, resulting in anomalous kinetic results. For the same reason a small amount of HRP (*ca.* $10^{-9}\ M$) was added to solutions containing a mixture of buffer, iodide, and nitrate to remove any oxidizing impurity in these solutions. The buffer and the HRP-II solutions were not mixed prior to the reaction in the stopped flow apparatus to minimize decomposition of HRP-II at low p*H*. On the Cary 14 the reaction was performed by pipetting a solution of buffer, iodide, and nitrate into the HRP-II solution.

Results and Discussion

The kinetic behavior of the HRP-II-iodide reaction is consistent with the equation

[1]An acronym for purity number, the ratio of absorbance at 403 and 280 nm.

$$[1] \qquad \text{HRP-II} + I^- \xrightarrow{k_1} \text{HRP} + \tfrac{1}{2}I_2$$

All experiments were carried out with $[I^-]$ at least twenty times greater than the [HRP-II]; under these pseudo-first-order conditions the differential rate expression is

$$[2] \qquad -\mathrm{d}\frac{[\text{HRP-II}]}{\mathrm{d}t} = k_{obs}[\text{HRP-II}]$$

Values of k_1 are obtained from the equation

$$[3] \qquad k_{obs} = k_1[I^-]$$

This relation was verified by measuring k_{obs} over a range of iodide concentrations at a given p*H*. Plots of k_{obs} *vs.* $[I^-]$ are linear as shown in Fig. 1 for p*H* 3.41. Similar studies were carried out at p*H*'s 2.71, 2.99, 6.00, 8.66, and 9.05. At p*H* values below 3.4 and above 8.5 the k_{obs} *vs.* $[I^-]$ plots have a positive intercept indicating an appreciable spontaneous rate of reaction. The values of these intercepts are found never to be greater than 15% of the largest measured value of k_{obs}.

The values of k_1 as a function of p*H* are listed in Table 1 and $\log k_1$ is plotted *vs.* p*H* in Fig. 2. Where it was possible to overlap buffers, similar kinetic behavior was observed, indicating that there is no detectable effect due to buffers. We believe the values of k_1, the errors in which are mainly dependent on the errors in k_{obs} and in p*H*, are accurate to within $\pm 10\%$.

In a recent publication, Björkstén reported a value for the second-order rate constant, for the reaction of HRP-II and iodide, of $1.8 \times 10^2\ M^{-1}\ s^{-1}$ at p*H* 6.19 (15). Considering the different techniques employed in the two studies the agreement is reasonable with our value for the rate constant, $7.1 \times 10^1\ M^{-1}\ s^{-1}$, at the same p*H*. We feel that our value for the rate constant is more accurate, since it does not depend on the concentration of HRP-II or knowledge of the molar absorptivity differences between HRP-II and HRP.

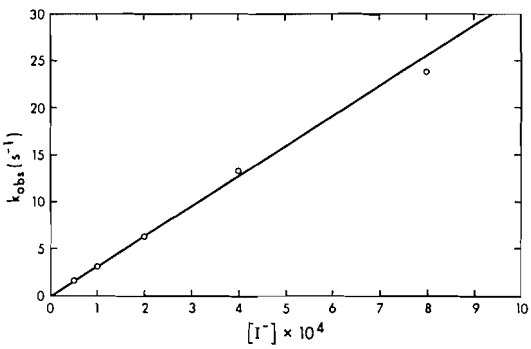

FIG. 1. Plot of k_{obs} *vs.* $[I^-]$ at p*H* 3.41 for the reaction between HRP-II and iodide. The straight line is the weighted linear least squares line. The slope, k_1, with its standard error is $(3.2 \pm 0.1) \times 10^4\ M^{-1}\ s^{-1}$. The intercept with its standard error is $-0.01 \pm 0.07\ s^{-1}$.

TABLE 1. Second-order rate constants for the HRP-II–iodide reaction at 25 °C

*A, acetic acid – NaOH; B, borax–HNO_3; C, $NaHCO_3$–NaOH; CA, cacodylic acid – NaOH; GH, glycine–HNO_3; P, KH_2PO_4–NaOH; and T, tris–HNO_3.

The plot of $\log k_1$ *vs.* p*H* is a straight line with a slope of -1 within experimental error. This behavior can be explained most simply by assuming that there is a kinetically important ionization on either the enzyme or substrate which is outside the p*H* range covered in the study. The pK_A of hydriodic acid has been reported to be approximately -9 (16, 17). Using this ionization constant it can be shown that iodide and not hydriodic acid must be the reacting species since, over the range of p*H* and iodide concentration covered in our study, the reaction of hydriodic acid would require a rate constant that exceeded the diffusion controlled limit by a factor of 10^7. Thus the kinetic results can be explained if HRP-II exists in two forms with the protonated form reacting much more rapidly than the unprotonated form with iodide. This reaction mechanism can be written in general terms as

$$[4] \qquad \begin{array}{ccc} & & \text{HP-II} + I^- \xrightarrow{k_2} \\ & K_p \downarrow\uparrow & \\ & & \text{P-II} + I^- \xrightarrow{k_3} \end{array}$$

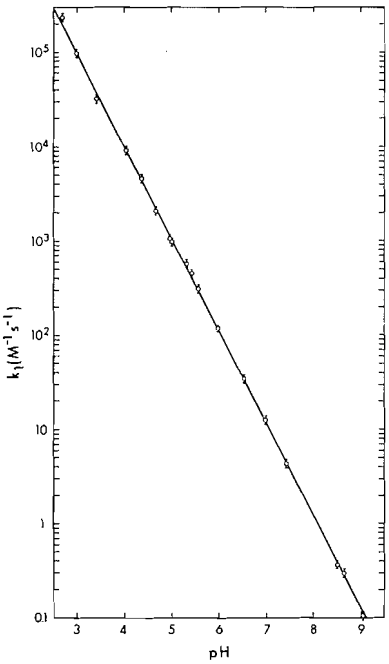

FIG. 2. Plot of log k_1 *vs.* p*H* for the reaction between HRP-II and iodide. The error limits drawn on the data points are based on an estimated standard deviation of ±10%. The solid line is the weighted linear least squares best fit line with a slope of −0.99 ± 0.006.

thus

$$[5] \qquad k_1 = \frac{k_2}{1 + \frac{K_p}{[H^+]}} + \frac{k_3}{1 + \frac{[H^+]}{K_p}}$$

Since the log k_1 *vs.* p*H* plot has a slope of −1 over the p*H* range of the study, we can conclude that (*1*) the term involving k_3 is negligible and (*2*) $K_p/[H^+] \gg 1$. The latter condition provides an estimate of the lower limit for K_p; the lowest p*H* of the study is 2.7 which means that K_p must be greater than 10^{-2} *M*. The maximum value of K_p must be such that k_2 does not exceed the diffusion-controlled limit ($10^{10}\ M^{-1}\ s^{-1}$). The combined effect of the above two conditions is to reduce eq. 5 to

$$[6] \qquad k_1 = \frac{k_2[H^+]}{K_p}$$

from which any point on the log k_1 *vs.* p*H* plot can be used to calculate that $k_2 = 10^8\ K_p$. Thus the maximum possible value of K_p would be 10^2 *M*. The minimum difference between k_2 and k_3 can be estimated at the highest p*H* on the log k_1 *vs.* p*H* plot. Assuming the minimum value for K_p of 10^{-2}, the relative concentrations of P-II and HP-II at p*H* 9.0 indicate that k_2 must be at least 10^7 times greater than k_3.

The log k_1 *vs.* p*H* plot for the iodide oxidation shows no indication of the kinetically important ionization with a pK_a value of 8.6, which exhibits a pronounced effect on the oxidation of ferrocyanide by Compound II (5).[2] If the rate determining steps for the reactions of the two substrates are the same, the influence of the ionization observed in the ferrocyanide reaction must result from interactions between HRP-II and substrate. The similarity in the overall acid catalysis for the two reactions suggests that the ionization characterized by K_p could exert its kinetic effect for all substrates of HRP-II. Further work involving different substrates is required to clarify the nature of these ionizations.

The authors are grateful to the National Research Council of Canada for financial support and to Dr. J. Critchlow for valuable discussion. R.R. acknowledges an NRCC Scholarship and a Government of Alberta Graduate Fellowship and M.E. an NRCC Postdoctoral Fellowship.

Molecular Beam Chemiluminescence. I. Kinetic Energy Dependence of the $NO + O_3 \rightarrow NO_2^* + O_2$ Reaction

ANTHONY E. REDPATH AND MICHAEL MENZINGER
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received April 23, 1971

The visible chemiluminescence of the $NO + O_3 \rightarrow NO_2^* + O_2$ reaction has been studied as a function of collision energy using a supersonic molecular beam of NO. The reaction threshold $E_0 = 3.00 \pm 0.45$ kcal/mol is found to lie significantly below the Arrhenius activation energy of $E_a = 4.18 \pm 0.3$ kcal/mol. This clearly demonstrates the basic difference between the two quantities.

La chimioluminescence visible de la réaction $NO + O_3 \rightarrow NO_2^* + O_2$, a été étudiée en fonction de l'énergie de collision en utilisant un rayon moléculaire supersonique de NO. Le seuil réactionnel, $E_0 = 3.00 \pm 0.45$ kcal/mol se trouve donc être relativement plus bas que l'énergie d'activation d'Arrhenius qui est de $E_a = 4.18 \pm 0.3$ kcal/mol. Ceci démontre clairement la différence fondamentale entre les deux quantités.

Canadian Journal of Chemistry, **49**, 3063 (1971)

Despite the importance which the total reaction crossection $\sigma(E)$ as a function of collision energy plays in theories of elementary gas phase kinetics (1, 2), there is only a small number of neutral–neutral processes (3) for which this function has been determined either by photochemical (4) or by beam (5, 6) methods.

Variable energy molecular beams (chemical accelerators (7)) appear to offer the most obvious means for measuring $\sigma(E)$, but the problem of detecting the total flux of neutral products is serious and has so far precluded a broad application of this approach (3). However, light emitted during a chemiluminescent reaction is relatively easy to detect and its intensity bears a close relationship to the excitation function $\sigma(E)$. The combination of molecular beam with photon detection techniques has been termed molecular beam chemiluminescence (8). Compared to the infrared chemiluminescence studies pioneered by Polanyi and co-workers (9), electronic chemiluminescence in molecular beams has the advantage that the initial energy distribution is not as easily degraded by subsequent collisions during the short radiative lifetime of the emitters (10^{-6} s or less). This is the case even at pressures considerably higher than those employed in the present work.

We wish to report here beam studies of the visible emission from the reaction (10)[1]

$$[1] \qquad NO + O_3 \rightarrow NO_2^* + O_2 \quad (\downarrow h\nu)$$

as a function of collision energy (11).[2] Reaction 1 has been studied in some detail thermally in a flow system (12) and the following Arrhenius

[1]The first beam study of this process and related ones was carried out by Harrison and Scattergood (10) using crossed thermal beams. Due to the low collision energy, no signal attributable to reaction 1 could be detected.

[2]Govers (11) studied the same reaction, which also occurs via a reaction channel leading to NO_2 in its electronic ground state, using a supersonic molecular beam, at collision energies up to 10 kcal/mol. NO_2 was detected by a mass spectrometric technique involving a scatter box but wall reaction seemed to seriously interfere with the beam reaction, and no definite conclusions were reached.

parameters are known: $A = (7.6 \pm 1.5) \times 10^{11}$ cm^3/mol s and $E_a = 4.18 \pm 0.3$ kcal/mol.

Experimental

A supersonic molecular beam (13) of NO (commercial grade (Matheson), purified by passage over Dry Ice cooled silica gel) seeded with varying amounts of hydrogen (Matheson, purity > 99.9%) for acceleration (14) of the heavy component was chopped, shot through a liquid nitrogen cooled, gold plated, scattering chamber, and monitored by an ionization gauge (15). Ozone was produced in a commercial ozonizer, selectively absorbed on Dry Ice cooled silica gel (11), and admitted to the scattering chamber through a Teflon needle valve. The scattering chamber pressure was measured by a conventional ionization gauge. The beam path within the scattering chamber was viewed by an RCA 6217 Photomultiplier. After lock-in amplification, the signal was measured as a function of the NO/H_2 mixing ratio, while the total nozzle pressure ($P_0 = 480$ Torr) and the scattering chamber pressure (typically $P_s = 3 \times 10^{-4}$ Torr) were kept constant. The kinetic energy of NO was computed from the formula (14)

$$[2] \quad E_{LAB} = \tfrac{1}{2} m_H V^2 = \frac{m_H}{m_M} \int_0^{T_0} C_{pM}\, dT$$

under the assumption of complete velocity equilibration of the two beam components during their isentropic expansion.

The formula expresses the final laboratory energy of the heavy component in terms of m_H, the molecular mass of the heavy component, m_M, the average mass of the gas mixture and C_M, the specific heat at constant pressure of the gas mixture. T_0 is the nozzle temperature. Considering the target molecules as stationary, the conversion to center of mass energies is straightforward. For an unambiguous analysis, a velocity selected beam should be used. Such work is now in progress and will be reported elsewhere.

Results and Discussion

Figure 1 gives the signal $S(E)$ as a function of collision energy. Since it was impractical to monitor the beam intensity with the ionization gauge, theoretical beam fluxes were obtained from the Valleau–Deckers theory (16). The normalized signal $S^n(E)$ is shown in Fig. 2.

As it turns out, the functional forms of $S(E)$ and $S^n(E)$ are similar, particularly up to a few kcal above threshold. As can be seen from $S^n(E)$, the levelling off of $S(E)$ above 8 kcal/mol is due to the intensity drop of the seeded beam at low NO/H_2 mixing ratios, and must not be mistaken for a similar trend in the reaction crossection. Care has to be taken in determining the threshold energy, in particular since the signal appears to approach zero asymptotically, and the measured

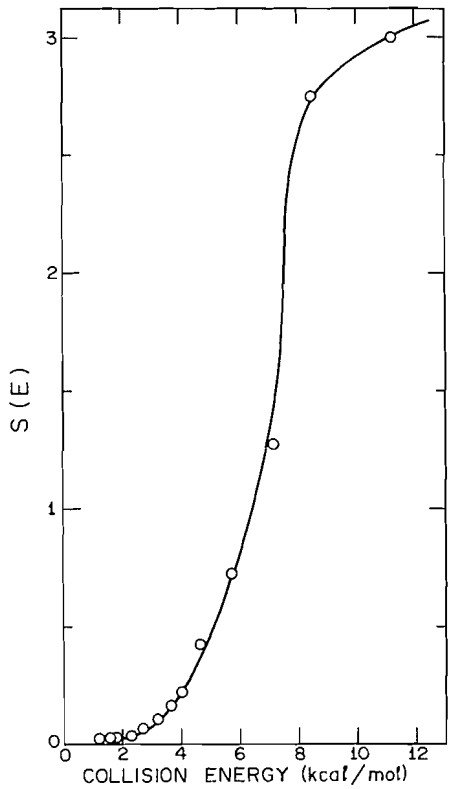

FIG. 1. Chemiluminescence signal (in arbitrary units) as function of the collision energy.

threshold depends sensitively on detection sensitivity and on the spread of collision energies. Our signal-to-noise ratio is $S/N \sim 75$ at 6 kcal/mol, and it decreases with decreasing energy (see insert to Fig. 2.). Subject to the finite detection sensitivity and to an assumed threshold law of the form

$$[3] \quad \sigma(E) = 0 \qquad \text{for } E < E_0$$
$$= C(E - E_0)^n \text{ for } E \geqslant E_0$$

where E_0 is the threshold and C and n are parameters, a least square fit of eq. 3 to $S^n(E)$ yields $E_0' = 2.20 \pm 0.25$ kcal/mol and $n = 2.00 \pm 0.15$. The true threshold E_0 is to be distinguished from the primed quantity E_0', which has not been corrected for the energy distribution in the beam. It has been observed (17) that contrary to theoretical expectations (18), the heavy component in a seeded beam can possess an energy spread of the order of RT_0, where T_0 is the nozzle temperature (300 °K in our case). Assuming this to be the case and taking the motion of the target

For personal use only.

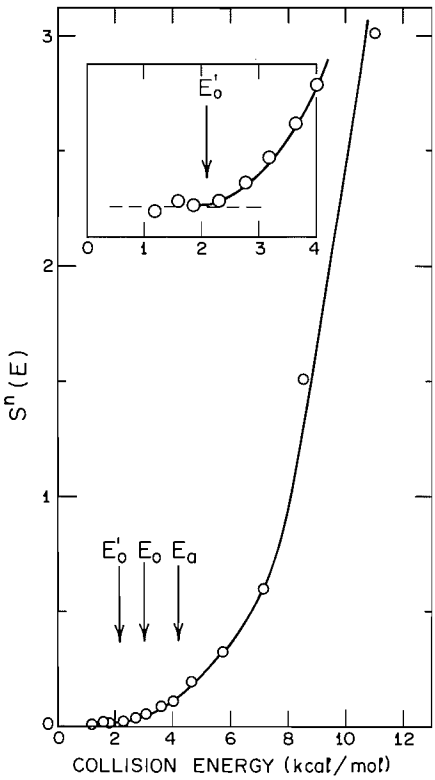

FIG. 2. Normalized signal (arbitrary units) as a function of the collision energy. The threshold region is shown enlarged in the insert. The constant background below 2 kcal is an apparative effect. E_0' is the onset of $S^n(E)$, E_0 is the true threshold energy, corrected for the energy distributions in beam and target, and E_a is the Arrhenius activation energy.

into account, the actual threshold E_0 will lie 0.8 ± 0.2 kcal/mol above the experimental value E_0'. A rigorous unfolding of the data has not been attempted due to our incomplete knowledge of the beam energy distribution. Subject to this restriction reaction 1 possesses a threshold at $E_0 = 3.00 \pm 0.45$ kcal/mol and the signal $S^n(E)$ rises above threshold according to the square ($n = 2.0 \pm 0.15$) of the excess energy.

While the meaning of the threshold energy E_0 is obvious, the Arrhenius activation energy E_a is not as simple a measure of microscopic collision energetics. It has been shown recently (19) that the activation energy is given by $E_a = \langle E^* \rangle - \langle E \rangle$ where $\langle E \rangle$ is the mean thermal energy of the reacting mixture ($\langle E \rangle = 3/2\ RT$ if internal degrees of freedom are neglected), and $\langle E^* \rangle$ represents the average energy of those collisions which lead to reaction. This latter quantity clearly depends on the threshold energy and on temperature as well as on the functional form of the reaction crossection $\sigma(E)$: if $\sigma(E)$ rises relatively quickly from threshold then $\langle E^* \rangle$ will lie close to E_0. On the other hand, if the reaction onset is very slow, as in the family of functions given by eq. 3 with $n > 2$, most of the reactive events occur at energies considerably in excess of E_0, and consequently the activation energy may greatly exceed the threshold. The considerable difference $E_a - E_0 = 1.18 \pm 0.75$ kcal is due primarily to the slow onset of the excitation function (19) and it clearly demonstrates the basic distinction between E_0 and E_a. For an excitation function $\sigma(E)$ of the form [3], an analytical expression for the activation energy E_a has been derived (20)

$$[4]\quad E_a = E_0 + RT\left\{(n + 1/2) - \frac{E_0}{E_0 + RT(n+1)}\right\}$$

The activation energies calculated from our E_0 and n values at the temperature limits and at the mean temperature of Clyne, Thrush, and Wayne's experiments (12*b*) are given in Table 1. The agreement between our computed activation energies and the experimental value of Clyne, Thrush, and Wayne is gratifying.

Furthermore, Table 1 shows that the computed activation energy carries a marked temperature dependence. A careful determination of the rate constant of reaction 1 over an extended temperature range should make this dependence suitable for direct experimental verification. In the above analysis we have tacitly substituted $S^n(E)$ for $\sigma(E)$. This seems justified since the thermal experiments (12) and the present study used the same detection technique.[3] $S^n(E)$ is to be regarded as

TABLE 1. Activation energy and temperature relationship

	E_a	
T (°K)	This work (kcal/mol)	Clyne–Wayne–Thrush (kcal/mol)

269	3.99 ± 0.48	4.18 ± 0.3
322	4.22 ± 0.50	

[3]Disregarding the somewhat different wavelength response of the photomultiplier used in (12*b*).

the partial crossection for formation of a detectable product.

To the best of the authors' knowledge this seems to be the first example of a reaction for which the threshold energy has been found to differ significantly from the activation energy.

Thanks are due to Professor J. M. Deckers who designed the vacuum chamber used in this work, and to Mr. K. Schaedlich, who helped during various stages of the experiment. Financial support by the National Research Council of Canada is gratefully acknowledged.

A Novel Nucleophilic Displacement of Benzoate by Sulfur During Thiation of 3-Deazauridine Tribenzoate[1,2]

MORRIS J. ROBINS
Department of Chemistry, The University of Alberta, Edmonton 7, Alberta

AND

BRUCE L. CURRIE, ROLAND K. ROBINS, AND ARTHUR D. BROOM
Departments of Chemistry and Biopharmaceutical Sciences, University of Utah, Salt Lake City, Utah

Received June 10, 1971

Thiation of 3-deazauridine tribenzoate [4-hydroxy-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-2-pyridone] (**1***a*) with phosphorus pentasulfide in moist β-picoline followed by debenzoylation gave 2-mercapto-1-(2-deoxy-β-D-arabinofuranosyl)pyridine-4-thione-$S_2 \rightarrow 2'$-cyclonucleoside (**2***b*). Thus, replacement of the heterocyclic oxygens by sulfur followed by a novel nucleophilic displacement of benzoate by mercaptide in the hot basic solution must have occurred.

L'action du pentasulfure de phosphore dans la β-picoline humide sur la déaza-3 uridine tribenzoate [hydroxy-4 (tri-2,3,5, *O*-benzoyl β-D-ribofuranosyl)-1 pyridone-2] (**1***a*) donne après débenzoylation le mercapto-2 (déoxy-2 β-D-arabinofuranosyl)-1 pyridine thione-4 cyclonucléoside-$S_2 \rightarrow 2'$ (**2***b*). Il en résulte qu'il s'est produit un remplacement des oxygènes hétérocycliques par du soufre, suivi d'un déplacement nucléophile du benzoate par un mercaptan, et ceci en solution basique chaude.

Canadian Journal of Chemistry, **49**, 3067 (1971)

Although several thio cyclonucleosides (heterocyclic $S \rightarrow$ sugar anhydronucleosides) have been synthesized by intramolecular nucleophilic displacement (1), sulfonyloxy or halogen leaving groups on the sugar have been employed (1, 2). For example, Wempen and Fox (1*c*) treated 3′-*O*-methanesulfonyl-2′-deoxy-2-thiothymidine with ethanolic triethylamine and obtained the corresponding $S_2 \rightarrow 3'$-cyclonucleoside.

Fox and coworkers (3) have reported the thiation of a number of benzoylated 4-ketopyrimidine nucleosides to give the corresponding 4-thione product using phosphorus pentasulfide in moist refluxing pyridine; and others (4) have used phosphorus pentasulfide in the higher boiling tetralin as solvent to introduce a 2-thione function into benzoylated 2-ketopyrimidine nucleosides. Indeed, benzoate is such a poor $B_{AL}2$ leaving group (5) it is not usually considered in nucleophilic displacement reactions except as a rather strong nucleophile in certain aprotic solvents (6) and the $B_{AL}1$ mechanism is highly unlikely unless stabilized carbonium ions result.

However, reaction of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-4-hydroxy-2-pyridone (2′,3′,5′-tri-*O*-benzoyl-3-deazauridine) (**1***a*) with phosphorus pentasulfide in refluxing moist β-picoline gave a 92% yield of crystalline product which gave analytical results compatible with replacement of two oxygens by sulfur and concomitant loss of

the elements of benzoic acid. Treatment of this product, **2***a*, with hot alcoholic ammonia gave a debenzoylated product in 38% yield in which no displacement of sulfur had occurred. Reaction of **2***a* with an aqueous alcohol solution of triethylamine at room temperature gave the same compound, **2***b*, in 70% yield. Analytical data for this free nucleoside, **2***b*, suggested replacement of two oxygens by sulfur and loss of water from the parent 3-deazauridine, **1***b*. In view of the formation of the $O_2 \rightarrow 2'$-arabinosyl cyclonucleoside of 3-deazauridine (7) by the phenyl carbonate procedure, the corresponding dithio structure, **2***b*, was considered. This 1-(2-deoxy-β-D-arabinofuranosyl)-2-mercaptopyridine-4-thione-$S_2 \rightarrow$ 2′-cyclonucleoside, **2***b*, had m.p. 241.5–242.5° (dec.); $[\alpha]_D^{27}$ −200° (*c* 1, 50% DMF:H_2O); u.v.$_{max}$ (p*H* 1) 339, 275, 240 nm (ε 19 800, 8610, 13 400); (p*H* 11) 340, 263, 238 nm (ε 29 100, 5520, 13 500).

Anal. Calcd. for $C_{10}H_{11}NO_3S_2$: C, 46.68; H, 4.31; N, 5.45; S, 24.92. Found: C, 46.80; H, 4.29; N, 5.49; S, 24.68.

The absence of ionizable groups on the pyridine base is consistent with the small p*H* variation of the u.v. spectra.

The n.m.r. spectrum of **2***b* was determined in DMSO-d_6 on a Varian HA100 spectrometer. Resonance positions and first order coupling constants are as follows: δ 3.46 (m, 2, $H_{5',5''}$), 4.09 (m, 1, $H_{4'}$), 4.34 (d of d, 1, $J_{3'-4'} = 3.8$, $J_{3'-2'} = 2.8$ Hz, $H_{3'}$), overlapped with 4.41 (d of d, 1, $J_{2'-3'} = 2.8$, $J_{2'-1'} = 6$ Hz, $H_{2'}$), 4.95 (t, 1, $J_{5'\text{-OH-}5',5''} = 5.3$ Hz, 5′-*OH*), 5.90 (d, 1, $J_{3'\text{-OH-}3'} = 4.3$ Hz, 3′-*OH*), 6.52 (d, 1, $J_{1'-2'} = 6$ Hz, $H_{1'}$), 6.97 (d of d, 1, $J_{5-3} = 1.8$, $J_{5-6} = 7$ Hz, H_5), 7.18 (d, 1, $J_{3-5} = 1.8$ Hz, H_3), 7.66 (d, 1, $J_{6-5} = 7$ Hz, H_6). This spectral pattern was very similar to that of 1-(β-D-arabinofuranosyl)-2-hydroxy-4-pyridone-$O_2 \rightarrow$ 2′-cyclonucleoside (7) (the oxygen analog of **2***b*) taking into account the downfield shift induced by a thione sulfur (8) and the upfield shift of alkyl thio *vs.* alkyl oxygen protons (2′-H).[3]

Confirmation of the above assignments was provided by double irradiation experiments. Irradiation of the doublet at δ 6.52 (1′-H) collapsed the low field region of the δ 4.41 (2′-H) multiplet and intense irradiation at δ 4.37 collapsed the δ 6.52 doublet (1′-H) to a sharp singlet and the δ 5.90 doublet (3′-OH) to a singlet. Irradiation of the δ 5.90 doublet (3′-OH) simplified the pattern in the high field region of the δ 4.34 (3′-H) multiplet and allowed first order analysis of the 2′ and 3′ couplings.

A further proof of the cyclonucleoside structure of **2***b* is the fact that addition of D_2O removed only the δ 4.95 triplet and the δ 5.90 doublet (hydroxyl hydrogens) and simplified the 5′,5″-protons absorption to a doublet of doublets centered at δ 3.49 ($J_{5'-4'}$ and $J_{5''-4'} = 5.8$ and 2.8 Hz) but did not reduce the δ 7.18 doublet (3-H) even after prolonged heating. This behavior is also observed in the oxygen cyclonucleoside analog which has a fixed bond structure and is in contrast to the complete loss of the 3-H signal from structures such as 3-deazauridine (**1***b*) which can undergo keto–enol tautomerism in the 3,4-(—CH=COH—) system of the heterocycle (7).

Thus, thiation of the 2- and 4-keto functions of the pyridine base followed by nucleophilic displacement of the 2′-benzoyloxy group by 2-thio anion in the hot picoline solution must have occurred. This novel displacement is of potential use in the preparation of deoxynucleosides (1*b*) in the pyridine series. It would be of interest to investigate the generality of this one-step procedure in other heterocyclic nucleoside systems.

Photoreactions of Nitroso Compounds in Solution.[1] XIX Stereochemistry of Nitrosamine Photoaddition to Olefin

Y. L. CHOW, S. C. CHEN, AND D. W. L. CHANG
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 25, 1971

The stereochemical course of the photoaddition of nitrosamines to a carbon–carbon double bond was shown to follow a free radical mechanism initiated by aminium radicals. The photoaddition to cyclohexene was highly stereoselective in which the addendum approached in *anti*-diaxial mode. Similar photoadditions to *cis*- and *trans*-2-butenes were less stereoselective, giving mixtures of the *erythro*- and *threo*-adducts, owing to the rotation of the carbon–carbon single bond in the intermediate stage.

Le processus stéréochimique de la photoaddition des nitrosamines sur une double liaison carbone–carbone a été établi comme obéissant à un mécanisme par radical libre initié par des radicaux aminium. La photoaddition sur le cyclohexène est hautement stéréosélective lorsqu'il y a approche *anti*-diaxiale du réactif. Des photoadditions semblables sur les butanes-2 *cis* et *trans* étaient moins stéréosélectives, et donnent des mélanges de produits d'addition *érythro* et *thréo*. Ceci est dû à la rotation de la liaison simple carbone-carbone dans l'étape intermédiaire.

Canadian Journal of Chemistry, **49**, 3069 (1971)

Although photoaddition of nitrosamine to olefin requires the presence of an acid (1–3), the reaction lacks characteristics of a carbonium ion or a radical chain mechanism. The studies by flash excitation (1) have now shown that the aminium radical derived from the singlet excited state of a nitrosamine is initiating the addition to olefinic bond. The attack of an aminium radical, though electrophilic in nature, has to occur via free radical process; a purely electrophilic addition leads to an intermediate which violates the octet rule at the nitrogen center. The stereochemical studies of nitrosamine photoaddition concur with the above conclusion and afford interesting comparisons with the addition reactions of other nitrosyl derivatives (4–7).

We have established that the primary product from the nitrosamine photoaddition is a *C*-nitroso compound (3). In order to preserve the stereochemistry of the primary adduct **1**, it was necessary to prevent tautomerization of **1** to oxime **2** and to divert the secondary reactions (3) to dimer **3** and *N*-nitrosohydroxylamine (**4**). Ideally the final product should be **4** since **3** can reversibly dissociate to **2** via **1** under the conditions of isolation. Photolysis conditions have been established whereby reasonable yields of **3** and/or **4** can be obtained (3).

When the photoaddition of *N*-nitrosodimethylamine to cyclohexene (>350 nm at −40°) was interrupted after half reaction, the *anti*-dimer of *trans*-1-nitroso-2-dimethylamino-cyclohexane (**3***a*, m.p. 115–116°) was isolated in 16% yield.[2] As it is well established that the dimerization process is spontaneous and extremely rapid (8), it is apparent that *trans*-**1***a* is formed predominantly, if not exclusively. Photoaddition with 3–4 *M* excess of the nitrosamine in a Pyrex apparatus at −40° gave *trans*-1-(*N*-nitrosohydroxylamino)-2-dimethylaminocyclohexane (**4***a*, m.p. 108–111°) in 35% yield.[3] Reduction with $LiAlH_4$, followed by acetylation, of either crude **3***a* or crude **4***a* gave the same single product, *trans*-1-acetamido-2-dimethylaminocyclohexane (**5***a*), m.p. 82–84°. The *trans*-configuration of **3***a*, **4***a*, and **5***a* was deduced from the magnitude of the coupling constant (J = 8–10 Hz) between the methine protons. Thus the stereochemistry of **1** was not disturbed during the transformation to **4**.

The photoaddition of *N*-nitrosopiperidine to *trans*-2-butene yielded *erythro*-**4***b* (m.p. 34–36°)

[1]For Part XVIII of this series, see ref. 1.

[2]The yield of **3***a* was *ca.* 35% based on the nitrosamine consumed. The n.m.r. of the crude reaction mixture showed major signals due to **3***a* and minor signals due to **2***a*: the estimated yield of **3***a* on the bases of the n.m.r. signals is *ca.* 75%. Signals expected for the corresponding *cis*-isomer of **3***a* were not present.

[3]Since nitrosohydroxylamines **4***a* and *b* are readily soluble in water, quantitative isolation has not been achieved. A comparison of the n.m.r. spectrum of crude **4** with that of pure **4** showed that the former was slightly contaminated with oxime **2**.

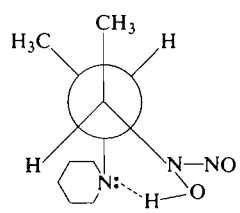
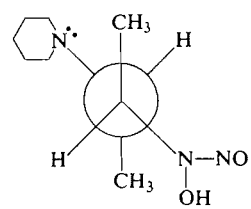
a R = $-(CH_2)_4-$
b R = $-CH_3$

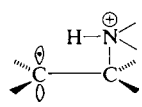
and *threo*-**4***b* (m.p. 54–55°) in 4:1 ratio. Similar photoaddition to *cis*-2-butene yielded the *erythro*- and *threo*-**4***b* in 4:6 ratio. The *erythro* and *threo* ratio of **4***b* was 4:6 from both *cis*- and *trans*-2-butenes if the photoreaction was performed using a Corex filter. Although the stereochemistry of the adducts could not be deduced from the coupling constants of their methine protons (J = 10.5 and 10 Hz, respectively), a decision on the stereochemistry was, however, possible by comparison of their chemical behavior. The coupling constants of the methine protons indicate that both *threo*-**4***b* and *erythro*-**4***b* are overwhelmingly populated with the conformers indicated in which intramolecular hydrogen bonding is favored only in *threo*-**4***b* but not in *erythro*-**4***b*. This physical difference is revealed in the following observations: (*i*) The chemical shift of the n.m.r. signal for OH in *threo*-**4***b* (τ −1.4) is independent of variation in concentration while that of *erythro*-**4***b* (τ 0.38) is not. (*ii*) *Erythro*-**4***b* forms a green Cu^{2+} complex instantaneously while *threo*-**4***b* does not. Dimer **3***b* obtained from these photoadditions was shown to be a mixture of all the possible combinations from *threo*- and *erythro*-**1***b*. Although the % yields of **3***b* and **4***b* are only fair a low stereoselectivity during the course of photoaddition is established. Further it has been ascertained that butenes are not isomerized during the photolysis by v.p.c. analyses.[4]



threo-**4***b*



erythro-**4***b*



6

Since the photoaddition of *N*-nitrosodimethylamine to 4-*t*-butylcyclohexene gives predominantly those oximes (corresponding to **2***a*) having axial dimethylamino group (10), the aminium radical approaches the olefinic bond preferentially from axial direction to give the radical cation intermediate **6** and the mode of the addition is *anti*-parallel in a stepwise process. The predominance of the *trans*-adduct to cyclohexene suggests that combination of radical cation **6** with NO (or the equivalent) is very rapid;[5] the process requires less activation energy than the inversion barrier of the cyclohexyl radical. The observed mixtures of *erythro*- and *threo*-isomers in the photoaddition to the butenes may result from comparable activation energies required for the radical combination step and the rotation about the C—C bond in **6**.

The authors wish to thank the National Research Council of Canada and the President's Research Fund of Simon Fraser University for financial support.

[4]It is pertinent to point out that a nitrosamine photolytically adds to dienes efficiently instead of isomerizing dienes by sensitization (9).

[5]The photoaddition of *N*-nitrosopiperidine to β-pinene gives the addition product without cleaving the four-member ring. This requires that the corresponding intermediate **6** has very short lifetime (unpublished result; H. H. Quon of this laboratory).

High Resolution Nuclear Magnetic Resonance Spectra of Bifluoride Ion and its Homologues

JOHN S. MARTIN AND FRED Y. FUJIWARA
Department of Chemistry, The University of Alberta, Edmonton 7, Alberta

Received June 1, 1971

The high resolution ^1H and ^{19}F nuclear magnetic resonance (n.m.r.) spectra of the four bihalide ions have been observed in aprotic solvents. The ^1H shielding is, in every case, 14 p.p.m. less than that in the related molecule. The spin–spin coupling in FHF^- is 120.5 ± 0.3 Hz.

Les spectres r.m.n. de ^1H et ^{19}F, à haute résolution, des quatre ions bihalogénures ont été pris dans des solvants aprotiques. Le blindage de ^1H est, dans tous les cas, inférieur de 14 p.p.m. à celui dans des molécules apparentées. Le couplage spin–spin dans FHF^- est de 120.5 ± 0.3 Hz.

Canadian Journal of Chemistry, **49**, 3071 (1971)

The bihalide anions, XHX^- (X = F, Cl, Br, I), which are stable in crystals and in solution, are chemical entities of unique structure. The hydrogen atom is located between the halogens. It is at the center of symmetry in FHF^- (1); in $ClHCl^-$ and $BrHBr^-$, its exact location appears to depend on its environment (2). The energies of formation from corresponding hydrogen halides and halide ions are in the range −15 to −40 kcal mol^{-1}. The three-center, hydrogen-bridged structure in these ions thus represents an extreme form of hydrogen bonding; its occurrence in such simple, symmetric systems makes their electronic structure one of fundamental interest.

The nuclear shieldings and couplings are sensitive probes of electronic structure. We have observed high resolution ^1H and ^{19}F spectra of the four bihalide ions, as tetraalkylammonium salts dissolved in aprotic solvents.

Tetrabutylammonium bifluoride was prepared from the bromide salt by exchange *in aquo* on a Dowex 21K fluoride column, then freeze dried, and pumped at 50°. On cooling, it gave waxy crystals of m.p. *ca.* 30°. In solution, this gave the ^1H spectrum shown in Fig. 1, at temperatures below +50° in CH_3CN and below −25° in CH_3NO_2. At higher temperatures, the multiplet structure broadened and collapsed, presumably because of interionic exchange.

The ^{19}F spectrum at low temperatures was a doublet, whose spacing, 120.5 ± 0.3 Hz, was equal to that in the ^1H spectrum. The spectra indicate that the two fluorines in FHF^- are symmetric with respect to the hydrogen, on the n.m.r. time scale.

The other bihalides were prepared in solution as follows. To a dilute solution of HCl, HBr, or HI was added the corresponding tetraalkylammonium halide salt. The single ^1H signal was observed to move to much lower shielding, as shown in Fig. 2. It remained sharp, thus indicating that, since it is exchanging rapidly between environments differing in shielding by *ca.* 14 p.p.m., the maximum residence times are of the order of a microsecond.

The high resolution ^1H and ^{19}F nuclear magnetic resonance (n.m.r.) spectra of the four bihalide ions have been observed in aprotic solvents. The ^1H shielding is, in every case, 14 p.p.m. less than that in the related molecule. The spin–spin coupling in FHF^- is 120.5 ± 0.3 Hz.

Les spectres r.m.n. de ^1H et ^{19}F, à haute résolution, des quatre ions bihalogénures ont été pris dans des solvants aprotiques. Le blindage de ^1H est, dans tous les cas, inférieur de 14 p.p.m. à celui dans des molécules apparentées. Le couplage spin–spin dans FHF^- est de 120.5 ± 0.3 Hz.

Canadian Journal of Chemistry, **49**, 3071 (1971)

The bihalide anions, XHX^- (X = F, Cl, Br, I), which are stable in crystals and in solution, are chemical entities of unique structure. The hydrogen atom is located between the halogens. It is at the center of symmetry in FHF^- (1); in $ClHCl^-$ and $BrHBr^-$, its exact location appears to depend on its environment (2). The energies of formation from corresponding hydrogen halides and halide ions are in the range −15 to −40 kcal mol^{-1}. The three-center, hydrogen-bridged structure in these ions thus represents an extreme form of hydrogen bonding; its occurrence in such simple, symmetric systems makes their electronic structure one of fundamental interest.

The nuclear shieldings and couplings are sensitive probes of electronic structure. We have observed high resolution ^1H and ^{19}F spectra of the four bihalide ions, as tetraalkylammonium salts dissolved in aprotic solvents.

Tetrabutylammonium bifluoride was prepared from the bromide salt by exchange *in aquo* on a Dowex 21K fluoride column, then freeze dried, and pumped at 50°. On cooling, it gave waxy crystals of m.p. *ca.* 30°. In solution, this gave the ^1H spectrum shown in Fig. 1, at temperatures below +50° in CH_3CN and below −25° in CH_3NO_2. At higher temperatures, the multiplet structure broadened and collapsed, presumably because of interionic exchange.

The ^{19}F spectrum at low temperatures was a doublet, whose spacing, 120.5 ± 0.3 Hz, was equal to that in the ^1H spectrum. The spectra indicate that the two fluorines in FHF^- are symmetric with respect to the hydrogen, on the n.m.r. time scale.

The other bihalides were prepared in solution as follows. To a dilute solution of HCl, HBr, or HI was added the corresponding tetraalkylammonium halide salt. The single ^1H signal was observed to move to much lower shielding, as shown in Fig. 2. It remained sharp, thus indicating that, since it is exchanging rapidly between environments differing in shielding by *ca.* 14 p.p.m., the maximum residence times are of the order of a microsecond.

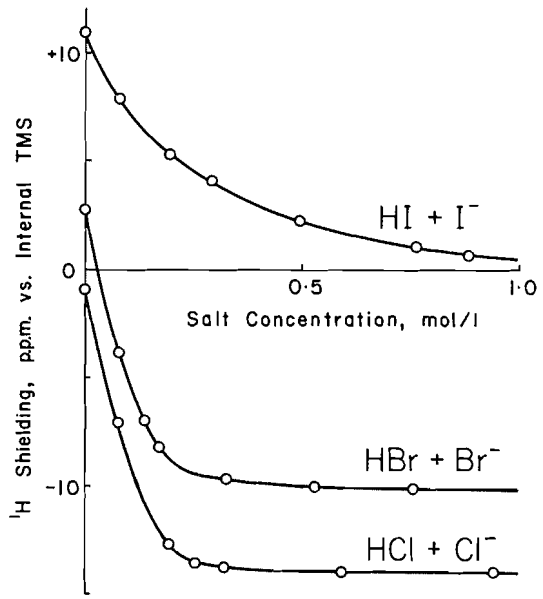

FIG. 2. Effect, on the ^1H shielding of 0.2 *M* hydrogen halide in symmetric tetrachloroethane, of added tetra-*n*-butylammonium halide.

It is evident from Fig. 2 that strong 1:1 complexes are formed between HCl and Cl^-, and between HBr and Br^-. The limiting shieldings, in excess salt, are taken as those of the bihalide ions, $ClHCl^-$ and $BrHBr^-$. It is evident that the iodide–HI complex is much weaker. The shielding of IHI^- was deduced by Benesi–Hildebrand–Scott analysis (3).

The observed ^1H shieldings are summarized in Table 1. To *ca.* 0.3 p.p.m., they are insensitive to the nature of the cation or the solvent, to concentration, and to temperature in the range studied (−80 to +70°). The absolute shieldings were determined using that of CH_4 (4).

It is remarkable that the decrease in ^1H shielding when a bihalide ion is formed happens to be nearly the same in all cases: about 14 p.p.m. This is an exceptionally large hydrogen bond shift, and represents a significant fraction of the total absolute shielding.

The ^1H shieldings may be accounted for by a simple "atom in a molecule" model, which provides a good description of the shieldings in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the hydrogen halides (7). In these cylindrically symmetric systems, it can be shown (8) that all significant contributions to the ^1H shielding increase with increasing 1s orbital population. The smaller shielding in the bihalide ion thus indicates that it has greater charge separation, in the sense $X^-H^+X^-$, than the molecule. This is in accord with recent s.c.f.-m.o. calculations (9), and with the nuclear quadrupole resonance (n.q.r.) spectra of $ClHCl^-$ and HCl (10).

The independent-electron m.o. model (11) predicts the opposite charge shift: greater 1s population in the ion than in the molecule. This presumably is a consequence of neglect of electron–electron repulsions, which *are* evaluated in the s.c.f. model. A very simple electrostatic picture of bihalide formation accounts for the charge shifts in an entirely natural way. As the halide ion, X^-, approaches the positive (H) region of the HX molecule, electronic charge is repelled out of the hydrogen orbital.

The ^{19}F shielding in bifluoride ion is somewhat temperature dependent, increasing from +67 to +71 p.p.m. *vs.* external neat CF_3COOH as the temperature increases from −20 to +70°. It agrees well with previous indirect determinations (12). Since the bifluoride ^{19}F shielding is intermediate between those of F^- and HF, it is also consistent with an electrostatic model of the FHF^- structure.

The H—F coupling in bifluoride, 120.5 ± 0.3 Hz, is about one fourth of that in the HF molecule, 521 Hz (13). This is also consistent with a smaller 1s population in the ion. A s.c.f.-m.o. calculation has already been published (14). While it failed by about 30% to fit the observed values of the couplings in HF and FHF^-, it nevertheless predicted with remarkable accuracy that they would be in the ratio 4:1.

Sur l'aptitude à l'extension du noyau pipéridique en fonction de la substitution de l'atome d'azote: réaction du diazométhane avec quelques pipéridones-4 et désamination nitreuse des aminométhyl-alcools correspondants[1]

H. FAVRE, Z. HAMLET,[2] R. LANTHIER,[3] ET M. MÉNARD[4]

Département de chimie, Université de Montréal, Montréal, Québec

Recu le 20 mai 1970[5]

L'aptitude à l'extension, mesurée par le rapport cétone agrandie/époxyde, varie considérablement en série pipéridique en fonction du substituant porté par l'atome d'azote. Elle est sensiblement la même lors de l'action du diazométhane sur les pipéridones-4 et de la désamination nitreuse des amino-alcools correspondants. Les valeurs sont de 0.01–0.1 pour un groupe phénylsulfonyle, de l'ordre de 0.3–0.6 pour un groupe benzoyle, et légèrement supérieures à 1 pour un groupe benzyle. Des effets électroniques (effets d'induction et de champ) sont à l'origine de ces différences. Le parallélisme entre les deux réactions indique que l'attaque nucléophile du diazométhane sur le groupe carbonyle peut fort bien engendrer la cétone agrandie et l'époxyde.

Aptitude to ring expansion in the piperidine series, measured by the ratio of ring expanded ketone to epoxide, varies considerably according to the nitrogen atom substituent. This ratio is essentially the same in the case of the reaction of diazomethane on 4-piperidones and the nitrous acid deamination of the corresponding aminoalcohols. The values of the ratio are 0.01–0.1 for a phenylsulfonyl group, of the order 0.3–0.6 for a benzoyl group and slightly greater than 1 for a benzyl group. Electronic effects (inductive and field effects) are the cause of these differences. Parallels between the two reactions indicate that nucleophilic attack of diazomethane on the carbonyl group can lead to the ring expanded ketone and the epoxide.

Canadian Journal of Chemistry, 49, 3075 (1971)

D'une manière générale, l'action des diazoalkanes sur les cyclanones **1** conduit à une extension de cycle (1, 2); il en va de même de la désamination nitreuse des aminométhyl-1 cyclanols **3** (1, 3). Dans les deux cas un époxyde spiranique **5** se forme, en quantité variable. Divers facteurs affectent le rapport cétone agrandie/époxyde; parmi ceux-ci, la présence d'un groupe électronégatif, tel que —OH, —Cl en α du groupe carbonyle, augmente la proportion d'époxyde. On peut ainsi s'attendre à ce que les hétérocycles saturés du type **1** (qui ont un groupe électronégatif en β du carbonyle) donnent à leur tour des proportions plus grandes d'époxyde que la tert-butyl-4 cyclohexanone: c'est en effet le cas (tableau 1) de la *p*-toluènesulfonyl-1 pipéridone-4 (**1***f*) (4), de la benzyl-1 pipéridone-4 (**1***b*) (5, 6), de la thiacyclohexanone-4 (**1***h*) (7); du côté des amino-alcools, la formation d'époxyde est nettement prédominante dans le cas de **3***g* (7); elle n'est pas connue pour l'aminoalcool **6** qui conduit à 45% de cétone agrandie (8). Ce mémoire traite d'une étude comparée de l'aptitude à l'extension des pipéridones-4 **1***b–e* et des amino-alcools correspondants **3***b*, *c*, et *e*.

**Séparation incomplète des composés de réaction.

Nous avons obtenu les phénylsulfonyl-1 et *p*-nitrobenzoyl-1 pipéridones-4 (**1***e* et *c*) en traitant le chlorhydrate de pipéridone-4 par les chlorures d'acides correspondants. Les benzoyl-1 et benzyl-1 pipéridones-4 sont connues (5, 9); la synthèse de la cétone **3***c* décrite par Morosawa peut être améliorée pour porter le rendement global de 30 à 69.5%.

Les amino-alcools **3***a–c* et *e* furent préparés par la voie classique: 1 → 2 → 3. La condensation de la cyclohexanone avec le nitrométhane s'effectue avec un rendement de 75% en présence d'une quantité équimoléculaire d'éthylate de sodium (10), tandis que le rendement baisse à 45% en présence d'une quantité catalytique du même composé (11). En présence d'une quantité équimoléculaire de méthylate de sodium, les cétones **1***c* et *e* conduisent aux nitro-alcools correspondants, avec des rendements respectifs de 66 et 85%. Seule une quantité catalytique de méthylate de sodium permet d'obtenir le nitro-alcool **1***b*: le rendement est alors de 85%.

Pour la réduction des nitro-alcools en amino-alcools nous avons mis en œuvre une méthode fort peu utilisée (12): les agents de réduction sont le sulfate ferreux et le fer en poudre, en milieu aqueux, neutre. Cette méthode permet de réduire quantitativement le nitrométhyl-1 cyclohexanol-1 (**2***a*) en amino-alcool **3***a*. Cette méthode permet d'obtenir, avec des rendements de 91 et 97% les amino-alcools **3***c* et *e*; elle ne s'applique pas au nitro-alcool benzylé **3***b*: dans ce cas, une réduction par le zinc dans l'acide acétique donne l'amino-alcool attendu. Les trois amino-alcools pipéridiques ont été oxydés en cétone par l'acide périodique, ce qui établit bien leur structure. Les amino-alcools **3***b* et *c* sont huileux et n'ont pas donné de sels cristallisés; ils ont été caractérisés par leurs spectres de r.m.n. et i.r.

Nous avons, pour fin de comparaison de l'action du diazométhane et de la désamination nitreuse, choisi les modes opératoires utilisés respectivement par Barbier (13), diazométhane engendré *in situ*, par décomposition de la nitrosométhylurée dans du méthanol en présence d'hydroxyde de potassium et par Tchoubar (14), acide acétique aqueux 25%. Au début de nos travaux, nous pensions que ces deux modes de réaction présentaient des analogies réelles, en ce que des essais préliminaires sur la cyclohexanone et sur l'amino-alcool correspondant indiquaient que la cétone agrandie représentait de 60 à 70% du mélange réactionnel, tandis que l'époxyde se formait à raison de 10–15%. Nous savons aujourd'hui, après des analyses poussées par chromatographie en phase gazeuse,[6] que ces deux modes opératoires ne présentent plus le parallélisme étroit du début (tableau 1). Ce qui était important, de toute façon, c'était de comparer le comportement des cétones et des amino-alcools dans des conditions identiques. Il s'est avéré que les méthodes choisies

[6]Le dosage de composés issus de la désamination a été publié (15); nous décrivons en détail les résultats de notre étude sur la formation des époxydes en série cyclohexanique à partir des cétones par l'action du diazométhane (39).

h X = S

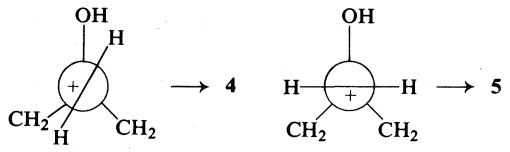
permettaient de telles comparaisons, puisque les cétones et les amino-alcools ont tous réagi dans les conditions imposées, et ceci avec des rendements du même ordre de grandeur. Les résultats sont rapportés au tableau 1.

Tous les pourcentages du tableau 1, à l'exception de ceux correspondant à la série cyclohexanique, correspondent à des composés isolés, soit à l'état pur, soit sous forme de dérivés. Les époxydes présentent, dans les spectres de r.m.n., le singulet caractéristique du groupe  ; les cétones agrandies montrent l'abaissement de la fréquence C=O en i.r. caractéristique de l'agrandissement de cycle; de plus, les époxydes ont été synthétisés par la méthode de Corey et Chaykowsky (16) qui conduit avec des rendements supérieurs à 90% aux époxydes pipéridiques **5***b–e*. A la suite des sérieuses difficultés rencontrées dans le dosage du mélange issu de l'action du diazométhane avec la benzoyl-1 pipéridone-4, nous avons étudié cette réaction sur la *p*-nitrobenzoyl-1 pipéridone-4; tous les composés de réaction étant cristallins, le dosage fut plus facile et corrobore celui obtenu dans la série benzoylée. Nous n'avons jamais pu mettre en évidence la présence de l'époxyde **5***e* dans la série benzylée, tant à partir de la cétone[7] que de l'amino-alcool; dans des conditions expérimentales différentes, Morosowa (6) a réussi à l'isoler; ses résultats et les nôtres concordent de façon satisfaisante en ce qui concerne la cétone agrandie. Nous avons cherché également à mettre en évidence la formation d'azacyclo-octanones par une réaction ultérieure du diazométhane avec la première cétone agrandie mais sans succès; en série cyclohexanique, il ne se forme que très peu d'ailleurs de cétones supérieures à la cycloheptanone (2–3%), dans les conditions choisies pour la réaction. Trois points ressortent nettement de cette étude: (*1*) la formation d'époxyde peut être prépondérante, même exclusive dans la réaction de Tiffeneau–Demjanov et dans l'action du diazométhane appliquées à la série hétérocyclique; les observations d'Overberger et Katchman (7) en série thiannique peuvent ainsi être généralisées; (*2*) le parallélisme étroit entre l'aptitude à l'extension dans les deux réactions; (*3*) la bonne réactivité des cétones hétérocycliques dans les conditions expérimentales choisies et la dépendance de l'aptitude à l'extension de ces conditions expérimentales (les cétones **1***e* et *f* ont été soumises à des conditions expérimentales très différentes, tableau 1).

Le mécanisme de la désamination nitreuse a été établi à la suite de nombreux travaux (17–21). L'étape déterminante est le passage de l'ion diazonium au carbocation; les groupes antipériplanaires par rapport à l'ion diazonium ne participent pas à la formation du carbocation; les composés formés dépendent des vitesses relatives de réaction et de rotation du carbocation (**7**

[7]L'époxyde peut réagir avec l'hydroxyde de potassium pour donner un hydroxy-éther (39); une faible concentration en base et une courte durée de réaction tendent à supprimer cette réaction secondaire. Casy et Birnbaum (41) ne rapportent également que la cétone agrandie.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

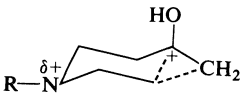


7 8

et **8** qui donnent **4** et **5**). Un groupe électronégatif, dans le cas des molécules **3***c*, *e*, et *f*, défavorisera la formation de la cétone agrandie en ralentissant la migration de la liaison C—C, celle-ci devant être fortement polarisée dans le sens du groupement électronégatif.

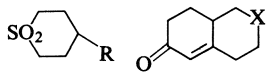
Une autre façon de considérer l'interaction entre le groupe électronégatif et le centre positif de réaction est de tenir compte de la distance qui sépare les points positifs (ou les dipôles) (22) au cours de l'extension de cycle et de la formation de l'époxyde; les charges positives sont plus rapprochées dans l'extension (**9***b*) que dans la formation de l'époxyde (**9***a*), défavorisant ainsi l'extension.[8]

9*a*



9*b*

Cette interaction entre charges positives se manifeste dans les amino-alcools, dont la basicité diminue en allant de la série cyclohexanique, à la série pipéridique et finalement à la série thiannique (tableau 2). Cette diminution de basicité, attribuable à un effet de champ, se retrouve en série pipérazinique (23). On connait d'autres exemples d'intervention d'un groupe sulfonyle. Le bioxyde d'amino-4 thianne (**10***a*) est nettement moins basique que l'amino-1 cyclohexane (24). Une interaction transannulaire se manifeste par un effet hypsochrome dans la série **11**, lorsque X passe de CH_2 à SO_2 (25, 26): il s'agit d'une opposition de deux charges positives, l'atome de soufre d'un côté, la structure de résonance $+C—C{=}C—O^-$ de l'autre. Le groupe sulfonyle empêche l'estérification de l'amino-alcool **10***b* (24). Finalement, le groupe sulfonyle retarde la solvolyse du système $C_6H_5SO_2(CH_2)_n C(CH_3)_2Cl$ par rapport à $H—CH_2—C(CH_3)_2Cl$: l'effet du groupe électronégatif s'atténue lorsque *n* passe de 1 à 2 à 3 (27). Cette dernière étude est intéressante par le fait qu'elle montre clairement, par une comparaison des groupes $=SO_2$ et $=SO$, que le groupe $=SO_2$ ne participe pas du tout à la réaction par ses oxygènes, comme le fait le groupe $=SO$ qui, en ce faisant, accélère la réaction (voir aussi (28)).



10 **11**

a R = NH_2
b R = $NHCH_2CH_2OH$

Le cas des amino-alcools comportant un deuxième groupe aminé basique soit **3***b* et **6** est intéressant. On se serait attendu, en raison de la charge positive sur l'azote tertiaire, en milieu acide, à une forte proportion d'époxyde dans ces désaminations, puisque la basicité d'une pipérazine est très faible lorsqu'un premier groupe NH est protoné (23) (tableau 2). Comme l'extension est prédominante, il faut admettre que la nature des interactions entre charges positives s'est profondément modifiée: l'apparition du carbocation pourrait modifier l'équilibre sel/base tertiaire; il se pourrait aussi que des interactions par ponts hydrogènes entre le sel d'ammonium de l'amine tertiaire et le groupe hydroxyle (par l'intermédiaire du solvant HOH (29, 30)) influent sensiblement sur l'aptitude du groupe hydroxyle à former un époxyde.

Nous n'avons jusqu'ici considéré que le seul effet électronégatif de l'hétéro-atome dans l'interprétation de l'aptitude à l'extension. On sait qu'il existe aussi des effets conformationnels (15, 31). D'une manière générale (32) on admet que la

SCHÉMA 1

conformation d'une cétone hétérocyclique est semblable à celle de la cyclanone correspondante. Dans le but d'obtenir des renseignements sur des déformations possibles des cétones hétérocycliques **1***b*, *c*, et *e*, nous avons examiné les constantes de dissociation de leurs cyanhydrines (tableau 3). Elles sont voisines les unes des autres et légèrement supérieures à celle de la cyclohexanone. La différence est toutefois trop petite pour expliquer la formation prépondérante d'époxyde: des substituants en position 4 de la cyclohexanone et de l'amino-alcool correspondant n'affectent pas le rapport cétone agrandie/époxyde (2, 3). Par ailleurs, nous avons, en série cyclohexanique, détecté un effet conformationnel dans la réaction de Tiffeneau–Demjanov (15); cet effet a été observé également en série décalinique (31). Il se produit plus d'époxyde lorsque le groupe —CH_2NH_2 est équatorial que lorsqu'il est axial. La conformation équatoriale ou axiale du groupe —CH_2—NH_2 dans les amino-alcools hétérocycliques est difficile à préciser. D'une part, la valeur d'énergie conformationnelle du groupe =$C(OH)CH_3$ n'est pas égale à la somme des énergies conformationnelles des substituants OH et CH_3 pris séparément (35, 36). D'autre part, un substituant fonctionnel électronégatif, tel que carbonyle, augmente la proportion d'isomère ayant un groupe OH axial lorsqu'il est situé en position 4 dans un cyclohexanol (37). Il faut relever cependant que l'aminométhyl-1 cyclohexanol-1 réagit entièrement comme amino-alcool à groupe —CH_2NH_2 équatorial (15) dans des conditions identiques de réaction. Avec aussi un groupe —CH_2NH_2 équatorial[9] (formule spatiale **3**), nous nous trouverions dans les conditions les plus favorables à la formation de l'époxyde.

En ce qui regarde l'action du diazométhane sur les cétones hétérocycliques, l'explication électronique donnée pour la réaction de Tiffeneau–Demjanov s'applique dans l'hypothèse d'une attaque nucléophile du diazométhane sur la cétone selon la voie 2 du schéma 1.

La question du mécanisme de réaction n'est toutefois pas tranchée. Pour Bradley *et al.* (38) les voies 1 et 2 sont possibles, la voie 2 étant favorisée en présence de grandes quantités d'alcool. Nous montrons dans un autre article (39) que la *tert*-butyl-4 cyclohexanone réagit bien dans ce sens. Pour Gutsche et Bowers (40), la voie 2 ne conduirait qu'à la cétone agrandie, l'époxyde résultant entièrement de la voie 1. Le fait que la désamination nitreuse conduise aux époxydes, allié à celui que la réaction se fait dans du méthanol pur, milite en faveur de la voie 2. De plus, les travaux de Henbest (22) indiquent que la formation d'une charge positive en γ de l'hétéroatome dans la voie 1 est défavorisée par rapport à la formation de l'ion diazonium ou du carbocation, lorsque X est égal à C_6H_5—SO_2—N= et

[9]Dans la formule spatiale **3**, les groupements C_6H_5-CO= et $C_6H_5SO_2$— adopteraient une conformation comprise entre une conformation plane (due à la résonance (33)) et une conformation équatoriale (dans la méthyl-4 benzoyl-1 pipéridine (34), le groupe benzamide se trouve de préférence en conformation non plane).

For personal use only.

C_6H_5—CO—N=; l'inverse sera vrai, par contre lorsque X est égal à C_6H_5—CH_2—N=; il est raisonnable, dès lors, d'envisager dans ce dernier cas que les deux voies 1 et 2 sont possibles.

Conclusion

Ce travail établit clairement que l'aptitude à l'extension des cétones hétérocycliques à six chaînons est limitée et fortement dépendante de la nature du substituant porté par l'atome d'azote dans les pipéridones-4.

Partie expérimentale[10]

1 Synthèse des cétones

*1.1 Benzyl-1 pipéridone-4 (**1b**)*

La synthèse de Morosawa (5) est améliorée par adjonction d'éthanol à la condensation de la benzylamine avec l'acrylate d'éthyle et l'utilisation d'une plus grande quantité d'acrylate d'éthyle (50 g d'amine, 100 ml d'éthanol anhydre et 200 g d'ester); le rendement est ainsi de 92%. L'utilisation d'hydrure de sodium, comme agent de cyclisation, augmente le rendement à 69.5%.[11]

*1.2 Benzoyl-1 pipéridone-4 (**1c**)*

Préparée selon (9), p. de f. 50–52°. Spectre i.r.: (CCl_4) 1723 (C=O), 1648 cm^{-1} (NC=O).

*1.3 p-Nitrobenzoyl-1 pipéridone-4 (**1d**)*

Benzoyle-1 carbéthoxy-3 pipéridone-4 (100 g) (9) sont chauffés à reflux pendant 2 h avec 400 ml d'acide chlorhydrique 6 *N*. L'acide benzoïque libéré est extrait à froid par de l'éther et la solution aqueuse est évaporée sous vide à une température inférieure à 60°. Le résidu est dissous dans 30 ml d'eau et transvasé dans un ballon à trois tubulures de 2 l surmonté d'un réfrigérant, d'un agitateur et d'une ampoule à addition. A cette solution, on ajoute 250 ml de chloroforme et, en agitant, 40 g de carbonate de sodium anhydre. Par l'ampoule, on laisse tomber lentement 67 g de chlorure de *p*-nitrobenzoyle dissous dans 300 ml de chloroforme. En agitant, on chauffe à reflux pendant 4 h.

Après ce temps, l'excès de chlorure de *p*-nitrobenzoyle est estérifié en refluant la solution avec 20 ml d'éthanol pendant 30 min. Le sel précipité est dissous dans le minimum d'eau glacée et décanté de la couche chloroformique; celle-ci est lavée successivement par Na_2CO_3 5% glacé, H_2O et HCl 5% et séchée sur Na_2SO_4. Par évaporation du solvant, on obtient un résidu huileux qui cristallise par addition d'éther. La recristallisation du résidu dans le butanol normal donne 63 g (70%) de **1***d* sous forme d'aiguilles incolores fondant à 118.5–119°. Spectre i.r.: (CCl_4) 1723 cm^{-1} (C=O).

Anal. calc. pour $C_{12}H_{12}O_4N_2$: C, 58.06; H, 4.87; N, 11.28. Trouvé: C, 57.76; H, 4.68; N, 11.31.

La 2,4-dinitrophénylhydrazone recristallisée dans le solvant mixte nitrométhane–éthanol, présente un p. de f. de 123–125°.

Anal. calc. pour $C_{18}H_{16}O_7N_6$: N, 19.22. Trouvé: N, 19.13.

L'oxime cristallise du mélange éthanol–eau sous forme d'aiguilles incolores fondant à 203.5–204°.

Anal. calc. pour $C_{12}H_{13}O_4N_3$: N, 15.96. Trouvé: N, 15.91.

*1.4 Phénylsulfonyl-1 pipéridone-4 (**1e**)*

La benzoyl-1 carbéthoxy-3 pipéridone-4 (100 g), obtenue selon McElvain et McMahon (9) est chauffée à l'ébullition à reflux avec 400 ml de HCl 6 *N* pendant 6 h. Après extraction de l'acide benzoïque par de l'éther, la solution est évaporée jusqu'à sec. Le résidu est dissous dans 40 ml d'eau on ajoute 400 ml de $CHCl_3$, 70 g de Na_2CO_3 finement pulvérisé et finalement sous bonne agitation et par petites portions 80 g de chlorure de benzènesulfonyle. Le mélange est agité durant 2 h à 25°, puis chauffé à l'ébullition pendant 2 h. Après filtration, la couche chloroformique est décantée, lavée avec HCl 5%, NaOH 5% puis avec une solution saturée de NaCl. Par distillation du solvant, on obtient un résidu rouge brun qui est repris par du tétrachlorure de carbone. Après traitement par du noir animal, on obtient la *phénylsulfonyl-1 pipéridone-4* (**1e**) sous forme de paillettes incolores, p. de f. 121–122° (rendement 74%). Spectre i.r.: (CCl_4) 1721 cm^{-1} (C=O).

Anal. calc. pour $C_{11}H_{13}O_3NS$: C, 55.21; H, 5.47; N, 5.85. Trouvé: C, 55.32; H, 5.48; N, 5.83.

L'oxime, cristallisée deux fois dans un mélange de méthanol et d'eau, fond à 172–173°.

Anal. calc. pour $C_{11}H_{14}O_3N_2S$: C, 51.95; H, 5.55; N, 11.02. Trouvé: C, 52.11; H, 5.92; N, 10.90.

La dinitro-2,4 phénylhydrazone, cristallisée dans l'éthanol, fond à 197°.

Anal. calc. pour $C_{17}H_{17}O_6N_5S$: C, 48.45; H, 4.54; N, 16.62. Trouvé: C, 48.74; H, 4.22; N, 16.78.

2 Nitro-alcools

*2.1 Benzyl-1 nitrométhyl-4 pipéridol-4 (**2b**)*

On dissout 40 g de benzyl-1 pipéridone-4 dans 75 ml de méthanol. On ajoute à cette solution 17.6 g de nitrométhane et 25 ml de méthanol dans lequel on a dissous auparavant 0.5 g de sodium. La solution résultante est refroidie pour quelques minutes puis laissée à la température ordinaire pendant 28 h. On verse le mélange réactionnel dans 400 ml d'eau glacée; il se dépose une huile que l'on extrait par du chloroforme. La solution est acidifiée par de l'acide acétique, puis rendue alcaline par addition d'une solution de $NaHCO_3$. La solution aqueuse est de nouveau extraite par du chloroforme. Les couches organiques sont réunies, lavées par une solution de $NaHCO_3$ et à l'eau et séchée sur Na_2SO_4 anhydre. Par

[10]Les points de fusion (p. de f.) ont été déterminés en tubes capillaires avec un thermomètre étalonné avec des substances pures de p. de f. connu. Les spectres i.r. ont été déterminés, en solution, au moyen d'un appareil Beckman IR 8, optique NaCl; en émulsion dans le Nujol, au moyen d'un appareil Perkin–Elmer modèle 112, double passage et simple faisceau, optique de chlorure de calcium. Les spectres de r.m.n. ont été enregistrés au moyen d'un appareil JEOL, 60 MHz, en solution dans le tétrachlorure de carbone, avec référence au tétraméthylsilane. Les analyses centésimales ont été effectuées par Geller Laboratories, Hackensack, New Jersey et M. Manser, Herrliberg.

[11]Une synthèse récente (42) conduit au chlorhydrate de benzyl-1 éthoxycarbonyl-3 pipéridone-4 avec un rendement de 52% à partir de l'amine.

For personal use only.

évaporation du solvant, on obtient un résidu huileux qui cristallise par addition d'éther de pétrole (p.éb. 20–40°), 44.0 g (85%). La cristallisation dans l'éther de pétrole (p.éb. 65–110°) donne de très longues aiguilles incolores du nitro-alcool **2***b*, p. de f. 79°.

Spectre i.r. (CCl_4) 3590 et 3340 (—OH), 1540 et 1380 cm^{-1} (—NO_2). Spectre de r.m.n. (CCl_4) δ 7.3 (s, 5H, C_6H_5—), 4.16 (s, 2H, —CH_2—NO_2), 3.5 (s, 2H, —CH_2—N), 2.86 (s, 1H, —OH), 2.5 (m, 4H, —CH_2— adjacents à N du cycle), 1.7 (m, 4H, autres —CH_2— du cycle).

Anal. calc. pour $C_{13}H_{18}O_3N_2$: C, 62.38; H, 7.25; N, 11.19. Trouvé: C, 62.58; H, 7.42; N, 11.01.

2.2 Benzoyl-1 nitrométhyl-4 pipéridol-4 (2c)

Dans un ballon de 2 l à trois tubulures, muni d'une ampoule à décantation, d'un réfrigérant surmonté d'un tube à $CaCl_2$, d'un thermomètre plongeant jusqu'au fond du ballon et d'un agitateur mécanique à joint de mercure, on introduit 500 ml d'éthanol absolu et 11.4 g de sodium fraîchement coupé.

Quand tout le sodium est dissous, on ajoute, goutte à goutte, à la solution agitée maintenue à une température de 40°, une solution de 100 g de benzoyl-1 pipéridone-4 et 40 ml de nitrométhane dans 200 ml d'éthanol absolu. On continue l'agitation à la même température pendant 3 h puis on laisse le mélange au repos pour la nuit.

On ajoute 500 ml d'éther afin de précipiter complètement le sel sodé du nitro-alcool **2***c* formé puis on filtre. Le précipité est lavé plusieurs fois à l'éther.

Le sel est ensuite décomposé par la dissolution dans l'eau froide et addition lente d'acide acétique (35 ml) glacial; il se dépose une huile qui se solidifie facilement. Le mélange est extrait au chloroforme puis la solution organique est décantée lavée par $NaHCO_3$ et à l'eau, et séchée sur Na_2SO_4. Par évaporation du solvant, on obtient un résidu solide qui est, par la suite, cristallisé dans un mélange égal d'éthanol absolu et d'éther de pétrole (65–110°); il se sépare de la solution des aiguilles incolores, p. de f. 131–132° (rendement 85%).

Spectre i.r. (Nujol) 3260 (—OH) 1600 (—CON<), 1580 cm^{-1} (—NO_2). Spectre de r.m.n. (DMSO-d_6) δ 7.32 (s, 5H, C_6H_5—), 4.52 (s, 2H, —CH_2—NO_2), vers 3.2 et 1.6 (2 massifs, 8H, protons cycliques), 5.3 (s, 1H, —O*H*, échangeable en présence de D_2O).

Anal. calc. pour $C_{13}H_{16}O_4N_2$: C, 59.08; H, 6.10; N, 10.60. Trouvé: C, 59.30; H, 6.25; N, 10.68.

2.3 Nitrométhyl-4 phénylsulfonyl-1 pipéridol-4 (2e)

Selon le mode opératoire 2.2, 33.2 g de phénylsulfonyl-1 pipéridone-4 donnent après cristallisation dans le butanol normal 27.5 g d'aiguilles incolores de nitro-alcool **2***e* p. de f. 148.5–149.5° (rendement 66%).

Anal. calc. pour $C_{12}H_{16}O_5N_2S$: C, 47.99; H, 5.37; N, 9.33. Trouvé: C, 48.32; H, 5.29; N, 9.24.

3 Amino-alcools

3.1 Aminométhyl-1 cyclohexanol-1 (3a)

Dans un ballon à trois tubulures muni d'un agitateur à joint de mercure et d'un réfrigérant, on introduit 2.8 g de $FeSO_4 \cdot 7H_2O$, 150 ml d'eau, 25 g de fer en poudre, et 3 g de nitrométhyl-1 cyclohexanol-1 (p.éb. 130–132° sous 18 mm). Tout en maintenant une bonne agitation, le mélange est chauffé à l'ébullition à reflux durant 3 h. On extrait soigneusement par du chloroforme, puis on rend la solution aqueuse fortement alcaline par addition de NaOH 40%. Après filtration ou mieux centrifugation de l'hydroxyde ferreux formé, la solution alcaline est extraite par le chloroforme. On obtient après évaporation du solvant un résidu huileux incolore correspondant à un rendement de 100% en *aminométhyl-1 cyclohexanol-1*. Cet amino-alcool fut caractérisé par son chlorhydrate p. de f. 212–213° (Dauben *et al.* (43) donnent 215–216°).

3.2 Aminométhyl-4 benzyl-1 pipéridol-4 (3b)

Dans un ballon à trois tubulures de 500 ml, muni d'un agitateur mécanique et d'un thermomètre plongeant jusqu'au fond du ballon, on introduit 125 ml d'acide acétique et 34 g de zinc en poudre. Tout en maintenant une forte agitation et une température inférieure à 30°, on ajoute, par petites portions 12 g de nitro-alcool. On poursuit l'agitation pendant 6 h à 25°. On filtre les produits de réaction et on lave avec un peu d'acide acétique le zinc non transformé. Les filtrats d'acide acétique sont réunis puis distillés sous 10 mm à une température de 40° pour conduire à un résidu liquide; ce dernier est repris par l'eau et la solution aqueuse rendue alcaline par addition d'une solution de NaOH à 40%. L'extraction par trois portions d'éther de 100 ml chacune donne après évaporation du solvant 9.5 g d'huile jaune pâle correspondant à l'amino-alcool brut. Rendement 91%. Le chlorhydrate, l'acétate et le picrate sont des produits trop hygroscopiques pour être purifiés et analysés.

Spectre i.r. (CCl_4) vers 3400 cm^{-1}, bande très forte correspondant à —OH et —NH_2. Spectre de r.m.n. (CCl_4) δ 7.4 (s, 5H, C_6H_5—), 3.55 (s, CH_2 benzylique), 2.6 (m, 6H, 2 CH_2 du cycle et —CH_2— adjacent à —NH_2), 1.6 (m, autres —CH_2— du cycle), l'intégration montre de plus qu'il y a trois protons sous les pics décrits à 3.55 et 2.6, —NH_2 et OH. L'adjonction d'acides (CH_3COOH et HCl) élargit les pics à 3.55 et 2.6, confirmant la présence de deux atomes d'azote basiques dans la molécule. Le spectre de r.m.n. montre de plus qu'il ne reste dans cette amine aucune trace du composé de départ **2***b*.

Oxydation periodique

On dissout 1.0 g d'huile obtenue dans l'expérience précédente dans 10 ml de méthanol, puis on ajoute à la solution 1.0 g de HIO_4 dissous dans 50 ml d'eau, on laisse au repos pendant 24 h. La solution est concentrée jusqu'à 10 ml sous pression de 10 mm à une température de 40°, rendue alcaline par addition de soude à 10% et finalement extraite à l'éther par deux portions de 20 ml chacune. La solution éthérée est séchée puis évaporée au bain-marie; le résidu obtenu est ensuite dissous dans 10 ml de méthanol et traité par 1.0 g de chlorhydrate de semicarbazone, 1.5 g d'acétate de sodium, et 10 ml d'eau. Après contact de 24 h, on filtre le solide formé et cristallise ce dernier dans le butanol secondaire, on obtient des lamelles incolores p. de f. 195°. Cette semicarbazone ne donne pas de dépression, à l'essai de mélange avec une préparation authentique de semicarbazone de benzyl-1 pipéridone-4.

3.3 Aminométhyl-4 benzoyl-1 pipéridol-4 (3c)

Selon le mode opératoire 3.1, 3 g de nitro-alcool **2***c* donnent 2.6 g d'un résidu huileux, rendement 97%, qui constitue l'amino-alcool **3***c* brut. La formation d'un dérivé cristallisé (chlorhydrate, oxalate, acétate et picrate) a échoué.

Spectre i.r. (Nujol) 3450 (bande large, —OH et —NH_2),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1600 cm^{-1} (—CON<). Spectre de r.m.n. ($CDCl_3$) 6.98 (s, 5H, C_6H_5—), vers 3.2 et 1.4 (2 massifs, 4H chacun, protons cycliques), 2.4 (s large, 2H, —CH_2—NH_2), 2.2 (s large, 3H environ, —NH_2 et —OH, échangeables en présence de D_2O).

Oxydation periodique

On dissout 1 g d'amino-alcool **2***c* dans 10 ml de méthanol puis on ajoute à la solution 1 g de HIO_4 dissous dans 50 ml d'eau. On agite pendant quelques minutes et on laisse au repos pendant 24 h. On extrait alors la solution aqueuse par deux portions de 50 ml de $CHCl_3$. Le résidu huileux obtenu par évaporation de la solution de chloroforme est dissous dans 10 ml de méthanol. On ajoute à cette solution 1.0 g de phénylhydrazine et quelques gouttes d'acide acétique; on chauffe jusqu'à ébullition et on laisse refroidir pour obtenir des aiguilles jaunes pâles p. de f. 133°. Le p. de f. mixte avec un échantillon authentique de phénylhydrazone de benzoyl-1 pipéridone-4 ne donne aucune dépression.

3.4 Aminométhyl-4 phénylsulfonyl-1 pipéridol-4 (3e)

Selon le mode opératoire 3.1, 20 g de nitro-alcool **2***e* donnent 16.4 g (91%) d'amino-alcool brut **3***e*, p. de f. 124–125° après cristallisations répétées dans l'acétate d'éthyle et l'éther de pétrole, puis dans l'eau.

Anal. calc. pour $C_{12}H_{18}O_3N_2S$: C, 53.31; H, 6.71; N, 10.36. Trouvé: C, 53.80; H, 6.99; N, 10.18.

Le chlorhydrate, préparé dans l'éther par adjonction d'acide chlorhydrique gazeux, fond à 221–222°, après cristallisation dans un mélange d'isopropanol et d'éther.

Anal. calc. pour $C_{12}H_{19}O_3N_2SCl$: C, 46.97; H, 6.24; N, 9.13. Trouvé: C, 47.05; H, 6.25; N, 9.07.

Oxydation periodique

On dissout 1.0 g d'amino-alcool **3***e* dans 10 ml de méthanol et ajoute 1.0 g de HIO_4 en solution dans 5 ml d'eau. On agite pendant quelques minutes et abandonne pendant 5 h à 25°. Le volume de la solution est alors porté à 50 ml par adjonction d'eau. Après 24 h de contact, on recueille sur un filtre le précipité formé et on le cristallise dans le tétrachlorure de carbone. La phénylsulfonyl-1 pipéridone-4 (**1***e*) ainsi obtenue fond à 121–122°, seule ou en mélange avec un échantillon authentique.

4 Désamination nitreuse

4.1 Désamination nitreuse de l'amino-alcool (3b)

L'amino-alcool **3***b* (10 g) est dissous dans 100 ml d'acide acétique à 25%. En agitant et à température de 0°, on y ajoute, en 45 min, une solution de nitrite de sodium (4 g dans 20 ml d'eau). Après 2 h d'agitation à 0°, on ajoute au mélange réactionnel 6 g de chlorohydrate de semicarbazide et 9 g de $CH_3CO_2Na \cdot 3H_2O$. On agite jusqu'à dissolution complète, puis on laisse au repos toute la nuit. La solution est évaporée à sec; le résidu repris par de l'eau et la solution rendue alcaline par l'addition de soude à 40%; il se produit une précipitation d'un solide brun, lequel, cristallisé plusieurs fois dans le butanol secondaire (prismes) fond à 182–184°. Rendement 60% (en semicarbazone).

Anal. calc. pour $C_{14}H_{20}ON_4$: C, 64.58; H, 7.74; N, 21.53. Trouvé: C, 64.77; H, 7.71; N, 21.44.

Spectre de r.m.n. (DMSO-d_6) δ 8.93 (s, 1H, =N—NH —CO—), 7.4 (s, 5H, C_6H_5—), 6.3 (s, 2H, —CO—NH_2), 3.6 (s, 2H, —CH_2—N), 2.55 (bande unique, 8H, CH_2— adjacents à —N et C=N—), 1.8 (m, 2H, CH_2 restant du cycle).

4.2 Désamination nitreuse de l'amino-alcool (3c)

L'amino-alcool **3***c* (1.7 g) est dissous dans 25 ml d'acide acétique à 25%. Après refroidissement de la solution à 0°, on y ajoute, goutte à goutte, tout en maintenant une bonne agitation, 10 ml d'une solution de $NaNO_2$ (0.6 g dans 10 ml d'eau). L'agitation est continuée à 0° pendant 2 h. Le mélange réactionnel est extrait au chloroforme; la couche organique est ensuite lavée avec une solution de $NaHCO_3$ à 5%, à l'eau et séchée sur Na_2SO_4. On obtient par évaporation du solvant, une huile rouge très visqueuse; la distillation de cette huile sous vide poussé conduit à 1.4 g d'un produit visqueux incolore p.éb. 168–172°/0.6 mm. Le produit est traité par le réactif P de Girard et Sandulesco; 1.4 g de distillat sont chauffés à reflux pendant 1½ h avec 1.5 g de réactif, 15 ml de méthanol, et 1.5 ml d'acide acétique glacial. La solution est refroidie puis versée sur de la glace (50 g). Le mélange est extrait par cinq portions d'éther de 50 ml chacune; on obtient une solution éthérée (solution *A*) et une solution aqueuse (solution *B*).

Solution A

La solution est séchée puis concentrée jusqu'à 10 ml; il se forme par refroidissement une cristallisation de 0.95 g de *benzoyl-1 oxa-1 aza-5 spiro[5.2]octane* (**5***c*) (aiguilles incolores), p. de f. 83.5°. Rendement 60%. Le spectre i.r. ne montre aucune bande carbonyle. Le spectre r.m.n. est le suivant, dans CCl_4, en valeurs δ: quatre massifs de 2H, 1.25–1.6, 1.7–2.05, 3.3–3.7, et 3.7–4.1; singulet à 2.61 (2H correspondant à ); pic fin centré à 7.45 (5H, phényle).

Anal. calc. pour $C_{13}H_{15}O_2N$: C, 71.86; H, 6.96; N, 6.44. Trouvé: C, 71.60; H, 7.36; N, 6.44.

Solution B

On ajoute dans la solution aqueuse 20 ml de HCl 6 *N* et on laisse en contact pour la nuit. L'extraction par deux portions de 50 ml chacune de benzène et évaporation du solvant organique donne 0.32 g d'une huile jaune pâle correspondant à la benzoyl-1 aza-1 cycloheptanone-4 (**4***c*). Cette cétone que l'on n'a pas pu purifier par distillation donne facilement une phénylhydrazone p. de f. 201° (éthanol). Rendement brut 20%.

Anal. calc. pour $C_{19}H_{21}ON_3$: C, 74.23; H, 6.88; N, 13.67. Trouvé: C, 74.17; H, 7.01; N, 13.70.

Cette mise au point pour la séparation des produits de réaction est le résultat de plusieurs essais; il fut impossible de séparer le mélange par distillation fractionnée (p.éb. 168–172°/0.6 mm) ou par chromatographie sur une colonne d'alumine ou encore par cristallisation fractionnée. Seul le réactif P de Girard et Sandulesco a permis une séparation satisfaisante des substances cétoniques des autres composants du mélange.

4.3 Désamination nitreuse de l'amino-alcool (3e)

L'acétate de l'amino-alcool **3***e* (17.1 g) est dissous dans 100 ml d'acide acétique à 25%. Cette solution est agitée et maintenue à 0° à l'aide d'un bain de glace et de sel. On y ajoute graduellement durant 45 min une solution de nitrite de sodium (4.3 g dans 20 ml d'eau); il se forme un

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

volumineux précipité blanc; l'agitation est continuée durant 2 h à 0°. On extrait par le chloroforme et isole à la manière habituelle 11.9 g d'un solide blanc p. de f. 102–105°. Par cristallisation du produit brut dans le butanol secondaire, on obtient le *phénylsulfonyl-5 oxa-1 aza-5 spiro[5.2]octane* (**5***e*) p. de f. 106–107°, aiguilles incolores. Le spectre i.r. ne montre aucune bande carbonyle. Le spectre r.m.n. est le suivant, dans CCl_4, en valeur δ quatre massifs de 2H, 1.1–1.6, 1.6–2.4, 2.4–3.1, et 3.3–3.8; singulet 2.51 (2H, correspondant à); massif de 7.3 à 7.9 (5H, phényle).

Anal. calc. pour $C_{12}H_{15}O_3NS$: C, 56.89; H, 5.97; N, 5.53. Trouvé: C, 56.96; H, 5.95; N, 5.49.

On chauffe à l'ébullition un mélange de 1.0 g du produit brut, 1.0 g de dinitro-2,4 phénylhydrazine, et 35 ml de méthanol; après refroidissement, on ajoute 5 ml d'acide acétique glacial et porte à l'ébullition pendant quelques minutes. On isole après repos à la glacière, 2 mg de dinitro-2,4 phénylhydrazone p. de f. 167°, correspondant à la cétone agrandie **4***e* identique à celle décrite à la section 5.4 (plus loin).

5 Action du diazométhane sur les cétones

*5.1 Action du diazométhane sur la benzyl-1 pipéridone-4 (**1***b*)*

On dissout dans un ballon de 50 ml à trois tubulures, muni d'un agitateur mécanique et d'un thermomètre plongeant jusqu'au fond du ballon, 3 g de KOH à 80% et 5 g de benzyl-1 pipéridone-4 (**1***b*) dans 15 ml de méthanol.

On ajoute dans la solution fortement agitée, maintenue à 0°, en 30 min, 2.8 g de nitrosométhylurée. A la fin de l'addition, le mélange réactionnel est abandonné à 0° pendant 1 h, puis filtré et acidifié par 6 ml d'acide acétique glacial.

La solution acide est traitée par 6 g de chlorhydrate de semicarbazide et 8 g de $CH_3CO_2Na \cdot 3H_2O$; on chauffe au bain-marie pendant quelques minutes puis on laisse au repos pour la nuit.

En rendant la solution alcaline, il se produit un précipité blanc que l'on isole par filtration (5.5 g).

Après cinq cristallisations dans le butanol secondaire, on isole 3.9 g d'un produit pur (prismes) p. de f. 182–184°. Rendement 60% (en semicarbazone).

Le p. de f. de cette semicarbazone ne donne pas de dépression à l'essai de mélange avec celle obtenue par désamination nitreuse (section 4.1 plus haut).

*5.2 Action du diazométhane sur la benzoyl-1 pipéridone-4 (**1***c*)*

Dans un ballon de 300 ml à trois tubulures, muni d'un agitateur mécanique et d'un thermomètre plongeant jusqu'au fond du ballon, on introduit 125 ml de méthanol et 30 g de KOH aqueux 50%. La solution est refroidie jusqu'à 0° puis on y ajoute 50 g de benzoyl-1 pipéridone-4.

Tout en agitant fortement la solution maintenue à 0°, on ajoute, par petites portions 26.4 g de nitrosométhylurée. Le mélange est ensuite laissé en contact pendant 5 h à 0°, puis filtré et la solution claire neutralisée par de l'acide acétique glacial. La solution est concentrée jusqu'à un volume de 50 ml sous vide partiel et le résidu est repris par $CHCl_3$. La solution de chloroforme est lavée à l'eau, séchée et évaporée; on obtient 48 g d'un résidu huileux.

Le résidu (10 g) est traité par le réactif P de Girard et Sandulesco. On isole:

(*a*) Le produit cétonique (3 g) (test positif au réactif du *m*-dinitro-benzène) qui distille sous 0.2 mm à 165–170°. Ce produit (1 g) est traité par 1 g de phénylhydrazine dans le méthanol. Par cristallisation fractionnée, on obtient 0.76 g de phénylhydrazone, p. de f. 201°, peu soluble, caractérisée comme la phénylhydrazone de l'homopipéridone-4 *N*-benzoylée **4***c* par le p. de f. d'un mélange avec un échantillon décrit à la section 4.2 plus haut et 0.20 g de phénylhydrazone très soluble dans le méthanol dont le p. de f. de 133° ne donne pas de dépression avec un mélange de la phénylhydrazone de la benzoyl-1 pipéridone-4.

(*b*) La fraction non-cétonique (5.5 g) (huile très visqueuse) qui après cristallisation dans l'éther donne 4.3 g, p. de f. 83.5°, de l'époxyde **5***c*, caractérisé par p. de f. de mélange avec un échantillon préparé plus haut à la section 4.2 et 1.2 g d'un résidu huileux.

Il n'est possible dans ce cas d'établir qu'approximativement le bilan de la réaction qui s'établirait comme suit: cétone non-réagie: 9%, époxyde **5***c*: 40%, extension de cycle **4***c*: 26%. Le reste consiste en des mélanges non-résolvables.

*5.3 Réaction du diazométhane sur la p-nitrobenzoyle-1 pipéridone-4 (**1***d*)*

A un mélange de 250 ml de méthanol et 11.2 g d'une solution aqueuse de KOH 50% maintenue à 0° sont ajoutés 24.8 g de *p*-nitrobenzoyle-1 pipéridone-4 et, en agitant fortement et par petites portions, 10 g de nitrosométhylurée; après chaque addition, il faut attendre que la solution devienne incolore avant d'ajouter la portion suivante: après la fin de l'addition, le mélange réactionnel est laissé à la température ambiante pour la nuit, puis neutralisée par l'acide acétique; le solvant est évaporé et le résidu repris par 100 ml d'eau et 100 ml de chloroforme; la fraction aqueuse est de nouveau extraite au chloroforme; les fractions organiques réunies sont lavées par Na_2CO_3 5%, séchées et évaporées sous vide.

Le résidu (25 g) après trois cristallisations dans le méthanol, donne 14.0 g (53%) de l'époxyde **5***d*, sous forme de prismes incolores fondant à 145–146°. Spectre r.m.n. ($CDCl_3$) valeurs δ massif de 1.17 à 2.30 (4H), s à 2.77 (1H,); deux massifs de 3.20 à 4.70 (4H); d, 7.63 (2H, J = 9 Hz); d, 8.33 (2H, J = 9 Hz).

Anal. calc. pour $C_{13}H_{14}O_4N_2$: C, 59.53; H, 5.38; N, 10.68. Trouvé: C, 59.63; H, 5.34; N, 10.60.

Les filtrats de cristallisation de l'époxyde sont évaporés et recristallisés trois fois dans le butanol normal pour donner 6.3 g (26%) de la *p*-nitrobenzoyle-1 aza-1 cycloheptanone (**4***d*) fondant à 134°. Spectre i.r. (CCl_4) 1710 (C=O), 1650 cm^{-1} (N—C=O).

Anal. calc. pour $C_{13}H_{14}O_4N_2$: C, 59.53; H, 5.38; N, 10.68. Trouvé: C, 59.42; H, 5.43; N, 10.71.

La 2,4-dinitrophénylhydrazone de **4***d*, recristallisée dans le solvant mixte nitrométhane–éthanol, présente un p. de f. de 233°.

Anal. calc. pour $C_{19}H_{18}O_7N_6$: N, 18.99. Trouvé: N, 18.78.

For personal use only.

Dosage de l'époxyde **5***d et de la cétone par la diéthylamine*

Le produit brut de l'action du diazométhane sur la cétone, 11 g, est chauffé 2 h à l'ébullition à reflux en présence de 5 g de diéthylamine dans 50 ml de méthanol. On abandonne pour la nuit à 25°. Les substances volatiles sont évaporées sous vide et le résidu repris par du chloroforme; on extrait par de l'acide acétique 10%. La solution chloroformique est lavée avec une solution aqueuse de carbonate de sodium 5%, séchée et évaporée. Le résidu, après deux cristallisations dans le butanol, donne 3.4 g (32%) de la cétone **4***d*.

La fraction "acide acétique" obtenue plus haut est saturée de carbonate de sodium et extraite par du chloroforme; on sèche cette solution et l'évapore; le résidu huileux est purifié par du charbon actif dans du butanol-2 et cristallisé dans ce solvant. On obtient 5.2 g de *diéthylaminométhyl-4 p-nitrobenzoyl-1 pipéridol-4* plaques incolores, p. de f. 113–114°. On obtient aussi ce composé à partir de l'époxyde **5***d* pur.

Anal. calc. pour $C_{17}H_{25}O_4N_3$: C, 60.88; H, 7.51; N, 12.52. Trouvé: C, 60.99; H, 7.42; N, 12.47.

*5.4 Réaction du diazométhane avec la benzènesulfonyl-1 pipéridone-4 (***1***e)*

On introduit dans un ballon à trois tubulures muni d'un agitateur mécanique et d'un thermomètre plongeant jusqu'au fond du ballon, 125 ml de méthanol, et 26 g de KOH aqueux 50%. La solution est refroidie jusqu'à 0°, puis on y ajoute 50 g de benzènesulfonyl-1 pipéridone-4; on agite jusqu'à dissolution complète, tout en maintenant la température à 0°. L'addition de 23.6 g de nitrosométhylurée pendant une période de 4 h provoque une évolution d'azote. Le mélange est abandonné durant 5 h à 0°; on filtre; la solution claire est neutralisée par de l'acide acétique glacial. On concentre jusqu'à un volume de 50 ml et on reprend par le chloroforme. On isole à la manière habituelle un résidu dont on retire par cristallisation dans l'alcool amylique tertiaire 4 g *de phénylsulfonyl-1 aza-1 cycloheptanone* (**5***e*), p. de f. 136–137°. Spectre i.r. (CCl_4) 1710 cm^{-1} (C=O).

Anal. calc. pour $C_{12}H_{15}O_3NS$: C, 56.89; H, 5.97; N, 5.53. Trouvé: C, 57.02; H, 6.12; N, 5.62.

Dinitro-3,4 phénylhydrazone: poudre orange, p. de f. 167°.

Anal. calc. pour $C_{18}H_{19}O_6N_5S$: N, 16.18. Trouvé: N, 16.02.

Par évaporation des eaux-mères de la cristallisation de la cétone **5***e*, on obtient un résidu (48.5 g); on traite ce dernier par 50 g de diéthylamine et 75 ml de méthanol à l'ébullition à reflux durant 6 h. Le mélange issu de la réaction est évaporé à sec et repris par le chloroforme. On sépare en partie neutre et partie basique par extraction par HCl 5%:

Partie neutre: 7.5 g de phénylsulfonyl-1 pipéridone-4 qui n'a pas réagi, p. de f. 121–122°.

Partie basique: 47.6 g de *diéthylaminométhyl-4 phénylsulfonyl-1 pipéridol-4*, p. de f. 87–88°. Cet amino-alcool est obtenu, avec un rendement de 84%, en mélangeant 2.0 g d'époxyde **5***e* pur, p. de f. 106–107°, obtenu à la section 4.3 plus haut, avec 15 g de diéthylamine et 50 ml de méthanol. Après repos de 1 h à température de 25°, on chauffe à reflux pendant 3 h. On évapore les substances volatiles et recristallise l'amino-alcool dans du cyclohexane pour obtenir des aiguilles incolores, p. de f. 87–88°.

Anal. calc. pour $C_{16}H_{26}O_3N_2S$: C, 58.86; H, 8.03; N, 8.58. Trouvé: C, 58.49; H, 8.23; N, 8.51.

Le bilan de la réaction s'établit comme suit: 50 g de cétone mise en réaction; 7.5 g retrouvée; 4 g de cétone agrandie et 47.6 g d'amino-alcool correspondant à 37 g d'époxyde **5***e*; l'époxyde et la cétone agrandie représentent respectivement 82 et 8.9% de rendement.

6 Synthèse des époxydes **5** *par la méthode de Corey et Chaykowsky (16)*

A une suspension agitée d'hydrure de sodium (10–12% d'excès par rapport aux 10 mmol requises) dans 30 ml de diméthylsulfoxyde anhydre, fraîchement distillé, on ajoute l'iodure de triméthylsulfoxonium (10–12% d'excès par rapport aux 10 mmol requises) sous forme de fine poudre, en maintenant le tout dans une atmosphère d'azote. Au bout de 20–30 min, on ajoute rapidement, toujours en atmosphère d'hydrogène, une solution de 10 mmol de la cétone dans 30 ml de diméthylsulfoxyde, anhydre et fraîchement distillé. Après agitation de 1 h, la température est portée à 50–60° pendant 1 h. Après refroidissement à 25°, le mélange est versé dans 500 ml d'eau glacée et le tout extrait par quatre portions de 100 ml de chloroforme. Après les lavages habituels à l'eau, séchage et évaporation, le résidu est cristallisé ou distillé. On prépare ainsi les époxydes: **5***b*, p.éb. 119–121° sous 0.45 mm, 96%,[12] caractérisé par son dérivé anilino de p. de f. 80–81°, décrit par Morosawa (6); **5***c*, p. de f. 84–85° (butanol-2), 93%; **5***d*, p. de f. 143–144° (butanol-2), 96%; au moment de l'introduction de la cétone dans la solution d'ylure à température de la pièce, une intense coloration bleue apparaît, qui devient bleu-vert foncé après 1 h à 50–60°; **5***e* p. de f. 107–108° (éther de pétrole), 86%. Les époxydes ainsi préparés et ceux obtenus par désamination nitreuse ou par l'action du diazométhane sur les cétones correspondantes sont identiques (c'est le cas de **5***c–e*).

7 Détermination des pK_a *des amino-alcools*

Les pK_a des amino-alcools étudiés furent déterminés suivant la méthode originale de Roberts *et al.* (48). L'aminométhyl-1 cyclohexanol fut préparé suivant la méthode décrite par Dauben *et al.* (43). Il fut fraîchement redistillé sous atmosphère d'azote avant les mesures. La valeur donnée pour le pK_a de l'amino-alcool **3***c* n'est qu'une valeur approchée puisqu'il fut impossible de purifier cet amino-alcool, soit par distillation, soit par cristallisation, soit par cristallisation d'un dérivé. La mesure fut donc effectuée sur le produit brut de la réaction, après élimination des impuretés non alcalines. La méthode décrite par Overberger et Katchman (7) fut employée pour l'obtention du bioxyde d'aminométhyl-4 hydroxy-4 thianne qui fut fraîchement sublimé avant les mesures.

Les échantillons (environ 0.5 mmol) furent titrés dans 100 ml d'éthanol 50% (v/v) fraîchement bouilli. Chacun des titrages fut effectué sous atmosphère d'azote avec une solution d'acide chlorhydrique fraîchement préparée dans l'éthanol à 50%. Les changements d'acidité au cours des titrages ont été suivis à l'aide d'un p*H*-mètre de marque

[12]On donne (44) un rendement de 33% pour cette réaction.

For personal use only.

Beckman Modèle H2 monté d'une électrode de verre et d'une électrode de référence au calomel. Les pK_a donnés dans le tableau 2 correspondent à l'acidité au demi-titrage déterminé graphiquement en supposant une activité des ions égale à l'unité et en supposant l'échelle de l'appareil égale au logarithme de l'inverse de la concentration en ions hydrogène. Le pK_a de la cyclohexamine a été effectué comme mesure de vérification avec la valeur donnée dans la littérature. La valeur trouvée est identique, 9.83 (46).

8 Constantes de dissociation des cyanohydrines de la cyclohexanone et des pipéridones-4

Les constantes de dissociation des cyanohydrines des cétones rapportées dans le tableau 2 furent déterminées suivant la méthode décrite par Prelog et Kobelt (47). La cyclohexanone fut purifiée par l'intermédiaire de son dérivé bisulfitique et distillée sous atmosphère d'azote. L'éthanol à 95% employé comme solvant est reflué pendant quatre heures avec de la poussière de zinc et de l'hydroxyde de potassium de façon à éliminer toute trace d'aldéhydes. La solution d'acide cyanhydrique est préparée par dissolution de 55 g d'acide cyanhydrique liquide dans 2 l d'éthanol à 95%.

La désamination nitreuse des aminométhyl-1 phénylsulfonyl-4 cyclohexanols-1 *cis* et *trans*[1]

H. Favre, Z. Hamlet,[2] M. Ménard,[3] G. Roblot,[4] et J. Temler
Département de Chimie, Université de Montréal, Montréal, Québec

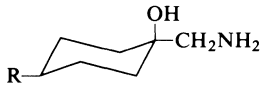
Reçu le 20 mai 1970[5]

La désamination nitreuse de l'aminométhyl-1 phénylsulfonyl-4 cyclohexanol-1 *cis* donne 60% d'époxyde et 23% de cétone agrandie, tandis que son isomère *trans* donne 28% d'époxyde et 60% de cétone agrandie. La forte proportion d'époxyde s'explique par un effet inductif et de champ du groupe phénylsulfonyle; un effet conformationnel, qui fait qu'un groupe —CH_2NH_2 donne plus d'époxyde en conformation équatoriale qu'axiale, se retrouve également dans cette réaction. Cette étude a nécessité la préparation des phénylthio-4 et phénylsulfonyl-4 cyclohexanols et méthyl-1 cyclohexanols *cis* et *trans*.

Nitrous acid deamination of *cis*-1-aminomethyl-4-phenylsulfonyl-1-cyclohexanol gives 60% of epoxide and 23% of ring-expanded ketone whereas the *trans* isomer gives 28% of epoxide and 60% of ring-expanded ketone. The large proportion of epoxide is accounted for by the inductive effect and the field effect of the phenylsulfonyl group; a conformational effect wherein the CH_2NH_2 group leads to more epoxide when in an equatorial conformation than in an axial is also observed in this reaction. This study required the preparation of 4-phenylthio and 4-phenylsulfonyl cyclohexanols and *cis*- and *trans*-1-methyl cyclohexanols.

Canadian Journal of Chemistry, 49, 3086 (1971)

Dans le but de connaître la résultante des effets stéréoélectroniques et des effets de champ et d'induction sur la formation des époxydes et des cétones agrandies dans la désamination nitreuse, nous avons étudié les aminométhyl-1 phénylsulfonyl-4 cyclohexanols-1 *cis* et *trans* (**1** et **2**).[6] Du côté des effets stéréoélectroniques, nous avons montré (1) qu'en série cyclohexanique la conformation équatoriale ou axiale du groupe aminométhyle influençait le cours de la réaction, l'amino-alcool **3** donnant 20% d'époxyde, son isomère **4** 5% seulement. Cette observation était confirmée plus tard, en série décalinique (2). Du côté des effets de champ et d'induction, la présence d'un groupe électronégatif augmente sensiblement la formation d'époxyde, aux dépens de la cétone agrandie. Le groupe sulfonyle influence particulièrement la réaction: c'est ainsi qu'en série thiannique l'amino-alcool **5** conduit à 67% d'époxyde pour 14% de cétone agrandie (3), tandis qu'en série pipéridique (**6**) la cétone agrandie ne représente que des traces, l'époxyde se formant à plus de 99% (4) (tableau 1).



1 R = $C_6H_5SO_2$—
3 R = *tert*-butyle

[5]Révision reçue le 6 mai 1971.

[6]Les configurations *cis* et *trans* correspondent aux groupes OH et $C_6H_5SO_2$ dans les composés **1**, **2**, **11**, **12**, **16**, et **17**, et OH et C_6H_5S dans **20** et **21**. Les époxydes seront *cis* et *trans* selon la configuration des alcools tertiaires d'ouverture.

La conformation des amino-alcools **1** et **2** doit comporter le groupe $C_6H_5—SO_2—$ équatorial dans les deux cas, vu la valeur *A* de 2.5 kcal/mol du groupe phénylsulfonyle (voir discussion plus loin).

TABLEAU 1. Pourcentages de formation d'époxyde et de cétone agrandie dans la désamination nitreuse

Amino-alcool de départ	Epoxyde (%)	Cétone agrandie (%)
		1	60*	23†
2	28‡	60*
3	20§	80§
4	5§	90§
5	67*	14
6	91*	Traces†

*Isolé comme tel.
†Isolé sous forme de dinitro-2,4 phénylhydrazone.
‡Isolé sous forme de pipéridino-alcool.
§Dosage par c.p.g.

lactone **7***a* sert de produit de départ (6, 7). Traitée par le thiophénolate de sodium (8), **7***a* donne l'acide ester **7***b*, qui conduit facilement au diester **7***c* et au diacide **7***d*. Une cyclisation de Dieckman du diester donne la cétone **8**, qu'il faut toutefois purifier par sa semicarbazone pour obtenir un produit très pur. Une oxydation par le peroxyde d'hydrogène dans l'acide acétique, selon (3), permet de convertir la cétone **8** en cétone **9**.

En présence d'une quantité équimoléculaire de méthylate de sodium (5, 9) (ou légèrement plus grande), la cétone **8** traitée par le nitrométhane conduit à un mélange de deux nitro-alcools isomères duquel nous avons retiré par cristallisation fractionnée 62% de l'isomère *trans* **10**, qui conduit par oxydation au nitro-alcool sulfonylé **11**. La cétone **9** ne conduit qu'à un nitro-alcool, qui est l'isomère *cis* **12**.

La réduction des nitro-alcools soit chimique par le fer en poudre et le sulfate ferreux, soit catalytique sur nickel de Raney (4), donne les deux amino-alcools isomères **1** et **2**. Les deux amino-alcools ont un pK_a identique et égal à 8.48; l'un **1**, fond à 130–131°, l'autre (**2**) à 171°.

La désamination nitreuse, effectuée dans les conditions déjà décrites (1, 4), solution aqueuse d'acide acétique à 25%, donne au départ de l'amino-alcool **1** un mélange de la cétone agrandie **14** et de l'époxyde **15**; par cristallisation, nous avons retiré du mélange 60% d'époxyde **15** pur, la cétone agrandie (23%) étant caractérisée par sa dinitro-2,4 phénylhydrazone. L'amino-alcool **2** engendre un mélange de la cétone agrandie **14** et de l'époxyde **13**; après traitement du mélange brut par de la pipéridine, nous avons obtenu par cristallisation, 60% de cétone **14** pure et 28% de pipéridino-alcool (**11***a*), correspondant à autant d'époxyde de **13**. Les pourcentages de cétones agrandies et d'époxyde sont rapportés au tableau 1.

(B) Configuration des amino-alcools 1 et 2

Le schéma 2 montre la corrélation de configuration qui permet d'attribuer la configuration *cis* à l'amino-alcool de p. de f. 130–131°. D'un côté, l'amino-alcool de p. de f. 130–131° (**1**) conduit par désamination nitreuse à l'époxyde de p. de f. 95–96° (**15**) et par hydrogénation de ce dernier, à l'alcool tertiaire de p. de f. 183–185° (**16**). D'un autre côté, l'action du méthylure de diméthyloxosulfonium (10) sur la phénylthio-4 cyclohexanone (**8**) conduit à un mélange des deux époxydes **18** et **19** dans le rapport 81:19, que nous avons transformé, par réduction par l'hydrure de lithium et d'aluminium, en un mélange des alcools tertiaires **20** et **21**; par cristallisation nous avons obtenu l'alcool **20** pur, de p. de f. 64.5–65°, qui donne par oxydation l'alcool sulfonylé **16**, de p. de f. 183–185°.

Du mélange résultant de l'action de l'iodure de méthylmagnésium sur la cétone **8**, nous avons tiré par chromatographie sur gel de silice, l'alcool **20** et son isomère **21**, de p. de f. 52–53° qui par oxydation conduit à l'alcool sulfonylé **17**, de p. de f. 55–56°. L'alcool **16** s'obtient également par cristallisation du mélange des alcools issus de l'action de l'iodure de méthylmagnésium sur la cétone **9**.

Nous avons choisi de déterminer les configurations des alcools **20** et **21**, pour connaître celle de l'amino-alcool **1** à l'aide de la corrélation établie plus haut, et nous avons mis en oeuvre la technique de r.m.n. Eliel et Gianni (11) ont montré que le signal de résonance du proton cyclohexanique adjacent au groupe C_6H_5—S— se situe à δ 2.85 pour le proton axial et à δ 3.52 pour le proton équatorial. Les spectres de r.m.n. des alcools **20** et **21** montrent un signal à, respectivement, δ 3.00 et 3.30; ces valeurs intermédiaires reflètent l'existence des équilibres **20***A* ⇄ **20***B* et **21***A* ⇄ **21***B*. Pour des valeurs de 0.35 kcal/mol pour $=C(OH)CH_3$ (12, 13) et 0.8 kcal/mol pour —S—C_6H_5 (11), les équilibres sont de l'ordre de 88:12 pour **20***A*:**20***B*, et 68:32 pour **21***A*:**21***B*. Pour fin d'attribution de configuration, il est clair que la valeur de δ 2.92 correspond à l'isomère qui contient le plus du

For personal use only.

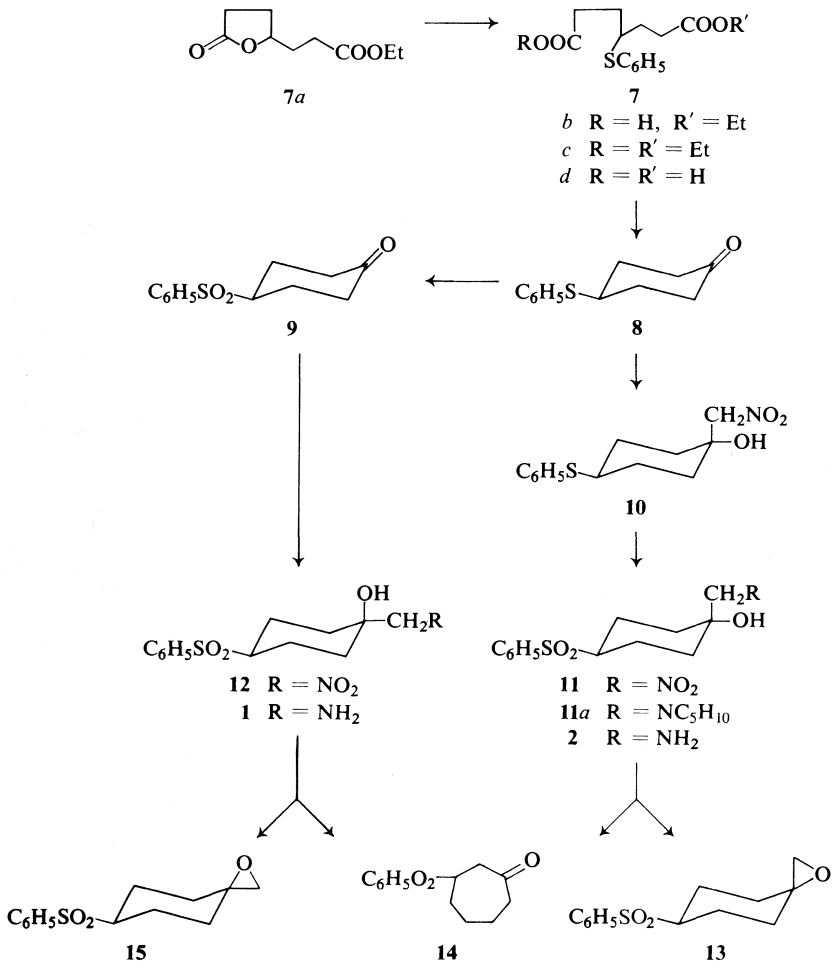

SCHÉMA 1

groupe C_6H_5—S— équatorial, soit l'isomère *cis* **20** (C_6H_5—S est *cis* par rapport à —OH).

De cette attribution de configuration, nous concluons que l'alcool sulfonylé **16**, qui résulte de l'oxydation de l'alcool **20**, doit avoir la configuration *cis* de même que les composés **1** et **15**.

Cette attribution de configuration n'est valable que si la règle de l'additivité des énergies conformationnelles des substituants —OH et C_6H_5—S s'applique à un cyclohexane porteur de ces groupes en position 1,4. Nous démontrons que cette condition est remplie par l'étude des phénylthio-4 cyclohexanols-1 *cis* et *trans* **24** et **25**; en déterminant sans ambiguité leur configuration, nous sommes en mesure de vérifier que les spectres de r.m.n. sont conformes aux équilibres conformationnels attendus. Il est bien entendu que nous utilisons la technique des déplacements chimiques dans un but strictement qualitatif et non quantitatif (14).

Nous avons synthétisé (schéma 3) les phénylthio-4 cyclohexanols-1 *cis* et *trans* par une méthode qui établit du même coup leur configuration, soit par la réaction du thiophénolate de sodium avec un tosylate. C'est une réaction S_N2 qui se fait avec l'inversion de configuration classique (15). Les monotosylates de cyclohexanediols 1,4 *cis* et *trans*, **23** et **22** sont connus (16); ils conduisent respectivement aux phénylthio-4 cyclohexanols-1 *trans* et *cis*, **25** et **24**. La valeur de l'énergie conformationnelle du substituant —OH varie entre 0.6 et 1.07 kcal/mol (11, 17–19) dans le tétrachlorure de carbone; celle du groupe —S—C_6H_5 dans ce solvant est fixée à 0.8 kcal/mol (11). En première approximation, ces valeurs permettent de retenir une

For personal use only.

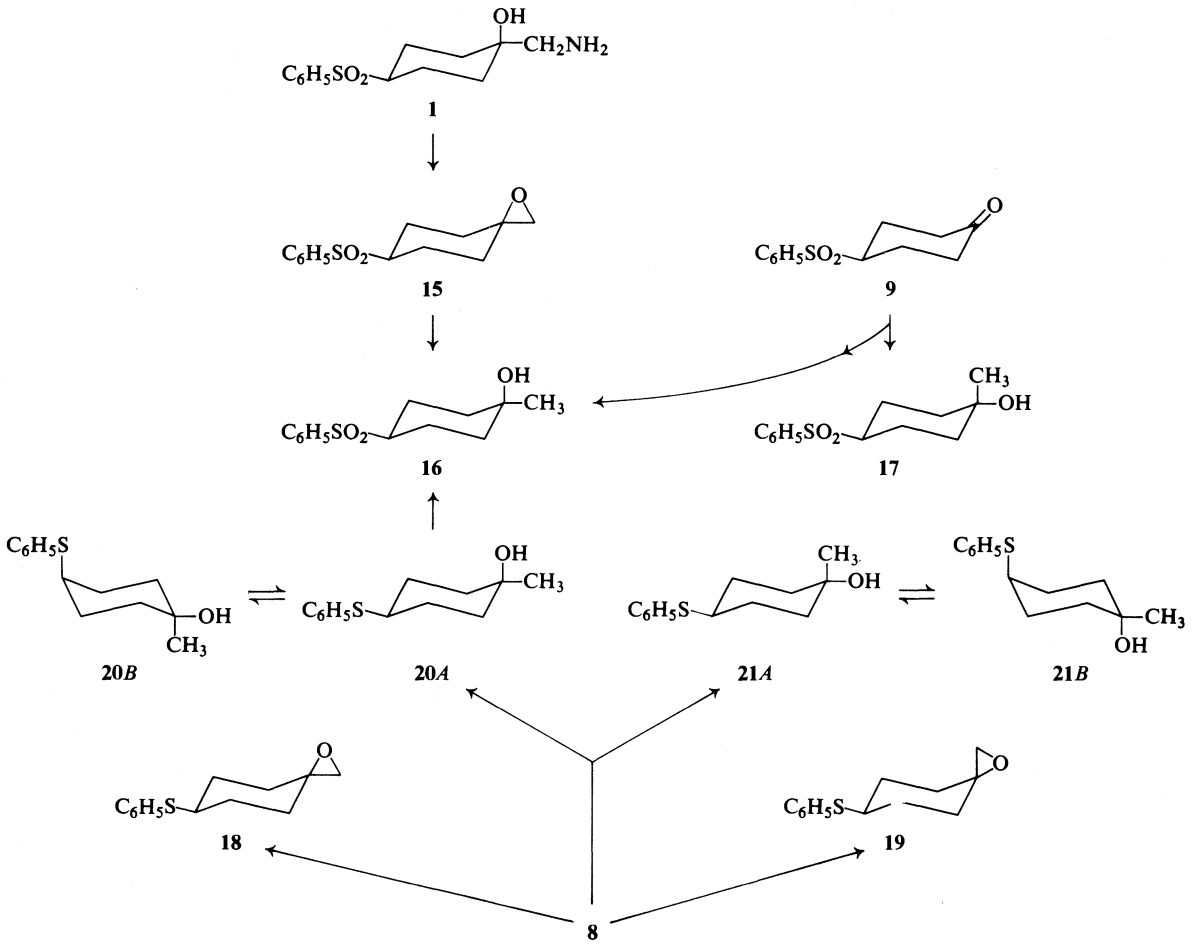

SCHÉMA 2

conformation diéquatoriale pour l'isomère *trans* et annoncent un équilibre voisin de 50:50 pour l'isomère **24***A*:**24***B cis*. Pour assurer la meilleure comparaison possible, nous choisissons le travail d'Eliel et Gianni (11) comme système de référence parce que les groupes C*H*—OH et C*H*—S—C_6H_5 y ont été étudiés dans des conditions identiques. Le tableau 2 rapporte les signaux observés dans les spectres de r.m.n. Il ressort clairement que l'isomère *trans*, comme attendu, a des valeurs inférieures à celles de l'isomère *cis*, tant pour le groupe C*H*—OH que pour le groupe C*H*—S—C_6H_5. Nous avons aussi mesuré les spectres r.m.n. dans le chloroforme deutérié; ils montrent des déplacements chimiques analogues. La règle de l'additivité jouant dans cette série, il est raisonnable de l'appliquer également aux cas des alcools tertiaires **20** et **21**.

Une confirmation des configurations *cis* et *trans* des alcools **24** et **25** vient de l'étude des phénylsulfonyl-4 cyclohexanols-4 *cis* et *trans* **26** et **27**. Par réduction catalytique sur nickel de Raney, la phénylsulfonyl-4 cyclohexanone (**9**) conduit à un alcool dont le spectre r.m.n., dans le chloroforme deutérié, présente une bande à δ 2.88 et une autre à 4.00 de largeur à demi hauteur de 9 Hz. Par réduction par l'hydrure de lithium et d'aluminium la cétone **9** conduit à un alcool dont le spectre r.m.n. montre une bande à δ 2.88 et une autre à 3.50 de largeur à demi hauteur de 23 Hz. On s'attend par l'examen des valeurs des énergies conformationnelles des groupes, SO_2—C_6H_5, 2.5 kcal/mol (20) et —OH, 0.6–1.07 (11, 17, 21) à ce que les deux alcools épimères aient un groupe phénylsulfonyle équatorial et se distinguent par l'orientation axiale et équatoriale du groupe hydroxyle. Il est manifeste dès lors que l'alcool de réduction catalytique est

SCHÉMA 3

l'alcool *cis* (**26**) et l'alcool de réduction chimique, l'alcool *trans* (**27**). La corrélation de configuration entre les alcools sulfurés et les alcools sulfonylés se fait par oxydation du groupe sulfure de l'isomère *cis* **24**, selon la méthode de Paquette (22): nous avons bien obtenu l'alcool **26**, comme attendu.

(C) Conclusions

La désamination nitreuse des aminométhyl-1 phénylsulfonyl-4 cyclohexanols-1 *cis* et *trans* est régie par des facteurs de deux ordres. Un facteur électronique, dû à l'effet électronégatif du groupe sulfonyle augmente, par rapport à un groupe *tert*-butyle, la formation des époxydes. Un facteur

conformationnel, soit l'orientation axiale ou équatoriale du groupe $—CH_2—NH_2$, fait que la formation de l'époxyde est plus grande pour une orientation équatoriale que pour une orientation axiale.

Partie expérimentale

Les points de fusion (p. de f.) ont été déterminés en tubes capillaires, avec un thermomètre étalonné avec des substances pures de p. de f. connu en provenance du Bureau des Standards de Washington. Les spectres i.r. ont été déterminés au moyen d'un appareil Beckman IR-8, dans du chloroforme. Les spectres de r.m.n. ont été enregistrés au moyen d'un appareil Jeolco H60, en solution de tétrachlorure de carbone ou de chloroforme deutérié, avec référence au tétraméthylsilane. Les chromatographies sur plaque en couche mince ont été faites selon la technique décrite par Stahl (17). Les analyses centésimales sont de Midwest-Microlab Co. Indianapolis.

1 Cétones

1.1 Phénylthio-4 pimélate d'éthyle (7c)

A une solution de 12.5 g (0.55 at g) de sodium dans 250 ml de méthanol anhydre on ajoute assez rapidement 60 g (0.55 mol) de thiophénol. On évapore la solution résultante de moitié, on y ajoute 500 ml de toluène anhydre et l'on évapore de nouveau jusqu'au point d'ébullition du toluène. On obtient ainsi une suspension de thiophénolate de sodium dans le toluène ne contenant plus de méthanol. A cette suspension on ajoute 101 g (0.55 mol) de la lactone de l'hydroxy-4 pimélate d'éthyle **7***a* préparée selon (7) et l'on enlève complètement le solvant au bain-marie maintenu à 165°. Après la fin de l'évaporation le résidu est chauffé encore ½ h à 165°, refroidi, repris par 150 ml d'eau et lavé à l'éther. La solution aqueuse est acidifiée par de l'acide chlorhydrique concentré et extraite par de l'éther. Celui-ci est séché et évaporé pour donner 130 g d'une huile jaune très visqueuse. Ce résidu brut de réaction, p.éb. 198–210°/0.4 mm, équivalent de neutralisation 235, correspond au *phénylthio-4 monopimélate d'éthyle* (**7***b*) contenant un peu de diacide correspondant. Il est ajouté lentement à une solution de 65 g de chlorure de thionyle dans 500 ml d'éthanol absolu maintenu à 0° dans un bain de sel et de glace. Après la fin de l'addition on laisse le mélange réactionnel revenir lentement à la température de la pièce, puis on chauffe à reflux pendant ½ h. L'éthanol est alors évaporé sous vide et le résidu repris par de l'éther; celui-ci est lavé par du carbonate de sodium à 10%, séché et évaporé. Par distillation du résidu on obtient 132.4 g (75%) de *phénylthio-4 pimélate d'éthyle* (**7***c*) p.éb. 162°/0.7 mm; $n_D^{25} = 1.5145$. Le résidu brut de la réaction du thiophénolate de sodium avec la lactone de l'hydroxy-4 pimélate d'éthyle (2.4 g), sont laissés pendant 24 h à la température de la pièce, dans une solution de 0.6 g d'hydroxyde de sodium dans 20 ml d'eau. Après ce temps la solution est acidifiée par l'acide chlorhydrique concentré et refroidie à 0°. Le précipité est filtré et recristallisé dans un mélange éther – éther de pétrole pour donner 2.1 g d'*acide phénylthio-4 pimélique* (**7***d*) p. de f. 80–82°. Equivalent de neutralisation calculé, 134.2; trouvé, 133.9.

Anal. calc. pour $C_{13}H_{16}O_4S$: C, 58.18; H, 6.01. Trouvé: C, 57.90; H, 5.93.

1.2 Phénylthio-4 cyclohexanone (8)

En opérant sous atmosphère d'azote et en prenant les précautions usuelles, 109.4 g (0.34 mol) de phénylthio-4 pimélate d'éthyle sont ajoutés à une suspension vivement agitée de 16.3 g (0.68 mol) d'hydrure de sodium dans 600 ml de benzène anhydre. L'addition de 2 ml d'éthanol absolu amorce la réaction et amène une évolution immédiate d'hydrogène. Après 3 h de reflux, l'évolution d'hydrogène a complètement cessé, indiquant la fin de la réaction. Le mélange réactionnel est alors refroidi à 0° et traité consécutivement par 0.68 mol d'acide acétique glacial et 2.04 mol d'eau. L'acétate de sodium trihydraté formé est filtré et lavé plusieurs fois par le benzène. Le résidu obtenu de l'évaporation des filtrats benzéniques est ensuite chauffé à l'ébullition à reflux pendant 4 h avec une solution composée de 150 ml d'acide acétique glacial, 75 ml d'eau et 25 ml d'acide chlorhydrique 18%. La solution refroidie est extraite par l'éther; l'extrait éthéré est lavé avec une solution aqueuse de carbonate de sodium (10%), puis à l'eau; après séchage et évaporation de l'éther, la distillation du résidu fournit 52.4 g (75%) de *phénylthio-4 cyclohexanone* (**8**) p.éb. 130–135°/0.5 mm; $n_D^{24} = 1.5789$. Spectre i.r. (CCl_4) 1719 cm^{-1} (C=O).

Anal. calc. pour $C_{12}H_{14}OS$: C, 69.86; H, 6.84. Trouvé: C, 69.76; H, 6.72.

1.3 Phénylsulfonyl-4 cyclohexanone (9)

On ajoute lentement 43.5 g de peroxyde d'hydrogène à 30% (10 ml par ½ h) à une solution de 38.7 g de phénylthio-4 cyclohexanone dans 300 ml d'acide acétique glacial maintenu à 5°. Après la fin de la réaction exothermique, le mélange réactionnel est agité à la température de la pièce pendant une nuit et chauffé au bain-marie pendant 2 h. Les solvants sont évaporés sous vide et le résidu est recristallisé dans l'isopropanol. On obtient ainsi 41.2 g (92%) de **9**, fondant à 125–125.5°. Spectre i.r. (CCl_4) 1725 cm^{-1} (C=O).

Anal. calc. pour $C_{12}H_{14}O_3S$: C, 60.47; H, 5.92. Trouvé: C, 60.32; H, 5.89.

2 Amino-alcool **1**

2.1 Nitrométhyl-1 phénylsulfonyl-4 cyclohexanol cis (12)

A une solution de 0.21 g (9×10^{-3} at g) de sodium dans 8 ml d'éthanol absolu on ajoute goutte à goutte une solution composée de 2 g (8.4×10^{-3} mol) de phénylsulfonyl-4 cyclohexanone, 0.8 g (13×10^{-3} mol) de nitrométhane et 15 ml de benzène anhydre. Le sel sodé du nitro-alcool précipite au fur-et-à-mesure de l'addition. Quand elle est terminée, le mélange est agité pendant 18 h à la température ambiante. On ajoute alors 20 ml d'éther

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

anhydre pour précipiter quantitativement le sel sodé du nitro-alcool; on le filtre, le dissout dans l'eau glacée et le neutralise avec 1 ml d'acide acétique glacial. Par filtration on obtient 2.33 g du nitro-alcool **12** brut fondant à 170–172°. Celui-ci recristallisé dans l'éthanol à 95%, donne 1.90 g (76%) de **12** fondant à 175–176°. Spectre r.m.n. (DMSO): δ 4.45, s, 2, $-CH_2NO_2$.[7]

Anal. calc. pour $C_{13}H_{17}O_5NS$: C, 52.16; H, 5.74; N, 4.69. Trouvé: C, 52.19; H, 5.75; N, 4.61.

2.2 Aminométhyl-1 phénylsulfonyl-4 cyclohexanol-1 cis (1)

(*a*) On hydrogène 6.0 g de nitro-alcool **12** dans 50 ml d'acide acétique glacial en présence de 2 g de nickel de Raney. La quantité théorique d'hydrogène est absorbée en 18 h. Le catalyseur est filtré et les filtrats sont évaporés sous vide. Le résidu est repris par l'eau, rendu fortement alcalin par de la soude à 20% et extrait par le chloroforme. Celui-ci est séché et évaporé pour donner 4.8 g (90%) de l'amino-alcool **1** fondant à 130–131° et ne présentant pas de dépression de p. de f. avec un échantillon préparé suivant *b*.

Anal. calc. pour $C_{13}H_{19}O_3NS$: C, 57.96; H, 7.11; N, 5.20. Trouvé: C, 57.92; H, 7.17; N, 5.28.

(*b*) Selon le mode opératoire 3.1 de notre travail antérieur (4), 1.6 g de nitro-alcool **12** donnent après cristallisation dans l'eau 1.2 g (83%) d'amino-alcool **1** sous formes de fines aiguilles fondant à 130.5–131°. Le pK_a, déterminé selon (4), est de 8.48.

3 Amino-alcool 2

3.1 Nitrométhyl-1 phénylthio-4 cyclohexanol trans (10)

En procédant comme décrit en 2.1, 60 g de phénylthio-4 cyclohexanone donnent 64 g d'une huile jaune pâle qui cristallise après quelques heures. Le p. de f. du produit brut est de 61–64°. Par crystallisation répétées dans un mélange éther – éther de pétrole on obtient 47.4 g (62%) de nitro-alcool **10** fondant à 69–70°. Les filtrats donnent une huile qu'il fut impossible de cristalliser.

Anal. calc. pour $C_{13}H_{17}O_3NS$: C, 58.44; H, 6.42; N, 5.24. Trouvé: C, 58.45; H, 6.49; N, 5.33.

3.2 Nitrométhyl-1 phénylsulfonyl-4 cyclohexanol-1 trans (11)

On dissout 25 g de nitro-alcool **10** dans un mélange de 30 ml d'anhydride acétique et de 30 ml d'acide acétique maintenu à 0–5° dans un bain de glace. A cette solution on ajoute lentement 30 ml de peroxyde d'hydrogène à 30%. Après la fin de la réaction exothermique, on laisse le mélange au repos pour la nuit. L'addition de 300 ml d'eau provoque une cristallisation abondante de fines aiguilles de nitro-alcool **11**, fondant à 126°. Par recristallisation dans un mélange éthanol–eau on obtient 21 g (75%) du nitro-alcool fondant à 132–134°. Spectre r.m.n. (DMSO) δ 4.55, s, 2, CH_2NO_2; $(CDCl)_3$, 4.53, s, 2, CH_2NO_2.[7]

Anal. calc. pour $C_{13}H_{17}O_5NS$: C, 52.16; H, 5.74; N, 4.69. Trouvé: C, 52.21; H, 5.92; N, 4.73.

3.3 Aminométhyl-1 phénylsulfonyl-4 cyclohexanol-1 trans (2)

(*a*) Selon le mode opératoire 2.2*a*, 18.2 g de nitro-alcool **11** sont hydrogénés et donnent 90% de l'amino-alcool **2** fondant à 171° et ne présentant pas de dépression de p. de f. avec un échantillon préparé suivant *b*.

Anal. calc. pour $C_{13}H_{19}O_3NS$: C, 57.96; H, 7.11; N, 5.20. Trouvé: C, 57.89; H, 7.14; N, 5.21.

(*b*) Selon le mode opératoire 3.1, de notre travail antérieur (4), 10 g de nitro-alcool **11** donnent après cristallisation dans l'eau 8.1 g (90%) d'amino-alcool **2** fondant à 171°. Le p. de f. de mélange avec son isomère *cis* est de 123–126°. Le pK_a, déterminé selon (4), est de 8.48.

4 Désamination nitreuse

4.1 Désamination nitreuse de l'aminométhyl-1 phénylsulfonyl-4 cyclohexanol cis (1)

A une solution de 1.1 g de l'amino-alcool **1** dans 10 ml d'acide acétique à 25% maintenue à 0° dans un bain de glace et de sel, on ajoute, goutte à goutte, une solution de 0.4 g de nitrite de sodium dans 2 ml d'eau. L'addition provoque la formation d'un volumineux précipité blanc. Le mélange est agité 2 h à 0° et extrait par du chloroforme. La couche organique est lavée par une solution aqueuse de bicarbonate de sodium à 10%, séchée et évaporée. On obtient ainsi 1.0 g d'une huile incolore qui cristallise lentement à froid. Par extraction du résidu avec trois portions de 150 ml d'éther, on isole une solution éthérée *B* et un résidu *C*. L'évaporation de la solution éthérée *B* donne 0.8 g d'un solide blanc fondant à 90–96°; celui-ci est recristallisé dans le butanol secondaire pour donner 0.6 g (60%) d'*époxyde de phénylsulfonyl-4 méthylène-1 cyclohexène cis* (**15**), p. de f. 95–96° après recristallisation dans le butanol-2.

Anal. calc. pour $C_{13}H_{16}O_3S$: C, 61.84; H, 6.39. Trouvé: C, 61.81; H, 6.48.

Le résidu *C* et les filtrats de cristallisation de l'époxyde **15** sont combinés, évaporés sous vide et traités par 10 ml d'une solution de dinitro-2,4 phénylhydrazine préparée suivant (23). On isole ainsi 0.4 g (correspondant à 0.23 g de cétone, soit 23%) de la dinitro-2,4 phénylhydrazone de la phénylsulfonyl-4 cycloheptanone (**14**) fondant à 196° et ne présentant pas de dépression de p. de f. avec un échantillon préparé suivant 4.2 plus loin.

4.2 Désamination nitreuse de l'aminométhyl-1 phénylsulfonyl-4 cyclohexanol trans (2)

L'amino-alcool **2** (14 g) est dissous dans 100 ml d'acide acétique à 25%. La solution résultante est maintenue à 0° dans un bain de glace et de sel. On y ajoute goutte à goutte, une solution de 4.2 g de nitrite de sodium dans 30 ml d'eau et l'on continue l'agitation pendant 2 h encore à la même température. Le mélange est extrait par le chloroforme; celui-ci est lavé par une solution aqueuse de bicarbonate de sodium à 5%, séché et évaporé. On isole ainsi 12.1 g d'une huile jaune pâle très visqueuse (*A*).

(*a*) L'huile *A* (3.0 g) fournit, après quatre cristallisations dans le solvant acétate d'éthyle – éther de pétrole 0.9 g (30%) de la *phénylsulfonyl-4 cycloheptanone* (**14**) fondant à 87–88°.

Anal. calc. pour $C_{13}H_{16}O_3S$: C, 61.87; H, 6.39. Trouvé: C, 61.81; H, 6.46.

Spectre i.r.: bande à 1709 cm^{-1} (C=O). Dinitro-2,4 phénylhydrazone: p. de f. 196–197° (chloroforme–éthanol).

Anal. calc. pour $C_{19}H_{20}O_6N_4S$: C, 52.77; H, 4.66; N, 12.95. Trouvé: C, 52.67; H, 4.68; N, 12.92.

[7]Pour fins de comparaison, les signaux de r.m.n. des *tert*-butyl-4 nitrométhyl-1 cyclohexanols-1 (1), apparaissent (CCl_4) comme singulets à δ 4.48 lorsque le groupe $-CH_2NO_2$ est axial, et à δ 4.30 lorsqu'il est équatorial.

For personal use only.

(*b*) L'huile *A* (5.6 g) est chauffée à l'ébullition pendant 2 h avec 6 ml de pipéridine et 20 ml de méthanol. Le méthanol est évaporé sous vide et le résidu est repris par 100 ml de chloroforme et 50 ml d'acide chlorhydrique à 10%. La couche organique est séchée et évaporée pour donner 3.3 g (60%) de phénylsulfonyl-4 cycloheptanone fondant à 87–88° après recristallisation dans l'isopropanol. Le point de fusion mixte avec un échantillon obtenu suivant *a* est de 87°. La couche acide est neutralisée par de la soude à 20% et extraite par du chloroforme. Après séchage et évaporation du solvant on isole 2.7 g (correspondant à 1.6 g de l'époxyde **13**, soit 28%) de *pipéridinométhyl-1 phénylsulfonyl-4 cyclohexanol-1 trans* (**11***a*) fondant à 98–104°. Après cristallisation dans un mélange éther–alcool le p. de f. est porté à 103–104°.

Anal. calc. pour $C_{18}H_{27}O_3NS$: C, 64.06; H, 8.06; N, 4.15. Trouvé: C, 64.00; H, 8.08; N, 4.12.

Chlorhydrate préparé dans l'éther et recristallisé dans l'isopropanol: p. de f. 232–233°.

*5 Méthyl-1 phénylthio-4 cyclohexanols-1 cis et trans (**20** et **21**)*

A une solution d'iodure de méthylmagnésium préparée à partir de 6.2 g de magnésium et 2.40 g d'iodométhane dans 100 ml d'éther anhydre, on ajoute 6.2 g de phénylthio-4 cyclohexanone (**8**) en solution dans 50 ml d'éther anhydre. Après ébullition de 1.5 h et repos à 25° de 11 h, on ajoute à la solution éthérée 100 ml d'une solution aqueuse saturée de chlorure d'ammonium et on isole à la manière habituelle 7.0 g d'une huile incolore. Le spectre i.r. montre l'absence complète de cétone de départ. La c.p.g. montre deux pics dans le rapport 45–55 correspondant aux alcools **21** et **20**. Les alcools ont été séparés par chromatographie sur colonne de gel de silice (1.2 m), en utilisant comme éluant des fractions de 20 ml de benzène–acétone 9:1. On obtient ainsi, à partir de 3.7 g de mélange, 2.0 g (54%), fractions (10–22), de l'alcool *cis* **20** et 1.3 g (35%), fractions 28–45 de l'alcool *trans* **21**. Alcool *cis* **20**, p. de f. 64.5–65°, identique à celui décrit en 5*a*. Spectre i.r. (CCl_4) 3615 (bande fine, —OH non associé); 3580–3250 cm^{-1} (—OH associé). Spectre de r.m.n. (CCl_4) (valeurs δ) 1.17 (s, 3, $—CH_3$); de 1.20 à 2.20 (massif, 9); 2.92 (bande large, 1, largeur à demi hauteur 26 Hz, —S—CH=); de 7.10 à 1.50 (massif, 5, C_6H_5—).

Anal. calc. pour $C_{13}H_{18}OS$: C, 70.24; H, 8.11; S, 14.42. Trouvé: C, 70.41; H, 8.09; S, 14.60.

Alcool *trans* **21**, p. de f. 52–53°. Spectre i.r. (CCl_4) 3615 (bande fine, —OH non associé); 3580–3250 cm^{-1} (—OH associé). Spectre de r.m.n. (CCl_4) (valeurs δ) 1.20 (s, 3, $—CH_3$); de 1.25 à 2.20 (massif, 9); 3.3 (bande large, 1, largeur à demi hauteur 14 Hz, —S—CH=); de 7.10 à 7.50 (massif, 5, C_6H_5—S).

Anal. calc. pour $C_{13}H_{18}OS$: C, 70.24; H, 8.11; S, 14.42. Trouvé: C, 70.59; H, 8.26; S, 14.71.

*5a Méthyl-1 phénylthio-4 cyclohexanol-1 cis (**20**)*

(*a*) En suivant le mode opératoire de Corey et Chaykovsky (10): 20.6 g de phénylthio-4 cyclohexanone conduisent à 18.9 g du mélange des époxydes **18** et **19**, p.éb. 136–140°/0.4 mm. Le spectre i.r. ne montre ni cétone, ni alcool.

Anal. calc. pour $C_{13}H_{16}OS$: C, 70.87; H, 7.33; S, 14.55. Trouvé: C, 71.18; H, 7.61; S, 14.29.

En c.p.g. les deux époxydes sortent dans l'ordre **19** et **18**, (4% de FS 1265 sur Anachrom ABS: colonne de verre de 5.40 m, température de la colonne 200°).

(*b*) Le mélange des époxydes préparés en (*a*), 2.1 g est réduit par une suspension de 2.0 g d'hydrure de lithium et d'aluminium, dans 75 ml d'éther anhydre. Après 2.5 h d'ébullition, on isole à la manière habituelle 2.3 g d'alcool brut, constitué des deux alcools **21** et **20** dans le rapport 18–82 comme le montre la c.p.g. dans des conditions identiques à celles décrites en 5*a*. Par cristallisation de l'alcool brut dans le pentane, on obtient l'alcool **20** pur p. de f. 64.5–65°, homogène en c.p.g., identique à celui plus haut en 5.

*6 Méthyl-1 phénylsulfonyl-4 cyclohexanol-1 cis (**16**)*

*6.1 Par hydrogénation de l'époxyde **15***

On hydrogène 147 mg d'époxyde **15** p. de f. 95–96°, dans 25 ml d'éthanol anhydre en présence de palladium à 1% sur carbonate de calcium. On obtient 146 mg d'alcool **16** p. de f. 183.5–185° après cristallisation dans le butanol-2. Le spectre r.m.n. ($CDCl_3$) (valeurs δ) montre une bande fine à 1.22 ($—CH_3$), un massif de neuf protons de 1.00 à 2.10, une bande étalée $—SO_2—CH=$ à 2.90 et les protons aromatiques 5H, de 7.20 à 8.00. Spectre i.r., 3615 (bande fine, —OH non associé); 3590–3300 cm^{-1} (—OH associé).

Anal. calc. pour $C_{13}H_{18}O_3S$: C, 61.38; H, 7.13. Trouvé: C, 61.33; H, 7.12.

6.2 Par réaction de Grignard

A une solution de 24 g de phénylsulfonyl-4 cyclohexanone préparée plus haut selon 1.3 dans 200 ml de benzène anhydre, on ajoute lentement une solution de 18 g d'iodure de méthylmagnésium fraîchement préparée dans 100 ml d'éther anhydre. Après la fin de l'addition le mélange réactionnel est chauffé à reflux pendant 2 h, puis traité par 100 ml d'une solution saturée de chlorure d'ammonium. La couche organique est décantée, séchée, et évaporée. On obtient ainsi 25.1 g d'une huile très visqueuse qui cristallise lentement. Le produit est dissous dans 500 ml de benzène, absorbé sur 500 g d'alumine (activité I) et élué par fraction de 125 ml, par 500 ml de benzène, 500 ml d'éther (5%) – benzène, 1000 ml d'éther (10%) – benzène, 1000 ml d'éther (30%) – benzène, 500 ml d'éther (50%) – benzène, 500 ml d'éther (75%) – benzène, 500 ml de chloroforme (5%) – éther, 500 ml de chloroforme (10%) – éther, 500 ml de chloroforme (50%) – éther, 2500 ml de chloroforme, et 500 ml de méthanol (5%) – chloroforme. Des fractions de 1 à 30 (3.48 g) on tire par cristallisation dans le butanol secondaire 2.8 g de phénylsulfonyl-4 cyclohexanone. Les fractions 55 à 65 (8.29 g de p. de f. 160–168°) donnent, après recristallisation dans le butanol secondaire, 5.3 g de *méthyl-1 phénylsulfonyl-4 cyclohexanol-1* (**16**) p. de f. 183–184.5°, identique (p. de f. de mélange) à celui obtenu en 6.1. Les fractions 31 à 54 (6.07 g de p. de f. 107–127°) ne purent être cristallisées de même que les fractions 66 à 75 (7.16 g d'huile brune très visqueuse).

*6.3 Par oxydation de l'alcool **20***

On dissout 170 mg (3.15 mol) d'alcool **20** dans un mélange de 0.5 ml d'anhydride acétique et 0.5 ml d'acide acétique glacial. On refroidit le tout dans un bain de glace, puis ajoute 0.5 ml de péroxyde d'hydrogène à 30%. On abandonne à 0° durant 2½ h, puis à 25° pendant 12 h; on chauffe ensuite sur bain-marie pendant 30 min. On

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ajoute goutte à goutte, à la solution chaude, de l'eau jusqu'à formation d'un léger trouble (10 gouttes environ). Par refroidissement dans l'armoire frigorifique, il se forme des aiguilles blanches, qui sont essorées, lavées avec de l'eau froide et séchées. Il s'agit de l'alcool qui fond à 183–185° et ne donne pas de dépression de point de fusion avec les échantillons préparés selon 6.1 et 6.2.

*7 Méthyl-1 phénylsulfonyl-4 cyclohexanol-trans (**17**)*

On oxyde l'alcool **21** (170 mg) comme décrit en 6.3 plus haut. L'alcool ne précipite pas sous forme cristalline, mais comme une huile. On évapore les solvants sous vide à 45° pendant 2 h et on ajoute au résidu 15 ml d'eau, chauffe à l'ébullition à reflux, concentre sous vide de 11 mm. Des cristaux précipitent à la température ambiante dans l'espace d'1/2 h. On essore les cristaux (90 mg), on les sèche à température ambiante. Il s'agit de l'alcool *trans*, qui se présente sous forme monohydratée, p. de f. 55–56°, avec décomposition. Spectre i.r. ($CHCl_3$) 3615 (bande fine, —OH non associé); 3590–3300 (—OH associé); 1310, 1150 cm^{-1} (—SO_2—). Spectre de r.m.n. ($CDCl_3$) (valeurs δ) 1.2 (s, 3, —CH_3); de 1.3 à 2.2 (massif, 9); 2.8 (bande large, 1, —SO_2—CH═); de 7.6 à 8.2 (massif, 5, C_6H_5—SO_2—). Spectre r.m.n. (DMSO-d_6) 1.1 (s, 3, —CH_3); 1.5 à 2.1 (massif, 8); 3.3 (bande large, 1, SO_2—CH═); 4.55 (s, 1, —OH); de 7.6 à 8.1 (massif, 5, C_6H_5—SO_2—). La bande due à la présence d'eau apparait à 3.47.

Anal. calc. pour $C_{13}H_{20}O_4S$: C, 57.32; H, 7.40; S, 11.77. Trouvé: C, 57.44; H, 7.25; S, 11.52.

*8 Phénylthio-4 cyclohexanol-1 cis (**24**)*

Une solution résultant de l'action de 0.137 g (6.0×10^{-3} at g) de sodium sur 10 ml d'éthanol anhydre additionnée de 0.73 g (6.64×10^{-3} mol) de thiophénol, est versée dans 80 ml d'une solution éthanolique de 1.5 g (5.6×10^{-3} mol) du monotosylate de cyclohexanediol-1,4 (**22**) p. de f. 108–111° (benzène – éther de pétrole) préparé selon Owen et Robins (16) p. de f. donné 112°. Après trois semaines à 25°, le précipité formé est filtré, et les eaux-mères, mises à sec, donnent 967 mg d'une huile dont la cristallisation dans l'éther de pétrole fournit 267 mg (23%) de *phénylthio-4 cyclohexanol-1 cis* (**24**) p. de f. 73–75°. La chromatographie sur couche mince ne montre qu'une seule tache (R_f 0.9; éluant: acétate d'éthyle, éther de pétrole, acétone, 3:1:1). Un échantillon analytique fond à 73.5–75° (éther de pétrole). Le spectre i.r. montre les bandes: OH libre 3610, OH lié 3430, C═C (aromatique) 1590 cm^{-1}; les suivantes apparaissent dans le composé *cis* mais sont absentes dans l'isomère *trans* 987 et 954 cm^{-1}. Le spectre r.m.n. montre ($CDCl_3$) (valeurs δ) entre 7.17 et 7.67 un massif correspondant à cinq protons (phényle); à 3.90 un pic correspondant à un proton (C*H*OH) (largeur à demi-hauteur 14 Hz); à 3.25 un pic correspondant à un proton (C*H*S) (largeur à demi-hauteur 16 Hz) entre 1.33 et 2.00, un massif correspondant à neuf protons. Le spectre, dans CCl_4, montre des bandes à 3.20, —SCH═ largeur à demi-hauteur 16 Hz et à 3.60 HOCH═ largeur à demi-hauteur 15 Hz.

Anal. calc. pour $C_{12}H_{16}OS$: C, 69.19; H, 7.74; S, 15.39. Trouvé: C, 69.53; H, 7.69; S, 15.19.

*9 Phénylthio-4 cyclohexanol trans (**25**)*

Une solution résultant de l'action de 0.529 g (2.3×10^{-3} at g) de sodium sur 10 ml d'éthanol–eau (4:1), additionnée de 2.57 g (23.4×10^{-3} mol) de thiophénol, est versée dans 70 ml d'une solution éthanol–eau (4:1) de 5.56 g (0.0205 mol) du monotosylate du cyclohexanediol-1, 4 *cis* **23**, p. de f. 93–93.5° (éther de pétrole – benzène) préparé selon Owens et Robins (16) p. de f. donné 94–95° (éther de pétrole – benzène). Après 7 jours à 0°, le solvant est évaporé sous vide et le résidu dissous dans du chloroforme. La solution, lavée successivement avec une solution de soude à 5% et à l'eau, puis séchée et évaporée fournit 2.94 g d'une huile jaune. Deux cristallisations dans l'éther de pétrole fournissent 0.736 g (17%) de *phénylthio-4 cyclohexanol trans* (**25**) p. de f. 73.5–74°. Cet alcool ne montre qu'une tache à la chromatographie sur couche mince (R_f 0.80, éluant: acétate d'éthyle, éther de pétrole, acétone, 3:1:1); deux taches apparaissent (R_f 0.8 et 0.9) quand il est mélangé avec le phénylthio-4 cyclohexanol *cis*. Le p. de f. mixte avec le phénylthio-4 cyclohexanol *cis* (**24**) est de 20° plus bas que ce dernier. Un échantillon analytique fond à 74.5–76° (éther de pétrole). Le spectre i.r. montre: OH libre 3610, OH lié 3430, C═C (aromatique) 1575 cm^{-1}; les pics suivants apparaissent dans le composé *trans* mais sont absents dans l'isomère *cis* 1447 (très fin), 1043, 750 cm^{-1} (très large). Le spectre r.m.n. montre ($CDCl_3$) valeurs δ entre 7.17 et 7.67, un massif de cinq protons (phényle); à 3.64, un pic correspondant à un proton (C*H*OH) (largeur à demi-hauteur 22 Hz); à 3.03, un pic correspondant à un proton (C*H*S) (largeur à demi-hauteur 22 Hz); entre 0.67 et 2.25, un massif correspondant à neuf protons. Le spectre r.m.n. dans CCl_4, montre le proton C*H*S à 2.92 (largeur à demi-hauteur 29 Hz) et le proton (C*H*OH—) à 3.48 (largeur à demi-hauteur 27 Hz).

Anal. calc. pour $C_{12}H_{16}OS$: C, 69.19; H, 7.74; S, 15.39. Trouvé: C, 68.87; H, 7.64; S, 14.94.

*10 Phénylsulfonyl-4 cyclohexanol-1 cis (**26**)*

10.1 Par réduction catalytique de la phénylsulfonyl-4 cyclohexanone

Le nickel de Raney (17 ml), préparé selon la méthode de Favre–Richer (24), est mélangé avec 10 g de phénylsulfonyl-4 cyclohexanone (9) et 1.5 l d'éthanol à 99%, dans une ampoule à hydrogénation. Quand l'hydrogénation est terminée, le mélange est filtré sous vide, sur de la terre de diatomée. Le solide est essoré avec 2 l d'acétone bouillante. L'évaporation fournit, après deux cristallisations dans le benzène, 5.73 g (57%) de *phénylsulfonyl-4 cyclohexanol-1 cis* (**26**) p. de f. 85–87° homogène à la chromatographie sur couche mince (R_f 0.7; éluant: acétate d'éthyle, éther de pétrole, acétone, 3:1:1). Les eaux-mères, incristallisables, présentent une bande carbonyle en i.r. Un échantillon analytique fond à 85–87° (benzène). Le spectre i.r. montre: OH libre 3610, OH lié 3510, C═C (aromatique) 1580, SO_2 1300, 1140 cm^{-1}; les pics suivants apparaissent dans le composé *cis*, mais sont absents dans l'isomère *trans* 950 (très fort), 925, 850, 750 (très large) cm^{-1}. Le spectre r.m.n. ($CDCl_3$) (valeurs δ) montre entre 7.33 et 8.08 un massif correspondant à cinq protons (phényle); à 4.00 un pic correspondant à un proton (C*H*OH) (largeur à demi-hauteur 9 Hz); à 2.88 un pic correspondant à un proton (C*H*SO_2—) (largeur à demi-hauteur 22 Hz); entre 1.00 et 2.17, un massif correspondant à neuf protons.

Anal. calc. pour $C_{12}H_{16}O_3S$: C, 59.97; H, 6.71; S, 13.34. Trouvé: C, 59.92; H, 6.60; S, 13.24.

p-Nitrobenzoate

Le *p*-nitrobenzoate est obtenu à partir de l'alcool *cis* selon la technique de Hennion et de Barrett (25) avec un rendement de 99%. Après six cristallisations dans l'éthanol anhydre, le p. de f. est constant, 168.5–170.5° (rendement 56%). Le p. de f. mixte avec le *p*-nitrobenzoate *trans* baisse de 25°. La chromatographie sur couche mince montre une seule tache, dès la première cristallisation (R_f 0.3; éluant: éther de pétrole, chloroforme, acétate d'éthyle, 3:1:1) tandis qu'un mélange de deux *p*-nitrobenzoates *cis* et *trans* donne deux taches (R_f 0.3 et 0.4) dans les mêmes conditions. Un échantillon analytique fond à 168.5–170.5° (éthanol anhydre). Le spectre i.r. montre: 1715 (C=O), 1300, 1140 (SO_2), 1520 (NO_2 sym.), 1340 cm^{-1} (NO_2 sym.); les pics suivants apparaissent dans le composé *cis* mais sont absents dans l'isomère *trans*: 1300, 990, 880, 850 cm^{-1}.

Le spectre r.m.n. présente ($CDCl_3$) (valeurs δ) de 7.41 et à 8.50, un massif correspondant à neuf protons (phényle); à 5.53, un pic correspondant à un proton (—C*H*—$OCOC_6H_5$) largeur à demi-hauteur 8 Hz; à 3.07, un pic correspondant à un proton (C*H*SO_2—) (largeur à demi-hauteur 22 Hz); entre 1.50 et 2.42, un massif correspondant à huit protons.

Anal. calc. pour $C_{19}H_{19}O_6NS$: C, 58.60; H, 4.92; S, 8.23. Trouvé: C, 58.41; H, 5.02; S, 8.33.

10.2 Par oxydation du phénylthio-4 cyclohexanol cis

On oxyde selon la technique de Paquette (22), 74 mg (0.356×10^{-3} mol) de phénylthio-4 cyclohexanol *cis*. On obtient, par extraction au chloroforme, 76.2 mg (89%) de phénylsulfonyl-4 cyclohexanol *cis* (**26**) qui recristallisé six fois dans le benzène, donne un p. de f. constant de 85–87° et ne montre pas de diminution de p. de f. quand il est mélangé avec le composé obtenu par réduction catalytique (0.1). De plus, il montre les mêmes spectres i.r. et r.m.n. que ce dernier.

*11 Phénylsulfonyl-4 cyclohexanol-1 trans (**27**)*

La phénylsulfonyl-4 cyclohexanone (**9**) (6.0 g, 0.025 mol) en solution dans 150 ml de tétrahydrofuranne (THF) anhydre, est ajouté goutte à goutte, à une suspension vivement agitée de 3.83 g d'hydrure de lithium aluminium (0.1 mol) dans 100 ml de THF anhydre. Le mélange devenu vert est chauffé jusqu'à reflux pendant 1½ h, puis, agité 10 h à 25°. L'excès d'hydrure est détruit avec 100 ml d'acide chlorhydrique à 10%. La solution est extraite au chloroforme. Les phases organiques réunies, lavées à l'eau, séchées, et évaporées sous vide à 20°, fournissent 6.0 g (100%) de *phénylsulfonyl-4 cyclohexanol trans* (**27**) brut.

Cet alcool brut est analysé en chromatographie sur couche mince, par un mélange de solvants: acétate d'éthyle, éther de pétrole, acétone 3:1:1; l'alcool brut de la réduction ci-dessus donne cinq taches: R_f 0.4 (très faible) non identifié; R_f 0.5, non identifié; R_f 0.6 phénylsulfonyl-4 cyclohexanol-1 *trans* (**27**), identifié par cochromatographie avec l'alcool *trans* pur; R_f 0.7 phénylsulfonyl-4 cyclohexanol *cis* (**26**) identifié en cochromatographie avec l'alcool *cis* pur obtenu en 6.1; R_f 0.9 non identifié.

L'alcool **27** brut fournit après plusieurs cristallisations dans l'eau le *phénylsulfonyl-4 cyclohexanol-1 trans* **27**, de p. de f. 40–50° (déc.). Un échantillon est cristallisé pour analyse dans le benzène: p. de f. 44–45° (déc.). Le spectre i.r. montre: OH libre 3610, OH lié 3510, C=C (aromatique) 1580 cm^{-1}; les pics suivants apparaissent dans le composé *trans* mais sont absents dans l'isomère *cis* 1148, 1050, (très forte intensité), 960, 720, 600 (forte intensité) cm^{-1}.

Le spectre r.m.n. ($CDCl_3$) (valeurs δ) montre de 7.33 à 8.00 un massif correspondant à cinq protons (phényle); à 3.50, un pic correspondant à un proton (C*H*OH) (largeur à demi-hauteur 23 Hz), à 2.88, un pic correspondant à un proton (C*H*SO_2—) (largeur à demi-hauteur 20 Hz) entre 0.83 et 2.58, un massif correspondant à neuf protons.

Anal. calc. pour $C_{12}H_{16}O_3S$: C, 59.97; H, 6.71; S, 13.34. Trouvé: C, 56.14; H, 7.02; S, 12.03.

Anal. calc. pour $C_{12}H_{16}O_3S{\cdot}H_2O$: C, 55.80; H, 7.02; S, 12.14.

p-Nitrobenzoate

On solubilise à chaud 0.835 g (5×10^{-3} mol) d'acide *p*-nitrobenzoïque et 1.20 g (5×10^{-3} mol) de phénylsulfonyl-4 cyclohexanol *trans* brut dans 65 ml de pyridine. La solution est additionnée de 1.24 g (6.5×10^{-3} mol) de chlorure de benzoyle, puis chauffée 2 h à 100° (préparation selon la technique de Hennion et de Barrett (25)). La solution refroidie, précipitée dans 200 ml d'un mélange glace-eau, filtrée, fournit 1.56 g (80%) de *p*-nitrobenzoate *trans*. Quatre cristallisations dans l'éthanol absolu donne le *p*-nitrobenzoate avec un p. de f. constant de 167–168.5° et un rendement de 27%. La chromatographie sur couche mince du *p*-nitrobenzoate brut avec un mélange: éther de pétrole, chloroforme, acétate d'éthyle, 3:1:1 donne deux taches à la première cristallisation (R_f 0.3 et 0.4): l'une (trace) correspond au *p*-nitrobenzoate *cis*, identifié par chromatographie avec le *p*-nitrobenzoate *cis* pur et l'autre, au *p*-nitrobenzoate *trans*, identifié par cochromatographie avec le *p*-nitrobenzoate *trans* pur p. de f. 167–168.5°. Un échantillon analytique fond à 167–168.5° (éthanol-anhydre). Le spectre i.r. montre les pics 1715 (C=O), 1520 (NO_2 asym.), 1340 (NO_2 sym.), 1300, 1140 cm^{-1} (SO_2); les pics suivants apparaissent dans le composé *trans* mais sont absents dans l'isomère *cis*: 1320, 940, 810, 610 cm^{-1}.

Le spectre r.m.n. ($CDCl_3$) (valeurs δ), montre entre 7.33 et 8.58, un massif correspondant à neuf protons (phényle); à 5.02, un pic correspondant à un proton ($CHOCOC_6H_5$) (largeur à demi-hauteur 23 Hz); à 3.05, un pic correspondant à un proton (C*H*SO_2—) (largeur à demi-hauteur 22 Hz) de 1.33 à 1.67, un massif correspondant à huit protons.

Anal. calc. pour $C_{19}H_{19}O_6NS$: C, 58.60; H, 4.92; S, 8.23. Trouvé: C, 58.46; H, 4.74; S, 8.30.

On mélange 2.66 g de *p*-nitrobenzoate *trans* (p. de f. 167–168.5°) avec une solution de 3.5 g de soude dans 30 ml d'eau et 45 ml de méthanol. Après 2 h de reflux, le méthanol est évaporé. Après 12 h au réfrigérateur, la suspension obtenue est filtrée. Un lavage à l'eau provoque une cristallisation instantanée dans le filtrat. La filtration fournit 0.38 g (23%) de phénylsulfonyl-4 cyclohexanol-*trans* (**27**) p. de f. 40–50° (déc.).

Nous remercions les Laboratoires Ayerst de Montréal et le Conseil National de Recherches du Canada de leur

aide financière (subventions T-14, A 0014 et A 5526, et bourse d'études à M.M.).

La réaction du diazométhane avec les phénylsulfonyl-4, tert-butyl-4, et phénylthio-4 cyclohexanones[1]

H. Favre, D. Gravel, Z. Hamlet,[2] M. Ménard,[3] et J. Temler[4]

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 6 mai 1971

Ce mémoire traite de l'action du diazométhane *in situ* dans le méthanol en présence d'hydroxyde de potassium sur les phénylsulfonyl-4, tert-butyl-4, et phénylthio-4 cyclohexanones. Dans les deux derniers cas, les réactions conduisent à des mélanges contenant surtout les cétones agrandies accompagnées d'un peu des époxydes correspondants. Dans le premier cas, la cétone agrandie et les époxydes correspondants se forment en quantités égales. Cette formation élevée d'époxydes témoigne d'interactions électroniques transannulaires entre le groupe sulfonyle et la bétaine intermédiaire. Dans les réactions *ex situ* dans le méthanol, mais en l'absence d'hydroxyde de potassium, la cétone sulfonylée conduit essentiellement à l'acétal diméthylique, alors que les réactions des cétones tert-butylée et phénylthio suivent le même cours que lors des réactions *in situ*. L'hydroxyde de potassium exerce de plus une action particulière, en ouvrant les époxydes spiranniques et en conduisant à des éthers-alcools du type $\diagdown C(OH)—CH_2—O—CH_3$. Cette ouverture d'époxyde est avantageusement mise à profit pour obtenir des époxydes purs à partir de mélanges d'époxydes épimères. Les époxydes formés dans la réaction des trois cétones étudiées sont des mélanges d'isomères *cis–trans*, riches en isomères *cis*.

This paper describes the reaction of diazomethane generated *in situ*, methanolic potassium hydroxide solution, on 4-phenylsulfonyl, 4-tert-butyl, and 4-phenylthio-cyclohexanones. In the latter two cases, the reaction leads to mixtures containing mostly the enlarged ketones along with minor quantities of the corresponding epoxides. In the first case, the enlarged ketone and the corresponding epoxides are formed in equal amounts. This marked increase in the production of epoxides is indicative of transannular interactions between the sulfonyl group and the intermediate betaine. In the *ex situ* reactions, methanolic solutions without potassium hydroxide, phenylsulfonylcyclohexanone yields the corresponding dimethyl acetal almost exclusively whereas the tert-butyl and phenylthioketones follow the same course as in the *in situ* reactions. Furthermore, it has been observed in all cases that, under the conditions used, the potassium hydroxide leads to opening of the epoxide rings to yield hydroxy-ethers of the type $\diagdown C(OH)—CH_2—O—CH_3$. This epoxide-ring-opening was advantageously used in the preparation of pure epoxides from epimeric mixtures. The epoxides generated from the three ketones studied are mixtures of *cis–trans* isomers, rich in *cis* epimer.

Canadian Journal of Chemistry, 49, 3097 (1971)

Poursuivant notre étude de l'influence du groupe sulfonyle sur l'aptitude à l'extension des cétones à six chaînons (1) et des amino-alcools correspondants (1, 2), nous avons examiné la réaction de la phénylsulfonyl-4 cyclohexanone (**1***a*) avec le diazométhane. Nous avons examiné également le comportement, vis-à-vis de ce réactif, de la tert-butyl-4 cyclohexanone (**1***b*), que nous prenons comme système de référence. Finalement, nous avons étudié la phénylthio-4 cyclohexanone (**1***c*), dans le but de mettre en évidence les effets conformationnels et électroniques découlant de la présence du groupe phénylthio.

Nous avons effectué les réactions de deux manières: (*A*) *in situ*, selon le mode opératoire de Barbier (3), mis en oeuvre précédemment en série hétérocyclique (1), et (*B*) *ex situ*, dans le méthanol comme solvant ou selon la méthode de Bradley *et al.* (4), c'est-à-dire dans l'éther contenant des quantités catalytiques de méthanol. Les résultats sont rapportés aux tableaux 1 et 2.

Les produits de réaction sont en règle générale

*La quantité de MeOH, exprimée en mmol, correspond à 1 mmol de cétone.
†Correspond à l'acétal **7**.
‡Composé de nature inconnue.
§Cétones agrandies plus lourdes que les cétones **2**.

les cétones agrandies **2***a–c*, et les époxydes *cis* et *trans* **3***a–c* et **4***a–c*. Dans les réactions *in situ*, faites en présence d'hydroxyde de potassium, nous retrouvons également les éthers-alcools *cis* **5***a–c* et *trans* **6***a–c* (X = —OCH_3); la cétone **1***a* engendre de plus l'acétal **7**. Nous examinerons d'abord la préparation et la caractérisation de ces divers composés et ensuite leurs dosages dans les mélanges réactionnels.

Les cétones agrandies

Deux d'entre elles sont connues, **2***a* (2) et *b* (5). La cétone **2***c* s'obtient aisément par extension de cycle préparative de la cétone **1***c*. D'une manière générale, dans les conditions d'opération décrites, l'agrandissement de cycle s'arrête à toutes fins pratiques à la cycloheptanone. Dans le cas de la cétone **1***b*, la réaction conduit à quelques pourcents de cétones plus lourdes que **2***b*, qui sont certainement les tert-butyl-4 et -5 cyclo-octanones. En effet, en répétant le travail d'Anet *et al.* (6) c'est-à-dire la préparation d'anneaux à huit chaînons par extension de la cétone **1***b* par le diazométhane en présence d'éthérate de trifluorure de bore, nous avons obtenu un mélange des cétones à 7 et 8 membres dont les pics sont superposables, en c.p.g. à ceux de l'extension de cycle faite dans nos conditions.

Les époxydes

Les époxydes **3***a*, *b*, *c* et **4***a*, *b*, *c* se préparent avec de bons rendements par les méthodes de Corey et Chaykovsky (7). Les pourcentages d'isomère *cis* **3** sont rapportés au tableau 4. Les époxydes purs **3***a* et *b* sont connus de travaux antérieurs, respectivement réfs. 2 et 7. Le mélange 80–20 des époxydes **3***c* et **4***c* est également connu, à la suite de notre travail (2); une simple chromatographie

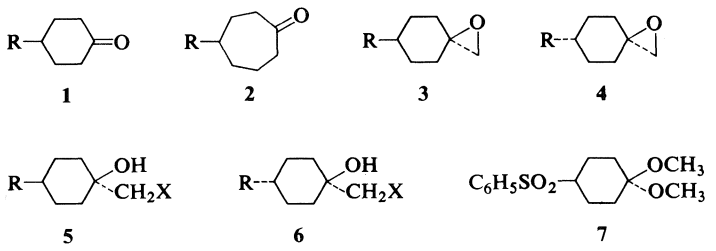
a R = $C_6H_5-SO_2-$; *b* R = tert-butyle; *c* R = C_6H_5-S-



1 2 3 4

5 6 7

de ce mélange sur gel de silice permet d'obtenir l'isomère **3***c* pur. L'obtention des isomères **4***a*, *b*, et *c* résulte d'une méthode inédite. En traitant par de l'hydroxyde de potassium dans le méthanol un mélange des époxydes **3***a*–**4***a* riche en isomère **4***a*, les époxydes se transforment en éthers-alcools **5***a* et **6***a* (X = —OCH_3). Il est possible cependant d'arrêter la réaction au moment où tout l'époxyde **3***a* a réagi, alors qu'il reste encore de l'époxyde **4***a* dans le milieu. Une chromatographie sur gel de silice permet l'isolement de l'époxyde **4***a* pur. De la même manière, les époxydes **4***b* et *c* s'obtiennent à l'état pur.

Les éthers-alcools 5 et 6 (X = —OCH_3)

Ils résultent de l'action de l'hydroxyde de potassium sur les époxydes **3** et **4** dans du méthanol. Les composés **5***a* et *b* s'obtiennent purs au départ des époxydes purs **3***a* et *b*, ce qui établit leur configuration. Les isomères **6***a* et *b* s'obtiennent par ouverture et séparation chromatographique des mélanges riches en époxydes **4***a* et *b*. Le mélange 80–20 des époxydes **3***c*–**4***c*, réduit par l'hydrure de lithium et d'aluminium, donne un mélange 81–19 des alcools connus **5***c* et **6***c* (X = —H) (2) et par traitement par l'hydroxyde de potassium à un mélange 80–20 des éthers-alcools **5***c*–**6***c* (X = —OCH_3), ce qui établit leur configuration. Les six éthers-alcools purs décrits sont des alcools tertiaires, comme le montrent les spectres de r.m.n. mesurés dans le diméthylsulfoxyde deutérié (8).

L'acétal 7

Il s'obtient pur par l'action du méthanol sur la cétone **1***a*, en présence d'éthérate de trifluorure de bore.

Réactions et dosages des mélanges réactionnels

Les expériences ont été menées soit à l'échelle analytique soit à l'échelle préparative. A l'échelle analytique, les dosages ont demandé une longue mise au point. Le cas le plus simple est celui de l'analyse du mélange réactionnel issu de la réaction de la tert-butyl-4 cyclohexanone (**1***b*). En effet, la c.p.g. permet de doser simultanément les cétones **1***b* et **2***b*, les époxydes **3***b* et **4***b*, les éthers-alcools **5***b* et **6***b* et même les cétones agrandies plus lourdes que **2***b*. L'analyse par c.p.g. des époxydes **3***a* et **4***a* est impossible, en raison de leur décomposition. Il est par contre facile de doser par c.p.g., simultanément, les cétones **1***a* et **2***a*, les éthers-alcools **5***a* et **6***a* et l'acétal **7**. Nous avons donc converti totalement les époxydes en éthers-alcools avant le dosage par c.p.g. Nous avons procédé de la même manière dans le cas du mélange réactionnel issu de la cétone **1***c*.

La r.m.n. montre que les mélanges issus des réactions *in situ* en présence d'hydroxyde de potassium contiennent et les époxydes et les éthers-alcools. Les pics des protons méthyléniques (O—CH_2—) des éthers-alcools sont nettement différenciés de ceux des époxydes.

A côté de ces expériences, nous avons travaillé à l'échelle préparative, au départ des cétones **1***a* et *c*. La cétone **1***a* conduit à l'époxyde **3***a*, isolé sous forme de bromhydrine (50%) ou de pipéridino-alcool (39%), et à la cétone agrandie **2***a* isolée sous forme de dinitro-2,4 phénylhydrazone (25%). La cétone **1***c* permet d'obtenir la cétone agrandie **2***c* (64%) et l'époxyde **3***c* isolé comme pipéridino-alcool (**5**, X = $C_5H_{10}N$—). Du point de vue préparatif, l'extension de cycle de la phénylthio-4 cyclohexanone se fait bien, tandis que celle de la phénylsulfonyl-4 cyclohexanone en cétone agrandie **2***a*, est peu intéressante du fait de la grande quantité de cétone de départ qui reste inchangée. Par contre la cétone **2***a* se prépare avantageusement par la méthode de Tiffeneau–Demjanof décrite précédemment (2).

Discussion

La discussion porte sur trois points. (*1*) L'influence de l'hydroxyde de potassium. (*2*) Le rapport cétone agrandie/époxyde. (*3*) Le rapport *cis*/*trans* des époxydes.

(1) Influence de l'hydroxyde de potassium

Dans les trois cas étudiés, l'hydroxyde de potassium dans le méthanol convertit les époxydes **3** et **4** en éthers-alcools **5** et **6** (X = —OCH_3). Dans la réaction des cétones avec le diazométhane, cette conversion est partielle. Une faible quantité de base, un court temps de réaction et une température voisine de 0° sont les conditions qui préservent le mieux les époxydes. A titre d'exemple, nous pouvons citer les extensions préparatives des cétones **1***a* et *c*, qui donnent respectivement 39 et 29% d'époxydes, isolés sous forme de pipéridino-alcools. Les expériences *3* et *4* du tableau 1 donnent une idée de l'influence de la température. En série hétérocyclique, il est aussi possible d'obtenir les époxydes avec de bons rendements (1).

L'hydroxyde de potassium exerce d'autre part une action prépondérante sur le cours de la réaction de la cétone sulfonylée **1***a*. Dans les réactions *ex situ* (expériences *9* et *10*, tableau 2), le composé de réaction prépondérant est l'acétal **7**, tandis que les réactions *in situ* conduisent à la cétone agrandie et aux époxydes (expériences *1* et *2*, tableau 1). La présence ou l'absence de l'hydroxyde de potassium ne joue aucun rôle, quant à la nature des produits formés, dans le cas des cétones tert-butylée **1***b* et phénylthio **1***c*. Hassan et Casy (9), ont montré que les sels d'ammonium quaternaire des pipéridones-4 (**8**) existaient en solution alcoolique sous forme d'hémi-acétal **9**. Nous en déduisons que la cétone sulfonylée **1***a*, porteuse d'un groupe attracteur d'électrons, se comportera de la même façon et que le diazométhane agira comme agent d'acétalisation, comme il le fait avec d'autres hémi-acétals (10) et alcools (11). L'action de l'hydroxyde de potassium serait alors de réduire la formation de l'hémi-acétal et de permettre ainsi l'attaque nucléophile du diazométhane sur le groupe carbonyle.

Dans les réactions *in situ*, le remplacement de l'hydroxyde de potassium par le carbonate de potassium diminue le taux de réaction des cétones **1***b* et *c*, mais ne change pas la nature des produits formés (expériences *3* et *5*, et *6* et *8*, tableau 1). Dans le cas de la cétone sulfonylée **1***a*, le changement de base entraîne un changement total dans les produits de réaction; cette réaction est encore à l'étude.

12 X = $C_6H_5SO_2N$=

(2) Rapport cétone agrandie/époxyde

Nous définissons l'aptitude à l'extension comme le rapport cétone agrandie/époxydes (CA/E), y compris les composés qui dérivent soit de la cétone agrandie soit des époxydes.

Les résultats des tableaux 1 et 2 indiquent que dépendant des conditions employées, les rapports CA/E varient pour une cétone donnée. Nous estimons cependant que dans des conditions expérimentales rigoureusement identiques une comparaison se justifie. Au tableau 3 figurent les rapports CA/E des cétones **1***a–c* obtenus *in situ* (expériences *1*, *3* et *6* du tableau 1) et celui obtenu dans le cas de la phénylsulfonyl-1 pipéridone-4 (**10**), dans des conditions expérimentales identiques (1). La cétone sulfonylée **1***a* occupe une position intermédiaire entre les deux extrêmes que représentent d'une part la tert-butyl-4 cyclohexanone (grande aptitude à l'extension) et la phénylsulfonyl-1 pipéridone-4 (**10**) (aptitude presque nulle à l'extension). Nous reviendrons plus loin au cas de la cétone **1***c*. Figurent aussi au tableau 3 les rapports CA/E pour les désaminations nitreuses des amino-alcools **5***a*, **6***a*, **5***b*, **6***b* (X = —NH_2) et **12** correspondant aux cétones **1***a*, **1***b* et **10** et celui de l'amino-alcool **11** étudié par Overberger et Katchman (12). Le parallélisme est remarquable entre l'action du diazométhane et les désaminations nitreuses: les amino-alcools **5***a* et **6***a* (X = —NH_2) occupent une position intermédiaire entre ceux dérivés de la tert-butyl-4 cyclohexanone (**5***b* et **6***b*) et ceux de la série hétérocyclique (**11** et **12**). Cette variation dans l'aptitude à l'extension témoigne d'interactions entre les groupes électronégatifs et les intermédiaires résultant de l'attaque nucléophile du diazométhane

TABLEAU 3. Aptitudes à l'extension (CA/E) de cétones cycliques et de leurs amino-alcools

Cétones de départ	Cétones agrandies (%)	Epoxydes (%)	CA/E	Référence	Amino-alcools	Cétones agrandies (%)	Epoxydes (%)	CA/E	Référence
1*b*	85*	13	6.5†		**5***b*	80	20	4	5
					6*b*	90	5	18	5
1*c*	65*	32	2†						
1*a*	34	38	0.9†		**5***a*	23	60	0.4	2
					6*a*	60	28	2	2
10	9	82	0.1	1	**12**	traces	91	0.01	1
					11	14	67	0.2	12

*Le chiffre indiqué comprend la cétone agrandie à 7 chaînons et tous les composés qui en dérivent (colonne "autres" du tableau 1).
†Tiré des expériences *1*, *3*, et *6* du tableau 1.

TABLEAU 4. Pourcentage de formation d'époxydes *cis* **3***a*, *b*, et *c*

Cétones **1**	CH_2N_2	$(CH_3)_2SO{=}CH_2$	$(CH_3)_2S{=}CH_2$
a	91–93	100	34
b	78–96	100*	32†
c	71–77	80	44

*Littérature (7) 100%.
†Littérature (7) 17%; la valeur de 32% que nous donnons ici résulte d'un dosage direct par c.p.g.

sur le groupe carbonyle et, d'un effet de distance, comme nous l'avons montré dans nos travaux antérieurs (1, 2).

Nos résultats nous amènent aussi à la conclusion que le groupe phénylthio de la cétone **1***c* n'exerce aucune influence sur le cours de la réaction, voir expériences *4* et *7*, *5*, et *8* du tableau 1, et *14* et *18* du tableau 2, car il se comporte d'une manière fort semblable au groupe tert-butyle, nécessairement inerte, de la cétone **1***b*. Les expériences *3* et *6* constituent cependant une exception.

Il est intéressant de relever que l'observation de Bradley *et al.* (4) au sujet de l'acétone - le rapport CA/E diminue avec la diminution de la quantité d'alcool utilisé comme catalyseur - s'applique aux cétones **1***b* et *c* (expériences *11–13*, *15*, *16* tableau 2). Cette augmentation, qui se fait toutefois au détriment du rendement en cétone agrandie et en époxydes, engendre des composés nouveaux dans le cas de la cétone **1***b*.

(3) Rapport cis/trans des époxydes

Il ressort clairement du tableau 4 que les époxydes *cis* prédominent largement dans les mélanges *cis*/*trans* dans la réaction du diazométhane avec des cyclohexanones substituées en position 4. Deux travaux ont récemment fait état de la prédominance de l'attaque équatoriale du diazométhane sur une décalone-2 (13) et un céto-3 stéroide (14). Notre étude confirme cette observation (tableau 4). Au départ de la tert-butyl-4 cyclohexanone (**1***b*), qui existe en conformation **13***b*, la formation prépondérante de l'époxyde *cis* **3***b*, ou en formule tridimentionnelle **14***b*, correspond à une attaque équatoriale du diazométhane. Il en sera de même pour la cétone **1***a*, en conformation **13***a*, qui engendre surtout l'époxyde *cis* **3***a*, donc **14***a*. Les résultats de la cétone **1***c* sont compatibles avec le fait que cette cétone existe sous les deux conformations **15**, qui par attaque équatoriale donneront un mélange des époxydes *cis* et *trans* **3***c*, **4***c* un peu plus pauvre en isomère *cis* que lorsque la cétone est rigide.

Nous comparons au tableau 4 les résultats de la formation des époxydes *trans* **3***a*, *b*, et *c* par l'action de trois réactifs: diazométhane, méthylures de diméthyloxosulfonium, et de diméthylsulfonium. On y retrouve un parallélisme certain entre l'action du diazométhane et celle du méthylure de diméthyloxosulfonium, cette dernière étant cependant beaucoup plus spécifique dans la formation des époxydes *cis*.

En conclusion, ce travail montre que, par rapport à un groupe tert-butyle en position 4 d'une cyclohexanone: un groupe phénylsulfonyle diminue considérablement l'aptitude à l'extension, mais ne touche pas à la formation prédominante d'époxyde équatorial; en revanche, un groupe phénylthio n'altère que peu l'aptitude à l'exten-

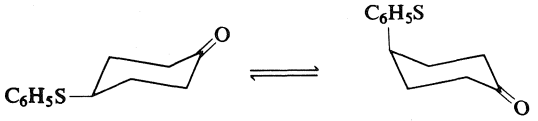
13*a*, *b* **14***a*, *b*

a R = $C_6H_5—SO_2—$

b R = tert-butyle



sion, mais donne par contre une moins grande stéréospécificité dans la formation des époxydes.

Partie expérimentale

Les spectres i.r. ont été déterminés à l'aide d'un spectrophotomètre Beckman IR8, avec un prisme à chlorure de sodium. Les spectres de r.m.n. ont été déterminés avec un appareil Jeolco C 60 H. Les valeurs sont exprimées en δ et données par rapport au tétraméthylsilane. Les liquides ont été distillés dans un tube à boules avant d'être analysés. Les analyses sont de C. Daesslé, Organic Microanalyses, Montréal.

1 Analyses par c.p.g.

Nous avons utilisé un appareil F & M 100, avec détection par ionisation à flamme.

Pour la cétone **1***a*, l'acétal **7**, la cétone **2***a*, et les éthers-alcools **5***a* et **6***a*, les temps de rétention sont les suivants, respectivement: 9, 10, 13, 15, et 19 min, dans les conditions suivantes: colonne de 3.8% de SE30 sur Anachrom ABS, 2.70 m de longueur, 8 mm de diamètre, température de 220° et débit de 70 ml/min; gaz porteur, He.

Pour les époxydes **3***b*, **4***b*, les éthers-alcools **5***b*, **6***b* et les cétones **1***b*, **2***b*, les temps de rétention sont les suivants, respectivement: 10, 12, 12.8, 16, 16.8, et 22 min; pour les cétones plus lourdes, probablement tert-butyl-4 et -5 cyclo-octanones, 25 et 27 min; dans les conditions suivantes: colonne de 4% QF1 sur Anachrom ABS, 6 m de longueur, 6 mm de diamètre, à température de 165° et débit de 45 ml/min, He. Les dosages des époxydes sont particulièrement délicats; il ne faut utiliser que des tubes de verre et surtout placer un tube de verre dans la chambre d'injection, pour éviter tout contact avec les parties métalliques de l'appareil.

Pour la cétone **3***c*, les éthers-alcools **6***c* et **5***c*, la cétone **2***c*, et les cétones plus lourdes que **2***c*, les temps de rétention sont respectivement: 15, 16, 18, 22.3, 26, et 28 min dans les conditions suivantes: colonne de 3.0% de QF1 sur Chromosorb G, 4.50 m de longueur et 3 mm de diamètre, à température de 195° et débit de 30 ml/min, He.

2 Epoxydes

2.1 Méthode au méthylure de diméthyloxosulfonium

Mode opératoire selon (7). La cétone **1***a* donne, avec 60% de rendement, l'époxyde **3***a*, p. de f. brut 70–80°, montant à 93–95° après une cristallisation dans l'éther, seul ou en mélange avec l'époxyde décrit en (2). La cétone **1***b* donne l'époxyde **3***b* pur, homogène en c.p.g. La cétone **1***c* donne, avec un rendement de 86%, un mélange 80–20 des époxydes **3***c* et **4***c* (dosage, section 3.33).

2.2 Méthode au méthylure de diméthylsulfonium

Mode opératoire selon (7). Les résultats sont donnés au tableau 4. Les époxydes **3***b*–**4***b* sont dosés par c.p.g. Les époxydes **3***a*–**4***a* sont dosés à la section 3.1.3 et les époxydes **3***c*–**4***c* à la section 3.3.3.

*3 Synthèse des éthers-alcools **5** et **6** (X = —OCH_3) et préparation des époxydes **3** et **4** purs*

3.1 Série de la phénylsulfonyl-4 cyclohexanone

*3.1.1 Préparation de l'époxyde **4***a* et des éthers-alcools **5***a* et **6***a* (X = —OCH_3)*

On dissout 1.1 g du mélange 34–66 des époxydes **3***a* et **4***a* dans 20 ml d'une solution préparée en dissolvant 3.7 g d'hydroxyde de potassium et 3.7 g d'eau dans 80 ml de méthanol. On agite 6 h à 24°. On neutralise par de l'acide acétique glacial, évapore sous vide à 40°. On reprend par du chloroforme; on lave cette solution par une solution aqueuse de bicarbonate de sodium, puis avec de l'eau jusqu'à neutralité. On sèche sur sulfate de magnésium et évapore le solvant. Le résidu, 1.0 g, est chromatographié sur 100 g de gel de silice; l'éluant est un mélange 58.0–38.2–3.8 d'acétate d'éthyle – cyclohexane – méthanol; on élue par des fractions de 15 ml. Les fractions 23 et 24 contiennent l'époxyde **4***a* (180 mg), les fractions 28–30 l'éther-alcool **6***a* (110 mg) et les fractions 33–37 l'éther-alcool **5***a* (250 mg).

*Epoxyde de méthylène-1 phénylsulfonyl-4 cyclohexane trans (**4***a*)*

Le p. de f. 79–80°. Spectre i.r. ($CHCl_3$): 3040 (époxyde), 1310 et 1150 cm^{-1} (—SO_2—). Spectre de r.m.n.:

($CDCl_3$): 1.4 à 2.5 (massif, 8H); 2.60 (s, 2H, ); 3.00 (1H, —SO_2—); de 7.5 à 8.1 (massif, 5H, C_6H_5—).

Anal. calc. pour $C_{13}H_{16}O_3S$: C, 61.84; H, 6.39; S, 12.69. Trouvé: C, 61.90; H, 6.59; S, 12.89.

*Méthoxyméthyl-1 phénylsulfonyl-4 cyclohexanol cis (**5***a*)*

Le p. de f. 112–113.5° (éther). Spectre i.r. ($CHCl_3$): 3580 (OH non associé), 1310 et 1140 cm^{-1} (—SO_2—). Spectre de r.m.n. ($CDCl_3$): de 1.0 à 3.06 (9H): de 3.1 à 3.7 (bande étalée, 1H); 3.2 (s, 2H, C—CH_2—O) 3.39 (s, 3H, —OCH_3); de 7.4 à 8.1 (5H, C_6H_5). Dans DMSO-d_6, singulet (alcool tertiaire) à 4.35.

Anal. calc. pour $C_{14}H_{20}O_4S$: C, 59.13; H, 7.09; S, 11.26. Trouvé: C, 58.84; H, 6.85; S, 11.41.

*Méthoxyméthyl-1 phénylsulfonyl-4 cyclohexanol trans (**6***a*)*

Le p. de f. 73–74°. Spectre i.r. ($CHCl_3$): 3580 cm^{-1} (OH non associé). Spectre de r.m.n. ($CDCl_3$): de 1.1 à 3.1 (massif, 10H); 3.36 (s, 2H, C—CH_2—O); 3.41 (s, 3H, —OCH_3); de 7.5 à 8.1 (5H, C_6H_5). Dans DMSO-d_6, singulet (alcool tertiaire) à 4.52.

Anal. calc. pour $C_{14}H_{20}O_4S$: C, 59.13; H, 7.09; S, 11.26. Trouvé: C, 59.10; H, 7.21; S, 11.21.

3.1.2 Ouverture de l'époxyde 3a

L'époxyde **3***a* est traité par le mélange MeOH–KOH–eau pendant 24 h comme à la section précédente 3.1.1. Il en résulte après isolement et une cristallisation dans l'éther le composé **5***a*, de p. de f. 112–113, 5°. Une analyse par c.p.g. (selon la section 1) du produit brut ne montre qu'un pic, établissant ainsi la pureté stérique de l'époxyde **3***a* préparé à la section 2.1.

3.1.3 Ouverture du mélange des époxydes 3a et 4a

Le mélange des époxydes **3***a* et **4***a* conduit, par traitement par le mélange MeOH–KOH–eau comme à la section 3.1.2, à un mélange des éthers-alcools **5***a* et **6***a*. Un dosage par c.p.g., comme à la section 1, établit que les deux éthers-alcools **5***a* et **6***a* se trouvent dans les proportions 34–66.

3.2 Série de la tert-butyl-4 cyclohexanone

3.2.1 Préparation de l'époxyde 4b et des éthers-alcools 5b et 6b (X = —OCH₃)

On dissout 3.8 g du mélange (rapport 32–68) des époxydes **3***b* et **4***b* dans 68 ml d'une solution préparée en dissolvant 3.7 g d'hydroxyde de potassium et 3.7 g d'eau dans 100 ml de méthanol. On agite à 24°. Après 20 h, le pic correspondant à l'époxyde **3***b* a complètement disparu en c.p.g.; la réaction est interrompue. On neutralise par de l'acide acétique glacial, évapore sous vide à 40°. On reprend par de l'éther et isole, comme en 3.1.1, 3.5 g de produit que l'on chromatographie sur colonne de gel de silice, en utilisant un mélange 94–6 d'éther de pétrole et d'acétone, et en éluant par des fractions de 20 ml. Les fractions 6 à 12 contiennent l'époxyde **4***b* pur, 1.4 g (37%), les fractions 14 à 24 le composé **5***b*, 1.3 g (28.7%), et les fractions 25 à 28 le composé **6***b*, 0.3 g (6.6%).

Epoxyde de tert-butyl-4 méthylène-1 cyclohexane trans (4b)

Liquide, $n_D^{28} = 1.4598$. Spectre i.r. (CCl_4): 3040 cm^{-1} (oxiranne). Spectre de r.m.n. (CCl_4): 0.9 (s, 9H, tert-butyle); massif de 1.00 à 2.2 (9H): 2.43 (s, 2H,).

Anal. calc. pour $C_{11}H_{20}O$: C, 78.51; H, 11.98. Trouvé: C, 78.25; H, 11.80.

tert-Butyl-4 méthoxyméthyl-1 cyclohexanol cis (5b)

Liquide, $n_D^{28} = 1.4580$. Spectre i.r. (CCl_4): 3600 cm^{-1}, —OH non associé. Spectre de r.m.n. (CCl_4): 0.86 (s, 9H, tert-butyle); massif de 1 à 1.8 (9H); 1.97 (s, 1H, —OH); 3.10 (s, 2H, O—CH_2—O); 3.37 (s, 3H, —O—CH_3). Dans DMSO-d_6: singulet (alcool tertiaire à 4.02.

Anal. calc. pour $C_{12}H_{24}O_2$: C, 71.95; H, 12.08. Trouvé: C, 71.98; H, 12.13.

tert-Butyl-4 méthoxyméthyl-1 cyclohexanol trans (6b)

Liquide, $n_D^{28} = 1.4612$. Spectre i.r. (CCl_4): 3600 cm^{-1}, —OH non associé. Spectre de r.m.n. (CCl_4): 0.86 (s, 9H, tert-butyle); massif de 1 à 2.1 (9H); 2.33 (s, 1H, —OH); 3.30 (s, 2H, C—CH_2—O); 3.40 (s, 3H, —O—CH_3). Dans DMSO-d_6: singulet (alcool tertiaire) à 4.02.

Anal. calc. pour $C_{12}H_{24}O_2$: C, 71.95; H, 12.08. Trouvé: C, 71.59; H, 11.81.

3.2.2 Ouverture de l'époxyde 3b

On traite, comme plus haut à la section 3.1.2, l'époxyde **3***b* pur par le mélange MeOH–KOH–eau. On obtient l'éther-alcool **5***b*, caractérisé par son spectre de r.m.n., contenant 3% d'époxyde de départ, comme le montre l'analyse par c.p.g. faite selon la section 1.

3.3 Série de la phénylthio-4 cyclohexanone

3.3.1 Préparation de l'époxyde 4c et des éthers-alcools 5c et 6c

On traite 2.5 g d'un mélange 80–20% des époxydes **3***c* et **4***c* par 35 ml d'une solution préparée en dissolvant 3.7 g d'hydroxyde de potassium et 3.7 g d'eau dans 100 ml de méthanol. Après agitation de 10 h à 24°, on isole comme en 3.2.1 2.4 g de produit que l'on chromatographie sur 108 g de gel de silice, en utilisant comme éluant un mélange 92–8 d'éther de pétrole – acétone, et en éluant par des fractions de 20 ml. Les fractions 21–26 contiennent l'époxyde **3***c* pur (1.1 g), les fractions 31–36 contiennent l'éther-alcool **6***c* et les fractions 50–53 contiennent l'éther-alcool **5***c*.

Epoxyde de méthylène-1 phénylthio-4 cyclohexane trans (4c)

Liquide. Spectre i.r. (CCl_4): 3045 (époxyde). Spectre de r.m.n. (CCl_4): de 1.2 à 2.3 (massif, 8H); 2.47 (s, 2H,); 3.30 (bande, largeur à demi-hauteur 15 Hz 1H, —S—CH=); 7.2 (m, 5H, C_6H_5—).

Anal. calc. pour $C_{13}H_{16}OS$: C, 70.87; H, 7.32; S, 14.55. Trouvé: C, 70.55; H, 7.31; S, 14.28.

Méthoxyméthyl-1 phénylthio-4 cyclohexanol cis (5c)

Liquide. Spectre i.r. (CCl_4): 3600 cm^{-1} (OH non associé). Spectre de r.m.n. (CCl_4): de 0.98 à 2.51 (massif, 9H); 3.09 (s, 2H, C—CH_2—O—); et 3.33 (s, 3H, —OCH_3); sous ces deux singulets se trouve une bande large, 1H, —S—CH=; 7.2 (m, 5H, C_6H_5—). Dans DMSO-d_6: singulet (alcool tertiaire) à 4.17.

Anal. calc. pour $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99; S, 12.69. Trouvé: C, 66.94; H, 8.23; S, 13.02.

Méthoxyméthyl-1 phénylthio-4 cyclohexanol trans (6c)

Liquide. Spectre i.r. (CCl_4): 3600 cm^{-1} (OH non associé). Spectre de r.m.n. (CCl_4): de 1.11 à 2.30 (massif, 9H); 3.2 (s, 2H, C—CH_2—O—) et 3.34 (s, 3H, —OCH_3); sous ces deux singulets se trouve une bande large, 1H, —S—CH=; 7.21 (m, 5H, C_6H_5—). Dans DMSO-d_6: singulet (alcool tertiaire) à 4.32.

Anal. calc. pour $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99; S, 12.69. Trouvé: C, 66.42; H, 7.76; S, 12.61.

3.3.2 Epoxyde de méthylène-1 phénylthio-4 cyclohexane cis (3c)

On chromatographie sur colonne de gel de silice (125 g) 2.5 g du mélange 80–20% des époxydes **3***c* et **4***c* préparé à la section 2.1. Comme éluant, on utilise des portions de 20 ml du mélange 58–38 d'acétate d'éthyle – cyclohexane. Les fractions 24–27 contiennent l'époxyde **3***c* pur (0.6 g). Liquide. Spectre i.r. (CCl_4): 3045 cm^{-1} (époxyde). Spectre de r.m.n. (CCl_4): de 1.1 à 2.38 (massif, 8H); 2.48 (s, 2H, ); 3.13 (bande de largeur à demi-hauteur de 22 Hz) (1H, —S—CH=); 7.4 (m, 5H, C_6H_5).

For personal use only.

Anal. calc. pour $C_{13}H_{16}OS$: C, 70.87; H, 7.32; S, 14.55. Trouvé: C, 70.96; H, 7.21; S, 14.36.

3.3.3 Dosage des époxydes 3c–4c en mélanges

La réduction des époxydes **3***c* et **4***c* par l'hydrure de lithium et d'aluminium conduit aux alcools **5***c* et **6***c* (X = H) déjà décrits (2). La réduction du mélange préparé en 2.1 plus haut conduit à un mélange contenant 81% d'alcool **5***c* et 19% d'alcool **6***c*, par analyse par c.p.g. dans les conditions décrites (2). Le même mélange d'époxydes conduit par traitement par le mélange MeOH–KOH–eau, comme en 3.3.1 plus haut, à un mélange des deux éthers-alcools **5***c* et **6***c* (X = —OCH_3) dans les proportions 80–20.

Le traitement par MeOH–KOH–eau, du mélange des époxydes **3***c*–**4***c* préparé en 2.2 conduit à un mélange des éthers-alcools **5***c* et **6***c* (X = —OCH_3) dans le rapport 44–56. La réduction du mélange des époxydes par l'hydrure de lithium et d'aluminium donne un mélange 50–50 des alcools **5***c* et **6***c* par analyse par c.p.g., selon (2).

4 Diméthoxy-1,1 phénylsulfonyl-4 cyclohexane (7)

On dissout 50 mg de la cétone **1***a* dans 3 ml de méthanol; on ajoute 0.05 ml d'éthérate de trifluorure de bore, et abandonne, avec agitation, pendant 12 h à 24°. On ajoute 7 gouttes d'une solution aqueuse saturée de bicarbonate de sodium. On évapore les solvants sous vide et reprend par du chloroforme. La solution chloroformique est lavée avec de l'eau, puis séchée sur sulfate de magnésium. On recueille 50 mg de cristaux blancs, qui après cristallisation dans l'éther, fondent à 92–93°. Spectre i.r. ($CHCl_3$): 2840 (OCH_3), 1310 et 1140 cm^{-1} (SO_2). Spectre de r.m.n. ($CDCl_3$): de 1.08 à 2.95 (massif, 9H); 3.09 (s, 3H, —OCH_3); 3.14 (s, 3H, —OCH_3); de 7.46 à 8.1 (massif, 5H, C_6H_5—).

Anal. calc. pour $C_{14}H_{20}O_4S$: C, 59.13; H, 7.09; S, 11.26. Trouvé: C, 59.21; H, 7.17; S, 11.37.

5 Réaction du diazométhane avec les cétones 1a, b, et c

5.1 Réactions in situ

Nous décrivons ici les réactions; les dosages par c.p.g., selon la section 1, figurent au tableau 1. La nitrosométhylurée se prépare selon (15).

5.1.1 Série de la phénylsulfonyl-4 cyclohexanone (1a)

Expérience 1

On dissout 238 mg (1 mmol) de cétone **1***a* dans 8 ml de méthanol refroidi à 0°; on ajoute à cette solution une solution de 112 mg d'hydroxyde de potassium dans 112 mg d'eau, puis par portions, pendant 90 min, 120 mg (1.15 mmol) de nitrosométhylurée. On agite à 0° 1 h de plus, puis à 24° pendant 18 h. On refroidi à 0°, neutralise par de l'acide acétique glacial, évapore le solvant, reprend le résidu par du chloroforme, lave une fois à l'eau, sèche sur sulfate de magnésium et évapore le chloroforme. On analyse par c.p.g.

Expérience 2

On manipule comme dans l'expérience *1*, sauf que l'agitation de 18 h à 24° est remplacée par une agitation de 5 h à 0°.

5.1.2 Série de la tert-butyl-4 cyclohexanone (1b)

Expérience 3

On prépare une solution de 37 ml de méthanol, 0.55 g d'hydroxyde de potassium et 0.55 g d'eau; on y dissout 771 mg de cétone **1** (5 mmol), refroidie à 0° et ajoute avec agitation, en 1.5 h 618.6 mg de nitrosométhylurée (6 mmol). On agite 1 h de plus à 0°, puis 18 h à 24°. On neutralise par de l'acide acétique, évapore le méthanol, reprend par de l'éther, lave à neutralité par de l'eau, sèche sur sulfate de magnésium et évapore l'éther. On dose par c.p.g.

Expérience 4

On opère comme au cours de l'expérience *3*, sauf que l'agitation de 18 h à 24° est remplacée par une agitation de 5 h à 0°.

Expérience 5

On opère comme à l'expérience *3*, sauf que l'hydroxyde de potassium et l'eau sont remplacés par 1.1 g de carbonate de potassium (pas d'eau).

5.1.3 Série de la phénylthio-4 cyclohexanone (1c)

Expérience 6 (tableau 1)

On dissout 206 mg (1 mmol) de cétone **1***c* dans 8 ml d'une solution préparée en dissolvant 0.55 g d'hydroxyde de potassium et 0.55 g d'eau dans 37 ml de méthanol. On y refroidi à 0°, et ajoute, avec agitation, en 90 min, 120 mg de nitrosométhylurée (1.15 mmol). On agite à 0° 1 h de plus, puis 18 h à 24°. On ajoute alors à la solution 8 ml d'une solution préparée en dissolvant 3.7 g d'hydroxyde de potassium et 3.7 g d'eau dans 100 ml de méthanol. On laisse agiter pendant 48 h. On neutralise par de l'acide acétique glacial, évapore le méthanol, reprend le résidu par de l'éther. On lave la solution éthérée à neutralité avec de l'eau, sèche sur sulfate de magnésium et évapore l'éther. On analyse par c.p.g.

Si l'on isole les composés de réaction après l'agitation de 18 h à 24°, on décèle un mélange d'époxydes et d'éthers-alcools, impossible à analyser par c.p.g.

Expérience 7

On manipule comme dans l'expérience *6*, sauf que l'agitation de 18 h à 24° est remplacée par une agitation de 5 h à 0°.

Expérience 8

On manipule comme dans l'expérience *6*, sauf que la solution initiale est faite de 8 ml de méthanol et 240 mg de carbonate de potassium.

5.2 Réactions ex situ

5.2.1 Préparation de la solution de diazométhane dans l'éther

En suivant les indications données en (15), on introduit par petites portions 20.6 g de nitrosométhylurée dans un ballon contenant 60 ml d'une solution aqueuse de KOH 50% et 200 ml d'éther pur maintenus à 5°. Une fois l'addition terminée, on adapte une colonne à distillation sur le ballon et distille lentement; la solution éthérée de diazométhane a un titre de 0.31 *M* (dosage par l'acide benzoïque).

5.2.2 Expérience 9–16 (tableau 2)

Expérience 9

A une solution de 238 mg (1 mmol) de cétone **1***a* dans 4 ml de méthanol maintenu à 24°, on ajoute d'un coup 3.6 ml (1.1 mmol) de la solution de diazométhane 0.31 *M* préparée en 5.2.1. On agite à température de 24° pendant 48 h, évapore les solvants et analyse par c.p.g. A cause de la très grande quantité d'acétal **7**, l'analyse des éthers-alcools est très approximative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

Expérience 10

On travaille comme dans l'expérience *9*, sauf que la température est maintenue à 0°.

Expérience 11

A une solution de 771 mg de cétone **1** (5 mmol), dans 20 ml d'éther, contenant 160 mg de méthanol (5 mmol), maintenue à 24 °C, on ajoute d'un coup 18 ml (6 mmol) d'une solution 0.31 *M* de diazométhane dans l'éther préparée de façon habituelle (22). On agite à température de 24° pendant 48 h et analyse par c.p.g.

Expérience 12

On opère comme au cours de l'essai *11*, sauf que la solution éthérée contient 320 mg de méthanol (10 mmol).

Expérience 13

On opère comme au cours de l'essai *11*, sauf que la solution est composée de 10 ml d'éther et 10 ml de méthanol (250 mmol).

Expérience 14

A une solution de 771 mg de cétone **1** (5 mmol), dans 20 ml de méthanol, à 0°, on ajoute pendant 1.5 h 18 ml d'une solution 0.31 *M* de diazométhane dans l'éther, gardée à 0°. On agite 1 h de plus à 0°, puis 18 h à 24°. On analyse par c.p.g.

Expérience 15

On prépare une solution de 206 mg (1 mmol) de cétone **1***c* dans 4 ml d'éther contenant 32 mg (1 mmol) de méthanol. A cette solution, maintenue à 24°, on ajoute d'un coup 3.6 ml (1.1 mmol) d'une solution 0.31 *M* de diazométhane dans l'éther préparée en 5.2.1 et maintenue à 24°. On laisse agiter 48 h à 24°, évapore le solvant. On ajoute au résidu 8 ml d'une solution formée en dissolvant 3.7 g d'hydroxyde de potassium et 3.7 g d'eau dans 80 ml de méthanol. Après agitation de 48 h, on neutralise par de l'acide acétique, évapore les solvants, reprend par de l'éther, lave une fois avec une solution aqueuse de bicarbonate de sodium puis à l'eau, sèche sur sulfate de magnésium anhydre et évapore l'éther. On dose le résidu par c.p.g.

Expérience 16

On opère comme dans l'expérience *15*, sauf que les 206 mg de cétone **1***c* étaient en solution dans 2 ml de méthanol (50 mmol) et 2 ml d'éther au début de la réaction.

Expérience 17

On opère comme dans l'expérience *15*, sauf que les 206 mg de cétone **1***c* étaient en solution dans 4 ml de méthanol au début de la réaction.

Expérience 18

On procède comme dans l'expérience *17*, sauf que la température était de 0° au lieu de 24° pour le début de la réaction.

*6 Réaction de la cétone **1***a *avec le diazométhane, à l'échelle préparative*

(*A*) On refroidit à 0° une solution de 11.0 de la cétone **1***a* dans 200 ml de méthanol. On y ajoute 5.6 g d'une solution d'hydroxyde de potassium 50% dans l'eau, puis par petites portions 5.0 g de nitrosométhylurée. On agite pendant 3 h à 0°, puis laisse revenir à 24° en 6 h. On neutralise par de l'acide acétique glacial, à 0°. On évapore les solvants sous vide, reprend le résidu par du chloroforme. On lave avec une solution aqueuse 10% de bicarbonate de sodium, on sèche sur sulfate de sodium et évapore le chloroforme. Le résidu est une huile jaune pâle (12.6 g).

(*B*) On agite pendant 1 h à 0°, 2.8 g du résidu obtenu en section *A* avec une solution de 3 ml d'acide bromhydrique à 40% dans 6 ml d'acétone. Une cristallisation abondante se produit. Par filtration, on recueille 1.8 g de *bromométhyl-1 phénylsulfonyl-4 cyclohexanol* (**5***a*, X = —Br), correspondant à 50% d'époxyde **3***a*, de p. de f. 160–162°, montant à 161–162° après une cristallisation dans l'acétone–eau.

Anal. calc. pour $C_{13}H_{17}O_3SBr$: C, 46.85; H, 5.14. Trouvé: C, 46.88; H, 5.21.

On agite 1.0 g de la bromhydrine **5***a*, 2 ml d'eau, 40 ml de méthanol, et 1.4 g d'oxyde d'argent fraîchement préparé pendant 2 h à 20°. On filtre l'oxyde d'argent, et on le lave avec du chloroforme. On évapore les solvants et recueille 0.7 g de l'époxyde **3***a*, p. de f. 95–96°, seul ou en mélange avec l'époxyde préparé antérieurement (2). Spectre de r.m.n. ($CDCl_3$): de 1.0 à 2.4 (massif, 8H); 2.67 (s, 2H,); 3.02 (bande de largeur à demi hauteur, 18 Hz, 1H, $—SO_2—CH=$); de 7.5 à 8.1 (massif, 5H, $C_6H_5—$).

(*C*) Les filtrats de formation et de cristallisation de la bromhydrine obtenus en section *B* sont évaporés sous vide de 11 mm, au bain-marie. Le résidu de 1.1 g est traité par 20 ml d'une solution de dinitro-2,4 phénylhydrazine préparée selon (19). On isole 2.7 g de dérivé fondant à 105–110°. Par cristallisation dans le chloroforme et l'éthanol on tire d'une part 0.7 g de dinitro-2,4 phénylhydrazone de la cétone **1***a* et 0.6 g de dinitro-2,4 phénylhydrazone de la cétone **2***a*, identiques à celles décrites (2).

(*D*) On chauffe à l'ébullition à reflux 6.2 g du résidu obtenu en section *A* avec 6 ml de pipéridine et 20 ml de méthanol. On évapore sous vide de 11 mm, au bain-marie et dissout le résidu dans 100 ml de chloroforme. On extrait la solution chloroformique par 50 ml d'acide chlorhydrique 10%. On décante la couche aqueuse, la neutralise par une solution d'hydroxyde de sodium 20% et extrait par du chloroforme. On sèche sur sulfate de sodium et évapore le chloroforme. On recueille 3.2 g (correspondant à 39% d'époxyde) d'amino-alcool fondant à 98–100°. Par cristallisation dans un mélange benzène-éther de pétrole on obtient le *phénylsulfonyl-4 pipéridinométhyl-1 cyclohexanol* (**5***a*, X = $—NC_5H_{10}$), p. de f. 115–116°. En mélange avec son isomère **5***b* de p. de f. 103–104°, déjà décrit (2) le p. de f. est de 74–77°.

Anal. calc. pour $C_{18}H_{27}O_3NS$: C, 64.06; H, 8.06; N, 4.15. Trouvé: C, 64.04; H, 8.07; N, 4.15.

Le *chlorhydrate* fond à 225–227°, après cristallisation dans l'isopropanol.

Anal. calc. pour $C_{18}H_{28}O_3NSCl$: C, 57.81; H, 7.55; N, 3.75. Trouvé: C, 57.81; H, 7.63; N, 3.74.

*7 Réaction de la cétone **1***c *avec le diazométhane, à l'échelle préparative*

(*A*) On prépare une solution à partir de 150 ml de méthanol, 2.75 g d'hydroxyde de potassium et 2.75 g d'eau; on le refroidit à 0°, y ajoute 10 g de la cétone **1***c*,

puis, par petites portions, 5 g de nitrosométhylurée. On attend que la solution soit redevenue incolore avant d'ajouter la portion suivante. On agite 3 h à 0°, laisse revenir à 20° en l'espace de 6 h, puis neutralise par de l'acide acétique glacial. On évapore sous vide de 11 mm, au bain-marie. On reprend le résidu par de l'éther, qu'on lave avec une solution 10% de bicarbonate de sodium, puis avec de l'eau; on sèche sur sulfate de sodium et évapore le solvant. Le résidu est une huile jaune pâle (10.8 g).

(*B*) On traite 1.06 g du résidu obtenu en section *A* par 1.0 g de chlorhydrate de semicarbazide et 1.0 g d'acétate de sodium dans 10 ml d'éthanol aqueux. On isole ainsi 0.69 g de *semicarbazone* de la cétone **2***c*, qui précipite (correspondant à 52% de cétone **2***c*), de p. de f. 168–169° après cristallisation dans l'éthanol étendu d'eau.

Anal. calc. pour $C_{14}H_{19}ON_3S$: C, 60.62; H, 6.91; N, 15.15. Trouvé: C, 60.55; H, 6.90; N, 15.15.

(*C*) On traite 0.50 g du résidu obtenu en section *A* par la dinitro-2,4 phénylhydrazine, selon (19). On obtient 0.51 g (correspondant à 56.5% de cétone **2***c*) de *dinitro-2,4 phénylhydrazone* de la cétone **2***c*, p. de f. 170–171° après cristallisation dans l'acétate d'éthyle – éthanol.

Anal. calc. pour $C_{19}H_{20}O_4N_4S$: C, 56.98; H, 5.03; N, 14.00. Trouvé: C, 56.88; H, 4.99; N, 14.04.

(*D*) On traite 9.0 g du résidu obtenu en section *A*, par 9 ml de pipéridine et 20 ml de méthanol à l'ébullition à reflux pendant 3 h. On évapore le méthanol sous vide, reprend le résidu par 150 ml d'éther et extrait par 50 ml d'acide chlorhydrique à 10%. La solution éthérée est séchée sur sulfate de sodium; on évapore l'éther. La distillation du résidu donne 5.75 g (64%) de *phénylthio-4 cyclohexanone* (**2***c*), p.éb. 128–130° sous 0.4 mm, n_D^{25} = 1.5755, homogène en c.p.g. selon les conditions données à la section 1. Spectre i.r. (CCl_4): 1707 cm^{-1} (C=O).

Anal. calc. pour $C_{13}H_{16}OS$: C, 70.86; H, 7.32. Trouvé: C, 70.97; H, 7.45.

La couche acide est neutralisée par de la soude à 20% et extraite par de l'éther. Après séchage et évaporation, du solvant on obtient 4.04 g (correspondant à 2.9 g d'époxyde **3***c*, soit 32% de rendement) de *phénylthio-4 pipéridinométhyl-1 cyclohexanol-1 cis* (**5***c*, X = —$C_5H_{10}N$—) sous forme d'une huile brune. Le *chlorhydrate*, préparé dans l'éther, fond à 157.5—159° après deux cristallisations dans le mélange isopropanol–éther.

Anal. calc. pour $C_{18}H_{28}ONSCl$: C, 63.22; H, 8.25; N, 4.10. Trouvé: C, 62.95; H, 8.14; N, 4.14.

On dissout 1.0 g de ce chlorhydrate dans 50 ml d'acide acétique à 50% refroidi à 0° et ajoute lentement une solution de 0.5 g de permanganate de potassium dans 10 ml d'acide acétique à 50%. Après décoloration par l'anhydride sulfureux et évaporation des solvants, le résidu est dissous dans de l'eau et lavé avec du chloroforme. La solution aqueuse est rendue alcaline par de la soude caustique à 20% et extraite par du chloroforme. On sèche et évapore le solvant. On obtient 1.0 g de phénylsulfonyl-4 pipéridinométhyl-1 cyclohexanol-1 *cis* (**5***a*, X = $C_5H_{10}N$—), p. de f. 98–100°, ne donnant pas de dépression en mélange avec un échantillon préparé plus haut à la section 6. Le p. de f. mixte avec l'isomère *trans*, obtenu antérieurement (2), est de 80–86°.

8 Réaction de la tert-butyl-4 cyclohexanone avec le diazométhane en présence d'éthérate de trifluorure de bore

A une solution de 771 mg de cétone **1***b* (5 mmol) dans 20 ml d'éther, à 0°, on ajoute 0.45 ml d'éthérate de trifluorure de bore fraîchement distillé, puis 20 ml d'une solution, refroidie à 0°, de diazométhane dans l'éther, préparée de la manière suivante: On ajoute 9.0 g de nitrosométhylurée à une solution refroidie à 0° de 20 ml d'hydroxyde de potassium à 50% et 40 ml d'éther, en 35 min, avec agitation. La couche éthérée est décantée et séchée sur de l'hydroxyde de potassium en pastilles, à 0°. L'addition se fait en 2 min, à raison de 4 portions de 5 ml chacune. L'analyse par c.p.g. donne les résultats suivants: (les pourcentages correspondent aux surfaces mesurées) **1***b*, 10%; **2***b*, 40%; cétones à 8 chaînons, 23 et 17%; cétones plus lourdes 10%. En ajoutant 40 ml de la solution de diazométhane dans l'éther, on obtient les résultats suivants: (les pourcentages correspondent aux surfaces mesurées) **1***b*, 0%, **2***b*, 10%; cétones à 8 chaînons, 37 et 26%; cétones plus lourdes à 31 et 33 min, 15%; à 39 min, 12%.

Nous remercions les Etablissements Dow Chemical of Canada Ltd, Montréal, de la tert-butyl-4 cyclohexanone mise à notre disposition. Nous remercions également les Laboratoires Ayerst, Montréal, le fonds de recherche non subventionnée de l'Université de Montréal et le Conseil National de Recherches du Canada de leur aide financière (subventions T-14, A-0014, et A-5526 et bourse d'études à D.G., Z.H. et M.M.).

Ion Pair Formation in Solutions of Alkali Halides in Dimethyl Sulfoxide: Ultrasonic Absorption Studies[1]

D. R. DICKSON AND P. KRUUS
Department of Chemistry, Carleton University, Ottawa, Canada

Received February 4, 1971

The ultrasonic absorption of dimethyl sulfoxide solutions of several alkali halides has been studied in the frequency range 1.5 to 52 MHz. An excess absorption, relaxing between 3 and 8 MHz, was observed. The relaxation was assigned to the final step in the stepwise formation of a contact ion pair, with the relaxation frequency controlled by the rate of movement of a solvent molecule rather than an ion. Data on the system water – dimethyl sulfoxide are also presented and the effect of water on the relaxation discussed.

L'absorption ultra-sonique de plusieurs halogénures alcalins dans le diméthyl sulfoxyde a été étudiée dans l'intervalle de fréquence allant de 1.5 à 52 MHz. Un excès d'absorption, dont la relaxation se fait entre 3 et 8 MHz a été observée. La relaxation est attribuée à l'étape finale dans la formation graduelle d'une paire d'ion de contact. La fréquence de relaxation est contrôlée par la vitesse de déplacement d'une molécule de solvant plutôt que par celle d'un ion. Les données relatives au système eau-diméthyl sulfoxyde sont également présentées et l'effet de l'eau sur la relaxation est discutée.

Introduction

Ion pairing was first studied by ultrasonics (1) following the observation of an anomalously large absorption coefficient for sea water. Detailed studies (2–6) have since shown that the stepwise ion association in aqueous solutions of 2–2 electrolytes could account for the absorption in excess of that expected from viscous losses. The assignment of mechanism was aided by a study of mixed solvent solutions of these salts (7); there are, however, still some discrepancies in both the data and its interpretation (4–6). The low concentration of ion pairs in aqueous solutions of 1–1 electrolytes excludes their showing an excess absorption except at salt concentrations much higher than that found in sea water (8). From extensive ultrasonic absorption measurements of aqueous solutions of the lanthanide salts it was concluded that the observed relaxation was a result of the formation of ion pairs (9). Absorption measurements of some aqueous electrolytes at hypersonic frequencies have recently been carried out by the method of Brillouin scattering. An excess absorption was only observed for multivalent electrolytes and very concentrated solutions of univalent salts (10).

Only a few ultrasonic studies of electrolytes dissolved in non-aqueous solvents have been attempted. Alkyl ammonium halides dissolved in nitrobenzene exhibit a relaxation in the region of 27 MHz; it was observed that addition of a small amount of methanol suppressed this relaxation (11). The excess absorption was attributed to the ion association equilibrium. It was suggested that the addition of methanol may have reduced the degree of ion pairing by solvating the anions, but the evidence was inconclusive. An investigation of the ultrasonic absorption properties of lithium chloride dissolved in a wide range of alcohols indicates that possibly two relaxations are present in these systems, one of which may be the ion association, ion pair dissociation equilibrium (12). A large single relaxation ascribed to this same equilibrium has been observed in solutions of hydrogen chloride in N,N-dimethyl formamide (13).

It was anticipated that an investigation by ultrasonics of dimethyl sulfoxide (DMSO) solutions of alkali halides might provide some information concerning ion pairing equilibria. This possibility was suggested by the results of previous studies of the physical chemistry of these solutions. Substantial ion pairing should be present, as discrepancies between experimentally determined activity coefficients and those predicted by the extended Debye–Hückel theory for lithium chloride and cesium iodide dissolved in DMSO have been accounted for by assuming ion pairing with an association constant of about 0.2 (14, 15).

Conductivity measurements suggest that only

(17) $CaCl_2$	0.44	<0.2→ —	948.0	60.0	3.9	63.0

*Using only data from 10.6 to 52.8 MHz to fit the single relaxation equation.

the cations are solvated significantly (16). This is reasonable as the positive end of the DMSO dipole, which corresponds to the position of the sulfur atom, is shielded by the two methyl groups. The radii in angstroms of several ions dissolved in DMSO were estimated from the conductance data (17); the crystallographic radii (18) are enclosed in brackets: Na^+, 3.2 (0.95); K^+, 3.0 (1.33); Br^- 1.7 (1.95); I^-, 1.7 (2.16). Solutions of alkali halides in DMSO can possibly be described by more simple but realistic models because the anions are essentially unsolvated.

Ultrasonic absorption measurements in the frequency range 1.5 to 52 MHz were carried out on some such systems. The results are reported in Table 1 and discussed in terms of the stepwise formation of ion pairs. Measurements were also made on several other related systems in a more limited frequency range (10.5 to 52 MHz).

Experimental

The ultrasonic absorption coefficients were measured in the frequency range from 0.5 to 3.5 MHz with the streaming apparatus described below, and from 10.5 to 52 MHz with the pulse apparatus previously described in detail (19). The temperature of the absorption cells was controlled by a thermostatted water bath. The viscosity of each solution was determined with a Cannon–Fenske viscometer immersed in this bath.

The design of the streaming apparatus was based on the observation that the energy absorbed by a liquid from a sound beam results in a flow or streaming of the liquid in the direction of the beam (20). The absorption coefficient is determined from the streaming velocity and the sound radiation intensity. Figure 1 is a schematic diagram

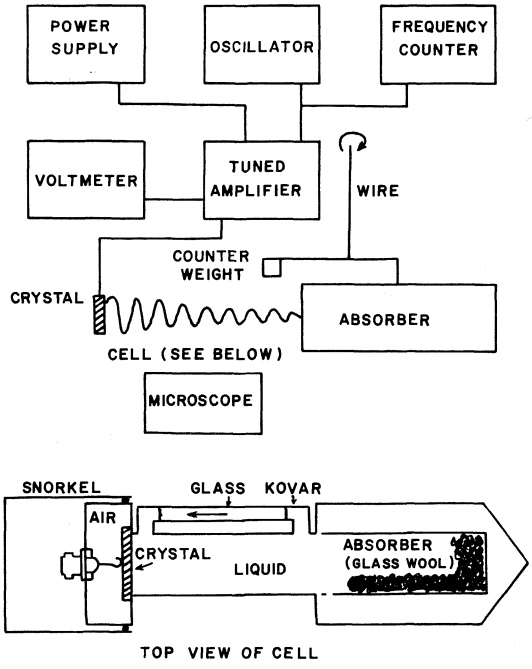

FIG. 1. Schematic diagram of the streaming apparatus.

of the cell and the electronics required to measure these quantities.

The stainless steel cell was constructed with a Pyrex side arm connected by means of Kovar glass-to-metal seals. The transducer was an X-cut quartz crystal of 2.8 cm diameter with a fundamental resonant frequency of 0.5 MHz. To ensure good electrical contact, the faces of the crystal were plated with a thin layer of gold or silver. The sound intensity was measured by the horizontal torque exerted by a stainless steel cylinder, 9.6 cm long

For personal use only.

and 2.6 cm in diameter, packed with glass wool, and suspended from a torsion balance incorporating a 0.18 mm rolled phosphor bronze wire so as to be completely submerged in the liquid being studied and in the path of the sound beam.

The transducer was driven at 0.5, 1.5, 2.5, and 3.5 MHz by the output of the tuned amplifier, which amplified up to 800 V r.m.s. a continuous signal of the appropriate frequency from the Marconi TF 1370 oscillator. The frequency of the signal was determined with a Hewlett–Packard 5245 L frequency counter, and the voltage output of the amplifier was measured with a Marconi TF 2604 electronic voltmeter coupled by a 100× attenuating probe to the output of the amplifier. The power leads to the transducer were protected from water contact with snorkel arrangement.

To operate, the streaming apparatus was filled with the solution to be studied, ensuring that no air bubbles were trapped in the absorber. To enable measurement of the rate of streaming through the side arm, aluminum dust was suspended in the solution prior to filling. With the aid of reflected light, the particles were then observed under 15× magnification with a Bausch and Lomb stereomicroscope, and their rate of flow past a graticule contained in one of the eyepieces was measured.

To determine the absorption coefficient, α, eq. 1 had to be evaluated (20).

$$[1]\quad (\exp[20.4\alpha] - 1)(\exp 3.6\alpha) = K\eta \frac{u}{V^2}\frac{\Delta(V^2)}{\Delta R}$$

η is the viscosity in poise, u is the streaming velocity at the applied voltage V, $\Delta(V^2)$ is the change in the square of the applied voltage required to cause a constant change in the sound intensity ΔR, as determined with the torsion balance. K is a constant of the apparatus, calculated from the streaming velocity and radiation pressure observed when the cell was filled with carbon tetrachloride or chlorobenzene, for which the absorption coefficients were measured with the pulse apparatus. Only at 0.5 MHz was any difficulty experienced in obtaining reproducible results, due to the low absorption coefficient and the consequent low streaming velocity.

Solutions for both streaming and pulse measurements were prepared in a dry box from reagent grade salts (from Fisher, Anachemia or Baker) which had been dried to constant weight at 95 °C and from Fisher or British Drug Houses dimethyl sulfoxide which had been stored over grade 4 molecular sieve. DMSO refluxed over BaO and vacuum distilled below 65 °C gave essentially the same results, so this procedure for removing water was not employed. Solutions of HCl and HBr were made by passing dried gas into a burette inverted in a cooled flask of DMSO.

In spite of these precautions, the solutions were found to contain a significant amount of water after the streaming measurements. This water, which was absorbed from the atmosphere during the course of the measurements, was estimated from the intensity of its infrared absorption spectrum at 3500 cm^{-1}.

Attempts to measure the water content by the Karl Fischer titration (21) (Fisher So-K-3) were not successful, although this is a common method for such determinations. When the titrations were done by titrating excess Karl Fischer reagent with standard water in methanol solution (Fisher So-W-2) the method gave negative values for the water content, suggesting the possibility that DMSO interferes with the reagent.

Results

The relaxation parameters of the systems that were studied over the complete frequency range, that is by both the streaming and pulse techniques, are listed in Table 1. In addition, the water content of the solutions before and after the streaming measurements is listed. The relaxation parameters were determined by fitting an equation for a single relaxation to the experimental points by an unweighted least squares program. This equation (22) is of the form

$$[2]\qquad \frac{\alpha}{f^2} = A\left(1 + \frac{f^2}{f_c^2}\right)^{-1} + B$$

where α is the absorption coefficient, f is the frequency, f_c is the relaxation frequency, and B is the absorption due to viscosity and higher frequency relaxation processes. A is related to the molar maximum excess absorption per wavelength, $\bar{\mu}_m$, the concentration, c, and the velocity of sound, v, by the equation

$$[3]\qquad A = 2c\bar{\mu}_m/f_c v$$

The term, B, includes absorptions contributed by two processes. One is viscous absorption, α_η, calculated from the viscosity, η, by the equation (22)

$$[4]\qquad \frac{\alpha_\eta}{f^2} = \frac{8}{3}\pi^2\frac{\eta}{v^3}$$

The other is a result of equilibria which relax at frequencies above the range of observation. These processes could include an equilibrium between various solvent structures and an equilibrium resulting from the addition of an electrolyte. The structural absorption was assumed to be constant and equal to the difference between the observed absorption coefficient of pure DMSO and that calculated from the viscosity. The absorption estimated for the viscosity and structural relaxation for each solution was in nearly all cases insufficient to account for the magnitude of B.

Table 2 shows the absorption data for pure DMSO, containing less than 0.1% by volume of water. The addition of water to pure DMSO gives rise to a maximum in the absorption coefficient at a DMSO volume fraction of 0.75, that is, a mole

TABLE 2. Ultrasonic absorption and velocity data for pure dimethylsulfoxide

Temperature (°C)	α/f^2	α_η/f^2	α_s/f^2	v
	$(10^{-17}\ cm^{-1}\ s^2)$			$(m\ s^{-1})$
19	36.6	15.6	21.0	1513
25	34.2	14.5	20.7	1489
30	34.0	13.7	20.3	1473

fraction of about 0.4. This maximum corresponds to a maximum in the viscous absorption, Fig. 2. The difference between the two gives a curve more characteristic of mixtures of unassociated liquids (22); any association process giving rise to the viscosity maximum does not directly contribute to the ultrasonic absorption at these frequencies. Low frequency data, Fig. 3, suggest the possible presence of an absorption relaxing at about 0.6 MHz in a mixture with 0.75 volume fraction DMSO.

The effect of addition of water to salt solutions is illustrated for 0.44 M sodium bromide in DMSO in Fig. 4. The magnitude of A decreases with increasing water content but B and f_c remain constant. A rough extrapolation to zero water content suggests that for most of the results which depend on streaming measurements, the values of A could be as much as 40% higher in a water free system. Consequently, the relaxation parameters, f_c and $\bar{\mu}_m$, are possibly in error, and much of the detail concerning their variation with conditions

may be obscured. Figure 5 shows a comparison of some curves generated from the relaxation parameters obtained from both pulse and streaming data with those obtained from pulse data alone. It was concluded that the low frequency data should be included when available, in spite of the error introduced by the absorption of water.

Only in the solutions of lithium bromide (systems 12, 13) does the shape of the relaxation

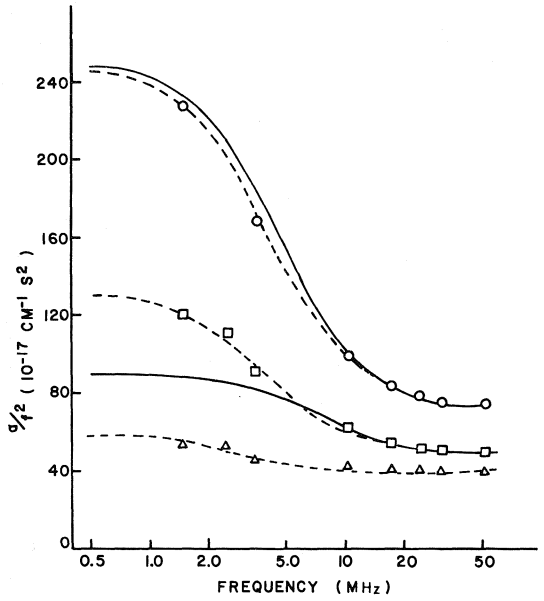

FIG. 5. Absorption in NaI solutions (systems 7 to 11, Table 1). ○ Experimental points, 1.00 *M*; □ experimental points, 0.55 *M*; △ experimental points, 0.26 *M*; — curve fitted using pulse data only; --- curve fitted using streaming and pulse data.

curves differ from those in Fig. 5. There appear to be two relaxations, one at about 7.5 MHz and the other at about 3 MHz. However, the data do not warrant fitting to an equation with more parameters than eq. 2. Because of this anomalous, but reproducible, nature of the LiBr relaxation curves, these two systems were not considered in searching for trends.

Some solutions were studied by the pulse apparatus in a limited frequency range; these were CsCl, CsI, HBr, $CaBr_2$, $MgBr_2$, HCl, KI, and LiCl. In the case of Cs salts, no excess absorption was found. The solutions of HBr had a large excess absorption but had strong odors of mercaptans. The $CaBr_2$ and $MgBr_2$ solutions also had large excess absorptions but could not be prepared without having considerable amounts of water present. Solutions of HCl (0.3 to 1.3 *M*) showed a strong absorption with $\bar{\mu}_m$ of the order of 60 and f_c at about 6 MHz. The KI (0.99 *M*) and LiCl (0.10 *M*) had, respectively, f_c equal to 2.3 and 4.1 MHz, and $\bar{\mu}_m$ 4.1 and 27.

The temperature dependence of f_c and $\bar{\mu}_m$ for solutions of NaI and NaBr was also investigated in this limited frequency range. A 10° rise in temperature did not affect the f_c or $\bar{\mu}_m$ significantly. In these systems the water content was <0.2%. However, there is considerable inaccuracy introduced in obtaining relaxation parameters in cases where the frequency range of the data does not extend below f_c.

The data in Table 1 show the relaxation frequency to be relatively independent of the salt concentration, the nature of the anion or cation, and the charge of the cation. This invariance may be real or it may be a result of the large experimental uncertainty of the low frequency data.

The molar excess absorption per wavelength on the other hand shows some variation with conditions. Three sets of systems, 2 to 4, 7 to 11, and 12 to 13, show increases in $\bar{\mu}_m$ with concentration while one, 15 to 17 shows a decrease. From a comparison of systems 1 with 2, and 3 with 7, it appears that $\bar{\mu}_m$ decreases with increasing anion size. Comparison of systems suggests that $\bar{\mu}_m$ also decreases with increasing cation size. The absence of an excess absorption for cesium salts and the data on KI and LiCl confirm these observations. Doubling the charge of the cation by substituting Ca^{2+} for Na^+ causes an approximately ten-fold increase in $\bar{\mu}_m$.

Discussion

Model for Ion Pairing Equilibria

The mechanism responsible for the excess absorption is assumed to be the stepwise association of free ions to form contact ion pairs. Proton exchange may be eliminated because of the low dissociation constant of the C—H bond of DMSO, and the relaxation of the ion atmosphere would contribute negligibly to the observed absorption coefficient. The ion association equilibria may be written as

$$[5]\quad M_s^+ + X^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} (M^+\text{–DMSO–}X^-)_s \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} (M^+\text{–}X^-)_s$$

1	2	3
Free ions	Solvent separated ion pair	Contact ion pair

where the subscript, s, denotes a solvated species.

The Bjerrum distance, that distance at which the electrostatic interaction energy between two ions becomes less than the mean thermal energy, is about 6 Å for an alkali halide in DMSO and about 12 Å for a 2–2 electrolyte in water. At separations exceeding these, the ions are considered to be free. Since two solvent molecules

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

are thought to separate the ions of the first ion pair formed by the association of 2–2 electrolytes in water (2), and since the DMSO molecule is larger than the water molecule, it is expected that steps intermediate to structures **1** and **2** need not be included in a description of the association of 1–1 electrolytes in DMSO.

Two relaxations should be observed for these coupled processes. The relaxation frequency, f_c, and the maximum excess absorption per wave length, $\bar{\mu}_m$, for each are given by equations available in references such as (23) and (24). They will not be given in detail here, as the lack of accuracy of the data as well as of necessary supporting thermodynamic data for the systems makes it impossible to apply these equations to the data.

Equilibrium 1 ⇌ 2

The rate coefficients for the diffusion controlled formation and dissociation of the solvent separated ion pair can be calculated by equations developed by Debye (26) and Eigen and DeMaeyer (27), respectively. For sodium bromide in DMSO, k_{12} is equal to 1.0×10^{10} l mol^{-1} s^{-1}, and k_{21} is equal to 3.0×10^9 s^{-1}. The relaxation frequency of this equilibrium should be about 10^9 Hz, much too high to account for the observed relaxation. The difference between B and the viscous absorption is probably partially due to this equilibrium.

Since the absorption coefficient of pure DMSO is much greater than the viscous absorption, losses due to a structural relaxation of the solvent are probably occurring. The addition of ions should tend to decrease the absorption resulting from this process, similar to the effect of dissolving alkali halides in water (24). The magnitude of the absorption due to the formation of the solvent separated ion pair is hence larger than the difference between the value of B obtained from the data and that estimated from viscous and structural absorption. The rate coefficients and thus the relaxation frequency of the association–dissociation equilibrium should not be very dependent on the nature of the cation due to shielding by the primary solvation sphere. However, if, as concluded from the conductance work, the anions are relatively unsolvated, the relaxation parameters should be anion dependent.

Equilibrium 2 ⇌ 3

The relaxation frequency of this equilibrium is governed by the magnitude of the rate constants k_{23} and k_{32}. It is, however, also dependent upon the magnitudes of k_{12}, k_{21}, the concentration of unpaired ions, and the activity coefficients of the system. The lack of a large variation of f_c with change of cation or anion suggests that the rate limiting step is governed more by the movement of a DMSO molecule into or out of the solvation sphere rather than the movement of any ion. The small change of f_c upon increasing the cation charge is somewhat puzzling. It may be that since the Bjerrum distance of the calcium ion is twice that of the alkali ions, the stepwise association mechanism should have two intermediate structures between the free ions and the contact ion pair, and therefore the relaxation observed at 3 to 4 MHz should be related to an equilibrium between two solvent separated ion pairs.

The magnitude of $\bar{\mu}_m$ is dependent among other things upon the degree of advancement of the equilibria, the rate constants, thermodynamic properties of the solution such as compressibility, thermal expansion, density, heat capacity, and activity coefficients. It is also dependent on the ΔV and ΔH of the equilibria. In view of the experimental uncertainties and the lack of knowledge of the equilibrium constant, K_{23}, an evaluation of any term such as ΔV or ΔH is impossible. $\bar{\mu}_m$ should be dependent on the concentration through the activity product, but the observed magnitude of the variation is surprising; this may be explained by a greater influence on the relaxation parameters due to water at lower concentrations. Increasing the size of the anion or cation causes a decrease in the excess absorption per wavelength, possibly as a result of a decrease in ΔV or ΔH, but most probably due to a change in the degree of association. The large decrease in A, and hence $\bar{\mu}_m$, upon addition of water to the solutions is presumably due to the hydration, and consequent stabilization with respect to association, of the free anions.

Conclusions

The relaxation observed in dimethyl sulfoxide solutions of alkali halides in the frequency range 3 to 8 MHz has been assigned to the second, final step of a stepwise association of the ions. Evidence of the presence of an absorption due to the first step was also obtained.

A limited experimental frequency range and difficulties in preventing atmospheric water from entering the solutions during measurement made

exact analysis of the phenomena impossible. The following qualitative trends were observed: (*1*) The relaxation frequency is relatively insensitive to changes in the cation, the anion, concentration, and temperature. (*2*) The molar excess absorption per wavelength decreases with increasing size of both the cation and the anion.

For a more quantitative, reliable analysis of the phenomena, it is necessary to acquire low frequency data on apparatus that would exclude atmospheric water from the solutions. It is expected that calculations of the energies of some simple but hopefully realistic models of the proposed structures, **2** and **3**, will also aid the analysis. Such work has been initiated with some preliminary successes (28).

The authors wish to thank Dr. J. E. Piercy and Mr. A. Raffler for assistance in planning and constructing the apparatus, Mr. D. G. Fecchio for Technical assistance, and Dr. C. H. Langford for helpful discussions. The project was supported financially by the National Research Council of Canada.

Aqueous Nonelectrolyte Solutions. Part X. Mercury Solubility in Water[1]

D. N. GLEW AND D. A. HAMES
Research Department, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received April 22, 1971

The solubility of mercury in water has been determined between 4 and 72 °C. Standard thermodynamic functions have been evaluated for mercury transfer from the liquid metal to aqueous solution and from aqueous solution to the gas phase. Mercury in water exhibits large positive deviations from Raoult's Law and shows a high relative volatility of 15 400 at 25 °C.

La solubilité du mercure dans l'eau a été déterminée entre 4 et 72 °C. Les fonctions thermodynamiques standards ont été évaluées pour le pasage du mercure du métal liquide à la solution aqueuse et de la solution aqueuse à la phase gazeuse. Dans l'eau, le mercure montre une déviation positive importante par rapport à la Loi de Raoult et une volatilité relative importante de 15 400 à 25 °C.

Canadian Journal of Chemistry, 49, 3114 (1971)

Introduction

Mercury dissolved in air-free water is monatomic and un-ionized with the zero-valent mercury atom in the spherically symmetric $^1S_0$ ground state (1).

The solubility equilibrium of liquid mercury with water has been measured previously (1–5) but these measurements are in serious disagreement at 25 °C. The early measurements at 25 °C, which are in good agreement with each other (2, 3), are considerably lower than more recent determinations using radioactive mercury (4) and neutron activation analysis (5). In contrast measurements at 85 °C are in good agreement (2, 5).

The temperature profile of the mercury solubility by Choi and Tuck (5) is suspect since it implies a constant enthalpy of mercury transfer into water which is inconsistent with the behavior of other aqueous nonelectrolytes (6–8).

In this work we have determined the solubility of mercury in water between 4 and 72 °C using atomic absorption for analysis.

Experimental

Material

Technical electrolytic grade mercury was purified by washing with 10% NaOH with agitation by a stream of air, washed with 5% HNO_3 with air agitation, filtered through a gold foil, rewashed with fresh 5% HNO_3, and distilled three times. A.C.S. grade sodium sulfite was supplied by Fisher Scientific Company, technical grade hydrazine hydrate by Matheson, Coleman and Bell, and reagent grade sodium borohydride by The British Drug Houses Limited. Grade A helium and Hi-Pure nitrogen were supplied by Liquid Carbonic Canadian Corporation Limited. Water was laboratory distilled.

Apparatus

The solubility cell previously described (9) was modified to include a 1 cm diameter fine glass frit at the lower end of the sampling tube 4 cm above the cell bottom. Cell temperatures, constant to ±0.01 °C, were maintained by the circulation of thermostated glycol–water through the outer jacket. The cell temperature was measured differentially with respect to a stainless steel block within the thermostat using a five-junction copper–constantan thermocouple. The temperature of the stainless steel block was measured using a standardized platinum resistance thermometer and Mueller bridge.

Method

The distilled water, continuously and vigorously stirred, was degassed for 2 h using a rotary oil pump. The pressure was restored to atmospheric several times by purging with nitrogen. Approximately 300 cm^3 water was then distilled under vacuum into the solubility vessel at 4 °C via an adaptor in the upper standard taper joint. Atmospheric pressure was restored by helium flow through the cell side-arm stopcock. After re-evacuation approximately 30 g mercury was then distilled into the cell. The helium flow was resumed, the adapter removed, approximately 0.001 *m* reducing agent (sodium sulfite, or hydrazine hydrate, or sodium borohydride) was added, and the cell stopper containing the upper Teflon bearing was replaced. The helium flow minimized air diffusion into the cell. The cell was evacuated again and restored to a slight positive pressure with helium. The cell contents were stirred continuously and the temperature adjusted to the preselected operating level.

The stirrer was stopped 2 h before sampling. A small helium pressure of 15 Torr above atmospheric was used to express a 5–10 g presample to clear the frit and tubing of non-equilibrated solution. A 10–20 g equilibrium sample was then immediately expressed into a weighed flask containing 1 ml 4% $KMnO_4$ and 1 ml 20% H_2SO_4. The flask was reweighed and the solution immediately

[1]Contribution No. 191.

For personal use only.

analyzed for mercury by an atomic absorption method (10). Solubilities were approached from both above and below saturation.

As first shown by Stock *et al.* (2), mercury was readily oxidized by even very small traces of air and it was necessary to add small quantities of reducing agent to ensure that no mercury oxidation took place. If reducing agent was not added a noticeable oxidation took place within two days despite all efforts to prevent air leakage. Solubility was found to be unaffected by reducing agents concentrations between 0.001 and 0.02 *m*, in agreement with results using hypophosphorous acid (4).

In order to avoid sampling suspended mercury, which would give high apparent solubilities, the stirrer was stopped and the solution was withdrawn through the glass frit after 2 h. Equilibrium was reached in less than one day under our continuously stirred conditions, compared with ten days without stirring estimated by Pariaud and Archinard (3). To eliminate losses of the highly volatile mercury solute from the saturated solution (see Discussion section) the sample was immediately run into an excess of acid-permanganate.

All equilibrium constants were derived by the method of least-squares assuming that the logarithms of the equilibrium constants were normally distributed: this was consistent with the experimental determination of x_2^0 which was known with a constant percentage error. The standard thermodynamic function change values and their estimated standard errors, σ, were determined by the Clarke–Glew method (12).

*a, sodium sulfite; *b*, hydrazine hydrate; *c*, sodium borohydride; and *d*, none.

Results

The temperature dependance of our measurements for the solubility of mercury in water between 4 and 72 °C is given by

$$[1] \quad \log_{10} x_2^0 = -122.811 + 4475.3/T + 40.2205 \log_{10} T$$

where x_2^0 is the mercury mole fraction and T is absolute temperature (0 °C = 273.15 K (11)). Table 1 compares our measured solubilities with those calculated from eq. 1. The estimated standard error on a single measurement is 7.5%. The final column of the table shows the reducing agent added, *a*, sodium sulfite; *b*, hydrazine hydrate; *c*, sodium borohydride; and *d*, no reducing agent. No significant difference was found between measurements taken with any of the three reducing agents over periods up to 14 days and with measurements after 1 day with no reducing agent.

A comparison of our solubilities with previous work (1–5) is shown in Fig. 1, where the logarithm of the mercury solubility in parts per million by weight is plotted against temperature. We find very good agreement between our measurements and the recent solubilities at 25 °C by Moser and Voigt (4) and by Choi and Tuck (5). Our extrapolated curve shows good agreement with the solubilities of Choi and Tuck at 80 and 90 °C (5), Stock *et al.* at 85 °C (2), and Bonhoeffer and Reichart at 120 °C (1). The earlier measurements at 25 °C by Stock *et al.* (2) and Pariaud and Archinard (3) are definitely too low and may have resulted from mercury losses caused by its very high relative volatility at this temperature. The measurements by Choi and Tuck at 35, 50, and 65 °C (5) are apparently too high. The measurement at 100 °C by Stock *et al.* (2) is also too high.

We derive the best equation for the mercury solubility x_2^0 in water between 0 and 120 °C.

$$[2] \quad \log_{10} x_2^0 = -128.089 + 4715.2/T + 42.0288 \log_{10} T$$

by the method of least squares combining the earlier measurements at 120 (1), 85 (2), 25 (4), and 25, 80, and 90 °C (5) with our measurements between 4 and 72 °C. The measurement by Stock *et al.* (2) at 100 °C was not included in determining eq. 2 because it was 28% above the value calculated from eq. 1.

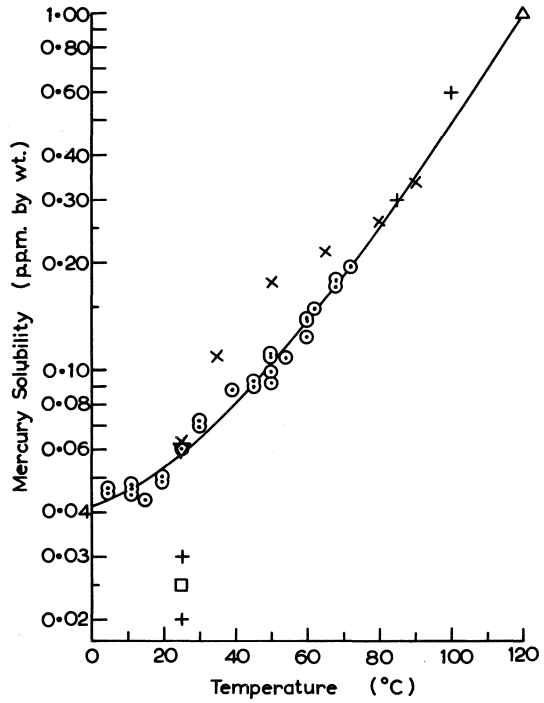

FIG. 1. The temperature dependence of the solubility of mercury △, Bonhoeffer and Reichart (1); +, Stock *et al.* (2); □, Pariaud and Archinard (3); ▽, Moser and Voigt (4); ×, Choi and Tuck (5); ⊙, this work. Solid curve calculated from eq. 2.

with its standard error, evaluated from eq. 2 between 0 and 120 °C, are presented in Table 2 and are shown by the solid line in Fig. 1. The table contains values with their errors, derived from eq. 2, for the standard thermodynamic function changes, $\Delta X_2^0(l_2 \rightarrow l_1)$, for the transfer at unit pressure of 1 mol mercury from the pure liquid metallic phase l_2 into an aqueous phase l_1 having unit mercury mole fraction.

Henry Law constants, $H_2 = p_2/x_2$ atm, were calculated as p_2^0/x_2^0 from the known mercury vapor pressure p_2^0 (13) with the experimental x_2^0 values used in calculating eq. 2. The least squares fit of this data, giving the best equation for the temperature dependence of H_2 between 0 and 120 °C, is

$$[3] \quad \log_{10} H_2 \text{ (atm)} = 135.636 - 8031.1/T - 42.8448 \log_{10} T$$

The Henry Law constant for mercury in water together with its standard error are evaluated from eq. 3 between 0 and 120 °C and presented in Table 3. The table contains values, derived from eq. 3, for the standard thermodynamic function changes, $\Delta X_2^0(l_1 \rightarrow g)$, for the transfer of 1 mol of mercury from the aqueous phase l_1 with unit mercury mole fraction and at 1 atm total pressure into the gas phase g containing an ideal mercury

vapor at 1 atm pressure. The standard errors on the thermodynamic functions in Tables 2 and 3 are nearly equal because the errors on the vapor pressures are very small compared with those on the solubility measurements.

Discussion

Mercury dissolved in water shows large positive deviations from Raoult's Law with activity coefficients $\gamma_2(\gamma_2 = 1/x_2^0)$ varying between 268 000 000 at 0 °C and 11 200 000 at 120 °C. The corresponding large positive values for $\Delta G_2^0(l_2 \rightarrow l_1)$ are predominantly due to the large negative entropy term at 0 °C, but to the large positive enthalpy term at 120 °C.

The Henry Law constants H_2, in Table 3, are very much greater than the known mercury saturation vapor pressure (13). The enthalpy change $\Delta H_2^0(l_1 \rightarrow g)$ of 13 490 ± 280 cal/mol at 0 °C is the largest yet determined for solute evolution from an aqueous solution, and directly reflects the strong attractive dispersion forces between the very polarizable mercury atom and its water neighbors. The very large $\Delta S_2^0(l_1 \rightarrow g)$ of 57.8 cal/deg mol at 0 °C is 37 cal/deg mol larger than Trouton's constant: this difference arises predominantly from orientation of water adjacent to the mercury solute. From the value of $\Delta C_{p_2}^0(l_1 \rightarrow g)$ and the heat capacity of mercury vapor (13) we obtain a partial molar heat capacity for aqueous mercury of 90.1 ± 5.6 cal/deg mol. This value is larger than expected for a small spherically symmetric monatomic solute (8) and indicates rapid thermal breakdown of the low temperature water orientations as the temperature is increased. H_2 attains a maximum value of 13 500 atm at 158 °C and then decreases with temperature.

The relative volatility of mercury solute with respect to water (H_2/p_1^0, where p_1^0 is the water vapor pressure in atm) is 15 400 at 25 °C and 8 360 at 100 °C, and shows the greater relative preference for mercury volatilization into the binary vapor phase at 25 than at 100 °C. The un-ionized monatomic mercury solute is readily lost by volatilization from its water solutions at normal temperatures.

Reaction of Diphenylcyclopropenethione with Heteroaromatic Nitrogen Compounds

J. W. LOWN AND K. MATSUMOTO[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 19, 1971

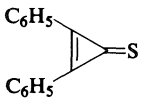
Diphenylcyclopropenethione reacts with a variety of heteroaromatic nitrogen compounds to give in excellent yields four types of products (*a*) 6,7-diphenyl-8-thionpyrazolo[1,2-*a*]pyridazine and -cinnolines, (*b*) azaindolizinthiols, (*c*) azaindolizine disulfides, and (*d*) 1-methoxy-1,2-diphenyl-3-thionpyrrolidino-[1,2-*a*]isoquinoline and similar structures. Proof of structure of products of type *a* rests on their independent synthesis by the action of phosphorus pentasulfide on the known oxo-analogs. Products of type *b* are converted readily into type *c* by air oxidation. In products of type *d* a molecule of solvent methanol is incorporated in the structures.

La diphénylcyclopropènethione réagit avec un grand nombre de composés, ayant l'azote comme hétéroatome, pour donner avec un excellent rendement quatre types de composés (*a*) diphényl-6,7 thion-1,8 pyrazolo [1,2-*a*] pyridazine et -cinnolines, (*b*) azaindolizinthiols, (*c*) disulfure d'azaindolizine, et (*d*) méthoxy-1 diphényl-1,2 thion-3 pyrrolidino [1,2-*a*] isoquinoléine et des produits de structure semblable. Les preuves de structure des produits du type *a* reposent sur leurs synthèses indépendantes par l'action du pentasulfure de phosphore sur les analogues oxo connus. Les produits du type *b* sont transformés facilement en ceux du type *c* par oxydation par l'air. Dans les produits du type *d* une molécule du solvant (méthanol) est incorporée dans la structure.

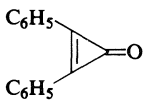
Canadian Journal of Chemistry, 49, 3119 (1971)

We recently confirmed (1) and provided structure proof of an earlier tentative report by Breslow *et al.* (2) that diphenylcyclopropenone reacts with pyridine in refluxing methanol to give 1,2-diphenyl-3-indolizinyl *cis*-1,2-diphenylacrylate. We extended the reaction to include a variety of heteroaromatic nitrogen compounds and obtained in good yield either (*a*) 1,2-diphenyl-3-indolizinyl *cis*-1,2-diphenylacrylates and aza analogs, or (*b*) 5,6-diphenyl-7-hydroxypyrrolo-[1,2-*b*]pyridazines and similar structures, or (*c*) adducts in which cycloaddition takes place to the nitrogen–nitrogen bond of 1,2-diazines. Cycloheptenocyclopropenone in the examples studied forms heterocycles of type *b*.

The chemistry of diphenylcyclopropenethione (**1**) (3–5) has not received as much attention as its oxygen analog, diphenylcyclopropenone (**2**), probably because of its relative thermal instability.



1



2

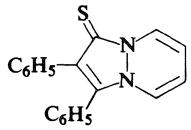
We report reactions of **1** with heteroaromatic nitrogen compounds which proceed smoothly at room temperature to give in excellent yield a variety of derivatives of aza analogs of indolizines.

The reactions of heteroaromatic nitrogen compounds with the thione **1** proved to be quite different from those with **2** reported earlier. The thione shows a marked propensity for addition to nitrogen–nitrogen double bonds whereas **2** undergoes such additions principally when addition to a carbon–nitrogen bond is precluded structurally (*e.g.* benzo[*c*]cinnoline (1)). In addition, the inability of the thione **1** to form sulfur analogs of indolizinyl *cis*-1,2-diphenylacrylates led to different behavior towards *e.g.* pyridine, pyrazine, and isoquinoline as was observed previously with **2**. Four principal product types were encountered.

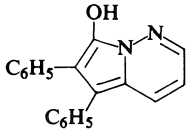
Thionpyrazolo Structures

Pyridazine reacted smoothly with **1** in chloroform at room temperature to give a 1:1 addition product in 93% yield formulated as the 6,7-diphenyl-8-thionpyrazolo[1,2-*a*]pyridazine (**3**). This type of product is in contrast to the 5,6-diphenyl-7-hydroxypyrrolo[1,2-*b*]pyridazine (**4**) which was obtained from **2**.

Compound **3** showed a thioamide band in the



3



4

[1]NRCC Postdoctorate Fellow, 1969 to present.

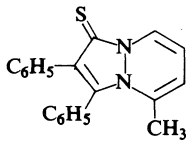
For personal use only.

i.r. spectrum and no evidence of the free thiol (negative tests with sodium nitroprusside and with 3,3′-dithiobis-(6-nitrobenzoic acid) (6)). In contrast **4** gave a positive ferric chloride test and exhibited a strong i.r. absorption at 3570 cm^{-1} for hydroxyl.

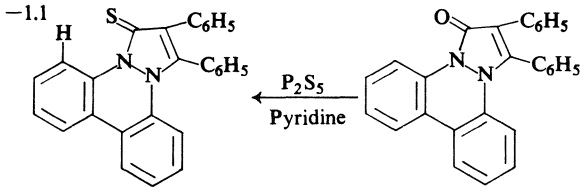
The thione also reacted readily with 3-methylpyridazine to give 4-methyl-6,7-diphenyl-8-thionpyrrolo[1,2-*a*]pyridazine **5**. The position of the methyl group in **5** is assigned on the basis of the known tendency of pyridazine to quaternize at the less hindered nitrogen (7) and since nucleophiles attack the carbon–sulfur bond of **1** (8) (*vide infra*).



5

Adducts of types **3** and **5** proved to be the predominant type for **1** with 1,2-diazines while they are the exception in the reactions of **2**.

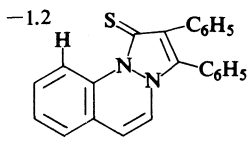
The thione **1** reacted quantitatively with benzo[*c*]cinnoline (where there is no vacant carbon alpha to nitrogen) to give 2,3-diphenyl-1-thionpyrazolo[1,2-*a*]benzo[*c*]cinnoline **6** with properties very similar to those of **3** and **5**. The structure of **6** was proven by its preparation in



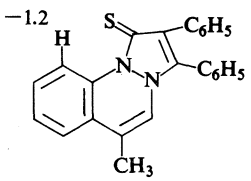
6 **7**

excellent yield from the known oxygen analog **7** (1) by heating with phosphorus pentasulfide in pyridine. Cinnoline also reacts with **1** in chloroform to give **8**, 2,3-diphenyl-1-thionpyrazolo-[1,2-*a*]cinnoline, in quantitative yield. 4-Methylcinnoline and cinnoline-4-carboxylic acid similarly reacted with the thione **1** to give 6-methyl-2,3-diphenyl-1-thionpyrazolo[1,2-*a*]-cinnoline (**9**), and 2,3-diphenyl-1-thionpyrazolo-[1,2-*a*]cinnoline-6-carboxylic acid (**10**), respectively in excellent yields.

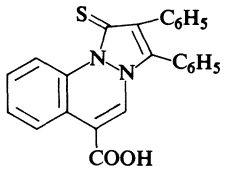
Neither compound **3**, **5**, **6**, **8**, **9**, nor **10** showed any evidence of a thiol grouping and n.m.r. integrations in **9** and **10** showed all aromatic



8



9



10

protons to be intact. Both **8** and **9** were prepared unambiguously by treatment of their respective oxygen analogs (prepared with diphenylcyclopropenone) with phosphorus pentasulfide in pyridine in excellent yields. The physical properties of these compounds were identical in every respect with those prepared directly from the thione, proving that the orientation of addition is the same for the thione **1** as for diphenylcyclopropenone and therefore that the initial attack by the heterocycles takes place at the C=S carbon. In agreement with this finding it has been shown recently that the thione undergoes nucleophilic attack at the C=S carbon by 1-(*N*-pyrrolidino)prop-1-ene (8). Structures containing pyrazolothione rings are well documented (9).

Substituents like the carbonyl group have generally very pronounced effects on the chemical shifts of *peri* protons (10). Such was found to be the case with the ketopyrazolo[1,2-*a*]cinnolines prepared previously with diphenylcyclopropenone, and the magnitude of the *peri*-effect for the adduct obtained with cinnoline was used to support the orientation of the addition (1). While no data are available in the literature on the magnitude of the *peri*-effect induced by an adjacent thione grouping, the magnitude of the paramagnetic shift on proton-12 in **6** (−1.10 p.p.m.), proton-10 in **9** (−1.20 p.p.m.), and proton-10 in **8** (−1.20 p.p.m.) indicate that the effect in these structurally unambiguous compounds is very similar to that of the carbonyl group. This property proved useful in assigning the structures of some 3-thionpyrrolidino compounds described below.

The analytical and spectral data for these new compounds are summarized in Tables 1 and 2.

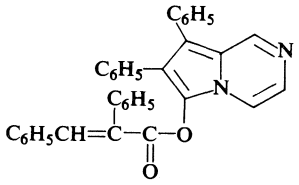
Azaindolizinthiol and Azaindolizine Disulfide Structures

Pyrazine reacted readily with the thione **1** in methanol–chloroform in the presence of air to form a different type of product, the di-(7,8-diphenylpyrrolo[1,2-*a*]pyrazinyl)-6-sulfide **11***a* corresponding to a dimeric structure containing a disulfide bridge. Repetition of this reaction under nitrogen with the careful exclusion of oxygen afforded a mixture of the monomer 7,8-diphenylpyrrolo[1,2-*a*]pyrazine-6-thiol **12***a* and **11***a*. The thiol **12***a* was very sensitive to oxidation and could be converted quantitatively into the disulfide **11***a* by refluxing an aerated solution in chloroform.

Similarly 2-aminopyrazine reacts smoothly with the thione in methanol–chloroform at room temperature in the presence of air to give di-(3-amino-7,8-diphenylpyrrolo[1,2-*a*]pyrazinyl)-6-sulfide (**11***b*), in 70% yield.

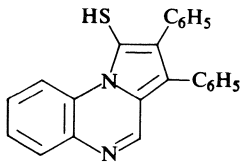
2-Methylpyrazine reacted with **1** to give 3-methyl-7,8-diphenylpyrrolo[1,2-*a*]pyrazine thiol **12***b*, in 75% yield. In this reaction only one structural isomer was obtained which is tentatively assigned with the methyl group in the 3-position on the plausible grounds that cyclization to the pyrazine ring will take place preferentially on the less hindered side. Little is known about the tautomeric behavior of potential 2-thiolpyrrole derivatives except that they are thought to parallel the oxygen analogs which prefer the oxo form (11). Since spectroscopic examination did not lead to a clear-cut distinction between the two possible tautomeric forms of **12***a–c* no bias in favor of the thiol forms should be construed from the nomenclature used except that **12***a* evidently reacts through the thiol tautomer to form **11***a*.

2,6-Dimethylpyrazine reacts with **1** to form 1,3-dimethyl-7,8-diphenylpyrrolo[1,2-*a*]pyrazine-6-thiol (**12***c*) in good yield. Compounds **12***a–c* and the monomers corresponding to **11***a* and *b* are the sulfur counterparts of the 1,3-dimethyl-7,8-diphenyl-6-hydroxypyrrolo[1,2-*a*]-pyrazine (**12***d*) obtained by reaction of 2,6-dimethylpyrazine with **2**. Compounds **12***a–c* cannot form sulfur analogs of **13** (which is produced from pyrazine and **2**). This fact together with their facile oxidation to the disulfides presumably account for the observed lack of reactivity of the thione **1** towards pyridine and picolines. In contrast, as has been shown by Breslow and by the present authors, **2** reacts very vigorously under such conditions to form 1,2-diphenyl-3-indolizinyl-*cis*-1,2-diphenylacrylates like **13** (1, 2).



13

Quinoxaline reacted smoothly with **1** to form 2,3-diphenylpyrrolo[1,2-*a*]quinoxaline-1-thiol (**14**). In this respect quinoxaline reacts as a substituted pyrazine and differs radically from the behavior of the isomeric quinazoline and phthalazine.



14

3-Thionpyrrolidino Structures

Isoquinoline and two nitrogen heterocycles quinazoline and phthalazine which share the same essential structural features with isoquinoline form a separate group in their reactions with **1**. Isoquinoline reacts very slowly with **1** in chloro-

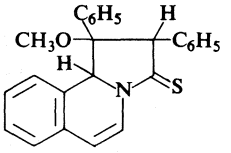
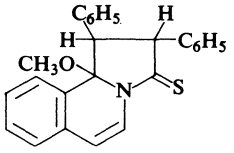
form but in a methanol–chloroform mixture a rapid reaction ensues leading to a 1:1:1 adduct of the heterocycle:thione:methanol which is formulated as the 1-methoxy-1,2-di-phenyl-3-thionpyrrolidino[1,2-*a*]isoquinoline (**15**) on the basis of analytical and spectral evidence.

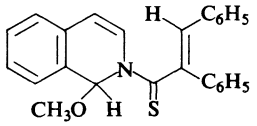
The n.m.r. spectrum shows the methine protons as two singlets at δ 5.25 and 6.31, the 5,6 protons as an AB quartet centered at δ 5.52 and 5.85 (J = 8 Hz) and the methoxy singlet at δ 3.30. This evidence disposes of the alternative structures, **16** (which would be expected to exhibit an AB quartet for the methine protons) and the Reissert-type structure **17** (which would show only one methine proton).



15

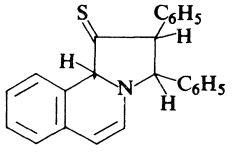


16



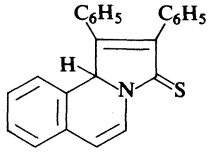
17

The absence of a low-field aromatic proton shifted by the *peri*-effect as observed in **5**–**8** discussed above argues against the alternative orientation of addition in **18**. Additionally, the compound **15** gives negative reactions with sodium nitroprusside and 3,3′-dithiobis-(6-nitrobenzoic acid), reagents which are specific for thiol groups, indicating the compound exists in the thione form shown.



18

As remarked above there are few data available in the literature on the tautomeric behavior of thione-substituted five-membered ring heterocycles, except that existing evidence points to a parallel behavior with that of the oxygen analog (11). Since potential 2-hydroxypyrroles exist almost exclusively in the oxo form (12) and since certain pyrrolones have been shown to undergo conjugate addition of water to the carbon–carbon double bond (13) then **15** is plausibly formed by initial addition of **1** across the 1-2 positions of isoquinoline to give **19** followed by addition of methanol to the latter.

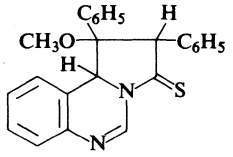


19

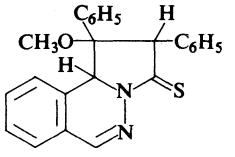
The corresponding product of the reaction of isoquinoline with **2** is 1,2-diphenyl-3-pyrrolo[1,2-*a*]isoquinolinyl *cis*-1,2-diphenylacrylate, in which addition has also taken place across the 1,2 carbon–nitrogen bond.

Controlled hydrolysis of **15** with 15 *N* sulfuric acid followed by neutralization afforded isoquinoline indicating that the isoquinoline moiety is retained in **15**.

Quinazoline similarly reacted with **1** in methanol–chloroform to give 1-methoxy-1,2-diphenyl-3-thionpyrrolidino[1,2-*c*]quinazoline **20**. As in the case of the analogous product formed with diphenylcyclopropenone, the structure is assigned on the basis of the known susceptibility of the 3-nitrogen of quinazoline to quaternize preferentially and the general reactivity of the 3,4 bond towards addition (14).



20



21

Phthalazine reacts with **1** to form the 1-methoxy-1,2-diphenyl-3-thionpyrrolidino[2,1-*a*]phthalazine (**21**). Evidently the 2,3 nitrogen–nitrogen bond in phthalazine has not a sufficiently high double bond character to dictate cycloaddition analogous to those of cinnoline, benzocinnoline, and pyridazine described earlier. Neither **20** nor **21** exhibit a *peri*-shifted aromatic proton suggesting a common orientation of addition of **1** to isoquinoline, quinazoline, and quinoxaline.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

Diphenylcyclopropenethione

This compound was prepared according to the method of Eicher and Frenzel (4), see also (15).

Reaction of Diphenylcyclopropenethione with Heteroaromatic Nitrogen Compounds

The reaction conditions and purification procedures are illustrated by the following examples of each of the principal product types. The analytical and spectroscopic properties of other compounds similarly prepared are summarized in Tables 1 and 2.

(a) Reaction of Diphenylcyclopropenethione with Cinnoline

To a stirred, cooled (10°) solution of 1.71 g (7.7 mmol) of diphenylcyclopropenethione in 15 ml of chloroform was added dropwise a solution of 1.00 g (7.7 mmol) of cinnoline. Stirring was continued after completed addition for a further 12 h at room temperature during which time the solution adopted a red color. A yellow crystalline solid which had separated was collected and recrystallized from chloroform–ethanol to give 2.63 g (96% yield) of 2,3-diphenyl-1-thionpyrazolo[1,2-*a*]cinnoline (**8**) m.p. 267° (dec.).

Anal. Calcd. for $C_{23}H_{16}N_2S$ (mol. wt. 352.1314): C, 78.40; H, 5.03; N, 7.95; S, 9.10. Found (352.1314 (mass spectrum)): C, 78.46; H, 4.96; N, 7.69; S, 9.06.

The i.r. spectrum ν_{max} (KBr disc) 1410, 1356, 1243 cm^{-1} (C=S). The n.m.r. spectrum δ_{TMS} (CF_3COOH): 7.18, 7.90 (2H, ABq J = 8 Hz, 5,6 protons); 7.35–7.9 (13H, m, aromatic protons), 8.65–8.95 (1H, m, proton-10).

(b) Reaction of Diphenylcyclopropenethione with Pyrazine

(i) In the Presence of Oxygen

To a solution of 1.11 g (3 mmol) of diphenylcyclopropenethione in 15 ml of chloroform was added with stirring a solution of 0.40 g (5 mmol) of pyrazine in 10 ml of methanol. Stirring was continued for 3 days at room temperature. Evaporation of the solvent gave a dark brown solid, trituration of which with methanol afforded 0.68 g (45% yield) of di-(7,8-diphenylpyrrolo[1,2-*a*]pyrazinyl)-6-sulfide (**11***a*) as a yellow solid, m.p. 230° (dec.) (from chloroform–ethanol).

Anal. Calcd. for $C_{39}H_{26}N_4S_2$ (mol. wt. 602.1612): C, 75.90; H, 4.35; N, 9.30; S, 10.65. Found (602.1599 (mass spectrum)): C, 75.51; H, 4.53; N, 9.21; S, 10.76.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 6.5–8.0 (m, aromatic protons).

(ii) In the Absence of Oxygen

A deoxygenated solution of 0.4 g (5 mmol) of pyrazine in 15 ml of methanol was added dropwise with stirring under nitrogen to a solution of 1.11 g (5 mmol) of diphenylcyclopropenethione in 15 ml of chloroform. The mixture was stirred for 2 days under nitrogen. After removal of the solvent *in vacuo*, methanol was added and the resulting yellow solid **11***a* identical with that obtained above was collected 0.42 g (28% yield) m.p. 230° (dec.). The filtrate was set aside at 0° for 1 day when a yellow crystalline solid separated which was collected, affording 0.38 g (25% yield) of 7,8-diphenylpyrrolo[1,2-*a*]pyrazine-6-thiol (**12***a*), m.p. 148° (from cold methanol under nitrogen).

Anal. Calcd. for $C_{19}H_{14}N_2S$: C, 75.46; H, 4.67; N, 9.27; S, 10.60. Found: C, 75.78; H, 4.71; N, 9.48; S, 10.83.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 6.5–8.0 (m, aromatic protons). The latter compound **12***a* could be converted in the disulfide **11***a* by recrystallization from hot aerated chloroform.

(c) Reaction of Diphenylcyclopropenethione with Isoquinoline

A mixture of 1.11 g (5 mmol) of diphenylcyclopropenethione and 0.65 g (5 mmol) of isoquinoline in 15 ml of chloroform and 10 ml of methanol was stirred at room temperature for 24 h. The resulting pale yellow solid which separated was collected (0.19 g). Upon setting aside the filtrate for 7 days a further 0.52 g of product was obtained, representing 1.43 g (78% yield) of 1-methoxy-1,2-diphenyl-3-thionpyrrolidino[1,2-*a*]isoquinoline **15**, m.p. 204° (chloroform–methanol) as colorless crystals.

Anal. Calcd. for $C_{25}H_{21}NSO$: (mol. wt. 383.1344): C, 78.29; H, 6.95; N, 3.65; S, 8.37. Found (383.1336 (mass spectrum)): C, 78.51; H, 5.58; N, 3.66; S, 8.29.

The i.r. spectrum ν_{max} (Nujol mull) 1067, 1288, 1560 cm^{-1}. The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.30 (3H, s, OCH_3); 5.25 and 6.31 (1H each, s, methine protons); 5.52, 5.85 (2H, ABq, J = 8 Hz, 5,6 protons), 6.7–7.7 (14H, m, aromatic protons).

Products of the three types exemplified above were obtained by similar procedures from other heteroaromatic nitrogen compounds. The analytical and spectral data are summarized in Tables 1 and 2.

Reaction of 2,3-Diphenyl-1-ketopyrazolo[1,2-a]cinnoline with Phosphorus Pentasulfide

A mixture of 0.34 g (1 mmol) of 2,3-diphenyl-1-ketopyrazolo[1,2-*a*]cinnoline and 0.44 g (2 mmol) of phosphorus pentasulfide in 20 ml of dry pyridine was heated under reflux for *ca.* 70 h with stirring. The solvent was removed *in vacuo* and the residual solid extracted with hot benzene. Evaporation of the benzene gave a yellow solid which was purified by recrystallization twice from chloroform–methanol to yield 0.30 g (88% yield) of 2,3-diphenyl-1-thionpyrazolo[1,2-*a*]cinnoline, m.p. 267°.

The physical and spectral characteristics of this com-

pound were identical with those of compound **8** prepared directly from the reaction of diphenylcyclopropenethione with cinnoline.

Reaction of Diphenylcyclopropenone with 4-Methylcinnoline

To a solution of 0.21 g (1 mmol) of diphenylcyclopropenone (15) in 15 ml of chloroform there was added with stirring at $-10°$ a solution of 0.14 g (1 mmol) of 4-methylcinnoline in 15 ml of methanol and stirring was continued for 2 h at $-10°$ and then 8 h at room temperature. The light green solid which separated was collected affording 0.32 g (91% yield) of 6-methyl-2,3-diphenyl-1-ketopyrazolo[1,2-*a*]cinnoline, m.p. 189° (chloroform–ethanol).

Anal. Calcd. for $C_{24}H_{18}N_2O$ (mol. wt. 350.1418): C, 82.26; H, 5.18; N, 7.99. Found (350.1419 (mass spectrum)): C, 82.14; H, 5.19; N, 8.00.

The i.r. spectrum ν_{max} (Nujol) 1641 cm^{-1} (C=O). The n.m.r. spectrum δ_{TMS}(CF_3COOH): 2.43 (3H, d, $J = 1$ Hz CH_3); 7.7–8.1 (13H, m, aromatic protons).

This material was converted into the thione in 84% yield identical in every respect to **9** by refluxing with phosphorus pentasulfide in pyridine. By a similar procedure compound **7** (1) was converted into **6**.

Acid-catalyzed Hydrolysis of 1-Methoxy-1,2-diphenyl-3-thionpyrrolidino[1,2-a]isoquinoline

A slurry of 0.766 g (2 mmol) of 1-methoxy-1,2-diphenyl-3-thionpyrrolidino[1,2-*a*]isoquinoline in 30 ml of 15 *N* sulfuric acid was heated to 80–100° for 2 h. A brown residue was collected and the filtrate neutralized with dilute aqueous potassium hydroxide and extracted with ether. Evaporation of the dried ($MgSO_4$) ether extract gave a yellow oil (0.33 g), the i.r. and n.m.r. spectra of which were superimposable with those of isoquinoline.

This research was supported by a grant from the National Research Council of Canada (to J.W.L.) and by the University of Alberta. We thank Mr. R. Swindlehurst and Dr. A. Hogg for the n.m.r. and mass spectra.

Etude polarographique des ozonides

J. GRIGNON ET S. FLISZÁR
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 30 avril 1971

La réduction polarographique des ozonides du stilbène et d'une série de styrènes substitués dans le noyau a été étudiée. Une relation linéaire est observée entre les potentiels de demi-vague et les constantes σ de Hammett pour les ozonides des styrènes substitués. La constante ρ est positive, ce qui indique que l'étape déterminante est une réaction nucléophile. Un mécanisme est proposé pour la réaction d'électrode conduisant à la formation de 2 mol d'aldéhyde par mole d'ozonide.

The polarographic reduction of the ozonides of stilbene and of selected ring-substituted styrenes, yielding 2 mol of aldehyde per mole of ozonide, has been studied. With the substituted styrenes a Hammett relationship is observed for the half-wave potentials. The positive ρ constant (0.20) indicates that the determining step is a nucleophilic process. Possible mechanisms are discussed.

Canadian Journal of Chemistry, **49**, 3127 (1971)

Dans le cadre de l'étude des produits d'oxydation des corps gras, des caoutchoucs, des polymères, et des essences, de nombreuses publications et revues (1–3) ont traité du comportement polarographique des produits peroxydiques. Kůta et Quackenbush (4) ont, notamment, signalé les possibilités d'application des techniques polarographiques à l'étude des produits d'ozonation. Ainsi les méthoxyhydroperoxydes, engendrés lors de l'ozonation d'oléfines en présence de méthanol, ont fait l'objet d'un récent travail (5) et l'application analytique de la polarographie pour l'étude du mécanisme d'ozonolyse a été exposée (5–7). Il a également été montré (7) que les hydroxyperoxydes $R_2CH(OOR_1)OH$, examinés en polarographie, peuvent être facilement reconnus à côté de leurs alcoxyhydroperoxydes $R_2CH(OOH)$—OR_1 isomères.

Quelques conclusions générales se dégagent de l'ensemble de ces travaux: (*i*) Les composés peroxydiques d'une même classe sont réduits dans un domaine de potentiel restreint. Ainsi, par exemple, les potentiels de demi-vague observés pour les α-méthoxyhydroperoxydes R—$CH(OCH_3)$—OOH dans le tampon McIlvaine à p*H* 7, en présence de méthanol, sont compris entre −0.838 (R = H) et −0.200 V (R = *t*-C_4H_9) (5). Les divers types de composés peroxydiques peuvent être classés comme suit, par ordre de potentiel négatif croissant: peracides < hydroperoxydes < peroxydes. (*ii*) La réduction, irréversible, procède par la rupture de la liaison oxygène–oxygène, avec la participation de deux électrons, en une seule étape.

Dans le présent travail, les techniques polarographiques ont été appliquées à l'étude des ozonides du stilbène et des styrènes substitués dans le noyau (**1–6**).

Résultats et discussion

Les polarogrammes ont été obtenus, à moins d'indications contraires, par polarographie avec une tension alternative surimposée. Le solvant utilisé était un mélange 1:1 de benzène–méthanol et l'électrolyte de support du chlorure de lithium 0.5 *M*. Les polarogrammes des ozonides enregistrés dans ces conditions montrent deux pics. Le courant de réduction enregistré à un potentiel de 0 V est dû au méthanol contenu dans le solvant. Des deux pics polarographiques observés, le premier, c'est-à-dire celui qui apparaît au potentiel le moins négatif, est dû à la réduction de l'ozonide, tandis que le deuxième est causé par la réduction de l'aldéhyde aromatique engendré lors de l'électrolyse de l'ozonide. Ce point sera démontré par l'étude des potentiels de demi-vague et des temps de rétention en c.p.g. des produits obtenus par électrolyse préparative.

For personal use only.

Le benzène–méthanol a été choisi comme solvant en raison de la faible solubilité des ozonides dans l'eau et dans le méthanol froid. Dans le benzène–méthanol, les ozonides subissent une décomposition lente: environ 15% de décomposition après 1 h à la température de 20 °C. Le méthanol semble être le principal agent affectant la stabilité des ozonides dans le solvant utilisé. Il est, en effet, généralement possible de conserver les ozonides pendant quelques semaines au réfrigérateur, purs ou en solution dans le benzène ou le tétrachlorure de carbone, tandis qu'en solution méthanolique ces mêmes ozonides sont presqu'entièrement décomposés en quelques jours. En raison de cette décomposition, les procédures expérimentales doivent être maintenues rigoureusement constantes.

Potentiels de demi-vague $E_{1/2}$

L'électrode de référence était constituée d'un fil d'argent plongé dans une solution d'électrolyte saturée en AgCl et séparée de la solution à analyser par un verre fritté fin.

Lors de l'utilisation d'un solvant non-aqueux la résistance de la solution n'est pas négligeable; il faut en tenir compte dans la mesure des potentiels de demi-vague. Il a été observé que la chute de tension due à la résistance de la solution est faible et indépendante de la concentration en dépolariseur dans le domaine de 1 à 32×10^{-4} *M* qui a été étudié. Elle est de 30 mV à un potentiel de -1.00 V et de 50 mV à -2.00 V. Dans ces conditions, l'aldéhyde benzoïque a un potentiel de demi-vague $E_{1/2}$ expérimental de -1.59 V, ce qui selon l'équation

$$E_{1/2} \text{ expérimental} = E_{1/2} \text{ corrigé} + iR$$

conduit à la valeur $E_{1/2}$ corrigé $= -1.55$ V, valeur voisine de celle de -1.58 V (par rapport à l'électrode de calomel saturée) observée par Willits *et al.* (8) dans une solution 0.3 *M* en LiCl dans le benzène–méthanol (1:1). Cette valeur du potentiel de demi-vague de l'aldéhyde benzoïque a été utilisée comme valeur étalon pour s'assurer de la reproductibilité de l'électrode de référence.

Les valeurs des potentiels de demi-vagues observées pour les ozonides étudiés sont rapportées au tableau 1. Il doit être noté que ces potentiels ont une légère tendance à être déplacés vers des valeurs plus négatives aux concentrations plus élevées. Les valeurs rapportées au tableau 1 ont été toutes mesurées à la concentration de 8×10^{-4} *M* en ozonide.

TABLEAU 1. Potentiels de demi-vague des ozonides $R_1C_6H_4—CH(O_3)CH—R_2$

R_1	R_2	$E_{1/2}$ expérimental (V)	$E_{1/2}$ corrigé (V)
p-CH_3O	H	−1.11	−1.08
p-CH_3		−1.05	−1.02
H		−1.01	−0.98
p-Cl		−0.98	−0.95
p-Br		−0.95	−0.92
m-NO_2		−0.87	−0.84
H	C_6H_5	−0.87	−0.84

Il ressort des résultats exposés au tableau 1 que les potentiels de demi-vague des ozonides des styrènes substitués dans le noyau varient régulièrement en fonction des substituants. La fig. 1 montre qu'une relation linéaire est obtenue en fonction des constantes de substituants σ de Hammett. La constante ρ est positive (+0.20), ce qui est en accord avec la majorité des processus de réduction électrochimique (9). Ceci indique que l'étape déterminant le potentiel est une réaction nucléophile, l'agent nucléophile étant probablement l'électron (ou l'électrode). Ceci exclut, donc, la possibilité d'une importance prédominante d'une attaque électrophile de la part, par exemple, d'un proton précédent le transfert d'électron.

Irréversibilité du processus d'électrode

Les oscillo-polarogrammes $i = f(E)$ ont montré, dans un grand domaine de vitesses de balayage, une irréversibilité complète du processus d'électrode pour tous les ozonides étudiés. En effet, aucun courant n'est observé sur la branche anodique des oscillo-polarogrammes pour des vitesses de balayage comprises entre 0.5 et 25 V/s. Pour des vitesses de balayage très grandes, par contre, supérieures à 200 V/s, un léger courant apparaît sur la branche anodique.

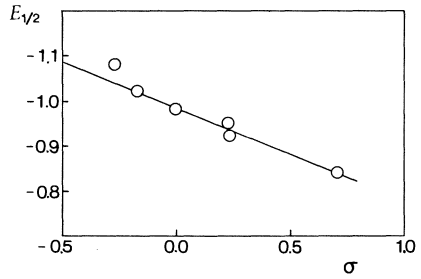

FIG. 1. Relation de Hammett entre $E_{1/2}$ et σ pour les ozonides des styrènes substitués.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Les pics cathodique et anodique sont alors décalés de 0.20 V.

L'irréversibilité du processus d'électrode, observée aux vitesses de balayage pas trop élevées, est confirmée par l'analyse logarithmique des courbes intensité-potentiel, d'après l'éq.:

$$E = E_{1/2} - (RT/\alpha nF) \ln[I/(I_1 - I)]$$

Le coefficient de transfert α calculé à partir des droites obtenues en portant $\ln[I/(I_1 - I)]$ en fonction de E est, pour tous les ozonides étudiés, de 0.10–0.13, compte tenu des deux électrons mis en jeu.

Nombre d'électrons mis en jeu dans le processus d'électrode

L'électrolyse à potentiel contrôlé a été effectuée sur des échantillons de 100 ml de solution environ 10^{-3} M en ozonide, en utilisant une nappe de mercure comme électrode. La température a été maintenue à 0 °C, afin de réduire la décomposition de l'ozonide: dans ces conditions le pic polarographique de l'ozonide demeure pratiquement inchangé après 1 h, ce qui est le temps généralement requis pour l'électrolyse. Le nombre d'électrons mis en jeu, n, a été déterminé d'après la quantité de courant requise pour réduire une quantité connue d'ozonide, ainsi que par l'étude des courbes $i = i(t)$ obtenues lors de l'électrolyse, d'après l'éq. (10):

$$\log \bar{i}_0 - \log \bar{i}_1 = \bar{i}_0 t/2.3nFC_{t=0}V$$

Les résultats des électrolyses rapportées au tableau 2 indiquent que la valeur expérimentale de n est voisine de 1.9 électron par molécule d'ozonide. Ce résultat, qui tend à montrer que $n = 2$, est en accord avec les valeurs de n observées lors de la réduction de divers composés peroxydiques (5, 7, 11).

Au cœur de la solution, la concentration en ozonide n'est pas identique à celle qui est mesurée à la surface de l'électrode. Ceci cause une erreur systématique qui pourrait expliquer, du moins en partie, le résultat approximatif obtenu.

TABLEAU 2. Détermination du nombre n d'électrons mis en jeu lors de la réduction des ozonides du stilbène et du styrène

Ozonide	Consommé (mmol)	Quantité d'électricité (C)	n*	n†
Stilbène	0.25	45	1.87	1.95
	0.20	34	1.76	1.63
Styrène	0.136	25.5	1.94	2.10
	0.133	24.8	1.93	1.73

*Calculé d'après la quantité d'électricité utilisée.
†Calculé d'après l'analyse logarithmique, par voie graphique.

Identification des produits d'électrolyse

L'électrolyse de 75 ml de solutions d'ozonide du stilbène, de concentrations comprises entre 5×10^{-3} et 1×10^{-2} M, a été effectuée à 0 °C avec une tension appliquée de −1.2 V par rapport à l'électrode Ag/AgCl. L'électrolyse a été conduite, dans chaque cas, jusqu'à la consommation complète de l'ozonide, attestée par l'absence du pic ozonide dans le polarogramme de la solution électrolysée. L'analyse de cette solution par c.p.g. a permis l'identification de l'aldéhyde benzoïque, par une comparaison des temps de rétention, au moyen d'un échantillon authentique de cet aldéhyde. Cette analyse a, de plus, permis de vérifier l'absence d'acide benzoïque dans la solution électrolysée. Les résultats sont rapportés dans le tableau 3.

Des expériences effectuées avec l'ozonide du stilbène, il ressort clairement que l'électrolyse d'une mole d'ozonide conduit à la formation de 2 mol d'aldéhyde benzoïque.

Des expériences similaires ont été faites avec l'ozonide du styrène. L'électrolyse de 100 ml de solution, environ 5×10^{-3} M en ozonide, a été effectuée à 0 °C sous une tension appliquée de −1.18 V par rapport à l'électrode Ag/AgCl. Après l'électrolyse, le polarogramme de la solution ne montre qu'un seul pic à −1.59 V, ce qui atteste la consommation complète de l'ozonide et confirme la présence de l'aldéhyde benzoïque. Comme pour l'ozonide du stilbène, le dosage de l'aldéhyde benzoïque a été effectué au moyen de son pic polarographique. Le deuxième produit attendu lors de l'électrolyse de l'ozonide du styrène, l'aldéhyde formique, ne se manifeste pas en polarographie. Dans le solvant utilisé, contenant 50% de méthanol, l'aldéhyde formique se retrouve, en effet, entièrement sous forme de son hémiacétal. Ce dernier n'étant pas réductible à l'électrode à goutte de mercure (9), il ne peut donc être décelé dans le polarogramme de la solution électrolysée. L'hémiacétal du formaldéhyde a été mis en évidence par c.p.g., par comparaison des temps de rétention avec une solution de styrène ozonée dans le méthanol. Son dosage a été effectué par une comparaison de la surface du pic chromatographique de l'hémiacétal dans

TABLEAU 3. Bilan matériel des électrolyses des ozonides du stilbène et du styrène

Ozonide	mmol consommé	PhCHO formé (mmol)	HCHO formé (mmol)	PhCHO / Ozonide	HCHO / Ozonide
Stilbène	0.75	1.42	—	1.89	—
	0.75	1.48	—	1.97	—
	0.395	0.773	—	1.96	—
Styrène	0.450	0.445	0.442	0.99	0.98
	0.448	0.433	0.399	0.97	0.92

la solution électrolysée avec la surface correspondante, déterminée à partir d'une solution de référence d'hémiacétal. La solution de référence a été obtenue par l'ozonolyse, à −20 °C, d'une quantité connue de styrène dans le méthanol pur, en tenant compte que l'ozonolyse d'une mole de styrène, dans ces conditions, conduit à la formation de 0.59 mol de formaldéhyde (12, 13), sous forme de son hémiacétal.

Les résultats exposés au tableau 3 indiquent clairement que l'électrolyse d'une mole d'ozonide de styrène aboutit à la formation d'une mole d'aldéhyde benzoïque et d'une mole d'aldéhyde formique.

Influence de la hauteur de la colonne de mercure

La proportionalité, observée au moyen d'un courant continu d'analyse, entre le courant limite et la hauteur (H) de la colonne de Hg, corrigée pour la tension interfaciale à la surface des gouttes de Hg (14), montre que ce courant est contrôlé par diffusion. Il s'est avéré nécessaire d'utiliser du bleu de méthylène pour supprimer les légers maxima qui apparaissent en polarographie lente. Il est à noter, cependant, que ces maxima disparaissent dès que la polarographie rapide ou à courant alternatif est utilisée.

Influence de la vitesse de balayage

Les courants maximum des oscillo-polarogrammes $i = f(E)$ ont été mesurés pour des vitesses de balayage comprises entre 0.5 et 25 V/s. Ainsi que le montre la fig. 2, les courants i_{max} sont linéairement reliés à la racine carrée de la vitesse de balayage, ce qui est caractéristique pour un courant contrôlé par diffusion, dans le cas d'un processus irréversible (15, 16). Le courant obéit alors à la relation:

$$i_{max} = k_2 qn(\alpha n_a)^{1/2} C D^{1/2} v^{1/2} \quad \text{(Ampère)}$$

Pour tous les ozonides étudiés, une légère influence de la vitesse de balayage sur les potentiels de demi-vague est également observé. Ces

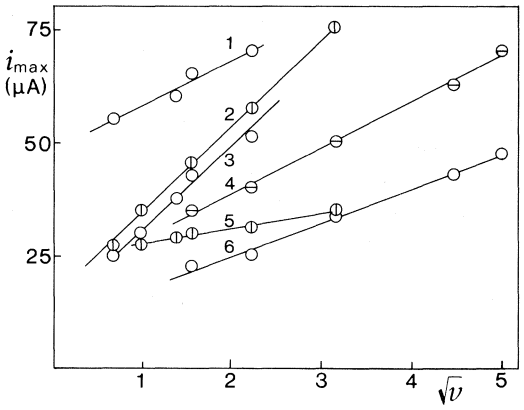

FIG. 2. Dépendance de i_{max} en fonction de la racine carrée de la vitesse (V/s) de balayage pour les ozonides du *p*-méthylstyrène (*1*), du *p*-méthoxystyrène (*2*), du *p*-bromostyrène (*3*), du styrène (*4*), du *p*-chlorostyrène (*5*), et du stilbène (*6*).

potentiels sont, en effet, d'autant plus déplacés vers les valeurs plus négatives que la vitesse de balayage est augmentée. En général, les potentiels sont plus négatifs d'environ 0.10 à 0.15 V pour $v = 25$ V/s qu'avec $v = 0.5$ V/s.

Influence de la température

L'influence de la température sur les pics polarographiques a été étudiée dans le domaine allant de 10 à 40 °C. Aucun effet notable n'a été relevé en ce qui a trait aux potentiels de demi-vague. Quant aux intensités de courants, leur dépendance de la température est illustrée par la fig. 3.

Les coefficients de température moyens, c'est-à-dire l'accroissement du courant par °C d'élévation de la température, rapportés à l'intensité de courant observée à 25 °C, dépendent de la nature de l'ozonide étudié (tableau 4).

Le sens de variation observé est l'inverse de ce à quoi on aurait pu s'attendre d'après les potentiels de demi-vague. La plus grande valeur observée,

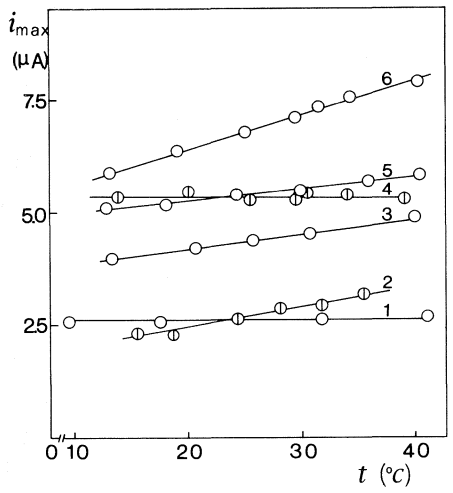

FIG. 3. Effet de température pour les ozonides du stilbène (*1*), du *p*-méthoxystyrène (*2*), du styrène (*3*), du *p*-bromostyrène (*4*), du *p*-chlorostyrène (*5*), et du *p*-méthylstyrène (*6*).

TABLEAU 4. Coefficients de température moyens pour la réduction des ozonides $R_1—C_6H_4—CH(O_3)CH—R_2$

R_2	R_1	Coefficients de température (%/°C)
H	*p*-CH_3O	1.8
	p-CH_3	1.1
	H	0.80
	p-Cl	0.50
	p-Br	0
C_6H_5	H	0

soit 1.8% par °C, correspond à celle indiquée par Zuman (17) pour le coefficient de température d'un courant contrôlé par diffusion.

Mécanisme proposé

L'ensemble des résultats expérimentaux suggère le mécanisme de réaction exposé ci-après (éq. 1);

[1] 
avec, pour les ozonides des styrènes substitués, $R_1 = RC_6H_4$ ou H, $R_2 =$ H ou RC_6H_4, et, pour l'ozonide du stilbène, $R_1 = R_2 = C_6H_5$.

L'étape 1 est bien confirmée par la corrélation des potentiels de demi-vague avec les constantes σ de Hammett (fig. 1) avec une pente ρ positive, ce qui montre que l'étape déterminante est une réaction nucléophile et exclut toute attaque électrophile précédent le transfert d'électrons en tant que processus déterminant la réaction.

L'étape suivante n'a, cependant, pas pu être précisée. Il est possible, en effet, d'expliquer la formation des produits observés par les réactions 2 et 3 ou, plus vraisemblablement, par une monoprotonation du dianion, selon la réaction 4.

[2] 
[3] 
[4] 
Il eut été intéressant d'étudier le comportement du potentiel de demi-vague et du courant limite en fonction du p*H*, en vue de mieux établir ces mécanismes. Cependant, en raison de la fragilité des ozonides et du milieu devant être employé, cette étude n'a pas pu être accomplie. Un essai a été effectué en utilisant un tampon constitué d'acide acétique et d'éthanolamine. Il s'est avéré que l'ozonide est rapidement décomposé dans ce milieu: environ 35% par heure, ce qui est attesté par la rapide décroissance du pic polarographique de l'ozonide. De plus, dans ce milieu, l'aldéhyde aromatique est réduit en deux étapes dans le domaine de p*H* compris entre p*H* 5 et 10 et l'un des deux pics de l'aldéhyde est très proche de

For personal use only.

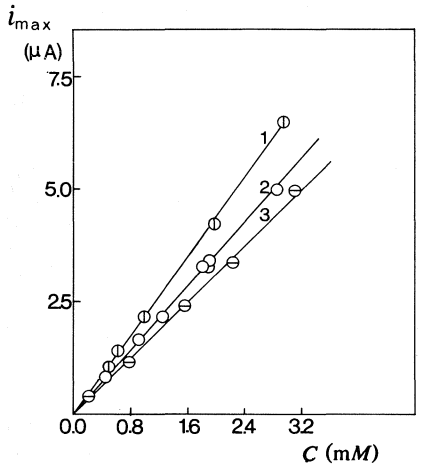

FIG. 4. Dépendance de i_{max} (μA) en fonction de la concentration C (mM) en ozonide du *p*-méthylstyrène (*1*), du *p*-bromostyrène (*2*), et du stilbène (*3*).

celui de l'ozonide, gênant ainsi considérablement les mesures.

Influence de la concentration en dépolariseur

L'intensité des courants limites a été étudiée en fonction de la concentration en ozonide, dans le benzène–méthanol (1:1) en présence de LiCl 0.5 *M*. Ainsi que l'indique la fig. 4, les intensités de courant enregistrés en polarographie à courant alternatif sont linéairement reliées aux concentrations en ozonide. Un contrôle soigneux des conditions expérimentales, en ce qui a trait, notamment, à la température, la pureté des solvants et le temps de dégazage, permet d'atteindre une reproductibilité satisfaisante ($\Delta i_{max} \leqslant 2\%$), ce qui permet des applications analytiques. Ainsi, dans le cas des ozonides des styrènes substitués où il n'y a pas de possibilité d'isomérie *cis–trans* et, par ailleurs, dans tous les cas où les proportions relatives des ozonides isomères *cis–trans* ne sont pas requises, la polarographie se révèle une méthode de dosage des ozonides, précise et très rapide.

Partie expérimentale

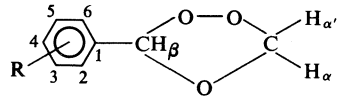
Les spectres de r.m.n. des ozonides préparés ont été enregistrés au moyen d'un spectromètre Jeolco C-60-H, en solution dans le tétrachlorure de carbone, en utilisant le tétraméthylsilane comme référence interne. Les spectres d'absorption i.r. ont été enregistrés au moyen d'un spectromètre Perkin–Elmer 621, en utilisant des solutions d'ozonide dans le tétrachlorure de carbone. Les analyses élémentaires ont été effectuées par le Dr. C. Daesslé (Organic Microanalyses, Montréal).

Produits utilisés

L'ozonide du stilbène (p.f. 74 °C) a été préparé selon Criegee *et al.* (18). Les ozonides **1–4** ont été préparés et purifiés selon (19) et les ozonides **5** et **6** ont été obtenus de manière similaire. L'ozonide du *p*-bromostyrène fond vers 15 °C.

Anal. calc. pour $C_8H_7O_3Br$: C, 41.58; H, 3.06; Br, 34.59. Trouvé: C, 41.42; H, 2.99; Br, 34.63.

Spectre r.m.n. (δ) dans le CCl_4: H_2, H_6, 7.58; H_3, H_5, 7.33; H_β, 5.95; H_α, 5.29; $H_{\alpha'}$, 5.24; J_{ortho} 8.0 Hz.



L'ozonide du *m*-nitrostyrène, liquide à la température ambiante, a donné l'analyse suivante.

Anal. calc. pour $C_8H_7O_3N$: C, 48.73; H, 3.58; N, 7.10. Trouvé: C, 48.80; H, 3.60; N, 6.90.

Spectre r.m.n. (δ) dans le CCl_4: H_2, H_4, 8.30; H_5, H_6, 7.75; H_β, 6.20; H_α, 5.43; $H_{\alpha'}$, 5.34. Les spectres r.m.n. d'une série d'ozonides de styrènes substitués dans le noyau ont fait l'objet d'une discussion antérieure (19). La position (*cis* ou *trans*) de H_α (ou de $H_{\alpha'}$) par rapport au cycle aromatique n'a pas pu être précisée à partir des présentes données expérimentales.

Polarographie

Les courbes intensité-potentiel ont été enregistrées à l'aide d'un polarographie Metrohm E-261-R. Cet appareil offre la double possibilité d'une analyse au moyen d'un voltage continu croissant linéairement ou d'une analyse à l'aide d'une tension alternative de faible amplitude surimposée au voltage continu d'analyse. Cette dernière technique, développée par Breyer *et al.* (20), a été utilisée dans la majeure partie du présent travail. La fréquence de la tension alternative utilisée a été de 60 Hz, et son amplitude de 50 mV. L'électrode à goutte de mercure était constituée d'un capillaire dont le mouvement de translation verticale, commandé par un électroaimant, assure un temps de goutte de 1/6 s pour un flux de mercure de 8.7 mg/s. L'électrode de référence était constituée d'un fil d'argent plongeant dans une solution d'électrolyte saturée en AgCl, séparée de la solution à analyser par un verre fritté fin. L'électrode auxiliaire était une électrode de tungstène commerciale.

La cellule de polarographie, d'une capacité utile de 25 ml, était munie d'une enceinte extérieure permettant une circulation d'eau à température constante. Le dégazage a été effectué à l'aide d'un courant d'azote saturé en solvant. La procédure polarographique consistait à placer 25 ml de solvant (benzène–méthanol, 1:1, LiCl 0.5 *M*) dans la cellule. Après un dégazage par un courant de N_2 (5 min), 1 ml de solution d'ozonide est ajouté. Après un deuxième dégazage le polarogramme est enregistré. Le benzène avait été purifié par un chauffage au reflux pendant 4 h, en présence de sodium, suivi d'une distillation. Le méthanol a été purifié par un chauffage au reflux en présence de copeaux de magnésium, pendant 4 h, suivi d'une distillation.

Oscillo-polarographie

Les oscillo-polarogrammes ont été obtenus à l'aide d'un appareillage comprenant: un générateur de tension

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

triangulaire Tacussel, un potentiostat Wenking-121, un oscilloscope Tektronix "Dual-Beam 502-A" muni d'une entrée différentielle X-Y et d'une boîte de résistance. Cet appareillage permet un balayage simple ou répétitif par une tension triangulaire. La gamme de vitesses de balayage va de quelques centièmes à quelques milliers de V/s. Pour l'étude du courant maximum en fonction de la racine carrée de la vitesse de balayage, un domaine restreint de vitesses intermédiaires allant de 0.5 à 25 V/s a été utilisé. L'utilisation de vitesses supérieures à 200 V/s a permis de noter l'apparition d'un léger pic anodique. Les électrodes utilisées sont les mêmes que celles décrites précédemment. Le temps de goutte a été ramené à 4 s.

Electrolyse à potentiel contrôlé

Les électrolyses ont été effectuées dans une cellule à trois compartiments, séparés par des verres frittés. La cellule était plongée dans un bain de glace afin de réduire la décomposition des ozonides. L'électrode de travail était constituée d'une nappe de mercure agitée au moyen d'un agitateur magnétique. L'électrode de contrôle était constituée d'un fil d'argent. L'électrode auxiliaire était une électrode de platine, immergée dans le compartiment central contenant du benzène–méthanol 1:1, 0.5 *M* en LiCl. La solution à électrolyser avait un volume de 75 à 100 ml.

Le solvant est dégazé par du N_2 et électrolysé au potentiel devant être utilisé par la suite pour l'ozonide, pendant 1 h ou jusqu'à la stabilisation du courant résiduel (0.1–0.3 mA). L'ozonide est ensuite ajouté et la solution est à nouveau dégazée pendant 10 min. Le courant d'azote est maintenu au-dessus de la solution durant toute la durée de l'électrolyse.

La tension était appliquée à l'aide d'un potentiostat Tacussel PRT-20, 2X. Le courant d'électrolyse a été noté au moyen d'un milliampèremètre, alors que son logarithme a été enregistré au moyen d'un enregistreur galvanométrique Graphispot GR VAC 2594, par l'intermédiaire d'un amplificateur à réponse logarithmique Logalex 0.1 A 8540 de Tacussel.

L'électrolyse de l'ozonide du stilbène a été effectuée sur des volumes d'environ 75–100 ml de solutions 5×10^{-3} à 10^{-2} *M* en ozonide. Le potentiel appliqué était de -1.2 V et la durée de l'électrolyse était de 1 à 2 h. A la fin de l'électrolyse, indiquée par un courant d'électrolyse proche de la valeur du courant résiduel et par un polarogramme ne présentant plus de pic à 0.87 V, un échantillon de 5 µl de la solution électrolysée a été analysé en chromatographie en phase gazeuse, au moyen d'un chromatographe F & M 5750 muni d'une colonne "Silicone-Rubber UCW-98" de 6 pd, à 100 °C. Les analyses ont bien confirmé que le temps de rétention du pic obtenu est identique à celui d'un échantillon authentique d'aldéhyde benzoïque. Le dosage de l'aldéhyde benzoïque au moyen de son pic polarographique révèle un rendement supérieur à 190% par rapport à l'ozonide consommé, ce que indique bien la formation de 2 mol d'aldéhyde par mole d'ozonide électrolysée.

L'électrolyse de l'ozonide du styrène a été effectuée dans les mêmes conditions que celles décrites pour l'ozonide du stilbène. L'analyse en c.p.g. a encore permi d'identifier et de doser l'aldéhyde benzoïque. Un autre échantillon de 5 µl de solution électrolysée, injectée sur une colonne "Carbowax 20M" de 6 pd à 30 °C permet l'identification de l'hémiacétal du méthanal, par comparaison du temps de rétention du pic obtenu avec celui d'une solution de styrène ozonée dans le méthanol. Le dosage de l'hémiacétal du méthanal a été effectué par comparaison des aires du pic de la solution électrolysée avec celui d'une solution de référence. La solution de référence a été préparée en ozonant 0.0171 g de styrène dans 25 ml de méthanol à -20 °C. Compte tenu du sens de clivage du styrène (13) qui est de 59% en faveur du méthanal, il se forme ainsi 3.88×10^{-3} *M* en hémiacétal de méthanal. Ces dosages ont révélé la formation d'une mole de chacune des aldéhydes par mole d'ozonide électrolysée.

Influence de la température et de la hauteur de la colonne de mercure

Ces deux études doivent être effectuées à l'aide d'un même échantillon d'ozonide dans tout le domaine de température ou de hauteur de colonne. Pour obtenir des mesures valables et reproductibles, il faut, avant chaque mesure, stabiliser soit la température, soit la hauteur de la colonne de mercure. La décomposition lente de l'ozonide exclut la possibilité de mettre un échantillon dans la cellule et d'effectuer toutes les mesures à l'aide de cet échantillon.

La méthode qui a donné les meilleurs résultats consiste à préparer une solution de base de 25 ml d'ozonide en utilisant comme solvant du benzène additionné d'un peu de méthanol (~1 ml). Cette solution est conservée dans la glace, à l'abri de la lumière. Pour chaque mesure, les conditions sont bien équilibrées avec 25 ml de solvant de polarographie. Ensuite 1 ml de la solution de base est ajouté. Après un dégazage, la mesure est enregistrée. Il a été vérifié que la solution de base reste inchangée durant une journée et que les premières mesures, reprises en fin de journée, redonnent les mêmes valeurs, aux erreurs expérimentales près. Il a également été vérifié que des polarogrammes pratiquement identiques, aux erreurs expérimentales près, sont enregistrés immédiatement après le dégazage de la solution et après un délai d'environ 3–5 min. Cette vérification permet de conclure que les coefficients de température observés (tableau 4) ne sauraient être imputés à une erreur due à la lente décomposition des ozonides.

Nous tenons à remercier M. le Dr. J. Carles de son aide précieuse lors de la préparation de quelques ozonides, ainsi que le Conseil National de Recherches du Canada pour une subvention qui a permis cette recherche.

Transannular Cyclizations of 6-Substituted Cyclodecynes[1]

R. J. Balf, Balaji Rao, and Larry Weiler[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

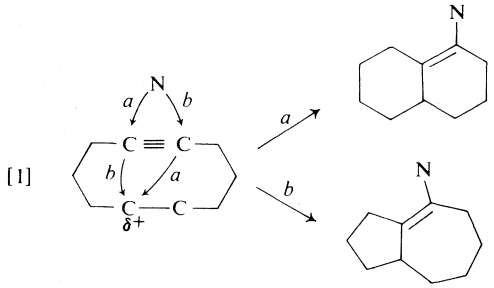
Received June 3, 1971

A series of 6-substituted cyclodecynes has been synthesized and the transannular cyclizations of these compounds were studied. The observed transannular cyclizations were highly stereoselective and give products containing the bicyclo[4.4.0]decane skeleton.

Une série de cyclodécynes substitués en position 6 a été synthétisée et les cyclisations *trans*-annulaires de ces composés ont été étudiées. Les cyclisations *trans*-annulaires observées sont très stéréosélectives et conduisent à des produits contenant le squelette du bicyclo[4.4.0] décane.

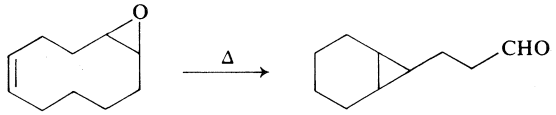
Canadian Journal of Chemistry, **49**, 3135 (1971)

Transannular reactions in medium-sized rings have been an area of extensive study for the past 15 years (1). We were interested in the transannular cyclizations of suitably substituted ten-membered rings as a new synthetic route to bicyclo[4.4.0]decanes and/or bicyclo[5.3.0]decanes. In particular we hoped to take advantage of the known susceptibility of the acetylenic bond to both electrophilic and nucleophilic attack (2). This is summarized in eq. 1. Most transannular



[1]

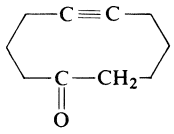
reactions in ten-membered rings appear to favor transition states involving six-membered rings (1, 3). However, the decomposition of cyclodecyl tosylhydrazone in an aprotic solvent yielded bicyclo[5.3.0]decane as the major product (4) and the peracid oxidation of cyclodecyne yielded *cis*-bicyclo[5.3.0]decan-2-one (5). Pyrolysis of epoxide **1** gave the aldehyde **2** (6). A transannular



1 **2**

cyclization to a bicyclo[5.3.0]decane has been proposed for this and other related rearrangements of sesquiterpene epoxides (6, 7). On the other hand the solvolysis of *cis*- and *trans*-cyclodec-5-en-1-yl tosylates gave products containing the bicyclo[4.4.0]decane skeleton only (1, 8), indicating that these transannular reactions occur via six-membered ring transition states. The report that the solvolysis of 6-octyn-2-yl tosylate in trifluoroacetic acid proceeded preferentially to products containing a cyclopentane ring (9) suggested that the related 6-substituted cyclodecynes may undergo transannular cyclizations to bicyclo[5.3.0]decanes. However, solvolysis of cyclodec-5-yn-1-yl tosylate has recently been found to yield predominantly *cis*- and *trans*-decalone-1 together with small amounts of bicyclo[5.3.0]decanone-2 (10).

Our initial studies were concerned with cyclodecyn-6-one **3** (11).[3] Ketone **3** was stable to



3

treatment with aqueous base. However, on treatment with aqueous acid the acetylenic ketone **3** gave an isomeric α,β-unsaturated ketone in high yield. It was quickly ascertained that this product was the octalone **4** by comparison of the spectroscopic properties and the v.p.c.

[1]A preliminary communication of a portion of this work has appeared. See ref. 27.

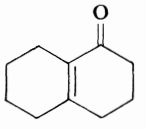
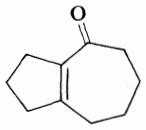
[3]We are grateful to Dr. Tanabe for a reference sample of **3** and spectral data as well as the details for the preparation of **3**.

retention times of the two materials. A sample of ketone **5** was prepared (12) and compared to the product from **3** and an authentic sample of **4**.



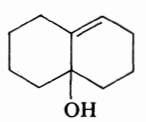
4



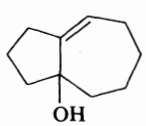
5

The ketones **4** and **5** could be clearly separated by v.p.c. and they had several differences in their i.r. spectra. When we carefully scrutinized the crude reaction mixture from the acid treatment of **3**, we could not find any trace of **5**. Several proton acids were found to be efficient catalysts in the isomerization of **3** to **4**. Lewis acids in aprotic solvents were also effective, for example, treatment of **3** with $BF_3 \cdot Et_2O$ in methylene chloride gave **4** in *ca.* 60% yield. We also studied the effect of solvent polarity on this isomerization. Although the isomerization was slower in nonpolar solvents, the yields of product **4** isolated were good (60–95%). One of the better procedures involves treating **3** with HCl in aqueous methanol to yield 95% **4**. In all of the above experiments we examined the crude reaction product for ketone **5** and in no case could any trace of **5** be detected in the reaction mixture. Furthermore, it was easy to show that ketone **5** is stable under these reaction conditions. All attempts to ketalize **3** gave only **4** and further reaction products of **4**.

The Birch reduction of open-chain γ-ethinyl ketones has been found to give only five-membered ring products (13). Hence we were interested in the course of this reduction of cyclodecyn-6-one **3**, since it is a cyclic γ-ethinyl ketone. On treatment with lithium in ammonia–tetrahydrofuran (13) **3** gave a mixture of the allylic alcohols **6** and **7** in the ratio of *ca.* 25:1 (*vide infra*) in excellent yield. These alcohols

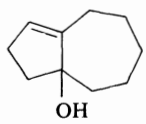


6

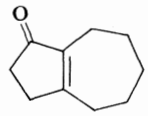


7

were rather prone to decompose and hence they were difficult to separate and fully characterize. For this reason these alcohols were oxidized in ethyl ether with aqueous chromic acid (14) to yield a mixture of **4** and **5** which could be readily separated and identified. This oxidative transformation and the spectral data of the alcohol **6** fully confirmed the structure of the major reduction product from **3**. A slight ambiguity existed in the case of the minor reduction product since structure **8** could be consistent with the spectral properties of this product.



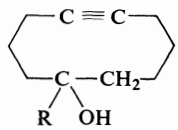
8



9

However, we rejected structure **8** by the fact that formation of **8** from **3** was unlikely on mechanistic grounds (13 and *vide infra*) and that the oxidative rearrangement of **8** to **5** was also unlikely. Alcohol **8** would be expected to give ketone **9** on oxidation. As the ketones **4** and **5** were separable by v.p.c. we used the ratio of **4**:**5** to estimate the ratio of alcohols in the reduction product from **3** since the alcohols themselves were not separable by the usual chromatographic techniques. Again the transannular cyclization of a cyclodecyne had occurred predominantly through a six-membered ring transition state; although in this case we did obtain a detectable amount of product arising from a five- (or seven-) membered transition state. This was consistent with the other transannular reactions of **3** but markedly different from the analogous reduction of open-chain compounds (13).

Reduction of cyclodecyn-6-one (**3**) with lithium aluminum hydride or sodium borohydride gave cyclodecyn-6-ol (**10**) in high yield.



10 R = H
11 R = Me

Treatment of **3** with methyllithium or methylmagnesium bromide gave the alcohol **11**. No transannular products could be detected either spectroscopically or chromatographically. Therefore the carbonyl group in **3** is more nucleophilic in hydride reduction than the acetylenic

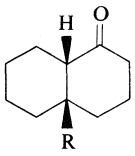
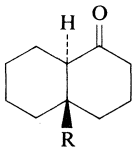
group. In fact we have not found a nucleophilic H, C, N, or O which will add to the triple bond in **3** before it attacks the carbonyl group. On treatment with excess dimethyllithium cuprate ketone **3** was recovered unchanged.

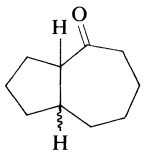
Treatment of cyclodecyn-6-ol (**10**) with refluxing methanolic HCl gave a good yield of *cis*- and *trans*-decalone-1 (**12** and **13**). We could not detect any of the isomeric bicyclo[5.3.0]decanone-2 (**14**) by v.p.c. The results differ slightly from the



12 R = H
18 R = Me



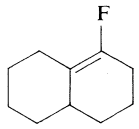
13 R = H
19 R = Me



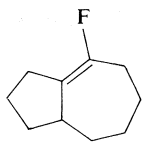
14

solvolysis and acetolysis of the tosylate from **10** which gave **12** and **13** as well as small amounts of *cis* and *trans*-**14** or either enol acetates (10). Since variation in solvent polarity did not effect the formation of **14** in the solvolysis experiments we cannot ascribe the difference between the solvolysis experiment (10) and the acid treatment of **10** to solvent effects.

When alcohol **10** was treated with $BF_3 \cdot Et_2O$ in methylene chloride a single very volatile product was obtained in good yield. The material was homogenous by t.l.c. and v.p.c., and no other product could be detected chromatographically or spectroscopically. Initially the spectroscopic data was confusing because of the presence of a band at 1705 cm^{-1} in the i.r. spectrum of the product. The molecular formula of this compound was established as $C_{10}H_{15}F$ by high resolution mass spectroscopy. The ^1H n.m.r. spectrum has a broad absorption between δ 1–3 and no other signals. The ^{19}F n.m.r. of the product has a relatively sharp singlet at 111 p.p.m. upfield from CCl_3F. These n.m.r. data are consistent with an olefinic fluorine (15) and the i.r. band at 1705 cm^{-1} is assigned to the double bond stretch of the fluoro olefin (15*b*, 16). The spectral data favor structure **15** for the fluoro olefin but they do not totally eliminate structure **16**. The ^{19}F n.m.r. data for a series of 1-fluorocycloalkenes are given in Table 1 (15*b*). Comparing the ^{19}F chemical shift and the J_{CH_2-CF} in the fluoro olefin from **10** with the data for the simple systems leads to the conclusion that these



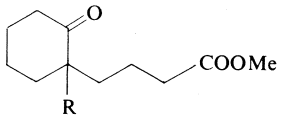
15



16

n.m.r. parameters favor the structure with the double bond in the smaller ring (15) for the fluoro olefin. This is further evidence of the homogeneity of the fluoro olefin, since **15** and **16** would be expected to show markedly shifted ^{19}F resonances.

To prove which structure was correct, **15** or **16**, we degraded the fluoro olefin in the following manner. The olefin was ozonized and the ozonide was worked-up oxidatively to give a keto acid with i.r. bands at 1705 and 1725 cm^{-1}. This is not consistent with a substituted cyclopentanone. In addition the acid was esterified to yield an ester with i.r. bands at 1705 and 1735 cm^{-1}. This ester was compared with an authentic sample of methyl 2-oxocyclohexylbutyrate **17** (17) which was prepared by the alkylation of the enamine from cyclohexanone



17 R = H
24 R = Me

with methyl γ-iodobutyrate. The two compounds were identical by spectroscopic data, v.p.c. retention times, and m.p. and mixed m.p. of their 2,4-DNP derivatives. Thus the fluoro olefin must have structure **15**. The chromatographic properties of **17** from the degradation of **15** again indicated that the fluoro olefin was a single compound.

The tertiary alcohol **11** was also treated with refluxing methanolic HCl and a mixture of ketones was isolated in reasonable yield. This

TABLE 1. The ^{19}F n.m.r. data for 1-fluorocycloalkenes (15*b*)

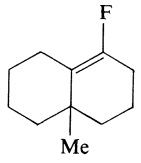
20 *cis*
21 *trans*

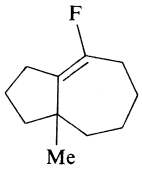
mixture consisted of **18**, **19**, **20**, and **21**. All four compounds could not be separated by v.p.c.; but by using a combination of v.p.c. and n.m.r. we were able to measure the relative amount of each isomer in the mixture. This transannular cyclization again was quite clean and free from side reactions. The ratios of **18**:**19** and **20**:**21** may be equilibrium values since they did not appear to change on prolonged acid treatment. We have not, as yet, investigated the reaction mixture at short reaction times to determine if the cyclization leads to a preference of either *cis* or *trans* isomer.

An authentic sample of the *cis* and *trans* isomers, **18** and **19**, was prepared by the conjugate addition of lithium dimethylcopper to the octalone **4** (18).[4] The conjugate addition yielded a predominance of the *cis* isomer **18**. These isomers could be equilibrated by acid or base and the *cis–trans* mixture was separable by v.p.c. The *cis* isomer **18** has an n.m.r. singlet at δ 1.02 and the *trans* isomer **19** has an n.m.r. singlet at δ 0.77 due to the angular methyl group. These assignments are in accord with n.m.r. signals for the C-19 methyl group in 5β-androstanone-4 (δ 1.12) and 5α-androstanone-4 (δ 0.74) (19). A sample of the *cis* and *trans* isomers, **20** and **21**, was prepared by the conjugate addition of lithium dimethylcopper to $\Delta^{1,7}$-bicyclo[5.3.0]-decanone-2 (**5**). These two isomers could also be separated by v.p.c. The *cis* isomer **20** has an n.m.r. singlet at δ 1.18 and the *trans* isomer **21** has an n.m.r. singlet at δ 0.72 due to the angular methyl group. All four isomers **18**–**21** could not be separated by v.p.c., however, by using a combination of v.p.c. and the intensity of the n.m.r. signals assigned to the angular methyl group in **18**–**21** we have found that the ratio of **18**:**19**:**20**:**21** from the acid-catalyzed cyclization of **11** was 1.0:1.4:0.1:0.25. This is the only example of transannular reactions of cyclodecynes in which we have found a significant amount of product resulting from cyclization through a five-membered ring transition state.

When alcohol **11** was treated with $BF_3 \cdot Et_2O$ in methylene chloride we again isolated a fluoro olefin in high yield. The product was homogeneous by a variety of chromatographic and spectroscopic techniques. The ^1H n.m.r. of this product has no vinyl protons but it does have a singlet at δ 1.05 due to the angular methyl group. The ^{19}F n.m.r. shows a relatively sharp singlet 110 p.p.m. upfield from CCl_3F. There is an i.r. absorption at 1700 cm^{-1} which is assigned to a monofluoro tetrasubstituted double bond stretching (*vide supra*). Again in this case there are two possible structures for the fluoro olefin, either **22** or **23**. The spectral data and our

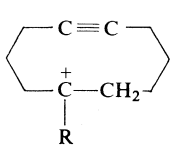


22

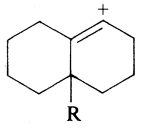


23

previous results led us to favor structure **22**. That is in fact the correct structure as proven by an oxidative sequence similar to that for compound **15**. Thus ozonolysis of the fluoro olefin from **11** and oxidative work-up gave a keto acid with a broad i.r. band at 1705 cm^{-1}. Esterification yielded methyl 1-methyl-2-oxocyclohexylbutyrate **24** which has i.r. bands at 1700 and 1730 cm^{-1}. No trace of the isomeric cyclopentanone which would arise from **23** could be found from the i.r. spectra of the keto acid and ester or from the v.p.c. of the ester.



25



26

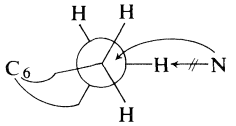
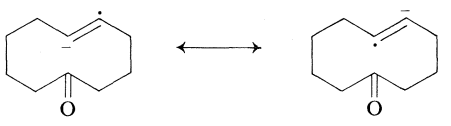
If these cyclizations were to proceed via a free carbonium ion, **25**, then we would expect a preference for formation of **27** since the intermediary linear vinyl cation (9) should be more readily accommodated in a seven-membered ring (**27**) than a six-membered ring (**26**). It could be argued that **27** may be formed initially, and subsequently it rearranges entirely to **26**. However, recent evidence indicates that in fact **26** (R = H) rearranges to **27** (R = H) (20). Those reactions most likely to yield carbonium ions, for example, the solvolysis of the tosylate from **10** and acid treatment of **11** did lead to products which can be considered to arise from **27**. An examination of a molecular model of **3** or **10** suggests that C-1 and -2 are very nearly equidistant from C-6 and hence we might expect mixture of bicyclo[4.4.0]decanes and bicyclo-[5.3.0]decanes. However, we have found that there is a very strong preference for transannular cyclizations which proceed via a six-membered ring transition state. We feel that these cyclizations are essentially concerted, that is, the acetylene is simultaneously attacked by the electrophilic C-6 and an external nucleophile. Assuming that carbon atoms 1 and 2 approach sp^2 hybridization in the transition state for cyclization, then it appears, from models, that the transition state leading to the bicyclo[4.4.0]-decane skeleton has less steric interference and less torsional strain (21) than the transition state leading to the bicyclo[5.3.0]decane skeleton. Structure **28** is a Newman projection along



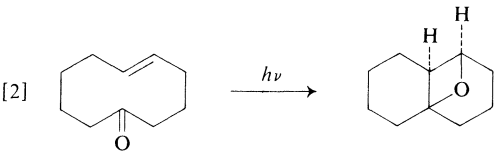
28

C-10, -1, -2, and -3. For *trans* coplanar addition of C-6 and a nucleophile to the triple bond it can be seen that one of the hydrogens on C-10 will sterically hinder the addition of the nucleophile to C-1; however, the nucleophile can add to C-2 with the two hydrogens on C-3 staggering it. This would explain the almost exclusive formation of products with a bicyclo[4.4.0]decane skeleton. Of course this does not explain the preponderance of **6** in the Birch reduction of **3**. Stork *et al.* (13*a*) have suggested that the Birch reduction of γ-ethinyl ketones involves a non-



29

linear vinyl radical anion as an intermediate. Assuming that the analogous reduction of **3** involves a similar intermediate **29** then inspection of models of **29** shows a clear preference for formation of the six-membered ring product **6**. A related radical cyclization may be involved in the photochemical closure shown in eq. 2 (22).



Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 700 and were calibrated using the 1601 cm^{-1} band of polystyrene. The ^1H n.m.r. spectra were recorded on either a Varian T-60 or Varian HA-100 and the ^{19}F n.m.r. spectra were recorded on a Varian T-60 equipped with a T-6-18 wide sweep module using CCl_3F as an internal standard. The mass spectra were obtained using an AEI MS-9 operating at 70 eV. Microanalyses were performed by Mr. Peter Borda, University of British Columbia. The v.p.c. analyses were performed with a Varian Aerograph 90-P-3 using column A, 5 ft × ¼ in. column of 3% SE 30 on Chromosorb W, and column B, 5 ft × ¼ in. column of 10% FFAP on Chromosorb W, or with a Perkin–Elmer Model 900 using column C, 5 ft × ⅛ in. column of 10% FFAP on Chromosorb W.

$\Delta^{1,7}$-Bicyclo[5.3.0]decenone-2 (5)

Compound **5** was prepared from $\Delta^{9,10}$-octalin by the method of Anderson and Nelson (12) to yield a product b.p. 114°/10 mm (lit. b.p. 126–128°/15 mm (12)).

Cyclodecyn-6-one (3)

A solution of 1.0 g (0.07 mol) of enone **5** in 20 ml of methanol was cooled in a water bath at 10° and treated with 10 ml of 30% hydrogen peroxide with stirring. A solution of 2 ml of 6 *N* sodium hydroxide in 5 ml of methanol was added dropwise over a period of ½ h and the resulting solution was stirred for an additional 15 h. The methanolic solution was diluted with 50 ml of water and extracted three times with methylene chloride. The extracts were combined, washed with brine solution until neutral, dried over anhydrous sodium sulfate, filtered, and the solvents were removed under reduced pressure. The residue was distilled at bath temperature 100°/0.6 mm to yield 0.82 g (74%) of 1,7-oxido-bicyclo[5.3.0]decanone-2.

A 1.61 g (0.097 mol) sample of the above epoxide was treated with tosylhydrazone under the conditions of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Schreiber *et al.* (11*b*) to yield cyclodecyn-6-one (**3**) which was distilled at a bath temperature of 55°/0.02 mm.

Acid Isomerization of Cyclodecyn-6-one (3)

(i) Methanolic Hydrochloric Acid

A 79 mg (0.53 mmol) sample of cyclodecyn-6-one (**3**) was dissolved in 1.5 ml of methanol containing one drop of concentrated hydrochloric acid and the solution was allowed to stand at room temperature for 12 h. Methanol was removed under reduced pressure, then the residue was dissolved in ether and washed with sodium bicarbonate solution. The organic extracts were dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residue was distilled at bath temperature of 70–80°/0.2 mm to yield 75 mg (95%) of octalone **4** which was compared by i.r. and v.p.c., column B, to an authentic sample of **4** prepared by the method of House and Thompson (23).

Compounds **4** and **5** were separated by v.p.c., column B, and no trace of **5** could be detected in crude reaction product above or in the sample of distilled **4**.

(ii) Boron Trifluoride Etherate in Methylene Chloride

A solution of 225 mg (1.5 mmol) of **3** in 10 ml of methylene chloride was treated with *ca.* 0.5 ml of boron trifluoride etherate. The solution was stirred and it turned dark green. After 10 min, the reaction mixture was washed with saturated aqueous sodium bicarbonate until the organic layer was colorless. The organic extracts were dried over anhydrous sodium sulfate, filtered, and the solvent removed under reduced pressure. The v.p.c. analysis, column B, showed only **4** to be present in the crude residue. This residue was distilled at bath temperature of 70–80°/0.2 mm to yield 133 mg (59%) of pure **4**.

(iii) Additional Conditions for Isomerization

The following conditions were also found to be effective in the isomerization of **3** to **4**: hydrochloric, hydrobromic, or perchloric acid in methanol, dioxane, or hexane at room temperature; refluxing acetic acid and zinc; *p*-toluenesulfonic acid in refluxing benzene; and mercuric chloride in refluxing methanol.

Attempted Ketalization of 3

A solution of 80 mg of **3**, 0.5 ml of ethylene glycol and a few crystals of *p*-toluenesulfonic acid in 50 ml of benzene was refluxed for 16 h. The benzene solution was washed with aqueous brine, dried over anhydrous sodium sulfate, filtered, and the solvent was removed under reduced pressure. A v.p.c., column B, and t.l.c. analysis indicated that the major component of the mixture was **4** and a small amount of unreacted **3**.

Birch Reduction of Cyclodecyn-6-one (3)

A solution of 165 mg (1.1 mmol) of **3** in 1 ml of dry tetrahydrofuran was added to 100 ml of liquid ammonia. The solution was stirred and very small pieces of lithium wire were added until a blue color persisted. Ammonium chloride was quickly added to render the solution colorless and the ammonia was allowed to evaporate. Water was added to the residue and the mixture was extracted with ethyl ether. The extracts were combined, washed with aqueous sodium chloride solution until neutral, dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure to yield 168 mg of crude product. This semisolid showed no carbonyl absorption in the i.r. and it was sublimed at 25°/0.005 mm to give quantitative yield of product m.p. 61–69°; ν_{max} (CH_2Cl_2) 3580, 1605 cm^{-1}; δ (CCl_4) 5.4 (m, 1H), 1.2–2.6 (m, 15H); *m/e* calcd. for $C_{10}H_{16}O$: 152.1201; found: 152.1198; 152 (15%), 134 (58%), 119 (40%), 105 (52%), 91 (100%).

Oxidation of Alcohols from Birch Reduction of 3

The solution of the above alcohols from **3** (10 mg) in ethyl ether was added to an ice cold solution of 100 mg of chromium trioxide in 5 ml of water and 0.5 ml of concentrated sulfuric acid. The mixture was stirred for 2.5 h at 0° and then the ether layer was washed with water until neutral. The ether solution was dried over anhydrous sodium sulfate, filtered, and the solvent removed under reduced pressure to give an oily residue, ν_{max} ($CHCl_3$) 1650, 1630 cm^{-1}. This was analyzed by v.p.c., column C, and was found to contain **4** and **5** in the ratio of 25:1.

Cyclodecyn-6-ol (10)

Following the procedure of Hanack and Heumann (10) 15.2 mg (1.01 mmol) of **3** was reduced with lithium aluminum hydride (15 mg) in 10 ml of refluxing ethyl ether for 1½ h. The reaction mixture was cooled, treated with 5 ml of a saturated aqueous solution of potassium sodium tartrate, and the resulting mixture was stirred for 5 min. The aqueous layer was extracted with 2 × 20 ml of ethyl ether. The extracts were combined, dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residue was distilled at bath temperature of 85–90°/0.5 mm to yield 145 mg (94%) of **10**, ν_{max} (CH_2Cl_2) 3360 cm^{-1}; δ (CCl_4) 1.2–1.9 (m, 10H), 1.94 (b.s, 1H, exchangeable in D_2O), 2–2.4 (m, 4H), 4.2 (m, 1H).

6-Methylcyclodecyn-6-ol (11)

A solution of 1.7 g (0.011 mol) of **3** in dry tetrahydrofuran was treated dropwise with 7 ml of 2.3 *M* solution of methyllithium under nitrogen. After addition of methyllithium the solution was stirred for an additional 3½ h at room temperature. Excess methyllithium was decomposed with water. The aqueous layer was saturated with sodium chloride and extracted with ethyl ether. The extracts were combined, dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure to yield an oily residue. This was purified by silica gel column chromatography using benzene – ethyl acetate (95:5 to 50:50) as eluant to give 500 mg (27%) of **11**. Due to its lability **11** could not be purified for combustion analysis; ν_{max} (film) 3390 cm^{-1}; δ ($CDCl_3$) 1.04 (s, 3H), 1.27 (s, 1H, exchangeable with D_2O), 1.2–1.8 (m, 10H), 1.9–2.4 (m, 4H); *m/e* 166 (8%), 151 (30%), 148 (26%), 133 (50%), 105 (52%), 91 (100%).

Acid Treatment of 10

A solution of 56 mg (3.71 mmol) of cyclodecyn-6-ol (**10**) and 2 drops of concentrated hydrochloric acid in 2 ml of methanol was refluxed for 3.5 h. The reaction mixture was poured into 30 ml of water and extracted with 30 ml of benzene – ethyl ether (1:1). The extracts were washed with 20 ml of saturated sodium bicarbonate solution and 20 ml of saturated sodium chloride, then dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residual oil was purified by preparative t.l.c. (silica gel – benzene – ethyl acetate, 9:1) to yield 8 mg of **10** and 42 mg (87%

based on unrecovered starting material) of decalones **12** and **13**. These were shown to be identical to authentic **12** and **13** by v.p.c., column C.

*cis- and trans-Decalone-1 (**12** and **13**)*

A mixture of **12** and **13** (24) was prepared by Birch reduction (Li, NH_3, NH_4Cl) of $\Delta^{9,10}$-octalone-1 (**4**) followed by Jones oxidation (25) of the 1-decol to **12** and **13**. The mixture so obtained was equilibrated as follows. A solution of 15 mg of **12** and **13** from above in 2 ml of methanol and 2 drops of 1 *N* sodium hydroxide was heated on a steam bath for 5 min and then diluted with 20 ml of water. The organic material was extracted with 20 ml of ethyl ether and the extracts were washed with saturated aqueous sodium chloride solution until the washings were neutral to litmus. These ketones were cleanly separable by v.p.c. on column B or C.

*cis- and trans-Bicyclo[5.3.0]decanone-2 (**14**)*

Birch reduction followed by Jones oxidation (25) of $\Delta^{1,7}$-bicyclo[5.3.0]decenone-2 (**5**) gave a mixture of isomers **14** which are equilibrated as above for **12** and **13**. Again the isomers **14** were separable by v.p.c. on column B or C.

*Treatment of **10** with Boron Trifluoride Etherate*

A solution of 190 mg (1.26 mmol) of cyclodecyn-6-ol (**10**) in 20 ml of dry methylene chloride was treated with 0.5 ml of boron trifluoride etherate and stirred at room temperature for 15 min. The brown reaction mixture was washed with saturated aqueous sodium bicarbonate until the organic layer became colorless. The methylene chloride solution then was dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The very volatile residue was purified by preparative t.l.c. (silica gel – benzene) to yield 163 mg (85%) of fluoroalkene **15** which was homogeneous by v.p.c., columns B and C; ν_{max} (film) 1705 cm^{-1}; ^1H n.m.r. δ ($CDCl_3$) 1–3 (m); ^{19}F n.m.r. δ_{CCl_3F} (CCl_4) 111; *m/e* calcd. for $C_{10}H_{15}F$: 154.1158; found: 154.1102; 154 (10%), 135 (100%).

*Ozonolysis of **15***

A solution of 100 mg of **15** dissolved in 2 ml of methanol was cooled in a Dry Ice – acetone bath and ozone was passed through the solution until a light blue color appeared. The excess ozone was removed under reduced pressure. The ozonide solution was treated with 0.5 ml of 30% hydrogen peroxide and refluxed on a steam bath for 15 min. The reaction mixture was poured into 25 ml of water and extracted with 3 × 20 ml of ethyl ether. The extracts were combined, dried over anhydrous sodium sulfate, and the solvents removed under reduced pressure to yield crude 2-oxocyclohexylbutyric acid; ν_{max} ($CHCl_3$) 1705, 1725 cm^{-1}.

The crude acid was esterified with diazomethane and the resulting keto ester **17** was purified by t.l.c. (silica gel – chloroform) to give pure **17**; ν_{max} ($CHCl_3$) 1705, 1735 cm^{-1}. This was converted to its 2,4-DNP derivative m.p. 109–111°, mixed m.p. with 2,4-DNP of authentic **17** 108–111° (lit. m.p. 112° (17)).

*Methyl 2-Oxocyclohexylbutyrate (**17**)*

A 10.6 g (70 mmol) sample of the pyrrolidine enamine of cyclohexanone (26) was dissolved in 100 ml of dry ethanol and treated with 7.6 g (33.6 mmol) of methyl γ-iodobutyrate. This mixture was refluxed under nitrogen for 20 h. Then the solvent was removed under reduced pressure. The residue was stirred (5 min) with 20 ml of water and extracted with 50 ml of ethyl ether. The ethereal solution was washed with 3 × 10 ml of saturated sodium chloride solution (neutral to litmus), dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residue was distilled to yield 4 gm (60%) of **17** b.p. 60°/0.2 mm; ν_{max} ($CHCl_3$) 1710, 1730 cm^{-1}. A small portion was converted to its 2,4-DNP derivative, m.p. 110–113° (lit. m.p. 112° (17)).

*Acid Treatment of **11***

6-Methylcyclodecyn-6-ol (**11**) (20 mg) was dissolved in 2 ml of methanol containing one drop of concentrated hydrochloric acid and refluxed for 3.5 h. The mixture was diluted with 20 ml of water and extracted with 3 × 10 ml of ethyl ether. The extracts were combined, washed with 20 ml of saturated sodium bicarbonate solution, and 20 ml of saturated sodium chloride solution, dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residue was distilled, bath temperature of 85°/0.2 mm, to yield 13 mg (65%) of a mixture of ketones **18**, **19**, **20**, and **21** (v.p.c., columns B and C); ν_{max} ($CHCl_3$) 1705 cm^{-1}, no —OH stretch; δ (CCl_4) 0.72 (s), 0.77 (s), 1.03 (s), 1.20 (s).

*cis- and trans-7-Methylbicyclo[5.3.0]decanone-2 (**20** and **21**)*

Dimethyllithium cuprate was prepared from 571 mg (3.0 mmol) of dry cuprous iodide and *ca.* 4 ml of 2.3 *M* methyllithium in 100 ml of ethyl ether at 0°. A solution of 450 mg (3.0 mmol) of $\Delta^{1,7}$-bicyclo[5.3.0]decanone-2 (**5**) in 2 ml of dry ether was added dropwise under nitrogen to the cooled solution of dimethyllithium cuprate. After the addition was complete, the solution was stirred at 0° for an additional 2 h. The copper complex was decomposed with a saturated ammonium chloride solution and this mixture was stirred at room temperature for 1 h. The ether layer was separated, washed with saturated aqueous sodium chloride solution, dried over anhydrous sodium sulfate, filtered, and the solvents removed under reduced pressure. The residue was purified by preparative t.l.c. (silica gel – benzene) to yield 350 mg (70%) of **20** and **21**. This mixture of isomers was separated by v.p.c., column B; to give *cis*-7-methylbicyclo[5.3.0]decanone-2 (**20**) which distilled at bath temperature of 80°/0.2 mm; ν_{max} ($CHCl_3$) 1695 cm^{-1}; δ (CCl_4) 1.18 (s, 3H).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 79.48; H, 10.83.

trans-7-Methylbicyclo[5.3.0]decanone-2 (**21**) was also obtained pure by v.p.c. This compound distilled at bath temperature of 82°/0.2 mm; ν_{max} ($CHCl_3$) 1695 cm^{-1}; δ (CCl_4) 0.72 (s, 3H).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 79.43; H, 10.80.

*Treatment of **11** with Boron Trifluoride Etherate*

A solution of 222 mg (1.34 mmol) of 6-methylcyclodecyn-6-ol (**11**) and 0.5 ml of boron trifluoride etherate in 20 ml of dry methylene chloride was stirred at room temperature for 15 min. The resulting brown solution was washed with saturated aqueous sodium bicarbonate until the organic layer became colorless. Then the organic layer was dried over anhydrous sodium sulfate, filtered

and the solvents removed under reduced pressure. The volatile residue was purified by preparative t.l.c. (silica gel – benzene) to yield 191 mg (86%) of fluoroalkene **22**; ν_{max} (film) 1700 cm^{-1}; ^1H n.m.r. δ (CCl_4) 1.05 (s, 3H), 1.2–2 (m, 12H), 2.05 (d, $J \simeq 6$ Hz, 1H), 2.7 (d, $J \simeq 12$ Hz, 1H); ^{19}F n.m.r. δ_{CCl_3F} (CCl_4) 110; *m/e* calcd. for $C_{11}H_{17}F$: 168.1314; found: 168.1314; 168 (35%), 153 (100%), 149 (40%).

Ozonolysis of ***22***

A solution of 100 mg of **22** was ozonized under the same conditions as **15** above to yield crude 1-methyl-2-oxocyclohexylbutyric acid ν_{max} ($CHCl_3$) 1705 cm^{-1} (br).

The crude acid was esterified with diazomethane and purified by t.l.c. (silica gel – chloroform) to yield pure **24**; ν_{max} ($CHCl_3$) 1700, 1730 cm^{-1}; δ ($CDCl_3$) 1.0 (s, 3H), 1.1–1.9 (m, 10H), 2.3 (m, 4H), 3.6 (s, 3H); *m/e* 212 (5%), 181 (5%), 152 (5%), 112 (90%), 55 (100%).

A small portion of **24** was converted to its 2,4-DNP derivative, m.p. 99–100°.

Anal. Calcd. for $C_{18}H_{24}N_4O_6$: C, 55.10; H, 6.16; N, 14.28. Found: C, 54.93; H, 6.11; N, 14.56.

Proton Magnetic Resonance Spectra of Some Amphetamines and Related Compounds and Observations on Rotamer Populations

K. Bailey, A. W. By, K. C. Graham, and D. Verner
Research Laboratories, Food and Drug Directorate, Ottawa, Canada

Received March 12, 1971

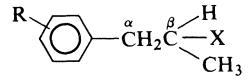
Data from the p.m.r. spectra of β-amino-, β-aminohydrochloride-, β-hydroxy-, and β-nitro-α-phenylpropanes having methyl or methoxy substituents on the phenyl ring (37 compounds in all) are presented. The α and β protons of the side-chain give a pattern usually analyzable as ABX. The data are discussed in terms of correlations of coupling constants and chemical shifts with electronegativity of the substituent groups, steric and electronic effects, and apparent changes in rotamer populations. Hydrogen-bonding between the amino group of amphetamines and a methoxyl function at the ortho position in the phenyl ring is indicated for the salts but not the free bases.

On présente les données relatives aux spectres r.m.p. de β-amine, chlorhydrate de β-amino, β-hydroxy, et β-nitro α-phénylpropanes, ayant des substituants méthyles ou méthoxy sur le noyau phényle (37 composés en tout). Les protons α et β sur la chaîne latérale donnent un spectre analysable habituellement selon un ABX. Les données sont discutées en fonction des relations des constantes de couplage et des déplacements chimiques avec l'électronégativité des groupes substituants, les effets stériques et électroniques et les modifications apparentes dans les populations des rotamères. La liaison hydrogène entre le groupe amine des amphétamines et le groupe méthoxy en position ortho sur le noyau phényle est établie dans les sels mais non dans les bases libres.

Canadian Journal of Chemistry, **49**, 3143 (1971)

The analysis of the p.m.r. spectra of organic molecules is an established technique in conformational analysis (1). 1,2-Disubstituted ethanes have received considerable attention (2) and the conformations of acetylcholine (3) and its seleno (4) and thio (4, 5) isologues and very recently its α- and β-methyl derivatives (6) have been investigated by these methods.

Some predictions have been made about the conformation of amphetamines (7). A model accounting for the psychotomimetic activity of methoxyamphetamines and phenethylamines was proposed (8) in which the conformational behavior of these compounds was suggested to be modified by intramolecular hydrogen bonding. Such models have been strongly criticized (7, 9). We were therefore interested in the possibility of analyzing the p.m.r. spectra of amphetamines having methoxy or methyl groups on the phenyl ring, and their salts (since amphetamines are virtually completely ionized at physiological p*H*), for rotamer populations. The methylene (benzylic, α) and methine (β) protons of the side-chain give rise to a spectral pattern ($\alpha_1\alpha_2\beta$) approximating the ABX type for fast rotation with unequal populations (1). To the end of investigating factors affecting the stability of the various rotameric forms, we also prepared and examined corresponding compounds **I** in which the amino function is replaced by hydroxyl and by nitro groups. Preliminary work on dimethoxyamphetamines has been presented (10).



I

Discussion

We will assume at first that compounds $ArCH_2CH(CH_3)X$ exist in a dynamic equilibrium between the three classically staggered rotamers A, B, and C shown in Fig. 1 having mole fractions *a*, *b*, and *c* respectively.[1] The correspondence of protons α_1 and α_2 *as depicted* with the upfield (α′) or downfield (α) observed benzylic signals is discussed later in terms of the compound type. Vicinal coupling between protons is indicated in the figure, superscripts A, B, or C denoting the rotamer and subscripts *t* or *g* the coupling type (*trans* or *gauche*).

If $J\alpha_1\beta$ and $J\alpha_2\beta$ are the two observed (mean) vicinal couplings, then

[1]An approximate analysis of such a three-spin system for determining conformational equilibria has been presented by Snyder (11).

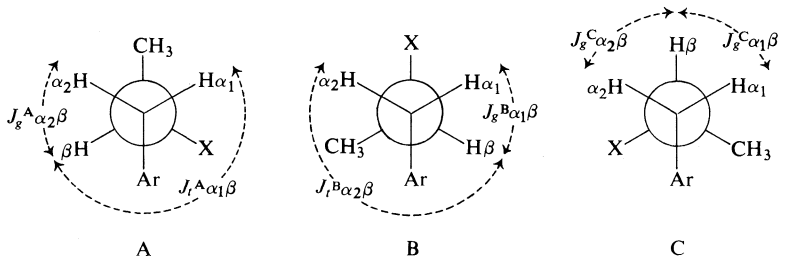


FIG. 1. Staggered rotamers of $ArCH_2CH(CH_3)X$; coupling constants indicated.

[1] $$J\alpha_1\beta = aJ_t^{A}\alpha_1\beta + bJ_g^{B}\alpha_1\beta + cJ_g^{C}\alpha_1\beta$$

[2] $$J\alpha_2\beta = aJ_g^{A}\alpha_2\beta + bJ_t^{B}\alpha_2\beta + cJ_g^{C}\alpha_2\beta$$

To simplify the present analysis for any one compound or series (X constant) the following approximations are made:

$$(i)\ J_t^{A}\alpha_1\beta = J_t^{B}\alpha_2\beta = J_t$$

$$(ii)\ J_g^{C}\alpha_1\beta \simeq J_g^{A}\alpha_2\beta = J_g$$

$$(iii)\ J_g^{C}\alpha_2\beta \simeq J_g^{B}\alpha_1\beta = J_{g'}$$

Equations 1 and 2 then reduce to the approximate form

[3] $$J\alpha_1\beta = aJ_t + bJ_{g'} + cJ_g$$

[4] $$J\alpha_2\beta = aJ_g + bJ_t + cJ_{g'}$$

also

[5] $$1 = a + b + c$$

The chief factors affecting these couplings in our series for constant dihedral angles depend on the electronegativities of the α and β substituents indicating that when X is more electronegative than CH_3, $J_{g'} > J_g$ (2, 12, 13). If the signals from the diastereotopic protons observed as α and α′ can be unambiguously assigned to the protons depicted as α_1 and α_2 in Fig. 1, and values of J_t, J_g, and $J_{g'}$, are available, then a, b, and c are easily obtained. If $J_g = J_{g'}$, simple algebra gives

$$a = \frac{J\alpha_1\beta - J_g}{J_t - J_g}$$

$$b = \frac{J\alpha_2\beta - J_g}{J_t - J_g}$$

and $$c = \frac{J_t + J_g - (J\alpha_1\beta + J\alpha_2\beta)}{J_t - J_g}$$

which are useful for preliminary estimates of rotamer stability.

The selection of suitable values for J_t, J_g, and $J_{g'}$ is hampered by the paucity of information on model compounds.

Other workers (14) have used $J_t = 12.0$ Hz as a starting point. This figure with the J_g and $J_{g'}$ values chosen below gives reasonable, greater than zero results for a, b, and c using our observed coupling constants. We therefore adopted $J_t = 12.0$ Hz as a suitable round number for the amphetamines. Abraham and Gatti (2) have recently devized precise equations for estimating vicinal coupling constants in 1,2-disubstituted ethanes, and it is reasonable that *changes* of the same order would be followed by our compounds. Averaging their coefficients and using Huggins' electronegativities (15) suggests that J_t decreases by about 0.7 Hz when X is changed from NH_2 to OH. The unchanged J_{vic} in triethylamine and tetraethylammonium salts (16) and work on *cis*-3-methyl-2-phenylmorpholine (17) indicates that J_t will be scarcely changed on protonation of the amphetamine amino group. 4-Nitro groups exert a negative increment on the (negative) geminal coupling of benzylic protons compared with NH_2 (18) and comparing compounds **1–6** with **19–24** (Table 1) shows a similar trend, the NO_2 seeming therefore to be less electronegative than NH_2 (10). Accordingly, J_t may increase (more positive) slightly when NO_2 is substituted for NH_2 in **I**.

The most important difference affecting the relative magnitudes of J_g and $J_{g'}$ seems to be the changing disposition of the CH_3 and X groups. Extrapolation of the coefficients for 1,2-disubstituted propanes (2) suggests the maximum difference (when X = N) to be about 1 Hz, and in the absence of definitive data $J_{g'} = 3.0$, $J_g = 2.0$, or $J_{g'} = J_g = 2.0$ are chosen as reasonable values for our compounds (19).

Table 2 shows how a, b, and c change with choice of J_t, J_g, and $J_{g'}$, for typical observed couplings. The calculated ratio of the two minor contributors is most affected by this choice, but

*τ-Values, measured with a Varian A-60A spectrometer using solutions at 40°, 10–15% in $CDCl_3$ containing TMS as internal standard. Signals (two recordings) were reproducible ± 0.01 p.p.m. Signals from the α and β protons were recorded at 100 Hz sweep width. Data from **10–14** have been presented before (10). Appropriate aromatic proton signals and integration ratios were observed.

†These signals were multiplets. Those from **34–37** were obscure: these salts are only moderately soluble in $CDCl_3$. Compound **32** crystallizes as a monohydrate, and the H_2O obscures the signal

‡Doublets: *J ca.* 6.5 Hz.

§Spectrum poor, lines 4 and 5 of ABX system not resolved, could lead to errors in $J_{\alpha_1\beta}$ and $J_{\alpha_2\beta}$.

whatever the chosen constants, it is seen that the *direction* in which a and b change for various observed couplings is determined by the *observed* coupling constants. It is obviously unwise to make dogmatic statements from our results about the stability of the sterically disfavored rotamer C relative to that of the other minor rotamer, and small (*i.e.*, less than 10%) differences in apparent rotamer populations comparing *series* (X changing) should be viewed cautiously.

Results

Table 1 presents p.m.r. data for solutions of our compounds in deuterochloroform at 40 °C. The benzylic protons and the β proton give signals $\alpha_1\alpha_2\beta$ which were analyzed in the second order as ABX, assuming that $J\alpha_1\alpha_2$ is negative and $J\alpha_1\beta$ and $J\alpha_2\beta$ are positive. At first it is not possible to say which of α_1 and α_2 (Fig. 1) is at higher field, and Table 1 merely describes them as α and α′. Because the β-H is coupled to the α-CH_3, only the AB part was used to find $J\alpha_2\beta$ (1). In general these eight lines (numbered 1–8 from high to low field) were plainly visible, but for compounds **1–3** and **7–9** line 1 was obscured by the aromatic methyl signal and was calculated from $J\alpha_1\alpha_2$ revealed by lines 2–4, 5–7, and 6–8. Further, it happened that the broad NH_2 signal of compounds **1–3** came in the $\alpha_1\alpha_2$ region, although the AB lines projected from the envelope. Changing the concentration somewhat shifted the NH_2 signal and addition of D_2O caused its disappearance, but did not cause any detectable shift in any of the other lines, and the values recorded for **1–3** are for $CDCl_3$ solutions with D_2O added. We also noted that the presence of impurities, even to the extent of some 50–60% of crude reaction mixture in some cases, had no effect on the spectral analysis on comparison with purified material. These observations lend confidence in the spectra.

Table 1 shows that at 60 MHz, the coupling between α_1 and α_2 is about the same as their chemical shift difference. Indeed for compounds **17** and **36** (2,4,6-trimethoxy-substitution pattern) the signals are degenerate, resemble the A_2B case, and were not calculable as ABX. The methoxyphenyl propanols **26** and **28** also present an A_2B-like pattern at 60 MHz: lines 4 and 6 are superimposed, 3 and 5 partially overlap, and 1, 2, 7, and 8 are extremely weak.

Chemical Shifts

There is a trend for the band center of the α-protons ($\overline{\alpha_1\alpha_2}$) to shift slightly upfield in the monosubstituted series **1–3**, **4–6**, **19–21**, **22–24**, and **26–28** as the substituent shifts further from the benzylic carbon. The coupling constant data discussed below show that this is not due to consistent changes in the relative rotamer populations. The center $\overline{\alpha_1\alpha_2}$ of the other compounds remains approximately constant except that for

2,3-disubstituted compounds it appears at rather lower field. Steric hindrance to rotation of the phenyl ring and through-space effects from substituents seem unlikely explanations for this and we suggest that the effect results from the changing magnitude of inductive effects on the benzylic carbon (20). These influences should change $J\alpha_1\alpha_2$ very slightly (18) but no consistent pattern emerges from our results for these series.

The chemical shifts of the β-H and the β-CH_3 in the series **1–3**, **4–6**, **19–21**, and **26–28** are generally shifted to slightly higher fields as the substituent changes from the ortho to meta to the para position. Decreasing the population of rotamer C with this change (increasing the shielding of the β-H by the *gauche* aryl group) is unlikely on steric grounds and not supported by rotamer population changes derived from coupling constant data. For the nitro compounds **22–25** the effect on β-H is very marked and is discussed further below.

The downfield shifts observed in the β-CH_3, the β-H (and the $\overline{\alpha_1\alpha_2}$ signals), when the NH_2 group is protonated are considerably smaller than when the NH_2 is replaced by NO_2. Accordingly the J_t and J_g changes are probably greater on conversion of the NH_2 into NO_2 than on hydrochloride formation, which is in line with our earlier discussion and the calculations presented below.

Coupling Constants and Rotamer Populations

These are best discussed in terms of the compound type.

Amphetamines

Rotamer populations calculated from the appropriate expressions using $J_t = 12.0$, $J_{g'} = 3.0$ and $J_g = 2.0$ and using $J_t = 12.0$, $J_{g'} = J_g = 2.0$ (10) are in the Depository of Unpublished Data. The range of values found shows that there is almost no change in the conformational equilibria of the amphetamines as a result of changing the aromatic substitution pattern for methyl and methoxy substituents (*a* or $b \simeq 65$, *b* or $a \simeq 20$, $c \simeq 15\%$). This is readily seen in the coupling constants of Table 2. Reasons for supposing that α_1 will be at lower field than α_2 have been given (10) and if this is so, then rotamer B is predominant, in agreement with calculations (7). The amino group exerts greater steric demands than a nitro group (21). Our results for nitro compounds (below) show that A and B are roughly equally populated, hence an increase in *b* and a decrease in *a* on going from the nitro, series to the amino series appears reasonable. We conclude that for aryl-substituted amphetamines, the rotamer in which the amino and aryl functions are *trans* is the most stable and that at 40 °C it is present as some 55–70% of the equilibrium mixture in $CDCl_3$ solution.

The proposition (8) that hydrogen-bonding between the amino group and an oxygen atom at the ortho position to the side chain could seriously affect the conformational equilibria is not confirmed by our work on these free bases. An investigation of intra-molecular NH....O bonding in compound **4** by the i.r. sequential dilution technique showed only free NH absorption at 3635 and 3605 cm^{-1} at a concentration below 0.4% in carbon tetrachloride.[2]

Amphetamine Hydrochlorides

For the reasons given above, we consider that J_t, $J_{g'}$, and J_g, will be little changed from their values in the free bases. Table 3 presents results for methoxylated compounds in $CDCl_3$. There is obviously a significant difference between salts with an ortho oxygen and those without. The population of rotamer C is very low and considered to be zero in the following discussion of the four possibilities (average % given).

Case 1. Compounds with *o*-CH_3O have 65% A, others have 25% A.

Case 2. Compounds with *o*-CH_3O have 65% A, others have 75% A.

Case 3. Compounds with *o*-CH_3O have 35% A, others have 75% A.

Case 4. Compounds with *o*-CH_3O have 35% A, others have 25% A.

The shielding effects of a *gauche* or *trans* $NH_3^{(+)}Cl^{(-)}$ moiety have not been defined, although what follows confirms an earlier inference (22) that a *gauche* $NH_3^+....Cl^-$ has a shielding effect. Therefore the definition of which observed α signal corresponds with α_1 or α_2 and hence which of the calculated rotamer percentages applies to A and which to B is not at first possible. The following points are pertinent:

(i) Chemical Shifts of the Benzylic Protons

Assuming that the chemical shift changes between α_1 and α_2 of the salts are primarily due to effects from the β groups, then a linear rela-

[2]We thank Mr. J. C. Ethier for this result.

*a, b, and c expressed as mole fractions %, using $J_t = 12, J_{g'} = J_g = 2$ Hz. For conditions of measurement see Table 1.
†Possible errors in $J\alpha\beta$ and $J\alpha'\beta$ (footnote §, Table 1) may be responsible for this apparently anomalous result.

tionship is expected between the chemical shift of α_1 with a rotamer percentage in one form A or B (C ≃ O) and similarly for α_2. There are fair fits with linearity when appropriate graphs are plotted for any of cases 1–4, and no conclusion can be drawn.

Case 1. For *o*-methoxylated salts, the H with larger coupling is α_1 which is observed upfield. Proton α_2 is shielded by a *gauche* CH_3 in both A and B, but when A dominates, α_1 has the greater *gauche* NH_3^+ effect which is therefore shielding. When A drops from 65 to 25%, α_2 shifts upfield (6.85 to 7.21 τ) because there is more *gauche* NH_3^+ influence. However, a deshielding effect of about 0.33 p.p.m. on α_1 (7.11 to 6.78 τ) for only a 40% decrease in *gauche* CH_3 influence (see A) seems to be somewhat excessive; *cis* and *trans* 3-methyl-2-phenylmorpholine hydrochlorides exist some 98% in the forms having *anti* and *gauche* 2-H/3-CH_3 conformations respectively in $CDCl_3$ solution and the 2-H signals are at 4.56 and 5.19 respectively (17).

Case 2. Similarly, shielding by *gauche* NH_3^+ is indicated, and as A increases, α_2 would shift downfield (6.85 to 6.78 τ) because (see rotamer B) there is a 10% decrease in the *gauche* NH_3^+ interaction. An upfield shift of about 0.1 p.p.m. (7.11 to 7.21 τ) for α_1 seems excessive for a 10% increase in the *gauche* CH_3 shielding.

Case 3. The relative magnitudes of the *gauche* CH_3 and NH_3^+ shielding or deshielding are important here and in case 4. The downfield shift for α_2 from 7.11 to 6.78 τ with decrease in B indicates that the *gauche* NH_3^+ has a shielding effect. Proton α_1 shifts from 6.85 to 7.21 τ which seems large for a 40% increase in the *gauche* CH_3 interaction.

Case 4. As in case 3, α_1 is at lower field because there is less shielding by the *gauche* CH_3 or because of *gauche* NH_3^+ effects. The shifts of α_2 (7.11 to 7.21 τ with increase in B) demonstrate that the *gauche* NH_3^+ has a shielding effect. The downfield shift in α_1 of about 0.07 p.p.m. (6.85 to 6.78 τ) for a 10% decrease in *gauche* CH_3 interaction is in fair agreement with the morpholine salts cited above.

Our initial assumptions and the small changes observed in the mean position of the benzylic signal with different substitution pattern do not allow a decision, although case 4 seems the most supportable. An important conclusion is that the NH_3^+ moiety *shields gauche* protons.

(ii) Chemical Shifts of the β-CH_3

If *a* is larger in the meta OCH_3 series, the β-CH_3 would be less shielded by the aryl group. Inspection of Tables 1 and 4 shows differences of β-CH_3 no greater than in the case of the free bases, where there is little change in rotamer populations, strongly suggesting that there is no major change in rotamer populations in the salts, *i.e.*, the "cross over" cases 1 and 3 are improbable. Table 4 shows that the downfield shifts of the β-CH_3 signal on going from the free amphetamines to their salts ($\Delta\tau$ CH_3) are generally greater for compounds with an *o*-CH_3O than for those without, *i.e.*, the increase of A in the ortho series on salt formation appears to be greater than for the meta series. The correlation is not good, but the results are best compatible with case 4.

From points *i* and *ii*, case 4 appears the most likely. Rotamer B is dominant, as for the free bases, but H-bonding or electrostatic interaction of some kind allows extra A in the ortho methoxyl series. Intramolecular hydrogen bonding between

the protonated amino group and an ortho methoxyl is suggested by Snyder's model (7), and a similar interaction was inferred (22) for 1-(4-methoxyphenyl)-1-methoxy-2-aminopropane hydrochloride. An interaction with the aromatic bonds has been suggested as stabilizing the corresponding conformation for β-phenylethanols (21). Even if our estimate of *c* is somewhat inaccurate, it certainly seems that C is a small contributor. Rotamers A and C both have *gauche* aryl and NH_3^+ groups, so this agrees with the sterically favored B being dominant. Other amphetamine hydrochlorides were insufficiently soluble in $CDCl_3$ for spectral measurement. Amphetamines are protonated at physiological p*H*. Unfortunately, investigation of conformational behavior in water (using D_2O) was frustrated by the resultant chemical shift and/or coupling constant (rotamer population) changes: lines 4 and 6 were superimposed and 3 and 5 barely resolved. Results for other systems (23) suggest that the gross conformational features of the salts would be the same in different solvents. Our results (Table 5) provide evidence that amphetamine salts indeed exhibit conformational behavior of the type postulated by Snyder (8) but this does not correlate well with the degree of psychotomimetic activity.

1-Aryl-2-nitropropanes

The rotamer populations in Table 6 were calculated using $J_t = 13, J_{g'} = 3$, and $J_g = 2$ Hz. The increase in the chosen coupling constant values from that in amphetamines is in accord with the earlier discussion, and receives some experimental justification in that within this *J* *gauche* range, J_t must be increased if $a + b \not> 1$. Table 6 shows that for any one compound, *c* is little affected by the choice of which of α_1 and α_2 is at higher field. Because steric effects probably determine populations trends, it might be supposed that the greatest difference in *a* and *b* should be observed for the compounds with the substituent CH_3 or OCH_3 ortho to the side-chain. This seems to be the case if α_1 is at low field for the methyl compounds, but at high field for the methoxy compounds. However, the chemical shifts of the benzylic protons are about the same in both series and rotamer populations are little changed, so it seems more reasonable to expect that the same proton depicted as α_1 or α_2 (Fig. 1) appears at higher field in *both* series (and for the 2,5-dimethoxy compound **25**). Preliminary evidence suggested that the NO_2 group strongly shields *gauche* protons of a similar type (22), but a *gauche* CH_3 also shields and population changes (Table 6) are too small to allow an estimate of the relative magnitude of the shielding by these two groups, critical in deciding which of α_1 and α_2 is which. Rotamer A places the β-CH_3 *trans* to the aryl ring, and on steric grounds ($CH_3 > NO_2$) A would be the more stable. Our data for meta and para substituted compounds suggest that B is slightly more stable whether α_1 or α_2 is at high field, but the calculated *a*, *b*, and *c* depend on the chosen coupling constants and small errors in their values could reverse the order of apparent stability, since *a* and *b* are nearly equal.

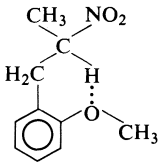
II



III

Extrapolation to the ortho compounds could be complicated by interactions of the type **II** and **III**. Although **II** is in our opinion unlikely, **III** is worth consideration: the β-H is rendered quite acidic by the nitro group. Type **III** may occur for rotamers A or B, probably with some distortion and lower symmetry imparted to the rotating phenyl ring. Evidence that this interaction occurs is found in the unusually low field resonance of the β-H in the ortho-methoxy compounds **22** and **25**. An increase in *c* might have such an affect (aryl group and β-H *trans*) but this does not seem to be the case for **22**. Further, the *o*-OCH_3 signal is at about 0.04 p.p.m. to lower field for **22** compared with **23** and **24**, whereas in the alcohols **26**–**28** and amphetamines **4**–**6** the differences are about 0.00 and 0.02 p.p.m. respectively. We conclude that for simple 1-aryl-2-nitropropanes the populations of rotamers A and B are roughly equal.

1-Aryl-2-propanols

A hydroxyl group is considerably less bulky than an amino group, and hence the ratio *b*:*a* is predicted to be less than in the case of amphetamines described earlier. In $CDCl_3$ solution at 40 °C the spectra of 1-aryl-2-propanols resemble the A_2B case. Since positive increments in J_{gem} result from the presence of more electronegative substituents (18) (*e.g.* O *cf.* N) the observation suggests that the chemical shift difference between the benzylic protons is now quite small. The same type of chemical shift *changes* occur as in the amino and nitro series. The low field position of $\overline{\alpha_1\alpha_2}$ in ortho methoxylated compounds is more marked; both it and the β-CH_3 signal are shifted by about 0.1 p.p.m. to lower field on changing the β substituent from NH_2 to OH, and the β-H is deshielded by about 0.8 p.p.m. Nibbering *et al.* (24) found that the corresponding vicinal couplings for solutions of 3,3,3-trideutero-1-phenylpropan-2-ol were not affected by concentration changes within the range 0.2–0.5 mol fraction in CCl_4. The benzylic protons were separated by about 6 Hz at 60 MHz. Their observed couplings (average 5.6 and 7.1 Hz) suggest populations of A (or B) about 36, B (or A) about 51, and C about 13%. Whatever assignment of signal to α_1 or α_2 is correct, the ratio *b*:*a* is lower than for the amphetamines, as predicted above.

Experimental

The compounds described here were prepared by standard methods, all were obtained as racemates.

Amphetamines

The appropriately substituted β-methyl-β-nitrostyrene was reduced using lithium aluminum hydride in ether or tetrahydrofuran. When a very impure amphetamine was obtained, it was generally isolated by regeneration from its hydrochloride. The common by-products of reaction seemed (p.m.r., i.r.) to be the corresponding oximes; their presence had no detectable effect on the p.m.r. spectrum of the amphetamine on the evidence from pure and impure materials. All 18 compounds were characterized as their hydrochlorides.

Amphetamine Hydrochlorides

These compounds were precipitated from ethereal solutions of the amphetamines on addition of a solution of hydrogen chloride in dry ether. All were recrystallized from isopropanol/hexane and gave satisfactory analyses (C, H, and N ±0.3%) except that 2,3- and 2,5-dimethylamphetamine hydrochloride were very hygroscopic:

Anal. Calcd. for $C_{11}H_{18}ClN$: C, 66.16; H, 9.09; N, 7.02; and Calcd. for $C_{11}H_{18}ClN \cdot \frac{1}{2}H_2O$: C, 63.28; H, 9.17; N, 6.71. Found: C, 63.18; H, 8.75; N, 6.76; and C, 63.94; H, 8.76; N, 6.70 respectively.

2,3,4-, 2,4,5-, and 2,4,6-Trimethoxyamphetamine appeared to be similarly hygroscopic.

Anal. Calcd. for $C_{12}H_{20}ClNO_3$: C, 55.09; H, 7.70; N, 5.35; and Calcd. for $C_{12}H_{20}ClNO_3 \cdot \frac{1}{2}H_2O$: C, 53.29; H, 7.82; N, 5.17. Found: C, 53.93; H, 7.41; N, 5.26; C, 53.87; H, 7.57; N, 5.27; and C, 53.71; H, 7.55; N, 5.37 respectively.

Satisfactory analyses were obtained after rigorous drying immediately before analysis. 3,4-Dimethoxyamphetamine hydrochloride was obtained as a stable monohydrate; 2,5-dimethoxyamphetamine hydrochloride deliquesces in moist air. We noted that literature values for the melting points of many amphetamine hydrochlorides differed considerably, and that our findings too were at variance; melting points seem to be affected by the presence of moisture absorbed from air.

1-Aryl-2-nitropropanes

The appropriately substituted β-methyl-β-nitrostyrene was reduced using sodium borohydride in methanol or ethanol at 30° (25). A large excess of reducing reagent was required before the yellow color of the nitrostyrene was completely discharged. Oximes appear to be the usual by-product, since on aqueous acid work-up, the corresponding phenylacetone (26) could be obtained. The nitropropane and phenylacetone were easily separated by silica gel column chromatography. The compounds were liquids, satisfactory analyses (C, H, and N) were obtained.

1-Aryl-2-propanols

The appropriately substituted phenylacetone was reduced using sodium borohydride in methanol. The alcohols were purified by column chromatography on silica gel.

We are grateful to Mr. H. W. Avdovich for his care in determining the p.m.r. spectra.

Influence of Lewis Acids on the Diels–Alder Reaction. IV. Reaction of 2-Methyl- and 2-Phenylfuran with Ethyl Propiolate[1]

A. W. McCulloch and A. G. McInnes

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

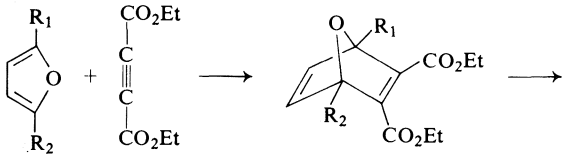
Received April 29, 1971

The $AlCl_3$-promoted reactions of 2-methyl- and of 2-phenylfuran with ethyl propiolate afford as major products ethyl 5-hydroxy-2-methyl- and 2-phenylbenzoates (**6***a*, **6***b*). Also isolated as minor by-products of these reactions are ethyl 3-(2-furyl-5-methyl)acrylate (**5***a*), ethyl 3-(2-furyl-5-phenyl)acrylate (**5***b*), ethyl 3,3-di(2-furyl-5-methyl)propionate (**10***a*), ethyl 3,3-di(2-furyl-5-phenyl)propionate (**10***b*), and ethyl 2-hydroxy-5-methylbenzoate (**8***a*).

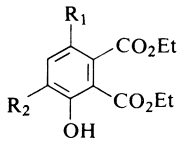
Les réactions amorcées par $AlCl_3$ entre le méthyl-2 et le phényl-2 furanne et le propiolate d'éthyle donnent comme produits majoritaires les hydroxy-5 méthyl-2 et phényl-2 benzoates d'éthyle (**6***a*, **6***b*). Ont été également isolés comme produits secondaires de ces réactions, le (furyl-2 méthyl-5)-3 acrylate d'éthyle (**5***a*), le (furyl-2 phényl-5)-3 acrylate d'éthyle (**5***b*), le di(furyl-2 méthyl-5)-3,3 propionate d'éthyle (**10***a*), le di(furyl-2 phényl-5)-3,3 propionate d'éthyle (**10***b*) et l'hydroxy-2 méthyl-5 benzoate d'éthyle (**8***a*).

Canadian Journal of Chemistry, 49, 3152 (1971)

We have recently reported the acid-catalyzed rearrangement of 1- and 1,4-substituted diethyl 7-oxabicyclo[2.2.1]2,5-heptadiene-2,3-dicarboxylate adducts **1** to 6- and 4,6-substituted diethyl 3-hydroxyphthalates **2** (1). Since formation of the adducts **1** is also accelerated by $AlCl_3$ this procedure has led to a one-step synthesis of polysubstituted aromatics.



1



2

In an attempt to investigate the generality of this one-step synthesis from furans and acetylenes we have studied the use of ethyl propiolate as a dienophile: a brief preliminary account of some of this work has appeared (2). The present paper details the results of our studies of the reactions of 2-methyl- and 2-phenylfuran with ethyl propiolate.

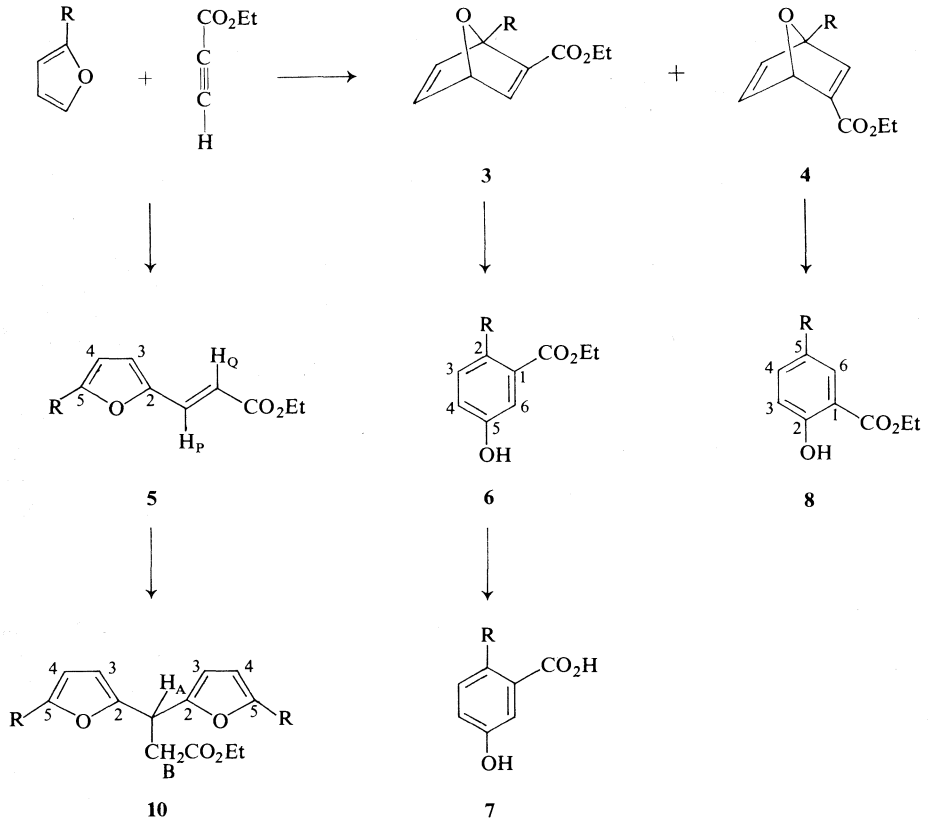
In principle, reaction of a 2-substituted furan with ethyl propiolate can lead to the formation of two stereoisomeric 1:1 adducts, **3** and **4**, subsequent rearrangement of which would afford the phenolic esters, **6** and **8** respectively. However, results of various studies on the reactions of 2-substituted butadienes, such as isoprene, with methyl vinyl ketone (3), acrolein (3), methyl acrylate (4, 5), and acrylonitrile (4), or of a 1-substituted butadiene such as *trans*-piperylene with methyl acrylate (6) have indicated that the presence of $AlCl_3$ leads to enhanced stereoselectivity. In all cases involving a 1-substituted butadiene derivative the major product of the accelerated Diels–Alder addition is the 1,2-disubstituted adduct (7). By analogy therefore we would expect the product ratio **3**:**4**, and consequently **6**:**8**, to be high.

In practice we have found that the reactions of 2-methyl and 2-phenylfuran with ethyl propiolate in the presence of $AlCl_3$ at room temperature or below do in fact yield the phenolic compounds **6***a* and *b* as the major products. At these temperatures the intermediate adducts, **3** or **4**, were not detected, and all attempts to isolate them were unsuccessful.

Reaction of 2-Methylfuran with Ethyl Propiolate

Analysis of the crude product from a typical experiment indicated (*i*) that **6***a* was the major reaction product, (*ii*) that a considerable amount of polymerized 2-methylfuran was present (p.m.r. signals for this material could be readily identified by comparison with those observed in the spec-

[1]NRCC No. 12097.



a R = CH_3;
b R = C_6H_5

trum of the orange gum obtained from a separate reaction involving only the diene and $AlCl_3$), and (*iii*) that **5***a*, **8***a*, and **10***a* were minor by-products (all <2%).

Compounds analogous to **5** are well known as reaction products from pyrroles and acetylenes (8) and are presumed to arise through a Michael-type addition process. Some speculation may be made regarding the mechanism. The reaction is presumably initiated by coordination of the carbonyl oxygen of the propiolate with $AlCl_3$. Nucleophilic attack by the furan on the β-carbon of the complexed ester would then lead (as shown in Scheme 1) to an allene-type intermediate, similar to that postulated by Huisgen *et al.* for the addition of amines to acetylenic esters (9). Abstraction of the ring proton then gives **5**: thus a process of *cis* addition yields a product having *trans* substituents. Formation of **10** may occur by a second analogous addition of the diene to **5**, again initiated by complexing between $AlCl_3$ and the ester carbonyl oxygen of **5**. We have isolated similar products from the $AlCl_3$-promoted reaction of *N*-methylpyrrole with methyl propiolate (10).

The meta-carbethoxyphenol **6***a* was readily soluble in base, whereas the strongly hydrogen-bonded ortho-carbethoxyphenol **8***a*, and the neutral components of the crude product, were insoluble. This facilitated isolation of **6***a*, which was obtained in *ca.* 30% yield after 30 min reaction at room temperature. The ester function of this compound underwent very facile hydrolysis. For example, if 5% NaOH was employed in the extraction procedure during work-up the product isolated after reacidification was predominantly **7***a*.

The by-products **5***a*, **8***a*, and **10***a* were separated from the resinified diene by column chromatography on silicic acid. Separation of the individual components required further purification by preparative t.l.c. and preparative g.l.p.c. The

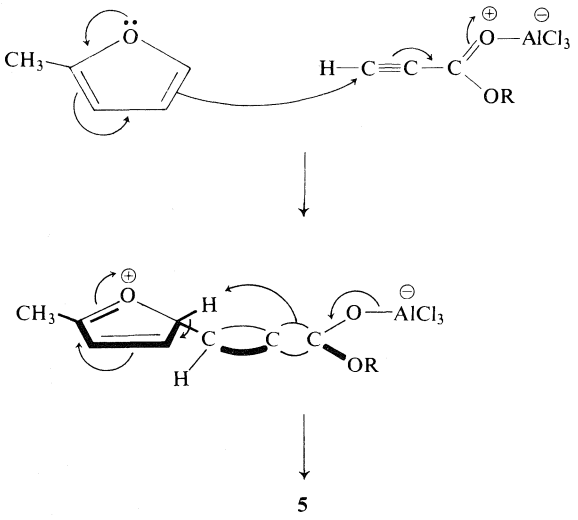

SCHEME 1

isolated yields of **5***a*, **8***a*, and **10***a* were 1.3, 0.2, and 0.7% respectively.

Reaction of 2-Phenylfuran with Ethyl Propiolate

The reaction with 2-phenylfuran followed an analogous pathway to that described above for 2-methylfuran, to give corresponding products. The reaction conditions, work-up procedures, and techniques of separation and purification were similar, but there were three important points of difference. (*i*) There was much less diene polymerization and consequently better product yields were obtained, (*ii*) although **5***b* (8%) and **10***b* (7%) could be isolated, no **8***b* was detected, indicating that steric control was greater in this reaction, and (*iii*) compound **6***b* was not readily hydrolyzed and so was the only compound obtained by base extraction of the crude reaction product.

Structures

The structures of the products were elucidated on the basis of p.m.r. (Tables 1–3), i.r., and mass spectral data (see Experimental).

Compounds 6a, 6b, and 8a

The acid-catalyzed rearrangement of 7-oxabicyclo[2.2.1]hepta-2,5-diene 2,3-dicarboxylates to 3-hydroxyphthalates is now well known (1). Analogous rearrangement of adducts **3** and **4** can lead *only* to structures **6** and **8** respectively. The major reaction products were unambiguously identified as **6***a* and *b* as follows:

(*a*) Non-bonded phenolic hydroxyl groups were evidenced by base solubility and by the chemical shift of the hydroxyl proton (3.00 in **6***a*, 3.49 τ in **6***b*). In the 3-hydroxyphthalates **2** (1), where the OH group is strongly hydrogen-bonded to an ortho carbethoxyl substituent, the chemical shift of the hydroxyl proton is at characteristically low field (*ca.* −1.0 τ).

(*b*) Both compounds showed i.r. absorptions for non-bonded ester carbonyl (1716 for **6***a*, 1713 cm^{-1} for **6***b*) and non-bonded phenolic hydroxyl (3610 for **6***a*, 3606 cm^{-1} for **6***b*) under conditions of high dilution (0.001 *M* in CCl_4). At higher concentrations absorptions for both free and intermolecularly hydrogen-bonded ester and hydroxyl were observed (see Experimental).

(*c*) Hydrolysis of **6***a* afforded the known hydroxy-acid **7***a*. The m.p. of the product (182–184°) was consistent with that reported in the literature (185°) (11).

(*d*) The chemical shifts of the carbethoxyl methylene (5.94 τ) and methyl (9.07 τ) hydrogens of **6***b* were diagnostic of an ortho phenyl substituent. Analogous shielding of carbethoxyl protons was observed (1) in diethyl 3-hydroxy-6-phenylphthalates (**2**, $R_1 = C_6H_5$).

The structure of **8***a* followed conversely from its insolubility in base, the relatively low-field position of the hydroxyl proton signal (−0.63 τ), and i.r. absorptions (0.002 *M* in CCl_4) for intramolecular hydrogen-bonded ester carbonyl (1666 cm^{-1}) and hydroxyl (broad band centered at 3200 cm^{-1}) groups.

Compounds 5a and b

The structures of the furylacrylate derivatives **5***a* and *b* were established on the basis of the following observations:

(*a*) The p.m.r. spectra (Table 2) of both compounds showed two very characteristic AB type systems for two olefinic and for two furan ring protons. The coupling ($J \approx 16$ Hz) between the olefinic protons suggests that these have a *trans* orientation (12), while that ($J \approx 3.4$ Hz) between the two ring protons indicates that they occupy positions 3 and 4 on the ring (13). Signals for carbethoxyl and ring methyl or phenyl hydrogens were also observed.

(*b*) Both **5***a* and *b* showed strong i.r. absorptions for conjugated ester carbonyl (1705 and 1700 cm^{-1} respectively) and for a conjugated double bond (1634 and 1620 cm^{-1} respectively). The *trans* stereochemistry of the double bond in **5***a*

For personal use only.

was indicated by an absorption at 970 cm^{-1}; a similar assignment could not be made in the case of **5***b* since several bands occurred in this region of its i.r. spectrum.

(*c*) The mass spectra of **5***a* and *b* were characterized by ions of high abundance at *m/e* 135 and 197 respectively, corresponding to loss of 45 mass units ($-OC_2H_5$). The spectra also showed ions at *m/e* 43 and 105 (corresponding to CH_3CO and C_6H_5CO fragments), not present in those of **6***a* and *b*.

Compounds 10a and b

Elucidation of the structures of the difuryl propionate derivatives **10***a* and *b* was based on the following:

(*a*) The most characteristic feature of the p.m.r. spectra (Table 3) of **10***a* and *b* was the AB_2 type system (one-proton "triplet" and two-proton "doublet") observed in each case for the adjacent methine and methylene hydrogens. The four furan ring protons of each compound gave an AB type spectrum (J = 3.1–3.4 Hz), similar to those observed for the ring protons of **5***a* and *b*.

(*b*) Both **10***a* and *b* showed strong i.r. absorption for a saturated ester carbonyl group (1732 and 1731 cm^{-1} respectively).

(*c*) The mass spectra had base peaks at *m/e* 175 (**10***a*) and 299 (**10***b*), corresponding to a very characteristic loss of 87 mass units (by cleavage of the $-CH_2CO_2C_2H_5$ fragment). The spectra were also characterized by strong ions at *m/e* 43 (**10***a*) and 105 (**10***b*), for the fragments CH_3CO and C_6H_5CO.

Conclusions

The $AlCl_3$-promoted reactions of 2-monosubstituted furans with ethyl propiolate provides a convenient one-step route to 2-substituted-5-hydroxybenzoates, and extends the usefulness of this procedure in the preparation of aromatic compounds. Yields of course are limited in some cases by competitive diene polymerization. The reaction appears to be further limited to furans carrying an electron-releasing substituent: under the same experimental conditions, furfural and ethyl propiolate do not react.

Furan itself reacts with ethyl propiolate under the same conditions to give a mixture of 2:1 diadducts (9). Similar reactions of 2,5-disubstituted furans give mixtures of isomeric polysubstituted phenols, the isomer distribution being dependent on reaction conditions and substituent type (2). The full results of these investigations will be published shortly.

Experimental

The p.m.r. spectra were recorded with a Varian A-60A spectrometer equipped with a V-6058A spin-decoupler, using $CDCl_3$ as solvent (unless otherwise stated) and tetramethylsilane as internal standard. The chemical shifts and coupling constants reported are judged to have an accuracy of ±0.02 p.p.m. and ±0.3 Hz respectively. Values of small long-range couplings were estimated by comparison of the half-band widths of the appropriate coupled and decoupled signals. The i.r. spectra were obtained on a Perkin–Elmer model 521 spectrometer, and the mass spectra with a Dupont-C.E.C. model 21-491 spectrometer.

Reaction of 2-Methylfuran with Ethyl Propiolate

A solution of 2-methylfuran (6.56 g) in CH_2Cl_2 (120 ml) was added, at about 20°, to a mixture of ethyl propiolate (7.84 g) and anhydrous $AlCl_3$ (10.64 g) in CH_2Cl_2 (300 ml), to give a mixture 0.2 *M* in all three reagents. This was allowed to stand, with occasional shaking, for 30 min at room temperature, and was then shaken vigorously with cold water. The organic layer was separated, dried (Na_2SO_4), and evaporated to dryness.

(i) Isolation of 6a and 7a

The residue was dissolved in ether and the solution extracted thoroughly with 5% NaOH solution. After re-acidification (HCl) of the base extract to p*H* 1, extraction with ether afforded a semi-crystalline material (4.07 g). This was fractionated on the basis of solubility in $NaHCO_3$ solution. The bicarbonate-soluble fraction, after reacidification and extraction with ether, gave a colorless solid. Crystallization from water gave **7***a* as needles (2.63 g, 22%), subliming >165°, m.p. 182–184° (lit. 185° (11)); characteristic i.r. absorption (KBr) at 1680 cm^{-1}.

The bicarbonate-insoluble fraction gave a brown oil. Distillation at 120°/0.5 mm gave **6***a* as a cream-colored solid (640 mg, 4%), m.p. 53–55.5°. Ion of highest mass at *m/e* 180 ($C_{10}H_{12}O_3$ requires 180); characteristic i.r. absorptions (KBr) at 3400, 1672, and 1604 cm^{-1}; (0.005 *M* in CCl_4) at 3610, 3445 (broad), 1716 and 1685 cm^{-1} (shoulder); (0.001 *M* in CCl_4) at 3610 and 1716 cm^{-1}.

(ii) Isolation of 5a, 8a, and 10a

The NaOH-insoluble portion (5.69 g) of the crude product was recovered and washed thoroughly with petroleum-ether (b.p. 60–80°). This gave an insoluble pale brown amorphous solid (3.6 g), p.m.r. of which showed no ester or olefinic signals. The petrol-soluble fraction afforded an orange oil (2.0 g). This was chromatographed on a silicic acid column, with $CHCl_3$ as eluant. Fractions were collected in the following order:

(*a*) A pale yellow oil (95 mg), which on preparative t.l.c. (silica gel G, benzene : petroleum ether (1:1) as eluant) gave impure **8***a* (52 mg) of R_f 0.4. Final purification by preparative g.l.p.c. (5% carbowax on chromosorb G 8′ × 5/8″ column, operating at 170°) afforded **8***a* as a colorless oil (30 mg, 0.2%). Ion of highest mass at *m/e* 180 ($C_{10}H_{12}O_3$ requires 180). Characteristic i.r.

absorptions (0.002 *M* in CCl_4) at 3200 (broad) and 1666 cm^{-1}.

(*b*) The next fractions gave **10***a* as a pale yellow oil (135 mg, 0.7%), $n_D^{26} = 1.6551$. Ion of highest mass at *m/e* 262 ($C_{15}H_{18}O_4$ requires 262); characteristic i.r. absorption (liquid film) at 1732 cm^{-1}.

(*c*) The later fractions gave a pale yellow oil which was purified by preparative g.l.p.c. (20% carbowax on chromosorb W 8′ × 5/8″ column, operating at 150°) to give **5***a* as a colorless oil (190 mg, 1.3%), $n_D^{23} = 1.6551$, which crystallized on cooling to 0°. Ion of highest mass at *m/e* 180 ($C_{10}H_{12}O_3$ requires 180); characteristic i.r. absorptions (liquid film) at 1705, 1634, 1580, 1525, and 970 cm^{-1}.

Reaction of 2-Phenylfuran with Ethyl Propiolate

A solution of 2-phenylfuran (576 mg) in CH_2Cl_2 (6 ml) was added, at about 20°, to a mixture of ethyl propiolate (392 mg) and $AlCl_3$ (532 mg) in CH_2Cl_2 (14 ml), to give a mixture 0.2 *M* in all three reagents. After standing for 30 min at room temperature, with occasional shaking, the dark red reaction mixture was hydrolyzed as above.

(i) Isolation of ***6b***

The crude product was dissolved in ether and the solution extracted with 5% NaOH solution. Reacidification (HCl) and ether extraction gave **6***b* as a pale yellow gum (465 mg, 48%) which crystallized from petroleum ether as needles, m.p. 63–64°. Ion of highest mass at *m/e* 242 ($C_{15}H_{14}O_3$ requires 242); characteristic i.r. absorptions (KBr) at 3380, 3290, 1701, 1685, and 1600 cm^{-1}; (0.005 *M* in CCl_4) at 3605, 3440, 1713, and 1690 cm^{-1}; (0.001 *M* in CCl_4) at 3606 and 1713 cm^{-1}.

(ii) Isolation of ***5b*** *and* ***10b***

The NaOH-insoluble portion (385 mg) of the product was recovered to give a yellow oil which partially crystallized at 0°. This was submitted to preparative t.l.c. (silica gel G, $CHCl_3$ as eluant), fractions being collected as follows:

(*a*) A band of R_f 0.6 yielded **10***b* as a pale yellow oil (113 mg, 7%), $n_D^{26} = 1.6030$. Ion of highest mass at *m/e* 386 ($C_{25}H_{22}O_4$ requires 386); characteristic i.r. absorption (liquid film) at 1731 cm^{-1}.

(*b*) A band of R_f 0.4 yielded **5***b* as a pale yellow solid (78 mg, 8%) which was crystallized from petroleum ether (b.p. 60–80°) as colorless prisms, m.p. 79.5–81°. Ion of highest mass at *m/e* 242 ($C_{15}H_{14}O_3$ requires 242); characteristic i.r. absorptions (KBr) at 1700 and 1620 cm^{-1}.

We wish to thank Mrs. M. G. Flack and Mr. J. Van Ingen for their excellent technical assistance. Thanks are also due to Mr P. F. Seto for the i.r. spectra.

Solvent and Temperature Effects on Nitrogen Nuclear Spin Relaxation in Methyl Nitrate

CHRISTINE M. SHEPPERD, T. SCHAEFER, AND (IN PART) B. W. GOODWIN AND J. T'RAA
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received February 22, 1971

Analysis of the proton resonance line shape yields quadrupolar relaxation times for the nitrogen nucleus in methyl nitrate, both neat and in solution with 14 different solvents. Variable temperature studies lead to activation parameters for molecular reorientation in dimethylformamide and in cyclohexane. Factors influencing the rotational rate of the solute molecule are elucidated; the results are analyzed in terms of various models for the correlation time characteristic of rotation in the liquid. None are successful in predicting the observed differences between reorientational rates in polar and nonpolar solvents. The Debye–Stokes model is evidently applicable to the solution in the polar dimethylformamide but not to the solution in the nonpolar saturated hydrocarbons. In the latter the inertial model of Steele is more satisfactory. Other solvents fall between these two extremes.

L'analyse de l'allure des bandes de résonance protonique donne les temps de relaxation quadripolaires pour l'atome d'azote du nitrate de méthyle à la fois pur et en solution dans quatorze différents solvants. Des études de variation de température permettent d'obtenir des paramètres d'activation pour la réorientation moléculaire dans la diméthylformamide et le cyclohexane. Les facteurs que influencent la vitesse de rotation de la molécule de soluté ont été élucidés; les résultats sont analysés en termes de modèles variables pour le temps de corrélation caractéristique d'une rotation dans le liquide. Aucun n'a permis de prédire avec succès les différences observées entre les vitesses de réorientation dans des solvants polaires et non polaires. Le modèle de Debye-Stokes est évidemment applicable à la solution dans la diméthylformamide polaire et non pas à la solution dans les hydrocarbures saturés non polaires. Dans ce dernier cas, le modèle rigide de Steele est plus satisfaisant. Pour les autres solvants, on se place entre ces deux extrêmes.

Canadian Journal of Chemistry, **49**, 3158 (1971)

Introduction

The existence of a quadrupole moment in the ^{14}N nucleus, and the presence of a non-spherically symmetric electric field at the nucleus due to the surrounding electron distribution, affect the magnetic resonance of the nitrogen nucleus and of other nuclei spin-coupled to it. Depending on the rate of the quadrupolar relaxation, the resonance of a spin-1/2 nucleus spin-coupled to a single nitrogen nucleus varies between the two extremes of a sharp triplet in the absence of relaxation and a sharp singlet when relaxation is very fast. It is possible to determine the quadrupolar relaxation time, T_q, of the nitrogen nucleus from an analysis of the proton resonance line shape (1).

T_q values provide a useful tool for the study of molecular reorientation in the liquid (2). The primary advantage of this approach rests on the premise that the electric field gradient is dominantly intramolecular and that the quadrupolar spin–lattice relaxation mechanism overwhelmingly predominates over the dipolar and spin-rotational relaxation of the ^{14}N nucleus. Accounting for relative translation in an expression for the relaxation time and the complication of including several mechanisms for relaxation can thus be neatly avoided by the use of quadrupolar nuclei. For a nucleus of spin 1 under conditions of extreme narrowing, the quadrupolar relaxation rate is given by (3)

$$[1] \qquad T_q^{-1} = 3/8(e^2qQ/\hbar)^2\tau_q$$

where $e^2qQ/\hbar$ is the nitrogen quadrupolar coupling constant and τ_q, the correlation time for molecular reorientation, is intimately coupled to molecular interactions. Hence the observed temperature, pressure, and solvent variations of T_q reflect the dependence of τ_q on these properties (the quadrupolar coupling constant, being an intramolecular parameter, is to a first approximation invariant to changes in temperature, etc.). In this paper we describe the procedure used to determine T_q and report the influence of temperature and solvent on the spin relaxation of ^{14}N in methyl nitrate. Our results will be discussed in terms of the various models proposed for molecular motion.

Experimental

1. Materials

Methyl nitrate was prepared by the esterification of methanol with nitric acid and purified by vacuum distillation. All solvents were of spectral grade and used without further purification. For temperature and solvent studies 15 mol% solutions of methyl nitrate plus a small amount of tetramethylsilane (TMS) were enclosed in glass tubes and carefully degassed by repeated freeze–pump–thaw cycles. Methyl nitrate is unstable to extremes of temperature and this fact was considered during the variable temperature work.

2. Nuclear Magnetic Resonance Measurements

All proton magnetic resonance (p.m.r.) spectra were measured on a Varian HA-100D spectrometer operated in the frequency sweep mode and locked to internal TMS. The spectrum of each sample was measured and calibrated (by a period averaging technique) at least six times, employing radiofrequency intensities well below saturation level and sweep rates of 0.02 Hz/s or less. The sample temperature was determined from a previously prepared calibration graph of dial-setting against actual temperature, as recorded by a thermocouple. Temperatures are accurate to ±1 °C.

3. Viscosity and Density Measurements

The viscosities and densities of 15 mol% methyl nitrate dimethylformamide (DMF) and methyl nitrate cyclohexane (C_6H_{12}) solutions were determined at different temperatures by standard techniques (Ostwald viscometer and pycnometer). The estimated error of the viscosity measurements is 2–3%.

Results and Discussion

1. Derivation of Relaxation Times T_q

The proton spectrum of methyl nitrate is shown in Fig. 1 at various temperatures in different solvents. The transition between singlet and triplet structures is clearly exhibited.

The theory underlying the shape of the absorption band was developed by Pople (1) and later modified to include the natural linewidth $(\pi T_2)^{-1}$ by Kintzinger *et al.* (4). The line shape expression $I(\nu)$ is given by

$$[2]\quad I(\nu) = \frac{C_1 + \Delta\nu^2(C_2 + \Delta\nu^2 C_3)}{C_4 + \Delta\nu^2[C_5 + \Delta\nu^2(C_6 + \Delta\nu^2)]}$$

where C_1 to C_6 are terms involving T_q, J (the ^{14}N—H coupling constant) and T_2 (the natural linewidth of the proton resonance in the absence of quadrupolar relaxation); $\Delta\nu$ is the shift in Hz from the center of the multiplet.

A program in Fortran IV was written for an IBM 360/65 computer equipped with a Calcomp plotter and used to construct theoretical absorption bands, $I(\nu)$, on the basis of eq. 2 for a variety of T_q values. Input parameters were J, T_2,[1] and a "reasonable" T_q value. A search was made around this central figure employing variable step sizes until iteration was almost complete. Spectra were then calculated at 0.0025 s

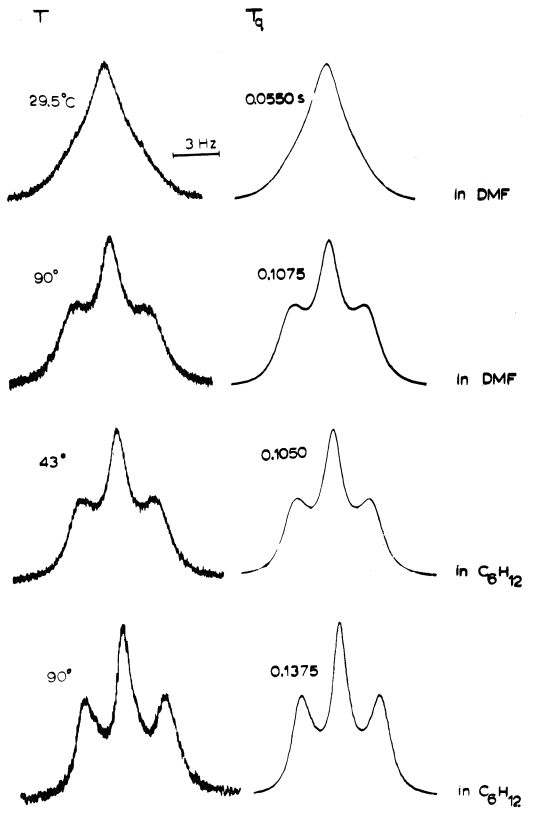

FIG. 1. Experimental and calculated resonance spectra of methyl nitrate in C_6H_{12} and DMF solutions at various representative temperatures and relaxation times.

[1]In none of the recorded spectra is the proton triplet sufficiently resolved to permit direct measurement of J and T_2. An effective T_2 was therefore determined from the solvent resonance since the linewidths of both solute and solvent (in the absence of exchange or relaxation effects) are determined by magnetic field inhomogeneities. $J(^{14}N—H)$ was obtained indirectly by recording the p.m.r. spectrum at high power and measuring the separation of the satellites caused ^{15}N—H coupling (0.36% abundance of ^{15}N). A neat sample and 50 mol% solutions in toluene and in chloroform all had $|J(^{15}N—H)| = 3.90 \pm 0.05$ Hz so that $|J(^{14}N—H)| = 2.78 \pm 0.04$ Hz because $\gamma^{15}N/\gamma^{14}N = -1.403$. This approach has been used previously (5) for ^{15}N–^{19}F coupling constants, but not, to our knowledge, for ^{15}N–^{1}H. It is interesting to note that Kintzinger (4) obtained a value of 2.75 Hz for $J(^{14}N—H)$ in methyl nitrate by complete line shape analysis involving iteration to a "best" set of J, T_2, and T_q values.

intervals, five on either side of the most probable T_q value, to enable a realistic error estimate to be made. Experimental and calculated spectra were compared visually by superimposing one on the other for different values of T_q until optimum agreement was found. For each temperature and solvent all experimentally recorded spectra were matched with the Calcomp plots; invariably this led to a "best" T_q value, with upper and lower limits estimated from the extreme T_q's which gave reasonable agreement. This is a rapid method for obtaining relaxation rates and also a reliable one since the entire line shape is fitted at the same time. However, at relaxation rates greater than the coupling constant $J(^{14}N—H)$, where the resonance is a broadened singlet, the fit is less sensitive to changes in T_q and the error limits are correspondingly larger.

In an attempt to overcome this problem an additional method of fitting the spectra was used in conjunction with visual matching. Application of a subroutine (developed previously for other rate studies) to the numerical output $I(\nu)$ of the main program generated certain characteristics of the resonance line shape which are sensitive to the rate of relaxation (*e.g.* positions of maxima and minima and their half-height linewidths). Comparison of these with the corresponding experimental parameters (as measured from the recorded spectra) permitted T_q values to be determined. Again, however, where the line shape is a broadened singlet fitting is less precise (T_q values are ± 0.005 s) than for a resolved triplet (where an error of ± 0.0025 s is associated with T_q). This represents an error of 2–5% in T_q which is somewhat less than that of conventional (spin-echo) methods for measuring ^{14}N spin–lattice relaxation times (6). Unfortunately this advantage is largely offset by the low sensitivity of the proton line shape to temperature. T_q changes by only 0.05 s in the entire 60 °C interval so that fitting of individual spectra to within at least 0.0025 s is necessary for an accurate determination of activation parameters. Examples of experimental and computer simulated spectra are given in Fig. 1. Tables 1 and 2 list the quadrupolar relaxation times for ^{14}N as a function of temperature (in the two solvents DMF and C_6H_{12}) and in 12 other solvents at ambient temperature.

TABLE 1. Quadrupole relaxation times, T_q, from fitted spectra for methyl nitrate

Dimethylformamide		Cyclohexane	
Temperature (°C)	T_q* (s)	Temperature (°C)	T_q* (s)
29.5	0.0550	28.5	0.0925
38.5	0.0625	38	0.1000 0.0975
49	0.0725	43	0.1050 0.1025
59	0.0800	48	0.1075 0.1050
69.5	0.0875	53	0.1100 0.1075

90	0.1075	63	0.1175 0.1150
		68	0.1200 0.1175
		80	0.1300 0.1275
		90	0.1375

*Estimated error ± 0.0025 s. Where two values are given at one temperature they are the error limits.

2. *Activation Parameters*

The quadrupolar correlation time τ_q is determined only by reorientational motions so that its temperature dependence leads to activation parameters which can be unambiguously assigned to molecular rotation. If the temperature dependence follows the Arrhenius rate equation (2) then

$$[3] \qquad \tau_q = \tau_q^0 \exp(E_a/RT)$$

where τ_q^0 is an inverse frequency factor (and approximately constant) and E_a is an effective activation energy. From eq. 1 one then has

$$[4] \quad \log T_q = \log\left[\tau_q^0 \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2\right]^{-1} - \frac{E_a}{2.303RT}$$

In Fig. 2 an Arrhenius plot of $\log T_q$ *vs.* $1/T$ is

TABLE 3. Activation parameters for the reorientation of methyl nitrate*

Compound	E_a (kcal/mol)	$\tau_q^0 \times 10^4$ (s)	$\Delta G^{\ddagger}$ (at 353 °K) (kcal/mol)	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$ (kcal/deg mol)
C_6H_{12}	1.36±0.05	15.5±1	1.4±0.1	0.70±0.06	−2.1±0.2
DMF	2.38±0.06	4.7±0.4	1.6±0.1	1.73±0.7	0.3±0.2

*Quoted values are standard errors derived from the least squares analysis. They do not include uncertainties in T_2 and are probably therefore overly optimistic, since the line shape (and thus T_q) is known to be sensitive to changes in T_2 (5, 8).

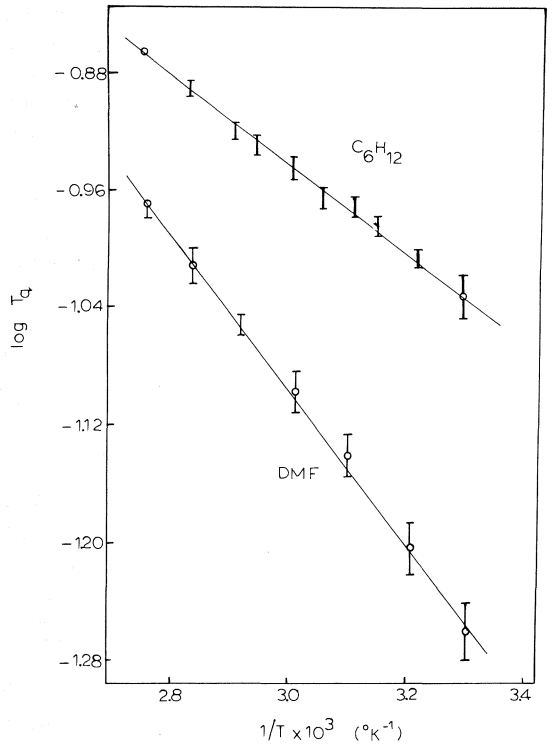

FIG. 2. A plot of log T_q *vs.* the reciprocal absolute temperature for the DMF and C_6H_{12} solution of methyl nitrate. The error bars were obtained as discussed in the text.

shown for the DMF and C_6H_{12} solutions. The points lie on a straight line within the limits of experimental accuracy but see refs. 2, 7. The activation energies and inverse frequency factors[2] are given in Table 3. Also listed are activation enthalpies and entropies[2] derived from plots of log T_q/T *vs.* $1/T$ as indicated by eq. 5 which follows from eq. 1 and the Eyring rate equation

$$[5] \quad \log \frac{T_q}{T} = \log\left(\frac{kf}{h}\right) - \log\left\{\frac{3}{8}\left(\frac{e^2qQ}{h}\right)^2\right\} + \frac{\Delta S^{\ddagger}}{4.577} - \frac{\Delta H^{\ddagger}}{4.577T}$$

k is the Boltzman constant and f the transmission coefficient (set equal to unity).

Comparison of the results of Table 3 with other work (see, for example 2, 4, 9–11) shows that the activation energies measured for methyl nitrate by the high-resolution p.m.r. method lie in the expected region; differences are generally compatible with the relative molecular shapes and sizes. A previously reported E_a value of 1.8 kcal/mol for the reorientation of methyl nitrate in tetrachloroethylene solution (4) lies between that found for DMF solution (2.38 kcal/mol) and C_6H_{12} solution (1.36 kcal/mol), demonstrating the effect of solvent on the activation parameters. While other workers have stressed the importance of viscosity in this respect (6, 12) the present results, involving two solvents of very similar viscosity (Table 2), show clearly that the dielectric constant is also significant; a larger barrier to molecular reorientation is presented by media of high dielectric constant than by less polar ones. This point is discussed further in the following sections.

3. *Solvent Dependence of Relaxation Rates*

It is apparent from the data in Tables 1 and 2 that T_q depends upon the nature of the solute–solvent system *i.e.* the rotational correlation time τ_q is sensitive to the solvent (6, 14–18). Bloembergen, Purcell, and Pound (19) applied Stokes' formula to Debye's theory of dielectric relaxation and proposed that for a sphere of radius a imbedded in a continuous medium of viscosity η

$$[6] \quad \tau_q = (4/3)\pi a^3 \eta / T$$

where T is the absolute temperature. Incorporating eq. 6 into eq. 1 shows that

[2]A knowledge of the ^{14}N quadrupole coupling constant in methyl nitrate is required in order to estimate the frequency factors and entropies from the intercept. Since e^2qQ/h has not been measured for this molecule an approximate value was estimated as in ref. 2; consequently the error in these activation parameters is doubtless larger than indicated in Table 3.

[7] $$T_q^{-1} = \frac{\pi a^3}{2}\left(\frac{e^2qQ}{\hbar}\right)^2 \frac{\eta}{T}$$

which predicts the temperature dependence of T_q^{-1} to parallel that of the ratio of viscosity to absolute temperature, provided the Debye–Stokes model is valid. Figure 3 shows these plots for C_6H_{12} and DMF solutions of methyl nitrate. With DMF solution the close agreement between activation energies computed from the relaxation rate curve of ^{14}N and the η/T curve indicates that the temperature dependence of the rotational motion is accurately described by the temperature dependence of η/T. These results support the Debye–Stokes model, eq. 6, where frictional forces alone are assumed to determine molecular motion. For the case of a strongly interacting solute–solvent system such as methyl nitrate/DMF (both highly polar) this approach appears to be a good approximation. Interestingly, Woessner *et al.* found a similar agreement for *n*-dodecane both neat and in carbon tetrachloride solution (17).

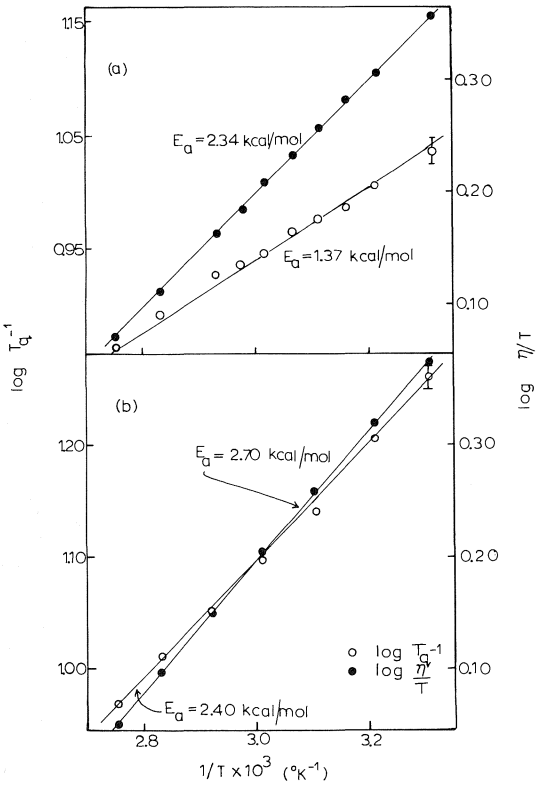

FIG. 3. The temperature dependences of the nitrogen relaxation rate and of viscosity for methyl nitrate in (*a*) C_6H_{12} solution and (*b*) DMF solution. Estimated error (shown only for one point) was obtained as discussed in the text.

However, for the methyl nitrate/C_6H_{12} system (and certain others (11, 20)) E_a for spin relaxation is found to be considerably less than that for η/T, yet large enough to rule out a dominance of molecular rotation by inertial effects, as has been suggested by Moniz *et al.* (21). This does not mean, however, that the rotation is independent of the moment of inertia. For a polar solute in a nonpolar solvent it is reasonable to assume that solute–solvent interactions will be less than for a polar solute/polar solvent pair *i.e.* that solute rotation in the former case involves less disturbance of neighboring molecules than in the latter system where simultaneous translation and rotation is probable. Now viscosity can be regarded as a measure of the momentum transfer between liquid layers moving with different velocities (a translational phenomenon) so that no relation between viscosity and rotational motion is expected unless simultaneous translation of other molecules is involved in rotation. Only in that case would the viscosity be a reasonable measure of the drag actually encountered by the rotating molecule. Thus the Debye–Stokes prediction of an equal temperature dependence for intramolecular relaxation and η (based on the assumption of a viscosity dependent rotational rate) depends critically on the nature of the molecular interactions in solution. It appears to be satisfactory for the rotation of methyl nitrate in DMF, but not in C_6H_{12} solution.

4. Solvent Dependence at Constant Temperature

It is also possible to test the dependence of correlation time on viscosity by changing the composition of the sample at constant temperature. The Debye–Stokes model predicts that the correlation time is directly proportional to the viscosity at a given temperature. Figure 4, using the data in Table 3, shows a scatter of points (greater than that found by Herbison-Evans and Richards (15) in similar studies) although a general trend of increasing relaxation rate with increasing viscosity and dielectric constant is apparent. It has been suggested (22) that the Debye–Stokes model could be improved by taking account of the discontinuous nature of the liquid medium through a microviscosity factor. This approach gives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[8] $$\tau_q = \frac{4\pi a^3 \eta}{3kT}\frac{a}{6b}$$

where b is the radius of the solvent molecule. Hence T_q^{-1} should depend linearly on η/b at constant temperature. However, this modification gave only marginal improvement to the plot in Fig. 4. An alternative approach, based on considerations of momentum transfer, has been given by Hill (23) and modified by Mitchell and Eisher (14). They obtain

[9] $$\tau_q = 2Ia\eta/\mu kT$$

where I is the average of the principal moments of inertia of the solute molecule and μ is the reduced mass of the solute–solvent system. A plot of T_q^{-1} *vs.* η/μ again gave a scatter of points similar to that in Fig. 4.

Closer examination of Fig. 4 and similar plots reveals that the data can be divided into two groups (ignoring for the moment points for the saturated hydrocarbons (9, 11–14). One 'straight' line can be drawn through the data for nonpolar but polarizable solvents (CS_2, $C_6H_5CH_3$, C_6D_6, CCl_4, (3, 5, 6, 8)) and another through the data for polar solvents as suggested by the broken lines in Fig. 4. Apparently an increase in dielectric constant enhances the relaxation rate over and above that brought about by an increase in viscosity. An empirical formula due to Murty (24),

[10] $$\tau_q = 6\pi\alpha\eta/(\varepsilon + 2)kT$$

(where α is the polarizability of the solute and ε the dielectric constant of the solvent) is successful for a number of liquids (25), although the methyl nitrate data certainly do not conform to eq. 10. In fact a plot of the data using eq. 10 shows that differences between polar and nonpolar solvents are accentuated.

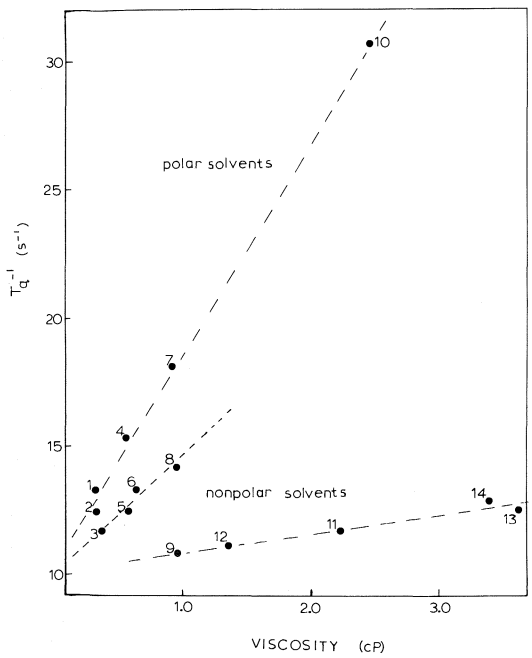

FIG. 4. ^{14}N relaxation rate as a function of viscosity for solutions of methyl nitrate, at ambient temperature. Solvents used were *1* = CH_3CN; *2* = acetone; *3* = CS_2; *4* = $CDCl_3$; *5* = $C_6H_5CH_3$; *6* = C_6D_6; *7* = DMF; *8* = CCl_4; *9* = C_6H_{12}; *10* = DMSO; *11* = C_8H_{16}; *12* = *n*-$C_{12}H_{26}$; *13* = *n*-$C_{16}H_{34}$; *14* = *cis*-decalin. The numbering is the same as in Table 2.

Figure 4 and plots based on eqs. 8 and 9 were designed to test the predictions of the Debye–Stokes, microviscosity, and modified Hill models, respectively. All appear to be inadequate as a description of the reorientation of methyl nitrate. In these plots a change in viscosity is accompanied by a change in numerous other physical properties associated with the new solvent; evidently the theories themselves are at fault or factors other than macroscopic viscosity are important in determining rates of molecular reorientation; or both may be true. That the data can be divided into two "straight" lines is probably significant and suggests that both the microviscosity and Hill theories are valid for a range of solvents where the molecular interactions do not vary appreciably. Indeed good agreement between experimental and calculated values of molecular correlation times has been variously reported for both theories (17, 18, 14, 26). The polarity of the solvent is clearly an important parameter, yet the relaxation rate does not depend on dielectric constant in the simple way suggested by Murty. Unfortunately our results do not suggest any alternative means of accounting explicitly for polar interactions in an expression for rotational correlation times.

5. *Relaxation in Saturated Hydrocarbon Solvents*

In Fig. 4 the points for ^{14}N relaxation in the saturated hydrocarbon solvents lie far below the rest and in fact show a relative independence of viscosity incompatible with any of the above theories. Moniz *et al.*'s model (21) of an inertial dominance of rotation is probably the most

satisfactory here, although the solute molecule is naturally not spherical or nonpolar!

Qualitatively, one might summarize as follows. The relatively large saturated hydrocarbon molecules each present a small segment of low polarizability to the polar methyl nitrate molecule and thus hinder the reorientation of the latter by almost the same amount, independently of the macroviscosity of the hydrocarbon liquid.[3] At the other extreme, the polar molecular DMF (and probably DMSO) interacts strongly with the solute molecule, dragging it along through the solvent and hence the macroviscosity of the solvent is a relatively acceptable measure of the hindrance to reorientation of the methyl nitrate molecule. The nonpolar but relatively polarizable solvents like CS_2 and CCl_4 (which also possess a large quadrupole moment relative to the saturated hydrocarbons) are then expected to and do fall between the two extremes represented by DMSO (point 10 in Fig. 4) and n-$C_{16}H_{34}$ (point 13 in Fig. 4).

Quantitatively it is difficult to see how a general model for these variations in relaxation time can be found.

6. *Internal Motion Effects of the Electric Field Gradient*

We assumed above that internal motions were not affecting T_q. Two internal motions able to reorient the field gradients at the nitrogen nucleus are rotation about the O—N bond and rotation of the methyl group about the C—N bond. If the nitrogen relaxation is to be affected the internal motion must reorient the field gradients relative to the molecular coordinate system at a rate comparable to the reorientation rate of the whole molecule.

The barrier to rotation about the O—N bond is 9.1 kcal/mol (27) and rotation about this bond is therefore much too slow to promote nitrogen relaxation in the temperatures under consideration. The barrier to internal rotation of the methyl group is 2.3 kcal/mol (27) and is therefore comparable to the barriers restricting the overall rotation. However, as pointed out by Wallach and Huntress (28) for the somewhat similar case of dimethylformamide, the orientations of the methyl group will likely have a very small effect on the orientation of the field gradient at the nitrogen (a large effect might be expected for deuterons placed in the methyl group).

[3]The chemical shift of the proton resonance of methyl nitrate in C_6H_{12} is independent of temperature, suggesting little dimerization of the solute molecules in these solvents.

We are grateful to the National Research Council of Canada for financial support.

Successive Nucleophilic Substitution at Four-Coordinate Boron. Some Novel Chelated and Polynuclear Boron($n+$) Salts

SUE A. GENCHUR,[1] GARY L. SMITH,[2] AND HENRY C. KELLY[3]
Department of Chemistry, Texas Christian University, Fort Worth, Texas 76129

Received March 22, 1971

Reactions of various polyamines with the mono- and diiodoborane adducts of trimethylamine yield chelated and polynuclear boron($n+$) ions. Treatment of excess trimethylamine-monoiodoborane with *N,N′*-dimethylpiperazine, triethylenediamine, and *N,N,N′,N″,N″*-pentamethyldiethylenetriamine give the corresponding di- and trinuclear salts. At about 30°, the diiodoborane combines with triethylenediamine to give a dinuclear ion, but in refluxing benzene, the product is a polynuclear salt. Trimethylamine-diiodoborane reacts with pentamethyldiethylenetriamine (in excess) to produce a bicyclic chelate. The reaction between *N,N,N′,N′*-tetramethylethylenediamine (TMED) and the diiodoborane gives two chelated products, $[TMED(CH_3)_3NBH]^{2+}.2I^-$ and $(TMEDBHI)^+.I^-$. The latter salt, unlike its *B*-bromo and *B*-hydrido analogs, exhibits acidic behavior. This is tentatively explained by assuming a relatively high lability of the boron-bonded iodine.

Les réactions entre un certain nombre de polyamines et les produits mono- et diiodoborane de la triméthylamine conduisent à des ions bore($n+$), chélatés et polynucléaires. Le traitement d'un excès de monoiodoborane de triméthylamine avec la *N,N′*-diméthylpipérazine, la triéthylénediamine et la *N,N,N′,N′,N″,N″*-pentaneméthyldiéthylènetriamine conduit aux sels correspondants di- et trinucléaire. A 30 °C environ, le diiodoborane se combine avec la triéthylènediamine pour conduire à un ion dinucléaire, alors que dans le benzène au reflux, le produit obtenu est un sel polynucléaire. Le diiodoborane de la triméthylamine réagit avec la pentaméthyldiéthylènetriamine (en excès) pour donner un chélate bicyclique. La réaction entre la *N,N,N′,N′*-tétraméthylènediamine (TMED) et le diiodoborane conduit à deux composés chélatés, $[TMED(CH_3)_3NBH]^{2+}.2I^-$ et $(TMEDBHI)^+.I^-$. Ce dernier sel présente un caractère acide, à l'inverse de ses analogues portant un brome ou un hydrure en position *B*. Une tentative d'explication est donnée d'après laquelle la liaison bore-iode serait très labile.

Canadian Journal of Chemistry, **49**, 3165 (1971)

Introduction

Displacement reactions on amine-haloboranes have been shown by Nöth, Beyer, and Vetter (1) to be useful for the preparation of four-coordinate boron cations. This type of reaction has been considered a possible mechanistic step in a modified synthesis of such ions by Douglass (2) and has been applied widely for the preparation of a variety of bis(ligand) boronium ion salts (3–5). In one variation of this reaction, amine-haloboranes have been treated with selected diamines to produce chelated boronium ions and dinuclear boron(2+) salts (4–6). In this paper further extensions of such consecutive nucleophilic displacement at four-coordinate boron are examined through reactions of polyfunctional amines with the mono- and diiodoborane adducts of trimethylamine. Interesting chelated and polynuclear boron($n+$) ions, resulting from competing intra- and intermolecular reactions, are described.

Experimental

Materials

Trimethylamine-borane was obtained from Matheson, Coleman and Bell and was used without further purification. The mo o- and diiodoborane adducts were synthesized by methods similar to those of Nöth and Beyer (7, 8) involving the reaction of trimethylamine-borane with the appropriate stoichiometric quantities of iodine in refluxing benzene. These products were recovered by flash evaporation of the solvent and purified by vacuum sublimation (at 50° for the monoiodoborane and at 75° for the diiodoborane). Benzene was boiled under reflux over sodium and distilled immediately before use. The *N,N,N′,N′*-tetramethylethylenediamine (TMED) was obtained from Matheson, Coleman and Bell and was purified by distillation, b.p. 120–122°. Pentamethyldiethylenetriamine (PMDT) from K & K Laboratories was distilled before use, b.p. 200–202°. The 1,4-diazabicyclo(2.2.2)-octane (triethylenediamine) and dimethylpiperazine (DMP) also were obtained from K & K and were used without further purification. Boronium ion salts were prepared as water-soluble iodides as described below. The relatively insoluble PF_6^- salts of these ions were obtained by addition of crystalline NH_4PF_6 to 2–3% aqueous solutions of the iodides.

Apparatus

Infrared spectra were obtained with KBr wafers using a Perkin–Elmer Model 237 infrared spectrophotometer. Each of the salts synthesized from trimethylamine-

monoiodoborane exhibited a doublet near 2500 cm^{-1}, indicative of the presence of the $—BH_2$ grouping, whereas spectra of salts prepared from the diiodoborane exhibited a singlet in this region characteristic of a single —B—H bond.

Proton nuclear magnetic resonance (n.m.r.) spectra (Table 1) were taken using a Varian A60-A n.m.r. spectrometer. Tetramethylsilane was used as an internal standard in acetonitrile-d_3 and dimethyl sulfoxide-d_6 and as an external standard with D_2O.

Conductivity measurements were made in acetonitrile and water employing a Fluke impedance bridge. The molar conductivities reported (Table 2) are for 0.001 *M* solutions of the salts.

Iodide and Hexafluorophosphate Salts of the N,N,N′,N′-Tetramethylethylenediaminetrimethylaminehydroboron(2+) Ion

A solution of 6.00 g (18.5 mmol) of trimethylaminediiodoborane in 10 ml of benzene was treated with 10 ml (65 mmol) of TMED and the mixture was stirred for 18 h at 75°. A solid product was recovered by vacuum filtration and a total of 2.05 g of unreacted diiodoborane was recovered from the filtrate by re-precipitation with petroleum ether. A portion of the solid reaction product was found to dissolve on the addition of methanol and the insoluble portion was separated by filtration. When the methanol filtrate was cooled in ice-water, some beige crystals identical to the original insoluble residue were obtained. This material was the iodide salt of the $(TMED)(CH_3)_3NBH^{2+}$ ion, which was identified as the PF_6^- salt (see below). Yield of iodide = 2.52 g (46.9% theory based on reacted diiodoborane). The iodide was recrystallized from methanol, m.p. 216–218° (decomp.). The hexafluorophosphate salt, obtained from an aqueous solution of the iodide and NH_4PF_6, was recrystallized from hot water, m.p. 272–273° (decomp.).

Anal. Calcd. for $C_9H_{26}BN_3^{2+}.2PF_6^-$ (477.06): C, 22.66; H, 5.49; N, 8.81. Found: C, 22.45; H, 5.50; N, 8.68.

N,N,N′,N′-Tetramethylethylenediamineiodohydroboron(1+) Iodide

This second product of the reaction of TMED with the diiodoborane was precipitated by the addition of benzene and petroleum ether to the methanol solution described above. Yield, 0.287 g (6.2% theory); m.p. 247–248° (decomp.).

Anal. Calcd. for $C_6H_{17}BIN_2^+.I^-$ (381.84): C, 18.87; H, 4.49; N, 7.34; I, 66.5. Found: C, 18.91; H, 4.63; N, 7.25; I, 65.0.

The iodide analysis was determined by a Volhard titration.

N,N,N′,N″,N″-Pentamethyldiethylenetriaminehydroboron(2+) Hexafluorophosphate

A total of 3.05 g (9.39 mmol) of trimethylaminediiodoborane was treated with 5 ml of pentamethyldiethylenetriamine (21 mmol) in 5 ml of benzene and the mixture was stirred for 18 h at 45°. The solid product was collected by filtration and dried *in vacuo*. Yield of the iodide, 0.301 g (7.9% theory). The hexafluorophosphate salt was precipitated and was purified by recrystallization from a mixture of acetonitrile and water, m.p. 211–213° (decomp.).

Anal. Calcd. for $C_9H_{24}BN_3^{2+}.2PF_6^-$ (475.05): C, 22.75; H, 5.09; N, 8.84. Found: C, 22.73; H, 5.32; N, 8.81.

Tris(trimethylaminedihydro)-μ3-N,N′,N″-(N,N,N′-N″,N″-pentamethyldiethylenetriamine)triboron(3+) Hexafluorophosphate

A 5.00 g (25.2 mmol) sample of trimethylamine-monoiodoborane was dissolved in about 50 ml benzene, and the solution treated with 20 ml of a benzene solution containing 0.726 g (4.19 mmol) of pentamethyldiethylenetriamine. After the mixture was stirred for 14 h at room temperature, the product was collected by filtration and dried *in vacuo*. Yield of the iodide, 2.35 g (73% theory). The PF_6^- salt was prepared and purified by recrystallization from hot water, m.p. (sealed capillary) 170–171° (decomp.).

Anal. Calcd. for $C_{18}H_{56}B_3N_6^{3+}.3PF_6^-$ (824.01): C, 26.24; H, 6.85; N, 10.20; P, 11.28. Found: C, 26.12; H, 6.71; N, 9.95; P, 11.07.

When the reaction was carried out using an excess of the triamine, the same product was formed in lower yield.

Bis(trimethylaminedihydro)-μ-N,N′-(N,N′-dimethylpiperazine)diboron(2+) Hexafluorophosphate

A 4.00 g (20.1 mmol) sample of trimethylaminemonoiodoborane was dissolved in 25 ml of dry benzene

under dry nitrogen and treated with 15 ml of a benzene solution containing 0.575 g (5.03 mmol) of dimethylpiperazine. The mixture was stirred at room temperature overnight. The product was collected by filtration and converted to the hexafluorophosphate salt which was purified by precipitation from dichloromethane solution *via* the addition of petroleum ether. Yield, 0.91 g (33% theory); m.p. (sealed capillary) 191.5–192.5° (decomp.).

Anal. Calcd. for $C_{12}H_{36}B_2N_4^{2+}.2PF_6^-$ (547.99): C, 26.30; H, 6.62; N, 10.22; P, 11.30. Found: C, 26.14; H, 6.66; N, 10.12; P, 11.07.

Bis(trimethylaminedihydro)-μ-N,N'-(1,4-diazabicyclo-(2.2.2)octane)diboron(2+) Hexafluorophosphate

A total of 5.00 g (25.2 mmol) of trimethylamine-monoiodoborane was dissolved in 30 ml benzene, and the flask was purged with dry nitrogen. A solution of 0.705 g (6.29 mmol) triethylenediamine in 30 ml benzene was added by means of an addition funnel. The solution was boiled under reflux for 2 h and then was allowed to stand at room temperature overnight. Yield of the iodide, 1.79 g (55.8% theory). The hexafluorophosphate salt was prepared, recrystallized from hot water, and dried *in vacuo*, m.p. 179.5–180.0° (decomp.).

Anal. Calcd. for $C_{12}H_{34}B_2N_4^{2+}.2PF_6^-$ (545.98): C, 26.40; H, 6.28; N, 10.26; P, 11.35. Found: C, 26.17; H, 6.42; N, 10.10; P, 11.07.

The experiment was repeated using an excess of triethylenediamine and the same product was obtained in lower yield.

Bis(trimethylamineiodohydro)-μ-N,N'-(1,4-diazabicyclo-(2.2.2)octane)diboron(2+) Hexafluorophosphate

A total of 1.49 g (13.3 mmol) of triethylenediamine was added to 7.14 g (22.0 mmol) of trimethylamine-diiodoborane in 30 ml benzene. The mixture was stirred at 30° for 12 h. The product was recovered by filtration and dried *in vacuo*. Yield, 2.05 g of the iodide salt (24.5% theory); m.p. 179–181° (decomp.). A hexafluorophosphate salt was obtained and was purified by recrystallization from hot water, m.p. 278–279° (decomp.).

Anal. Calcd. for $C_{12}H_{32}B_2I_2N_4^{2+}.2PF_6^-$ (797.77): C, 18.06; H, 4.04; N, 7.02. Found: C, 18.26; H, 3.97; N, 6.84.

Polymeric diazabicyclo(2.2.2)octanetrimethylamine-hydroboron(2+) Iodide

An 11.08 g (34.1 mmol) sample of trimethylamine-diiodoborane was dissolved in 100 ml benzene. A total of 5.67 g (51 mmol) of triethylenediamine was added slowly and the mixture was boiled under reflux for 40 h. Yield of the iodide, 13.62 g (93.8% theory); m.p. 164–171°, 171–180° (decomp.).

Anal. Calcd. for $C_{84}H_{208}B_{10}I_2N_{28}{}^{18+}.18I^-$: C, 23.70; H, 4.93; N, 9.21. Found: C, 23.81; H, 4.90; N, 9.21.

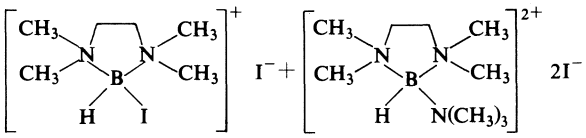
The theoretical analytical data are calculated assuming a chain length corresponding to ten boron atoms. The tetraphenylborate salt was formed by the addition of sodium tetraphenylborate to an aqueous solution of the iodide salt, m.p. 187–189° (decomp.).

Anal. Calcd. for $C_{84}H_{208}B_{10}I_2N_{28}{}^{18+}.18(C_{24}H_{20}B^-)$: C, 80.29; H, 7.42; N, 5.08; I, 3.29. Found: C, 63.87; H, 6.47; N, 6.46; I, 18.00.

Results and Discussion

Nucleophilic displacement by polyfunctional amines at four-coordinate boron in haloborane-amines may proceed by inter- and intramolecular pathways, and as expected, the dominant path is dependent on the nature of the substrate and on reaction conditions. Where chelation is possible, this route is generally favored when excess amine is employed. Thus, displacement in $(CH_3)_3NBHI_2$ with TMED in stoichiometric excess gives rise to chelation products **1** and **2**, essentially to the exclusion of a dinuclear complex.

[1] $(CH_3)_3NBHI_2 \xrightarrow[\text{(excess)}]{\text{TMED}}$



1 **2**

In a limited study of those reaction conditions favoring individual chelation products, it was found that the dipositive ion, **2**, was the only isolable product when the diiodoborane was employed in excess or when the reaction was carried out in refluxing benzene or refluxing neat TMED. Yields of **1** were improved when a large excess of TMED was employed and when a reaction temperature $< 60°$ was maintained (Table 3). It should be noted, however, that since the combined yields of **1** plus **2** were low in nearly all cases, a highly definitive statement on conditions affecting relative yields is not possible.

With $(CH_3)_3NBH_2I$ as a substrate, the hydride counterpart of **1**, namely, $TMEDBH_2{}^+I^-$ is obtained, and the *B*-bromo analog is formed from the reaction of TMED with $(CH_3)_3NBHBr_2$ (5). The fact that the bromide salt of the dipositive ion, **2**, was not observed in the reaction of the dibromoborane adduct with TMED is presumably due to bromide ion being a poorer leaving group than iodide. Moreover, **2** would not be expected to form via displacement in $(CH_3)_3NBH_2I$ since this would require the departure of the even poorer leaving group, H^-.

Unlike its *B*-bromo analog, complex **1** behaves as a moderately strong acid. A 0.011 *M* aqueous solution of this iodide salt exhibits a p*H* = 4.2. One equivalent of base is consumed on titration

TABLE 3. Product distribution for reaction of TMED with $(CH_3)_3NBHI_2$

Condition	Time (h)	Temperature (°C)	Recover yield, %* 1	2
20 ml TMED added to 6.00 g trimethylamine-diiodoborane in 10 ml benzene	24	51	20.1	—
3.57 g trimethylamine-diiodoborane dissolved in 35 ml neat TMED	24	55	4.3	—
10 ml TMED added to 6.00 g trimethylamine-diiodoborane dissolved in 10 ml benzene	24	56	12.2	11.0
	18	75	6.2	46.9
	3	80	—	31.8
	5	80	—	32.3
0.46 g TMED added to 3.48 g trimethylamine-diiodoborane dissolved in 10 ml benzene	44	65	—	3.4

*Products were separated and unreacted diiodoborane was recovered. Yields are based upon amounts of reacted diiodoborane.

[2] 
1 3

to the first (sharp) equivalence point (Fig. 1) and on further titration, a second equivalent is taken up with the development of a more gradual endpoint analogous to that obtained on neutralization of boric acid in the absence of a complexing agent such as mannitol or glycerol. Further, treatment of the iodide salt of **1** with $AgNO_3$ results in precipitation of all contained halogen (including boron-bonded iodine) as opposed to precipitation of only ionic bromide in the corresponding bromide salt of the *B*-bromo chelate. As a tentative explanation, it is suggested that the boron bonded iodine, unlike bromine, is relatively labile and that the acidity of complex **1** is due to hydrolytic dissociation.

There is no direct evidence for the *B*-hydroxo cation **3**, although it might be speculated that such a species is responsible for the consumption of a second equivalent of base (through the B—OH function). Addition of mannitol after the first equivalence point does not lower the p*H* of the solution, indicating that boric acid itself has not been formed. From Fig. 1, the pK_a of the more weakly acidic species is estimated to be 9.2. Conductivity measurements on aqueous solutions of **1** give a value for the molar conductance of 241 ohm^{-1}. This is in excess of the range of values expected for a 1:1 electrolyte, further suggesting that cation **1** may be partially dissociated in solution.

The reaction of excess pentamethyldiethylenetriamine (PMDT) with $(CH_3)_3NBHI_2$ resulted in successive intramolecular substitution to give (in low yield) the iodide salt of the chelated ion, **4**. This may reflect a somewhat greater tendency

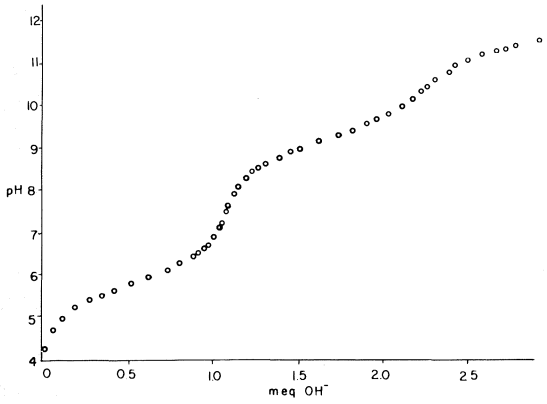


FIG. 1. Titration of 0.426 g (1.12 mmol) of (TMED)-$BHI^+.I^-$ with 0.120 *N* NaOH.

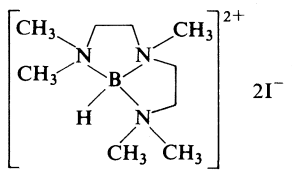

4

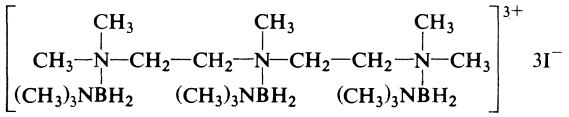
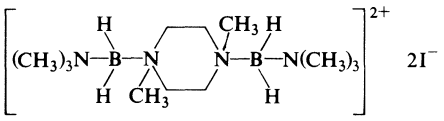
for chelation to occur with the diiodo adduct relative to the monoiodoborane, since the only isolable product obtained from the reaction of this triamine with $(CH_3)_3NBH_2I$ was one arising from intermolecular displacement, namely the trinuclear complex **5**.



5

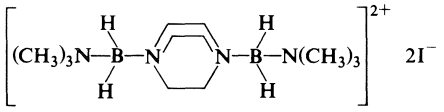
When dimethylpiperazine was reacted with a stoichiometric excess of the monoiodoborane, the dinuclear complex **6** was formed.



6

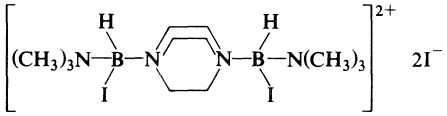
A bicyclic chelated boron(1+) ion containing dimethylpiperazine has been recently reported elsewhere (7).

With nitrogen at bridgehead positions as in diazabicyclo(2.2.2)octane (triethylenediamine), intramolecular substitution with chelation is precluded. The reaction of this difunctional nucleophile with $(CH_3)_3NBH_2I$ gave the dinuclear complex **7**.



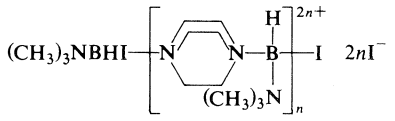
7

With the diiodoborane at 30°, the corresponding *B*-iodo derivative **8** was obtained.



8

When the latter reaction is carried out with excess diamine in refluxing benzene, the formation of what is believed to be a polynuclear complex **9** occurs.



9

The theoretical analytical data for the polyion have been calculated assuming an average chain length corresponding to ten boron atoms, since at about this length, the analytical data change very slightly with change in size of the polymer. The ^1H n.m.r. spectrum of **8** shows a 3:2 ratio of methyl to methylene protons, while in the polymer, this ratio is about 5:6. This integration also is consistent with a polymer containing about ten boron atoms. The ratio would be expected to approach 3:4 as the length of the polymer chain becomes large. The tetraphenylborate salt of **9** was difficult to obtain in high purity as evidenced by the high iodine content and other discrepancies in the analytical data for this salt, as well as by the low intensity of the signal attributed to the phenyl protons of the $(C_6H_5)_4B^-$ ion in the ^1H n.m.r. spectrum. This is probably a result of the co-precipitation of I^- on formation of the insoluble tetraphenylborate salt. Such co-precipitation also has been observed during the isolation of other boron–nitrogen polyions prepared by vinyl polymerization reactions (9).

This research was supported by the Office of Saline Water, Grant No. 14-01-0001-2175 and by the Robert A. Welch Foundation and the Texas Christian University Research Foundation. Mr. Dennis L. Deavenport assisted in obtaining the n.m.r. spectra.

Borane Adducts of Hydrazines and (Trifluoromethylphosphino) Hydrazines: a Nuclear Magnetic Resonance Study

L. K. PETERSON AND G. L. WILSON

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 17, 1971

Direct reactions between BX_3 (X = Me, F, Cl) and the methylhydrazines $MeNHNH_2$, Me_2NNH_2, Me_2NNHMe, and Me_2NNMe_2 yield 1:1 adducts in all cases except (*a*) BMe_3 and Me_2NNMe_2, which do not react; (*b*) BCl_3 and $MeNHNH_2$, Me_2NNH_2 or Me_2NNHMe, which result in hydrazinolysis of the B—Cl bond; and (*c*) BCl_3 with Me_2NNMe_2, which yields a dark brown, viscous liquid. However, the unstable 1:1 adducts $Me_2NNH_2BCl_3$ and $Me_2NNHMeBCl_3$ were prepared in solution, but were not isolated. On the basis of n.m.r. studies, it is concluded that adduct formation occurs at the more highly methylated nitrogen atom of Me_2NNH_2 and Me_2NNHMe; for $MeNHNH_2$, two isomeric adducts are formed with BF_3, in a 5:1 molar ratio, corresponding to complexation at the methylated nitrogen, and at the unsubstituted nitrogen atoms, respectively. A similar study of adduct formation between BX_3 and the trifluoromethylphosphinohydrazines $(CF_3)_2PNMeNMe_2$, $(CF_3)_2PNHNMe_2$, $(CF_3)_2PNMeNH_2$, and $(CF_3)_2PNHNHMe$ indicates that 1:1 adducts are formed in all cases except (*d*) BMe_3 with $(CF_3)_2PNMeNMe_2$, for which no reaction was observed; and (*e*) BCl_3 with $(CF_3)_2PNMeNH_2$ and $(CF_3)_2PNHNHMe$, for which elimination of $(CF_3)_2PCl$ was observed. The adducts are volatile white solids, except $(CF_3)_2PNMeNH_2BMe_3$, which is a colorless liquid at room temperature, and $(CF_3)_2PNMeNMe_2BCl_3$, which is a non-volatile solid. In only one case was it possible to deduce an unambiguous stereochemistry for the adduct from n.m.r. data, *viz.* $(CF_3)_2PNMeNH_2BX_3$, (X = Me, F) where complexation occurs at the terminal, least substituted nitrogen atom. In $(CF_3)_2PNMeNMe_2BF_3$ and in $(CF_3)_2PNHNHMeBF_3$, the NMe and the NMe_2 groups, and the PNH and NNH protons, respectively, are deshielded by the same, or very similar extents, so that an exclusive choice of structure cannot be made.

Les réactions directes entre BX_3 (X = Me, F, Cl) et les méthylhydrazines $MeNHNH_2$, Me_2NNH_2, Me_2NNHMe et Me_2NNMe_2 donnent dans tous les cas des produits d'addition 1:1 excepté: (*a*) BMe_3 et Me_2NNMe_2 qui ne réagissent pas; (*b*) BCl_3 et $MeNHNH_2$, Me_2NNH_2 et Me_2NNHMe ou il y a hydrazinolyse de la liaison B—Cl; et (*c*) BCl_3 avec Me_2NNMe_2 qui donne un liquide visqueux marron foncé. Toutefois, les produits d'addition 1:1 instables $Me_2NNH_2BCl_3$ et $Me_2NNHMeBCl_3$ ont été préparés en solution mais n'ont pas été isolés. Des études r.m.n. ont permis de conclure que la formation du produit d'addition se fait sur l'atome d'azote le plus complètement méthylé de Me_2NNH_2 et Me_2NNHMe. Pour $MeNHNH_2$, deux produits d'addition isomères se forment avec BF_3 dans le rapport molaire 5:1 ce qui correspond respectivement à la complexation sur l'azote méthylé et aux atomes d'azote non substitués. Une étude semblable de formation de produit d'addition entre BX_3 et les trifluorométhylphosphinohydrazines $(CF_3)_2PNMeNMe_2$, $(CF_3)_2PNHNMe_2$, $(CF_3)_2PNMeNH_2$, et $(CF_3)_2PNHNHMe$ indique que les produits d'addition 1:1 se forment dans tous les cas excepté pour (*d*) BMe_3 avec $(CF_3)_2PNMeNMe_2$ où aucune réaction n'est observée et; (*e*) BCl_3 avec $(CF_3)_2PNMeNH_2$ et $(CF_3)_2PNHNHMe$ pour lesquels on observe l'élimination de $(CF_3)_2PCl$. Les produits d'addition sont des solides volatiles blancs, sauf $(CF_3)_2PNMeNH_2BMe_3$ qui est un liquide incolore à la température ordinaire et $(CF_3)_2PNMeNMe_2BCl_3$ qui est un solide non volatile. Seulement dans un cas, il a été possible de déduire à partir des données r.m.n. une stéréochimie non ambiguë pour le produit d'addition, $(CF_3)_2PNMeNH_2BX_3$ (X = Me, F). Dans ce cas, la complexation se fait sur l'atome d'azote terminal, le moins substitué. Dans le cas de $(CF_3)_2PNMeNMe_2BF_3$ et de $(CF_3)_2PNHNHMeBF_3$, les groupes NMe et NMe_2 et les protons des groupements PNH et NNH, respectivement, sont déplacés avec des valeurs semblables ou très proches ce qui ne permet pas un choix exclusif de structure.

Discussion

The phosphinohydrazine skeleton, P—N—N, is potentially tribasic, with the two nitrogen atoms able to function as σ donors, while both σ and π acceptor capacity are possible for the phosphorus atom (1). In the case of (phenylphosphino) hydrazines $R_nP(NR'NMe_2)_{3-n}$ (n = 1, 2; R = C_6H_5; R′ = H, Me), studies of alkylation and chloramination reactions have shown that the phosphorus atom is more basic than either of the nitrogen atoms; the corresponding hydrazinophosphineoxides $R_nP(O)(NR'NMe_2)_{3-n}$ do not undergo alkylation or chloramination, indicating that both nitrogens are unreactive toward electron acceptor species (2). Similarly, adduct formation with boranes (3) and with carbonium species (2, 3) takes place at the phosphorus atom; surprisingly, even the terminal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nitrogen atom is unreactive toward electron acceptor molecules. Likewise, as in the case of aminophosphines, it is the phosphorus, rather than the nitrogen atom, that functions as the donor site toward acceptors based on boron (4), aluminum (5), phosphorus (6), carbonium (7), and transition metal species (8). Such findings are in keeping with the fact that trimethylphosphine is the most basic, toward BF_3, of the trimethyl derivatives of Group V elements (9). In the case of the P—N—N skeleton of $(CF_3)_2PNR'NMe_2$, one might expect diminished basicity of P due to the electronegative CF_3 substituents, and diminished basicity of the central N atom, due to π-bonding with phosphorus, thus leaving the terminal N atom as the most basic site in the molecule. This situation might be expected to preserve the P—N bond against cleavage reactions (10, 11) commonly found with aminophosphines and acidic species such as HCl (10), BF_3, and BCl_3 (12). However, if the lone pairs of electrons on the hydrazine moiety reside in essentially delocalized molecular orbitals, then the deactivating effect of the $(CF_3)_2P$ group may be transmitted to the terminal N atom as well. In order to resolve these speculations, the formation and stereochemistry of the adducts of a series of methylhydrazines, and of trifluoromethylphosphinohydrazines were studied, using mainly n.m.r. techniques.

The chemical shift for a given nucleus depends on several factors: (*a*) diamagnetic shielding caused by the electron cloud about the nucleus, (*b*) bulk diamagnetic susceptibility effects, (*c*) neighboring group anisotropic shielding, (*d*) intramolecular electric field effects, and (*e*) intermolecular interactions (13). By using internal reference standards, the need to correct for (*b*) was avoided. The effects (*c*) and (*d*) were assumed to be constant within each series of adducts studied. The solvent–solute and solute–solute interactions (*d*) may influence the chemical shift in terms of solvent, concentration, and temperature effects; variations among such effects were minimized by standardizing the experimental conditions for each series of adducts.

The possibility of exchange, for pure 1:1 adduct in solution, and for adduct in the presence of excess base, was checked using variable temperature n.m.r. studies.

Adducts of Amines and Hydrazines

A study of n.m.r. data pertaining to the adducts of ammonia and methylamines with BMe_3 and BF_3 shows that the latter acid is always more deshielding than the former; for the adjacent proton H—N→BX_3, the difference between the effects of BF_3 and BMe_3 is ~1.0 τ, whereas, for protons remote by two bonds, *e.g.* in H_3C—N→BX_3, the difference is ~0.2 τ (14).

The experimental n.m.r. data for hydrazines and their BX_3 adducts is collected in Table 1. A study of exchange processes indicated that, for the system $Me_2NNHMeBX_3 + Me_2NNHMe$ (X = Me, F, Cl), exchange was slowed by cooling to 10°; both intra- and intermolecular exchange of BX_3 among the basic centers is possible. For $Me_2NNH_2BMe_3 + Me_2NNH_2$, two separate signals for the NMe_2 groups of complexed and uncomplexed species were observed at −45°, the coalescence temperature being −25°. Thus an exchange rate $>25\ s^{-1}$ at room temperature is indicated (15). For $Me_2NNH_2BX_3 + Me_2NNH_2$ (X = F, Cl), separate signals for complexed and uncomplexed species were observed at +35°; for comparison within the set, measurements were made at −45°.

As for the methylamines, deshielding effects within the adducts of hydrazines, >N—N(R)-
| |
BX_3 and R—N—N→BX_3, are likewise trans-
|
mitted throughout the molecule, presumably with diminishing intensity as the number of intervening bonds increases. The NH chemical shifts, however, appear to be extremely sensitive to traces of moisture, and are therefore less reliable for stereochemical interpretations than data obtained for MeN protons. In $Me_2NNHMeBX_3$, the major deshielding effect occurs at the Me_2N group, indicating complexation at the more substituted N atom, *viz.*, $X_3B{\cdot}Me_2NNHMe$. In $Me_2NNH_2BX_3$, however, both the NH_2 and Me_2N protons experience substantial deshielding; the results for the NH_2 group were variable, depending upon the efficacy of drying. The data for the Me_2N group was comparable to that for the corresponding group in the BX_3 adducts of Me_2NNHMe, suggesting similar structures for the two complexes *viz.*, $X_3B{\cdot}Me_2NNHMe$.

The room temperature ^1H n.m.r. spectrum of $MeNHNH_2$ consists of two sharp peaks, of equal intensity, at 6.77 and 7.41 τ, corresponding to exchanging NH and NH_2 protons and to the Me group, respectively. At +39°, a 1:1 molar mixture of $MeNHNH_2$ and BMe_3 shows the same band at 7.41 τ for the MeN group, while a broad band

*Chemical shifts were measured, using ~10% solutions, relative to (*a*) internal TMS; (*b*) external TMS, for ^1H nuclei (τ for TMS = 10.00); and (*c*) relative to external $CFCl_3$, for ^{19}F nuclei.
†Temperature dependent ^1H spectrum; see Discussion.
‡The NH peaks assigned thus: for $F_3BNH(Me)NH_2$, τ(NH), 1.85; (NH_2), 6.70; for $MeNHNH_2BF_3$, τ (exchanging NH and NH_2), 2.62; see Discussion.
§The MeN peaks assigned thus: $F_3BNH(Me)NH_2$, 7.33; $MeNHNH_2BF_3$, 7.23 τ; see Discussion.
‖The ^{19}F peaks assigned thus: $F_3BNH(Me)NH_2$, 159.2 p.p.m. J_{BF}, 1515 Hz; $MeNHNH_2BF_3$, 151.6 p.p.m., J_{BF}, 17.0 Hz; BF_4^- 149.3 p.p.m., J_{BF}, 1.0 Hz; see Discussion.
¶The B–F coupling constants were: for $Me_2NNH_2BF_3$, J_{BF}, 13.5 Hz; for $Me_2NNHMeBF_3$, J_{BF}, 14.2 Hz.

appears at 6.03 τ for the exchanging NH and NH_2 protons; at −40°, the spectrum consists of two doublets (mid points, 6.27 and 7.35 τ), in the intensity ratio 2:3. At the low temperature, it appears that exchange between NH and NH_2 has ceased, thus permitting coupling between the NH proton and (*a*) the MeN group (J_{NNCN} 5.8 Hz), and (*b*) the NH_2 group (J_{HNNH} 4.5 Hz). The theoretical 12-line spectrum of the NH proton was not observed. Similarly, at 39°, the spectrum for a mixture of $MeNHNH_2BMe_3$ and $MeNHNH_2$ (1:2 molar ratio) consisted of two peaks, indicative of equivalent NMe protons and equivalent NH and NH_2 protons. Thus the adduct is either fully dissociated at 39°, or rapid intermolecular exchange of BMe_3 amongst the hydrazine molecules is present. At −40°, however, the bands for complexed and uncomplexed species are distinguished. The bands were assigned on the basis of their relative intensities and the known composition of the mixture. Surprisingly, the signal for MeN (complexed) appears upfield relative to MeN (uncomplexed); an enhancement of hydrogen bonding interactions between complexed and free hydrazine may account for the deshielding of the free base, and may compensate for the deshielding, due to the BMe_3 moiety, within the complexed molecule.

The reaction of BF_3 with $MeNHNH_2$ gives a white crystalline adduct which is insoluble in $CDCl_3$, in CH_2Cl_2, and CH_2Cl_2, but dissolves in DMSO. The latter solvent, unfortunately, is unsuitable for low temperature n.m.r. studies. Both the ^1H and ^{19}F n.m.r. spectra are consistent with the presence of two isomers, (*a*) $F_3B{\cdot}MeNHNH_2$ and (*b*) $MeNHNH_2{\cdot}BF_3$, in a 5:1 molar ratio.

The ^1H n.m.r. spectrum consisted of bands which were assigned to MeN and to NH protons: two signals at 7.33 and 7.23 τ, in a 5:1 intensity ratio, corresponded to the MeN protons of isomers (*a*) and (*b*), respectively. The former signal is a poorly resolved 1:1:1:1 quartet, indicating coupling to the spin 3/2 ^{11}B nucleus (J_{BNCH} ~1.50; *cf.* J_{BNCH} for Me_3NBF_3, 1.54; for Me_2NHBF_3, 1.79; for $MeNH_2BF_3$, 2.05 Hz (14)). The three broad NH signals were assigned on the basis of their integrated intensities. Two bands for isomer (*a*) (at 6.70 (NH_2 group), and 1.85 τ (NH)) indicated the absence of exchange among the NH protons, whereas only one band (at 2.62 τ) indicated rapid intramolecular exchange among the corresponding protons of isomer (*b*); the intensity ratio was 2:1:3 for the three bands. The addition of excess $MeNHNH_2$ to a solution of the adduct gave rise to singlet MeN (at 7.43 τ) and NH (4.88 τ) signals, indicating rapid intermolecular exchange at +39°. The ^{19}F spectrum consisted of two major bands and an impurity band, the latter

$(CF_3)_2PNHNHMe$ **4**	Taken	0.535 (**4**) : 0.529	1.276 (**4**) : 1.270	*[c]

*In all cases, volatile white solid 1:1 adducts were formed, except (*a*) $(CF_3)_2PNMeNMe_2 + BMe_3$, no evidence for adduct formation; (*b*) $(CF_3)_2PNMeNH_2 + BMe_3$, a colorless liquid 1:1 adduct; (*c*) in reactions between BCl_3 and $(CF_3)_2PNMeNH_2$ or $(CF_3)_2PNHNHMe$, the B—Cl bond was solvolyzed in preference to adduct formation; (*d*) $(CF_3)_2PNMeNMe_2 + BCl_3$, white, non-volatile 1:1 adduct.

†The adducts, or the component mixtures, were soluble in $CDCl_3$ and in $CFCl_3$.

‡Reactions were carried out: (*a*) in the absence of solvent; (*b*) in toluene; (*c*) in cyclohexane; (*d*) in chlorobenzene.

§For n.m.r. studies, the adduct was prepared in situ in an n.m.r. tube; a solution of the adduct in $CFCl_3$ slowly yielded a dark brown liquid, immiscible with $CFCl_3$.

‖A solution of the adduct in $CFCl_3$ slowly turned brown, and precipitated a white solid.

indicating the presence of a small amount of BF_4^- (a 1:1:1:1 quartet, δ at 149.3 p.p.m.; J_{BF} 1.0 Hz; spectrum for authentic BF_4^-, 149.8 p.p.m. and 1.0 Hz (16)). The main bands, in a 5:1 intensity ratio, were assigned to isomers (*a*) (δ, 150.2 p.p.m.; J_{BF} 15.5 Hz) and (*b*) (δ, 149.3 p.p.m.; J_{BF} 17.0 Hz), respectively; the higher field ^{19}F shift for isomer (*b*) is in accord with the expected greater basicity of the MeN center. The J_{BF} coupling constant is sensitive to the steric environment of the four coordinate nitrogen atom (*cf.* $Me_3N{\cdot}BF_3$, J_{BF} 13.8; $NH_3{\cdot}BF_3$, 13.8; $Me_2NH{\cdot}BF_3$, 15.5; $MeNH_2{\cdot}BF_3$, 15.7 Hz; (14)).

Adducts of Phosphinohydrazines

The (trifluoromethyl)phosphinohydrazine borane adducts were prepared by the reaction of BX_3 (X = Me, F, Cl) with the appropriate phosphinohydrazine dissolved in an inert solvent. Experimental details are summarized in Table 2.

The adducts of $(CF_3)_2PNMeNMe_2$ (**1**), $(CF_3)_2PNHNMe_2$ (**2**), $(CF_3)_2PNMeNH_2$ (**3**), and $(CF_3)_2PNHNHMe$ (**4**) with BX_3 (X = Me, F, Cl) vary in stability, both with respect to dissociation and with respect to chemical reaction. Thus $(CF_3)_2PNRNR'R''{\cdot}BCl_3$ adducts[1] undergo cleavage reactions, slowly for compounds **1** and **2**, but rapidly for **3** and **4**. In spite of the potential polybasic nature of the donor molecule, only 1:1 adducts were observed. The stoichiometry and stereochemistry of adduct formation were deduced from the n.m.r. spectra, and from determinations of the reaction ratios. In all cases the deshielding of the P atom, as measured by changes in the ^{19}F chemical shifts of the $(CF_3)_2P$ group upon complexation of the phosphinohydrazines, was relatively small (Table 3). Considerable deshielding effects were observed for protons attached directly, or indirectly via carbon, to the N atoms. The weak basicity of the P atom must be due to the electronegative CF_3 groups, which effectively reduce basicity in molecules such as $(CF_3)_2PMe$ and $(CF_3)_3P$. Of the two nitrogen atoms, one may be designated as "central", and the other as "terminal", within the P—N—N skeleton. The possible structures of complexes are illustrated in Fig. 1. These structures may be distinguished by the fact that BX_3 may be adjacent to, or one atom removed from, the (P)NR or (N)NR′R″ (R, R′, and R″ = H or Me) groupings. In theory, the actual location of the BX_3 group may be revealed by the observable deshielding effects on R or R′, on the basis that the order of deshielding will be: adjacent protons > protons remote by one bond > protons remote by two bonds.

As in the case of amines and hydrazines, more effective deshielding of N—H and N—CH_3 protons in the phosphinohydrazines is brought about by adduct formation with BF_3 than with BMe_3.

*Measurements were made using ~10% solutions in (*a*) $CDCl_3$, (*b*) $CFCl_3$.
†The ^{1}H chemical shifts are given relative to internal TMS, $\tau = 10.00$; ^{19}F shifts are given in p.p.m. relative to internal $CFCl_3$; coupling constants are reported in Hz.
‡A doublet, coupling not assigned.
§Temperature dependent signals; a doublet at +39°, with $J = 5.0$ Hz; coalescence temperature, 49°.
‖Temperature dependent signals: at +39°, a doublet of quartets, J_{F-F}, 8.0; first quartet, J_{PCF}, 86.0; second quartet, J_{PCF}, 87.0 Hz; coalescence temperature, 72°.

In many cases, however, the deshielding effect is transmitted to both of the N atoms of the hydrazine moiety, to essentially the same extent, so that a choice of structure cannot be made; for example, the NMe and NMe_2 groups in $(CF_3)_2PNMeNMe_2BF_3$, and the PNH and NNH protons in $(CF_3)_2PNHNHMeBF_3$, are deshielded to the same, or very similar, extents.

The band for the NMe protons in $(CF_3)_2PNMeNMe_2$, and in its adduct with BF_3, consists of two overlapping septets, indicative of coupling with the ^{31}P and ^{19}F nuclei. The NMe_2 group appears as a single absorption, devoid of fine structure. In $(CF_3)_2PNMeNMe_2BCl_3$, however, only one septet is present for the NMe protons, suggesting through-space coupling as the mechanism of the proton-fluorine interaction, while the band for the NMe_2 protons consists of a doublet (J(?)[2] 1.4 Hz). With $(CF_3)_2PNHNMe_2$ and its adducts, coupling between the ^{31}P nucleus and the NH proton is observed only for $(CF_3)_2PNHNMe_2BF_3$, suggesting coordination at the NH site. The possibility of a π-complex type of structure (Fig. 2), as has been suggested for hydrazine alane-complexes (17), cannot be excluded. In only one case, *viz.* $(CF_3)_2PNMeNH_2$-

		No evidence for adduct formation		Colorless, non-volatile liquid adduct; insoluble in DCl_3, CH_2Cl_2; soluble in DMSO‡	

*Details are given for reactions performed in the absence of solvent; similar results were obtained for reactions carried out in solution.
†Reactions between (*a*) BCl_3 and $MeNHNH_2$ resulted in hydrazinolysis of the B—Cl bond; (*b*) BCl_3 and Me_2NNH_2 or Me_2NNHMe gave unstable 1:1 adducts only from reactions carried out in solution in cyclohexane; the adducts were insoluble in $CDCl_3$ and in CH_2Cl_2, but dissolved in DMSO; (*c*) BCl_3 and Me_2NNMe_2 proceeded vigorously at −33°, giving a dark brown viscous liquid, insoluble in $CDCl_3$ and CH_2Cl_2 but soluble in DMSO.
‡On standing, the solution became dark brown.
§This quantity, and those directly below, indicate mmoles of methylhydrazine taken.

BX_3 (X = Me, F) was it possible to deduce the stereochemistry of the adduct. The dominant deshielding effect occurs at the NH_2 protons, and of all adducts of phosphinohydrazines studied, the deshielding (by BF_3) of NH protons is greatest in this case. Thus the preferred structure involves complexation at the terminal, least substituted nitrogen atom (Fig. 3). With isomeric $(CF_3)_2$-PNHNHMe, where the central N atom is less sterically constrained, deshielding in the BX_3 adducts is experienced by both N atom centers. With $(CF_3)_2PNMeNMe_2$ and BMe_3, the absence of interactions associated with adduct formation was noted; indeed, a study with models showed severe steric crowding in the possible 1:1 adducts with BMe_3, but not with BF_3. A study of the shielding of the BX_3 moiety upon complexation reveals differing requirements for BMe_3 and BF_3: thus the largest shielding effect on BMe_3 occurs with $(CF_3)_2PNHNHMe$, whereas, in the case of BF_3, it is with $(CF_3)_2PNHNMe_2$. The greater steric requirements of the NMe_2 group, relative to NHMe, may be compensated by the possibility for hydrogen bonding in the BF_3, but not in the BMe_3, adduct (Fig. 3).

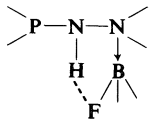

FIG. 3. Phosphinohydrazine–BF_3 structure showing hydrogen bonding.

Experimental

All materials were handled using a high vacuum system or a dry, inert atmosphere system. Hydrazine, methylhydrazine, and 1,1-dimethylhydrazine (K & K Chemicals) were dried over anhydrous barium hydroxide and further purified by low temperature column distillation and by vacuum fractionation. Trimethylhydrazine and tetramethylhydrazine were prepared and purified by the method of Class *et al.* (18). Trimethylboron, prepared by the method of Brown (19), boron trifluoride (Allied Chemicals), and boron trichloride (K & K), tetramethylsilane (Stohler Isotope Chemicals), and trichlorofluoromethane (Matheson, Coleman, and Bell) were purified by vacuum fractionation. Phosphinohydrazines were made according to published methods (20). Solvents were rigorously dried by standard methods, and purified by distillation or by vacuum fractionation.

The n.m.r. spectral measurements were made using a Varian A56/60 n.m.r. spectrometer, fitted with a Varian V-6057 variable temperature system which allowed spectral measurements from −60 to +200 °C. Temperature calibration was achieved using methanol or ethylene glycol.

Preparation of Adducts

Adducts were prepared in cold finger attachments on the vacuum system or *in situ* in n.m.r. tubes. In general, the borane was added to the pure hydrazine or phosphinohydrazine, or to a solution of the hydrazine, in the reaction tube; mixtures were allowed to equilibrate at −33° and at room temperature, and products were separated by vacuum fractionation. Volatile adducts were distilled under vacuum into n.m.r. tubes; non-volatile

For personal use only.

derivatives were either prepared *in situ*, or were transferred in solution by means of a syringe, to n.m.r. tubes fitted with syringe caps. Details of experiments are summarized in Table 4. For consistency, n.m.r. measurements were made on solutions of the same concentration (see Table 2).

The Preparation of Some Heterocyclic Analogues of Triptycene

D. M. McKinnon and J. Y. Wong
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

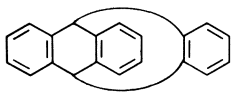
Received May 10, 1971

A variety of anthracenes react with dibenzoylethylene and diacetylethylene to give substituted bicyclooctadienes as Diels–Alder adducts. Treatment of these with phosphorus pentasulfide gives derivatives of benzenonaphtho[*c*]thiophenes, which are thiophene analogues of triptycene. Reaction of the anthracenes with dibenzoylacetylene gave substituted bicyclooctatrienes, which on treatment with phosphorus pentasulfide gave inseparable mixtures of the benzenonaphtho[*c*]thiophenes and benzenonaphtho[*c*]-furans. Attempted retro Diels–Alder reactions of the thiophenes were unsuccessful.

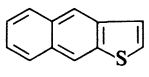
Quelques anthracènes réagissent avec le dibenzoyléthylène et le diacétyléthylène pour donner des bicyclooctadiènes substitués, qui sont des produits de la réaction de Diels–Alder. Le traitement de ces composés par le pentasulfure de phosphore conduit à des benzénonaphto[*c*]thiophènes, qui sont des composés du thiophène analogues au triptycène. La réaction entre les anthracènes et le dibenzoylacétylène conduit à des bicyclooctatriènes, qui par traitement au pentasulfure de phosphore donnent des mélanges non séparables de benzénonaphto[*c*]thiophènes et benzénonaphto[*c*]furannes. Les réactions retro Diels–Alder avec les thiophènes ne donnent aucun résultat.

Canadian Journal of Chemistry, 49, 3178 (1971)

Although the synthesis and properties of the interesting rigid symmetrical hydrocarbon triptycene (**1**) are well known (1), only a few examples are described of heterocyclic analogues, in which one or more of the ortho linked benzene rings are replaced by heterocyclic systems, particularly those with aromatic character. Recently some thiophene analogues have been made (2) by Diels–Alder type additions to naphtho[2,3-*b*]thiophene (**2**), and some 3,4-furo- and 4,5-pyridazo-analogues have been prepared (3*a*, *b*) from anthracene (**3***a*) via its adduct **4***a* with *cis*-dibenzoylethylene. Also, some heterotriptycenes, in which hetero atoms replace one or more bridgehead methine groups have been synthesized (4*a*, *b*).



1



2

As part of our research on benzo[*c*]thiophene derivatives, we became interested in the preparation of these compounds, especially the hitherto unreported thiophene derivatives **5**, since in certain cases these contain the benzo[*c*]thiophene skeleton as an element of structure. The method of Wynberg used for the isomeric benzo[*b*]thiophenes is unsuitable for this type, particularly where monocyclic substituting rings are required. In addition the thiophenes **5** have higher symmetry and are more suitable for some spectroscopic investigations. Also, such compounds are of potential interest in investigations on interannular phenomena, such as have been suggested for triptycene (5, 6) in investigations on the reactivity of bridgehead substituents (6, 7), and as possible precursors of dehydrothiophene. These compounds are conveniently prepared by the following scheme.

trans-Dibenzoylethylene reacted with a variety of substituted anthracenes to give the corresponding dibenzodibenzoylbicyclooctadienes, **4***a–h*. In some cases Lewis acid catalysis by aluminum chloride was used. Treatment of these adducts with phosphorus pentasulfide in pyridine gave the desired thiophenes **5***a–h*, although in rather low yield, probably because of competing Diels–Alder reactions. Indeed when the reaction was attempted in other media only retro Diels–Alder products were obtained. Likewise dibenzoylacetylene reacted with anthracenes to give dibenzoyldibenzobicyclooctatrienes, **6***a–d*. Generally yields of these were better, in accord with its enhanced dienophilic properties compared to dibenzoylethylene. Surprisingly, although related compounds give thiophenes satisfactorily on treatment with phosphorus pentasulfide (8, 9) these adducts gave mixtures whose analyses and spectroscopic properties were consistent with mixtures of the desired thiophenes **5** and the corresponding furans. These could not be separated satisfactorily. Although the conversion

of the adducts **4** to the thiophenes **5** corresponds to a simple well-known thiophene synthesis (10), successful conversion of the adducts **6** must involve a reduction stage, perhaps by loss of sulfur or oxygen. A possible mechanism would proceed via a Cope-type rearrangement of a sulfurized (partially or complete) adduct **6** to a 1,2-thioxin or 1,2-dithiin respectively, which could extrude sulfur, similarly to known reactions (11), to form the furan or thiophene respectively.

7

The preparations of the dibenzoylethylene and dibenzoylacetylene adducts of a variety of substituted anthracenes are summarized in Tables 1 and 2 respectively. The thiophenes **5***a–h* were colorless or pale yellow. Their structures follow from their analyses and mass spectral data. Partly to confirm the structures of the initial dibenzoylethylene adduct, a pyrrole derivative **7** was made by reaction of the adduct **4***a* with ammonium acetate, corresponding to a Paal–Knorr pyrrole synthesis (12, 13).

Acridine was also treated with dibenzoylethylene in an attempt to make a precursor of an azatriptycene analogue, but no adduct could be isolated.

We also attempted to obtain some other heteroanalogues starting from naphtho[2,3-*b*]thiophene (**2**) (14, 15). Unsuccessful attempts had been made to form a triptycene analogue from this by reaction with dehydrobenzene, but this compound is the basis of the successful preparation of Wynberg *et al.* (2). However, reaction with dibenzoylethylene in xylene was unsuccessful.

Attempts were also made to produce compounds without the bulky phenyl substituents on the thiophene ring. Thus anthracene (**3***a*) and 9-methylanthracene (**3***b*) reacted with diacetylethylene to form adducts, **4***i* and *j* respectively. One of these, **4***i*, has been previously reported (16) but with a different melting point. This is possibly due to the existence of optical isomers. Treatment of these with phosphorus pentasulfide in toluene gave the thiophenes, **5***l* and *j* respectively. Sulfurization in pyridine was unsuccessful, possibly due to the formation of base-catalyzed condensation products (16). With 2,5-dimethoxy-2,5-dihydrofuran, which would have permitted synthesis of compounds without substituents in the thiophene ring, anthracene did not form an adduct under any of the conditions tried.

These compounds are probably best named as derivatives of thiophene, although similar compounds have been named as substituted bicyclooctatrienes (3) or as derivatives of the correspon-

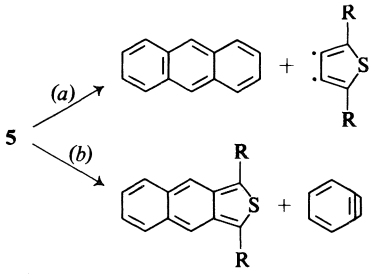
ding polynuclear hydrocarbon (2). Thus the compound **5***a* would be named 1,3-diphenyl-4,9-dihydro-4,9-*o*-benzenonaphtho[2,3-*c*]thiophene. Where the three rings attached to the central methine carbon atoms are different, the compounds will be a mixture of enantiomers.

The n.m.r. spectra of these compounds are consistent with their analyses and properties. The methine protons give sharp singlets in a similar range to those found for triptycene (17, 18) and for a thiophene analogue (2). Values, however, for the compounds with phenyl substituents on the thiophene ring, lie at slightly lower field, probably due to the deshielding effects of the phenyl groups. In the phenanthro-compound **5***g* the shifts of the two methine protons are quite different from each other. In part this may be due to the difference in deshielding by the angularly fused aromatic ring, but it is more probably a steric effect, caused by interference of the 4 and 5 protons. Similar effects have been used to explain low field absorption of the 4,5-protons in phenanthrene (19, 20). The positions of the methine protons in the methyl compounds **5***i* and *j* are slightly higher than for triptycene. This once more probably represents a deshielding due to different effects of the dimethylthiophene compared to a benzene ring. In general the aromatic peaks in these thiophenes **5***a–h* are rather complex, but in the anthra-compound **5***h* a sharp singlet for the 5,10-protons was obtained. These are uncoupled to the other aromatic protons. Similar effects have been observed for the corresponding protons in anthracene and naphthacene (19, 21).

These thiophenes **5** are also of interest in that retro Diels–Alder reactions might provide interesting products. Two possible reactions might be envisaged for the compounds **5**.

Scheme 1*a* might provide a route to 3,4-dehydrothiophenes. Although the formation of some



SCHEME 1

2,3-dehydrothiophenes has been demonstrated (22*a*, *b*) attempted preparation of the former led to products derived from the latter by rearrangement of the dehydrothiophene intermediate. Such rearrangements would be less likely with a 2,5-disubstituted intermediate such as in Scheme 1*a*, and the dehydrothiophene might be detectable, although decomposition to an acyclic diyne, as has been found in a related investigation (23), is also a possibility. Scheme 1*b* is interesting in that it could provide naphtho[2,3-*c*]thiophenes and dehydrobenzene. A similar reaction was proposed by Wynberg *et al.* (2). The dehydrobenzene could be trapped by a suitable diene, or in its absence, might react with the thiophene ring of the naphtho-[2,3-*c*]thiophene with eventual formation of a naphthacene derivative. Cava and VanMeter (24) have shown that in naphtho[2,3-*c*]thiophene Diels–Alder reactions occur in the heterocyclic ring. However, heating a mixture of the thiophene **5***a* and 9-methylanthracene gave substantially unchanged starting materials, along with only traces of other material.

Examination of the mass spectra of these compounds **5***a–d* indicated no significant peaks corresponding to decomposition by Scheme 1*a* or *b*. Apart from the parent peak, there were large peaks corresponding to mass 121, probably Ph·CS. Loss of this may occur by a similar process which leads to loss of HCS from Wynberg's compound (2), and from other thiophenes (25, 26). However, the mass spectra of the 1,3-dimethylcompounds **5***i* and *j* gave large ions for the parent anthracenes and for a mass of 110, which may correspond to decomposition by Scheme 1*a*. A chemical proof of this was sought by heating the thiophene **5***i* with 9-methylanthracene. However, only starting material was isolated, and no anthracene and thiophene **5***j* were obtained. We are forced to conclude that these proposed retro Diels–Alder reactions are not important.

Experimental

The n.m.r. spectra were obtained on a Varian model 56/60A spectrometer in deuterochloroform solution using tetramethylsilane as an internal standard. Mass spectra were obtained on a Finnegan 1015 quadrupole Mass spectrometer. Chromatography was performed on a "Camag" silica gel type D.S.F.5 supplied by Mondray Ltd. as 1 mm layers on glass plates. Development of plates, unless otherwise stated, was carried out using benzene with increasing proportions of chloroform. Melting points (m.p.) were obtained as a Fisher–Johns apparatus.

Reaction of Anthracenes with Dibenzoylacetylene to Form Substituted Dibenzodibenzoylbicyclooctatrienes, 6a–d

Equimolar amounts of the anthracenes and dibenzoylacetylene (27) were refluxed together in suitable solvents for suitable times. The solvents were removed by evaporation and the crude products were purified by chromatography. The results are summarized in Table 1.

Reaction of Anthracenes with trans-Dibenzoylethylene or trans-Diacetylethylene to Form Substituted Dibenzobicyclooctadienes 4a–i

Equimolar quantities of the anthracene and diacetylethylene (28) or dibenzoylethylene were refluxed together in a suitable solvent. In one case, **3***g*, the reaction was performed at room temperature under catalysis by a trace of aluminum chloride. The mixtures were worked up and the products purified by chromatography. The results are summarized in Table 3.

Conversion of Dibenzodibenzoylbicyclooctadienes to the Thiophenes, 5a–h

The diketones were refluxed with a small excess of phosphorus pentasulfide in pyridine for varying times. The mixtures were poured into water, and benzene extraction gave crude products which were purified by chromatography using benzene/petroleum ether as a developing solvent. Under u.v. light, two purple fluorescent bands were evident. The first was the parent anthracene, and the second was the required thiophene. The results are summarized in Table 3. Reaction in other solvents tried gave either retro Diels–Alder reactions or did not give satisfactory results. The n.m.r. spectra are summarized in Table 4.

Sulfurization of Diacetyldibenzobicyclooctadiene (4i, j) to form 1,3-Dimethyl-4,9-dihydro-4,9-o-benzenonaphtho[2,3-c]thiophene (5i, j)

These were prepared as for the previous compounds except toluene was used as a solvent. The products were crystallized from petroleum ether. Results are summarized in Table 3 and n.m.r. data in Table 4.

Sulfurization of Dibenzodibenzoylbicyclooctatriene (6a)

The diketone (0.5 g) and phosphorus pentasulfide (1 g) in pyridine (10 ml) were refluxed for 6 days. The mixture was poured into water and extracted with benzene. The dried extract was examined by chromatography and a colorless band separated. Evaporation gave a colorless amorphous material whose properties were consistent with a mixture of **5***a* and the corresponding furan prepared according to ref. 3.

Similar results were obtained for the compounds **6***b–d*.

Preparation of 1,3-Diphenyl-4,9-dihydro-4,9-o-benzenonaphtho[2,3-c]pyrrole (7)

Dibenzodibenzoylbicyclooctadiene (**4***a*) (0.5 g) and excess ammonium acetate in acetic acid (10 ml) were refluxed for 2½ h. Addition of water precipitated the pyrrole and thorough washing gave analytically pure material m.p. 269–271° (74%).

Anal. Calcd. for $C_{30}H_{21}N$: C, 91.14; H, 5.32; N, 3.54. Found: C, 90.98; H, 5.25; N, 3.49.

The n.m.r. spectrum of **7**, 4.52 (2H singlet, methine protons), 3.33 to 2.60 τ (19H bands, protons on the aromatic ring and proton on nitrogen).

Attempted Reaction of Acridine with trans-Dibenzoylethylene

Acridine (179 mg, 1 mmol) and dibenzoylethylene (236 mg, 1 mmol) in toluene (20 ml) were refluxed for 2 days. Examination of the mixture afforded only unreacted starting material. Different solvents likewise gave unsuccessful results.

Reaction of Naphtho[2,3-b]thiophene with trans-Dibenzoylethylene to Form 8

Naphtho[2,3-*b*]thiophene (276 mg, 1.5 mmol) and dibenzoylethylene (3.56 mg, 1.5 mmol) were heated together in xylene (10 ml) for 48 h. No adduct was obtained.

Attempted Reaction of Anthracene with 2,5-Dimethoxy-2,5-dihydrofuran

Anthracene (330 mg, 2 mmol) and 2,5-dimethoxy-2,5-dihydrofuran (520 mg, 4 mmol) were heated together in a variety of solvents for varying times. Under none of the conditions tried could adducts be isolated.

Attempted Reaction of 9-Methylanthracene and 1,3-Dimethyl-4,9-dihydro-4,9-o-benzenonaphtho-[2,3-c]thiophene

9-Methylanthracene (384 mg, 2 mmol) and the thiophene (288 mg, 1 mmol) were fused together at 240° for 2 h. The t.l.c. examination of the product indicated only unreacted starting material along with traces of other material.

19-Hydroxy Steroids. II. The Synthesis of 3β,5,19-Trihydroxy-5β-cholestane[1]

PETER MORAND AND MORRIS KAUFMAN
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received June 3, 1971

Chemical evidence is presented in support of the structures assigned to the isomeric epoxides **4***a* and **5***a* obtained by peracid oxidation of the double bond in 3β-acetoxycholest-5-en-19-ol (**2***a*). Reduction of 3β-acetoxy-5,6α-oxido-5α-cholestan-19-ol (**4***a*) with lithium aluminum hydride leads exclusively to the C-5 alcohol while reduction of 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) with the same hydride results in the isolation of the C-5 and -6 alcohols in a ratio of 1:5. When an attempt was made to reduce the 5β,6β-epoxide **5***a* with lithium trimethoxyaluminohydride a rearrangement occurred. A structure is postulated for the compound isolated and a mechanism for its formation is discussed.

Des preuves chimiques sont présentées pour prouver les structures attribuées aux époxydes isomères **4***a* et **5***a*, obtenus par oxydation au péracide de la double liaison de l'acétoxy-3β cholestène-5 ol-19 (**2***a*). La réduction de l'acétoxy-3β oxydo-5,6α cholestan-5α ol-19 (**4***a*) par l'hydrure de lithium et d'aluminium conduit exclusivement à l'alcool en C-5 alors que la réduction de l'acétoxy-3β oxydo-5,6β cholestan-5β ol-19 (**5***a*) avec le même hydrure donne les alcools en C-5 et -6 dans un rapport 1:5. Une transposition se produit lorsqu'on tente de réduire l'époxyde-5β,6β, **5***a*, par l'hydrure de lithium triméthoxyaluminium. Une structure est proposée pour le composé isolé et on discute du mécanisme de sa formation.

Canadian Journal of Chemistry, **49**, 3185 (1971)

During the course of our investigation of approaches to the synthesis of cardiac-active steroids containing an oxygen atom at C-19 and hydroxyl groups in the 3β- and 5β-positions (1, 2) we were concerned with preparation of the model compound 3β,5,19-trihydroxy-5β-cholestane (**6***a*). The synthesis of this compound is described in this paper as well as the reactions and stereochemistry of some of the intermediates involved.

Epoxidation of 3β-Acetoxycholest-5-en-19-ol (2a) and of 3β,19-Diacetoxycholest-5-ene (2b)

Henbest and Wilson (3) have shown that hydroxyl groups play an important role in the stereoselective epoxidation of allylic double bonds in six-membered rings. More recently, non-allylic double bonds have been shown (4) to be similarly influenced by neighboring hydroxyl groups. For example, it has been reported that epoxidation of the ethylene ketal of 19-hydroxyandrost-5-ene-3,17-dione with monoperphthalic acid yields the 5β,6β-epoxide exclusively. These results were rationalized by assuming that in the transition state the peracid will be located on the β-side of the molecule because of interaction between the peracid, the hydroxyl group, and the double bond.

We found that, on treatment of 3β-acetoxycholest-5-en-19-ol (**2***a*) with excess monoperphthalic acid in ether, it is possible to obtain both 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) and 3β-acetoxy-5,6α-oxido-5α-cholestan-19-ol (**4***a*). These compounds were isolated in yields of 72 and 14%, respectively. As expected, epoxidation of 3β,19-diacetoxycholest-5-ene (**2***b*) gave predominantly the 5α,6α-epoxide **4***b* along with a significant amount of the 5β,6β-epoxide **5***b*. The structures of these isomeric epoxides were first assigned on the basis of elemental analysis and i.r. and n.m.r. spectra which have been reported elsewhere (1). The chemical reactions described below confirm these configurational assignments.

Treatment of 3β-acetoxy-5,6α-oxido-5α-cholestan-19-ol (**4***a*) with a methanolic solution of hydrogen chloride afforded a compound which was identified as 6β,19-oxido-5α-cholestane-3β,5-diol (**1**). Mass spectral and elemental analyses for this compound indicated an empirical formula of $C_{27}H_{46}O_3$ and the i.r. spectrum showed the characteristic C-19 methylene band (5) of 6β,19-oxides at 1498 cm^{-1}. When 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) was similarly treated with a methanolic solution of hydrogen chloride the product isolated gave a mass spectral analysis consistent with the empirical formula $C_{27}H_{45}ClO_2$ and the i.r. spectrum indicated a 6β,19-oxide (band at 1498

[1]For Part I, see ref. 1

For personal use only.

cm^{-1}). This compound must therefore be 5-chloro-6β,19-oxido-5α-cholestan-3β-ol (**3**) (6) as would be expected from a 5β,6β-epoxide.

Reduction of Diastereomeric Epoxides

In acyclic compounds the reductive opening of epoxides with lithium aluminum hydride generally occurs at the least substituted carbon atom (7) to produce the more highly substituted alcohol. The addition of aluminum chloride has been found (8) to alter the course of such reductions yielding the least substituted alcohol as a product. However, in the case of epoxides in six-membered rings, hydride reduction is complicated by factors implicit in the Fürst–Plattner rule (9). For example, although the lithium aluminum hydride reduction of 5,6α-oxido-5α-cholestane leads exclusively to the C-5 alcohol (10), Hallsworth and Henbest (11) have reported that 5,6β-oxido-5β-cholestane yields both 5β-cholestan-5-ol (60%) and 5α-cholestan-6β-ol (31%) under these conditions. It is apparent that both the Fürst–Plattner rule and steric factors play a role in determining the course of the reduction for such epoxides. More recently Sweet and Brown (12) have shown that polar effects can be considered to influence the course of the lithium aluminum hydride reduction in *cis*- and *trans*-3,4-oxido-2-alkoxytetrahydropyrans.

Treatment of the 5α,6α-epoxide **4***b* with lithium aluminum hydride and acetylation of the product resulted in the isolation of 3β,19-diacetoxy-5α-cholestan-5-ol (**7**) whose empirical formula, $C_{31}H_{52}O_5$, was confirmed by elemental and mass spectral analyses. An examination of the half-band width (28 Hz) of the signal for the C-3 proton in the n.m.r. spectrum of this compound indicated an axial orientation (13). This is consistent with a 5α-hydroxyl group, arising from the reductive opening of the 5α,6α-epoxide in the normal manner (10).

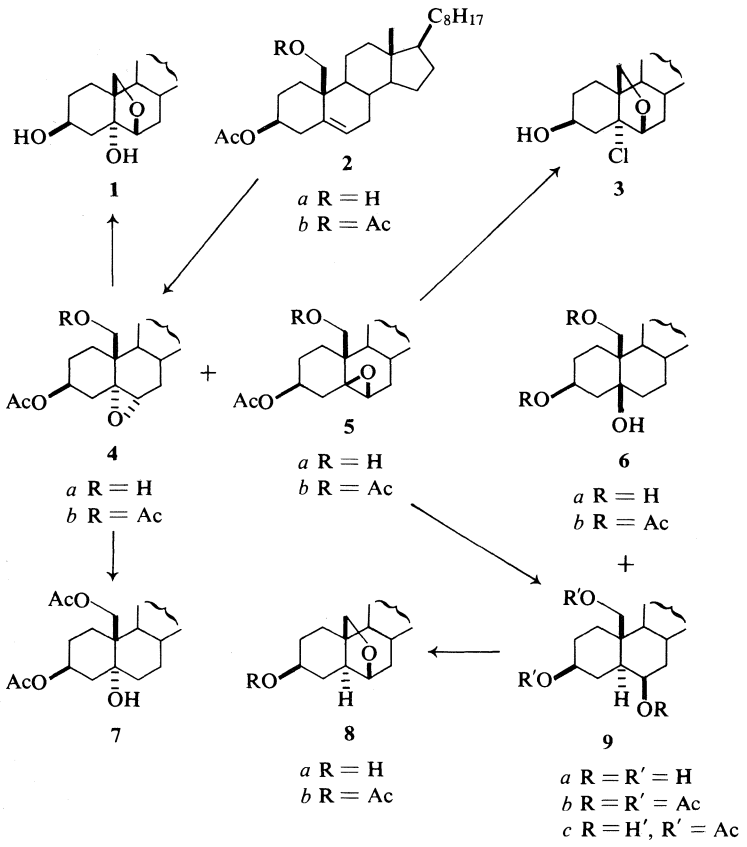
Reduction of 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) with lithium aluminum hydride and subsequent acetylation of the crude product led to the isolation of two substances in a ratio of about 1:5. The major product, after hydrolysis, treatment with a methanolic solution of hydrogen chloride, and reacetylation of the product, gave a substance which was identified as 3β-acetoxy-6β,19-oxido-5α-cholestane (**8***b*). The i.r. spectrum of the latter showed the characteristic absorption band (5) due to the C-19 methylene group of 6β,19-oxides indicating the presence of a 6β-hydroxyl group in the reduction product. In the n.m.r. spectrum, the observed value of 17 Hz for the half-band width of the signal for the C-3 proton was taken as evidence (13) for a *trans* A/B-ring junction. The structure of the major product in the lithium aluminum hydride reduction of the 5β,6β-epoxide must therefore be the one shown (**9***a*) in Scheme 1.

The second product isolated was identified, on the basis of its n.m.r. spectrum, as 3β,19-diacetoxy-5β-cholestan-5-ol (**6***b*). A half-band width of 9 Hz was observed for the signal for the 3α-proton indicating (13) that the A/B-ring junction must be *cis*. Hydrolysis of this substance led to the isolation of 3β,5,19-trihydroxy-5β-cholestane **6***a* whose empirical formula, $C_{27}H_{48}O_3$, was confirmed by elemental and mass spectral analyses.

The sharp decrease in the amount of the 5β-alcohol **6***a* formed compared to the proportion of this alcohol obtained in the case of the lithium aluminum hydride reduction of 5,6β-oxido-5β-cholestane (11) remains unexplained. However, since we were interested in finding means of improving the yield of 5β-alcohol by reduction of the 5β,6β-epoxide we turned our attention to other reducing agents. Brown and Weissman (14) have reported that in the reduction of unsymmetrical epoxides with lithium trimethoxyaluminohydride, hydride transfer occurs almost exclusively at the least substituted carbon. In view of this observation it might be predicted that the use of this reagent would lead to a higher yield of the 5β-alcohol **6***a*. Reduction of 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) led to the formation of two products, neither of which resembled (t.l.c.) the compounds obtained on reduction with lithium aluminum hydride.

The separation of these materials was effected by column chromatography of the acetylated mixture. On the basis of the chemical and physical data presented below the structure of the first substance (50%) eluted from the column is formulated as (5*S*)-3β,6β,19-triacetoxy-1(10 → 5)*abeo*-cholest-9(10)-ene (**10***b*). The second substance (34%) could not be identified.

The n.m.r. spectrum of **10***b* was observed to be similar to that of 3β,6β,19-triacetoxy-5α-cholestane (**6***b*) in that two secondary and one primary acetoxy groups are indicated. Hydrolysis of this compound gave the corresponding triol **10***a*. Evidence that reduction had not occurred was obtained by examination of the mass spectrum



SCHEME 1

which showed an apparent molecular ion peak at 418 and not at 420 as would have been expected on reduction of the epoxide.

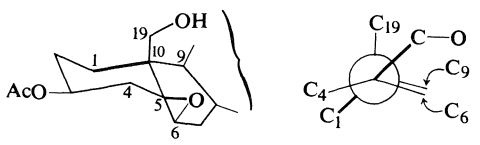
Treatment of this triol **10***a* with a dry methanolic solution of hydrogen chloride led to the isolation of a product which was identified as 5-chloro-6β,19-oxido-5α-cholestan-3β-ol (**3**), a compound prepared earlier from 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*). The two compounds were found to be identical by comparison of their mass spectra and melting points.

Several attempts were made to oxidize the triol **10***a* in order to examine the i.r. spectrum of the product for carbonyl absorption but we were unable to find the right conditions for the reaction to proceed cleanly enough to allow for separation of the products obtained.

Discussion

In order to rationalize the non-reductive rearrangement of the 5β,6β-epoxide **5***a*, a few observations should be made regarding the conformation of the A/B-rings of **5***a* and the nature of lithium trimethoxyaluminohydride as a reducing agent.

It can be seen from Dreiding models that the preferred conformation of the A-ring in 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) is the "non-steroid" one (15, 16). As shown below, this conformation places the bond (C_1—C_{10}) which must migrate to form the 5,5′-spiro compound in a *trans* coplanar position (17) to the C—O bond at C-5.



It is known (18) that in the formation of alkoxyaluminohydrides (Scheme 2) each successive step proceeds more slowly than the preceding one (*i.e.* A-1 > A-2 > A-3 > A-4). Resonance interaction of the type below which would assist the

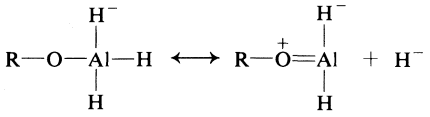
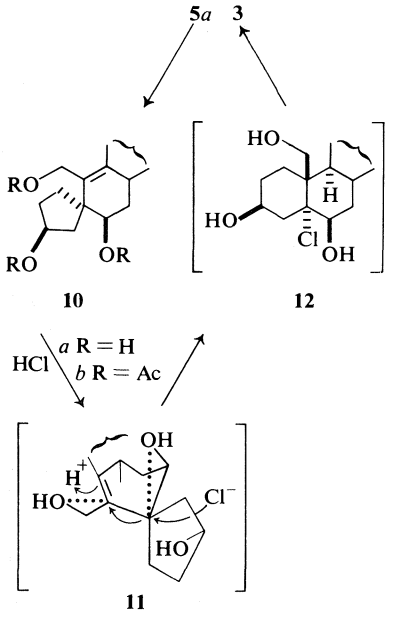
$$AlH_4^- \xrightarrow[CH_3OH]{A\text{-}1} H_3Al{-}OCH_3^- \xrightarrow[CH_3OH]{A\text{-}2} H_2Al{-}(OCH_3)_2^- \xrightarrow[CH_3OH]{A\text{-}3} HAl{-}(OCH_3)_3^- \xrightarrow[CH_3OH]{A\text{-}4} Al{-}(OCH_3)_4^-$$

SCHEME 2



transfer of a hydride ion and accelerate the reaction, is not very effective because such overlap is between the 2p orbital electrons on oxygen and the vacant 3p orbitals of aluminum. This may result in the electron-withdrawing effect of the alkoxy group being dominant, thus retarding the reaction involving loss of a hydride ion.



SCHEME 3

On treatment of 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) with lithium trimethoxyaluminohydride the C-19 hydroxyl group, which lies directly above the 5β,6β-epoxide, may participate in the reaction by the formation of an intermediate with lithium trimethoxyaluminohydride similar to those postulated by others (19–21). The presence of such a complex could lead to the weakening of the C—O bond at C-5 with concomitant migration of the C_1—C_{10} bond and collapse of the proton at C-9 to give a C_9—C_{10} double bond (see Scheme 3).

The fact that only one major product is obtained on treatment of the 5,5′-spiro compound **10***a* with a solution of methanolic hydrogen chloride implies that the rearrangement involved in forming the 5α-chloro-6,19-oxide **3** is stereospecific. Here again, a participating role may be invoked for the C-19 hydroxyl group. If protonation of the C_9—C_{10} double bond is assumed to occur from the α-side of the molecule, the developing carbonium ion at C-10 would be protected from attack on the β-side by interaction with the C-19 hydroxyl group as shown in the postulated intermediate **11**. Migration of the bond of the five-membered ring attached to C-5 would then proceed from the α-side. Similarly the chloride ion would be directed to the α-side of the carbonium ion forming at C-5 due to interaction with the C-6 hydroxyl group situated on the β-side.

Experimental

Melting points were determined on a Hoover Uni-Melt apparatus and are uncorrected. The i.r. and n.m.r. spectra were recorded on a Beckman IR-8 infrared spectrophotometer and on a Varian V-4302 60 Mc spectrometer, respectively. Microanalyses were performed in the Microanalytical Laboratory of Dr. A. Bernhardt, Max Planck Institute, West Germany. SilicaR (200–300 mesh) was used as adsorbant for column chromatography and silica gel G (according to Stahl) was used as adsorbant for t.l.c. with sulfuric acid as spraying agent. In working up the products of reactions, the organic extracts were washed with dilute hydrochloric acid and/or sodium bicarbonate solution, dried over anhydrous magnesium sulfate, and evaporated to dryness under reduced pressure. In the hydride reduction experiments, excess reagent was destroyed with methanol and water and insoluble inorganic material was dissolved with 20% hydrochloric acid.

Epoxidation of 3β-Acetoxycholest-5-en-19-ol (2a)

Treatment of an ether solution of 3β-acetoxycholest-5-en-19-ol (**2***a*) (22) with an excess of monoperphthalic acid led to the isolation (1) of both *3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol* (**5***a*) (72%, m.p. 129–130.5°) and *3β-acetoxy-5,6α-oxido-5α-cholestan-19-ol* (**4***a*) (14%, m.p. 184–186°).

Epoxidation of 3β,19-Diacetoxycholest-5-ene (2b)

3β,19-Diacetoxycholest-5-ene (**2***b*, 1.8 g, 2.5 mmol), prepared by acetylation of 3β-acetoxycholest-5-en-19-ol (**2***a*), was treated in ether solution with monoperphthalic acid (0.8 g, 5.0 mmol) at room temperature for 2 h. The solution was washed with a 20% aqueous solution of sodium sulfite and dried ($MgSO_4$). The phthalic acid was removed by elution on a silica gel (300 g) column with ether. Separation of the three main components of the crude product (0.73 g) was achieved by column chromatography using silica gel (300 g) as adsorbant and benzene as eluant.

The first substance (29 mg) collected from the column had the same R_f value as the starting material **2***b* by t.l.c. and was not characterized further. The second fraction (308 mg), which could not be crystallized, was identified as *3β,19-diacetoxy-5,6α-oxido-5α-cholestane* (**4***b*). A sample which appeared to be pure on t.l.c. exhibited n.m.r. ($CDCl_3$): τ 5.0 (multiplet, 3α-H, $w/2$ = 25 Hz), 6.0 (singlet, —CH_2O—), 7.02 (doublet, 6β-H, J = 3.0 Hz), 7.90, 8.0 (singlets, 19- and 3β-OAc, respectively); mass spectrum (70 eV) *m/e*: 442 and 382 (mol. wt. 502). The last component (210 mg) eluted from the column was identified as *3β,19-diacetoxy-5,6β-oxido-5β-cholestane* (**5***b*). The substance isolated exhibited n.m.r. ($CDCl_3$): τ 5.08 (multiplet, 3α-H, $w/2$ = 24 Hz), 5.65 (quartet, —CH_2O—, J_{AB} = 11 Hz), 7.0 (singlet, 6α-H), 7.86, 7.94 (singlets, 19- and 3β-OAc, respectively); mass spectrum (70 eV) *m/e*: 502 (molecular ion), 442, 382. 3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*, 50 mg, 1.08 mmol) obtained in the epoxidation of 3β-acetoxycholest-5-en-19-ol (**2***a*) was treated with acetic anhydride (1.0 ml) and pyridine (4.0 ml) for 12 h at 10°. Working-up in the usual manner gave a colorless oil (50 mg) which had identical n.m.r. and mass spectra as the product obtained in the epoxidation of 3β,19-diacetoxycholest-5-ene (**2***b*).

6β,19-Oxido-5α-cholestane-3β,5-diol (1)

3β-Acetoxy-5,6α-oxido-5α-cholestan-19-ol (**4***a*, 0.40 g, 0.87 mmol) was dissolved in methanol (50 ml) saturated with hydrogen chloride, and stirred at room temperature for 18 h. The volume of this solution was decreased under reduced pressure and then diluted with ether. The residue (0.39 g), obtained after working-up in the usual way, consisted mainly of two substances (t.l.c.) and was chromatographed on silica gel using benzene as eluant. In this manner 6β,19-oxido-5α-cholestane-3β,5-diol (**1**, 176 mg) was isolated, an analytical sample of which was obtained by crystallization from methanol; m.p. 222°; i.r. ($CHCl_3$): 3610 (OH groups), 1498 (—CH_2O—) cm^{-1}; mass spectrum (70 eV) *m/e*: 418 (molecular ion), 400, 382, 351.

Reduction of 3β,19-Diacetoxy-5,6α-oxido-5α-cholestane (4b) with $LiAlH_4$

Lithium aluminum hydride (0.10 g, 2.1 mmol) was added to a solution of 3β,19-diacetoxy-5,6α-oxido-5α-cholestane (**4***b*, 0.14 g, 0.32 mmol) in dry tetrahydrofuran (50 ml) and the mixture refluxed for 2 h. Working-up in the usual manner yielded a white solid (0.11 g) which was acetylated in a solution of acetic anhydride (1.0 ml) and pyridine (4.0 ml) at room temperature for 12 h. A crude product (130 mg) was isolated which yielded, upon crystallization from methanol, an analytical sample of *3β,19-diacetoxy-5α-cholestan-5-ol* (**7**) exhibiting m.p. 53–54°; n.m.r. ($CDCl_3$): τ 4.65 (multiplet, 3α-H, $w/2$ = 28 Hz), 5.65 (quartet, —CH_2O—, J_{AB} = 12 Hz), 7.90, 7.98 (singlets, 19- and 3β-OAc respectively); mass spectrum (70 eV) *m/e*: 444, 426, 384, 366 and 353 (mol. wt. 504).

Anal. Calcd. for $C_{31}H_{52}O_5$: C, 73.76; H, 10.38. Found: C, 73.77; H, 10.24.

Reduction of 3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (5a) with $LiAlH_4$

3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*, 0.50 g, 1.08 mmol) was dissolved in dry tetrahydrofuran (300 ml). To this solution $LiAlH_4$ (1.5 g, 24.5 mmol) was added and the reaction mixture was refluxed with stirring for 24 h. Working-up in the usual way yielded a crude product (475 mg) which was found to consist of two substances (t.l.c.). This material was then acetylated with acetic anhydride (2.0 ml) and pyridine (8.0 ml) at room temperature for 12 h. A crude product (490 mg) was obtained from which three substances were isolated after chromatographic separation on silica gel (250 g) using benzene as eluant.

The first compound (140 mg, oil) was identified as *3β,6β,19-triacetoxy-5α-cholestane* (**9***b*) by its n.m.r. spectrum ($CDCl_3$) which exhibited signals at τ 5.15 (singlet, 6α-H, $w/2$ = 8 Hz), 5.25 (multiplet, 3α-H, $w/2$ = 26 Hz), 5.65 (singlet, —CH_2O—), 7.94, 7.98, 8.01 (singlets, 3 acetoxyl groups).

The second substance (65 mg, oil) eluted from the column was identified as *3β,19-diacetoxy-5β-cholestan-5-ol* (**6***b*) on the basis the n.m.r. spectrum ($CDCl_3$) which exhibited peaks at τ 4.80 (singlet, 3α-H, $w/2$ = 9 Hz), 5.64 (singlet, —CH_2O—), 7.95, 7.97 (singlets, 2 acetoxyl groups).

A third compound (161 mg, oil) eluted from the column was identified as *3β,19-diacetoxy-5α-cholestan-6β-ol* (**9***c*) by its n.m.r. spectrum ($CDCl_3$) which exhibited peaks at τ 5.30 (multiplet, 3α-H), 5.57 (singlet, —CH_2O—), 6.26 (singlet, 6α-H, $w/2$ = 7 Hz), 7.95, 8.0 (singlets, 2 acetoxyl groups).

A mixture (241 mg) containing 3β,6β,19-triacetoxy-5α-cholestane (**9***b*) and 3β,19-diacetoxy-5α-cholestan-6β-ol (**9***c*) was hydrolyzed in a 30% aqueous methanol – 30% sodium hydroxide solution at room temperature for 24 h. Working-up in the usual manner gave *3β,6β,19-trihydroxy-5α-cholestane* (**9***a*) and an analytical sample was obtained by crystallization from methanol–tetrahydrofuran; m.p. 230–231°; mass spectrum (70 eV) *m/e*: 402, 384, 372, 354 (mol. wt. 420).

Anal. Calcd. for $C_{27}H_{48}O_3$: C, 77.09; H, 11.50. Found: C, 77.15; H, 11.32.

3β,19-Diacetoxy-5β-cholestan-5-ol (**6***b*) was hydrolyzed in the same manner described above. An analytical sample of *3β,5,19-trihydroxy-5β-cholestane* (**6***a*), obtained by crystallization from methanol exhibited m.p. 145–146°; mass spectrum (70 eV) *m/e*: 402, 384, 372, 354 (mol. wt. 420).

*Reduction of 3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) with Lithium Trimethoxyaluminohydride*

Lithium aluminum hydride (0.78 g, 20.8 mmol) was added to dry tetrahydrofuran (100 ml) in a three-necked flask, equipped with a stirrer and condenser. The system was purged with a steady stream of nitrogen. To this solution was added dry methanol (2.5 ml, 62.5 mmol) over a period of 10 min. 3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*) (0.50 g, 1.08 mmol) was added and the solution refluxed for 20 h. Working-up in the usual manner yielded a crude product (500 mg) which was acetylated in acetic anhydride (4.0 ml) and pyridine (10 ml) at room temperature for 12 h. The oil which was isolated was chromatographed on silica gel (300 g) using benzene as eluant. In this manner two substances were isolated, the first of which was identified as *(5S)-3β,6β,19-triacetoxy-1(10 → 5)abeo-cholest-9(10)-ene* (**10***b*) (240 mg). The n.m.r. spectrum of this compound showed peaks at τ 4.65 (multiplet, 3α-H, *w*/2 = 27 Hz), 4.85 (singlet, 6α-H, *w*/2 = 7 Hz), 5.45 (singlet, —CH_2O—), 7.86, 7.92, 7.99 (singlets, 3 acetoxyl groups). The second substance (170 mg) could not be identified.

Hydrolysis of the triacetate **10***b* isolated above with an aqueous (10%) methanolic solution of NaOH (10%) at room temperature provided, after crystallization from methanol, an analytical sample of *(5S)-3β,6β,19-trihydroxy-1(10 → 5)abeo-cholest-9(10)-ene* (**10***a*); m.p. 179–181°; mass spectrum (70 eV) *m/e*: 418 (molecular ion), 400, 388, 382, 370, 352.

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.46; H, 11.08. Found: C, 76.84; H, 11.35.

*5-Chloro-6β,19-oxido-5α-cholestan-3β-ol (**3**)*

*(a) From 3β-Acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*)*

Treatment of 3β-acetoxy-5,6β-oxido-5β-cholestan-19-ol (**5***a*, 100 mg, 0.27 mmol) with a dry methanolic solution of hydrogen chloride at room temperature for 12 h yielded, after working-up in the usual manner, a white solid (94 mg). Crystallization of this material from aqueous acetone gave an analytical sample of 5-chloro-6β,19-oxido-5α-cholestan-3β-ol (**3**); m.p. 126–127.5° (lit. (6) m.p. 139–140°); i.r. ($CHCl_3$): 3610 (OH), 1498 (—CH_2O—) cm^{-1}; mass spectrum (70 eV) *m/e*: 436 (molecular ion), 418, 400, 382, 351.

*(b) From (5S)-3β,6β,19-Trihydroxy-1(10 → 5)abeo-cholest-9(10)-ene (**10***a*)*

(5*S*)-3β,6β,19-Trihydroxy-1(10 → 5)*abeo*-cholest-9(10)-ene (**10***a*, 30 mg, 0.09 mmol) was treated with a dry methanolic solution of hydrogen chloride at room temperature for 12 h. Working-up in the usual manner gave a crude product which was purified by chromatography on silica gel (10 g). Crystallization from aqueous acetone of the substance eluted gave a compound with m.p. 126–127.5°. A mixed m.p. with the 5-chloro-6β,19-oxido-5α-cholestan-3β-ol (**3**) prepared from **5***a* was undepressed. The i.r. and mass spectra of this compound were identical to that of the 5α-chloro-6β,19-oxide (**3**) obtained from **5***a*.

The authors are grateful to Dr. T. Durst for helpful discussions and acknowledge the financial support of the National Research Council of Canada.

Alkaline Epoxidation of Carbohydrate Nitroolefins[1,2]

HANS H. BAER AND WERNER RANK
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received April 21, 1971

Action of hydrogen peroxide in a weakly alkaline medium upon nitroolefinic sugar derivatives led to α-nitroepoxides in excellent yields. Thus, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**), its β-anomer **2**, and its α-D-*threo* epimer **3** stereospecifically gave methyl 2,3-anhydro-4,6-*O*-benzylidene-3-*C*-nitro-α-D-mannopyranoside (**6**), the β-D-*allo* isomer **7**, and the α-D-*talo* isomer **8**, respectively. The corresponding β-D-*threo* olefin **4** produced a mixture of the β-D-*gulo* (**9**) and β-D-*talo* (**10**) epoxides, with **9** strongly preponderating. The β-L-*gulo* (**11**) and β-L-*talo* (**12**) derivatives were made from the enantiomer **5** of **4**. Another route to α-nitroepoxides, originating from 3-bromo-3-deoxy-3-nitro sugars, furnished the β-D-*manno* isomer **13**.

L'action du peroxyde d'hydrogène en milieu faiblement basique sur des dérivés nitrooléfiniques des sucres, conduit à des α-nitroépoxydes avec un excellent rendement. Ainsi, le méthyl *O*-benzylidène-4,6 didéoxy-2,3 nitro-3 α-D-*érythro* hexène-2 pyranoside (**1**), son anomère β (**2**), et son épimère α-D-*thréo* (**3**) conduisent stéréospécifiquement et respectivement à l'anhydro-2,3 *O*-benzylidène-4,6 *C*-nitro-3-α-D-mannopyranoside (**6**), à l'isomère β-D-*allo* **7**, et à l'isomère α-D-*talo* **8**. L'oléfine β-D-*thréo* **4** correspondante, conduit à un mélange des époxydes β-D-*gulo* (**9**) et β-D-*talo* (**10**), le composé **9** étant en très grande prépondérance. Les dérivés β-L-*gulo* (**11**) et β-L-*talo* (**12**) ont été préparés à partir de l'énantiomère **5** de **4**. Une autre voie d'accès aux α-nitroépoxydes, ayant pour origine les dérivés bromo-3 déoxy-3 nitro-3 des sucres, conduit à l'isomère β-D-*manno* **13**.

Canadian Journal of Chemistry, **49**, 3192 (1971)

Recently, Newman and Angier (3) recorded the preparation and some chemical properties of compounds containing a hitherto unknown structural feature, namely, a nitro-substituted oxirane ring. They obtained such epoxides by the action of alkaline hydrogen peroxide upon phenyl and cyclohexyl derivatives of nitroethylene. We wish to report the synthesis of carbohydrate α-nitroepoxides which are believed to hold much promise for a considerable range of synthetic purposes.

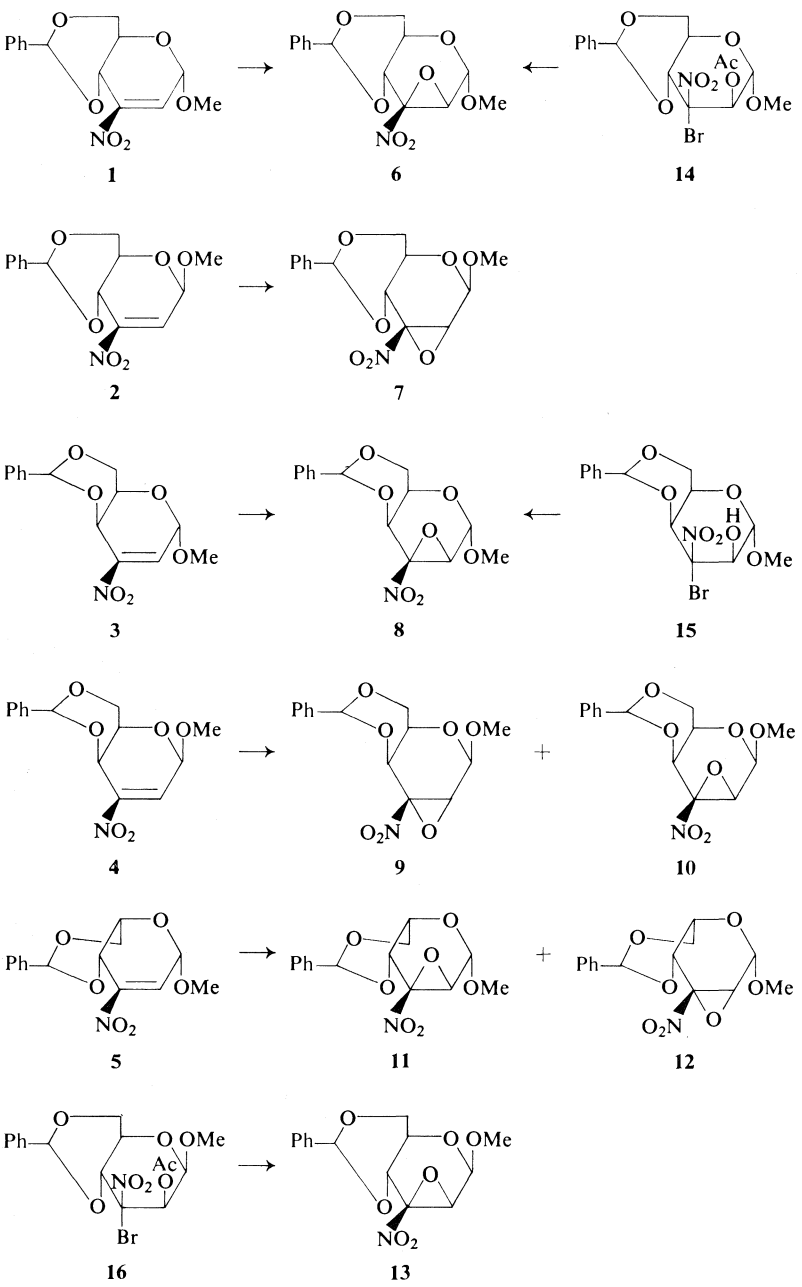
The methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-hex-2-enopyranosides **1–5** all reacted smoothly, in ethanolic solution at room temperature, with aqueous, 30% hydrogen peroxide at p*H* 8–9. Crystalline methyl 2,3-anhydro-3-*C*-nitrohexopyranosides were produced in yields of 75–90%. Epoxidation of the α- and β-D-*erythro* glycosides, **1** and **2**, and of the α-D-*threo* isomer, **3**, furnished single epoxides having the α-D-*manno* (**6**), β-D-*allo* (**7**), and α-D-*talo* (**8**) configurations, respectively.[3] As no evidence for formation of the alternative diastereoisomers was uncovered, these reactions appeared to be highly stereoselective. A lesser degree of stereoselectivity was observed with the β-D-*threo* isomer **4** which gave a mixture from which the β-D-*gulo* (**9**) and β-D-*talo* (**10**) products were isolated in a ratio of 5:1. In order to verify the differential behavior of **4**, the same reaction was performed with its enantiomer **5**, and the β-L-*gulo* (**11**) and β-L-*talo* (**12**) glycosides were obtained in a similar ratio of 6:1. Hence, in all cases epoxidation occurred preferentially from the side of the ring opposite to the glycosidic methoxyl group.

A different route to α-nitroepoxides was found in connection with a study on α-halonitro sugars which will be described in detail in a forthcoming article (5). Thus, the compounds **6** and **8** were also obtained by the action of base upon the 3-bromo-3-deoxy-3-nitro glycosides **14** and **15**, respectively. An additional α-nitroepoxide,

[1]Part XX in a series on the reactions of nitro sugars. For Part XIX see ref. 1.

[2]Reported on May 25, 1970, before the Chemical Institute of Canada and the American Chemical Society (2).

[3]After our preliminary report (2) appeared, a short communication (4) describing the preparation of **7** from **2** by the action of sodium hypochlorite was published.



namely that with the β-D-*manno* configuration **13**, arose from the bromodeoxynitro glycoside **16**.

The structure of the stereoisomeric epoxides **6**–**13** was confirmed by elemental analysis and spectroscopy. Strong i.r. bands at about 1560 cm^{-1} indicated the nitro group, and n.m.r. spectra in $CDCl_3$ showed, except for the β-*talo* compounds **10** and **12**,[4] the presence of the benzy-

[4]Because of poor solubility no useful n.m.r. spectra were obtained from **10** and **12**.

TABLE 1. Chemical shifts (τ) of methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitrohexopyranosides

Compound	Configuration	$PhCHO_2$	H-1	H-2	H-4	H-5	H-6	H-6′	OCH_3
6	α-D-*manno*	4.44	5.15	6.29	~6.0	6.23	5.71	~6.0	6.55
7	β-D-*allo*	4.28	5.18	6.23	4.95	6.39	5.65	6.12	6.45
8	α-D-*talo*	4.33	4.91	6.29	4.37	6.24	5.63	5.76	6.56
9	β-D-*gulo*	4.37	5.21	5.74	5.10	6.59	5.67	5.94	6.46
13	β-D-*manno*	4.40	4.94	6.14	5.88	6.41	5.64	6.13	6.42

lidene acetal group (aromatic 5-proton multiplet near τ 2.6 and methine singlet near τ 4.3–4.4) and of the glycosidic methoxyl group (3-proton singlet at τ 6.42–6.46 in β-anomers, at 6.55–6.56 in α-anomers). Integration of the remaining signals revealed the presence of six skeletal protons in each case, as required by the structure. The chemical shifts measured in $CDCl_3$ solution are given in Table 1.

The configurations were assigned by means of n.m.r. data and circular dichroism (c.d.) curves (Fig. 1). Since the configurations at C-1, -4, and -5 of each compound were defined by the starting materials, it was necessary only to determine the steric dispositions of the epoxide oxygen atoms. Thus compounds **7** and **13**, which have identical stereochemistry with respect to C-1, -4, and -5, evidently differ only in the orientation of the epoxide ring. The stereochemical environment of the nitro chromophore is thereby made different, and as a result the compounds exhibit Cotton effects with opposite signs, even though they have the same anomeric configuration. Compound **6** (which on the basis of its origin could be the α-anomer of either **7** or **13**) shows the same Cotton effect as **13** and consequently is assigned the same epoxide configuration. Further evidence was provided by the n.m.r. spectra. It has been pointed out (6, 7) that in 2,3-anhydrohexopyranosides (including 4,6-*O* benzylidene derivatives) the anomeric proton shows no coupling with H-2 when these protons are *trans*-related, and that a small coupling is observed when they are *cis*-related. In **6** and **7** the H-1 signals were sharp singlets (100 MHz spectra at 250 Hz sweep width), whereas **13** gave an anomeric doublet with 0.8 Hz splitting. This is in agreement with the α-D-*manno* and β-D-*allo* configurations for **6** and **7**, respectively, and with the β-D-*manno* configuration for **13**.[5]

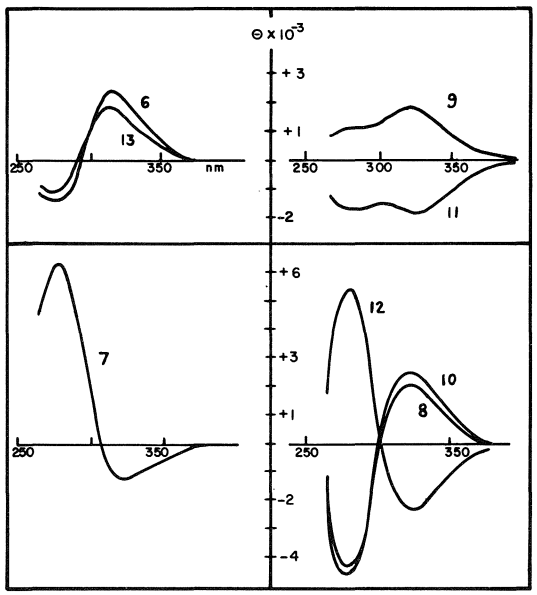

FIG. 1. Circular dichroism of carbohydrate α-nitroepoxides at 25° in dioxane. The authors are indebted to Dr. J. Kovář for these spectra.

Among the epoxides with *cis*-fused benzylidene rings, **8** and **10** give virtually identical c.d. curves. For this reason **10**, rather than **9**, is thought to be the anomer of **8**. The sign of the Cotton effect of **8** and **10** is the same as that of the anomeric pair **6** and **13**, and the two pairs are therefore allocated identical configuration with respect to the

[5]Methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside exhibits $J_{1,2} = 0$ Hz whereas the α-D-*allo* isomer shows $J_{1,2} = 2.5$ Hz (6); the corresponding α-D-*allo* 4,6-diacetate shows $J_{1,2} = 1.5$ Hz, and the α-D-*manno* and β-D-*allo* 4,6-diacetates display $J_{1,2} = 0$ Hz (7). If **6**, **7**, and **13** would possess the α-D-*allo*, β-D-*manno*, and β-D-*allo* configurations, respectively, one would expect to find small $J_{1,2}$ couplings in the first two and no coupling in the last one, *i.e.* the reverse of what has been found. The value of **13** is somewhat smaller than had been anticipated, but it is to be noted that, in the half-chairs which these compounds are assumed to occupy, the dihedral angle between 1,2-*cis* protons varies slightly, depending on whether the protons are situated on the upper side of the ring (as in the α-D-*allo* case) or on the lower side (as in the β-D-*manno* case). Moreover, the nitro group may well exert some influence on the magnitude of this coupling.

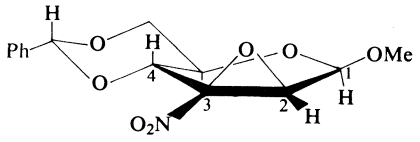
†In dimethylformamide.

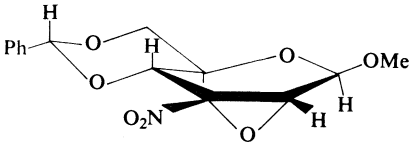
epoxide ring. From the assignment of the α- and β-D-*talo* configurations to **8** and **10**, it follows that **9** must possess the β-D-*gulo* configuration. Although **9** shows an abnormal c.d. curve which is as yet unexplained (Fig. 1), both **9** and **8** exhibit zero coupling of H-1 and -2, conforming with *trans* arrangements of these protons.

The enantiomerism of **9** and **11**, and of **10** and **12**, was borne out by physical constants (Table 2), identical i.r. spectra, mirror image c.d. curves, and (for **9** and **11**)[4] identical n.m.r. spectra.

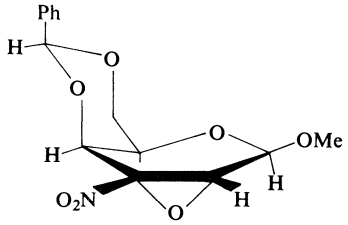
Inspection of Table 1 reveals a number of noteworthy regularities in chemical shifts. Thus, in the compounds having a *trans*-fused benzylidene ring, the methine proton resonates at higher field when the epoxide ring is *cis* to it than when it is *trans* (τ 4.44 and 4.40 *vs.* 4.28), and the same holds to a much stronger degree for H-4 (τ 6.0 and 5.88 *vs.* 4.95). In the compounds having a *cis*-fused benzylidene ring the chemical shifts of the H-4 protons (5.10 *vs.* 4.37) and of the methine protons (4.37 *vs.* 4.33) follow the same trend (although the last-mentioned difference is small and may not be significant). Ferrier and Prasad (7) have observed dependencies of H-4 shifts on the orientation of the 2,3-epoxy ring, but the effects they noted were much smaller than those in our compounds, and one has therefore to conclude that here the nitro group makes an important contribution. On the other hand, the chemical shifts of the protons H-2 differ little, and the same applies to the protons H-5. An exception is provided by **9** which gives an H-2 signal appreciably downfield, and an H-5 signal noticeably upfield, from the corresponding signals of the isomers. It is tempting to speculate



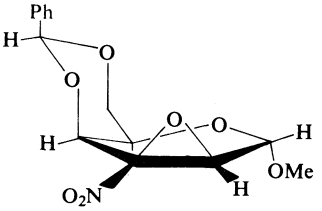
13



7



9



8

that this is caused by the same stereochemical feature that gives rise to the anomalous c.d. curve. No doubt the preferred torsional angle of the nitro group, which presumably is governed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by steric or dipolar effects originating chiefly from O-4 and O-2,3, is a determinant factor in both c.d. and p.m.r.[6]

Experimental

Melting points were taken using capillaries in an electrically heated aluminum block apparatus. The t.l.c. was performed on silica gel G (E. Merck AG, Darmstadt) with 3:2 (v/v) ethyl acetate – petroleum ether (b.p. 30–60°), and spots were made visible by ceric sulfate and heating. Optical rotations were measured in a Perkin–Elmer 141 automatic polarimeter, and c.d. curves were recorded with a Jasco ORD/UV-5 instrument. The n.m.r. spectra (100 MHz) were obtained, at sweep widths of 1000 and 250 Hz, from solutions in $CDCl_3$ containing tetramethylsilane.

General Procedure for Epoxidation

The starting compounds, namely the methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohex-2-enopyranosides with α-D-*erythro* (**1**) (8), β-D-*erythro* (**2**) (9), α-D-*threo* (**3**) (8), and β-D-*threo* (**4**) (10) configuration were prepared according to the references cited, or by improved modifications (11, 12) of the original procedures. The β-L-*threo* isomer **5** (m.p. 159–161°, $[\alpha]_D$ +47.1° in dimethylformamide) was obtained from methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-L-galactopyranoside (13) by the method elaborated (10, 12) for its enantiomer **4** for which has been recorded m.p. 162°, $[\alpha]_D$ −47.8°.

To a solution of a given nitroolefinic sugar (200 mg) in ethanol (20 ml) was added 1 ml of aqueous, 30% hydrogen peroxide (reagent grade), and the p*H* of the mixture was adjusted to 8–9 by adding a few drops of *N* sodium hydroxide solution. The reaction mixture was stirred at room temperature for a specified time (Table 2) during which the epoxide began to crystallize, usually at an early stage. The reactions were monitored by t.l.c. which enabled a clear distinction between starting material and product in all cases. Complete consumption of the starting material was observed. The white, crystalline precipitate was removed by filtration, washed with a small amount of cold water (for **6** and **7**) or cold ethanol (for **8**, **10**, and **12**), and dried in a desiccator. By adding some water to the mother liquor and concentrating the solution under diminished pressure, second crops were obtained of **6** and **8**, whereas the mother liquors of sparingly soluble **10** and **12** furnished the more soluble **9** and **11**, respectively, which constituted the major reaction products. The products so obtained gave single spots on t.l.c. and had reasonably sharp melting points which were raised a few degrees only by recrystallization from 95% ethanol. Yields, physical constants, and microanalytical data for the epoxides **6**–**12** are given in Table 2. Also included in Table 2 are data for the β-D-*manno* isomer **13** although this compound was obtained in a different way (5).

[6]A substantially different over-all conformation as cause of the anomalous characteristics of **9** seems unlikely. Although **9** (and **8**) may exist with an inverted pyranose half-chair ($HC^5{}_O$) instead of the depicted half-chair ($HC^O{}_5$), the n.m.r. spectra militate against such inversion. Both compounds display only small vicinal couplings (2–2.5 Hz) in their H-5 and -6 signals, whereas the $HC^5{}_O$ form with a *cis*-fused 1,3-dioxane chair would have a 180° dihedral angle between H-5 and one of the H-6 protons, calling for a large *J* value. Compounds **7** and **13** indeed show the corresponding, large splitting (10 Hz) as required by the conformation depicted.

We thank the National Research Council of Canada for support of this work.

A Study of Steric Effects on Nitromethylene Acidity and the Mechanism of Epimerization in Partially Blocked Nitro Hexoses[1]

HANS H. BAER AND WERNER RANK
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received April 21, 1971

The extent of nitronate formation in seven methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides and four methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohexopyranosides in dilute potassium hydroxide solution was compared by means of u.v. spectroscopy. Considerable differences were found to exist in the nitromethylene acidities, and these were correlated with stereochemical features of the molecules. A facile *manno* → *gluco* epimerization occurring in this series was investigated. It was shown that, in alkaline alcoholic solution, the epimerization proceeds by an elimination–addition via an intermediate nitroalkene if the hydroxyl group at C-2 is acetylated. However, if the hydroxyl is free, the nitroalkene is not an intermediate and, in accord with the low nitromethylene acidity in this particular case, the mechanism is suggested to involve a reverse Henry reaction.

Le degré de formation de nitronate à partir de sept méthyl *O*-benzylidène-4,6 déoxy-3 nitro-3 hexopyranosides et de quatre méthyl *O*-benzylidène-4,6 didéoxy-2,3 nitro-3 hexopyranosides, en solution dans de l'hydroxyde de potassium dilué, a été comparé par spectroscopie u.v. Des différences considérables ont été trouvées en ce qui concerne les acidités des groupes nitrométhylènes; celles-ci ont été reliées aux caractères stéréochimiques des molécules. L'épimérisation facile *manno* → *gluco* qui se fait dans cette série a été étudiée. Il a été montré que, en solution alcoolique et alcaline, l'épimérisation se fait par une élimination–addition via un nitroalcène intermédiaire, si le groupe hydroxyle en C-2 est acétylé. Cependant, si l'hydroxyle est libre, le nitroalcène n'est pas un intermédiaire et, en accord avec la faible acidité du nitrométhylène dans ce cas particulier, le mécanisme implique probablement une réaction d'Henry inverse.

In a preceding part of this series the influence of configuration on the thermodynamic stability of pentopyranoside nitronates was discussed (1). It was shown that conformational preferences and equilibria of epimerization in the sodium salts of methyl 3-deoxy-3-nitropentopyranosides can be rationalized on the basis of the nonbonded interaction between the nitronate group and an adjacent, equatorial hydroxyl group ($A^{(1,3)}$ effect). Concurrent studies with hexose derivatives provided further insights regarding the influence of steric factors on reactivity in nitro sugars. The present article reports observations concerning the behavior of 4,6-*O*-benzylidene derivatives of methyl 3-deoxy-3-nitrohexopyranosides in alkaline medium. Such acetals are useful derivatives that can serve for the separation of stereoisomers and as starting points for many syntheses (2, 3). However it has been recognized for some time (4) that the benzylidene group is prone to cleavage by way of base-promoted β-elimination, which may detract from its usefulness as a blocking group. The degree of sensitivity appears to be dependent on configuration, for it has been observed (5) that methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside undergoes reactions which entail the loss of the benzylidene group rather more readily than its *gluco* isomer. The first step in this type of reaction and in various other base-catalyzed reactions of primary and secondary nitro compounds is generally assumed to be proton abstraction to give a nitronate ion, and it was therefore decided to undertake a comparative study of nitronate formation in this series.

The extent of nitronate formation in the available methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro- and 2,3-dideoxy-3-nitrohexopyranosides in 0.01–0.001 *N* ethanolic potassium hydroxide solution was examined by u.v. spectroscopy, making use of the high-intensity absorption in the 250 nm region which is due to the nitronate chromophore (4, 6, 7).[2] Table 1 lists molar absorbances (A_M) of

[1]Part XXI in a series on the reactions of nitro sugars. For Part XX see ref. 15.

[2]The absorption maximum of sodium methanenitronate in water is at 232 nm (8), and the maxima of the sodium salts of other primary and secondary nitroalkanes and nitrocycloalkanes fall in the region 226–244 nm (9).

TABLE 1. The u.v. absorptions produced by nitro glycosides in ethanolic potassium hydroxide solution

Compound	Configuration	Normality in KOH	λ_{max} (nm)	A_M*
1	α-D-*talo*	0.001	251	21700
2	α-D-*galacto*	0.01	254	10900
3	β-D-*galacto*	0.001	258	12100
		0.01	258	13500
4	α-D-*gluco*	0.001	250–260	500
5	β-D-*gluco*	0.001	250–260	500
6	α-D-*manno*	0.001	250–260	500
7	β-D-*manno*	0.001	250–260	500
8	α-D-*lyxo*	0.01	251	14100
9	β-D-*lyxo*	0.001	253	13800
		0.01	253	14500
10	α-D-*arabino*	0.001	252	1050
11	β-D-*arabino*	0.001	252	1050

*Molar absorbance = absorbance of a solution 10^{-4} *M* in nitro compound, multiplied by 10 000. The value would represent the molar extinction coefficient of the nitronate anion only in case of complete ionization.

the nitro compounds, which may be taken as a measure for the amount of nitronate present under the given conditions of alkalinity. The values recorded are maximum values, attained about 8 min after the addition of alkali to the nitro compounds. It is to be noted that establishment of the nitro–nitronate equilibrium, though rapid, is not instantaneous, and in systems developing a reasonably strong absorption the growth of the nitronate peak can be readily monitored in an automatic spectrometer. For example, **1** showed A_M 13 600, 15 400, 20 400, and 21 700 after 0.6, 1.5, 4, and 8 min (in 0.001 *N* KOH in ethanol). Then the peak decreased again (A_M 21 000 and 19 300 after 16 and 64 min), with concomitant appearance of a new peak near 300 nm. The latter phenomenon is due to a slow elimination reaction leading to an unsaturated nitronate (4).

It is seen that methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-α-D-talopyranoside (**1**) forms nitronate most easily. The α- and β-D-*galacto* isomers, **2** and **3**, do so less readily but still extensively, whereas the α- and β-D-*gluco* isomers, **4** and **5**, produce hardly any nitronate absorption and the amount of salt formed must be very small.[3] The α- and β-D-*manno* isomers, **6** and **7**, give rise to the same, insignificant absorptions and thus appear to behave like the *gluco* isomers. This seemed surprising at first sight but became understandable when their chemical fate was examined, as will be disclosed in a subsequent paragraph. The methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α- and β-D-*lyxo*-hexopyranosides (**8** and **9**) appear to form nitronate somewhat more readily than the D-*galacto* derivatives, and their α- and β-*arabino* isomers, **10** and **11**, behave similarly to the D-*gluco* derivatives but give rise to slightly greater absorptions. In summary, high-intensity absorption is observed when the oxygen atom O-4 is linked axially, and low absorption, when it is linked equatorially. In both cases, replacement of an equatorial hydroxyl group at C-2 by hydrogen moderately enhances the absorption. An axial hydroxyl at C-2 causes a strong increase when O-4 is axial also, but is without visible effect when O-4 is equatorial. We offer the following explanation for these observations.

In the nitronates expected to arise from the compounds that bear a *trans*-fused acetal ring (**4–7**, **10**, and **11**), one of the nitronate oxygens faces nonbonded interaction from the equatorial O-4. This condition [$A^{(1,3)}$ effect (10)], which is associated with an interaction energy of about 2 kcal/mol (1) and which cannot, in these rigid bicyclic systems, be relieved by a conformational change, constitutes a severe impediment to nitronate formation. In the compounds having a *cis*-fused acetal ring (**1–3**, **8**, and **9**), the (axial) O-4 does not so interfere. An equatorial hydroxyl group at C-2 could likewise be expected to hinder nitronate formation, and the lower extinctions given by the D-*galacto* and D-*gluco* compounds

[3]At higher concentration of alkali (0.1 *N* aqueous NaOH), **5** does produce a peak at 253 nm (4).

in comparison with their respective 2-deoxy analogs might be taken to bear this out. However the differences are small, and they may in fact be due entirely to a change in the inductive effect of C-2. At any rate it is clear that an equatorial hydroxyl at this position does not seriously interfere with nitronate formation, and one may therefore assume that its $A^{(1,3)}$ interaction is diminished substantially by a distortion of the pyranoside chair. A molecular model shows that flattening which the chair tends to incur by sp^2 hybridization of C-3 will mainly affect the position of C-2 (in the more flexible part of the ring), allowing an equatorially-attached hydroxyl to move downward and thus to recede from the nitronate oxygen atom. This movement should be opposed by an axial anomeric methoxyl group and indeed, the α-D-galactoside **2** seems to produce slightly less nitronate than its β-anomer **3** while the corresponding anomers **8** and **9** of the 2-deoxy series expectedly exhibit no significant difference. The ring distortion just mentioned also implies a lessening of steric interaction between an axially attached oxygen at C-4 and an opposing axial atom or group at C-2. Undoubtedly this is conducive to nitronate formation in the *galacto* and *lyxo* compounds, and it provides an especially pronounced driving force in the *talo* isomer **1**.

We have also estimated the pK_a values of some of the compounds by half-titration with sodium hydroxide in aqueous dioxane (Table 2). The

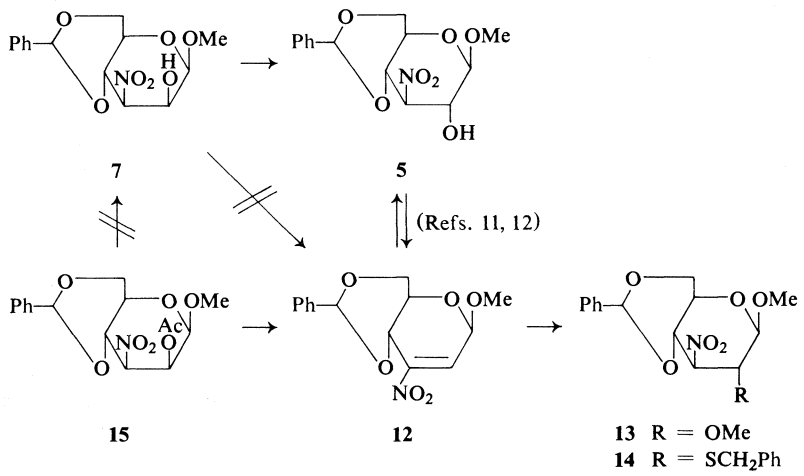

SCHEME 1

nitromethylene acidities so found qualitatively parallel the spectroscopically determined tendencies of salt formation, bearing out the influence of configuration.[4]

Although an equatorial disposition of O-4 obviously is the chief obstacle to facile nitronate formation in these benzylidenated glycosides, it nevertheless seemed remarkable that the mannosides **6** and **7**, with their axial 2-hydroxyl, did not perceptibly differ spectroscopically from the glucosides. However, it is recalled that the mannoside **7** was *epimerized* to **5** by refluxing in toluene or benzene in the presence of basic alumina or solid potassium hydroxide catalyst (11, 12). We have now found that it epimerizes more rapidly yet in alcoholic, alkaline solution at room temperature, and the observed u.v. spectrum therefore may well represent largely **5** rather than **7**. This epimerization, the facile occurrence of which was ascertained by isolation of **5** in preparative experiments using ethanolic potassium hydroxide or methanolic sodium methoxide solutions (and which was also performed with the α-anomer **6**), was of considerable interest with regard to its mechanism.

TABLE 2. Nitromethylene acidities

*The p*H*-values observed potentiometrically in approximately 0.01 *M* solutions in dioxane upon half-titration with 0.002 *N* sodium hydroxide in water. We thank Dr. Jan Kovář for kindly performing these measurements.

It had been demonstrated that the glucoside **5** is dehydrated by heating in toluene (or benzene) in the presence of a solid base to give the nitroolefin **12**, and that **12** in turn can be easily hydrated back to **5**, so that it was reasonable to assume that the epimerization of **7** took the same course, via **12** (11, 12) (see Scheme 1). There is still no evidence to discount that pathway for the reaction under the conditions then employed. However, a mechanism that does not involve **12** has now been established to operate under the present conditions. If **12** were produced from **7**, then, in a methanolic medium containing sodium methoxide, **12** should add methanol to produce the 2-*O*-methyl ether (**13**) of **5**, rather than **5** itself. It has been shown previously (13) that **12** does indeed give **13** with great ease and we have now convinced ourselves that it does so even in the presence of a stoichiometric amount of water.[5] Furthermore, when **7** was treated with the strong nucleophile, sodium benzylmercaptide in meth-

[4]Compare also the similar dependence of acidity on the stereochemistry of the methyl 3-deoxy-3-nitropentopyranosides (1). Note that the spectroscopic and potentiometric data apply to different solvents; quantitative conclusions are not intended.

[5]By providing 1 mol of water per mol of **12** in excess methanol we simulated the conditions that would obtain upon dehydration of **7**.

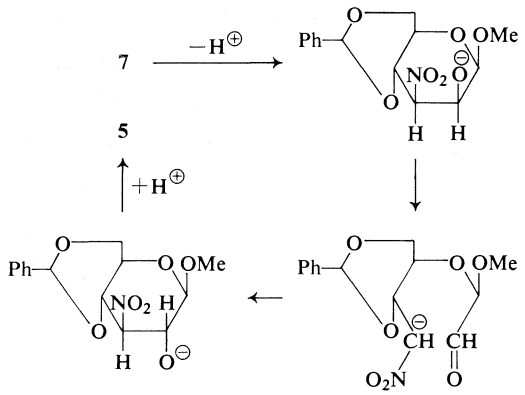

SCHEME 2

anol, the product was **5** and not the known benzylthio derivative **14**. An intermediacy of **12** can therefore be ruled out for these reactions. On the other hand, the *O*-acetyl derivative (**15**) of **7** furnished the methyl ether **13** in 88% yield upon reaction with methanolic potassium hydroxide, the reaction being complete within a few minutes at room temperature. This can only be explained by β-elimination of the acetoxy group to give intermediate **12**, and subsequent nucleophilic addition of methanol. For if **15** had suffered methanolysis of its acetyl rather than β-elimination of its acetoxy group, then **7** and hence **5** would have resulted. Numerous elimination–additions of this kind had previously been performed with the 2-acetates of the glucosides **4** and **5**. The conclusion can be drawn that abstraction of H-3 by base, however small its extent, is sufficient in the 2-acetates to permit elimination of the good leaving group, acetate ion, whereas in **7** it is not effective enough to induce departure of the poor leaving group, hydroxyl ion. Because of the difficulty in forming its nitronate, **7** incurs competitive deprotonation of the 2-hydroxyl group, and this leads to ring opening by reversal of a nitroalkane cyclization. Subsequent recyclization produces the thermodynamically more stable β-D-*gluco* epimer[6] (Scheme 2). Although the intermediate aldehydonitronate should have a high extinction coefficient, its concentration is not expected to reach a spectroscopically observable level. This mechanism was originally proposed by Grosheintz and Fischer (14) for the easy, epimeric equilibration of deoxynitroinositols, but it lacked experimental support and was not adopted in our subsequent work on nitro sugars, mainly because of theoretical considerations (2) and because of accumulating evidence for the role of nitroolefin intermediates in various base-catalyzed transformations (2, 4–7, 11–13). However, our recent studies on the epimerization of nitro pentosides (1) and of the above mannosides have demonstrated that the nitronate ⇄ nitroolefin pathway does not apply when the nitromethylene acidity is strongly reduced for steric reasons. In these cases, the secondary nitro group might be termed pseudo-tertiary, and it is suggested that a reverse Henry reaction (reverse nitroalkane-aldehyde addition), known to be facile only in β-hydroxy-*tert*-nitro compounds, must then account for epimerization.

[6]In contrast to the situation in the nitronates, there is no special hindrance between a nitro group on a tetrahedral carbon and an adjacent, equatorial hydroxyl.

Experimental

For general procedures and instrumental techniques, see preceding parts of this series (1, 15).

Materials

The following nitro glycosides were obtained according to the references given in parentheses: **1**, **8**, **10** (16); **3**, **4**, **7**, **15** (17); **5**, **11**, **12** (18); **9** (19). Preparation of the new α-D-*galacto* compound **2** (m.p. 166–167°; $[\alpha]_D$ +205°, *c* 0.5 in chloroform) and α-D-*manno* compound **6** (m.p. 138–139°); $[\alpha]_D$ +27.7°, *c* 0.8 in chloroform) will be disclosed elsewhere (3).

Ultraviolet Spectra

Accurately weighed samples (about 3.6 mg) of the nitro glycosides were dissolved in 10.00 ml of 99% ethanol. Aliquots containing 0.31 mg of **1**–**7** (mol. wt. 311) or 0.295 mg of **8**–**11** (mol. wt. 295) were withdrawn and their volumes (*e.g.* 0.85 ml) were made up to 10.00 ml with 0.01 or 0.001 *N* ethanolic potassium hydroxide solution as specified (Table 1), to give solutions that were 10^{-4} *M* in nitro compound. The spectra were measured in a Perkin–Elmer 202 spectrophotometer using 1-cm cells, with the reference cell containing ethanolic KOH of the same normality.

Reactions Concerning the manno → gluco Epimerization

(*a*) The β-D-mannoside **7** (62 mg) was dissolved in 0.1 *N* ethanolic potassium hydroxide (20 ml). After standing for 10 min at 25° the solution was deionized by cation exchange, filtered, and evaporated to give a solid that was recrystallized from methanol–water. The product (55 mg, 89%) melted at 180–181° and gave an i.r. spectrum identical with that of an authentic sample of the β-D-glucoside **5**; lit. (18), m.p. 181–182°. In a parallel run employing methanolic potassium hydroxide and ice cooling, t.l.c. revealed that the conversion of **7** was complete within a few minutes.

(*b*) A similar preparative experiment using the α-D-mannoside **6** furnished 81% of the α-D-glucoside **4**, m.p. 165–166°, $[\alpha]_D$ +82.1° (*c* 0.63 in ethanol), with an i.r.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

spectrum identical to that of an authentic sample; lit. (17), m.p. 167°, $[\alpha]_D$ +82°.

(*c*) Compound **7** (62 mg) was dissolved in 20 ml of 0.1 *N* methanolic sodium methoxide solution. After standing at 25° for 2.5 h the solution was deionized and evaporated to give 57 mg (92%) of crystals which on recrystallization from methanol–water amounted to 53 mg (85%), m.p. 180–181°. They were identical with **5** according to t.l.c. and i.r. spectrum.

(*d*) Thiobenzyl alcohol (0.2 ml) was mixed with 0.1 *N* sodium methoxide solution (33 ml). After 15 min the mannoside **7** (103 mg) was added, and the reaction mixture was stirred at room temperature. According to t.l.c. **7** was completely converted into **5** after 30 min, and work-up after 60 min yielded 89 mg (86%) of recrystallized **5**, m.p. 179–181°. There was no evidence for formation of the known (13) benzylthio derivative **14**.

(*e*) To an ice cold solution of the 2-acetate **15** (70.5 mg) in methanol (5 ml) was added a 0.2 *N* methanolic potassium hydroxide solution (20 ml). It was revealed by t.l.c. that the reaction was complete after 2 min. Work-up by deionization and evaporation after 25 min furnished 57 mg (88%) of **13**, m.p. 184–185°, which was identified with an authentic sample by i.r. spectroscopy and an undepressed mixture melting point.

We thank the National Research Council of Canada for support of this work.

Acetonation of 3-Deoxy-3-nitro-D-glucose and Formation of a Derivative of 3-Deoxy-3-nitro-D-allose[1]

JAN KOVÁŘ AND HANS H. BAER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 28, 1971

Reaction of 3-deoxy-3-nitro-D-glucose (**1**) with acetone and triethyl orthoformate in the presence of hydrogen chloride gave crystalline 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucopyranose (**2**), 3-deoxy-1,2:4,6-di-*O*-isopropylidene-3-nitro-α-D-glucopyranose (**3**), and 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**5**) in proportions varying with the acid concentration. The furanose derivative **5** is thermodynamically favored. Partial acid hydrolysis of **5** gave 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**4**), whereas action of mild base caused epimerization to 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-nitro-α-D-allofuranose (**6**).

La réaction du déoxy-3 nitro-3 D-glucose (**1**) avec l'acétone et le triéthyl orthoformate en présence d'HCl conduit au déoxy-3 *O*-isopropylidène-1,2 nitro-3 α-D glucopyranose (**2**), au déoxy-3 di-*O* isopropylidène-1,2;4,6 nitro-3 α-D-glucopyranose (**3**), et au déoxy-3 di-*O*-isopropylidène-1,2;5,6 nitro-3 α-D-glucofuranose (**5**) en proportions variables selon la concentration en acide. Le dérivé furanosique **5** est thermodynamiquement favorisé. L'hydrolyse acide partielle de **5** donne le déoxy-3 *O*-isopropylidène-1,2 nitro-3 α-D-glucofuranose (**4**), alors que l'action d'une base faible provoque l'épimérisation en déoxy-3 di-*O*-isopropylidène-1,2;5,6 nitro-3 α-D-allofuranose (**6**).

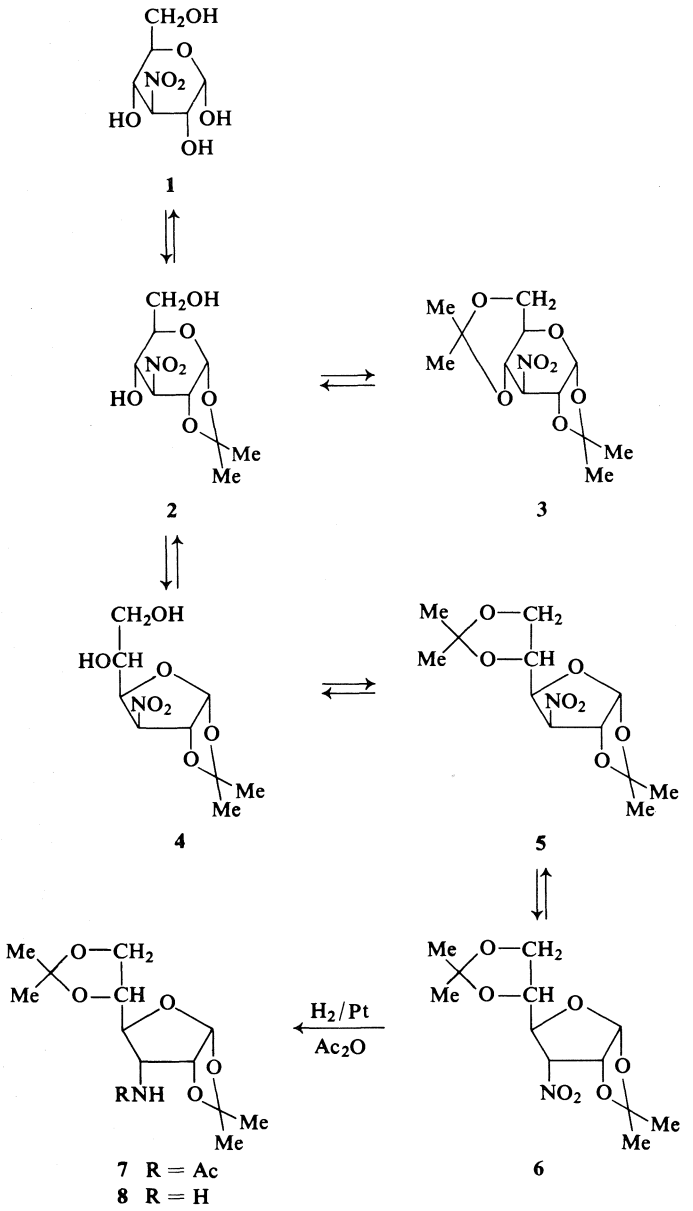
Canadian Journal of Chemistry, **49**, 3203 (1971)

The familiar derivatization of carbohydrates with acetone has been applied to nitro sugars and nitro inositols in a few instances only (1–3). Thus, it has served as a means of separating a mixture of 6-deoxy-6-nitro-D-glucose and -L-idose, a pair of sugars that give furanoid di-*O*-isopropylidene derivatives even though one of the ketal moieties possesses the unfavorable, six-membered ring structure bridging C-3 and -5 (1). With a view to preparing a partially blocked compound for some synthetic project we decided to investigate the acetonation of 3-deoxy-3-nitro-D-glucose (**1**). This was undertaken in the expectation that the 1,2-mono- and 1,2:5,6-di-*O*-isopropylidene derivatives of the furanose form of **1** would be obtained, and no particular problems were anticipated. Although the goal was reached, a number of noteworthy complications occurred in its pursuit.

To begin with, the reaction of acetone with **1** appeared to be considerably less facile than that of D-glucose and most simple aldoses (4). A variety of conditions that included catalysis with boron trifluoride or cupric sulfate and sulfuric acid gave unsatisfactory results. High degrees of acetonation were eventually achieved when mixtures of acetone and triethyl orthoformate were employed and anhydrous hydrogen chloride in dioxane was provided as a catalyst (5). However, several products were formed in varying proportions, and the results of individual experiments seemed difficult to reproduce. The reaction remained vexing until influences of acid concentration and work-up operations had been studied in detail. Altogether five new products were encountered (see Scheme 1): 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucopyranose (**2**), 3-deoxy-1,2:4,6-di-*O*-isopropylidene-3-nitro-α-D-glucopyranose (**3**), 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**4**), 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**5**), and 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-nitro-α-D-allofuranose (**6**). Structural proof will be described in a later paragraph.

When acetonation of **1** was allowed to take place for 3 days at 4°, the predominant product at low hydrogen chloride concentration was the monoacetone pyranose **2**, and this was accompanied by the diacetone pyranose **3** and the diacetone furanose **5**. Among these minor products, **3** preponderated over **5** at lowest acidity of the medium. As the acidity was increased the proportion of **2** decreased relative to the combined amount of the diacetone derivatives, and in the latter, the proportion of **5** rose while that of **3**

[1]Part XXIII in a series on reactions of nitro sugars. For part XXII see ref. 27.



SCHEME 1

diminished. At sufficiently high acidity **5** thus became the predominant product. This is illustrated in Fig. 1 by data obtained in a set of preparative experiments performed under standardized conditions. It was possible to fractionate a given product mixture, by virtue of differential solubilities in chloroform and ethyl acetate, into unreacted **1**, monoacetone derivative **2**, and a fraction comprising the diacetone derivatives **3** and **5**. The ratios **3**:**5** were derived from n.m.r. spectra of the mixtures which displayed well-separated H-1 signals suitable for intensity comparison by integration. It is evident from the results that the nitro glucose reacts fastest in its pyranose form to give **2** and even **3** although these molecules, especially **3**, are sterically disfavored. The diacetone furanose **5** is formed comparatively slowly, but it is seen to be the thermodynamically most favored component since it begins to predominate when establishment of equilibrium is

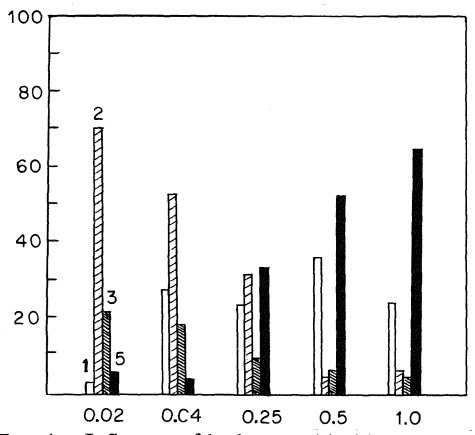

FIG. 1. Influence of hydrogen chloride concentration on the acetonation of **1**. Ordinate: Percentage composition of the reaction mixture. Abscissa: Normality of medium in hydrogen chloride.

promoted by growing amounts of catalyst.[2] In acetonations of D-glucose itself, ketals of the furanose form are produced invariably, and ketals of the pyranose form have not to our knowledge been encountered, presumably because kinetic control does not normally prevail. In the case of **1** apparently the slower over-all acetonation process permits isolation of kinetic products. As far as conversion of the compounds into **5** is concerned one must assume that the route passes through a monoacetone furanose. However, no such intermediate was detected under the reaction conditions discussed so far, and one has therefore to conclude that it rapidly accepts a second isopropylidene group.

The monoisopropylidene furanose **4** was, however, obtained from **5** by partial hydrolysis with 0.01 *N* sulfuric acid. Quite unexpectedly it was also produced when **5** was chromatographed on a column of silica gel.[3] Equally unexpected was the finding that similar chromatography of **5** on a different brand of silica gel[4] yielded yet another diisopropylidene sugar, namely the allofuranose derivative **6**. The phenomena thus associated with chromatographic work-up operations were not conducive to an easy unravelling of the acetonation reaction. We have now realized that the first-mentioned adsorbent[3] reacts sufficiently acidic to cause partial deacetonation whereas the second adsorbent[4] shows a weak base reactivity that catalyzes epimerization at the nitromethylene asymmetric center. Indeed, the two adsorbents are stained red and green, respectively, by a yellow chloroform extract of p*H* universal indicator paper. The same epimerization (**5** → **6**) was also brought about by the action of solid sodium bicarbonate in acetone, under which conditions an equilibrium containing the D-*gluco* and D-*allo* compounds in a ratio 4:5 was reached (Table 1). Although this epimerization is not very fast it may well lead to contamination of **5** by **6** during work-up of acetonations if, for removal of the acid catalyst, excessive amounts of bicarbonate are used for prolonged periods of time and without cooling of the mixture.

Attention has been drawn on many occasions (1, 2, 7–16) to the extraordinary ease with which certain structural and configurational changes are effected in nitro sugars by the action of base. However, the present instance is the first *gluco* → *allo* epimerization to be observed in this area. 3-Deoxy-3-nitro hexose derivatives with the *gluco*, *manno*, *galacto*, and *talo* configurations have been subjected to column chromatography (17, 18) or exposed to more strongly basic media (8, 10, 15, 16), and no inversions at C-3 were observed although other changes did occur. But the compounds referred to had the pyranose structure, with an equatorial nitro group having no tendency to become axial.[5] In the furanoses **5** and **6**,

TABLE 1. Epimeric equilibration of a mixture of **5** and **6**

Time (h)	Composition (%)		
	5	**6**	(3)*
0	74	21	5
0.75	70	25	5
2.5	66	30	4
20	47	49	4
44	44	52	4
116	43	52	5
150	41	53	6

*The starting mixture used for this particular experiment contained 5% of isomer 3. The amount of this component remained unchanged within the limits of experimental error, and its presence is considered irrelevant.

[2]The reaction is considered to be a reversible transacetalation involving 2,2-diethoxypropane (6) that originates from acetone and triethyl orthoformate.

[3]The silica gel used was designated as "desiccant, mesh 100–200, specification MIL D3716" and was supplied by Davison Chemical, Baltimore, Maryland.

[4]Silica gel designated "for column chromatography, mesh 70–325", supplied by E. Merck A.G., Darmstadt, Germany.

[5]Compare also our recent discussion of the preference for an equatorial nitro group in the methyl 3-deoxy-3-nitropentopyranosides (14).

For personal use only.

a 3,4-*cis* arrangement obviously implies more strain than a 3,4-*trans* arrangement, and this factor seems to override the opposing strain difference in the 2,3-*cis* and -*trans* arrangements, thus favoring epimerization. This situation parallels that existing in recently reported syntheses (13, 19) of 3-deoxy-3-nitropentofuranosides by nitroalkane cyclization, where the main products had the *ribo* (3,4-*trans*) rather than the *xylo* (3,4-*cis*) configuration.

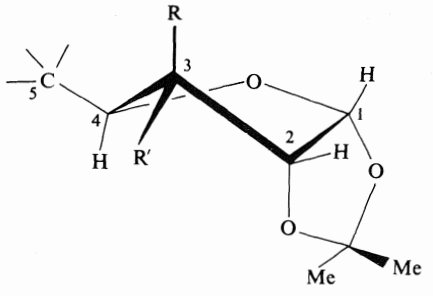

FIG. 2. The T_2^3 conformation of the furanose ring in **4** and **5** (R = NO_2; R′ = H) and **6** (R = H; R′ = NO_2).

Assignment of Structure

The monoisopropylidene sugar **4** consumed 1 *M* equiv of periodate, thereby being degraded to an aldehyde which was transformed, by reduction and subsequent deacetonation (20), into 3-deoxy-3-nitro-D-xylose. This established the constitution and configuration of **4** and its preparative precursor, the diacetone derivative **5**. The isomeric monoacetone derivative **2** was resistant against periodate, in keeping with the pyranoid structure assigned to it. It must also possess the D-*gluco* configuration since it yielded **5** on further acetonation, a fact which rules out the remote possibility that a configurational change had occurred in its formation or isolation. The diacetone compound **6** was elucidated by catalytic hydrogenation in the presence of acetic anhydride. This afforded a crystalline acetamido compound which was identified with the known (21) 3-acetamido-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**7**) obtained by *N*-acetylation of an authentic sample of the parent amine **8** (21–23) (kindly provided by Dr. D. H. Ball, Natick, Massachusetts). Finally, the structural assignment for **3** was based on the nonidentity of this compound with the isomers **5** and **6** and appears reasonable in view of its formation from **1**, along with **2**, under mild conditions of acetonation.

In deuterochloroform solution the diacetone compounds **3**, **5**, and **6** are readily distinguished by the positions of their n.m.r. signals for H-1 (doublets with $J_{1,2}$ = 3.5–4.5 Hz), which occur at τ 4.40, 3.92, and 4.11, respectively. Whereas the monoacetone furanose **4** cannot be differentiated from **5** through the H-1 signal (τ 3.91), its H-5 and -6 signals (τ 6.2–6.4) occur farther upfield than those of **5** (τ 5.9–6.1) and may thus serve for distinction. In derivatives of 1,2-*O*-isopropylidene-α-D-glucofuranose the furanose ring has been deduced from n.m.r. spectra to exist in the T_2^3 twist conformation (24, 25). Our data for **4** and **5** tend to bear out this conformation as we found zero coupling between H-2 and -3, indicating a dihedral angle of the order of 90° between these protons. Although the spectrum of the *allo* compound **6** did not provide a similar indication for the conformation since the H-2, -3, and -4 signals were difficult to analyze, it appears reasonable to assume the same T_2^3 form. In the latter, **6** has an approximately 90° dihedral angle between the C_3—NO_2 and C_4—C_5 bonds, and this condition would explain the somewhat greater stability of **6** as compared to **5** where that angle is only about 30° (Fig. 2). In the inverted, T_3^2 form of **6**, the nitro group would interfere severely with one of the isopropylidene methyl groups, and the compound would be expected to be less stable than **5**.[6]

Experimental

For general preparative and instrumental techniques see preceding articles of this series (13–17, 26). 3-Deoxy-3-nitro-α-D-glucopyranose (**1**) was prepared as described (26); m.p. 182–184°, $[\alpha]_D$ +119 (2 min) → +112 (6 min) → +83° (2 h, in water). Reported, m.p. 176–177° (dec.), $[\alpha]_D$ +99.6 (6 min) → +73.9° (130 min). The t.l.c. was performed on 7-cm plates of silica gel G (E. Merck A.G., Darmstadt, Germany) and proved useful for distinguishing the nitro glucose **1** from the two monoisopropylidene derivatives **2** and **4** and the three diisopropylidene derivatives **3**, **5**, and **6**, as follows (R_f values in parentheses): *a*, with ethyl acetate, **1** (0.4), **2** and **4** (0.9), **3**, **5**, and **6** (1.0); *b*, with 1:1 ethyl acetate – chloroform, **1** (0.05), **2** and **4** (0.4), **3**, **5**, and **6** (0.9); *c*, with 1:5 ethyl acetate – chloroform, **1** (0.0), **2** and **4** (0.1), **5** (0.6), **6** (0.7), and **3** (0.85). The n.m.r. data (100 MHz) were obtained from $CDCl_3$ solutions unless other-

[6]NOTE ADDED IN PROOF: Nakagawa and coworkers have briefly reported (28) the synthesis of **6** by another route, and they have also obtained (29) a pyranoid diketal of **1**, namely, the cyclohexylidene analog of **3**.

wise indicated, and are expressed on the τ-scale with reference to internal tetramethylsilane.

3-Deoxy-1,2-O-isopropylidene-3-nitro-α-D-glucopyranose (2) and 3-Deoxy-1,2:4,6-di-O-isopropylidene-3-nitro-α-D-glucopyranose (3)

A solution of the nitro glucose **1** (335 mg, 1.6 mmol) in acetone (3.3 ml, dried over $CaCl_2$) and triethyl orthoformate (1.6 ml) was acidified with 0.03 ml of 4.9 *N* hydrogen chloride in dioxane. The reaction mixture was allowed to stand at about 25° for 3 days and was then neutralized by shaking with dry sodium bicarbonate for 1 min and filtered with some activated charcoal through layers of Dowex-1X2 ($CH_3CO_2^-$) and Amberlite IR-120 (H^+) (1 ml each, prewashed with acetone). The filtrate was evaporated to give a resinous material that was co-evaporated thrice with benzene, dried *in vacuo*, and then extracted with a total of 5–6 ml of boiling benzene, in three portions. A brown residue (62 mg) was discarded, and the extract was chromatographed on a column containing silica gel Merck[4] (15 g, containing 10% of added water). Elution with benzene (165 ml) furnished colorless crystals (116 mg) which upon recrystallization from ligroin gave pure **3** (49 mg), m.p. 128–129°, $[\alpha]_D$ + 134° (*c* 0.23, in methanol). The i.r. spectrum in chloroform showed NO_2 bands at 1555 and 1370 cm^{-1}, and bands at 1365, 1320, 1200, 1045, and 1010 cm^{-1} which were not present in the spectra of **5** and **6**. The n.m.r. data: τ 4.40 (doublet, J = 4.5 Hz, H-1), 5.2–5.6 (2-proton multiplet, H-2, -3), 5.8–6.3 (4-proton multiplet, H-4, -5, -6, -6′), 8.43, 8.57, 8.65, 8.65 (3-proton singlets, CH_3).

Anal. Calcd. for $C_{12}H_{19}NO_7$ (289.3): C, 49.81; H, 6.62; N, 4.85. Found: C, 49.77; H, 6.55; N, 5.03.

The ligroin mother liquor of the above recrystallization furnished a small amount of crystals melting at 110–111°. These were identical with compound **6** described further below.

After the elution of **3**, the chromatographic column was eluted with benzene containing increasing amounts of ethanol. With benzene–ethanol (20:1), compound **2** (115 mg) was obtained. It was recrystallized from ethyl acetate – ligroin; m.p. 180–181°, $[\alpha]_D$ +37° (*c*, 0.26, in methanol). The compound was almost insoluble in chloroform. The n.m.r. data (in acetone-d_6): τ 4.78 (doublet, J = 3 Hz, H-1), 5.2–5.5 (2-proton multiplet, H-2, -3), 5.9–6.4 (4-proton multiplet, H-4, -5, -6, -6′), 8.56, 8.70 (3-proton singlets, CH_3).

Anal. Calcd. for $C_9H_{15}NO_7$ (249.2): C, 43.39; H, 6.07; N, 5.62. Found: C, 43.53; H, 6.09; N, 5.77.

3-Deoxy-1,2:5,6,di-O-isopropylidene-3-nitro-α-D-glucofuranose (5)

A solution of **1** (414 mg) in dry acetone (5 ml) and triethyl orthoformate (1 ml) was acidified with 0.2 ml of 2.8 *N* hydrogen chloride in dioxane and kept at 25° for 4 days. The mixture was neutralized by stirring for 3 min with solid sodium bicarbonate, filtered, and evaporated to give a residue which was extracted three times with hot benzene. An amount of 148 mg of what was mainly unreacted **1** remained undissolved. The benzene extract was evaporated to give an oil which was transferred by means of chloroform onto a column containing 10 g of silica gel.[3] Elution with chloroform produced an oil (356 mg) that crystallized in part by trituration with petroleum ether (b.p. 30–60°). Recrystallization from petroleum ether gave **5** (122 mg), m.p. 60–62°, $[\alpha]_D$ +28° (*c*, 0.3, in benzene), and +4.5° (*c*, 0.3, in methanol). The i.r. spectrum in chloroform exhibited NO_2 bands at 1550 and 1370 cm^{-1} and, in the fingerprint region, was similar in general to, but different in some details from, the spectra of **3** and **6**. Especially a peak at 1085 cm^{-1} distinguished **5** from the isomers.

The n.m.r. data: τ 3.92 (doublet, $J_{1,2}$ = 3.5 Hz, H-1); 4.90 (doublet, $J_{3,4}$ = 4.0 Hz, H-3), 5.01 (doublet, $J_{1,2}$ = 3.5 Hz, H-2); 5.66 (quartet, $J_{3,4}$ = 4.0 and $J_{4,5}$ = 8 Hz, H-4); 5.9–6.1 (3-proton multiplet, H-5, -6, -6′); 8.50, 8.59, 8.69, 8.72 (3-proton singlets, CH_3).

Anal. Calcd. for $C_{12}H_{19}NO_7$ (289.3): C, 49.81; H, 6.62; N, 4.85. Found: C, 50.01; H, 6.60; N, 4.72.

A similar experiment was performed using 620 mg of **1** in 9 ml of a 5:1 acetone – triethyl orthoformate mixture acidified with 2 ml of 4.9 *N* hydrogen chloride in dioxane. The reaction was allowed to proceed at +4° for 3 days. The mixture was neutralized under ice cooling with sodium bicarbonate (2 g). The residue obtained on filtration and evaporation was extracted with cold chloroform (3 × 5 ml). The part that remained undissolved (250 mg) was mainly **1** (t.l.c.). The chloroform extract was concentrated to a small volume, cooled, and placed for 1 day in a refrigerator where it deposited crystals (58 mg) consisting mainly of **2** (t.l.c.). The filtrate from these crystals on evaporation gave an oil (720 mg) which according to n.m.r. spectroscopy contained **5** as the only carbohydrate besides dioxane (τ 6.32), acetone (τ 7.91), and acetone self-condensation products. These non-carbohydrate materials were removed by passing a chloroform solution of the oil through a column of silica gel Merck[4] (15 g) which was eluted with the same solvent (75 ml). Although the recovered carbohydrate (523 mg) was mainly **5** it now contained about 15% of **6**, according to n.m.r. spectroscopy. Two parts (109 and 155 mg) of this material were rechromatographed in the same manner, on 3 and 5 g of silica gel,[4] respectively. The materials recovered (94 and 139 mg, approximately 90%) contained **5** and **6** in the ratios of 75:25 and 67:33. See also the description of the formation **6** given further below.

Another experiment was performed similar to that just described, except that the monoacetone pyranose **2** served as the starting material, and passage of the product through silica gel was omitted. The experiment yielded **5** (70%) and a mixture of **1** and **2** (15–20%).

Influence of Hydrogen Chloride Concentration on the Acetonation

The results shown in Fig. 1 were obtained as follows. Samples of nitro glucose **1** (approximately 209 mg, 1 mmol) were suspended in 3 ml of a 5:1 (*v*/*v*) mixture of acetone and triethyl orthoformate. The suspensions were cooled with dry ice while hydrogen chloride in dioxane was added in amounts providing the acid normalities specified in Fig. 1. The reaction mixtures were stored at +4° for 3 days and then neutralized by stirring with solid sodium bicarbonate under ice cooling, filtered through cotton wool, and evaporated to dryness.

In each run the mixture of products so obtained was extracted three times with chloroform. The combined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

extract (10 ml) was dried over $MgSO_4$ and evaporated to give an oil that was dissolved[7] in 0.5 ml of $CDCl_3$ for n.m.r. spectroscopic determination of the ratio of diisopropylidene derivatives. After evaporation, the dry weight was determined and taken to be the combined yield of **3** and **5**, as no monoisopropylidene derivative was present (t.l.c.) and the amount of **6** was negligible.

The chloroform-insoluble part of the reaction product was triturated with cold ethyl acetate (1 ml). After storage for 12 h at 4° the supernatant solution was removed from the undissolved residue. The latter was washed, dried, and weighed; it was mainly unreacted **1** as confirmed by t.l.c. and optical rotation (with mutarotation). The ethyl acetate solution was evaporated and the residue was weighed; it consisted mainly of the monoisopropylidene compound **2** (m.p. 180–181°; t.l.c.). There was some cross-contamination in the fractions of **1** and **2** but, in determining the weights, this was considered to cancel. Compound **4**, which in contrast to **2** is readily soluble in chloroform, was not encountered in these experiments.

3-Deoxy-1,2-O-isopropylidene-3-nitro-α-D-glucofuranose (4)

Compound **5** (126 mg) in acetone (1.2 ml) and 0.01 *N* sulfuric acid (12.5 ml) were boiled for 10 min. The cooled solution was treated with 0.7 ml of Dowex-1X2 (acetate form, prewashed with *N* acetic acid) for removal of the sulfuric acid. The solution was then evaporated and the residue (109 mg), after drying *in vacuo*, was triturated with cold benzene to give crystalline **4** (50 mg), m.p. 82–83°, $[\alpha]_D$ +64° (in benzene), +25° (in methanol), +41° (in water) (*c*, about 0.3). Infrared bands in chloroform were at 3580 and 3460 (broad, OH), 1545 and 1370 cm^{-1} (NO_2). The fingerprint pattern differed from those of **3**, **5**, and **6** by a band at 1055 cm^{-1}. The n.m.r. data: τ 3.91 (doublet, J = 3.5 Hz, H-1), 4.82 (doublet, J = 4.0 Hz, H-3), 4.98 (doublet, J = 3.5, H-2), 5.52 (quartet, $J_{3,4}$ = 4.0 and $J_{4,5}$ = 8 Hz, H-4), 6.2–6.4 (3-proton multiplet, H-5, -6, -6′), 8.50, 8.69 (3-proton singlets, CH_3).

Anal. Calcd. for $C_9H_{15}NO_7$ (249.2): C, 43.39; H, 6.07; N, 5.62. Found: C, 43.49; H, 6.19; N, 5.81.

Spectroscopically pure **5** (55 mg) dissolved in chloroform was chromatographed on silica gel Davison[3] (1.2 g). The column was successively eluted with chloroform (15 ml) and chloroform containing 2% of ethanol (12 ml). The latter eluant produced crystalline **4** (37 mg, 80%), m.p. 82–84°, in spectroscopically pure form. Similarly, **4** was several times obtained in 40% yield (based on **1**) when **1** was acetonated as described above for the preparation of **5** and the crude reaction mixture was chromatographed in this manner. However, attempted conversion of **5** into **4** by the action of silica gel failed in some experiments, **5** being recovered unchanged.

3-Deoxy-1,2:5,6-di-O-isopropylidene-3-nitro-α-D-allofuranose (6)

Compound **6** was first obtained in an attempt to prepare **5** as described above, with the use of an excess of sodium bicarbonate for neutralization (at room temperature for 20 min), and with the use of silica gel Merck[4] for chromatography. From mixtures of diisopropylidene derivatives so produced, **6** separated by crystallization from ligroin. It melted at 111.5–112° and had $[\alpha]_D$ +101° (*c*, 0.24, in methanol). Infrared bands (in chloroform) were at 1550 and 1370 cm^{-1} (NO_2), and in the fingerprint region the spectrum differed from that of **5** by the presence of bands at 1305 and 1100 cm^{-1} and absence of bands at 1335 and 1085 cm^{-1}.

The n.m.r. data: τ 4.11 (doublet, J = 3.5 Hz, H-1); 4.9–5.2 (3-proton multiplet, H-2, -3, -4); 5.8–6.2 (3-proton multiplet, H-5, -6, -6′); 8.48, 8.63, 8.70, 8.70 (3-proton singlets, CH_3).

Anal. Calcd. for $C_{12}H_{19}NO_7$ (289.3): C, 49.81; H, 6.62; N, 4.85. Found: C, 49.88; H, 6.65; N, 4.96.

A mixture[8] of diisopropylidene derivatives (180 mg) containing **5**, **6**, and **3** in the ratio 74:21:5 as determined by n.m.r. spectroscopy was dissolved in acetone (0.5 ml), sodium bicarbonate (50 mg) was added, and the mixture was allowed to stand at room temperature, with occasional swirling. At intervals, the change in composition (Table 1) was determined by recording the n.m.r. spectrum of the solution. It is noted that the amount of **3** remained unchanged during the epimeric equilibration of **5** and **6**. See also the formation of **6** mentioned above in the section dealing with **5**.

3-Acetamido-3-deoxy-1,2:5,6-di-O-isopropylidene-α-D-allofuranose (7)

A solution of **6** (25 mg) in methanol (2.5 ml) and acetic anhydride (0.15 ml) was hydrogenated over platinum dioxide at ordinary temperature and pressure. The reduction of the nitro group was monitored by u.v. spectroscopy (disappearance of nitronate absorption at 251 nm in alkaline medium) and required about 26 h. The filtered solution was evaporated to give a crystalline residue which upon recrystallization from ethyl acetate – ligroin afforded **7** (11 mg), m.p. 131.5–132°, $[\alpha]_D$ +76° (in chloroform), in good agreement with recorded values (21). The i.r. and n.m.r. spectra were superimposable with those of a sample that had been obtained by *N*-acetylation of authentic amine **8** (21–23).

We thank the National Research Council of Canada for financial support and Mrs. Siegrid Hancock and Mrs. Lisa Siemsen for technical assistance.

Chemistry of 2-Substituted Adamantanes. III.[1] Mass Spectra of 1- and 2-Adamantanethiol, 2-Adamantanol, and 2-Adamantanamine

J. W. GREIDANUS[2]

Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received November 16, 1970

The mass spectra of 1- and 2-adamantanethiol (**1** and **2***a*), 2-adamantanol (**2***c*), and 2-adamantanamine (**2***d*) have been studied. The isomeric thiols give almost identical spectra and loss of the sulfhydryl radical produces the most abundant ion, while the molecular ion peaks have 9 and 21% relative intensity for **1** and **2***a*, respectively. Elimination of H_2S is an insignificant process. In the fragmentation of **2***c* and *d*, loss of H_2O and NH_3 as a single group occurs (metastable peaks), giving M-H_2O and M-NH_3 ions, both at *m/e* 134; this produces the base peak for **2***c* and the second most intense (93%) peak for **2***d*. Further fragmentation of these ions results in very similar peak patterns for **2***c* and *d*. The amine shows a very intense molecular ion peak (79%) and an M-1 base peak ion. The mass spectra of **2***c* and *d* are very different from those of 1-adamantanol and 1-adamantanamine.

Les spectres de masse des adamantanethiols-1 et -2 (**1** et **2***a*), de l'adamantanol-2 (**2***c*), et de l'adamentanamine-2 ont été étudiés. Les thiols isomères donnent des spectres pratiquement identiques et la perte du radical sulfhydrile conduit à l'ion le plus abondant alors que l'intensité relative des pics dues aux ions moléculaires de **1** et **2***a* est respectivement de 9 et 21%. L'élimination de H_2S est un processus insignifiant. Dans la fragmentation de **2***c* et *d*, la perte des seuls groupes H_2O et NH_3 se produit (pics métastables), pour donner les ions M-H_2O et M-NH_3, tout deux situés à *m/e* = 134; ceci conduit au pic de base pour **2***c* et au deuxième pic le plus important (93%) pour **2***d*. La fragmentation ultérieure de ces ions conduit à des systèmes très semblables pour **2***c* et *d*. L'amine présente un ion moléculaire très intense (79%) et un pic de base à M-1. Les spectres de masse de **2***c* et *d* sont très différents de ceux de l'adamantanol-1 et de l'adamantamine-1.

Canadian Journal of Chemistry, 49, 3210 (1971)

Introduction

Some time ago Dolejšek *et al.* (1) reported the mass spectra of a variety of 1-substituted adamantane compounds, and suggested a number of fragmentation reactions to account for the observed data. Although there has been very much interest in the chemistry of adamantanes in the last few years, no mass spectral study has been reported to our knowledge for 2-substituted adamantanes. Such a study was started by us because of its intrinsic interest, as well as for the purpose of identification and, if possible, of analysis of isomer mixtures by low-resolution mass spectroscopy.

As will be seen from the results, such an analysis would be well feasible in some cases, but would be much harder in another instance.

Experimental

The compounds investigated were obtained from commercial sources (1-adamantanamine, 2-adamantanamine) or prepared by published procedures (1-adamantanol (2), 2-adamantanol (3), 1-adamantanethiol (4), 2-adamantanethiol (5), and 2-methylthioadamantane (5)), and carefully purified.

The mass spectra, some of which are shown in Figs. 1 and 2, were recorded with a Varian Atlas CH-5 spectrometer, with a nominal ionizing energy of 70 or 12 eV, a source temperature of 250°, and by use of a direct probe (20–25°). The relative intensities of the peaks are given as percentages of the most intense peak (base peak) in a spectrum. Peaks with a relative intensity lower than 2% were not reproduced, unless they had a special significance.

Results and Discussion

1- and 2-Adamantanethiol

The molecular ion peaks (*m/e* 168) in the mass spectra (70 eV) of the thiols **1** (Fig. 1*a*) and **2***a* (Fig. 1*b*) are of medium to high relative intensity (8.5 and 21%, respectively) and the base peak in both spectra is found at *m/e* 135. A metastable peak for the transformation M → (M-SH) is present at *m/e* 108.5 (calcd. 108.5) in the spectra (at 70 and 12 eV).

Elimination of hydrogen sulfide is a process of very minor significance, especially in the tertiary thiol **1** where peak *m/e* 134 has a relative intensity of only 0.5% (70 eV). Although it has been

[1]For Part II of this series, see ref. 5.

c R = OH
d R = NH_2

established (6) that loss of H_2S is an important fragmentation of the molecular ion of secondary thiols (especially at low electron energies), we observed on lowering the ionizing energy to 12 eV only negligible changes in the relative intensities of the *m/e* 134 peaks in either of the thiols. At this low ionizing energy the molecular ion gave rise to the base peak (*m/e* 168) and peak M-33 had a relative intensity of 89%. No metastable peak corresponding to the loss of hydrogen sulfide from the molecular ion could be found in the spectrum of **2***a*. The finding that loss of H_2S from the molecular ion of **1** does not play any role in the fragmentation is not surprising as a favorable spatial relationship for a 1,3- or 1,4-elimination is not present in the molecule.

The M-H_2S ion (*m/e* 134) is a likely precursor (eq. 1) for the formation of fragment $C_9H_{11}^+$ as

[1] $C_{10}H_{14}^+$ (*m/e* 134) $\xrightarrow[*]{-CH_3^\cdot}$ $C_9H_{11}^+$ (*m/e* 119)

the metastable peak for this transformation (*m/e* 105.7) is present in the spectrum of **2***a*.

Loss of the neutral fragment $C_4H_9^\cdot$ from the molecular ion of various 1-substituted adamantanes gives rise to the most abundant ion in the spectra of 1-adamantanol (**3***a*) and 1-adamantanamine (**3***b*). These fragmentations have been formulated by Dolejšek *et al.* (1) as the formation of protonated phenol (**5***a*) and aniline (**5***b*), respectively (eq. 2).

In the spectrum of 1-adamantanethiol (**1**) only a weak peak is present at *m/e* 111 (2.4% relative intensity) and the fragmentation M → M-57 plays therefore no significant role in this compound. This behavior was unexpected as sulfur is known (7) to participate readily in the type of new bond formation that would lead to **4** (X = SH).

The approximately ten times higher intensity of the peaks at *m/e* 134 and 119, and the double intensity of the molecular ion peak in the spectrum of **2***a* are the main differences between the spectra of **1** and **2***a*. Except for some minor variations in relative intensities the rest of the spectra are virtually the same even when the many metastable peaks are compared.

It is clear that 1-adamantanethiol (**1**) belongs in

the same group as 1-nitro, 1-bromo-, and 1-alkyladamantane (1). All lose their substituent readily, forming $C_{10}H_{15}^+$ which upon further fragmentation produces many even-electron ions. Metastable peaks for the transformations involving $C_{10}H_{15}^+$ and its derived ions are listed in Table 1. Those for the transformations numbered 6 and 10 were not reported by Dolejšek *et al.* (1) for any of their 1-substituted adamantanes which showed the same fragmentation behavior. These

TABLE 1. Metastable ion peaks (*m/e*) for transformations $A^+ \rightarrow B^+ + C$ involving $C_{10}H_{15}^+$ and smaller fragments in the spectra of **1** and **2***a*

Transformation no.	A(*m/e*)	B(*m/e*)	C	*m/e**
1	$C_{10}H_{15}$(135)	C_8H_{11}(107)	C_2H_4	84.8
2	$C_{10}H_{15}$(135)	C_7H_9(93)	C_3H_6	64.1

9	C_6H_7(79)	C_6H_5(77)	H_2	75.0
10	C_5H_7(67)	C_3H_5(41)	C_2H_2	25.1

*Calculated values; observed values differed at the most 0.2 *m/e* units from these.

authors suggested that a metastable peak at *m/e* 37.1 probably arose from fragmentation of an ion *m/e* 121 (eq. 3). However in their spectra, as in

[3] $C_9H_{13}^+$ (121) $\rightarrow C_5H_7^+$ (67) + C_4H_6

ours, the peak *m/e* 121 has very low relative intensity (<0.5%). It is much more likely that one or both of the fragmentations *m/e* 81 → *m/e* 55 and *m/e* 41 → *m/e* 39 (for which metastable ion peaks at *m/e* 37.4 and 37.1, respectively, are calculated) give rise to this metastable peak.

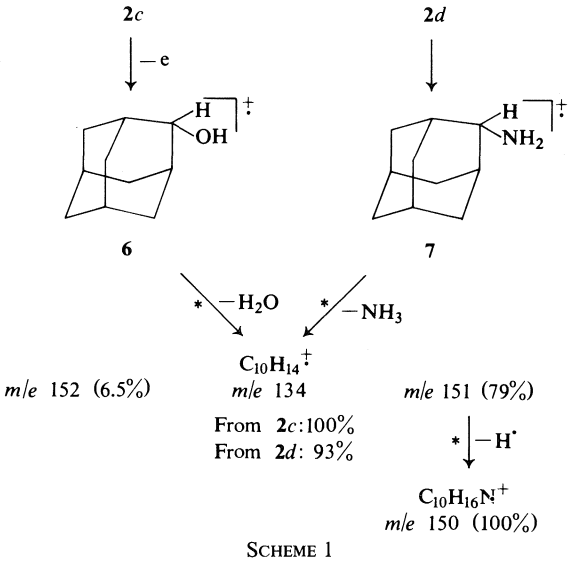
It should be noted here that the mass spectrum of 2-methylthioadamantane (**2***b*) also has its base peak at *m/e* 135 and is at *m/e* < 135 almost identical with that of **1** and **2***a*. It shows metastable ion peaks corresponding to the transformations numbered 1, 2, and 4–9 in Table 1, and to the loss of $CH_3S^\cdot$ from the molecular ion at *m/e* 100.2 (calculated for M(*m/e* 182) → M-CH_3S(*m/e* 135) : *m/e* 100.1). A peak at *m/e* 134 (relative intensity 3.5%) indicates that elimination of CH_3SH occurs as well, analogous to the loss of H_2S from **2***a*.

The compounds **1**, **2***a* and **2***b* give rise to an abundant even-electron ion $C_{10}H_{15}^+$ which may or may not be the same in all three cases, but which appears to give identical fragmentations. Apparent intramolecular 1,2-hydride shifts in adamantanes have very recently been shown to be intermolecular processes (8) *in solution*. At this time it is not known whether the energetically unfavorable twisted transition state for such an intramolecular 1,2-hydride shift (8) can occur in an adamantyl cation in a state of high energy *under conditions which exclude an intermolecular process*. Very recently reported results (9) of the study of electron-impact fragmentation of various deuterated bicyclic alcohols indicate that very rapid hydride and C—C bond shifts occur in these systems while H_2O elimination takes place. At the present time 1,2-hydride shifts in adamantyl carbonium ions of high energy, such as occur in electron-impact fragmentation reactions, cannot be discounted.

2-Adamantanol and 2-Adamantanamine

The striking similarity of the mass spectra (Fig. 2) of 2-adamantanol (**2***c*) and 2-adamantanamine (**2***d*) is apparent at first glance. The amine gives a much more abundant molecular ion and shows a large number of peaks of considerable relative intensity (nine peaks with more than 40% relative intensity). The base peak for **2***c* and the second most intense peak in the spectrum of **2***d* (both at *m/e* 134) represent loss of H_2O and NH_3 from the molecular ions **6** and **7**, respectively (Scheme 1).

The presence of a metastable peak at *m/e* 118.2



SCHEME 1

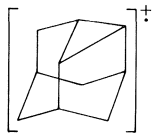
(calcd. 118.1) for the transformation **6** (*m/e* 152) → $[C_{10}H_{14}]^{+\cdot}$, and at *m/e* 118.9 (calcd. 118.9) for the transformation **7** (*m/e* 151) → $[C_{10}H_{14}]^{+\cdot}$ indicates that 18 and 17 mass units, respectively, are lost as a single group. These metastable peaks occur also in spectra run at low ionizing energy (12 eV). The loss of NH_3 appears to be one of the major fragmentation processes of 2-adamantanamine and the M-17 peak is in fact the second strongest peak (relative intensity 57%) in its 12 eV mass spectrum. The facility with which this fragmentation occurs is surprising as loss of NH_3 from primary amines is an uncommon reaction (10). A 1,3-elimination, for which the spatial relationship is favorable, would give rise to the molecular ion (**8**) of 2,4-dehydroadamantane (tetracyclo-[3.3.1.$1^{3,7}$. $O^{2,4}$]decane (11)).



8

The source of the hydrogen atoms in the dehydration of cyclohexanols as a result of electron impact has been thoroughly investigated (12, 13). The main course for which good evidence is available in the case of cyclohexanol is a 1,4-elimination involving *cis*-oriented groups (13). An example has been reported (14) where 1,4-elimination was impossible (as it is in 2-adamantanol). In this case a diaxial 1,3-elimination occurred exclusively. In cyclohexanol it has been demonstrated that the hydroxyl-bearing carbon atom does not supply also the hydrogen for the dehydration (12). This finding has been corroborated recently (9) in the case of several bicyclic alcohols, where evidence for rapid 1,3-hydride shifts and/or C—C bond shifts was obtained. The adamantane skeleton would permit analogous 1,3-hydride shifts but these would result in identical cations. Stabilization may occur ultimately by loss of a hydrogen atom. We tentatively interpret the formation of radical ion **8** from either **6** or **7** as resulting from this process.

In the mass spectrum (Fig. 2) of **2***c* M-1 and M-2 peaks occur with a relative intensity slightly lower than that of the molecular ion peak.

Loss of a hydrogen atom from the molecular ion (**7**) of 2-adamantanamine gives rise to the most abundant species $C_{10}H_{16}N^+$ (*m/e* 150) in its 70 eV spectrum (Fig. 2*a*) and to a strong metastable peak at *m/e* 149.1 for the transformation M → M-1 (calcd. *m/e* 149.0). It is the fragmentation of **7** and of $C_{10}H_{16}N^+$ with retention of nitrogen in the fragment ions which probably gives rise to the main differences between the spectra of **2***c* and *d*. It is surprising that these differences are still so minor (in view of the fact that $C_{10}H_{16}N^+$ (*m/e* 150) causes the base peak) except for the very intense (75%) peak at *m/e* 30, representing the fragment $CH_2{=}\overset{+}{N}H_2$, a frequently occurring abundant species in the spectra of many primary amines. No metastable peak could be found for a fragmentation involving this ion.

The metastable peaks assigned to transformations of $C_{10}H_{14}^{+\cdot}$ (*m/e* 134) and its smaller fragments as they occur in the spectra of **2***c* (Fig. 2*a*) and *d* (Fig. 2*b*) are listed in Table 2. Apart from the peak at *m/e* 30 and the very intense M and M-1 peaks in the spectrum of **2***d*, the most characteristic difference between Figs. 2*a* and *b* is the presence of a peak at *m/e* 108 (relative intensity 20%) in the spectrum of the amine. This ion may be directly derived from the molecular ion $C_{10}H_{17}N^{+\cdot}$ (**7**) or from ion $C_{10}H_{16}N^+$ by elimination of $C_3H_7^{\cdot}$ (eq. 4) and C_3H_6 (eq. 5), respectively.

[4] $C_{10}H_{17}N^{+\cdot}$ (*m/e* 151) → $C_3H_7^{\cdot}$ + $C_7H_{10}N^+$ (*m/e* 108)

[5] $C_{10}H_{16}N^+$ (*m/e* 150) → C_3H_6 + $C_7H_{10}N^+$ (*m/e* 108)

If the first fragmentation [4] would give rise to a metastable peak one would expect it at *m/e* 77.3. The mass spectrum of **2***d* shows indeed a metastable peak at *m/e* 77.2, but this has been tentatively assigned to transformation number 10 in Table 2, as it occurs also in the spectrum of **2***c*.

Cleavage of the carbon–carbon bond adjacent to the nitrogen after electron impact is the preferred reaction of amines and elimination of a hydrogen atom does not normally result in an abundant species (15). The fact that the M-1 ion gives rise to the base peak in the case of the amine and that NH_3 elimination occurs to such an extent must be considered as additional evidence that the adamantane skeleton resists fragmentation (16).

It was one of the original goals of this investigation to see whether it would be possible to distinguish easily between 1- and 2-substituted adamantane isomers by means of low-resolution mass spectroscopy. Our 70 eV spectra of 1-

*See text regarding this assignment.

adamantanol and 1-adamantanamine agree closely with those reported by Dolejšek *et al.* (1) and with one exception we agree with their findings and tentative interpretations which need not be discussed again. It was reported (1) that in the spectrum of 1-adamantanamine a metastable peak was present at *m/e* 21.5, corresponding to transformation [6]. In our work this peak was not

[6] $C_{10}H_{17}N^{\cdot+}$ (*m/e* 151) $\rightarrow C_3H_7N^{\cdot+}$ (*m/e* 57) + C_7H_{10}

observed, but instead there was a metastable peak at *m/e* 22.4 which was assigned to transformation [7]. For fragmentation [7] a metastable peak is

[7] $C_{10}H_{17}N^{\cdot+}$ (*m/e* 151) $\rightarrow C_3H_8N^{+}$ (*m/e* 58) + $C_7H_9^{\cdot}$

expected to occur at *m/e* 22.3. It was also found in the 12 eV spectrum and at that ionizing energy the peak *m/e* 58 (relative intensity 8%) is the third strongest in the spectrum after those at *m/e* 151 (base peak) and 94. It is characteristic for the 1-substituted adamantane compounds of group II as defined by Dolejšek *et al.* (1)) to which 1-adamantanol and 1-adamantanamine belong, that they retain their substituent in the main fragmentation of the molecular ion, with the formation of an M-57 ion (after loss of $C_4H_9^{\cdot}$), which gives rise to the base peak. This behavior is so different from that of the secondary alcohol (**2***c*) with the base peak at *m/e* 134, and 2-adamantanamine (**2***d*) with base peak at *m/e* 150, that no confusion between the identity of the isomers seems possible. This situation contrasts sharply with that of the two isomeric thiols, which were found to give almost identical spectra.

Precise analyses of the proton and some fluorine magnetic resonance spectra in acetone solution are reported for the three monofluorobenzaldehydes as well as for 2-chloro-6-fluorobenzaldehyde and for 4-fluoro-2-nitrobenzaldehyde. The conformational dependence of the coupling parameters allows the measurement of energy differences between the *O-cis* and *O-trans* conformations. The energy differences are in better agreement with the INDO predictions than they are with energies derived from i.r. data. Dipole moments are computed reliably and their measurement is suggested as a good guide to conformational preferences for molecules of this kind. The spin–spin coupling constants between the aldehyde proton and the ring protons and fluorine nuclei are computed for benzaldehyde and the three monofluorobenzaldehydes by the INDO and CNDO molecular orbital approximations. In many instances the agreement between calculated and observed couplings is quantitative.

Les analyses détaillées des spectres de résonnance magnétique du proton et du fluor en solution dans l'acétone sont rapportées pour les trois monofluorobenzaldéhydes ainsi que pour le chloro-2 fluoro-6 benzaldéhyde et le fluoro-4 nitro-2 benzaldéhyde. La relation entre les paramètres de couplage et la conformation permet de mesurer la différence d'énergie entre les conformations *O-cis* et *O-trans*. Les différences énergétiques sont en meilleur accord avec les prévisions données par la méthode INDO qu'avec celles obtenues à partir des données i.r. Les moments dipolaires sont calculés avec certitude et leur mesure constitue un bon exemple de préférence conformationnelle pour des molécules de ce type. Les constantes de couplage spin–spin entre le proton aldéhydique et les protons du cycle et le noyau du fluor sont calculées pour le benzaldéhyde et les trois monofluorobenzaldéhydes par les approximations INDO et CNDO d'orbitales moléculaires. Dans plusieurs cas, l'accord entre les couplages calculés et observés est quantitatif.

Canadian Journal of Chemistry, **49**, 3216 (1971)

Introduction

The spin–spin coupling constants over six bonds between ring protons and methyl protons in toluene derivatives are dominated by π electron contributions, which are also important in the analogous couplings to ortho and meta ring protons (1). In benzaldehyde, on the other hand, the coupling between the aldehydic protons and the para ring protons is not sensibly different from zero (2) but the coupling over five bonds to the meta protons is strongly stereospecific and is probably dependent on a σ electron mechanism (3–5).

The spin–spin coupling constants between fluorine nuclei and methyl protons in derivatives of the fluorotoluenes depend primarily on a π electron mechanism, their signs being opposite to the analogous ring proton – methyl proton couplings in the toluenes. The sign opposition has its reasonable origin in the signs of the hyperfine interaction constants: $Q_{CF} > 0$ and $Q_{CH} < 0$ (6).

[1]Holder of an NRCC Scholarship, 1971–1972.

In brief, ${}^{4,6}J_{o,p}{}^{H,CH_3} < 0$, ${}^{4,6}J_{o,p}{}^{F,CH_3} > 0$, ${}^{5}J_{m}{}^{H,CH_3} > 0$, ${}^{5}J_{m}{}^{F,CH_3} < 0$, ${}^{5}J_{m}{}^{H,CHO} > 0$, ${}^{6}J_{p}{}^{H,CHO} = 0$, where left superscripts give the number of bonds intervening between the coupled nuclei, indicated in the right superscript. In the right subscripts, *o*, *m*, and *p* signify ortho, meta, and para positions of the substituents relative to the fluorine or proton ring positions.

A recent sign determination gave ${}^{6}J_{p}{}^{F,CHO} < 0$ in *p*-fluorobenzaldehyde (7) suggesting a negative *Q* value for an aldehyde group coplanar with the ring if this is indeed a π electron coupling. On the other hand, the sign sequence of fluorine–proton couplings in pentafluorobenzaldehyde (8) is evidently the same as in the fluorotoluene derivatives (6) but with a much larger magnitude of ${}^{5}J_{m}{}^{F,CHO}$ than of ${}^{5}J_{m}{}^{F,CH_3}$. A resolution of this apparent contradiction and a base for the more general study of the coupling mechanisms in benzaldehyde derivatives (9) demands reliable coupling data for the three monofluorobenzaldehydes. A careful analysis of the p.m.r. spectra of these compounds, as well as of two of their

For personal use only.

derivatives, is reported in this paper. Fluorine spectra are reported where necessary.

The model in which σ and π electron mechanisms for the couplings are separately considered is very successful for the toluene (1), fluorotoluene (6, 10), and fluoropicoline (11) derivatives. In this model ring substituents affect spin couplings between ring protons, and between ring protons and ring fluorine substituents, primarily via a polarization of the σ system (12, 13); while their effect on long-range couplings between side-chain nuclei and ring protons or fluorine substituents is much less marked. It is of interest to discover whether such a simple model can also be used in discussing the couplings in benzaldehyde derivatives. Therefore, INDO and CNDO molecular orbital methods (13–15) are used to compute the long-range couplings between the aldehyde proton and the ring protons and fluorine nuclei. The differences between the couplings found by the two methods are an indication of the π electron contribution to the couplings (14).

Conformational preferences are deduced from the observed long-range couplings over five bonds.

Experimental

The compounds were obtained commercially and were used without further purification, except for the nitro derivative from which ferromagnetic dust had to be removed. Thirty mole percent solutions in acetone-d_6, containing tetramethylsilane (TMS) as an internal reference, were degassed by the freeze–pump–thaw technique. Other solvents that were tried gave very tightly coupled spectra and made an accurate analysis difficult at 100 MHz. At 60 MHz even the acetone solutions did not allow completely reliable analyses in one or two cases.

The p.m.r. spectra were recorded in the frequency sweep mode on an HA100-D spectrometer at a probe temperature of 30 ± 1 °C. The calibration procedure is described for *m*-fluorobenzaldehyde and applies to the other compounds. The ring proton peak positions were determined by reading manual and sweep oscillator frequencies at intervals of less than 3 Hz, each peak being calibrated at least five times. Proton resonance peaks were normally less than 0.12 Hz wide at half-height. The aldehyde proton peaks were calibrated ten times. The average standard deviations of the measured peak frequencies were 0.017 Hz for the protons and 0.019 Hz for the aldehyde protons (this compares with an r.m.s. error of 0.019 Hz in the analysis, see below). Sweep rates were 0.01 Hz/s.

Some spectra were also recorded at 60 MHz on a DA-60-I spectrometer at a probe temperature of 31 ± 1 °C. Fluorine resonance spectra were measured on an A56-60 spectrometer at a probe temperature of 32 ± 1 °C. When the solutions were prepared it was not considered that fluorine spectra would be required and therefore no internal fluorine reference material was present. At any rate, the observed fluorine spectra were needed only to confirm the sign of certain coupling constants. The fluorine resonance peaks were normally less than 0.20 Hz wide at half-height.

Certain decoupling and tickling experiments were carried out in the usual way (16).

Results and Discussion

(1) Analysis of Spectra

(a) p-Fluorobenzaldehyde

The proton resonance is the $[AB]_2X$ part of an $[AB]_2XR$ spectrum and was analyzed using the computer program LAOCN3 (17) in a manner similar to the analysis recently described for *p*-fluorotoluene (10). Of the 128 calculated transitions with intensity greater than 0.01, 106 were assigned to experimental peaks. The r.m.s. error was 0.012 Hz when all parameters were allowed to vary in the iteration. The probable error in all parameters was less than or equal to 0.003 Hz. The final parameters are given in Table 1. Extensive tickling experiments (16) confirmed the negative sign of $^6J_p^{F,CHO}$.

(b) 2-Nitro-4-fluorobenzaldehyde

The analysis of the proton resonance spectrum using LAME (18) was straightforward except that the peaks from the ring proton ortho to the nitro group were somewhat broadened by incompletely relaxed coupling to the quadrupolar ^{14}N nucleus. This means that the shift of this proton, H_3, is precise to only ±0.1 Hz and that $J_o^{H_3,F}$ is known to only ±0.1 Hz. All of the 48 transitions for H_1, H_5, and H_6 were assigned. The r.m.s. error between observed and calculated transitions was 0.007 Hz. Three elements in the correlation matrix were greater than 0.05 and these lay between 0.05 and 0.17. The probable error was 0.004 Hz or less for all but the two parameters above and the error in the small $^6J_p^{H,CHO}$ is realistically put at 0.02 Hz. Final parameters are tabulated in Table 1.

(c) o-Fluorobenzaldehyde, ABCDXR

Of 183 transitions calculated to have intensity greater than 0.01, 156 were assigned to experimental peaks, yielding an r.m.s. error of 0.018 Hz when all parameters were allowed to vary in the LAOCN3 analysis. The probable errors in the parameters was less than or equal to 0.005 Hz. Parameters are given in Table 1.

No splittings attributable to $^5J_p^{HF}$ were observed in the H_5 resonance region. However, after assigning all the transitions in the low-field H_5 region a negative value of J_p^{HF} was obtained on

$^5J_m^{H_5,CHO}$	0.739	0.739	0.739	0.739
$^4J_o^{H_6,CHO}$	−0.152	−0.152	0.152	−0.152

iteration. The negative sign was clearly confirmed by comparison of the observed ^{19}F resonance spectrum with calculated spectra using various sign combinations. Weak irradiation experiments confirmed the negative sign of $^4J_o^{F,CHO}$, as did the observed ^{19}F spectrum. The ring proton resonance spectrum was *not* sensitive to the sign of $^4J_o^{F,CHO}$.

For reasons of space we give here only the observed and calculated spectra at 100 and 60 MHz of the aldehyde proton, Fig. 1 (agreements in the other regions were excellent). The correct

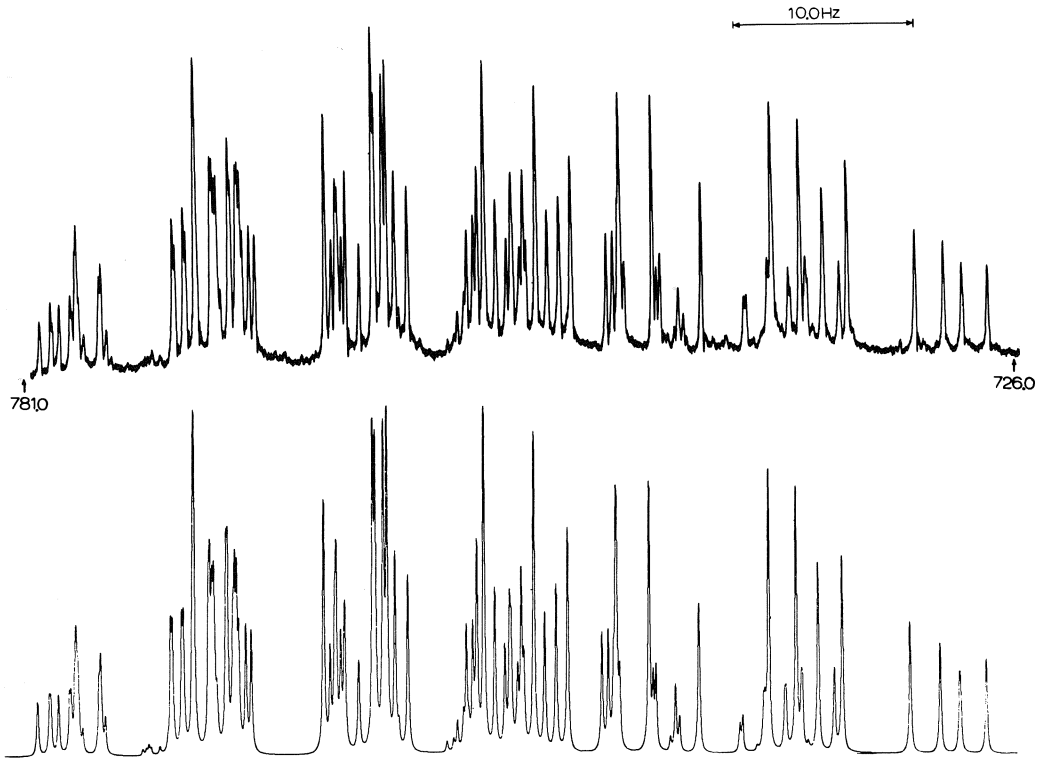

FIG. 2. The observed and calculated ring proton magnetic resonance spectra at 100 MHz of a 30 mol % solution of *m*-fluorobenzaldehyde in acetone. The calculated spectrum uses the parameters in Table 1. There are present a few impurity peaks, their presence becoming obvious only when proper assignments of peak position are complete.

There are one or two peaks which appear unresolved in the calculated spectrum, a consequence of the Lorentzian line shape. A calculated spectrum in which the right hand half of the peaks is "brought down" more sharply than for a Lorentzian, thereby simulating spectrometer conditions, showed better agreement with the observed spectrum for these peaks.

signs of all the long-range couplings to the aldehyde proton are easily found from Fig. 1 even in the absence of double resonance experiments. The effective T_2 in the calculated spectra in Fig. 1 was deliberately increased beyond the value indicated by the observed spectrum at 100 MHz because it makes comparisons more obvious without vitiating any conclusions.

(d) m-Fluorobenzaldehyde, ABCDXR

The chemical shift between H_2 and H_5 is only about 0.015 p.p.m., presenting some analysis problems. In a preliminary experiment the ring proton spectrum was calibrated twice while decoupling the aldehyde proton. Several trial and error calculations with LAOCN3, followed by some iterative runs, finally yielded the correct relative chemical shifts of H_5 and H_2. The coupling parameters so obtained agreed to within about 0.02 Hz with the results of the complete analysis to follow.

Proper calibration procedures on the complete proton spectrum, and assignment of 126 of the 137 ring proton transitions with intensities greater than 0.01, gave the parameters in Table 1. The r.m.s. error was 0.019 Hz and the probable errors varied between 0.003 and 0.006 Hz (two values). No agreement between calculated and observed ring proton spectra could be obtained unless $^4J_o^{H_6,CHO}$ was -0.116 Hz. Observed splittings in the H_6 region could not be predicted if this coupling was held at 0.00 Hz in the interaction and, furthermore, the small doublet splittings (0.1 Hz) in the H_6 region between 795 to 810 Hz (see Fig. 2) disappeared when the aldehyde protons were irradiated. One might note that at 60 MHz these splittings are *not* observable. In Fig. 2 the calculated and observed ring proton spectra are compared. Apart from a few obvious, weak impurity peaks, the agreement is quite satisfactory.

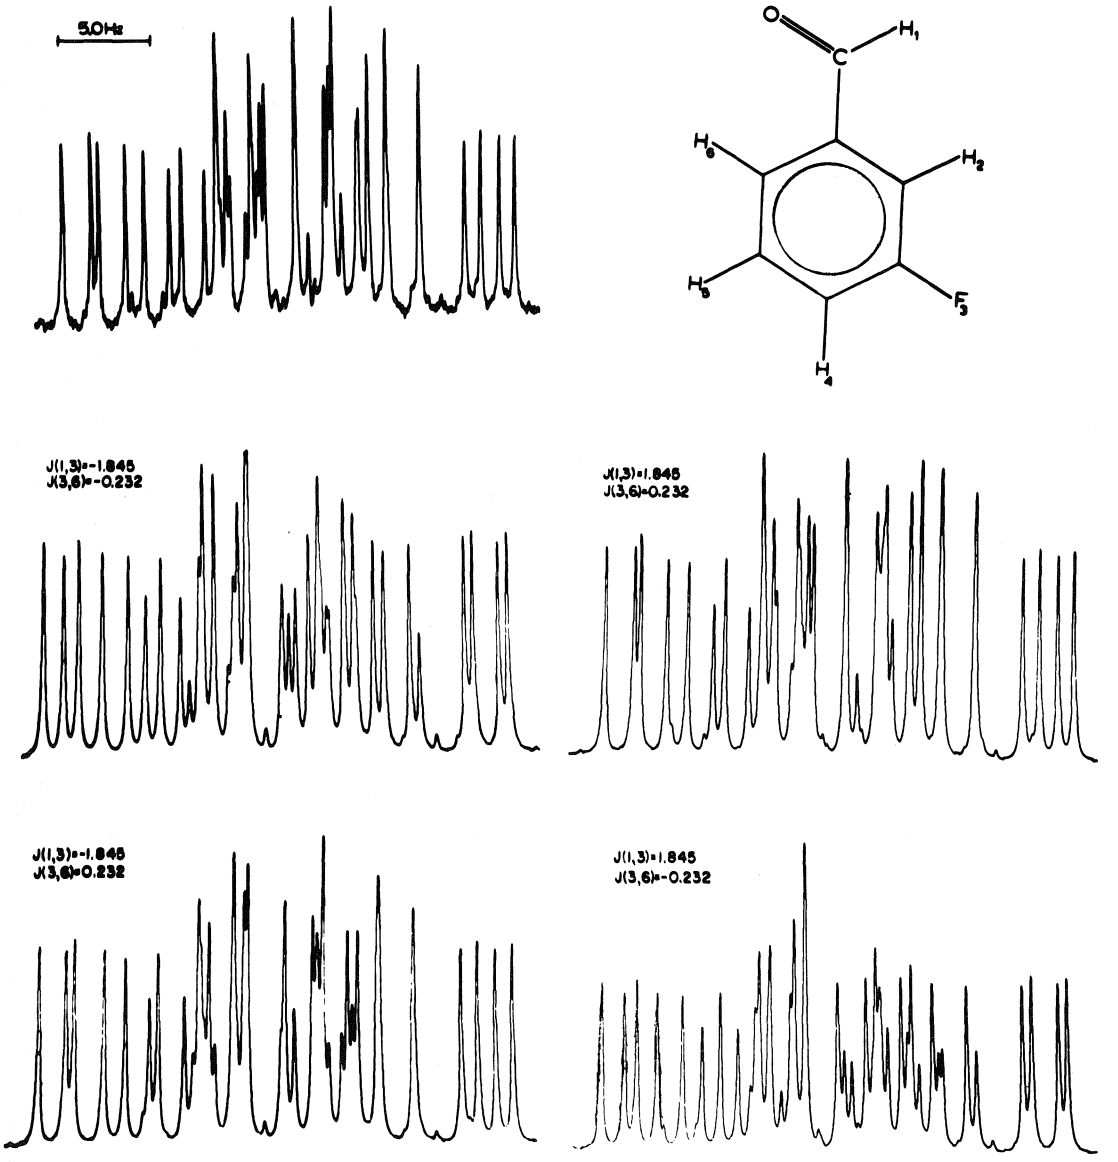

FIG. 3. The observed and calculated ^{19}F magnetic resonance spectra at 56 MHz of a 30 mol % solution of *m*-fluorobenzaldehyde in acetone. The calculated spectra use the spectral parameters in Table 1 and different sign combinations for $^5J_m^{F,CHO}$ and $^5J_p^{HF}$. There is no doubt that the calculated spectrum with both signs positive is the correct one.

The aldehyde proton resonance displayed asymmetry about its midpoint[2] and could be reproduced only by a positive value of $^5J_m^{F,CHO}$. Because a negative value could be inferred from previous work (8) it was felt necessary to compare the ^{19}F spectrum with those calculated for different signs of $^5J_m^{F,CHO}$. In Fig. 3 the various sign combinations of $^5J_m^{F,CHO}$ and $^5J_p^{HF}$ very clearly demonstrate the positive sign of these two couplings. A positive $^5J_p^{HF}$ had previously been known only in fluorobenzene itself (19) and was negative in those derivatives studied to date (10).

Finally, it might be stressed for the benefit

[2]Because of multiple degeneracies in the aldehyde proton resonance the estimated error in the *shift* of the aldehyde proton and in $^5J_m^{F,CHO}$ is 0.02 Hz.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of other analysts that the near degeneracy of the H_2 and H_5 chemical shifts allows the presence of $^4J_o^{H_6,CHO}$ to go undetected at 60 MHz.

(e) 2-Fluoro-6-chlorobenzaldehyde

The analysis of the proton resonance spectrum as an ABCX part of an ABCXR spectrum by LAOCN3 was straightforward. The negative signs of $^5J_p^{HF}$ and $^4J_o^{F,CHO}$ were confirmed by double irradiation experiments. The r.m.s. error was 0.010 Hz and probable errors were 0.004 Hz or less. Parameter values are given in Table 1.

(2) The Chemical Shifts

The chemical shifts are solvent dependent (20) and will not be discussed in detail. The relative shifts of the ring protons are consistent with the predictions (21) based on mesomeric and inductive interactions of the substituents with the aromatic ring, as modified by magnetic anisotropy effects from the carbonyl group at the ortho proton (21), for example, and by the sizeable reaction field (22) shifts caused by the polar solvent. The shifts of the aldehydic protons show some evidence for deshielding effects caused by steric interactions (21, 23) with ortho substituents.

(3) The Spin–Spin Coupling Constants in the Ring

(a) The Proton–Proton Couplings

Taking J_o^{HH} as 7.54, J_m^{HH} as 1.38, and J_p^{HH} as 0.63 Hz in benzene (24) the additivity of substituent effects on these couplings was examined by using the parameters for fluorobenzene in acetone solution (19) and for benzaldehyde in CCl_4 solution (25). The agreement between predicted and observed proton–proton couplings was perfect for *p*-fluorobenzaldehyde, deviations ranging between 0.00 and 0.04 Hz for the four values. For *m*-fluorobenzaldehyde agreement was also good, the average deviation for six values being less than 0.04 Hz. The biggest deviation was 0.07 Hz for one of the J_o^{HH} couplings.

In *o*-fluorobenzaldehyde the mean deviation between predicted and observed couplings was 0.07 Hz (six values), not quite large enough to decide whether the substituent effect of the aldehyde group depends on its conformation (24). The INDO calculations suggest no conformational dependence (13). In later sections it is shown that *m*-fluorobenzaldehyde probably exists almost equally in the *O-cis* and *O-trans* conformations whereas *o*-fluorobenzaldehyde exists predominantly in the *O-trans* conformation indicated in Table 1.

For 2-fluoro-6-chorobenzaldehyde and 2-nitro-4-fluorobenzaldehyde the average deviation rises to 0.27 and 0.11 Hz, respectively. A saturation phenomenon (26) is indicated for three substituents in that the deviations of the calculated from the observed couplings are in the direction expected if the effect of a substituent has been decreased by the presence of the other two substituents. The saturation phenomenon is evidently most marked when the three substituents are placed 1, 2, 3 on the ring.

(b) The Proton–Fluorine Couplings

The substituent effect of the aldehyde group on these coupling constants has not been previously measured. Considering the aldehyde group as more electronegative than hydrogen, the observed changes in these couplings are, with one exception, in the direction found by Goldstein and co-workers (27) for a series of fluorobenzene derivatives. The exception is $J_o^{H_2,F}$ in *m*-fluorobenzaldehyde where a decrease of 0.4 Hz relative to its value in fluorobenzene is observed instead of a predicted increase (27). It is noted that, in contrast to ring proton–proton couplings, ring proton–fluorine couplings are measurably solvent dependent (28) so that a further uncertainty is present here.

In fluorobenzene in acetone solution $^5J_p^{HF} = 0.3$ Hz and the methyl group replacement technique (6, 29) implies that σ and π contributions to this coupling are of opposite sign, resulting in a value near zero (10). Electronegative substituents decrease the positive σ electron contribution, giving rise to a negative value observed in known fluorobenzene derivatives (10, 27). A substituent placed ortho to fluorine has a markedly larger effect than one placed meta to fluorine (10). Therefore, the small negative value of J_p^{HF} (-0.18 Hz) in *o*-fluorobenzaldehyde and the small positive value in *m*-fluorobenzaldehyde (0.23 Hz) are in agreement with the known regularities, as is the larger negative value (-1.07 Hz) in 2-fluoro-6-chlorobenzaldehyde.

(4) Spin–Spin Couplings to the Aldehydic Protons

(a) To Meta Protons over Five Bonds, $^5J_m^{H,CHO}$, and Conformational Preferences

In benzaldehyde $^5J_m^{H,CHO}$ is 0.38 Hz (2), an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

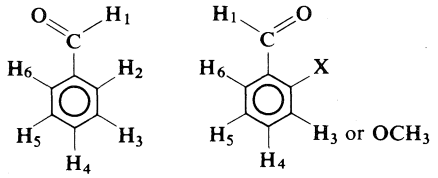
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

average of the two couplings in **1**. In a series of 4-substituted derivatives of **1** a maximum increase of 0.1 Hz is found for strongly electron donating groups like OCH_3 but $^5J_m^{H,CHO}$ is never less than 0.38 Hz, even for electron attracting groups (3). The coupling is stereospecific. In 2-hydroxybenzaldehyde (9), 2-aminobenzaldehyde,[3] 2-hydroxy-3-methoxybenzaldehyde (5*a*), all of which correspond to **2** because of hydrogen



1 **2**

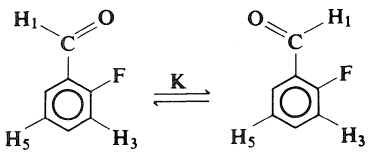
bonding of the carbonyl group to X, $^5J_m^{H_5,CHO}$ is undetectably small. When X = OCH_3 or Br the aldehyde group adopts a conformation in which the carbonyl oxygen and X are *trans* to one another. In these two cases $^5J_m^{H_3,CHO}$ is not detectably different from zero while $^5J_m^{H_5,CHO}$ is 0.84 and 0.77 Hz for X = OCH_3 and Br, respectively (9).

Consideration of *all* of these data strongly suggests that in benzaldehyde $^5J_m^{H_3,CHO} = 0.00$ Hz while $^5J_m^{H_5,CHO} = 0.76$ Hz when numbering as in **1**, in good agreement with theoretical models (30). Note particularly that the coupling increases in 2-methoxybenzaldehyde compared to 2-bromobenzaldehyde in a manner analogous to the 4-substituted derivatives, but that $^5J_m^{H_3,CHO}$ (non zig-zag) does *not* increase above zero.

To a very good approximation, therefore, the accurate data in Table 1 can be used to derive the proportions of the two possible conformations of each of the compounds in acetone solution.

(i) o-Fluorobenzaldehyde

One has the two possible conformations, **3** and **4**, called *O-cis* and *O-trans*, respectively.



3 **4**

[3]Unpublished work in this laboratory.

On the assumption that the 1,5 coupling in **3** is zero the data in Table 1 give the populations as $P_3 = 0.14$ and $P_4 = 0.86$ or $K = 6.1$. Hence the free energy difference at 31 °C is 1.1 kcal/mol, *O-trans* more stable. This conclusion differs markedly from that reached by far i.r. torsional data in the gas phase (31), $K = 1.6$, or from that obtained by i.r. intensity measurements in solution (32), 32% *trans*, $K < 1$. On the other hand, the INDO calculations yield an energy difference of 0.94 kcal/mol, *O-trans* more stable. The entropy difference between **3** and **4** is presumably small and although the polar acetone will somewhat favor the more polar *O-cis* form, the agreement between INDO and our result is still remarkably good.[4] The only other conformational data on this system is for the radical anion, where only one conformation is observed, assigned to the *O-trans* form (33).

There is no evidence that **4**, the predominant isomer, is nonplanar; while **3** would have a maximum out-of-plane twist of 20° of the carboxyl group (34), the available coupling data on 2,6-dichloro- and 2,6-dinitro-benzaldehydes imply no measurable change in $^5J_m^{H,CHO}$ for this degree of nonplanarity (34).

(ii) m-Fluorobenzaldehyde

$^5J_m^{H,CHO}$ is 0.39 Hz, strongly implying a zero free energy difference between the two conformations. INDO computes an energy difference of 0.16 kcal/mol, *O-trans* more stable. The acetone solvent favors the *O-cis* form and therefore the agreement is quite close, INDO having $K = 1.3$ for zero entropy difference between conformations. In contrast, torsional frequency measurements in the gas phase (31) have $K = 10$, *O-cis* more stable. Band intensity measurements in the i.r. suggest 70% *O-trans* in nonpolar solvents (32), while other i.r. data for chloroform solutions give $K = 2.3$, *O-cis* more stable (31). The radical anion of this molecule contains comparable populations of two isomers (33).

(iii) 2-Fluoro-6-chlorobenzaldehyde

The procedure yields a free energy difference of 0.41 kcal/mol, *O-trans* to chlorine being more stable. The coupling constant data on 2,6-dichlorobenzaldehyde (34) suggest a maxi-

[4]Note that the assumption of a zero ^5J_m in the non zig-zag conformation (1,5 in **3**) puts a lower limit on $K = P_4/P_3$ and, therefore, on the free energy difference.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mum twist of 20° of the carbonyl group from the plane of the ring when it lies *cis* to chlorine. In that compound $^5J_m^{H,CHO}$ is 0.40 Hz, implying the validity of the population analysis above, *i.e.*, a small twist of the carbonyl group does not noticeably affect $^5J_m^{H,CHO}$.

(iv) 2-Nitro-4-fluorobenzaldehyde

The free energy difference obtained from the coupling constants is 0.87 kcal/mol, *O-trans* to the nitro group more stable. Note that the sum of the coupling constants is 0.79 Hz, almost the same as in benzaldehyde and in 2,6-dinitrobenzaldehyde, 0.78 Hz (34). The INDO energy difference is 1.64 kcal/mol, *O-trans* to nitro more stable. But the calculation was done for completely planar conformations so that 1.64 kcal/mol is very much of an upper limit. The *O-cis* to nitro form must have strong steric hindrance between the N—O and C=O bonds. Our previous measurements on 2,6-dinitrobenzaldehyde indicate a maximum twist of 25° of the carbonyl group out of the plane of the ring. No doubt the nitro group will also twist out of plane. The INDO computations were not done for nonplanar conformations of this molecule. For benzaldehyde our INDO calculations on nonplanar forms are not encouraging for standard geometries.

(v) Suggested Dipole Moment Measurements

The INDO computations on 2-fluoro- and 3-fluorobenzaldehydes predict dipole moments of 4.32 (2.95) and 3.47 (1.13) D, respectively, the *O-trans* moment being given in brackets. For benzaldehyde we calculate 2.75 D, measured values ranging from 2.8 to 3.0 D in solution (35). For *p*-fluorobenzaldehyde we calculate 1.87 D, observed being 1.98 D (35). The good agreement encourages the measurement of the dipole moments of the other two isomers as a check on the conformational information reported in this paper. We emphasize that small long-range couplings *can* be measured accurately and if this is done, we feel that relatively reliable conformational information can be obtained (complete analyses of spectra and repeated calibration of peak positions by patient personnel is absolutely essential, however).

(b) To Fluorine over Four Bonds, $^4J_o^{F,CHO}$, and Five Bonds, $^5J_o^{F,CHO}$

The population analyses in previous sections can be used in calculating values of $^4J_o^{F,CHO}$ when the C—H bond of the aldehyde group lies *cis*, J_c, and when it lies *trans*, J_t, to the fluorine. Thus, for *o*-fluorobenzaldehyde write $0.14\,J_t + 0.86\,J_c = 0.38$ Hz (Table 1) while for 2-fluoro-6-chlorobenzaldehyde write $0.66\,J_t + 0.34\,J_c = 1.08$ Hz. Then $^4J_c^{F,CHO}$ is -0.2 and $^4J_t^{F,CHO}$ is -1.6 Hz. This result is insensitive to the assumptions concerning $^5J_m^{F,CHO}$. An assumption that it is 0.1 Hz in the non ziz-zag path yields $^4J_c^{F,CHO}$ as -0.4 and $^4J_t^{F,CHO}$ as -1.4 Hz.

For 2,6-difluorobenzaldehyde one predicts $^4J_o^{F,CHO}$ to be -0.9 Hz. For pentafluorobenzaldehyde there is a report of $+1.0$ Hz for this coupling (8), a reasonable magnitude but a questionable sign. In ortho fluoro derivatives of benzalchloride a negative sign and a similar stereochemical dependence is found for $^4J_o^{F,CHCl_2}$ (36).

In *m*-fluorobenzaldehyde $^5J_m^{F,CHO}$ is $+1.84$ Hz. There is a reported value of -1.3 Hz for this coupling in pentafluorobenzaldehyde (8) and must be the mean of its values in *O-cis* and *O-trans* conformations with respect to one meta fluorine substituent. The population analysis implies 1.84 Hz as the average value for the two equally populated *O-cis* and *O-trans* forms of *m*-fluorobenzaldehyde. If $^5J_m^{F,CHO}$ has a conformational dependence similar to that of $^5J_m^{H,CHO}$ then $^5J_m^{F,CHO}$ lies between $+3$ and 4 Hz in the *O-cis* form of *m*-fluorobenzaldehyde (as actually calculated by INDO, see below). If -1.3 Hz is the correct value in pentafluorobenzaldehyde, a very large substituent effect exists in this molecule.

(c) INDO and CNDO–MO Calculations[5] of J

These were carried out on an IBM 360/65 system, using standard geometries (14). As many as 76 cycles in the s.c.f. procedure were necessary to obtain convergence of the calculated coupling constants to 0.01 Hz; as few as 50 were sufficient for CNDO. As a check the proton couplings in benzene were calculated and agreed to within less than 0.01 Hz with the values quoted in ref. 14. The $J(^{13}C—H)$ value in benzaldehyde was calculated as 159.08 Hz, in exact agreement with the value given in ref. 37.

In Table 2 the calculated coupling constants to the aldehyde proton are reported for the planar

[5]We are indebted to Dr. G. Maciel who kindly sent us a CDC listing of the finite perturbation subroutine for INDO and to a referee for a firm prod towards these calculations.

*Benzaldehyde is planar in the gas phase (38) and it is assumed that it and *p*-fluorobenzaldehyde are planar in solution. The fractional contributions of the *O-cis* and *O-trans* forms of the *o*- and *m*-fluorobenzaldehydes are taken from section *4a*, as derived from the five-bond proton–proton coupling constants. All data are in Hz.

conformations of benzaldehyde and the three fluorobenzaldehydes. In view of the expense of these calculations, they were not done for the other two compounds in Table 1. In Table 3 the observed and calculated coupling constants are compared. All conformations are planar, benzaldehyde and *p*-fluorobenzaldehyde naturally having two equally populated forms, while the fractional populations of the *o*-fluorobenzaldehyde and *m*-fluorobenzaldehyde were taken from section *4a* above.

(i) Calculated Couplings in Table 2

Inasmuch as the INDO approximation considers one-center exchange integrals (14) it includes the π electron contribution, expected to be negative over four or six bonds and positive over five bonds. The expectation is borne out by, for example, the two sets of data for benzaldehyde in Table 2. However, it is probable that our calculations using standard geometries somewhat overestimate the π electron contributions to $^5J_m^{H,CHO}$ (see below). The data in Table 2 may well be of interest in the study of those molecules in which the carbonyl group is fixed by intramolecular hydrogen bonding. Note that the presence of the fluorine substituents has a negligible effect on the calculated magnitudes of $^5J_m^{H,CHO}$ and $^6J_p^{H,CHO}$ and probably constitutes support for the conformational arguments in section *4a*. The insensitivity to substituent *and solvent* effects of the long-range couplings between protons on a side-chain and ring protons is experimentally known for a variety of benzene derivatives (3, 6, 10).

(ii) Observed and Calculated Couplings in Table 3

A stringent comparison between observed and calculated values can be made for benzaldehyde and *p*-fluorobenzaldehyde. INDO is in excellent agreement with the observed $^4J_o^{H,CHO}$ data while CNDO yields rather too large values, indicating the importance of π electron contributions (for that matter, INDO is also in striking agreement with the two different observed $^4J_o^{H,CHO}$ values in *m*-fluorobenzaldehyde).

On the other hand, CNDO agrees quantitative-

TABLE 4. Computed aldehydic proton coupling constants in benzaldehyde and *p*-fluorobenzaldehyde for perpendicular orientations of the carbonyl group

		$^4J_o^{H,CHO}$	$^5J_m^{H,CHO}$	$^6J_p^{H(F),CHO}$
	INDO	−0.43	1.01	−0.76
	CNDO	0.48	0.19	0.01
	INDO	−0.49	0.98	1.45
	CNDO	0.46	0.17	0.13

ly with the $^5J_m^{H,CHO}$ measurements while INDO overestimates their magnitude substantially, suggesting that π electron contributions to $^5J_m^{H,CHO}$ are very small. This suggestion is verified by our observations on appropriate compounds that a methyl group, replacing the ring or aldehyde proton, does not couple to the remaining proton. It should couple if a π electron contribution were important (29). Furthermore, the five-bond coupling is not known for the anti-zig-zag arrangement and (in Table 2) CNDO calculates less than 0.03 Hz for this situation while INDO finds 0.2 Hz, which would be easily observed.

Again, CNDO predicts a vanishing $^6J_p^{H,CHO}$, as observed for all molecules in Table 3, while INDO overestimates this coupling by −0.3 Hz.

The agreement between calculated and observed H, F couplings in Table 3 is not terribly good, an exception being $^5J_m^{F,CHO}$ in the INDO approximation. Both methods calculate a positive $^6J_p^{F,CHO}$ in *p*-fluorobenzaldehyde, contrasting with the negative observed value. Similar disagreements for H, F couplings in other molecules are mentioned by Pople and co-workers (14).

In general the agreement between theory and experiment for the present molecules is impressive and the use of the combined CNDO and INDO theories in conjunction with precise experimental, long-range coupling data is suggested as an improved tool in conformational studies.

(d) Calculations of J for nonplanar Conformations

It has been argued (39) that, as the carbonyl group twists about the C—C bond in benzaldehyde $^6J_p^{H,CHO}$ should become large and negative, displaying an extremum when the carbonyl group lies perpendicular to the ring plane. Similarly, $^6J_p^{F,CHO}$ in *p*-fluorobenzaldehyde should become large and positive (7). In Table 4 the computed long-range couplings of the aldehydic proton in benzaldehyde and *p*-fluorobenzaldehyde are presented for conformations in which the plane of the carbonyl group lies perpendicular to the aromatic plane. The INDO calculations bear out the previous predictions as expected if, in the qualitative model (7, 39), the coupling to the para position now goes mainly via a π electron mechanism. The synthesis of the 2,6-di-*t*-butyl derivatives is suggested.

Finally, it may be remarked that the presence of a substituent distorts the benzene ring and it would be of interest to perform a systematic series of calculations in which such a distortion is introduced.

We are grateful to Dr. J. B. Rowbotham for help with the computer program and to the NRCC for financial support.

NOTES

K-Absorption Spectroscopic Investigations on Mixed Valency

H. L. NIGAM AND U. C. SRIVASTAVA
Chemistry Department, Allahabad University, Allahabad, India

Received March 10, 1971

Evidence for the existence of mixed valency Cu(I)–Cu(II) in some copper complexes has been adduced from X-ray absorption spectroscopic study. Two distinct edges K_1 and K_2 have been observed for the uni and divalent states of copper.

Des preuves concernant l'existence d'une valence mixte Cu(I)–Cu(II) dans quelques complexes avec le cuivre, sont apportées par suite d'une étude spectroscopique d'absorption aux rayons X. Deux valeurs distinctes K_1 et K_2 ont été observées pour les états mono et divalent du cuivre.

Canadian Journal of Chemistry, **49**, 3229 (1971)

The valency-dependence of the relative shifts in the position of the X-ray K-absorption discontinuity of a particular metal in its different compounds is well known (1–4). Thus Boehm *et al.* (1) and Mande and Chetal (2) have decided the valency of cobalt in vitamin B_{12} and in Co–thiomalic acid complex, respectively, on the basis of the shifts in the Co K-edge in them. However, the possibility of gaining evidence for the co-existence of two different oxidation states in the same compound from X-ray absorption spectra does not appear to have been explored hitherto. Very recently, however, Vishnoi (5) has shown that the L_{III}-edge shift for lead in Pb_3O_4 (involving Pb(II) and Pb(IV)) is intermediate between those due to PbO and PbO_2. Although, theoretically, the above possibility follows from the valency-dependence of edge-shifts, an experimental verification of the same may be feasible only in those cases where the separation between the wavelengths of the absorption edges corresponding to different valence-states can be resolved on the spectra. With this end in view, we have investigated the K-absorption edges of copper in some complexes which have been otherwise shown to involve Cu(I) and Cu(II) existing together. It may be noted that Beaman *et al.* (6) have shown from their K-absorption studies on copper salts that, in general, the $1s \rightarrow 4p$ absorption (*i.e.* the K-absorption maximum) in Cu(I) salts occurs at about 10 eV lower energy than that in Cu(II) salts.

The complexes, *viz.* Cu–thiomalic acid (Cu–TMA) and Cu–thio vanol (Cu–TV), have been prepared and studied in this laboratory using other physico-chemical methods by Nigam *et al.* (7–10). Earlier, the Cu–TMA complex has also been studied by Klotz *et al.* (11) and by Cheney *et al.* (12). Their magneto-chemical (9) and polarographic (7, 11, 12) studies have consistently shown that Cu–TMA involves a mixed-valency system (–Cu(II)–SR–Cu(I)). The complex has recently been examined in solution by Smith *et al.* (13) using electron spin resonance (e.s.r.) measurements. The broad resonance observed in the frozen aqueous solutions of the complex between p*H* 1.9 and 9.8 have been attributed to the cuprous–cupric charge delocalization. However, the delocalization envisaged does not seem to be extensive. Also, it is dependent largely on the concentration factor. The measurements described in this paper have been done in solid form. The Cu–TV complex, when freshly prepared, is a yellow powder and has been shown to involve Cu(I) (10) in a polymeric chain structure $—(—R—O—Cu(I)—S—R—)_n$. However, on long exposure to dry air or oxygen the solid slowly turns green, presumably due to the formation of Cu(II); the phenomenon is usual to copper complexes formed with reducing sulfur ligands (14).

The K-absorption spectra of these complexes have been recorded photographically using a 40 cm radius Cauchois type curved crystal spectrograph using $(\bar{2}01)$ reflection planes of mica as analyzer. The source of radiation was a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Machlett sealed tungsten-target X-ray tube which was operated at 16 kV and 12 mA. The set up, standardized by resolving $Mo\beta_{1,3}$ doublet in the first order, gave a dispersion of about 12.5 x.u. per mm. The reference lines used were $L\alpha_1$, $L\alpha_2$, $L\beta_1$, $L\beta_4$ of tungsten. Thin and uniform absorption screens were prepared by evenly spreading the substance in fine powder form on scotch tape and were placed between the X-ray tube window and the analyzing crystal. Due care was taken to keep the Cu–TV (yellow) screen air tight so as to prevent oxidation during exposure to X-rays. The exposure time varied from 15–20 h. Several spectrograms were taken for each sample. The microphotometer records were taken on a Kipp and Zonen Moll microphotometer with magnification of 25 and 8, the latter having been used for measurements. Figure 1 shows the energy *vs.* absorption coefficient ($\log I_0/I$) curve (plotted from the microphotometer traces) for Cu–TMA while Fig. 2 shows the curves for Cu–TV (*a*, for the freshly prepared sample and *b*, when exposed overnight to dry air).

It can be observed that the absorption jump in case of Cu–TMA (Fig. 1) exhibits an unusual edge-structure. The complete edge apparently consists of two edges, shown as K_1 and K_2. The low energy peak A_1 is well defined in intensity and is situated ~10 eV to the lower energy side of the main peak. Further, in case of Cu–TV no such edge-structure shows up for the freshly prepared sample (Fig. 2*a*) whereas in case of the oxidized sample the normal edge apparently splits up into two (Fig. 2*b*) as in Cu–TMA and the first absorption maximum A_1 again appears ~10 eV below the main peak. If the oxidized form is considered to form simply a separate phase with no mixed valency present, the edge structure should be, as can be seen in the literature, very different from the one observed here. It may thus appear as if the two edges K_1 and K_2 correspond to Cu(I) and Cu(II) in conformity with Beaman's observation (6) (ut supra) and that Cu(I) in Cu–TV (yellow) may have only partially oxidized to Cu(II) in the green sample.

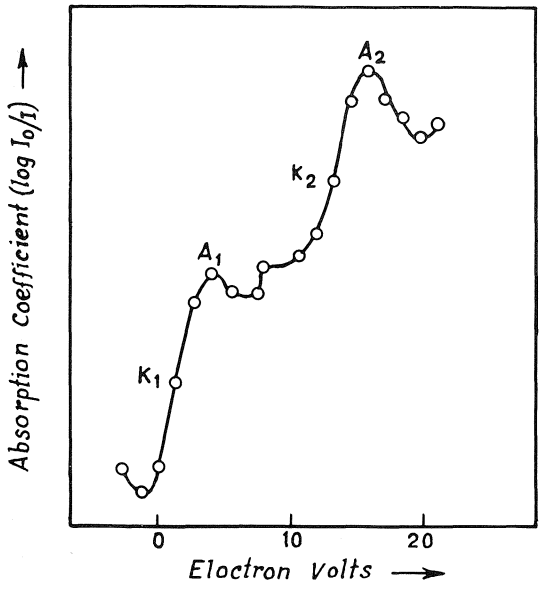

FIG. 1. K-edge of Copper in Cu–TMA.

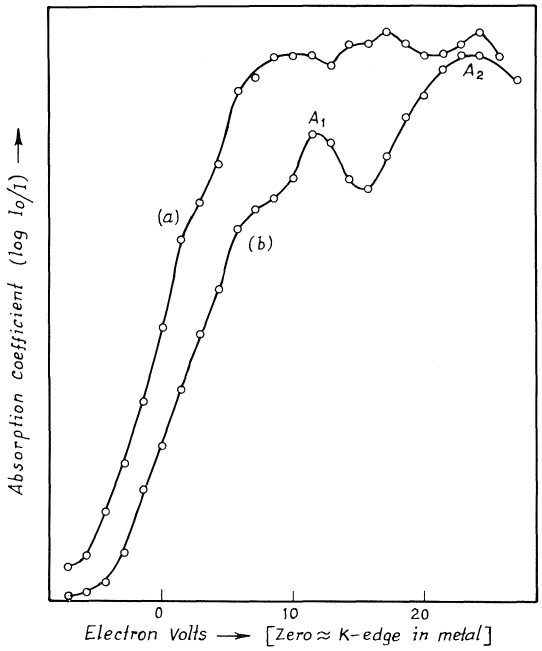

FIG. 2. K-absorption edge of copper in (*a*) Cu–TV (yellow), (*b*) Cu–TV (green).

The Pressure Dependence of the Activation Volume

D. L. GAY
Xavier College, Sydney, Nova Scotia

Received September 8, 1970[1]

The analysis of the pressure dependence of the activation volume, $(\partial\Delta V^*/\partial P)_T$, in terms of ion-dielectric theory has been performed. The values of $(\partial\Delta V^*/\partial P)_T$ obtained on this basis are in good agreement with those found for the hydrolyses of organic halides. These results further indicate that contributions to $(\partial\Delta V^*/\partial P)_T$ arising from compression of the molecule or ion are by far more important than those arising from electrostriction of the dielectric medium. Also, the effects of quadrupole moments can be very important since the contributions from this are as great as those from dipole moments. Nevertheless it seems that ion-dielectric theory gives only a partial answer to the question of the nature and origin of $(\partial\Delta V^*/\partial P)_T$. Apparently, the contributions from solvent structure, unaccounted for on this model, cannot be ignored.

Une analyse de la dépendance du volume d'activation par rapport à la pression, $(\partial\Delta V^*/\partial P)_T$, a été réalisée en fonction de la théorie ion-diélectrique. Les valeurs de $(\partial\Delta V^*/\partial P)_T$ obtenues sur cette base, sont en bon accord avec celles trouvées pour l'hydrolyse des halogénures organiques. Ces résultats indiquent de plus que les contributions à $(\partial\Delta V^*/\partial P)_T$ provenant de la compression des molécules ou des ions sont de beaucoup plus importantes que celles provenant de l'électrostriction du milieu diélectrique. De plus, les effets des moments quadrupolaires peuvent être très importants puisque leurs contributions sont aussi grandes que celles des moments dipolaires. Néanmoins, il semble que la théorie ion-diélectrique ne donne qu'une réponse partielle à la question de l'origine et de la nature de $(\partial\Delta V^*/\partial P)_T$. Apparemment, les contributions dues à la structure du solvant, non interprétées dans ce modèle, ne peuvent être ignorées.

Canadian Journal of Chemistry, **49**, 3231 (1971)

Recently some attention has been focussed upon finding an analytical function which best expresses the pressure dependence of reaction rates (1–3). This situation is essential since the activation volume, ΔV^*, is pressure dependent (1–7). The pressure dependence of the activation volume, $(\partial\Delta V^*/\partial P)_T$, for the hydrolytic reactions of organic halides usually lies in the range 0 to +10 ml/kbar mol (1–7). This has been attributed to differences in the compression of the ground state and transition state (1, 4, 9).[2] However, this does not give as clear a picture of the factors contributing to ΔV^* and the associated parameter $(\partial\Delta V^*/\partial P)_T$ as is desirable. Benson and Berson

[1]Revision received May 10, 1971.

[2]A referee has calculated $(\partial\Delta V^*/\partial P)_T$, assuming the initial and transition state compressibilities to be the same (K), on the following basis

$$(\partial\Delta V^*/\partial P)_T = -\Delta V^* \times K$$

If $\Delta V^* = -15$ ml/mol and $K = 100 \times 10^{-6}$ bar^{-1}, then $(\partial\Delta V^*/\partial P)_T = 1.5$ ml/kbar mol. This is in the range found for the reactions being considered in this paper.

The Pressure Dependence of the Activation Volume

D. L. GAY
Xavier College, Sydney, Nova Scotia

Received September 8, 1970[1]

The analysis of the pressure dependence of the activation volume, $(\partial\Delta V^*/\partial P)_T$, in terms of ion-dielectric theory has been performed. The values of $(\partial\Delta V^*/\partial P)_T$ obtained on this basis are in good agreement with those found for the hydrolyses of organic halides. These results further indicate that contributions to $(\partial\Delta V^*/\partial P)_T$ arising from compression of the molecule or ion are by far more important than those arising from electrostriction of the dielectric medium. Also, the effects of quadrupole moments can be very important since the contributions from this are as great as those from dipole moments. Nevertheless it seems that ion-dielectric theory gives only a partial answer to the question of the nature and origin of $(\partial\Delta V^*/\partial P)_T$. Apparently, the contributions from solvent structure, unaccounted for on this model, cannot be ignored.

Une analyse de la dépendance du volume d'activation par rapport à la pression, $(\partial\Delta V^*/\partial P)_T$, a été réalisée en fonction de la théorie ion-diélectrique. Les valeurs de $(\partial\Delta V^*/\partial P)_T$ obtenues sur cette base, sont en bon accord avec celles trouvées pour l'hydrolyse des halogénures organiques. Ces résultats indiquent de plus que les contributions à $(\partial\Delta V^*/\partial P)_T$ provenant de la compression des molécules ou des ions sont de beaucoup plus importantes que celles provenant de l'électrostriction du milieu diélectrique. De plus, les effets des moments quadrupolaires peuvent être très importants puisque leurs contributions sont aussi grandes que celles des moments dipolaires. Néanmoins, il semble que la théorie ion-diélectrique ne donne qu'une réponse partielle à la question de l'origine et de la nature de $(\partial\Delta V^*/\partial P)_T$. Apparemment, les contributions dues à la structure du solvant, non interprétées dans ce modèle, ne peuvent être ignorées.

Recently some attention has been focussed upon finding an analytical function which best expresses the pressure dependence of reaction rates (1–3). This situation is essential since the activation volume, ΔV^*, is pressure dependent (1–7). The pressure dependence of the activation volume, $(\partial\Delta V^*/\partial P)_T$, for the hydrolytic reactions of organic halides usually lies in the range 0 to +10 ml/kbar mol (1–7). This has been attributed to differences in the compression of the ground state and transition state (1, 4, 9).[2] However, this does not give as clear a picture of the factors contributing to ΔV^* and the associated parameter $(\partial\Delta V^*/\partial P)_T$ as is desirable. Benson and Berson

[1]Revision received May 10, 1971.

[2]A referee has calculated $(\partial\Delta V^*/\partial P)_T$, assuming the initial and transition state compressibilities to be the same (K), on the following basis

$$(\partial\Delta V^*/\partial P)_T = -\Delta V^* \times K$$

If $\Delta V^* = -15$ ml/mol and $K = 100 \times 10^{-6}$ bar^{-1}, then $(\partial\Delta V^*/\partial P)_T = 1.5$ ml/kbar mol. This is in the range found for the reactions being considered in this paper.

(8) estimate a 50% change in ΔV^* over a 3 kbar range. This would result in $(\partial \Delta V^*/\partial P)_T$ in the expected range. However, this estimate takes into account only the electrostriction of the solvent and any compression of the cavity containing the initial and transition states is taken to be negligibly small. Walling and Tanner (9) have pointed out that if the transition state is not a volume extremum, pressure displaces the transition state along the reaction-coordinate. A theoretical treatment of the pressure dependence of the activation volume then becomes particularly difficult. They further state that only for a small group of non-ionic reactions will the transition state have compressibility factors of normal molecules. These conclusions have been amply refuted by Benson and Berson (10) who have shown that perturbations of the parameters ΔV^* and ΔF^* are negligibly small in the pressure ranges commonly employed, even for extremely compressible transition states. It seems, therefore, that an estimate of the pressure dependence of the activation volume taking into consideration a larger number of factors is wholly desirable. This will then allow a clearer understanding of the nature and origin of $(\partial \Delta V^*/\partial P)_T$ as well as providing useful information about the transition states involved. Results will be discussed in terms of the hydrolytic reactions of organic halides for which there is by far the largest body of accurate data.

The activation volume may be split up into two terms, $\Delta V^*(r)$ and $\Delta V^*(s)$ (11). $\Delta V^*(r)$ is the change in the van der Waals volume when the transition state is formed, that is the volume change due directly to the changing interaction of the reacting molecules with each other. The main contributions to it are due to changes in bond length, changes in the non-bonded interactions within the molecules, and changes in electron densities around nuclei. $\Delta V^*(s)$ is the volume change due directly to the changing interaction of the reacting molecules with the solvent. These changes are not all localized in the solvent but may also be localized within the molecules (11, 14, 15). As yet there is no adequate molecular theory which is both accurate and detailed enough to treat the interaction of a molecule with its solvent. By far the most applicable is that of Whalley (14). In this model the molecule is considered to be in a spherical cavity in a continuous dielectric medium. The cavity is both expansible and compressible and has a dielectric constant equal to unity. If the dielectric constant of the medium is very much greater than unity, the electrostatic volume of solvation, $\Delta V^*(s)$, due to the changing electrostatic interaction between the molecule and the dielectric (solvent) is given by eq. 1,

$$[1] \quad V^*(s) = (Nz^2e^2/2a_0)\,[(\partial \varepsilon_0^{-1}/\partial P) + (1 - 1/\varepsilon_0)(\partial \ln a_0/\partial P)] + (3N\mu^2/2a_0^3)\,[(\partial \varepsilon_0^{-1}/2\partial P) + (1 - (3/2\varepsilon_0))(\partial \ln a_0/\partial P)] + (5Nq^2/2a_0^5)\,[(\partial \varepsilon_0^{-1}/3\partial P) + (1 - (5/3\varepsilon_0))(\partial \ln a_0/\partial P)]$$

for an ion of charge ze, with point dipole (μ) and quadrupole moment (q) at the center. $\Delta V^*(s)$ is the sum of terms due to charge, dipole, and quadrupole. $\Delta V^*(s)$ can be further split up into two terms. These terms are $\Delta V^*(c)$ and $\Delta V^*(e)$. $\Delta V^*(c)$ is the change in volume of the cavity (molecule) caused by the force, resulting from the electrostatic interaction with the dielectric (solvent), exerted on it by the dielectric (solvent) and represented by terms in $(\partial \ln a_0/\partial P)$. These changes are not localized in the solvent but in the cavity (molecule). $\Delta V^*(c)$ is not an electrostriction of the cavity (molecule) which is zero if the dielectric constant is unity. $\Delta V^*(e)$ is the change in the volume of the dielectric (solvent). This change is localized in the solvent and is represented by terms in $(\partial \varepsilon_0^{-1}/\partial P)$. According to Whalley's analysis (14) compression of the cavity contributes more to the electrostatic volume of solvation than does electrostriction of the dielectric (2). Whalley was also able to show that quadrupole moments may be important in some reactions.

Let us assume that the part of the activation volume $\Delta V^*(r)$ is not significantly pressure dependent, as would be expected if a critical amount of change in the bond length(s) is needed for reaction. Then the variation of the activation volume with pressure must be explained in terms of the variation of $\Delta V^*(s)$ with respect to pressure. In fact it has long since been recognized that solvation effects can be very important in determining the effects of pressure on reaction rates (13, 16, 17). An estimate of this pressure dependence of the activation volume, $(\partial \Delta V^*/\partial P)_T$, may be obtained by differentiating Whalley's expression for $\Delta V^*(s)$, eq. 1, with respect to pressure. The resulting expression for $(\partial \Delta V^*/\partial P)_T$ ob-

TABLE 1. Factors contributing to $(\partial\Delta V^*/\partial P)_T$[a]

1. Charge	$\frac{Nz^2e^2}{2a_0}\left[\frac{\partial^2\varepsilon_0^{-1}}{\partial P^2} - 2\left(\frac{\partial \ln a_0}{\partial P}\right)\left(\frac{\partial\varepsilon_0^{-1}}{\partial P}\right) + \left(1-\frac{1}{\varepsilon_0}\right)\left(\frac{\partial^2 \ln a_0}{\partial P^2}\right) - \left(1-\frac{1}{\varepsilon_0}\right)\left(\frac{\partial \ln a_0}{\partial P}\right)^2\right]$
2. Dipole	$\frac{3N\mu^2}{2a_0^3}\left[\frac{\partial^2\varepsilon_0^{-1}}{\partial P^2} - 3\left(\frac{\partial \ln a_0}{\partial P}\right)\left(\frac{\partial\varepsilon_0^{-1}}{\partial P}\right) + \left(1-\frac{3}{2\varepsilon_0}\right)\left(\frac{\partial^2 \ln a_0}{\partial P^2}\right) - \left(1-\frac{3}{2\varepsilon_0}\right)\left(\frac{\partial \ln a_0}{\partial P}\right)^2 \times 3\right]$
3. Quadrupole	$\frac{5Nq^2}{2a_0^5}\left[\frac{\partial^2\varepsilon_0^{-1}}{\partial P^2} - \frac{10}{3}\left(\frac{\partial \ln a_0}{\partial P}\right)\left(\frac{\partial\varepsilon_0^{-1}}{\partial P}\right) + \left(1-\frac{5}{3\varepsilon_0}\right)\left(\frac{\partial^2 \ln a_0}{\partial P}\right) - 5\left(1-\frac{5}{3\varepsilon_0}\right)\left(\frac{\partial \ln a_0}{\partial P}\right)^2\right]$

[a] $(\partial^2 \ln \varepsilon_0/\partial P^2)_T = 67.28 \times 10^{-10}$, ref. 22.
$(\partial^2 \ln \varepsilon_0/\partial P)_T = 46.7 \times 10^{-6}$, ref. 22.
$\varepsilon_0 = 80.2$, ref. 22.
$(\partial \ln a_0/\partial P)_T = -5 \times 10^{-6}$ bar^{-1}, ref. 14.
$(\partial \ln a_0/\partial P^2)_T = 1.2 \times 10^{-9}$ bar^{-2}, computed from compressibility data in ref. 23.
$e = 4.8 \times 10^{-10}$ e.s.u.
$\mu = 10$ D (two point charges $+\frac{1}{2}e$ and $-\frac{1}{2}e$ about 4 Å apart).
$q = 0.2 \times 10^{-24}$ e.s.u. (two point charges each $\frac{1}{2}e$ that are 4 Å apart).
$z = 1$.
$a_0 = 3$ Å.
$N = 6.02 \times 10^{23}$ mol^{-1}.

TABLE 2. Contributions to $(\partial\Delta V^*/\partial P)_T$ from charge, dipole, and quadrupole

	Term (ml/kbar mol)				$(\partial\Delta V^*/\partial P)_T$
	1	2	3	4	(ml/mol kbar)
1. Charge	0.3	0.02	3.1	0.06	3.3
2. Dipole	0.1	0.02	5.1	0.19	5.0
3. Quadrupole	0.1	0.0	3.1	0.3	2.8

TABLE 3. Values of $(\partial\Delta V^*/\partial P)_T$ for some organic hydrolysis reactions

Substrate	Temperature (°C)	$(\partial\Delta V^*/\partial P)_T$ (ml/kbar mol)	Reference
Methyl bromide	70.0	5.5	6
Isopropyl bromide	50.0	6.0	6
Benzyl chloride	50.0	2.6	21
Allyl chloride	50.25	1.6	5
β-Methyl allyl chloride	50.25	1	5
trans-γ-Methyl allyl chloride	12.02	4.7	5

tained by this process is separated into contributions from charge, dipole, and quadrupole in Table 1 and evaluated on a term by term basis in Table 2. The calculated value of 5.0 ml/kbar mol for $(\partial\Delta V^*/\partial P)_T$ for a dipolar transition state agrees reasonably well with those for a number of hydrolytic reactions of organic halides, Table 3, whose transition states are thought to be dipolar.

The important contributions to the activation volume for the hydrolysis of organic halides probably arise from (*1*) an increase in the C—Cl bond length, (*2*) a contraction due to the possible formation of a new C—O bond to the incoming water, and (*3*) a contraction of the solvent and the transition state caused by an increased electrostatic interaction with the solvent due to the electric moments of the transition state. Contributions (*1*) and (*2*) may be equated to ΔV^*(r) and (*3*) to ΔV^*(s). In general there is no firm evidence about the relative contributions of these three factors to the overall activation volume (ΔV^*) and hence $(\partial\Delta V^*/\partial P)_T$. Baliga and Whalley (2) estimate that ΔV^* for the hydrolysis of tertiary butyl chloride in water is made up of contributions of +12 and −14 ml/mol from ΔV^*(r) and ΔV^*(s), respectively. If this is so we may estimate the value of $(\partial\Delta V^*/\partial P)_T$ on the following basis[2]

$$[2] \qquad (\partial\Delta V^*/\partial P)_T = -\Delta V^*.K$$

and

$$[3] \qquad \Delta V^* = \Delta V^*(\text{r}) + \Delta V^*(\text{s})$$

therefore

$$[4] \qquad (\partial \Delta V^*/\partial P)_T = -\Delta V^*(\mathrm{r}).K + \Delta V^*(\mathrm{s}).K$$

substituting the above values for ΔV^*(r) and ΔV^*(s) estimated by Baliga and Whalley (2), together with the assumed value of K,[2] we then have

$$[5] \qquad (\partial \Delta V^*/\partial P)_T = (-1.2 \times 10^{-3} + 1.3 \times 10^{-3}) \text{ ml/mol atm} = 0.1 \times 10^{-3} \text{ ml/atm mol}$$

This value is in the range found for this reaction in water (2). On this basis it seems that the pressure dependence of the activation volume must be viewed in terms of the compensation of the two terms in eq. 4. Also it seems likely that the pressure dependence of ΔV^*(r) may be making a significant contribution to the pressure dependence of the overall activation volume. That is to say that $(\partial \Delta V^*(\mathrm{r})/\partial P)_T \neq 0$, thus its contribution to $(\partial \Delta V^*/\partial P)_T$ may not be ruled out a priori. A theoretical analysis of the factors influencing $(\partial \Delta V^*(\mathrm{r})/\partial P)_T$ is not very straightforward and will not be attempted here. Thus further use will be made of ion-dielectric theory in trying to understand the origin and nature of $(\partial \Delta V^*/\partial P)_T$ as reflected in the behavior of $(\partial \Delta V^*(\mathrm{s})/\partial P)_T$.

There is a marked lack of sensitivity of the activation volume to temperature changes (5, 6, 24–27). Values of $(\partial \Delta V^*/\partial T)_P$ usually lie in the range 0.2 ml/mol deg for a variety of reactions. The implication of this is that $(\partial \Delta V^*/\partial P)_T$ should not be very temperature dependent, if $(\partial \Delta V^*/\partial P)_T$ is simply equal to $-\Delta V^*.K$. On the basis of ion-dielectric theory this behavior must be explained in terms of the changing interaction between the molecule(s) and the solvent with changing temperature. This would result in a change in ΔV^*(s) and ΔV^*(r), perhaps less C–Cl elongation as well as C—O formation. Thermodynamically $(\partial \Delta V^*/\partial T)_P = -(\partial \Delta S^*/\partial P)_T$. The complex behavior of $(\partial \Delta S^*/\partial P)_T$ cannot be explained in terms of ion-dielectric theory (6) as has been found for the hydrolysis of methyl and isopropyl bromide in water. Thus we can conclude also that the temperature dependence of the activation volume is difficult to explain quantitatively on this basis. Qualitatively this apparent lack of sensitivity of ΔV^* to temperature may be attributed to the fact that the initial and transition state volumes vary similarly with respect to temperature. The implication here being that water molecules are being held as tightly in the initial state as in the transition state, which is highly polar. The importance of initial state solvation and its relation to solvent structure has been quite adequately demonstrated by Arnett *et al.* in their work on the partial molal heats of solution in aqueous organic solvents (18).

If terms involving $(\partial^2 \ln a_0/\partial P^2)_T$ are by far the more important in determining the pressure dependence of the activation volume, as is evident from the results in Table 2, then it would be expected that the pressure dependence of the activation volume would be neither temperature nor pressure dependent, if the dielectric constant is very much greater than unity. In this case "a" would not be sensitive to dielectric constant. This lack of sensitivity of $(\partial \Delta V^*/\partial P)_T$ to temperature and solvent is not unknown (5, 20, 21). The temperature sensitivity of this parameter has been discussed earlier. However, the sensitivity of $(\partial \Delta V^*/\partial P)_T$ to solvent may be very large (2, 4, 7, 28), contrary to predictions of ion-dielectric theory as outlined in this paper. Thus it becomes evident that ion-dielectric theory does not totally account for all that is happening in solution under these conditions. Similar conclusions have been reached previously by Baliga and Whalley (2, 28, 29) who observed large variations in the activation volume for reactions which occur without large changes in the interactions with solvent. A detailed analysis of this large variation of the contribution of this interaction with solvent is not known in terms of ion-dielectric theory. Hence most workers have resorted to the approach of Arnett *et al.* (18) and have analyzed the effect of solvent on the activation volume in terms of the solvent effect on initial and transition state partial volumes (2, 20, 21, 32). The result of this approach is that in most cases the variation of partial volume of the initial state is more responsible for the variation of the activation volume with solvent composition than the transition state (2, 20, 30). In some cases the variation of the partial volume of the transition state may be more responsible (20). It also seems likely that when there is no variation of the activation volume with solvent that both the initial and transition state partial volumes are undergoing similar changes as solvent composition changes (21). In all cases

$(\partial \Delta V^*/\partial P)_T$ undergoes parallel changes (30). The implication of all this is that solvent structure is playing a part in influencing this kinetic behavior. This has been illustrated in other studies (18, 19, 30). However, at present a quantitative estimate of the extent of this cannot be made.

It is worthwhile to mention that in all of those studies quoted in the previous paragraph involved aqueous-organic solvent mixtures. It is known that the structural nature of these systems is quite complex. This complexity is reflected in the kinetics in these systems. However, when the variation of activation volume with solvent is related to a change from one pure solvent to another (*e.g.* ethanol, methanol, etc.), Eckert and co-workers (31–33) have found that then the variation of ΔV^* with solvent can be explained on the basis of ion-dielectric theory. All of the solvents involved in these studies are structurally similar, so structural influences are ruled out and a less complicated behavior results.

One further conclusion worth mentioning here, is the fact that the contributions to the pressure dependence of the activation volume from quadrupole moments can be quite significant and cannot be ignored. The contribution from quadrupole moments is about equal to that from dipole moments, Table 2.

To summarize, we may say that although these calculations are not very refined mainly because of the rough estimates of the parameters involved, that ion-dielectric, as applied here, does afford a clearer understanding of the nature and origin of the pressure dependence of the activation volume. Valuable information about the transition state can also be extracted on this basis. However, it may be constantly borne in mind that the contribution to ΔV^* and $(\partial \Delta V^*/\partial P)_T$ arising from structural properties of the aqueous binary solvent must be considered.

The author wishes to thank the National Research Council of Canada and the Council for Research, St. Francis Xavier University for support of this research.

The preparation of nitro sugar acetates by standard acetylation techniques is sometimes attended with difficulties due to occurrence of dehydration or dehydroacetylation and other complications that may ensue (1). Boron trifluoride catalysis (2, 3) has proved very efficient in the acetylation of various sensitive compounds, circumventing some of the difficulties mentioned, but in one recent instance it has caused acetolysis of a trityl ether function (4). This was overcome by the use of equivalent amounts of acetyl chloride and triethylamine in ether solution at 0°. The method, which involves an intermediate generation of ketene, has now been applied to methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**1**), -β-D-galactopyranoside (**2**), and -α-D-talopyranoside (**3**).

Whereas **1** and **2** gave high yields of the expected (and known) 2-acetates **1***a* and **2***a*, respectively, the taloside **3** furnished in 92% yield an abnormal product. Elemental analysis of the crystalline material (m.p. 136–137°) corresponded to $C_{18}H_{21}NO_9$, and the n.m.r. spectrum revealed that *two* acetyl groups had entered although the benzylidene acetal as well as the anomeric methoxyl group were retained. The i.r. spectrum was free from hydroxyl absorption and showed an ester carbonyl band at 1750 cm^{-1}, but it lacked the band expected for the nitro group in the 1550 cm^{-1} region. Instead, there was a sharp peak at 1800 cm^{-1} attributable to an acid anhydride structure, and an intense band occurred at 1620 cm^{-1}, in the region where nitronic acids and their esters show strong C=N absorption (5). The product exhibited high-intensity u.v. absorption (λ_{max} 242 nm, ε 8000, in methanol) in the range in which nitronic acids and their salts are known to absorb strongly (5) in contrast to nitroalkanes that have very low absorption in

that range. Although the compound was remarkably stable in the crystalline state and could be recrystallized from ethyl acetate, it suffered loss of both acetyl groups when chromatographed on silica gel, giving in 85% yield the known methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*threo*-hex-2-enopyranoside (**5**). This fact demonstrated that the acetylation of **3** had masked but not irreversibly altered or removed the nitro group at C-3. On the basis of all the spectroscopic and chemical evidence we allocate to the new compound the structure **4** of a mixed nitronic acid–acetic acid anhydride. Although the chemistry of nitronic esters has been investigated extensively, only a few nitronic carboxylic anhydrides have been described in the literature, and spectral data do not seem to be available (5, 6). In nitronic esters, the occurrence of geometrical isomerism has been established, and the same may be predicted for anhydrides. This matter has not yet been examined in connection with **4**, and the formula depicted is arbitrary with respect to the C=N bond geometry.

We have recently shown that nitronate formation with base occurs in **3** much more readily than it does in **1** and **2**, and the differences in nitromethylene acidity of these and a number of similar glycosides were interpreted by stereochemical considerations (7). Apparently the unusual behavior of **3** reported here is another manifestation of the special ease with which this isomer is converted into the *aci*-nitro form.

Experimental

*Methyl 2-O-Acetyl-4,6-O-benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**1a**)*

Triethylamine (1.93 ml, 13.8 mmol) in anhydrous ether (30 ml) was chilled in an ice water bath, and acetyl chloride (1.04 ml, 14.7 mmol) was added with magnetic stirring. A voluminous white precipitate of triethylammonium chloride occurred. After 5 min a solution of the nitro mannoside **1** (8) (206 mg, 0.66 mmol) in dry dichloromethane (4 ml) was added and the reaction mixture was stirred for 30 min at 0°. The mixture was then agitated with cold water, and after phase separation, the aqueous layer was extracted twice with ether. The combined ether solution and extract was washed three times with water, dried over sodium sulfate, and evaporated giving crystalline **1***a* (223 mg, 95%). Upon recrystallization from chloroform – petroleum ether the material (194 mg, 83%) showed m.p. 162–163°, $[\alpha]_D$ −88.7° (*c*, 0.53 in $CHCl_3$), lit. (8), m.p. 136–137° after recrystallization from aqueous ethanol; $[\alpha]_D$ not reported. Because of the melting point discrepancy the earlier acetylation procedure (8) was repeated but the product was recrystallized from chloroform – petroleum ether. The product (yield, 79%, m.p. 159–160°) was identical with that prepared by the new method according to mixed melting point, i.r. spectrum (8), and n.m.r. spectrum (100 MHz in $CDCl_3$): τ 2.6 (5-proton multiplet, phenyl), 4.13 (1-proton doublet, H-2, with $J_{2,3} = 3.5$, $J_{1,2} = 0$ Hz), 4.33 (1-proton singlet, $PhCHO_2$), 5.20 (1-proton quartet, H-3, with $J_{2,3} = 3.5$, $J_{3,4} = 10.5$ Hz), 5.48 (sharp singlet, H-1, overlapped by H-6,6′ multiplet), 6.05 (symmetrical 1-proton triplet with 10.5 Hz splitting, H-4), 6.50 (3-proton singlet, OCH_3, overlapping H-5 multiplet), 7.89 (3-proton singlet, *O*-acetyl).

*Methyl 2-O-Acetyl-4,6-O-benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside (**2a**)*

The nitro galactoside **2** (8) (206 mg) was dissolved in 10 ml of dichloromethane and acetylated as described above for **1**. Upon decomposition of the reaction mixture with water, the main part of the product **2***a* (160 mg) separated as crystals which were collected, washed with cold water, and dried; m.p. 149–151°. An additional crop (43 mg, m.p. 146–148°) was obtained by work-up of the reaction mixture as described for **1**. Total yield, 87%. The i.r. spectrum was superposable with that of **2***a* prepared earlier (2).

*Methyl 2-O-Acetyl-3-(O-acetyl-aci-nitro)-4,6-O-benzylidene-3-deoxy-α-D-lyxo-hexopyranoside (**4**)*

The nitro taloside **3** (9) (103 mg, 0.33 mmol) in dichloromethane (3 ml) was treated as described above for **1** with acetylating reagent consisting of acetyl chloride (0.52 ml, 7.3 mmol) and triethylamine (0.97 ml, 6.9 mmol) in anhydrous ether (20 ml). The aforementioned work-up procedure gave 120 mg (92%) of crystals that were homogeneous on t.l.c. with carbon tetrachloride – ethyl acetate (2:3, v/v). Recrystallization from ethyl acetate gave a first crop of **4** (29 mg, m.p. 136–137°), and a second crop (83.5 mg, m.p. 132–135°) upon addition of petroleum ether to the mother liquor. For i.r. and u.v. data, see discussion. The n.m.r. data (100 MHz, in $CDCl_3$): τ 2.5–2.7 (5-proton multiplet, phenyl), 4.35 (overlapping signals with 2-proton intensity, H-2 and $PhCHO_2$), 4.9–6.2 (signals corresponding to 5 ring protons), 6.62 (3-proton singlet, OCH_3), 7.83, 7.96 (3-proton singlets, *O*-acetyl).

Anal. Calcd. for $C_{18}H_{21}NO_9$ (395.4): C, 54.65; H, 5.35; N, 3.54. Found: C, 54.61; H, 5.18; N, 3.64.

A sample of **4** (100 mg) was chromatographed on a column (1.5 × 30 cm) containing 20 g of silica gel (0.05–0.20 mm, E. Merck AG, Darmstadt, Germany) with carbon tetrachloride – ethyl acetate (2.0:1.5, v/v) as eluent. The effluent was monitored by t.l.c., and only a single compound appeared. Evaporation furnished crystalline nitroolefin **5** (63 mg, 85%), m.p. 187–188°, whose i.r. spectrum was superposable with that of an authentic sample; reported, m.p. 185–186° (9).

We thank the National Research Council of Canada for support of this work.

Synthesis of 3-Deoxy-3-nitro-D-xylose[1]

JAN KOVÁŘ AND HANS H. BAER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 28, 1971

Crystalline 3-deoxy-3-nitro-α-D-xylose (**5**) was obtained in 40% over-all yield by periodate oxidation of 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**2**) followed by borohydride reduction and acid hydrolysis. In addition to the intermediate 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-xylofuranose (**4**), a small amount of an isomer probably having the D-*ribo* configuration was isolated. The title compound (**5**) was also obtained by hydrolysis of its methyl β-pyranoside (**1**).

Le déoxy-3 nitro-3 α-D-xylose (**5**) cristallisé, a été obtenu avec un rendement global de 40% par oxydation au periodate du déoxy-3 *O*-isopropylidène-1,2 nitro-3 α-D-glucofuranose (**2**), suivie par une réduction au borohydrure et hydrolyse acide. En plus du produit intermédiaire, le déoxy-3 *O*-isopropylidène-1,2 nitro-3 α-D-xylofuranose (**4**), une petite quantité d'un isomère ayant probablement la configuration du D-*ribo*, a été isolée. Le composé (**5**) a également été obtenu par hydrolyse de son méthyl β-pyranoside.

Canadian Journal of Chemistry, **49**, 3238 (1971)

For a study (1) on conformational and configurational equilibria in methyl 3-deoxy-3-nitropentopyranosides it was desirable to prepare the methyl β-pyranoside **1** of 3-deoxy-3-nitro-D-xylose (**5**). The glycoside was known to be a minor by-product in the nitromethane cyclization of L′-methoxydiglycolaldehyde; its formation had been revealed by isolation of the corresponding amine subsequent to catalytic hydrogenation, but the nitro glycoside itself had not been isolated (2). Although new efforts to separate **1** in crystalline condition from the products of nitromethane cyclization eventually proved successful (1), an independent synthesis of the parent sugar **5** was concurrently undertaken, and this synthesis, the first of a free nitro pentose, is recorded here.

3-Deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**2**) (3) was oxidized with sodium metaperiodate and the resulting pentodialdose derivative **3**, which was not isolated, was reduced with sodium borohydride to give syrupy but sufficiently well-characterized 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-xylofuranose (**4**) as the main product. A crystalline by-product arose in small proportion and was revealed by analysis and spectroscopy to be an isomer of **4**. Although its configuration was not established by chemical means, it most likely was the D-*ribo* isomer, formed by alkali-catalyzed epimerization during the borohydride reduction.[2] The n.m.r. spectra of **4** and its isomer are in accord with this assumption and suggest, moreover, the T_2[3] conformation for both compounds, *i.e.* the same conformation that has been assigned (3) to the glucofuranose derivative **2**. As in the latter, the xylofuranose **4** exhibits zero coupling between H-2 and -3 and a coupling of 4 Hz between H-3 and -4. The isomer, on the other hand, shows coupling between H-2 and -3 (although its value could not be determined by first-order analysis), and it exhibits a 10 Hz coupling between H-3

[2]Compare the analogous, D-*gluco* → D-*allo* epimerization described in the preceding article (3).

and -4. Acid hydrolysis of the main product **4** afforded **5**, the over-all yield from **2** being 40%. The reducing sugar crystallized as the downward mutarotating α-anomer. Acid hydrolysis of the previously described (1) methyl xyloside **1** furnished a sugar identical with **5**, thus ascertaining the structures of the latter as well as those of its precursors **4** and **2**.

Experimental

3-Deoxy-1,2-O-isopropylidene-3-nitro-α-D-xylofuranose (4) and Isomer

To a solution of 3-deoxy-1,2-*O*-isopropylidene-3-nitro-α-D-glucofuranose (**2**) (164 mg, 0.66 mmol) in water (7 ml) was added sodium metaperiodate (155 mg, 0.72 mmol), and the mixture was stirred at room temperature for 10 min. The excess of periodate was destroyed by ethylene glycol (2 drops), the solution was cooled in an ice water bath, and carbon dioxide gas was passed through. Sodium borohydride (45 mg) was added, followed after 15 min by another 45 mg of the same reagent. After a further 15 min the reaction solution was deionized by stirring with Dowex-1X2 (HCO_3^-) and Amberlite IR-120 (H^+) ion exchange resins. Evaporation furnished a pale yellow oil (141 mg) which exhibited 2 spots (R_f 0.53 and 0.65) on t.l.c. with chloroform – ethyl acetate (1:1). By column chromatography on silica gel (Davidson Chemical; see footnote 3 in ref. 3) with chloroform as eluent, compound **4** was obtained as a colorless oil (66 mg, 43%) that was homogeneous on t.l.c., corresponding to the faster moving spot. It distilled at 1 mm Hg at 90–95° (bath temperature) and showed $[\alpha]_D$ +61° (*c*, 0.23 in $CHCl_3$). Prominent i.r. bands in $CHCl_3$: 3600 (OH), 3000, 2950, 2910 (CH), 1558 and 1370 (NO_2), 1460, 1385, 1260, 1170, 1090, and 1025 cm^{-1}. The n.m.r. data (in $CDCl_3$): τ 3.85 (doublet, J = 3.5 Hz, H-1), 4.90 (doublet, J = 3.5 Hz, H-2), 4.95 (doublet, J = 4.0, H-3), 5.37 (quartet, J = 4.0 and 5.5 Hz, H-4), 6.18 (2-proton doublet, $J_{4,5} = J_{4,5'}$ = 5.5 Hz, H-5, -5′), 8.45, 8.62 (3-proton singlets, CH_3).

Anal. Calcd. for $C_8H_{13}NO_6$ (219.2): C, 43.85; H, 5.98; N, 6.38. Found: C, 44.11; H, 6.12; N, 6.47.

Further elution of the chromatographic column produced a crystalline *isomer* (22 mg) which melted at 74–75° after recrystallization from carbon tetrachloride; $[\alpha]_D$ +122° (*c*, 0.2 in $CHCl_3$). Prominent i.r. bands in $CDCl_3$: 3610 (OH), 3000, 2945, 2890 (CH), 1558, and 1360 (NO_2), 1455, 1385, 1380, 1310, 1255, 1220, 1165, 1135, 1110, 1030–1015 cm^{-1}. The n.m.r. data (in $CDCl_3$): τ 4.13 (doublet, J = 3.5 Hz, H-1), 4.9–5.1 (2-proton multiplet, H-2 and -3), 5.27 (sextet, $J_{3,4}$ = 10 and $J_{4,5} = J_{4,5'}$ = 2 Hz, H-4), 5.95, 6.17 (2-proton quartet of doublets due to H-5 and -5′, $J_{5,5'}$ = 13 and $J_{4,5} = J_{4,5'}$ = 2 Hz), 8.48, 8.67 (3-proton singlets, CH_3).

Anal. Calcd. for $C_8H_{13}NO_6$ (219.2): C, 43.85; H, 5.98; N, 6.38. Found: C, 43.80; H, 5.86; N, 6.36.

3-Deoxy-3-nitro-α-D-xylose (5)

From 4

The isopropylidene derivative **4** (27 mg) was refluxed for 1 h in methanol (1 ml) containing 2 drops of 2.8 *N* hydrogen chloride in dioxane. The solution was then filtered through 0.2 ml of Dowex 1X8 (acetate form, prewashed with methanol) and evaporated to give a residue that crystallized upon trituration with chloroform. The product (20.7 mg, 94%) melted at 144–145° (dec.) after recrystallization from acetone–chloroform. An n.m.r. spectrum in D_2O showed no peaks attributable to isopropylidene or methoxyl groups. $[\alpha]_D$ +90 (2 min) → +65 (12 min) → +55° (30 min, final, *c*, 0.12 in water).

Anal. Calcd. for $C_5H_9NO_6$ (179.1): C, 33.52; H, 5.06; N, 7.82. Found: C, 33.72; H, 4.91; N, 7.76.

From 1

Methyl 3-deoxy-3-nitro-β-D-xylopyranoside (**1**) (16 mg) (1) was boiled for 5 min in 1 ml of half-concentrated hydrochloric acid. The cooled solution was treated with activated charcoal, filtered, and evaporated *in vacuo*. The product (11 mg, 74%) gave an n.m.r. spectrum (in D_2O) superposable on that of **5** obtained from **4**. After recrystallization from acetone–chloroform it melted at 144–146°, undepressed on admixture of the preceding sample.

The Structure of the Hofmann Base Derived from Lycopodine Methiodide

N. CHIN-YOU, D. B. MACLEAN, A. PRAKASH, AND C. CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 29, 1971

A new structure, **4***a*, based on chemical and X-ray crystallographic data, is proposed for the Hofmann base derived from lycopodine.

Une nouvelle structure, **4***a*, fondée sur des données chimiques et de cristallographie au rayons-X, est proposée pour la base du type Hofmann dérivant de la lycopodine.

Canadian Journal of Chemistry, **49**, 3240 (1971)

The methiodide of lycopodine ($C_{16}H_{25}NO$, **1***a*), on treatment with potassium tertiary butoxide in boiling tertiary butyl alcohol, gives in high yield the Hofmann base ($C_{17}H_{27}NO$), to which structure **2** was assigned (1). On similar treatment the methiodide of clavolonine (**1***b*) is reported to yield a compound to which structure **3***b* was assigned (2). It seemed unlikely that lycopodine and clavolonine would yield products of different structure under the same reaction conditions and this led us to reinvestigate this reaction. It is also of mechanistic interest to clarify these structures for the formation of a compound of structure **2** from lycopodine methiodide is not in harmony with accepted views on the mechanism of displacement reactions (3).

We show here that the Hofmann base derived from lycopodine has structure **4***a* formed from lycopodine methiodide in a remarkable rearrangement. Mass spectral data indicate that its analogue derived from clavolonine has structure **4***b*.

The evidence which led to the proposal of structure **2** is now summarized. The Hofmann base did not have a double bond, had an *N*-methyl group and was tetracyclic; in its formation a carbon–nitrogen bond must have broken and a new carbon–carbon bond must have formed. The new base has only two hydrogens alpha to the carbonyl group (by deuterium exchange) in contrast to lycopodine which has three and both hydrogens are in a methylene group (i.r.). The isomer, **3***a*, was precluded since it was already known (4).

4

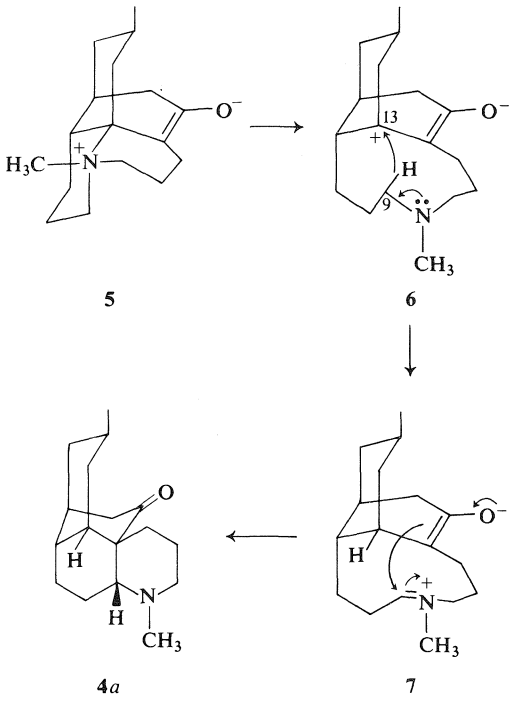
a R = H
b R = OH

Mass spectral evidence provided the first clue that structure **2** is untenable. The spectra of both **1***a* and **3***a* have base peaks at M-57 formed by elimination of the original bridging atoms of lycopodine and a hydrogen. The Hofmann base, however, has only a very weak ion at M-57 but has its base peak at *m/e* 57 of composition

C_3H_7N. To study the genesis of this ion we prepared the Hofmann base from lycopodine methiodide-*N*-Me-d_3 and from lycopodine methiodide -9,9-d_2.[1] There was no loss of deuterium in either reaction. In the first instance the peak at *m/e* 57 shifted completely to *m/e* 60 showing that the N—CH_3 group is a constituent of this ion while in the second case the base peak remained at *m/e* 57 (there was a small shift to *m/e* 58), a fact that precludes **2** from further consideration. The formation of the M-57 ion in lycopodine and its derivatives is thought to be initiated by fission of the C_{13}—C_{14} bond producing a stable immonium ion (5). The absence of an ion at M-57 in the spectrum of the Hofmann base implies that the N—C_{13} bond is no longer present.

The n.m.r. spectrum of the methiodide of the Hofmann base has three protons, aside from those of the two *N*-methyl groups, shifted downfield relative to their positions in the base itself suggesting the presence of three protons on carbons adjacent to nitrogen. In the spectrum of the methiodide of the Hofmann base derived from lycopodine methiodide-9,9-d_2 the low field proton at 4.65 δ is absent but those at 4.08 and 3.80 δ are present and unaltered in any way. These data suggest structure **4***a* for the Hofmann base. The configuration at C-9 is assigned on the basis of n.m.r. data since one of the two *N*-methyl groups of **4***a* methiodide appears at 2.90 δ (the other at 3.50) and must be situated in the shielding cone of the carbonyl group.

We suggest that **4***a* is formed by the sequence shown in Scheme 1. The enolate **5**, formed from lycopodine methiodide, undergoes solvolysis to **6** which stabilizes itself by hydride transfer from C-9 to -13 to give the immonium ion **7**. The latter then cyclizes as shown to **4***a*. Since there is no loss of deuterium in the reaction of the 9,9-d_2 derivative, the hydrogen transferred must come from C-9. This is not unexpected since 1,5 hydride transfer in 10-membered rings is well documented (6). The possibility that fission of the N—C_{13} bond occurs homolytically and that a hydrogen radical transfer occurs cannot be ruled out. Radical mechanisms have been demonstrated in nitrogen ylide rearrangements (7) and transannular hydrogen atom transfers have been observed (8).



SCHEME 1

The final structure has been verified by an X-ray crystallographic study of the hydrobromide of **4***a* which was purified by recrystallization from a methanol–ether mixture. The orthorhombic crystals proved to have space group $P2_12_12_1$ with a = 12.10(1), b = 7.06(1), c = 19.68(3) Å, and Z = 4. The structure was solved from the Patterson projections of the [100] and [001] zones using data measured from integrated precession photographs taken with MoKα radiation. The structure was refined using the intensities of 2647 independent reflections measured with the Syntex P1 automatic diffractometer of which 1264 were sufficiently intense to be measured, and a full matrix least squares computer program written for the CDC 6400. The model contained independent positional and isotropic thermal parameters for all the light atoms except the hydrogen atoms and positional and anisotropic thermal parameters for the Br. The final value agreement index,

[1]Lycopodine-9,9-d_2 was obtained by reduction of the corresponding lactam with lithium aluminum deuteride and oxidation of the dihydrolycopodine-5,9,9-d_3 so obtained with Jones reagent.

$$R = \frac{\sum ||F_o| - |F_c||}{\sum |F_o|}$$

is 0.078 while the weighted reliability index,

$$R_w = \left\{\frac{\sum W(|F_o| - |F_c|)^2}{\sum WF_o^2}\right\}^{1/2}$$

is 0.085. Weights were chosen so that the local value of F_o would be independent of the magnitude of F_o. All the individual bond distance and angles are those expected for structure **4***a*.

The Solvolysis of 5,5-Diphenylcyclononyl *p*-Toluenesulfonate. A Reinvestigation

JOHN M. MCINTOSH,[1] M. H. MISKOW,[2] AND GORDON WOOD

Department of Chemistry, University of Windsor, Windsor, Ontario

Received June 8, 1971

Reinvestigation of the acetolysis of 5,5-diphenylcyclononyl tosylate (**1**) has confirmed the absence of any transannular processes and deamination of the corresponding amine **16** gave a similar result. Trifluoroacetolysis of **1** caused extensive transannular hydride migration but no phenyl migration. The former may be due to secondary acid-catalyzed rearrangements.

Une étude concernant l'acétolyse du tosylate du diphényl-5,5 cyclononyle (**1**) a confirmé l'absence de tout processus *trans* annulaire; la désamination de l'amine **16** correspondante conduit à un résultat similaire. La trifluoroacétolyse de **1** provoque une forte migration *trans* annulaire d'hydrure mais aucune migration de phényle. Ceci peut être dû à une transposition acido catalysée secondaire.

Canadian Journal of Chemistry, **49**, 3243 (1971)

The facility with which transannular rearrangements occur in medium-sized ring compounds is well documented (1, 2). However, in spite of the efforts made by several groups, the only established case of transannular migration of a group *other than hydride* in such compounds is found in the formation (1%) of 1,5-diphenylcyclooctene from 5,5-diphenylcyclooctyl tosylate in trifluoroacetic acid (3). The lack of other examples is intriguing when considered in the light of data for 1,2-migrations where phenyl migration is a more facile reaction than that involving hydride (4).

A maximum on the graph of total ring strain *vs.* ring size (5) indicates that a nine-membered ring might be expected to provide the most favorable situation for rearrangement in the medium-ring series. The solvolytic behavior of cyclononyl tosylate has been well investigated (1, 6) and Blomquist and Hallam have reported the kinetics and product distribution obtained from the acetolysis of 5,5-diphenylcyclononyl tosylate (**1**) (7). It was concluded by these workers that the latter compound gave no products of transannular rearrangement, nor was anchimeric assistance involved in the reaction. However, the analytical techniques available at the time were such that the presence of a minor component in the solvolysis mixture could have been overlooked. In addition, the effect of solvent on the products formed from 5,5-diphenylcyclooctyl tosylate (3) suggested that a study of the effect of solvent on the solvolysis of **1** would be useful.

Many comparisons have been drawn between deamination and solvolytic reactions (8). The results of these comparisons can be summarized in part by noting that both the ratio of substitution to elimination reactions and the amount of rearrangement are found to be larger in deamination reactions. Further, since bimolecular substitution reactions with medium-ring substrates are slow compared to carbonium ion reactions, and since the only protons in the favorable *trans*-coplanar arrangement for concerted elimination in the diazonium cation intermediates are sterically inaccessible to an external base, virtually all products in the deamination of medium-ring amines are derived from carbonium ion intermediates (1). In contrast, it has recently

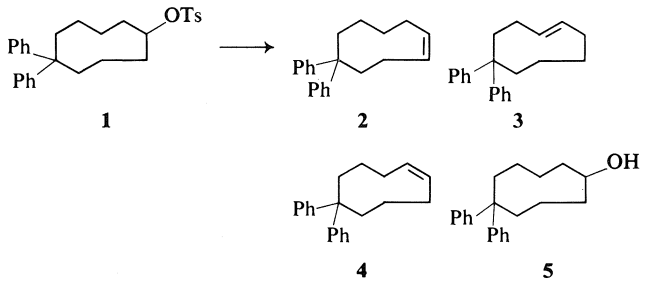

CHART 1

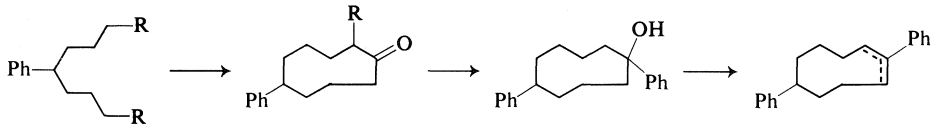

CHART 2

been noted (9–11) that partitioning of the carbonium ions in solvolysis reactions with E1 mechanisms may vary with the nature of the leaving group. It appears that a substantial portion of the proton removal from the β-carbon is effected by the counter ion, affording a route for elimination which is not available in the deamination reaction. With these concepts in mind we prepared 5,5-diphenylcyclononyl amine (**16**) and compared the products of its deamination with those of the solvolytic reactions of **1**.

Acetolysis of **1** in unbuffered acetic acid for 12 half-lives, followed by hydride reduction of the product according to the original procedure (7) afforded the products shown (Chart 1) in the amounts indicated in Table 1. These were identified by their molecular weights (mass spectra) and spectral characteristics. Gas chromatographic comparison of the acetolysis mixture with an authentic sample of 1,5- and/or 1,6-diphenylcyclononene (**6**), the expected product of phenyl migration, showed the absence of a detectable amount (1%) of **6** in the mixture. The preparation of **6** from 5-phenylazelanitrile is shown in Chart 2.

Repetition of the experiment in buffered trifluoroacetic gave the products shown in Chart 3. The yields are shown in Table 1. Again, none of the compound **6** could be detected. The results of the deamination of 5,5-diphenylcyclononyl amine (**16**) in acetic acid are summarized in Chart 4 and Table 1.

CHART 4

Discussion

The data on which the distinction between **2**, **3**, and **4** rest are worthy of some discussion. The n.m.r. spectrum of **4** shows two envelopes centered at δ 2.2 and 1.5 with relative areas of 8:4. The spectrum of **2** shows more complex and broad absorptions centered at δ 2.2 and 1.2. The chemical shift of the bulk of the high-field part of the spectrum of **2** suggests that the protons are separated from the olefinic bond and the aromatic nuclei by a larger distance than similar protons in **4**. Hence, the structural assignments were made on the basis of the relative symmetry of the two spectra and the chemical shifts of the methylene protons in the two compounds. However, when the signals near δ 2.2 were irradiated, the olefinic protons in both **2** and **3** collapsed to give singlets whereas **4** afforded two doublets (J = 11 Hz) separated by 17 Hz. It appears that the structural assignments require the reverse to be true. This olefinic non-equivalence can be rationalized by the existence of **4** mainly in an asymmetric conformation, but the same explanation may apply to the case of the methylene protons, in which case the structural assignments for **2** and **3**, and **4**, must be reversed. The remainder of the structures seem secure on the basis of their spectra.

Because of the known isomerization of olefins by acetic and trifluoroacetic acids, the stability of a mixture of olefins **2**, **3**, and **4** to the reaction conditions was determined. In acetic acid, very little isomerization was noted, but a significant amount (18%) of addition did occur. The reverse was true in trifluoroacetic acid where little addition, but significant isomerization to **12** and **13** occurred, with concurrent disappearance of **3**. Under deamination conditions, **3** was completely isomerized into **2**.

It is difficult to draw conclusions from the results in trifluoroacetic acid, since the olefins would be present initially in a homogeneous state in the reactions, whereas the isomerization experiments were heterogeneous throughout. A similar problem has been reported previously (3).

Conclusion

From the results of these experiments, it seems clear that, at least in acetic acid, the presence of the *gem*-diphenyl moiety restricts the conformations of **1** to those in which *both* hydride and phenyl transannular migrations are unfavorable. This is in agreement with the previous work (7). In trifluoroacetic acid, the results are not so clear with regard to hydride migrations since the olefin stability tests indicate that secondary rearrangements may account for the observed product distribution.

Experimental

Melting points are uncorrected. The i.r. spectra were obtained on a Beckman IR-12 in 10% (*w*/*w*) carbon tetrachloride solution. Unless otherwise noted, n.m.r. spectra were recorded on a Jeolco JNM-C60HL instrument in 10% (*w*/*v*) carbon tetrachloride solution and shifts are in δ units relative to tetramethylsilane. Small samples were accumulated on a Jeolco JRA-1 spectrum accumulator. The u.v. spectra were recorded on a Beckman DK-1 in cyclohexane. The mass spectra were obtained from Morgan Schaeffer Corp., Montreal. The g.l.c. analyses were carried out on an F and M Model 720 Gas Chromatograph utilizing one of the following columns: *A*, 10 ft × 0.25 in. XE-60 (Silicone gum nitrile); *B*, 6 ft × 0.25 in. QF-1; *C*, 6 ft × 0.25 in. Carbowax 20M; all 10% on 60–80 mesh Chromosorb W. Area measurements were made by planimeter. Except as noted the drying agent was magnesium sulfate. Liquid column chromatography was performed using Fisher certified neutral alumina, Brockman Activity 1 (80–200 mesh). Composition of mixtures are stated in terms of moles unless otherwise noted.

5,5-Diphenylcyclononanol

This compound was prepared by the published (7) procedure except that the ketone was purified by chromatography using methylene chloride followed by recrystallization from cyclohexane at −20°.

5,5-Diphenylcyclononyl Tosylate (1)

The method of Brown and Ham (12) was used and a yield of 90% based on the alcohol was common, m.p. 102–104°. This compound was relatively unstable and consequently was never heated above 30° nor kept for long periods of time; i.r.: 1360, 1170 (d), 1090 and 885 (br) cm^{-1}; n.m.r. ($CDCl_3$): 7.50 (4H, q, J = 8), 7.1 (10H, s), 4.70 (1H, m), 2.42 (3H, s), 2.4–0.9 (14H, m).

Acetolysis of 5,5-Diphenylcyclononyl Tosylate

The tosylate (1.8 g) was dissolved in 108 ml anhydrous

acetic acid and stirred at 35° for 36 h (12 half-lives) (7). The solvolysis product was quenched with 300 ml cold water and extracted with four 50 ml portions of ether. The combined ether portions were then washed with five 50 ml portions of water, two 40 ml portions of saturated sodium bicarbonate solution, and dried. After filtering and removing the ether there remained 1.16 g of an amber viscous liquid which was dissolved in 50 ml anhydrous ether, 100 mg lithium aluminum hydride added, and the mixture stirred for 3 h. Water (0.5 ml) was added dropwise, followed by magnesium sulfate (1–2 g). The mixture was stirred for 1 h, filtered, and the ether removed leaving 1.03 g of a colorless oil. This was subjected to column chromatography on 70 g alumina using petroleum ether (30–60°) (1020 ml) as eluent from which 804 mg of a white solid (fraction *1*) was obtained. The eluent was then changed to ether (1200 ml) followed by methylene chloride (1200 ml) but gave a combined total of only 39 mg of white solid (fraction *2*). Finally three methanol fractions were collected, combined, and the solvent removed. The residue was dissolved in methylene chloride, filtered in order to remove any column residue, and concentrated, to give 191 mg brown oil (fraction *3*). The total amount recovered from the column was 1.03 g.

The three fractions were analyzed by g.l.c. on column *B* (175°). Fraction *1* consisted only of compounds **2** and **3** (80%) and **4** (20%), while the second fraction contained a small amount of **5** in addition to **2**, **3**, and **4**. Fraction *3* consisted mainly of compound **5** and other small unidentified compounds (total 1%). The overall distribution was **2** + **3** (68%), **4** (15%), and **5** (16%). Sufficient quantities of **2** and **3**, **4**, and **5** were collected by g.l.c. (column *A*) for spectral examination. Fraction *1* gave only **2** when subjected to gas chromatography on an acid contaminated column *C* (205°). The n.m.r. of **3** was obtained by subtraction of the portion due to **2***a*. Compound **5** was shown by comparison of the i.r., n.m.r., and g.l.c. retention times to be identical to 5,5-diphenylcyclononanol.

Compound **2**: i.r. 1653 (w), 1580 (w), 725, 700 cm^{-1}; n.m.r. 7.18 (10H, s), 5.68 (2H, t, J = 6), 2.5–0.9 (12H, m).

Compound **3**: i.r. (in addition to those of **2**) 992 cm^{-1}; n.m.r. 7.13 (10H, s), 5.45 (2H, m), 2.5–0.8 (12H, m); u.v. (56:44 mixture of **2** and **3**) λ_{max} (C_6H_{12}) 270 (log ε 2.65), 266 sh (2.67), 263 (2.75), 259 (2.78), 254 (2.79), 249 (2.78), 244 (2.75), 218 inf (4.14) mμ; *m/e* 276 (P), 277 (P + 1, 23.2%), and the following additional prominent peaks: 193 (B), 180, 179, 178, 167, 165, 117, 91, 41.

Compound **4**: i.r. 1650 (w), 1598, 1580 (w), 700 cm^{-1}; n.m.r. 7.17 (10H, s), 6.0–5.0 (2H, m), 2.6–1.1 (12H, m); u.v. λ_{max} (C_6H_{12}) 270 (log ε 2.79), 265 sh (2.82), 263 (2.88), 259 (2.90), 254 (2.90) 249 (2.88), 244 (2.84), 219 inf (4.52) mμ; *m/e* 276 (P), 277 (P + 1, 23.2%), and the following additional prominent peaks: 205, 193, 181, 180 (B), 179, 178, 167, 165, 129, 115, 103, 91, 77, 41.

Trifluoroacetolysis of 5,5-Diphenylcyclononyl Tosylate (1)

The tosylate (4 g) was added to 35 ml trifluoroacetic acid (Eastman highest purity) containing 1.43 g (0.3 *M*) sodium trifluoroacetate and the mixture was stirred at 5° for 23 h. An aliquot taken after 18 h showed virtually no tosylate in the i.r. spectrum. The mixture was poured cautiously into 500 ml cold saturated sodium bicarbonate solution and extracted with five 50 ml portions of ether. The combined ether portions were washed twice with 25 ml of water, dried, filtered, and concentrated to give 2.16 g of a brown oil (small 1780 cm^{-1}, trifluoroacetate). This was dissolved in 150 ml dry ether, 0.15 g lithium aluminum hydride was added, and the mixture stirred magnetically for 30 min. After the dropwise addition of 1 ml of water, the solution was stirred for 30 min, a few grams of magnesium sulfate were added, the mixture filtered through Celite, and the solvent removed to give 1.9 g of an amber oil. This was chromatographed on 70 g alumina using pentane as eluent. Fraction *1* (500 ml) was 1.03 g of a yellow oil, which by g.l.c. on column *A* (180°) consisted of **12**, **13**, **14**, and **15**, (65:24:3:8). Over the next ten 100 ml fractions methylene chloride was added gradually up to 5% by volume and these fractions combined to give 0.31 g yellow oil (fraction *2*), which by g.l.c. consisted mainly of the same four compounds in the ratio 30:10:20:37 and a few other peaks (all < 1%). The eluent was then changed to 10:1 ether–methanol to give 0.36 g of a brown oil (fraction *3*), which by g.l.c. consisted of mainly **14** and **15** (7 and 17%, respectively) and 45% **5**. The total recovery was 1.70 g with the following composition: **12** (47%), **13** (17%), **15** (15%), **5** (9%), with the remainder totalling a maximum of 5% (all individually less than 1%). None of compound **6** could be detected. Sufficient quantities of compounds **12** to **15** were collected for spectral analysis:

Compound **12**: i.r., 1598, 1572 (w), 702 cm^{-1}: n.m.r. 7.01 (10H, s), 2.66 (4H, m), 1.67 (10H, br s); u.v. λ_{max} (C_6H_{12}) 246 sh (log ε 3.97) mμ; *m/e* 276 (P), 277 (P + 1, 23.4%), and the following prominent peaks: 115, 105, 91 (B), 77.

Compound **13**: i.r., 1600, 1585 (w), 1575 (w), 703 cm^{-1}; n.m.r. 7.22 (10H, s), 2.19 (4H, s), 1.48 (10H, br s); u.v. λ_{max} (C_6H_{12}) 245 sh (log ε 3.68) mμ.

Compound **14**: i.r. 1599, 1584 (w), 1574 (w) 702 cm^{-1}; n.m.r. 7.13 and 7.00 (10H), 5.79 (1H, t, J = 8.6), 4.22 (1H, m), 2.47 (2H, m), 1.71 (10H, br s); u.v. λ_{max} (C_6H_{12}) 238 sh (log ε 3.74) mμ; *m/e* 276 (P), 277 (P + 1, 23.1%), and the following additional prominent peaks: 205, 129, 117, 115, 91 (B).

Compound **15**: i.r. 1600, 702 cm^{-1}; n.m.r. 7.25 (10H, s), 5.85 (1H, d, J = 10), 3.30 (1H, m), 2.3 and 1.68 (12H); u.v. λ_{max} (C_6H_{12}) 274 (log ε 3.09), 2.67 (3.11), 260 (3.06), 254 (2.97), 224 inf (4.09) mμ; *m/e* 276 (P), 277 (P + 1, 23.4%), and the following additional prominent peaks: 205, 192, 179, 115, 91 (B).

5,5-Diphenylcyclononylamine (16)

Hydrogenation of the oxime of 5,5-diphenylcyclononanone was extremely slow, while reduction with lithium aluminum hydride gave mainly a secondary amine. To 6.2 g tosylate **1** dissolved in 120 ml dry dimethylsulfoxide was added 1.7 g sodium azide. The solution was stirred magnetically for 5 days at room temperature, poured into 250 ml cold water, and extracted with four 50 ml portions of ether. The combined ether portions were washed in turn with four 25 ml portions of water, dried over sodium sulfate, filtered, and concentrated to give 3.5 g of azide (i.r. 2100 cm^{-1}). This was dissolved in 150 ml dry tetrahydrofuran, 2.0 g lithium aluminum hydride added, and the mixture heated to reflux for 2 h,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

then left stirring overnight. After the addition of 2 ml of water, 2 ml of 15% sodium hydroxide was added, followed by 6 ml of water. The resulting solid was filtered and the filtrate dried with sodium sulfate. After removal of solvent there remained 3.6 g of a colorless viscous oil. This was dissolved in 40 ml 95% ethanol and 80 ml of a saturated ethanolic picric acid solution added. The solution was heated to reflux, left overnight, and the picrate filtered and dried (dec. 236–238°).

Anal. Calcd. for $C_{27}H_{30}N_4O_7$: C, 62.06; H, 5.79; N, 10.72. Found: C, 62.15; H, 5.72; N, 10.60.

The picrate was dissolved in 400 ml of 5% sodium hydroxide solution (heated) and the amine extracted with three 100 ml portions of ether. The ether fractions were combined and washed with a small portion of 5% sodium hydroxide solution, then passed through about 50 g Rexyn 201 ion exchange resin, followed by 200 ml of ether. The ether solution was dried with sodium sulfate, filtered, and concentrated. The pure amine was dried under reduced pressure at 100° in a drying tube to give 1.45 g white solid, m.p. 95–96°, which turned brown on exposure to air. The overall yield was 38%, i.r. 3320 cm^{-1}; n.m.r. 7.27 (10H, s), 2.73 (s, 10), 3.7 (1H, m), 2.6–0.5 (16H, m).

Anal. Calcd. for $C_{21}H_{27}N$: C, 85.95; H, 9.27. Found: C, 85.73; H, 8.99.

Acetamide: m.p. 233–235° (from ethyl acetate – cyclohexane). i.r. (KBr) 3280, 2940, 1640, 1560, 1490, 1450, 750, 705 cm^{-1}; *m/e* 335 (P), 276, 206, 205, 193, 168, 167, 166, 140, 129, 127, 117, 115, 114, 100, 91 (B), 70, 60, 57, 56, 44, 43.

Deamination of 5,5-Diphenylcyclononylamine

An attempt with sodium nitrite and trifluoroacetic acid gave large amounts of aromatic nitration (i.r., strong 1525 and 1350 cm^{-1}), possibly from the dinitrogen tetroxide produced. Substitution of isoamyl nitrite in trifluoroacetic acid gave an unknown solid, m.p. 190–195°, with a large increase in weight and no olefin after an hour at reflux. Hence glacial acetic acid was used. Amine **16** (0.54 g) was dissolved in 10 ml glacial acid in a 25 ml two-neck flask equipped with a septum and condenser with calcium chloride drying tube. Using a syringe, 290 μl (1.1 equiv) of freshly distilled isoamyl nitrite was added and the solution heated at reflux (bath 130°) with magnetic stirring for 5 h, then cooled and left stirring overnight. The solution was poured into 25 ml cold water, extracted with three 25 ml portions of ether, which in turn were combined and washed with two portions of water and saturated sodium bicarbonate solution, then dried. After filtration and ether removal there remained 0.8 g of a brown viscous oil (i.r., strong 1735 cm^{-1}). This was chromatographed on 40 g alumina. Fraction *1* (petroleum ether, 560 ml) gave 0.17 g of amber product which by g.l.c. (column *A*) and n.m.r. was shown to be a 62:38 mixture of compounds **2** and **4**. While slowly increasing the amount of methylene chloride up to 50%, 1050 ml were collected to give 0.25 g of an amber oil, which was identical by i.r. and n.m.r. (mixed with authentic) to 5,5-diphenylcyclononyl acetate (7) (decomposed under g.l.c. conditions). Recrystallization from petroleum ether (30–60°) gave the acetate as a white solid, m.p. 98–100°, (undepressed with authentic material). Elution with pure methylene chloride (350 ml) gave 0.1 g brown oil which by i.r. and n.m.r. was shown to be a 50:50 mixture (80:20 by weight) of 5,5-diphenylcyclononanol **5** and isoamyl alcohol. Hence, the overall yield was 0.50 g which consisted of 37% olefin, 46% acetate, and 17% alcohol.

5-Phenylazelanitrile (7)

This compound was synthesized by the method of Cope and Kinnel (13) using the reported dimethylsulfoxide method of nitrile synthesis rather than refluxing ethanol.

Dimethyl 5-Phenylazelate (8)

The dinitrile **17** (23 g) was hydrolyzed by heating at reflux for 16 h in 200 ml concentrated hydrochloric acid. The cooled solution was made basic with 15% sodium hydroxide, extracted with several portions of ether, then acidified to p*H* 2.

Extraction with ether gave 25 g of an amber liquid which was dissolved in 175 ml methanol and heated at reflux for 6 h in the presence of 10 ml concentrated sulfuric acid. The cooled solution was poured into water and extracted with three 150 ml portions of ether. The combined ethereal extracts were washed with saturated brine, dried, and evaporated. The residue was distilled and the fraction boiling from 185–191° (2.5 mm) was collected (n_D^{23} = 1.4950) to give diester **8** (21.4 g) in 67% yield.

5-Phenylcyclononanone (10)

Diester **8** (15.8 g) was cyclized in the same manner used in the preparation of **1** (7). The crude acyloin **9** (2.6 g) was isolated by distillation (b.p. 149–158° (0.2 mm)). This material was reduced by the same method used in the preparation of **1** and the product purified by column chromatography on 50 g of alumina. Elution with petroleum ether gave 0.4 g of hydrocarbon. The solvent was then changed gradually to pure methylene chloride and elution continued until a dark band was about to be eluted. Concentration of the fraction gave 0.6 g of a brown liquid which was purified by g.l.c. collection (8 ft × 0.5 in. 10% XE-60, 230°). The ketone **10** (0.34 g) was obtained in 3% yield from diester **8**. i.r.: 1704 cm^{-1}; n.m.r. 7.21 (5H, s), 2.43 (5H, m), 1.80 (10H, m).

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 82.98; H, 9.23.

1,5-(1,6)-Diphenylcyclononene (6)

To a solution of phenyl lithium prepared from 0.8 g each of bromobenzene and lithium wire (high sodium content) in 10 ml dry ether, 0.3 g of ketone **10** in 5 ml dry ether was added slowly. The solution was heated at reflux for 1 h, cooled and stirred for 2 h, then 15 ml water added. The aqueous layer was separated, extracted twice with 15 ml of ether, and the combined organic phases dried over sodium sulfate. After filtration and solvent removal there remained 0.5 g of a brown oil (i.r., strong OH), which was dissolved in 100 ml dry benzene containing a few crystals of iodine. The solution was heated at reflux for 26 h under a Dean–Stark water trap, then cooled and washed with 10 ml of saturated sodium thiosulfate solution, two 5 ml water portions,

and dried over sodium sulfate. The brown liquid (0.4 g) obtained was purified by preparative g.l.c. (8 ft × 0.50 in. 10% SE-30, 225°). The olefin had a retention time of about 40 min.

Compound **6**: i.r. 1665 (w), 1642 (w), 1600, 701 cm^{-1}; n.m.r. 7.27 and 7.13 (10H). 5.85 (1H, t, $J = 8.6$), 3.0–2.1 (5H, m), 1.70 (8H, m); u.v. λ_{max} (C_6H_{12}) 293 inf (log ε 2.31), 241 (3.86) mμ.

Anal. Calcd. for $C_{21}H_{24}$: C, 91.25; H, 8.75. Found: C, 90.98; H, 8.73.

Olefin Stability Tests

To 1.8 ml trifluoroacetic acid containing 70 mg (0.3 *M*) sodium trifluoroacetate and 80 mg *p*-toluenesulfonic acid (1 equiv) was added 100 mg of an olefin mixture consisting of 45% **2**, 45% **3**, and 10% **4**. This was stirred in a sealed vial for 23 h at 5° (heterogeneous throughout), poured into 15 ml saturated sodium bicarbonate solution, and extracted with ether. The ether layers were washed with water and dried over sodium sulfate. After filtration and solvent removal, the residue (i.r. small 1780 cm^{-1}) was shown by g.l.c. to consist of 27% **12**, 8% **13**, 54% **2** (no **3** in i.r.), and 11% **4**. Small amounts of **14** and **15** would have been obscured under the last two peaks and hence could not be detected.

After heating the same olefin mixture in 1 ml of glacial acetic acid containing 35 mg (1 equiv) *p*-toluenesulfonic acid at 35° for 35 h, the solution was worked-up in analogous manner. By i.r. and n.m.r. comparison of a mixture of known concentration, the product was estimated to contain 18% (23% by weight) of the acetate of **1**.

About 20 mg of the olefin **6** was dissolved 0.5 ml glacial acetic acid with 19 μl isoamyl nitrite, and the solution heated at reflux (130°) for 5 h, then left stirring overnight. After an identical work-up to that of the deamination product, the residue (i.r., strong 1740 cm^{-1}, acetate) was estimated by n.m.r. to be about 35% of the mixture.

Treatment of a 42 mg sample of the same olefin mixture used in the trifluoroacetolysis test in the same manner as the olefin **6** above resulted in complete isomerization of **3** to **2** (no **3** detectable by i.r. nor n.m.r.), with the formation of only a small amount of acetate.

Solvent Effects in Free Radical Copolymerization

A. M. CHATTERJEE[1] AND C. M. BURNS[2]
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario

Received May 13, 1971

Acrylamide and *N*-vinyl pyrrolidone were copolymerized at 60° in binary aqueous solutions containing 0, 5, 67, and 80% glycerol by weight. A marked increase in the reactivity of acrylamide relative to that of *N*-vinyl pyrrolidone was observed. This increase is interpreted in terms of the relative reactivity of monomer and polymeric radical in the reaction medium.

L'acrylamide et la *N*-vinyl pyrrolidone ont été copolymérisés à 60°, dans les solutions aqueuses binaires contenant 0, 5, 67 et 80% de glycérol en poids. Un accroissement notable de la réactivité de l'acrylamide par rapport à celle de la *N*-vinyl pyrrolidone a été observée. Cet accroissement s'interprète en termes de réactivité relative du monomère et du radical du polymère dans le milieu réactionnel.

Canadian Journal of Chemistry, **49**, 3249 (1971)

In our previous communication (1) we examined the effect of the molecular structure of the monomer on the relative reactivities of the two monomers in free radical copolymerization. We have now extended our investigations to determine what effect the solvent for the reaction can have on the relative reactivities of the two monomers.

Relative reactivities in nonaqueous media had been found to undergo very little change with varying dielectric constants (2, 3). In aqueous media, readily ionizable monomers such as methacrylic acid had relative reactivities which depended on the p*H* of the medium (4). These results were explained on the basis of different reactivities of ionized and unionized forms of the same species.

For our investigation we chose a relatively neutral aqueous medium with varying ratios of water and glycerol. For comonomers, we chose two amides, acrylamide (AA) and *N*-vinyl pyrrolidone (NVP). These two monomers, their homopolymers, and their copolymers were soluble in glycerol–water mixtures up to 80% glycerol by weight. From the analysis of the relative amounts of the two monomers assimilated into the copolymers at various relative concentrations of the two monomers, it was possible to determine the relative reactivity of the two monomers. By varying the solvent composition, the effect of solvent on the relative reactivity of the two monomers in free radical copolymerization could be determined.

Experimental

Materials

Acrylamide and *N*-vinyl pyrrolidone were purchased from Monomer-Polymer Laboratories, Philadelphia. The acrylamide was used as received; it was characterized by a melting point of 84.0 °C. *N*-vinyl pyrrolidone was purified by distillation under reduced pressure (13 mm Hg at 95 °C), using a Vigreaux column and retaining the middle fraction.

Cumene hydroperoxide (Matheson, Coleman and Bell) was stored at −5 °C and used as received. Glycerol (British Drug Houses Analar) and deionized water were used as solvents. Acetone (Fisher Scientific Company, Reagent Grade) was used for precipitation.

Polymerization Procedure

The monomers were copolymerized in glass polymerization tubes approximately 4.5 in. long by 1 in. in diameter. The comonomers, initiator, and solvent were introduced by syringe. Approximately 5 g of monomer mixture was used with 25 ml of the solvent mixture. The reaction mixture was subjected to repeated freezing and thawing under vacuum. After sealing, the tubes were immersed in a water bath maintained at 60 ± 0.1 °C. Conversions were kept below 10%.

The product was isolated after brief cooling by pouring the contents into 600 ml of acetone with stirring. Hydroquinone had been added to stop the polymerization. The copolymer which precipitated was removed by filtration and dried under vacuum. It was purified twice by redissolving in water and reprecipitating in acetone.

The homopolymer of acrylamide was prepared by the same procedure. The homopolymer of *N*-vinyl pyrrolidone was prepared by bulk polymerization at 60 °C for 12 h. The two homopolymers were purified in the same manner as the copolymers.

Analysis of the Composition of the Copolymers Formed

The composition of the AA–NVP copolymers was determined by ultraviolet absorption spectroscopy in

[1]Present address: Department of Polymer Science and Engineering, University of Massachusetts, Amherst, Massachusetts 01002, U.S.A.

[2]To whom correspondence should be addressed.

aqueous solution at room temperature, using a Bausch and Lomb Spectronic 505 Recording Spectrophotometer. Both poly (AA) and poly (NVP) were found to have an absorption maximum at 201 mμ. Absorbance at this wavelength for different concentrations of poly (AA) and poly (NVP) were determined and plotted against concentration. Beer's law was seen to be obeyed up to concentrations of 0.08 g/l for poly (AA) and 0.03 g/l for poly (NVP). Measurement of the slopes of the straight lines gave the specific extinction coefficients of 8.34 l g^{-1} cm^{-1} for poly (AA) and 26.50 l g^{-1} cm^{-1} for poly (NVP). Thus determination of the absorbance of a solution of a copolymer of known total copolymer concentration enables the relative amounts of AA and NVP in the copolymer to be determined. The composition of a copolymer determined by this photometric method was confirmed by CHN elemental analysis, to determine that possible complications in the ultraviolet analysis by interactions between groups in the same chain were not occurring.[3]

Binary Solvent Compositions

Four solvent media were used, containing 0, 5, 67, and 80% by weight glycerol.

Treatment of Data (1)

The relative reactivity of the two monomers is conveniently expressed in terms of the two reactivity ratios, r_1 (AA) and r_2 (NVP), where r_1 (AA) = k_{11}/k_{12} = the ratio of the rate constants for monomers AA and NVP adding to a polymer radical ending in AA. r_2 (NVP) = k_{22}/k_{21} = the ratio of the rate constants for monomers NVP and AA adding to a polymer radical ending in NVP. The values of r_1 and r_2 can be obtained from the copolymer composition equation which relates the copolymer composition to the comonomer composition and the reactivity ratios. Several methods including a computerized "least squares" method can be used.

Results and Discussion

The mole fraction of acrylamide assimilated into the copolymer at various comonomer compositions is shown in Fig. 1. Although there is some scatter in the data, there is a definite trend for the copolymer being formed to be more enriched in acrylamide at higher glycerol concentrations.

For copolymerization in water alone, there is a "cross-over" point beyond which at higher concentrations of acrylamide in the feed the copolymer is enriched in *N*-vinyl pyrrolidone. In this case each polymeric radical prefers the alternate monomer and the reactivity ratios are less than 1. From the linear "least squares" treatment of the data the values of r_1 and r_2 are 0.66 and 0.17,

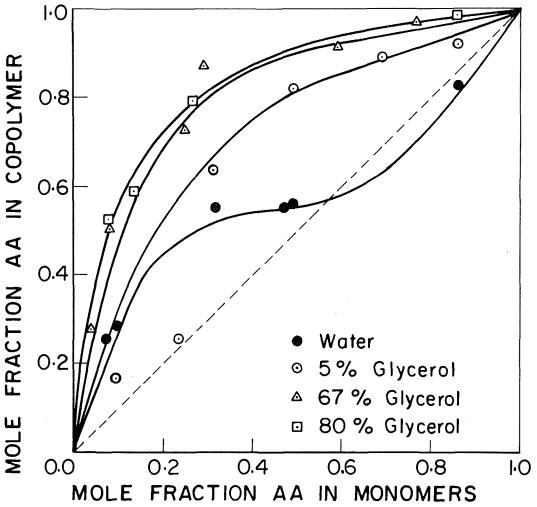

FIG. 1. Variations of copolymer composition with composition of comonomers at varying solvent compositions. AA, acrylamide. Comonomer *N*-vinyl pyrrolidone. 60°.

respectively. These values of r_1 and r_2 are consistent with the existence of a cross-over point or "azeotrope" shown in Fig. 1 since they are both less than unity (5). The linear "least squares" treatment was used to obtain the best fit of the experimental data. The standard deviations of the reactivity ratios obtained by this method are not reported, however, due to considerable controversy concerning their significance (6).

Although the reactivity ratios for this combination of monomers has not been reported before, an estimate of their reactivity ratios can be made from the Q and e values of the two monomers (7). Using average values obtained over widely varying temperatures, an estimate of r_1(AA) = 0.006 and r_2(NVP) = 0.0002 can be made. These estimates would predict an even stronger alternating tendency than was observed in this experiment. There is considerable uncertainty in the literature values of Q and e for these monomers, however, since they have not been copolymerized with monomers like styrene from which more reliable Q and e values can be obtained.

At higher glycerol concentrations in Fig. 1, there is a definite shift away from alternating behavior to increasing enrichment of the copolymer in acrylamide. The value of r_1 must be increasing with increasing glycerol concentration.

The changes in r_1 and r_2 with glycerol concen-

[3]Elemental analyses were performed in the laboratory of Alfred Bernhardt, 5251 Elbach uber Engelskirchen, Fritz-Pregl-Strasse 14–16, West Germany.

For personal use only.

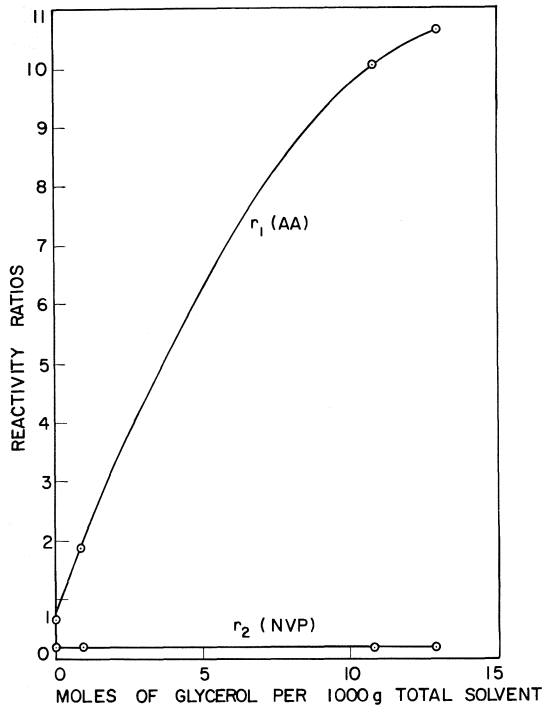

FIG. 2. Variation of reactivity ratios with composition of solvent. r_1, acrylamide; r_2, *N*-vinyl pyrrolidone.

tration can be seen more clearly in Fig. 2. A marked increase in r_1 occurs; r_2 decreases by about 35%. Each reactivity ratio represents the reactivity of the two monomers with that radical. The increase in r_1 corresponds to an increase in the relative reactivity of the acrylamide radical towards acrylamide monomer relative to *N*-vinyl pyrrolidone. The decrease in r_2 in turn corresponds to a decrease in the reactivity of the *N*-vinyl pyrrolidone radical towards *N*-vinyl pyrrolidone monomer relative to acrylamide monomer. However, r_2 only decreases from 0.17 to 0.11 while r_1 increases by a factor of 15 from 0.66 to 10.6. Thus the increase in the relative reactivity of acrylamide monomer as reflected in r_2 (or $1/r_2$) is not sufficient to account completely for the increase in r_1. Hence the presence of glycerol must also increase the reactivity of the polymeric acrylamide radical towards the acrylamide monomer in this copolymer system.

Specific influences of water have been observed earlier by DeSchryver, Smets, and Van Thielen (8). They investigated the homopolymerization of methacrylic acid in water–dioxane–ethanol mixtures and found that the rate of polymerization increased with the concentration of water at constant dielectric strength. At constant concentration of water, however, the rate of polymerization did not change with changes in the dielectric constant of the reaction medium. Using different solvents, Kerber (9) correlated the changes in the reactivity ratios of styrene and acrylic acid with associations of the solvent with acrylic acid through hydrogen bonding. Uno *et al.* (10) have concluded from a copolymerization study of acrylic esters with styrene in benzene and dioxane that the more polar solvent would break up the hydrogen bonding of the —NH and —OH groups of the monomer around the polymer. This work, then, indicates that the presence of glycerol enhances the hydrogen-bonding of acrylamide monomer to the polymer and in particular to the polymer radical ending in an acrylamide unit.

Synthesis and Reactivity of Halide Bridged, Cationic Complexes of Platinum and Palladium

K. R. Dixon and D. J. Hawke

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received June 1, 1971

The chloride bridged complex, $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$, reacts with C_2F_4 and H_2O or with aldehydes to yield *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$ and with HCOOH to cause catalytic decomposition of the acid to CO_2 and H_2. These reactions are of interest in mechanistic comparisons with other d^8 complexes. Similar reactions of related platinum and palladium complexes are also described, together with the synthesis of the new complexes, $[Pd_2X_2(PR_3)_4][BF_4]_2$, where X = Br or I for R = phenyl and X = Br for R = ethyl, *cis*-$[MCl(PEt_3)_2(Py)][BF_4]$ and $[MCl(PPh_3)_3][BF_4]$ where M = Pd or Pt.

Le complexe ponté chloruré, $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ réagit avec C_2F_4 et H_2O ou avec les aldéhydes pour donner $[PtCl(CO)(PEt_3)_2][BF_4]$-*trans*. Avec HCOOH le complexe provoque une décomposition catalytique de l'acide en CO_2 et H_2. Ces réactions sont intéressantes si l'on compare les mécanismes avec d'autres complexes d^8. Des réactions semblables, avec des complexes apparentés du platine et du palladium, sont également décrites. On rapporte aussi la synthèse de nouveaux complexes, $[Pd_2X_2(PR_3)_4][BF_4]_2$, où X = Br ou I pour R = phényle et X = Br pour R = éthyle, $[MCl(PEt_3)_2(Py)][BF_4]$-*cis* et $[MCl(PPh_3)_3][BF_4]$ où M = Pd ou Pt.

Canadian Journal of Chemistry, 49, 3252 (1971)

Introduction

Complexes of d^8 transition metal ions are currently the subject of intensive study and in particular many unusual reactions of $[RhCl(PPh_3)_3]$ and *trans*-$[IrCl(CO)(PPh_3)_2]$ have been described (1). Isoelectronic Pt(II) and Pd(II) systems have received less attention although the synthesis and some reactions of the *trans*-$[PtCl(CO)(PEt_3)_2]^+$ cation and related complexes have been reported (2–5).

In reactions of $[RhCl(PPh_3)_3]$ reactive intermediates are often formed by ligand substitution and we considered it possible that halogen bridged cations, $[M_2X_2(PR_3)_4]^{2+}$, where M = Pd or Pt, X = halogen and R = ethyl or phenyl, might generate similar intermediates by bridge cleavage. We therefore studied the reactivity of these species and the present paper reports their reactions with organic carbonyl compounds and a reaction with C_2F_4 and H_2O which also yields a carbonyl. No direct evidence for bridge cleavage as a first step has been obtained but the reactions appear mechanistically similar to those of Ir(I) and Rh(I) systems and represent the closest reactivity parallels yet obtained between the d^8 ions of the platinum and rhodium groups.

Results and Discussion

(1) Synthesis

The complexes, *trans*-$PdX_2(PR_3)_2$, where X = Cl, Br or I for R = phenyl and X = Cl or Br for R = ethyl, react with $AgBF_4$ (1 mol) in dry acetone to give the halogen bridged complexes, $[Pd_2X_2(PR_3)_4][BF_4]_2$, in high yield. Several studies of the synthesis of analogous platinum and palladium complexes have been reported previously, using reactions of $MX_2(PR_3)_2$ complexes with either BF_3 (2, 4) or $AgBF_4$ (6) but, of the above triethyl- and triphenylphosphine complexes of palladium, only the chlorides were known (3). We were unable to prepare $[Pd_2I_2(PEt_3)_4][BF_4]_2$ and we note that the platinum analogue is also unknown (4).

(2) Reactivity

Reactions of pyridine with $[M_2Cl_2(PEt_3)_4][BF_4]_2$, M = Pd or Pt, and of triphenyl phosphine with $[M_2Cl_2(PPh_3)_4][BF_4]_2$ give the new complexes *cis*-$[MCl(PEt_3)_2(Py)][BF_4]$ and $[MCl(PPh_3)_3][BF_4]$. The triphenylphosphine complexes are especially interesting since they are analogues of Wilkinson's complex, $[RhCl(PPh_3)_3]$, and were not accessible by the methods employed previously for the synthesis of $[MClL_3][BF_4]$ complexes (3).

For personal use only.

(a) Reactions with Tetrafluoroethylene

Preliminary experiments with ethylene and cyclohexene gave no evidence of bridge cleavage reactions similar to the above but $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ (complex **1**) reacts with C_2F_4 at 80° in reagent grade acetone (~0.5% H_2O) to give the known complex, *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$, in high yield. $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ gives a similar reaction but palladium complexes give only degradation to palladium metal as is expected from the known instability (3) of *trans*-$[PdCl(CO)(PEt_3)_2][BF_4]$.

Similar hydrolyses have been reported previously in the reactions of $[RhCl(PPh_3)_3]$ (7) or *trans*-$[PtHCl(PEt_3)_2]$ (2) with C_2F_4 in the presence of traces of water to yield *trans*-$[RhCl(CO)(PPh_3)_2]$ or *trans*-$[PtCl(CO)(PEt_3)_2]^+$, respectively. In the rhodium reaction the π-C_2F_4 complex, *trans*-$[RhCl(C_2F_4)(PPh_3)_2]$, is an isolable intermediate but we have been unable to isolate a corresponding platinum complex in the reaction of **1**. In the absence of isolable intermediates, substituent effects or kinetic data, meaningful discussion of mechanism is not possible. However, we feel it is important to point out that the mechanism proposed[1] by Kemmitt and Nichols (7) for the hydrolysis of *trans*-$[RhCl(C_2F_4)(PPh_3)_2]$ is clearly incorrect in detail since the overall stoichiometry is

$$[RhCl(C_2F_4)(PPh_3)_2] + H_2O + H^+ \rightarrow [RhCl(CO)(PPh_3)_2] + \tfrac{1}{2}CF_2H.CF_2H + 2HF$$

The charge balance problem cannot be solved if $CF_2H.CF_2H$ is a product. In our reactions with **1**, no fluorocarbon products are detected[2] and the stoichiometry appears to be

$$[Pt_2Cl_2(PEt_3)_4]^{2+} + C_2F_4 + 2H_2O \rightarrow 2[PtCl(CO)(PEt_3)_2]^+ + 4HF$$

although the estimate is subject to error in that the two platinum complexes are difficult to separate, leading to possible error in the yield of carbonyl. We consider that the rhodium and platinum reactions are likely to have similar mechanisms and that $CF_2H.CF_2H$ is a product of some side reaction in the rhodium case. Further work is in progress to test this suggestion.

(b) Reactions with Aldehydes

1 reacts with benzaldehyde at 80° in acetone to yield *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$ and benzene. The conditions and yields for reactions of **1** with other aldehydes (Table 2) suggest that the order of reactivity is $CCl_3CHO > C_6H_5CHO > CH_3CHO > n\text{-}C_6H_{13}CHO$, although CCl_3CHO functions mainly as a chlorinating agent. $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$, with more electron withdrawing phosphines than **1**, does not react with benzaldehyde at 80°.

Decarbonylation of aldehydes by $[RhCl(PPh_3)_3]$ has been extensively studied by Wilkinson and co-workers (8) who propose a mechanism involving nucleophilic attack by the metal on the carbon atom of the aldehyde, leading to oxidative addition of the aldehyde C—H bond to the metal. This mechanism should be promoted by electron withdrawing substituents on the aldehyde, and by electron donating ligands on the metal, and our results are therefore consistent with the operation of a similar mechanism with bridge cleavage replacing the initial ligand substitution step.

In reactions with other carbonyl compounds, **1** gives some decarbonylation of acetyl chloride although the main reaction is chlorination of the platinum complex giving *cis*-$[PtCl_2(PEt_3)_2]$. Reaction of **1** with acetone gives no evidence of decarbonylation.

(c) Reactions with Formic Acid

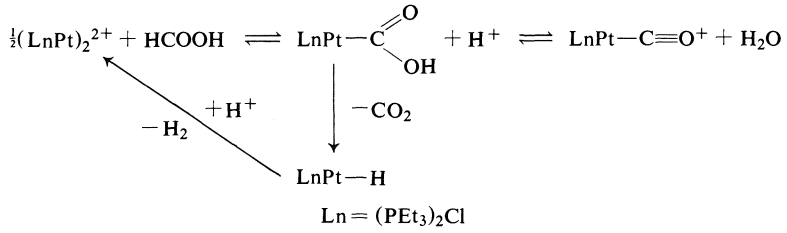
1 does not react with benzoic or acetic acid but it catalytically decomposes formic acid to CO_2 and H_2 at a rate similar to those reported previously (9) for other transition metal complexes. Degradation of the catalyst is quite rapid in our system and the products include *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$, which suggests that catalysis proceeds according to Scheme 1.

The feasibility of the scheme is confirmed by reaction of *trans*-$[PtHCl(PEt_3)_2]$ with fluoroboric acid to give **1** and H_2 in good yield. Also, the hydrolysis of *trans*-$[PtCl(CO)(PEt_3)_2]^+$ to *trans*-$[PtHCl(PEt_3)_2]$ and CO_2 is known and its mechanism has been discussed in terms of an intermediate $[PtCl(COOH)(PEt_3)_2]$ complex (5).

$[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ gives a similar, but

[1]A similar mechanism has been proposed for analogous reactions of iridium complexes (17).

[2]Except C_4F_8 which is a normal trace product of heating C_2F_4.



SCHEME 1

slower, catalytic decomposition of formic acid and the solid products show infrared absorptions at 3500 (wb), 2110 (s), and 1650 (sb) cm^{-1}, consistent with the presence of a carbonyl and a carboxylic intermediate. The carboxylic acid could be formed by oxidative addition to platinum of the C—H bond of the aldehyde, followed by proton loss. The oxidative addition step should be slower for more positive metal centers (1) and in agreement with this we find that $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ reacts 10 times slower than **1** and $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ shows essentially no catalytic activity. Carboxylic complexes of iridium have recently been isolated and shown to undergo pyrolysis to CO_2 and a hydride complex (10). However, formates have been shown to undergo similar reactions (11, 12) and, since the 3500 cm^{-1} infrared absorption is very weak, the possibility that the intermediate is more correctly formulated as a formate, [LnPt(HCOO)], cannot be excluded at present.

Our reactions generally gave less H_2 than CO_2 but no explanation for this is available at present.

Experimental

Reactions 1–3 below were conducted in an atmosphere of dry nitrogen and reactions 4–7 in evacuated, thick-walled Pyrex glass tubes (~50 ml capacity) or in an evacuated, stainless steel autoclave (60 ml capacity). Products were stable and were isolated and purified in the atmosphere. The solvents used for recrystallizations are included in Table 1. Where solvent pairs were used, the second solvent was added dropwise to a concentrated solution of the complex in the first solvent until crystallization began.

Complexes, *trans*-$[PdX_2(PR_3)_2]$ (3) and *trans*-$[PtHCl(PEt_3)_2]$ (13), were prepared as previously described. $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ and $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ were prepared as previously described (3) or by a procedure similar to 1(*a*) below. Solvents and organic reagents were dried over molecular sieves (type 4A) before use.

Details of the characterization of new complexes are included in Table 1. The conductance measurements were made on $\sim 10^{-3}$ *M* solutions in nitromethane using a dip-type cell connected to a conductivity bridge, Model RC16B2 of Industrial Instruments Inc. The results obtained are in the ranges expected for 1:1 or 1:2 electrolytes as appropriate (14).

Infrared spectra were recorded, with accuracy ± 5 cm^{-1} from 4000 to 250 cm^{-1}, for all products described below, using a Beckman IR 20 spectrophotometer calibrated against polystyrene film or water vapor. Where additional characterization is not given these served to identify the products. Absorptions other than those due to internal vibrations of ligands or anions are included in Table 1. Although the assignment of absorptions *ca.* 400 cm^{-1} to metal–phosphorus stretching modes has been shown to be incorrect (15), these absorptions are included in Table 1 since the number of bands in this region may still be used to assign stereochemistry, especially in complexes of triethylphosphine (16). The complexes, $[MCl(PEt_3)_2(Py)][BF_4]$, M = Pd or Pt, were assigned *cis* stereochemistry on the basis of infrared and nuclear magnetic resonance criteria as discussed previously (2).

(1) Preparation of $[Pd_2X_2(PR_3)_4][BF_4]_2$ Complexes

(*a*) A solution of *trans*-$[PdBr_2(PEt_3)_2]$ (0.50 g. 1.0 mmol) in acetone (~10 ml) was added dropwise to a stirred solution of $AgBF_4$ (0.196 g, 1.0 mmol) in acetone (~10 ml) at 25°. After stirring for 30 min, filtration gave AgBr (0.170 g, 0.90 mmol). The filtrate was evaporated under reduced pressure to small volume (~2–5 ml) and added to diethyl ether (~100 ml) giving $[Pd_2Br_2(PEt_3)_4][BF_4]_2$ (0.39 g, 0.38 mmol) as a yellow precipitate.

(*b*) A similar procedure using *trans*-$[PdI_2(PEt_3)_2]$ with $AgBF_4$ gave a more complex reaction whose products could not be characterized.

(*c*) A similar procedure using a suspension of *trans*-$[PdBr_2(PPh_3)_2]$ (0.20 g, 0.025 mmol) in acetone with $AgBF_4$ (0.056 g, 0.029 mmol) gave AgBr (0.046 g, 0.025 mmol) and $[Pd_2Br_2(PPh_3)_4][BF_4]_2$ (0.19 g, 0.012 mmol).

(*d*) A similar procedure at −10° using a suspension of *trans*-$[PdI_2(PPh_3)_2]$ (0.27 g, 0.30 mmol) in acetone with $AgBF_4$ (0.06 g, 0.30 mmol) gave AgI (0.064 g, 0.27 mmol) and $[Pd_2I_2(PPh_3)_4][BF_4]_2$ (0.22 g, 0.13 mmol). *Trans*-$[PdI_2(PPh_3)_2]$ (0.02 g, 0.02 mmol) was present in the AgI precipitate.

(*e*) Similar procedures using *trans*-$[PdCl_2(PEt_3)_2]$ or *trans*-$[PdCl_2(PPh_3)_2]$ with $AgBF_4$ gave the known complexes $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ and $[Pd_2Cl_2(PPh_3)_4][BF_4]_2$ in ~90% yield, much better than the 30–40% yields obtained previously using BF_3 instead of $AgBF_4$.

(2) Reactions with Pyridine

(*a*) **1** (0.11 g, 0.10 mmol) was heated with pyridine (0.055 g, 0.70 mmol) in acetone (5 ml) under reflux for

Pd	C_2H_5	C_6H_5	80°, 48 h	Degradation to metallic Pd

*Unless stated otherwise, reactions were conducted in evacuated thick-walled glass tubes without solvent.
†A reaction without solvent gave extensive decomposition of the heptanaldehyde but no evidence for $[PtCl(CO)(PEt_3)_2][BF_4]$.

8 h. Addition of the resulting solution to diethyl ether (~200 ml) gave *cis*-$[PtCl(PEt_3)_2(Py)][BF_4]$ (0.126 g, 0.199 mmol) as a white precipitate.

(*b*) A similar procedure using $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ (0.093 g, 0.10 mmol) with pyridine (0.055 g, 0.70 mmol) gave *cis*-$[PdCl(PEt_3)_2(Py)][BF_4]$ (0.095 g, 0.175 mmol).

(3) Reactions with Triphenylphosphine

(*a*) $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ (0.120 g, 0.071 mmol) was stirred in CH_3NO_2 (3 ml) with PPh_3 (0.050 g, 0.190 mmol) at 25° for 30 min. Addition of the resulting solution to diethyl ether (~100 ml) gave $[PtCl(PPh_3)_3][BF_4]$ (0.153 g. 0.139 mmol) as a white precipitate.

(*b*) A similar procedure using $[Pd_2Cl_2(PPh_3)_4][BF_4]_2$ (1.568 g, 1.04 mmol) with PPh_3 (0.61 g, 2.3 mmol) in CH_3NO_2 (20 ml) gave $[PdCl(PPh_3)_3][BF_4]$ (1.96 g, 1.93 mmol) as a precipitate from diethyl ether (~300 ml).

(4) Reactions with C_2F_4

(*a*) **1** (0.162 g, 0.147 mmol) was heated with a large excess of C_2F_4 (~10 mmol) in reagent grade acetone (3 ml) at 110° for 20 h in a thick-walled glass tube. Small amounts of CO_2 and cyclo-C_4F_8 were detected in the gaseous products. Addition of the solution to diethyl ether gave *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$ (0.155 g, 0.266 mmol) as a white precipitate which was recrystallized from benzene. M.p. 168–170° (lit. (2) 168–171°). The glass reaction tube was visibly etched suggesting that HF had been formed during the reaction.

Various similar experiments using lower temperatures and carefully dried solvents gave no evidence of an isolable intermediate olefin complex.

At lower C_2F_4 pressures the yield of carbonyl was poor but an estimate of the reaction stoichiometry was possible. For example, **1** (0.209 g, 0.189 mmol) with C_2F_4 (0.064 g, 0.64 mmol) at 85° for 20 h in a steel autoclave gave $[PtCl(CO)(PEt_3)_2][BF_4]$ (0.130 g, 0.224 mmol). Infrared and mass spectral analysis of the gaseous products showed only C_2F_4 (0.055 g, 0.55 mmol).

(*b*) A similar procedure using $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ (0.15 g, 0.09 mmol) with C_2F_4 (~50 mmol) in CH_2Cl_2 (5 ml) at 110° for 60 h in a steel autoclave gave $[PtCl(CO)(PPh_3)_2][BF_4]$ (0.07 g, 0.08 mmol).

(*c*) Preliminary experiments under similar conditions using $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ gave only degradation to palladium metal.

(5) Reactions with Aldehydes

(*a*) **1** (0.18 g, 0.16 mmol) was heated with C_6H_5CHO (4.0 ml, 39 mmol) at 80° for 48 h in a thick-walled glass tube. Excess benzaldehyde was removed under vacuum and the residue dissolved in acetone. Addition of the resulting solution to diethyl ether gave $[PtCl(CO)(PEt_3)_2][BF_4]$ (0.12 g, 0.21 mmol) as a white precipitate. After recrystallization from benzene it had m.p. 168–169° (lit. (2), 168–171°). Analysis of the excess benzaldehyde by gas–liquid chromatography showed the presence of benzene (~0.15 mmol).

(*b*) Reactions with other complexes and aldehydes were carried out in a similar manner and the results are summarized in Table 2.

(6) Reactions with Carboxylic Acids

(*a*) **1** (0.11 g, 0.10 mmol) was heated with HCOOH (2.00 g, 43.6 mmol) in acetone (5 ml) at 110° for 20 h in a steel autoclave. Separation of the volatile products by standard vacuum techniques gave CO_2 (34.6 mmol) and H_2 (26.6 mmol) which were identified by mass and infrared spectroscopy. This corresponds to a rate of acid decomposition ~0.2 mol l^{-1} h^{-1} (*cf.* ref. 9). Addition of the acetone solution to diethyl ether gave **1** (0.04 g, 0.036 mmol) whose infrared spectrum showed the presence of some $[PtCl(CO)(PEt_3)_2][BF_4]$, $\nu(C{\equiv}O)$ = 2110 cm^{-1}. Similar reactions in glass tubes using smaller quantities of HCOOH gave higher rates of catalyst recovery. For example after ~75 catalytic cycles (measured by CO_2 evolution) 70% of **1** was recovered. In some experiments the solid products showed very weak infrared absorptions at 2200 and 2160 cm^{-1}.

(*b*) A similar procedure using $[Pt_2Cl_2(PPh_3)_4][BF_4]_2$ (0.126 g, 0.075 mmol) with HCOOH (2.00 g, 43.6 mmol) gave CO_2 (~3.5 mmol) and H_2 (~3.5 mmol). The solid products (0.124 g) had infrared absorptions at 3500 (vb), 2110 (s), and 1650 (b) cm^{-1} but pure complexes could not be isolated.

(*c*) A similar procedure using $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ (0.093 g, 0.10 mmol) with HCOOH (2.00 g, 43.6 mmol) gave traces of CO_2 (~0.1 mmol) and H_2 (~0.1 mmol)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and recovery of $[Pd_2Cl_2(PEt_3)_4][BF_4]_2$ (0.090 g, 0.097 mmol) contaminated with formate ion.

(*d*) Similar procedures using **1** with benzoic or acetic acid gave no evidence of reaction except for some replacement of BF_4^- by acetate.

(7) Other reactions

(*a*) **1** (0.11 g, 0.10 mmol) was heated in acetone (15 ml) at 80° for 200 h in a thick-walled glass tube. There was no evidence for formation of *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$.

(*b*) **1** (0.11 g, 0.10 mmol) was heated in acetyl chloride (0.5 ml) at 80° for 48 h in a thick-walled glass tube. Addition of the solution to light petroleum gave *cis*-$[PtCl_2(PEt_3)_2]$ (0.09 g, 0.18 mmol) as a white precipitate. Evaporation of the filtrate gave a residue whose infrared spectrum showed the presence of *trans*-$[PtCl(CO)(PEt_3)_2][BF_4]$.

(*c*) *Trans*-$[PtHCl(PEt_3)_2]$ (0.19 g, 0.41 mmol) was heated with 48% aqueous HBF_4 (0.1 ml) in acetone (5 ml) at 70° for 90 min in a glass tube. H_2 was detected in the gaseous products by mass spectrometry. Addition of the solution to diethyl ether gave **1** (0.075 g, 0.068 mmol) as a white precipitate. The filtrate contained mainly unreacted *trans*-$[PtHCl(PEt_3)_2]$.

Received April 13, 1971

Structure analysis of (−) scopolamine *N*-oxide (**1**) hydrobromide monohydrate by X-ray crystallography has proven that the *N*-methyl group is axial and the amineoxide function is equatorial. The absolute configuration of the tropic acid residue has also been determined by anomalous scattering as being *S*, in complete agreement with chemical correlation experiments.

The *N*-stereoisomer of **1** has also been detected as a minor product **2** for the first time, as a result of using 100 MHz n.m.r. spectroscopy in the product analysis of the oxidation of (−) scopolamine with hydrogen peroxide in ethanol. A similar n.m.r. study was undertaken with atropine and tropine and correlation of chemical shifts with *N*-configuration in the *N*-oxides, **3**–**6**, was attempted. *N*-oxidation of scopolamine, and by analogy of related tropane bases, has taken a preferentially equatorial course, similar to other quaternization reactions.

L'analyse de la structure du monohydrate de l'hydrobromure du *N*-oxide (**1**) de la (−) scopolamine par cristallographie RX a prouvé que le groupe *N*-méthyle est axial et que la fonction aminéoxyde est équatoriale. La configuration absolue du résidu, l'acide tropique, a également été déterminée par diffusion anormale comme étant *S*, ce qui est en parfait accord avec les expériences de corrélation chimiques. Le *N*-stéréoisomère de **1** a été aussi détecté pour la première fois, comme un produit secondaire **2** par l'utilisation de la spectroscopie r.m.n. à 100 MHz dans l'analyse du produit provenant de l'oxydation de la (−) scopolamine par le peroxyde d'hydrogène dans l'éthanol. Une étude r.m.n. semblable a été entreprise avec l'atropine et la tropine et un essai de corrélation des déplacements chimiques avec la configuration-*N* dans les *N*-oxydes, **3**–**6**, a été fait. La *N*-oxydation de la scopolamine et par analogie avec ce qui a été fait sur le tropane a provoqué une orientation préférentiellement équatoriale, ce qui est similaire aux autres réactions de transformation en dérivés quaternaires.

Canadian Journal of Chemistry, **49**, 3258 (1971)

The steric course of electrophilic additions to nitrogen, particularly of quaternizations has been extensively studied during the last 15 years (1–7). The most adequate model chosen by one of us (G.F. and his associates (1)) was the 3-azabicyclo[3.2.$1^{1,1,5}$]octane, *i.e.* nortropane, system for three main reasons. Firstly, because it represents the skeleton of a wide-spread group of natural products of considerable practical, especially pharmacological interest. Secondly, because it is a half-rigid system where the product of quaternization closely resembles the transition state, unlike piperidines, which easily undergo conformational changes, thus making conclusions drawn from product as to transition state geometry rather risky. Thirdly, unusually high steric selectivity was observed (1, 8) when *N*-alkylating or carboxymethylating tropane bases (1). After a long-lasting polemic over equatorial (1) *vs.* axial (5) course, quite recently a critical summary paper (8) appeared on tropane quaternization. A variety of alkyl and substituted alkyl groups were used herein and the conclusions were based on X-ray structure determinations of four well-characterized major products combined with n.m.r. product analysis of quaternizations and chemical correlation between the major products. These data, along with those achieved by Bottini *et al.* (2), have proven that the major attack on nitrogen was equatorial (1, 8) in all those cases. Thus, some of the previous axial assignments (9, 10) of configuration based on empirical n.m.r. had to be revised.

The present paper deals with the structure

analysis of the major product of *N*-oxidation of scopolamine, itself commercially available and used as an ingredient of the sleeping pill "Sominex". It was claimed by Polonovski (11) that **1**, when heated, underwent transannular reaction to a tetrahydro 1,4-oxazol derivative "scopylium bromide", thus substantiating the axial position for the *N*-oxide function. On the other hand, the position of the *N*-methyl n.m.r. signal in both **1** and its hydrobromide seemed to be in line with N—Me equatorial position (10) due to deshielding through space by the epoxide atom (12).

In order to get the final answer to this configurational problem an X-ray study was commenced by one of us (C.S.H.) and is being described now in detail. Furthermore, a new n.m.r. investigation was carried out on a number of *N*-oxides of the tropane series.

Crystal Data

Scopolamine *N*-oxide hydrobromide monohydrate, $C_{17}H_{22}NO_5Br.H_2O$, mol.wt. = 418.3 Orthorhombic, $a = 13.115\,(10)$, $b = 21.131\,(15)$, $c = 6.740\,(6)$ Å (based on $\lambda\,(CuK\alpha_1) = 1.54051$ and $\lambda\,(CuK\alpha_2) = 1.54433$ Å). $D_m = 1.47_3$ g cm^{-3}, $Z = 4$, $D_x = 1.487$ g cm^{-3}, $V = 1867.9$ Å^3. Space group: $P2_12_12_1$. $\mu(CuK\alpha) = 35.9_9$ cm^{-1}.

Experimental

The colorless lath-shaped crystals belong to the orthorhombic system. Systematic absences $h00$ if h is odd, $0k0$ if k is odd, and $00l$ if l is odd, which were observed on preliminary Weissenberg and precession photographs, showed the space group to be $P2_12_12_1$. The density was measured by flotation in a bromobenzene–chlorobenzene mixture.

A crystal of 0.22 × 0.19 mm in cross-section was cut to a length (along b) of about 0.32 mm and mounted with b parallel to the ϕ-axis of a Picker diffractometer. Cell dimensions and relative intensities were measured at room temperature with Cu radiation, using a scintillation counter and pulse-height analyzer. A Ni filter was used for the cell dimension measurements and for remeasuring (at reduced tube current) all intensities with initial peak counts over 6000, but not for recording the weaker intensities. The adequacy of the pulse-height analyzer in discriminating against Cu$K\beta$ radiation was confirmed by checking the profiles of many low-angle reflexions; no discernable Cu$K\beta$ peak was present except in the case of a few of the strongest reflexions, all of which were included in the remeasurements. The θ–2θ scan technique was used with scan ranges varying from 2.0 to 4.0° in 2θ, and a 2θ scan speed of 2 deg min^{-1}. Background counts were accumulated for 20 s at the beginning and end of each scan. Reflexions with net count less than 10, or for which the net count was less than 1/10 of the total background count, were considered "unobserved" and were given zero weight in subsequent least-squares calculations. Of the 1845 independent reflexions with $2\theta < 130°$, 1800 were "observed". A standard reflexion was monitored at frequent intervals during the data collection, and these standard intensities were used to reduce all the intensities to the same relative scale. Appropriate Lorentz-polarization corrections were applied, and the intensities were also corrected for absorption using a Gaussian integration formula. With a grid of 6 × 10 × 6 subdivisions (parallel to ***a***, ***b***, ***c***) the calculated transmission factors varied from 0.455 to 0.589.

Structure Solution and Refinement

The coordinates of the bromine atom were obtained from an unsharpened three-dimensional Patterson map. An electron-density map phased on the Br atom showed 22 of the other 24 non-hydrogen atoms in the structure, and the remaining two atoms were revealed on a subsequent difference map. All of these atoms were entered in the block-diagonal least-squares calculations as carbon initially; the nitrogen and oxygen atoms were identified as their temperature factors dropped to anomalously low values. All but one of the hydrogen atoms were located on difference maps during the course of the refinement. Initially their contributions were included in the structure factors; later their parameters were refined also. The last hydrogen atom, belonging to the water molecule, was located only on the final difference map. Its position, however, is probably quite reliable as it forms the missing link in a very reasonable hydrogen bonding scheme, to be discussed later.

Anomalous scattering corrections (13) were introduced for the bromine atom during the analysis and structure factors were calculated for both possible absolute configurations. The ratio between the two R values, 0.0593/0.0504, is more than large enough, according to Hamilton's test (14), to establish the correctness of the configuration giving the lower R value. Continued refinement with the correct absolute configuration led to a final R value of 0.045 for all observed reflexions. During the final least-squares cycle the average ratio of parameter shift/estimated standard deviation was 0.11; the largest shift for the non-hydrogen atom parameters was 0.4 σ.

The quantity minimized in the least-squares calculations was $\sum\omega(|F_o| - |F_c|)^2$. Various weighting schemes were used successively during the refinement; these were chosen to minimize the dependence of $\sum\omega\Delta^2$ on $|F_o|$ and on $\sin^2\theta$. The final scheme was of the form

$$\sqrt{\omega} = \left[1 + \left(\frac{|F_o| - P_2}{P_1}\right)^2\right]^{-\frac{1}{2}}$$

$$\sqrt{\omega} = \sqrt{\omega} \times \frac{\sin^2\theta}{P_3} \quad \text{if} \quad \sin^2\theta < P_3$$

with $P_1 = 15.0$, $P_2 = 10.0$, $P_3 = 0.35$. Fifteen strong reflexions which suffered noticeably from extinction were assigned zero weight in the least-squares calculations. Without these reflexions the final R is 0.0408.

Scattering factor values were those of Cromer and Waber (15) for Br^{-1}, of Hanson *et al.* (16) for carbon, nitrogen and oxygen, and of Stewart *et al.* (17) for hydrogen. The calculations were performed on IBM 360/50 and IBM 360/67 computers at the NRC Computation Center, using programs of Ahmed *et al.* (18).

X-Ray Results and Discussion

Final coordinates and thermal parameters with corresponding e.s.d.'s are given in Table 1. The e.s.d.'s were calculated from the diagonal elements of the inverse to the normal equations matrix. Observed and calculated structure amplitudes based on the final parameters have been placed in the Depository of Unpublished Data.[2]

[2]Photocopies may be obtained free of charge, upon request, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

An agreement summary is given in Table 2. The discrepancies for the reflexions in categories 3 and 4 appear to be mainly due to extinction, and most of these reflexions were given zero weight in the least-squares calculations.

The molecular structure and absolute configuration may be seen in Fig. 1, which is a stereoscopic view of the contents of one asymmetric unit drawn by Johnson's ORTEP program (19). The numbering scheme used for the organic cation is shown in Fig. 2.

Thermal Vibration Analysis

The thermal vibration of the organic cation as a whole and of selected groups of atoms was analyzed for rigid-body motion using the program of Schomaker and Trueblood (20). This program calculates **T** (translational), **L** (rotational), and **S** (screw) tensors from the observed u_{ij} values.

The rigid-body approximation is not appropriate for the whole organic cation; the differences between observed u_{ij} values and those calculated from **T** and **L** were about twice as large as the e.s.d. 's of the observed u_{ij}'s. However, the agreement between observed and calculated u_{ij}'s was considerably better for analyses of two groups: the "aromatic" group [C(13), C(16)···C(21)], and the "bicyclic" group [N(1) ···O(10), C(22), O(23)]. Some results of these analyses are listed in Table 3.

The principal axis corresponding to maximum libration (rotational oscillation), with an r.m.s. amplitude of 8.0°, of the aromatic group is 18° from the C(13)—C(16) bond direction, indicating significant twisting of the aromatic ring about this bond. The second principal axis of libration, with r.m.s. amplitude 4.6°, is 25° from the normal to the benzene ring plane, suggesting some wagging in the plane of the ring.

The libration of the bicyclic group is less anisotropic than that of the aromatic group. The principal axis of maximum libration, 5.6°, is parallel (within 2°) to the direction C(8)···C(22). For both groups the translational vibration is fairly isotropic. Corrections for rotational vibration have been calculated for the bond lengths and angles in both the aromatic and the bicyclic groups. The corrections to the bond angles are in all cases less than the corresponding e.s.d.'s, however, and have therefore been omitted.

It seems probable that the N(1)—C(22) and

N(1)—O(23) bonds may be involved in non-rigid-body motion, and corrections for these bonds and for C(11)—O(12) and C(14)—O(15) have therefore been calculated assuming "riding motion", using the procedure of Busing and Levy (21). The bond lengths given in Fig. 2 and used in later discussion include the riding-motion corrections for these four bonds and the rigid-body corrections for the others except O(10)—C(11), C(11)—C(13), and C(13)—C(14) which are uncorrected.

Bond Lengths and Angles

The e.s.d.'s of the bond lengths and angles have been increased from their calculated values by 50% to allow for the omission of interaction

between atoms. The uncorrected bond lengths and angles not involving hydrogen are listed with their e.s.d.'s in Table 4. Those involving hydrogen atoms are quite normal; the C—H and O—H bond lengths vary between 0.89 and 1.12 Å.

The three N^+—C_{sp3} bonds have an average length of 1.522 Å, and none deviates significantly from this value. This average may be compared with the value 1.53 Å found in *N*-methylrhoeagenine iodide (22). The value found here for a N^+—O bond length, 1.465 Å, appears to be quite reasonable. One would expect it to be comparable to a C—O single bond, as N^+ and C are isoelectronic, and in fact it agrees very well with the C(8)—O(10) bond length, 1.466, and with C(3)—O(4), 1.457, and C(5)—O(4), 1.458 Å. The N^+—O bond length of 1.427 Å reported in the structure of sparteine-*N*(16)-oxide sesquiperchlorate (23) was not corrected for thermal motion, and its quoted e.s.d. of 0.007 Å is probably underestimated by 50% (23); the difference between it and the uncorrected value 1.443 Å found in the present analysis is not significant. The agreement of the epoxide C—O bond lengths with the corresponding value 1.47 Å quoted in International Tables (24) is satisfactory.

The C_{sp^3}—C_{sp^3} single bond C(3)—C(5) is very significantly shortened (to 1.449 Å) due to the bridging oxygen atom; any lengthening of this bond would force the C—C—O angles to even smaller values than their present average of 60.3°. The adjacent bonds, C(2)—C(3) and C(5)—C(6) are also shorter than the usual C_{sp3}—C_{sp3} bond length, 1.537 Å (25). It seems that this may be due more to the particular ring geometry than to any electronic effect of the epoxide oxygen atom; in several compounds containing 6-membered oxido-rings (26–28) the bonds adjacent to C—O are lengthened rather than shortened.

Differences between presumably equivalent bond lengths in the 6-membered heterocyclic ring might be due to the close approach of the bromide ion to H(21), H(61), H(81) and H(92), as described

TABLE 4. (*a*) Bond lengths (Å) and their e.s.d.'s

Bond	Uncorrected bond length

later, but the equality of the angles C(6)—C(7)—C(8) and C(8)—C(9)—C(2), and N(1)—C(2)—C(9) and N(1)—C(6)—C(7) may be an indication that the bond length differences are not significant.

Two of the aromatic C—C bonds, C(18)—C(19), and C(19)—C(20), are significantly shorter than the usual length, 1.394 Å (25), even after rigid-body libration corrections. The most likely explanation for this is that C(19) and C(20) have extremely large u_{ij} values, as can be seen in Table 1, and probably are involved in considerable non-rigid vibration.

The rest of the bond lengths in the structure agree within experimental error with corresponding standard values and require no further comment.

The enlarged angles O(10)—C(11)—O(12), which is 124.4 instead of 120.0°, and C(11)—O(10)—C(8), which is 6.8° larger than the tetrahedral value, both contribute to relieving the O(12)····H(81) repulsion. The O(12)····H(81) distance is only 2.34 Å, and the usual O····H van der Waals separation is 2.6 Å. The C(22)—N(1)—C(2) and C(22)—N(1)—C(6) angles are also significantly larger than 109.5°, and this is probably due to repulsion between H(72) and H(222) and between H(92) and H(222). These two non-bonded interatomic distances are 2.03 and 2.25 Å respectively, while the usual H····H van der Waals contact is 2.4 Å.

Conformation

The bicyclic portion of the cation has an almost exact mirror plane of symmetry through N(1), O(4), C(8). C(2) and C(6), and C(3) and C(5) are symmetrically related within experimental error, and C(22) and O(23) are displaced only 0.009 and 0.008 Å from the plane, respectively. However, C(7) and C(9), while displaced equally from the plane, are not exactly opposite each other.

The piperidine ring N(1), C(2), C(6), C(7), C(8), C(9) is approximately chair-shaped; C(2), C(6), C(7), C(9) show small but possibly significant deviations from planarity, and N(1) and C(8) show markedly unequal displacements from the mean plane (0.873 and −1.355 Å, respectively). The enlarged angles C(6)—C(7)—C(8) (113.2°), C(7)—C(8)—C(9) (114.4°) and C(8)—C(9)—C(2) (113.8°) indicate some flattening of the ring at the unbridged end, while the reduced C(2)—N(1)—C(6) angle (101.7°) reflects the distortion introduced by the bridge. Very similar conformation is observed in the crystal structure of pseudotropine (29). O(23) is equatorial and C(22) is axial with respect to this ring. In the crystal structure of (−)hyoscine, *i.e.* scopolamine, hydrobromide (30) the *N*-methyl group is also axial, whereas in some other related structures, such as pseudotropine (29), the *N*-methyl is equatorial. The 5-membered ring is envelope-shaped, with C(2), C(3), C(5), C(6) planar and N(1) 0.64 Å out of this plane. O(4) is displaced 1.185 Å from the plane in the same direction.

The O(10), C(11), O(12), C(13) group is planar within experimental error, and C(8) is only 0.074 Å out of the plane, in keeping with the partial double-bond character of the O(10)—C(11) bond. The dihedral angle between the carboxyl group plane and the plane through N(1), O(4), C(8) is 34°. This gives a larger O(12)····H(81) distance than would a coplanar configuration, and, as mentioned earlier the observed distance is shorter than the usual van der Waals separation. The O(12)····H(91) and O(12)····H(71) distances are 2.78 and 4.15 Å, respectively.

The absolute configuration at C(13), as determined by anomalous scattering, is **S** in the notation of Cahn *et al.* (31). Fodor and Csepreghy (32) have chemically correlated (−)tropic acid with D-(−)alanine and deduced **S** absolute configuration for (−)hyoscine and (−)hyoscyamine. The torsional angle C(11)—C(13)—C(14)—O(15) is 63°, giving a staggered conformation about the C(13)—C(14) bond.

The aromatic ring shows small but possibly significant departures from planarity, and C(13) is displaced 0.10 Å from the mean plane. Equations of the various mean planes are given in Table 5.

It is of interest to compare the various non-bonded N····O distances in the present structure with those in the closely related scopolamine hydrobromide. In this structure the N····O(4), N····O(10), N····O(12), and N····O(15) distances are 2.63, 3.85, 5.46, and 7.11 Å respectively whereas in scopolamine hydrobromide the corresponding distances are 2.47, 3.88, 5.41, and 8.04 Å. These distances are similar to N····O distances in muscarinic agents (30); both scopolamine hydrobromide and scopolamine *N*-oxide hydrobromide are antagonists of the muscarinic actions of acetylcholine, but show greater ratios

of ganglionic blocking to post-ganglionic blocking (antimuscarinic) activity than such compounds as atropine (33).

Packing Arrangement

The organic cations are hydrogen-bonded alternately with water molecules in infinite spirals about the screw axes parallel to the Z-axis. At the same time the hydrogen bond network links the two hydroxy groups of a given molecule. The arrangement is shown in Fig. 3. The $Br^-\cdots O(23)$ distance (3.47 Å) is actually larger than the corresponding sum of van der Waals radii (3.35 Å), and is also larger than the $Br^-\cdots O(4)$ distance (3.38 Å), but the $Br^-\cdots H(231)$ distance, 2.78 Å, is 0.37 Å shorter than the usual $Br^-\cdots H$ van der Waals separation; according to Hamilton and Ibers (34) the H····heavy-atom distance is the critical factor indicating the presence of a hydrogen bond, and on this basis Br^- and O(23) should be regarded as hydrogen-bonded. The pertinent angles are also consistent with a bifurcated hydrogen bond connecting O(23) with O(4) and Br^-. In another case of a bifurcated hydrogen bond involving an intramolecular and an intermolecular contact, Cady and Larson (35) found the intermolecular hydrogen bond to be consistently weaker than the intramolecular link, as it is here. In addition to the intermolecular contacts involving

hydrogen bonds, there are a number of others which are also shorter than the usual van der Waals separation. These include H(21)····Br$^-$ (2.88), H(61)····Br$^-$(3.05), H(81)····Br$^-$(2.97), H(92)····Br$^-$(2.91), and H(223)····Br$^-$(3.00 Å). With these in mind, inspection of Fig. 3 suggests that there is considerable Coulomb attraction between the bromide ion and the positively charged but inaccessible nitrogen atom.

Nuclear Magnetic Resonance Studies

The most vulnerable point of our previous assignments (10) was the lack of comparison of both *N*-epimer amine oxides. Therefore, we have carried out a systematic product analysis by n.m.r. of amine-oxide formation from scopolamine and a number of related bases. Unfortunately, the new technique used by Cymerman Craig and Purushotaman (36) of *N*-oxidation by *m*-chloroperbenzoic acid followed by chromatographic liberation of the free bases has not worked in our case, owing to very low reactivity of scopolamine towards that reagent. However, oxidation with hydrogen peroxide in ethanol[3] of scopolamine, atropine and tropine and the use

[3]This technique was used by Werner and his associates (37). We express our thanks for this suggestion, also for informing us of some of their related study prior to their publication.

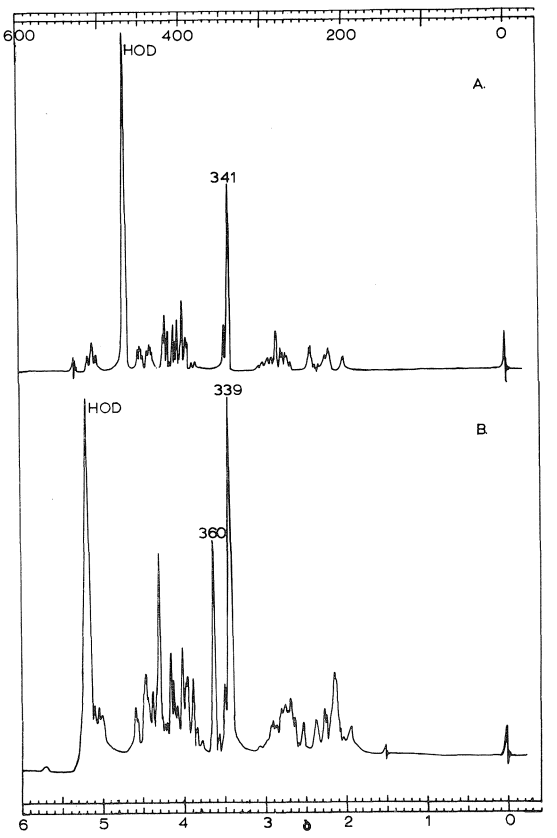

FIG. 4. Nuclear magnetic resonance (100 MHz) spectrum of *A*. scopolamine *N*-oxide hydrobromide *B*. scopolamine *N*-oxide.

of 100 MHz n.m.r. spectroscopy finally allowed us to detect two quaternary *N*-methyl signals in all three cases. Experimental details of spectra are recorded in Table 6 and Figs. 4, 5, and 6.

Scopolamine *N*-oxide (**1**) has a major *N*-methyl signal at δ 3.39 identical with that of the hydrobromide of the commercially available, *i.e.*, purified stereoisomer. The *N*-methyl protons of the minor product, **2**, resonate at 3.60 δ in much lower field than in the major product, **1**, (Fig. 4). Based on the configuration now ascertained by X-ray analysis of the major product as hydrobromide of **1** one can state that the neighboring epoxide oxygen (10, 12) has an additional deshielding effect upon the equatorial N—Me. This all fits well with our experience with n.m.r. chemical shifts in *N*,*N*-dialkyl tropanium salts (8).

On the other hand, both atropine (Fig. 5) and tropine (Fig. 6) gave a product ratio 3:1 of the *N*-oxides, the major stereoisomer showing

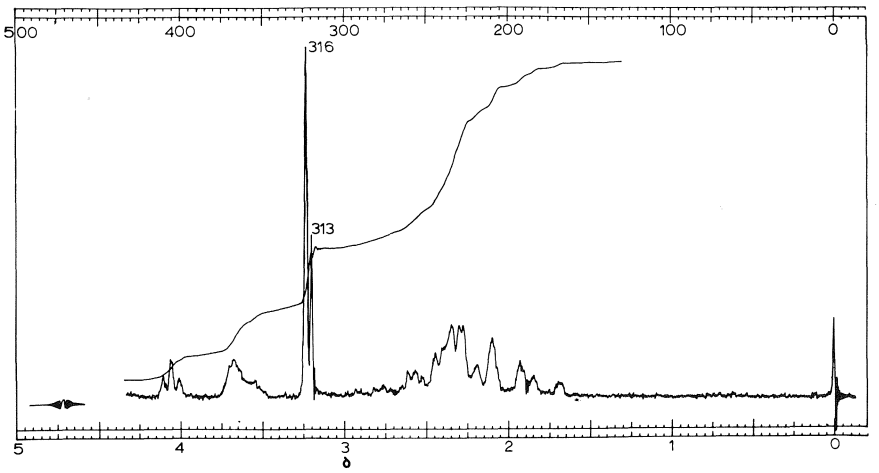

FIG. 6. Nuclear magnetic resonance (100 MHz) spectrum of tropine *N*-oxide.

$\overset{+}{N}$—Me resonance at a lower field. Our recent extensive studies (8) have shown that in epimeric *N*-deuteromethyltropanium bromides the axial $\overset{+}{N}$—Me resonates in a lower field, that is, the axial methyl is more deshielded than the equatorial one (38) unless the latter is exposed to a stronger deshielding effect, for example, by a hydroxyl or epoxide function. Based on this, "reversal" of the $\overset{+}{N}$—Me signal positions when passing from atropine *N*-oxide to scopolamine *N*-oxide can be explained. In addition, there is no reason to assume a qualitatively different steric course to operate for scopolamine than for atropine, therefore, we suggest structure of equatorial *N*-oxides **3** and **5** to the major products and **4** and **6** to their stereoisomers also in the cases of products of *N*-oxidation of atropine and tropine. We are aware of the fact that this conclusion is based on analogy, however, we don't think that there is any need to support this view by a series of further X-ray studies.

As to the explanation we can offer for preferential equatorial attack by the peroxide electrophile upon nitrogen we have to reiterate our views

expressed previously (1*c*, 8). The strong, 1,3-diaxial interaction by 2,4-placed hydrogens in the somewhat flattened (3, 8, 29, see also the present X-ray work) piperidine moiety of tropanes, which is proven by n.m.r. and X-ray data, does not give preference to a transition state involving axial attack although this would resemble the ground state of the bases that have an equatorial methyl group in a very high population (3, 29). Therefore, the transition state of lower energy would imply an attack by the solvated oxygen electrophile from the less hindered equatorial side of the molecule, even when this should put the *N*-methyl group in the more compressed axial position. However, the group already present can bear such an interaction more easily[4] than the strongly solvated and charge-separated incoming group, be the latter originally bulkier or not than the methyl. This was shown by the steric selectivity of deuteromethylation as being practically the same as of ethylation or methoxycarbonylmethylation. Hence, amineoxide formation, at least in this series, is not an exception to the general pattern of quaternization. As an extension of these studies on *N*-quaternizations in the field of *N*-methyl*trans*decahydroquinolines one of us (G.F.) and Sh. Abidi are now investigating the optimum steric course of cyanation by cyanogen bromide and $CNCl{\cdot}SbCl_5$, respectively.

Preparative Data

All melting points were taken in open capillary tubes using Thomas–Hoover capillary m.p. apparatus and are uncorrected. The n.m.r. spectra were measured on a Varian HA-100 spectrometer operated in the frequency-sweep mode with a normal probe temperature of 30 ± 1°. Deuterium oxide was used as a solvent for all of the samples (10 to 15% solution) and a 2% solution (100 μl) of 3-(trimethyl silyl)-1-propane sulfonic acid sodium salt (Tiers' salt) in D_2O was added to the samples. Benzene was used as an external lock signal for scopolamine *N*-oxide and its hydrobromide. The field-frequency lock was set on HOD peak for tropine *N*-oxide and aromatic protons singlet for atropine *N*-oxide. The signal due to methyl protons in Tiers' salt was adjusted to 0 p.p.m. before setting the field-frequency lock. Chemical shifts are expressed either on δ scale in p.p.m. or in Hz. The following letters were used for the signal splittings due to proton–proton coupling and also for the separation of signals: s, singlet; d, doublet; t, triplet; and m, multiplet. The results reported in Table 6 indicate the product analysis on all preparations before purification. The commercial sample of scopolamine *N*-oxide hydrobromide was used after several recrystallizations for n.m.r. and X-ray diffraction studies. Tropine *N*-oxide was obtained from Aldrich Chemical Company as tropine *N*-oxide dihydrate (m.p. 224° dec.) and used as such for n.m.r. measurements.

Tropine N-Oxide

To a solution of tropine (2.0 g) in 20 ml ethanol was added 30% hydrogen peroxide (20 ml) and the mixture was stirred for 2 days. The solvent was removed in vacuum at 30° to give an oil. Product analysis by n.m.r. indicated two *N*-methyl signals corresponding to two isomers in the ratio 25:75. Trituration of the oily product with acetone gave tropine *N*-oxide as white powder (1.8 g) which melted at 162° (reported (37, 10) m.p. 216 and 238° (dec.)).

Scopolamine N-Oxide

This was prepared by treatment of scopolamine with aqueous hydrogen peroxide as described below. To a stirred solution of scopolamine (2.02 g) in ethanol (25 ml) was added 30% hydrogen peroxide (20 ml) and the mixture was left at 30° with stirring for 2 days. Evaporation of solvent *in vacuo* gave scopolamine *N*-oxide as a thick syrup (2.1 g) which was submitted to product analysis by n.m.r. Trituration with acetone gave a solid which was purified by recrystallization from methanol–acetone, m.p. 130–133° (reported (10) m.p. 132–134°).

Atropine N-Oxide

This was prepared by hydrogen peroxide method following the same procedure as described for scopolamine *N*-oxide. Thus, 1.2 g of atropine in 20 ml ethanol and 20 ml 30% hydrogen peroxide gave crude atropine *N*-oxide (1.1 g) as a thick oil which was analyzed by n.m.r. Further purification yielded crystalline material, m.p. 129–131° (reported (11) m.p. 127–128°).

Infrared and Raman Spectra of Potassium and Sodium Borohydride

K. B. HARVEY[1] AND N. R. MCQUAKER[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 22, 1971

Using both infrared and laser Raman techniques the low temperature vibrational spectra of KBH_4, KBD_4, $NaBH_4$, and $NaBD_4$ have been recorded. The spectra of the external lattice vibrations are consistent with the following borohydride ion site symmetries: T_d for potassium borohydride and D_{2d} for sodium borohydride. Translational frequencies are assigned and librational frequencies are inferred from absorptions tentatively assigned as second overtones. Comparison of the low and high temperature vibrational spectra suggests the following disorder–order phase changes: $O_h^5 \rightarrow T_d^2$ for potassium borohydride and $O_h^5 \rightarrow D_{2d}^9$ for sodium borohydride.

En utilisant les techniques de l'infrarouge et du laser Raman, les spectres de vibration à basse température de KBH_4, KBD_4, $NaBH_4$ et $NaBD_4$ ont été enregistrés. Les spectres de vibration du réseau externe sont consistants avec les sites de symétrie suivants pour les ions borohydrures: T_d pour le borohydrure de potassium et D_{2d} pour le borohydrure de sodium. Les fréquences de translation sont assignées et les fréquences de vibration déduites à partir des absorptions qu'il est possible d'assigner aux deuxièmes harmoniques. La comparaison des spectres de vibration à basse et haute température suggère les changements de phase désordre-ordre suivants: $O_h^5 \rightarrow T_d^2$ pour le borohydrure de potassium et $O_h^5 \rightarrow D_{2d}^9$ pour le borohydrure de sodium.

Canadian Journal of Chemistry, **49**, 3272 (1971)

Introduction

The high temperature modifications of both KBH_4 and $NaBH_4$ are known to be face-centered cubic (O_h^5-*Fm3m*) with four molecules per unit cell (1–3). Under the symmetry requirements of the O_h^5 space group the BH_4^- tetrahedra may randomly take up the two equivalent orientations possible in the lattice. This gives rise to the disordered structure known as phase *I* (4).

The heat capacity of KBH_4 has been obtained in the temperature interval 0 to 700 °K (5). An anomaly appeared at 77.2 °K and it was associated with a disorder–order transformation whose onset was identified with a broad transition from about 450 to 200 °K which appeared in the heat capacity. That the onset of the disorder–order transformation is at a higher temperature than that fixed by the anomaly is also suggested by the fact that the anomaly accounts for only 0.70 of the 1.38 e.u. expected for the excess entropy of transition in a simple disorder–order transformation. It is known that the structure of KBH_4 remains cubic down to 90 °K (6). However, no crystal studies have been undertaken below the temperature of 77.2 °K fixed by the anomaly. Thus, the structure of the completely ordered crystal is not known. The spectrum of the BH_4^- lattice vibrations should be sensitive to any change in site symmetry accompanying the transition. Accordingly, we have recorded the infrared spectra of KBH_4 and KBD_4 at 295 and at 10 °K. Raman spectra of these compounds have been recorded at 295 and 80 °K.

The mid-infrared spectrum of $NaBH_4$, at various temperatures in the interval 191 to 298 °K, has been reported by Schutte (4) and by Schutte and Ketelaar (7). These authors observed spectral changes which could be related to a phase transformation in $NaBH_4$. An anomaly in the heat capacity of $NaBH_4$ has placed this phase transformation at 189.9 °K (8). The excess entropy of transition of 1.22 e.u. suggests a simple disorder–order transformation analogous to that found in the ammonium halides (9–12). The transformation at 189.9 °K results in a contraction along what becomes the *c* axis of a body centered tetragonal structure (2). If a simple disorder–order transformation involving the orientations of the BH_4^- ions is assumed the low temperature phase *II* structure ($Z = 2$) must be consistent with the space group D_{2d}^9-$I\bar{4}m2$.

The low temperature infrared spectrum of $NaBH_4$ reported by Schutte (4) is compatible with BH_4^- ions which lie on the D_{2d} sites predicted by the D_{2d}^9 space group. As a continuation of Schutte's work we have recorded both the

[1]Dr. K. B. Harvey passed away September 27, 1970.

[2]Present address: Department of Electrical Engineering, University of Waterloo, Waterloo, Ontario.

infrared and Raman spectrum of $NaBH_4(I)$ at 295 °K and $NaBH_4(II)$ at 80 °K. A similar study has been made of $NaBD_4$.

Experimental

The KBH_4 and $NaBH_4$ were obtained from Metal Hydrides Inc. and the KBD_4 and $NaBD_4$ were obtained from Merck, Sharp and Dohme (Canada) Ltd. All compounds had an assay of not less than 98%. They were used without further purification.

In the mid-infrared (4000–500 cm^{-1}) studies the samples were prepared by mechanically depositing thin films of polycrystalline material on potassium bromide supports. This was accomplished by first grinding one surface of the polished support with a very fine emery paper (Carbimet 600 grit). A small mound of very finely divided crystalline powder, thoroughly moistened with carbon tetrachloride, was then rubbed between the ground surface of the support and the surface of a ground glass plate. The sample support was slid off the ground glass plate before "sticking" occurred. Next, any excess crystal powder was carefully brushed off the surface of the support. For studies in the region 600–50 cm^{-1} Nujol mulls and either cesium iodide or polyethylene supports were used. All samples were prepared in a dry nitrogen atmosphere provided by a glove box. While they were still in this atmosphere the sodium borohydride samples were fitted into a Hornig type low temperature cell. The potassium borohydride samples were fitted into a liquid helium cryostat, described elsewhere (13), under a stream of dry nitrogen.

The infrared spectra were recorded against a dry air background purged of CO_2. Two complementary double beam grating spectrophotometers were used: the Perkin–Elmer 421 and the Perkin–Elmer 301. The 421 was used in the region 4000–500 cm^{-1} and the 301 was used in the region 600–50 cm^{-1}. Both spectrophotometers were calibrated against known spectra (14). The error of measurement is estimated to be less than ± 2 cm^{-1}.

The samples for the Raman studies were also prepared in a dry nitrogen atmosphere. Polycrystalline material was compressed into a conical cavity at the end of a brass rod which fitted into a low temperature cell similar in design to the one described by Carlson (15). The Raman spectra were recorded with a Cary 81 spectrophotometer which was equipped with a Spectra-Physics He–Ne Laser. The instrument was calibrated with emission lines from a neon lamp and the uncertainty in the measured frequency shifts is less than ± 2 cm^{-1}.

Results and Discussion

(A) KBH_4 and KBD_4

The Lattice Vibrations and Their Combinations and Overtones

As the samples were cooled from 295 to 10 °K the absorptions appearing in the spectra of both KBH_4 and KBD_4 showed a progressive sharpening (Fig. 1) which gave no evidence of any static field (site group) splitting. The KBD_4 ν_4 absorption at 10 °K has a half-height band width of only 3.5 cm^{-1} and hence any unresolved site group splitting would have to be very small indeed. The only splittings which appear are the ^{10}B–^{11}B isotope shifts. In the case of KBD_4 these splittings (Fig. 3) are fully resolved. Since there is an absence of site group splitting at 10 °K the BH_4^- ions must lie on cubic sites in the ordered phase. If the phase transformation is effectively a simple order–disorder transformation involving the orientations of the BH_4^- ions then the low temperature modification will be consistent with the space group T_d^2-$F\bar{4}3m$. In order to distinguish this modification from the low temperature tetragonal modification of $NaBH_4$, known as phase *II* (4), we shall refer to it as phase *III*.

Under the T_d factor group the irreducible representations for the internal, optical translatory(o.t.), optical libratory(o.l.), and acoustical translatory(a.t.) KBH_4 lattice vibrations are:

$$\Gamma \text{ (internal)} = A_1 + E + 2F_2$$
$$\Gamma \text{ (o.t.)} = F_2$$
$$\Gamma \text{ (o.l.)} = F_1$$
$$\Gamma \text{ (a.t.)} = F_2$$

Only the vibrations of F_2 symmetry may appear in the infrared. Vibrations of A_1, E, and F_2 symmetries may produce Raman scattering. The borohydride ion $\nu_3(F_2)$ and $\nu_4(F_2)$ lattice vibrations show a negligible frequency shift as the temperature is lowered from 80 to 10 °K. Therefore, in Table 1 we have included the $\nu_1(A_1)$ and $\nu_2(E)$ frequencies as observed at 80 °K (Fig. 2) in the phase *III* results. On this basis the wavenumbers of the internal normal vibrations of $KBH_4(III)$ are 2314.5, 1251.5, 2281, and 1121 cm^{-1}, respectively, for $\nu_1(A_1)$, $\nu_2(E)$, $\nu_3(F_2)$, and $\nu_4(F_2)$. The corresponding $KBD_4(III)$ wavenumbers are 1199.5, 892, 1724, and 855 cm^{-1}. In the infrared spectra $KBH_4(III)$ and $KBD_4(III)$ absorptions appear at 178 and 172 cm^{-1}. The frequency ratio of 0.97 indicates that these absorptions are due to translations.

In the second order spectra of the phase *III* potassium borohydrides only three principal lines are observed. These are $2\nu_4(A_1 + E + F_2)$, $\nu_2 + \nu_4(F_1 + F_2)$, and $2\nu_2(A_1 + E)$. Enhanced intensities and/or anomalous predicted–observed frequency shifts in the second order spectra indicate that both $2\nu_4(F_2)$ and $\nu_2 + \nu_4(F_2)$ interact with $\nu_3(F_2)$. In the Raman spectrum of

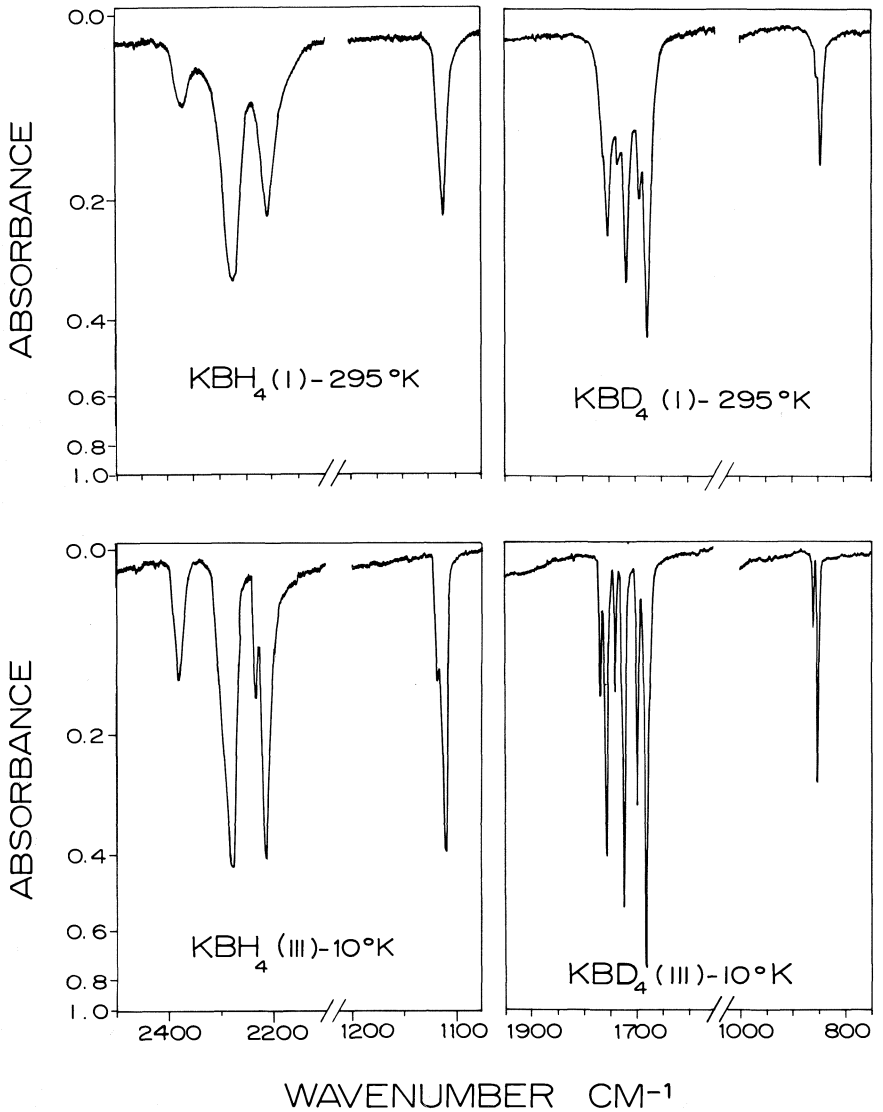

FIG. 1. The infrared spectra of KBH_4 and KBD_4 at 295 and 10 °K.

$KBH_4(III)$ the appearance of a $2\nu_4$ doublet results from a further interaction. In this case $\nu_1(A_1)$ and $2\nu_4(A_1)$ undergo Fermi resonance.

The vibrational assignments for KBH_4 and KBD_4 at 295 °K appear in Table 2.

(B) $NaBH_4$ and $NaBD_4$

Internal Lattice Vibrations and Their Combinations and Overtones

The irreducible representation for the internal fundamentals of $NaBH_4(II)$ may be summarized as follows

$$\Gamma \text{ (internal)} = 2A_1 + B_1 + 2B_2 + 2E$$

Since there is only one molecule in the primitive unit cell there are no correlation field effects. Thus, the four vibrations of the free BH_4^- ion become the precursors of 7 crystal modes which arise from a splitting of the degenerate vibrations by the static field. The correlation diagram showing this is found in Table 3. All 7 internal vibrations may produce Raman scattering. Only vibrations of B_2 and E symmetries may be infrared active.

The high and low temperature spectra (Figs. 4 and 5) indicate that $NaBD_4$ undergoes a phase transformation analogous to the one observed

ν_3	F_2	→	B_2, E
ν_4	F_2	→	B_2, E

in $NaBH_4$ (8). The low temperature spectra of both compounds can then be explained on the basis of the D_{2d} factor group analysis. We may note that the vibrations of compounds containing naturally occurring boron may be sensitive to ^{10}B–^{11}B isotope shifts. In the case of the sodium borohydrides this is true of ν_3 and ν_4. In order to distinguish between splittings arising from isotope shifts and splittings arising from the static field we may compare the low temperature vibrational spectra of the sodium borohydrides with that of the cubic potassium borohydrides. The appropriate ^{10}B–^{11}B isotope shifts are compared in Table 4.

Since the vibrational spectrum of $NaBD_4(II)$ is characterized by sharp well resolved lines (Figs. 4, 5, and 6) we choose this salt for a discussion of vibrational assignments. The assignments for $NaBH_4(II)$ are, for the most part, completely analogous. An intense Raman scattering at 1622 cm^{-1} in the spectrum of $NaBD_4$(II) (Fig. 5) is assigned as $\nu_1(A_1)$. The two expected components of ν_2 also appear. The scattering at 916 cm^{-1} is arbitrarily assigned as $\nu_2(A_1)$ and the 904 cm^{-1} scattering is then assigned as $\nu_2(B_1)$. (It will be seen shortly that these assignments can be con-

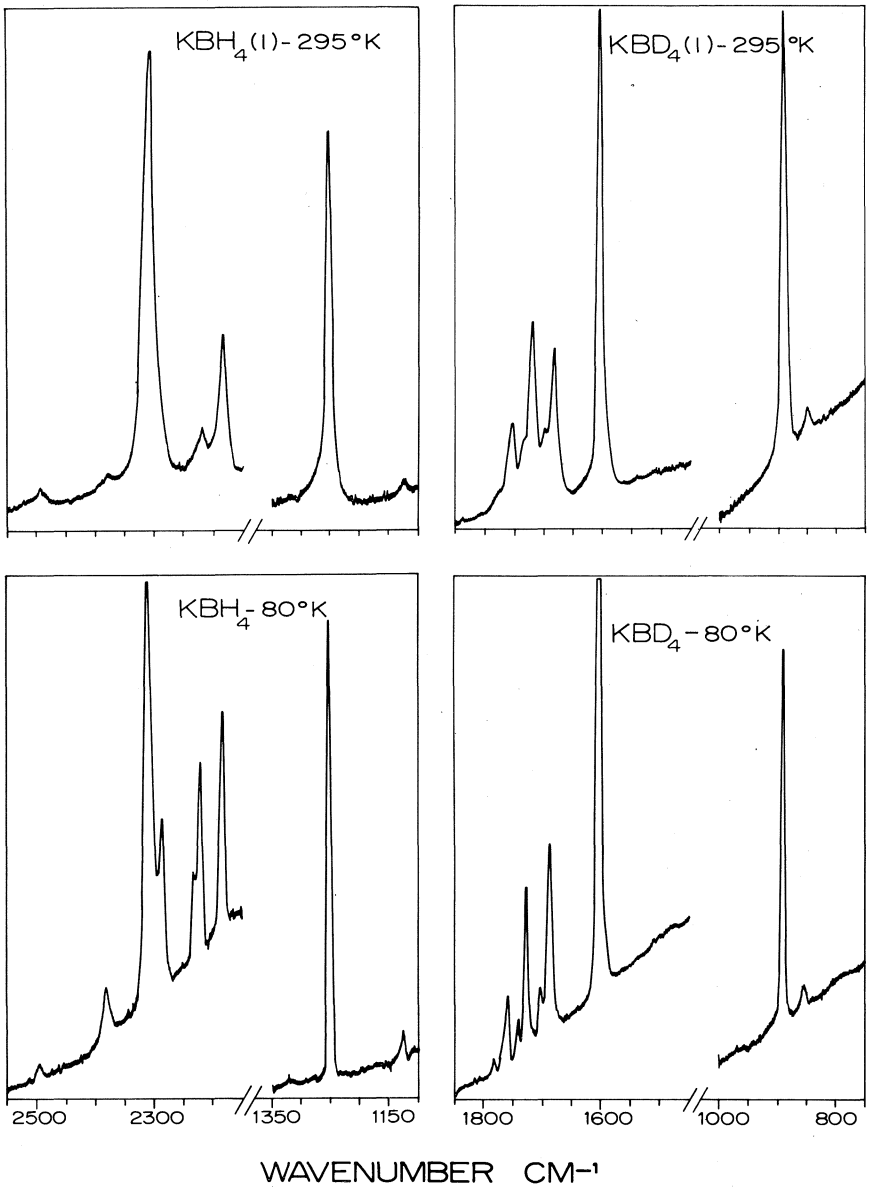

FIG. 2. The Raman spectra of KBH_4 and KBD_4 at 295 and 80 °K.

firmed when the possible combinations for $\nu_2 + \nu_4$ are considered.) In the region 800–1000 cm^{-1} four absorptions appear in the infrared (Figs. 4 and 6). The most intense absorption appearing at 854.5 cm^{-1} is assigned as $\nu_4(E)$; $^{10}\nu_4(E)$ appears at 865 cm^{-1}. This leaves two absorptions, either one of which could be assigned as $\nu_4(B_2)$. The most reasonable choice is the 870 cm^{-1} absorption since, as will be seen later, it predicts $2\nu_4$ and $\nu_2 + \nu_4$ overtones and combinations which are consistent with the observed spectral results. The assignment for the anomalous line at 877 cm^{-1} is discussed later.

The region 1650–1850 cm^{-1} is very rich in spectral information. The prominent absorption at 1735.5 cm^{-1} is assigned as $\nu_3(E)$; $^{10}\nu_3(E)$ appears at 1755 cm^{-1}. A second absorption possessing striking intensity is found at 1692

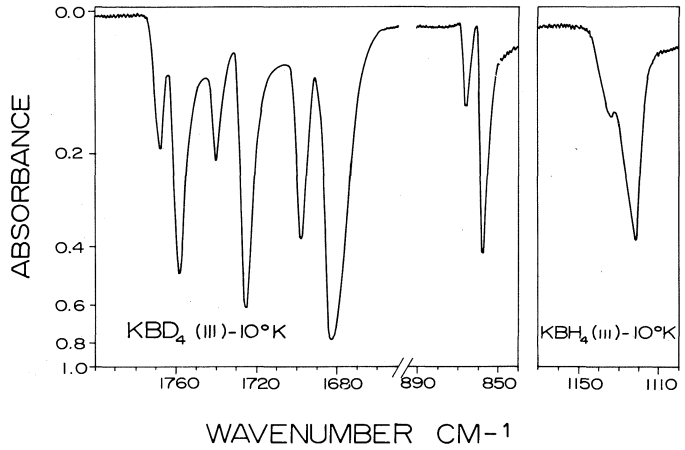

FIG. 3. Detail in the infrared spectra of KBD_4(III) and KBH_4(III).

TABLE 4. ^{10}B–^{11}B isotope shifts (in cm^{-1}) in the low temperature BH_4^- lattice vibrations of sodium and potassium borohydride

Compound	$^{10}\nu_3$	ν_3	Shift	$^{10}\nu_4$	ν_4	Shift
KBH_4	2297 (sh)	2281	26	1131	1121	10
$NaBH_4$	2334 (sh)	2303	31	1134	1122	12
KBD_4	1739	1724	15	864	855	9
$NaBD_4$	1755	1735.5	19.5	865	854.5	10.5

cm^{-1} and it is assigned to a component of $2\nu_4$. Since it is observed with such enhanced intensity it can be assumed to be undergoing Fermi resonance with $\nu_3(E)$. This selects E type symmetry and hence it must originate from the combination $\nu_4(E) + \nu_4(B_2) = 2\nu_4(E)$. The predicted–observed frequency shift of 33 cm^{-1} is also consistent with an interaction of $\nu_3(E)$ and $2\nu_4(E)$. The absorption appearing at 1715 cm^{-1} on the high frequency side of $2\nu_4(E)$ can be assigned as $2\,^{10}\nu_4(E)$. Assuming a $^{10}\nu_4(B_2)$ frequency of 880 cm^{-1} gives a predicted–observed frequency shift of 30 cm^{-1} for $2\,^{10}\nu_4(E)$. Besides $2\nu_4(E)$ there are two other possible $2\nu_4$ components. These are $\nu_4(B_2) + \nu_4(B_2) = 2\nu_4(A_1)$ and $\nu_4(E) + \nu_4(E) = 2\nu_4(A_1 + B_1 + B_2)$. The later component is expected to appear in the infrared with a predicted frequency of 1709 cm^{-1}. However, no evidence was found for its appearance. (We may note that it appears in the Raman spectrum of $NaBH_4$(*II*) as a result of interaction with $\nu_1(A_1)$ (Fig. 5).) The remaining absorption on the low frequency side of $\nu_3(E)$ at 1724 cm^{-1} is assigned as $\nu_3(B_2)$. The absorptions appearing at 1764, 1773, 1789, and 1798 cm^{-1} must be assigned to combinations of $\nu_2 + \nu_4$. There are 8 possible predicted combinations. These are

$$\begin{aligned}
\nu_2(B_1) + \nu_4(E) &= 1759(E)\\
^{10}\nu_2(B_1) + {}^{10}\nu_4(E) &= 1769(E)\\
\nu_2(A_1) + \nu_4(E) &= 1771(E)\\
^{10}\nu_2(A_1) + {}^{10}\nu_4(E) &= 1781(E)\\
\nu_2(B_1) + \nu_4(B_2) &= 1774(A_2)\\
^{10}\nu_2(B_1) + {}^{10}\nu_4(B_2) &= 1784(A_2)\\
\nu_2(A_1) + \nu_4(B_2) &= 1786(B_2)\\
^{10}\nu_2(A_1) + {}^{10}\nu_4(B_2) &= 1796(B_2)
\end{aligned}$$

The combinations of B_2 and E symmetry types will be both infrared and Raman active, while the combinations of A_2 symmetry type will be inactive. Since combinations of E symmetry can undergo Fermi resonance with $\nu_3(E)$ and those of B_2 symmetry can interact with $\nu_3(B_2)$, it can be expected that the observed combinations may have enhanced intensities and may also lie at frequencies slightly higher than those predicted. On this basis the assignments for the 1764, 1773, 1789, and 1798 cm^{-1} absorptions are $\nu_2(B_1) + \nu_4(E)$, $\nu_2(A_1) + \nu_4(E)$, $\nu_2(A_1) + \nu_4(B_2)$ and

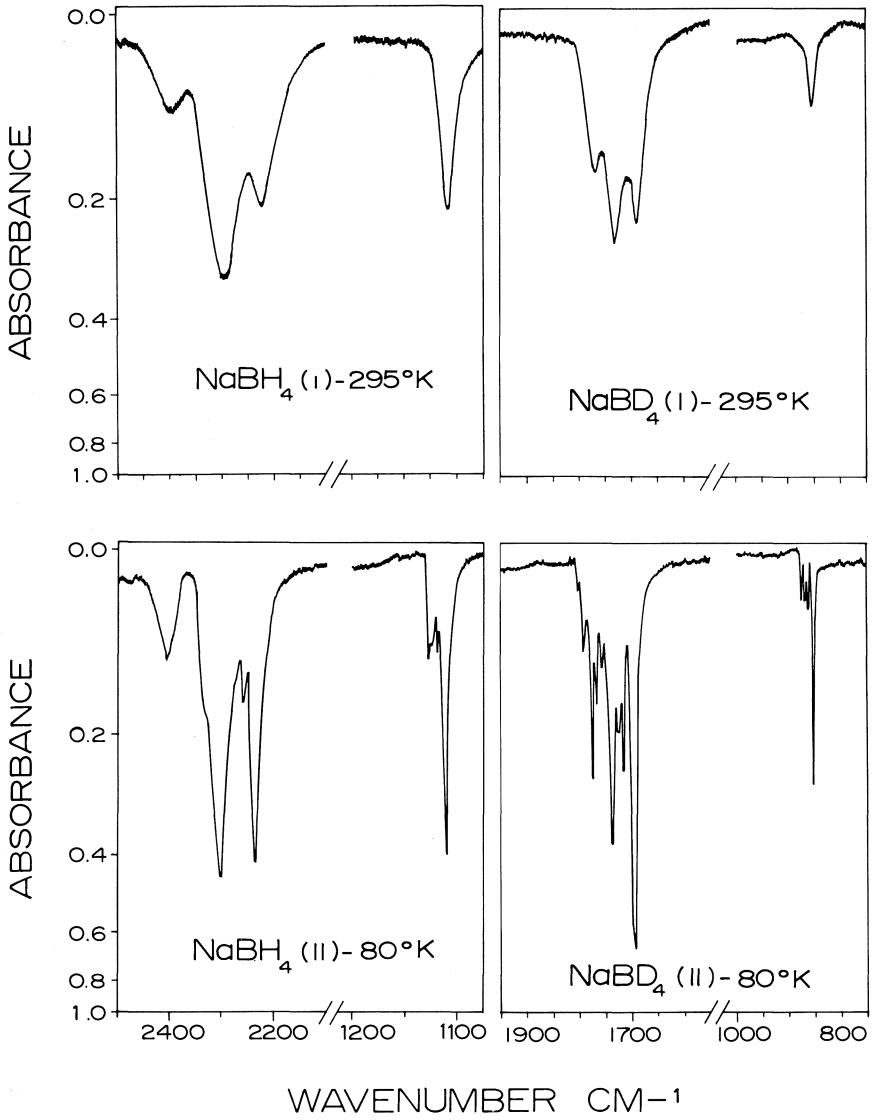

FIG. 4. The infrared spectra of $NaBH_4$ and $NaBD_4$ at 295 and 80 °K.

$^{10}\nu_2(A_1) + {}^{10}\nu_4(B_2)$. This choice of assignments is the only reasonable one and removes the arbitrariness associated with the assignments $\nu_2(A_1)$, $\nu_2(B_1)$, and $\nu_4(B_2)$.

The foregoing $NaBD_4(II)$ assignments along with those for $NaBH_4(II)$ are summarized in Table 5. The assignments for the high temperature disordered cubic phases appear in Table 6. Table 7 compares the earlier low temperature results obtained by Schutte (4) for $NaBH_4$ with those obtained in this work. A comparison of the results shows that Schutte reports two $2\nu_4$ absorptions which are not compatible with the results of this work. It is possible that the 2223 cm^{-1} absorption could be assigned as $\nu_4(E) + \nu_4(E) = 2\nu_4(B_2)$ which has a predicted frequency of 2244 cm^{-1}. However, if this is the case such a line should also be observed in the spectrum of $NaBD_4(II)$. The shoulder reported at 2197 cm^{-1} appears to be completely spurious. Also, the 2287 cm^{-1} absorption reported by Schutte does not appear in our spectra. Since it is reported as a

*v = very, w = weak, m = medium, s = strong, sh = shoulder.

strong distinct absorption it is difficult to associate it with the shoulder we observe at 2272 cm^{-1}. The shoulders we observe at 1148 and 2334 cm^{-1} may have been missed in the earlier work because of their low intensity. A possible explanation for the discrepancies between the results is that Schutte's samples may have been prepared while exposed to the atmosphere. Earlier work done in this laboratory[3] has shown that such exposure can allow for the occurrence of slight decomposition and possibly the formation of hydrated forms of $NaBH_4$ (16). Such introduction of impurities into the sample could easily explain the discrepancies. The point to be emphasized though is that Schutte's results, like

[3]N. R. McQuaker, unpublished results.

For personal use only.

those of this work, show an unambiguous splitting of ν_4 which may be associated with the disorder–order phase transformation.

External Lattice Vibrations

The irreducible representations for the optical translatory (o.t.), optical libratory (o.l.), and acoustical translatory (a.t.) fundamentals of $NaBH_4(II)$ are the following

$$\Gamma(\text{o.t.}) = B_2 + E$$
$$\Gamma(\text{o.l.}) = A_2 + E$$
$$\Gamma(\text{a.t.}) = B_2 + E$$

None of the Raman active external fundamentals produced observable scattering, and in the infrared spectra of the sodium borohydrides only one absorption appears which may be associated with the external fundamentals. In the spectrum of $NaBH_4(II)$ it appears at 172 cm^{-1} and in the $NaBD_4(II)$ spectrum it appears at 167 cm^{-1}. The frequency ratio of 0.97 indicates that these absorptions are due to translations. The anomalous absorption appearing in the $NaBD_4(II)$ spectrum at 877 cm^{-1} may be associated with the anomalous $NaBH_4(II)$ absorption appearing at 1153 cm^{-1}. A tentative assignment is $3\nu_L$. The assumption of the $3\nu_L$ assignment places librations, without correction for anharmonicity, at 384 cm^{-1} for $NaBH_4(II)$ and at 292 cm^{-1} for $NaBD_4(II)$; the frequency ratio is 0.76 which compares with an expected ratio of 0.71. There is only one piece of experimental information with which to check the $3\nu_L$ assignment. Stockmeyer and Stephenson (17) using heat capacity data have estimated that ν_L for $NaBH_4(II)$ should lie at about 350 cm^{-1}. While this result does not exclude the $3\nu_L$ assignment, it does not give exceptionally strong support for it either and hence the $3\nu_L$ assignments must be regarded as only tentative.

Low Temperature Infrared and Raman Spectra of Lithium Borohydride

K. B. HARVEY[1] AND N. R. MCQUAKER[2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 22, 1971

The infrared spectra of polycrystalline $LiBH_4$ and $LiBD_4$ have been recorded in the region 4000–50 cm^{-1} at 80 °K. Raman spectra of polycrystalline samples were also recorded at this temperature. The spectra of the BH_4^- and BD_4^- lattice vibrations are consistent with symmetrically equivalent borohydride ions which lie on either general positions, two-fold axes or mirror-planes. Six lattice vibrations of translatory origin appear in the infrared spectrum of $LiBH_4$ and a mode of libratory origin is inferred from an absorption tentatively assigned as a second overtone of a librational mode. Similar spectral results are obtained for $LiBD_4$. The inferred librational frequencies are 418 cm^{-1} for the BH_4^- ions and 319 cm^{-1} for the BD_4^- ions.

Les spectres infrarouges du $LiBH_4$ et du $LiBD_4$ sous la forme polycristalline ont été enregistrés dans la région de 4000–50 cm^{-1} à 80 °K. Les spectres Raman des échantillons polycristallins ont été aussi enregistrés à cette température. Les spectres de vibration dans le réseau pour BH_4^- et BD_4^- sont compatibles avec une symétrie équivalente pour les ions borohydrure qui se trouvent sur l'une ou l'autre des positions d'un axe de symétrie d'ordre deux ou des plans de symétrie. Les six vibrations du réseau dues à un mouvement de translation apparaissent dans le spectre infrarouge du $LiBH_4$ et un mode d'une origine oscillatrice qui est déduite d'une absorption peut être assigné à titre d'essai comme une seconde harmonique d'un mode d'oscillation. D'autres spectres analogues sont obtenus pour $LiBD_4$. Les fréquences oscillatrices déduites sont 418 cm^{-1} pour les ions BH_4^- et 319 cm^{-1} pour les ions BD_4^-.

Canadian Journal of Chemistry, 49, 3282 (1971)

Introduction

The room temperature mid-infrared spectrum of $LiBH_4$ was reported by Price in 1949 (1). Evidently no vibrational studies of this compound or its deuterated analog, $LiBD_4$, have been reported since. An early X-ray crystal study of $LiBH_4$ (2) indicated an orthorhombic structure (D_{2h}^{16}-*Pcmn*) with four molecules per unit cell. Under the D_{2h}^{16} space group both the lithium ions and the boron atoms lie on mirror-plane positions of multiplicity four while the hydrogen atoms lie on two independent sets of general positions of multiplicity eight. The four BH_4^- ions in the unit cell are symmetrically equivalent; *i.e.*, they are symmetrically related by a center of symmetry and two axial glide planes at $x = 1/4$ and $x = 3/4$. Heat capacity data for $LiBH_4$ (3) showed no anomalies in the temperature interval 15–303 °K. Recently, the nuclear spin lattice relaxation times, T_1, for protons and deuterons in polycrystalline $LiBH_4$ and $LiBD_4$ have been measured (4, 5). The results have been interpreted as indicating that both $LiBH_4$ and $LiBD_4$ contain borohydride ions of two crystallographically independent kinds. Thus there is an apparent discrepancy between the X-ray and nuclear magnetic resonance (n.m.r.) results.

The vibrational spectra of the BH_4^- and BD_4^- lattice vibrations should be sensitive to the geometry of the borohydride ions. Accordingly, we have recorded the infrared and laser Raman spectra of both $LiBH_4$ and $LiBD_4$. Several fundamental frequencies have been assigned. Librational frequencies for the BH_4^- and BD_4^- ions have been inferred from absorptions assigned as second overtones of librational modes.

Experimental

The $LiBH_4$ was obtained from Metal Hydrides Inc. and the $LiBD_4$ was obtained from Merck, Sharpe and Dohme (Canada) Ltd. Both compounds were of reagent grade and had an assay of not less than 98%. They were used without further purification.

In the low temperature infrared study the samples were prepared as Nujol mulls in a dry nitrogen atmosphere. Both cesium iodide and polyethylene supports were used. While still in the dry nitrogen atmosphere the samples were fitted into a Hornig type low temperature cell. For the Raman studies the sample preparation was identical to that described for KBH_4 and KBD_4 (6).

The infrared and Raman spectra were recorded at 80 °K using the instrumentation described previously (6).

Results and Discussion

Internal Lattice Vibrations

If the structure of lithium borohydride is consistent with the D_{2h}^{16}-*Pcmn* space group then the

[1]Dr. K. B. Harvey passed away September 27, 1970.

[2]Present address: Department of Electrical Engineering, University of Waterloo, Waterloo, Ontario.

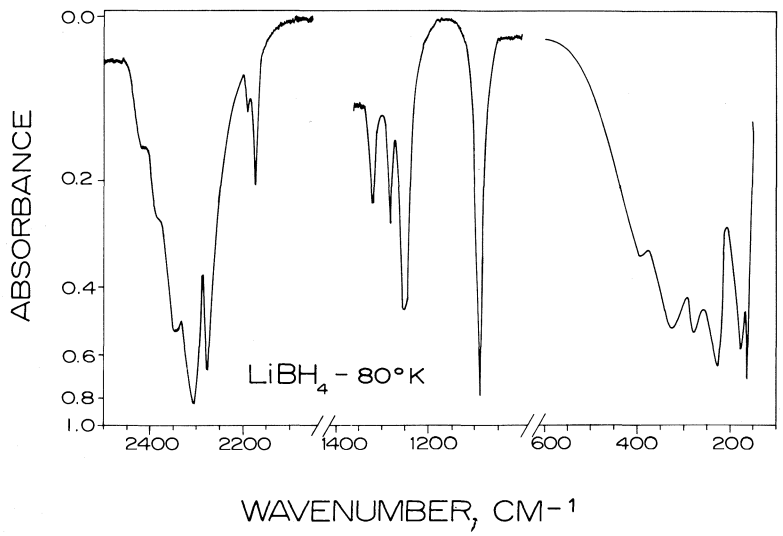

FIG. 1. The infrared spectrum of $LiBH_4$ at 80 °K.

irreducible representation for the internal fundamentals may be summarized as

$$\Gamma(\text{internal}) = 6A_g + 3B_{1g} + 6B_{2g} + 3B_{3g} + 3A_u + 6B_{1u} + 3B_{2u} + 6B_{3u}$$

These 36 internal normal vibrations may be considered to arise from the 9 normal vibrations of the BH_4^- ion through a correlation field effect resulting from the presence of four BH_4^- ions in the unit cell. The correlation diagram for the static field (site group) splitting which gives the 9 normal vibrations of the BH_4^- ion is found in Table 1. Under the D_{2h} factor group the correlation field splitting results in each A' mode giving four crystal modes of symmetries A_g, B_{2g}, B_{1u}, and B_{3u}. Similarly each A'' mode will give four crystal modes of symmetries B_{1g}, B_{3g}, A_u, and B_{2u}. Vibrations of gerade symmetry are all Raman active and vibrations of B_{1u}, B_{2u}, and B_{3u} symmetries may appear in the infrared.

In practice, it is usually found that correlation field effects do not give measurable splittings (see for example, ref. 7). Accordingly, we may make the infrared assignments according to the following scheme:

$\nu_1(B_{1u} + B_{3u})$
$\nu_2(B_{1u} + B_{3u}), \nu_2'(B_{2u})$
$\nu_3(B_{1u} + B_{3u}), \nu_3'(B_{1u} + B_{3u}), \nu_3''(B_{2u})$
$\nu_4(B_{1u} + B_{3u}), \nu_4'(B_{1u} + B_{3u}), \nu_4''(B_{2u})$

For the Raman assignments the corresponding scheme is:

$\nu_1(A_g + B_{2g})$
$\nu_2(A_g + B_{2g}), \nu_2'(B_{1g} + B_{3g})$
$\nu_3(A_g + B_{2g}), \nu_3'(A_g + B_{2g}), \nu_3''(B_{1g} + B_{3g})$
$\nu_4(A_g + B_{2g}), \nu_4'(A_g + B_{2g}), \nu_4''(B_{1g} + B_{3g})$

If the factor group splitting is small the frequencies of corresponding assignments for the two schemes will essentially coincide.

In the region 2400–2200 cm^{-1} the infrared spectrum of $LiBH_4$ (Fig. 1) has as its most prominent feature a triplet of intense absorptions which appear at 2277, 2307, and 2350 cm^{-1}. These absorptions may be associated with the broad unresolved absorption band observed by Price (1) at 2320 cm^{-1} and which he assigns to the BH_4^- stretching vibrations. With respect to the triplet we observe, the two most intense absorptions are assigned as $\nu_3(B_{1u} + B_{3u}) = 2277\ cm^{-1}$ and $\nu_3'(B_{1u} + B_{3u}) = 2307\ cm^{-1}$. The highest wavenumber component is then assigned as $\nu_3''(B_{2u}) = 2350\ cm^{-1}$. It is found that the two low wavenumber ν_3 components also appear in the Raman spectrum (Table 2). A very intense

$3\nu_L$	1253	1254	959	957

*Frequencies in parentheses for ν_L have been inferred from $3\nu_L$.

Raman scattering at 2300 cm^{-1} is assigned as $\nu_1(A_{1g} + B_{2g})$. The presence of $\nu_1(B_{1u} + B_{3u})$ in the infrared spectrum is evidently obscured by the intense ν_3 absorptions. This is not so for $LiBD_4$ (Fig. 2). In this case ν_1 appears in the infrared at 1605.6 cm^{-1}. This compares with an intense Raman scattering observed at 1606 cm^{-1}. The structure of the ν_3 $LiBD_4$ absorptions is similar to that observed for $LiBH_4$.

In the region 1400–1000 cm^{-1} four absorptions appear in the infrared spectrum of $LiBH_4$. The lowest lying absorption which appears at 1089 cm^{-1} may be associated with the absorption Price reports at 1096 cm^{-1} and which he assigns to a BH_4^- bending vibration. In the series KBH_4, $RbBH_4$, and $CsBH_4$ ν_4 is found to appear at about 1100 cm^{-1} with ν_2 appearing some 120 cm^{-1} higher.[3] Assuming this order is preserved for

$LiBH_4$ we can assign the 1089 cm^{-1} absorption as a component of ν_4. Unexpectedly no other nearby absorptions are observed which may be assigned to the two remaining predicted components. A similar situation exists in the case of $LiBD_4$ where the ν_4 absorption appears at 828 cm^{-1}. It is very sharp and has a half-height band width of only 6 cm^{-1}. Therefore it is unlikely that more than one ν_4 component contributes to its intensity. The 837 cm^{-1} absorption appearing on the high wavenumber side of the 828 cm^{-1} ν_4 absorption is the result of a ^{10}B–^{11}B isotope shift. Since none of the ν_4 components of either $LiBH_4$ or $LiBD_4$ appear in the Raman spectra only the one component can be assigned in each case. Of the three remaining absorptions appearing in the bending region of the spectrum of each of the lithium borohydrides, two are assigned to the two predicted ν_2 components. In the spectrum of $LiBH_4$ we may associate the two sharpest absorptions with ν_2. If we choose the most intense of these absorptions as $\nu_2(B_{1u} + B_{3u})$ then the assignments are $\nu_2(B_{1u} + B_{3u}) = 1284\ cm^{-1}$ and $\nu_2'(B_{2u}) = 1323\ cm^{-1}$. The corresponding assignments for $LiBD_4$ are 919 and 933 cm^{-1}, respectively. The mean ν_2 frequencies for the crystalline BH_4^- and BD_4^- ions are 1304 and 926 cm^{-1} and the frequency ratio is 0.711. This compares with a predicted frequency ratio of 0.707 for the "free" ions. After assigning the components of ν_2 there remains an anomalous line at 1254 cm^{-1} in the spectrum of $LiBH_4$ and an anomalous line at 957 cm^{-1} in the spectrum of $LiBD_4$. The assignment for these lines is commented on later.

The spectra associated with the BH_4^- and BD_4^- lattice vibrations (Table 2) are consistent with symmetrically equivalent borohydride ions. (If there were crystallographically non-equivalent borohydride ions involved we could expect to see a set of lattice vibrations arising from each crystallographically non-equivalent ion.) The appearance of ν_1 and the two components of ν_2 in the infrared spectra allows three possibilities for the site symmetry of the borohydride ions; *i.e.*, the BH_4^- and BD_4^- ions must be on either general positions, two-fold axes or mirror-planes. This result is consistent with the symmetrically equivalent mirror-plane positions indicated by the X-ray study (2). It is likely that the rather broad minima observed for the proton and deuteron T_1 *vs.* temperature curves are due to crystallographically non-equivalent hydrogen and deuterium atoms and not crystallographically non-equivalent borohydride ions as has been suggested (4, 5).

External Lattice Vibrations

The external lattice vibrations include those of optical translatory(o.t.), optical libratory(o.l.), and acoustical translatory(a.t.) origin. The respective irreducible representations are

$$\Gamma(\text{o.t.}) = 4A_g + 2B_{1g} + 4B_{2g} + 2B_{3g} + 2A_u + 3B_{1u} + B_{2u} + 3B_{3u}$$

$$\Gamma(\text{o.l.}) = A_g + 2B_{1g} + B_{2g} + 2B_{3g} + 2A_u + B_{1u} + 2B_{2u} + B_{3g}$$

$$\Gamma(\text{a.t.}) = B_{1u} + B_{2u} + B_{3u}$$

In the vibrational Raman spectra of the lithium borohydrides none of the predicted modes of either libratory or translatory origin appear. In the infrared no modes were observed which could be assigned to libratory oscillations but 6 $LiBH_4$ and 5 $LiBD_4$ translatory vibrations were observed. In the zero wavevector limit 7 infrared active translations are predicted. These will arise from out of phase motions involving the lithium and borohydride ions. The highest wavenumber translations labelled T_1, T_2, T_3, and T_4 (Table 2) possess $LiBD_4$–$LiBH_4$ frequency ratios in the range 0.85 to 0.95. These compare with a calculated frequency ratio of 0.89. The two lowest wavenumber translations appearing in the $LiBH_4$ spectrum at 175.5 and 162.5 cm^{-1} evidently compare with the 149.5 cm^{-1} translation of $LiBD_4$. Assignments for the translations with respect to symmetry type must be reserved until a study involving single crystals and polarized radiation is made.

Combinations and Overtones

The combinations and overtones appearing in the $LiBH_4$ and $LiBD_4$ spectra which involve internal fundamentals are readily assigned to components of $2\nu_4$ and $\nu_2 + \nu_4$ (Table 2). The components of $\nu_2 + \nu_4$ are found to have higher frequencies than those predicted by the observed ν_2 and ν_4 frequencies. This may be attributed to Fermi resonance with components of ν_3.

Finally, we come to the anomalous $LiBH_4$ and $LiBD_4$ absorptions at 1254 and 957 cm^{-1}. It is likely that they have the same origin as the anomalous $NaBH_4$ and $NaBD_4$ absorptions which appear at 1153 and 877 cm^{-1} and have tentatively been assigned to second overtones of librational modes (6). If the same $3\nu_L$ assignment

is made for the lithium borohydrides, modes of libratory origin without correction for anharmonicity are placed at 418 and 319 cm^{-1} for the BH_4^- and BD_4^- ions. The frequency ratio is 0.76 which compares with an identical frequency ratio for the sodium borohydrides. The predicted frequency ratio is 0.71. In the spectra of the sodium borohydrides these absorptions appear only in the spectra of the ordered tetragonal phases. This situation is comparable with that observed for the ammonium halides (8) where absorptions involving librational modes appearing in the second order spectra suffer a striking loss in intensity as a result of a transition from an ordered phase to a disordered phase. Also with respect to the series KBH_4, $NaBH_4$, and $LiBH_4$, where the BH_4^- ions suffers a progressive distortion (from T_d to D_{2d} to C_s site symmetry), it is found that the relative intensity of $3\nu_L$, starting with zero observable intensity for KBH_4, is progressively enhanced (6). This is evidently a result of the fact that for the series KBH_4, $NaBH_4$, and $LiBH_4$ there are a progressively greater number of possible components which can contribute to the intensity of $3\nu_L$. It is expected that neutron inelastic scattering studies of the alkali-metal borohydrides will be undertaken in the near future (9). These studies will, no doubt, place the modes of libratory origin and in so doing will indicate if the assignments $3\nu_L$ are indeed correct.

Ion Scavenging by Neopentane in γ-Irradiated Liquid Alkanes

J. A. STONE AND G. MATSUSHITA
Chemistry Department, Queen's University, Kingston, Ontario

Received May 7, 1971

The γ-radiolysis of low concentrations of neopentane in liquid cyclo-C_5H_{10} and C_2H_6 at 0.25 g ml^{-1} density leads to methane yields much greater than expected from the mixture compositions. In cyclo-C_6H_{12}, *n*-C_6H_{14}, cyclo-$C_6H_{11}CH_3$, and 3-methylpentane the yields are much less than expected. The effect is explained in terms of positive ion scavenging which is enhanced by added electron scavengers. The efficiency of scavenging by $C(CD_3)_4$ in C_2H_6 is equal to that of ND_3. The efficiency in cyclo-C_5H_{10} is less than that in C_2H_6 but is greater than that observed previously in this solvent.

La radiolyse-γ, à faible concentration de néopentane dans le cyclopentane et C_2H_6 à une densité de 0.25 g ml^{-1}, conduit à des rendements en méthane nettement plus grands à ceux prévus d'après les compositions du mélange. Dans le cyclohéxane le *n*-C_6H_{14}, le méthyl cyclohéxane et le méthyl-3 pentane les rendements sont inférieurs à ceux prévus. Les résultats sont expliqués par le piègage des ions positifs qui est augmenté par l'adjonction d'agents piègeurs électroniques. L'efficacité du piègage par $C(CD_3)_4$ dans C_2H_6 est la même que celle de ND_3. L'efficacité dans le cyclohéxane est moindre que dans C_2H_6 mais plus grande que celle observée précédemment dans ce solvant.

Canadian Journal of Chemistry, **49**, 3287 (1971)

Introduction

The yields of products from the radiolysis of liquid binary mixtures of saturated hydrocarbons are often non-linear functions of the constituent electron fractions (1, 2). This is usually taken to imply some form of "energy transfer" subsequent to the initial energy deposition which is assumed to occur according to the electron fraction. We have previously studied "energy transfer" by measuring HD and D_2 yields from low concentrations of perdeuterocarbons in hydrocarbon solvents (3, 4). The results obtained are interpretable in terms of positive charge transfer which is always exothermic when judged by gas phase ionization potentials. HD and D_2 yields above those expected for the electron fraction of perdeuterocarbon are obtained when the protiated solvent has the higher ionization potential and the reverse occurs when the solvent has the lower ionization potential. The reactions leading to enhanced yields may be represented by the equations

$$[1] \qquad R_1H \rightsquigarrow R_1H^+ + e$$

$$[2] \qquad R_1H^+ + R_2D \rightarrow R_1H + R_2D^+$$

$$[3] \qquad R_2D^+ + e \rightarrow D, D_2 \rightarrow HD, D_2$$

By confining ourselves to studying only hydrogen yields and using only low concentrations of perdeuterocarbon we have a sensitive technique and we avoid possible complications inherent in the measurement of liquid products such as the change in identity of radicals resulting from metathetical reactions (3, 5).

We find that charge transfer between liquid saturated hydrocarbons is an inefficient process when compared with other ion scavenging reactions such as proton transfer to ND_3 (6) or C_2H_5OD (7). For example 0.43 *M* C_2H_5OD scavenges 2.1 G ions in cyclo-C_5H_{10} whereas 0.42 *M* cyclo-C_6D_{12} scavenges only 0.5 G (8). By comparison the cycloalkane cyclo-C_3H_6, which reacts by H_2 transfer with other alkane molecular ions, is practically as efficient as NH_3 (9). However H_2 transfer to a saturated hydrocarbon is apparently peculiar to this one molecule. The reason for the relatively low efficiency of the charge transfer reaction is not known but the process becomes more efficient in a given solvent the greater the difference in gas phase ionization potential between donor and acceptor (4). In contrast H_2 transfer is favored by a closeness in ionization potentials (10).

In order to obtain more information on the charge transfer process we have used a new hydrocarbon solute, neopentane. This allows study of the formation of another gaseous product, methane, in addition to hydrogen. $G(H_2) = 2.5$ and $G(CH_4) = 3.9$ for pure liquid $C(CH_3)_4$ the latter value being little affected by up to 10 mol% N_2O (11). Some CH_4 must arise from ionic precursors and the lack of an effect of the electron scavenger on $G(CH_4)$ is due to the instability of the molecular ion. This decom-

poses in one of two ways in the liquid phase to yield CH_4 or $\cdot CH_3$ (12)

[4] $C(CH_3)_4^+ \rightarrow C(CH_3)_3^+ + \cdot CH_3$

[5] $C(CH_3)_4^+ \rightarrow i\text{-}C_4H_8^+ + CH_4$

Since most $CH_3\cdot$ radicals will abstract from the solvent at the dose rates we employ (13) the measured CH_4 yield provides information on the ion scavenging ability of $C(CH_3)_4$.

In a preliminary communication (14) we described some results obtained in the cyclo-C_5H_{10}/$C(CH_3)_4$ system. Results for other hydrocarbon solvents have now been obtained. For studies in C_2H_6, which itself yields radiolytic CH_4, $C(CD_3)_4$ has been employed with the added advantage that HD and D_2 as well as CD_4 and CHD_3 yields may be measured.

Experimental

Neopentane (Matheson CP grade) and neopentane-d_{12} (Merck, Sharpe and Dohme of Canada) were used after trap-to-trap distillation under vacuum. Cyclohexane (Fisher Spectroanalyzed), cyclopentane (Phillips Research Grade), methylcyclohexane, and 3-methylpentane (3MP) (Phillips Pure Grade) were used as received. Ethane (Phillips Research Grade) was subjected to trap-to-trap vacuum distillation. Removal of cyclopentene from cyclopentane by treatment with concentrated H_2SO_4 followed by fractional distillation did not change the results from those observed in the absence of this treatment.

All samples except those containing ethane were irradiated in Pyrex ampoules with a low vapor to liquid volume ratio. In all calculations it is assumed that the $C(CH_3)_4$ is completely in the liquid phase. Ethane samples were irradiated at a density of 0.25 g ml^{-1} at 318 °K in a stainless steel vessel of 4.2 ml volume to a dose of 1.6×10^{19} eV/g. The other samples received doses of $\sim 2 \times 10^{19}$ eV/ml. The dose rate in the γ-source (Gammacell 220) was 9.3×10^{17} eV/g min in the Fricke dosimeter.

Gases non-condensible at 77 °K (H_2, HD, D_2, and methane) were measured volumetrically and analyzed by mass spectrometry. Methane could be removed quantitatively (> 98%) from all hydrocarbon solvents except ethane by two or three freeze–pump–thaw cycles. With ethane samples two cycles were employed and the remaining methane was determined by gas–solid chromatography. The results obtained by this combined analysis are not as precise as those from the single measurement.

Results

CH_4 yields from solutions of $C(CH_3)_4$ in cyclo-C_5H_{10} and cyclo-C_6H_{12} are shown in Fig. 1, curves *I* and *III*. The non-zero intercept of 0.04 for curve *I* is the CH_4 yield from pure cyclo-C_5H_{10}. The value is in agreement with that

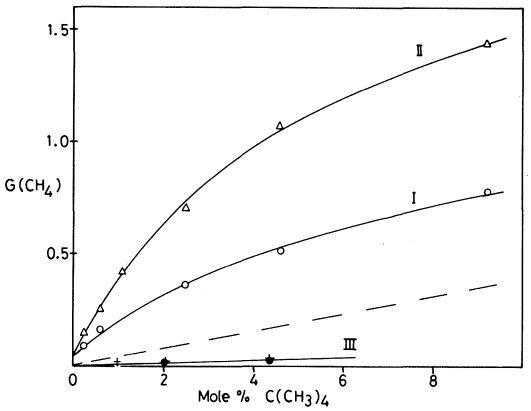

FIG. 1. Methane yields from $C(CH_3)_4$ in: *I*, cyclo-C_5H_{10}; *II*, *c*-C_5H_{10}/2.5 mol% CCl_4; *III*, cyclo-C_6H_{12}+, cyclo-C_6H_{12} + 2.5 mol% CCl_4 ●, ---- "expected" yield.

obtained by Hughes and Hanrahan (15). Yield curves for CH_4 from $C(CH_3)_4$ in *n*-C_6H_{14}, cyclo-$C_6H_{11}CH_3$, and 3MP after correction for CH_4 from the solvent alone are, within experimental error, indistinguishable from that for cyclo-C_6H_{12}. The broken line is the expected yield from direct radiolysis taking $G(CH_4) = 3.9$ for pure $C(CH_3)_4$.

The electron scavengers CCl_4 and SF_6 increase $G(CH_4)$ in the $C(CH_3)_4$/cyclo-C_5H_{10} system but slightly decrease it in *n*-C_6H_{14}, cyclo-$C_6H_{11}CH_3$ and 3MP. In cyclo-C_5H_{10} $G(CH_4)$ increases with increasing CCl_4 concentration up to ~1 mol% and then remains constant up to at least 3 mol%. Curve *II*, Fig. 1 shows the yields at 2.5 mol%. The decreased yields in cyclo-C_6H_{12} are shown by the filled symbols slightly below curve *III*.

The addition of 7 mol% C_2H_5OH to cyclo-C_5H_{10} containing 4.1 mol% $C(CH_3)_4$ and 2.3 mol% CCl_4 reduces $G(CH_4)$ by 55% while $G(H_2)$ remains constant.

The yields of CHD_3 and CD_4 from $C(CD_3)_4$ in C_2H_6 at 0.25 g ml^{-1} and 318 °K are shown in Fig. 2. No other deuterated methanes were detected ($G < 0.2$ at ~4 mol% $C(CD_3)_4$). The broken line represents the methane yield expected from the stoichiometric composition assuming that deuteration has no effect on *G*(methane). A partial confirmation of this was obtained when *G*(methane) from C_2H_6 containing 3.7 mol% $C(CD_3)_4$ and 1.05 mol% $C(CH_3)_4$ was equal to that from C_2H_6 containing 4.75 mol% $C(CD_3)_4$.

The yields of HD and D_2 from C_2H_6/$C(CD_3)_4$ in the presence and absence of SF_6 are shown in

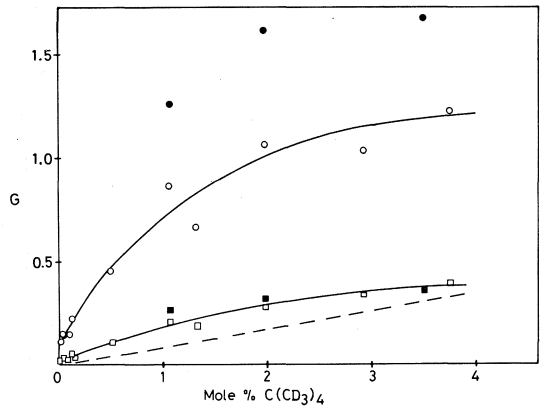

FIG. 2. Methane yields from $C(CD_3)_4$ in C_2H_6: ○, CHD_3; ●, CHD_3 with 1.1 mol% SF_6; □, CD_4; ■, CD_4 with 1.1 mol% SF_6; ---- "expected" yield.

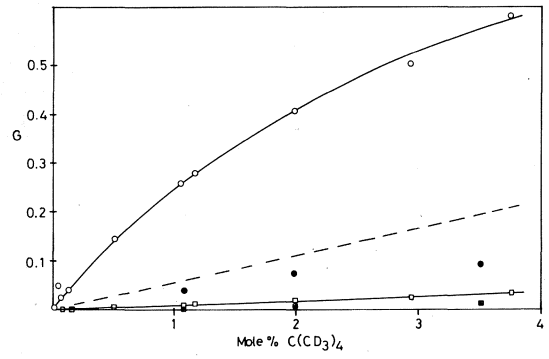

FIG. 3. ○ HD and □ D_2 yields in $C_2H_6/C(CD_3)_4$; ● HD and ■ D_2 in the presence of 1.1 mol% SF_6; ---- expected total hydrogen by direct radiolysis of $C(CD_3)_4$.

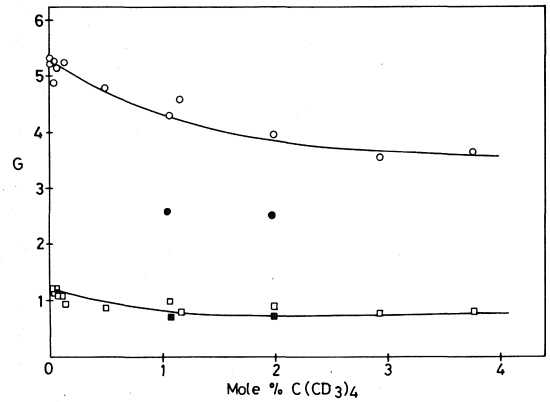

FIG. 4. ○ H_2 and □ CH_4 yields in $C_2H_6/C(CD_3)_4$; ● H_2 and ■ CH_4 in the presence of 1.1 mol% SF_6.

Fig. 3 while Fig. 4 shows the corresponding H_2 and CH_4 yields.

For purposes of comparison 1.2 mol% *n*-C_4D_{10} was irradiated in C_2H_6. G(HD) was 0.27 and $G(D_2)$ was 0.15. There was no measurable change in G(total hydrogen). Similarly 1.96 mol% cyclo-C_6D_{12} in C_2H_6 under the same conditions gave G(HD) = 0.6 and $G(D_2)$ = 0.3.

Discussion

The participation of ions in the enhancement of yields in cyclo-C_5H_{10} and C_2H_6 over those expected from the solution compositions is shown by the effects of electron and positive ion scavengers.

(*i*) $G(HD + D_2)$ in $C_2H_6/C(CD_3)_4$ is reducible to a much greater proportion by electron scavengers than is either the total hydrogen yield or the yield of H_2 in pure liquid $C(CH_3)_4$ (11).

(*ii*) While $G(HD + D_2)$ is drastically decreased by SF_6 the yield of methane ($CHD_3 + CD_4$) is increased. Hydrogen is formed subsequent to charge neutralization by an electron but not by an anion while methane is formed prior to neutralization (reactions 4 and 5). The lower mobility of the anion relative to the electron allows greater opportunity for the occurrence of ion molecule reactions before neutralization which leads to an increased methane yield. It is possible that some methane might be formed following neutralization by an anion of ions which would otherwise yield hydrogen since the observed decrease in $G(HD + D_2)$ is accompanied by an increase in $G(CHD_3 + CD_4)$. Such formation is unlikely since there is no increase in $G(CH_4)$ when N_2O reduces $G(H_2)$ in liquid $C(CH_3)_4$ (11) and the increase in $G(CH_4)$ in cyclo-$C_5H_{10}/C(CH_3)_4$ is much too large if it is assumed that the ratio of hydrogen to methane from the solute is the same as that in C_2H_6.

(*iii*) The addition of C_2H_5OH as a competitive ion scavenger to the system cyclo-C_5H_{10}/$C(CH_3)_4/CCl_4$ decreases $G(CH_4)$.

We will assume in subsequent discussion that all yields from neopentane above those expected from direct radiolysis as determined by the stoichiometric composition are a measure of the extent of ion scavenging by the neopentane.

The gas phase ionization potentials of the hydrocarbons employed are shown in Table 1, the value for neopentane referring to the production *i*-$C_4H_{10}^+ + CH_4$; the appearance potential for $C(CH_3)_3^+ + CH_3$ is 0.18 eV higher (16).

TABLE 1. Gas phase ionization potentials (ref. 23)

Alkane	Ionization potential (eV)
C_2H_6	11.65
C_4H_{10}	10.63
cyclo-C_5H_{10}	10.53
$C(CH_3)_4$	10.35
$CH_3CH_2CH(CH_3)CH_2CH_3$	10.08
cyclo-C_6H_{12}	9.88
cyclo-$C_6H_{11}CH_3$	9.85

In agreement with previous studies the "activating" solvents have a higher ionization potential than neopentane. We suggest that the enhanced yields of methane that we observe in cyclopentane and ethane are mainly due to charge transfer from the solvent molecular ion followed by prompt formation of either CH_4 or CH_3 (reaction 2 followed by 4 or 5). Two other possibilities are hydride ion transfer and proton transfer. It is unlikely that hydride ion transfer makes a major contribution since the majority of scavengeable ions in cyclo-C_5H_{10} are molecular (10) and the same appears to be true in C_2H_6 at 0.26 g ml^{-1} (17). Also there is no reason why H^- transfer by neopentane should be more facile than that by other hydrocarbons and indeed the reverse is more probable (18). For proton transfer to neopentane to play a major role the protonated molecular ion of the solvent would have to be formed in improbably high yield. $C_2H_7^+$ has been observed in the ion source of a mass spectrometer (19) but evidence for stable protonated forms of higher hydrocarbons in the gas phase is lacking. There is no direct evidence for their occurrence in the liquid phase.

In cyclo-$C_5H_{10}/C(CH_3)_4$ G(methane + hydrogen) is constant within experimental error over the mixture composition studied. In $C_2H_6/C(CD_3)_4$ there is a gradual increase with increasing $C(CD_3)_4$ concentration which is 0.2 G at 3.76 mol%. This implies that in general the neopentane ions formed by charge scavenging lead to either methane or hydrogen but the formation of two of these molecules from a single charge transfer process is a rare event. The $C_2H_6^+$ ions which charge transfer to $C(CD_3)_4$ are precursors of both CH_4 and H_2 in the absence of this solute.

Charge scavenging by $C(CH_3)_4$ in cyclo-C_5H_{10} is more efficient than that by cyclo-C_6D_{12} or cyclo-$C_6D_{11}CD_3$ (1) but not as efficient as that

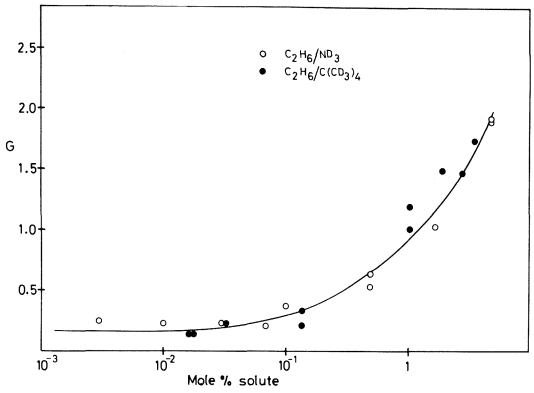

FIG. 5. Positive ion scavenging in C_2H_6 at 0.25 g ml^{-1}. ● $C(CD_3)_4$, ○ ND_3 (24).

by C_2H_5OH or NH_3 (8). However $C(CD_3)_4$ is as efficient as ND_3 in C_2H_6. This comparison is made in Fig. 5 where G(ions scavenged) is calculated as 4/3 G(HD) for C_2H_6/ND_3 (6) and as $G(HD + D_2 + CHD_3 + CD_4)$ corrected for yields from direct radiolysis for $C_2H_6/C(CD_3)_4$. This high efficiency of $C(CD_3)_4$ in C_2H_6 can be related in part to the large difference in ionization potential between it and C_2H_6. However, cyclo-C_6D_{12} and n-C_4D_{10} are not as efficient even though they are also favored by a large exothermicity in charge transfer. A contributing factor for $C(CD_3)_4$ could be the rapidity of loss of CD_3 (reaction 4) or CD_4 (reaction 5) which may occur in the period of one C—C vibration and which constitutes an efficient chemical relaxation process analogous to the protonation of ND_3. Such a chemical step prior to charge neutralization does not appear to be available to the other perdeuterocarbons and physical relaxation of the excited ion formed by charge transfer may not be rapid enough for efficient trapping. Since most of the HD and some of the D_2 in $C_2H_6/C(CD_3)_4$ is formed following neutralization it appears that either some neopentane ions are stabilized in solution or, if they do decompose, then little methane is formed but the resulting ionic fragment yields D atoms after neutralization.

The scavenging plot (Fig. 3) appears typical for positive ion scavenging (9). The limiting yield at low solute concentrations is attributable to the yield of freely diffusing ions and $G \sim 0.2$ is consistent with the value found for similar alkanes, albeit at higher phase density (20). At higher solute concentrations scavenging in the spurs takes place but the experimental points for both ND_3 and $C(CD_3)_4$ do not conform to the

usual square root relationship, the yields increasing more steeply than predicted (9). This will be discussed more fully in a succeeding communication.

The ratios of isotopic hydrogens and methanes in the $C_2H_6/C(CD_3)_4$ system are of interest. As might be expected very little D_2 is produced relative to HD. However, about 25% of the methane arising from $C(CD_3)_4$ is CD_4. This is unexpected since the mass spectrum of $C(CH_3)_4$ shows that loss of 15 mass units is twenty times as probable as loss of 16 units. This large percentage of ionic unimolecular decomposition is, however, in accord with the recent value of ~20% obtained by Collin and Ausloos (12) from a study of the radiolysis of liquid neopentane. It is possible that some of the CD_4 in our work arises from a cage disproportionation involving $CD_3\cdot$ and a deuterated ion or radical. With the present information this cannot be distinguished from reaction 5.

If the values of gas phase ionization potentials are taken to apply precisely to the liquid phase then reactions 2 and 4 are overall very slightly endothermic or thermoneutral when *c*-C_5H_{10} is the solvent. In two experiments performed with $C(CD_3)_4$ in this solvent $G(CD_4)/G(CHD_3)$ was 0.42 and 0.39 in the presence and absence of CCl_4, respectively. This implies that both reactions 4 and 5 occur but that with the lower recombination energy of cyclo-$C_5H_{10}^+$ reaction 5 assumes greater importance. Thermoneutral charge transfer is bidirectional. However, the fast decomposition of the neopentane molecular ion will provide a bias in favor of products from this ion. Such a bias will not be present in mixtures in which products are formed subsequent to ion electron combination.

In the above discussion it has been presumed that the species present in solution are the single, molecular ions. However, Ausloos and coworkers (21, 22) have shown that in the gas phase radiolysis of ethane stable dimer ions play a role. Presumably these and higher agglomerations will be of importance in the liquid phase. Reaction equations written in terms of single ions will therefore have no physical meaning. However, our present and previous studies show that the relative order of gas phase ionization potentials still holds in the liquid and can therefore be used to predict the direction of charge transfer. The actual mechanism of product formation will of course be dependent on the state of aggregation.

Conclusion

Neopentane is a highly efficient ion scavenger in C_2H_6 at 0.25 g ml^{-1} and is a fairly efficient one in liquid cyclopentane. This can be correlated with positive charge scavenging which increases in efficiency with increase in difference in ionization potential between donor and acceptor. An added factor may be the formation of the neopentane molecular ion in a repulsive state, the resulting rapid loss of $\cdot CH_3$ or CH_4 in $\sim 10^{-13}$ s enhancing the trapping efficiency.

Epimerization of Monosaccharides Under Acetolysis Conditions

WALTER SOWA

Department of Organic Chemistry, Ontario Research Foundation, Sheridan Park, Ontario

Received May 17, 1971

Monosaccharides with a *cis*-configuration at C-2 and -3 readily undergo inversion at C-2 in an acetolysis medium composed of acetic acid, acetic anhydride, and sulfuric acid. The acetolysis-inversion reaction has been carried out with 2,3;5,6-di-*O*-isopropylidene-D-gulofuranose, 2,3;6,7-di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose, 2,3-*O*-isopropylidene-D-ribose, D-ribose, and D-mannose using chromatography for isolation of the deacetylated epimeric products. The reaction requires a medium with a high concentration of acetic acid (*ca.* 90%) and appears to take place only with furanose structures. Inversions observed with the unsubstituted pyranoses D-ribose and D-mannose probably occur because of tautomerization to furanose forms. The epimerization proceeds in the direction which yields a smaller number of *cis*-oriented groups at C-2, -3, and -4 of the furanose forms of monosaccharides.

Les monosaccharides avec une configuration *cis* au C-2 et -3 subissent une inversion rapide au C-2 dans un mélange acétolysant composé d'acide acétique, d'anhydride acétique et d'acide sulfurique. La réaction d'acétolyse produisant une inversion a été effectuée avec le di-*O*-isopropylidène-2,3;5,6, D-gulofuranose, le di-*O*-isopropylidène-2,3;6,7 D-*glycéro*-D-*gulo*-heptose, le *O*-isopropylidène-2,3 D-ribose, D-ribose, et le D-mannose utilisant la chromatographie pour l'isolation des composés désacétylés épimères. La réaction exige un milieu avec une grande concentration d'acide acétique (*ca.* 90%) et semble fonctionner uniquement avec des structures furanosiques. Les inversions observées avec les pyranoses non substitués tel que le D-ribose et le D-mannose sont probablement dûes à la tautomérisation vers les formes furanosiques. L'épimérisation s'oriente dans la direction qui donne un plus petit nombre de groupements orientés en position *cis* au C-2, -3, et -4 des formes furanosiques des monosaccharides.

Canadian Journal of Chemistry, 49, 3292 (1971)

Introduction

Several years ago Jerkeman (1) made the unusual observation that D-glucose was formed from certain derivatives of D-mannose when they were acetolyzed. Treatment of 2,3;5,6-di-*O*-isopropylidene-D-mannofuranose, methyl β-D-mannofuranoside or 1,5,6-tri-*O*-acetyl-2,3-*O*-isopropylidene-D-mannofuranose with a mixture of acetic acid, acetic anhydride, and sulfuric acid at room temperature yielded, after deacetylation, a 4:1 mixture of D-glucose and D-mannose. No C-2 inversion was observed on acetolysis of ethyl 2,3,4,6-tetra-*O*-acetyl-β-D-mannopyranoside, methyl α-D-mannopyranoside, methyl β-D-glucopyranoside or derivatives of D-galactofuranose, D-xylofuranose, and L-arabinofuranose; phenyl β-D-glucofuranoside gave a trace of D-mannose. It was suggested that epimerization of D-mannofuranose derivatives occurs under acetolysis conditions through conversion of a *cis–trans* arrangement of three contiguous hydroxyl groups into a *trans–cis* arrangement via cyclic acetoxonium intermediates. Protonation causes the two *cis*-acyloxy groups at C-2 and -3 to join in a seven-membered ring which undergoes nucleophilic attack by an acyloxy group *trans*-situated on an adjacent carbon. The second cyclic ion which is formed then hydrolyzes to afford the epimer D-glucose. There are several related interconversions of carbohydrates which are considered to take place by similar successive neighboring acyloxy group participation. Cyclohexane polyols epimerize at elevated temperatures in 95% acetic acid – toluenesulfonic acid (2*a*), 95% acetic acid – sulfuric acid (2*b*, *c*, *d*), acetic acid – acetic anhydride – sulfuric acid (2*d*) and acetic acid – sulfuric acid (2*d*). More recently cyclopentane polyols have been isomerized in 95% acetic acid – sulfuric acid (3). Other reports describing different media include the deacylation–inversion of cyclitols (4*a*), polyhydroxytetrahydropyrans (4*b*), and aldoses (4*c*) in liquid hydrogen fluoride, and the transformations of carbohydrate acetates by antimony pentachloride (5), by zinc chloride in acetic anhydride (6), and by phosphorus pentachloride and aluminum chloride in chloroform (*cf.* 7).

Acetolysis has many valuable applications in carbohydrate chemistry (8). The general desirability of avoiding inadvertant production of artefacts made further examination of the acetolysis-inversion reaction of interest. It was highly unlikely that such epimerization was unique to D-mannofuranose derivatives. It was also of

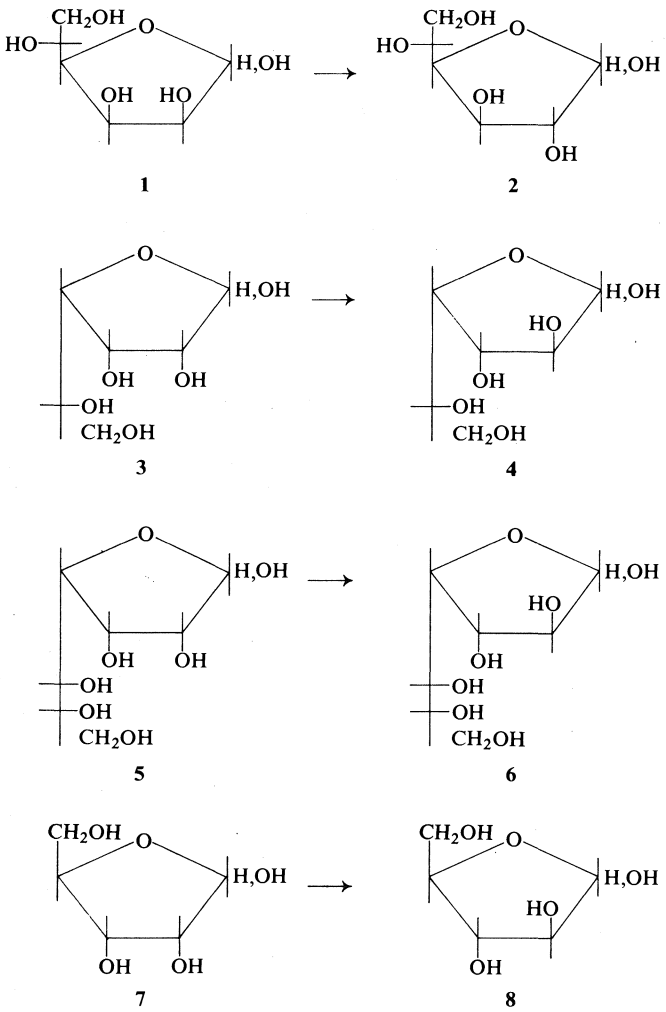

FIG. 1. Furanose structures of D-mannose (**1**), D-glucose (**2**), D-gulose (**3**), D-idose (**4**), D-*glycero*-D-*gulo*-heptose (**5**), D-*glycero*-D-*ido*-heptose (**6**), D-ribose (**7**), and D-arabinose (**8**).

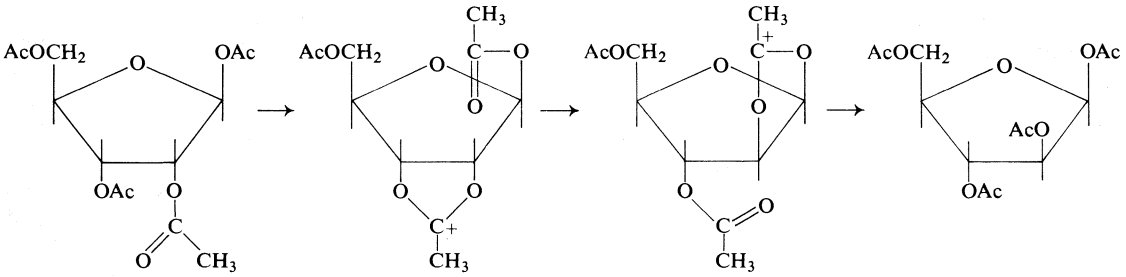
interest to investigate the acetolysis-inversion reaction since, unlike the inversions mentioned above, it appeared to be confined to furanose sugars. In addition, the reaction appeared to have some value in synthesis for carrying out C-2 hydroxyl inversion without resort to the Lobry de Bruyn – Alberda van Ekenstein transformation (9) which normally requires an alkaline medium.

Results and Discussion

The close similarity between the furanose structures of D-mannose (**1**) and D-gulose (**3**) (Fig. 1) suggested that carbohydrate derivatives with the *gulo* configuration might be convertible to the *ido* by acetolysis. 2,3;5,6-Di-*O*-isopropylidene-D-gulose (10) and 2,3;6,7-di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose (11) were each treated with the mixture of acetic acid, acetic anhydride, and sulfuric acid described by Jerkeman (1). Experiments followed by t.l.c. indicated that the maximum yield of epimers from both *gulo* sugars occurred at about 30 h. This time is one-half that reported for the conversion of D-mannose to D-glucose (1). After treatment of the reaction mixtures with triethylamine for deacetylation, the products were isolated chromatographically and weighed. From 2,3;5,6-di-*O*-isopropylidene-D-gulose, D-idose and D-gulose were obtained in a ratio of approximately 3 to 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



The ratio ranged between 2.5 to 1 and 3.4 to 1, possibly because of decomposition of sugars during acetolysis and variability in chromatographic recovery which in turn may have been related to the scale of the experiment. The yield of D-idose varied between 36 and 51%. The 2,3;6,7-di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose on acetolysis gave D-*glycero*-D-*ido*-heptose and D-*glycero*-D-*gulo*-heptose in a ratio of 2 to 1; the yield of D-*glycero*-D-*ido*-heptose was 47%. The use of triethylamine for deacetylation is a procedure communicated to Jerkeman by Whelan (1). The possibility of epimerization under deacetylation conditions was investigated by deacetylation of D-*glycero*-D-*gulo*-heptose hexaacetate and examination of the product by t.l.c. No D-*glycero*-D-*ido*-heptose was detected.

Jerkeman, after finding that derivatives of D-galactose, D-xylose, and L-arabinose did not rearrange on acetolysis, suggested that C-2 inversion would be observed with the furanosidic acetates of their epimers (1). The prediction has now been confirmed for ribose. 2,3-*O*-Isopropylidene-D-ribofuranose (12) was acetolyzed at room temperature for 90 h, not necessarily the optimum time, and worked-up in the usual manner. D-Arabinose and D-ribose were isolated chromatographically in the ratio of 0.8 to 1.

An observation relating to furanoses is that acetolysis of the 1,2-*O*-isopropylidene derivatives of D-glucofuranose triacetate and D-xylofuranose diacetate leaves the sugars in the furanose form with little or no conversion to pyranose acetate taking place (1, 13). A recent synthesis of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose from methyl D-ribofuranoside takes advantage of the stability of the acetylated furanose structure in an acetolysis medium (14). It appeared possible that if free sugars were dissolved in an acetolyzing medium, tautomerization might occur with the formation of relatively large amounts of furanoses. The acetolysis-inversion data accumulated thus far show that derivatives of certain sugars epimerize only in the furanose form. Therefore a pyranose to furanose conversion of the free sugars should be indicated by the appearance of epimers. This expectation was borne out by results of experiments with D-ribose and D-mannose. Crystalline D-ribose, which has a pyranose structure (15), and α-D-mannopyranose were each acetolyzed for 24 h in the usual manner. From the reaction with D-ribose, D-arabinose and D-ribose were isolated in the ratio of 0.85 to 1, while D-mannose yielded a mixture of D-glucose and D-mannose in 0.3 to 1 ratio. The epimerizations are indirect evidence for the existence of furanose modifications of the two monosaccharides in the acetolysis medium which was employed.

In the original work on C-2 inversion of D-mannofuranose (1), the formation of a seven-membered cyclic acetoxonium ion as the first species was favored in conformity with a mechanism postulated for transformations of cyclitol acetates in hydrogen fluoride (4*a*). An alternative mechanism with five-membered cyclic acetoxonium ions was preferred to explain the epimerization of cyclitols in acetic acid – sulfuric acid (2*d*). More recently direct evidence for a five-membered cyclic structure has been provided from n.m.r. studies of *cis* and *trans* isomers of 1,2-diacetoxycyclohexane in hydrogen fluoride (16). The *trans* isomer was unreactive while the *cis* was quantitatively converted to a 2-methyl-1,3-dioxolenium ion and acetic acid. The cyclic ion was isolated as the crystalline tetrafluoroborate. In the case of furanoses in an acetolysis medium, inversion at the central carbon of a *cis–trans* sequence of substituents probably proceeds through a transient tricyclic system of five-membered rings in which little change in position is required for the atoms directly involved.

The data collected in the present work and that of Jerkeman (1) indicate that only monosaccharides with a *cis*-2,3 configuration epimerize in an acetolysis medium. The inversion can be related to the nonbonded repulsive interactions in the furanose forms of such monosaccharides. The initial configuration of the anomeric group is unimportant since it can be assumed to readily take up a configuration *trans* to its neighbor. It is apparent then that the C-2 inversion of monosaccharides in an acetolyzing medium proceeds in the direction which yields a smaller number of *cis*-groups at C-2, -3, and -4 of the furanose form. The conversions which have been observed and the number of groups in a *cis*-orientation are as follows: D-mannose (**1**) to D-glucose (**2**) (3 and 2), D-gulose (**3**) to D-idose (**4**) (3 and 2), D-*glycero*-D-*gulo*-heptose (**5**) to D-*glycero*-D-*ido*-heptose (**6**) (3 and 2) and D-ribose (**7**) to D-arabinose (**8**) (2 and 0). The case of furanoses with all *cis* substituents at C-2, -3, and -4 (mannose and gulose configurations) is interesting. They have comparatively high free energies and n.m.r. spectra of aqueous equilibrium solutions of D-mannose and D-lyxose show no furanose while that of D-*glycero*-D-*gulo*-heptose shows very little (17). In water the interactions between *cis* substituents on adjacent carbon atoms are relieved by a ring expansion to the pyranose form which accommodates bulky groups in equatorial positions. In an acetolysis medium of a suitable composition, an alternative device consisting of a furanose (*cis*) to furanose (*trans*) transformation by way of acetoxonium ions becomes feasible. The mild conditions under which the inversion takes place with furanoses are in remarkable contrast to similar inversions reported with other five-membered cyclic structures, the cyclopentanepolyols (3). The latter require heating in 95% acetic acid – sulfuric acid for many hours.

The easy C-2 inversion of D-ribose in an acetolyzing medium appeared to be inconsistent with the results of Reist *et al.* who acetolyzed 4-*S*-benzoyl-4-thioribopyranose derivatives to 4-thio-ribofuranose compounds without epimerization of the latter (18). When their experimental conditions were used with D-ribose, the starting material was recovered accompanied by only a trace of D-arabinose detectable by paper chromatography. The experiment was repeated maintaining the 1:1 ratio of acetic acid:acetic anhydride but in one case increasing the concentration of sulfuric acid and in another raising the temperature from 0° to room temperature. These modifications had no effect on the extent of epimerization and again only a trace of D-arabinose was detectable. Under the more vigorous reaction conditions an unidentified compound with a chromatographic mobility greater than that of D-ribose was formed. It was not examined further. Epimerization in an acetolysis medium is thus related to the concentration of acetic acid since inversion occurs in a medium of 10:1 but not 1:1, acetic acid:acetic anhydride.

The importance of acetic acid concentration explains why C-2 inversion has not been observed more often during the long history of acetolysis. Epimerization takes place in a medium of 10:1 acetic acid:acetic anhydride in the presence of sulfuric acid. In contrast the classic "isomerizing mixture" first used by Hudson and associates in 1934 (ref. 19 and refs. in 20) for anomerization and for acetolysis of glycosides, acetals, and anhydrosugars was a 3:7 or 1:2 mixture of acetic acid and acetic anhydride plus sulfuric acid. On one occasion, D-*glycero*-D-*gulo*-heptose was treated for 48 h at 20° with a 1:2 mixture of acetic acid and acetic anhydride, with 2.5% by volume of sulfuric acid (21). An 80% yield of α- and β-hexaacetates of D-*glycero*-D-*gulo*-heptose was obtained. On the other hand in the present work with an "epimerizing mixture", acetolysis of the isopropylidene derivative of the same heptose yielded the *ido* isomer as the major product. A preparation of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose by acetolysis of a methyl ribofuranoside mixture has been described (14). In one variation the ratio of acetic acid to acetic anhydride was 1.5 to 2 while in the other it was 30 to 7. In the latter case an unidentified component was detected by t.l.c. It is possible that this is the acetate of D-arabinose. Studies of anomerization mechanisms have not been inconvenienced by C-2 inversions since they have been conducted usually, but not always, with low acetic acid:acetic anhydride ratios of 1:1 (22) and 3:10 (23) and confined to acetylated pyranoses. For the acetolysis of polysaccharides, a valuable technique in structural investigations (8), it is customary to use mixtures containing from 0 to 50% acetic acid. It appears that, fortuitously, undesirable C-2 inversions have been avoided. The present work suggests that particular care should be taken if acetolyses are carried out for

structural analysis of polysaccharides containing furanose sugars with *cis*-2,3 configurations. The existence of such polysaccharides has been reported recently following the discovery of D-ribofuranose in antigenic lipopolysaccharides of *Salmonella* (24).

Experimental

General

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were obtained with a Carl Zeiss photoelectric polarimeter Model 0.005° using a sodium spectral light source. Visualization reagents for paper chromatography and t.l.c. were *p*-anisidine hydrochloride (25) and silver nitrate – sodium hydroxide (26). Dibenzyl dithioacetals were prepared by treatment of the sugar with toluenethiol in the presence of trifluoroacetic acid (27) for 2 h at room temperature, followed by evaporation of the mixture to dryness.

*Acetolysis of 2,3;5,6-Di-O-isopropylidene-*D*-gulofuranose*

2,3;5,6-Di-*O*-isopropylidene-D-gulofuranose was prepared by sodium borohydride reduction of 2,3;5,6-di-*O*-isopropylidene-D-gulonolactone in ether containing acetic acid (10). Yields up to 93% were obtained by using powdered borohydride from a freshly-opened bottle and by prolonging the reaction time to *ca.* 3 days. Acetolysis was carried out as described by Jerkeman (1). Preliminary experiments followed by paper chromatography indicated that the highest ratio of D-idose to D-gulose occurred at around 30 h. The following procedure was then used. To a stirred and cooled solution of 2,3;5,6-di-*O*-isopropylidene-D-gulofuranose (200 mg) in acetic acid (6 ml) and acetic anhydride (0.8 ml) was added sulfuric acid (0.3 ml). The reaction mixture was left at room temperature for 30 h and then poured into ice-water. The aqueous solution was extracted with chloroform and the extract washed with saturated sodium bicarbonate solution followed by water. The chloroform solution was evaporated to a syrup which was deacetylated overnight by a mixture of methanol (16 ml), water (2 ml), and triethylamine (2 ml). The resulting mixture was evaporated to a syrup (80 mg) which was separated on Whatman No. 4 paper in ethyl acetate – pyridine–water (5:2:5 *v*/*v*, top layer). Appropriate zones were extracted with water to yield D-idose (50 mg, 36% yield based on di-*O*-isopropylidene-D-gulose) and D-gulose (20 mg). The ratio of D-idose to D-gulose and the yield were not constant as the scale was varied. For example, in acetolysis on a 12 g scale the ratio of D-idose to D-gulose was 3.4 to 1 after chromatography on 10 sheets (46 × 57 cm) of Whatman 3MM paper; the yield of D-idose from di-*O*-isopropylidene-D-gulose was 51%.

The syrupy D-idose, $[\alpha]_D^{22}$ +16.2° (*c* 2.5 in water), was acetylated in pyridine – acetic anhydride but the resulting acetate did not crystallize. The syrupy acetate (100 mg) was then treated with a mixture of acetic anhydride (1 ml), acetic acid (0.5 ml), and sulfuric acid (0.02 ml) for 43 h. After work-up in the usual manner there was obtained 1,2,3,4,6-penta-*O*-acetyl-α-D-idopyranose, m.p. 92–94° and $[\alpha]_D^{22}$ +54.7° (*c* 2 in chloroform). Literature values are m.p. 91–92° and $[\alpha]_D^{21}$ +54° (*c* 1.6 in chloroform) (28).

*Acetolysis of 2,3;6,7-Di-O-isopropylidene-*D*-glycero-*D*-gulo-heptose*

2,3;6,7-Di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose, m.p. 93–95°, and $[\alpha]_D^{21}$ −29.8° (*c* 1.2 in chloroform), was prepared by condensation of acetone with D-*glycero*-D-*gulo*-heptose as described by Brimacombe and Tucker (11) except that the sulfuric acid catalyst was replaced by zinc chloride – phosphoric acid (29) and in column chromatography ether was used in place of acetone–toluene. With zinc chloride – phosphoric acid instead of sulfuric acid as acetalation catalyst, the heptose appeared to dissolve and react more readily with less formation of acetone condensation by-products.

Small scale experiments followed chromatographically were carried out to determine the duration of acetolysis for maximum formation of the *ido* epimer of the heptose. The following procedure was then used. To a cooled and stirred mixture of 2,3;6,7-di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose (500 mg), acetic acid (15 ml), and acetic anhydride (2 ml) was added concentrated sulfuric acid (0.75 ml). After 24 h at room temperature, the reaction was worked-up and the product deacetylated as described above for the hexose. A portion (140 mg) of the syrupy mixture (320 mg) was separated by preparative t.l.c. on two plates (20 × 20 cm) of cellulose using ethyl acetate – pyridine–water (10:4:3 *v*/*v*) as developing solvent. D-*glycero*-D-*ido*-Heptose (76 mg, 49% yield based on di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptose) and D-*glycero*-D-*gulo*-heptose (36 mg) were isolated. The D-*glycero*-D-*ido*-heptose was characterized as its dibenzyl dithioacetal, m.p. 129–130° and $[\alpha]_D^{21}$ +70° (*c* 1 in pyridine). Literature values are m.p. 130–131° and $[\alpha]_D^{20}$ +71.4° (*c* 2.6 in pyridine) (30).

To test whether any epimerization occurred in the deacetylation step, a crude crystalline mixture of α- and β-D-*glycero*-D-*gulo*-heptose hexaacetates, m.p. 122–124°, was prepared from D-*glycero*-D-*gulo*-heptose and acetic anhydride using boron trifluoride etherate as catalyst. The heptose acetate was treated with trimethylamine in the same way as the acetolysis product. Only the starting sugar, D-*glycero*-D-*gulo*-heptose, was detectable by t.l.c.

*Acetolysis of 2,3-O-Isopropylidene-*D*-ribose*

2,3-*O*-Isopropylidene-D-ribose (12) (1.0 g, b.p.$_{0.1}$ 122–124°) was acetolyzed for 90 h at room temperature in a mixture of acetic acid (30 ml), acetic anhydride (4 ml), and sulfuric acid (1.5 ml). The reaction mixture was worked-up and a portion (300 mg) of the deacetylated product was separated by t.l.c. on four plates of cellulose (20 × 20 cm) developed twice in ethyl acetate – pyridine–water (8:2:1 *v*/*v*). D-Arabinose (95 mg) and D-ribose (118 mg) were isolated. The D-arabinose, on crystallization from aqueous ethanol had m.p. 158–159° and $[\alpha]_D^{22}$ −107° (*c* 2.3 in water). Literature values are m.p. 158.5–160° and $[\alpha]_D^{25}$ −105 ± 3° (equilibrium; *c* 2 in water) (31*a*). The syrupy D-arabinose also yielded *N*-(4-nitrophenyl)-D-arabinosylamine, m.p. 204°, on reaction with *p*-nitroaniline. The literature m.p. is 206° (31*a*). The recovered D-ribose crystallized with m.p. 87–89° and $[\alpha]_D^{22}$ −18.3° (*c* 2.8 in water). Literature values are m.p. 87° and $[\alpha]_D^{25}$ −19° (equilibrium; water) (31*b*).

Epimerization of D-*Ribose in an Acetolysis Mixture*

Crystalline D-ribose (1.0 g) was treated with a mixture of acetic acid (30 ml), acetic anhydride (4 ml), and sulfuric acid (1.5 ml) at room temperature for 24 h. The reaction mixture was worked-up and a portion (200 mg) of the deacetylated product (0.84 g) was separated by chromatography on a sheet of Whatman 3MM paper developed in butanol–pyridine–water (6:4:3 *v/v*). D-Arabinose (70 mg) and D-ribose (82 mg) were isolated. The D-arabinose, $[\alpha]_D^{22}$ −107° (*c* 1.8 in water), was characterized as the dibenzyl dithioacetal, m.p. 148–149° and $[\alpha]_D^{22}$ +17.8° (*c* 1.2 in pyridine). Literature values for the thioacetal are m.p. 149° and $[\alpha]_D$ +18.6° (*c* 3.88 in pyridine) (32).

Epimerization of D-*Mannose in an Acetolysis Mixture*

Crystalline D-mannose (1.0 g) was treated for 24 h at room temperature with a mixture of acetic acid (30 ml), acetic anhydride (4 ml), and sulfuric acid (1.5 ml). The reaction mixture, after work-up and deacetylation in the usual manner, yielded a syrupy product (0.8 g). A portion (300 mg) of the mixture was separated by chromatography on Whatman 3MM paper in ethyl acetate – pyridine–water (8:2:1 *v/v*). D-Glucose (53 mg), $[\alpha]_D^{23}$ +50.1° (*c* 0.78 in water) and D-mannose (189 mg), $[\alpha]_D^{23}$ +14.6° (*c* 1.1 in water), were isolated as syrups. The D-glucose was converted to its dibenzyl dithioacetal, m.p. 136–138° and $[\alpha]_D^{22}$ −97.6° (*c* 0.8 in pyridine). Literature values are m.p. 139° and $[\alpha]_D^{15}$ −98.4° (pyridine) (33). The D-mannose was characterized as its phenylhydrazone, m.p. 200–201°. The literature value is m.p. 199–200° (34).

Non-epimerization of D-*Ribose in an Acetolysis Mixture*

The acetolysis conditions used by Reist *et al.* (18) for converting 4-*S*-benzoyl-4-thio-ribopyranosides to 4-thio-ribofuranose derivatives without observable C-2 epimerization were applied to D-ribose. To an ice-cold solution of acetic acid (38 ml), acetic anhydride (38 ml), and sulfuric acid (2.3 ml) was added 0.9 g (0.06 mol) of D-ribose. The reaction mixture was kept at 0° for 48 h and then decomposed by the addition of anhydrous sodium acetate (8.5 g). The resulting mixture was evaporated to dryness *in vacuo* with the bath temperature below 30°. The residue was partitioned between water (50 ml) and chloroform (20 ml). The aqueous layer was extracted with chloroform (3 × 10 ml) and the combined chloroform extracts were dried (anhydrous sodium sulfate) and evaporated to dryness. The residue was evaporated with methanol several times and then redissolved in chloroform (20 ml). The chloroform solution was washed with saturated sodium bicarbonate solution (3 × 10 ml), dried (anhydrous sodium sulfate), and evaporated to dryness. The resulting syrup (1.27 g) was deacetylated overnight in a solution of methanol (20 ml), water (2.5 ml), and triethylamine (2.5 ml). Evaporation of the mixture yielded a syrup (0.78 g) which was examined by paper chromatography in butanol–pyridine–water (10:3:3 *v/v*). It was composed of ribose with only a trace of arabinose. The syrupy D-ribose crystallized with m.p. 85–86°, mixed m.p. 85–87°, and $[\alpha]_D^{23}$ −18.5° (*c* 1.3 in water)

The above experiment was repeated using the same conditions (0° for 48 h) except that the concentration of sulfuric acid was increased from 2.3 to 3.3 ml. The reaction mixture was worked-up and examined chromatographically. Again, the syrupy product contained mainly D-ribose with only a trace of D-arabinose, barely detectable with the *p*-anisidine and silver nitrate reagents. The mixture contained *ca.* 10% of an unidentified component giving a positive reaction with both spray reagents and having a mobility relative to D-ribose (R_{ribose}) of 1.9.

In another variation, the procedure was repeated as before (D-ribose 0.9 g, acetic acid 38 ml, acetic anhydride 38 ml, sulfuric acid 2.3 ml, time 48 h) but the temperature was room temperature (23°) instead of 0°. The product, after work-up, was examined chromatographically. D-Ribose was the major component with a trace of D-arabinose, *ca.* 30–40% of the component with R_{ribose} 1.9 and a small amount of a second unidentified component with R_{ribose} 2.2.

The author gratefully thanks Mrs. Brigitte Licht for valuable technical assistance and help with translations. This work was made possible by funds received from the Province of Ontario through the Department of Trade and Development.

The Reaction of 5-Unsubstituted-1,2-Dithiole-3-thiones with some Activated Acetylenes

D. M. McKINNON AND J. M. BUCHSHRIBER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 20, 1971

5-Unsubstituted 1,2-dithiole-3-thiones undergo addition reactions with dimethyl acetylenedicarboxylate and dibenzoylacetylene to give amorphous 2-thioformylmethylene-1,3-dithioles. In certain cases these may undergo further addition of activated acetylene to give thiopyranspiro-1,3-dithioles, but may also lose sulfur to give bis-1,3-dithiolylidene-2-butenes, which are probably formed via initial dimerization of the thioformylmethylenedithioles. The stereochemistry of the products is discussed briefly.

Les dithiol-1,2 thiones-3 non substitués en -5 subissent des réactions d'addition avec l'acétylènedicarboxylate de diméthyle et le dibenzoylacétylène pour donner les thioformylméthylène-2 dithioles-1,3 amorphes. Dans certains cas, ceux-ci peuvent additionner de l'acétylène activé pour donner les bis-dithiolylidène-1,3 butènes-2; ces derniers sont probablement formés par une dimérisation initiale des thioformylméthylènedithioles. La stéréochimie des produits est discutée brièvement.

Canadian Journal of Chemistry, **49**, 3299 (1971)

While the reaction of various activated acetylenes with 1,2-dithiole-3-thiones **1** has been studied extensively (1–5), most of these reactions have involved the use of 5-substituted 1,2-dithiole-3 thiones **1***a*. The initial products of the reaction are then 3-thioacylmethylene-1,3-dithioles **2***a*, formed by addition to the thione. Likewise, the reaction of 5-unsubstituted-1,2-dithiole-3-thiones **1***b*, would provide 3-thioformylmethylene-1,3-dithioles, **3**. These, being thials, would be expected to be much less stable than the thiones **2** (6). Little is reported on this type of reaction, but 4-phenyl-1,2-dithiole-3-thione (**1***c*) reacted with dibenzoylacetylene (5) to produce an unstable adduct which was demonstrated to be a thial, and **1***c* reacted with ethyl phenylpropiolate to give a product formed via a thial intermediate (7). It seemed desirable to investigate these reactions further to identify intermediates and products. It was also interesting to determine if the initial adducts reacted with more activated acetylene to form the spiran di-adducts **4** of the type reported for other 5-substituted-1,2-dithiole-3-thiones (3, 5). Most of our studies were performed on 1,2-dithiole-3-thione (**1***d*) and 4-phenyl-1,2-dithiole-3-thione (**1***c*). The activated acetylenes were dimethyl acetylenedicarboxylate and dibenzoylacetylene, and in one case, ethyl phenylpropiolate.

1,2-Dithiole-3-thione (**1***d*) reacted with 1 equiv of dimethyl acetylenedicarboxylate at room tem-

perature to provide two compounds, after only a short reaction time (3 h). The major component, which was not crystalline and was unstable, is probably the compound **3***a*, since its n.m.r. indicated the presence of a proton within the accepted range for thials (8).

A minor component was the only product identified when the reaction was allowed to proceed for 1 day, although then two other products were obtained as uncrystallizable glasses. This other component was probably the tetra-carboxylic ester **5***a* which could have been formed by extrusion of the thial sulfur atoms from two molecules of the thial **3***a*. Confirmation of this was achieved by heating **3***a* in benzene. From the solution **5***a* was obtained, although there were a number of other minor products. Treatment of the thione **1***d* with excess acetylenic ester gave rather similar results. Under no conditions were we able to obtain any diadduct of the type **4**.

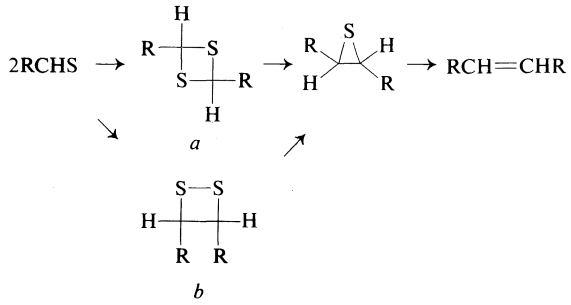
The compounds **5***a* could exist as two geometrical isomers with respect to the central double bond, but we are unable to distinguish what was actually formed, although the *trans* form seems more likely. This compound is probably formed by stepwise extrusion of two sulfur atoms from an initially formed dithiacyclobutane (Scheme 1). Presumably the formation of pyrylenes and dithiopyrylenes (9) from 4*H*-pyran-4-thiones and 4*H*-thiopyran-4-thiones proceeds via a similar scheme. Although the formulation "*b*" of the dimer cannot be excluded, the structure "*a*" appears more likely on the basis of results with other thiocarbonyl compounds. Such dimers are well known (10), although trimers may also be obtained. Thiaphosgene forms dimers (11, 12) and recently such intermediates have been proposed in the reaction of carbon disulfide with dimethyl acetylenedicarboxylate (13). No direct evidence appears to be available for the loss of sulfur from "*a*" to form the episulfide, but certain thiones under the influence of acetylides form both dithiacyclobutanes and episulfides (14). Possibly the former are precursors of the latter. Also, a dithiacyclobutanedioxide loses sulfur dioxide to form an episulfide (15). The last stage in the proposed scheme, the loss of sulfur from the episulfide to form the olefine, is a well-known reaction (16, 17). The geometry of the olefine would be determined by that of the initially formed dithiacyclobutane "*a*" or possibly "*b*". Although a *trans* geometry appears more likely, *cis* cannot be excluded. *Trans* products are common in many such cycloadditions (18).



SCHEME 1

The two other non-crystalline products obtained from the reaction of the acetylenic ester with **1***d* over 1 day were not identified. Spectroscopy (i.r. and n.m.r.) indicated that they were methyl esters of carboxylic acids, but lacking analytical data no satisfactory structure can be advanced.

Very similar results were obtained by treatment of the thione **1***d* with dibenzoylacetylene. Reaction over a short time provided the thial **3***b* as an amorphous brown solid. This was the major product. No tetraketone **5***b* was obtained, but it was the major product when the reaction was performed in boiling benzene for 1 day, and **3***b* gave **5***b* on further heating in benzene. Numerous other fractions were obtained by t.l.c. in these reactions, but in only trace amounts. As in the previous case, no assignment of the geometry of **5***b* was possible. No diadduct of the type **4** was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

isolated under any of the conditions tried with dibenzoylacetylenes, but when the thial **3***b* was heated with dimethyl acetylenedicarboxylate, the compound **5***b* was obtained, along with an orange oil. This could not be crystallized, but its spectroscopic properties indicated it might be the spiran **4***a*.

4-Phenyl-1,2-dithiole-3-thione (**1***c*) reacted with dimethyl acetylenedicarboxylate to give the thial mono-adduct **3***c* as a pasty brown solid. This was insufficiently stable to permit proper isolation, although evidence for the presence of a thial group was obtained. This was accompanied by a trace amount of the aldehyde **6***a* which was also obtained from the thial **3***c* by treatment with mercuric acetate. Further boiling of **3***c* in benzene or xylene gave the tetracarboxylic ester **5***c*, and treatment with more dimethyl acetylenedicarboxylate provided the spiran tetracarboxylic ester **4***b*. Compound **3***c* failed to react with ethylpropiolate. The aldehyde **6***a* was obtained in trace amounts in all these reactions, even when performed under nitrogen and in dry solvents. It appears that it is formed from unreacted thial by aerial oxidation or hydrolysis on the t.l.c. plates, prior to developing.

With dibenzoylacetylene, 4-phenyl-1,2-dithiole-3-thione (**1***c*) has been reported (5) to give an unstable thial. This reaction was further investigated to determine the products of further reaction. The thial **3***d* was obtained as a pasty solid which could not be purified satisfactorily. Refluxing it in benzene gave the tetraketone **5***d* in low yield, but better conversion was achieved in xylene. Small amounts of the spiran tetraketone **4***c* were also obtained from the reaction of the thione **1***c* with dibenzoylacetylene, and this was the major product when the thial **3***d* was treated with dibenzoylacetylene, although small amounts of the tetraketone **5***d* were also found. In all of these reactions, small amounts of the aldehyde **6***b* were obtained. As in the reaction of **1***c* with dimethyl acetylenedicarboxylate, this is probably formed by aerial oxidation of unreacted thial **3***d*.

From the above products, a sequence of reactions may be seen. Reaction of the initial 1,2-dithiole-3-thione **1***c* or *d* with the activated acetylene, first produces a thial mono-adduct, which may react in three ways. One reaction common to all studied is that producing the butendiylidenedithioles **5**. However, where the thial group is stabilized by conjugation to a phenyl group, as in **3***c* or *d*, it is possible that this reaction becomes slower, and other reactions may compete effectively with it, *i.e.* the thial may react with a suitably activated acetylene to form a di-adduct **4** or it may form the corresponding aldehyde **6** by hydrolysis or oxidation.

The n.m.r. spectra of the products derived from dimethyl acetylenedicarboxylate in deuterochloroform are interesting in that while the phenyl substituted compounds **3***c* and **5***c* demonstrate non-equivalence of the methyl groups on the ester function due to their different environments with respect to the exocyclic double bond, the methyl groups on the ester functions of **3***a* and **5***a* are equivalent. Related phenomena have been observed for the reaction products **2***a* of a variety of 1,2-dithiole-3-thiones with acetylenes (1, 4, 19–21). Where the acetylene is unsymmetrical, two geometrical isomeric products are obtained. The detection of non-equivalence or of isomers then seems to be related to the presence of a substituent α to the thiocarbonyl group in the thioacylmethylene-1,3-dithioles (originally a 4-substituent on the starting 1,2-dithiole-3-thione). However, the data for the analogous acylmethylene-1,3-dithioles **2***b* (22, 23) indicate that two isomers are present even where there is no α substituent. Interconversion of the two forms of the thioacyl compounds by isomerization about the exocyclic double bond has been suggested (21), and similar phenomena could render the ester functions equivalent in **3***a*, **5***a*, and other such derivatives of dimethyl acetylenedicarboxylate, but the magnetic equivalence of substituents seems to be merely co-incidental since the n.m.r. spectrum of **5***c* in hexadeuterobenzene, because of its solvent shift effects (24) indicated that the two ester groups had different shifts. The two isomers, however, may be interconvertible by a rate slower than the n.m.r. time scale. Unfortunately, **3***c* was insufficiently soluble in cold benzene to allow any conclusions to be made, and heating caused rapid formation of **5***c*. The aldehyde **6***a* also demonstrated non-equivalence of the ester functions.

Experimental

The i.r. spectra were performed on a Perkin–Elmer model 337 spectrophotometer, in liquid paraffin mulls except where otherwise stated. The n.m.r. spectra were obtained on a Varian Model 50/60A spectrometer, and unless otherwise stated in deuterochloroform solution using tetramethylsilane as an internal standard. Some of these were done in methylene chloride solution but peaks

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were not properly resolved in this. The t.l.c. was performed on 1 mm thick layers of silica gel type D.S.F. 5 supplied by Mondray Ltd. Development of plates was carried out using benzene with increasing proportions of chloroform. Where bands were not properly separated, the separate fractions were re-chromatographed. Melting points were obtained on a Fisher-Johns apparatus. Mass spectra were obtained on a Finnegan 1015 quadrupole mass spectrometer.

Reaction of 1,2-Dithiole-3-thione with Dimethyl Acetylenedicarboxylate

1,2-Dithiole-3-thione (25)(134 mg, 1 mmol) and dimethyl acetylenedicarboxylate (142 mg, 1 mmol) in benzene (30 ml) were stirred at room temperature for 3 h. The solvent was removed in the cold under reduced pressure, and t.l.c. of the crude material gave **3***a* as a brown paste (70%) which could not be purified further.

The n.m.r. of **3***a*, 5.78 (6H singlet, two equivalent CH_3 groups), 1.55 (1H doublet, $J = 7.5$ Hz, vinyl proton), -1.65 τ (1H doublet, $J = 7.5$ Hz, thial proton). The i.r. spectrum 1725 cm^{-1} (C=O str) broad peak in methylene chloride.

Traces of **5***a* (~10 mg) were also obtained as a purple solid. A repeat of the above reaction but for 24 h, and in boiling benzene gave **5***a* as purple matted needles from nitromethane, m.p. 195–197° (42%).

Anal. Calcd. for $C_{18}H_{16}S_4O_8$: C, 44.27; H, 3.28; S, 26.23. Found: C, 44.54; H, 3.06; S, 26.33.

The n.m.r. of **5***a*, 6.20 (12H singlet, four equivalent CH_3 groups), 4.15 τ (4H multiplet, methine protons). The i.r. spectrum, 1740, 1725, 1710 cm^{-1} (C=O str). In deuterobenzene, the methyl groups were evident at 6.77 and 6.75 τ.

Two other fractions were also isolated by t.l.c. (~30 mg each). These were obtained as uncrystallizable orange glasses. The n.m.r. indicated they were methyl esters.

Similar results were obtained when the thione **1***d* was allowed to react with excess acetylenic ester.

*Conversion of Dimethyl 2-Thioformylmethylene-1,3-dithiole-4,5-dicarboxylate (**3***a*) into Tetramethyl 1,4-Butenediylidene-2,2′-bis(1,3-dithiole-4,5-dicarboxylate) (**5***a*)*

The ester **3***a* (100 mg, 0.3 mmol) in benzene (25 ml) was refluxed for 24 h. Examination of the solution gave **5***a* (40%) along with six other fractions which gave only traces of material.

Reaction of 1,2-Dithiole-3-thione with Dibenzoylacetylene

The thione (134 mg, 1 mmol) and dibenzoylacetylene (26) (234 mg, 1 mmol) in benzene (25 ml) were stirred together at room temperature for 3 h. The solvent was removed in the cold under reduced pressure, and t.l.c. of the crude material gave **3***b* as a brown solid (74%). This could not be sufficiently purified for analysis.

The n.m.r. of **3***b*, 2.17 (1H doublet, $J = 7.5$ Hz, vinyl proton), 3.03 to 2.45 (10H bands, aromatic protons), 0.78 τ (1H doublet, $J = 7.5$ Hz, thial proton). The i.r. spectrum, 1660 cm^{-1}, broad, (C=O str) in methylene chloride.

A repeat of the above reaction for 18 h in boiling benzene gave **3***b* (4%) and the tetraketone **5***b* as dark green plates m.p. 203–205° from nitromethane (38%).

Anal. Calcd. for $C_{38}H_{24}S_4O_4$: C, 67.86; H, 3.57; S, 19.04. Found: C, 68.08; H, 3.67; S, 18.97.

The n.m.r. spectrum, 4.31 to 3.70 (4H multiplet, the methine protons), 2.90 to 2.40 τ (20H bands, aromatic protons). The i.r spectrum, 1630 and 1655 cm^{-1} (C=O str).

Ten other bands were also separated, but gave only traces of products. Similar results were obtained when the thione was treated with excess dibenzoylacetylene.

*Reaction of 4,5-Dibenzoyl-2-thioformylmethylene-1,3-dithiole (**3***b*) with Dimethyl Acetylenedicarboxylate to form **4***a*

The thial (20 mg, 0.055 mmol) and the ester (7.7 mg, 0.055 mmol) in benzene (3 ml) were refluxed for 3 h. From the mixture was isolated **5***b* (60%) and a small amount (~10 mg) of an orange glass which was possibly **4***a*.

*Conversion of 4,5-Dibenzoyl-2-thioformylmethylene-1,3-dithiole-(**3***b*) into 1,4-Butenediylidene-2,2′-bis(4,5-dibenzoyl-1,3-dithiole) (**5***b*)*

The diketone (150 mg, 0.24 mmol) in benzene (30 ml) was refluxed for 18 h. Work-up of the mixture gave **5***b* (43%) and ten other minor fractions.

Reaction of 4-Phenyl-1,2-dithiole-3-thione with Dimethyl Acetylenedicarboxylate

The thione (210 mg, 1 mmol) and the ester (142 mg, 1 mmol) in benzene (30 ml) were stirred at room temperature for 1.5 h. Work-up gave **3***c* as a brown pasty solid (85%) which could not be purified satisfactorily.

The n.m.r. spectrum of **3***c*, 6.25 and 6.17 (two 3H singlets, methyl groups), 2.73 (5H singlet, aromatic protons), 0.35 τ (1H singlet, thial proton). The i.r. spectrum, 1740 cm^{-1} (C=O) broad, methylene chloride solution.

Along with this compound was obtained a trace of **6***a*.

*Conversion of Dimethyl α-Phenylthioformylmethylene-1,3-dithiole-4,5-dicarboxylate (**3***c*) into Tetramethyl 1,4-Diphenyl-1,4-butenediylidene-2,2′-bis(1,3-dithiole-4,5-dicarboxylate) (**5***c*)*

The thial (230 mg, 0.65 mmol) in benzene (30 ml) was refluxed for 24 h. Work-up gave the tetracarboxylic ester as reddish-purple needles from nitromethane, m.p. 212–216° (43%).

Anal. Calcd. for $C_{30}H_{24}S_4O_8$: C, 56.25; H, 3.75; S, 20.00. Found: C, 56.17; H, 3.75; S, 19.82.

The n.m.r. spectrum of **5***c*, 6.22 and 6.27 (two 6H singlets, methyl protons), 4.23 (2H singlet, methine protons), 2.92 to 2.42 τ (10H bands, aromatic protons). The i.r. spectrum, 1725 and 1750 cm^{-1} (C=O str).

When the reaction was performed in boiling xylene, the yield was raised to 80%. A small amount (~5 mg) of **6***a* was also obtained in the reaction.

*Preparation of Dimethyl-2-α-phenylformylmethylene-1,3-dithiole-4,5-dicarboxylate (**6***a*)*

The thial **3***c* (120 mg, 0.34 mmol) was added to a hot solution of excess mercuric acetate in acetic acid (10 ml). The dark color of the thial disappeared almost instantaneously. The solution was diluted with water and the benzene extract purified by t.l.c. The product was obtained as orange prisms, m.p. 127–129°, from ethanol:benzene 1:1 (80%).

For personal use only.

Anal. Calcd. for $C_{15}H_{12}S_2O_5$: C, 53.53; H, 3.57; S, 19.04. Found: C, 53.61; H, 3.56; S, 19.21.

The n.m.r. of **6***a* 6.23 and 6.18 (two 3H singlets, methyl groups), 2.73 (5H singlet, aromatic protons), 0.75 τ (1H singlet, thial proton). The i.r. spectrum, 1770 and 1750 (C=O str, from ester), 1630 cm^{-1} (C=O str, from aldehyde).

Reaction of Dimethyl-2-α-phenylthioformylmethylene-1,3-dithiole-4,5-dicarboxylate (3c) with Dimethyl Acetylenedicarboxylate

The thial (274 mg, 0.78 mmol) and the ester (122 mg, 0.78 mmol) in benzene (30 ml) were refluxed for 3 h. Work-up gave the diadduct **4***b* as an uncrystallizable orange glass (40%). Mass spectrum showed a parent ion at *m/e* 494, calcd. 494, *m/e* 435 ($M-CO_2CH_3$)

The n.m.r. spectrum, 6.32 (6H singlet, two equivalent methyls on the dithiole ring), 6.18 and 6.13 (two 3H singlets, methyls on the thiopyran ring), 3.67 (1H singlet, vinyl proton), 2.78 to 2.50 τ (5H bands, aromatic protons). The i.r. spectrum 1720 cm^{-1} (C=O str) broad, in methylene chloride.

Attempted Reaction of Dimethyl α-Phenylthioformylmethylene-1,3-dithiole-4,5-dicarboxylate (3c) with Ethyl Phenylpropiolate

The thial (176 mg, 0.5 mmol) and the ester (87 mg, 0.5 mmol) in benzene (30 ml) were refluxed for 24 h. Only **5***c* was isolated from the mixture. The n.m.r. examination of all fractions indicated none with an ethyl group.

Reaction of 4-Phenyl-1,2-dithiole-3-thione with Dibenzoylacetylene

The thione (420 mg, 2 mmol) and dibenzoylacetylene (464 mg, 2 mmol) in benzene (40 ml) were stirred at room temperature for 2½ h. Work-up of the mixture gave **3***d* as a brown powder, which could not be purified sufficiently for analysis (71%).

The n.m.r. of **3***d*, 2.99 to 2.50 (15H bands, the aromatic protons), −0.65 τ (1H singlet, the thial proton). The i.r. spectrum 1655 cm^{-1} (C=O str) broad, in methylene chloride.

Compound **4***c* was also isolated as a yellow powder, m.p. 89–92° (14%).

Anal. Calcd. for $C_{41}H_{20}S_3O_4$: C, 72.57; H, 3.83; S, 14.22. Found: C, 72.47; H, 3.80; S, 14.06.

The n.m.r. spectrum of **4***c*, 3.45 (1H singlet, vinyl proton), 3.10 to 2.11 τ (25H bands, the aromatic protons). The i.r. spectrum 1675 and 1640 cm^{-1} (C=O str).

Conversion of 2-α-Phenylthioformylmethylene-4,5-dibenzoyl-1,3-dithiole (3d) into 1,4-Diphenyl-1,4-butenediylidene-2,2′-bis(4,5-dibenzoyl-1,3-dithiole) (5d)

The thial (160 mg, 0.36 mmol) in xylene (26 ml) was refluxed for 24 h. Examination of the mixture gave **5***d* as purple needles, m.p. 244–246° (51%).

Anal. Calcd. for $C_{50}H_{32}S_4O_4$: C, 72.94; H, 3.90; S, 15.54. Found: C, 72.72; H, 4.04; S, 15.39.

The n.m.r. spectrum of **5***d*, 4.10 (2H singlet, methine protons), 3.00 to 2.35 τ (30H bands, the aromatic protons). The i.r. spectrum, 1675 cm^{-1} (C=O str) broad.

Also obtained was **6***b* as an orange oil which could not be crystallized (16%). This compound was also prepared below.

The n.m.r. of **6***b*, 3.07 to 2.33 (15H bands, the aromatic protons), 0.72 τ (1H singlet, the aldehydic proton). The i.r. spectrum, 1655 and 1625 cm^{-1} (C=O str). The mass spectrum *m/e* 428 (parent peak) calcd. 428.

Preparation of 2-α-Phenylformylmethylene-4,5-dibenzoyl-1,3-dithiole (6b)

The thial **3***d* (200 mg, 0.45 mmol) in boiling acetic acid (10 ml) was treated with an excess of mercuric acetate. The solution turned yellow after 5 min and the mixture was poured into water and extracted with benzene. Evaporation gave **6***b* as an uncrystallizable oil (85%). The mass spectrum, *m/e* 428 (parent peak), 234 ($M-(PhCO\cdot C)_2$), 194; 105 ($PhCO^+$).

Reaction of 2-α-Phenylthioformylmethylene-4,5-dibenzoyl-1,3-dithiole (3b) with Dibenzoylacetylene

The thial (165 mg, 0.47 mmol) and dibenzoylacetylene (110 mg, 0.47 mmol) were refluxed in benzene (20 ml) for 18 h. Examination of the mixture gave **4***c* (70%), **5***d* (6%), and **6***b* (6%). Also isolated was 49 mg of another orange solid, m.p. 190–193°. The mass spectrum *m/e* 573 (possibly metastable peak), 105 ($PhCO^+$).

Anal. Found: C, 73.08; H, 3.88; S, 13.98. This possibly corresponds to an isomer of **4***c*.

Anal. Calcd. for $C_{41}H_{20}S_3O_4$: C, 72.57; H, 3.83; S, 14.22.

The n.m.r. spectrum of the compound, 3.05 to 2.15τ (25H bands, aromatic protons). The i.r. spectrum 1700, 1655, and 1645 cm^{-1} (probably C=O str).

The authors wish to thank Mr. R. Dickinson for the preparation of n.m.r. spectra, and Mr. M. Arneson for mass spectra. Financial support by the National Research Council of Canada is gratefully acknowledged.

Isomers of 1-(4-Chlorophenyl)-2,3-dimethylisoindoline

K. R. Freter and F. K. Hess
Pharma-Research Canada Ltd., 250 Hymus Blvd., Pointe Claire, Québec
AND
J. Sygusch and F. Brisse
Département de Chimie, Université de Montréal, Montréal, Québec

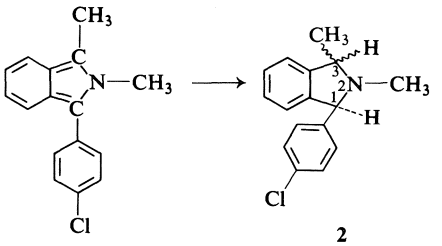
Received June 21, 1971

The chemical properties and n.m.r. data of the two isomers of 1-(4-chlorophenyl)-2,3-dimethylisoindoline are reported. The crystal structure of one of the isomers was determined by X-ray diffraction.

Les propriétés chimiques et les données r.m.n. relatives aux deux isomères du (chloro-4 phényl)-1 diméthyl-2,3 isoindoline sont rapportées. La structure cristalline de l'un des isomères a été déterminée par diffraction de rayons-X.

Canadian Journal of Chemistry, 49, 3305 (1971)

Reduction of 1-(4-chlorophenyl)-2,3-dimethylisoindole (**1**) with zinc in acetic acid gave in a good overall yield the expected isoindolines (**2***a* and *b*), which could be separated by column chromatography on silica with chloroform.



1 → **2**

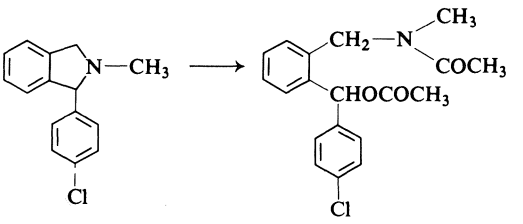
a 15%
b 58%

Each isomer could be equilibrated with the other, in acetic anhydride solution in the presence of boron trifluoride. This finding corresponds with the recently published result on 1,3-dimethylisoindolines (1).

Refluxing of either of the isomers in acetic anhydride even for several days left them unchanged. This was unexpected in view of the fact, that the 3-unsubstituted isoindoline, **3**, like phenyl substituted-tetrahydrocarbolines (2) or -tetrahydroisoquinolines (3), yields the corresponding benzhydrol **4** in a matter of hours (4).

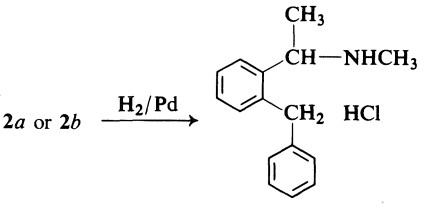
Catalytic hydrogenolysis of **2***a* or *b* on the other hand, followed smoothly the expected course yielding in both instances the same *o*-benzyl-benzylamine, **5**.

The n.m.r. signals (Table 1) for both isomers show pronounced differences. The chemical



3 → **4**

shifts of the methine protons of **2***a* and *b* (as hydrochlorides) differ considerably (see Table 1). More interesting is the fact, that the signals of these protons (the H-1 singlet and the H-3 quartet), show splitting (**2***a*, J = 2.7 Hz; **2***b*, J = 2.5 Hz), when the spectra of the free bases are measured. This seems to be an example of long-range coupling "across" a non-aromatic heterocycle; the coupling constants are considerably greater than usually observed for long-range coupling along 4σ bonds (5).[1] A conclusion, however,



5

[1]While this work was in progress, another related example of long-range coupling in the dihydrofuran series was reported (6), where coupling constants of $J_{2,5}$ = 0.4 Hz for *cis*- and 4.0 Hz for *trans*-derivatives were found.

TABLE 1. The n.m.r. data for isoindolines **2***a* and *b*

	τ (ppm)*			
Proton	**2***a* HCl (D_2O)	**2***b* HCl (D_2O)	**2***a* Base ($CDCl_3$)	**2***b* Base ($CDCl_3$)
8H	2.1–3.0 m	2.0–2.9 m	2.7–3.5 m	2.7–3.5 m
C_1-H	3.93 s	3.61 s	5.54 d (J = 2.7)	5.14 d (J = 2.5)
C_3-H	4.84 q (J = 7)	4.64 q (J = 7)	6.30 q (J = 6.5) d (J = 2.7)	5.66 q (J = 6.5) d (J = 2.5)
N-CH_3	6.74 s	6.95 s	7.63 s	7.72 s
C-CH_3	8.00 d (J = 7)	7.98 d (J = 7)	8.53 d (J = 6.5)	8.74 d (J = 6.5)

*All J-values are Hz.

about *cis–trans* assignment on grounds of the difference in these long-range coupling constants cannot be drawn.

The same holds true for the difference in chemical shifts. Interpretation in the case of symmetrically substituted isoindolines has previously led to erroneous assignments (7), which could be corrected only by application (8) of the *N*-benzyl method of Hill and Chan (9). This, of course, is of no help in this case of unsymmetrical substitution.

The shielding and deshielding effects of the chlorophenyl ring in 1-position on the protons of the 3-methyl group and on the 3-proton are opposite for both isomers. While in **2***a* the 3-methyl signal is shifted to lower field and the H-3 signal to higher field, the reverse is true for **2***b*. A decision, in which case the 1-chlorophenyl substituent exerts its shielding or deshielding influence, rests solely on the question, which orientation this substituent takes.

We were unable to predict from model studies, whether this substituent takes a coplanar or perpendicular position, or any intermediate angle relative to the (almost) planar isoindoline system.

A recent publication (10) about similarly substituted phthalans augmented our hesitation, to predict the stereochemistry on grounds of n.m.r. studies alone.

An X-ray diffraction study was then undertaken to determine the relative stereochemistry of the substituents at C-1 and -3.

Good crystals of indoline **2***a* were obtained from methanol solutions. Precession photographs indicated that the space group is $P2_1/c$ and that there are four molecules in a monoclinic unit cell of dimensions: a = 9.071(2), b = 12.443(3), c = 11.945(4) Å and β = 93.19(10)°. Three dimensional intensity data were collected with an automatic Picker diffractometer using MoKα radiation. Of the 1851 measured reflexions, 1639 were observed. The phases of 234 reflexions with normalized structure factors E greater than 1.50 were determined by the symbolic addition procedure for non-centrosymmetric crystals as described by Germain *et al.* (13). An E-map calculated with the 234 phased reflexions yielded all the non-hydrogen atoms. The atomic parameters were refined by the least-squares procedure using the programs written by Ahmed *et al.* (11). After five cycles of isotropic temperature factor refinement followed by two cycles of anisotropic temperature factor refinement, the R-factor decreased to 9.9%.

At this stage a Fourier difference map revealed the positions of 10 hydrogen atoms which were subsequently included in the refinement. So far the refinement, still in progress, has reached an R-factor of 7.6%.

The molecular structure projected on the 100 plane is shown in Fig. 1. Indoline **2***a* can thus be said to be *cis*-1-(4-chlorophenyl)-3-methyl-2-methylisoindoline. The bond distances and angles are in good agreement with expected values. The complete results of the X-ray investigation will be published elsewhere.

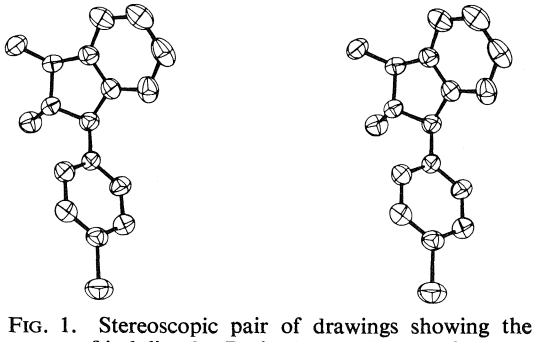

FIG. 1. Stereoscopic pair of drawings showing the structure of indoline **2***a*. Projection on the 100 plane.

Experimental

The n.m.r. spectra were determined on a Varian Associates Model T-60. Melting points were taken on a Fisher-Johns Apparatus and are uncorrected. Microanalyses were carried out by Dr. C. Daesslé, Montreal, Québec.

1-(4-Chlorophenyl)-2-methylisoindolone-(3)

2-(4-Chlorobenzoyl)benzoic acid was treated with aqueous methylamine at 180° as described for the unsubstituted phenyl compound (12); m.p. 128–129 °C; mol. wt. 257; yield 75%.

Anal. Calcd. for $C_{15}H_{12}ClNO$: C, 70.00; H, 4.67; N, 5.44; Cl, 13.74. Found: C, 70.11; H, 4.71; N, 5.65; Cl, 13.93.

1-(4-Chlorophenyl)-2,3-dimethylisoindole (1)

This compound was prepared in 60% yield, from the above isoindolone according to Theilacker and Schmidt (12) with methyl lithium solution; m.p. 124–126 °C; mol. wt. 255.7.

Anal. Calcd. for $C_{16}H_{14}NCl$: C, 75.20; H, 5.52; N, 5.48; Cl, 13.85. Found: C, 74.77; H, 5.86; N, 5.75; Cl, 13.75.

1-(4-Chlorophenyl)-2,3-dimethylisoindoline (2a and b)

The isoindole (**1**) (26.7 g) was dissolved in glacial acetic acid (150 ml) and water (100 ml), and zinc dust (25 g) was introduced under stirring in several portions. The mixture was heated to reflux for 30 min, diluted with water (200 ml), filtered to remove excess zinc, and made basic with concentrated ammonia. The basic material was extracted with ether, the combined ether extracts were washed with water, dried over magnesium sulfate, and evaporated to dryness. The oily residue (22.6 g) was separated on a silica gel column using chloroform as eluant. Two major basic fractions were obtained. The one leaving the column first (**2***a*) was a colorless oil (4g, 14.8%) which was converted to the hydrochloride by addition of ethereal hydrochloric acid. It was recrystallized from acetone/ether and had an m.p. of 210–219 °C (dec.); m.p. of the free base 87–88° (acetone–water).

The second fraction, **2***b*, 15.8 g of colorless oil (58.5%) was transformed to the hydrochloride by the same method. After recrystallization it had an m.p. of 208–218 °C (dec.); m.p. of the free base 83° (acetone–water); mol. wt. 294.2.

Anal. Calcd. for $C_{16}H_{16}ClN{\cdot}HCl$: C, 65.35; H, 5.82; N, 4.79; Cl, 24.08. Found for **2***a* (R_F 0.6): C, 65.03; H, 5.83; N, 4.89; Cl, 24.06. Found for **2***b* (R_F 0.2): C, 65.39; H, 5.41; N, 4.51; Cl, 24.08.

The R_F values refer to t.l.c. on silica, chloroform as eluant.

2-Benzyl-α,N-dimethylbenzylamine (5)

The above isoindoline (either isomer as free base) (4 g) was dissolved in ethanol (100 ml), palladium-on-charcoal (5%, prehydrogenated) (1 g) was added, and the mixture was shaken in an atmosphere of hydrogen at room temperature and atmospheric pressure.

The uptake of hydrogen came to an end, when 770 ml were consumed (calculated 750 ml). The mixture was filtered and evaporated to dryness. The residue was crystallized from ethanol and had an m.p. of 175–176 °C; 3 g (75%); mol. wt. 261.8.

Anal. Calcd. for $C_{16}H_{19}N{\cdot}HCl$: C, 73.20; H, 7.69; N, 5.35; Cl, 13.55. Found: C, 73.20; H, 7.82; N, 5.60; Cl, 13.70.

The n.m.r. (τ) in D_2O, 1.8–2.7 m (9H), 5.17 q (J = 7.0 Hz) (1H), 5.68 s (2H), 7.35 s (3H), 8.37 d (J = 7.0 Hz) (3H).

Conversion from 2b into 2a

The free base, liberated from the hydrochloride of **2***b* (2g), was dissolved in acetic anhydride (20 ml), 2 drops of boron trifluoride were added, and the mixture was heated for 2 days to reflux. The mixture was then poured on ice–ammonia, extracted with chloroform, and the residue of the chloroform extract separated as described above. An oil (0.7 g) was obtained, which was identical with respect to i.r., m.p. of hydrochloride, and t.l.c. with **2***a*.

The fact, that equilibrium could be reached by subjecting **2***a* to the same conditions, was established only by t.l.c.

The authors wish to thank Mrs. A. Thomas for her skillful assistance.

Hydration of CN^-, NO_2^-, NO_3^-, and OH^- in the Gas Phase

J. D. PAYZANT, R. YAMDAGNI, AND P. KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alberta

Received April 14, 1971

By measuring the $A^-(H_2O)_{n-1} + H_2O = A^-(H_2O)_n$ equilibria in the gas phase and their temperature dependence, the equilibrium constants and $\Delta H_{n,n-1}$ and $\Delta S_{n,n-1}$ for some of the hydrates of NO_2^-, NO_3^-, CN^-, and OH^- were determined. Available thermochemical data are used for the evaluation of the total heats of hydration of the above ions. The total heats of hydration were then compared with the $\Delta H_{1,0}$. Relative to the total hydration energies the $\Delta H_{1,0}$ of the above ions were found larger than the $\Delta H_{1,0}$ of the halide ions.

An approximate linear correlation was found to exist between $\Delta H_{1,0}$ of negative ions and the heterolytic bond dissociation energy $D(A^- - H^+)$. With this relationship independent estimates for the electron affinities of NO_2 and NO_3 could be obtained.

The $\Delta H_{n,n-1}$ of OH^- were found in essential agreement with earlier measurements from this laboratory and in disagreements with recent measurements (Friedman) which gave much higher values.

En mesurant les équilibres $A^-(H_2O)_{n-1} + H_2O = A^-(H_2O)_n$ en phase gazeuse et leurs dépendances par rapport à la température, pour quelques hydrates de NO_2^-, NO_3^-, CN^- et OH^-, les constantes d'équilibre, $\Delta H_{n,n-1}$ et $\Delta S_{n,n-1}$ ont été déterminées. Les données thermodynamiques disponibles ont été utilisées pour évaluer les chaleurs totales d'hydratation de ces ions. Les chaleurs totales d'hydratation ont été comparées avec $\Delta H_{1,0}$. Relativement aux énergies totales d'hydratation, les valeurs $\Delta H_{1,0}$ pour ces ions sont plus importantes que les valeurs de $\Delta H_{1,0}$ pour les ions halogénés.

Une corrélation presque linéaire existe entre les valeurs de $\Delta H_{1,0}$ des ions négatifs et l'énergie de dissociation de la liaison hétérolytique $D(A^-—H^+)$. Au moyen de cette corrélation, des estimations indépendantes de l'électron affinité de NO_2 et NO_3 ont été obtenues.

Les valeurs $\Delta H_{n,n-1}$ de OH^- ainsi trouvées sont en bon accord avec les mesures obtenues antérieurement dans ce laboratoire et sont en désaccord avec des mesures récentes (Friedman) conduisant à des valeurs bien plus élevées.

Canadian Journal of Chemistry, 49, 3308 (1971)

I. Introduction

The present work is a continuation of gas phase ion equilibria studies dealing with the interaction of polar molecules with positive and negative ions. The studies consist in experimentally determining the temperature dependence of the equilibrium constant $K_{n,n-1}$ for the general reaction $(n,n-1)$ occurring in the gas phase. Van't Hoff plots of the equilibrium constants lead then to the enthalpy and entropy changes

$$A^{\pm}(B)_n = A^{\pm}(B)_{n-1} + B \qquad (n,n-1)$$

$\Delta H_{n,n-1}$ and $\Delta S_{n,n-1}$. Previous studies include the positive ions H^+ with B = H_2O (1), NH_3 (2), CH_3OH (3), the alkali ions with B = H_2O (4), the negative ions: F^-, Cl^-, Br^-, I^- with H_2O (5) and OH^- with H_2O (6).

The choice of CN^-, NO_2^-, and NO_3^- was dictated by several considerations. Firstly these ions play an important part in reactions in aqueous solutions. After the study of the spherical halide ions an investigation of some non-spherical ions seemed of interest.

The ions NO_2^-, NO_3^- and their hydrates $NO_2^-(H_2O)_n$ and $NO_3^-(H_2O)_n$ are probably of importance to the ionic chemistry in the D region of the ionosphere. The recent rocket borne mass spectrometer measurements by Narcissi (7) indicate that $NO_3^-(H_2O)_n$ is the dominant negative ion at altitudes below 90 km. Laboratory measurements of the hydration equilibria of NO_3^- thus for this reason also appeared of interest. The equilibrium constants would permit the calculation of the equilibrium concentrations of $NO_3^-(H_2O)_n$ at different water concentrations and temperatures and set limits on the $NO_2^-(H_2O)_n$ ratios that might be expected in the ionosphere. A comparison with the calculated (8) ionospheric ratios of the hydrated positive ions $H^+(H_2O)_n$ could then also be made. The equilibrium constants can be also used for the evaluation of the reverse reactions once the rate constants for the forward reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

have been determined by laboratory measurements. In most cases the rate constants for the forward reactions have not been determined. Nevertheless the $\Delta H_{n,n-1}$ remain useful guides to the decomposition rates of the clusters n since the activation energies for the decomposition E_n should be very close to the enthalpy changes $\Delta H_{n,n-1}$. An example of a situation where a qualitative guide to the dissociation rate constants is of value is the interpretation of the rocket borne mass spectrometer data of the lower ionosphere. The ions before sampling pass through a shock front caused by the motion of the rocket. Depending on the temperature in the front some clusters might decompose while others with high $\Delta H_{n,n-1}$ values might survive. Knowledge of the $\Delta H_{n,n-1}$ values allows a check on the consistency of the mass spectral data even though they might be affected by the shock wave.

One final reason for selecting the NO_2^- and NO_3^- ions was the existence of a relationship between the hydration interaction $\Delta H_{1,0}$ and the electron affinity of the uncharged species (6). This relationship permits an estimate of the as yet not completely established values of the electron affinities of NO_2 and NO_3.

Results from this laboratory for the $\Delta H_{n,n-1}$ of the OH^- hydration were published not too long ago (6). However, a more recent investigation by Friedman and co-workers (9, 10) based on a different (non equilibrium) method reported substantially higher $\Delta H_{n,n-1}$ values. The earlier equilibrium determinations (6) were not done with a pulsed electron beam, *i.e.* the time dependence of the ion concentrations was not followed. (See Experimental section.) It was therefore thought important to repeat the equilibrium experiments with measurements of the time dependence of the ions so as to place the equilibrium data on a firmer footing.

II. Experimental

(a) Apparatus, Method of Measurement, and Experimental Data

The measurements of the equilibrium constants $K_{n,n-1}$ were made by mass spectrometric detection of the ions escaping from a reaction chamber. The pressure in the reaction chamber – ion source was in the Torr range, typically 0.5 to 5 Torr. Ionization was obtained by a 2000 V electron beam of some 10^{-8} A entering the field-free reaction chamber through a narrow slit. The ion exit slit was about 4 mm below the electron beam. For these conditions the average ion escaping through the slit had spent some 1 ms in the reaction chamber. The ion currents detected with the mass spectrometer were assumed proportional to the concentrations of the ions in the reaction chamber.

The above apparatus has been described in greater detail in a previous publication (5). In the present work data were obtained by two different procedures. In some measurements continuous electron irradiation was used and the measured ion currents were assumed to come predominantly from ions which have spent sufficiently long time in the reaction chamber to have achieved equilibrium. In other experiments the electron beam was pulsed, using a program in which the beam was on for some 10 or 50 μs and off for some 5 ms. The off time was equal to time required for the ion current to decay essentially to zero. The mass analyzed individual ion pulses, after amplification, were fed into a multiscaler where the ions were collected in different chanels according to the time of arrival after the electron pulse. The intensity–time dependence plots so obtained were used to examine whether the ion ratios become stationary with time. Constant ion ratios with time must be present if the equilibrium is achieved. The above procedure is essentially identical to the method used for kinetic studies of ion molecule reactions described in previous publications (11). The only difference is the use of the multiscaler with which the effective sensitivity is greatly increased. Figure 1 shows the time dependence of the ion intensities for NO_2^- and $NO_2^-.H_2O$. The ratio of the ion intensities is seen to be essentially independent of time. The initial history of the reaction, *i.e.* the de-

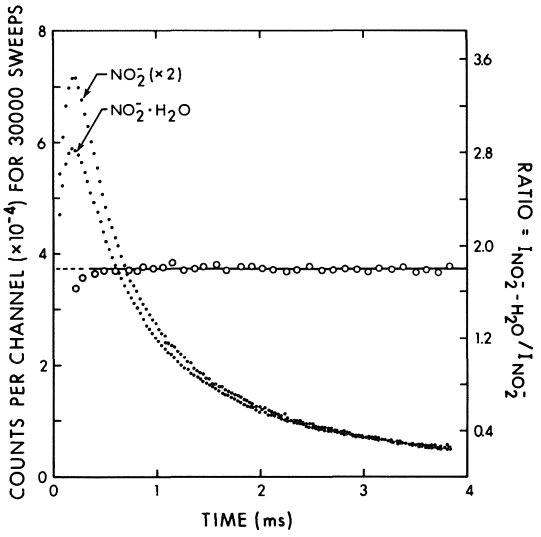

FIG. 1. Time dependence of NO_2^- and $(NO_2H_2O)^-$ ions escaping from ion source after start of short (10 μs) electron pulse. Ion source pressure 4.1 Torr H_2O vapor, temperature 164 °C. Ion intensity ratio required to be constant if equilibrium $NO_2^- + H_2O \rightleftharpoons (NO_2H_2O)^-$ is achieved.

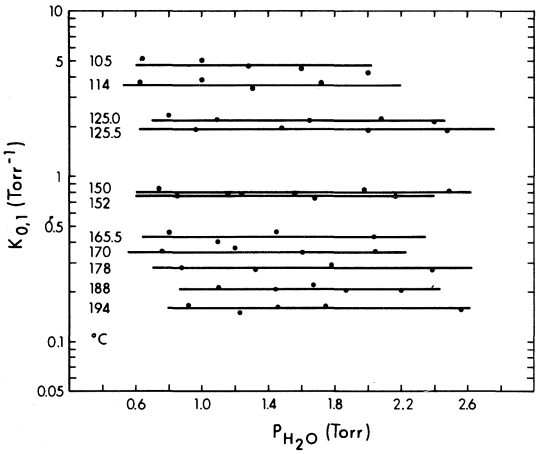

FIG. 2. Equilibrium constant $K_{0,1}$ for reaction: $CN^- + H_2O \rightleftharpoons (CNH_2O)^-$ *vs.* pressure of water in ion source.

crease of NO_2^- and the increase of $NO_2^-.H_2O$ on the approach to equilibrium, cannot be seen on the figure since concentration conditions are so selected that equilibrium is rapidly achieved. Thus the rate constant for the third body dependent forward reaction 1 should be (12) $k_1 \approx 10^{-28}$ cm^6 molecule^{-2} s^{-1}.

[1] $$NO_2^- + 2H_2O \rightleftharpoons NO_2^-.H_2O + H_2O$$

At a pressure of 4 Torr H_2O, this leads to a half-life of about 1 μs for the NO_2^- ion with regard to disappearance by the forward step of reaction 1.

Shown in Fig. 2 is the pressure independence of the equilibrium constants $K_{1,0}$ for the CN^- hydration reactions. The equilibrium constants were evaluated from the known H_2O pressure and the stationary ion ratios. Van't Hoff plots for the NO_2^-, NO_3^-, and CN^- hydration reactions are shown in Fig. 3. The present data for the NO_2^- hydration equilibrium can be compared with earlier results from this laboratory. In an earlier general survey of negative ion hydration (Kebarle, Arshadi, and Scarborough (5)) the equilibrium constants $K_{1,2} \approx 46$ and $K_{2,3} \approx 3$ (Torr^{-1}) were measured at ~292 °K. The present data in Fig. 3 extrapolated to 292 °K lead to $K_{1,2} \approx 44$ and $K_{2,3} \approx 2$. This represents fairly good agreement, considering the difference of the apparatus used, temperature and pressure measurement (the previous work was done in the presence of O_2 as the major gas component).

(b) Production of NO_2^- and NO_3^-

The NO_2^- and NO_3^- ions were produced by the addition of some 5×10^{-2} Torr of $C_2H_5ONO_2$ to the water vapor which was in the Torr range. This method of production had been used in the earlier investigation (5). Primary and secondary electrons slowed down to near thermal velocities are probably involved in dissociative electron capture by the ethyl nitrate. The products of slow electron dissociative capture and ion molecule reactions at low pressures in ethyl nitrate have been

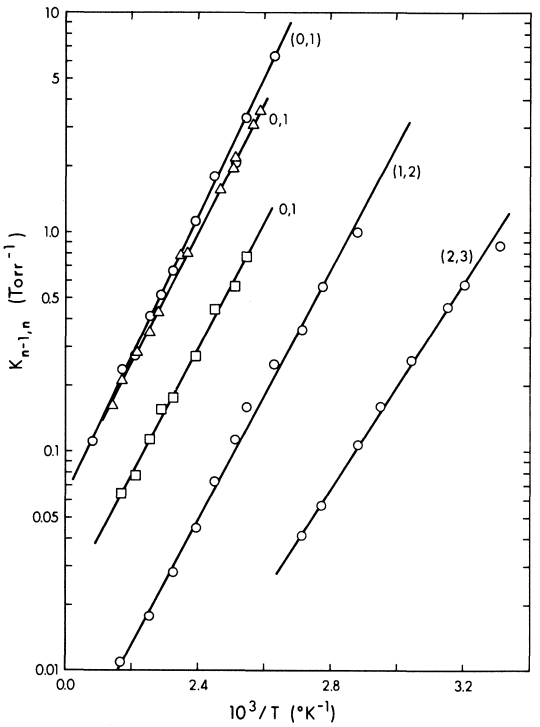

FIG. 3. Van't Hoff plot of equilibrium constants $K_{n-1,n}$ for reactions $A^-(H_2O)_{n-1} + H_2O = A^-(H_2O)_n$ in the gas phase. ○, NO_2^-; △, CN^-; □, NO_3^-.

studied by Kriemler and Buttrill (13). NO_2^- is the major product of the electron capture, $C_2H_3O^-$, $C_2H_5O^-$, OH^-, and HNO_2^- are also produced by the same process and found to yield NO_3^- by ion molecule reactions with ethyl nitrate.

The presence of NO_3^- in the present (high pressure) experiments is probably explained by the same processes. Interestingly the NO_3^- to NO_2^- yield (roughly 1:4) was found to decrease at low temperature. Near room temperature very little NO_3^- was formed. This prevented measurement of the higher hydration equilibria ($n = 2$ and 3) of NO_3^- which occur near and below room temperature.

(c) Production of CN^-

The cyanide ion was produced by the addition of some 5×10^{-2} Torr of cyanogen iodide to oxygen carrier gas (~5 Torr) containing variable pressures of H_2O (0.8–2.5 Torr). The CN^- ion is probably produced by dissociative capture, reaction 2,

[2] $$e + CNI \rightarrow CN^- + I$$

of the electrons slowed down by the gas in the reaction chamber. Reaction 2 is exothermic (with thermal electrons). Unfortunately only the 1,0 hydration equilibrium was measured. No experimental difficulties should exist for the measurement of the equilibria for the higher hydrates of this ion.

(d) Reproducibility and Error Estimate

Measurements under different experimental conditions and apparatus have shown that the equilibrium constants can be reproduced within 10–20% when measured on the same instrument. The error increases to ~50% if the clustering gas is a minor component of the gas mixture used. This is due to errors in the concentration determination of this component. A systematic 50% error in the equilibrium constant leads to ~0.3 kcal error in the ΔG^0 and no error in the ΔH. In practice the ΔH determinations have been found reproducible to within 5% when different instruments were used. These deviations are probably due to errors in temperature measurement. The nature of the experiments is such that no absolute error limit can be quoted.

III. Discussion of Results

(a) Hydration of CN^-, NO_2^-, and NO_3^-

The $\Delta H_{n,n-1}$ and $\Delta S^0_{n,n-1}$ obtained from the slopes of the intercepts of the Van't Hoff plots (Fig. 3) are given in Table 1. The previously determined values for the halide ions are also given in Table 1 for comparison purposes.

The total single ion heats of hydration $\Delta H_h(A^-)$ also given in Table 1 correspond to the enthalpy change for the process $A^-_{(gaseous)} \rightarrow A^-_{(aquated)}$. The values for F^-, Cl^-, Br^-, and I^- were taken from the review article of Desnoyers and Joliceur (15). The values for OH^-, CN^-, NO_2^-, and NO_3^- were calculated from the thermochemical data given in Table 2. The calculation of these values is discussed in section *IIIc*.

TABLE 2[a]

A^-	$\Delta H_f(A^-,aq)conv$	$\Delta H_f(A,g)$	e.a.(A)
OH^-	−55[b]	9.31[b]	42.5[c]
CN^-	36[b]	106.5[d]	88[d]
NO_2^-	−25[b]	7.9[b]	~55[f]
NO_3^-	−45.6[b]	16.6[e]	~90[f]

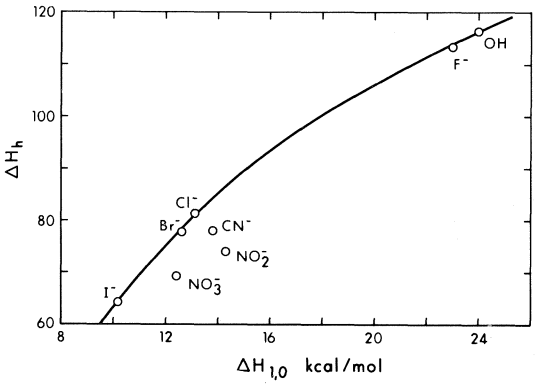

FIG. 4. Plot of total heat of hydration for negative ions A^- *vs.* $\Delta H_{1,0}$, where $\Delta H_{1,0}$ corresponds to enthalpy change for reaction $AHOH^- \rightarrow A^- + H_2O$.

The $\Delta H_{1,0}$ values are compared with the total single ion heats of hydration in Fig. 4. One finds that the halide ions give a continuous curve in this plot. The CN^-, NO_2^-, and NO_3^- ions are displaced from this curve towards relatively larger $\Delta H_{1,0}$ values than those for the halogens. The relatively stronger interactions with the initial water molecules for the unsymmetrical ions are not unexpected. They probably reflect specific hydrogen bonding to the electro negative groups (O atoms in NO_2^- and NO_3^- and N atom in CN^-).

An examination of the change of $\Delta H_{n,n-1}$ with n would be of considerable interest. Unfortunately

For personal use only.

values up to $n = 3$ were obtained only for the NO_2^- ion (Table 1). The oxygen atoms in NO_2^- are known to form an angle of $\sim 115°$ and the N–O distance is 1.24 Å. The electronic structure of NO_2^- indicates an excess of electronic charge on the O atoms. Therefore, one would expect that the first two water molecules would hydrogen bond to the O atoms and the third one to the N atom. Furthermore the $\Delta H_{2,1}$ should only be a little smaller than $\Delta H_{1,0}$ while the $\Delta H_{3,2}$ should be appreciably lower than the $\Delta H_{2,1}$. The experimental values are 14.3, 12.9, and 10.4 kcal/mol showing a drop of 1.4 kcal between $\Delta H_{1,0}$ and $\Delta H_{2,1}$ and 2.5 kcal between $\Delta H_{2,1}$ and $\Delta H_{3,2}$. The difference of 1.4 kcal between $\Delta H_{1,0}$ and $\Delta H_{2,1}$ for the NO_2^- ion appears somewhat larger than what would be expected. Unfortunately the accuracy of the experimental determinations which is estimated at around 5% is insufficient so that one cannot be certain whether the relatively large drop of 1.4 kcal is real or not.

(b) Relationship between $\Delta H_{1,0}$ for Hydration of Negative Ions B^- and Heterolytic Bond Energy B^-—H^+

An approximate correlation of the enthalpy change $\Delta H_{1,0}$ for the (1,0) reaction: $(BHOH)^- \rightarrow B^- + HOH$ with the heterolytic bond energy $D(B^-—H^+) = D(B—H) + I_p(H) - e.a.(B)$ might be expected on the grounds that the strength of the hydrogen bond B^----HOH which is broken in reaction (1,0) should be related to $D(B^-—H^+)$ since the bridging H atom in the hydrate $(BHOH)^-$ must carry appreciable positive charge induced by the negative group B^-. A plot of $\Delta H_{1,0}$ *vs.* $D(B^-—H^+)$ is shown in Fig. 5 for $B^- = I^-, Br^-, Cl^-, F^-, OH^-$, and the newly measured NO_2^-, NO_3^-, and CN^- ions. The first group of ions can be fitted by a straight line. Of course there is no *a priori* reason that the relationship, if it exists, needs be linear. The observed deviation of Cl^- is almost certainly due to experimental error since it must be expected that the halogens should give a smooth curve. Probably the experimental $\Delta H_{1,0}$ for Cl^- is low by 0.8 to 1 kcal. The deviation of OH^- (relative to F^-) may be due to experimental error or to a real departure from the relationship due to the structural difference between F^- and OH^-. The electron affinities (e.a.) of NO_2 and NO_3 are not well established. Therefore, using the experimental $\Delta H_{1,0}$ we have placed these two ions on the

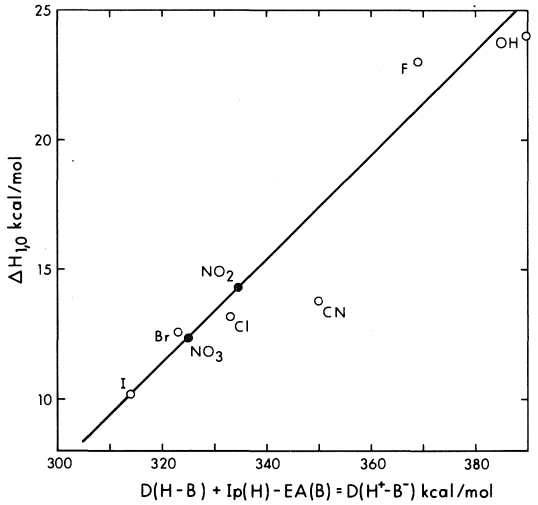

FIG. 5. Plot of $H_{1,0}$ for hydrate $(AHOH)^-$ *vs.* the heterolytic bond dissociation energy $D(H^+ — A^-)$ corresponding to process $HA \rightarrow H^+ + A^-$.

line. The values for $D(B^-—H^+)$ defined by this procedure lead to electron affinities of NO_2 and NO_3. With the supporting thermochemical data $\Delta H_f(HNO_{2,g}) = -19$ kcal (15), $\Delta H_f(HNO_{3,g}) = -32.3$ kcal (15), $\Delta H_f(NO_2) = 7.9$ kcal (15), $\Delta H_f(NO_3) = 16.6$ kcal (16) one obtains e.a.(NO_2) = 57 kcal or 2.5 eV and e.a.(NO_3) = 90 kcal or 3.9 eV. These values are close to what might be expected. Berkowitz and Chupka (17) in their recent determinations of electron affinities by endothermic charge transfer conclude that $2.1 <$ e.a.$(NO_2) < 2.3$ eV. For NO_3 Berkowitz and Chupka suggest $3.09 <$ e.a.$(NO_3) < 3.2$ eV. The present estimate of 3.9 is somewhat higher and agrees with a value based on an old lattice energy calculation (18) which need not be considered very accurate. The $\Delta H_f(NO_3) = 16.6$ kcal was determined by a somewhat questionable method. This heat of formation leads to $D(H—NO_3) = 100.6$ kcal while $D(H—NO_2) =$ 80 kcal can be evaluated from the data given above.

The difference between the two dissociation energies appears too large. A lower $D(H—NO_3)$ corresponding to a lower $\Delta H_f(NO_3)$ would lead to a lower e.a.(NO_3) which would be in better agreement with the limits of Berkowitz and Chupka quoted above.

The CN^- ion does not fit well in the plot shown in Fig. 5. The deviation is too large to be explained on the basis of experimental error in $\Delta H_{1,0}$ or the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

thermochemical data used for $D(H^+—CN^-)$. The deviation probably reflects the somewhat special situation for CN. CN^- is believed to have a dipole moment with negative charge on the nitrogen. Thus on the basis of simple electrostatic arguments the water molecule should be attached to the nitrogen and not to the carbon. The heterolytic bond energy used for the plot relates to bonding to carbon. Thus it is possible that the special polarity of the CN^- ion might be responsible for the deviation from the plot.

(c) Hydration of OH^-

The experimental $\Delta H_{1,0} = 24.0$ and $\Delta H_{2,1} = 17.9$ kcal/mol for the hydration of OH^- are given in Table 1 together with the results from an earlier determination (6). The present results are higher by about 1.5 kcal. The reason for this is probably due to temperature measurement differences. The newer results were done under otherwise similar conditions to those used earlier (6) but with the pulsing technique (see section *IIa*) with which it was established that the OH^- and its hydrates have stationary concentration ratios with time. The present results are still very much lower than the data obtained by Friedman and co-workers (9, 10) $\Delta H_{1,0} = 34.5$ and $\Delta H_{2,1} = 23.0$ kcal/mol. We don't understand the reason for the discrepancy between the two sets of results, particularly since the $\Delta H_{n,n-1}$ for $H^+(H_2O)_n$ measured by the two different methods (1, 15) were in good agreement. If the present results are correct, they will also invalidate the theoretical calculations (10) and the conclusion (9) that the $\Delta H_{n,n-1}$ (for $n = 1$ to 3) of $H_3O^+(H_2O)_n$ and $OH^-(H_2O)_n$ are the same. This condition was used by Friedman and co-workers to derive a total heat of hydration for the proton (9). While this report was examined by the referees a paper by Kraemer and Diercksen (20) has come to our attention. These authors have done s.c.f.-m.o. calculations on the system $(HOHOH)^-$. The binding energy found relative to OH^- and HOH was 24 kcal/mol which is in close agreement with the present results. Earlier calculations by the above authors gave $D(H_3O^+—H_2O) = 32$ kcal which is a fairly good agreement with the experimental results of 36 kcal/mol (1, 15).

(d) Calculation of the Total Heats of Hydration of CN^-, NO_2^-, NO_3^-, and OH^-

The heats of hydration $\Delta H_h(A^-)$ corresponding to the enthalpy change for the process $A^-_{(gaseous)} \rightarrow A^-_{(aquated)}$ were calculated with the equations

$$\Delta H_h(A^-) = \Delta H_f(A^-, aq)abs - \Delta H_f(A^-, g)$$

$$\Delta H_f(A^-, aq)abs = \Delta H_f(A^-, aq)conv - \Delta H_f(H^+, aq)abs$$

$$\Delta H_f(A^-, g) = \Delta H_f(A, g) - e.a.(A)$$

where, $\Delta H_f(A^-,aq)abs$ is the absolute heat of formation of the aquated ion A^- while $\Delta H_f(A^-,aq)conv$ is the "conventional" heat of formation relative to $\Delta H_f(H^+,aq)conv = 0$. For the absolute heat of formation of the H^+ aquated ion $\Delta H_f(H^+,aq)abs = 95.6$ kcal/mol was used. This value is based on $\Delta H_f(H^+,g) = 365.6$ and $\Delta H_h(H^+) = -270$ kcal/mol. The proton hydration value of 270 kcal (Desnoyers and Jolicoeur (14)) is based on data by Randles and is consistent with gas phase hydration measurements from this laboratory (5). The uncertainties of the values quoted in Table 2 are hard to estimate. Probably the electron affinities are the least reliable with an estimated 5 kcal uncertainty. The $\Delta H_f(NO_3,g) \sim 16.6$ kcal/mol is also believed to be not very reliable. On the whole one might judge that the newly calculated ΔH_h for CN^-, NO_2^- have an error of about ± 4 kcal while the error for the $\Delta H_h(NO_3^-)$ is somewhat larger.

Nuclear Magnetic Resonance Studies of Co(II) Complexes of Thiourea and Related Ligands

D. R. Eaton and K. Zaw

Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 28, 1971

A number of tetrahedral Co(II) complexes of thiourea, *N*-methyl thiourea, and *N,N'*-dimethyl thiourea have been studied by nuclear magnetic resonance (n.m.r.). All the complexes are paramagnetic and the proton resonances show large isotropic shifts in acetone-d_6 solutions. The origin of these shifts is discussed. Two sets of resonances are observed for each position and this is attributed to restricted rotation about the C—N bond. The barrier for this rotation is higher in the complexes than in the free ligands. For all complexes the exchange between free and coordinated ligand is fast at room temperature but slow below −80 °C. The complexes are dissociated to a greater or lesser extent in acetone solution and equilibrium constants and other thermodynamic data are reported for this dissociation. Entropy differences are more important than energy differences in determining the extent of dissociation. It has been demonstrated that both associative and dissociative mechanisms play a part in the ligand exchange process. The relative importance of the two mechanisms differs in the various complexes.

Un nombre de complexes tétrahédriques du cobalt(II) de la thiourée, la *N*-méthyl thiourée et de la *N,N'*-diméthyl thiourée a été étudié par r.m.n. Tous les complexes sont paramagnétiques et les protons en résonance montrent de larges déplacements isotopiques dans les solutions d'acétone-d_6. L'origine de ces déplacements est discutée. Deux séries de résonance sont observées pour chaque position et ceci est attribué à la rotation qui est limitée autour du lien C—N. La barrière pour cette rotation est plus élevée dans les complexes que dans les ligands libres. Pour tous les complexes, l'échange entre le ligand libre et le ligand complexé est rapide à la température ambiante, mais lente au-dessous de −80 °C. Les complexes sont dissociés pour une plus grande ou plus petite quantité dans une solution d'acétone et les constantes d'équilibre ainsi que les autres facteurs thermodynamiques sont donnés pour ces dissociations. Les différences d'entropie sont plus importantes que les différences d'énergie dans l'établissement du pourcentage dissocié. Il a été démontré que les deux mécanismes d'association et de dissociation jouent un rôle dans le processus d'échange des ligands. L'importance relative des deux mécanismes est différente dans plusieurs complexes.

Canadian Journal of Chemistry, **49**, 3315 (1971)

Introduction

Most transition metal complexes are labile. We define labile complexes as those for which ligand exchange occurs in a time shorter than, or comparable to, the time taken to perform an analytical experiment on the ligand distribution in the system. If proton n.m.r. is the chosen analytical method, as it is in our case, the relevant period is of the order of several minutes which represents the time needed to prepare a solution containing complex and free ligand and to obtain its n.m.r. spectrum. By this criterion Co(III) complexes and some other complexes with multidentate ligands are stable or non-labile. Most other complexes are labile, even those containing "good" bidentate ligands such as β-diketones (1, 2).

A second criterion for ligand lability is provided by the condition for "fast exchange" in a n.m.r. experiment. If the lifetime of a complexed ligand engaged in an exchange process with free ligand is small compared to $1/2\pi\Delta\nu$ (where $\Delta\nu$ is the frequency separation between the n.m.r. lines in the free and complexed environments) a n.m.r. experiment will reveal only a single resonance at the average position. For the paramagnetic complexes we are concerned with $\Delta\nu \sim 10^2$–10^3 Hz so the critical lifetime is 10^{-3}–10^{-4} s. The lifetime range of 10^{-4} to 10^2 s for ligand exchange rather nicely defines a class of complexes which can plausibly function as intermediates in homogeneously catalyzed reactions. The mechanisms of such reactions catalyzed by transition metal complexes involve a sequence of ligand exchange steps. The occurrence of a more stable complex in such a sequence will seriously impede the reaction. More labile complexes are likely to have such a transient existence that they are unimportant in determining the overall effectiveness of the reaction.

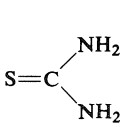
These considerations have led us to undertake some detailed studies of ligand exchange mecha-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

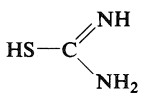
nisms involving systems at the shorter lifetime end of the above scale. A number of additional considerations dictated our choice of systems for such studies. If the results are to have relevance to most homogeneous catalysis they should be restricted to exchange between neutral species in non-aqueous solvents. The majority of studies of ligand exchange mechanisms carried out thus far have involved charged species in aqueous solution. Thus Wilkins in a recent review (3) remarks that "the study of ligand substitution in non-aqueous solutions has barely commenced." We also require a synthetically flexible system which will enable us to vary the metal atom, the geometry of the complex, and both the exchanging and non-exchanging ligands in a fairly systematic manner. We started these studies with some prejudice (4, 5) that outer sphere complexes might play a key role in exchange mechanisms. We therefore thought it desirable to optimize the possibility of detecting such complexes by providing some hydrogen bonding sites at the periphery of the complexes. Previous experience with exchange reactions with phosphine complexes have demonstrated to us that the n.m.r. spectra of complex mixtures can become rapidly uninterpretable. We therefore prefer ligands with only one or two different types of proton. A combination of these factors has led to the choice of thiourea complexes as a basis for ligand exchange studies. In subsequent papers we shall report exchange studies of these complexes with anilines and other ligands and shall return to a detailed consideration of the role of the second coordination sphere. Thiourea and substituted thiourea complexes have been reported for most of the first row transition metal elements. They have been extensively investigated using spectroscopic and magnetic measurements (6–11) and some X-ray structural work has been reported (12–14). They have not previously been studied by n.m.r. For our purposes it is essential that we know how the lability and degree of dissociation of these complexes in solution vary from compound to compound. We also wish to know the mechanism (associative or dissociative) of the ligand exchange process. This information can be conveniently obtained by n.m.r. In the present paper we report the pertinent data for a series of Co(II) complexes.

Results

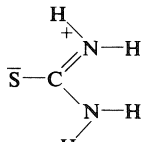
Some twelve Co(II) complexes of thiourea, *N*-methyl thiourea, and *N*,*N*′-dimethyl thiourea have been examined. All these complexes are paramagnetic. We also report data on three Zn(II) complexes, which are diamagnetic, for comparison purposes. The proton spectrum of thiourea does not appear to have been previously examined in solution although there are reports of solid state n.m.r. studies (15, 16). ^{14}N spectra have also been reported (17). A recent study discusses restricted rotation in *N*-methyl thiourea using n.m.r. as the experimental technique (18). The structures of urea and thiourea constitute a classic problem involving tautomerism but there is now a concensus of opinion that **1** rather than **2** is correct (19). The n.m.r. spectrum of thiourea



1



2



3

in acetone-d_6 (Fig. 1*A*) is consistent with structure **1**, having a single proton peak 6.33 p.p.m. to low field of TMS. On cooling to −70 °C this peak splits into a doublet of equally intense lines. This is still inconsistent with involvement of the tautomer **2** and a more reasonable explanation invokes restricted rotation about the C—N bond arising from contribution of structure **3**. Such a structure would be planar with different environments for the "inside" and "outside" hydrogens. Restricted rotation is scarcely surprising since it occurs in many other amides and the phenomenon has been widely studied by n.m.r. (20). Given this explanation the interpretation of the spectra of *N*-methyl thiourea (18) and *N*,*N*′-dimethyl thiourea (Fig. 1) follows naturally. It is interesting to note that the rotational barriers are apparently higher for methyl derivatives. This possibly represents a steric effect, although it is also consistent with the greater electron donating properties of the methyl group.

Turning to the thiourea complexes two structural conclusions have been drawn from the magnetic and spectroscopic studies of the Co(II) and Zn(II) compounds reported in the literature. It has been concluded, mostly from infrared data, that they are all bonded through the sulfur atom. They are also all thought to have tetrahedral or distorted tetrahedral geometry about the metal atom. The only cases where this has been challenged are $Co(TU)_4(NO_3)_2$ for which

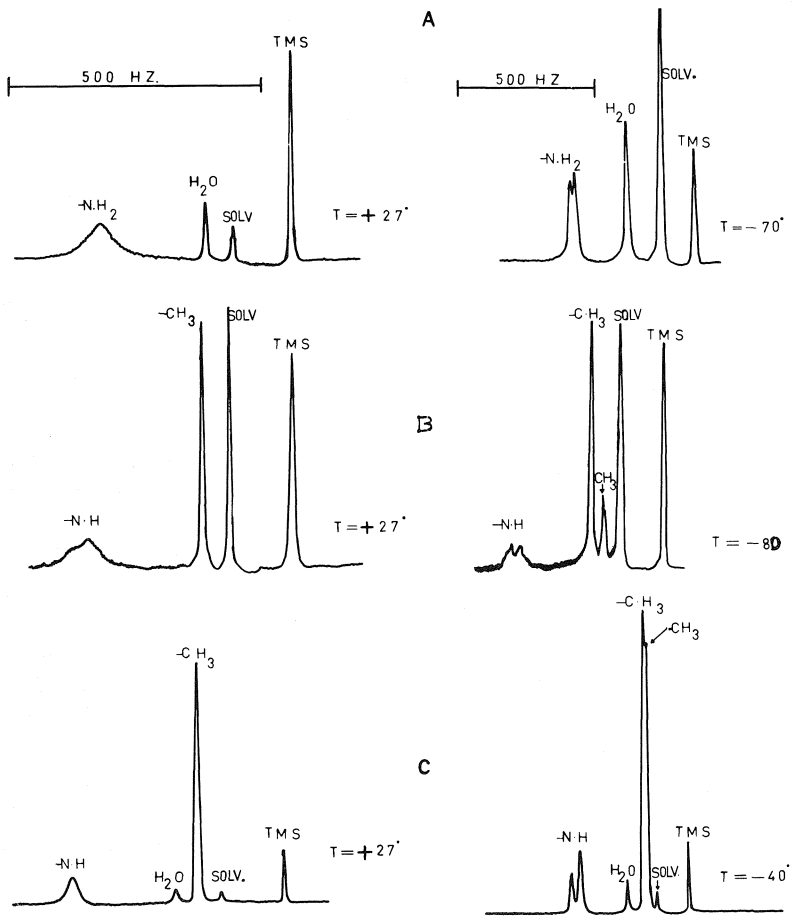


FIG. 1. Nuclear magnetic resonance spectra of thiourea ligands: *A*, thiourea; *B*, *N*-methyl thiourea; *C*, *N,N'*-dimethyl thiourea.

six coordination was suggested (6) and some complexes of stoichiometry $Co(TU)_3X_2$ for which five coordination was postulated (21). However, later workers (11, 22) have concluded that these compounds are also tetrahedral or distorted tetrahedral in solution. Spectroscopic studies have also shown that in solvents such as acetone these compounds are partly dissociated although no quantitative results have been reported. In compounds such as $Co(TU)_2Cl_2$ where there is a choice of dissociating ligands, conductivity studies indicate that it is the thiourea which dissociates. The present results are entirely compatible with all these conclusions.

Figure 2 shows the n.m.r. spectra of $Zn(TU)_2Cl_2$. The NH_2 resonance has been shifted downfield relative to free thiourea. Addition of free ligand shifts the resonance to high field indicating fast exchange. On cooling a solution of $Zn(TU)_2Cl_2$ to around 0 °C the thiourea resonance is split into a doublet, which is again attributed to restricted rotation about the C—N bond. Cooling a solution containing excess ligand to −80 °C gives no free ligand peak, *i.e.*, the ligand exchange remains fast. The spectra of $Zn(TU)_4(NO_3)_2$ and $Zn(TU)_4(ClO_4)_2$ are similar except that a temperature of ~ −25 °C is necessary to freeze out the C—N bond rotation in the nitrate and the line remains a singlet to −80 °C in the perchlorate. Chemical shift data for these complexes and for the free ligands are summarized in Table 1.

Figures 3 and 4 show some representative spectra of Co(II) thiourea complexes. As anticipated for paramagnetic compounds the shifts are much larger than those of the diamagnetic

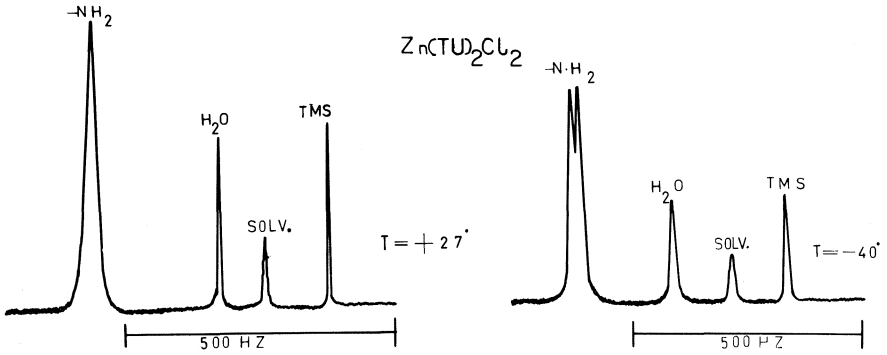

FIG. 2. Nuclear magnetic resonance spectra of $Zn(TU)_2Cl_2$.

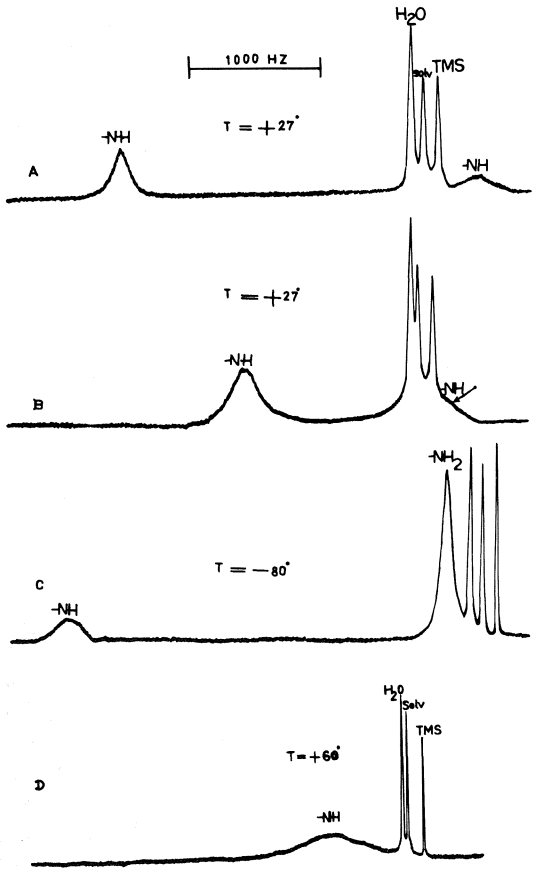

FIG. 3. Nuclear magnetic resonance spectra of $Co(TU)_2Cl_2$: *A*, room temperature; *B*, excess ligand added; *C*, as in *B*; temperature, −80 °C; *D*, as in *B*, temperature, +60 °C (NH_2 is free ligand resonance).

zinc complexes. In all cases there is a doubling of the resonances attributable as before to restricted rotation about the C—N bond. There is no collapse of any of these doublets up to the boiling point of acetone. (In view of the zinc results mentioned above the most likely cases to observe such a collapse are perhaps the perchlorates. We have however refrained from making any measurements above room temperature on these compounds out of respect for the known explosive properties of heavy metal perchlorates in organic solutions.) The large chemical shifts greatly facilitate quantitative measurements on the dissociation and ligand exchange equilibria of these compounds. Addition of free ligand to these solutions at room temperature leads to a single set of resonances at an average position demonstrating fast exchange. This is illustrated in Fig. 3*b*. Cooling a solution containing complex and free ligand leads to the appearance of both contact shifted and free ligand lines (Fig. 3*c*). The ligand exchange process has become slow. Heating such a solution averages the two N—H lines (Fig. 3*d*). Ligand dissociation has been followed by rotation about the C—N bond. The frequencies of the resonances are concentration dependent demonstrating dissociation of the thiourea. The qualitative behavior of the *N*-methyl thiourea and *N*,*N*′-dimethyl thiourea complexes is similar. Room temperature spectra are shown in Fig. 4.

Before proceeding with any quantitative analysis of these spectra we must first deal with two possible difficulties. Firstly it may be noted that all the spectra show a small resonance attributable to water present in the acetone-d_6. Since water is itself a potential ligand it could play an important role in the system. Addition of water enhances this resonance but does not affect the line due to acetone-d_5. There is therefore no fast proton exchange between water and acetone under the conditions of these experiments. The amount of water in the original solvent

can therefore be estimated from the integrated intensities of the resonances obtained by adding measured increments of water. Values of between 1 and 2% were obtained. Acetone-h_6 can be obtained somewhat drier without too much difficulty and a sample was shown to have 0.3% water by comparative integration of the acetone ^{13}C satellites. In acetone-h_6 resonances in the diamagnetic region are largely obscured by the solvent but it was shown that the isotropically shifted peaks of cobalt thiourea complexes occurred in the same positions in this solvent as in the acetone-d_6. The effect of adding increasing amounts of water on the thiourea and water resonances of $Co(TU)_2Cl_2$ and $Co(TU)_4(ClO_4)_2$ has been investigated. The thiourea resonance is not affected initially but then moves towards its diamagnetic position. The water resonance initially occurs at its diamagnetic position but is shifted to low field if a large excess of water is added. Fast exchange of both water and thiourea between coordinated and free environments is indicated. On a mole fraction basis a 40-fold excess of water is needed to displace half the thiourea of $Co(TU)_2Cl_2$ and an 8-fold excess to displace half the thiourea of $Co(TU)_4(ClO_4)_2$. At −80 °C both exchange equilibria are slow and the coordinated water appears as a broad line at about −7000 Hz from TMS. This is consistent with literature values for the shift of water complexed to Co^{2+} in other solvents (23). These results are not consistent with an equilibrium of the type

[1] $Co(TU)_2Cl_2 + H_2O \rightleftharpoons Co(TU)(H_2O)Cl_2 + TU$

with an equilibrium constant independent of

solvent composition. For such a situation addition of excess of one of the ligands must always lead to a decrease in the average shift for that ligand whereas the water shift is increased by addition of water. The situation is rather that the complexing abilities of thiourea and water depend strongly on the nature of the solvent system. This conclusion has also been reached by Shul'man *et al.* (24) from electrochemical studies. At low concentrations of water the water is a very poor ligand and does not compete with thiourea. At higher concentrations it competes much more favorably. At the 1–2% level the observed shift from the diamagnetic position is less than 5 Hz and since the full contact shift at room temperature is ~5000 Hz and there is fast exchange a negligible amount of water is complexed. We can therefore neglect the equilibrium 1 under these conditions. A plausible rationalization of these observations is that if the cobalt is formally neutral, *i.e.*, if the chloride ion is not dissociated from $Co(TU)_2Cl_2$, water is a poor ligand. With increasing dielectric constant there is some ionization and water becomes a better ligand. Water obviously competes somewhat more favorably in the perchlorate complex which is charged. In any event we can safely disregard small percentages of water provided its resonance occurs within a few Hz of its diamagnetic position.

The second point which deserves some preliminary consideration concerns the coordination number of the cobalt. The concensus of opinion, as we have noted above, is that only four coordinated tetrahedral species are present in solutions of cobalt thiourea complexes. Swaminathan and Irving (25), however, have studied cobalt perchlorate thiourea in 95% ethanol and concluded that $Co(TU)_6^{2+}$ is an important species. If this were the case in acetone it would invalidate the analysis of the data given below. The coordination number of the cobalt in solutions containing excess thiourea can be obtained in the following manner. The limiting shift for thiourea fully complexed to cobalt can be obtained directly at low temperatures, where the exchange is slow, and indirectly at higher temperatures (see below). Given this limiting shift the fraction of thiourea complexed in any fast exchanging solution is readily obtained from the observed contact shift. Knowing the total thiourea concentration the number of moles complexed can be compared with the number of moles of cobalt present and a coordination number obtained. A series of results for $Co(TU)_2Cl_2$ and $Co(TU)_4(ClO_4)_2$ each in the presence of excess thiourea is given in Table 2. In all cases the total coordination number remains somewhat below four. There is however a possible flaw in this argument. If the limiting shift of a five or six coordinated species were substantially less than that of the four coordinated species, low apparent coordination numbers would be obtained. If this were so though, at low temperatures we would obtain a different (smaller) limiting shift in the presence of excess thiourea. Experiment shows that this does not occur and that at −80 °C excess ligand merely increases the free ligand resonance without shifting the complexed resonance. We therefore agree with the conclusions of Cotton and co-workers (6), Hall and Horrocks (22), and Maneces *et al.* (26) that five or higher coordination numbers are not important for these compounds in solution. This does not preclude the presence of small concentrations of such species which might act as intermediates in the exchange process. We will also express some reservations later about the situation at very low temperatures for one compound. However, it seems reasonable to attempt initial analysis of the data on the basis of four coordination.

On this assumption, the principle equilibrium present is

[2] $Co(TU)_2X_2 + S \rightleftharpoons Co(TU)SX_2 + TU$

(where S represents a solvent molecule). In some cases it may also be necessary to consider the further dissociation

[3] $Co(TU)SX_2 + S \rightleftharpoons CoS_2X_2 + TU$

In the fast exchange situation, if the degree of dissociation is small, the shift of the undissociated compound may be obtained by plotting the observed shifts against the reciprocal of the square root of the concentration.[1] A typical plot is shown in Fig. 5. In the slow exchange situation at low temperatures the limiting shift is obtained directly. If this analysis is correct, the limiting shifts should plot against $1/T$ throughout the temperature range. Figure 6 shows these plots for $Co(TU)_2X_2$ where X = Cl, Br, I. It may be noted that there is some indication of non-

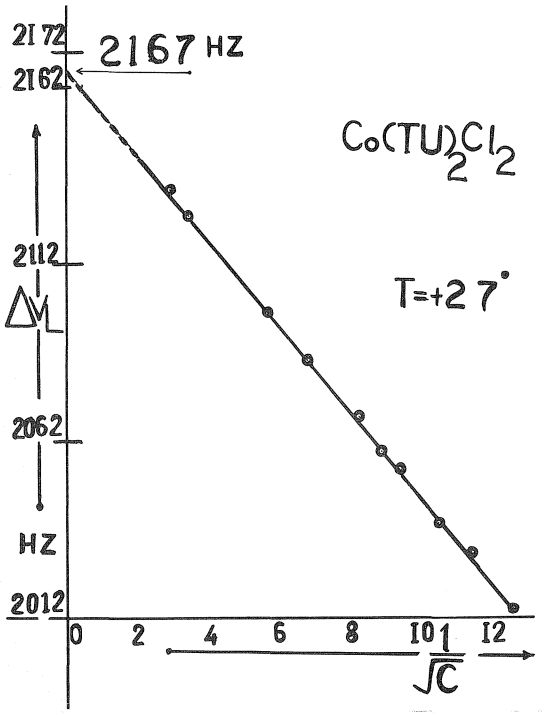

FIG. 5. Concentration dependence of NH shift of $Co(TU)_2Cl_2$.

[1]Degree of dissociation $\alpha = (k/c)^{1/2}$, $\Delta\nu_0 = \Delta\nu_L \times$ fraction complexed, hence $\Delta\nu_0 = \Delta\nu_L [1 - (1/n)(k/c)^{1/2}]$ when n is number of TU molecules in complex.

linearity at the lowest temperatures for the bromide and iodide. The perchlorate and nitrate complexes show similar behavior. With one exception the MTU and DMTU complexes closely parallel the TU complexes. The exception is $Co(MTU)_2I_2$ which appears to be anomalous in both the concentration and temperature dependence of the shifts. It is believed that this discrepancy arises from poor experimental data resulting from overlap of different resonances at certain concentrations and temperatures. It is possible that the slightly anomalous shifts at low temperature indicate the formation of new and different complexes. More probably they simply represent a "normal" deviation from Curie law behavior. However, the general consistency of the high and low temperature data leads us to believe that the values obtained for the limiting shifts are reliable.

Given this reassurance we may then use the limiting shifts to calculate the degrees of dissociation and equilibrium constants for reaction 2 for all cases where we have fast exchange. The temperature dependence of the equilibrium constant

gives values of ΔH and ΔS for reaction 2. Some experimental data for the cobalt complexes is given in Table 3. Limiting shifts, equilibrium constants at room temperature, and values of ΔH and ΔS for all the compounds examined are given in Table 4. The data at low concentrations was then reexamined to investigate the effect of the second dissociation (eq. 3). In all cases very small values (10^{-9}–10^{-10}) were obtained for the second dissociation constants. The differences between the values for different compounds are probably not significant and they are therefore not quoted here.

We next turn to a consideration of the rates and mechanism of the ligand exchange process. In principle rate constants can be determined from the line broadening in a fast exchange situation. In practice quantitative experiments along these lines give very questionable results. We will therefore be content with some qualitative observations. $1/2\pi\Delta\nu$ for these systems is of the order of 10^{-4} s and this gives a measure of the lifetime of free or complexed ligand. The temperature at which coalescence of free and complexed ligand signals occurs is a qualitative measure of relative exchange rates. The variation of this temperature among the different compounds is surprisingly modest (−40 to −60 °C) and we hesitate to ascribe significance to the differences. Information on the mechanism of ligand exchange can be obtained by studying the line widths of the free and complexed ligand as a function of ligand concentration in the slow exchange region. Data for two of these compounds is shown graphically in Fig. 7 and spectra for a third in Fig. 8. These results will be discussed below.

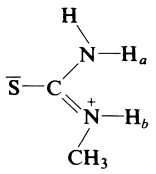
Discussion

(a) The Nuclear Magnetic Resonance Spectra

All the n.m.r. data can be readily interpreted on the assumption that thiourea is bonded to the metal though sulfur and rotation about the C—N bond is completely restricted. Thus all TU complexes show two resonances, one shifted to high field and one to low field. The high field resonance is significantly broader than the low field resonance. Since the predominant relaxation mechanism is likely to be dipolar interaction with the unpaired electrons on the cobalt the hydrogen closer to the metal will be broader. A model gives distances of 5.88 and 4.62 Å for the "inside" and "outside" hydrogens, respectively. The high field line is therefore assigned to the "outside" position. For all DMTU complexes two hydrogens and two methyls are observed. Both methyls are shifted to low field but the less shifted line is broader. This is therefore assigned to the outer position. $Co(MTU)_2Cl_2$ and $Co(MTU)_4(ClO_4)_2$ both show two methyl resonances and three hydrogens, two to low field and one to high field, under appropriate conditions. Presumably we are distinguishing between hydrogens *a* and *b* in structure **4**.



4

The relative intensities of the various lines suggest that isomers with "outside" methyl groups are preferred as might be anticipated on steric grounds. The enhanced barrier to rotation on complexing the thiourea suggests that ionic

structures such as **4** make a greater contribution when the thiourea interacts with a positively charged metal ion. This seems not unreasonable.

The origin of the isotropic shifts is not unambiguous. The choice lies between a dipolar mechanism which requires the complex to be magnetically anisotropic, a contact mechanism which requires delocalization of spin density to the ligand or a combination of the two (27). Since the ground state of tetrahedral Co(II) is orbitally non-degenerate the magnetic anisotropy might be expected to be small and the dipolar shifts correspondingly not important. This argument is, however, far from water-tight since there are low-lying excited states. We are more impressed by the observation that octahedral $Ni(TU)_6(ClO_4)_2$ also shows a large splitting between "inside" and "outside" NH protons (28). In this case significant dipolar shifts are very unlikely and the difference must arise from differing contact interactions. Thus although it is tempting to postulate that the difference in shift of the "inside" and "outside" hydrogens arises from differences in the $(3\cos^2\theta - 1)/r^3$ term in the expression for dipolar shifts, this explanation will not hold for Ni complexes and therefore seems less likely for Co complexes. We prefer the possibility that the difference reflects the difference in electronic environments resulting from differing hydrogen bonding interactions of the two hydrogens. Effects of this type do not appear to have been reported previously. It is interesting to note that Piovesana and Furlani (29) have recently suggested that the infrared spectra of these complexes provide evidence for intramolecular hydrogen bonding between an "outside" hydrogen and a halide ligand. There are possibilities of delocalizing spin into both the σ and π orbitals of the ligand. Since both high and low field shifts are observed both types of delocalization may be contributing. It is quite plausible that the relative contributions should depend critically on the energy of the N—H bonding orbital relative to that of the molecular orbital containing the unpaired electron and hence on the hydrogen bonding. It is also interesting that the contact shifts change smoothly in the series Cl, Br, and I with the low field shifts decreasing and the high field shifts increasing. Attempts have been made to explain similar trends observed in Co(II) pyridine and hexamethylphosphoramide complexes in terms of changes in the metal ligand bonding (30). The significance of this correlation has however been challenged (31) and an alternative explanation based on steric factors put forward. Either type of explanation could be applied to the present case and we do not feel that we can add much towards the resolution of this particular controversy.

(b) Ligand Dissociation

The equilibrium constants of Table 4 show that the degree of dissociation of all three series of complexes depends on the anion present and increases in the order $Cl < Br < I < ClO_4$. The differences between corresponding compounds of TU, MTU, and DMTU are relatively small but indicate that the DMTU perchlorate is least dissociated followed by MTU and TU in that order. The data of Table 4 also show that the entropy term is at least as important as the enthalpy term in determining the amount of dissociation. The indicated errors are obtained by least squares analysis on the data. The results with aqueous acetone have indicated that thiourea becomes a poor ligand if the positive charge on the cobalt atom becomes large. Presumably back donation to the π^* orbital makes a significant contribution to the bond strength. The significantly lower values of ΔH for the ionic perchlorates is consistent with this picture. We tentatively ascribe differences in ΔS to variations in the hydrogen bonding interactions which determine the structure of the second coordination sphere. This structure will be discussed in more detail in a subsequent publication.

(c) The Ligand Exchange Process

The similarity of the temperature of coalescence of free and complexed ligand resonances shows that the rates of ligand exchange for all these complexes are comparable. We doubt whether attempts at quantitative measurements of line widths would add substantially to this conclusion. We can however make some deductions regarding mechanism from the variation of the line widths with concentration. If the mechanism of ligand exchange is associative, *i.e.*

$$\text{Co complex} + \text{TU}^* \rightleftharpoons \text{Co complex TU}^* \rightleftharpoons \text{Co complex} + \text{TU}$$

it can be readily shown that

$$1/\tau_c = k[\text{TU}] \qquad 1/\tau_L = k[\text{Co complex}]$$

where τ_c and τ_L are the lifetimes of complexed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and free ligand and $1/\tau_c$ and $1/\tau_L$ are a measure of the respective line widths under conditions such that separate lines are observed for the two environments. If on the other hand we have a dissociative mechanism, it follows that

$$1/\tau_c = k$$

and

$$1/\tau_L = k[\text{Co complex}]/[\text{TU}]$$

We cannot distinguish between a dissociative mechanism involving a lower coordination number for cobalt and one in which the coordination number is maintained by substituting solvent molecules. The latter is much more likely and the observation of the second type of kinetics most probably indicates that the rate determining step for thiourea ligand exchange is

$$\text{Co complex} + \text{S} \rightleftharpoons \text{Co complex S} + \text{TU}$$

This is then followed by fast reaction of the solvent containing complex with free thiourea. It is apparent that the key experiment is to determine the behavior of the line widths as a function of free ligand concentration. The results of Fig. 7 show very clearly that both types of mechanism must be considered. Thus the lines *A* and *A'* for $Co(TU)_2Cl_2$ show that the line width of the complexed thiourea resonance is independent of free thiourea concentration whereas that of the free thiourea decreases with added ligand. On the other hand *B*, *C*, and *C'* clearly demonstrated that the linewidths of complexed MTU and DMTU increase with added ligand. For TU complexes a dissociative mechanism predominates, for MTU and DMTU complexes an associative mechanism is more important. Most probably both processes occur for all complexes and only their relative contributions are changing.

Finally we draw attention to the spectra of $Co(DMTU)_4(ClO_4)_2$ shown in Fig. 8. These spectra were obtained at -80 °C and the sharp resonances at the free ligand positions show that free ligand is not involved in fast exchange with the complex. However, addition of free ligand clearly shifts the positions of the complexed ligand lines. A fast equilibrium between complexed ligand and ligand in a fifth coordination position or an outer sphere site is indicated. We cannot distinguish between these possibilities in the present case. This is the only complex in the present series which shows this type of behavior with thiourea as the competing ligand but we shall report in a subsequent paper more substantial evidence for the existence of both types of higher coordination number complexes in exchange reactions between these compounds and aniline ligands.

Conclusions

This study has been of a preliminary nature with the objective of establishing the n.m.r. characteristics of thiourea complexes. As anticipated all the complexes studied are partly dissociated and undergo fast ligand exchange. There are significant differences in the degree of dissociation but qualitatively the rates of ligand exchange do not differ. In spite of this more than one exchange mechanism is operative. There is indirect evidence that the interactions of a complex with its surroundings, *i.e.*, the "second coordination sphere," plays an important part in determining the chemical reactivity. This is reflected in the influence of the entropy term on the degree of dissociation and in the large differences in the chemical shifts of "inside" and "outside" NH protons which are attributed to intra or intermolecular hydrogen bonding effects. We are undertaking extension of this type of study to thiourea complexes of other transition metals and to exchange reactions involving ligands other than thiourea. More detailed discussion of the factors influencing the ligand exchange mechanisms will be deferred until this additional datum has been presented.

Experimental

The following compounds were synthesized by literature methods:
$Co(TU)_2Cl_2$ (6), $Co(TU)_2Br_2$ (6), $Co(TU)_2I_2$ (11), $Co(TU)_4(NO_3)_2$ (6), $Co(TU)_4(ClO_4)_2$ (6); $Co(MTU)_2Cl_2$ (7), $Co(MTU)_2Br_2$ (7), $Co(MTU)_4(ClO_4)_2$ (7); $Co(DMTU)_2Cl_2$ (7), $Co(DMTU)_2Br_2$ (7), $Co(DMTU)_4(ClO_4)_2$ (7); $Zn(TU)_2Cl_2$ (32), $Zn(TU)_4(NO_3)_2$ (32), $Zn(TU)_4(ClO_4)_2$ (32). Starting materials were purchased from Fisher Sci. Co., Alfa Inorganics, and Pfaltz and Bauer Inc. Products were characterized by their melting points and visible spectra all of which agreed well with data in the literature. $Co(DMTU)_2Cl_2$ is very sparingly soluble in acetone and n.m.r. data is not reported for this reason.

$Co(MTU)_2I_2$ and $Co(DMTU)_2I_2$ do not appear to have been reported previously. They were prepared as follows.

$Co(MTU)_2I_2$

Stoichiometric quantities of $CoI_2.2H_2O$ and MTU were dissolved in a mixture of chloroform and alcohol 1:3 by volume and the solution heated for 30–40 min.

The hot solution was filtered and allowed to evaporate at room temperature for several days. The dark green oily liquid obtained was washed several times with ether and the remaining ether pumped off. The resulting dark green liquid was dried in vacuo over P_4O_{10} to give a crystalline solid. The melting point of the product was 80–82°. The visible spectrum shows the triplet of bands characteristic of tetrahedral Co complexes (14 800, 13 900, and 13 050 cm^{-1}).

$Co(DMTU)_2I_2$

The procedure was similar to the above except that ethyl alcohol was used as a solvent. Melting point of product was 113–115 °C; absorption bands observed at 15 500, 14 500, and 13 800 cm^{-1}. All compounds were dried over P_4O_{10} under vacuo before using. Nuclear magnetic resonance spectra were obtained with a Varian DP 60 spectrometer operating at 56.4 MHz and equipped with a variable temperature probe. Acetone-d_6 was used as purchased. Spectroscopically pure acetone-h_6 was dried over a molecular sieve and redistilled. Tetramethyl silane was used as an internal reference throughout.

We are indebted to the National Research Council of Canada for financial support of this research and to the Canadian International Development Agency for a scholarship to one of us (K.Z.).

Quasichemical Treatment of the Solubility of Reactive Gases in Fused Salts

A. Block-Bolten and S. N. Flengas

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received June 2, 1971

A quasichemical model applicable to solubilities of reactive gases in fused salts has been developed. The treatment is based on local ordering effects, and accounts for next-nearest neighbor anion repulsions.

The present calculation is applicable to common ion fused salt systems where complex ions with a pronounced heat of formation do not form. The treatment allows the evaluation of structural parameters from available experimental data.

On a développé une méthode quasi-chimique applicable aux solubilités des gaz réactifs dans des sels fondus.

La méthode est fondée sur les effets locaux de classement et tient compte des répulsions provoquées par le prochain plus proche anion voisin. Cette méthode de calcul est applicable aux systèmes de sels fondus ioniques avec un ion commun où les ions complexés ayant une chaleur de formation importante ne se forment pas. Cette étude permet une évaluation des paramètres structuraux à partir de données expérimentales disponibles.

Canadian Journal of Chemistry, **49**, 3327 (1971)

Introduction

In a previous investigation the solubilities of bromine vapor in molten AgBr were reported (1). The results were interpreted as indicating the presence of Br_3^- ions in the melt. In this system, in addition to negative limiting heats of mixing, the partial molar entropies of mixing $\overline{\Delta S}_{Br_2}$ for liquid bromine were positive.

The partial molar heats of mixing, on the assumption that the $AgBr_3$ species are present, may be represented by the reaction

$$Br_{2\ (liquid)} + [(AgBr)_{m-n}\cdot(AgBr_3)_n] \rightarrow [(AgBr)_{m-n-1}\cdot(AgBr_3)_{n+1}]$$

for which

$$[1] \qquad \overline{\Delta H}_{Br_2} = \overline{\Delta H}_{AgBr_3} + \Delta H_R^0$$

where ΔH_R^0 is the heat for formation of $AgBr_3$ from pure liquid bromine and AgBr.

The formation of a Br_3^- species may be thought of as the result of attachment of the non-polar bromine molecule to a Br^- ion in the melt, by ion-induced dipole type interactions. Such species are usually described as triplets $Br^-(B^+...Br^-)$. The energy accompanying the ion-induced dipole interaction is expected to be of rather low magnitude, and therefore the term ΔH_R^0 should not constitute a significant contribution to the total energy of mixing. On the contrary, the dissolved bromine which is closely associated with the Br^- ions in the form of the Br_3^- triplet is not expected to be sufficiently polarized as to occupy distinctive anionic and cationic positions in the liquid sublattices. In this sense the dissolved bromine should occupy the same lattice site as the carrier Br^- anion. Such host Br^- ions are shielded from the surrounding Ag^+ cations by the attached bromine molecules and a volume disturbance in the local symmetry of the ionic distributions is expected to occur.

The net result should be that the next nearest neighbor repulsions of the type Br^-–Ag^+–Br^-, Br^-–Ag^+–Br_3^- and Br_3^-–Ag^+–Br_3^- are expected to be significantly different and a pronounced heat effect due to the distribution of those interactions should be the predominant factor in the heat of mixing given by eq. 1.

It also follows that the partial molar entropies of mixing reported previously (1) may be attributed to local ordering effects.

In the present quasichemical treatment the thermodynamic properties of dilute solutions of reactive gases X_2 in ionic melts AX are treated on the basis of local ordering and on the predominance of next-nearest neighbor anion type repulsions. The method for calculating local ordering is based on the statistical treatment of adsorption of gases on surfaces by Chang (2), and its application to solid solutions by Wasastjerna (3). An extension of this theory to the partial molar properties of reciprocal and simple binary fused salt systems has also been made by Block-Bolten (4). The present calcula-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tions are applicable to dilute solutions of common cation fused salt systems where complex ions having pronounced heats of formation do not form.

The calculation of the number of significant interactions by the present method depend entirely on the measured partial molar heats of mixing, and the calculated values are then used to predict accurately the partial entropies of mixing.

Quasichemical Treatment of Local Order

Considering the solubility of a gaseous species X_2 in the melt A^+X^- according to

$$[2] \qquad X_2 + A^+X^- \rightleftharpoons A^+X_3^-$$

the types of significant interactions present in the solution are the X^-–A^+–X^-, X^-–A^+–X_3^-, and X_3^-–A^+–X_3^-, where A^+ is the common cation. In general, solutions of this type represent a binary mixture AX–AY in which only next-nearest anion to anion repulsions are taken to be significant.

If a dilute solution contains n_1 g-mol of solute AX dissolved in n_2 g-mol of AY, the *real* fractions of the next-nearest neighbor pairs in the anion sublattice, of the type, X^-Y^-, X^-X^-, and Y^-Y^-, are given by λ, κ, ν, respectively. The total number of pairs in the solution are equal to $\frac{1}{2}NZ(n_1 + n_2)$, where N is the Avogadro number and Z is the coordination number.

A "local order" parameter σ is defined as the fraction of the number of ionic pairs XY present in excess of the same type of pairs calculated for a randomly distributed solution. Hence

$$[3] \qquad \sigma = \frac{P_{XY} - N_X \cdot N_Y}{N_X \cdot N_Y}$$

P_{XY}, is the probability of finding the actual pairs XY, and N_X, N_Y are the corresponding ionic fractions.

When $P_{XY} < N_X N_Y$, the system exhibits positive deviations from ideality. In the case of compound formation $P_{XY} > N_X N_Y$. Accordingly, $1 \geqslant \sigma \geqslant -1$. $\sigma = 0$ for the random solution.

By dividing the pair number for a given ion pair by the total number of significant ionic pairs in the solution given as

$$[4] \qquad \tfrac{1}{2}N(n_1 + n_2)Z(\kappa + \nu + 2\lambda)$$

where $\kappa + \nu + 2\lambda = 1$ by definition, the following expressions are readily derived

$$[5] \qquad \lambda = N_X N_Y(\sigma + 1)$$

$$[6] \qquad \kappa = N_X^2 - N_X N_Y \sigma$$

$$[7] \qquad \nu = N_Y^2 - N_X N_Y \sigma$$

The energy of the solution is also given by

$$[8] \qquad E_S = \tfrac{1}{2}N\,Z(n_1 + n_2)[\kappa\varepsilon_{XX} + 2\lambda\varepsilon_{XY} + \nu\varepsilon_{YY}]$$

where ε_{XX}, ε_{YY}, and ε_{XY} are the repulsive pair interaction energies for the ionic pairs XX, YY, and XY, respectively.

Partial differentiation of eq. 8 yields

$$[9] \qquad \overline{\Delta H}_{AX} = \left[\lambda + (n_1 + n_2)\frac{\partial\lambda}{\partial n_1}\right]RTb$$

where

$$[10] \qquad b = \tfrac{1}{2}Z\,N(n_1 + n_2)[2\varepsilon_{XY} - \varepsilon_{XX} - \varepsilon_{YY}]$$

Hence the partial molar heat of mixing for the solute AX depends upon the number of X^-Y^- pairs and on the rate of increase of such pairs with solute concentration.

The partial molar entropies of mixing may also be calculated from configurational considerations.

Per gram mole of solution the gross distribution of the number of pairs XX, XY, and YY, in the total number of available paired sites, which is $\frac{1}{2}ZN$, is given as

$$[11] \qquad \left[\frac{\left(\frac{Z}{2}N\right)!}{\left(\frac{Z}{2}\kappa N\right)!\left(\frac{Z}{2}\nu N\right)!\left[\left(\frac{Z}{2}\lambda N\right)!\right]^2}\right]^{2/Z}$$

In this calculation the fractions κ, ν, and λ are quantities to be eventually determined from the treatment of the experimental data. The permutation number $((Z/2)N)!$, however, includes many more configurations because of site overlapping. Accordingly, the distributions must be normalized by a factor giving the random distribution of pairs in paired positions where the only restriction is that each pair must contain at least one X^- or one Y^- ions. The combinatory number in such a random system is given as

$$[12] \qquad \left[\frac{\left(\frac{Z}{2}N\right)!}{\left(\frac{Z}{2}NN_X\right)!\left(\frac{Z}{2}NN_Y\right)!}\right]^{2/Z}$$

where, the $2/Z$ exponent in expressions 11 and 12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is introduced to correct the number of distributions to truly independent ones, as each central cation is surrounded by $Z/2$ pairs of anions.

The normalized combinatory number is obtained by dividing eq. 11 by eq. 12, and is given as

$$[13]\quad C=\left[\frac{\left(N\frac{Z}{2}N_X\right)!\left(N\frac{Z}{2}N_Y\right)!}{\left(N\frac{Z}{2}\kappa\right)!\left(N\frac{Z}{2}\nu\right)!\left[\left(N\frac{Z}{2}\lambda\right)!\right]^2}\right]^{2/Z}$$

This expression was first derived by Chang (2). Accordingly, the integral entropy of mixing for $n_t = n_1 + n_2$ g-moles of mixture is given as

$$[14]\quad \Delta S_M = n_t k \ln C$$

Using Stirling's approximation

$$[15]\quad \Delta S_M = n_t R \ln \frac{N_X^{N_X} N_Y^{N_Y}}{\kappa^{\kappa}\cdot\nu^{\nu}\cdot\lambda^{2\lambda}}$$

which is independent of Z.

The partial molar entropy of mixing for the solute AX is calculated from eq. 15 by partial differentiation

$$[16]\quad \overline{\Delta S}_{AX} = R \ln \frac{N_X}{\kappa^{(\kappa+(\partial\kappa/\partial n_1)n_t)}\lambda^{2(\lambda+(\partial\lambda/\partial n_1)n_t)}\nu^{(\nu+(\partial\nu/\partial n_1)n_t)}}$$

Using the transformations

$$[17]\quad \kappa + \frac{\partial\kappa}{\partial n_1} n_t = 1 - \left(\lambda + \frac{\partial\lambda}{\partial n_1} n_t\right)$$

$$[18]\quad \nu + \frac{\partial\nu}{\partial n_1} n_t = -\left(\lambda + \frac{\partial\lambda}{\partial n_1} n_t\right)$$

eq. 16 reduces to

$$[19]\quad \overline{\Delta S}_{AX} = R \ln \frac{N_X}{\kappa\left(\frac{\lambda^2}{\kappa\nu}\right)\left(\lambda + \frac{\partial\lambda}{\partial n_1} n_t\right)}$$

For the equilibrium between ion-pairs,

$$[20]\quad [XX] + [YY] \rightleftarrows 2[XY]$$

the equilibrium constant is written as

$$[21]\quad \frac{\lambda^2}{\kappa\cdot\nu} = e^{-\Delta G_R^0/RT}$$

where, ΔG_R^0 is the standard free energy for the exchange reaction 20.

If the standard entropy change for this reaction is taken to be insignificant, then the standard free energy may be approximated by the energy of the exchange reaction 20, ΔE_X^0. However, according to eqs. 8 and 9, since the pressure–volume work is also insignificant, $\Delta E_X^0 = \Delta H_X^0$, where ΔH_X^0 is the enthalpy change for reaction 20.

Combining eqs. 9, 19, and 21, the expression for the partial molar entropy of mixing becomes

$$[22]\quad \overline{\Delta S}_{AX} = R \ln \frac{N_X}{\kappa} + \frac{\overline{\Delta H}_{AX}}{T}$$

It should be noted that eq. 22 which has been derived by the quasichemical method on the assumption of local ordering only has the same form as the classical expression for entropy. Accordingly, the activity and the activity coefficient are

$$[23]\quad a_{AX} = \kappa/N_X$$

and

$$[24]\quad \gamma_{AX} = \kappa/N_X^2$$

For the "ideal" totally dissociated and random solution where $\sigma = 0$, $\kappa_{ideal} = N_X^2$. The activity coefficient is therefore given as the ratio of the real over the ideal number of pairs XX.

Application of the Theory

From previous measurements in the Br_2–AgBr system activity coefficients for the $AgBr_3$ component have been derived, as well as heat and entropy data. For this system XX, YY, and XY represent the interactions, Br_3^-–Br_3^-, Br^-–Br^-, and Br^-–Br_3^-, respectively.

The data are summarized in Table 1. Using the determined values of $\overline{\Delta H}_{AgBr_3}$, κ is given as $\kappa = \gamma_{AgBr_3}^{H}\cdot N_{Br_3^-}^2$ and the order parameter σ is evaluated from eq. 6; γ^H is the activity coefficient where Henry's Law is applicable. Similarly, ν and λ are calculated from eqs. 5, 6, 7, and 21. The partial molar entropies of mixing are then calculated directly from eq. 22 using κ and the experimentally determined partial molar heats of mixing. The results of these calculations are also included in Table 1.

Table 1 also includes the fraction κ of pairs Br_3^-–Br_3^- in the "ideal" solution which is given as $N_{Br_3^-}^2$. Comparing κ_{ideal} to κ, it is apparent that the real system contains γ^H times more Br_3^-–Br_3^- pairs than the random system.

Furthermore, λ is slightly less than the ideal fraction of Br_3^-–Br^- type pairs, which indicates that the thermodynamic properties are mainly determined by the formation of Br_3^-–Br_3^- type pairs.

*$\overline{\Delta S}_{AgBr_3} = \overline{\Delta S}^{xs}_{AgBr_3} + RT \ln N_{Br_3^-}$, where $\overline{\Delta S}^{xs}$ is given in eq. 6 of ref. 1.
†b average: −3.785.

The interaction parameter b is a property of the system and may be calculated as follows:

From $N_X - \lambda = \kappa$, for the dilute solutions

$$[25] \qquad \lambda = N_X - \gamma^H \cdot N_X^2$$

where $N_X = n_1/n_t$. By differentiation and addition,

$$[26] \quad \lambda + n_t(\partial\lambda/\partial n_1) = 1 + N_X\gamma^H(N_X - 2)$$

Combining eqs. 9 and 26 the limiting heat of mixing is given as

$$[27] \quad \overline{\Delta H}_{AX,\,lim} = RTb(1 - 2\gamma_{AX}{}^H N_X + \gamma_{AX}{}^H N_X{}^2)$$

The b values calculated from this relationship are shown in Table 1 and have an average value of, $b = -3785$ cal.

This value is reasonably constant and appears to increase slightly with temperature.

Similarly, the partial molar entropy of mixing for dilute solutions may be written as

$$[28] \quad \overline{\Delta S}_{AX} = -R \ln \gamma_{AX}{}^H \cdot N_X + Rb(1 - 2\gamma^H \cdot N_X + \gamma^H \cdot N_X{}^2)$$

where the first term has the meaning of $-\overline{\Delta G}_{AX}/T$.

The $\lambda + n_t\,(\partial\lambda/\partial n_1)$ terms have also been calculated and tabulated in Table 1. Considering the importance of the two terms in eq. 9 which determine the heats of mixing, it is evident that the *change* of the number of unlike ion pairs, with concentration, is predominant. Values of the order parameter σ are also included in this Table and are of the order of 3×10^{-3}; as incidated earlier $\sigma = 0$ for a random mixture.

In conclusion it has been shown that the thermodynamic properties of the solutions are directly related to structure and to order–disorder effects which are created because of local interactions. The treatment allows the evaluation of these parameters from available experimental data.

Nuclear Magnetic Resonance Investigation of Possible Molecular Motion in Coronene, Perylene, and Triphenylene in the Solid State

C. A. FYFE
Chemistry Department, University of Guelph, Guelph, Ontario

AND

B. A. DUNELL AND J. RIPMEESTER[1]
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received May 5, 1971

Broad-line nuclear magnetic resonance (n.m.r.) and spin lattice relaxation time measurements on solid coronene indicate the presence of a molecular reorientation process at 160 °K. The activation energy for the process has been determined at 5.9 kcal/mol and the nature of the motion deduced as being reorientation in the plane of the molecule. No motional processes are observed for perylene or triphenylene.

The results are discussed with respect to thermodynamic data and the molecular structures.

La largeur de raie en r.m.n. ainsi que les mesures du temps de relaxation spin réseau de coronène solide indique la présence d'un processus de réorientation à 160 °K. L'énergie d'activation du processus a été déterminée comme étant de 5.9 kcal/mol et la nature du mouvement a été précisée comme étant une orientation dans le plan de la molécule. Aucun processus de mouvement n'a été observé pour le perylène et tryhénylène.

Les résultats sont discutés en fonction des données thermodynamiques et des structures moléculaires.

Canadian Journal of Chemistry, 49, 3332 (1971)

Introduction

Molecular motion of benzene about its molecular axes in the solid state was shown by Andrew in 1950 (1). An investigation of naphthalene and anthracene did not show any evidence for motion (2). Recently however, a similar type of motion has been observed for pyrene in the solid (3). The purpose of the present work was to investigate possible reorientation processes in a variety of large symmetrical polycyclics. Coronene, perylene, and triphenylene were chosen as they were approximately circular and planar. Their crystal structures have been determined (4–6).

Experimental

The spectrometer used was a conventional crossed-coil type previously described (7). Spin–lattice relaxation times were determined by the "adiabatic fast passage" technique (8). Calculations were carried out using Fortran IV programmes on an I.B.M. 360–50 computer. Materials were from commercial sources and gave m.p.'s consistent with literature values.

[1]Present address: School of Chemical Sciences, University of Illinois, Urbana, Illinois, U.S.A.

Results and Discussion

A. Coronene

At 100 °K coronene gives linewidth and second moment values of 9.3 ± 0.3 G and 8.5 ± 0.3 G^2, respectively. As the temperature is increased, these values drop to 1.5 ± 0.2 G and 1.2 ± 0.2 G^2, respectively (Figs. 1, 2). The linewidth transition is quite abrupt, centered at 160 °K, but the second moment transition is quite smooth. Calculation of the rigid-lattice second moment by the procedure of Van Vleck (9) using the crystal structure data of Robertson and White (4) and assuming C—H = 1.08 Å, yields a value of 7.0 G^2 in reasonable agreement with the low temperature experimental value (Table 1). The difference

TABLE 1. The observed and calculated* second moment values (G^2) for coronene, perylene, and triphenylene

Compound†	Observed	Calculated
Coronene (S)	8.5 (120 °K)	7.0
Coronene (R)	1.13 (298 °K)	1.3
Perylene (S)	8.0 (298 °K)	11.0
Triphenylene (S)	9.3 (298 °K)	10.2

*For details see text.
†(S) = stationary, (R) = rotating.

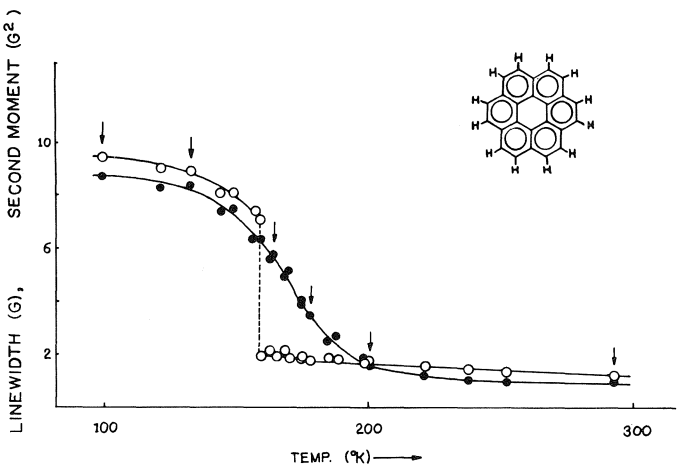

FIG. 1. The observed temperature dependence of the linewidth (open circles) and second moment values (filled circles) of the proton resonance of coronene in the solid state. The vertical arrows indicate the temperatures of the typical spectra shown in Fig. 2.

between the observed second moment of 8.5 G^2 at 120 °K and the calculated rigid lattice value of 7.0 G^2 may be due to a reduction in the lattice dimensions from the room temperature values, or to a small change in crystal structure. Coronene shows a thermal anomaly between 215 and 250 °K (12). Molecular reorientation of the molecule in the plane of the ring lowers this value to 1.3 G^2 by the formulae of Andrew and Eades (10), in agreement with the value experimentally observed. The change of second moment is attributed chiefly to reorientation of the coronene molecules about their six-fold axes. Other possible motions are excluded by the size of the molecule and the crystal structure data.

The sudden discontinuous change in linewidth with temperature may be due to a contribution from some unresolved structure in the spectrum observed at low temperatures when the lattice is rigid (adjacent hydrogen atoms on a given ring are close), or to some structural peculiarity which is present at low temperatures but which is relieved at 160 °K with the motion or the rings. It is not possible because of this asymmetry to obtain an estimate of the activation energy from the linewidth data by the B.P.P. approximation. It is also found that the variation of second moment with temperature does not lead to a straight line plot of ln ν_c *vs.* T^{-1} by use of the treatment proposed by Powles (13).

An activation energy can, however, be obtained from T_1 measurements. These are shown in Fig. 3 plotted as their logarithms against the reciprocal of absolute temperature. The gradient of the curve yields the activation energy for the process, found to be 5.8 kcal/mol. The empirical Waugh estimate based on the temperature of the linewidth transition (11) yields 5.9 kcal/mol, but the closeness of the agreement is probably fortuitous.

It is of interest to note that above $T^{-1} = 0.0047$ (below $T = 213$ °K) no values of T_1 have been given. This is because the intensity of the adiabatic rapid passage signals is very poor over the temperature range where the second moment is changing rapidly. This effect, which has been observed previously and will be reported in more detail in a separate communication, is characteristic of motional transitions which occur over a range of temperature without involving a phase change.

B. Perylene and Triphenylene

At room temperature, perylene gives a linewidth of 8.4 ± 0.3 G and a second moment of 9.3 ± 0.4 G^2. This latter value is in approximate agreement (Table 1) with the rigid lattice value calculated from the crystal structure data of Ahmed and Trotter (5). There is, however, little change in this value on raising the temperature to 520 °K. Similarly, at 298 °K triphenylene gives a linewidth of 7.6 ± 0.3 G, and the second moment of 9.3 ± 0.4 G^2 is in agreement with a

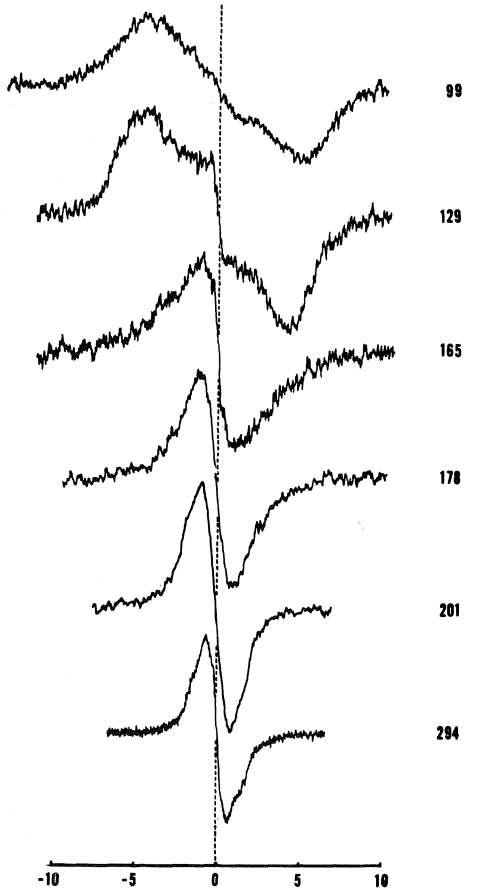

FIG. 2. Representative spectra of the ^1H n.m.r. spectrum of solid coronene recorded at the temperatures indicated. The corresponding points on the second moment curve are indicated by vertical arrows in Fig. 1. Abscissa in gauss.

calculated second moment value from the crystal structure data of Camerman and Trotter (6) (Table 1). Again there is only a slight change with temperature up to 470 °K.

The lack of exact agreement between the observed second moments and the calculated rigid lattice values is thought to be due to the fact that there are relatively large contributions to the second moments from close approaches of pairs of protons within one molecule. The exact positions of these sterically interacting atoms cannot be found with any degree of certainty, so their exact contributions to the total second moment is not known. The tendency in the molecule will be to minimize these steric interactions, so the calculated second moment will, if anything, tend to overestimate them.

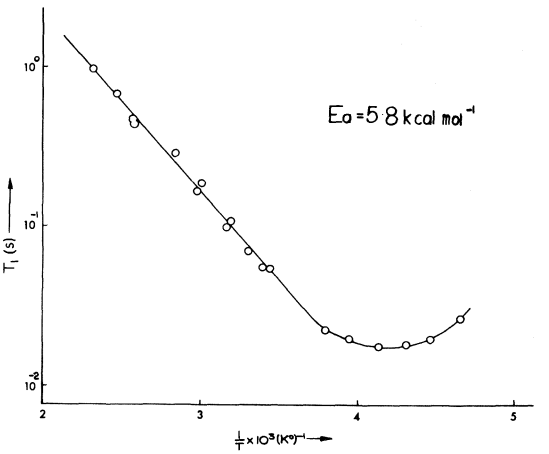

FIG. 3. The spin lattice relaxation time (T_1) of coronene in the solid state plotted on a logarithmic scale against the reciprocal of absolute temperature.

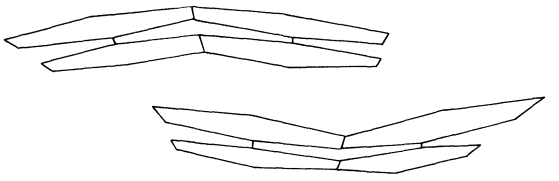
Discussion

Of the three polycyclics investigated, only one shows a motional transition (Table 1). This is in agreement with the thermodynamic data of Wong and Westrum (12), who investigated the heat capacities of a whole series of polycyclics. Of these, only pyrene and coronene showed anomalously small entropies of melting, indicative of molecular motion in the solid before melting.

A possible explanation may lie in the detailed molecular structure of the compounds in their crystal lattices. Thus, there is a small, but significant deviation of the perylene molecules from planarity (6). This is interpreted as being due to inter- rather than intra-molecular forces as no steric interactions are relieved by the distortion. The non-planarity of the molecules allows for a more favorable energy of packing. A side view is shown below.



The approach between the two molecules is close, and rotation of the molecules about their

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

centers would increase the intermolecular contacts and would be opposed, therefore, by a heightened energy barrier. It would be possible for rotation around a two-fold axis to occur without serious intermolecular contacts if the molecules passed through a planar configuration during the motion, but this would require an increase in lattice energy equal to the stabilizing effect on the lattice of the distortion of the molecules from planarity, and the rotation would be opposed by a correspondingly higher activation energy. Considering that the activation energy for the rotation in the molecular plane of pyrene, which is of roughly the same size as perylene, is *ca.* 14 kcal/mol (3), one can see that an increase in the energy barrier produced by the above effects could prevent rotational reorientation at frequencies detected by n.m.r. at accessible temperatures.

Triphenylene also shows significant deviations from planarity, two rings being raised with respect to the plane of the center ring, and the third lowered (5). It is thought that both inter- and intra-molecular forces may contribute to this distortion. However, rotation of the molecule would necessitate either a complete rotation of the distorted molecule by 360°, or the attainment of a planar structure during the motion, with again an increase in the activation energy for the process.

Distortion from a planar structure is not found in the two complexes of perylene whose structures have been determined (14, 15), and n.m.r. measurements on these may provide a guide to the correctness of the explanation given above.

The authors would like to thank Professor C. A. McDowell for his interest in this work and Professor E. F. Westrum for the communication of the thermodynamic data quoted prior to its publication. They would also like to thank the National Research Council of Canada for a scholarship (to J.R.) and grants-in-aid of research (to C.A.F. and B.A.D.).

The Effect of SF_6 and N_2O on the 2537 Å Photolysis of Aqueous I^- and $Fe(CN)_6^{4-}$ [1]

M. Crawford and R. Rumfeldt

Department of Chemistry, University of Windsor, Windsor, Ontario

Received May 10, 1971

The solvated electron yield from the 2537 Å photolysis of aqueous I^- containing N_2O and SF_6 is given by $\phi(e_{aq}^-) = \phi(F^-/6) + \{\phi(I_2) + \phi(N_2)\}$ with the calculated ratio $k_{e+SF_6}/k_{e+N_2O} = 2.00 \pm 0.2$. $\phi(e_{aq}^-)$ from the 2537 Å photolysis of aqueous $Fe(CN)_6^{4-}$ was measured using SF_6, N_2O, and mixtures of N_2O and SF_6 as the scavengers with the material balance being represented by $\phi(e_{aq}^-) = \phi(F^-/6) + \phi(N_2) = \phi(Fe(CN)_6^{3-})/2$. The average value obtained was $\phi(e_{aq}^-) = 0.67 \pm 0.03$ and the calculated values of k_{e+SF_6}/k_{e+N_2O} were 2.20 ± 0.2 from the product ratio's at low $[SF_6]$ and 1.86 ± 0.2 from a competition plot at higher $[SF_6]$. A mechanism is presented describing the specificity of SF_6 as a scavenger of e_{aq}^-.

Le rendement en électron solvaté, obtenu par photolyse à 2537 Å de I^- aqueux contenant N_2O et SF_6, est donné par $\phi(e_{aq}^-) = \phi(F^-/6) + \{\phi(I_2) + \phi(N_2)\}$ avec le rapport calculé $k_{e+SF_6}/k_{e+N_2O} = 2.00 \pm 0.2$. Le rendement $\phi(e_{aq}^-)$, obtenu par photolyse à 2537 Å de $Fe(CN)_6^{4-}$ aqueux, a été mesuré en utilisant SF_6, N_2O et des mélanges de N_2O et SF_6 en tant qu'agents piégeurs et avec un bilan matériel pouvant être représenté par: $\phi(e_{aq}^-) = \phi(F^-/6) + \phi(N_2) = \phi(Fe(CN)_6^{3-})/2$. La valeur moyenne obtenue est $\phi(e_{aq}^-) = 0.67 \pm 0.03$ et les valeurs calculées de k_{e+SF_6}/k_{e+N_2O} sont de 2.20 ± 0.2 à partir du rapport de produit à faible $[SF_6]$ et de 1.86 ± 0.2 à partir d'un tracé compétitif à $[SF_6]$ plus élevé. Un mécanisme est présenté pour décrire la spécificité de SF_6 en tant qu'agent piégeur de e_{aq}^-.

Canadian Journal of Chemistry, **49**, 3336 (1971)

Introduction

It has recently been demonstrated (1, 2) that the molecule SF_6 can be used quantitatively as a scavenger for solvated electrons generated either by the γ-radiolysis or photolysis of a variety of anions in aqueous solution. Whereas with the radiation chemical systems the kinetic evidence has confirmed the specificity of SF_6 as a hydrated electron scavenger, no such evidence has been offered with the photochemical systems. While it seems reasonable to assume that the rate constants or rate constant ratios should be independent of the method used to generate e_{aq}^-, it is a relatively simple matter to replace the assumption with experimental data.

The 2537 Å photolysis of aqueous I^- containing the competing solutes of SF_6 and N_2O was chosen as a model system since (*a*) the photolysis of aqueous I^- has been thoroughly studied (3) and should not present a source of anomalies, (*b*) the competing solutes are both neutral molecules thus eliminating the usual ionic strength corrections, (*c*) all the products of interest are easily and quantitatively measurable, and (*d*) the absolute rate constants and the rate constant ratios of e_{aq}^- with SF_6 and N_2O have been measured by the methods of radiation chemistry.

A second system of interest is the 2537 Å photolysis of $Fe(CN)_6^{4-}$. Although there can be no doubt that e_{aq}^- is produced, three widely differing values (1.0 (4), 0.66 (5), and 0.35 (6)) for $\phi(e_{aq}^-)$ have been reported. Since at least two of these values ($\phi(e_{aq}^-) = 0.66$ (5) and 0.35 (6)) were determined from very detailed studies of the $Fe(CN)_6^{4-}$ system, the origin of the disagreement is not obvious. Waltz and Adamson (7) have recently reported $\phi(e_{aq}^-) = 0.66$ thus tending to confirm the results of Airey and Dainton (5). However, it seems appropriate to study the effect of SF_6 on this system hopefully to substantiate, using this different scavenger, one or other of the previously reported values and, if possible, to elucidate the origin of the discrepancies.

Experimental

The apparatus and procedures are essentially the same as those described previously (2). In addition, an Oriel model C-13-62 low pressure Hg lamp operated with a stabilized power supply was used for most experiments. As a further precaution to assure the constancy of intensity, the actinometry was repeated immediately before and after each run.

All salts used in these experiments were reagent grade and used without further purification.

The iodine yields were measured as I_3^- using the spectrophotometric absorption at 353 mμ and the extinction coefficient $2.64 \times 10^4\ M^{-1}\ cm^{-1}$. The total iodine yield is given by the sum $I_3^- + I_2$ where I_2 was calculated using $742\ M^{-1}$ as the equilibrium constant for $I^- + I_2 \rightleftharpoons I_3^-$. The absorption at 420 mμ with $\varepsilon_{420\ m\mu} = 1.03 \times 10^3$ was used to calculate the $Fe(CN)_6^{3-}$ yields.

Results

(a) Photolysis of I^- Solution Containing SF_6 and N_2O

The products measured after irradiation with 2537 Å light of aqueous $5 \times 10^{-2}\ M\ I^-$ solutions containing SF_6 and N_2O were N_2, $I_2(I_3^-)$, and F^- the yields of which were linear with time for the irradiation times used. The total iodine yield is given by $\phi(I_2 + I_3^-)$, however, for convenience it shall simply be represented by $\phi(I_2)$. The relationships between the yields were $\phi(I_2) = \phi(N_2)$ and $\phi(e_{aq}^-) = \phi(F^-/6) + \phi(I_2)$, where $\phi(e_{aq}^-)$ has been determined from I^- solutions containing only SF_6 or N_2O at an equivalent concentration (see ref. 2 or 3).

The relative yields of F^- and I_2 depend upon the competing reactions depicted stoichiometrically by reactions 2 and 3.

[1] $$I^- + h\nu\ (2537\ Å) \rightarrow e_{aq}^- + I$$

[2] $$e_{aq}^- + SF_6 \rightarrow 6F^-, SO_4^{2-}, 8H^+$$

[3] $$e_{aq}^- + N_2O \rightarrow N_2, I_2, 2OH^-$$

Under the conditions used in these experiments, reaction 3 always predominated thus preventing a sufficient increase in $[H^+]$ to suppress the F^- yield. Accordingly, the pH of the photolyzed solutions were near neutral or slightly alkaline. The linear equation describing this competition

[4] $$[\phi(F^-/6]^{-1} = [\phi(e_{aq}^-)]^{-1} + [\phi(e_{aq}^-)]^{-1} k_3[N_2O]/k_2[SF_6]$$

(1) where k_2 and k_3 are the rate constants for reactions 2 and 3, respectively, requires that $\phi(e_{aq}^-)$ be constant over the range of scavenger concentrations employed, a condition not satisfied by the concentration range employed here ($[SF_6] = 1.8 \times 10^{-4}\ M$ and $[N_2O] = 1.0 \times 10^{-3}$ to $3 \times 10^{-3}\ M$ for which $\phi(e_{aq}^-)$ is known to vary).

By combining eq. 4 with the equivalent equation for $\phi(I_2)$ it is easily shown that the yield ratio is given by eq. 5.

[5] $$\phi(F^-/6)/\phi(I_2) = k_2[SF_6]/k_3[N_2O]$$

The mean value taken from six runs was $k_2/k_3 = 2.00 \pm 0.2$ and, within the limits of the experimental error, this value is in excellent agreement with that measured from the γ-radiolysis of aqueous SF_6–N_2O solutions (1). The effect of added salts on $10^{-2}\ M\ I^-$ solutions with $[SF_6] = 1.8 \times 10^{-4}\ M$ and $[N_2O] = 1.8 \times 10^{-3}\ M$ was tested using $4 \times 10^{-2}\ M$ of F^-, Cl^-, and Br^-, respectively. The yields from these solutions (including the $5 \times 10^{-2}\ M\ I^-$ solutions) differed by less than 3%, indicating no significant effect.

(b) Photolysis of $Fe(CN)_6^{4-}$ Solutions

(i) $Fe(CN)_6^{4-}$–N_2O Solutions

The main products measured on photolysis of aqueous $3.5 \times 10^{-3}\ M\ Fe(CN)_6^{4-}$ solutions containing $[N_2O] = 2 \times 10^{-2}\ M$ were N_2 and $Fe(CN)_6^{3-}$. A relatively low yield of CN^- was also measured, however, this was found to be the result of photohydrolysis which is the dominant process at exciting wavelengths longer than 2537 Å (9). The formation of $Fe(CN)_5H_2O^{3-}$ implied by the yield of CN^- would be too low to cause an error in the determination of $Fe(CN)_6^{3-}$ whose spectrum overlaps that of $Fe(CN)_5H_2O^{3-}$ at the analytical wavelength employed.

The quantum yield of N_2 was independent of the irradiation time and when the $Fe(CN)_6^{3-}$ yields were measured prior to the gas analysis, linear yield *vs.* time plots were obtained. Based on these plots the relationship and the average yield was found to be $\phi(Fe(CN)_6^{3-})/2 = \phi(N_2) = 0.64 \pm 0.04$ and independent of the lamp intensity over the range 2×10^{-4} to 6×10^{-6} einstein l^{-1} min^{-1}. These results are in excellent agreement with Airey and Dainton (5) and Waltz and Adamson (7).

The lower yields of Ohno (6) could not be reproduced although it was observed that the repeated freeze–thaw cycles employed in the gas analysis procedure caused a substantial reduction (~30%) in the optical density at 420 mμ; however, on standing the optical density slowly increased, approaching its original value.

(ii) $Fe(CN)_6^{4-}$–SF_6 Solutions

The variation of the F^- yield with irradiation time for the 2537 Å photolysis of $5 \times 10^{-3}\ M$ $Fe(CN)_6^{4-}$ solutions containing $[SF_6] = 1.4 \times 10^{-3}$ and $1.9 \times 10^{-4}\ M$ is shown in Fig. 1. The pronounced curvature in the F^- yields when $[SF_6] < 10^{-3}\ M$ is easily understood in terms of depletion of SF_6 as well as the competition for

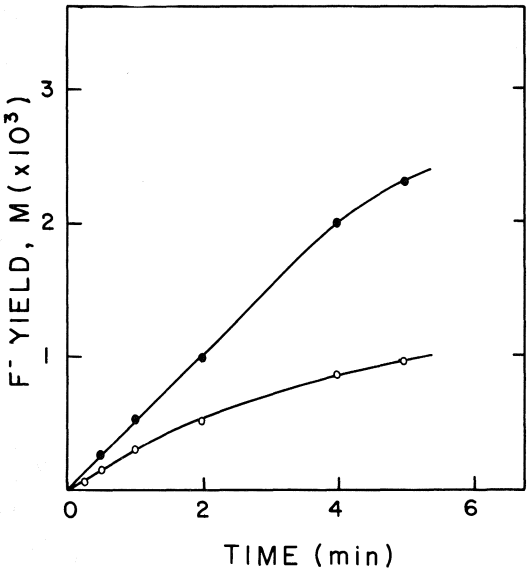

FIG. 1. The dependence of F^- yields on the irradiation time at an intensity of 1.24×10^{-4} einstein l^{-1} min^{-1} in the 2537 Å photolysis of aqueous $Fe(CN)_6^{4-}$ containing $[SF_6] = 1.9 \times 10^{-4}$ (○) and 1.4×10^{-3} *M* (●).

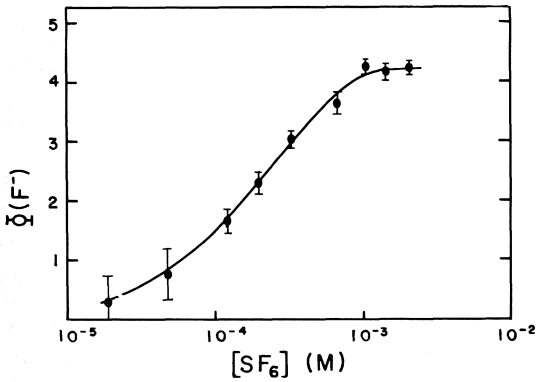

FIG. 2. The variation of $\phi(F^-)$ with $[SF_6]$ in the 2537 Å photolysis of $Fe(CN)_6^{4-}$.

e_{aq}^- by the product ions $Fe(CN)_6^{3-}$ and H^+ (the latter being indicated by a decrease in p*H*). Figure 2 illustrates the dependence of $\phi(F^-)$ on $[SF_6]$ where $\phi(F^-)$ has been determined from the initial linear portion of plots such as those in Fig. 1. When $[SF_6] < 10^{-4}$ *M* the yield *vs.* time plots exhibited continuous curvature precluding an accurate determination of $\phi(F^-)$ thus these values are necessarily only approximate. Using the plateau value of Fig. 2 and assuming a 1:6 ratio between e_{aq}^- and F^- as found in other systems then $\phi(e_{aq}^-) = \phi(F^-/6) = 0.69 \pm 0.02$. Again, good agreement is obtained with the value of Airey and Dainton (5).

In contrast to the N_2O–$Fe(CN)_6^{4-}$ system, the CN^- yields from the photolysis of SF_6–$Fe(CN)_6^{4-}$ solutions were relatively large (*i.e.* ~50% of the F^- yield) and due to the contribution of $Fe(CN)_5H_2O^{3-}$ at 420 mμ does not provide a reliable measure of the $Fe(CN)_6^{3-}$ yield. For example the apparent yield when $[SF_6] = 1.4 \times 10^{-3}$ *M* was $\phi(Fe(CN)_6^{3-}) = 1.90 \pm 0.10$. If $\phi(e_{aq}^-) = \phi(F^-/6) = \phi(Fe(CN)_6^{3-})/2$ then the material balance ratio, $\phi(F)/\phi(Fe(CN)_6^{3-})$, should be 3.0; however, values ranging from 2.5 to 1.7 were obtained depending upon $[SF_6]$ and irradiation time.

(iii) $Fe(CN)_6^{4-}$–N_2O–SF_6 Solutions

Solutions for which $[Fe(CN)_6^{4-}] = 3.5 \times 10^{-3}$ *M* and containing N_2O and SF_6 in the range $[N_2O] = 8.6 \times 10^{-4}$ to 1.5×10^{-2} *M* and $[SF_6] = 1.80 \times 10^{-4}$ to 1.4×10^{-3} *M* were photolyzed. In the experiments using $[SF_6] > 1.8 \times 10^{-4}$ *M* the high pressure cell employed was not readily attached to the gas analysis system, thus only F^- yields were measured. Since the sum $[N_2O] + [SF_6]$ was maintained sufficiently large to ensure that $\phi(e_{aq}^-)$ would be constant, eq. 4 was applicable. The appropriate plot is depicted in Fig. 3 from which the values $\phi(e_{aq}^-) = \phi(F^-/6) = 0.67 \pm 0.05$ and $k_2/k_3 = 1.85 \pm 0.2$ were calculated from the intercept and slope.

At the lower $[SF_6]$ both F^- and N_2 were determined. The p*H* of the photolyzed solutions remained near neutral and the CN^- yields were comparable to those of the $Fe(CN)_6^{4-}$–N_2O solutions, thus the absorbance at 420 mμ was

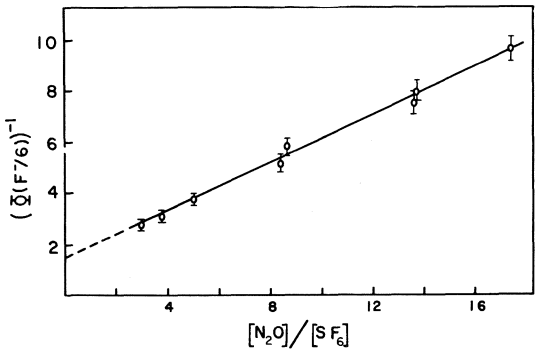

FIG. 3. The effect on $\phi(F^-/6)$ of varying $[N_2O]/[SF_6]$ in the 2537 Å photolysis of aqueous $Fe(CN)_6^{4-}$ in which $[N_2O] + [SF_6] > 10^{-3}$ *M*.

assumed to provide an acceptable measure of $Fe(CN)_6^{3-}$. The yield relationship was found to be $\phi(F^-/6) = \phi(Fe(CN)_6^{3-})/2$. Applying eq. 5 to the data from nine experiments in which $[SF_6] = 1.8 \times 10^{-4}$ *M* and $[N_2O]$ was in the range 8.6×10^{-4} to 2.9×10^{-3} *M* resulted in $k_2/k_3 = 2.20 \pm 0.20$.

Discussion

The values calculated for k_2/k_3 obtained from the photolysis of either aqueous I^- or $Fe(CN)_6^{4-}$ containing SF_6 and N_2O are seen to be in good agreement with those obtained by the techniques of radiation chemistry (Table 1). The independence of k_2/k_3 with respect to ionic strength is predictable on the basis of the Brönsted–Bjerrum theory; however, a specific ion effect which might have been anticipated was also absent. Anbar and Hart (10) have shown that the absorption maximum of e_{aq}^- is sensitive to both a change in solvent and added non-reactive solutes and have measured a substantial decrease in the rate of reaction 3 in concentrated electrolyte solutions. Unfortunately, these authors make no comment about the reduced solubility of N_2O in salt saturated solutions and by taking account of published solubility data (11) a substantial reduction in $[N_2O]$ is to be expected. Thus, it is uncertain whether the reported effect on reaction 3 is due to a reduction in $[N_2O]$ or k_3. In any event, for the photochemical systems studied k_2/k_3 was independent of the specific ionic atmosphere. It must be noted, however, that the solute concentrations may not have been sufficiently high to develop the potential effect thus the invariance observed cannot be assumed to be conclusive.

Over the range of $[N_2O]$ and $[SF_6]$ studied the material balance equations

$$[6] \quad \phi(e_{aq}^-) = \phi(F^-/6) + \{\phi(I_2) = \phi(N_2)\}$$

and

$$[7] \quad \phi(e_{aq}^-) = \phi(F^-/6) + \phi(N_2) = \phi(Fe(CN)_6^{3-})/2$$

were satisfied although the $Fe(CN)_6^{3-}$ yields cannot be assumed to be completely reliable. The evidence clearly confirms the relationship $\phi(e_{aq}^-) = \phi(F^-/6)$ despite the fact that in the I^- system there is no net oxidation while in the $Fe(CN)_6^{4-}$ system an overall oxidation of the $Fe(CN)_6^{4-}$ is indicated and which is equivalent to that obtained in the presence of N_2O alone.

The average value, $\phi(e_{aq}^-) = 0.67 \pm 0.03$, for the 2537 Å photolysis of $Fe(CN)_6^{4-}$ as determined from the three different systems ($\phi(N_2)$ from N_2O saturated solutions, $\phi(F^-/6)$ from solutions in which $[SF_6] = 2 \times 10^{-3}$ *M* and the intercept of the competition plot) provides convincing support for the value reported by Airey and Dainton (5). The larger value previously reported (4) may have resulted by not taking account of the presence of a high yield of $Fe(CN)_5H_2O^{3-}$; however, an adequate explanation for the low yields reported by Ohno (6) is not apparent and this discrepancy remains unresolved.

The special advantage of SF_6 is in the quantitative relationship $\phi(e_{aq}^-) = \phi(F^-/6)$ and in its specificity towards e_{aq}^-. Even hydrogen atoms fail to react with SF_6, suggesting that its reactions are kinetically controlled. An apparent exception to the inert character of SF_6 is the reaction with exploding metals (12). While seemingly unrelated, a similarity between these latter "reagents" and e_{aq}^- is in their low ionization potentials suggesting that reaction with SF_6 is an electron transfer process, determined in part by the high electron affinity of SF_6 and the low ionization potential of the donor species.

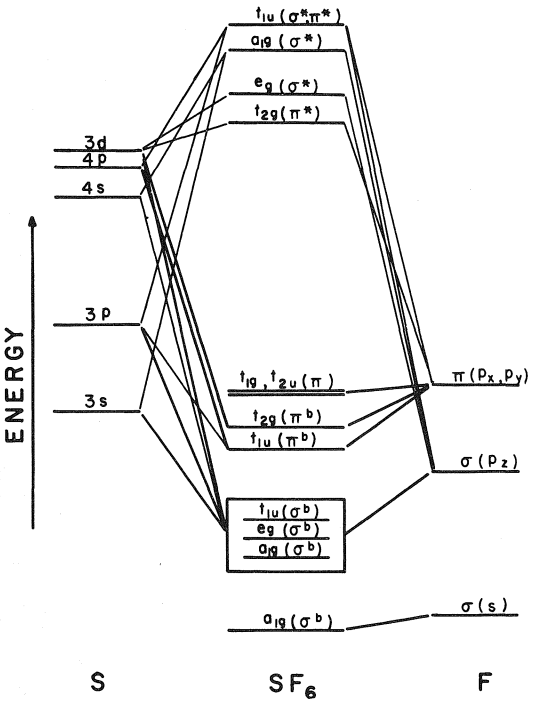

FIG. 4. Molecular orbital scheme for SF_6 based on the orbital transformation properties in O_h symmetry.

Figure 4 represents a qualitative molecular orbital diagram of SF_6 based on the orbital transformation properties in O_h symmetry. For simplicity the core approximation is made for the fluorine 2s electrons leaving a p^5 valence configuration for fluorine. It can be seen that the valence 3s and 3p electrons of sulfur would become localized on the fluorine principally through the a_{1g} and t_{1u} (σ) orbitals. Hypothetically this would leave sulfur in an extremely electron deficient state, thus some balancing of the charge density would be required and can conveniently be visualized as involving the t_{1u} and $t_{2g}(\pi)$ molecular orbitals. This partial withdrawal of charge from the fluorine through the π bonds would be augmented if there was a contraction of the nonbonding t_{1g} and t_{2u} orbitals, thereby reducing the effective nuclear charge of the fluorines. Such a scheme describes SF_6 with effectively no accessible lone pairs which would account for its lack of any discernible nucleophilic character, extremely low solubility and generally inert character. In particular this marked reduction in the availability of fluorine electrons would inhibit the formation of a transition state in possible highly exothermic abstraction reactions with reagents such as hydrogen atoms. On the other hand this scheme also describes the fluorines as being relatively electron deficient as compared to F^-, thus causing an overall high molecular electron affinity.

Further reference to Fig. 4 shows that the addition of an electron to SF_6 to yield SF_6^- would involve the use of a high energy anti-bonding orbital (presumably the $e_g(\sigma^*)$ or $t_{2g}(\pi^*)$ thus destabilizing the molecule. Dissociation of SF_6^- could follow a variety of paths (13) however, maximum π bonding would be maintained by the dissociative process

$$[8a] \qquad e + SF_6 \rightarrow SF_6^-$$

$$[8b] \qquad SF_6^- \rightarrow SF_5 + F^-$$

where SF_5 would have a trigonal bipyramidal structure. The reaction of SF_5 with an oxidizable substrate should simply parallel that proposed for SF_6 *i.e.*

$$[9a] \qquad SF_5 + A^- \rightarrow SF_5^- + A$$

$$[9b] \qquad SF_5^- \rightarrow SF_4 + F^-$$

resulting in SF_4 which also has a trigonal bipyramidal structure (14) with the lone pair being in the trigonal plane. Reactions 8*b* and 9*b* are not meant to imply the existence of SF_6^- or SF_5^- as intermediates as these species may be in repulsive states in which case reaction 8*a* with 8*b* and 9*a* with 9*b* would constitute single concerted reactions.

The hydrolysis of SF_4 has been found to yield SOF_2 (12) which further hydrolyses to SO_3^{2-}. In systems such as I^- the final redox balance would be achieved by the reduction of I_2 either by SOF_2 or SO_3^{2-} which are stoichiometrically equivalent. In the case of $Fe(CN)_6^{4-}$ material balance requires that SOF_2 must be hydrolyzed without a further increase in the oxidation state of sulfur. Unfortunately, in this system the final state of sulfur could not be determined, however, SO_3^{2-} seems the most likely product.

These mechanistic considerations can be summarized by the following general reaction scheme

$$[10] \qquad SF_6 + A^- \rightarrow SF_6^- + A$$

$$[8b] \qquad SF_6^- \rightarrow SF_5 + F^-$$

$$[9a] \qquad SF_5 + A^- \rightarrow SF_5^- + A$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[9*b*] $$SF_5^- \rightarrow SF_4 + F^-$$

[11] $$SF_4 + H_2O \rightarrow SOF_2 + 2H^+2F^-$$

[12] $$SOF_2 + 2H_2O \rightarrow SO_3^{2-} + 4H^+2F^-$$

[13] $$SO_3^{2-} + 2A + H_2O \rightarrow SO_4^{2-} + 2H^+ + 2A^-$$

While this reaction sequence is consistent with the essential features observed in the radiation chemistry and photochemistry of aqueous solutions containing SF_6, it does not preclude the possibility of additional significant reactions. For example, from conductometric pulse radiolysis studies of aqueous SF_6 in the absence of added solutes the intermediate SF_5 was found to react directly with H_2O (15). Since reaction 14

[14] $$SF_5 + H_2O \rightarrow SF_4 + F^- + OH + H^+$$

is effectively equivalent to reaction 9*a* with 9*b*, then no change in the stoichiometry would result. Of potential greater consequence are those reactions which describe the reactivity of the product F^- in the particular medium investigated. The use of simple reagent blanks should ordinarily provide a reasonable basis for assessing the lability of F^- and consequently the validity of the relationship $\phi(e_{aq}^-) = \phi(F^-/6)$.

Total Synthesis of DL-Glucose, 3-*O*-Methyl-DL-glucose, and 3-Deoxy-DL-*ribo*-hexopyranose from 1,6:3,4-Dianhydro-β-DL-*allo*-hexopyranose, a Product Obtained from Acrolein Dimer

U. P. SINGH[1] AND R. K. BROWN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 7, 1971

The reaction of butyllithium in ether with 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**1**), a substance obtained in five steps from acrolein dimer, gave 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose (**2**). The compound 1,6:3,4-dianhydro-β-DL-*allo*-hexopyranose (**3**), obtained from **2**, was converted by reaction with aqueous barium hydroxide followed by hydrolysis of the product, to DL-glucose **5**. Treatment of **3** with sodium methoxide in methanol followed by acid hydrolysis of the 1,6-anhydro intermediate **6**, gave 3-*O*-methyl-DL-glucose (**7**). The same intermediate, **6**, along with the methyl glycoside **8**, could be obtained by the acid-catalyzed reaction of **3** with methanol. Lithium aluminum hydride reacted with **3** to form 1,6-anhydro-3-deoxy-β-DL-*ribo*-hexopyranose (**9**), which was hydrolyzed readily to 3-deoxy-DL-*ribo*-hexopyranose (**10**).

Yields were excellent throughout. All products obtained from the oxirane **3** were those resulting only from *trans* diaxial opening of the oxirane ring.

La réaction du butyllithium dans l'éther avec le 1,6:2,3-dianhydro-4-déoxy-β-DL-*ribo*-hexopyranose (**1**), une substance obtenue en cinq étapes à partir du dimère de l'acroléine, a donné le 1,6-anhydro-3,4 didéoxy-β-DL-*erythro*-hex-3-énopyranose (2). On a converti le composé 1,6:3,4-dianhydro-β-DL-*allo*-hexopyranose (**3**), obtenu de **2**, en DL-glucose **5**, par la réaction avec l'hydroxyde de baryum en solution aqueuse suivie de l'hydrolyse du produit. Le 3-*O*-méthyl-DL-glucose (**7**) fut obtenu à partir de la réaction de **3** avec le méthoxyde de sodium dans le méthanol, suivie par l'hydrolyse acide de l'intermédiaire 1,6-anhydro **6**. On a pu obtenir le même intermédiaire **6**, avec le glycoside de méthyl **8**, par la réaction catalysée par les acides de **3** dans le méthanol. L'hydrure de lithium et d'aluminium a réagi avec **3** pour former le 1,6-anhydro-3-déoxy-β-DL-*ribo*-hexopyranose (**9**), qu'on a hydrolysé facilement en 3-déoxy-DL-*ribo*-hexopyranose (**10**).

Les rendements se sont avérés partout excellents. Tous les produits obtenus à partir de l'oxirane **3** étaient ceux résultant de l'ouverture *trans* diaxiale du noyau oxirane.

Canadian Journal of Chemistry **49**, 3342 (1971)

Introduction

A preliminary communication (1) from this laboratory reported the synthesis of DL-glucose from 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose (**1**), an intermediate product obtained in five steps from acrolein dimer. This note provides the experimental details for the synthesis of DL-glucose, and as well describes the conversion of **1** to 3-deoxy-DL-*ribo*-hexopyranose and to 3-*O*-methyl-DL-glucose and its methyl glycoside, thus indicating the synthetic utility of compound **1**.

Results and Discussion

The sequence of reactions and the compounds obtained are shown in Scheme 1. The 100 MHz p.m.r. spectra obtained for all of the isolated compounds are in full agreement with the structures shown. The signals for most of the protons could be determined by spin decoupling, and these provided observed couplings which clearly supported these structures and the conformations indicated.

The reaction of *n*-butyllithium readily converted **1**, in ether, to 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose (**2**) whose *O*-methyl and *O*-acetyl derivatives have been described elsewhere (2). The reaction of *m*-chloroperoxybenzoic acid with **2** gave only the *exo* oxirane, **3**, as expected (3), with no evidence for simultaneous formation, even in small amount, of the *endo* oxirane isomer. Opening of the oxirane ring by base gave 1,6-anhydro-β-DL-*gluco*-hexopyranose (**4**, R = H), in good yield, and this product was hydrolyzed to DL-glucose (**5**, R = H), a crystalline solid. The 100 MHz p.m.r. spectra of **5** (R = H) in D_2O and of its pentaacetate in $CDCl_3$ were identical

to those of authentic D-glucose and its penta-acetate.

The oxirane **3**, treated with sodium methoxide in methanol, gave a very good yield of 1,6-anhydro-3-*O*-methyl-β-DL-*gluco*-hexopyranose (**6**, R = H), a viscous oil, as the only isolable product. The p.m.r. spectra of **6** (R = H) and of its diacetate (also a viscous oil) were in accord with the assigned structures. Hydrolysis of the diacetate of **6** with 1 *N* hydrochloric acid gave an excellent yield of 3-*O*-methyl-α,β-DL-glucopyranose (**7**, R = H) whose 100 MHz p.m.r. spectrum in D_2O was identical to that of authentic 3-*O*-methyl-α,β-D-glucopyranose. Compound **6** (R = H) was also obtained as the major product when **3** was heated in methanol containing *p*-toluenesulfonic acid monohydrate. This was accompanied by the product **8** (R = H) whose formation could not be avoided. Treatment of **3** with a mixture of methanol and Amberlite IRA-120 (H^+) gave an excellent yield of what is believed to be methyl 3-*O*-methyl-α,β-DL-glucopyranoside (**8**, R = H). The 100 MHz p.m.r. spectrum of **8** (R = H) in D_2O showed two doublets ($J \sim 3.5$ and 8 Hz) in the anomeric proton region, corresponding to a mixture of the α- and β-pyranose isomers, the latter being present to the extent of ~5–10%. All the signals of the D_2O p.m.r. spectrum of authentic methyl 3-*O*-methyl-α-D-glucopyranoside (in which the anomeric proton signal for the β-isomer was absent) were found in the spectrum of the DL-glucopyranoside. However, there were additional signals present in the spectrum of the DL-glucopyranoside, but these could be due to the presence of the contaminating β-isomer. Better corroboration of the structure of **8** was found when it was converted to a crystalline triacetate, whose 100 MHz p.m.r. spectrum in $CDCl_3$ was identical to that of the triacetate of authentic methyl 3-*O*-methyl-α-D-glucopyranoside.

Treatment of a solution of **3** in tetrahydrofuran (THF) with $LiAlH_4$ gave a nearly quantitative yield of 1,6-anhydro-3-deoxy-β-DL-*ribo*-hexopyranose (**9**, R = H). Acid-catalyzed hydrolysis of **9** (R = H) gave **10** (R = H) whose p.m.r. spectrum in D_2O possessed four sets of doublets in the anomeric proton signal region, indicating that **10** (R = H) in D_2O existed as an equilibrium mixture of α- and β-pyranose and furanose structures, with the β-pyranose isomer as the major component. Acetylation of **10** (R = H) gave an excellent yield of a solid tetraacetate whose 100 MHz p.m.r. spectrum identified the structure as 1,2,4,6-tetra-*O*-acetyl-3-deoxy-β-DL-*ribo*-hexopyranose.

It is interesting that the only isolable products obtained from the reaction of **3** with each of the reagents, aqueous base, sodium methoxide in methanol, methanol containing an acid, and $LiAlH_4$ in THF, were those arising from a *trans* diaxial opening of the oxirane ring, a reaction course which has been found to take place preferentially with other oxiranes (3–6).

Experimental

Melting points and boiling points are uncorrected. Elemental analyses were made by Mrs. D. Mahlow and Mrs. A. Dunn of our microanalytical laboratory. The i.r. absorption spectra were obtained by Mr. R. Swindlehurst, of this Department, using a Perkin–Elmer Model 421 spectrophotometer. The 100 MHz p.m.r. spectra and spin decoupling experiments were made by Mr. G. Bigham and associates in this Department. Tetramethylsilane was the internal reference. Signal assignments were made with the aid of double irradiation spin decoupling. The reported coupling constants were estimated from the signal spacings where possible, and are therefore approximate values.

Column and thin layer chromatography was carried out using Silica Gel G (Merck and Co.) as adsorbent. Solvents were usually removed by rotary evaporator under vacuum, unless otherwise stated. The drying agent employed for organic solutions was anhydrous sodium sulfate.

*1,6-Anhydro-3,4-dideoxy-β-DL-erythro-hex-3-enopyranose (**2**, R = H)*

A solution of 2.56 g (0.02 mol) of the oxirane **1** (7) in 50 ml of anhydrous ether, was kept at 0° while 12 ml of a 22% solution of *n*-butyllithium (0.041 mol) in hexane was added dropwise over a 15 min period. Throughout the reaction the solutions were protected from the atmosphere by nitrogen. The yellow reaction mixture was allowed to warm slowly to room temperature and then left overnight. It was treated cautiously with water and the ether layer was then separated. The aqueous layer was extracted continuously for 24 h with dichloromethane. The combined ether layer and dichloromethane extracts were dried and freed from drying agent and solvent. The resulting yellow oil solidified when cooled, and gave after crystallization from chloroform–hexane, 2.10 g (82%) of **2** (R = H), m.p. 67–68°.

Anal. Calcd. for $C_6H_8O_3$: C, 56.25; H, 6.25. Found: C, 56.31; H, 6.60.

The i.r. spectrum in chloroform showed strong absorption at 3575 (sharp) and 3445 cm^{-1} (broad) for OH.

The 100 MHz p.m.r. spectrum in $CDCl_3$ had signals at τ 4.34 for H-1 (narrow triplet, $J_{1,2} \sim 2.0$, $J_{1,3} \sim 1.5$ Hz); 6.27–6.50 for H-2, (min.)-6_{exo} and (min.)-6_{endo} (multiplet); 4.26 for H-3 (doublet of quartets), $J_{2,3} \sim$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

3.5, $J_{3,4} \sim 10.0$ Hz); 3.88 for H-4 (doublet of doublets, $J_{4,5} \sim 4.5$ Hz); 5.25–5.45 for H-5 (multiplet); 6.82 for O*H* (singlet, $w/2 \sim 6$ Hz).

*1,6:3,4-Dianhydro-*β*-*DL*-allo-hexopyranose (**3**)*

To a solution of 2.56 g (0.02 mol) of **2** (R = H) in 100 ml of dry dichloromethane was added 6.88 g (0.04 mol) of 80% *m*-chloroperoxybenzoic acid. The reaction mixture was protected from moisture while being stirred at room temperature for 24 h. The precipitated *m*-chlorobenzoic acid was removed and the filtrate stirred with excess anhydrous sodium carbonate. The solids were then removed by filtration and the filtrate freed of solvent. The crude **3**, contaminated with *m*-chlorobenzoic acid, was purified by chromatography using dichloromethane – ethyl acetate (2:1) as eluent. The first fraction contained the *m*-chlorobenzoic acid; the second contained **3** which gave colorless needles from dichloromethane – *n*-hexane, m.p. 108–109°; yield, 2.31 g (80%).

Anal. Calcd. for $C_6H_8O_4$: C, 50.00; H, 5.59. Found: C, 49.79; H, 5.25.

The i.r. spectrum in chloroform showed bands at 3515 (OH) and 1250 cm^{-1} (oxirane).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed signals at τ 4.75 for H-1 (narrow multiplet, $J_{1,2} \sim 1.0$, $J_{1,3} \sim 2.0$ Hz); 6.39 for H-2 (quartet, $J_{2,3} \sim 4.5$, $J_{2,OH} \sim 12$ Hz); 6.65 for H-3 (triplet of quartets, $J_{3,4} \sim 4.5$, $J_{3,5} \sim 0.7$ Hz); 6.77 for H-4 (doublet of doublets, $J_{4,5} \sim 1.8$ Hz); 5.28 for H-5 (complicated doublet); 6.01 for H-6_{endo} (doublet of doublets, $J_{6exo,6endo} \sim 7.5$, $J_{5,6endo} \sim 0.7$ Hz); 6.22 for H-6_{exo} (doublet of doublets, $J_{5,6exo} \sim 4.3$ Hz); 7.14 for O*H* (doublet).

*1,6-Anhydro-*β*-*DL*-glucopyranose (**4**, R = H)*

The oxirane **3** (0.5 g) was heated for 15 h under nitrogen with 10% barium hydroxide in a 2:1 water–dioxane solution. The solution was then cooled, diluted with dioxane, and neutralized with carbon dioxide. The barium carbonate precipitate was removed, and the filtrate freed of solvent, leaving 450 mg (80%) of colorless syrup.

A portion of this syrup (200 mg) was treated with a mixture of 5 ml of acetic anhydride and 5 ml of pyridine at room temperature for 24 h, giving 1,6-anhydro-β-DL-glucopyranose triacetate (**4**, R = CH_3CO) as a colorless syrup, b.p. 130–131° at 0.1 mm; yield, 325 mg (91%).

Anal. Calcd. for $C_{12}H_{16}O_8$: C, 50.00; H, 5.59. Found: C, 49.78; H, 5.29.

The i.r. spectrum in chloroform showed strong absorption at 1740 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum was identical to that of authentic 1,6-anhydro-β-D-glucopyranose triacetate.

*α,β-*DL*-Glucose (**5**, R = H)*

A quantity (200 mg) of **4** (R = H) in 10 ml of 1 *N* aqueous hydrochloric acid was heated for 5 h in an oil bath at 100°. The mixture was cooled and neutralized with Amberlite IRA-400 ($OH^{\ominus}$) and then filtered. The filtrate was freed from solvent and the residue was freeze dried, giving a colorless glassy solid which produced needles from aqueous ethanol – ether, m.p. 113–115°; yield, 190 mg (81%). Reported m.p. of a 1:1 mixture of D- and L-glucose, 112–113.5 (8).

Anal. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.71. Found: C, 39.60; H, 6.64.

DL-Glucose gave the same spectral characteristics shown by D-glucose and showed the presence of two anomeric proton signals in the area ratio of 1:2 for the α and β anomers.

Hydrolysis of the triacetate of **4** as above gave α,β-DL-glucose in 87% yield.

*α,β-*DL*-Glucose Pentaacetate (**5**, R = CH_3CO)*

Acetylation of 50 mg of **5** (R = H) as was done for compound **4** (R = H) above, gave a viscous liquid which deposited colorless prisms from chloroform – petroleum ether, m.p. 115–117°; yield, 97 mg (90%).

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.24; H, 5.64. Found: C, 49.60; H, 5.50.

The 100 MHz p.m.r. spectrum of this material in $CDCl_3$ was identical to that of authentic fully acetylated D-glucose and showed the presence of two anomeric proton signals in the area ratio of 1:2 for the α and β anomers.

*1,6-Anhydro-3-O-methyl-*β*-*DL*-glucopyranose (**6**, R = H)*

A solution of 400 mg of the oxirane **3** in 30 ml of dry methanol, previously treated with 1.0 g of sodium metal, was heated under reflux, and meanwhile protected by a nitrogen atmosphere. The disappearance of **3** was followed by t.l.c. using 1% methanol in chloroform as solvent. The reaction was complete after 30 h. The solution was cooled, then neutralized with IRA-120 ($H^{\oplus}$) in methanol. The resin was removed and the filtrate freed from solvents to provide, after distillation, pure **6** (R = H) as a colorless syrup, b.p. 140–143° at 0.1 mm; yield, 380 mg (80%).

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.73; H, 6.87. Found: C, 47.40; H, 6.66.

*2,4-Di-O-acetyl-1,6-anhydro-3-O-methyl-*β*-*DL*-glucopyranose (**6**, R = CH_3CO)*

A quantity (250 mg) of **6** (R = H) was treated with 10 ml of a 1:1 mixture of acetic anhydride and pyridine for 1 h at 60°. From this was obtained 335 mg (90%) of crude diacetate which when distilled at 100–105° at 0.1 mm gave a viscous oil.

Anal. Calcd. for $C_{11}H_{16}O_7$: C, 50.77; H, 6.20. Found: C, 51.06; H, 5.91.

The i.r. spectrum in chloroform showed strong absorption at 1735 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in $CDCl_3$ had signals at τ 4.74 for H-1 (singlet, $w/2 \sim 3.5$, $J_{1,2} \sim 1.5$ Hz); 5.38–5.65 for H-2, (min.)-4 and (min.)-5 (multiplet, $J_{5,6endo} \sim 1.5$, $J_{5,6exo} \sim 5.5$ Hz); 6.83–6.95 for H-3 (multiplet); 6.05 for H-6_{endo} (doublet of doublets, $J_{6exo,6endo} \sim 7.5$ Hz); 6.30–6.55 for H-6_{exo} (multiplet); 6.63 for OCH_3 (singlet); 7.94 and 7.96 (singlets for two CH_3CO).

*3-O-Methyl-α,β-*DL*-glucose (**7**, R = H)*

A solution of 280 mg of **6** (R = CH_3CO) in a mixture of 10 ml of 1 *N* aqueous hydrochloric acid and 5 ml of dioxane was heated at 80° for 5 h in an oil bath. The reaction mixture was cooled and neutralized with Amberlite IRA-400 ($OH^{\ominus}$) and filtered. The solvent was removed from the filtrate and the residue was freeze-dried. The resulting colorless syrup, when crystallized from methanol–ether, gave fine hygroscopic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

needles, m.p. 135–137° (shrinking at 80°); yield, 190 mg (91%). The above syrup could also be distilled at 155–157° at 0.1 mm to provide a viscous oil which crystallized when seeded.

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.30; H, 7.27. Found: C, 43.31; H, 7.18.

The 100 MHz p.m.r. spectrum of **7** (R = H) in D_2O after the solution had stood 24 h to allow completion of mutarotation, was identical to that of authentic 3-*O*-methyl-α,β-D-glucose.

*Methyl 3-O-Methyl-α,β-DL-glucopyranoside (**8**, R = H)*

A solution of the oxirane, **3**, (600 mg) in 50 ml of anhydrous methanol containing 2 g of Amberlite IRA-120 ($H^{\oplus}$) was heated under reflux for 60 h. The solution was cooled, separated from the resin by filtration, and the filtrate freed from solvent. The colorless syrup so obtained (800 mg, 92%) gave a single spot on a t.l.c. plate (solvent, methanol–chloroform, 1:10), and also gave an R_f value similar to that of the corresponding authentic D compound.

The i.r. spectrum of this syrup and that of authentic methyl 3-*O*-methyl-D-glucopyranoside (both in $CHCl_3$) were identical.

The 100 MHz p.m.r. spectrum of **8** (R = H) in D_2O showed signals at τ 4.97 for H-1 of the α isomer (doublet, $J \sim 3.5$ Hz); 5.38 for H-1 of the β isomer (doublet, $J \sim 8.0$ Hz) with the α anomer in large predominance. The signal for the β isomer was absent in the spectrum of the authentic D-glucopyranoside as were several other signals found in the spectrum of the DL-substance. The origin of these extra signals is unknown, but could be due to contaminating β isomer.

Acceptable evidence for the structure was obtained by conversion of **8** (R = H) to its triacetate, isolated after work-up as a colorless syrup which crystallized from ether and petroleum ether as needles, m.p. 81–81°; yield 845 mg (87%).

Anal. Calcd. for $C_{14}H_{22}O_9$: C, 50.30; H, 6.63. Found: C, 50.30; H, 6.82.

The spectral characteristics of this triacetate were identical to those of the authentic D isomer.

*Reaction of **3** with Methanol Containing p-Toluenesulfonic Acid Monohydrate*

A solution of **3** (500 mg) in 50 ml of anhydrous methanol containing 250 mg of *p*-toluenesulfonic acid monohydrate was heated under reflux for 10 h. The disappearance of **3** during the reaction was followed by t.l.c. (solvent, ethylacetate–chloroform, 2:1). The mixture was cooled and then brought to $pH \sim 9$ with sodium methoxide. The methanol was removed and the residue was diluted with 50 ml of water and this mixture was subjected to continuous liquid–liquid extraction with chloroform for 48 h. The chloroform solution was freed from solvent and gave a syrup which showed two spots on t.l.c. (2% methanol in chloroform). The two components were separated by column chromatography. The first fraction obtained by elution with 1% methanol in chloroform gave 337 mg (60%) of material identical with product **6** (R = H). The second fraction obtained by elution with 5% methanol in chloroform gave a syrup (216 mg, 30%), which on acetylation with acetic anhydride and pyridine provided 312 mg (91%) of crystalline material, m.p. 81–82°, which was identical to the triacetate of **8** above.

*1,6-Anhydro-3-deoxy-β-DL-ribo-hexopyranose (**9**, R = H)*

A solution of 500 mg of **3** in 25 ml of dry, freshly distilled tetrahydrofuran (THF) was added slowly and dropwise to a stirred suspension of $LiAlH_4$ (400 mg) in 30 ml of dry THF at room temperature and under nitrogen. After addition was completed, the reaction mixture was stirred overnight at room temperature, and then heated to reflux for 45 min. The solution was cooled and treated with 15 ml of THF saturated with water and then with 2 ml of 15% aqueous sodium hydroxide solution. The granular precipitate was removed by filtration and the filtrate was dried. Removal of the drying agent and then the solvent gave a syrup which solidified on cooling. This material showed only one spot on t.l.c. (solvent, dichloromethane). Sublimation at 100–105° at 0.1 mm provided colorless needles, m.p. 117–119°; yield, 497 mg (98%).

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90. Found: C, 49.45; H, 6.66.

The i.r. spectrum in chloroform showed absorption at 3600 and 3470 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in $CDCl_3$ showed signals at τ 4.60 for H-1 (singlet, $w/2 \sim 4$ Hz); 5.75–6.50 for H-2, (min.)-4, -6_{exo}, (min.)-6_{endo}, 20H (multiplet); 7.75–8.30 for H-3_{exo}, -3_{endo} (multiplet); 5.30–5.54 for H-5 (multiplet).

*2,4-Di-O-acetyl-1,6-anhydro-3-deoxy-β-DL-ribo-hexopyranose (**9**, R = CH_3CO)*

Treatment of 300 mg of **9** (R = H) with 10 ml of a 1:1 mixture of acetic anhydride and pyridine at 60° for 0.5 h, and the solution then left overnight at room temperature, gave a colorless solid which was sublimed at 90–95° at 0.2 mm. Colorless needles, m.p. 123–124°; yield, 357 mg (96%).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.19; H, 6.13. Found: C, 52.31; H, 6.11.

The i.r. spectrum in chloroform showed strong absorption at 1735 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in $CDCl_3$ had signals at τ 4.54 for H-1 (doublet, $J_{1,2}$ 1.5 Hz); 5.20–5.45 for H-2, (min.)-4, and (min.)-5 (multiplet); 7.55–8.25 for H-3_{exo}, -3_{endo} (multiplet); 6.05–6.25 for H-6_{exo}, -6_{endo} (multiplet); 7.84 and 7.86 (two singlets for CH_3CO).

*3-Deoxy-α,β-DL-ribo-hexopyranose (**10**, R = H)*

A solution of 250 mg of **9** (R = H) in a mixture of 10 ml of 1 *N* aqueous hydrochloric acid and 5 ml of dioxane was heated at 80° for 5 h with an oil bath. The mixture was cooled and then neutralized with Amberlite IRA-400 ($OH^{\ominus}$). Removal of the solvent from the filtrate gave a residue which was freeze dried. The resulting pale yellow syrup showed only one spot on t.l.c. (solvent, 7% methanol in chloroform, or 3% methanol in ethyl acetate). Distillation at 139–145° at 0.01 mm gave **10** (R = H) as a colorless viscous oil; yield 235 mg (91%); lit. m.p. of the D isomer, 108–111° (9).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 44.27; H, 7.23.

The 100 MHz p.m.r. spectrum in D_2O, taken after the compound had been in solution 48 h, showed

signals at τ 4.72 (doublet, $J \sim 4.0$ Hz), 4.91 (doublet, $J \sim 3.5$ Hz), 5.04 (doublet, $J \sim 3.0$ Hz) and 5.47 (doublet, $J \sim 8.0$ Hz) for H-1 of the α- and β-furanose and pyranose isomers, with the β-pyranose quite predominant. No change was observed in the spectrum taken again after the solution had stood for a week.

*3-Deoxy-β-DL-ribo-hexopyranose Tetraacetate (**10**, R=CH_3CO)*

Acetylation of 150 mg of **10** (R=H) as had been done for **9** (R=H) above gave a syrup from which the tetraacetate was obtained as colorless needles from ether and hexane, m.p. 114–115°; yield, 278 mg (91%).

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.71; H, 6.02.

The i.r. spectrum in chloroform showed strong absorption at 1745 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in $CDCl_3$ indicated that only one compound, the β-pyranose isomer, was present. Signals occurred at τ 4.39 for H-1 (doublet, $J_{1,2} \sim 8.0$ Hz); 5.05–5.35 for H-2, (min.)-4 (multiplet); 7.30–7.55 for H-3_{endo} (multiplet); 8.10–8.60 for H-3_{exo} (multiplet); 6.10–6.40 for H-5 (multiplet); 5.75–5.95 for the two C-6 protons; 7.93, 7.97, 7.99, 8.00 (four singlets for CH_3CO).

The filtrate from the above tetraacetate provided a material which had the same i.r. spectrum and R_f value on a t.l.c. plate (solvent, chloroform) as did the tetraacetate, but the 100 MHz p.m.r. spectrum showed four doublets in the anomeric proton signal region indicating the presence of both the α- and β-furanose and -pyranose isomers with the β-pyranose isomer predominant; τ 3.70 (d, $J \sim 4.0$ Hz), 3.84 (d, $J \sim 3.80$ Hz); 3.90 ($J \sim 0$ Hz) and 4.36 (d, $J \sim 8.0$ Hz).

The authors thank the National Research Council of Canada for financial support for this work.

A Novel S_N1 Displacement: The Reaction of Tertiary Amines with Acetic Anhydride

R. P. MARIELLA AND K. H. BROWN[1,2]

Department of Chemistry, Loyola University, Chicago, Illinois 60626

Received September 3, 1970[3]

The action of acetic anhydride on tertiary amines at reflux may cause the displacement of one of the R groups from the amine. The groups which are displaced are benzyl, *t*-butyl, benzhydryl, trityl, and cinnamyl; the groups which are not displaced are methyl, ethyl, *n*-butyl, phenyl, α-naphthyl, *iso*-propyl, allyl, and propargyl. An S_N1 mechanism with special steric requirements is consistent with the experimental results.

L'action de l'anhydride acétique sur les amines tertiaires à reflux, peut provoquer le déplacement de l'un des groupes R de l'amine. Les groupes qui sont déplacés sont benzyle, *t*-butyle, benzhydryle, tritYle, et cinnamyle; les groupes qui ne sont pas déplacés sont méthyle, éthyle, *n*-butyle, phényle, α-naphtyle, *iso*-propyle, allyle, et propargyle. Un mécanisme S_N1 avec des conditions stériques spéciales est consistant avec les résultats expérimentaux.

Canadian Journal of Chemistry, **49**, 3348 (1971)

In the course of studying the acetylation of amines (1) we have examined the reaction of several tertiary amines with acetic anhydride. It was found that certain special tertiary amines underwent displacement of one of the groups attached to nitrogen by the acetic anhydride, while other tertiary amines were inert.

$$[1]\quad RR'R''N + (CH_3CO)_2O \xrightarrow{\text{Reflux}} RR'NCCH_3 + CH_3C{-}OR''$$

Table 1 shows the results of the reaction of the various tertiary amines with acetic anhydride at reflux (eq. 1). The results of Table 1 show that the groups displaced are benzyl, *t*-butyl, benzhydryl, trityl, and cinnamyl; and that the groups which are not displaced are methyl, ethyl, *n*-butyl, phenyl, α-naphthyl, *iso*-propyl, allyl, and propargyl. A pure S_N2 mechanism would require that methyl be most easily displaced, hence the results preclude any S_N2-like mechanism. A pure S_N1 mechanism would require that allyl and propargyl be displaced along with the others mentioned. The data, however, does not substantiate these predictions either. However, an ionization mechanism seems to be the most reasonable based on the evidence given here and on the para substitution results from the reaction of acetic anhydride with benzyldimethylamines (2).

Among the evidence which was used to choose a mechanistic pathway was the reaction of cinnamyldimethylamine. The cinnamyl group, as expected from the rule of vinylogy (3) reacts like the benzyl group, hence cinnamyldimethylamine undergoes displacement of the cinnamyl group on reaction with acetic anhydride. This reaction gave two products; 60% cinnamyl acetate, $CH_3COOCH_2CH{=}CHC_6H_5$, and 30% α-phenylallyl acetate, $CH_3COOCH(C_6H_5)$-$CH{=}CH_2$. This is a typical product spread for an allylic rearrangement in an S_N1 process (4).

The results of our experiments indicate the general mechanistic pathway shown in eq. 2 with its associated rate (eq. 3).[4]

Those amines which underwent displacement *via* C—N bond cleavage *all* have one group which can stabilize an incipient carbonium ion and *at least* one methyl group attached to nitrogen. This suggests that an ionization mechanism is taking place, but with steric requirements also present. An examination of the mechanism shown in eq. 2 and of its associated rate expression shown in eq. 3 indicates that CH_3COOR'' will not form at a reasonable rate if $K_{eq}(3)$ is very small, where $K_{eq}(3) = k_1/k_{-1}$. Also, if k_{-1}/k_2

‡In the case of unreacted amines, the starting amines were recovered quantitatively, and were not destroyed by other reactions.
§See Experimental section for preparation.

is much less than one, then the rate will be dependent only on k_1. If k_{-1}/k_2 is much greater than one, the reaction rate will be drastically diminished.

We postulate three fundamental reasons why reaction occurred or did not occur:

A. For amines with phenyl substituents, electronic considerations make k_1 rather small due to electron-withdrawal by the aromatic ring. Hence **3** is never reached.

B. For *very* sterically hindered amines, K_{eq}(**3**) is very small due to a decrease in k_1. Thus, the rate will decrease as a function of k_1.

C. For the R'' group to be displaced by C—N cleavage *via* ionization, R'' must be a good carbonium ion, *and* **3** must be bulky enough to require a collapse to product in order to lower its energy. Both of these considerations necessitate a large k_2, which makes the denominator of the rate equation unity. Thus, the rate is only a function of k_1, which is large enough for all the amines studied except the anilines and perhaps the very sterically crowded amines.

There are thus two structural requirements, electronic and steric; and it is the subtle interplay of these factors which determines whether or not C—N bond cleavage will occur. Intermediate **3** must be sterically crowded enough to undergo S_N1 displacement to products due to the release of energy associated with steric strain, but not so

[2] $$RR'R''N + (CH_3CO)_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \left[CH_3C(=O)O\text{–}C(CH_3)(=O)\text{–}\overset{\oplus}{N}RR'R'' \right] \xrightarrow{k_2} CH_3CNRR' + CH_3C{-}OR''$$

$(C_6H_5)_2CHN(CH_3)_2$	(*C*)	$(C_6H_5CH_2)_3N$	(*B*)
$(C_6H_5)_3CN(CH_3)_2$	(*C*)	$C_6H_5CH_2NC_6H_5$ (CH$_2$CH$_3$)	(*A*)

*The *A*, *B*, or *C* after each amine refer to the reasons set forth in the discussion. These reasons can be applied to justify the above amines as concerns their reactivities.

sterically crowded so as to prevent its formation at all; for the prevention of its formation would preclude any question of how **3** would go to product. The electronic considerations are that no groups can be present on the amine which make k_1 very small; phenyl qualifies as such a group. Also, in order for the displacement from **3** to products to occur, there must be present a potentially stable carbonium ion, one which can undergo S_N1 displacement.

Table 2 shows whether each amine can fulfill *both* the electronic *and* the steric requirements of the reaction, as detailed above. Satisfying one of the requirements is not enough for a successful reaction. The amine *must* satisfy *both* requirements in order to go to products. Those amines which satisfy both requirements were, in fact, the only ones which experimentally were found to undergo C—N cleavage (see Table 1).

The lone inconsistent result is that of allyldimethylamine. The steric requirements of cinnamyldimethylamine, in the preferred *trans* isomer, are quite the same as those of the allyldimethylamine since the vinyl group removes the phenyl ring from the reaction site. Thus, the allyl group should be displaced as is the cinnamyl group. The fact that the allyldimethylamine is inert with acetic anhydride is thus explained only on the grounds that the electronic factors for the formation of a good carbonium ion are not sufficient for the allyl group.

Besides acetic anhydride, the displacement of the benzyl group from benzyldimethylamine was successfully accomplished using trifluoroacetic anhydride. This result supports the proposed mechanism since k_1 will be larger due to the electron-withdrawing effect of the three fluorine atoms, while the steric requirements are approximately the same as the parent acetic anhydride.

Experimental

All melting points were obtained on a Fisher-Johns hot plate and are uncorrected. All boiling points were obtained using standard vacuum distillation techniques and are uncorrected. All n.m.r. spectra were taken on a Varian A-60A instrument as 50% CCl_4 solutions, using 1% TMS as internal standard, except in those cases where solubility considerations required $CDCl_3$ as solvent. All i.r. spectra were taken as neat smears (for liquids) or as KBr pellets (for solids), and were performed on a Beckman IR-5A spectrophotometer. Elemental analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

Acetylation of Tertiary Amines

Since all the reactions of the tertiary amines with acetic anhydride were nearly the same, a general procedure will be used to illustrate how each amine was reacted with the acetic anhydride.

The Reaction of Acetic Anhydride with Tertiary Amine

Tertiary amine (0.1 mol) was added dropwise to a well-stirred mixture of acetic anhydride (140 ml) and anhydrous sodium acetate (1 g). The temperature of the reaction mixture remained the same during the addition. The mixture was heated at reflux for 24 h and then rotary evaporated at 80° and 30 mm for 1 h, leaving a thick sludge. Water (100 ml) was added to the sludge and the aqueous mixture was extracted with 100 ml of ether (25 ml per extraction), and the combined ether layer was dried ($MgSO_4$), filtered, and concentrated on the rotary evaporator at reduced pressure, leaving a crude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

product. The product was purified by usual techniques of distillation (for liquids) and crystallization (for solids). The i.r. and n.m.r. spectra were taken of the product and compared with the spectra of the starting material. The cases of benzyl acetate and *t*-butyl acetate were verified by comparison with authentic samples of these compounds.

Preparation of Trityldimethylamine

Dimethylamine was bubbled slowly into a 500 ml flask of benzene (100 ml) at 10° with stirring until 15 g (0.33 mol) was added. Then triphenylmethyl chloride (27.9 g, 0.1 mol) in benzene (75 ml) was added dropwise over a 20 min period to the cold (+10°) solution. The mixture was then stirred at 25° for 6 days in a well-stoppered flask. Hydrochloric acid (200 ml, 3 *N*) was added and the aqueous layer was made basic with 40% KOH. A voluminous solid precipitated out of solution. The white solid was removed from the mixture by filtration and then was extracted with ether (200 ml) four times. The combined ether layer was dried (KOH pellets), filtered, and concentrated at reduced pressure, leaving a crystalline white solid (24 g, 83%), m.p. 94.5–97.0°; mixed m.p. with trityl chloride gave a m.p. range of 80–120°; n.m.r. (CCl_4), τ 2.4–3.0 (multiplet, phenyl protons, 15H): 7.96 (singlet, methyl protons, 6H).

Anal. Calcd. for $C_{21}H_{21}N$: C, 87.81; H, 7.32; N, 4.88. Found: C, 87.74; H. 7.51; N, 5.00.

Preparation of Cinnamyldimethylamine

Dimethylamine was bubbled into a flask of cold (10°) benzene (75 ml) until 8.75 g (0.20 mol) was added. Cinnamyl chloride (8.60 g, 0.05 mol) was added dropwise over 20 min and the mixture was stirred at 25° for 4 days in a well-stoppered flask. Hydrochloric acid (200 ml, 3 *N*) was added and the aqueous layer was made basic with 40% KOH. A white solid precipitated from solution. The mixture was extracted with ether (200 ml, 50 ml per extraction), and the combined ether layer was dried (K_2CO_3), filtered, and concentrated at reduced pressure, leaving a viscous yellow liquid (8.0 g, 83%), b.p. 61–63°/0.25 mm (2); n.m.r. (CCl_4), τ 2.7 (singlet, phenyl protons, 5H); 3.5 (multiplet, vinyl protons, 2H); 7.03 (doublet, methylene protons, 2H); 7.80 (singlet, methyl protons, 6H); i.r. (neat), ν (cm^{-1}) 1370 (methyl stretch).

The Acetylation of Cinnamyldimethylamine to Cinnamyl Acetate and α-Phenylallyl Acetate (2)

Cinnamyldimethylamine (4.03 g, 0.025 mol), acetic anhydride (75 ml), and sodium acetate (0.5 g) were stirred together at reflux for 48 h. The mixture was then rotary evaporated at 80° and 5 mm for 3 h to remove the acetic anhydride. The residue was then treated with water (100 ml) and then extracted with ether (250 ml, 50 ml per extraction). The combined ether layer was dried ($MgSO_4$), filtered, and concentrated at reduced pressure, leaving 4.1 g of red liquid. The red liquid was distilled under vacuum through a 4-in. Vigreux column. Two products were distilled; first was 1.0 g of a clear white liquid, α-phenylallyl acetate (b.p. 61–65°/0.025 mm); n.m.r. (CCl_4), τ 2.71 (singlet, phenyl protons, 4.9H); 3.70 (doublet, vinyl proton alpha to phenyl, 1H); 4.00 (multiplet, vinyl proton, 1H); 4.90 (multiplet, terminal methylene, 2H); 8.06 (singlet, methyl protons, 3H); second product was a 2.0 g fraction of clear white liquid, cinnamyl acetate (b.p. 81–84°/0.025 mm); n.m.r. (CCl_4), τ 2.70 (singlet, phenyl protons, 5H); 3.40 (doublet, vinyl proton alpha to phenyl, 1H); 3.5–4.0 (multiplet, vinyl proton beta to phenyl, 1H); 5.33 (doublet, methylene protons, 2H); 8.02 (singlet, methyl protons, 3H).

The cinnamyl acetate (0.58 g) was then placed in a mixture of acetic anhydride (13 ml), acetic acid (0.5 g), and sodium acetate (0.05 g). The mixture was heated at reflux for 24 h, then worked-up as above leaving a single pure compound which had an i.r. and n.m.r. identical with cinnamyl acetate.

Product Data

The yields of the successful reactions were as follows: dimethyl-*t*-butylamine gave 50% *t*-butyl acetate; dimethylbenzylamine gave 40% benzyl acetate; *N,N*-α-trimethylbenzylamine gave 55% α-methylphenethyl acetate; dibenzylmethylamine gave 10% benzyl acetate; *N*-benzyl-*N*-methylethanolamine gave 30% benzyl acetate; dimethylcinnamylamine gave 70% of a 2:1 mixture of cinnamyl acetate and α-phenylallyl acetate; benzhydryldimethylamine gave 25% benzhydryl acetate; trityldimethylamine gave a small yield (< 10%) of trityl acetate.

Biosynthesis of Cernuine[1]

Y. K. Ho, R. N. Gupta, D. B. MacLean, and Ian D. Spenser
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 10, 1971

The biosynthesis of cernuine (**9**), an alkaloid of *Lycopodium cernuum*, was studied in intact plants. Specific incorporation of lysine, cadaverine, Δ^1-piperideine, and pelletierine was demonstrated. The alkaloid is not a modified dimer of pelletierine, as might have been anticipated on the basis of structural relations, since only one pelletierine unit is incorporated.

La biosynthèse de la cernuine (**9**), un alcaloide issu du *Lycopodium cernuum*, a été étudiée sur des plantes intactes. L'incorporation spécifique de la lysine, de la cadavérine, de la Δ^1-pipérideine, et de la pelletierine, a été démontrée. L'alcaloide n'est pas un dimère modifié de la pellétierine, comme on pourrait le supposer d'après les relations structurales puisque seule une unité de pellétierine est incorporée.

Canadian Journal of Chemistry, **49**, 3352 (1971)

Introduction

In our previous work on the biosynthesis of the Lycopodium alkaloids (2–5) attention was focussed on the precursors of lycopodine (**6**), the major alkaloid of the group. We now report on the origin of cernuine (**9**), a Lycopodium alkaloid whose skeletal type is exceptional in that it does not bear a simple structural relationship to lycopodine.

Lysine (**1**) (3, 4), cadaverine (**2**) (4), Δ^1-piperideine (**3**) (5), and acetate (4) were found to serve as specific precursors of lycopodine. These results lent credence to the hypothesis (Scheme 2) which prompted the work, that lycopodine and its structural relatives were modified dimers of a $C_5N—C_3$ unit, such as pelletierine (**4**), which in turn arises from lysine (Scheme 1). A dinitrogeneous species (*e.g.* **5**) is assumed to be an intermediate in the pathway to lycopodine (**6**). Other alkaloids, such as lycodine (**7**) and α-obscurine (**8**), could arise from the same intermediate. It is now known that pelletierine (**4**) cannot be the monomer unit, $C_5N—C_3$, demanded by the hypothesis, since only one intact pelletierine moiety was incorporated into lycopodine when multiply labelled pelletierine was administered to *Lycopodium tristachyum* (3, 5). It nevertheless appears likely on the basis of the mode of incorporation of the other precursors that a $C_5N—C_3$ unit related to pelletierine is implicated in the biosynthesis of lycopodine, and that a dinitrogeneous species with a lycodine–obscurine type skeleton serves as an intermediate.

Cernuine (**9**), like lycodine, can be formally dissected into, and could conceivably arise from, two $C_5N—C_3$ units (Scheme 3), but the manner in which the two units are joined is entirely different in the two systems. It is noteworthy that *L. cernuum*, the species which yields cernuine, does not elaborate alkaloids of the lycodine or the lycopodine type. It was of interest, therefore, to determine whether the substrates known to be involved in the biosynthesis of lycopodine are also implicated in cernuine biosynthesis, and, in particular, whether pelletierine (**4**) is incorporated and if so, whether it serves as a precursor of one or of both halves of the cernuine system. The work here reported leads to the conclusion that there is complete analogy in the biosynthesis of cernuine and of lycopodine.

Methods and Results

The plant used in this investigation was *Lycopodium cernuum* L., a subtropical Lycopodium species. A voucher specimen, authenticated by Dr. C. D. Adams, Department of Botany, University of the West Indies, is deposited in the University herbarium, Mona, Jamaica. Feeding experiments were carried out at the field station of the Institute of Jamaica, at Mason River.

Specifically labelled samples of lysine, cadaverine, Δ^1-piperideine, and pelletierine were administered to intact plants and also to cuttings. A summary of these experiments is presented in

[1]A preliminary account of part of this work has been published (1).

labelled lysine into cernuine (experiment 2) (Table 3). To determine the distribution of ^{14}C, the labelled samples of cernuine were partially degraded, by reactions to be discussed presently, into the degradation products shown in Scheme 4. The specific activities of the degradation products are listed in Tables 2 and 4. Indicated limits are standard deviation of the mean.

The samples of 2-*n*-butyl-4-methyl-6-*n*-pentylpyridine (**10**) obtained from cernuine derived from 2-^{14}C-lysine (experiment 2), 6-^{14}C-lysine (experiment 3), and 1,5-^{14}C-cadaverine (experiment 4) retained approximately three-quarters of the activity of the intact alkaloid. The pyridine derivative (**10**) from the cernuine derived from 6-^{14}C-Δ^1-piperideine (experiment 5), contained approximately one-half of the original activity. β-Alanine (**11**) and γ-aminobutyric acid (**12**), recovered from 2-^{14}C-lysine-derived cernuine (experiment 1), contained one-quarter of the original activity. Finally, the fraction of activity recovered in the acetate obtained by Kuhn–Roth

oxidation of pelletierine-derived cernuine was identical with the fraction of activity at the carbonyl carbon atom of the precursor (experiment 6) (Table 4).

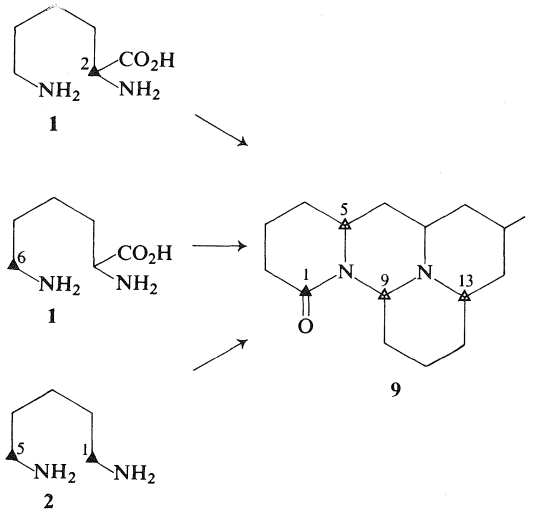
Discussion

Even though degradation of cernuine was only partial and the activity of the intact molecule was not fully accounted for in terms of the activities of degradation products representing individual labelled sites, the results nevertheless support the view that the radioactive precursors were incorporated into cernuine in a manner which is completely analogous to their mode of incorporation into lycopodine.

Lysine enters each of the two C_5 units of lycopodine, C-1 to -5 and C-9 to -13, in a symmetrical manner, and with equal efficiency (2, 4). Cadaverine, a symmetrical molecule and a likely stage of the pathway, is incorporated similarly (4). Analogous entry of lysine and cadaverine into cernuine would be predicted to place activity derived from 2-^{14}C-lysine, from 6-^{14}C-lysine, and from 1,5-^{14}C-cadaverine equally into four sites, C-1, -5, -9, and -13. One quarter of the activity of cernuine, derived from 2-^{14}C-lysine (experiment 2), 6-^{14}C-lysine (experiment 3), and 1,5-^{14}C-cadaverine (experiment 4) was indeed found at C-1 (cernuine minus pyridine derivative (**10**)) (Table 2) (Scheme 5).

In experiment 1 access to C-1 was gained in another manner. Reduction of cernuine with lithium aluminum hydride followed by oxidation of the reduction product with chromic acid gave β-alanine and γ-aminobutyric acid derived, respectively, from C-1 to -3 and C-1 to -4 of cernuine. Both acids, obtained by degradation of cernuine derived from 2-^{14}C-lysine, contained one-quarter of the activity of the intact alkaloid. This result confirms those of the previous experiments in which the activity at C-1 was obtained by difference. The finding of one-quarter of the activity of cernuine at C-1 from cernuine derived from 2-^{14}C-lysine, 6-^{14}C-lysine, and 1,5-^{14}C-cadaverine is in complete analogy with the results found for lycopodine.

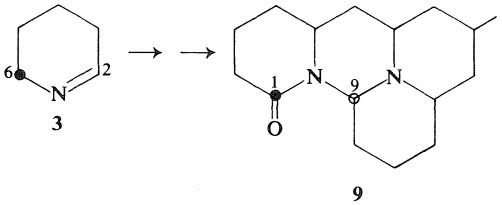
Δ^1-Piperideine is another substrate whose specific incorporation into lycopodine has been demonstrated (5). The precursor enters both "halves" of the alkaloid with equal efficiency. Its mode of incorporation differs from that of



SCHEME 5. Incorporation of lysine (**1**) and cadaverine (**2**) into cernuine. Sites of activity derived from 2-^{14}C- and 6-^{14}C-lysine and from 1,5-^{14}C-cadaverine, established by degradation (▲) (~25% of total activity from each of the three substrates) or inferred (Δ).

lysine in that the individuality of C-2 and -6 of Δ^1-piperideine is preserved in the course of its route into lycopodine. Analogous entry of Δ^1-piperideine into cernuine would be predicted to place label derived from 6-^{14}C-Δ^1-piperideine equally into the two sites, C-1 and -9. In accord with this prediction C-1 of cernuine derived from 6-^{14}C-Δ^1-piperideine was found to account for approximately half the activity of the intact alkaloid (cernuine minus pyridine derivative (**10**)) (experiment 5) (Table 2) (Scheme 6).

The evidence is clearly consistent with the view that cernuine, like lycopodine, is a modified dimer of an intermediate, C_5N—C_3, whose piperidine nucleus is, in turn, derived from lysine (**1**) via



SCHEME 6. Incorporation of Δ^1-piperideine into cernuine. Sites of activity from 2-^{14}C-Δ^1-piperideine, established by degradation (●) (~50%) or inferred (○).

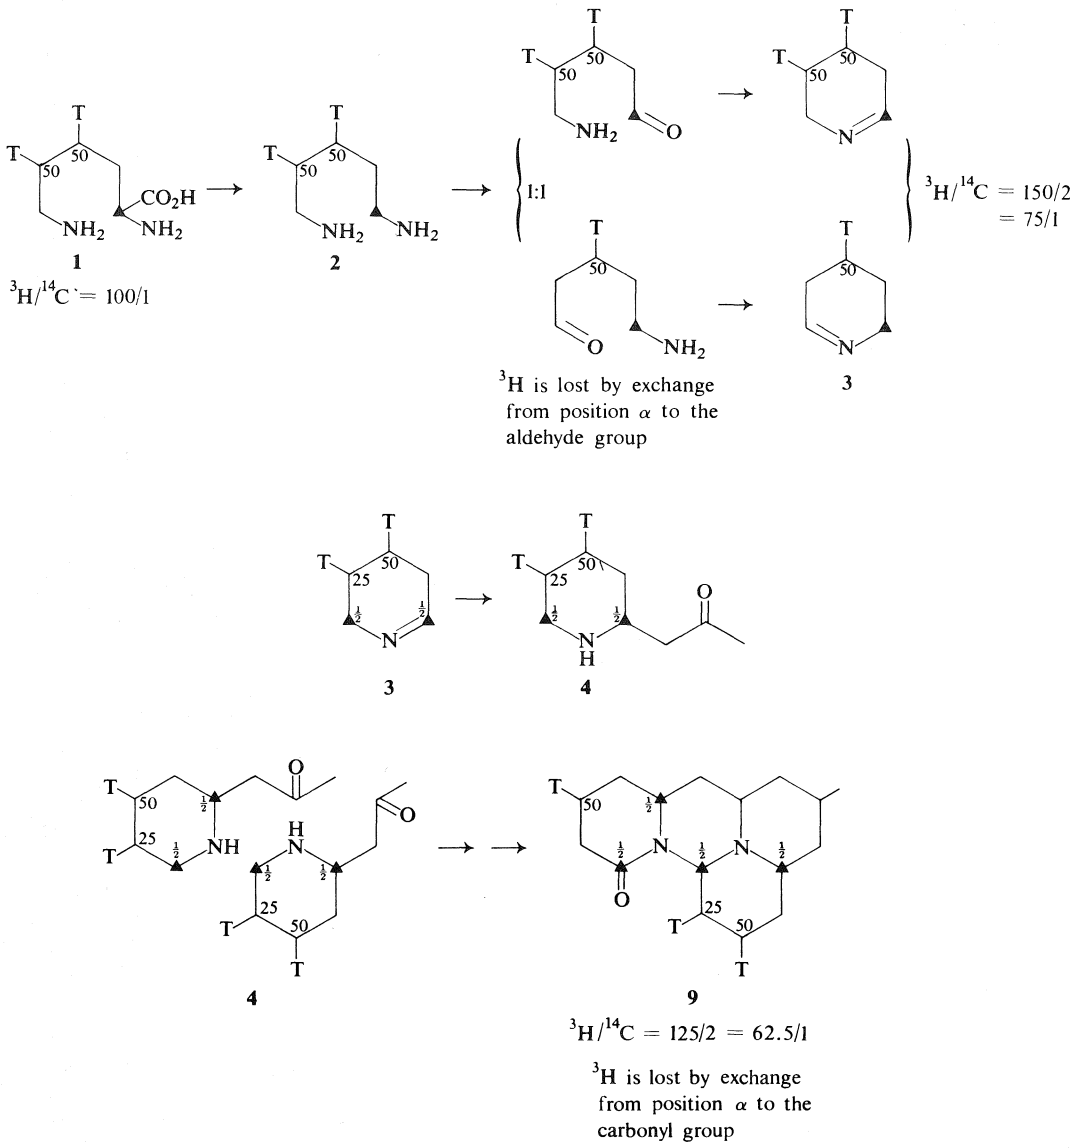

SCHEME 7. Predicted mode of incorporation of 4,5-$^3H_2$,2-^{14}C-lysine into cernuine. (Both of the two $C_5N—C_3$ units, postulated as cernuine precursors, are here arbitrarily represented as pelletierine).

cadaverine (**2**) and Δ^1-piperideine (**3**) (*cf.* Scheme 1).

Further evidence supporting this sequence to cernuine is provided by the result of the feeding experiment with multiply labelled 4,5-$^3H_2$, 2-^{14}C-lysine (experiment 2). As shown in Scheme 7, a loss of 37.5% tritium, relative to ^{14}C, is predicted by the hypothetical sequence to occur in the course of the incorporation of this lysine into cernuine. The observed loss of 39% (experiment 2) (Table 3) is in remarkable agreement with this prediction.

To throw light on the nature of the postulated intermediate, $C_5N—C_3$, a multiply labelled sample of pelletierine (**4**) of known isotope distribution was administered to *L. cernuum* (experi-

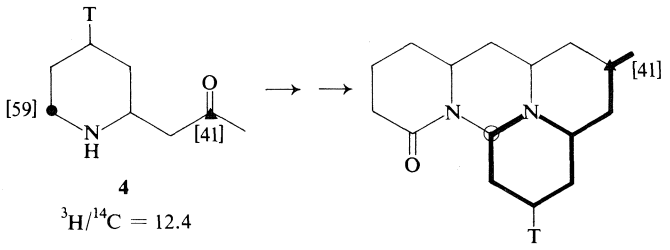

SCHEME 8. Incorporation of pelletierine into cernuine. Sites of activity established by degradation (▲) (~41% of total activity) or inferred (○, T).

ment 6). Consistent with the hypothesis (Scheme 3), that pelletierine was the intermediate whose dimerization leads to cernuine, the ^3H:^{14}C ratio of the precursor was maintained in the product (Table 3). Degradation of the cernuine showed, however, that only one intact pelletierine unit had been incorporated. The acetic acid, obtained from the C_2 unit, C-15,16, of the cernuine by Kuhn–Roth oxidation, contained 41% of the activity of the intact alkaloid, a distribution corresponding to the fraction of ^{14}C-activity within the sidechain of the precursor (Table 4). Entry of two intact pelletierine units would have led to a Kuhn–Roth acetate containing 20% of the activity of the original cernuine. An intact pelletierine moiety thus serves as the precursor of the C_8 unit, C-9 to -16, but not of the C_8 unit, C-1 to -8, of cernuine (Scheme 8). This biosynthetic relationship is entirely analogous to the mode of entry of pelletierine into lycopodine (3, 5). The problems of interpretation, raised by these experimental results, have been discussed (5).

The Chemistry of the Degradation Reactions

The methods used to degrade cernuine are outlined in Scheme 4. Kuhn–Roth oxidation gave C-15 and -16 as acetic acid which was converted to its α-naphthylamide derivative for purification and radioactive assay. Dehydrogenation of cernuine over palladium–charcoal by the method of Ayer *et al.* (6, 7) gave compound **10** which was purified and assayed as its picrolonate. Compound **10** contains all the carbons of cernuine except C-1 and thus the activity at this center is obtained by difference. The third degradation of Scheme 4 in which C-1 is isolated as β-alanine or γ-aminobutyric acid deserves further comment.

The treatment of cernuine with lithium aluminum hydride has been reported to give a single compound, dihydrodeoxycernuine (7). We obtained, however, a small amount (<7%) of an isomer, dihydrodeoxyepiallocernuine (8), in addition to the expected product. Dihydrodeoxyepiallocernuine differs in configuration at C-9 and -13 from dihydrodeoxycernuine but the mechanism by which the isomerization occurs is not known. Fission of the N—C_9 bond does not accompany the reduction of the amide as we suggested earlier (1). Since both isomers are expected to yield the same oxidation products the mixture was oxidized without further purification. β-Alanine and γ-aminobutyric acid were isolated, identified, and assayed for radioactivity as their 2,4-dinitrophenyl derivatives. As shown in Scheme 4 the carbon atoms of the amino acids are expected to be derived from C-1 to -3 and C-1 to -4 of cernuine.

To verify that the amino acids come solely from C-1 to -3 and C-1 to -4 of cernuine we prepared a mixture of dihydrodeoxycernuine-1,1-d_2 and its isomer, subjected the mixture to oxidation, and examined the amino acids for their deuterium content. Deuterium was incorporated into the dihydrodeoxy compounds by carrying out the reaction of cernuine with lithium aluminum deuteride. Two products, both of mass 250, were obtained from this treatment and the ratio of the two, determined by g.l.c., was the same as that obtained in the hydride reduction. Oxidation of the mixture gave β-alanine-d_2 and γ-aminobutyric acid-d_2 isolated as their 2,4-dinitrophenyl derivatives. The mass spectra of the 2,4-dinitro-

For personal use only.

phenyl derivatives showed no evidence of the presence of undeuterated acids. It can be concluded that the degradation proceeds specifically as shown in Scheme 4.

Experimental

Administration of Labelled Compounds to Lycopodium cernuum

Two methods were used for the administration of tracers to *Lycopodium cernuum* L. Firstly, a solution containing the labelled compound was infused through cotton wicks into the stems of intact plants growing in their natural environment. Cotton thread was inserted into the stems and the end of each thread was placed into a small glass beaker. The tracer solution (10 ml) was divided among the beakers and was absorbed by the plants through the wicks. After the original tracer solution had been absorbed, the beakers were repeatedly refilled with glass-distilled water. The plants were kept in contact with the tracer for 48–72 h and were then harvested.

Secondly, fresh cuttings (12–18 in. high) were packed with cut stems downward into a 100 ml beaker. The labelled compound, dissolved in glass-distilled water (10 ml), was added to the beaker. Refilling and harvesting was carried out in the same manner as above.

A summary of the feeding experiments which were carried out is outlined in Table 1.

6-^{14}C-Δ^1-Piperideine (experiment 5) was prepared (5) from 6-^{14}C-DL-lysine (Commissariat à l'Energie Atomique, France). 6-^{14}C-Pelletierine and 4-^{3}H-pelletierine were synthesized by condensation of labelled Δ^1-piperideine prepared from 6-^{14}C-DL-lysine (Commissariat à l'Energie Atomique, France), and from 4-^{3}H-DL-lysine (Commissariat à l'Energie Atomique, France), respectively, with inactive acetoacetic acid (9). 2′-^{14}C-Pelletierine was obtained by condensation of 3-^{14}C-acetoacetic acid (prepared by hydrolysis of ethyl 3-^{14}C-acetoacetate (New England Nuclear)) with Δ^1-piperideine obtained from inactive lysine. An intermolecularly triply labelled sample, 4-^{3}H,6,2′-$^{14}C_2$-pelletierine (experiment 6), was obtained by mixing these samples.

Isolation of Cernuine and Lycocernuine (cf. ref. 7)

Aerial parts of *L. cernuum* were dried and ground to a fine powder in a blendor (Osterizer Galaxie 500). The powder (500 gm) was moistened with ammonia (0.6 *M*, 1 ml/gm) and was continuously extracted with chloroform for 48 h. The chloroform extract was concentrated to one-tenth of its volume and ether was added. The solution was then extracted with hydrochloric acid (0.6 *M*, 5 × 30 ml). The aqueous extract was washed twice with ether, basified with ammonia (1.2 *M*), and was then extracted with chloroform (5 × 25 ml). The chloroform extract was dried (anhydrous sodium sulfate) and concentrated almost to dryness and a small amount of acetone was added. Lycocernuine (110 mg), which precipitated, was recrystallized from acetone and melted at 228–229° (lit. 230–231°)(7).

The mother liquors from the crystallization were dissolved in benzene and applied to a column of neutral alumina, activity I (40 g). Elution with benzene and benzene–ether (1:1) gave a mixture of minor bases. Anhydrous ether then gave cernuine, and elution with chloroform gave lycocernuine. Finally, methanol gave a mixture of minor bases.

The cernuine was sublimed at 110° and 3 × 10^{-3} mm, and was recrystallized from hexane, m.p. 101–102° (lit. 103–104°)(7). In several instances, particularly in the case of radioactive samples, the cernuine was dissolved in ether and the solution was neutralized with an ethereal solution of perchloric acid. The solvent was evaporated and the cernuine perchlorate so obtained was recrystallized from water or from ethanol–ether, and melted at 110° (lit. 110°) (10).

Several variations of the isolation procedure were employed in early experiments. When ether instead of chloroform was used as extracting solvent, the extraction of alkaloids was incomplete. The alkaloid extract, on the basis of g.l.c. analysis, contained twice as much cernuine as lycocernuine whereas the reverse was true when a better solvent such as chloroform (see above) or methanol (see below) was used. Thus when ether was used, only part of the lycocernuine was extracted from the plant material.

Methanol was employed as solvent in large scale batch extraction (7). Finely ground *L. cernuum* was extracted at room temperature with methanol for 36 h and the methanolic extract was concentrated at reduced pressure. Extraction was repeated twice with fresh solvent and the combined extracts were warmed with hydrochloric acid (0.6 *M*). Acid-insoluble material was removed by filtration and was then re-extracted with hydrochloric acid. The filtrates were combined, non-basic material was extracted with ether, and the aqueous layer was made strongly basic with ammonia. The alkaloidal fraction was then extracted into chloroform and worked-up as already described.

Degradation of Cernuine

Reduction of Cernuine (7)

Cernuine (250 mg) was added to a slurry of lithium aluminum hydride (0.50 g) in anhydrous ether (20 ml, dried over sodium hydride), and the resulting mixture was refluxed for 20 h, and was then cooled in ice. Excess hydride was decomposed by dropwise addition of water (0.5 ml) followed by sodium hydroxide (4 *M*, 0.5 ml). More water (1.5 ml) was then added and the mixture was stirred for 20 min, and filtered with suction. The granular precipitate was washed thoroughly with ether and the ethereal filtrate was dried over sodium sulfate and concentrated at reduced pressure. The crystalline residue was sublimed at 100° and 4 × 10^{-3} mm. The mass spectrum of the sublimed product showed a signal, *m/e* 248, which was regarded as due to the molecular ion of the reduction product. However, two components, retention times 2.0 min and 3.2 min, were detected by g.l.c. (1% Carbowax 20 M, coated with 5% KOH on Chromosorb W, 4 ft × 0.125 in., 130–210° at 10°/min and a helium flow rate of 40 ml/min). The retention time of the minor component (< 7%) was 2 min, identical with that of an authentic sample of dihydrodeoxyepiallocernuine.[2] When a sample of the reduction product, mixed with authentic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.25.42 on 03/03/15
For personal use only.

For personal use only.

dihydrodeoxyepiallocernuine,[2] was injected, only two components with retention times 2.0 and 3.2 min, respectively, were observed. The intensity of the peak of the minor component increased with the amount of the authentic dihydrodeoxyepiallocernuine added. The major component was regarded as dihydrodeoxycernuine. These two components were not further separated and were used for the oxidation described below. The same procedure was used to prepare the dideuterated compounds, except that lithium aluminum deuteride was substituted for the hydride.

β-Alanine and γ-Aminobutyric Acid from Cernuine

The above reduction product (192 mg) of cernuine was dissolved in hot aqueous sulfuric acid (6 *M*, 4 ml) and chromium trioxide (500 mg) in water (2 ml) was added in several portions. The mixture was heated under reflux with stirring for 48 h. The cooled mixture was extracted several times with ether. The ether layer was rejected. The aqueous layer was diluted with water (10 ml) and warmed, and hot saturated aqueous barium hydroxide solution was added until the solution was neutral. The precipitate was filtered off and washed repeatedly with hot water. The filtrate was evaporated to dryness. The residue was dissolved in water (1 ml) and aqueous sodium bicarbonate (1.2 *M*) was added until the p*H* of the solution was 9. A solution of 1-fluoro-2,4-dinitrobenzene in methanol (10%, *v/v*, 1.5 ml) was then added. The mixture was allowed to stand with occasional shaking for 1 h, the p*H* being maintained at 8–9 with additional bicarbonate solution. After 1 h, water (4 ml) and bicarbonate solution (0.5 ml) were added and excess reagent was removed by extraction with ether (2 × 6 ml). The solution was then acidified with hydrochloric acid (6 *M*) and extracted with ether (3 × 6 ml). The dried (sodium sulfate) ether extract was concentrated and the yellow dinitrophenyl (DNP) amino acids were separated by preparative t.l.c. (silica gel, developed with benzene – pyridine – acetic acid (80:20:2)).

Three yellow bands were observed. The major band showed an R_f value (R_f 0.69) identical with that of an authentic sample of *N*-2,4-dinitrophenyl-β-alanine. A second band (R_f 0.84) corresponded to *N*-2,4-dinitrophenyl-γ-aminobutyric acid. The minor band (R_f 0.28) was not further examined, but may have been *N*-2,4-dinitrophenylglycine. The amino acid derivatives were eluted separately from adsorbent with methanol. The methanolic extract of the β-alanine band (R_f 0.69) which was the most abundant was evaporated to dryness. The residue was dissolved in water (1 ml), hydrochloric acid (6 *M*, 1 ml), was added, and the mixture was extracted with ether (3 × 5 ml). The ether layer was washed with water (2 ml), dried (sodium sulfate), and evaporated to dryness. The residue was sublimed at 160–170° and 1×10^{-3} mm when the DNP derivative of β-alanine was obtained as a yellow crystalline solid; yield, 8 mg. The band of the DNP derivative of γ-aminobutyric acid (R_f 0.84) was worked-up similarly; yield, 5 mg.

The same procedure was applied to the product obtained by reduction of cernuine with lithium aluminum deuteride. The DNP derivatives of β-alanine and γ-aminobutyric acid were analyzed mass spectrometrically showing molecular ions at *m/e* 257 and 271, respectively. There were no peaks at 255 and 269 corresponding to undeuterated acid.

Kuhn–Roth Oxidation of Cernuine

A solution of chromic acid (2 g) in water (3 ml) was added to a solution of cernuine (100 mg) in sulfuric acid (2 *M*, 5 ml). The mixture was heated under reflux for 2 h. Steam was then passed through the mixture until 200 ml of distillate had been collected. The distillate was neutralized with sodium hydroxide (0.1 *M*) and evaporated to dryness. The sodium acetate so obtained was converted into acetyl-α-naphthylamide (11) which was purified by sublimation at 135° and 1×10^{-3} mm. The white sublimate was crystallized from benzene and the product resublimed. Acetyl-α-naphthylamide, m.p. 158–159°, was obtained as colorless needles.

Dehydrogenation of Cernuine (7)

Cernuine (100 mg) was dehydrogenated with 5% palladium-on-charcoal, as described by Ayer *et al.* (7), and the basic products separated by preparative t.l.c. on silica gel (0.5 mm thickness, developed with ether/ammonia (75 ml/2 drops)). The most polar component (R_f 0.65), which was the most abundant one (20 mg), was eluted from the adsorbent with chloroform and subjected to high vacuum distillation at 50° and 4×10^{-3} mm to yield 2-*n*-butyl-4-methyl-6-*n*-pentylpyridine (14 mg), identical with an authentic sample.[2] The pyridine derivative was converted into the picrolonate, which after recrystallization from ethanol–ether melted at 137–139°.

Anal. Calcd. for $C_{25}H_{33}N_5O_5$: C, 62.09; H, 6.88; N, 14.48. Found: C, 62.10; H, 6.91; N, 14.33.

It was also converted into the chloroplatinate, which was recrystallized from ethanol containing a drop of hydrochloric acid. The orange crystals so obtained melted at 186–188° (lit. 189–190°)(7). The minor components of the dehydrogenation were not examined.

Radioactivity Measurements

Radioactivity was assayed on samples of finite thickness on aluminum planchettes with a low background gas flow system (Nuclear Chicago Corporation, Model 4342). Samples were plated with the aid of a 1% solution of collodion in dimethylformamide. The usual corrections for background and self-absorption were applied. The ^3H:^{14}C ratios were measured by liquid scintillation counting (Mark I, Liquid Scintillation Computer, Model 6860, Nuclear Chicago Corporation). Radioactivity due to ^3H and ^{14}C was determined simultaneously by external standardization counting with ^{133}Ba. Samples were dissolved in benzene or methanol and the solution was dispersed in a solution of Liquifluor (Nuclear Chicago Corporation) diluted 25 times with toluene. Duplicate samples of each compound were counted under comparable conditions of quenching. The confidence limits shown in the results (Tables 1–4) are standard deviation of the mean.

We are indebted to many friends and colleagues in Kingston, Jamaica. Without their help this investigation could not have been undertaken. We owe a particular debt of gratitude to Dr. C. D. Adams, Department of

[2]We are greatly indebted to Dr. W. A. Ayer for supplying this sample.

Botony, University of the West Indies, for the taxonomic identification of the species used in our experiments; to Mr. G. R. Proctor, Institute of Jamaica, for permission to use the facilities of the field station of the Institute at Mason River; and to Dr. W. R. Chan, Department of Chemistry, University of the West Indies, and Dr. B. S. Mootoo, Government Analyst, for their unfailing help, generosity and patience. We thank Dr. C.-K. Yu and Miss T. Nguyen of this department for the preparation and analysis of the deuterated compounds.

The Effect of *S*-Substituent Variation on the Pyrolysis of Xanthates of Primary Alcohols[1]

R. E. GILMAN AND M. J. BOGDANOWICZ

Department of Chemistry, Rochester Institute of Technology, One Lomb Memorial Drive, Rochester, New York

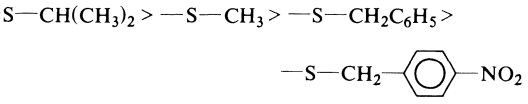
Received June 10, 1971

A study of the pyrolysis of a series of *S*-substituted xanthates of cyclohexanemethanol was undertaken to determine the effect of variations in the nature of the *S*-substituent on the course of the pyrolysis of xanthates. Xanthates with the following *S*-substituents were prepared by standard reactions and pyrolyzed at 240°: *n*-hexyl, 2-phenylethyl, benzyl, phenacyl, and diphenylmethyl. Evidence is presented that supports the view that a competitive homolytic pathway becomes more significant as the stability of the free radical derived from the *S*-substituent increases. At the two extremes, the *S*-hexyl xanthate yields 90% methylenecyclohexane and no cyclohexanemethanol whereas the *S*-diphenylmethyl xanthate yields only 25% alkenes (methylenecyclohexane and 1-methylcyclohexene) along with 65% cyclohexanemethanol.

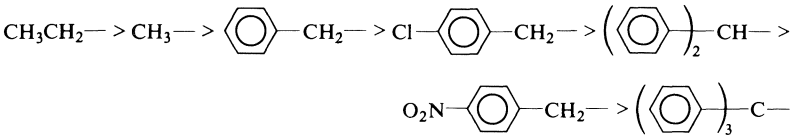
Une étude a été effectuée sur une série de xanthates de la cyclohexaneméthanol *S*-substitués afin de déterminer l'influence du *S*-substituant sur le cours de la pyrolyse des xanthates. Les xanthates avec les *S*-substituants suivants ont été préparés par des méthodes classiques et pyrolysés à 240°: *n*-hexyle, 2-phénylèthyle, benzyle, phénacyle, et diphénylméthyle. Des preuves sont présentées pour confirmer le fait qu'un processus homolytique compétitif peut devenir plus important si la stabilité du radical libre issu du *S*-substituant augmente. Aux deux extrêmes, le xanthate *S*-hexyle conduit à 90% de méthylènecyclohexane sans trace de cyclohexaneméthanol, alors que le xanthate *S*-diphénylméthyle conduit à seulement 25% d'alcène (méthylènecyclohexane et méthyl-1 cyclohexène) et à 65% de cyclohexaneméthanol.

Canadian Journal of Chemistry, **49**, 3362 (1971)

The pyrolysis of xanthate esters, the Chugaev reaction, has been primarily studied with xanthates that contain an *S*-methyl substituent (1, 2). McAlpine, who was the first to report a systematic study of xanthates with a variety of *S*-substituents, suggested that the presence of electronegative groups on the thiol sulfur decreases the thermal stability of xanthates and this results in a lower initial pyrolysis temperature (3). The order of stability of *S*-substituted xanthates of menthyl alcohol was found to be as follows:



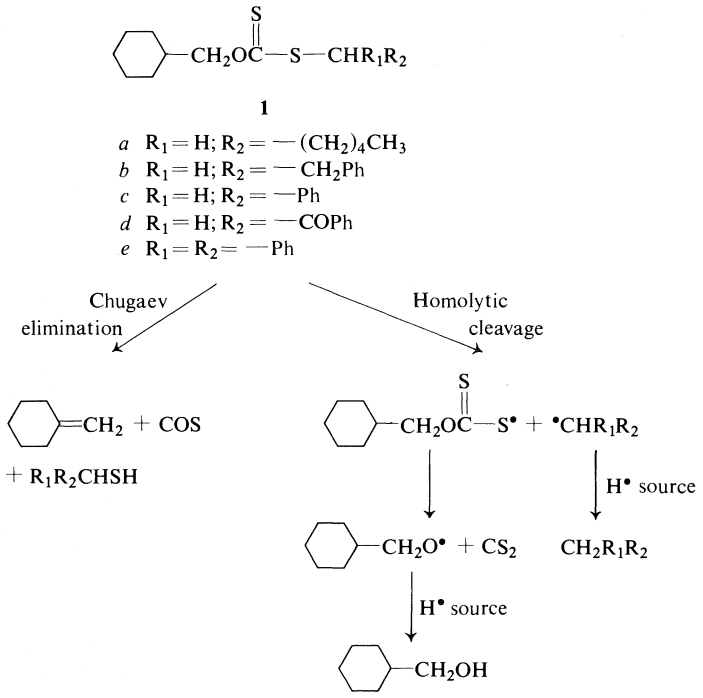
A more recent study by O'Connor and Nace indicated much the same order of stability for *S*-substituted xanthates of cholesterol (4). Kinetic studies of the pyrolysis of these xanthates showed that an increase in the electronegativity of the *S*-alkyl group decreased the stability of the xanthate in the order shown below:



In our earlier studies of *S*-*p*-bromophenacyl xanthates of primary alcohols, we found evidence that an alternate pathway competes with the normal Chugaev elimination when the strongly electronegative *S*-*p*-bromophenacyl group is present (5). Based on a product analysis study we proposed that this alternate pathway involves an initial thermally induced homolysis of the type shown in Scheme 1.

In order to test the validity of this explanation for the formation of these non-Chugaev products, we studied a series of xanthates of cyclohexanemethanol that contained *S*-substituents that would yield homolysis intermediates of considerably different stability. If our initial postulate of a

[1]Presented at the 158th National Meeting of the American Chemical Society, New York, New York, September, 1969.



SCHEME I

free radical mechanism is correct, we should observe a direct relationship between the extent of the competitive cleavage and the stability of the free radical generated in the homolytic cleavage of the sulfur–carbon bond. The cyclohexanemethyl group was chosen as the *O*-substituent since the alkene product of the normal Chugaev elimination, methylenecyclohexane, is known to be unstable with respect to rearrangement to 1-methylcyclohexene. Furthermore, these isomeric alkenes are easily separated and analyzed by g.l.p.c. We thus could study both the extent of alkene rearrangement under the pyrolysis conditions and the ratio of Chugaev to non-Chugaev reaction. An additional question of practical interest is the extent of elimination of β-hydrogens of the *S*-alkyl group. Any elimination of this type would lead to alkenes derived from the *S*-alkyl group and be detrimental to the practical synthesis of pure alkenes from primary alcohols.

We now report the results of a study of the pyrolysis of xanthates **1***a–e* that were prepared from cyclohexanemethanol and the respective alkyl halides by standard methods (7, 8). The pyrolyses of these xanthates were carried out in a manner previously described (5) and the products were analyzed by gas chromatographic methods (see Experimental). The results are shown in Table 1. The most striking feature of these results is the overall variation in alkene and cyclohexanemethanol yields as the nature of the *S*-substituent is changed. The total yield of alkene (methylenecyclohexane plus 1-methylcyclohexene) is greatest for those *S*-substituents that would lead to the least stable free radicals if the homolytic pathway proposed in Scheme 1 were followed. Thus the total alkene yield decreases in the following order:

$$-S(CH_2)_5CH_3 \simeq -S-CH_2CH_2Ph > -S-CH_2Ph > -S-CH_2\overset{O}{\overset{\|}{C}}Ph > -S-CHPh_2$$

With the exception of the *S*-phenacyl group, for which no data concerning the relative stability of the corresponding phenacyl radical could be found, this order is the inverse of the order of stability of the free radicals derivable from the homolytic cleavage of the sulfur–carbon bond (9).

The variations in the yields of cyclohexanemethanol with change in the *S*-substituent are equally striking. In this case the alcohol yields are

[1] 
directly proportional to the order of stability of the *S*-substituents as free radicals and are inversely proportional to the order of total alkene yields. The combined variations in alkene and alcohol yields thus lend strong support to our proposal that the alternative pathway shown in Scheme 1 is correct. Whether or not the homolysis is a step-wise sequence (Scheme 1) or involves a concerted homolysis of the C—O and S—C bonds (eq. 1) cannot be determined from present data. Whether step-wise or concerted, the transition state for the homolysis must involve the formation of an incipient free radical from the *S*-substituent of the xanthate. Only in this way could the relative stability of the *S*-substituent as a free radical have such a dramatic effect on the course of the xanthate pyrolysis.

An alternative explanation for these results could involve the formation of ion pairs, rather than radical pairs. Detailed kinetic studies would be needed in order to distinguish between these possibilities (effect of solvent type on reaction rates), but our results with the *S*-phenacyl group are indicative that the radical pair is the correct choice. The formation of an ion pair with positive charge build-up on the carbon adjacent to the carbonyl carbon would be particularly unfavorable. We would thus expect the *S*-phenacyl xanthate to give a much higher yield of alkene, and correspondingly lower yield of alcohol, than the *S*-benzyl xanthate if the ion pair mechanism were operative.

The yields of toluene observed in the distillates are also dependent on the nature of the *S*-substituent. The absence of toluene in the pyrolysates of the *S*-hexyl and *S*-2-phenylethyl xanthates, that pyrolyze smoothly without tar formation, and the presence of substantial amounts in all other cases strongly suggests that toluene is formed in secondary reactions (dehydrogenation of the alkenes) that are significant only when tarry by-products are formed. In the *S*-benzyl xanthate, toluene would also be formed via homolytic cleavage of the carbon–sulfur bond followed by hydrogen abstraction from some donor species. However, since the non-Chugaev pathway is oc-

For personal use only.

curring to only about 7% of the total reaction (as determined from the yield of cyclohexanemethanol), most of the toluene formed in this case must also be derived from the alkenes.

The phenacyl and diphenylmethyl mercaptans were not isolated. Phenacyl mercaptan would be expected to decompose under the reaction conditions in a manner similar to that found for *p*-bromophenacyl mercaptan to yield acetophenone along with considerable tar (5). The acetophenone formed in the pyrolysis of xanthate **1***d* must, therefore, be formed via both the non-Chugaev pathway (about 50% based on the yield of cyclohexanemethanol) and the thermal decomposition of the phenacyl mercaptan formed from the normal Chugaev pathway. Diphenylmethyl mercaptan would also be expected to decompose at these temperatures since diphenylmethyl disulfide is known to thermally decompose to thiobenzophenone and diphenylmethane (6). Thus the diphenylmethane formed in the pyrolysis of xanthate **1***e* probably arises from both the homolytic pathway (about 60% based on the yield of cyclohexanemethanol) and the normal Chugaev pathway.

Finally, from a practical viewpoint, the extent of alkene rearrangement and formation of alkenes derivable from the *S*-substituent of the xanthate are of importance. While the variation in alkene rearrangement is not as regular as are the variations in total alkene and alcohol yields, the trend is clear. Those xanthates that undergo clean pyrolysis without tar formation (*S*-hexyl and *S*-2-phenylethyl) yield little or no rearranged alkene (1-methylcyclohexene). Those xanthates that undergo pyrolysis by both pathways (plus tar formation) yield considerably more rearranged alkene. We have previously demonstrated that the pyrolysis residue promotes the rearrangement of methylenecyclohexane to 1-methylcyclohexene (5). Low yields of 1-hexene and styrene were observed for the two xanthates that contain *S*-substituents with hydrogens beta to the sulfur. Whether these alkenes were formed through β-elimination via the *S*-alkyl group of the xanthate or subsequent elimination of hydrogen sulfide from the mercaptan products is not known.

In view of these results, it is now apparent that the course of primary alcohol xanthate pyrolysis can be controlled by proper choice of the *S*-substituent. The use of *S*-substituents larger than methyl enables the formation of crystalline xanthates that can be purified more readily than can high boiling oils. Smooth pyrolysis to alkenes should then take place as long as the *S*-substituent does not lead to a relatively stable free radical via homolysis of the carbon–sulfur bond.

Experimental

Melting points were taken on a Fisher–Johns Melting Point Apparatus and are corrected. Boiling points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 257 recording spectrophotometer. The n.m.r. spectra were recorded on a Hitachi Model R-20 spectrometer and chemical shift data are given in p.p.m. downfield (δ) from tetramethylsilane as an internal standard (multiplicity: s, singlet; d, doublet; t, triplet; m, multiplet). Elemental analyses were performed by Baron Consulting Company, Orange, Connecticut.

Sodium Cyclohexylmethyl Xanthate (2)

Cyclohexanemethanol (57 g, 0.5 mol) was added dropwise (15 min) to a suspension of sodium hydride (24.4 g, 0.6 mol of 56% oil dispersion) in 150 ml of anhydrous ether. The mixture was stirred for 15 min and then carbon disulfide (76 g, 1.0 mol) was added with stirring and cooling over a period of 45 min. Additional portions of ether (250 ml total) were added as needed to keep the suspension fluid. Stirring was continued for 30 min and then the solid product (115 g) was collected by filtration and purified in 10 g portions. The crude sodium salt (10 g) was dissolved in reagent anhydrous acetone (25 ml) and filtered to remove impurities. Concentration of this solution to 10 ml and dilution with anhydrous ether (500 ml) resulted in the formation of 5.8 g of crystalline material after refrigeration overnight. Concentration of the filtrate to 50 ml, followed by the addition of 200 ml of anhydrous ether, gave an additional 1.6 g. The total yield of 7.4 g represents an 80% conversion of the starting alcohol to crystalline sodium xanthate (**2**). This salt was used for the preparation of all of the cyclohexylmethyl *S*-substituted xanthates without characterization or further purification.

Cyclohexylmethyl S-Hexyl Xanthate (1a)

Sodium cyclohexylmethyl xanthate (**2**) (26.6 g, 0.125 mol) was dissolved in anhydrous reagent acetone (50 ml). 1-Bromohexane (18.1 g, 0.110 mol) was added rapidly to the solution and mixed for 2 h at room temperature. Ice water (200 ml) was added and the water–acetone layer decanted from the resulting oil. The oil was dissolved in ether (200 ml), dried over calcium chloride, filtered, and the ether evaporated to yield a yellow oil (27.3 g, 91%): b.p. 142°/0.5 mm; ν_{max} (neat) 2937, 2862, 1453, 1382, 1221, 1065, 972, 939, 913, 892, 846, 729 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.75–2.00 (22H, broad m), 3.07 (2H, t, J = 7 Hz, SCH_2), 4.32 (2H, d, J = 6 Hz, OCH_2).

Anal. Calcd. for $C_{14}H_{26}OS_2$: C, 61.29; H, 9.55; S, 23.37. Found: C, 61.58; H, 9.25; S, 23.72.

Cyclohexylmethyl S-2-Phenylethyl Xanthate (1b)

Sodium cyclohexylmethyl xanthate (**2**) (18.5 g, 0.08 mol) was dissolved in anhydrous acetone (150 ml). 1-Bromo-2-phenylethane (14.8 g, 0.08 mol) was added

rapidly and the solution was stirred for 10 min. The addition of cold water (300 ml) yielded an oil that solidified on cooling. Recrystallization from 95% ethanol gave 16.2 g (74%) of crystalline **1***b*: m.p. 43.0–43.5°; ν_{max} (melt) 3090, 3068, 3031, 2928, 2855, 1609, 1496, 1448, 1228, 1062, 969, 934, 911, 890, 844, 828 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.75–2.00 (11H, broad m), 3.09 (4H, m, SCH_2CH_2), 4.31 (2H, d, J = 6 Hz, OCH_2), 7.13 (5H, s, phenyl).

Anal. Calcd. for $C_{16}H_{22}OS_2$: C, 65.26; H, 7.53; S, 21.78. Found: C, 65.13; H, 7.49; S, 21.82.

Cyclohexylmethyl S-Benzyl Xanthate (1c)

Sodium cyclohexylmethyl xanthate (**2**) (25.0 g, 0.118 mol) was dissolved in anhydrous acetone (100 ml). Benzyl bromide (17.1 g, 0.10 mol) was added rapidly and the solution was stirred for 15 min. Cold water (350 ml) was added and the water–acetone layer was decanted from the precipitated oil. An ether solution of this oil was dried ($CaCl_2$) and evaporated to give a brilliant yellow oil (25.7 g, 92%): b.p. 175°/0.4 mm; ν_{max} (neat) 3096, 3070, 3039, 2935, 2860, 1605, 1499, 1453, 1225, 1062, 972, 936, 916, 856, 770, 700 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.75–2.00 (11H, broad m), 4.19 (2H, s, SCH_2), 4.23 (2H, d, J = 6 Hz, OCH_2), 7.06 (5H, s, phenyl).

Anal. Calcd. for $C_{15}H_{20}OS_2$: C, 64.27; H, 7.19; S, 22.88. Found: C, 64.56; H, 7.34; S, 22.63.

Cyclohexylmethyl S-Phenacyl Xanthate (1d)

A solution of 1-bromoacetophenone (19.9 g, 0.10 mol) in anhydrous acetone (50 ml) was added rapidly to a solution of **2** (25.0 g, 0.12 mol) in anhydrous acetone (100 ml). The solution was stirred for 15 min and then diluted with cold water (300 ml). The oil that precipitated solidified on standing at −5°. Recrystallization from ethanol–ether gave 19.3 g (64%) of crystalline **1***d*: m.p. 36–37°; ν_{max} (melt) 3062, 2929, 2855, 1688, 1599, 1581, 1450, 1237, 1060, 988, 750, 690 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.75–2.00 (11H, broad m), 4.26 (2H, d, J = 6 Hz, OCH_2), 4.55 (2H, s, SCH_2), 7.6 (5H, m, phenyl).

Anal. Calcd. for $C_{16}H_{20}O_2S_2$: C, 62.33; H, 6.54; S, 20.79. Found: C, 62.11; H, 6.39; S, 20.63.

Cyclohexylmethyl S-Diphenylmethyl Xanthate (1e)

Sodium cyclohexylmethyl xanthate (**2**) (21.2 g, 0.10 mol) and chlorodiphenylmethane (20.2 g, 0.10 mol) were placed in a 1 l flask with anhydrous reagent acetone (375 ml). This solution was refluxed on a steam bath for 22 h. Ice water (600 ml) was added and a precipitate formed. The water–acetone solution was decanted from the oil and the oil was dissolved in ether, dried ($MgSO_4$), filtered, and the ether evaporated to give a yellow–green oil. Crystallization of this oil from 95% ethanol gave 15.9 g (44%) of **1***e*: m.p. 35–37°; ν_{max} (melt) 3090, 3065, 3032, 2930, 2855, 1601, 1495, 1450, 1236, 1053, 970, 931, 911, 781, 749, 699 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.75–2.00 (11H, broad m), 4.21 (2H, d, J = 6 Hz, OCH_2), 6.00 (1H, s, SCH), 7.19 (10H, s, phenyl).

Anal. Calcd. for $C_{21}H_{24}OS_2$: C, 70.77; H, 6.78; S, 17.99. Found: C, 70.59; H, 6.75; S, 18.11.

Pyrolysis of Xanthates

All pyrolyses were carried out at 240° until gas evolution stopped (2–4 h) in the apparatus that has been described in a previous publication (5).

Analysis of Pyrolysis Products

The components of the pyrolysis mixtures (distillate) were separated by preparative scale g.l.p.c. on a Varian 1520B gas chromatograph using a 10 ft × 3/8 in. column of 15% Carbowax 20M on Chromosorb W, 30–60 mesh. Comparison of the i.r. spectra of these collected compounds with those of authentic samples showed the mixture to consist of the components shown in Table 1. Quantitative gas chromatographic analysis was done with the Perkin–Elmer 800 gas chromatograph with a 12 ft × 1/8 in. column of 15% Carbowax 20M on Chromosorb W, 30–60 mesh. The area normalization method was used to compute the yields shown in Table 1.

Determination of the Bond Dissociation Energy $D(C_2H_5Hg—C_2H_5)$ by the Toluene Carrier Method

A. C. LALONDE AND S. J. W. PRICE

Department of Chemistry, University of Windsor, Windsor, Ontario

Received June 9, 1971

The pyrolysis of diethylmercury has been studied in a toluene carrier flow system from 601 to 673 °K using total pressures of 1.04 to 7.75 mm. The progress of the reaction was followed by measuring the amounts of unreacted alkyl. Partial solution of butane in the toluene condensed at the outlet of the reactor made full product analysis difficult. Complete analysis in a number of runs did yield a good material balance between alkyl decomposed and $C_4H_{10} + \frac{1}{2}(C_2H_6 + C_2H_4 +$ *n*-propylbenzene).

[1] $$Hg(C_2H_5)_2 \rightarrow HgC_2H_5 + C_2H_5$$

[3] $$C_2H_5 + C_6H_5CH_3 \rightarrow C_2H_6 + C_6H_5CH_2$$

[4] $$2C_2H_5 \rightarrow C_4H_{10}$$

[5] $$2C_2H_5 \rightarrow C_2H_4 + C_2H_6$$

The Arrhenius equation for reaction 1, $\log k_1(s^{-1}) = 15.4 - (45\,700 \pm 1\,000)/2.3\,RT$, is in excellent agreement with that estimated by Benson and O'Neal. Based on a number of simplifying approximations, $\log k_3(cm^3\ mol^{-1}\ s^{-1}) = 10.9 - (9\,300 \pm 2\,000)/2.3\,RT$. The estimated disproportionation to combination ratio, $k_5/k_4 = 0.09 - 0.12$ is in good agreement with earlier work.

Approximate correction of E_1 to absolute zero yields $D(C_2H_5Hg—C_2H_5) = 43.7$ kcal mol^{-1} and therefore by difference $D(Hg—C_2H_5) = 6.5$ kcal mol^{-1}.

La pyrolyse du diéthylmercure a été étudiée dans un système ou le courant porteur est le toluène, entre 601 et 673 °K et en utilisant des pressions totales de 1.04 à 7.75 mm. L'avancement de la réaction est suivie en mesurant la quantité d'alkyle n'ayant pas réagi. La condensation de solution de butane dans le toluène, à la sortie du réacteur, rend dificile l'analyse complète des produits. L'analyse complète sur plusieurs essais, donne un bon équilibre au point de vue produit entre la décomposition de l'alkyle et $C_4H_{10} + \frac{1}{2}(C_2H_6 + C_2H_4 +$ *n*-propylbenzène)

[1] $$Hg(C_2H_5)_2 \rightarrow HgC_2H_5 + C_2H_5$$

[3] $$C_2H_5 + C_6H_5 \rightarrow C_2H_6 + C_6H_5CH_2$$

[4] $$2C_2H_5 \rightarrow C_4H_{10}$$

[5] $$2C_2H_5 \rightarrow C_2H_4 + C_2H_6$$

L'équation d'Arrhenius pour la réaction 1, $\log k_1\ (s^{-1}) = 15.4 - (45\,700 \pm 1\,000)/2.3\,RT$, est en excellent accord avec celle estimée par Benson et O'Neal. Fondé sur un certain nombre de simplifications approximatives $\log k_3\ (cm^3\ mol^{-1}s^{-1}) = 10.9 - (9\,300 \pm 2\,000)/2.3RT$. L'estimation du rapport dismutation sur combinaison, $k_5/k_4 = 0.09 - 0.12$ est en bon accord avec un travail précédent.

L'extrapolation approximative de E_1 ou zéro absolu donne $D(C_2H_5Hg—C_2H_5) = 43.7$ kcal mol^{-1} d'où par différence $D(Hg—C_2H_5) = 6.5$ kcal mol^{-1}.

Canadian Journal of Chemistry, **49**, 3367 (1971)

Introduction

Three previous investigations of the pyrolysis of diethylmercury have been reported. In a nitrogen carrier flow system (1) over the temperature range 593–693 °K the decomposition was essentially homogeneous. Total pressures of 10 ± 1 mm were used with contact times of 0.1 to 0.3 s. Under these experimental conditions, it is unlikely that the reactant gases reached thermal equilibrium until an appreciable part of the reaction zone had been traversed. In some experiments a partial pressure of 0.4 mm of toluene was added. The presence of toluene was reported to have no effect on the rate constant, the ethane/ethylene ratio (approximation 1) or the C_4/C_2 ratio (approximation 4). These ratios were independent of temperature. The mechanism proposed both in the presence and absence of toluene involved, in addition to the decomposition steps, only the combination and disproportionation of C_2H_5.

The extent of decomposition was measured both by the mercury produced and by $C_4H_{10} + \frac{1}{2}(C_2H_4 + C_2H_6)$. Good agreement was ob-

tained between the two methods. The Arrhenius equation obtained was log k (s^{-1}) = 14.1 − (42 500/2.3 RT). If the activation energy is accepted as a reasonable measure of $D_1(C_2H_5Hg—C_2H_5)$ then by difference $D_2(C_2H_5—Hg)$ = 7.7 kcal mol^{-1} (2) (approximate correction to 0 °K would give D_1 = 40.5 kcal mol^{-1} and therefore D_2 = 9.7 kcal mol^{-1}). An earlier study (3) using essentially the same experimental procedures gave a slightly lower activation energy, 41.5 kcal mol^{-1}, but should be considered only as a preliminary investigation to the work discussed above.

A static system study (4) carried out between 496–566 °K using pressures of 1–10 mm gave log k (s^{-1}) = 14.4 − (41 900/2.3 RT). Extrapolation to higher temperatures yields rate constants about a factor of two greater than those observed in the N_2 carrier work. A zero order heterogeneous reaction with an activation energy of 22.1 kcal mol^{-1} was also reported.

Experimental

Materials

(*a*) Toluene from sulfonic acid (Eastman Organic X325) was prepared for use by refluxing over sodium under vacuum and then degassing twice by bulb-to-bulb distillation.

(*b*) Diethylmercury was prepared by a standard Grignard reaction using ethyl magnesium iodide and mercuric chloride. The resulting ether solution was dried over $CaCl_2$, fractionally distilled and the alkyl stored under its own vapor pressure. Vapor pressure data are given in Table 1. These data are in good agreement with previous data (5) and yield ΔH_{298}(vap) = 10.7 kcal mol^{-1} *cf.* the N.B.S. selected value (6) of 10.8 kcal mol^{-1}.

Apparatus and Procedure

The present work was carried out in a toluene carrier flow system using contact times selected to minimize both thermal equilibrium and diffusion errors (7, 8). In order to check for surface effects a vessel packed with quartz tubes was used. This vessel had a volume of 117 cm^3. The unpacked vessel used had a volume of 165 cm^3. The surface-to-volume ratios of the unpacked and packed vessels were respectively 1.25 and 21.2 cm^2/cc. Before use, the packing material and both vessels were treated with boiling concentrated nitric acid and vacuum baked without rinsing.

TABLE 1. Vapor pressure data for diethylmercury

t (°C)	p(mm)
0.0	0.55
14.3	1.40

44.0	8.90
62.0	22.00

Refrigerated traps at the outlet of the furnace were intended to remove toluene, unreacted alkyl, *n*-propylbenzene, dibenzyl and related compounds while allowing ethane, ethylene, butane, and other minor gaseous products to be collected in a gas burette. The products from the gas burette were analyzed using a Perkin–Elmer 154 gas chromatograph, equipped with a 1/4 in. × 6 ft silica gel column. A flow rate of He of 60 cc/min was used with a column temperature of 80 °C.

A Perkin–Elmer 800 gas chromatograph was used to analyze the condensed toluene for *n*-propylbenzene and residual alkyl. The analyses were carried out on a 0.02 in. × 150 ft polypropylene glycol open tubular column at 60 °C using a flow rate of N_2 of 10 cc/min. Following most runs the toluene in the traps was warmed to room temperature and then frozen down into a single trap to ensure collection of all residual alkyl. In selected runs where the toluene was to be analyzed for dissolved butane in addition to alkyl and *n*-propylbenzene, the toluene was allowed to warm to only −5 °C. This temperature was high enough to prevent loss of alkyl by fractional crystallization and low enough to minimize loss of butane before analysis. In these runs the 1 μl syringe used for injecting the gas chromatography sample was precooled to −10 °C.

The standard mixture needed for calibration of the gas chromatographs were prepared by standard gravimetric and volumetric procedures with the exception of the butane standard for the Perkin–Elmer 800. To prepare this standard a known weight of toluene was allowed to flow through the system and condense in a trap cooled by an acetone and Dry Ice bath in the same manner as in an ordinary run. The acetone and Dry Ice bath was replaced by a liquid N_2 bath. A known quantity of butane was distilled on to the toluene by replacing the toluene bulb with a butane vessel and allowing the butane to flow through the system in the same way as the toluene. After the distillation was complete, the liquid N_2 bath was replaced with the acetone and Dry Ice bath. About 75% of the butane then went into solution with the toluene and the remainder was collected and measured in the gas burette. The amount of butane recovered was subtracted from the initial amount distilled into the toluene. Consequently, the concentration of butane in toluene was known. This liquid standard was then removed from the system and analyzed under the same conditions as the liquid samples collected at the end of a run. It was felt that preparing and handling the standard in this way would duplicate systematic errors and lead to a more meaningful calibration.

Results and Discussion

The full experimental results are given in Table 2. They may be discussed in terms of the following mechanism.

[1] $$Hg(C_2H_5)_2 \rightarrow HgC_2H_5 + C_2H_5$$

[2] $$HgC_2H_5 \rightarrow Hg + C_2H_5$$

[3] $$C_2H_5 + C_6H_5CH_3 \rightarrow C_2H_6 + C_6H_5CH_2$$

[4] $2\,C_2H_5 \rightarrow C_4H_{10}$

[5] $2\,C_2H_5 \rightarrow C_2H_4 + C_2H_6$

[6] $C_2H_5 + C_6H_5CH_2 \rightarrow C_6H_5C_3H_7$

plus the following minor reactions

[7] $C_2H_5 \rightarrow C_2H_4 + H$

[8] $H + C_6H_5CH_3 \rightarrow CH_3 + C_6H_6$

[9] $H + C_6H_5CH_3 \rightarrow H_2 + C_6H_5CH_2$

[10] $CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2$

[11] $CH_3 + C_2H_5 \rightarrow C_3H_8$

[12] $CH_3 + C_6H_5CH_2 \rightarrow C_6H_5C_2H_5$

Reactions 8–12 are a consequence of reaction 7. The yields of methane, propane, and ethylbenzene were too low for accurate quantitative analysis, but indicated that even at the highest temperature used only about 2% of the ethyl radicals were removed by reaction 7.

Based on the proposed mechanism material balance considerations require that

$$\left[\begin{matrix}\mathrm{Hg(C_2H_5)_2}\\ \text{decomposed}\end{matrix}\right] = [C_4H_{10}] + \tfrac{1}{2}([C_2H_6] + [C_2H_4] + [C_6H_5C_3H_7])$$

Values of k_1 may therefore be calculated either from the quantity of unreacted alkyl (k_m) or from the products shown on the right side of the preceding equation (k_g). It is immediately obvious from Table 2 that gross discrepancies exist between values of k_g and k_m. The discrepancies exist because in the bulk of the work only the gaseous products were analyzed for butane. As shown by a few selected runs in which the butane in the liquid products was also analyzed (see Table 3), full analysis leads to good agreement. The slightly lower values of k_g reflect the fact that either loss of butane from solution or loss of residual alkyl tend to make $k_g < k_m$.

Because the analysis of the liquid products for butane was rather time consuming, once the agreement between k_g and k_m was established all further considerations were based on k_m. Throughout the work attempts were made to find various trap conditions that would allow the bulk of the butane to reach the gas burette. Initially two traps, both kept at −80 °C, were used. It was soon found convenient to have the second trap at −196 °C so that all products other than traces of methane and hydrogen could be frozen out. This trap was warmed to −80 °C after the run was over and the gaseous products collected. Later a third trap was installed between the furnace and the two original traps. Test runs were carried out with this trap at −20, −30, −40, −60, −65, and −70 °C. None of these tests were successful. In almost all cases $k_g \leqslant 0.5\,k_m$. In one run with the three traps at −30, −80, and −196 °C, respectively, $k_g = 0.9\,k_m$ was achieved but this result could not be reproduced. The results in Table 3 were obtained with a trap temperature sequence of −60, −80, and −196 °C.

Tests for the effect of alkyl concentration, total pressure, and contact time on k_m are shown in Tables 4, 5, and 6, respectively. The decomposition is essentially first order (Table 4). At the temperatures and pressures used the unimolecular decomposition of a molecule as complex as $Hg(C_2H_5)_2$ should be at, or near, the high pressure limit. The limited results in Table 5 tend to confirm this. The results in Table 6 indicate that significant thermal equilibrium and longitudinal diffusion errors have been avoided. As shown in Table 2, a 17-fold increase in surface-to-volume ratio produced a

maximum increase in k_m of 50%, indicating that the reaction in the unpacked vessel is essentially a homogeneous process.

From the Arrhenius plot of k_m shown in Fig. 1, $\log k_m$ (s^{-1}) = 15.4 − (45 700 ± 1 000/2.3 RT). As may be seen from Fig. 2, the rate constants from the present work are in basic agreement with those from previous work (1, 4). The slightly lower rate constants and the low activation energy obtained in the N_2 carrier work (1)

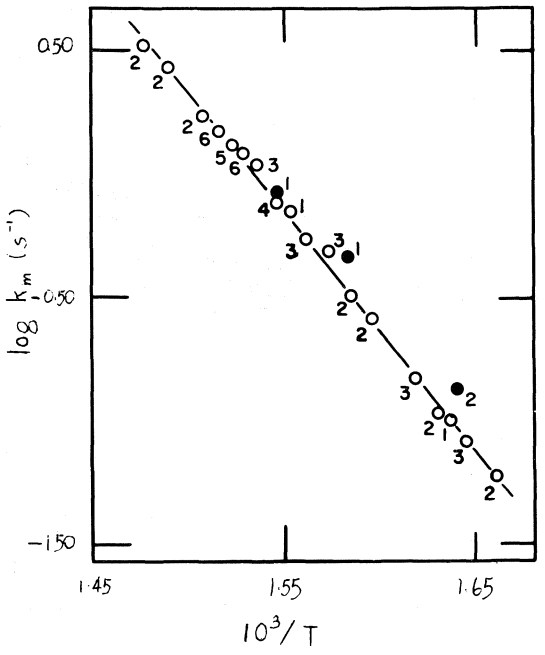

FIG. 1. Arrhenius plot for the decomposition of diethylmercury based on residual alkyl analysis. Numbers indicate number of runs averaged. ●, packed vessel; ○, unpacked vessel.

are possibly the results of thermal equilibrium problems caused by the rather short contact times used. The higher rate constants and lower activation energy from the static system work possibly reflect failure to completely isolate the homogeneous reaction. The present A factor and activation energy are in excellent agreement with the estimated "preferred" values given by Benson and O'Neal (2).

Using $D_1(C_2H_5Hg—C_2H_5) + D_2(Hg—C_2H_5)$ = 50.2 kcal mol^{-1} (2) and accepting the present activation energy as a reasonable measure of D_1 gives D_2 = 4.5 kcal mol^{-1} (approximate correction of E_1 to 0 °K would give D_1 = 43.7 kcal mol^{-1} and D_2 = 6.5 kcal mol^{-1}).

Although the total butane yield was determined in only a few runs, the material balance established allows the total butane to be estimated for all runs with full gas analysis from

$$\text{total butane} = \text{alkyl used} - \text{residual alkyl} - \tfrac{1}{2}([C_2H_6] + [C_2H_4] + [C_6H_5C_3H_7])$$

This process is somewhat inaccurate since all errors will accumulate in the calculated butane

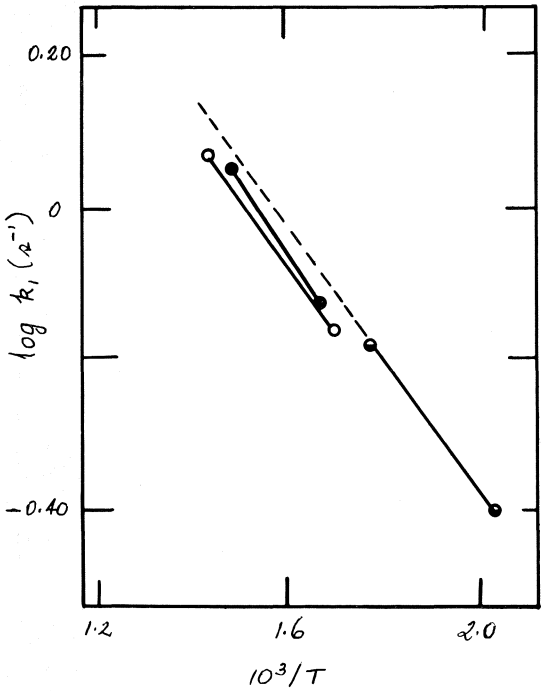

FIG. 2. Arrhenius plots for the decomposition of diethylmercury. Points indicate the temperature range studied. ○ N_2 flow system study, ◒ static system study, ● this work.

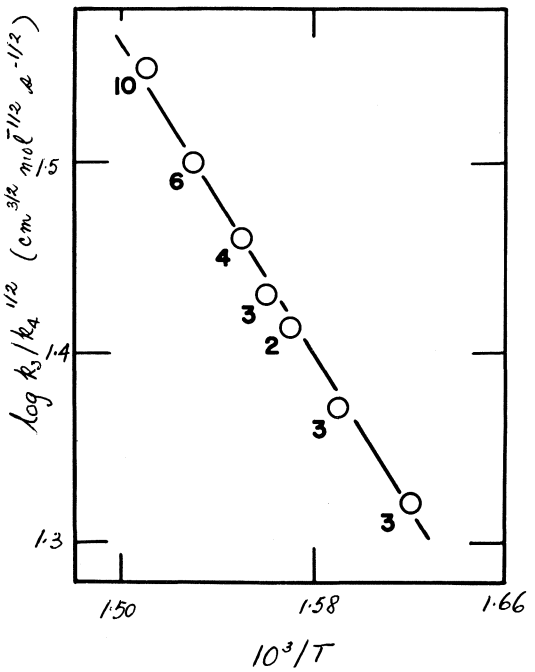

FIG. 3. Arrhenius plot of $k_3/k_4^{1/2}$. Numbers indicate number of runs averaged.

yield. However, a number of interesting tentative conclusions may be reached in this way.

First, if an approximate correction to the ethylene yield is made to allow for reaction 7 (the ethylene from reaction 7 varies from about 35% at the highest temperature used to about 10% at the lowest) this then allows values of $k_3/k_4^{1/2}$ to be calculated from

$$k_3/k_4^{1/2} = \frac{(\text{moles } C_2H_6 - \text{moles } C_2H_4)\ 760 \times 82 \times T}{(\text{moles } C_4H_{10})^{1/2}(Vt)^{1/2}P}$$

when T = run temperature (°K), V = volume of the reaction zone (cm^3), t = duration of alkyl flow (s), and P = toluene pressure (mm). The Arrhenius plot shown in Fig. 3 was constructed using values of $k_3/k_4^{1/2}$ calculated in this way. The curve obtained from the average points is quite good, but it should be noted that a scatter of up to ± 25% in $k_3/k_4^{1/2}$ occurred at the highest three temperatures. This scatter was reduced to about ±10% in the case of the lower four points. The Arrhenius equation obtained is

$\log k_3/k_4^{1/2}$ ($cm^{3/2}$ $mol^{-3/2}$ $s^{-1/2}$) = 4.62 − (9 300 ± 2 000/2.3RT).

If $\log k_4$(cm^3 mol^{-1} s^{-1}) = 12.6 at all temperatures used (9) then $\log k_3$ (cm^3 mol^{-1} s^{-1}) = 10.9 − (9 300 ± 2 000/2.3RT). Past experience with methyl radical reactions in similar systems (10) would indicate that, within the experimental temperature range, values of k_3 calculated from this equation should be reasonable. However, because of the increasing non-uniformity of radical concentrations with increasing percent decomposition, the individual Arrhenius parameters are of limited significance. Studies over a wide range of temperature using a variety of C_2H_5 sources would be required to obtain significant A and E values. If k_3 is calculated at 650 °K, a value of 0.63×10^8 cm^3 mol^{-1} s^{-1} is obtained. This value is of the same order of magnitude as the corresponding rate constants for hydrogen abstraction by methyl radicals from toluene, 2.46×10^8 cm^3 mol^{-1} s^{-1}.

It is also interesting to consider values of k_5/k_4. These are again somewhat scattered but with minor exceptions are in the range 0.10–0.15 with the majority between 0.11–0.14. No temperature dependence was noted. If an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

estimated correction for C_2H_4 from reaction 7 is made the range of ratios for the majority of runs would shift to 0.09–0.12. These results are in agreement with several previous studies (11) and lend some additional support to the general conclusion that $E_5 - E_4$ is approximately zero.

Since the present results for k_1 are based to a large extent on analysis of residual alkyl, one further point of considerable importance should be considered. Based on the present value of k_3 and the literature value for k_{13} (12).

[13] $C_2H_5 + Hg(C_2H_5)_2 \rightarrow C_2H_6 + C_2H_5HgC_2H_4$

$k_{13}/k_3 = 1.5$ at 650 °K and will show little variation over the temperature range used. This leads to the conclusion that in the least favorable case in the present study, the $Hg(C_2H_5)_2$ undergoing reaction 13 is only 0.003 of that decomposing by reaction 1. The general conclusion that reaction 13 is unimportant under the present experimental conditions is supported by the failure to observe any significant variation in k_m over a wide range of toluene to alkyl ratios.

This work has been supported by a grant from the National Research Council of Canada.

The Dissolution of Magnesium Oxide in Dilute Sulfuric Acid[1]

DIGBY D. MACDONALD AND D. OWEN
Whiteshell Nuclear Research Establishment, Research Chemistry Branch, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received May 5. 1971

The kinetics of dissolution of sintered magnesium oxide pellets in dilute sulfuric acid at 4.00 and 25.00 °C have been investigated using the rotating disc technique. The rate of depletion of hydrogen ions in the bulk solution is found to be controlled by both transport through the diffusion layer and chemical reaction with the oxide surface. The chemical reaction occurring at the oxide surface has an activation energy of 13 kcal mol^{-1}. The diffusion coefficients for hydrogen ion in dilute sulfuric acid at the two temperatures of interest have been calculated. These coefficients yield an activation energy of 3.6 kcal mol^{-1} for the diffusion of hydrogen ions to the oxide surface.

Les cinétiques de dissolution de pastilles d'oxyde de magnésium fritté dans de l'acide sulfurique dilué, ont été étudiées à 4.00 et 25.00 °C, au moyen de la technique du disque tournant. La vitesse de diminution des ions hydrogène dans le volume de la solution est contrôlée à la fois par le phénomène de transport à travers la couche de diffusion et par la réaction chimique avec la surface de l'oxyde. La réaction chimique se fait à la surface de l'oxyde a une énergie d'activation de 13 kcal mol^{-1}. Les coefficients de diffusion de l'ion hydrogène dans l'acide sulfurique dilué ont été calculés pour les deux températures; ces coefficients conduisent à une énergie d'activation de 3.6 kcal mol^{-1} pour la diffusion des ions hydrogène vers la surface de l'oxyde.

Canadian Journal of Chemistry, **49**, 3375 (1971)

Introduction

The dissolution behavior of metal oxides in aqueous solution is important to many fields of chemistry and technology. A great number of studies have been reported in which the dissolution experiment is performed upon powdered samples. In view of the fact that dissolution is a heterogeneous process this technique suffers from many drawbacks. Perhaps the two most serious disadvantages are the lack of a well defined hydrodynamic or transport regime and an inherent uncertainty as to the actual (or even apparent) surface area of the sample. Accordingly, most studies of this type are reduced to qualitative interpretation.

In the present study the dissolution of magnesium oxide in dilute sulfuric acid was investigated using a rotating disc (1, 2). The rotating disc technique allows the dissolution reaction to be studied under closely controlled hydrodynamic conditions while maintaining a relatively constant surface area. The results of this study clearly demonstrate that the rates of dissolution of magnesium oxide in dilute sulfuric acid are highly reproducible and permit quantitative interpretation of the process involved.

[1]A.E.C.L. No. 4003.

Experimental

Materials

Weighed portions (1.80 g) of British Drug Houses (B.D.H.) or Anachemia reagent grade magnesium oxide powder were pressed into pellets at 7500 p.s.i.g. and sintered in air at 800 °C for 1½ h. The sintered pellets were strong, easily polished and showed no tendency to "flake" when rotated in sulfuric acid. The density of the pellets was found to be 2.00 g cm^{-3}. This figure is well below the theoretical density of 3.58 g cm^{-3} and suggests considerable porosity in the sample. However, longer sintering times (up to 4 h) did not increase the density markedly so all pellets used in this work were prepared as described above. The dissolution reaction was limited to a well defined area by painting the sides and one face of each pellet with polyurethane varnish. Pellets prepared in this manner using both the B.D.H. and Anachemia oxides gave identical results within experimental error.

Dilute sulfuric acid solutions (0.005–0.050 *M*) were prepared by diluting reagent grade concentrated sulfuric acid with deionized distilled water.

Apparatus

The rotating disc used in this study was similar to that described previously (3) and incorporated features recommended by Riddiford (2). The disc was machined from Teflon and contained an inset on the underside of sufficient size to accept a magnesium oxide pellet. Immediately before a run was started the pellet was pressed into place and the exposed face was ground down to within 0.5 mm of the surrounding Teflon surface with No. 600 silicon carbide paper. Any free magnesium oxide grindings were washed away with distilled water. The disc was screwed on to a threaded stainless steel shaft

which passed through a roller bearing assembly at the top of the reaction vessel. This bearing was designed to ensure minimum eccentricity of the disc (<1% of the pellet radius). The shaft was rotated by an adjustable speed electric motor via a pulley-belt arrangement. Rotational velocities were measured using a General Radio Type 1531-AB stroboscope. The temperature of the reaction vessel was maintained to within ±0.05 °C of the desired value using a water bath thermostat.

Method

The reaction vessel was assembled and thermostated for 1 h to ensure thermal equilibrium with the water bath. The reaction was initiated by pipetting 300 ml of prethermostated dilute sulfuric acid into the reaction vessel and starting the electric motor which had been preset at the desired rotational velocity. The underside of the disc was viewed with a mirror to ensure that no gas bubbles were trapped on the magnesium oxide surface. Aliquots (10 ml) of reaction solution were removed at regular time intervals and analyzed for magnesium ion by titration with standard disodium EDTA solution using Erichrome Black T as indicator. The duration of each run was such that more than 50% of the available hydrogen ions were consumed.

Rotational velocities were restricted to the range 10.47–104.72 rad s^{-1} (100–1000 r.p.m.). The upper limit was chosen so that the maximum Reynolds number (eq. 1),

$$[1] \qquad Re_{max} = r^2\omega/\nu$$

where ν and ω represent the kinematic viscosity and angular velocity, respectively, did not exceed the critical value (2×10^5) for transition to turbulent flow (2). Substituting r and ν equal to 0.952 cm and 8.9×10^{-3} cm^2 s^{-1} (4), respectively, into eq. 1 yields a maximum Reynolds number of 1.07×10^4, *i.e.* well below the critical value given above. The lower limit (10.47 rad s^{-1}) is sufficiently high to ensure negligible contribution to mass transport to or from the oxide surface by natural convection (2).

Results

The stoichiometry of the reaction between magnesium oxide and hydrogen ion in solution is represented by eq. 2

$$[2] \qquad MgO + 2H^+ \rightarrow Mg^{2+} + H_2O$$

In order to determine the kinetic order of the dissolution process with respect to hydrogen ion and to formulate a rate expression for the reaction, it is necessary to determine the actual concentration of hydrogen ion in solution at any given time. This can be accomplished by assuming that the first dissociation of sulfuric acid is complete and that the concentration of hydrogen ion at any given time is determined by reaction 2 and the second dissociation represented by eq. 3

$$[3] \qquad HSO_4^- \overset{K_2}{\rightleftharpoons} H^+ + SO_4^{2-}$$

The material balance equations for hydrogen and sulfate are therefore given by eqs. 4 and 5,

$$[4] \qquad \{H\}_{Total} = [H^+] + [HSO_4^-] + 2c = 2a$$

$$[5] \qquad \{SO_4\}_{Total} = [HSO_4^-] + [SO_4^{2-}] = a$$

where a denotes the number of moles of H_2SO_4 per liter of solution at zero time assuming no dissociation and c is the concentration of magnesium ion at the time of interest. Since the concentration of sulfate ion is determined by eq. 6

$$[6] \qquad [SO_4^{2-}] = \frac{K_2[HSO_4^-]}{[H^+]}$$

it is possible to eliminate $[SO_4^{2-}]$ and $[HSO_4^-]$ using eqs. 4, 5, and 6 and to express $[H^+]$ as a function of the known parameters c, K_2, and a.

$$[7] \qquad [H^+]^2 + (K_2 - a + 2c)[H^+] + 2K_2(c - a) = 0$$

or

$$[8] \qquad [H^+] = -(1/2)(K_2 - a + 2c) + (1/2)\{(K_2 - a + 2c)^2 - 8K_2(c - a)\}^{1/2}$$

In all subsequent calculations K_2 was taken as 1×10^{-2} and 2×10^{-2} M at 25 and 4 °C, respectively (5).

The kinetic order of the reaction between magnesium oxide and hydrogen ion was determined by calculating $\ln \{d[H^+]/dt\}_{t\rightarrow 0}$ graphically from plots of $[H^+]$ *vs.* time for runs differing only in the initial concentration of sulfuric acid and plotting this quantity against $\ln [H^+]_{t=0}$ as shown in Fig. 1. The solid line is drawn with a gradient equal to one. This plot clearly establishes that the dissolution reaction is first order with respect to hydrogen ion. Accordingly, the rate equation can be written as eq. 9,

$$[9] \qquad -d[H^+]/dt = (kA/V_t)[H^+]$$

where A is the projected surface area of the exposed oxide and V_t is the volume of the solution. Since the concentration of magnesium ion, c, (and therefore $[H^+]$) is determined by removing aliquots of solution, V_t must be regarded as time dependent when integrating eq. 9. This integration yields eq. 10 (6),

$$[10] \qquad -\sum V_t \ln ([H^+]_t/[H^+]_{t-\delta t}) = kAt$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

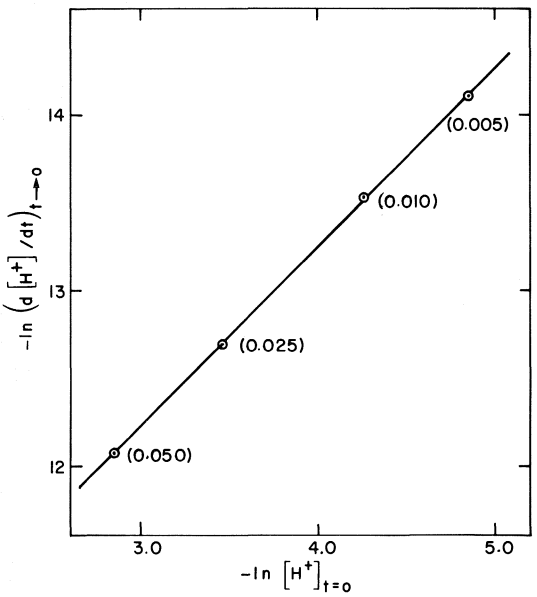

FIG. 1. Dependence of the initial rate on hydrogen ion concentration. $T = 25.00 \pm 0.05$ °C, $\omega = 31.42$ rad s^{-1}. The numbers in parentheses represent the initial concentrations of sulfuric acid.

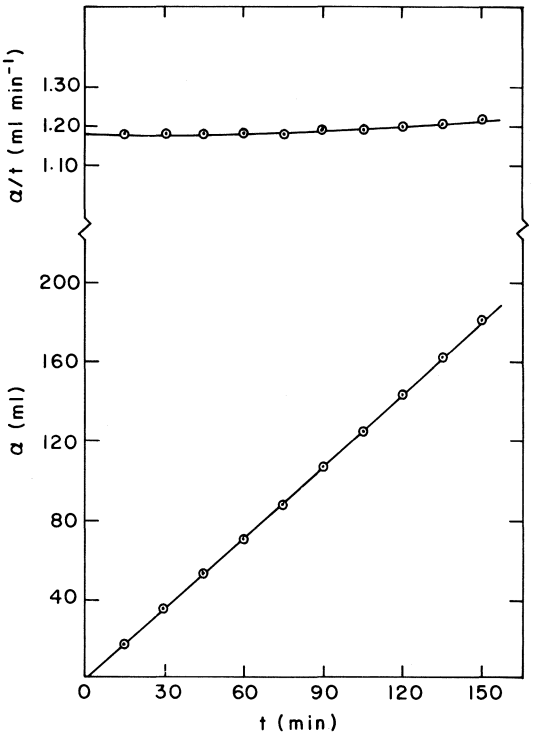

FIG. 2. Rate plot for the dissolution of magnesium oxide in dilute sulfuric acid. $a = 0.050$ M, $T = 4.00 \pm 0.05$ °C, and $\omega = 52.40$ rad s^{-1}. $\alpha = \Sigma V_i \ln \{[H^+]_{t-\delta}/[H^+]_t\}$.

where V_t is the volume of solution in the time interval $t - \delta t$ to t. A typical plot of eq. 10 is shown in Fig. 2. These plots were quite linear over most of the reaction studied. In some cases, however, and especially so for high rotational velocities, the rate plots deviated slightly from linearity near the end of the run. This phenomenon is illustrated in Fig. 2 by the plot of $\{\sum V_t \ln ([H^+]_t/[H^+]_{t-\delta t})\}/t$ *vs.* t. A strictly linear rate plot would yield a horizontal line. In practice, however, the plot "curls" upwards near the end of the run with an apparent increase in kA (see eq. 10) of 2–3%. Consequently, all rate constants were calculated from $(kA)_{t\to 0}$ and the projected area of the exposed oxide surface. The time dependence of kA most likely arises from the influence of a steadily roughening surface on the hydrodynamics of the system and possibly from the concomitant increase in surface area.

Rate constants for the dissolution of magnesium oxide in sulfuric acid are listed in Table 1. Each value represents the mean of at least three determinations. The uncertainties quoted are the average deviations from the means. These average deviations are seldom more than ±2% of the corresponding rate constants and demonstrate the high reproducibility that can be obtained by careful control of the hydrodynamics of the system.

Discussion

The reaction between hydrogen ion and magnesium oxide takes place in the following sequence: (*a*) transport of hydrogen ion to the oxide surface, (*b*) chemical reaction at the surface,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and (*c*) transport of the products from the surface to the bulk liquid. The transport processes, (*a*) and (*c*), are determined by the hydrodynamics of the system whereas the rate of the chemical process reflects the difference in free energy between the initial state and the transition state for the kinetic path involved. Of the three processes identified above only the first two involve the rate of depletion of hydrogen ions in the bulk solution. The role played by both of these processes in the dissolution of magnesium oxide in sulfuric acid is examined in detail in the following discussion.

According to the Nernst theory (7) for diffusion controlled reactions the rate constant for transport of hydrogen ions to the oxide surface can be expressed by eq. 11

$$[11] \qquad k_T = D/\delta$$

where D is the diffusion coefficient of the reactant (hydrogen ion) and δ is the thickness of the "ideal" Nernst diffusion layer. Solution of the Navier–Stokes equations for nonturbulent transport to the surface of a rotating disc yields eq. 12 for the transport rate constant (1, 2)

$$[12] \qquad k_T = 0.620\, D^{2/3}\nu^{-1/6}\omega^{1/2}$$

where ν and ω have been defined previously (see eq. 1). Equation 12 predicts that if the rate of depletion of hydrogen ions in the bulk solution is purely transport controlled then a plot of k_T *vs.* $\omega^{1/2}$ will be linear. Plots of this type for the dissolution of magnesium oxide in sulfuric acid at 4.00 and 25.00 °C are shown in Fig. 3. These plots are not linear and exhibit greatest curvature at the lowest temperature. The direction of curvature suggests that the observed rate constant approaches a limiting value at high rotational velocities. This indicates that over the range of rotational velocities employed in the present study both the transport and chemical processes exert some control of the overall rate of depletion of hydrogen ions in the bulk solution. Accordingly, the concentration of hydrogen ion at the oxide surface is neither effectively zero (transport control) nor equal to the concentration in the bulk solution (chemical control). Since the chemical reaction at the oxide surface is first order with respect to hydrogen ion then the rate of reaction can be written as eq. 13.

$$[13] \qquad -V_t(\mathrm{d}[H^+]/\mathrm{d}t)s = k_c A'[H^+]_s$$

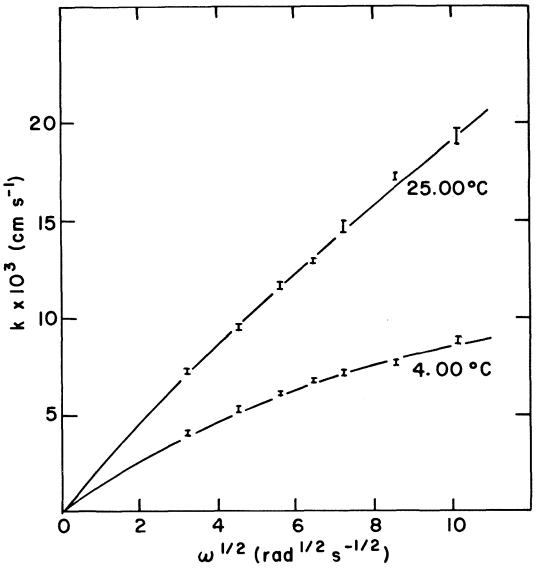

FIG. 3. The dependence of rate on rotational velocity.

where A' is the true surface area of the oxide. Similarly, the rate of transport of hydrogen ions to the surface is given by eq. 14,

$$[14] \qquad -V_t\mathrm{d}[H^+]/\mathrm{d}t = k_T A([H^+] - [H^+]_s)$$

where $[H^+]_s$ represents the hydrogen ion concentration at the oxide surface. At steady-state $\mathrm{d}[H^+]_s/\mathrm{d}t$ is identical to $\mathrm{d}[H^+]/\mathrm{d}t$ and hence $[H^+]_s$ can be expressed in terms of the bulk hydrogen ion concentration and the two rate constants k_T and k_c.

$$[15] \qquad [H^+]_s = k_T A[H^+]/(k_c A' + k_T A)$$

Substitution of eq. 15 into eq. 14 yields the following expression for the rate of depletion of hydrogen ions in the bulk solution.

$$[16] \qquad -V_t\frac{\mathrm{d}[H^+]}{\mathrm{d}t} = \left(\frac{k_T k_c \alpha}{k_T + k_c \alpha}\right) A[H^+]$$

where α is the roughness factor for the oxide surface, *i.e.* (A'/A). Comparison of eqs. 16 and 9 reveals that the observed rate constant is related to k_T and k_c by eq. 17.

$$[17] \qquad k = k_T k_c \alpha/(k_T + k_c \alpha)$$

or, by substituting eq. 12 for k_T and rearranging

$$[18] \qquad k^{-1} = (\alpha k_c)^{-1} + 1.613\, D^{-2/3}\nu^{1/6}\omega^{-1/2}$$

Plots of k^{-1} *vs.* $\omega^{-1/2}$ for the dissolution of magnesium oxide in sulfuric acid at 4.00 and

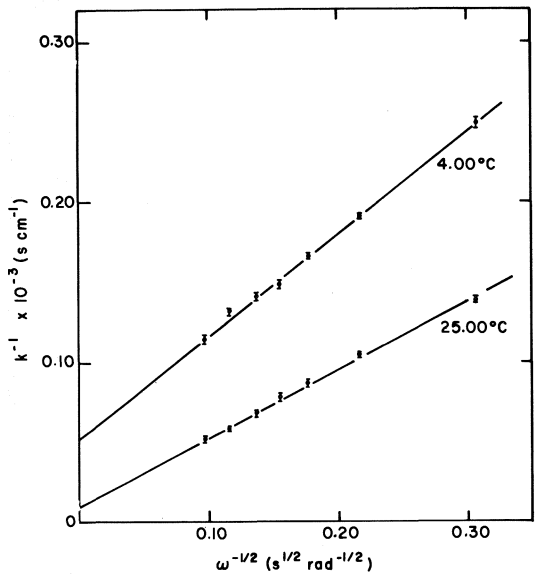

FIG. 4. Plot of reciprocal rate constant *vs.* $\omega^{-1/2}$.

25.00 °C are presented in Fig. 4. The plots are linear as predicted by eq. 18 for consecutive first order rate processes. If the dissolution process were completely transport controlled over the range of rotational velocities and temperatures studied then the lines drawn in Fig. 4 should pass through the origin. However, this is not the case and the finite intercepts at $\omega^{-1/2} = 0$ demonstrate the existence of joint transport/chemical control.

The intercepts at $\omega^{-1/2} = 0$ yield numerical values for (αk_c) of 1.92×10^{-2} cm s^{-1} and 10.0×10^{-2} cm s^{-1} at 4.00 and 25.00 °C, respectively. If it is assumed that α is independent of temperature then the (αk_c) values listed above correspond to an activation energy of 13 kcal mol^{-1} for the reaction of hydrogen ions with the magnesium oxide surface.

Vermilyea (8) has shown in a recent study that the dissolution behavior of powdered magnesium oxide is quite similar to that for the magnesium hydroxide. This led him to conclude that the magnesium oxide surface is rapidly converted to the hydroxide (eq. 19) and that this later species reacts with hydrogen ion in the dissolution reaction.

[19] $MgO + H_2O \rightleftarrows Mg(OH)_2$

$\Delta G^0 = -6.45$ kcal mol^{-1}

The calculated standard free energy change (9) for reaction 19 is sufficiently negative to support this view. In the present study, therefore, it seems reasonable to associate the chemical process occurring at the surface with the rapid hydration of MgO to produce $Mg(OH)_2$ which in turn reacts with protons in the rate determining step (eq. 20).

[20] $Mg(OH)_{2,\,s} + H^+ \xrightarrow{\text{slow}} Mg(OH)_{aq}^+ + H_2O$

[21] $Mg(OH)_{aq}^+ + H^+ \xrightarrow{\text{fast}} Mg_{aq}^{2+} + H_2O$

The proposed rate determining step is consistent with the observed activation energy.

The gradients of the k^{-1} *vs.* $\omega^{-1/2}$ plots presented in Fig. 4 permit determination of the diffusion coefficients for hydrogen ion in dilute sulfuric acid at the two temperatures of interest. The viscosity and density of dilute sulfuric acid solutions (<0.1 *M*) differ little from the corresponding quantities for pure water (10). Accordingly, the kinematic viscosities for pure water (4) at 4 °C (1.57×10^{-2} cm^2 s^{-1}) and at 25 °C (8.91×10^{-3} cm^2 s^{-1}) are used here to calculate the hydrogen ion diffusion coefficients. These calculations result in values of $4.5_1 \times 10^{-5}$ and $7.1_3 \times 10^{-5}$ cm^2 s^{-1} at 4 and 25 °C, respectively. Riddiford (2) has recently summarized previous determinations of D_{H^+} at 18–25 °C and found that the most reliable values fall in the range 2.8×10^{-5} to 1×10^{-4} cm^2 s^{-1} depending upon the solution employed. While no specific values are quoted for 0.050 *M* sulfuric acid, the diffusion coefficients reported in the present study seem very reasonable. The temperature dependence of D_{H^+} can be represented by eq. 22

[22] $$D_{H^+} = Z_D \exp(-E_D/RT)$$

where Z_D is the pre-exponential factor and E_D is the activation energy for the diffusion process. The diffusion coefficients calculated in this study yield a value of 3.6 kcal mol^{-1} for E_D. This value lies within the range 2–6 kcal mol^{-1} normally associated with diffusion of ions in aqueous solution.

The authors wish to thank Dr. S. Banerjee for his interest in this work.

Preparation and Transformations of Three *p*-Menthane-3-methanesulfonyloxy-4,8-diols

G. L. Lange and M. Bosch

Department of Chemistry, University of Guelph, Guelph, Ontario

Received July 9, 1971

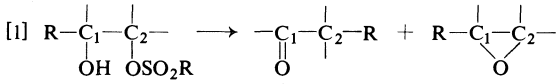
Three diastereomeric *p*-menthane-3-methanesulfonyloxy-4,8-diols were synthesized from (+)-pulegone. Treatment of each methanesulfonate with aqueous base resulted in a stereospecific reaction involving antiperiplanar groups to give one product: either an α-ketol by a pinacol-type rearrangement or an epoxide by an intramolecular S_N2-type reaction. Although the possibility existed for 1,3- as well as 1,2-diol monomethanesulfonate transformations, only products from the latter type of reaction were isolated.

Les trois diastéréoisomères du *p*-menthane méthanesulfonyloxy-3 diols-4,8 ont été synthétisés à partir de la (+)-pulégone. Le traitement de chaque méthanesulfonate par une base aqueuse, conduit à une réaction stéréospécifique qui implique des groupes antipériplanaires et qui donne un seul produit: soit un α-cétol par une transposition pinacolique, soit un époxyde par une réaction intramoléculaire du type S_N2. Bien qu'il existe des possibilités de transformation pour les monométhanesulfonate diols-1,3 et -1,2, seuls les produits correspondant au dernier type de réaction ont été isolés.

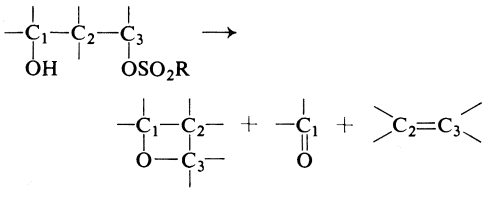
Canadian Journal of Chemistry, **49**, 3381 (1971)

Introduction

The literature contains numerous examples of transformations of 1,2- and 1,3-diol monosulfonates, usually tosylates or methanesulfonates (mesylates). Monosulfonates of 1,2-diols upon treatment with base commonly undergo a pinacol-type rearrangement to give a carbonyl compound (1) or they undergo an intramolecular displacement of the sulfonate to yield an epoxide (2) (eq. 1). The 1,3-diol monosulfonates may yield an oxetane (3) or fragmentation products (3, 4) (eq. 2). Of course, in both systems the sulfonate group could also undergo intermolecular displacement



[2]



or elimination. In cyclic systems, the relative stereochemistry of the hydroxyls in the starting material and the stability of the reacting conformation are generally critical factors in determining which reaction pathway will be followed.

A 1,2,3-triol monosulfonate (*e.g.* tertiary hydroxyl, tertiary hydroxyl, secondary sulfonate) would involve competition among all the pathways described above. A compound with such a triol moiety (the sulfonate being replaced by its biological equivalent) has been suggested by Barton and Gupta (5) as a precursor to the sesquiterpene, zierone. Transformations of related triol monotosylates have been employed in the synthesis of some A-norcholesteryl derivatives (6).

This report describes the preparation and transformations of three *p*-menthane-3-mesyloxy-4,8-diols, which are examples of the triol monosulfonates discussed above. They were prepared by epoxidation of (+)-pulegone (**1**) to give the ketoepoxides **2**, followed by reduction to the hydroxyepoxides **3**, hydrolysis to the triols **4** and finally selective monomesylation. The preparation of each of these synthetic intermediates and the base-catalyzed transformations of the monomesylates **5** will be discussed in detail.

Results and Discussion

Preparation of Hydroxyepoxides (3)

(+)-Pulegone (**1**) was epoxidized with alkaline hydrogen peroxide to give pulegone oxides **2***a* and *b* (64:36%, respectively) as previously reported (7). The two stereoisomeric ketoepoxides were separated and reduced with sodium borohydride in methanol. Compound **2***a* gave a mixture of two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydroxyepoxides, **3***a* and *b* (47:53%, respectively), which were separated by spinning band distillation, while **2***b* gave only one product, **3***c*.

Infrared and n.m.r. spectroscopy were conclusive in establishing the assigned configurations and major conformations for the three hydroxyepoxides (Scheme 1). An i.r. study of hydrogen bonding in dilute carbon tetrachloride solutions revealed the presence of intramolecular hydrogen bonding (3565, 3602 cm^{-1}) in **3***a* where the epoxide and the C-3 hydroxyl are *cis*, while in **3***b* where these functional groups are *trans* and the hydroxyl is axial, only free hydroxyl absorption (3628 cm^{-1}) was observed. Compound **3***c* showed intramolecular hydrogen bonding (3583 cm^{-1}) which is consistent with the *trans* orientation of the epoxide and the equatorial hydroxyl.

The n.m.r. spectra of the hydroxyepoxides, particularly the resonances of the C-3 hydrogens and hydroxyls, were quite instructive. Analysis of the C-3 hydrogens in both **3***a* and *c* was complicated by intramolecular hydrogen bonding of the C-3 hydroxyl with the epoxide oxygen, which slowed the rate of OH exchange sufficiently to allow the observation of H—C—O—H coupling. Fraser *et al.* (8) recently devised a Karplus-type equation to calculate these vicinal coupling constants (eq. 3). If one assumes the C-3 hydroxyl

$$[3]\quad J_{HCOH} = 10.4\cos^2\phi - 1.5\cos\phi + 0.2$$

is directed towards the epoxide oxygen, Dreiding models of the conformations depicted in Scheme 1 give H—C—O—H dihedral angles of 140 and 95° for **3***a* and *c* respectively. Calculation of the coupling constants using these angles gives the following comparison with the values actually observed for the hydroxyl coupling: for **3***a*, $J_{calcd.} = 5.3$; $J_{obs.} = 7$ Hz; and for **3***c*, $J_{calcd.} = 0.2$, $J_{obs.} = 2$ Hz. Considering the limitations of the method (8) and the possibility of steric interactions between the hydroxyl and the C-10 methyl, the calculated and observed values agree reasonably well.

Exchange of the C-3 hydroxyl with deuterium oxide simplifies the analysis of the C-3 hydrogen as it eliminates the H—C—O—H coupling. The half-band width ($w/2$) of hydrogens α to the hydroxyl (H_α) is very useful in determining the axial or equatorial nature of these hydrogens. The axial H_α would be expected to have a relatively broad half-band width (~15 Hz) because of the large axial–axial vicinal coupling while $w/2$ for the equatorial H_α would be narrower (~6 Hz) because of the smaller equatorial–equatorial and equatorial–axial coupling constants (9). In **3***a* the H_α appears at τ 6.25 as a distorted quartet ($w/2$ = 15 Hz) while in **3***c* it appears at τ 6.15 again as a quartet ($w/2$ = 15 Hz). Consequently both these hydroxyepoxides must possess an axial hydrogen and an equatorial hydroxyl at C-3.

The H_α in **3***b*, where there is no complication with intramolecular hydrogen bonding, exhibits a multiplet (τ 6.40, $w/2$ = 7 Hz) characteristic of an equatorial hydrogen, and thus an axial hydroxyl. The chemical shift of this equatorial hydrogen is an unusual feature of this spectrum as it appears at higher field than the corresponding axial hydrogens in **3***a* and *c* (τ 6.25 and 6.15 respectively). Normally axial hydrogens appear at higher field than equatorial in cyclohexane (10). This upfield shift may be due to the shielding effect of the C-10 methyl or the epoxide ring (11) on this equatorial hydrogen, which is situated directly above the plane of the epoxide. Shielding by a cyclopropane ring has been invoked to explain the upfield position of an equatorial H_α relative to an axial H_α (12).

Examination of Dreiding models for the two ketoepoxides **2***a* and *b* provides support for the product distribution obtained upon borohydride reduction. Compound **2***a* does not exhibit any significant difference in the steric environment of the carbonyl group from either the α- or the β-face and this is reflected in the 47:53% distribution obtained for hydroxyepoxides **3***a* and *b*. Compound **2***b* exhibits considerably less hindrance on the α-face and borohydride attack from this side gives the β-alcohol, **3***c*, which is the only product detected.

Hydroxyepoxides **3***a* and *c* were previously prepared by another route (13). There are some differences in the physical constants reported for **3***a* while **3***c* and the *p*-nitrobenzoate derivatives for both show good agreement (see Experimental).

*Preparation of Triols (**4**) and Monomesylates (**5**)*

Treatment of the hydroxyepoxides with aqueous acid afforded one triol in each case: **3***a* → **4***a*, **3***b* → **4***b* and **3***c* → **4***c* (Scheme 1). The insolubility of the triols in solvents used for obtaining solution i.r. spectra precluded a study of hydrogen bonding but n.m.r. spectra run in hexadeuterioacetone provided useful information. When interpreting these spectra it was assumed the very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bulky dimethylcarbinol group at C-4 would be in the equatorial position. The half-band width of the H_α was then used to determine the configuration at C-3. In **4***a*, the broad signal for this hydrogen (τ 6.12, $w/2 = 17$ Hz) indicates an axial hydrogen and an equatorial hydroxyl. The narrow signals for H_α in **4***b* (τ 6.05, $w/2 = 7$) and **4***c* (τ 6.05, $w/2 = 8$) indicate the presence of axial hydroxyls at C-3. The structural assignments for the three triols are consistent with this n.m.r. data and with the transformations to be described later. During the acid-catalyzed opening of the epoxide ring, the protonated epoxide intermediate must have undergone attack by water at the less hindered C-8 position in preference to C-4 (14).

Attempts to effect selective monotosylation of the triols **4** at the C-3 secondary hydroxyl were unsuccessful presumably because of the considerable steric hindrance of the neighboring groups. But preparation of the monomesylates **5** was successful in all three cases. Mesylation has been shown to proceed via the less sterically demanding sulfene intermediate (15). Mesylate **5***a* was stable and was fully characterized while **5***b* and *c* were unstable and the crude material was used in the next step. With the desired *p*-menthane-3-mesyloxy-4,8-diols in hand, it was then possible to examine the base-catalyzed transformations of these diastereomers.

Transformation Products of Monomesylates (5)

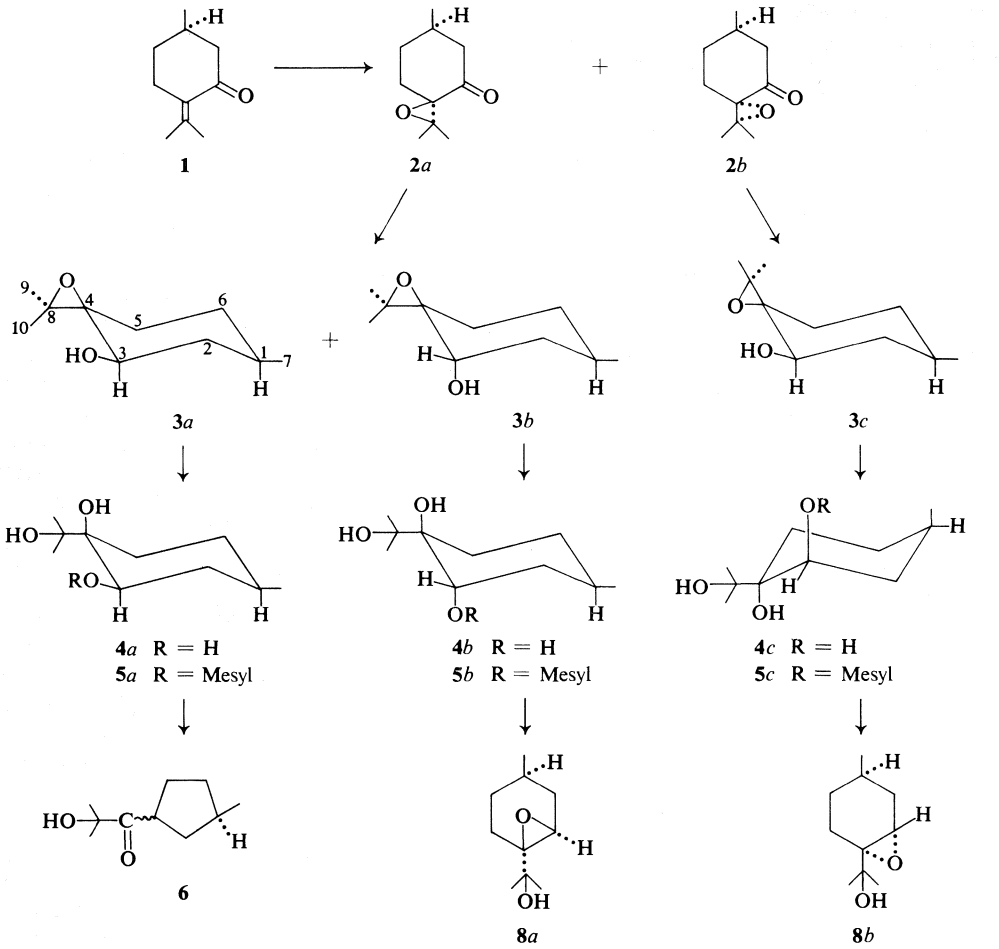
Treatment of pure monomesylate **5***a* with dilute aqueous base afforded a 90% yield of one compound as analyzed by g.l.c. and t.l.c. The i.r. spectrum of this substance indicated a carbonyl group (1705 cm^{-1}) and an intramolecularly hydrogen bonded hydroxyl (3500 cm^{-1}), features characteristic of α-ketols (16). The n.m.r. spectrum included a six-proton peak (τ 8.64) appropriate for the methyl groups in the moiety $(CH_3)_2C(HO)-C(=O)-$. A structure consistent with these data and its derivation from **5***a* is 1-[3-(R)-methylcyclopentyl]-2-hydroxy-2-methyl-1-propanone (**6**).

The structure was confirmed by an unambiguous synthesis. The Grignard reagent of 3-(R)-methylcyclopentyl chloride was prepared by the following route: (+)-pulegone → 3-(R)-methyladipic acid (17) → 3-(R)-methylcyclopentanone (17) → 3-(R)-methylcyclopentanol → 3-(R)-methylcyclopentyl chloride (presumably a mixture of diastereomers). This Grignard reagent was reacted with the cyanohydrin of acetone (eq. 4) to yield ketol **6** (35%), identical with the product from **5***a*, and an alcohol (23%) which was not fully characterized but presumably is **7** by analogy with similar displacements in cyanohydrin–Grignard reactions (18). The intermediate imine in this reaction was very stable in aqueous acid and could be extracted from an ether solution of the crude reaction mixture with 1 *N* hydrochloric acid, thus separating the imine and the alcohol (**7**). Hydrolysis of the imine in 0.1 *M* sodium hydroxide solution proceeded readily to give the ketol (**6**) as the only product. The imine could also be hydrolyzed by heating to reflux in 0.5 *N* hydrochloric acid for 16 h but some dehydration occurred under these conditions to give an α,β-unsaturated ketone (1670, 1615 cm^{-1}) (30% by g.l.c.) in addition to the ketol (70%). As both the synthetic ketol and that formed by rearrangement of **5***a* were prepared under alkaline conditions, epimerization at the cyclopentyl position adjacent to the carbonyl group would be expected. The g.l.c. analysis of the ketol indicated only one symmetrical peak while the n.m.r. spectrum exhibited two methyl doublets (τ 8.90, $J = 6$ Hz; τ 8.98, $J = 6$ Hz) of approximately equal area for the 3-methyl group on the cyclopentyl ring.

[4] $(CH_3)_2C(OH)-CN$ + ClMg–(cyclopentyl)–H → **6** + $(CH_3)_2C(OH)$–(cyclopentyl)–H (**7**)

Examination of conformation **5***a* (Scheme 1) shows the antiperiplanar (180°) (19) relationship of the C-3 mesyloxy group and the C_4—C_5 bond, the preferred orientation for a pinacol-type rearrangement, which would result in displacement of the mesyloxy group and formation of the ring contracted product **6**.

Treatment of crude mesylate **5***b* with dilute base gave 83% (based on **4***b*) of hydroxyepoxide **8***a*. This structure is based on spectral data, comparison with an authentic sample and examination of its mode of formation. The i.r. spectrum showed an intramolecularly hydrogen bonded



SCHEME 1

hydroxyl (3552 cm^{-1}) and bands characteristic of an epoxide (800–950 cm^{-1}) (20) while the n.m.r. spectrum indicated a dimethyl carbinol group (three-proton singlets at τ 8.82 and 8.83) and a trisubstituted epoxide (τ 6.78, 1H). In DMSO the hydroxyl appeared as a singlet at τ 5.85 indicating the alcohol was tertiary (21).

The reaction of 3-*p*-menthen-8-ol (22) with *m*-chloroperbenzoic acid gave a mixture of two hydroxyepoxides, **8***a* (30%) and *b* (70% by g.l.c.). Rickborn and Lwo have shown in the case of 4-methylcyclohexene (23) that the methyl substituent exerts only a slight steric effect in favor of the *trans* product (53.6-46.4%) and thus the dimethyl carbinol group must be exerting some additional influence in favor of the *trans* product **8***b*. The minor component in the epoxidation, **8***a*, was identical to the product obtained from mesylate **5***b*. Analysis of the resonance for the C-3 hydrogen in the n.m.r. spectra of **8***a* and *b* was conclusive in distinguishing between these two epoxides. In **8***a* this hydrogen appeared as a doublet (τ 6.78, J = 5 Hz) while in **8***b* it was a narrow multiplet (τ 6.74). Coupling constants for the C-3 hydrogens were calculated using Tori's revised Karplus equation (24) for 1,2-epoxycyclohexanes (eq. 5). The following dihedral angles (ϕ) between the C-3 and the two C-2 hydrogens were

$$[5] \qquad J = 5.1 \cos^2 \phi$$

measured from Dreiding models: for **8***a*, ϕ = 17 and 103°; and for **8***b*, ϕ = 65 and 55°. These angles predict $J_{calcd.}$ = 4.7 and 0.3 Hz, respectively, for **8***a* and $J_{calcd.}$ = 0.9 and 1.7 Hz, respectively, for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

8*b*. Thus one would expect the C-3 hydrogen in **8***a* to be a doublet with a coupling constant of about 5 Hz while in **8***b* this hydrogen would be expected to be a narrow unresolved multiplet. These predictions are in good agreement with the observed values and support the structures proposed for **8***a* and *b*.

In the conformation proposed for **5***b* the C-3 mesyloxy and C-4 hydroxyl groups are in a *trans* diaxial orientation. Displacement of the mesyloxy by the hydroxyl in an S_N2-type reaction would lead directly to **8***a*.

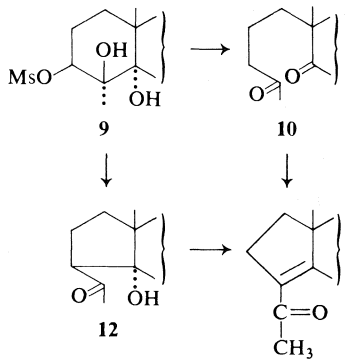
Crude monomesylate **5***c* upon treatment with aqueous base gave **8***b* as the only product in 74% yield (based on **4***c*). The assignment was also based on spectral data, comparison with an authentic sample, and its mode of formation. The major product (70%) from epoxidation of 3-*p*-menthen-8-ol (see above) was identical to transformation product **8***b*. An S_N2-type displacement of the axial mesyloxy group by the C-4 hydroxyl in **5***c* would give this α-epoxide.

Treatment of the triols (**4**) themselves under the basic conditions employed in the transformation of the mesylates (**5**) resulted in complete recovery of starting triol indicating the necessity of the mesyloxy group in these transformations.

Summary

The two types of reactions common to the 1,2-diol monosulfonate systems, namely pinacol-type bond migration and epoxide formation, were the only reactions observed with the triol monomesylates investigated. In these transformations the group antiperiplanar to the departing mesyloxy group was always involved in the reaction. A probable reason for the lack of any 1,3-diol monosulfonate reactions (*i.e.* fragmentation and oxetane formation) in these systems is the thermodynamic instability of the conformations in which the bulky dimethylcarbinol group must assume an axial position if the reaction is to proceed.

In one reported example of a 1,2,3-triol monomesylate transformation in the steroid field (6*b*), it was suggested that the monomesylate **9** first undergoes fragmentation to give diketone **10** which then gives the dehydrated aldol product **11** under the basic conditions of the reaction. By analogy to the rearrangement of our mesylate **5***a*, another plausible mechanism would be a pinacol-type rearrangement to give ring-contracted product **12** followed by dehydration to **11**.



Experimental

The i.r. spectra were recorded on a Beckmann IR5A spectrometer with the exception of the hydrogen bonding spectra which were run on a Beckmann IR12 spectrometer using *ca.* 0.005 *M* carbon tetrachloride solutions in a variable path length cell. The n.m.r. spectra were determined on a Varian A-60A spectrometer using tetramethylsilane as internal standard. Optical rotations were measured on a Bellingham and Stanley polarimeter. The g.l.c. analyses and separations were carried out on a Model A-700 "Autoprep" using a 1/4 in. × 6 ft column with 20% Carbowax 20 M on 60/80 Chromosorb W operating at 120° with a He flow rate of 75 cc/min. For analytical t.l.c., a 0.25 mm thickness of GF-254 Silica Gel was employed while for preparative t.l.c., a 1.0 mm thickness of PF-254 Silica Gel was used, both with the solvent system 40:60 ethyl acetate – benzene. Spinning band distillations were carried out on a Nester–Faust 117 apparatus with a column length of 18 in. Melting points were determined on a Gallenkamp apparatus and are uncorrected. Microanalyses were performed by A. G. Gygli, Toronto, Ontario, and H. S. McKinnon, Department of Chemistry, University of Guelph, Guelph, Ontario.

The pulegone used in these experiments was Bakers, practical grade, $[\alpha]_D^{25}$ + 26° (neat).

p-Menthane-4,8-epoxy-3-ols (3)

The pulegone oxides (**2**) were prepared from (+)-pulegone and separated according to a procedure described (*7a*). To an ice-cooled stirred solution of **2***a* (33.2 g, 0.20 mol) in 200 ml methanol was added dropwise over 15 min a solution of sodium borohydride (7.5 g, 0.20 mol) in 40 ml water and 200 ml methanol. After stirring for an additional 30 min at room temperature the reduction mixture was poured into 800 ml water and extracted with ether (4 × 250 ml). The combined extracts were washed with water and brine and dried (Na_2SO_4). Removal of the solvent *in vacuo* gave a colorless oil (30.9 g, 91%), shown by g.l.c. to contain two components, **3***a* and *b*, in a ratio of 47:53 respectively. Spinning band distillation of the oil separated the two components: (−)-4,8-epoxymenthol (**3***a*); b.p. 110–111°/4 mm; i.r. (CCl_4) 3450, 2875, 1455, 1378, 1138, 1100, 1052, 854, 652 cm^{-1}, hydroxyl region at 0.005 *M*, 3602, 3565 cm^{-1}; n.m.r. (CCl_4) τ 8.93 (3H, d, J = 6 Hz), 8.68 (3H, s), 8.52 (3H, s), 7.39 (1H, d, J = 7 Hz, disappeared on addition of D_2O),

*p-Menthane-3,4,8-triols (**4**)*

(*a*) To hydroxyepoxide **3***a* (2.0 g, 12 mmol) was added a solution of 2 drops concentrated sulfuric acid in 20 ml water and the suspension was heated over a steam bath for 5 min with vigorous agitation. The reaction mixture was cooled and extracted with ether (3 × 30 ml) and the combined extracts were washed with water (2 × 25 ml), brine (1 × 25 ml), and dried (Na_2SO_4). Removal of the solvent *in vacuo* gave a colorless oil (2.0 g, 91%). The t.l.c. indicated the product contained a major component (R_f 0.18) and two impurities (R_f's 0.25 and 0.49). Isolation of the major band by preparative t.l.c. afforded the crystalline (+)-4,8-dihydroxymenthol (**4***a*); m.p. 66.0–67.5°; i.r. (CCl_4) 3425, 2940, 1380, 1180, 1138, 1100, 1040, 1020, 858 cm^{-1}; n.m.r. (CCl_4) τ 9.03 (3H, d), 8.85 (3H, s), 8.71 (3H, s), 6.92, 6.50, 6.35 (total of 3H, disappeared on addition of D_2O), 6.12 (1H, m, $w/2 = 17$ Hz); $[\alpha]_D^{25}$ +16° (*c*, 2 in chloroform)

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.80; H, 10.71. Found: C, 63.66; H, 10.65.

(*b*) Hydroxyepoxide **3***b* (2.0 g, 12 mmol) was treated with aqueous sulfuric acid as described above to give a white precipitate. Extraction with ether gave a crude product which upon crystallization from chloroform gave 1.98 g (90%) of (+)-4,8-dihydroxyneomenthol (**4***b*); m.p. 166.5–167.0°; i.r. (KBr) 3225, 2900, 1455, 1420, 1370, 1170, 1138, 1112, 1068, 1002, 985, 975, 954, 917, 845 cm^{-1}; n.m.r. (CD_3COCD_3) τ 9.16 (3H, d, $J = 5$ Hz), 8.82 (3H, s), 6.68 (3H, s), 7.16, 6.85, 5.80, 5.60, 5.56 (total of 3H, disappeared on addition of D_2O), 6.05 (1H, m, $w/2 = 7$ Hz); $[\alpha]_D^{25}$ +22° (*c*, 2 in methanol).

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.80; H, 10.71. Found: C, 64.01; H, 10.97.

(*c*) Hydroxyepoxide **3***c* (2.0 g, 12 mmol) after treatment with aqueous sulfuric acid as described above, work-up, and crystallization from chloroform gave (−)-4,8-dihydroxyneoisomenthol (**4***c*) (1.55 g, 70%); m.p. 165.0–166.0°; i.r. (KBr) 3350, 2900, 1425, 1375, 1210, 1180, 1145, 1070, 1012, 955, 915 cm^{-1}; n.m.r. (CD_3COCD_3) τ 8.88 (3H, d, $J = 6$ Hz), 8.80 (3H, s), 8.72 (3H, s), 7.22, 6.80, 5.79, 5.55, 5.00 (total of 3H, disappeared on addition of D_2O) 6.05 (1H, m, $w/2 = 8$ Hz); $[\alpha]_D^{25}$ −27° (*c*, 2 in methanol).

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.80; H, 10.71. Found: C, 63.78; H, 11.00.

*p-Menthane-3-methanesulfonyloxy-4,8-diols (**5**)*

(*a*) To a stirred solution of triol **4***a* (3.0 g, 16 mmol) in 40 ml dry pyridine at 5° was added dropwise methanesulfonyl chloride (2.1 g, 18 mmol). After stirring for 24 h at 5° (precipitate of pyridinium chloride), the reaction mixture was combined with 80 ml water and the aqueous phase was extracted with ether (3 × 100 ml). The combined extracts were washed with cold 6 *N* hydrochloric acid (2 × 50 ml), saturated sodium bicarbonate solution (1 × 50 ml), water (2 × 50 ml), and brine (1 × 50 ml) and then dried (Na_2SO_4). Removal of the solvent gave a yellow oil (2.96 g, 70%) which was crystallized from 2:1 pentane–ether to give the pure mesylate **5***a*; m.p. 66.5–67.5°; i.r. ($CHCl_3$) 3500, 2950, 1350, 1250, 1210, 1175, 952, 918, 880, 693 cm^{-1}; n.m.r. (CCl_4) τ 9.00 (3H, d), 8.85 (3H, s), 8.64 (3H, s), 7.59, 6.80 (each 1H, disappeared on addition of D_2O), 6.97 (3H, s), 5.10 (1H, m).

Anal. Calcd. for $C_{11}H_{22}O_5S$: C, 49.60; H, 8.30. Found: C, 49.28; H, 8.15.

(*b*) Similarly, to a stirred solution of triol **4***b* (1.4 g, 7.4 mmol) in 20 ml dry pyridine at 5° was added dropwise methanesulfonyl chloride (1.1 g, 9.6 mmol) and after stirring for 24 h at 5° the reaction was worked-up as described above. Removal of the solvent gave crude mesylate **5***b* which was unstable and was used directly in the next step [see (*b*) of following section].

(*c*) A solution of triol **4***c* (1.8 g, 9.6 mmol) in 25 ml dry pyridine was reacted with methanesulfonyl chloride (1.4 g, 12 mmol) as described above and then worked-up to give crude mesylate **5***c* which was unstable and was used directly in the next step [see (*c*) of following section].

*Transformations of Mesylates (**5**)*

(*a*) A solution of mesylate **5***a* (2.96 g, 11.1 mmol) in 8 ml dioxane and 8 ml 0.45 *M* sodium hydroxide solution was stirred at 65° under nitrogen for 2 h. The reaction mixture was cooled, poured into 30 ml water and extracted with ether (3 × 75 ml). The combined extracts were washed with water (2 × 25 ml), brine (1 × 25 ml), and dried (Na_2SO_4). Removal of the solvent *in vacuo* gave a pale yellow oil (1.70 g, 90%) which exhibited only one spot on t.l.c. and one peak on g.l.c. An analytical sample was prepared by preparative g.l.c. The compound was shown to be 1-[3-(R)-methylcyclopentyl]-2-hydroxy-2-methyl-1-propanone (**6**); i.r. (film) 3500, 2950, 2850, 1705, 1460, 1170, 1070, 970 cm^{-1}, hydroxyl region at 0.005 *M* in CCl_4, 3500 cm^{-1}; n.m.r. (CCl_4) τ 8.64 (6H,s), 8.98, 8.90 (total 3H, two d, $J = 6$ Hz in each case), 6.60 (1H, broad m), 6.20 (1H, s, disappears on addition of D_2O); $[\alpha]_D^{25}$ −9° (*c*, 2 in chloroform).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65. Found: C, 70.61; H, 10.69.

(*b*) Crude mesylate **5***b* (prepared from 1.4 g, 7.4 mmol of **4***b*) was dissolved in 4 ml dioxane and 4 ml 0.45 *M* sodium hydroxide solution and stirred at 65° under nitrogen for 4 h. Work-up as described previously gave a yellow oil (1.05 g, 83% based on **4***b*) which exhibited only one spot on t.l.c. and one peak on g.l.c. (retention time 14.3 min). An analytical sample was prepared by preparative g.l.c. The compound was shown to be *trans-p*-menthan-3,4-epoxy-8-ol (**8***a*); i.r. (CCl_4) 3552, 2925, 1450, 1365, 1340, 1195, 1155, 1125, 975, 955, 875, 855, 845 cm^{-1}; n.m.r. (CCl_4) τ 9.12 (3H, d, $J = 5$ Hz), 8.83 (3H, s), 8.82 (3H, s), 8.29 (1H, s, disappeared on addition of D_2O), 6.78 (1H, d, $J = 5$ Hz); n.m.r. (DMSO) τ 5.85 (1H, s, disappeared on addition of D_2O).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65. Found: C, 70.46, H, 10.72.

(*c*) Similarly, crude mesylate **5***c* (prepared from 1.8 g, 9.6 mmol of **4***c*) was dissolved in 4 ml dioxane and 4 ml 0.45 *M* sodium hydroxide solution and stirred at 65° under nitrogen for 4 h. Work-up as described above gave a yellow oil (1.22 g, 75% based on **4***c*) which exhibited only one spot on t.l.c. and one peak on g.l.c. (retention time 13.4 min). An analytical sample was prepared by preparative g.l.c. The compound was shown to be *cis-p*-menthan-3,4-epoxy-8-ol (**8***b*); i.r. (CCl_4) 3552, 2900, 1450, 1365, 1340, 1180, 1160, 1125, 1085, 1025, 955, 920, 905, 848 cm^{-1}; n.m.r. (CCl_4) τ 9.13 (3H, d, $J = 5$ Hz), 8.85, (6H, s), 8.23 (1H, s, disappeared on addition of D_2O), 6.74 (1H, narrow m).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65. Found: C, 70.58; H, 10.73.

Preparation of Authentic Samples

(a) 1-[3-(R)-Methylcyclopentyl]-2-hydroxy-2-methyl-1-propanone (6)

3-(R)-Methylcyclopentanone (17) after reduction with sodium borohydride gave 3-(R)-methylcyclopentanol, which upon reaction with calcium chloride in concentrated hydrochloric acid (25) gave 3-(R)-methylcyclopentyl chloride, b.p. 54–56°/55 mm. A solution of 3-(R)-methylcyclopentyl chloride (7.1 g, 0.06 mol) in 30 ml dry ether was added dropwise to magnesium turnings (1.46 g 0.06 g atm) under nitrogen at a rate to maintain reflux. The reaction was completed by heating to reflux for an additional 30 min. The Grignard solution was cooled in an ice bath and stirred mechanically while a solution of acetone cyanohydrin (2.55 g, 0.03 mol) (26) in 10 ml ether was added dropwise. The resultant slurry was stirred and heated at 35° for 3 h. The reaction mixture was cooled and a solution of ammonium chloride (3.2 g, 0.06 mol) in 25 ml water was added with stirring. The two phases were separated and the aqueous phase was extracted with ether (6 × 25 ml). The combined organic phases were extracted with 1 *N* hydrochloric acid (5 × 20 ml) (retained), saturated sodium bicarbonate solution (1 × 20 ml), brine (1 × 20 ml), and dried ($MgSO_4$). Removal of the solvent gave a colorless oil (1.0 g, 23%), which was >90% one compound by g.l.c. and was tentatively formulated as 3-(R)-methylcyclopentyldimethylcarbinol (7); i.r. (film) 3350, 2860, 1455, 1375, 1295, 1265, 1250, 935 cm^{-1}; n.m.r. (CCl_4) τ 9.02, 8.98 (total of 3H, two d, $J = 6$ Hz in each case), 8.88 (6H, s), 8.45 (1H, s, disappeared on addition of D_2O); $[\alpha]_D^{25}$ +2° (c, 2 in chloroform).

The 100 ml of the hydrochloric acid phase from above, which contains the imine salt, was basified with 4.4 g sodium hydroxide to give a solution *ca.* 0.1 *M* in sodium hydroxide and 10 ml ethanol was added to promote dissolution of the organic compound. The solution was heated to reflux for 4 h, cooled, saturated with sodium chloride, and extracted with ether (5 × 50 ml). The extract was washed with brine (2 × 25 ml), dried ($MgSO_4$), and the solvent removed to give a colorless oil (1.78 g, 35%) which exhibited only one peak on g.l.c. at the same retention time as the transformation product **6** from mesylate **5***a*. The i.r. and n.m.r. spectra were identical to **6** (see above) and $[\alpha]_D^{25}$ −10° (*c*, 2 in chloroform).

Hydrolysis of the imine could also be effected in 0.5 *N* hydrochloric acid solution heated under reflux for 16 h. Work-up gave a yellow oil shown by g.l.c. to be a mixture of two components (30:70), the latter having the same retention time as **6**; i.r. of mixture (CCl_4) 3500, 2950, 1705, 1670, 1615, 1160, 970 cm^{-1}.

(b) cis- and trans-p-Menthan-3,4-epoxy-8-ols (8)

To a stirred solution of 3-*p*-menthen-8-ol (1.0 g, 6.5 mmol) (22) in 10 ml dichloromethane at room temperature was added dropwise a solution of *m*-chloroperbenzoic acid (1.8 g, 10.5 mmol) in 20 ml dichloromethane. The reaction was stirred for 20 min and a 10% sodium sulfite solution was added to destroy the excess peracid. The organic layer was washed with saturated sodium bicarbonate solution (1 × 10 ml) and brine (1 × 10 ml) and dried ($MgSO_4$). Removal of the solvent *in vacuo* gave a colorless oil (0.99 g, 90%), which was shown by g.l.c. to be a 70:30 mixture of two components with retention times of 13.4 and 14.3 min, respectively. These compounds were separated by preparative g.l.c. and shown to be identical to **8***b* and *a* (see above) respectively, the transformation products of mesylates **5***c* and *b*, respectively.

Radiolysis of Trifluoroacetic Acid

J. BETTS[1] AND E. A. CHERNIAK[2]

Department of Chemistry, Carleton University, Ottawa, Canada

Received November 6, 1970[3]

The gaseous products of the ^{60}Co-γ radiolysis of liquid CF_3COOH at 23 °C and solid CF_3COOH at −196 °C have been identified and their *G*-values have been determined. The products and *G*-values are, for the radiolysis of liquid CF_3COOH; CO_2(7.1), CO(0.71), CF_3H(0.27), C_2F_6(1.36), H_2(0.031) and, for the radiolysis of solid CF_3COOH; CO_2(2.5), CF_3H(0.30), C_2F_6(0.39). CO and H_2 are not produced in the radiolysis of solid CF_3COOH and CF_4 and C_2F_4 are not produced in the radiolysis of solid and liquid CF_3COOH. The mechanisms of gaseous product formation in the radiolysis of solid and liquid CF_3COOH are compared.

Les produits gazeux provenant de la radiolyse par le ^{60}Co-γ de CF_3COOH liquide à 23 °C et de CF_3COOH solide à −196 °C ont été identifiés et leurs valeurs de *G* ont été déterminées. Les produits et les valeurs de *G* sont pour la radiolyse de CF_3COOH liquide, : CO_2(7.1), CO(0.71), CF_3H(0.27), C_2F_6-(1.36), H_2(0.031) et pour la radiolyse de CF_3COOH solide: CO_2(2.5), CF_3H(0.30), C_2F_6(0.39). CO et H_2 ne sont pas produits dans la radiolyse de CF_3COOH solide et CF_4 et C_2F_4 ne sont pas produits dans la radiolyse de CF_3COOH solide et liquide. Les mécanismes de la formation de produit gazeux dans la radiolyse de CF_3COOH solide et liquide sont comparés.

Canadian Journal of Chemistry, **49**, 3389 (1971)

Although considerable progress has recently been made in understanding the radiation chemistry of acetic acid (1), very little is known about the effects of ionizing radiation on trifluoroacetic acid. An electron spin resonance (e.s.r.) study[4] has shown that the only transient species trapped at −196 °C, in the γ-radiolysis of polycrystalline CF_3COOH, was $\cdot CF_3$ and that by −175 °C the disappearance of this species was complete. By contrast, the only transient species trapped at −196 °C in the γ-radiolysis of polycrystalline CH_3COOH, was the radical anion, $CH_3\dot{C}\bar{O}OH$ (1). The disappearance of this anion was complete by −86 °C and beyond that temperature, the species trapped were $\cdot CH_2COOH$ and $CH_3\dot{C}O$. The radical anion, $CF_3\dot{C}\bar{O}OH\cdots NH_3$, has been detected at −196 °C in γ-irradiated single crystals of $CF_3COO^- NH_4^+$ but it is unstable and by −78 °C it has transformed completely into $\cdot CF_2CO\bar{O}\ NH_4^+$ and F^- (2). Both $\cdot CF_2CO\bar{O}\ NH_4^+$ and the radical $CF_3C\dot{O}O$ are products of the room temperature γ-radiolysis of single crystals of $CF_3COO^-NH_4^+$ (2).

In this study the gaseous products of the ^{60}Co-γ radiolysis of liquid CF_3COOH at room temperature and of polycrystalline CF_3COOH at −196 °C have been identified and their *G*-values have been measured. Comparison of yields of gaseous products obtained from CF_3COOH at two greatly different temperatures and from two different phases provides useful information on the mechanism of radiolysis.

Experimental

Eastman Kodak White Label CF_3COOH was refluxed with a small quantity of concentrated sulfuric acid, distilled, treated with anhydrous sodium sulfate, de-aerated by trap-to-trap distillation *in vacuo* and sealed into Pyrex vials at −196 °C. These vials were cleaned with chromic acid, a mixture of dilute nitric acid and hydrogen peroxide, hot tap water and triply distilled water and then were baked out on the vacuum line. All taps and joints were lubricated with Apiezon grease as CF_3COOH vapor was adsorbed on silicone grease.

Approximately 5 ml samples were irradiated in a 100 Ci ^{60}Co-γ "well" source at about 23 °C. Two irradiations at −196 °C were performed in a 600 Ci ^{60}Co-γ "cave" source. Electron density corrected Fricke dosimetry was used to obtain absorbed doses.

After irradiation the contents of the vials were distilled, through a breakseal, into a −196 °C trap and then into a −131 °C trap. The volatile products were divided into fractions which were non-condensible at −210 and −145 °C, using a solid N_2 trap and Ward-LeRoy still, and then were measured in a gas buret and analyzed mass spectrometrically. The volatile products from a few

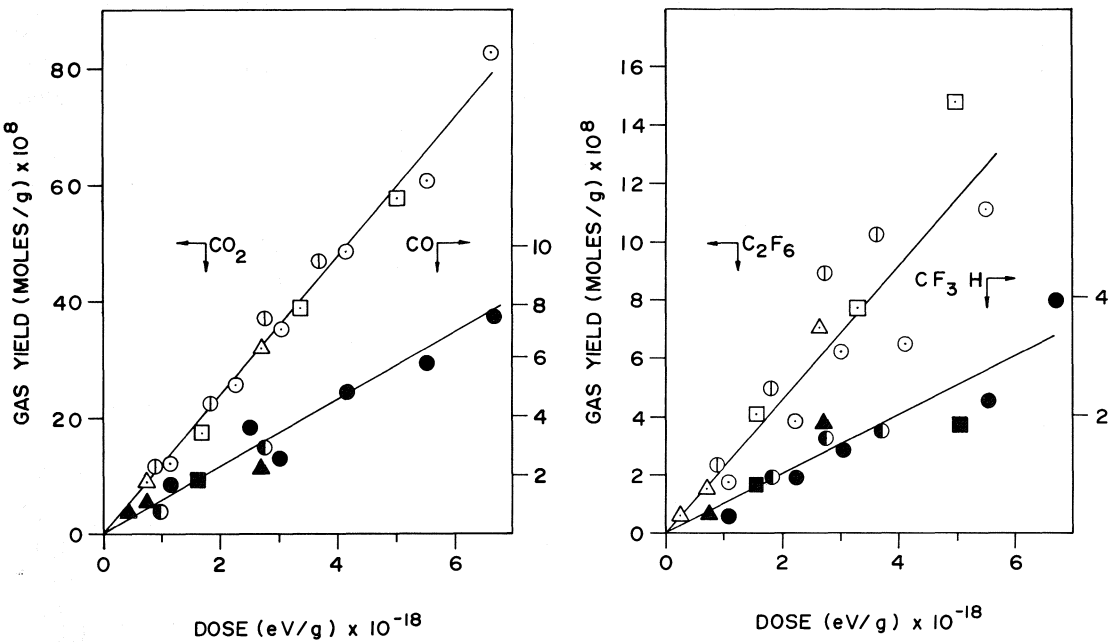

FIG. 1. CO_2, CO, CF_3H, and C_2F_6 yields as a function of dose and dose rate in the radiolysis of liquid CF_3COOH at 23 °C. Dose rates (units of 10^{14} eV g^{-1} s^{-1}): □, ■ 14.0; ⊙, ● 9.27; ◑, ◐ 2.57; △, ▲ 1.07.

TABLE 1. *G*-values of gaseous products for ^{60}Co-γ radiolysis of CF_3COOH and CH_3COOH

System	*G*-values (molecules/100 eV)						
	CO_2	CO	CF_3H	C_2F_6	H_2	CF_4	Reference
CF_3COOH liquid, 23 °C	7.1±0.3	0.71±0.20	0.27±0.06	1.36±0.30	0.031±0.008	0	This work
CF_3COOH solid, −196 °C	2.5±0.4	≃0	0.30±0.04	0.39±0.02	≃0	0	This work
CH_3COOH liquid, 27 °C	6.0	0.73	3.34 (CH_4)	0.62 (C_2H_6)	0.35		3

samples were examined by gas–solid chromatography, using a 10 ft alumina column at 0 °C, hydrogen carrier gas and a hot wire detector. No attempt was made to analyze the products which were condensible at −145 °C.

Results and Discussion

Mass spectrometric analysis of the volatile products showed that the fraction which was non-condensible at —210 °C, consisted of H_2 and CO, while the fraction which was non-condensible at −145 °C, consisted of CF_3H, C_2F_6, and CO_2. Gas–solid chromatographic analysis showed that CF_4 was not a radiolysis product. Mass spectrometric analysis showed that C_2F_4 was not a radiolysis product and that SiF_4 was not present in the gases analyzed.

The dependence of gaseous product yields on absorbed dose and dose rate, in the radiolysis of liquid CF_3COOH, is shown in Figs. 1 and 2. These yields are independent of dose rate in the range (1.07–14.0) × 10^{14} eV g^{-1} s^{-1}. Gaseous product *G*-values, obtained from Figs. 1 and 2, are compared, in Table 1, with analogous gaseous product *G*-values obtained by Johnsen (3) in studies on the ^{60}Co-γ radiolysis of liquid CH_3COOH at a dose rate of 5 × 10^{15} eV g^{-1} s^{-1}. Table 1 also contains average gaseous product *G*-values obtained in the radiolysis of solid CF_3COOH at −196 °C at a dose rate of 1.85 × 10^{14} eV g^{-1} s^{-1}.

The data in Table 1 show that in the radiolysis of liquid CF_3COOH at 23 °C, the gaseous products are CO_2, CO, CF_3H, C_2F_6, and H_2, which are identical to those found by Mearns and Back (4) in their study of the continuous (low pressure mercury arc) photolysis of CF_3COOH vapor in the temperature range 90 to 190 °C. In the radiolysis of solid CF_3COOH at −196 °C, the gaseous products are CO_2,CF_3H, and C_2F_6. The gases

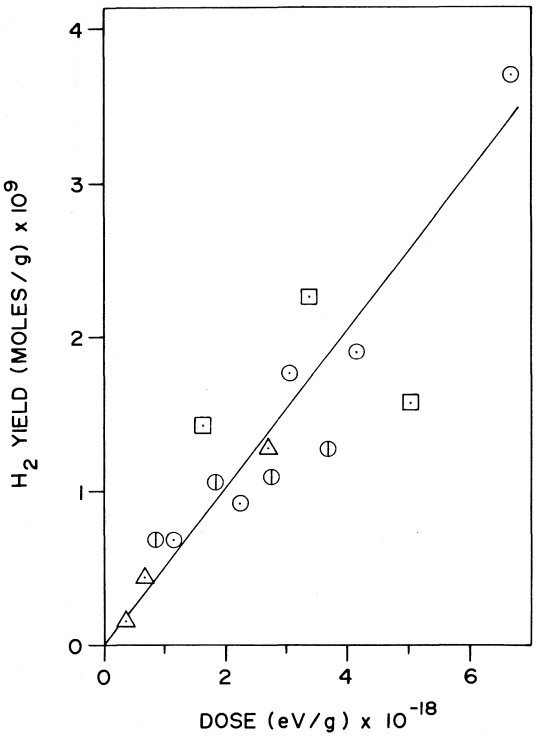

FIG. 2. H_2 yields as a function of dose and dose rate in the radiolysis of liquid CF_3COOH at 23 °C. Dose rates (units of 10^{14} eV g^{-1} s^{-1}): ⊡ 14.0, ⊙ 9.27, ◑ 2.57, △ 1.07.

SiF_4, C_2F_4, and CF_4 are not produced in the radiolysis of either liquid or solid CF_3COOH. Thus, in the γ-radiolysis of liquid and solid CF_3COOH, HF and $:CF_2$ are not radiolysis products and disproportionation reactions involving pairs of $\cdot CF_3$ radicals as well as abstraction of F atoms by H· and $\cdot CF_3$ do not occur. The species $:CF_2$ is a known transient in the isothermal flash photolysis of CF_3COOH vapor (5) and C_2F_4 (as well as C_2F_6) are final products of both the flash and (high pressure xenon arc) photolyses of CF_3COOH vapor (6).

The data in Table 1 also show that $G(CO_2)$ (liquid) = (2.9 ± 0.6) × $G(CO_2)$(solid), $G(C_2F_6)$ (liquid) = (3.6 ± 1.0) × $G(C_2F_6)$(solid) and $G(CF_3H)$(liquid) = $G(CF_3H)$(solid), within the limits of experimental error. Also, if an oxygen atom balance is assumed, considerable losses of H and F atoms have taken place. For H the losses are 96% (liquid) and 88% (solid) and for F the losses are 60% (liquid) and 57% (solid). Approximately 28% of the C atoms remain unaccounted for in the radiolysis of the liquid and the solid. These figures suggest that in the γ-radiolysis of liquid and solid CF_3COOH considerable numbers of H and F atoms have been incorporated into non-gaseous products.

The fact that $G(CO_2)$(liquid)/$G(CO_2)$(solid) ≃ $G(C_2F_6)$(liquid)/$G(C_2F_6)$(solid) implies that CO_2 and C_2F_6 have a common precursor. This may be the radical cation, $CF_3\dot{C}\overset{+}{O}OH$, which is formed in the primary ionization [1] and which is consumed exclusively in the very rapid proton transfer reaction 2. Reaction 2 is facilitated by hydrogen bonding which exists in gaseous CF_3COOH (7), in liquid CF_3COOH (8, 9) and, by inference, in solid CF_3COOH, since the crystal structure of this solid, unlike that of solid CH_3COOH (10), is not known. In reactions 1 and 2 CF_3COOH, $CF_3\dot{C}\overset{+}{O}OH$, and $CF_3COOH_2^+$ represent segments in long hydrogen bonded chains of parent molecules.

$$[1] \qquad CF_3COOH \rightsquigarrow CF_3\dot{C}\overset{+}{O}OH + e^-$$

$$[2] \qquad CF_3\dot{C}\overset{+}{O}OH + CF_3COOH \rightarrow \cdot CF_3 + CO_2 + CF_3COOH_2^+$$

$\cdot CF_3$ radicals and CO_2 molecules produced in reaction 2 are hot species as ΔH[3] is approximately −15 kcal/mol.[5] Because $G(CO_2) \gg G(C_2F_6)$, in both phases, a very large number of $\cdot CF_3$ radicals do not recombine

$$[3] \qquad CF_3C\dot{O}O \rightarrow \cdot CF_3 + CO_2$$

to form C_2F_6. Further reactions of this species are reactions 4 to 7, inclusive. Reaction 4 probably occurs in spurs and involves hot $\cdot CF_3$ radicals as Mearns and Back (4) have shown that reaction 4 does not occur in the gas phase. Since the probability of escape of hot $\cdot CF_3$ radicals from spurs in the liquid is greater than the probability of escape of these radicals from spurs in the solid, the yield of CF_3H from reaction 4 is expected to be less in

$$[4] \quad \cdot CF_3 + CF_3COOH \rightarrow CF_3H + \cdot CF_3 + CO_2$$

$$[5] \quad \cdot CF_3 + \cdot COOH \rightarrow CF_3H + CO_2$$

[5] $\Delta H_f^\circ(CF_3C\dot{O}O) = -193$ kcal/mol was obtained from the expression: $D(CF_3COO{-}H) = \Delta H_f^\circ(CF_3C\dot{O}O) + \Delta H_f^\circ(H\cdot) - \Delta H_f^\circ(CF_3COOH)$ where $D(CF_3COO{-}H) \simeq D(CH_3COO{-}H) = 111$ kcal/mol (11) and $\Delta H_f^\circ(H\cdot) = 52$ kcal/mol (12). The group additivity method of Benson (13) was used to obtain $\Delta H_f^\circ(CF_3COOH) = -252$ kcal/mol. $\Delta H_f^\circ(\cdot CF_3) = -114$ kcal/mol and $\Delta H_f^\circ(CO_2) = -94$ kcal/mol are from ref. 12.

[6] $\cdot CF_3 + CF_3COOH \rightarrow CF_3\dot{C}(OH)OCF_3$

[7] $\cdot CF_3 + CF_3\dot{C}(OH)OCF_3 \rightarrow (CF_3)_2C(OH)OCF_3$

liquid than in the solid. However, the yield of CF_3H from reaction 5 is expected to be greater in the liquid than in the solid, where recombination to yield CF_3COOH is more probable. Thus reaction 5, which is an important source of CF_3H in the photolysis of CF_3COOH vapor (4), together with reaction 4, can be used to explain the observed lack of dependence of $G(CF_3H)$ on temperature and phase. The ·COOH radical is a product of one of two probable neutral dissociation processes, [8] and [9], which occur in the radiolysis.

[8] $CF_3COOH \dashrightarrow \cdot CF_3 + \cdot COOH$

[9] $CF_3COOH \dashrightarrow CF_3\dot{C}O + \cdot OH$

The dissociation of CF_3COOH to H· and $CF_3C\dot{O}O$ is considered unimportant because of the magnitude of $D(CF_3COO—H)$[5] and the very small $G(H_2)$ obtained in this study.

The addition of $\cdot CF_3$ to carbonyl groups is well established (6, 14). Gordon (15) has shown that the activation energy for the addition of $\cdot CF_3$ to CF_3COCF_3 is 9.7 kcal/mol, the activation energy for the dissociation of $(CF_3)_2\dot{C}OCF_3$ to $\cdot CF_3$ and CF_3COCF_3 is 30.6 kcal/mol and $\cdot CF_3$ and $(CF_3)_2\dot{C}OCF_3$ combine readily to form perfluoro *t*-butyl methylether. For the non-gaseous product of reaction 7, C:F:H is 1:2.3:0.3. The C:F:H values for atoms which are unaccounted for in the radiolysis of solid CF_3COOH is 1:2.0:3.0 and in the radiolysis of liquid CF_3COOH is 1:2.1:4.2. Thus reactions 6 and 7 are important in the radiolysis of both solid and liquid CF_3COOH and other mechanisms for H atom loss exist.

Various products of the interaction of electrons, released in reaction 1, with $CF_3COOH_2^+$ and CF_3COOH are possible. Processes 10 to 13 inclusive are consistent with the absence of H_2 in

[10] $CF_3COOH_2^+ + e^- \rightarrow CF_3\dot{C}O + H_2O$

[11] $CF_3COOH_2^+ + e^- \rightarrow CF_3CHO + \cdot OH$

[12] $CF_3COOH + e^- \rightarrow \cdot CF_3 + HCOO^-$

[13] $CF_3COOH + e^- \rightarrow CF_3\dot{C}O + OH^-$

the radiolysis of solid CF_3COOH and the very small $G(H_2)$ observed in the radiolysis of liquid CF_3COOH, the indirect evidence for the absence of HF, the absence of CO in the radiolysis of solid CF_3COOH and the F and H atom losses noted in this work.

The activation energy for reaction 14 is estimated to be $E_{14} = 17$ kcal/mol.[6] Amphlett and

[14] $CF_3\dot{C}O \rightarrow \cdot CF_3 + CO$

Whittle (17) have obtained a lower limit to E_{14} which is 10 kcal/mol and have shown that the frequency factor for reaction 14 is abnormally low. Thus, in the radiolysis of solid CF_3COOH at −196 °C, no CO is expected and $CF_3\dot{C}O$ radicals are likely to recombine or to react with other radicals (*e.g.* ·OH, $\cdot CF_3$) to form non-gaseous products. In the radiolysis of liquid CF_3COOH at 23 °C some $CF_3\dot{C}O$ radicals will decompose to CO and the remainder will form non-gaseous products, as in the solid. Non-gaseous products (HCOOH and H_2O) will also be formed in the reactions of $HC\dot{O}O$ and OH^- with $CF_3COOH_2^+$.

We thank the National Research Council of Canada for financial support and for providing one of us (J.B.) with a National Research Council Postdoctoral Fellowship. We also thank Dr. F. P. Lossing and Mr. R. Pilon for assistance with the mass spectrometric analyses and the Defence Research Board of Canada for the use of their irradiation facilities.

---

[6] $E_{14} = \Delta H[14] + E_{-14} = 17$ kcal/mol. $\Delta H_f^0(CF_3\dot{C}O) = -152$ kcal/mol was obtained from the expression: $D(CF_3CO—OH) = \Delta H_f^0(CF_3\dot{C}O) + \Delta H_f^0(\cdot OH) - \Delta H_f^0(CF_3COOH)$ where $D(CF_3CO—OH) \simeq D(CH_3CO—OH) = 109$ kcal/mol (11), $\Delta H_f^0(\cdot OH) = 9$ kcal/mol (12) and $\Delta H_f^0(CF_3COOH) = -252$ kcal/mol.[5] $\Delta H_f^0(CO) = -26$ kcal/mol is from (12). It is assumed that E_{-14} is the same as the activation energy (5 kcal/mol) for $\cdot CH_3 + CO \rightarrow CH_3\dot{C}O$, obtained by Kerr and Calvert (16). $D(CF_3—\dot{C}O) = 12$ kcal/mol has also been estimated from the relation: $D(CF_3CO—OH) + D(CF_3—\dot{C}O) = \Delta H_f^0(\cdot OH) + \Delta H_f^0(CO) + \Delta H_f^0(\cdot CF_3) - \Delta H_f^0(CF_3COOH)$.

NOTES

Lignin and Related Compounds. III. An Improved Synthesis of 3-(4-Hydroxy-3-methoxyphenyl)-1-propanol and 3-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol

J. M. Pepper, G. S. Sundaram, and G. Dyson

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received June 7, 1971

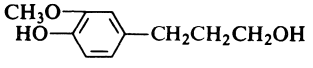
3-(4-Hydroxy-3-methoxyphenyl)-1-propanol (dihydroconiferyl alcohol) (**1**) and 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (dihydrosinapyl alcohol) (**2**) have been synthesized in good yields from 4-allyl-2-methoxyphenol (eugenol) and 4-allyl-2,6-dimethoxyphenol by means of the hydroboration reaction.

L'(hydroxy-4 méthoxyphényl-3)-3 propanol-1 (alcool dihydroconiferyle) (**1**) et l'(hydroxy-4 diméthoxyphényl-3,5)-3 propanol-1 (alcool dihydrosinapyle) (**2**) ont été synthétisés avec un bon rendement à partir de l'allyl-4 méthoxy-2 phénol (eugénol) et l'allyl-4 diméthoxy-2,6 phénol au moyen d'une réaction d'hydroboration.

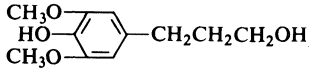
Canadian Journal of Chemistry, **49**, 3394 (1971)

Introduction

Studies in these laboratories on the catalytic hydrogenolysis of spruce and aspen lignins (1, 2) have shown that significant quantities of 3-(4-hydroxy-3-methoxyphenyl)-1-propanol (dihydroconiferyl alcohol) (**1**) and 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (dihydrosinapyl alcohol) (**2**) may be obtained. In order to study the properties and potential uses of these compounds it was necessary to synthesize them in adequate amounts. Previously reported syntheses involved



1



2

the ultimate reduction of ethyl dihydroferulate or ethyl dihydrosinapate using either sodium in alcohol or lithium aluminum hydride (3–5). The preparation of these esters from the available starting materials, vanillin and syringaldehyde, involved several steps resulting in low overall yields.

This note reports the direct conversion by hydroboration and subsequent alkaline oxidation of the commercially available compounds, 4-allyl-2-methoxyphenol (eugenol) and 4-allyl-2,6-dimethoxyphenol, into **1** and **2** respectively. The required primary alcohol isomer is the major product representing ninety percent of the total. Separation of the two isomers may be achieved by repeated recrystallization from carbon tetrachloride – chloroform (5:1) mixture to give white crystals of the desired products **1** and **2** in approximately 80 and 75% yields, respectively. The success of the synthesis is dependent on the use of rigorously anhydrous conditions.

The characterization of the products was confirmed through their n.m.r. and mass spectra.

Experimental

Synthesis of 3-(4-Hydroxy-3-methoxyphenyl)-1-propanol (1)

Eugenol (9.7 g), obtained by fractional distillation (b.p. 78–80°/1 mm), was added to a 500 ml, three-necked flask which had been dried for 1 h at 110°. The flask was immediately fitted with a thoroughly dry pressure equating dropping funnel, a calcium chloride drying tube, and an inlet for dry nitrogen. Tetrahydrofuran (50 ml) previously dried over calcium hydride for 12 h and redistilled from $LiAlH_4$, was added to the flask which was then stoppered.

Borane (1 *M* in tetrahydrofuran) (60 ml) was added dropwise (30 drops per min) through the funnel to the

stirred solution in the flask which was maintained at 0° by an ice bath. The solid, substituted borane separated near the end of the addition. Stirring was continued for an extra 30 min, at which time water (20 ml) was added to decompose the excess borane. This was followed by the addition of 3 *M* NaOH (24 ml), after which the mixture was allowed to warm to room temperature and 30% H_2O_2 (14 ml) added carefully and stirring continued for 1.5 h. The resulting pale yellow solution was extracted with diethyl ether (6 × 50 ml), saturated with NaCl, acidified with HCl (50 ml 2 *M*) and further extracted with ether (3 × 50 ml). The combined ether extracts were dried and concentrated to leave a yellow oil which slowly crystallized on standing at −15 °C. A gas chromatographic analysis (using a 6 ft, 1/8 in. stainless steel column packed with 10% SE30 on Chromosorb W, programmed from 100 °C at 4°/min) showed the two isomeric alcohols separated by 6.2 min.

Two crystallizations from carbon tetrachloride – chloroform (5:1) gave 3-(4-hydroxy-3-methoxyphenyl)-1-propanol (**1**), 8.7 g, (81%), m.p. 64–65° (reported m.p. 63–65° (4)).

Synthesis of 3-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol (2)

Using the same procedure as described above, 4-allyl-2,6-dimethoxyphenol (10.7 g) was converted into 3-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (**2**), 9.0 g (77%) m.p. 75–76° (reported m.p. 75–76.5° (4)).

This work was supported by an EMR grant from the Department of Forestry and Fisheries for which grateful acknowledgment is made.

An Approach to Stereochemical Analysis by Ion Cyclotron Resonance. Distinguishing *exo*- and *endo*-Norborneol

Maurice M. Bursey[1] and Michael K. Hoffman
Venable Chemical Laboratory, The University of North Carolina, Chapel Hill, North Carolina 27514

Received March 8, 1971

The ion cyclotron resonance spectra of mixtures of biacetyl and *exo*- or *endo*-norborneol show differences in the acetylation of the alcohol by the *m/e* 129 ion formed from biacetyl. The differences may be interpreted as a difference by a factor of four in rates of acetylation; a steric effect is proposed as the cause of the difference.

Les spectres de résonance cyclotron-ion de mélanges de biacétyle et d'*exo*- ou d'*endo*-norbornéol, montrent des différences dans l'acétylation de l'alcool, par l'ion *m/e* 129 qui se forme à partir du biacétyle. Les différences peuvent être interprétées comme une différence dans les vitesses d'acétylation par un facteur de quatre; il est suggéré qu'un effet stérique est la cause de cette différence.

Canadian Journal of Chemistry, **49**, 3395 (1971)

The reaction rates of *exo*- and *endo*-norborneol with acetylated biacetyl in the gaseous phase (eq. 1) differ by a factor of 4.

[1] $C_7H_{11}OH + C_6H_9O_3^+ \rightarrow C_7H_{11}O(H)OC_2H_3^+ + C_4H_6O_2$

We have proposed that ion–molecule reactions studied by ion cyclotron resonance (i.c.r.) may be of use in the identification of organic functionality (1). Thus, 2,3-butanedione undergoes an ion–molecule reaction with itself (eq. 2) to give a species ("triacetyl", **1**) capable of transferring a specific (2) acetyl group to most oxygen- and nitrogen-containing functional groups (eq. 3). Our purpose in pursuing such studies is to explore the possibilities for reactions capable of distinguishing epimers, a problem which has been

[1]Research Fellow of the Alfred P. Sloan Foundation, 1969–1971.

[5] $$\frac{k_{exo}}{k_{endo}} = \left\{\frac{P_s}{(P_s + 1.44P_p)[B]}\right\}_{exo} \Big/ \left\{\frac{P_s}{(P_s + 1.44P_p)[B]}\right\}_{endo}$$

explored by conventional mass spectrometry for many systems (3) but whose general solution by this technique is not satisfactory from the viewpoint of establishing predictive rules.

The epimers *exo*- and *endo*-norborneol appeared to offer an especially attractive case for detecting large differences in reactivity. These types of systems have been studied for many years, beginning with the study of acetolysis of the tosylates and brosylates, where a ratio of rate constants equal to 350 was observed (4).[2] For the present case, the well known controversy over the nature of the intermediate carbonium ion in such systems is not pertinent. One school of thought presents the observed differences in reactivity in similar systems as the result of steric interference (6), while the other group claims that σ delocalization is responsible (7). The differences in steric environment of the alcohol function in *exo*- and *endo*-norborneol, in any event, are well known.

At an ionizing energy of 13 eV and pressures of *ca.* 2×10^{-5} Torr each of 2,3-butanedione and *exo*- or *endo*-norborneol, the only ion–molecule reaction product observed (other than "triacetyl," **1** and the irrelevant ions protonated biacetyl, and a self-reaction of norborneol at *m/e* 138) occurs at *m/e* 155. This mass corresponds to the addition of 43 mass units to the molecular weight of norborneol. Double-resonance experiments demonstrate that this ion originates entirely from **1** (eqs. 1, 4) and that the reaction occurs only in the analyzer section of the i.c.r. cell.[3] The reaction is therefore interpreted as a transfer of the acetyl ion from "triacetyl," **1**, to the alcohol, analogously to examples we have studied before (1, 2).

Prior experience and consideration of the relative rates for reactions of the epimeric alcohols would lead to the thought that under similar conditions the same amount of acetylated product would be produced from each of the epimers. Solution chemistry proves a better guide than prior experience in gas-phase ionic chemistry here, however, since the *exo* isomer forms the acetylated product approximately four times as rapidly as the *endo* isomer.

Examination of one formulation (8) of the derivation of the rate constant for the decomposi-

[2]This ratio refers to formation of the carbonium ion, not that of the oxonium ion generated here, of course. Studies of the carbonium ion by i.c.r. have been reported (5).

[3]Since the precursor **1** is a secondary ion, production of *m/e* 155 from it should occur to a greater extent in the analyzer than the source, where secondary ions have not yet formed to so great an extent from the primary ions. The precursor of **1** $(CH_3COCOCH_3)^{+\cdot}$, is observed as a precursor of *m/e* 155 to a very small extent only in the analyzer but this is a result of its role in the formation of **1**.

For personal use only.

tion of a precursor ion to one non-decomposing secondary ion, in the absence of competing reactions of the precursor,[4] leads to the approximation [5] where P_s is power absorption by the secondary ion **2**, P_p is the power absorption by the precursor ion **1**, [B] is the concentration of norborneol in the chamber, and 1.44 is the factor $155^2/129^2$. Note that **1**, "triacetyl," is the same in both cases.[5]

Evaluation of several sets of data in the total pressure range 1×10^{-5} to 3×10^{-5} Torr for each isomer leads to a factor of approximately 4 for k_{exo}/k_{endo} for the pair of compounds. The initial consideration of ion–dipole interaction (11) suggests very similar rates for these reactions; even inclusion of the additional term (12) brought in by the locked-dipole model (13) does not suggest a difference of more than a few percent, since the dipole moments of the two compounds differ only by 6% (14).

The differences in relative rates are considerably smaller than the large differences observed in solution chemistry, but still are impressive for gas-phase ionic chemistry, where previous experience has shown similar cross-sections for similar functionalities. Presumably the difference in rates, and cross-sections, may be explained by differences of the steric environment of the *exo* and *endo* hydroxyl group. For the *endo* isomer, the bulkiness of the "triacetyl ion" appears to prevent attack from the hindered underside, so that fewer collisions can result in transfer than in the *exo* isomer, where attack of the "triacetyl ion" appears possible on either side of the alcohol molecule. It appears possible that other, more selective acylating agents can be devised, such as the selective nitryl transfer agents described recently (15). Thus the value of 4 is only a preliminary estimate of the difference in reactivity to be found with acyl transfer reactions, since the ability of "triacetyl" to acetylate most oxygen and nitrogen functionalities points to its great lack of discrimination. We are exploring other species for improvement of the k_{exo}/k_{endo} ratio so that obvious identification of hydroxyl stereochemistries may eventually be made on the basis of *a priori* reasoning.

[4]The acetylated product **2** is formed only from **1**, by ion cyclotron double resonance. Although there is an *m/e* 95 peak in the spectrum, corresponding to the norbornyl cation, which might be considered a product of loss of acetic acid from **2**, it is partially the result of unimolecular decomposition of the molecular ion of norborneol and otherwise the result of a reaction of *m/e* 86 (biacetyl) or 87 (protonated biacetyl) with norborneol. Ion ejection experiments (9) indicated a barely detectable dependence on **1** in one of several experiments performed, but never a dependence on **2**. Hence our assumptions are justified.

[5]An expression for the rate constant differing in coefficients of residence times, which cancel in the derivation from ref. 8, has been proposed as an approximate solution to the general equation (10). No tests have been performed, to our knowledge, to distinguish between the expressions of refs. 8 and 10.

Experimental

Kleinfelter and Schleyer's procedure for the preparation of *exo*-norborneol (16) was used: m.p. 126–127°, reported m.p. 127–128°. Toivonen's procedure was used (17) for the preparation of the *endo* isomer: m.p. 148–149°, reported m.p. (18), 149–150°. The 2,3-butanedione sample was freshly drawn each day (Aldrich Chemical Co., Inc.).

The i.c.r. techniques employed here, except for ion ejection double resonance (9), were those described by Henis (19). Our ionizing current was 0.05 μA; total ion current, < 10 pA; typical cell voltages were: trap, 0.48 V; analyzer, split (20), 0.24 and 0.26 V; source drift, split (20), −0.11 and +0.35 V; magnetic field sweep, 10 min; response, 0.1 s; field modulation amplitude, 10 G. The fixed frequency (130.53 kHz) defined 85 G/a.m.u.; its r.f. level was 0.6 μA. Pressure readings were monitored by a VacIon pump used for ultimate pumping of the cell.

This study was supported by the National Institute of General Medical Sciences (GM 15 994), the National Science Foundation (GP 8096, GU 2059), and the Advanced Research Projects Agency (Contract SD-100 with the University of North Carolina Materials Research Center). The ICR-9 spectrometer was purchased through support by Hercules, Inc., the Shell Companies Foundation, the National Science Foundation (GU 2059), and the North Carolina Board of Science and Technology (159).

Pulse Radiolysis of Formamide and Formamide–Water Mixtures

D. C. WALKER AND S. C. WALLACE[1]
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received June 7, 1971

From the optical absorption spectrum observed by a sub-nanosecond pulse radiolysis method it is concluded that irradiated pure liquid formamide (dielectric constant = 109) does not yield solvated electrons with lifetimes $>10^{-11}$ s. In formamide–water mixtures the hydrated electron is formed in low yield and the position of the absorption band of e_{aq}^- is not altered by changing the composition. Apparently formamide reacts much more rapidly with thermalized electrons than it does with hydrated electrons. The latter may be formed in formamide–water mixtures due to aggregates of water molecules.

Le spectre d'absorption optique observé par la méthode de radiolyse avec une pulsation en dessous de la nanoseconde a permis de conclure que la formamide liquide pure irradiée (constante diélectrique = 109) ne donne pas d'électrons solvatés avec des temps de vie supérieurs à 10^{-11} s. Dans les mélanges formamide–eau, l'électron hydraté se forme avec un faible rendement et la position de la bande d'absorption de e_{aq}^- n'est pas altérée par un changement de composition. Apparemment, la formamide réagit beaucoup plus rapidement avec des électrons chauffés qu'elle ne le fait avec des électrons hydratés qui pourraient se former dans les mélanges formamide–eau, par suite des conglomérats de molécules d'eau.

Canadian Journal of Chemistry, **49**, 3398 (1971)

For a wide range of liquids (*e.g.* hydrocarbons, ethers, amines, alcohols, water)[2] there is, in general, an increase in both the radiation yield and the energy of the optical absorption band maximum of solvated electrons with increasing static dielectric constant (1, 2). Thus the pulse radiolysis of formamide ($HCONH_2$) is of interest because it has an exceptionally high dielectric constant (109 at 20 °C). On the basis of polaron theory and the fact that the positive end of the molecule is dispersed over an NH_2 group, one would anticipate an absorption band for electrons solvated in this medium to be in the visible or near i.r. region of the spectrum.

We present data on the sub-nanosecond pulse radiolysis absorption spectrum of pure liquid formamide and various formamide–water mixtures, taken by measuring the reabsorption of the system's own Cerenkov light when subjected to an intense 3 ns pulse of 500 kV electrons from a Febetron accelerator. We have demonstrated the qualitative potentiality of this technique (3) and will deal with the quantitative assessment of data elsewhere (4). It will be shown that for absorbing species whose mean lifetime exceeds the pulse duration (thus their concentration builds up throughout the pulse whereas the light intensity has the same time profile as the pulse) and when using spectrographic detection the relationship [1] should be used.

$$[1] \qquad I_0/I_t = G\varepsilon\,(23.03\ D/N)$$

where I_0 is the number of Cerenkov light photons per pulse when there is no reabsorption, I_t that obtained when there is partial reabsorption, G is the 100 eV radiation yield of absorbing species, ε the absorption coefficient at a particular wavelength, D the incident dose per pulse (in eV cm^{-2}) measured using a calorimeter thick enough to completely stop the high energy electrons, and N Avagadro's number. The I_0 data was obtained from concentrated solutions of H^+ and other scavengers and the relative intensity agreed with that theoretically predicted (5) from other compounds and mixtures. For any spectrum so obtained (23.03 D/N) is a constant but does change from pulse to pulse due to slight variations in the electron pulse intensity. In fact, because the characteristic curves for the film sensitivity as a function of wavelength were established by a multiple pulse method (4), these variations were averaged out and the relative magnitude of $G\varepsilon$ for the various solutions should be quite reliable.

Figure 1 shows the absorption spectra for pure formamide, 20% H_2O, 36% H_2O, 50% H_2O, and pure H_2O within the wavelength range 300 to 900 nm.[3] Because of a fairly rapid decay of the band centered at 680 nm in the formamide–water mixtures ($k = 3.5 \times 10^8\ s^{-1}$ in the 50% solution, see later) very small corrections (< 10%) were applied to the $G\varepsilon$ values given in Fig. 1 to account for the diminished lifetimes in the mixtures (4).)

High concentrations of H^+ (2 M) completely removed the band centered at 680 nm in all the water-containing solutions and also eliminated the weak band seen as a shoulder at ~520 nm in the pure formamide. The long wavelength edge of the u.v. band in pure formamide was also somewhat reduced by the presence of H^+.

Several features of these spectra are important. (*i*) For the case of pure formamide, only a very weak absorption band in the range 400–500 nm seems to be related to species formed by thermalized-electron capture. Since the yield of long-lived ($> 10^{-8}$ s) free-ions in irradiated pure formamide has been shown by N_2O scavenging to be 3.3 ± 0.3 (6), commensurate with its high dielectric constant, then the absorption band at $\lambda \sim 520$ nm must have $\varepsilon \sim 300\ M^{-1}\ cm^{-1}$ if it is to be attributed to the species responsible for the free-ion yield. Although we cannot measure the lifetime of the species absorbing at 520 nm others have reported bands in the range 400–550 nm with lifetimes of microseconds and longer (7–9) so that the 520 nm band does not appear to arise from a very short lived ($\sim 10^{-11}$ s) strongly absorbing species.

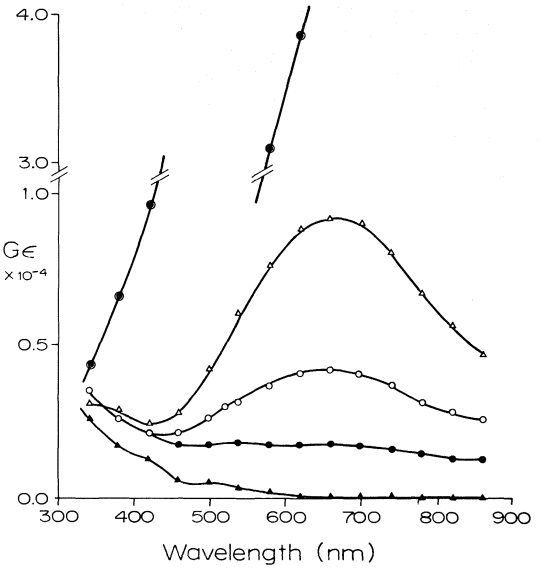

FIG. 1. Absorption spectra of pulse irradiated formamide and formamide–water mixtures. ▲, pure formamide; ●, 20% H_2O; ○, 36% H_2O; △, 50% water; and ◉, pure H_2O (% by volume).

For the wavelength range 600–900 nm there is no detectable absorption, which means $G\varepsilon < 500\ M^{-1}\ cm^{-1}\ (100\ eV)^{-1}$ for species with lifetimes > 3 ns. By conventional pulse radiolysis methods using 40 ns pulses this has been shown to continue out to 2000 nm (9). We can also conclude that $G\varepsilon < 4 \times 10^3$ for species having lifetimes $\sim 10^{-10}$ s, or $G\varepsilon < 4 \times 10^4$ if the lifetimes were $\sim 10^{-11}$ s.

Solvated electrons in formamide would be expected to have a broad and intense absorption band with ε in the range (1.5–3) $\times 10^4\ M^{-1}\ cm^{-1}$ at λ_{max} by analogy with other solvents

[3]The spectra in Fig. 1 are somewhat different to the preliminary oral presentation of this work at the Marianské Lazné Discussion (13) for two reasons. Firstly, those spectra showed the optical density of the film divided by the gamma of the film, which subsequent analysis shows to be proportional to log ($G\varepsilon$). Secondly, the absorption containing distinct peaks at ~500 nm for 10 and 20% solutions are artifacts arising from reciprocity law failure in a region of low film sensitivity. In the work reported in the current paper this problem was overcome by establishing characteristic curves for the photographic film using a multiple pulse method and working to constant film density (4).

and thus we conclude that solvated electrons with lifetimes $>10^{-11}$ s are not formed in pure liquid formamide. Perhaps the weak band at $\lambda \sim 520$ nm arises from solvent anions, or decomposition fragments, because it is eliminated by acids.

(*ii*) For all solutions containing large quantities of water a single absorption band centered at ~680 nm was observed, in addition to the u.v. band of formamide and perhaps the shoulder at 520 nm. This main band corresponds very closely in position and shape to that of the hydrated electron. There is no evidence of any shift in the band position or its shape on changing the composition of the mixture. (In this respect they are somewhat analogous to solutions of alcohols in hydrocarbons (10).) This suggests that the solvation shells of the solvated electrons formed in these solutions consist almost entirely of H_2O molecules and are not representative of potential well depths (or solvation energies) intermediate between pure H_2O and pure formamide.

Using the technique of kinetic laser photometry (11) it was shown that the decay of the species responsible for absorption at 632.8 nm proceeds by a pseudo-first order process giving a rate constant for the reaction

$$e_{aq}^- + HCONH_2 \rightarrow \text{Products}$$

of $k = (1.8 \pm 0.2) \times 10^7\ M^{-1}\ s^{-1}$, which is independent of formamide concentration over the range studied, 2.5 to 12.6 M. This k must be compared with values of 4×10^7 (12) and ~$10^6\ M^{-1}\ s^{-1}$ (7) obtained at concentrations of formamide ~$10^{-2}\ M$ in H_2O by microsecond pulse radiolysis methods.

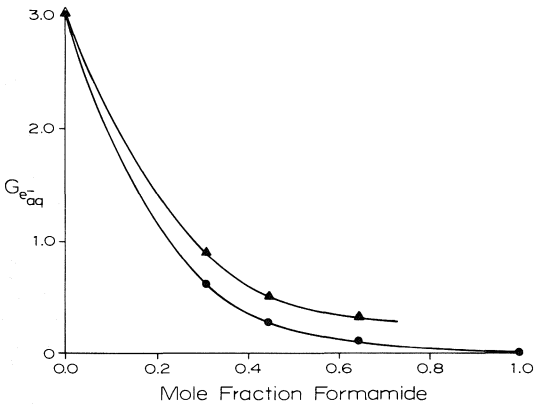

FIG. 2. Plot of $G(e_{aq}^-)$ as a function of mole fraction of formamide. ●, $G(e_{aq}^-)$ values were obtained from the spectra of Fig. 1 taking $\varepsilon(e_{aq}^-)_{580} = 1.1 \times 10^4\ M^{-1}\ cm^{-1}$. ▲, the values of $G(e_{aq}^-)$ divided by the mole fraction of water.

(*iii*) By taking $\varepsilon\ (e_{aq}^-)_{580} = 1.1 \times 10^4\ M^{-1}\ cm^{-1}$ one can plot the value of $G(e_{aq}^-)$ observed as a function of the mole fraction of the mixture, as in Fig. 2 (lower line). If these values of $G(e_{aq}^-)$ are divided by the mole fraction of water then the upper line of Fig. 2 is obtained. These data suggest that formamide molecules are in competition with aggregates of water molecules (perhaps 4 or 6) for the capturing of thermalized electrons formed by the radiolysis. A detailed knowledge of oligomer formation in these solutions would be required to extend this argument to a quantitative level. However, it is quite evident that formamide reacts much more rapidly (by several orders of magnitude) with the precursors of the hydrated electrons than it does with hydrated electrons, once formed.

Our conclusions are that formamide does not form solvated electrons but that it reacts rather rapidly with thermalized electrons, perhaps to give solvent anions which then represent the "free-ion" species which may reduce several electron scavengers (6). In formamide–water mixtures the solvated electrons formed have solvation shells consisting only of water molecules.

We are most grateful to Dr. Geraldine Kenney-Wallace for kind assistance with the laser photometry experiments and to the National Research Council of Canada for financial support.

Crystal and Molecular Structure of the 1:1 Complex of Chloral Hydrate and 7-Bromo-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one

R. F. DUNPHY AND H. LYNTON
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 11, 1971

The structure of a 1:1 complex of chloral hydrate and 7-bromo-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one has been determined by the heavy atom method. The complex crystallizes in the orthorhombic system, space group *Pbca*, with unit cell dimensions $a = 13.45(1)$, $b = 26.74(2)$, $c = 11.23(1)$ Å and 8 molecules in the unit cell. The 1:1 complex of chloral hydrate and diazepam, 7-chloro-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one, is isomorphous with the above compound and has unit cell dimensions $a = 13.43(1)$, $b = 26.60(2)$, $c = 11.20(1)$ Å. The final atomic parameters have been obtained from a block-diagonal least squares refinement using anisotropic thermal parameters. The final agreement residual for 575 observed reflections is $R = 0.079$.

The structure consists of chains of chloral hydrate and Br-diazepam molecules linked by hydrogen bonds.

La structure d'un complexe 1:1 entre l'hydrate de chloral et le bromo-7 dihydro-2,3 méthyl-1 phényl-5 benzodiazépin-1,4 one-2 a été déterminée par la méthode de l'atome lourd. Le complexe cristallisé dans le système orthorhombique, groupe d'espace *Pbca*. La maille élémentaire, contenant 8 molécules, a pour dimensions: $a = 13.45(1)$, $b = 26.74(2)$ et $c = 11.23(1)$ Å. Le complexe 1:1 entre l'hydrate de chloral et le diazépam, chloro-1 dihydro-2,3 méthyl-1 phényl-5 benzodiazépin-1,4 one-2, est isomorphe du composé précédent et la maille élémentaire a pour dimensions: $a = 13.43(1)$, $b = 26.60(2)$ et $c = 11.20(1)$ Å. Les paramètres atomiques ont été affinés par moindre carrés (diagonalisation par blocs) en utilisant des facteurs thermiques anisotropes. L'indice d'accord final est $R = 0.079$ pour 575 réflexions observées.

Crystal and Molecular Structure of the 1:1 Complex of Chloral Hydrate and 7-Bromo-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one

R. F. DUNPHY AND H. LYNTON
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 11, 1971

The structure of a 1:1 complex of chloral hydrate and 7-bromo-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one has been determined by the heavy atom method. The complex crystallizes in the orthorhombic system, space group *Pbca*, with unit cell dimensions $a = 13.45(1)$, $b = 26.74(2)$, $c = 11.23(1)$ Å and 8 molecules in the unit cell. The 1:1 complex of chloral hydrate and diazepam, 7-chloro-2,3-dihydro-1-methyl-5-phenyl-1,4-benzodiazepin-2-one, is isomorphous with the above compound and has unit cell dimensions $a = 13.43(1)$, $b = 26.60(2)$, $c = 11.20(1)$ Å. The final atomic parameters have been obtained from a block-diagonal least squares refinement using anisotropic thermal parameters. The final agreement residual for 575 observed reflections is $R = 0.079$.

The structure consists of chains of chloral hydrate and Br-diazepam molecules linked by hydrogen bonds.

plex is isomorphous with the other and offers the advantage of a heavy atom in the structure.

Crystal Structure Analysis

Crystal data are as follows:

$C_{16}H_{13}BrN_2O \cdot C_2H_3Cl_3O_2$ f.w. = 494.6
Orthorhombic, a = 13.45(1), b = 26.74(2), c = 11.23(1) Å, V = 4038.9 Å^3, ρ_0 = 1.60(3), z = 8, ρ_c = 1.627 (20 °C, MoK$\bar{\alpha}$, λ = 0.71069 Å).

$C_{16}H_{13}ClN_2O \cdot C_2H_3Cl_3O_2$ f.w. = 450.2
Orthorhombic, a = 13.43(1), b = 26.60(2), c = 11.20(1) Å, V = 4001.1 Å^3, ρ_0 = 1.47(3), z = 8, ρ_c = 1.445 (20 °C, MoK$\bar{\alpha}$, λ = 0.71069 Å).

The unit cell dimensions and their estimated standard deviations for both complexes were obtained from least squares evaluations of the positions of 12 independent reflections. In both cases the space group is *Pbca* (D_{2h}^{15}), No. 61 in ref. 1. X-Ray powder patterns for both complexes show similar intensity distributions.

Intensity data for the bromo complex were collected on a Picker computer-controlled four-angle diffractometer using a $\theta/2\theta$ scan with β-filtered MoKα radiation and a scintillation detector. The *hkl* octant was explored to the maximum limit of measurable intensity, $2\theta = 30°$. Of the 830 accessible reflections in this region, 575 were considered observed. The threshold was taken as 10% of the total background count or 18 counts, whichever was greater. The specimen used for intensity data was a colorless needle-shaped crystal 0.48 mm long and 0.24 mm in cross section, the long direction being parallel to the a axis. This crystal was sealed in a glass capillary tube and mounted with the a axis parallel to the ϕ direction of the diffractometer. The linear absorption coefficient for MoKα radiation is 25.5 cm^{-1}. No absorption or extinction corrections were applied.

The position of the bromine atom was established from a three dimensional Patterson synthesis and the remaining atoms, with the exception of the hydrogens, from successive Fourier syntheses. All atoms occupy general positions. The quantity $R_2 = \sum w(|F_o| - |F_c|)^2$ was minimized for the observed reflections only by successive cycles of block-diagonal least squares using 3 × 3 matrices for the positional parameters and 6 × 6 matrices for the anisotropic thermal parameters of each atom. The weighting function used was $w = \{1/(1 + [(|F_o| - P_2)/P_1]^4)\}$ with P_1 = 65 and P_2 = 75. Scattering factor

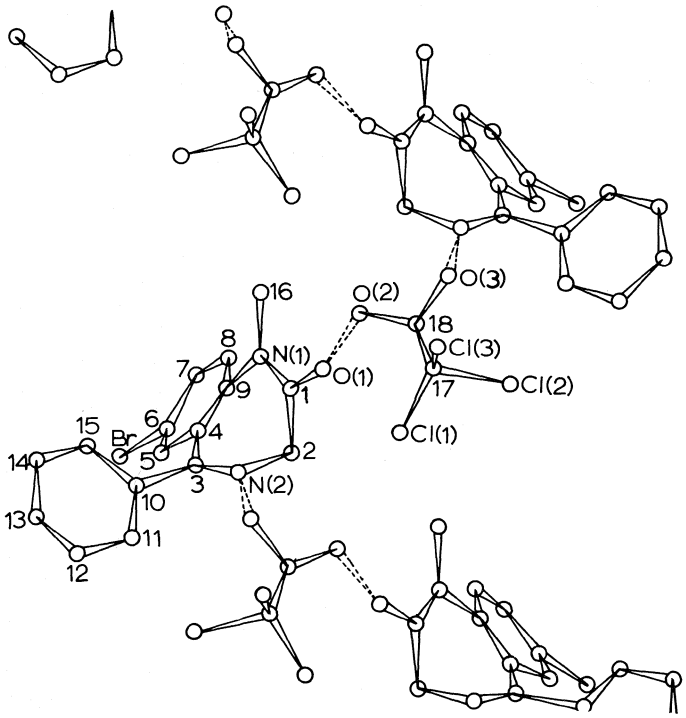

FIG. 2. The structure of the complex as projected along the *a* axis.

curves for Br, Cl, O, N, and C were those given in ref. 2. The bromine scattering curve was corrected for anomalous dispersion (3).

The final agreement residual $R = \sum(||F_o| - |F_c||)/\sum|F_o|$ was 0.079. In the last cycle no parameter shift exceeded 0.3 times the estimated standard deviation. A difference synthesis showed a small amount of remaining electron density no where greater than $0.5e$ Å^{-3}, probably due to the hydrogens, but the resolution was not sufficient to determine their positions. A set of structure factors for the final parameters given in Table 1 has been placed in the Depository of Unpublished Data.[1]

Discussion

The numbering scheme used in this paper and the general structure of the complex are shown in Fig. 2. Each Br–diazepam molecule is hydrogen bonded through the carbonyl group oxygen, O(*1*) and the nitrogen atom N(*2*) to the two hydroxy groups, O(*2*) and O(*3*), of two different chloral hydrate molecules. The hydroxy groups of each chloral hydrate molecule are thus hydrogen bonded to two different Br-diazepam molecules. This results in four staggered chains through the cell in the *c* direction. The hydrogen bonding is evidenced by the relatively short O(*1*) · · · O(*2*) and N(*2*) · · · O(*3*) distances 2.75(3) and 2.77(4) Å (4, 5, 7).

The bond lengths and angles, although of low accuracy (e.s.d.'s 0.03–0.05 Å), are comparable with those for many organic structures found in the literature. The structure of the chloral hydrate molecule is similar to that found by Ogawa (6). The structure of diazepam shown in Fig. 1 is confirmed.

We wish to thank Dr. C. Podesva of Delmar Chemicals Limited, La Salle, Quebec for suggesting the problem and supplying samples of the complexes, Mr. M. J. R. Clark for the determination of the preliminary crystallographic data, Dr. F. R. Ahmed of the "Biochemistry Laboratory", NRCC for use of his computer programs, and the National Research Council of Canada for financial support.

Reactions of Some Fluorinated Acetylenes with Tetrakis(triphenylphosphine)platinum(0)

W. R. CULLEN AND F. L. HOU

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received June 23, 1971

The reactions of tetrakis(triphenylphosphine)platinum(0), (**1**) with 3,3,3-trifluoropropyne and 3,3,4,4,4-pentafluorobutyne produce *cis*-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ and $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$, respectively. The analogous reaction between (**1**) and hexafluoro-2-butyne yields the known $(P(C_6H_5)_3)_2Pt(F_3CC_2CF_3)$.

Les réactions du tétrakis (triphénylphosphine) de platine(0), (**1**) avec le trifluoro-3,3,3 propyne et le pentafluoro-3,3,4,4,4 butyne conduisent respectivement au *cis*-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ et $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$. Une réaction analogue entre (**1**) et l'hexafluoro butyne-2 donne le composé connu $(P(C_6H_5)_3)_2Pt(F_3CC_2CF_3)$.

Canadian Journal of Chemistry, **49**, 3404 (1971)

Although a number of platinum–acetylene complexes have been prepared (1–8), only a few platinum acetylides are known. Chatt and Shaw (2) first prepared some acetylides of the type *trans*-$(P(C_2H_5)_3)_2Pt(C{\equiv}CR)_2$ (R = H, CH_3, C_6H_5) by the reaction of the sodium acetylide with *cis*-$(P(C_2H_5)_3)_2PtCl_2$ in liquid ammonia. A similar bisacetylide, *trans*-$(P(C_2H_5)_3)_2Pt(C{\equiv}CCF_3)_2$, was isolated by Stone and co-workers (4) from the reaction of *trans*-$(P(C_2H_5)_3)_2PtCl_2$ with trifluoropropynylmagnesium iodide. Recently, Roundhill and co-workers (5) also prepared a platinum bisacetylide hydride by the reaction of tetrakis(triphenylphosphine)platinum(0), (**1**), with 1-ethynylcyclohexanol.

Harbourne and Stone (3) have reported that 3,3,3-trifluoropropyne reacts with (**1**) to yield the π-bonded complex $(P(C_6H_5)_3)_2Pt(CF_3C_2H)$. We wish to report that this reaction affords the σ-bonded complex *cis*-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (**2**) in low yield if excess propyne is used and if the reactants are left for longer periods. A similar product $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)$ (**3**) is obtained when (**1**) and 3,3,4,4,4-pentafluorobutyne react at 20°.

The structure of (**2**) follows from its infrared and ^{19}F nuclear magnetic resonance (n.m.r.) spectra. The former shows absorptions at 2115 and 2060 cm^{-1} which are characteristic of $C{\equiv}CCF_3$ groups σ-bonded to a metal (4, 9, 10). The presence of two $C{\equiv}C$ stretching frequencies suggests that the fluorocarbon groups are *cis* to each other in this compound. The ^{19}F n.m.r. spectrum confirms this stereochemistry and shows a triplet of doublets centered at 44.2 p.p.m. [$J_{^{195}Pt-CF_3}$ 29.8 Hz; J_{P-CF_3} 3.8 Hz]. The chemical shift and ^{195}Pt–CF_3 coupling constant are similar to those found for analogous bisacetylide *trans*-$(P(C_2H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (4), which shows, however, a triplet of triplets in its ^{19}F n.m.r. spectrum because the fluorocarbon groups are *trans* to each other. The spectrum of (**2**) arises because only *one* phosphorus atom is significantly coupled to the CF_3 group. Since it has been found (3, 6, 11) that

Harbourne and Stone (3) have reported that 3,3,3-trifluoropropyne reacts with (**1**) to yield the π-bonded complex $(P(C_6H_5)_3)_2Pt(CF_3C_2H)$. We wish to report that this reaction affords the σ-bonded complex *cis*-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (**2**) in low yield if excess propyne is used and if the reactants are left for longer periods. A similar product $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)$ (**3**) is obtained when (**1**) and 3,3,4,4,4-pentafluorobutyne react at 20°.

The structure of (**2**) follows from its infrared and ^{19}F nuclear magnetic resonance (n.m.r.) spectra. The former shows absorptions at 2115 and 2060 cm^{-1} which are characteristic of $C{\equiv}CCF_3$ groups σ-bonded to a metal (4, 9, 10). The presence of two $C{\equiv}C$ stretching frequencies suggests that the fluorocarbon groups are *cis* to each other in this compound. The ^{19}F n.m.r. spectrum confirms this stereochemistry and shows a triplet of doublets centered at 44.2 p.p.m. [$J_{^{195}Pt-CF_3}$ 29.8 Hz; J_{P-CF_3} 3.8 Hz]. The chemical shift and ^{195}Pt–CF_3 coupling constant are similar to those found for analogous bisacetylide *trans*-$(P(C_2H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (4), which shows, however, a triplet of triplets in its ^{19}F n.m.r. spectrum because the fluorocarbon groups are *trans* to each other. The spectrum of (**2**) arises because only *one* phosphorus atom is significantly coupled to the CF_3 group. Since it has been found (3, 6, 11) that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$J_{P\ trans\text{-}CF_3}$ is usually greater than $J_{P\ cis\text{-}CF_3}$ it seems reasonable to assign the coupling in (**2**) to the interaction between the CF_3 groups and the phosphorus atoms *trans* to them. However, the value of 3.3 Hz found for *trans*-$(P(C_2H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (4) makes this assignment less certain.

Although $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$ (**3**) shows only one C≡C stretching absorption at 2125 cm^{-1}, this is not sufficient evidence to assign a *trans* structure. Unfortunately, the ^{19}F n.m.r. spectrum was not obtainable due to its low solubility. Since (**3**) was made by the same procedure as (**2**) a *cis* geometry seems more likely.

Additional evidence that (**3**) is formulated correctly is provided by its mass spectrum which shows a parent multiplet at $m/e = 1000 \pm 10$. The calculated parent multiplet, $m/e = 1005$, for (**3**) is well within counting error. Furthermore, the observed relative intensities of the parent multiplet are in good agreement with the calculated values as shown in Table 1. Additional multiplets are observed in the spectrum indicating that the molecule fragments by loss of triphenylphosphine, fluorocarbon and phenyl groups.

The reaction of hexafluorobutyne-2 with (**1**) produces $(P(C_6H_5)_3)_2Pt(F_3CC_2CF_3)$, (**4**) which has been obtained previously by different routes (6, 7). This compound in which the acetylene moiety is π-bonded was identified by microanalysis, and by its infrared and n.m.r. spectra.

Experimental

All reactions were carried out under a nitrogen atmosphere and volatile reagents were manipulated in a standard vacuum system. Melting points were determined in evacuated capillaries and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 457 spectrophotometer, mass spectra on an AEI MS-9 spectrometer, and n.m.r. spectra on Varian T-60 and HA-100 spectrometers. Chemical shifts are given in p.p.m. downfield from external TMS and upfield from external $CFCl_3$. Microanalyses were performed by Mr. P. Borda of this department.

TABLE 1. Relative intensities in the parent multiplet of the mass spectrum of $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$

	Relative intensity	
m/e	Observed	Calculated
1002	2.2	1.55
1003	2.4	0.77
1004	61	65.71
1005	100	100
1006	91	91.89
1007	35	34.55
1008	22	21.92
1009	8.7	8.29

3,3,3-Trifluoropropyne was prepared by the dechlorination of 1,1,2-trichloro-3,3,3-trifluoropropene with zinc dust in dimethylformamide (12). 3,3,4,4,4-Pentafluorobutyne was a gift from Dr. M. C. Waldman. Hexafluorobutyne-2 was purchased from Peninsular ChemResearch Inc. and potassium tetrachloroplatinite from Platinum Chemicals, Inc.

Preparation of cis-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (2)

Tetrakis(triphenylphosphine)platinum(0), (**1**), was prepared by the action of an aqueous solution of 0.4 g of sodium borohydride on an aqueous alcoholic solution of triphenylphosphine (2.1 g, 8 mmol) and potassium tetrachloroplatinite (0.83 g, 2 mmol). The precipitated complex, (**1**) was filtered under nitrogen, dissolved in 50 ml of hot benzene, and transferred into a Pyrex tube 3,3,3-Trifluoropropyne (1.4 g, 15 mmol) was then condensed into the Pyrex tube. After 5 months at room temperature, the tube was opened and the solvent and excess alkyne were removed under reduced pressure. The residue was washed with pentane and ethanol and the crude product was crystallized twice from diethyl ether at −78° to give white solid *cis*-$(P(C_6H_5)_3)_2Pt(C{\equiv}CCF_3)_2$ (0.16 g, 9%), m.p. 180° (dec.).

Anal. Calcd. for $C_{42}H_{30}F_6P_2Pt$: C, 55.7; H, 3.3; F, 12.6. Found: C, 55.4; H, 3.3; F, 12.4.

The ^1H n.m.r. spectrum (acetone solution) showed a multiplet at 7.00 p.p.m. and the infrared spectrum ($CHCl_3$ solution) showed the following absorptions: 2990 (br), 2115 (s), 2060 (sh), 1590 (w), 1480 (w), 1435 (w), 1420 (sh), 1335 (w), 1300 (sh), 1220 (br), 1097 (s), 1030 (sh), 998 (w), 905 (w), 867 (w), 610 (w), 522 (m), 504 (sh), 435 (w) cm^{-1}.

Preparation of $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$ (3)

A benzene solution of 3,3,4,4,4-pentafluorobutyne (2.2 g, 16 mmol) and (**1**) (2.5 g, 2 mmol) was sealed in a Pyrex tube. The tube was left at room temperature for 5 months. After opening the tube, the solvent and excess alkyne were removed under reduced pressure. The residue was washed with methanol. Crystallization from dichloromethane at −78° gave a white solid $(P(C_6H_5)_3)_2Pt(C{\equiv}CC_2F_5)_2$ (0.10 g, 5%), m.p. 220° (dec.).

Anal. Calcd. for $C_{44}H_{30}F_{10}P_2Pt$: C, 52.5; H, 3.0; F, 18.9. Found: C, 52.4; H, 2.9; F, 18.6.

It showed a multiplet at 7.17 p.p.m. in its ^1H n.m.r. spectrum and infrared absorptions ($CHCl_3$ solution) at: 3000 (br), 2125 (m), 1585 (w), 1480 (w), 1435 (w), 1338 (w), 1176 (s), 1098 (m), 1072 (m), 1028 (m), 1000 (w), 520 (s), 510 (sh), 434 (w) cm^{-1}.

Preparation of $(P(C_6H_5)_3)_2Pt(CF_3C_2CF_3)$ (4)

Hexafluorobutyne-2 (2.6 g, 16 mmol) and (**1**) (2.5 g, 2 mmol) in benzene were reacted for 14 days at 20°. After removal of solvent and excess alkyne the crude residue was extracted with dichloromethane and crystallized at −78° to yield white crystals of $(P(C_6H_5)_3)_2Pt(F_3CC_2CF_3)$ (0.70 g, 40%), m.p. 216° (lit. value (6) 215–216°).

Anal. Calcd. for $C_{40}H_{30}F_6P_2Pt$: C, 54.5; H, 3.4. Found: C, 54.8; H, 3.3.

We thank the National Research Council of Canada for financial support, Dr. M. C. Waldman for the gift of 3,3,4,4,4-pentafluorobutyne, and Mr. J. E. H. Ward for technical assistance.

Molecular Screening in Helium Molecular Ion[1]

C. M. WANG AND B. MUSULIN
Department of Chemistry, Southern Illinois University, Carbondale, Illinois 62901

Received May 3, 1971

Variational energy calculations for He_2^+ were performed and the results were used to evaluate a semi-empirical method for choosing orbital exponents in quantum chemical calculations.

Des calculs relatifs aux variations d'énergie de He_2^+ ont été effectués, et les résultats ont été utilisés pour évaluer une méthode semi-empirique pour le choix de la représentation des orbitales dans les calculs de chimie quantique.

Canadian Journal of Chemistry, **49**, 3406 (1971)

Introduction

Harriss *et al.* (1) have demonstrated that the use of a molecular screening parameter may be used to simplify the variational energy calculations of the LiH and Li_2 problems in the valence electron approximation, *i.e.*, the calculations were treated as two-electron problems through the neglect of core-electrons. In this method the exponential parameter occurring in molecular wave functions is given by

$$[1] \qquad Z = Ae^{-R} + B$$

where Z is the exponential paramter, R is the diatomic internuclear distance, and A and B are arbitrary parameters to be determined from the screening constants of the united and separated atoms. In the aforementioned test calculations, the results depended not only upon the concept of a distance dependent screening constant but also upon the method of averaging used to determine A and B in eq. 1.

For example, in the case of He_2^+, the separated atoms are He and He^+ for which the atomic screening constants, according to Slater's (2) rules, are 1.70 and 2.00, respectively. The average values of the screening constant which is the value of B ($\lim_{R\to\infty} Z$) in eq. 1 is 1.80. Likewise the united atom, Be^+, has electrons, with screening constants 3.70 and 2.30, whose average value is 3.23. Since $\lim_{R\to 0} Z = A + B$, the value of A for He_2^+ is found to be 1.43. The purpose of this investigation is to determine the distance dependence of the orbital parameter in energy calculations of a diatomic molecule containing only electrons which are in 1s orbitals in the separated atoms, *i.e.*, He and He^+. The results are compared to those predicted by eq. 1 in order to test the propriety of the averaging assumption.

Method

In calculations associated with He_2^+, three atomic orbital wave functions are used. Within the framework of the valence bond method (3), there have been three variation calculations of increasing complexity, *viz.*, a single orbital exponent (4), different exponents for the orbitals of He and He^+ (5), and distinct exponents for each of the three orbitals (6). In each of these calculations, a variation was performed so as to obtain the best value(s) of the orbital parameter(s) at the equilibrium (experimental or theoretical) internuclear distance.

The present calculation was also performed within the framework of the valence bond method, *i.e.*, the trial wave function was a linear combination of Slater determinantal wave functions representing the ground state configuration. The optimum value(s) for the orbital parameter(s) in, first, a Pauling-type calculation, and in, second, a Weinbaum-type calculation, for various values of the internuclear distance, R, was (were) determined. The spacing of R values was finer in the region of the experimental equilibrium distance, R_e. The original Pauling and Weinbaum calculations were reproduced in order to both test the computer programs and obtain potential curves for comparison purposes.

The calculations were performed on an IBM 1620 computer with 40K storage utilizing programs written in FORTRAN II. The subroutine for the exponential integral, $-Ei(-x)$, was based upon the Hastings approximation (7).

Results and Discussion

Table 1 presents sample results of the present Pauling-type calculation along with results of similar calculations for comparison purposes. Corrections to the original Pauling calculation (8) have been verified. The most striking fact shown in Table 1 is that the energy curve obtained from a complete variation of Z is so little different from that found by Pauling using the value of Z obtained at R_e. The difference never is as great as 1 kcal. Also surprising is the fact that the optimum value of Z is not a monotonic function of R. Apparently for He_2^+ the optimum value of Z at each R is fairly close to the value at R_e. The near accordance results from the facts that the optimum value of Z is a slowly varying function of R and that the optimum value of Z passes through a maximum not too far from the Pauling value and then decreases towards the Pauling value. As a result, the energy values obtained by the two methods are very close.

Although the three orbital average does not have the monotonic functional form assumed by eq. 1, the semi-empirical results are superior at large R to the results obtained with the Pauling constant orbital exponent. Relative to experimental values, discrepancies in calculations with only 1s orbitals (He_2^+) are less than discrepancies in calculations averaging 1s and 2s orbitals (LiH and Li_2). This result substantiates the limitations on eq. 1 suggested by Empedocles (9). The Pauling-type results do not warrant any comments concerning the method of assigning values to A and B in eq. 1.

Table 2 presents sample results of the present Weinbaum-type calculation along with results of the Weinbaum calculation for comparison purposes. As expected there is improvement for every R value except at R_e where the two methods coincide. The most important fact in Table 2 is that one of the orbital parameters does exhibit

*Z = 1.833.

the monotonic decreasing form of eq. 1 while the second parameter approximates the same functional form. The implication is that in many-electron systems the number of orbital parameters used must correspond to the number which, in a variational calculation, allows each exponent to assume what appears to be the normal monotonically decreasing form.

The present work also demonstrates that a semi-empirical method, like *ab initio* methods, may be chosen according to the complexity required or allowed. The use of a single semi-empirical exponent yielded results comparable only to the Pauling calculation and in no way as accurate as the Weinbaum calculation. On the other hand, the use of the semi-empirical exponent economizes the calculation by eliminating the variation of the exponent. Even if two semi-empirical exponents were used to obtain a calculation corresponding to the Weinbaum calculation, the effort would be correspondingly less than the true variation calculation.

Table 3 presents the results of a Pauling-type calculation for the first excited state. Unlike the ground state, the orbital exponent is a monotonically increasing function. The results substantiate the theorem given by Harriss and Frost (10) that the optimum Z for the first excited state is always lower than the optimum Z for the ground state. With the modification of functional form, the semi-empirical techniques used in this investigation can be extended to excited states.

Computing facilities available precluded any attempt to extend the Csavinsky (6) calculation with three distinct orbital exponents.

Infrared Spectra of Hydroxyl Groups on the Surface of Platinum

B. A. MORROW AND P. RAMAMURTHY
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received July 12, 1971

Infrared spectroscopy has been used to show that two types of PtOH species exist on the surface of silica-supported platinum. One of these is produced when O_2 is allowed to react with hydrogen covered platinum (ν(OH) = 3497 cm^{-1}) and the other is produced when H_2O reacts with a reduced platinum oxide (ν(OH) = 3544 cm^{-1}).

La spectroscopie infrarouge a été utilisée pour montrer qu'il existe deux types d'espèce PtOH sur la surface du platine fixée sur un support en silice. L'une d'elles est produite lorsqu'on laisse O_2 réagir avec le platine recouvert d'hydrogène (ν(OH) = 3497 cm^{-1}) et l'autre est produite lorsque H_2O réagit avec un oxyde de platine réduit (ν(OH) = 3544 cm^{-1}).

Canadian Journal of Chemistry, **49**, 3409 (1971)

There have been many recent investigations of the gas phase reactions of hydrogen, oxygen, and water on platinum catalysts (1–3) but at no time has there been any evidence for the existence of surface PtOH groups, nor is this species generally considered in discussions of this subject. On the other hand, electrochemists have for a number of years postulated that surface PtOH groups play an important role in many electrochemical processes (4–6). In this communication we present the first spectroscopic evidence for the existence of hydroxyl groups on the surface of platinum.

Silica-supported samples were prepared by standard techniques (3, 7) involving the slurrying of sufficient silica (Cab-O-Sil, H-5) with H_2PtCl_6 in acetone (or water), such that after pressing 200 mg of the dried powder into thin discs and reducing in H_2 at 350 °C for several hours, 16% by weight of Pt was incorporated. The silica had been previously heated in air at 800 °C in order that a minimum residual band in the 3700–3300 cm^{-1} region due to hydrogen-bonded surface silanol groups would be present. A typical background spectrum in the 4000–3000 cm^{-1} region is given by curve (*a*) in Fig. 1 showing the well known infrared band due to non-interacting silanol groups at 3749 cm^{-1} (8, 9).

All attempts to detect PtOH surface species by adsorbing H_2O on freshly reduced platinum proved futile. Only the well known broad featureless absorption between 3700–3400 cm^{-1} could be detected (9) and a similar band could be produced using silica alone. However, when O_2 was

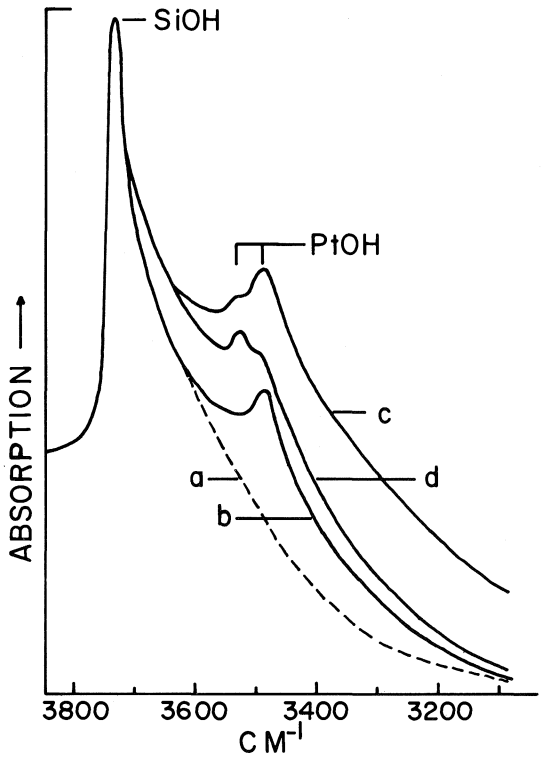

FIG. 1. (*a*) Background spectrum of fully reduced silica-supported platinum showing the SiOH absorption at 3749 cm^{-1}; (*b*) spectrum obtained after adding O_2 to (*a*); (*c*) spectrum obtained after adding O_2 to a sample which had been pretreated with H_2 and H_2O; (*d*) spectrum obtained after degassing (*b*) at 400 °C (background same as in (*a*)) followed by the addition of H_2O vapor.

For personal use only.

added to a "hydrogen covered" (7) platinum sample, the spectrum shown in Fig. 1 curve (*b*) was obtained in which there is an additional sharp absorption band at 3497 cm^{-1}. Hydrogen covered platinum was prepared by first cooling the sample in hydrogen to 20 °C after reduction (or regeneration) and then evacuating the hydrogen for 5 min until the pressure was less than 10^{-3} Torr (7). Upon addition of O_2 to a sample which was covered with both H_2 and H_2O, curve (*c*) was obtained in which an additional weak feature at 3544 cm^{-1} is present. Regardless of the method of production, neither band changed in intensity after prolonged evacuation at 20 °C, but the intensity of both bands slowly diminished on heating under vacuum at 100–200 °C, the lower wavenumber band decreasing at the faster rate, and then disappeared entirely leaving a clear background spectrum if evacuated at 400 °C for 2 h. Finally, upon addition of H_2O after the above mentioned type of evacuation procedure (400 °C), curve (*d*) was obtained in which both bands are present, but the 3544 cm^{-1} absorption is the more intense. The above effects were not observed when pure silica alone was utilized.

These spectra strongly indicate that two types of PtOH groups are probably formed under these conditions on silica-supported platinum. The OH stretching frequency in $(CH_3)_3PtOH$ is reported to be at 3559 cm^{-1} (10), and in the model compound $Ag_2[PtCl_5OH]$ synthesized by ourselves as a confirmation of this expected wavenumber region, the OH stretching frequency is at 3512 cm^{-1}. Both bands of the adsorbed species show the appropriate isotopic shifts characteristic of OH species when deuterium (either D_2 or D_2O) is substituted (2609 and 2580 cm^{-1}) and the 3544 cm^{-1} band shifts 11 cm^{-1} to lower wavenumber when $H_2{}^{18}O$ is used. The latter is the same shift previously reported for ^{18}O silanol groups (8).

We do not consider that these bands are due to physically adsorbed water (which might result from some particular metal-support interaction) because adsorption of water alone on a freshly reduced Pt sample does not produce these bands, nor is there any evidence for the growth of a band near 1600 cm^{-1} due to the HOH deformation mode. The same bands cannot be detected using alumina-supported platinum because of the almost total absorption due to the support hydroxyl groups in this region, but again, under similar reaction conditions, no band near 1600 cm^{-1} is observed.

As further evidence that these bands are probably attributable to PtOH species, when ethylene or ethylene-^{13}C is added, the PtOH bands immediately disappear and a spectrum of adsorbed ^{12}CO or ^{13}CO is observed near 2050 cm^{-1}. No such reaction occurs when water alone is present on silica-supported platinum.

The reason for two types of PtOH species is obscure at the moment. One possible explanation is that there may be several types of surface site, for example (111) and (100) crystal planes, but this would not readily account for the differences in the conditions required to produce these groups. Since heating under vacuum at 400 °C after admission of O_2 is likely to lead to a more reduced platinum oxide surface, the most probable explanation is that the 3497 cm^{-1} band is due to PtOH on a fully oxidized surface, whereas the 3544 cm^{-1} band would correspond to a PtOH on a more reduced surface. Further investigations of this aspect of the problem are underway.

In conclusion, this work provides the first direct confirmation of the views of the electrochemists concerning the possible existence of surface PtOH groups. Further, the fact that they are formed when O_2 is added to hydrogen covered platinum has important consequences in connection with the H_2/O_2 titration reaction on platinum. Thus, several recent controversies (1, 2) concerning the stoichiometry of these reactions may have to be re-examined in the light of this work.

The Specific Activity of Silica Supported Platinum for the Catalysis of Hydrogen – Water Deuterium Exchange[1,2]

N. H. SAGERT AND R. M. L. POUTEAU

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received April 26, 1971

Some rate data are reported for deuterium exchange between water and hydrogen using a series of platinum–silica catalysts. Three different methods of preparing catalysts were used to give different series of metal particle sizes. Within each series, the particle size was increased by sintering batches in air, at temperatures up to 700 °C. These methods produced platinum particles ranging from 5 to 250 Å in diameter. Metal surface areas and particle sizes were measured by hydrogen chemisorption, X-ray diffraction, and electron microscopy.

The specific rates, *i.e.*, rates per unit surface area of platinum varied by a factor of three within each series, reaching a maximum for sintering temperatures of about 500 °C. These maximum rates, measured at 127 °C with a water-to-hydrogen ratio of 0.31, varied from 1.9×10^{-8} to 5×10^{-8} mol D_2 cm^{-2} s^{-1}. Thus no effect of particle size on rate was observed, and the differences noted are ascribed to other effects of the methods of preparing the catalysts.

Certaines données de vitesse sont reportés pour l'échange du deutérium entre l'eau et l'hydrogène lorsqu'on utilise une série de catalyseurs platine–silice. Trois méthodes différentes de préparation des catalyseurs ont permis d'obtenir différentes séries de taille de particule métallique. Dans chaque série, la taille de la particule a été augmentée par frittage dans l'air à des températures supérieures à 700 °C. Ces méthodes ont donné des particules de platine dont la gamme des diamètres varie de 5 à 250 Å. Les aires de surfaces métalliques et les tailles des particules sont mesurées par chimisorption de l'hydrogène, par diffraction aux rayons-X et par microscopie électronique.

Les vitesses spécifiques, c'est-à-dire les vitesses par unité de surface du platine, varient avec un facteur de trois dans chacune des séries, atteignant un maximum pour des températures de frittage de l'ordre de 500 °C. Ces vitesses maximales mesurées à 127 °C avec un rapport eau-hydrogène de 0.31, varient de 1.9×10^{-8} à 5×10^{-8} mol D_2 cm^{-2} s^{-1}. Par contre, aucun effet de la taille des particules n'a été observée et les différences notées sont assignées aux autres effets des méthodes de préparation des catalyseurs.

Canadian Journal of Chemistry, 49, 3411 (1971)

Introduction

Because supported metal catalysts are industrially important, they have been studied for many years. Two types of studies are specific to such catalysts. These are investigations of the role of metal-support interaction and, for a given metal and support, the effect of the degree of metal dispersion. Such investigations have only become possible in recent years because methods have been developed for measuring the surface area of exposed metal in the presence of supports with surface areas perhaps hundreds of times larger than those of the metal (1).

Changes in the metal particle size might be expected to affect rates in two ways. As the particle size is decreased the fraction of edge and corner atoms rises markedly (2). This will affect reactions requiring certain geometries. Secondly, as the particle size decreases, the electronic properties of the particles must change from those of the

bulk metal to, ultimately, those of a single atom (3).

Both metal-support and metal-dispersion effects have been observed, but their relative importance is still debatable. For a number of hydrogenation reactions, the specific activity, *i.e.*, the activity per unit surface area of metal, has been shown to remain constant with changes in the support and with metal particle size (4–7). On the other hand, it has been shown for nickel on silica catalysts that the specific activity for hydrogenolysis of ethane remained constant with changing nickel particle size (8), whereas for nickel on silica–alumina, the specific activity varied with particle size (9, 10). It was also much lower than for nickel on silica. Dorling *et al.* (11) found, for the hydrogenation of ethylene on platinum–silica catalysts, that the methods used to create differences in particle size led to differences in specific activity. However, they found the difference in activity arose from factors such as poisoning and chlorine content of the catalyst.

We have studied the effect of platinum particle size on the hydrogen – water deuterium isotope exchange. This reaction is of interest to the nuclear industry as a means of obtaining enriched deuterium. In addition, it has several practical advantages. The products differ only isotopically from the reactants, so that no chemical changes occur in the catalyst–reagent system with time, or along the catalyst bed. Furthermore, the heat of reaction is negligible, so that the heat effects in the bed can be neglected. If the amount of D_2O in the water is kept low then only reaction 1

$$[1] \qquad HDO + H_2 \rightleftarrows H_2O + HD$$

need be considered, and the kinetics are considerably simplified (12). The reaction is conveniently followed by measuring the amount of HD formed. Early work on the kinetics of the reaction has been summarized by Bond (13). No attempt was made in this work to study mechanistic details.

Experimental Procedures

Kinetic Studies

Rate measurements were carried out in a flow system at atmospheric pressure. The hydrogen stream was saturated at 63.5 °C with water vapor containing 4.0% D_2O. The stream was then passed downward through the reactor which contained from 25 to 200 mg of catalyst mixed with glass beads to give a constant volume of catalyst bed. The catalyst bed was 0.5 cm in diameter and 1.5 cm long. It was kept at constant temperature (±0.5 °C) in a furnace. After the gas stream left the reactor, water was stripped out using a Dry Ice – acetone trap. Glass–teflon stopcocks were used throughout the system to avoid contamination by grease.

The amount of HD in the gas stream was determined gas chromatographically using a 1 m activated charcoal column at 25 °C and a thermal conductivity detector. Hydrogen containing about 100 p.p.m. deuterium was used as the carrier gas and the signal obtained was proportional to the difference in HD content between the reactor gas stream and the carrier gas (12). The chromatograph was calibrated at regular intervals by analyzing the HD mass spectrometrically on a Consolidated 21–130 mass spectrometer, and by using large amounts of catalyst to give the equilibrium amount of HD from water containing 1, 2, and 4% D_2O. Flow rates were controlled by regulators and precision needle valves. The flows were measured either with rotameters which had been calibrated with a positive displacement meter, or with a linear mass flowmeter which had been similarly calibrated. Temperatures were measured with an iron–constantan thermocouple.

Unless otherwise noted, prior to rate measurements, the catalysts were evacuated to 10^{-5} Torr for at least 1 h while the temperature was raised to 350 °C. They were then reduced at that temperature for 12 h in a hydrogen stream and cooled to reaction temperature in flowing hydrogen. Catalysts were often slowly deactivated, losing at most 5% of their activity per day. As measurements on any given catalysts were made within 2 or 3 days, corrections for loss of activity were small. Calculations based on equations given by Satterfield (14) showed that the efficiency factor for pore diffusion was close to unity and that the linear velocity through the bed was high enough to ensure plug flow.

Materials

(i) Reagents

Ultra High Purity hydrogen (99.999% min) was passed through a Deoxo unit to remove traces of oxygen, and through a cold trap to remove water. The 4% D_2O in water was made by adding D_2O to deionized, distilled water.

(ii) Catalysts

The catalysts used contained about 1% platinum by weight on porous chromatographic grade silica gel (40–60 mesh). Before adding the platinum, the gel was calcined at 600 °C for 16 h. Platinum was then put on the gel by ion exchanging with $Pt(NH_3)_4(OH)_2$, by impregnating with H_2PtCl_6, or by impregnating with $Pt(NH_3)_2(NO_2)_2$.

Catalysts prepared with $Pt(NH_3)_4(OH)_2$ were made by following the procedure of Benesi *et al.* (15). The hydroxide was prepared from $Pt(NH_3)_4Cl_2$ by ion exchange with the hydroxide form of a strong base resin. A solution 10^{-2} *M* in hydroxide and 10^{-3} *M* in chloride was added dropwise to a stirred suspension of the silica gel, keeping the p*H* between 7.5 and 9. The product was filtered, dried overnight at 120 °C, sieved, and pre-reduced in 15 g lots in a stream of hydrogen at 200 °C. Portions were then sintered in air for 5 h at temperatures up to 700 °C.

Catalysts prepared with H_2PtCl_6 were made by wetting the gel with a solution containing the required amount of platinum, followed by evaporation to dryness with stirring.

Catalysts prepared from $Pt(NH_3)_2(NO_2)_2$ were made

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by dissolving sufficient compound in hot water, and evaporating to dryness with the gel.

All catalysts were then dried, sieved, pre-reduced, and sintered as described before. The actual amount of platinum on the catalysts was determined by atomic absorption spectrometry (16).

Surface Area and Particle Size Measurements

Total surface areas were measured by adsorption of nitrogen at 77 °K using a standard volumetric B.E.T. apparatus, and assuming the surface area of the nitrogen molecule to be 16.2 Å^2. Platinum surface areas were calculated from hydrogen chemisorption isotherms measured at 25 °C, following procedures of Dorling *et al.* (17), except that a commercial quartz spiral bourdon gage was used as a manometer. It was assumed that one hydrogen atom was adsorbed per exposed platinum atom, and that the surface area of the platinum atom was 8.9 Å^2 (17). Catalysts were subjected to the same reduction as those used for kinetic studies, and were then evacuated to 2×10^{-6} Torr overnight at 300 °C before isotherms were measured.

For samples with crystallites in the larger size ranges the size of the platinum crystallites was determined from the broadening, B, of X-ray diffraction lines. A Phillips counter diffractometer, fitted with a step-scanning attachment, was used to measure the position and profile of the (111) line of platinum. Filtered copper radiation was used, and the Kα doublet was resolved by a graphical method (18). Corrections for instrumental broadening were made from Warren's expression

$$[2] \qquad \beta^2 = B^2 - b^2$$

where b is the half width of the instrumental broadening and β is the true half width. The crystalline size, D, was obtained from the Scherrer expression

$$[3] \qquad D = K\lambda/\beta \cos\theta$$

where λ is the wavelength, θ the Bragg angle, and K the classical Scherrer constant, taken as 0.9 (18).

Electron microscopy was done with an Hitachi HU 200E microscope using a high resolution stage. Samples were prepared by mulling the catalyst in ethyl alcohol. After the coarse particles had settled, a portion of the supernatant liquid was deposited on a carbon substrate supported on a 200 mesh copper grid, using a special atomizer. Micrographs were obtained at a plate magnification of 100 000 ×, and were magnified photographically for particle size counting.

Results

The reaction rate, k, given as moles of D_2 transferred per gram of catalyst per second was calculated (12) from eq. 4.

$$[4] \qquad k = \frac{F}{(\alpha + \gamma)W} \ln \frac{n_e - n_0}{n_e - n}$$

Here, F is the hydrogen flow rate in mol/s, W is the weight of the catalyst in g, α is the reciprocal of the equilibrium constant for reaction 1, γ is the ratio of the partial pressure of hydrogen to water, n_0 and n are the deuterium concentrations in the hydrogen before and after reaction respectively, and n_e is the equilibrium concentration of deuterium in the hydrogen after reaction. The value of n_e is calculated (12) from eq. 5

$$[5] \qquad n_e = \frac{N_0 + \gamma n_0}{\alpha + \gamma}$$

where N_0 is the deuterium concentration of the water vapor from the saturator. The value of α was calculated (19) from eq. 6.

$$[6] \qquad \log_{10}\alpha = \frac{205}{T(°K)} - 0.129$$

Thus k may be calculated from the initial slope of a plot of $\ln (n_e - n_0)/(n_e - n)$ against W/F. Such a plot is shown in Fig. 1 for a 0.75% platinum on silica catalyst prepared by $Pt(NH_3)_4^{2+}$ exchange. The catalyst temperature is 80 °C and γ is 3.18. The rate is $2.6_1 \times 10^{-4}$ mol D_2/g s and the yield is linear to quite high conversions. Rates were reproduced to within ±5% and are probably accurate to within ±10%.

The temperature dependence of the rates is shown in Fig. 2, plotted in the Arrhenius form, for catalysts prepared from $Pt(NH_3)_4^{2+}$. At temperatures above 100 °C, a reasonably linear relationship was obtained, and the apparent activation energy corresponded to 9.3 ± 0.5 kcal/mol. At temperatures below 100 °C, catalysts of lower metal surface area tended to show a decrease in rate from the Arrhenius dependence, while those with the larger areas actually showed an increase in rate at lower temperatures. Catalysts made from H_2PtCl_6 and from $Pt(NH_3)_2$-

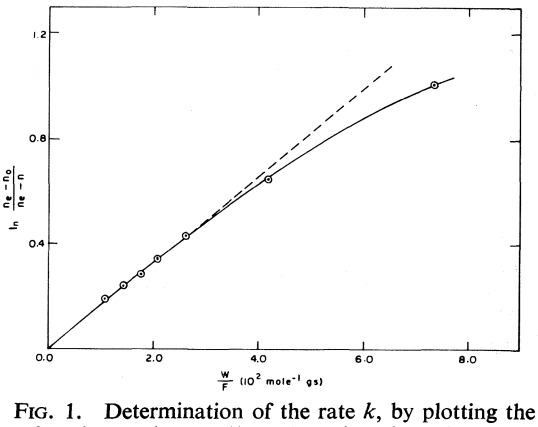

FIG. 1. Determination of the rate k, by plotting the rate function, $\ln (n_e - n_0)/(n_e - n)$, against the reciprocal of the flow. Catalyst: 0.75% Pt prepared from $Pt(NH_3)_4^{2+}$ and unsintered. Reaction temperature 80 °C.

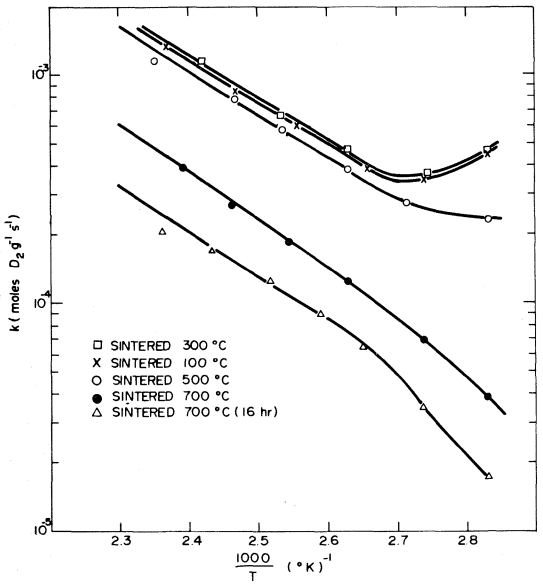

FIG. 2. Arrhenius plot for catalysts containing 0.75% Pt prepared from $Pt(NH_3)_4^{2+}$ and sintered at various temperatures.

$(NO_2)_2$ gave straight lines or showed slight downward deviations from Arrhenius behavior at lower temperatures. Some less well reduced catalysts prepared from H_2PtCl_6 gave upward deviations from Arrhenius behavior at low temperatures. Apparent activation energies for the catalysts prepared with H_2PtCl_6 were in the range 7.5 ± 1 kcal/mol except for a value of 9.6 for the catalyst sintered at 700 °C. Apparent activation energies for catalysts prepared from $Pt(NH_3)_2(NO_2)_2$ were in the range of 9 ± 1 kcal/mol.

The B.E.T. surface area of the silica gel after air drying at 600 °C was 323 m^2/g. Some typical hydrogen chemisorption isotherms are shown in Fig. 3 for catalysts prepared with $Pt(NH_3)_4^{2+}$ and sintered at various temperatures. Under these conditions, hydrogen adsorption on the silica gel itself was negligible. The linear portion of the isotherm at higher pressure was extrapolated to zero pressure and this adsorbed volume was used to calculate the metal surface area assuming monolayer coverage. From this area an average particle size can be calculated, assuming a geometry for the particle. We assumed the crystallites were spheres exposing their entire surface. The average size obtained is equivalent to $\sum n_i d_i^3 / \sum n_i d_i^2$ (15), *i.e.*, an area averaged diameter, where d_i is the diameter of the ith particle.

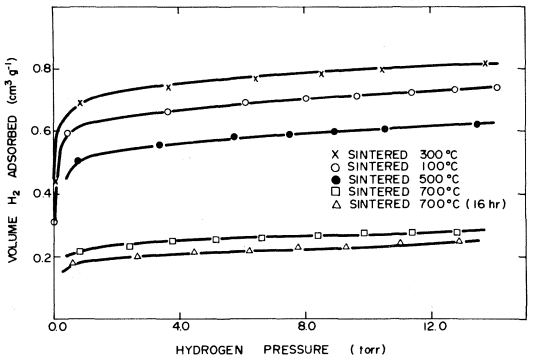

FIG. 3. Hydrogen adsorption isotherms for catalysts with 0.75% Pt prepared from $Pt(NH_3)_4^{2+}$ and sintered at various temperatures.

The X-ray method gives a volume averaged diameter $\sum n_i d_i^4 / \sum n_i d_i^3$ and furthermore measures "crystallite size" rather than particle size (20). However, twinning has been shown to be of minor importance for most supported catalysts (21). From the electron micrographs a true average diameter $\sum n_i d_i / \sum n_i$, as well as the other two averages, can be calculated. Table 1 compares the three methods of obtaining particle sizes for catalysts prepared by H_2PtCl_6. Table 2 shows the different types of particle diameter averages obtained by electron microscopy compared with the same type obtained by other methods, where possible. The agreement shows that the particle

size distribution is reasonably narrow, for this catalyst at least.

Neither electron microscopy nor X-ray diffraction were suited to the smaller ranges of particle size of the catalysts prepared by ion exchange. However, for catalysts prepared in this way and sintered to high temperatures these methods did show that the particle size distribution was probably at least bimodel since there seemed to be at least a few particles of quite large size (~100 Å). For the catalysts prepared by $Pt(NH_3)_2(NO_2)_2$ impregnation, good agreement was obtained between adsorption methods and electron microscopy, although the number of particles counted was necessarily small. The X-ray diffraction results gave poorer agreement, probably because of the large corrections for instrumental broadening.

From a knowledge of k, and the metal surface area, the specific rate is obtained. Figure 4 shows some specific rates at 127 °C as a function of particle size as measured by hydrogen chemisorption. Within each catalyst series, a maximum specific rate is obtained for sintering temperatures of about 500 °C. The variations in specific rate within each catalyst series are greater than the variations between the three series, and no well-defined variation in specific rate solely with particle size is observed.

A series of catalysts containing 0.12 to 0.75% platinum was prepared by $Pt(NH_3)_4^{2+}$ exchange. These catalysts were not sintered and were reduced *in situ* at 350 °C. Specific rates were in the range $3.0 \pm 0.8 \times 10^{-8}$ mol D_2/cm^2 Pt s, and apparent activation energies were in the range 8.8 ± 1.0 kcal/mol. Rather larger errors were involved in measuring surface areas at the lowest platinum concentrations. However, the approximately constant specific rates and apparent activation energies confirm that pore diffusion is relatively unimportant in this system (14). They also confirm that our results are not changed by the slightly different platinum loadings used.

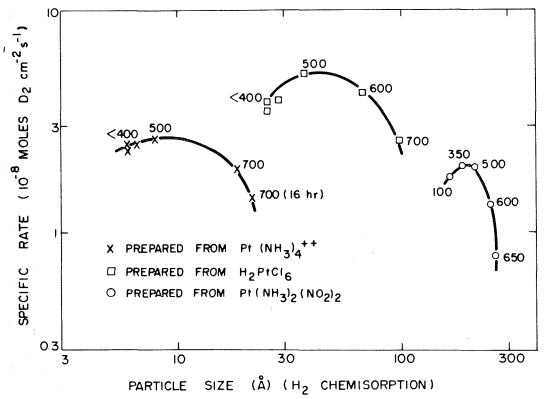

FIG. 4. Specific rates measured at 127 °C for the catalysts studied. The figures beside points give the sintering temperature.

Discussion

From Fig. 2, it is apparent from the changes in the Arrhenius slope that the reaction shows complex behavior below 100 °C. A number of possibilities suggest themselves as explanations for this behavior. For example, if the water adsorption characteristics of the support are important, it should be noted that at 80 °C, with a saturation temperature of 63.5 °C, the relative pressure of water is about 0.5. Hence the water adsorption isotherms may be quite complex. However, a study of the complicated behavior below 100 °C was not within the scope of this work. Further discussion will be confined to the region above 100 °C where reasonably straight Arrhenius plots and nearly constant activation energies were obtained.

We have noted above that no clear effect of particle size on the specific rate at 127 °C has been demonstrated. This observation was somewhat surprising. Both theoretical and experimental work have indicated that electronic properties undergo drastic changes in going from atomic dispersion to the bulk metal (22–24). For platinum the first ionization potential of the atom is 9.0 eV (25), whereas the work function of metallic platinum is 5.4 eV (26). At least part of the change from atomic to metallic properties should occur in going from 6 to 300 Å particles, and yet no gross effects on the specific rates are noted over this range. Thus, the hydrogen–water isotopic exchange seems insensitive to changes in electronic properties of the metal catalyst. It joins a growing list of reactions for which varying platinum particle size does not change the specific rate. These include hydrogen–deuterium exchange (4), various hydrogenation reactions (4–7), dehydrogenation of cyclohexane and isopropanol (27), and hydrogenolysis of cyclopentane (27).

Certain reactions, the best example of which is the isomerization of neopentane (28), show sensitivity to changes in the metal particle size.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

These have been termed "demanding" reactions by Boudart, and the major factor making them demanding is thought to be a requirement for a definite geometric arrangement of surface atoms (28). The isomerization of neopentane is thought to require triadsorption of neopentane at triple adsorption sites. For the simpler reactions, such as the exchange reaction considered here, apparently there is no strict geometrical requirement.

There appears to be some variation of specific activity with the method of catalyst preparation. Some of this may be illusory. The $Pt(NH_3)_4^{2+}$ exchanged catalyst adsorbed sufficient hydrogen that, for the most highly dispersed catalysts, the ratio of H-to-Pt was almost 1.5. Similar behavior was noted by Poltorak and Boronin (29) and, to a lesser extent, by Benesi *et al.* (15). The results given in Fig. 4 are presented in terms of particle size, based on the assumption that one H atom is adsorbed per platinum atom. There is evidence that, for particles 15 Å in diameter and larger, this is a good assumption (17), but if, with very small particles, more than one H atom is taken up per platinum atom, the actual surface areas will be smaller than measured and hence the specific rates will be larger. A 50% decrease in measured areas would bring the $Pt(NH_3)_4^{2+}$ catalyst rates close to those from H_2PtCl_6 catalysts. Other differences between the series are the acidity of the medium in which the platinum is deposited, and the chlorine content. There is evidence that chloride acts as a promoter for hydrogenation reactions (11).

There also appears to be a very characteristic variation in specific rate within each series of catalysts. That is, a maximum in specific rate is observed for each series for catalysts sintered about 500 °C. In some cases, the small decreases observed at lower sintering temperatures may not be real, but the decreases at higher temperatures definitely are. Three possible explanations suggest themselves for this behavior, although no definite conclusions can be reached. The heats of adsorption of water on silica gel vary from 5 to 1 kcal/mol for gels degassed at 150 and 810 °C, for 50 mg water adsorbed per g of gel (30). Thus the gels degassed at higher temperatures are less hydrophilic, and, if water adsorbed on the gel plays any part in the kinetics, lower rates may result. On the other hand, a very high coverage of water molecules may slightly inhibit diffusion of water to the platinum, lowering the specific rate. Another possibility is that when platinum crystallites are heated much above 480 °C, the low energy (111) face will be preferentially developed (4). It is possible that this face has a lower specific activity. Thirdly, a maximum in oxidation–reduction activity has been observed for alumina and silica–alumina heated to about 600 °C (31). Although this type of activity has not been observed for silicas, it is possible that oxidation–reduction activity, too low to form the cations and anions studied by Flockhart *et al.* (31) can effect the properties of the platinum in this system. In any case, the fact that the curves in Fig. 4 have the same shape suggests that platinum particle size has relatively little to do with the rate of exchange.

Although a true kinetic study was not undertaken, some comments on the reaction mechanism can be made. In several places in the foregoing discussion we have alluded to the possible effects of the silica support. Thus, non-linear adsorption of water was suggested as being responsible for the behavior at reaction temperatures less than 100 °C. Furthermore, whatever the source and size of the platinum particles, maximum specific rates were obtained for silicas heated to about 500 °C. When the silicas were heated to high temperatures the specific rate fell, and it was suggested that the hydrophobic character of the silicas is responsible. It is noted that the maximum specific rate occurs where the gel is about half covered with surface hydroxyls (32). These observations suggest that the silica support plays an important role in the catalysis, and that this role is far more important than the platinum particle size. It is tentatively suggested that water vapor is adsorbed on the support, and that this adsorbed water reacts with hydrogen at the platinum particles. If the rate at which water can be transferred to the platinum is indeed important then it is not surprising that no effect of particle size was noted. However, any real discussion of the role of the support must await a thorough study of this factor.

Generally reactions which involve hydrogen transfer are facile reactions, as noted above. However, Poltorak and Boronin found very large changes in specific rates for reactions involving oxygen (29), and this was attributed to the loss of metallic character when small particles of platinum have a high coverage of oxygen atoms. Now one type of mechanism for hydrogen–water

exchange (33) is the following sequence

[7] $$HDO + Pt \rightarrow HD + PtO$$

[8] $$H_2 + PtO \rightarrow H_2O + Pt$$

Our results suggest that, if this is the mechanism, the coverage of oxygen atoms remains low during reaction.

We would like to thank S. C. Cribbs for doing the platinum analyses, D. Faulkner and E. E. Sexton for taking the electron micrographs, and A. Sawatzky and A. M. Duclos for measuring the X-ray diffraction patterns. Discussions with G. G. Strathdee and E. A. Symons are gratefully acknowledged.

Crystal and Molecular Structure of Dichlorobis(4-methylpyridine)zinc(II), $Zn(4\text{-}CH_3Py)_2Cl_2$

H. Lynton and M. C. Sears

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received May 12, 1971

Crystals of dichlorobis(4-methylpyridine)zinc(II), $Zn(4\text{-}CH_3Py)_2Cl_2$, are monoclinic, space group $P2_1/c$, with $a = 14.294(13)$, $b = 7.885(8)$, $c = 13.473(11)$ Å, $\beta = 100.60(5)°$ and 4 molecules in the unit cell. The final atomic parameters were obtained from a block-diagonal least squares refinement using anisotropic thermal parameters. The hydrogen atom positions were established but the parameters were not refined. The final agreement residual for 1348 observed reflections is $R = 0.043$. The zinc atom is tetrahedrally coordinated.

Les cristaux de dichloro bis-(méthyl-4 pyridine) zinc(II), $Zn(CH_3\text{-}4\ Py)_2Cl_2$, cristallisent dans le système monoclinique, groupe d'espace $P2_1/c$.

La maille élémentaire contenant 4 molécules d'eau a pour dimensions $a = 14.294(13)$, $b = 7.885(8)$, $c = 13.473(11)$ Å, $\beta = 100.60(5)°$. Les paramètres atomiques ont été affinés par moindre carrés (diagonalisation par blocs) en utilisant des facteurs thermiques anisotropes. La position des atomes d'hydrogène a été établie mais les paramétres n'ont pas été affinés. L'indice d'accord final pour 1348 réflexions observées est $R = 0.043$. L'atome de zinc est coordonné d'une façon tétrahédrique.

Canadian Journal of Chemistry, 49, 3418 (1971)

Introduction

Previous papers (1, 2) published in this laboratory reported the stereoconfigurations for $Zn(4\text{-}CH_3Py)_2Cl_2$, $Hg(4\text{-}CH_3Py)Cl_2$, and $Cd(4\text{-}CH_3Py)Cl_2$, as determined by infrared spectroscopy and a normal coordinate analysis. In order to confirm the stereochemistry, crystal structure determinations of the above complexes were attempted. Crystals of the Cd(II) complex were not sufficiently large and crystals of the Hg(II), while adequate in size, were found to be extensively twinned. The analogous bromide complexes yielded similar results. However, good single crystals of the Zn(II) complex were obtained and the crystal structure determined.

Crystal Structure Analysis

Crystal data are as follows:

$C_{12}H_{14}N_2ZnCl_2$ f.w. = 322.5

Monoclinic, $a = 14.294(13)$, $b = 7.885(8)$, $c = 13.474(11)$ Å, $\beta = 100.60(5)°$, $v = 1492.5$ Å^3, $\rho_0 = 1.42(2)$, $z = 4$, $\rho_c = 1.435$ (20 °C, MoK$\bar{\alpha}$, $\lambda = 0.71069$ Å).

The unit cell dimensions and their estimated standard deviations (in parentheses) were obtained from a least squares evaluation of the positions of 12 independent reflections. The space group is $P2_1/c$ (C_{2h}^5), No. 14 in *International Tables for X-ray Crystallography*, Vol. I (3).

Intensity data were collected on a Picker computer-controlled four-angle diffractometer using a $\theta/2\theta$ scan with β-filtered MoKα radiation and a scintillation detector. The two octants hkl and $\bar{h}kl$ were explored to a maximum 2θ of 45°. There were 1960 accessible reflections in this region of which 1348 were considered observed. The threshold was taken as $0.10\times$ the background count or 36 counts, whichever was greater. The specimen was plate-like, with dimensions $0.35 \times 0.30 \times 0.17$ mm, the shortest diagonal being parallel to the b axis. The b axis of the crystal was mounted parallel to the ϕ direction of the diffractometer. The linear absorption coefficient for MoKα radiation is $\mu = 19.9$ cm^{-1}. No absorption or extinction coefficients were applied.

The position of the zinc atom was established from a three-dimensional Patterson synthesis. All of the carbon, nitrogen, and chlorine atoms were then located from successive three-dimensional Fourier syntheses. All atoms occupy general positions. The method of refinement was by successive cycles of block-diagonal least squares, using 3×3 matrices for the positional parameters and 6×6 matrices for the anisotropic thermal parameters of each atom. The quantity minimized was $\sum w(|F_o| - |F_c|)^2$ for observed reflections only, using the weighting function $w = 1/(1 + [(|F_o| - P_2)/P_1]^4)$

with $P_1 = 25$ and $P_2 = 30$ (14). This weighting function gives almost equal weights in the middle range of $|F_o|$ but reduced weights for the higher and lower values. Scattering factor curves used were those for Zn, Cl, N, C, and H given in *International Tables for X-ray Crystallography*, Vol. III (4). The real and imaginary dispersion corrections were applied to the scattering curves of zinc and chlorine (5).

The final agreement residual $R = \sum(||F_o| - |F_c||)/\sum|F_o|$ for all atoms except hydrogen was 0.056. A difference synthesis at this point showed the positions of all the hydrogens as peaks with electron density between 0.4–0.5 e Å^{-3}, and no other residual electron density greater than 0.25 e Å^{-3}. The hydrogens were assigned isotropic thermal parameters by the following scheme: for hydrogens on methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

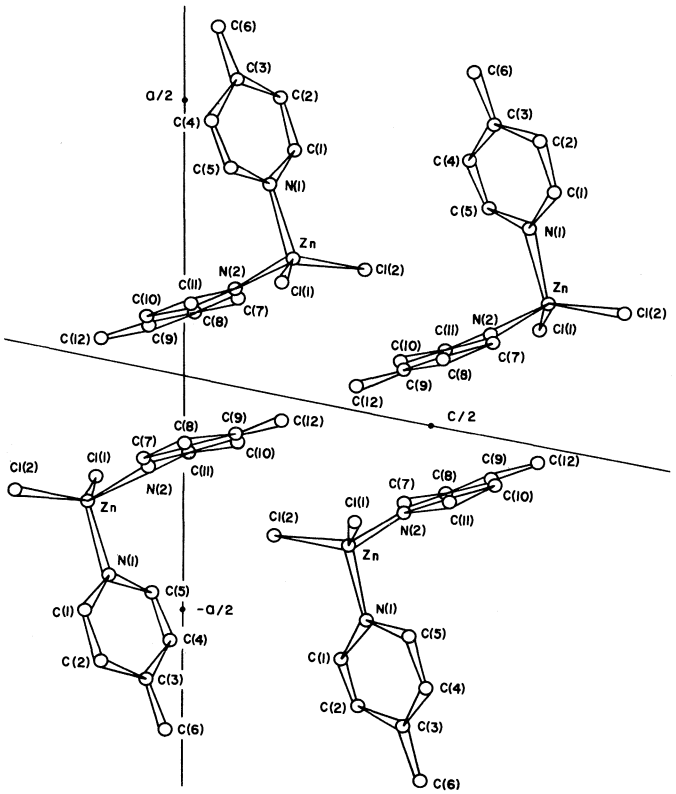

FIG. 1. Stereochemistry of the molecule and packing in the unit cell.

groups, $B = 8.00$; and for hydrogens on ring carbons, $B = 5.00$ Å^2. The positional and thermal parameters for the hydrogens were not refined during subsequent least squares cycles. The final agreement residual for all atoms was $R = 0.043$. Hamilton's significance test on the crystallographic R factor was applied and at a significance level of 0.01(1%) the reduction in the R factor from 0.056 to 0.043 was significant. A set of structure factors for the final parameters given in Tables 1 and 2 has been placed in the Depository of Unpublished Data.[1]

Discussion

The intramolecular bond distances and angles are given in Table 3. The stereochemistry of the molecule, the packing in the unit cell, and the numbering scheme are shown in Fig. 1.

The coordination about the zinc atom is distorted tetrahedral. The large Cl–Zn–Cl angle 121.8(1)° may be attributed to repulsions between nonbonding electrons on adjacent chlorine atoms. Similar large values have been reported for this angle in $Zn(Py)_2Cl_2$ (6) (121.0°), dichloro-(2,9-dimethyl-1,10-phenanthroline)zinc(II) (7) (121.2°), and dichlorobis(1-methyltetrazole) zinc(II) (8) (118.4°).

The Zn—N bond distances of 2.046(5) and 2.042(5) Å are not significantly different. There are few precise values of the Zn—N and Zn—Cl bond lengths reported in the literature for comparison with this study. A recent summary of Zn—N and Zn—Cl bond distances, in a number of complexes where zinc is tetrahedrally coordinated, is given by Baenziger and Schultz (8). The Zn—N distances fall in the range 1.99–2.10 Å. The Zn—N bond lengths found in this investigation fall well within this range and agree, within experimental error, with the Zn—N distances of 2.04(1) and 2.06(1) Å determined for dichlorobis(1-methyltetrazole)zinc(II), and are similar to the corresponding distances of 2.02(4) and 1.99(4) Å reported for $Zn(Py)_2Cl_2$.

[a]Referred to an orthogonal set of axes, X along a, Y along b, and Z along c^*.

The Zn—Cl bond distances of 2.211(2) and 2.04(2) Å are possibly significantly different ($t = 2.47$) according to Cruickshank's criterion (9). In the Baenziger–Schultz summary, the Zn—Cl distances lie between 2.18 and 2.30 Å. The Zn—Cl bond lengths in this work are quite close to the Zn—Cl distances of 2.06(5) and 2.198(5) Å reported for dichlorobis(1-methyltetrazole)zinc(II), and 2.19(1) and 2.18(1) Å determined for $Zn(Py)_2Cl_2$.

An examination of chemically equivalent bonds in the two 4-methylpyridine rings suggests that the C(8)—C(9) bond distance is significantly different ($t = 2.68$) from one of its three equivalent bond distances and possibly different ($t = 2.28$ and $t = 2.30$) from the other two. However, the C(8)—C(9) distance is not significantly different from the mean value of 1.368 Å. There are no distinguishing features of the environment about this particular bond which would explain this result. The remaining chemically equivalent distances are not significantly different from each other.

Table 4 compares the mean bond distances in the 4-methylpyridine rings with those given for the microwave study of pyridine (10), the pyridine ligand in the $Zn(Py)_2Cl_2$ structure (6), the 3,5-dimethylpyridine ligand in the Ni(3,5-dimethylpyridine)$_4(ClO_4)_2$ structure (11) and the 4-methylpyridine ligand in the structure of (+)-4-methylpyridinetrimethylaminebromohydroboronhexafluorophosphate (12). Within limits of accuracy, the bond lengths in the above ligands agree quite well with this investigation, the exception being that the C—C (top) distances (adjacent to the methyl group) in this structure are somewhat lower than the pyridine microwave study. In addition, the C—CH_3 average value of 1.504 Å is in excellent agreement with the average value of 1.505(5) Å for a number of bonds between tetrahedral carbon atoms and aromatic rings (13).

Comparable bond angles in the 4-methylpyridine rings are not significantly different. Table 5 compares the means of the ring angles in this study and some of the ligands mentioned

For personal use only.

above. The ring angles in the recently reported 4-methylpyridine complex are in good agreement with this work. Within experimental error, the 4-methylpyridine rings are planar (see Table 6).

The closest approach distance between two molecules in this structure is 3.560(7) Å between Cl(1) of one molecule and C(8) of the molecule in the next cell along the *b* direction.

We wish to thank Dr. D. G. Brewer of the University of New Brunswick for suggesting the problem, Dr. F. R. Ahmed of the Biochemistry Laboratory, National Research Council of Canada for use of his computer programs and the National Research Council of Canada for financial support.

Complexes of Cu(II), Co(II), and Ni(II) with "QPyNO"

MARIE TONG AND D. G. BREWER
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 1, 1971

A new ligand, 2,3-di(2-pyridine *N*-oxide) quinoxaline and its complexes with copper(II), cobalt(II), and nickel(II), have been prepared. A detailed investigation of the magnetic and spectral properties of these compounds has led to some tentative suggestions as to their structures.

Un nouveau ligand, le di-(pyridine-2 *N*-oxyde)-2,3 quinoxaline et ses complexes avec le cuivre(II), le cobalt(II) et le nickel(II), ont été préparés. Une étude détaillée sur les propriétés magnétiques et spectrales de ces composés a permis de faire certaines suggestions quant à la structure de ces composés.

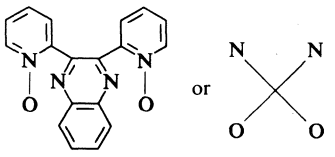
Introduction

The coordination properties and the complexes of pyridine *N*-oxide (1, 2) and quinoxaline (3, 4) have been studied extensively. The present paper reports the results of an investigation on the complexes of a new ligand, 2,3-di(2-pyridine *N*-oxide) quinoxaline, with some metals of the first transition series, *viz.*, Cu(II), Co(II), and Ni(II).

The ligand 2,3-di(2-pyridine *N*-oxide) quinoxaline (hereafter called QPyNO), with the structure **1**, contains both coordinating oxygen and nitrogen atoms, and can act as a chelating agent with the formation of a six-membered ring with the metal ion. Since this ligand has two similar sites, it is capable of functioning either as mono-bidentate or a bis-bidentate chelating agent.



1

The complex, QPyNO–ICl, in which QPyNO can only act as a unidentate agent, due to the linear bonding requirement for the iodine atom (5), was prepared using the method described by Kauffman and Stevens (6). The large differences between the i.r. spectra of all the metal complex compounds in this study and that of QPyNO–ICl suggests that QPyNO is not acting as a unidentate ligand.

A molecular model of QPyNO was constructed and shows that the most probable geometry, involving the ligand in a six-membered ring with the metal ion, would place two pyridine *N*-oxide rings parallel and about 45° to the plane of the quinoxaline ring. This kind of arrangement leaves one oxygen atom above, and the other oxygen atom below, the plane of the quinoxaline ring. This arrangement is consistent with the structure proposed by Geary for the 2,3-di(2-pyridyl) quinoxaline complexes (7).

Experimental

Starting Materials

Analytical grade metal salts were used without further purification.

o-Phenylene diamine was purified by sublimation.

2,2′-Pyridil 1,1′-dioxide was prepared and purified according to the method described by Daihei Oda (8).

2,3-di(2-Pyridine *N*-oxide) quinoxaline was prepared by refluxing equimolar quantities of 2,2′-pyridil 1,1′-dioxide and *o*-phenylene diamine in ethanol until all the 2,2′-pyridil 1,1′-dioxide had been dissolved (approximately 2 h). Ethanol was removed by evaporation. The product was recrystallized from ethanol, m.p. = 268 °C.

Anal. Calcd. for $C_{18}H_{12}N_4O_2$: C, 68.34; N, 17.72; O, 10.13; H, 3.80. Found: C, 68.14; N, 17.70; O, 10.31; H, 3.68.

Preparation of Complexes

All the complexes except $Ni_3Cl_6(QPyNO)_4 \cdot 4H_2O$ were prepared by mixing stoichiometric molar quantities of ligand and metal salt in ethanol and refluxing for 1 h. Complexes were formed either immediately after mixing or upon heating. The precipitates were separated by filtration, washed thoroughly with ethanol, and were dried in a desiccator.

The complex $Ni_3Cl_6(QPyNO)_4 \cdot 4H_2O$ was prepared by mixing equimolar quantities of ligand and nickel chloride in ethanol without heating. The green precipitate was separated by filtration, washed thoroughly with ethanol, and dried in a desiccator.

Analytical data are given in Table 1.

Magnetic Measurements

Magnetic susceptibilities of all the complexes were obtained at room temperature, using a Gouy type balance equipped with a Newport 1½ in. Electromagnet

Type C. $Ni(en)_3S_2O_3$ was used for the calibration (en = ethylenediamine).

Spectrophotometric Measurements

The infrared spectra were recorded on a Beckman IR-12 filter/grating spectrophotometer, using Nujol mull.

The electronic spectra were recorded on a Hitachi Ratio Recording spectrophotometer, model EPS-3T, using Nujol mull.

Results and Discussion

Infrared Spectra

The infrared spectra of all the complexes are very complicated, and no meaningful structure correlation can be deduced from them alone. The i.r. spectra of the complexes and that of the ligand are quite similar. However, in the 1200–1300 and 800–900 cm^{-1} regions, a noticeable shift is observed. These are listed in Table 2. These assignments are made by comparing the i.r. spectra of pyridine *N*-oxide and 2,2′-bipyridine 1,1′-dioxide complex compounds (9, 10) with the QPyNO complexes.

All the hydrated complexes show a broad band around 3400 cm^{-1}. However, from the i.r. data alone, it is not possible to determine whether the water molecule is coordinated to the metal or not.

The complexes $CoCl_2$(QPyNO)·$1\frac{1}{2}H_2O$, $CoBr_2$(QPyNO)·H_2O, CoI_2(QPyNO)·H_2O, $Ni_3Cl_6$$(QPyNO)_4$·$4H_2O$, $NiBr_2$$(QPyNO)_2$·$H_2O$, and $NiI_2$$(QPyNO)_2$·$H_2O$ in which the ligand is mono-bidentate, all have a strong absorption band around 455 cm^{-1}, and it is likely that this band can be associated with mono-bidentate QPyNO.

Nickel Complexes

The electronic spectra and magnetic moments (Table 3) clearly indicate that all the nickel complexes are octahedral (11). For the complexes $NiBr_2$$(QPyNO)_2$·$H_2O$ and $NiI_2$$(QPyNO)_2$.$H_2O$, it is obvious that an octahedral structure can be formed when each of the QPyNO acts as a mono-bidentate ligand (**2**). (The *trans* arrangement of the ligands is tentatively proposed due to its reduced steric hindrance.)

Nickel chloride easily forms complexes with

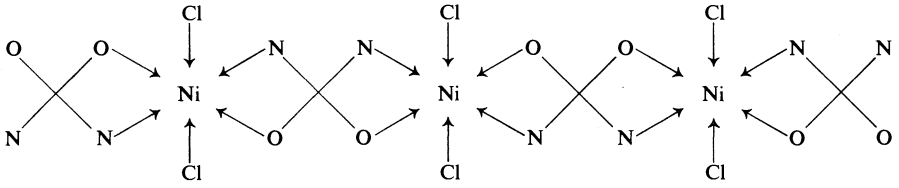
*sh = shoulder, vw = very weak, br = broad.



3

QPyNO. When prepared at room temperature, a green complex, $Ni_3Cl_6(QPyNO)_4\cdot 4H_2O$, is obtained. The structure of this compound is proposed as **3**.

In this arrangement, two QPyNO are acting as bis-bidentate ligand, whereas the other two are acting as mono-bidentate ligand. A more stable yellow complex, $Ni_5Cl_{10}(QPyNO)_4\cdot 4H_2O$, is obtained, when nickel chloride and QPyNO are refluxed together in ethanol. In this compound, two more metal atoms are coordinated to the two "free" ends of the $Ni_3Cl_6(QPyNO)_4\cdot 4H_2O$ complex and four water molecules also enter into coordination to give the structure **4**.

The insolubility of these two nickel chloride complexes in ordinary organic solvents, makes it very difficult to study their properties in more detail.

Cobalt Complexes

According to the electronic spectra and magnetic data (Table 3), cobalt halides form tetrahedral complexes with the mono-bidentate QPyNO (12). The visually estimated center of gravity of the ν_2 and ν_3 modes are used to calculate the values of D_q and B (13). These are listed in Table 4. During this study, a paper was published on the complexes of the 2,3-di(2-pyridyl) quinoxalines (7). By comparing the two sets of B values, an increase in stability and electronic delocalization in our system over the 2,3-di(2-pyridyl) quinoxaline system is indicated (14).

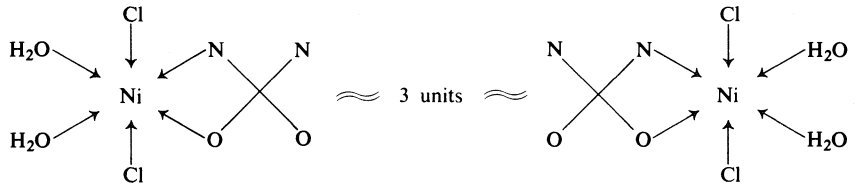
TABLE 4. D_q and B values of cobalt complexes

Complexes	ν_2 (cm^{-1})	ν_3 (cm^{-1})	D_q	B
$CoCl_2(QPyNO)\cdot 1\frac{1}{2}H_2O$	6 192	14 728	357	679
$CoBr_2(QPyNO)\cdot H_2O$	6 472	14 793	374	668
$CoI_2(QPyNO)\cdot H_2O$	5 747	13 967	331	652
$CoCl_2(DPYQ)$*	5 510	16 200	315	820
$CoBr_2(DPYQ)$*	5 390	16 000	310	810

*From ref. 7.

Copper Complexes

The visible spectra of the $CuCl_2$ and $CuBr_2$ complexes show a single broad band around 800–900 nm and are characteristic of six-coordinate copper. Thus, a tetragonal structure is



4

For personal use only.

expected in the complexes, with the QPyNO coordinating as a bridging bis-bidentate ligand. The insolubility of these two complexes in organic solvents is also an indication of their polymeric nature.

Stereochemistry of Dehydrogenation by D-Galactose Oxidase[1]

A. MARADUFU,[2] G. M. CREE,[3] AND A. S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec

Received June 1, 1971

The stereochemistry of dehydrogenation of the primary carbinol group of D-galactose by D-galactose oxidase has been determined. Using D-galactose-6-*d* and methyl β-D-galactopyranoside-6-*d*, it has been established that the reaction involves removal of the *pro-S* 6-hydrogen atom. This conclusion is based on product analysis, and on the relative impact of the deuterium isotope effect on oxidation rates of substrates having different *R*:*S* deuteration patterns. The absolute configurations at C-6 of these substrates have been determined by selective chemical transformations to products of known configuration. The rotational conformation of the 6-carbinol group of D-galactose and its possible relationship to the specificity of the enzyme are discussed, as well as the stereochemistry of reductive deuteration of *aldehydo* sugar derivatives.

On a déterminé la stéréochimie de déshydrogénation du groupement carbinol primaire du D-galactose par le D-galactose oxydase. Il a été établi, en utilisant le D-galactose-6-*d* et le méthyl β-D-galactopyranoside-6-*d*, que la réaction implique le départ de l'atome d'hydrogène-6 *pro-S*. Cette conclusion se base sur le produit d'analyse et sur l'impact relatif de l'effet de l'isotope deutérium sur les vitesses d'oxydation des substrats ayant des modèles différents de deutération *R*:*S*. Les configurations absolues en C-6 de ces substrats ont été déterminées par des transformations chimiques sélectives en produits de configuration connue. La conformation rotationnelle des groupements carbinole-6 du D-galactose et sa relation possible avec la spécificité de l'enzyme sont discutées, de même que la stéréochimie de deutération réductive des dérivés *aldéhydo* des sucres.

Canadian Journal of Chemistry, **49**, 3429 (1971)

D-Galactose oxidase from *Polyporus circinatus* (1, 2) (D-galactose oxireductase) catalyzes the reaction

$$\text{D-Galactose} + O_2 \rightarrow \text{DL-Galactohexodialdose} + H_2O_2$$

that is, it converts the primary carbinol group of D-galactose to an aldehyde. D-Galactopyranosides and unsubstituted D-galactopyranosyl residues of various oligo and polysaccharides also are oxidized by the enzyme (2–4), but attack is inhibited or retarded by the introduction of substituents at secondary positions of the D-galactopyranosyl moiety (5).

It was assumed *a priori* that D-galactose oxidase must effect a stereospecific removal of one of the C-6 hydrogen atoms, as is true for several dehydrogenases that have been examined (6–9), and this was subsequently found to be the case. To examine the precise stereochemistry involved, the well-established approach of utilizing a partially deuterated substrate of known configuration (6–11) was adopted.

The chirality of the 6-carbinol group may be described *e.g.*, as for methyl β-D-galactopyranoside (**1**), in terms of replacement of a hydrogen atom by deuterium (9, 12, 13). That is, H_S is designated as the *pro-S* hydrogen (deuterium in this position would confer an *S* configuration upon the carbinol group as in **2**) and H_R, the *pro-R* hydrogen as in the *R* diastereomer **3**. From the correlations of absolute configuration described below, it is concluded that the *pro-S* hydrogen is removed specifically by D-galactose oxidase.

Samples of methyl β-D-galactopyranoside[4] monodeuterated at position-6 (**1***a* and *b*) were prepared as substrates for this study by reaction sequences involving, as the key step, reduction of 1,2:3,4-di-*O*-isopropylidene-α-D-galactohexodialdose-1,5-pyranose (**4***a*) (14) with sodium borodeuteride (for **1***a*), and reduction of the dialdose-6-*d* **4***b* with sodium borohydride (for **1***b*)[5] (Scheme 1). Analysis of **1***a* (below) showed that the distribution of deuterium in the 6-car-

[3]Harold Hibbert Memorial Fellow, 1967–1968.

[4]This glycoside, which is one of the most reactive substrates of D-galactose oxidase (3), proved to be more satisfactory in some respects than D-galactose itself. However, the stereochemistry of the reaction with D-galactose was found to be the same, as shown below.

[5]An attempt to achieve stereospecific deuteration by reduction with yeast (15) was unsuccessful: although the yeast culture rapidly reduced benzaldehyde, it had no noticeable effect on the deuterated *aldehydo* sugar derivative **4***b*.

Erratum: Stereochemistry of Dehydrogenation by *D*-Galactose Oxidase

A. MARADUFU, G. M. CREE, AND A. S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec

Received December 6, 1971
(Ref.: Can. J. Chem. **49**, 3429 (1971))

Canadian Journal of Chemistry, **50**, 768 (1972)

On p. 3429, right-hand column, lines 5 and 6, the numbers **2** and **3** should be interchanged, *i.e.* the lines should read:

"... upon the carbinol group as in **3**) and H_R, the *pro-R* hydrogen as in the *R* diastereomer **2**. From ..."

On. p. 3430, left-hand column, lines 10 and 11, Scheme 1 should read Scheme 2, *i.e.*:

"... configurational correlations illustrated on Scheme 2."

binol group corresponded to a mixture of 3.6 parts of the *R*-diastereomer and 1 part of the *S*-diastereomer; *i.e.*, 3.6 of **2**: 1 of **3**. In **1***b*, the distribution of isotope constituted a diastereoisomeric mixture of 1 part of (*R*)(**2**) to 3.0 parts of (*S*)(**3**). The stereochemistry of these reductions is considered further below.

These stereochemical descriptions of the C-6 chiral centers in **1***a* and *b* were obtained *via* the configurational correlations illustrated in Scheme 1.[6] D-Galactose-6-*d* (**5***a* or *b*), obtained in the course of synthesis of **1***a* or *b*, respectively, was degraded to D-threose-4-*d* by oxidation with lead tetraacetate (16) and the tetrose, then acetylated to give crystalline tri-*O*-acetyl-α-D-threofuranose-4-*d* (**6***a* or *b*) respectively. The absolute configuration at the 4-position of **6** was then deduced by reference to tri-*O*-acetyl-α-D-threofuranose-4-*d* (**6***c*) prepared from D-xylose-5-*d* of known absolute configuration (11). This latter sequence (Scheme 2) comprised *O*-benzoylation of 1,2-*O*-isopropylidene-α-D-xylofuranose-5-*d*, hydrolysis, lead tetraacetate oxidation of 3,5-di-*O*-benzoyl-D-xylofuranose-5-*d*, and finally, conversion of the latter to **6***c*. A comparison of the isotope distribution at C-4 of **6***a*, *b*, and *c* was readily carried out by measuring the relative intensities of the well-separated H-4 signals in the p.m.r. spectrum of each of these products (Fig. 1). This showed that **6***a* and *c* are virtually indistinguishable but strikingly different from **6***b*. Since the configuration at C-5 of the D-xylose-5-*d* utilized as a reference point is predominantly *R*[7] (11), it follows that the configuration of D-galactose-6-*d* (**5***a*) also is predominantly *R*, and hence **5***b* predominantly *S*, as indicated above.

Glycosides **1***a* and *b* having been characterized, they were then used as substrates for D-galactose oxidase. The 6-aldehydo products (**7***a* and *b*, respectively) of these oxidations were acetylated in pyridine, with concomitant β-elimination, which afforded the known (18) unsaturated aldehyde, *i.e.*, methyl 2,3-di-*O*-acetyl-α-L-*threo*-4-deoxy-hex-4-enodialdopyranoside-6-*d* (**8***a* and *b* respectively). Measurements of the residual 6-deuterium and 6-protium contents of **8** and its dinitrophenylhydrazone by mass spectrometry and p.m.r. spectroscopy concurred in showing that the enzymatic dehydrogenation of **1***a* had involved loss of 80% of a 6-hydrogen present originally, whereas in **1***b* 75% of the corresponding 6-hydrogen remained. That is, in both instances the results demonstrate a specific removal of the *pro-S* 6-hydrogen atom.

This same stereospecificity for D-galactose oxidase has been deduced by comparing oxidation rates for D-galactose, D-galactose-6-*d* (**5***a* and *b*), and D-galactose-6,6′-d_2 (Table 1). Firstly, the relative rates for D-galactose and the dideuterio compound show that the dehydrogenation is subject to a kinetic isotope effect of about 7.7. Accordingly, **5***a* and *b* show intermediate, and substantially different, oxidation rates that reflect the relative proportions of hydrogen and deuterium removed in the process. Moreover, there is good agreement between the observed rates and those calculated, indicating that there is no substantial secondary kinetic isotope effect. Since **5***b* experiences a slower rate than **5***a*, and possesses a correspondingly higher proportion of the *S*-diastereomer, these results also demonstrate that the oxidative attack on D-galactose

[6]It is assumed that in all of these reactions the new chiral centers generated within the primary carbinol group by deuteration are unaffected.

[7]D-Xylose-5-*d* prepared in the current (and also in an earlier (17)) study contains a slightly higher preponderance of the *R* diastereomer than does D-xylose-5-*d* described initially by Lemieux and Howard (11); the current procedure differs in using sodium borodeuteride – water in place of lithium aluminum deuteride – ether.

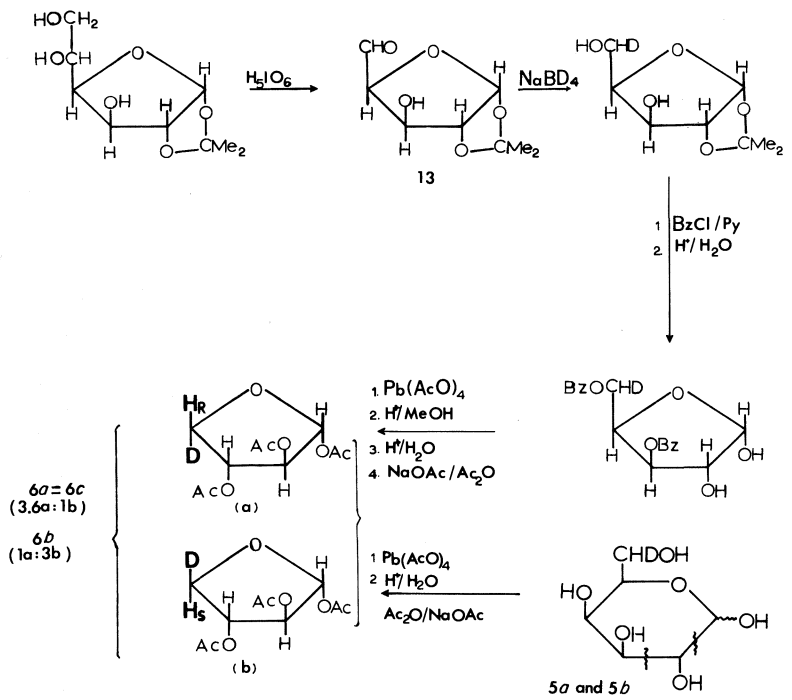

SCHEME 2. Sequence of reactions used in determining the absolute configuration of the 6-carbinol group in methyl β-D-galactopyranoside-6-*d* (**1***a* and *b*).

involves stereospecific abstraction of the *pro-S* 6-hydrogen atom.

Not only is the axial 4-hydroxyl group of D-galactose essential to the enzymatic oxidation, but substitution of its H atom (with methyl or glycosyl (5)) inhibits the reaction. By contrast, similar blocking of the 2- or 3-hydroxyl group has only a retarding effect on the rate, and modification at the 1-position influences rate even less. Evidence from the p.m.r. spectra of D-galactopyranose peracetates (19, 20) and spectral information provided below, suggests that a favored rotational conformation of the 6-carbinol group is one in which the *pro-S* hydrogen and the 4-hydroxyl group stand in a *cis*-1,3 relationship with respect to each other, as illustrated in **1**. It may be pertinent that in such an arrangement, the approaching enzyme would find the specificity-determining 4-hydroxyl group, the *pro-S* 6-hydrogen that is to be removed and the 6-hydroxyl group all in close spatial proximity to each other on the same face of the D-galactose substrate.[8] Perhaps an orientational relationship such as this accounts for the contrasting action of D-galactose oxidase with respect to ethanol dehydrogenase (from yeast (6) and liver (9)) or glycolic acid dehydrogenase (from plants (8)). That is, these latter enzymes remove H_R rather than H_S from the primary carbinol group.

Some information about how the 6-carbinol group of D-galactose derivatives is oriented has been deduced from H-5, H-6 coupling constants (19, 20): the two observed values of 7 and 5.5–6.0 Hz have been attributed to the *trans*–diaxial and *gauche* arrangements, respectively, of **9** or **10**. Rotamer **11** is unfavorable because it would involve eclipsing between OH-6 and axial OH-4 (19, 20). Examination of selectively deuterated acetates **1***a* and *b* at 220 MHz (Fig. 2) shows clearly that the larger spacing (7.2 Hz) arises from coupling between H-5 and H_S-6 (*i.e.*, as in **1** and **9**, though not as in **10**); at this higher frequency, the H-5, H_R-6 spacing is 6.3 Hz. These data may be interpreted most directly by assuming that in by far its most favorable orientation, the 6-carbinol group is close to **9** but rotated about 25° clockwise; which, incidentally, minimizes the O-4, H_S-6 eclipsing interaction, as found in **1**.

[8]However, no information is as yet available concerning the geometry of the active site of D-galactose oxidase, and the "favorableness" of such an arrangement of groups cannot be assessed.

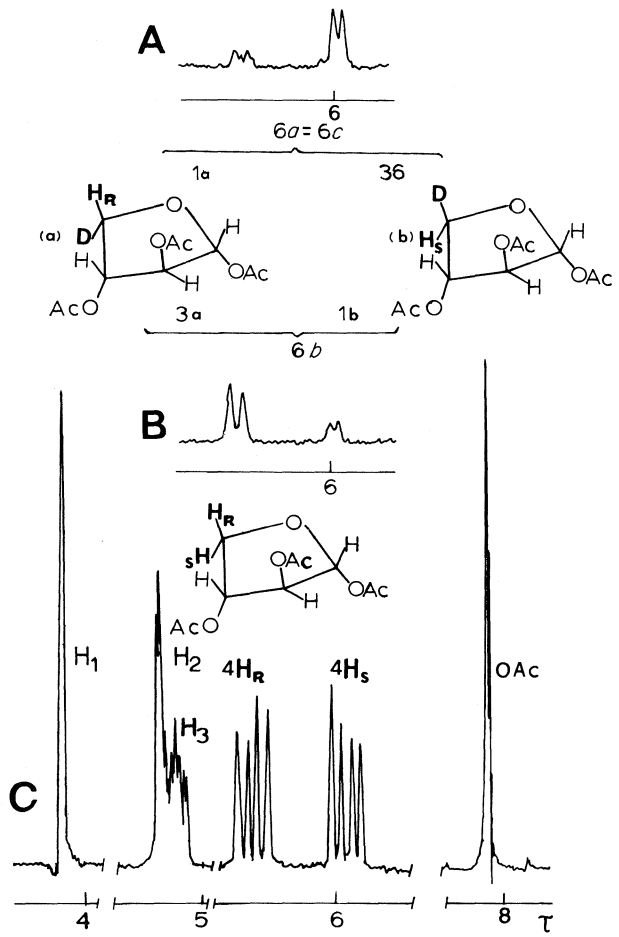

FIG. 1. The p.m.r. spectra at 100 MHz (in deuterochloroform), of 1,2,3-tri-*O*-acetyl-α-D-threofuranose and partially 4-deuterated specimens of this tetrose derivative (**6***a* and *b*); (*A*) H_4 signals of **6***a* and *c*, (*B*) H_4 signals of **6***b*, (*C*) the total spectrum of the undeuterated compound, with the acetoxyl proton signal (OAc) being recorded at about 2/3 relative intensity. The conformations depicted are taken to be approximately representative of the spectral information (unpublished results).

TABLE 1. Rates of oxidation of D-galactose and deuterated D-galactoses by D-galactose oxidase*

Substrate	Rate† (observed)	Contribution due to C—H	Contribution due to C—D	Rate (calculated)
D-Galactose	0.77	—	—	—
D-Galactose-6-*d* (3.6*R*:1*S*)	0.66	0.60	0.02	0.62
D-Galactose-6-*d* (1*R*:3*S*)	0.28	0.19	0.08	0.27
D-Galactose-6,6′-d_2	0.10	—	—	—

*Colorimetric assay at 420 nm (Experimental).
†Slope of the plot of optical density *vs.* reaction time from 2 to 12 min; during this initial period each plot was virtually a straight line.

According to the Karplus curve (21), the expected couplings then are $J_{5,6(S)}$ 7.5 and $J_{5,6(R)}$ 6.0 Hz, which are close to the splittings observed. Nevertheless, it is reasonable to expect that a mixed population of rotamers exists, in which energy differences are relatively small. In this event, the large coupling shown to take place between H-5 and H_S-6 indicates that **9** should be an important contributor to the rotational itinerary.

The stereochemistry of hydride reduction of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

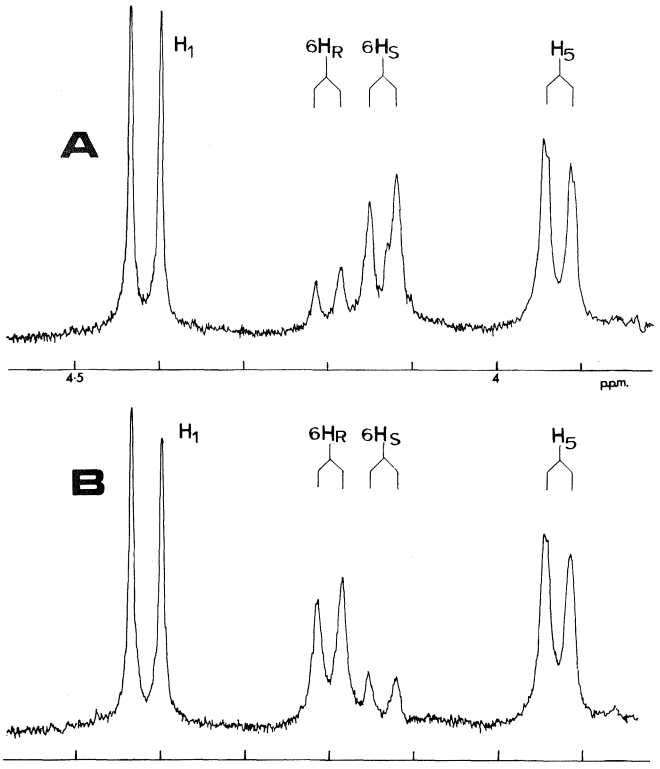

FIG. 2. Partial p.m.r. spectrum at 220 MHz (in deuterochloroform) of methyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside-6-*d* (**1***a* (*A*) and *b* (*B*)).

6-*aldehydo* compound **4** merits comment. A predominance of the *R* carbinol product, as found, is accounted for most readily by a topology in which the hydride ion approaches from the least hindered, *re*-face (12, 22–24), and by assuming (24, 25) that the stereochemistry of the starting material and product are closely similar. According to the p.m.r. spectrum of **4**, which shows that H-6 is not coupled with H-5, the C=O group appears to be oriented preferably *gauche* with respect to the C_4—C_5 bond (as in **12**); this deviates somewhat from the Karabatsos model (24) in which the C=O group would be eclipsed with one of the C-5 substituents. From the alternative possibility, *i.e.*, C=O *gauche* with respect to the C_5—O_5 bond, a predominantly *S* carbinol should be formed, contrary to the result obtained. Conceivably, however, O-5 might participate in stabilizing the transition complex, as in the "cyclic model" of Cram *et al.* (22, 23), but then could lead to a predominantly *R* product only if attack from the *more* hindered *si*-face were facilitated in the complex. The slightly lower

degree of stereoselectivity in the reduction of **4***b* than of **4***a* is attributable possibly to a slower transfer of a deuteride (26, 27), than of a hydride, anion with a concomitant increase in 'the randomness of the reaction. Reduction of the 5-*aldehydo* pentose derivative **13** with aqueous borohydride presumably involves a topology similar to that for **4**, because of the similar diastereomeric makeup of both products, despite the fact that **13** exists as a *gem* diol (in deuterium oxide (17)). More directly comparable with **4** as an *aldehydo* compound is the 3-*O*-benzyl derivative of **13** which, when reduced with lithium aluminum deuteride, also gives rise predominantly to the corresponding *R* carbinol (11), as already noted.

Experimental

Melting points were taken with a Fisher–Johns hot-plate apparatus and are uncorrected. The i.r. spectra were recorded using KBr discs or in solution with a Unicam Sp-200 G spectrometer. Electronic spectra were recorded with a Unicam Ultraviolet spectrometer. Mass spectra were recorded with a double-focusing AEI spectrometer; the energy of ionization was 70 eV. The n.m.r. spectra were recorded with a Varian 100 MHz HA-100 spectrometer using an internal TMS lock signal, or a Varian A60 spectrometer. Spectra at 220 MHz were provided by the Canadian 220 MHz NMR Centre, Sheridan Park, Ontario.

Column chromatography was performed using cellulose powder for aqueous systems and silica gel (Macherey, Nagel and Co.) for non-aqueous systems. The t.l.c. plates were prepared from silica gel G according to Stahl and were dried in a 100 °C oven for 1 h, and cooled in a vacuum desiccator. Descending chromatography on Whatman No. 1 was used for all paper chromatography work; reducing sugars were detected with silver nitrate (28) or with aniline oxalate (29). Solvents for paper chromatograms were butanol:ethanol:water (4:1:5 upper layer) (28) or *n*-propanol:acetic acid:water (6:1:2) (3), unless otherwise specified. Visualization of t.l.c. plates was effected with 5% concentrated sulfuric acid in ethanol or 2,4-dinitrophenylhydrazine in phosphoric acid and ethanol; with both reagents, carbohydrates and derivatives showed up as dark spots on a lighter background; α, β-unsaturated aldehydes and benzoates were also visualized with a u.v. lamp.

*1,2:3,4-Di-O-isopropylidene-α-D-galactohexodialdose-1,5-pyranose (**4a**)*

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose (prepared by de-*O*-acetylation of the crystalline 6-acetate, m.p. 109–110° (30)) was oxidized with methyl sulfoxide in the presence of triethylamine – sulfur trioxide as described previously (14). The diketal (1.5 g) was dissolved in methylsulfoxide (10 ml), triethylamine (3 ml) was then added, followed by a solution of sulfur trioxide – pyridine (2.8 g) in methylsulfoxide (10 ml). On shaking, the mixture rapidly became warm and darkened (reaction was complete within a few minutes, as indicated by t.l.c.) (benzene:ether (1:1)). It was then cooled in acetone–CO_2 and slowly diluted with chloroform (200 ml), then washed successively with 2 *N* hydrochloric acid, water, dilute sodium bicarbonate, water (2 ×). The dried chloroform solution was concentrated to a syrup (1.0 g), which was chromatographed on a column of silica gel with benzene:ether (1:1) as eluant to separate the aldehyde **4** (1.0 g) from a small amount (50 mg) of accompanying 1,2:3,4-di-*O*-isopropylidene-6-*O*-(methylthio)-methyl-α-D-galactopyranose.

6-O-Acetyl-1,2:3,4-di-O-isopropylidene-α-D-galactopyranose-6-d (3.6 R : 1 S)

To a stirred solution of 1,2:3,4-di-*O*-isopropylidene-α-D-galactohexodialdose-1,5-pyranose (**4***a*) (1.0 g) in ice-cold ethanol:water (1:1(15 ml), a solution of sodium borodeuteride (0.2 g) in ice water (5 ml) was slowly added, and stirring was continued for 30 min (reduction complete as shown by t.l.c.). Excess of Amberlite IR-120 resin was added, the solution was evaporated to dryness, and boric acid was removed by repeatedly dissolving the residue in methanol, followed by concentration to dryness. The reduction product (0.9 g) was acetylated with acetic anhydride (2.5 ml) in pyridine (5 ml), affording crystalline 6-*O*-acetyl-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose-6-*d* (0.7 g); m.p. 107–108°.

*Methyl β-D-Galactopyranoside-6-d (**1a**)*

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose-6-*d* (prepared from the above 6-acetate) (1.0 g) was dissolved in 0.1 *N* sulfuric acid (40 ml), the solution was heated at 95° for 45 min, cooled, and neutralized with barium carbonate. Filtration was facilitated by use of Celite, the filtrate was treated with Amberlite IR-120 resin, then concentrated, and the residue was crystallized with cold methanol; yield of α-D-galactose-6-*d* (**5***a*) 0.5 g, m.p. 164–166°. The sugar (1.0 g) was converted successively by well-established procedures (31–33) to 1,2,3,4-6-penta-*O*-acetyl-β-D-galactopyranose-6-*d*, 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl-6-*d*-bromide, methyl tetra-*O*-acetyl-α-D-galactopyranoside-6-*d* and, finally, to methyl β-D-galactopyranoside-6-*d* (**1***a*) m.p. 176–177° (0.3 g).

6-O-Acetyl-1,2:3,4-di-O-isopropylidene-α-D-galactopyranose-6,6′-d_2

1,2:3,4-Di-*O*-isopropylidene-α-D-galacturonic acid (34) (m.p. 158.5–159.5°) was converted to the methyl ester with diazomethane. The ester (7.5 g) in ether (100 ml) was reduced with lithium aluminum deuteride (1.0 g) dissolved in ether (150 ml), the deuteride being added over a period of 30 min with good stirring and under gentle reflux. Ethyl acetate (2 ml) and water (50 ml) were added in succession, followed by acidification with 2 *N* hydrochloric acid and dilution with water (100 ml). The aqueous layer was extracted with chloroform, and the combined chloroform and ether solutions (after washings with sodium bicarbonate and water) were dried and concentrated. Acetylation of the residue (6.1 g), as above, afforded 6-*O*-acetyl-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose-6,6′-d_2 (6.5 g), m.p. 110°.

*Methyl β-D-Galactopyranoside-6-d (**1b**)*

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose-6,6′-d_2 (5.2 g) (prepared from the 6-acetate, previous section) was oxidized to the 6-deuterio dialdose (**4***b*) as

described for **4***a* above;[9] yield, 4.0 g. This syrupy aldehyde, in ethanol:water (1:1)(30 ml) was reduced at 10° with sodium borohydride (0.4 g), the product was purified by chromatography on silica gel (benzene:ether (1:1) as eluant) (yield, 2.8 g), and then acetylated with acetic anhydride – pyridine to give 6-*O*-acetyl-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose-6-*d*; m.p. 109–110°. The latter was deacetylated and hydrolyzed, and the D-galactose-6-*d* (**5***b*) (0.9 g) obtained was converted via the acetobromo derivative, as described above, to methyl β-D-galactopyranoside-6-*d* (**1***b*) (0.3 g); m.p. 167°.

*1,2,3-Tri-O-acetyl-α-D-threofuranose-4-d (**6***a and b)*

D-Galactopyranose-6-*d* (**5***a* or *b*) was oxidized in acetic acid solution with 2 mol of lead tetraacetate per mole (16). The syrupy formate ester obtained was hydrolyzed, and the product acetylated with acetic anhydride – sodium acetate, yielding 1,2,3-tri-*O*-acetyl-α-D-threofuranose-4-*d* (**6***a*, m.p. 120–121°, $[\alpha]_D$ +35° ($CHCl_3$); or **6***b*, m.p, 120–121°, $[\alpha]_D$ +37° ($CHCl_3$)).

*1,2,3-Tri-O-acetyl-α-D-threofuranose-4-d (**6***c)*

1,2-*O*-Isopropylidene-α-D-xylofuranose-5-*d* (17) (6.0 g) was converted to 3,5-di-*O*-benzoyl-D-xylofuranose-5-*d*, using conditions for benzoylation and partial hydrolysis described by Baker and Schaub (35). The syrupy dibenzoate obtained (5.6 g), dissolved in acetic acid (300 ml), was oxidized for 1 h with a solution of lead tetraacetate (8.5 g) in acetic acid (250 ml), and after removal of most of the solvent the product was extracted into benzene; yield, 4.5 g of syrup. Methanolysis of this syrup was effected with methanol (200 ml) containing acetyl chloride (1.6 ml), under reflux for 18 h, the solution was neutralized with silver carbonate, concentrated, and the product was hydrolyzed with 0.1 *N* sulfuric acid (30 ml) at 95° for 1 h. The hydrolysate, after neutralization with barium carbonate and Amberlite IR-120 resin, was found by chromatography to consist mainly of threose; a small proportion of xylose was detected, as well as some other minor, unidentified, components. By column chromatography on cellulose (eluant: one-quarter saturated butanol), the threose was separated out (0.3 g) and then was acetylated to yield, finally, 1,2,3-tri-*O*-acetyl-α-D-threofuranose-4-*d* (**6***c*); m.p. 118–120°.

*Oxidation of Methyl β-D-Galactopyranoside-6-d (**1***a and b) with D-Galactose Oxidase*

In a typical experiment, the substrate (40 mg) was dissolved in phosphate buffer (4 ml; 0.2 *M*, p*H* 7.0) and incubated with D-galactose oxidase (5 mg, 125 units) and catalase (5 mg) at 37 °C for 3 h (t.l.c examination showed the presence of a major product (R_f 0.63 as compared with R_f 0.47 for the intact glycoside), and two minor products (R_f 0.75 and 0.46, respectively)). A mixture of Amberlite IR-120 (H^+) and Dowex-1 (bicarbonate) was added to the digest with stirring, the suspension was filtered, the filtrate concentrated, and then lyophilized. The product (36 mg) was treated with pyridine (0.8 ml) and acetic anhydride (0.4 ml) at room temperature for 18 h, the reaction mixture was concentrated, and the syrupy residue chromatographed on a column of silica gel (eluant, benzene:ether (9:1)). This afforded methyl 2,3-di-*O*-acetyl-α-L-*threo*-4-deoxy-hex-4-enodialdopyranoside (**8***a* or *b*)[10] (10 mg) followed by methyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside (3 mg from the undeuterated glycoside; 7 mg from **1***a*; 12 mg from **1***b*). The subsequent use of benzene:ether (1:4) caused elution of a third component which has been characterized (unpublished results), as a dimer originating from the aldehydic oxidation product having R_f 0.46.

2,4-Dinitrophenylhydrazone of Methyl 2,3-Di-O-acetyl-α-L-threo-4-deoxyhex-4-enodialdopyranoside

The α,β-unsaturated aldehyde (10 mg) was dissolved in ether (0.5 ml) and to this solution was added 2,4-dinitrophenylhydrazine (0.1 *M* in phosphoric acid – ethanol (36) (3–4 drops). Orange–yellow crystals which soon formed on standing, were washed with ethanol and ether; m.p. 148–152°, undepressed on admixture with a specimen prepared from an authentic sample of the α,β-unsaturated aldehyde (18). The n.m.r. and mass spectra of the two hydrazones were indistinguishable. A higher melting form of this hydrazone (m.p. 167°) which, however, is indistinguishable from the current product by n.m.r. and mass spectrometry also has been obtained (18).

Measurement of Reaction Rates for D-Galactose Oxidase

Kinetic measurements were carried out using "Galactostat" (Worthington). The "Galactostat" solution consisted of D-galactose oxidase (20 units), peroxidase (2.5 mg), and the chromogen *o*-tolidene (2.5 mg) in 0.01 *M* phosphate buffer (50 ml; p*H* 7.0). Two milliliters of this solution were added to the substrate (*ca.* 50 mg in 2 ml of water), the reaction mixture was incubated at 37 °C and absorbance was monitored at 420 nm with a Gilford automatic recording spectrophotometer. In some experiments the absorbance at a given time was checked after stopping the reaction by addition of glycine buffer (6 ml; 0.25 *M*, p*H* 9.7).

The authors gratefully acknowledge the generous financial support of the Pulp and Paper Research Institute of Canada and the National Research Council of Canada. The p.m.r. spectra at 100 MHz were kindly recorded by Dr. H. J. Koch and R. Simoneau, and the 220 MHz spectra by Dr. A. Grey at the Canadian 220 MHz NMR Centre, Sheridan Park, Ontario.

[9]In this reaction the proportion of 6-*O*-methylthiomethyl ether was much higher (almost 1/4) than in the oxidation of the undeuterated carbinol.

[10]Examination of the reaction mixture prior to acetylation showed that most of this product is formed during the acetylation procedure. The minor product having R_f 0.75 (above) is, in fact, the corresponding, unacetylated, α,β-unsaturated aldehyde (unpublished results).

Effect of Solvent Upon the Vicinal Proton Coupling Constants of Complex Substituted Ethanes. III. 1,2-Dihaloalkanes

D. A. DAWSON[1] AND W. F. REYNOLDS
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 20, 1970[2]

The n.m.r. spectra of eight 1,2-dihaloalkanes have been determined in solvents of differing polarity. The relative rotamer stabilities for each compound have been deduced from the variation of the difference and sum of vicinal coupling constants with solvent. Variations in geminal and long range coupling constants with solvent are also attributed to conformational changes.

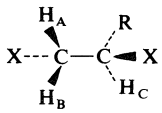
Les spectres de r.m.n. de huit dihalogéno-1,2 alkanes ont été déterminés dans des solvants de polarité différente. Les stabilités relatives des rotamères de chaque composé ont été déterminées en fonction des variations de la différence et de la somme des constantes de couplage vicinale selon le solvant. Les variations, selon le solvant, des constantes de couplage geminale et à longue distance sont également attribuables aux modifications conformationnelles.

Canadian Journal of Chemistry, 49, 3438 (1971)

Introduction

Abraham and co-workers have developed an electrostatic theory which allows one to predict energy differences, ΔE, between rotational isomers (rotamers) of substituted ethanes with two or more polar substituents in media of different dielectric constants, ε (1–3). This theory has been successfully applied to the investigation of a number of simple substituted ethanes in which two of the three rotamers are degenerate in energy (4).

We have been interested in the determination of ΔE values for tri-substituted ethanes of type **1**



1

where X is a polar group and R is non-polar (5). In these compounds, all three rotamers have different energies. In principle, it is possible to determine ΔE values from the variation of vicinal coupling constants with ε (3). In practice, this is impossible for this system since there are eight unknowns (two ΔE values and six non-equivalent coupling constants) to be determined from the variation of two (averaged) coupling constants with solvent.

An alternative, more qualitative, approach has been described which allows one to determine relative rotamer energy levels for **1** from the variation of vicinal coupling constants with solvent (5). If rotamer 1 is more stable than rotamer 2 (see Fig. 1), then $J_{AC} > J_{BC}$ and $|J_{AC} - J_{BC}|$ decreases with increasing ε while if $E_1 > E_2, J_{BC} > J_{AC}$ and $|J_{AC} - J_{BC}|$ increases with increasing ε. Therefore, the sign of ΔE_{2-1} can be determined from the variation of $|J_{AC} - J_{BC}|$ with ε. Rotamer 3 is generally less stable than the other two since it has the maximum steric interaction. Any increase in the fractional population, p_3, of rotamer 3 with ε should lead to a decrease in $J_{AC} + J_{BC}$. However, if $E_3 \gg E_1, E_2; p_3 \approx 0$, and $J_{AC} + J_{BC}$ will remain essentially constant. Assumptions involved in this approach have been previously discussed (5). The fundamental assumption that more polar rotamers will be relatively stabilized in solutions of higher ε appears to hold for all of the dihaloethane derivatives which have been investigated (4, 5), provided that aromatic (2, 5,

*Long-range coupling to the methine proton split A and B protons into very poorly resolved doublets. Corrected r.m.s. values were obtained by treating both experimental and computer-generated peak positions as singlets.

6) or hydroxylic (2) solvents are avoided. However, the assumption may not hold in systems where strong specific hydrogen bonding can occur (7, 8). Consequently, these systems should be avoided.

It has been concluded that it should be possible to determine relative rotamer stabilities for a series of closely related compounds of type **1**, using this approach (5). In order to test this conclusion, we have determined the n.m.r. spectra of a series of eight 1,2-dihaloalkanes (X = Cl, Br; R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$)in different solvents.

Experimental

1,2-dihalopropanes were obtained commercially. Other 1,2-dihaloalkanes were prepared by the halogenation of the appropriate olefins. All reactions were carried out in CCl_4 in the dark. Products were fractionally distilled before use and purities were checked by n.m.r. spectroscopy. Compounds were dissolved in freshly distilled ACS grade solvents with 5% tetramethylsilane added as lock and reference signal. Solutions of 1,2-dihalopropanes and butanes were degassed and sealed under vacuum before use. Other samples were not degassed since their spectra contained less fine structure. Spectra were recorded on a Varian HA-100 spectrometer operated in frequency sweep mode at a sweep rate of 0.01–0.05 Hz/s. Calibration procedures were identical to those previously reported (5).

Results

1,2-dibromo- and 1,2-dichloro-3,3-dimethylbutane (R = *t*-butyl) gave ABC spectra with negligible coupling to the *t*-butyl group. Spectra were analyzed using the exact method (9). Results are given in Table 1.

The computer programs which were available

to us did not allow total spectral analysis for 1,2-dihalo-3-methylbutanes (R = isopropyl) and 1,2-dihalobutanes (R = ethyl). The spectra of the first two compounds were analyzed as ABCD spectra, using the iterative computer program LAOCN3 (10). Only a chemical shift was assigned for D (the methine proton of the isopropyl group), based upon the weight average position of the D multiplet. Calculated coupling constants were completely insensitive to minor (10 Hz) variations in ν_D since the spectra were close to the ABCX limit ($\nu_C - \nu_D/J_{CD} \approx 70$). Results are given in Table 2. The spectra of the 1,2-dihalobutanes were analyzed as ABCDE spectra using a similar approach (spectra were nearly ABCXY). Results are given in Table 3. 1,2-Dichlorobutane was only run in CCl_4 since in polar solvents, $\nu_A - \nu_B \approx 0$, making it impossible to determine J_{AC} and J_{BC} accurately.

1,2-Dihalopropanes gave $ABCD_3$ spectra which were analyzed using LAOCN3. Signs of long-range coupling constants were determined by spin-tickling experiments, using standard techniques (11). Results are given in Table 4.

Only coupling constant data are presented. Chemical shift data have been deposited in the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Canada, K1A 0R6.

Discussion

(A) Vicinal Coupling Constants

The difference in vicinal coupling constants increases with increasing ε for 1,2-dibromo- and 1,2-dichloro-3,3-dimethylbutane.[3] This establishes that rotamer 2 is more stable than rotamer 1 in both compounds and that the larger coupling constant is J_{BC}. In both cases, $J_{AC} + J_{BC}$ remains constant, indicating $p_3 \approx 0$. Consequently, the order of energy levels is $E_3 \gg E_1 > E_2$. The similar values of J_{AC} and J_{BC} suggest that there is little difference in conformational preference between the two compounds.

This energy level order corresponds to that deduced by Buza and Snyder (12) from the vicinal coupling constant of a specifically deuterated derivative of the dibromo compound. The coupling constants of both compounds in CCl_4 are in good agreement with those reported by Jackman and Kelly (13). Finally, Altona and Hageman concluded (from dipole moment measurements) that for the dibromo compound, p_2 is 0.73 in CCl_4 and 0.83 in C_6H_6 and that $p_3 \approx 0$ in both solvents (6). Assuming reasonable values of J_{trans}(rotamer 2) = 11.5 and J_{gauche}(rotamer 1) = 2.0 Hz (based upon low temperature n.m.r. measurements (14)) and $p_3 = 0$, our values of 9.11 and 9.65 Hz for J_{BC} in CCl_4 and C_6H_6 correspond to $p_2 = 0.75$ and 0.81 respectively, in good agreement with previous results (6).

For the remaining compounds which were run in two or more solvents, $|J_{AC} - J_{BC}|$ decreased with increasing ε, establishing that $E_2 > E_1$ and $J_{AC} > J_{BC}$. $J_{AC} + J_{BC}$ decreased in all cases, implying that p_3 is not negligible in these compounds. $J_{AC} + J_{BC}$ is smallest and most solvent sensitive for 1,2-dichloropropane. Therefore, we believe that p_3 is greater in this compound than in any of the other compounds investigated. Since rotamer 3 is known to be the least stable rotamer for 1,2-dichloropropane in both the gas phase and the neat liquid (15), we conclude that in all of the six methyl, ethyl, and isopropyl derivatives the energy level order is $E_3 > E_2 > E_1$.

In these six compounds, $J_{AC} - J_{BC}$ is larger for the dibromo compounds than for the dichloro compounds. While this might in part reflect the effect of electronegativity upon vicinal coupling constants (16), we believe that the differences are primarily due to changes in conformational preference. Rotamer 2 should be relatively less stable in the dibromo compounds because of greater

[3]Results in C_6H_6 suggest an increased stabilization of polar rotamers beyond that expected from ε. Similar "benzene effects" have been noted in previous investigations (2, 5, 6).

halogen–halogen steric interactions, resulting in an increase in p_1 and $J_{AC} - J_{BC}$. This contrasts with the behavior when R = *t*-butyl where no difference in conformational preference was noted. In the latter case, *t*-butyl – halogen steric interactions are presumably much larger than halogen–halogen steric interactions. Consequently, a decrease in halogen size should decrease both steric interactions to a similar extent.

There are much smaller changes in $J_{AC} - J_{BC}$ when R is changed from methyl to isopropyl, but the changes do occur in a regular manner. For example, for the dibromo derivatives in CCl_4, $J_{AC} - J_{BC}$ is 6.83, 6.57 and 6.41 Hz for methyl, ethyl, and isopropyl derivatives respectively. It seems reasonable to attribute these differences to changes in rotamer populations since the electronic effects of the alkyl substituents should be similar. A decrease in $J_{AC} - J_{BC}$ corresponds to a decrease in p_1, which can be attributed to increased alkyl–halogen repulsions in rotamer 1. The changes are small, however, reflecting the ability of ethyl and isopropyl groups to minimize steric interactions by adopting their most favorable conformations, *i.e.* with the methyl group(s) rotated away from the halogen.

Our energy level order is consistent with previous results for 1,2-dibromo- and 1,2-dichloropropane (15, 17). Coupling constants for these compounds differ by an amount greater than the experimental error from those reported by Finegold (17), probably because the latter measurements were made at higher concentrations. Little data is available for the other compounds.

(B) Geminal and Long-range Coupling Constants

Geminal coupling constants vary with substituent within a given series. For example, for the dibromo series in CCl_4, J_{AB} is respectively -9.92, -10.16, -10.33, and -11.37 Hz for methyl, ethyl, isopropyl, and *t*-butyl derivatives. J_{AB} is also solvent dependent. Changes in J_{AB} with R substituent and solvent closely parallel the corresponding changes in vicinal coupling constants, even to the extent of showing anomalous results for C_6H_6. This strongly suggests that the changes in J_{AB} discussed above are primarily due to conformational changes, although the variation of J_{AB} with solvent could be partly due to reaction field effects (18). The results suggest that J_{AB} is significantly more negative in rotamer 2 than rotamer 1, since p_2 should increase at the expense of p_1 as the size of R or ε increases. The difference in J_{AB} for the two *t*-butyl derivatives may reflect electronegativity effects.

The long range coupling constants in 1,2-dihalopropanes are similar to those previously reported (17). Changes in J_{AD} and J_{BD} with solvent also appear to reflect conformational changes, assuming that the long-range coupling constant to the methyl group is positive when the methyl group is *trans* to a methylene proton and negative when it is in a *gauche* orientation.

Conclusions

The effect of solvent upon the sum and difference of vicinal coupling constants in compounds of type **1** can be used to determine the order of rotamer energies. It is also possible to deduce changes in conformational preference within a series of compounds of type **1**, provided that the electronic effects of substituents do not change markedly from compound to compound.

Reactions of Carbonyl Ylides

J. W. Lown and K. Matsumoto[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received June 22, 1971

2,3-Diphenylindenone oxide **1** undergoes thermal 1,3-dipolar cycloadditions via a carbonyl ylide with symmetrical olefinic dipolarophiles to give (*i*) with *cis* addends mixtures of *endo* and *exo* adducts in which *endo* adducts generally predominate in agreement with results obtained with 1-cyclohexyl-6-(cyclohexylimino)-1*a*-phenylindano[1,2-*b*]aziridine and (*ii*) with *trans* addends adducts in which the 2-*exo*-3-*endo* product predominates. The pyrilium oxide **4** is efficiently trapped with benzyne. 1,3-Diphenylisobenzofuran reacts with *cis*-addends to give *endo–exo* mixtures in which the *endo* adducts generally predominate. 2-Acetyl-5,5-pentamethylene-2-phenyl-Δ^3-1,3,4-oxadiazoline undergoes regiospecific cycloaddition via a carbonyl ylide with unsymmetrical olefinic dipolarophiles in accordance with substituent electronic effects, and with 1,4-naphthoquinone a previously postulated type of intermediate adduct is isolated.

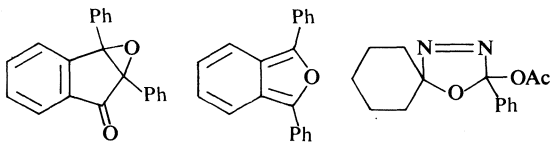
L'oxyde de diphénylindenone-2,3 **1** peut réagir pour donner des cycloadditions dipolaires-1,3 thermiques, par l'intermédiaire d'une ylure de carbonyle possédant des dipolarophiles oléfiniques symétriques. On obtient ainsi (*i*) avec des mélanges *endo* et *exo* des produits *cis*, des produits d'addition où la forme *endo* prédomine habituellement, en accord avec les résultats obtenus avec le cyclohexyl-1 (cyclohexylimino)-6 phénylindano-1*a* aziridine[1,2-*b*] et (*ii*) avec les produits *trans*, des produits d'addition où la forme *exo*-2-*endo*-3 prédomine. L'oxyde de pyrilium **4** peut être recueilli efficacement dans le benzène. Le diphénylisobenzofuranne réagit avec les produits *cis* pour donner des mélanges *endo–exo*, où les produits d'addition *endo* prédominent généralement. Le 2-acétyl-5,5 pentamethylène-2 phényl-Δ^3-1,3,4-oxadiazoline peut réagir pour donner des cycloadditions régiospécifiques, via une ylure de carbonyle possédant des dipolarophiles oléfiniques non-symétriques, selon les effets électroniques du substituant; avec la naphthoquinone-1,4, on isole un produit d'addition intermédiaire postulé précédemment.

Canadian Journal of Chemistry, **49**, 3443 (1971)

Introduction

Examination of the orbital symmetry controlled generation of azomethine ylides from aziridines and exploration of their synthetic potential via 1,3-dipolar cycloaddition to a wide variety of multiple and heteromultiple bonds has recently proved extremely fruitful (1–18). The isoelectronic carbonyl ylides which are of equal importance have not received as much attention (19–29). Strong evidence has been obtained for the predicted (30) thermal conrotatory (27) and the photochemical disrotatory (26, 27) opening of suitable oxirane precursors to carbonyl ylides. We report an examination of the cycloaddition reactions of certain carbonyl ylides with reference to their stereochemistry, regiospecificity (31), steric, and electronic requirements.

The model compounds chosen as carbonyl ylide precursors were **1**, **2**, and **3**, affording an opportunity to examine these dipoles under as wide a range of reaction conditions as possible. The thermally induced tautomerization of **1** to **4** was reported by Ullmann and Milks (22) and



1 **2** **3**

species **4** was shown to react as a carbonyl ylide in 1,3-dipolar cycloaddition to give, with norbornadiene, an adduct which was assigned the *exo* structure **5**.

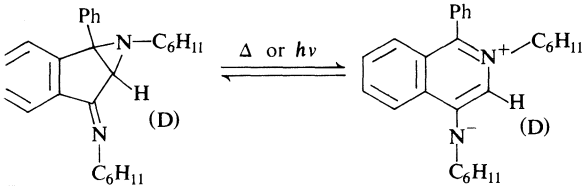
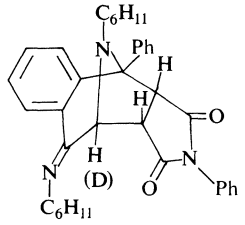
The isoelectronic 1-cyclohexyl-6(cyclohexylimino)-1*a*-phenylindano[1,2-*b*]aziridine (**6**) was recently shown by Lown and Matsumoto (32) to undergo valence tautomerization both thermally and photochemically to the isoquinolinium imine **7**. The azomethine ylide species **7**



6 **7**

was trapped efficiently by olefinic dipolarophiles to give exclusively *endo* adducts, *e.g.* **8**. The

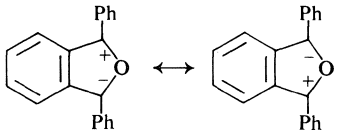


8

diametrically opposed configurational results obtained with **1** and **6** posed the questions of (*i*) whether this reflected a fundamental difference in properties of the apparently similar species of carbonyl ylides and azomethine ylides or whether (*ii*) other factors operating in **7** (*e.g.* steric hindrance from the *N*-substituent) accounted for the differences observed. However since identical results, *i.e.* exclusively *endo* adducts, are obtained with N—CH_3 analogs of **6** the problem required further investigation. Also in view of the controversy attending the mechanism of the Diels–Alder reaction it was of interest to determine if a trend towards general *endo* adduction also obtains in the related 1,3-dipolar cycloaddition reaction.

Results and Structural Assignments

Unlike the situation with **6**, wherein specific deuterium labelling allowed an unambiguous assignment of configuration by examination of the n.m.r. coupling constants (33) a similar method could not be applied to the adducts of **1**. Although diphenylisobenzofuran is normally regarded as a diene, contribution of resonance forms such as those shown below allow one to regard it as a



masked carbonyl ylide (28). Accordingly several 1,3-dipolar cycloaddition adducts were prepared in parallel from **1** and **2** for comparison and to aid in the n.m.r. assignments. The cycloaddition of dienophiles to **2** has been observed to give predominantly *endo*-adduction with pyracyclo-quinone and pyracyclene (33); *exo*-addition with cyclopropene (34), norbornadiene and norbornene (35), and predominantly *exo*-addition with chlorocyclopropene (36). In the latter case, which has been substantiated by Battiste and Sprouse (34), *endo* protons in the adducts were shielded by the benzene ring relative to the *exo* protons which is consistent with n.m.r. observations in other similar bicyclic adducts (37). The stereochemistry of the adducts of **2** have been assigned on this basis.

A number of other relationships became apparent upon examining the n.m.r. spectra of many adducts of **1** and **2**.

(*1*) For adducts of **2**: (protons) δ *exo* > *endo*; and (methylester) δ *endo* > δ *exo*.

(*2*) For adducts of **1**: (*i*) *J cis* (2-*exo*-3-*exo*) > *J cis* (2-*endo*-3-*endo*); (*ii*) *J trans* (2 *endo*-3-*exo*) > *J trans* (2 *exo*-3-*endo*); (*iii*) from protons, δ 3-*exo* > δ 3-*endo*; δ 2-*exo* > δ 2-*endo*; (*iv*) For *trans* adducts of **1**, Δ(δ 2-*endo*-3-*exo*) > Δ(δ 2-*exo*-3-*endo*) (see Table 3).

While these observations are empirical they serve as a check for internal consistency in the stereochemical assignment.

To obtain an accurate determination of isomeric proportion in the products, n.m.r. spectra were taken on the initially obtained mixtures before attempted purification.

Reaction of **2** separately with *cis*- and *trans*-1,2-dichloroethylene gave one adduct in each case, the product of the former being assigned the *endo* structure **9***a*. Similarly only one adduct **10***a* was obtained upon addition of *cis*-1,2-dichloroethylene with **1**.

Addition of *trans*-1,2-dichloroethylene afforded an isomeric mixture of **10***b* and *c* in the ratio of 1:4 in which the 2-*exo*-3-*endo* product predominates. Comparison of the methine proton chemical shifts and coupling constants with those of **9***a* and *b* allows assignments to be made and shows no evidence of epimerization indicating

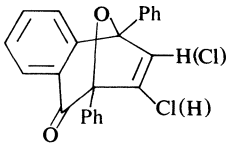
stereospecific cycloadditions. The *cis*-configuration of **10***a* was confirmed by the facile *trans*-elimination of hydrogen chloride upon recrystallization to give **11** in which the direction of elimination is not determined. Compounds **10***b* and *c* in contrast were quite stable to heating and showed no tendency to eliminate hydrogen chloride.



11

Diphenylisobenzofuran **2** reacted with acenaphthylene to give an isomeric mixture of the *endo* and *exo* adducts **9***c* and *d* in the ratio of 3:1. Trost recently reported reaction of **2** with the closely analogous pyracycloquinone to give an *endo*:*exo* ratio of 3:1 (33). The *exo* methine protons in the latter case resonate at δ 5.42 closely comparable with the analogous protons in **9***c* at 5.12, supporting the structural assignments. The indenone oxide **1** afforded with acenaphthylene a mixture of the analogous adducts **10***d* and *e* in the *endo*:*exo* proportion of 3:2 suggesting **2** is a good analog of **1**.

Vinylene carbonate adds to **2** to form adducts in which the ratio of the *endo* to *exo*–*cis* adducts **9***e* to *f* is 6:1. The indenone oxide similarly affords the *endo* and *exo* adducts **10***f* and *g* in a ratio of 3:1.

Exclusive formation of the endo adducts of **1** was observed with maleic anhydride **10***h* and with *N*-phenylmaleimide **10***i*.

In the addition of **1** to dimethyl maleate and dimethyl fumarate all four possible stereoisomeric adducts were observed allowing a closer comparison of chemical shifts, coupling constants, and the steric requirements of the cycloadditions. With dimethyl fumarate for example two isomeric adducts **10***j* and *k* were obtained in a ratio of 3:1 and assigned by comparison with the single adduct **9***h* of unambiguous structure obtained from **2**. Similarly two isomeric adducts **10***l* and *m* in the proportion of 3.6:1 were obtained by reaction of **1** with dimethyl maleate.

The assignments of **10***l* and *m* were proven by mild acid hydrolysis of the *endo*-maleic anhydride adduct **10***h* to the *cis-endo*-diacid **12** (see Scheme 1). A single diacid was obtained indicating that epimerization had not occurred. Treatment of **12** with diazomethane in ether gave **10***m* in quantitative yield. Direct reaction of diazomethane in ether on **10***h* also gave **10***m* in quantitative yield.

trans-Stilbene afforded two isomeric adducts **10***n* and *o* in the ratio of 5:2. Similarly *trans*-1,2-dicyanoethylene gave rise to two isomeric adducts **10***p* and *q* in the ratio of 7:1 in which assignments were made by comparison with the

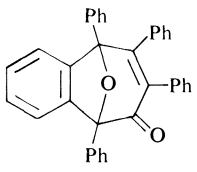
SCHEME 2

adduct **9***j* obtained from **1**. With very bulky groups like benzoyl on the addend one observes exclusive formation of the 2-*exo*-3-*endo* isomer as in **10***r* obtained from *trans*-dibenzoylethylene. *cis*-Stilbene gives rise to mixtures of *endo* and *exo* adducts **10***s* and *t* in the ratio of 2:3.

A result which parallels observations made with the indanoaziridine **6** (38) was that although commercial crotonitrile consists of a *cis–trans* mixture, reaction with both **1** and **2** gave exclusively *endo* adducts **10***u* and **9***l* respectively, corresponding only to addition of the *cis*-isomer in an *endo* direction. Comparison of the proton–proton coupling with those in the ABC analysis of the methine protons in the adduct **10***v* obtained from acrylonitrile, confirm the *cis* assignments in **10***u* and **9***l*.

In the reaction of **1** with diphenylcyclopro-



14

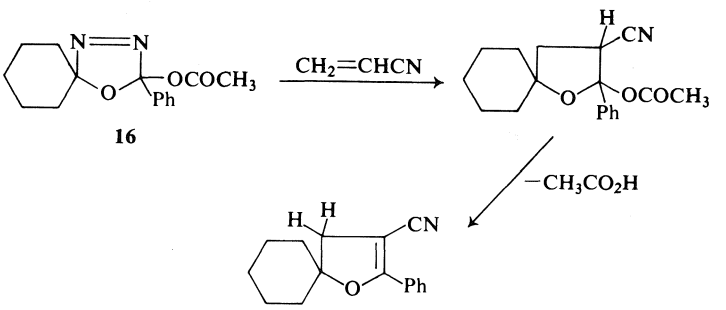

SCHEME 3

penone (see Scheme 2), cycloaddition of the carbonyl ylide takes place to the carbon–carbon double bond. Subsequent spontaneous loss of the carbon monoxide from the intermediate produces **13** which is also obtained directly with diphenylacetylene. The behavior of diphenylcyclopropenone towards **2** is quite different and involves instead initial attack at the carbonyl bond to form **14** (39).

Species **4** can also be trapped with the reactive "acetylenic" dipolarophile benzyne, generated *in situ* from diphenyliodonium-2-carboxylate to give **15**.

Δ^3-1,3-4-Oxadiazolines provide convenient precursors for acyclic carbonyl ylides. Recently prepared by Hoffman and Luthardt (24) they have been shown by these authors and by Rajagopalan and Advani (23) to cleave at moderate temperatures to carbonyl ylides which may be trapped by acetylenic dipolarophiles.

2-Acetyl-5,5-pentamethylene-Δ^3-1,3,4-oxadiazoline (**16**) reacted with acrylonitrile regiospecifically to give a single product **17** (see Scheme 3). In common with the experience of other workers (23, 24) acetic acid was eliminated from the initial product of cycloaddition. The single orientation represented by **17** was proven by the absence of a vinylic absorption in the n.m.r. spectrum. The identical regiospecificity of addition was exhibited in the cycloaddition of **16** to methyl acrylate and to crotonitrile to give **18** and **19** respectively as the only products. The orientation of addition is obvious from the n.m.r. spectra, that of **18** shows a two proton singlet at δ 2.83, and that of **19** shows a methyl group doublet at δ 1.20. Identical products **20** are obtained from both dimethyl maleate and dimethyl fumarate, corresponding to the elimination of acetic acid. Fumaronitrile affords a single adduct **21** in good yield in which acetic acid has also been eliminated during the reaction. Dibenzoylethylene reacted with **16** to give adduct **22**. The previously suggested intermediate (23) in the 1,3-dipolar cycloadditions of olefinic dipolarophiles to carbonyl ylides of this type was isolated in the case of 1,4-naphthoquinone as adduct **23**.

Discussion

Numerous attempts have been made to account for the Alder *endo* addition rule (40) in the Diels–Alder reaction. Recently the rule has been reinterpreted in quantum mechanical terms by Hoffmann and Woodward who note that the *endo* transition state is stabilized relative to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

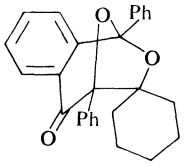
exo transition state by symmetry controlled secondary orbital interaction (41). This view was supported by Herndon and Hall with extended Hückel calculations (42) but more recently these authors have concluded that such secondary orbital interactions may be relatively unimportant and that geometrical overlap relationships of the π-orbitals at only the primary bonding center need be considered (43). Other interpretations have been made in terms of inductive forces (44), charge-transfer interactions (45), and dipole–dipole interactions (46).

While the related (4 + 2)π 1,3-dipolar cycloaddition reaction might be expected to involve similar secondary effects leading to preferential *endo* addition, no systematic study has been undertaken. Woller and Cromwell have reported one example of cycloaddition to an aziridine, the direction of which appears to be dictated by maximum overlap of the π-orbitals of the two components (47).

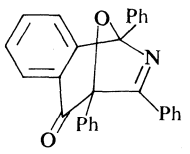
Orientation phenomena in 1,3-dipolar cycloadditions reactions have been interpreted as an interplay of steric and electronic factors (48). Examination of the stereochemistry of addition of symmetrical dipolarophiles to the indenone oxide should minimize electronic factors. The stereospecificity observed in such additions noted above is in agreement with recent conclusions derived from intramolecular isotope effects on the concerted nature of 1,3-dipolar cycloadditions of tetracyanoethylene oxide to allenes (25). Two tendencies are apparent from the above results. First a general preference under these conditions for *endo* additions of *cis*-addends to **1** and **2** but exceptions are noted in the case of dimethyl maleate and *cis*-stilbene. This is in agreement with other reported examples in the case of **2** (33). Arnold and Karnischky have recently shown that the carbonyl ylide derived from the thermal cleavage of 5-oxabicyclo[2,1,0]-pentane forms a mixture of *exo* and *endo* adducts with maleonitrile (27). The *endo* preference for **1** is in agreement with the results obtained with the indanoaziridine **6** (32, 38) and removes the apparent discrepancy between the hitherto observed orientation of additions to **1** and **6**.

A second tendency is apparent during the cycloaddition of *trans*-addends to **1** for the two substituents to adopt 2-*exo*-3-*endo* positions. Although the adducts obtained from **1** appear to be configurationally stable under their conditions of preparation, however, until it is demonstrated that the product distribution in these reactions is kinetically controlled (in view of the high temperatures that must be used), any attempts to formulate a general *endo* rule for such 1,3-dipolar cycloadditions is premature.

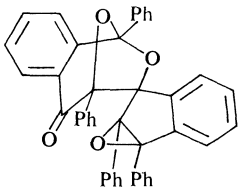
Electronic effects might be expected to play a significant role in determining the regiospecificity of addition of unsymmetrical dipolarophiles to **1** and **2**. Ullmann and Milks have reported in the addition of unsymmetrical addends to **1** a regiospecificity to place the substituents remote from the 1-phenyl group (22) *e.g.* **28**, **29**, **30**.



28



29



30

While steric hindrance factors will contribute here the orientation of all three additions is consonant with electronic directional effects.

Electronic factors may similarly be predominant in producing the regiospecificity observed in the additions to the acyclic ylide derived from **3** *i.e.*., in **17**, **18**, and **19** all of which correspond to the structures expected on the basis of electronic effects.

Experimental

The m.p.'s. were determined with a Fisher–Johns apparatus. The i.r. spectra were recorded with a Perkin–Elmer model 421 spectrophotometer. The n.m.r. spectra were recorded with Varian A-60 and A-100 spectrometers for *ca.* 5–10% (w/v) solutions and were taken on the initially obtained reaction mixtures to obtain an accurate determination of isomeric ratios; line positions are reported in p.p.m. from tetramethylsilane. Mass spectra were determined with an A.E.I. MS12 double-focusing high-resolution mass spectrometer (ionization energy usually 70 eV). Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. In those cases where mixtures of isomers were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

obtained, peak measurements were determined on the analytical samples and no attempts were made to separate the isomers. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated silica sheets were used for t.l.c. Microanalyses were carried out by Mrs. D. Mahlow of this department.

Preparation of Substrates

2,3-Diphenylindenone oxide and 1,3-diphenylisobenzofuran were prepared by the methods of Weitz and Scheffer (49) and of Newman (50) respectively.

General Procedure for 1,3-Dipolar Cycloadditions

The following experiments are representative of the reaction conditions employed throughout, thereafter the results are summarized in tabular form.

Reaction of 2,3-Diphenylindenone Oxide with Dimethyl Fumarate

A solution of 0.893 g (3 mmol) of 2,3-diphenylindenone oxide and 0.432 g (3 mmol) of dimethyl fumarate in 30 ml of dry toluene was heated to 135° in a sealed tube for 12 h under nitrogen. Evaporation of the solvent *in vacuo* and trituration of the residue with 95% ethanol afforded a mixture of adducts **10***k* and *j* in a ratio of (1:3) as shown by the n.m.r. spectrum, 1.22 g (92% yield), m.p. 188–189° as colorless crystals (from 95% ethanol).

Anal. Calcd. for $C_{27}H_{22}O_6$ (mol. wt. 442.1416): C, 73.3; H, 5.0. Found (442.1410 (mass spectrum)): C, 73.25; H, 5.0.

The i.r., spectrum ν_{max} ($CHCl_3$) 1734, 1705 cm^{-1} (C=O). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 3.20; 3.39 (4.5H, s, CO_2CH_3 (**10***j*)); 3.32, 3.59 (1.5H, s, CO_2CH_3 (**10***k*)); 4.03, 4.19 (0.5H, ABq, J = 4 Hz (**10***k*) methines); 4.04, 4.57 (1.50H, ABq, J = 5.5 Hz (**10***j*) methines); 6.8–8.3 (14H, m, aromatic protons).

Reaction of 2,3-Diphenylindenone Oxide with Dimethyl Maleate

A solution of 0.596 g (2 mmol) of 2,3-diphenylindenone oxide and 0.576 g (4 mmol) of dimethyl maleate in 25 ml of dry toluene was heated at 135° for 48 h in a sealed tube under nitrogen. Evaporation of the solvent *in vacuo* and trituration of the residue with 50% ethanol afforded a mixture of adducts **10***l* and *m* in the ratio of (3.6:1) as shown by the n.m.r. spectrum 0.82 g (94% yield), m.p. 155–158° as colorless crystals (from 50% aqueous ethanol).

Anal. Calcd. for $C_{27}H_{22}O_6$: (mol. wt. 442.1416): C, 73.3; H, 5.0. Found (442.1409 (mass spectrum)): C, 73.2; H, 4.9.

The i.r. spectrum ν_{max} ($CHCl_3$) 1745, 1714 cm^{-1} (C=O). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 3.27, 3.40 (4.68 H, s, CO_2CH_3(**10***l*)); 3.50, 3.59 (1.29H, s, CO_2CH_3 (**10***m*)); 3.84, 3.96 (1.56H, ABq, J = 9 Hz, (**10***l*) methines); 4.13, 4.31 (0.43H, ABq, J = 11.5 Hz (**10***m*) methines); 6.8–8.3 (14H, m, aromatic protons).

Reaction of 2,3-Diphenylindenone Oxide with cis-Dichloroethylene

A solution of 0.596 g (2 mmol) of 2,3-diphenylindenone oxide and 15 ml of *cis*-1,2-dichloroethylene in 15 ml of dry toluene was heated to 135° for 12 h under nitrogen. Evaporation of the solvent and excess of dichloroethylene *in vacuo* and trituration of the residue with 95% ethanol afforded **10***a* 0.566 g (72% yield), m.p. 129–131° as colorless crystals; δ ($CDCl_3$) 4.88, 5.05 (2H, ABq, J = 9 Hz, methines). Recrystallization of **10***a* from 95% ethanol or chromatography on alumina afforded the dehydrochlorinated product **11**, m.p. 130–131°, as a pale yellow crystalline solid (from 95% ethanol) in quantitative yield.

Anal. Calcd. for $C_{23}H_{15}O_2{}^{35}Cl$ (mol. wt. 359.0842): C, 77.0; H, 4.2; Cl, 9.8. Found (359.0842 (mass spectrum)): C, 77.4; H, 4.4; Cl, 9.3.

The i.r. spectrum ν_{max} ($CHCl_3$) 1710 cm^{-1} (C=O).

Reaction of 1,3-Diphenylisobenzofuran with cis-1,2-Dichloroethylene

A solution of 1.08 g (4 mmol) of 1,3-diphenylisobenzofuran and 15 ml of *cis*-1,2-dichloroethylene in 15 ml of dry benzene was heated under reflux at 100° for 12 h. Evaporation of the solvent and excess of dichloroethylene *in vacuo* and trituration of the residue with 95% ethanol afforded **9***a* 1.06 g (73% yield), m.p. 138–140°, as colorless crystals (from ether – 95% ethanol).

Anal. Calcd. for $C_{22}H_{16}O^{35}Cl_2$ (mol. wt. 366.0579): C, 71.95; H, 4.4; Cl, 19.3. Found (366.0570 (mass spectrum)): C, 71.8; H, 4.4; Cl, 19.3.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 4.90 (2H, s, methines); 7.0–8.1 (14H, m, aromatic protons).

Reaction of 2,3-Diphenylindenone Oxide with Diphenyliodonium-2-carboxylate

A mixture of 0.894 g (3 mmol) of 2,3-diphenylindenone oxide and 2.0 g (6 mmol) of diphenyliodonium-2-carboxylate (51) in 40 ml of *sym*-trimethylbenzene was rapidly raised to reflux temperature and then heated under reflux with stirring for 3 h at which time no remaining 2,3-diphenylindenone oxide could be detected by t.l.c. Evaporation of the filtered solution to remove excess of solvents *in vacuo* gave a yellow oil which was subjected to chromatography on 100 g of alumina. Elution with *n*-pentane removed aromatic by-products, while the main fraction was obtained by elution with benzene, the main portion of which was a pale yellow oil which crystallized from 95% ethanol to give **15**, 0.869 g (80% yield), as a pale yellow solid, m.p. 78–80° (from 95% ethanol).

Anal. Calcd. for $C_{27}H_8O_2$ (mol. wt. 374.1306): C, 86.6; H, 4.85. Found (374.1300 (mass spectrum)): C, 86.7; H, 4.9.

The i.r. spectrum ν_{max} ($CHCl_3$) 1704 cm^{-1} (C=O). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 6.6–8.2 (m, aromatic protons).

*Relation of the Configuration of the Adducts of 2,3-Diphenylindenone Oxide with (a) Maleic Anhydride **10***h* and (b) Dimethyl Maleate **10***m*

(*A*) A mixture of 0.04 g (1 mmol) of adduct **10***h* and a 2% solution of hydrochloric acid in 15 ml of 25% aqueous dioxane was heated under reflux gently for 2 h. After cooling the solid which had precipitated was collected representing the diacid **12**, 0.341 g (82% yield), m.p. 150°, which was shown by t.l.c. and n.m.r. to consist of only one isomer.

A solution of 0.2 g (0.5 mmol) of **12** in 20 ml of methanol was treated with a solution of diazomethane prepared from 0.82 g (4 mmol) of *p*-toluenesulfonylmethylnitrosamide (Diazald) and the mixture stirred for 12 h. Removal of the solvents *in vacuo* and recrystallization of the residual solid from aqueous methanol afforded the diester **10***m*, 0.21 g (95% yield), m.p. 160–161°. The

spectral properties of this material were identical with those of the minor component obtained by direct addition of **1** to dimethyl maleate.

(*B*) The identical product was obtained directly by reaction of **10***h* with a solution of diazomethane in ether in 87% yield.

By the above general procedures a series of adducts of **1** and **2** were prepared. Their analytical and spectral data are summarized in Tables 1–3.

Reaction of 2-Acetyl-5,5-pentamethylene-2-phenyl-Δ³-1,3,4-oxadiazoline with Acrylonitrile

A solution of 1.37 g (5 mmol) of 2-acetyl-5,5-pentamethylene-2-phenyl-Δ³-1,3,4-oxadiazoline and 10 ml of acrylonitrile in 20 ml of dry benzene was heated under gentle reflux for 6 h. Evaporation of the solvent and excess of acrylonitrile *in vacuo* gave a brown oil which was subjected to chromatography on 90 g of B.D.H. alumina. Elution with benzene first removed epoxide by-product while elution with chloroform gave **17** as a pale brown solid which was purified by recrystallization from petroleum ether (b.p. 40–60°) 0.628 g (53% yield), m.p. 107–110°.

Anal. Calcd. for $C_{16}H_{17}NO$ (mol. wt. 239.1310): N, 5.85. Found 239.1310 (mass spectrum)): N, 5.9.

The i.r. spectrum ν_{max} ($CHCl_3$) 2197 cm^{-1} (CN). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 1.0–2.4 (10H, m, C_6H_{11}); 3.42 (2H, s, methylene); 7.1–8.2 (5H, m, aromatic hydrogens).

Reaction of 2-Acetyl-5,5-pentamethylene-2-phenyl-Δ³-1,3,4-oxadiazoline with Dimethyl Fumarate

A solution of 1.37 g (5 mmol) of 2-acetyl-5,5-pentamethylene-2-phenyl-Δ³-1,3,4-oxadiazoline and 0.729 g (5 mmol) of dimethyl fumarate in 30 ml of dry benzene was heated under gentle reflux for 4 h when the evolution of nitrogen ceased. Evaporation of the solvent *in vacuo* gave a yellow oil which was subjected to chromatography on 90 g of B.D.H. alumina. Elution successively with hexane, hexane/benzene (9:1), and hexane/benzene (4:1) removed a small amount of epoxide by-product. Elution with benzene gave the main fraction **20** as a colorless solid 1.63 g (73% yield), m.p. 70° (from ether–pentane).

Anal. Calcd. for $C_{19}H_{22}O_5$ (mol. wt. 330.1467): C, 69.1; H, 6.7. Found (330.1460 (mass spectrum)): C, 69.3; H, 6.6.

The i.r. spectrum ν_{max} ($CHCl_3$) 1700 (br) (C=O). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 1.0–2.4 (10H, m, C_6H_{11}); 3.63, 3.72 (3H each, s, CO_2CH_3), 7.2–8.0 (5H, m, aromatic protons).

For personal use only.

An identical product was obtained by reaction of 2-acetyl-5,5-pentamethylene-2-phenyl-Δ^3-1,3,4-oxadiazoline with dimethyl maleate.

Reaction of 2-Acetyl-5,5-pentamethylene-2-phenyl-Δ^3-1,3,4-oxadiazoline with 1,4-Naphthaquinone

A solution of 1.10 g (4 mmol) of 2-acetyl-5,5-pentamethylene-2-phenyl-Δ^3-1,3,4-oxadiazoline and 0.63 g (4 mmol) of 1,4-naphthaquinone in 40 ml of dry benzene was heated under reflux for 5 h when a dark red solution was obtained. Evaporation of the solvent *in vacuo* gave a dark red oil which was subjected to chromatography on 90 g of B.D.H. alumina. Elution successively with 200 ml of hexane and 300 ml of (3:2) hexane/benzene removed some epoxide by-product and unreacted 1,4-naphthaquinone, while elution with 200 ml of benzene afforded the main fraction. Evaporation of the solvent gave a yellow–green oil, trituration of which with 95% ethanol gave **23** as a pale-green solid 0.63 g (40% yield), m.p. 169–171° (from 95% ethanol).

Anal. Calcd. for $C_{25}H_{24}O_5$ (mol. wt. 404.1624): C, 82.4; H, 6.2. Found (404.1616 (mass spectrum)): C, 82.05; H, 6.5.

The i.r. spectrum ν_{max} ($CHCl_3$) 1672, 1753 cm^{-1} (C=O). The n.m.r. spectrum δ_{TMS} ($CDCl_3$) 1.3–2.4 (10H, m, C_6H_{11}), 1.87 (s, 3H, CH_3); 5.76, 6.65 (2H, ABq, J = 10.5 Hz, methin 6.7–8.2 (9H, m, aromatic protons).

By the above procedures a series of adducts of **16** were prepared. Their analytical and mass spectral data are summarized in Table 4 in which the numbered groups refer to the following structure

Cyclic Imides. II. Silylsuccinimides

A. F. JANZEN AND E. A. KRAMER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received June 1, 1971

A number of silylsuccinimides containing silicon substituents —H, —CH_3, —C_2H_5, —$CH{=}CH_2$, —$CH_2CH{=}CH_2$, —C_6H_5, as well as disuccinimides, have been prepared and characterized by i.r., n.m.r., and mass spectrometry. The results are compared with previous studies of silylphthalimides.

On a préparé et caractérisé par i.r., r.m.n., et spectre de masse un certain nombre de silylsuccinimides contenant des substituants du silicium, tels —H, —CH_3, —C_2H_5, —$CH{=}CH_2$, —$CH_2CH{=}CH_2$, —C_6H_5, ainsi que des disuccinimides. On compare les résultats avec des études antérieures sur les silylphthalimides.

Canadian Journal of Chemistry, **49**, 3456 (1971)

We have previously reported the preparation and characterization by i.r. and mass spectrometry of a number of silylphthalimides (1). As a continuation of this study we now describe a variety of silylsuccinimides **1–9** listed in Table 1. Silicon substituents include —H, —CH_3, —C_2H_5, —$CH{=}CH_2$, —$CH_2CH{=}CH_2$, —C_6H_5, and compounds **8** and **9** are disuccinimides. Although a number of silylsuccinimides have been prepared previously[1] few details of their spectral properties or synthetic applications have been reported.

Silylsuccinimides **1–9** were conveniently prepared from the corresponding chlorosilane and potassium succinimide and purified by vacuum distillation or recrystallization. In general, silylsuccinimides appeared more susceptible to hydrolysis than silylphthalimides, in particular disuccinimides, and they were handled in a vacuum system or nitrogen atmosphere. All compounds were liquids or low melting solids and, on the basis of i.r. and n.m.r. studies, compounds **1–9** are *N*-silylated and no evidence was found for *O*-silylation.

The i.r. spectra were examined in the region 4000–400 cm^{-1}. Two bands were found in the carbonyl region. The more intense band was found in the region 1696 $\pm$ 4 cm^{-1} and may be assigned to the vibrationally coupled asymmetric mode of vibration (3) analogous to the situation in silylphthalimides where C=O (asymmetric) bands were found in the region 1700 $\pm$ 7 cm^{-1} (1). The symmetric mode was of weaker intensity and appeared at higher frequency, in the region 1764 $\pm$ 4 cm^{-1}. Values of C=O (asymmetric) and C=O (symmetric) are recorded in Table 1. Typical i.r. spectra recorded as liquid films, clearly showing two bands in the carbonyl region, are reproduced in Fig. 1.

Splitting of the C=O bands due to vibrational interactions is consistent with the presence of two equivalent carbonyl groups (4) and therefore *N*-silylation, rather than *O*-silylation, must have occurred.

Compounds **3** and **4** showed Si—H stretching vibrations at 2201 and 2199 cm^{-1}, respectively, in the region expected for silicon–hydrogen bonds (5).

A band of strong intensity was found for all silylsuccinimides in the region 1165–1178 cm^{-1}, illustrated in Fig. 1, and this band may tentatively be assigned to a Si—N vibration. Wallwitz *et al.* have previously assigned a strong band in the region 1170–1180 cm^{-1} to a Si—N vibration in *N*-silylheterocycles (6).

The n.m.r. spectra at 40° of silylsuccinimides **1–9** showed a single sharp peak in the region −2.66 to −2.54 p.p.m. assigned to the succinimido hydrogens. The succinimido hydrogens must therefore be equivalent, consistent with *N*-silylation, and the possibility of isomeric structures resulting from the addition of silicon–hydrogen (7) or silicon–nitrogen (8) bonds across the carbonyl bond is eliminated.

The equivalence of the succinimido hydrogens is of significance with regard to the stereochemistry at the nitrogen atom. If the succinimido ring defines a plane of symmetry then the hydrogens will be equivalent if the silicon atom is in the plane of the succinimido ring or if rapid nitrogen inversion is occurring. On the other hand, pyramidal geometry at the nitrogen atom, or slow

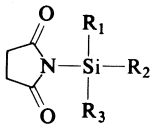
TABLE 1. The i.r. data of silylsuccinimides



No.	R_1	R_2	R_3	Infrared (cm^{-1})* C=O (asymmetric)	C=O (symmetric)	Si—H
1	CH_3	CH_3	CH_3	1696	1761	
2	C_2H_5	C_2H_5	C_2H_5	1697	1763	
3	CH_3	CH_3	H	1700	1764	2201
4	CH_3	C_6H_5	H	1699	1766	2199
5	CH_3	CH_3	C_6H_5	1692	1761	
6	CH_3	C_6H_5	C_6H_5	1694	1764	
7	CH_3	CH_3	$CH_2CH{=}CH_2$	1699	1768	
8	Succ†	CH_3	CH_3	1698	1764	
9	Succ	CH_3	$CH{=}CH_2$	1698	1768	

*Band positions are accurate to ± 2 cm^{-1}. Compounds 5 and 6 were dissolved in Nujol; all others were neat liquid films.
†Succ = succinimido.

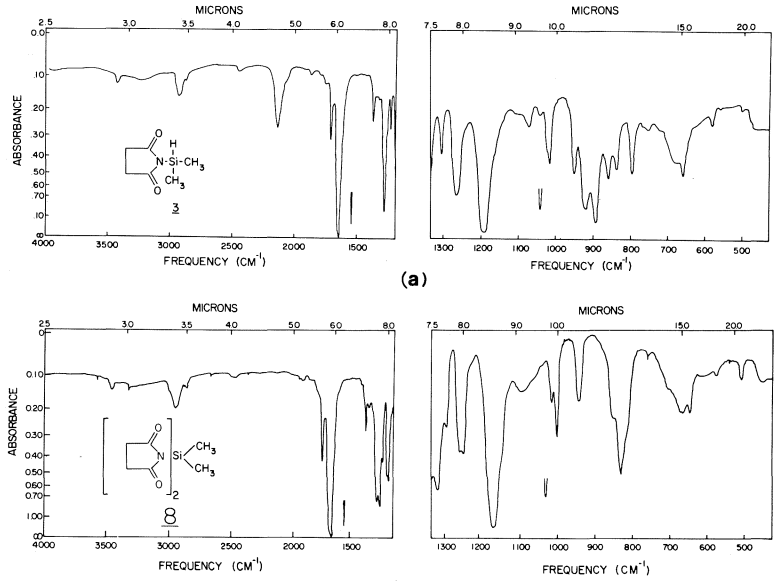


FIG. 1. Typical i.r. spectra: (*a*) *N*-(dimethylsilyl)succinimide (**3**) and (*b*) *N*-(*N'*-succinimidodimethylsilyl)succinimide (**8**) recorded as neat liquid films.

pyramidal inversion, would destroy the equivalence and a complex spectrum would be expected.

Since all compounds **1–9** showed single sharp peaks at $+40°$, therefore changing substituents on silicon has no effect on the equivalence of the succinimido hydrogens nor does the introduction of a second succinimido ring.

The n.m.r. spectrum of *N*-(triethylsilyl)succinimide (**2**) in $CHCl_3$ was recorded down to $-80°$ with the aim of establishing temperature dependent inversion. Although the succinimido peak is somewhat broadened relative to the sharp singlet triethylsilyl peak, the effect is small, and at $-80°$ silylsuccinimides must still be undergoing rapid inversion as has previously been found for *N*-substituted imines (9).

Attempts to slow down the rate of inversion at room temperature by forming complexes with $SnCl_4$ (10) and thereby introducing steric hindrance via carbonyl–metal complexing were unsuccessful. In a similar experiment, $AlCl_3$ was added to **2** and the n.m.r. spectrum recorded down

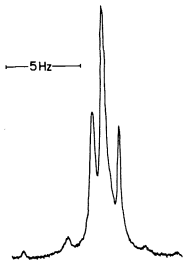

FIG. 2. The ^1H n.m.r. spectrum of *N*-(triethylsilyl)-succinimide (**2**) in benzene showing triethylsilyl region only.

to $-80°$, but the line broadening was not greater than without added $AlCl_3$.

It was noted above that the spectrum of *N*-(triethylsilyl)succinimide (**2**) in $CHCl_3$ solution gave a sharp singlet assigned to the triethylsilyl group. To confirm that the singlet was due to an A_3B_2 type of spectrum expected for an ethyl group, the sample was re-run in benzene solution and the complex pattern shown in Fig. 2 was obtained, consistent with an A_3B_2 spectrum (11).

Mass Spectra

Silylsuccinimides generally showed weak molecular ions *a* and the most prominent peaks resulted from loss of alkyl, aryl, or hydrogen,

[1] 
a *b*

R = CH_3, C_2H_5, C_6H_5, H

$a \xrightarrow{-R} b$ (eq. 1). If methyl and phenyl substituents, or if methyl and hydrogen substituents were present, then in both cases loss of methyl gave the more abundant peak.

There were no peaks in the mass spectra of silylsuccinimides which could be assigned to CO_2 elimination. This was rather interesting in view of the prominent loss of CO_2 observed in silylphthalimides (1) (eq. 2). The loss of CO_2 must therefore be characteristic of the phthalimido group, since *N*-alkyl- and *N*-silylphthalimides readily lose CO_2 (12, 13) whereas *N*-alkyl- and *N*-silylsuccinimides do not (13, 14).

Loss of CO has been observed in *N*-alkylsuccinimides and is also found in *N*-silylsuccinimides. For example, the ion *d*, of 23% relative abundance, in the mass spectrum of *N*-(dimethylsilyl)-

[2] 
[3] 
c, m/e 157 (8%) *d*, m/e 129 (23%)

succinimide **3** (eq. 3) may result from loss of CO, by analogy with the loss of CO from *N*-methylsuccinimide (eq. 4). The latter process was confirmed by high resolution mass spectrometry and the presence of a metastable ion (14).

[4] 
Silylsuccinimides showed peaks of varying intensity assigned to $R_3SiO\overset{+}{S}iR_2$, $R_2\overset{+}{S}iOH$, and R_3Si^+. These peaks may originate in the hydrolysis and condensation of silyl derivatives (eq. 5),

[5] 
as has been noted before in mass spectral studies (15). As a further possibility siloxanes may result from skeletal rearrangements as has been found for trimethylsilyl ethers (16).

Additional peaks found at *m/e* 56, 55, 28 have also been found in *N*-alkylsuccinimides (13, 14) and must be characteristic of the succinimido ring.

Experimental

General

All compounds were manipulated in a conventional vacuum manifold or under dry nitrogen atmosphere. Organochlorosilanes were purchased from Peninsular Chemresearch and succinimide from Aldrich Chemical Co. Solvents were dried and distilled prior to use. Elemental analyses were carried out by A. Bernhardt, West Germany.

The i.r. spectra were determined on a Perkin–Elmer 337 spectrophotometer using KBr windows and calibrated against polystyrene film. Mass spectra were obtained on a Finnigan 1015 quadrupole or Hitachi Perkin–Elmer RMU-6D mass spectrometer at 50 eV. Proton n.m.r. spectra were obtained on a Varian A-56/60A spectrometer at 60 MHz in 10% (v/v) $CDCl_3$ solutions using a small amount of $CHCl_3$ as internal standard. Chemical shifts are reported relative to external tetramethylsilane

†Reactivity of **9** prevented satisfactory elemental analysis.

(TMS) using the formula δ p.p.m. ($CHCl_3$ internal) − 7.23 p.p.m. = δ p.p.m. (TMS external). All chemical shifts were found to be downfield from TMS.

Preparation of N-(Triethylsilyl)succinimide (2)

Triethylchlorosilane (4.50 g, 29.9 mmol) was slowly added to potassium succinimide (4.10 g, 29.9 mmol), prepared from potassium metal and succinimide in tetrahydrofuran, at 0° under nitrogen atmosphere. Potassium chloride was filtered off and solvent and unreacted triethylchlorosilane pumped off leaving a pale yellow liquid. Vacuum distillation gave a clear colorless liquid identified as *N*-(triethylsilyl)succinimide.

The typical procedure outlined for *N*-(triethylsilyl)succinimide was repeated for each silylsuccinimide. Products were purified by vacuum distillation, with the exception of **5** and **6** which were recrystallized from benzene, and the yield of purified product was about 25–35% for compounds **1**–**7** and 10–15% for **8** and **9**.

The i.r. data for **1**–**9** are reported in Table 1 and elemental analyses, boiling points or melting points, and n.m.r. data are reported in Table 2.

Enthalpies and Excess Enthalpies of Transfer of *n*-Alkylamine Hydrobromides from H_2O to D_2O at 25 °C

J. E. Desnoyers, R. Francescon, P. Picker and C. Jolicoeur
Department of Chemistry, University of Sherbrooke, Sherbrooke, Quebec

Received June 1, 1971

Differences in heats of solution and in heats of dilution of electrolytes in H_2O and D_2O were measured directly with a previously described cell-type differential microcalorimeter. In addition to NaCl and NaBr, most of the homologous salts RNH_3Br were studied from R = methyl to R = *n*-octyl. The results of the two simple salts are in excellent agreement with the best literature values.

The enthalpies of transfer at infinite dilution, ΔH_{tr}^0 ($H_2O \rightarrow D_2O$), are mainly a measure of the structural ion–solvent interactions and of the exchange reaction

$$RNH_3^+(D_2O) + 3\,D_2O \rightarrow RND_3^+(D_2O) + 3HDO$$

Up to R = *n*-propyl, the relative apparent molal enthalpies of transfer, $\Delta\phi_L(H_2O \rightarrow D_2O) = \Delta H_{tr}^{EX}$, are negative, approximately zero for *n*-butyl and positive for the higher members. This gradual change in the excess enthalpies of transfer is interpreted in terms of the increasing importance of hydrophobic interactions between the cations. When association occurs through micelle formation (R = *n*-octyl), there is a rapid increase in $\Delta\phi_L(H_2O \rightarrow D_2O)$ which results from hydrophobic bonding.

On a mesuré directement la différence entre les chaleurs de solution et entre les chaleurs de dilution d'électrolytes dans H_2O et D_2O, au moyen d'un microcalorimètre différentiel de type cellule. En plus de NaCl et NaBr, la plupart des sels homologues RNH_3Br ont été étudiés à partir de R = méthyle à R = *n*-octyle. Les mesures sur les deux sels simples sont en excellent accord avec les valeurs de la littérature.

Pour les bromohydrate de *n*-alcoylamine, les enthalpies de transfert à dilution infinie, ΔH_{tr}^0 ($H_2O \rightarrow D_2O$), sont surtout une mesure des interactions structurales entre les ions et le solvant et de la réaction d'échange.

$$RNH_3^+(D_2O) + 3D_2O \rightarrow RND_3^+(D_2O) + 3HDO$$

Jusqu'à R = *n*-propyle, les enthalpies apparentes molaires relatives de transfert, $\Delta\phi_L(H_2O \rightarrow D_2O) = \Delta H_{tr}^{EX}$, sont négatives, approximativement nulles pour le n-butyle et positives pour les autres. Ce changement graduel dans les enthalpies d'excès de transfert reflète l'importance croissante des interactions structurales entre les cations. Lors de l'association des cations, sous forme de micelles, il y a un accroissement rapide de $\Delta\phi_L(H_2O \rightarrow D_2O)$ indiquant la formation de liens hydrophobes.

Canadian Journal of Chemistry, **49**, 3460 (1971)

Introduction

Most properties of aqueous solutions reflect to some extent the structural changes of the solvent in the vicinity of the solute (1, 2). However, the contribution to the thermodynamic functions or excess thermodynamic functions, arising from changes in the hydrogen bond distribution in the water, are not easily separated from the more classical solute–solvent and solute–solute interactions. The H_2O/D_2O isotope effect has often been useful in this respect; because of the similarity in the dipole moment, dielectric constant, and variation of the dielectric constant with temperature of both liquids (3), first order solute–solvent and solute–solute interactions will be equal in both solvent system (4). On the other hand, because of the zero-point energy effect on the hydrogen bond, there is more structural order in D_2O than in H_2O (5). This structure is unstable and, as a result, any perturbation of the solvent structure will be more pronounced in D_2O than H_2O. Moreover, the isotopic effect on thermodynamic and transport properties, which are sensitive to structural effects, is generally larger at low temperature and pressure (6). Studies of conductance (7, 8), densities (9), and thermochemical properties (4, 10–15) show that structural changes caused by solutes are usually larger in D_2O.

The study of excess enthalpies of transfer requires very accurate heats of dilution in each solvent (11). However, it is now possible, using a differential microcalorimeter recently described (17), to measure directly the difference between heats of solution or heats of dilution in the two solvents. Thus, the transfer enthalpies and excess transfer enthalpies from H_2O to D_2O can be obtained with reasonably high accuracy.

The chosen system to initiate this study was the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

homologous series *n*-alkylamine hydrobromides. Previous studies (13, 18–22) had shown that this model system was very informative in the study of hydrophobic interactions and bonding (micelle formation). Since the physical distance of closest approach between the ionic head and the counterion remains essentially constant, it is reasonable to assume that the variation in the excess functions as the chain length is increased will reflect mostly the interactions of the alkyl group with itself and with the anion. The study of the solvent isotope effect should confirm the previous propositions (19, 20) on the structural nature of these interactions.

Experimental

The heavy water (99.8%) was obtained from Stohler Isotope Chemicals and was used without further purification. The H_2O content was checked periodically by n.m.r. before and after use and was found to be within specifications. The water was doubly distilled from an alkaline permanganate solution. The alkylammonium salts were prepared and purified as previously described (19). Most manipulations were made in dry (Nalgen) plastic ware to minimize contamination of the D_2O with H_2O.

The twin-cell isothermal microcalorimeter has been described elsewhere (17); the cells used to measure differential heats of dilution were also described earlier (17) while those required for heats of solution measurements are detailed in Fig. 1. In the inverted position, the inner cell (*A*) is filled with salt and closed with a Teflon stopper (*D*) fixed to a rod (*E*). This inner cell is inserted in the main cell (*B*), which is partially filled with mercury. The outer compartment is then filled with the solvent and closed with a Teflon plug (*F*). Once the cells are fixed on the supports, the inner stopper (*D*) is lowered by means of the central rod (*E*). Mixing is prevented by the mercury which traps the salt in the inner cell. The calorimeter is then closed and evacuated; once equilibrium conditions are reached (~10 min), mixing is obtained by tipping the calorimeter.

To achieve true differentiation in the heat of solution measurements, the same weight of salt and the same number of moles of solvent were placed in each cell. The final concentrations were then at the same aquamolality (*m* mol of salt per 55.51 mol of solvent).

For differential measurements of heats of dilution, the salt solutions were prepared by weighing the salt in stoppered Nalgen bottles and then adding the calculated weight of D_2O or H_2O with a syringe. The weight of the concentrated solution and of the pure solvent were controlled so as to keep equal number of moles of salt and equal aquamolalities in both cells before and after the dilution.

Test Procedures

To verify the procedure for measurement of differential heats of solution, five experiments were performed with equal amounts of NaCl in H_2O in both cells, and, within experimental uncertainty, the resulting heat was negligible.

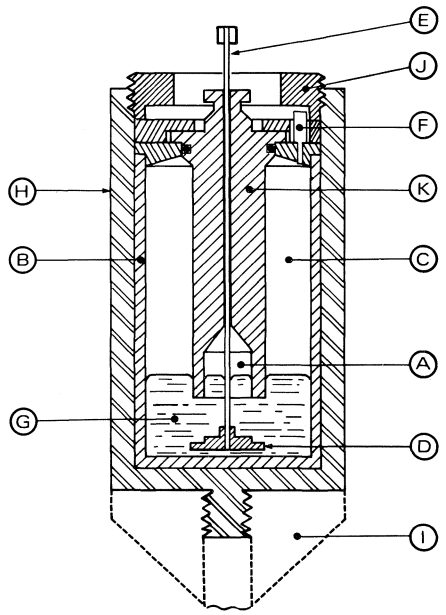

FIG. 1. Cell for heat of solution measurements: *A*, inner cell; *B*, Teflon main cell; *C*, outer compartment; *D*, Teflon inner stopper; *E*, stainless steel central rod; *F*, Teflon plug; *G*, mercury seal; *H*, copper outer cell; *I*, copper cell support; *J*, nylon ring; *K*, removable assembly.

As a test for differential measurements of excess enthalpies, the difference in the heats of dilution of NaCl and KCl in water from 1 to 0.5 *m* were measured. The average of four experiments gave $\Delta\phi_{L(KCl)}^{0.5 \rightarrow 1.0\ m} - \Delta\phi_{L(NaCl)}^{0.5 \rightarrow 1.0\ m}$ equal to 6.68 ± 0.10 cal mol^{-1} which can be compared with 8 ± 2 cal mol^{-1} obtained from Parker's data (23).

Results

The enthalpies of transfer from water to heavy water, $\Delta H_{tr}(H_2O \rightarrow D_2O)$, are derived directly from the difference in the integral heats of solution,

$$[1] \quad \Delta H_{tr}(H_2O \rightarrow D_2O) = \Delta H_{IS}(D_2O) - \Delta H_{IS}(H_2O)$$

which is also equal to the measured heat divided by the total number of moles of solute. The standard enthalpy of transfer, $\Delta H_{tr}^0(H_2O \rightarrow D_2O)$, is obtained by correcting ΔH_{tr} for the difference in the integral heats of dilution to zero concentration.

Wood *et al.* (11) have shown that the excess enthalpies of transfer are often a quadratic function of the aquamolality. Therefore, defining the transfer function from H_2O to D_2O, the excess

TABLE 1. Parameters k_1 and k_2 of eq. 2 for the excess enthalpies of transfer of NaCl and NaBr from H_2O to D_2O at 25 °C*

	k_1		k_2	
Salt	This work	Reference 11	This work	Reference 11
NaCl	−51.4	53.6	7.7	−7.1
NaBr	−50.0	51.3	7.2	−7.1

*The units of k_1 and k_2 refer to heats in calories and to concentrations in number of moles of solute per 55.51 moles of solvent.

enthalpy of transfer, ΔH_{tr}^{EX}, is given by the difference between the relative apparent molal enthalpy of the solute in D_2O and H_2O, *i.e.*

$$[2] \quad \Delta H_{tr}^{EX} = \Delta\phi_L(H_2O \rightarrow D_2O) = k_1 m + k_2 m^2$$

where m is the aquamolality. ΔH_{tr}^{EX} is therefore an integral and not a differential heat. For a given dilution experiment between the initial and final aquamolalities, m_i and m_f, the difference in the integral heats of dilution is given by the experimental heat q divided by the number of moles of salt, *i.e.*

$$[3] \quad \Delta H = (q/n)\left\{\begin{matrix} H_2O \rightarrow D_2O \\ m_i \rightarrow m_f \end{matrix}\right\} = \Delta\phi_L(m_f) - \Delta\phi_L(m_i) = k_1(m_f - m_i) + k_2(m_f^2 - m_i^2)$$

Dividing both sides by $m_f - m_i$,

$$[4] \quad \Delta H/(m_f - m_i) = k_1 + k_2(m_f + m_i)$$

Then by plotting the left-hand side of eq. 4 against $m_f + m_i$, the two constants k_1 and k_2 are obtained as the intercept and slope, respectively.

As a further test, the enthalpies of transfer and excess enthalpies of transfer of NaCl and NaBr were measured at 25 °C. The constants k_1 and k_2 derived from the data below 3 m are given in Table 1. All heats are expressed in absolute calories (4.184 J). The constants k_1 and k_2 are well within the uncertainty of Wood's data (11). Our constants have signs opposite to those of Wood since he defines the transfer process from D_2O to H_2O.

The enthalpies of transfer, corrected to the standard state of infinite dilution with the excess enthalpies of transfer, are given in Table 2. The agreement with the data of Davies and Benson (24) and Lange and Martin (25, 26) is such that we do not expect our data to be in error by more than a few cal mol^{-1}. From the present work, the difference $\Delta H_{tr}^0(Br^-) - \Delta H_{tr}^0(Cl^-)$ is 102 ± 3 cal mol^{-1}; this value should be preferred to the value 135 suggested by Arnett and McKelvey (16).

‡Reference 25: 650.

The actual uncertainties in ΔH_{tr}^0 and ΔH_{tr}^{EX} depend to a large extent on the magnitude of the heats of solution or dilution in each solvent. With the systems in the present study, we believe ΔH_{tr}^0 within 1 or 2 cal mol^{-1}, while ΔH_{tr}^{EX} should be reliable to 0.2 cal mol^{-1}.

The differences in integral heats of dilution ΔH of the homologous salts *n*-alkylamine hydrobromides are given in Table 3. From these data, $\Delta H/(m_f - m_i)$ were calculated and plotted against $m_f + m_i$ in Fig. 2. The large variation of the differential heats of dilution of *n*-octylamine hydrobromide at low concentrations makes the extrapolation very difficult. However, a plot of k_1 *vs.* the number of carbon atoms, n, in the chain is linear for n equals 3 to 6 (Fig. 3). Therefore, it is possible to obtain k_1 of the *n*-octyl salt by extrapolation in Fig. 3.

The derived parameters k_1 and k_2 and the limit of applicability of eq. 2 for ΔH_{tr}^{EX} of *n*-alkylamine hydrobromides are given in Table 4. The enthalpies of transfer ΔH_{tr} of most of these salts are given in Table 5 along with the values corrected to infinite dilution ΔH_{tr}^0.

These standard enthalpies of transfer can be compared with the data of Krishnan and Friedman (13) on the *n*-alkylamine hydrochlorides. The difference between the bromides and the chlorides varies between 80 to 90 cal mol^{-1} while the difference between NaBr and NaCl was 102

cal mol^{-1}. This agreement is excellent in view of the uncertainty of 30 cal mol^{-1} quoted by Krishnan and Friedman.

Discussion

It is possible to interpret the data on ΔH_{tr}^0 and ΔH_{tr}^{EX} through structural changes affecting both the solute–solvent and solute–solute interactions. However, this interpretation is meaningful only if the assumptions made are clearly stated. For the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

enthalpy of transfer from H_2O to D_2O, three basic assumptions are required.

(1) Water is a structured liquid and the presence of solutes will increase or decrease its structure. Knowledge of the exact nature of the water structure is not required for the present purpose; only shifts in the hydrogen bond distribution or changes in the number of bonded and unbonded species are needed.

(2) D_2O is more structured than H_2O and its structure is more sensitive to any perturbation (T, P or solutes). For interpretation of thermodynamic properties, it is immaterial if the number of bonds is larger or if the bonds are stronger in D_2O. The important point is that structural changes are more important in D_2O and that the isotope effect decreases with increasing temperature (4–7).

(3) The H_2O/D_2O transfer functions mostly reflect structural changes. This assumption is reasonable in view of the similarity in the dielectric constant, variation in the dielectric constant with temperature and dipole moment, and since differences between H_2O and D_2O are largest in those properties which are most sensitive to slight structural differences (6). Evidence for the correctness of this assumption is also obtained from a comparison with transfer functions in other systems such as propylene carbonate → water and dimethylsulfoxide → water (13).

These assumptions are sufficient to interpret thermodynamic transfer functions such as ΔH_{tr}^0, ΔS_{tr}^0, and ΔV_{tr}^0, but with properties such as heat capacities, which depend on the second derivative of the chemical potential with respect to temperature, further assumptions must be made regarding the variation of the strength of the hydrogen bonds with respect to temperature and pressure (27, 28).

The structural changes caused by a solute molecule can best be represented by an imaginary co-sphere, as suggested by Gurney (29), and the concentration effect as an overlap of these co-spheres. The larger structural change in D_2O solutions can be symbolized by a larger co-sphere. In the framework of assumptions *1–3*, the signs of the three functions, enthalpy, entropy, and volume, are easily predicted by assuming that some ice has melted in the co-sphere of structure breakers and that some water has frozen near structure makers (assumption *1*). From assumption *3*, it is clear that the transfer functions from H_2O to D_2O always have the same sign as the structural change in either co-sphere. Therefore ΔH_{tr}^0 should be positive for structure breakers and negative for structure makers. Structure maker is used here exclusively in the sense of hydrophobic ions and not hydrophilic ions such as F^-, Li^+, and Na^+. In most cases where sufficiently reliable data exists in the literature, the above predictions are verified: *e.g.* enthalpies and entropies (16) and volumes (9).

With the alkylamine hydrobromides, the standard enthalpies of transfer ΔH_{tr}^0 always include the exchange reaction

[4] $RNH_3^+(D_2O) + 3D_2O \rightarrow RND_3^+(D_2O) + 3HDO$

and there is no simple way of measuring this heat separately. If the deuterate ammonium salt was used for the heat of solution in D_2O, the exchange reaction would not be involved, but the reference state (pure solid) would not cancel out since both salts would be different. Krishnan and Friedman (13), by comparing their results for RNH_3^+ with R_4N^+, have estimated this heat to be -50 cal mol^{-1}. Correcting our results for this exchange heat would indicate that the three lower members of the series are net structure breakers (positive ΔH_{tr}^0), *n*-octylamine hydrobromide is a net structure maker (negative ΔH_{tr}^0), and *n*-butylamine hydrobromide is a weak structure maker.

While it is sufficient to consider two types of interactions when discussing properties at infinite dilution, a minimum of four different structural interactions are required when excess functions are considered (30). Such a model was suggested earlier (30) from an examination of the concentration dependence of the thermodynamic functions ($\bar{G}$, $\bar{H}$, $\bar{S}$, and $\bar{V}$) of electrolytes in aqueous solution. The qualitative description arrived at can also be applied to excess transfer functions. Since solvent structural modifications are larger in D_2O than in H_2O (assumption *2*), their contribution to excess thermodynamic functions can also be expected to be larger. Schematically, this can be represented as a larger overlap of co-spheres. Therefore, if the transfer is defined from H_2O to D_2O, the sign of the excess transfer function will be the same as that of the structural contribution to the total excess function in either solvent. By analogy with the model previously described (30), the predicted signs of ΔH_{tr}^{EX}, ΔS_{tr}^{EX}, and ΔV_{tr}^{EX} for interactions between different solutes can be summarized as follows:

Nature of interaction	ΔH_{tr}^{EX}	ΔS_{tr}^{EX}	ΔV_{tr}^{EX}
(1) hydrophobic–hydrophobic	+	+	−
(2) hydrophobic–hydrophilic	+	+	−
(3) hydrophilic–hydrophilic (same sign)	+	+	−
(4) hydrophilic–hydrophilic (opposite sign)	−	−	+

Because of the accuracy required and the limited data available in the literature, this extension of the original model cannot be verified thoroughly. Still the heats of dilution of Wood *et al.* (11) and of Snell and Greyson (15, 31) and the apparent molal volume of Conway and Laliberté (9) are in agreement with the model.

The present excess transfer data on *n*-alkylamine hydrobromides are now readily explained. This is best seen by plotting ΔH_{tr}^{EX} against the aquamolality (Fig. 4). The low concentration enthalpies were calculated directly from the constants k_1 and k_2, while, at the higher concentrations, ΔH_{tr}^{EX} were obtained directly from the experimental data (Table 3). For the three first members of the series, ΔH_{tr}^{EX} is negative indicating that the predominant structural interaction is the one between the $-NH_3^+$ group and the Br^- ion. As the chain length increases this interaction remains essentially constant, but the interaction involving the hydrophobic R-groups steadily increases. With *n*-$BuNH_3Br$, it seems that all interactions nearly cancel out, but with the higher members, hydrophobic interactions prevail. Hydrophobic–hydrophobic and hydrophobic–hydrophilic interactions both exist, but the former certainly predominates with *n*-octylamine hydrobromide, since the rapid increase in

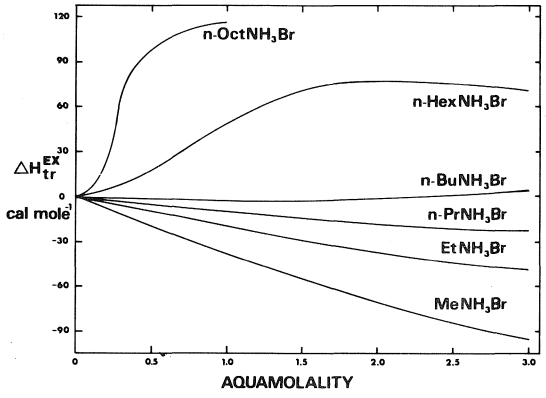

FIG. 4. Excess enthalpies of *n*-alkylamine hydrobromides from H_2O to D_2O at 25 °C.

ΔH_{tr}^{EX} corresponds to the region where micelles are formed (19, 20). Even if we consider micelle formation as a limiting case of hydrophobic interactions, some distinction between these situations may be expected from the shape of the concentration dependence. Hydrophobic interactions depend on the extent of co-sphere overlap and, as a first approximation, are linear in concentration (4); on the other hand, association or aggregation may often vary differently with concentration, as in the case of *n*-octylamine and *n*-hexylamine hydrobromides. Therefore a sharp increase in ΔH_{tr}^{EX} at some concentration is probably always related to hydrophobic bonding.

The concentration dependence of ΔH_{tr}^{EX} of the RNH_3Br salt is similar to the deviation from the Debye–Hückel theory of the relative apparent molal enthalpies (32), which confirms the above statement that the transfer excess functions have the same sign as the structural interactions in either liquid.

The present results are in excellent agreement with those of Snell and Greyson (15) on ΔH_{tr}^{EX} of the sodium salts of carboxilic acids. As in the present case, ΔH_{tr}^{EX} are negative for chain lengths up to sodium isobutyrate and positive from there on. They have suggested that the sign of ΔH_{tr}^{EX} should always be opposite that of ΔH_{tr}^{0}. If this is correct, a salt which has no net ΔH_{tr}^{0} should also have no excess transfer function. If ΔH_{tr}^{0} of RNH_3Br were plotted against k_1 (not shown), ΔH_{tr}^{0} would be equal to -70 cal mol^{-1} when $k_1 = 0$, and this would then be the heat of the exchange reaction (eq. 4). This value is of the same order of magnitude as that evaluated by Krishnan and Friedman (13). However, we should bear in mind that, with RNH_3Br salts, it is incorrect to say that one particular salt has no structural influence on the solvent. In actual fact, the amount of structure broken by the $-NH_3^+$ group and Br^- ion just balances out the increase in structure near the R-group. It is not at all obvious that similar cancellations would also affect the solute–solute structural interactions. Therefore, this analogy can at best be taken as an indication that the heat of the exchange reaction (eq. 4) is of the order of -50 to -70 cal mol^{-1}.

In the above discussion it was implied that the exchange reaction had no effect on ΔH_{tr}^{EX}. This would be true if the exchange was complete at all concentrations and if the heat of the exchange reaction was not concentration dependent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Neither assumptions are probably correct. Therefore, the concentration dependences of the true ΔH_{tr}^{EX} should all be more negative by a small but unknown amount.

Structural interactions offer a simple explanation for solvent isotope effects in aqueous solutions. However, it should be noted that some data in the literature cannot be readily interpreted. The ΔH_{tr}^{0} of halide ions vary differently with their size than the alkali metal ions (12), F^- appears as a structure maker while divalent cations are structure breakers (31). This probably reflects the zero-point energy difference between the $F^- \cdots$ HOH and the $F^- \cdots$ DOD interactions, obscuring structural effects beyond the first coordination shell of the ions. However, it is quite possible that, in other transfer properties, the structural changes in the solvent and the solute–water interactions (or hydrogen bond distribution) will have different relative contributions. Further work on $H_2O \rightarrow D_2O$ transfer are therefore desirable, particularly with different sensitive properties such as expansitivities, compressibilities and heat capacities. The latter should also provide critical tests of the qualitative picture used presently to interpret the heat measurements.

Grateful acknowledgement is made to the Defence Research Board of Canada for financial support of this project.

The Effect of *N*-Substitution on the Rates of Saponification of Some Amino Acid Esters[1]

JOCELYN E. PURDIE AND N. LEO BENOITON[2]
Department of Biochemistry, University of Ottawa, Ottawa, Canada

Received May 25, 1971

The saponification rates (measured at 25° by a titrimetric method) of the unprotonated forms of the methyl esters of glycine, alanine, leucine, valine, and phenylalanine were compared with those of the *N*-methyl, the *N*-acetyl, and the *N*-acetyl,*N*-methylamino acid analogues. *N*-Acetylation slightly increased or decreased the rate but *N*-methylation caused a reduction by as much as a factor of ten, depending on the complexity of the side-chain. The esters of the *N*-acetyl,*N*-methylamino acids, which exist as *cis* and *trans* isomers, were saponified at rates intermediate between those of the esters of the *N*-acetylamino acids and *N*-methylamino acids. Activation parameters were obtained for the phenylalanine and leucine derivatives. *N*-Methylation resulted in an increase in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ which was attributed in part to solvation effects. The hydrolysis of the cationic esters of glycine and alanine was still evident at p*H* 11.0. *N*-Methylation had little effect on the rates of saponification of the charged forms.

On a comparé les vitesses de saponification (mesurées à 25° au moyen d'une méthode titrimétrique) des formes non-protonées des esters méthyliques des acides aminés tel que la glycine, l'alanine, la leucine, la valine, et la phénylalanine avec celles obtenues en utilisant les analogues *N*-méthyle, *N*-acétyle et *N*-méthyle,*N*-acétyle des mêmes acides aminés. On constate une légère augmentation ou diminution de la vitesse dans le cas de la *N*-acétylation, mais la *N*-méthylation occasionne une réduction de cette vitesse par un facteur allant jusqu'à dix, dépendant de la complexité de la chaîne latérale. Les esters de la forme *N*-acétyle,*N*-méthyle des acides aminés, qui sont des isomères *cis* et *trans*, ont été saponifiés à des vitesses intermédiaires entre celles obtenues pour les dérivés *N*-acétyle et *N*-méthyle des acides aminés. On a calculé les paramètres d'activation pour les dérivés de la phénylalanine et de la leucine. La *N*-méthylation a causé une augmentation du $\Delta H^{\ddagger}$ et du $\Delta S^{\ddagger}$, ce qu'on attribue en partie aux effets de solvation. L'hydrolyse des esters cationiques de la glycine et de l'alanine était encore évidente à p*H* 11.0. On remarque peu d'effet causé par la *N*-méthylation sur les vitesses de saponification des formes chargées.

Canadian Journal of Chemistry, **49**, 3468 (1971)

Introduction

Amino acid esters and their *N*-acylated derivatives are widely used as enzyme substrates and in peptide synthesis. *N*-Methylamino acids occur in peptides of bacterial origin. The chemical synthesis of peptides of *N*-methylamino acids presents problems due to 'steric hindrance' and a marked tendency of the dipeptides to cyclize (1). We have recently devised a new method for the synthesis of *N*-methylamino acid derivatives (2). During the course of this work, difficulties were encountered with the saponification of esters. From this arose the present study which is concerned with the effect of *N*-substitution on the rates of saponification of amino acid esters with side-chains of graduated complexity.

Experimental

The amino acid and sarcosine methyl esters were the hydrochlorides obtained from the amino acids (General Biochemicals) using hydrogen chloride/methanol. The *N*-methylamino acid methyl esters were the hydrobromides already described (2). *N*-Acetylamino acid esters were prepared from the *N*-acetylamino acids (Nutritional Biochemicals) using diazomethane (3). All were crystalline except for alanine which was an oil. The *N*-acetyl,*N*-methylamino acid methyl esters were prepared from the *N*-acetylamino acids using sodium hydride/methyl iodide as previously described (2) except for the following modifications. After the work-up, the methylation was repeated and the products were purified by distillation at 80°/5 mm for alanine, 98°/1.2 mm for leucine, and 95°/1.8 mm for valine. In addition, for alanine, because of the solubility of the derivative in water, the reaction mixture was not washed with water at any time. The products showed no i.r. absorbance at 1521 and 3280 cm^{-1} (2).

Ester hydrolysis was followed titrimetrically in thermostatted reaction vessels using a Radiometer p*H*-stat type PHM 26c/TT11a/SBUI/SBR2/TTA3 as described previously (4) except that a special slow delivery tube was used (Radiometer). The titrant was 0.1 *N* NaOH standardized with potassium hydrogen phthalate. The syringe was calibrated by weighing the water delivered for various distances of piston travel. The electrodes were glass, type G202B and calomel, type K401. The system was standardized before, after, and once during a day's run with the primary standard buffers borate p*H* 9.18 at 25° and phthalate p*H* 4.01 at 25°. The iso p*H* adjustment together

with the calibrated adjustment for electrode sensitivity were used to compensate for the fact that the electrode sensitivity is less than 100%. When the electrode sensitivity had decreased below 98% or the response time had noticeably increased, the electrode was discarded. For temperatures above 25°, the electrodes were kept continuously at the experimental temperature to avoid any drifting caused by hysteresis of the calomel electrode. All solutions and rinsing water were likewise kept at the experimental temperature.

Solutions were prepared and kept under nitrogen and titrations were carried out under a stream of nitrogen saturated with water. Solutions (~2.5 mM) of esters were made up in 0.1 M NaCl just before use. *N*-Acetyl,*N*-methyl-DL-valine methyl ester and the leucine analogue presented solubility problems, the solutions showing the Tyndall effect.

The apparent pK' for the dissociation of an amino acid or its ester is defined by the following equation:

$$RNH_3^+ \rightleftharpoons RNH_2 + H^+$$

$$K' = a_{H^+} \frac{[RNH_2]}{[RNH_3^+]}$$

The pK's were determined in 0.1 M NaCl by applying the Henderson–Hasselbalch equation to various points on the corrected titration curve. If the pK values obtained at various degrees of neutralization varied by more than 0.01 units the data were not used.

For following the rate of saponification 20 ml of ester solution were quickly brought to the required pH by manual addition of 0.1 N NaOH and the subsequent uptake of alkali due to hydrolysis was recorded on the SBR2 recorder as a function of time. The increase in volume of the reaction mixture during a run was about 0.5 ml. Above pH 11.0, it was necessary to correct for this; the additional alkali consumed to titrate this water was found from solvent titration curves. At 25° runs were not made at pH > 11.25. At higher pH's stronger titrant is required and hence more concentrated ester solutions are necessary thus introducing the risk of diketopiperazine formation. Also the electrode system is less stable at higher pH especially in runs of long duration. At 40 and 55° the buffering of the solvent was evident at lower pH's because the pK_w of water decreases.

For the first order log plots the observed rates were corrected for the ionization of the amino acid produced (correction for ester ionization was not necessary at pH > 10) using the apparent pK. The following expression was used:

$$2.303 \log_{10} \left[\frac{V_\infty}{V_\infty - V_{t_{corr}} f} \right] = k_{obs} t$$

where V_∞ = NaOH equivalent of ester
$V_{t_{corr}}$ = volume of NaOH added at time t and corrected for increase in volume of reaction mixture;
f = [1 + antilog (pK' − pH)]

For fast runs such as with *N*-acetylglycine methyl ester, Guggenheim plots (5) were used as this avoided the initial time error (and hence the error in V_t). pK' was not needed for this treatment, but as the reaction must be followed for more than two half-lives, this introduced errors due to 'drifting' in slow reactions. In such cases, log plots tended to be concave upwards and the V_∞ calculated from a Guggenheim plot was larger than expected from the initial ester concentration. Thus, where possible, both types of plots were made and the results discarded if the derived rate constants did not agree within an acceptable limit.

The concentration of hydroxide ions in the reaction mixture was determined from the pH and a curve of pH *vs.* concentration of NaOH, constructed from the titration of solvent (0.1 M NaCl) at the experimental temperature. The first order constant was divided by the concentration of alkali to give the second order constant k_2* on a concentration basis. $\Delta H^\ddagger$ and $\Delta S^\ddagger$ were calculated from the transition state theory equation

$$k_2^* = \frac{kT}{h} e^{\Delta S^\ddagger/R} e^{-\Delta H^\ddagger/RT}$$

A plot of $\log_{10} [k_2^*/T]$ *vs.* $[1/T]$ was linear for each ester but $\Delta H^\ddagger$ was obtained by using the k_2* values in three combinations, evaluating the error on each from the error in the k_2* values. A weighted mean value of $\Delta H^\ddagger$ was then calculated and this was used to obtain a value of $\Delta S^\ddagger$ at each temperature and its weighted mean was evaluated.

Results

The apparent or 'mixed' pK's of the amino acids and their esters are shown in Table 1. These are not thermodynamic quantities and were used on an empirical basis for correcting the observed titrimetric rates.

In the saponification mixtures the initial ester concentration was about 2.5 mM. This was considered a reasonable compromise between the sensitivity of the titrimetric method and the hazard of diketopiperazine formation. The latter is necessarily a bimolecular process so it was hoped that at 2.5 mM ester the reaction with hydroxide ion would predominate. Only leucine, *N*-methylleucine, and their methyl esters were detected by t.l.c. of partial hydrolysates. However, *N*-methylated diketopiperazines are difficult to detect. After saponification of *N*-methylalanine methyl ester at pH 11.0 and immediate neutralization, the hydrolysate gave only the titration curve of the amino group of an equivalent amount of *N*-methylalanine. Furthermore, consistent deviation from first order kinetics was not detected for any ester. Glycine (up to 2.5 mM) had no effect on the rate of alkali consumption in the hydrolysis of glycine methyl ester at pH 11.0. Thus we concluded that saponification of the ester was the only significant reaction occurring.

The results at 25° are shown in Table 2. For the unsubstituted esters the order of reactivities was that found by Hay *et al.* (6–8). *N*-Acetylation had

little effect on the rate for alanine and leucine, a slight enhancement for valine, and a marked increase for glycine and phenylalanine. In contrast, *N*-methylation reduced the rate by an order of magnitude for phenylalanine and leucine and by a factor of five for alanine; the reduction for glycine was less again but as sarcosine methyl ester was never obtained free of amino acid it was not subjected to more detailed studies. Somewhat unexpectedly the rates for the esters of *N*-acetyl, *N*-methylleucine, -valine, and -alanine fell between those of the unsubstituted and the *N*-methylated esters. It was not certain however that true solutions were obtained, especially for the valine and leucine derivatives so the reported rates may be lower than the rate in a homogeneous aqueous solution.

As observed by Hay *et al.* (7, 8) and Wright (9) for glycine and alanine, below p*H* 11.2 the second order rate constant increased as the p*H* decreased (the results with valine were not precise enough to see this effect). This was attributed to the hydrolysis of the charged form of the ester (7, 9) which proceeds about 100 times faster than the uncharged form. In principle, both rate constants can be obtained from the following equation developed by Hay and Porter (7):

$$k_2^* [[H^+] + K_E] = k_2^+ [H^+] + k_2 K_E$$

where k_2^* = observed second order rate constant
k_2^+ = second order rate constant for charged form
k_2 = second order rate constant for uncharged form
K_E = acid dissociation constant of the ester

At p$H > 10$, $[H^+] \ll K_E$, thus a plot of k_2^* *vs.* $[H^+]$ has slope k_2^+/K_E and intercept k_2. For *N*-methyl-L-alanine methyl ester such a plot gave

$$k_2^+ = 70 \pm 6\ M^{-1}\ s^{-1}$$
$$k_2 = 0.20 \pm 0.01\ M^{-1}\ s^{-1}$$

For calculating $[H^+]$, the value of 0.83 was used for the activity coefficient of hydrogen ion, at ionic strength 0.1 *M* (10).

It is difficult to determine the rate constant for the charged form by using a titrimetric technique because of the slow overall rate at the lower p*H*'s necessarily studied and because of the buffering of the amino acid product (p*K* 9–10). For example, for *N*-methylalanine methyl ester at p*H* 10, the observed rate was one half of the true rate. Thus, although this rate constant is very desirable the accuracy with which it can be determined by this technique is rather low (*vide* lack of agreement between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for glycine esters (7, 9)). Phenylalanine and its esters have relatively low p*K*'s and no variation in k_2^* was detected at 25° above p*H* 10.6, so phenylalanine was selected for a more detailed study. As the rates of saponification at 25° of the methyl esters of phenylalanine and *N*-acetylphenylalanine differed relative to those of leucine methyl ester and *N*-acetylleucine ester, the activation parameters were also obtained for the latter pair.

The results with *N*-methylalanine methyl ester showed that the cationic form was hydrolyzed about 350 times faster than the uncharged form. Because of this and the higher p*K*'s of *N*-methylated esters, it is likely that k_2^* would contain a contribution from k_2^+ at the highest p*H* consistent with the required degree of reproducibility of the titrimeter. Also, because of the slow reaction rates a greater number of runs were required to obtain reliable values. For this reason only *N*-methyl-L-phenylalanine ester was studied at higher temperatures. The saponification of the *N*-acetyl,*N*-methylamino acid esters was not studied at higher temperatures because their lower solubilities precluded a quantitative study in a purely aqueous environment, within the sensitivity limits of the titrimetric method.

At this juncture it should be emphasized that the main advantages of the automatic p*H*-stat method for our work are speed and the absence of buffer ions. The latter is important because esters activated in the acyl moiety are subject to general base-catalyzed hydrolysis (11).

The activation parameters for the saponification of the leucine and phenylalanine derivatives are given in Table 3.

Discussion

pK's of Amino Acids and their Esters

The α-amino group of an ester is a stronger acid than that of the parent amino acid by about two orders of magnitude. This can be qualitatively explained by the differences in inductive and electrostatic effects and in solvation between the acidic and basic forms. The ester cation resembles the monoalkyl ammonium ions whereas the acidic form of the amino acid is a zwitterion with

the positive and negative substituents on adjacent carbon atoms.

The values shown in Table 1 are 'mixed' constants containing the activity coefficients of the acidic and basic forms of the amino acid or its ester. As it is difficult to assign values to the activity coefficients of zwitterions no attempt was made to convert pK' to the thermodynamic values. However this probably does not invalidate the observation that with the exception of glycine, *N*-methylation of the α-amino group causes similar shifts in pK' to those reported for the monomethyl- and dimethylamines (12) (pK = 10.62 and 10.77, respectively, at 25°). *N*-Methylation should increase the basicity of the nitrogen but would change the pattern of solvation. The resulting change in ΔG may be small due to compensation behavior and an isokinetic relationship (13, 14).

Saponification of the Esters

The saponification of esters of carboxylic acids is considered to be a nucleophilic reaction proceeding through a tetrahedral intermediate whose rate of formation is the rate-limiting step (eq. 1). The evidence for this mechanism has been reviewed recently (15). Electron-withdrawing substituents in R^1 or R^2 enhance the rate of formation of the intermediate by reducing the charge density on the carbonyl carbon.

[1] $$R^1\text{—}\overset{\overset{O}{\|}}{C}\text{—}OR^2 + OH^- \rightleftharpoons R^1\text{—}\overset{\overset{O^-}{|}}{\underset{\underset{OH}{|}}{C}}\text{—}OR^2 \rightarrow R^1\text{—}\overset{\overset{O}{\|}}{C}\text{—}OH + R^2O^-$$

Influence of the Amino Acid Side-chain

For the unsubstituted esters we found the order of reactivities to be valine ≪ leucine < phenylalanine < alanine ~ glycine. This is in agreement with Hay *et al.* (6–8) except that the absolute values differ somewhat. Using Taft σ* values, and alanine methyl ester as reference compound, they found that the saponification rates of most amino acids followed the Taft equation (16) but the slope was very shallow (ρ* = 0.65). This means that the polar effect of the side-chain is minor (unless an isokinetic relationship exists with a compensation temperature near 25°). Valine and isoleucine which have branching on the β-carbon atom were much less reactive and did not follow the Taft relationship. Peptide bonds at the valine carbonyl are notoriously resistant to acid hydrolysis (17, 18). This was attributed to steric hindrance of the peptide bond to access by reagent. Long and Lillycrop (Purdie) have shown that the rate of acid-catalyzed hydrolysis of the Leu—Gly and Gly—Leu bonds in di- and tripeptides can be explained by solvation effects (19). This aspect of the effect of alkyl groups is considered in more detail below.

Effect of N-Methylation

The slow hydrolysis of the *N*-methylamino acid esters at 25° is at first sight rather surprising. The polar effect of the —$NHCH_3$ group would be slightly less favorable than that of the —NH_2. In terms of the shielding of the carbonyl carbon from attack by OH^-, the —$NHCH_3$ group is much more effective than the —NH_2, but the —N-$(CH_3)COCH_3$ should be at least as effective in this respect, which is not reflected in the relative rates. Hence other factors must be operative.

In the transition state for the formation of the tetrahedral intermediate there is a partial bond between the OH^- and the polarized carbonyl carbon of the ester. The reaction site has an overall unit negative charge in place of the dipolar condition of the ground state, leading to stronger solvation. This would cause a further decrease in $\Delta S^{\ddagger}$ (over that due to the formation of one entity from two). On the other hand the transition state will be stabilized by solvation which will be reflected in a lower $\Delta H^{\ddagger}$. For several reaction series and processes occurring in water, changes in ΔG and $\Delta G^{\ddagger}$ are much less marked than the changes in ΔH and $\Delta H^{\ddagger}$ and ΔS and $\Delta S^{\ddagger}$. That is, compensatory changes occur in the enthalpy and entropy so that the free energy change is minimized. This has been attributed by Laidler (20) to solvation and to the properties of liquid water (14).

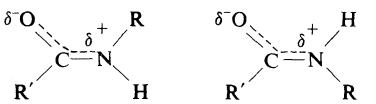
In the amino acid esters, β-alkyl substituents would tend to antagonize the orientation of the water molecules around the negatively charged area and promote 'iceberg' formation. An α-*N*-methyl group would considerably intensify this effect because then both front and back of the carbonyl group would be partially shielded (depending on the relative population of the conformers). Thus by changing the pattern of solvation around the carbonyl group, *N*-methylation could lead to an increase in $\Delta H^{\ddagger}$ and a less nega-

tive $\Delta S^{\ddagger}$. This is the case with L-phenylalanine methyl ester and its *N*-methyl analogue. The less negative $\Delta S^{\ddagger}$ does not compensate at room temperature for the increase in $\Delta H^{\ddagger}$ but at higher temperatures there is less disparity in saponification rates. For alanine, the ratio of saponification rates for the ester of the *N*-methylated acid to the unsubstituted acid is $\sim$1:5 compared to 1:10 for the phenylalanine and leucine pairs. For sarcosine and glycine the ratio is greater than 1:3. These figures reflect the lack of interference from β-substituents in the glycine and alanine derivatives.

Effect of N-Acetylation

At 25°, *N*-acetylation causes a 50–60% increase in rates for glycine and phenylalanine, a slight enhancement for valine and a small decrease for leucine and alanine. Charton's 'inductive' substituent constants σ′ (21) for $-CH_2NH_2$ and $-CH_2NHCOCH_3$ are 0.08 and 0.07 respectively so the purely polar effects of these substituents are very similar.

The peptide (or amide) bond is a rigid planar system due to the interaction of —NH and —CO groups to produce a resonance hybrid with considerable double bond character. This leads to *cis–trans* isomerism as illustrated below:

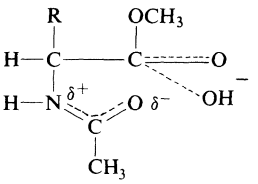


trans *cis*

Normally, in open-chain compounds, the *trans* form is the energetically more favorable. *N*-acetylleucine ethyl ester exists almost exclusively in the *trans* form in the solid state and in solution in chlorinated hydrocarbons (22). In this isomer, the $-CH_3$ of the acetyl group is distal to the ester bond with the polar peptide linkage in between. Thus the *trans* *N*-acetyl group *per se* should not greatly affect solvation of the transition state although it may interact with the alkyl side-chains to cause a less favorable conformation to be adopted.

Apart from the effects mentioned above, the ambident nucleophilic character of the peptide bond raises the possibility of anchimeric assistance or of an intramolecular nucleophilic reaction. The latter reaction has been implicated in the very rapid alkaline hydrolysis of 'active' esters of *N*-acylated glycine in which the cyclic oxazolinones were shown to occur as intermediates (23). However, no build-up of oxazolinone was detected during the saponification of the 'stable' ester methyl hippurate which is not hydrolyzed much faster than glycine methyl ester (rate constants 1.7 M^{-1} s^{-1} and 1.3 M^{-1} s^{-1} respectively (24)). Thus it is unlikely that this mechanism is important in the saponification of the esters of the *N*-acetylamino acids described here.

For the peptide bond to provide anchimeric assistance, it must stabilize the transition state of the rate-determining step (25). Assuming again that this state occurs in the formation of the tetrahedral intermediate, it can be represented as



Dreiding models show that H-bonding of the *N*-acetyl oxygen to the hydroxyl group of the intermediate is sterically possible. Whether such an interaction could occur and stabilize the transition state would depend on the extent of bond formation to (and hence, charge transfer from) the incoming hydroxyl ion. There may also be a detrimental electrostatic interaction between the hydroxide ion and the *N*-acetyl oxygen. However, whichever factors are operating, *N*-acetylation of the α-amino group has a relatively small net effect on the observed rate of saponification and on the related activation parameters. The latter quantities perhaps suggest that solvation effects are of most importance in the case of the leucine esters.

N-Methylation of the *N*-acetyl derivative increases the proportion of the *cis* isomer at room temperature. Evidence for this has been obtained from n.m.r. studies of sarcosine methyl ester (26), *N*-methylalanine methyl ester (27), acetyl-D-alanyl-*N*-methyl-D-alanine methyl ester (28), and several *N*-acetyl,*N*-methylamino acids (29, 30). For sarcosine methyl ester the *trans* form is predominant while for the alanine dipeptide ester up to 20% *cis* isomer was observed. The n.m.r. spectra in $CDCl_3$ of *N*-acetyl,*N*-methylglycine, -alanine, -valine, -leucine, and -isoleucine showed splitting of the *N*-CH_3 and α-CH resonances. The ratio of the integrals for major to minor peaks ranged from 5.4 for glycine to 2.0 for isoleucine.

Insufficient data were available for assignment of the individual peaks to *cis* or *trans* forms but the ratio is probably different for the esters in aqueous solution.

From n.m.r. data on the hindered rotation of *N*,*N*-dimethylacetamide (31) and other *N*-substituted acetamides (32), it is likely that the rates of interconversion of our esters are very much greater than their rates of saponification at 25°. As there will be different transition states for each isomer the observed rate constant for saponification is

$$k_{obs} = \frac{k_{trans}}{1 + K} + \frac{k_{cis}}{1 + K} K$$

where K is the equilibrium constant [*cis*]/[*trans*].

Molecular models show that the *N*-methyl group is about the same distance from the ester carbonyl in both isomers, but the positions of *C*-methyl and —CO differ. In the *cis* isomer the *C*-methyl is always directed towards, and the oxygen of the —CO group away from the main chain. The position of these groups are interchanged in the *trans* isomer so that the ester carbonyl is less 'hindered'. On this basis the higher the proportion of *cis* isomer the more slowly the ester would be saponified. This also implies that according to the observed rates, *N*-methylation does not greatly reduce the rate of saponification of the *trans* isomer. The positive inductive effect of the *N*-methyl group will tend to increase the partial negative charge on the *N*-acetyl oxygen. In the *trans* isomer, the distal *N*-methyl group would not sterically prevent anchimeric assistance. Also, the polar peptide bond in the *trans* conformation could offset to some extent the promotion of 'ice-berg' formation by the *N*-methyl group. Both these effects would be enhanced by the increased negative charge on the acetamido oxygen and perhaps offer a partial explanation of the faster saponification of the esters of the *N*-methyl,*N*-acetylamino acids than of their *N*-methyl analogues.

Effect of N-Protonation

N-Protonation produces by far the greatest effect on the rate of saponification. Some literature values for glycine and alanine esters together with those from the present work are shown in Table 4.

Holmquist and Bruice (33) have shown that for a series of *o*-nitrophenyl esters of XCOOH where X contained neutral and positively charged groups, electrostatic facilitation of hydroxide-ion catalysis is not important. Bell and Coller (34) obtained a linear plot of log k_{OH} *vs.* pK for a series of substituted acetic acid esters including betaine and glycine esters. Apparently the favorable inductive effect of the positive charge far outweighs any adverse effect of the *N*-methyl groups, in the case of glycine and alanine esters. This is also illustrated by the greater enhancement of rate when *N*-methylalanine ester is protonated than is the case for the non-methylated derivative; there is little difference between the k_2 values for the charged forms of alanine methyl ester and *N*-methylalanine ester (Table 4). It would be of interest to study the betaines of other amino acids to see whether the rate enhancement is maintained in the presence of bulky side-chains.

TABLE 4. Saponification rates of esters of *N*-methylated glycine and alanine at 25°[a]

The Configuration Dependent Cyclization of β-2-Hydroxyaroylacrylic Acids

P. C. Arora and P. Brassard
Département de Chimie, Université Laval, Québec, Québec

Received June 14, 1971

Several alleged chromanone-2-carboxylic acids were reexamined. Some were found to have the assigned structures but others are in fact 2-coumaranonylacetic acids. Diagnostic proof was obtained by analysis of the n.m.r. spectra of the corresponding reduced substances. Useful correlations of the spectra with the structures of the keto acids are proposed.

L'étude des présumées carboxy-2 chromanones a été reprise. Les attributions de structure ont été confirmées dans certains cas mais plusieurs substances sont en fait des acides coumaranonyl-2 acétiques. Les preuves de structure ont été obtenues par l'analyse des spectres de r.m.n. des composés réduits correspondants. Des corrélations utiles entre les spectres et les structures des deux groupes d'acides sont proposées.

The ambiguities associated with the cyclization of β-2-hydroxyaroylacrylic acids have been pointed out by Barr *et al.* (1). However the factors invoked (mainly steric effects) in the formation of 2-coumaranonylacetic acids and the method suggested for the determination of ring size (the evaluation of dissociation constants) do not appear to be unequivocal. Indeed the aluminum chloride catalyzed reaction between citraconic anhydride and 1,4-dimethoxybenzene gave rise, among other products, to 2-methyl-5-methoxy-2-coumaranonylacetic acid (**13**) (2). This unexpected result strongly suggested that a reexamination of some chromanone-2-carboxylic acids should be undertaken.

Syntheses of alleged chromanone-2-carboxylic acids have been affected or attempted by various means (3–5); however the conclusion has been reached (1) that one of the compounds isolated from the Friedel–Crafts condensation of 3,5-xylenol with maleic anhydride is in fact a coumaranone (**9**), whereas the colorless compounds obtained under similar conditions from β-naphthol and resorcinol as well as the one resulting from a triethylamine catalyzed cyclization of methyl β-[2-hydroxy-3,5-dimethylbenzoyl]-acrylate are claimed to be chromanones.

The syntheses of most of the known substances of these two types of oxygen-ring compounds have been repeated. It was found moreover, while attempting to degrade some β-2-hydroxybenzoylacrylic acids with aqueous barium hydroxide (6), that most of these compounds cyclize readily, thus contradicting fragmentary evidence to the contrary in the literature as to their behavior toward strong base (Jarowski *et al.* (3) found that chromanone-2-carboxylic acid yielded the corresponding 2-hydroxybenzoylacrylic acid while it has been observed (1) that β-(2-hydroxy-3,5-dimethylbenzoyl)-acrylic was not affected).

In particular, 2-hydroxy-5-methyl, *trans*-2-hydroxy-3,5-dimethyl, and 2,4-dihydroxybenzoylacrylic acids all cyclize readily to oxygen-ring compounds in the presence of barium hydroxide. *cis*-β-(2-Hydroxy-3,5-dimethylbenzoyl)-acrylic acid does not yield a monomeric compound under these conditions but can be cyclized by the use of weaker bases such as triethylamine. Moreover the oxygen-ring compounds obtained directly from *p*-cresol and resorcinol by Friedel–Crafts condensations are respectively identical to those obtained by base-catalyzed cyclizations of the corresponding benzoylacrylic acids.

Nuclear magnetic resonance spectroscopy seemed to be the most reliable method of resolving the problems of structure in these systems. Examination of the spectra of these oxygen-ring compounds revealed that they could be separated into two well defined groups. The aliphatic protons of group A (eventually found to be coumaranones) present a typical ABX pattern while those of group B (chromanones) give a more simple spectrum, *i.e.* there is no discernible splitting due to coupling of the geminal protons (Tables 1 and 2). This last pattern has also been observed in a nitrogen analog, kynurenine yellow (7). Another characteristic feature of the two groups of isomers was the difference in the chemical shifts of the methine protons. A quadruplet centered at about 5.0 p.p.m. appeared in the

*Pair of superimposed doublets.

spectra of all members of group A whereas it was observed at about 5.3 p.p.m. in the others. A somewhat analogous difference for methine protons at C-2 has been reported for flavanones and benzylcoumaranones (8).

These superficial distinctions are obviously not valid indications of particular structures nor are they even proof that two types of heterocycles are present since both isomers could conceivably give either (or both) type of spectra and moreover the difference in the chemical shifts for methine protons is small. However the validity of this original classification was eventually borne out by incontrovertible proof of structure. This evidence was obtained by examination of the n.m.r. spectra of the corresponding reduction products. Chromanones have been reduced to chromanols by a variety of agents which usually yield benzofurans when applied to coumaranones. However sodium borohydride was found to reduce both types of heterocycles to the corresponding alcools; the compound tentatively considered to be 7-hydroxy-2-coumaranonyl-acetic acid proved resistant to this reagent.

The compounds of group A (coumaranones) again were found to have the same general characteristics. They yielded only lactones without identifiable traces of hydroxy acids. Their n.m.r. spectra revealed that the coupling of the newly introduced methine proton resulted in the appearance of doublets at about 5.4–6.3 p.p.m.; on the other hand, the compounds of group B (chromanones) gave only or mainly hydroxy acids and the resulting methine protons appeared at about 4.7–5.2 p.p.m. as quartets in the n.m.r. spectra (Scheme 1).

Conclusions

The evidence presented here indicates that, in the case where both the *cis*- and *trans*-isomers of a β-2-hydroxyaroylacrylic acid are available, they can be cyclized respectively to a coumaranonylacetic acid and a chromanonecarboxylic acid. The reduction of some of these two types of heterocycles demonstrates unequivocally that the compound variously considered as 5,7-dimethyl-2-carboxychromanone (4) or as 4,6-dimethyl-2-coumaranonylacetic acid (1) is indeed a coumaranone while those described as 6,8-dimethyl, 5,6-benzo, and probably also 7-hydroxy 2-carboxychromanones are in fact the corresponding coumaranones. The structure of 6-methyl-2-carboxychromanone was confirmed and those of a few new compounds were also definitely established.

The cyclization of the *trans*-acids to chromanones is fairly straight-forward and follows from basic electronic considerations known to prevail in molecules of this type. However, in the case of the *cis*-acids, it is debatable whether a different mode of cyclization results from a difference in stereochemistry or whether it proceeds through the lactol tautomer. Most *cis*-β-aroylacrylic acids show a definite tendency to exist in varying degrees in the lactol form (9), a preference which however is not shown by the *o*-hydroxylated congeners (these compounds are highly colored and show i.r. bands quite characteristic of the acyclic forms). It would seem possible then that under mildly basic catalysis, the strong hydrogen bond which prevents lactol formation is disrupted giving rise to the cyclic tautomer and thence exclusively to the coumaranones (strong bases are known to produce acyclic anions) (9). The isolation of the compound now thought to be 7-hydroxy-2-coumaranonylacetic acid would indicate that electronic effects may in certain cases take precedence over configurational ones as would be expected particularly in this instance (1). These two last aspects of the mechanism involved are now being actively investigated (Scheme 2).

The reduction of three 2-coumaranonylacetic acids indicated rather surprisingly that the action of sodium borohydride is completely stereoselective. The attack occurs from the side opposite to the carboxylic group and yields lactones even when the substrate was 2,2-disubstituted. These reductions would then seem to illustrate a particularly effective case of "electrostatic shielding" (10) or of the "electrostatic influence or remote substituent dipoles" (11).

On the other hand, only two chromanone-2-carboxylic acids were reduced. In one case (**6**) a hydroxy acid was found to be the sole product formed either by borohydride reduction or by catalytic hydrogenation. The large values obtained for $|J_{ax} + J_{bx}|$ and $|J_{am} + J_{bm}|$, 12.3 and 13.3 Hz, from the n.m.r. spectrum establish that both substituents are equatorial and therefore *cis* (12). The other keto acid which was 2,2-disubstituted gave mainly a hydroxy acid (and a small amount of lactone). From the n.m.r. spectrum it can be deduced that the hydroxyl group is probably equatorial ($|J_{ax} + J_{bx}| = 9.6$ Hz), but the relative positions of the two substituents in the heterocycle have not yet been determined with certainty although they are assumed to be *cis* by analogy with the other compounds in these series.

Experimental

All melting points were taken in capillary tubes with a calibrated thermometer (Thomas–Hoover Apparatus). The i.r. spectra were recorded with a Beckman IR-4 spectrometer. The n.m.r. spectra were determined with a Varian A-60 spectrometer using tetramethylsilane as internal standard. (All values for AB patterns are corrected; for the sake of consistency all chemical shifts and coupling constants in more complex patterns are apparent and not corrected.)

(A) Preparation of Starting Materials

The following compounds were prepared according to known methods or by the authors in another context:

β-(2-Hydroxy-5-methylbenzoyl)-acrylic acid (**1**), m.p. 172–173.5° (lit. 173–174° (4)); δ ($(CD_3)_2CO$) 2.44 (s) (methyl), 7.10 (d), and 8.22 (d) (olefinic protons, $J =$ 15.5 Hz).

cis-β-(2-Hydroxy-3,5-dimethylbenzoyl)-acrylic acid (**2**), m.p. 152–155.5° (lit. 149–153° (5)); $\lambda_{max}(CHCl_3)$ 6.13, 5.82, 3.33 μ; δ ($(CD_3)_2CO$) 2.32 (s) and 2.35 (s) (methyl), 6.47 (d), and 7.22 (d) (olefinic protons, $J = 12.2$ Hz).

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72. Found: C, 70.04; H, 4.62.

(B) The Base-catalyzed Cyclization of β-2-Hydroxybenzoylacrylic Acids

The β-2-hydroxybenzoylacrylic acid (1.0 g) in an aqueous solution (25 ml) of barium hydroxide (1.0 g; 1.75 g for the dihydroxy compound) was stirred for several hours then acidified with hydrochloric acid and extracted with methylene chloride (all compounds gave negative ferric chloride tests).

6-Methylchromanone-2-carboxylic acid (**6**) from **1** (40%), m.p. 156.5–157.5° (chloroform and petroleum ether).

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89. Found: C, 63.89; H, 4.92.

6,8-Dimethylchromanone-2-carboxylic acid (**8**) from **3** (33%), m.p. 185–186° (methylene chloride) (lit. 166–170° (dec.) (1)).

6-Hydroxy-2-coumaranonylacetic acid (**10**) from **4** (40%), m.p. and mixture m.p. 223–224.5°.

2-Methyl-6-methoxychromanone-2-carboxylic acid (**12**) from **5** (75%), m.p. 130–131° (benzene and petroleum ether).

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.12; O, 33.87. Found: C, 61.30; H, 4.83; O, 34.01.

(C) The Aluminum Chloride-catalyzed Cyclization of β-2-Hydroxybenzoylacrylic Acids

β-2-Hydroxy-5-methylbenzoylacrylic acid (1.0 g) was added to a molten mixture of aluminum chloride (10.0 g) and sodium chloride (1.5 g) at 170–180°. The melt was stirred at this temperature for 15 min then cooled and decomposed with ice and hydrochloric acid. Extraction with methylene chloride yielded 6-methylchromanone-2-carboxylic acid (**6**) which was identical (m.p., mixture m.p., and i.r. spectrum) with the compound prepared by the base-catalyzed cyclization. Prolonged heating (1 h) gave 4-hydroxy-7-methyl-3-oxoindane-1-carboxylic acid (0.3 g) by the usual method, m.p. 143.5–145° (water) (lit. 149–150° (4)) (positive ferric chloride test: dark blue); δ ($CDCl_3$) 2.30 (s) (methyl), 2.96 (d) (methylene, J = 5.0 Hz), 4.24 (t) (methine, J = 5.0 Hz), 6.80 (d) and 7.38 (d) (aromatic protons, J = 8.5 Hz), and 10.25 (carboxyl).

(D) The Triethylamine-catalyzed Cyclization of cis-β-2-Hydroxybenzoylacrylic Acids

Triethylamine (5 ml) was added to a solution of *cis*-β-(2-hydroxy-3,5-dimethylbenzoylacrylic acid (0.5 g) in ether (50 ml) and the mixture was allowed to stand for 48 h. After evaporation, acidification with dilute hydrochloric acid, and extraction with ether, 5,7-dimethyl-2-coumaranonylacetic acid was obtained, m.p. 164–165.5° (methylene chloride) (80%).

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49. Found: C, 65.14; H, 5.48.

(E) The Reduction of Oxygen-ring Keto Acids with Sodium Borohydride

The chromanone-2-carboxylic acid or 2-coumaranonylacetic acid (1.0 g) was dissolved in dioxane (25 ml) and absolute ethanol (5 ml); sodium borohydride (0.25 g) was added and the mixture was stirred at room temperature for 24 h. The solvents were evaporated under vacuum, the residue acidified with dilute hydrochloric acid, and extracted with ether. The ether extract after washing with a 5% solution of sodium bicarbonate yielded the lactone while the hydroxy acids were recovered in the usual way from the bicarbonate extract.

cis-4-Hydroxy-6-methylchroman-2-carboxylic acid (**15**) from **6** (60%), m.p. 160.5–161.5° (acetone – petroleum ether).

Anal. Calcd. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81. Found: C, 63.79; H, 5.92.

cis-3-Hydroxy-4,6-dimethyl-2-coumaranylacetic acid lactone (**16**) from **9** (70%), m.p. 135–136° (methanol).

The Meyer Reaction of Phenylnitromethane in Acid. I. The Reactions of Phenyl-*aci*-nitromethane in Acid[1]

J. T. EDWARD AND P. H. TREMAINE
Department of Chemistry, McGill University, Montreal, Quebec

Received December 14, 1970[2]

Phenyl-*aci*-nitromethane reacts in aqueous sulfuric acid at room temperature to form phenylnitromethane and benzohydroxamic acid. The relative amounts of these two products depend on the concentration of the acid. Benzohydroxamic acid is formed by reaction of the intermediate, benzonitrile oxide, with water.

Solvent effects, substituent effects, and isotope effects have been studied to determine mechanisms for these reactions of phenyl-*aci*-nitromethane.

Le phényl-*aci*-nitrométhane au contact de l'acide sulfurique à température ambiante, donne deux produits: le phénylnitrométhane et l'acide benzohydroxamique. Un changement dans la concentration de l'acide sulfurique fait varier la proportion des deux produits. L'acide benzohydroxamique provient de la réaction de l'intermédiaire, l'oxyde de benzonitrile, avec l'eau.

L'influence du solvant et des substituants et les effets isotopiques ont été étudiés dans le but de découvrir le mécanisme de ces réactions.

Canadian Journal of Chemistry, **49**, 3483 (1971)

Introduction

Primary nitroalkanes in hot concentrated mineral acids give a carboxylic acid and hydroxylamine. This reaction was first reported by Meyer and Wurster in 1873 (1), and is now used commercially for the production of hydroxylamine.

It has been claimed (2, 3) that the rate-determining step in the Meyer reaction (illustrated in eqs. 1–3 for a phenylnitromethane) is the acid-catalyzed formation of the *aci*-form **2** of the nitroalkane **1**

[1] $$\underset{\mathbf{1}}{ArCH_2NO_2} \rightarrow \underset{\mathbf{2}}{ArCH{=}\overset{+}{N}\begin{matrix}O^-\\OH\end{matrix}}$$

[2] $$\underset{\mathbf{2}}{ArCH{=}\overset{+}{N}\begin{matrix}O^-\\OH\end{matrix}} \xrightarrow[H_2O]{H^+} \underset{\mathbf{3}}{ArC\begin{matrix}O\\NHOH\end{matrix}}$$

[3] $$\underset{\mathbf{3}}{ArCONHOH} + H_2O \rightarrow \underset{\mathbf{4}}{ArCO_2H} + NH_2OH$$

(eq. 1), followed by its rapid transformation into a hydroxamic acid **3** (eq. 2), which is then hydrolyzed to a carboxylic acid **4** and hydroxylamine (eq. 3). However, the nature of the steps involved in the transformation summarized in eq. 2 has remained obscure. Recently Cundall and Locke (3) have investigated the kinetics of the hydrolysis of nitromethane, and have proposed two possible mechanisms (one involving a nitrile oxide intermediate). However, they were unable to distinguish between these two alternatives.

In this and the following two papers we report on our studies of the mechanism of the Meyer reaction of phenylnitromethane, which in hot concentrated acid is converted into benzoic acid and hydroxylamine (4). The presence of the phenyl group makes it possible to study this reaction conveniently by u.v. spectrophotometry. In this paper we report on the mechanism of the reactions of phenyl-*aci*-nitromethane (**2**; Ar = Ph) and substituted phenyl-*aci*-nitromethanes; *i.e.*, on the mechanism of some of the reactions summarized by eq. 2, and the mechanism of **2** → **1**, the reverse of eq. 1.

Experimental

Materials

Phenylnitromethane was prepared by alkaline nitration of phenylacetonitrile (5). Nitration of phenylnitromethane with fuming nitric acid was used to prepare *m*-nitrophenylnitromethane, m.p. 96–97.5 °C (lit. 92–94 °C (6)). *p*-Methylphenylnitromethane, b.p. 76–78 °C/2 mm (lit. 99 °C/3 mm) was prepared by the reaction of α-chloro-*p*-xylene with silver nitrite in diethyl ether (7). *o*-Methylphenylnitromethane, b.p. 86–89 °C/2 mm (lit. 137–139 °C/23 mm) was synthesized in a similar manner from

For personal use only.

α-chloro-*o*-xylene, and characterized by formation of the benzal derivative, m.p. 93.5–94 °C (lit. 92 °C (8)).

The sodium salt of phenylnitromethane was prepared by addition of a methanol solution of phenylnitromethane to an equivalent amount of sodium methoxide in methanol. The solution was partially evaporated to precipitate the *aci*-salt, filtered, and the precipitate washed well with anhydrous ether. The white powder obtained was dried *in vacuo*. A stock solution of the sodium salt of phenylnitromethane was prepared by dissolving 7.5 mg of the salt in 0.01 *N* sodium hydroxide solution (10 ml).

The salts and the stock solutions of *m*-nitrophenylnitromethane, *p*-methylphenylnitromethane, and *o*-methylphenylnitromethane were prepared by a similar procedure.

Kinetic Runs

For each run, a 1.00 ml aliquot of the *aci*-salt stock solution at the reaction temperature was added to 25.00 ml of dilute sulfuric acid at the reaction temperature. After mixing, a spectrophotometer cell was rinsed with the reaction mixture, was then filled, and was placed in the temperature-controlled cell block of a Unicam SP800 spectrophotometer. After an equilibration period of 1 min, the u.v. spectra of the cell contents were obtained as a function of time by scanning at intervals. "Infinity" readings were obtained after at least seven half-lives. The pseudo-first-order rate constant (k_ψ) was calculated from the data for the optical density *vs.* time by a least-squares computer program. The concentration of the sulfuric acid was determined by titration of the reaction mixture with standard sodium hydroxide solution.

Phenyl-aci-nitromethane-α-d

Phenylnitromethane (194 mg) was dissolved in 2.5 *N* sodium deuteroxide in deuterium oxide (1 ml). The progress of the exchange was followed by p.m.r. spectroscopy. After heating to 70 °C for 6 h, the resonance from the α-proton (τ 2.9) had been reduced to 10% of the starting value. A 4 μl aliquot of this solution was added to 25.00 ml of dilute sulfuric acid and the kinetics were followed as above.

Isolation of Benzonitrile Oxide

A solution of 100 mg of the sodium salt of phenylnitromethane in 0.01 *N* sodium hydroxide solution (2 ml) was added to 3.5 *M* sulfuric acid (8 ml), resulting in a 2.8 *M* concentration of sulfuric acid. Ninety seconds after mixing, the solution was shaken with an equal volume of carbon tetrachloride; the organic layer was separated and cursorily dried over magnesium sulfate. The i.r. spectrum of the carbon tetrachloride solution was found to be identical with the spectrum of a solution of authentic benzonitrile oxide, prepared by the procedure of Wiley and Wakefield (9).

A similar extraction, carried out only 30 s after mixing, showed only a small peak at 2280 cm^{-1}, where benzonitrile oxide absorbs strongly, and a peak at 1650 cm^{-1} due to the *aci*-nitro group (10).

The first procedure above was repeated for the isolation of *m*-nitrobenzonitrile oxide from *m*-nitrophenyl-*aci*-nitromethane, but the medium used was 6.2 *M* sulfuric acid instead of 2.8 *M*. The i.r. spectrum of *m*-nitrobenzonitrile oxide in carbon tetrachloride showed characteristic absorptions at 2295, 1538, 1380, and 1350 cm^{-1}; these were observed also in the spectrum of authentic *m*-nitrobenzonitrile oxide (9).

Results and Discussion

Effect of Acid Concentration

Kornblum and Graham (11) isolated phenylnitromethane in 81% yield after addition of an excess of 20% hydrochloric acid to a strongly basic solution of phenylnitromethane at 5 °C, and Kornblum and Brown (12) isolated *p*-nitrophenylnitromethane in 93% yield after the *aci*-form had been allowed to react with 3.5 *N* sulfuric acid for 45 min. However, when the sodium salt of *p*-nitrophenylnitromethane was added to 85% sulfuric acid at room temperature, an 86% yield of *p*-nitrobenzohydroxamic acid was isolated after a few minutes. Alkylhydroxamic acids have frequently been isolated from the Meyer reaction in concentrated acid, in which their hydrolysis to a carboxylic acid and hydroxylamine is slow (13).

It is evident, then, that phenyl-*aci*-nitromethane in acid can give either phenylnitromethane or the Meyer reaction products, depending on whether the acid is dilute or concentrated.

Branch and Jaxon-Deelman (14) studied the transformation of phenyl-*aci*-nitromethane (**2**; Ar = Ph) to phenylnitromethane (**1**; Ar = Ph) in weak aqueous acid at 0 °C. They came to the conclusion that the tautomerization proceeds by ionization of the *aci*-form (**2**) to the anion (**5**) (eq. 4) which is then C-protonated by the solvent to form the nitro tautomer (**1**) (eq. 5)

[4] $H_2O + \underset{\mathbf{2}}{ArCH{=}NO_2H} \rightleftharpoons \underset{\mathbf{5}}{ArCH{=}NO_2^-} + H_3O^+$

[5] $\underset{\mathbf{5}}{ArCH{=}NO_2^-} + H_3O^+ \rightarrow \underset{\mathbf{1}}{ArCH_2NO_2} + H_2O$

We studied the kinetics of the disappearance of phenyl-*aci*-nitromethane in acid by u.v. spectroscopy at 274 nm. The rate of disappearance of the *aci*-form increased with increasing acidity (Table 1). It was evident from the u.v. spectra (Fig. 1) that the nitro-form was not the only product from the reaction in 2 *M* sulfuric acid at 25.1 °C. The spectra showed clearly the decay of the *aci*-form (λ_{max} 274 nm), the formation and subsequent decay of an intermediate having a u.v. peak at 241 nm, and finally the formation of benzohydroxamic acid, having a peak at 230 nm. Phenylnitromethane, the other

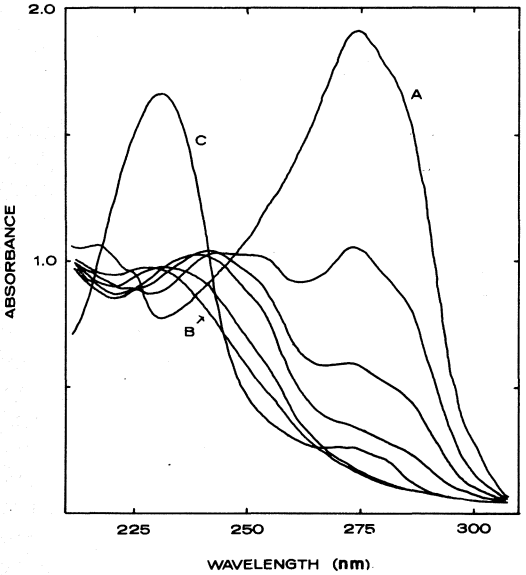

FIG. 1. The u.v. spectra recording the reaction of 0.00018 *M* phenyl-*aci*-nitromethane in 1.99 *M* sulfuric acid, after 60 s at 25.1 °C (*A*), after 3000 s at 25.1 °C (*B*), and after 2 days at 70° (*C*).

product from the *aci*-form, showed only end-absorption. On heating the reaction mixture to 70 °C for 2 days, both benzohydroxamic acid and phenylnitromethane were converted to benzoic acid (λ_{max} 230 nm), so that the peak at 230 nm increased by about 50%. Using the extinction coefficients at 230 nm of phenylnitromethane, benzohydroxamic acid, and benzoic acid, it was possible to calculate the rates of formation of phenylnitromethane (k_{-1}) and of the intermediate leading to benzohydroxamic acid (k_2) (15) (Table 1 and Fig. 2).

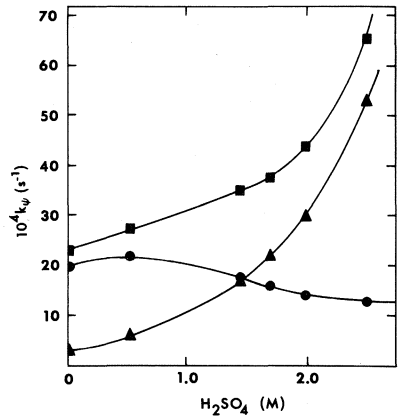

FIG. 2. Rate profiles (k_ψ) for the reaction of phenyl-*aci*-nitromethane in sulfuric acid at 25.1 °C: ■, pseudo-first-order rate constants for the disappearance of the *aci*-form; ●, pseudo-first-order rate constants for the formation of the nitro-form; ▲, pseudo-first-order rate constants for the formation of benzonitrile oxide.

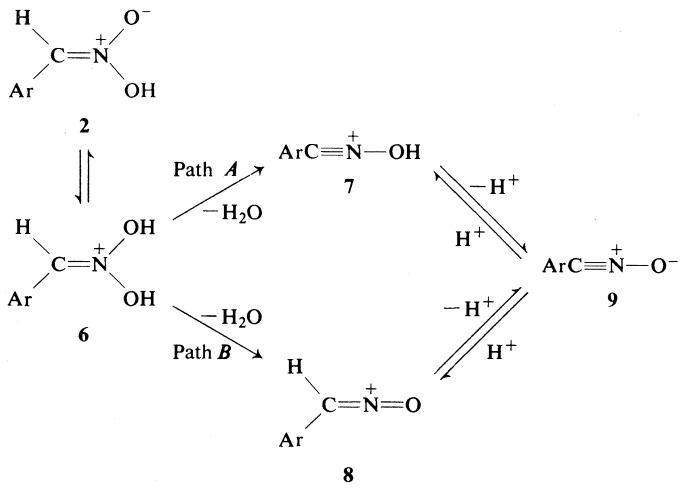
The intermediate was extracted from a more concentrated reaction mixture into carbon tetrachloride and identified as benzonitrile oxide (9) by i.r. spectroscopy. It is shown in a following paper that benzonitrile oxide is hydrolyzed in acid cleanly to benzohydroxamic acid under the conditions of temperature and acid concentration employed in the present study.

Two mechanisms may be postulated (Scheme 1) for the conversion of phenyl-*aci*-nitromethane (**2**) to benzonitrile oxide (**9**). Cundall and Locke (3) proposed path *B*, without any experimental evidence to support the proposal, as well as another path not involving a nitrile oxide. However, an alternative pathway (*A*) to benzonitrile oxide may be envisaged. These two paths *A* and *B* are discussed below, and a choice between them is made. For the present it is sufficient to note that both mechanisms involve the formation of the protonated *aci* compound **6**, and hence both require acid-catalysis for the formation of the nitrile oxide **9**, as is observed (Fig. 2).

On the other hand, the formation of phenylnitromethane from phenyl-*aci*-nitromethane is inhibited by high acidities (Fig. 2). This evidence is in accord with the mechanism proposed in eqs. 4 and 5 (14, 16), high acidities preventing the formation of the anion **5** and hence the nitro compound **1**.

Isotope Effects

In an attempt to discriminate between the two



SCHEME 1

possible paths *A* and *B* in the formation of the nitrile oxide **9** from the *aci* compound **2**, we have determined the rates for the reactions of α-deuterio-*aci*-phenylnitromethane in acid solution. Significant stretching of the carbon–deuterium bond in the rate-controlling step would cause at least a two-fold decrease in the reaction rate (17). The results (Table 2) indicate that the α-hydrogen bond is not stretched in the transition state for the rate-determining step in the formation of the nitrile oxide. These results would seem to exclude path *A*, since the step **6** → **7** would certainly be the slow step in this mechanism. The evidence can be construed as evidence in support of reaction path *B* if the dehydration **6** → **8** is the slow step in the reaction.

No primary isotope effect would be expected for the tautomerization **2** → **1**, if it proceeds by the mechanism of eqs. 4–5, and none is found (Table 2).

Substituent Effects

The rate of disappearance of *m*-nitrophenyl-*aci*-nitromethane in sulfuric acid at room temperature was followed by u.v. spectrophotometry at 285 nm (Table 3 and Fig. 3). In dilute acid, the disappearance of this substituted *aci*-form was faster than the disappearance of the unsubstituted *aci*-form. Cooke and Macbeth (16) observed a similar increase in tautomerization rates of other substituted phenyl-*aci*-nitromethanes in water when the substituents were electron-withdrawing. This can be understood in terms of the mechanism of eqs. 4 and 5, if the effect of the electron-withdrawing substituent in making the substituted *aci*-form a stronger acid, and hence increasing the concentration of the anion **5** (eq. 4) is more important than its effect in decreasing the rate of protonation of **5** to form **1** (eq. 5).

In dilute acid, the *m*-nitro group can be expected not only to accelerate the conversion

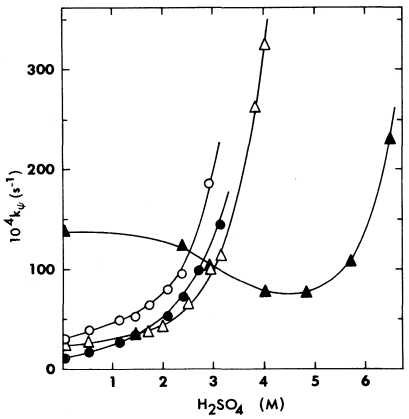

FIG. 3. Rate profiles (k_ψ) for the disappearance of phenyl-*aci*-nitromethanes in sulfuric acid: △, phenyl-*aci*-nitromethane (25.1 °C); ○, *o*-methylphenyl-*aci*-nitromethane (25.4 °C); ●, *p*-methylphenyl-*aci*-nitromethane (25.4 °C); ▲, *m*-nitrophenyl-*aci*-nitromethane (25.4 °C).

of the *aci*-form **2** to the nitro form **1**, but to retard the formation of *m*-nitrobenzonitrile oxide **9** (and thence of *m*-nitrobenzohydroxamic acid) by making the *aci*-form **2** a weaker base in the reaction **2** → **6** (Scheme 1). For these reasons, no *m*-nitrobenzonitrile oxide or *m*-nitrobenzohydroxamic acid are observed as products in dilute acid (<4 *M*). However, at high enough acid concentrations the rate of formation of the nitro compound is sufficiently depressed (by repression of reaction 4), and the rate of formation of the nitrile oxide sufficiently enhanced (by protonation of **2** → **6**), for *m*-nitrobenzonitrile oxide (λ_{max} 243 nm) to become apparent in the reaction mixture. It rapidly adds water to form *m*-nitrobenzohydroxamic acid (λ_{max} 215 nm). Some *m*-nitrobenzonitrile oxide was extracted from a concentrated solution of the *aci*-compound in 6.2 *M* sulfuric acid, and identified by its i.r. spectrum.

The rates of disappearance of *p*-methylphenyl-*aci*-nitromethane and *o*-methylphenyl-*aci*-nitromethane in sulfuric acid were determined by following the decay of their absorption peaks at 280 nm (Table 3 and Fig. 3). Even in 1 *M* sulfuric acid, some *o*- and *p*-methylbenzonitrile oxide is observed during the reaction of both substituted *aci*-forms, so the observed rate of disappearance is a combination of the rate of tautomerization to the nitro-form and the rate of dehydration to *o*- and *p*-methylbenzonitrile oxide. It is evident from the results that both of these reactions are accelerated by the proximity of the methyl group to the reaction site. The molecular model of the ortho-substituted *aci*-form shows some crowding, which is relieved on dehydration by path *A* or *B* of Scheme 1. The strain is also relieved on tautomerization to the nitro-form. A steric acceleration of the tautomerization in water has already been observed for *o*-chloro- and *o*-bromophenyl-*aci*-nitromethane (16).

Activation Parameters

The entropies of activation calculated for the disappearance of phenyl-*aci*-nitromethane in acid are negative (Table 4) over a range of acid concentration. It must be kept in mind that the disappearance of the *aci*-form takes place by two paths: tautomerization to the nitro-form and dehydration to benzonitrile oxide. As the acid concentration is increased, the increase in the entropy of activation is due to the greater contribution of the dehydration path to the disappearance. Such a process would be expected to have a higher entropy of activation than the proton transfer necessary for tautomerization (18).

There is little change in the enthalpy of activation for the disappearance of the *aci*-form as the acid concentration is increased, demonstrating the equality of the energy barriers for the two competing modes of disappearance. This indicates that for a particular acid concentration,

TABLE 4. Activation parameters for disappearance of phenyl-*aci*-nitromethane in sulfuric acid

34.2	2.51	165.		

*1 *M* standard state.

the ratio of the rates of the two reactions (tautomerization and dehydration) would remain approximately constant as the temperature is raised.

Conclusions

This study has shown that the pseudo-first-order rate constant (k_ψ) for the disappearance of phenyl-*aci*-nitromethane (**2**) in acid is made up of two rate constants: k_{-1} for the tautomerization to the nitro form (**1**), and k_2 for the dehydration to benzonitrile oxide (**9**) (eq. 6) The mechan-

$$[6]\quad \underset{\mathbf{1}}{ArCH_2NO_2} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{2}}{ArCH{=}NO_2H} \overset{k_2}{\rightarrow} \underset{\mathbf{9}}{ArC{\equiv}\overset{+}{N}{-}O^-} + H_2O$$

isms of these reactions have been discussed, and account for the fact that while in dilute acid $k_{-1} > k_2$, in strong acid $k_2 \gg k_{-1}$. The activation parameters indicate that the relative rates would not change greatly with temperature.

Kinetic isotope studies indicate that benzonitrile oxide is formed from the protonated *aci*-form by slow elimination of water from the two hydroxyls attached to nitrogen, followed by rapid proton loss from carbon.

The Meyer Reaction of Phenylnitromethane in Acid. II. Reactions in Acid of Benzonitrile Oxide and Benzohydroxamic Acid[1]

J. T. EDWARD AND P. H. TREMAINE
Department of Chemistry, McGill University, Montreal, Quebec

Received December 14, 1970[2]

The kinetics of the transformation of benzonitrile oxide in dilute sulfuric acid into benzohydroxamic acid have been followed by u.v. spectrophotometry at a temperature near room temperature. A mechanism is proposed on the basis of the effects of substituents and sulfuric acid concentration.

The rate profile for the hydrolysis of benzohydroxamic acid in hot dilute sulfuric acid has been obtained.

The results of these studies are applied to the detailed mechanism of the Meyer rearrangement – hydrolysis of phenylnitromethane in acid.

La cinétique de formation de l'acide benzohydroxamique à partir de l'oxyde de benzonitrile dans l'acide sulfurique a été étudiée à la température ambiante. Afin de proposer un mécanisme pour cette réaction on a étudié l'influence de divers substituants et de différentes concentrations d'acide.

La vitesse de l'hydrolyse de l'acide benzohydroxamique a été étudiée à 68.8 °C en variant la concentration de l'acide sulfurique.

Les conclusions de ces études sont appliquées au mécanisme de la réaction de Meyer sur le phénylnitrométhane.

Canadian Journal of Chemistry, **49**, 3489 (1971)

Introduction

In an example of the Meyer reaction, phenylnitromethane forms benzoic acid and hydroxylamine when heated in mineral acid (1). The slowest step in the reaction sequence is the formation of phenyl-*aci*-nitromethane (eq. 1) (2), and in the preceding paper (3) we have studied the rate at which phenyl-*aci*-nitromethane reverts to phenylnitromethane (k_{-1} of reaction 1) and the rate at which it is dehydrated to benzonitrile oxide (k_2 of reaction 2). It is already know that benzonitrile oxide in acid solution adds water to form benzohydroxamic acid (eq. 3) (4) (which has been isolated in small yield from the reaction of phenylnitromethane in hot acid (5)), and that benzohydroxamic acid is hydrolyzed to benzoic acid and hydroxylamine (eq. 4) (6), but no kinetic studies have been reported for these reactions. We now report these, as a part of an overall study of the Meyer reaction of phenylnitromethane described in this and two accompanying papers (3, 7).

$$[1] \quad ArCH_2NO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ArCH{=}NO_2H$$

$$[2] \quad ArCH{=}NO_2H \xrightarrow[k_2]{} ArC{\equiv}\overset{+}{N}{-}O^- + H_2O$$

$$[3] \quad ArC{\equiv}\overset{+}{N}{-}O^- + H_2O \rightarrow ArCONHOH$$

$$[4] \quad ArCONHOH + H_2O \rightarrow ArCO_2H + NH_2OH$$

Experimental

Preparation of Benzonitrile Oxide

Benzohydroximoyl chloride (m.p. 50–52 °C) was prepared by the chlorination of benzaldoxime in hydrochloric acid (8). A solution of 30 mg of benzohydroximoyl chloride in 5 ml of carbon tetrachloride was shaken with 5 ml of water, the organic layer was drawn off and dried with magnesium sulfate at 0 °C. The i.r. spectrum of this solution showed the same distinctive absorptions at 2290, 1368, 1096, and 1029 cm^{-1} that are found in the spectrum of authentic benzonitrile oxide prepared using sodium carbonate solution (8). The carbon tetrachloride solution was extracted with water and the u.v. spectrum of the extract showed an absorption at 245 nm with a slight shoulder at 253 nm. This is identical with the spectrum of authentic benzonitrile oxide in water.

The addition of aqueous sodium carbonate to this solution of benzonitrile oxide in the spectrophotometer cell initiated a change in the u.v. spectrum, which passed with an isosbestic point from an absorption with λ_{max} 245 nm to one with λ_{max} 268 nm. The product was identified as benzohydroxamate anion on the basis of its u.v. spectrum and the spectrum of benzohydroxamic acid obtained on acidification (λ_{max} 230 nm).

Kinetic Runs on the Benzonitrile Oxides

(1) From Benzohydroximoyl Chloride

A 10^{-3} *M* stock solution of benzonitrile oxide was prepared by dissolving 15 mg benzohydroximoyl chloride in 25 ml distilled water. A 1 ml aliquot of this stock solu-

[1]The research for this paper was supported in part by the Defence Research Board of Canada, Grant number 9530–57.

[2]Revision received July 21, 1971.

For personal use only.

tion at the reaction temperature was added to 25.00 ml dilute sulfuric acid, which was pre-equilibrated at the reaction temperature. After mixing, a 1 cm spectrophotometer cell was rinsed with the reaction mixture, was then filled, and placed in the temperature-controlled cell block of a Unicam SP800 spectrophotometer. After an equilibration period of at least 1 min, the u.v. spectrum was scanned at recorded time intervals. The spectrum at "infinite" time was recorded after at least seven half-lives. The optical densities (A) were measured from the spectra at 243 nm, and the first-order rate constant was obtained from a computer-calculated least-squares plot of ln $(A_t - A_\infty)$ *vs.* time. The concentration of the sulfuric acid solution was determined after the run by titration of the reaction mixture with standard alkali. A similar procedure was used for preparation of *m*-nitrobenzonitrile oxide from *m*-nitrobenzohydroximoyl chloride for the kinetic experiments in dilute sulfuric acid.

(2) From Phenyl-aci-nitromethane

The procedure used to determine the rate of reaction of phenyl-*aci*-nitromethane in acid solution has been described in the preceding paper (3). At some acid concentrations, the u.v. spectra still show the presence of benzonitrile oxide after at least 90% of the phenyl-*aci*-nitromethane has reacted. The disappearance of this benzonitrile oxide has been followed by repetitive scanning at recorded time intervals with an equilibrium reading taken after at least seven half-lives. The data for the optical density *vs.* time were treated as above to obtain the first-order rate constant.

A similar procedure was used to follow the reactions of *m*-nitrobenzonitrile oxide at 245 nm, *o*-methylbenzonitrile oxide at 250 nm, and *p*-methylbenzonitrile oxide at 256 nm.

Hydrolysis of Benzohydroxamic Acid

One milliliter of an aqueous stock solution of benzohydroxamic acid was added to 25.00 ml of dilute sulfuric acid to produce a final concentration of benzohydroxamic acid of 0.0007 *M*. Two milliliter aliquots of this reaction mixture were measured into screw-capped glass vials. These sample tubes were heated in a thermostatted water bath to 68.8 °C. After an equilibration period of 45 min, tubes were removed at different time intervals, cooled in ice, and quenched with 3 ml of cold 9 *N* sodium hydroxide solution. The samples were then scanned with the Unicam SP800 to determine benzohydroxamate anion at 270 nm. The sample for determination at "infinite" time was withdrawn after at least seven half-lives. The data for the optical density and time were treated as above to obtain the first-order rate constant.

Results and Discussion

(A) Preparation of Benzonitrile Oxide and Substituted Derivatives

In concentrated solution, unhindered benzonitrile oxides dimerize quickly to form furoxans (9). Dilute solutions of unhindered benzonitrile oxides are stable enough for their i.r. spectra to be recorded (8). We have found that 10^{-3} *M* solutions of benzonitrile oxide in water are stable for hours, but that they react rapidly to form benzohydroxamic acid on addition of sulfuric acid. The addition of sodium carbonate to an aqueous solution of benzonitrile oxide results in the formation of benzohydroxamate anion in a few minutes.

A stock solution of benzonitrile oxide was prepared by dissolving benzohydroximoyl chloride in water; water is sufficiently basic to bring about the immediate formation of benzonitrile oxide from benzohydroximoyl chloride under these conditions. An aliquot of the stock solution was added to a sulfuric acid solution and the disappearance of benzonitrile oxide was followed by u.v. spectrophotometry.

In the same manner, it was possible to prepare a stock solution of *m*-nitrobenzonitrile oxide from *m*-nitrobenzohydroximoyl chloride. However, it was found more convenient to prepare this nitrile oxide by allowing *m*-nitrophenyl-*aci*-nitromethane to react in strong acid solution. The products of this reaction are *m*-nitrophenylnitromethane, which is stable (under the conditions of the reaction), and *m*-nitrobenzonitrile oxide, which reacts further to form *m*-nitrobenzohydroxamic acid. The latter reaction can be followed by u.v. spectrophotometry.

Both *p*-methylbenzonitrile oxide and *o*-methylbenzonitrile oxide were prepared in similar fashion from the corresponding methylphenyl-*aci*-nitromethanes.

(B) The Reaction in Acid of the Benzonitrile Oxides.

Effect of Acid Concentration

In sulfuric acid, benzonitrile oxide reacts cleanly to form benzohydroxamic acid. This is shown by the u.v. spectra, which during the reaction exhibit a sharp isosbestic point at a wavelength between those of the absorption peaks of starting material at 245 nm and of product at 228 nm. Increasing the acid concentration of the medium causes an increase in the rate of the reaction (Table 1). This marked effect of acid concentration suggests an equilibrium protonation (eq. 5) preceding the nucleophilic attack by water (eq. 6) The carbonyl form of benzohydrox-

[7] 
amic acid has already been identified, by u.v. and i.r. spectroscopy (10, 11), as the stable tautomer (hence eq. 7).

Over the range of acid concentrations studied, the rates of reaction of benzonitrile oxide are slightly slower than the rates of its formation from the *aci*-form. This accounts for the observation of benzonitrile oxide as an intermediate during the reaction of the *aci*-form, as described in the preceding paper (3).

Substituent Effects

With increasing acid concentration, *m*-nitrobenzonitrile oxide exhibits an increase in the rate of reaction (Table 2). However, compared to unsubstituted benzonitrile oxide, the onset of the rapid increase in the rate of reaction is delayed until higher acid concentrations. This behavior may be explained by reference to eqs. 5 and 6: the electron-withdrawing group makes the *m*-nitrobenzonitrile oxide less basic than unsubstituted benzonitrile oxide, requiring a more strongly acidic medium to form the same concentration of protonated substrate. On the other hand, the rate of reaction 6 is subject to an increase when Ar is substituted with an electron-withdrawing group, because of the enhanced electrophilicity of the substituted compound. The two effects (on reactions 5 and 6) are in opposition, but in the present instance the effect of the *m*-nitro group on reaction 5 is greater than its effect on reaction 6, so that a slower reaction results. A similar result has been reported for the acid-catalyzed hydrolysis of benzalanilines (12) and benzamides (13). Jencks (14) has recently discussed this balance between the substituent effects for a rate-determining step and a preceding equilibrium.

Up to a concentration of at least 9 M sulfuric acid, the rate of destruction of *m*-nitrobenzonitrile oxide is slower than its rate of formation from the *aci*-form, so *m*-nitrobenzonitrile oxide should be observed spectroscopically if it is an intermediate during the reaction of *m*-nitrophenyl-*aci*-nitromethane in acid. Consequently, failure to observe *m*-nitrobenzonitrile oxide during the reaction of *m*-nitrophenyl-*aci*-nitromethane in sulfuric acid of less than 4 M concentration (3) indicates that in these acid concentrations $k_{-1} \gg k_2$.

trate the rate decrease caused by the proximity of a methyl group to the reaction site. The steric effect lends support to the designation of reaction 6 as the rate-determining step in the hydrolysis of nitrile oxides, since the formation of *o*-methylbenzohydroxamic acid would be slowed by hindrance to nucleophilic attack by water.

Activation Parameters

The rates of reaction of benzonitrile oxide in 1.45 M sulfuric acid at 20.6, 25.1, and 35.0 °C (Table 1) have been used to calculate the approximate enthalpy and entropy of activation for the reaction: $\Delta H^{\ddagger} = 17$ kcal/mol, and $\Delta S^{\ddagger} = -19$ e.u. The entropy of activation is negative, as expected for a nucleophilic attack of water in the rate-determining step (15). Similar values are obtained from the data in Table 2 for *m*-nitrobenzonitrile oxide in 5.69 M sulfuric acid: $\Delta H^{\ddagger} = 17$ kcal/mol, and $\Delta S^{\ddagger} = -19$ e.u.

(C) The Hydrolysis of Benzohydroxamic Acid

The rates of hydrolysis of benzohydroxamic acid in sulfuric acid were obtained at 68.8 °C by quenching aliquots of the reaction mixture in base (Table 4). This procedure permitted determination of the resulting benzohydroxamate anion by u.v. spectrophotometry at 270 nm, where benzoate anion does not interfere (10). Over the range of acid concentrations, the rates observed are greater than the rates of the Meyer rearrangement – hydrolysis of phenylnitromethane at 68.8 °C (7); this accounts for the failure under these conditions to observe benzohydroxamic acid as an intermediate. The rate of hydrolysis of benzohydroxamic acid, like that of benzamide (16), passes through a maximum as the acid concentration is increased, and probably involves a similar mechanism (16, 17), given in eqs. 8 and 9.

The Meyer Reaction of Phenylnitromethane in Acid. III. The Tautomerization to the *aci*-Form[1]

J. T. Edward and P. H. Tremaine
Department of Chemistry, McGill University, Montreal, Quebec

Received December 14, 1970[2]

The rate-acidity profiles for the Meyer rearrangement–hydrolysis of phenylnitromethane in sulfuric, perchloric, and hydrochloric acid show a maximum near 3 *M* acid. Ring-substituted phenylnitromethanes also show a maximum in their rate profiles, at slightly different acid concentrations. These maxima arise because the slow formation of the *aci*-form is followed by two competing reactions: fast tautomerization back to the nitro-form, and fast rearrangement–hydrolysis to the Meyer products. The rearrangement is rate-limiting in dilute acid and is acid-catalyzed, causing the rate increase. In more concentrated acid, the rate-limiting step is the nitro to *aci* tautomerization, which is not acid-catalyzed, and which goes more slowly as the activity of water decreases.

The tautomerization was studied by means of primary and solvent deuterium isotope effects, and was found to occur through proton abstraction by water, through a transition state closely resembling the products.

En variant la concentration d'acide sulfurique, hydrochlorique, ou perchlorique, on obtient un maximum aux environs de 3 *M* acide dans la vitesse de la réaction de Meyer sur le phénylnitrométhane. Avec les phénylnitrométhanes substitués on obtient aussi un maximum de vitesse, mais à de différentes molarités d'acide.

La présence de ce maximum peut être expliquée par ce schéma de réaction: la formation lente de la forme *aci*, suivie par deux réactions rapides et concurrentes: une réaction de tautomérisation redonnant la forme nitro, et une réaction de réarrangement menant finalement aux produits Meyer. Au-dessous du maximum, la réaction de réarrangement, catalysée par l'acide, contrôle la vitesse de la réaction globale menant aux produits Meyer. Au-dessus du maximum, la réaction de tautomérisation redonnant la forme nitro est supprimée par l'acide, de sorte que la vitesse de la réaction globale de Meyer est contrôlée par la formation lente de la forme *aci*. Celle-ci est ralentie à mesure qu'on augmente la concentration de l'acide.

Afin d'éclaircir le mécanisme de la formation lente de la forme *aci*, on a étudié les effets produits par une substitution de deutérium dans le solvant ou dans le phénylnitrométhane. Les resultats indiquent que l'abstraction du proton α par l'eau passe par un état de transition ressemblant fortement aux produits.

Canadian Journal of Chemistry, **49**, 3493 (1971)

Introduction

The work done up to 1955 on the Meyer reaction (1) (a rearrangement–hydrolysis) has been reviewed by Noland (2), who proposed the formation of the *aci*-nitroalkane (eq. 1) as the slow step, followed by a series of rapid reactions in the acidic medium. This mechanism was based on the work of Junell (3), who showed that the rate of hydrolysis of nitroethane in 1 *N* hydrochloric acid was the same as its rate of bromination. Our study of the reaction of phenyl-*aci*-nitromethane in acid (4) has shown that, at least for phenylnitromethane in dilute acid, this reaction scheme must be modified by the addition of a fast back-reaction from phenyl-*aci*-nitromethane to phenylnitromethane (eq. 2). The identification of benzonitrile oxide formed by the mechanism of eqs. 3–5, as an intermediate in the rearrangement of phenyl-*aci*-nitromethane to benzohydroxamic acid was also reported at that time. The mechanism of the

$$[1] \qquad RCH_2NO_2 \xrightarrow{k_1} RCH{=}NO_2H$$

$$[2] \qquad RCH{=}NO_2H \xrightarrow{k_{-1}} RCH_2NO_2$$

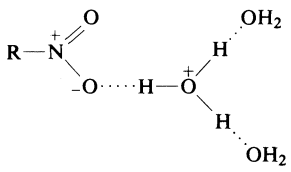
[7] $2H_2O + RC{\equiv}\overset{+}{N}{-}OH \rightarrow RCONHOH + H_3O^+$

[8] $H_3O^+ + RCONHOH \rightarrow RCOOH + NH_3OH^+$

hydration of benzonitrile oxide (eqs. 6 and 7), and of the hydrolysis of benzohydroxamic acid (eq. 8) were discussed in a second paper (5). In the present paper we consider reaction 1, the rate-determining step under some (but as it will be shown, not all) conditions of the reaction.

The details of this rate-determining step may be tested by following the dependence of the overall reaction rate on the acidity of the medium. Cundall and Locke (6) found that the rate profile for the Meyer reaction of nitromethane in hydrochloric acid passed through a maximum at 4 *M* hydrochloric acid. After a slight decline, the rate continued to increase with increasing acidity up to 10*M* hydrochloric acid, the highest concentration studied. A possible explanation for the maximum at 4 *M* acid in the rate profile could have been the essentially complete protonation of nitromethane at that acidity; however, Gillespie (7) had already reported that nitromethane is only 21% protonated in 100% sulfuric acid. Alternatively, the maximum could be explained by the essentially complete formation of a hydrogen-bonded complex (8–11), in 4 *M* acid:



Similar hydrogen-bonded complexes of ketones in moderate concentrations of acid have been proposed (12), and may be intermediates in the enolization of ketones in acid (13). However, Haldna *et al.* (8) have presented evidence that the formation of a hydrogen-bonded complex of nitromethane does not affect the rate of bromination of nitromethane in dilute sulfuric acid, and we show in this paper that the maximum in the rate of formation of Meyer products from phenylnitromethane also is not explained by formation of such a complex.

Experimental

Materials

The preparation of phenylnitromethane, *m*-nitrophenylnitromethane, *p*-methylphenylnitromethane, and *o*-methylphenylnitromethane has been described in a previous paper (4). *p*-Nitrophenylnitromethane, m.p. 89–91.5 °C (lit. 89–90.5 °C) (14) and *p*-chlorophenylnitromethane, m.p. 31–31.5 °C (lit. 33 °C) (15), were prepared by reaction of the substituted benzyl halide with silver nitrite in diethyl ether. 2,4,6-Trimethylphenylnitromethane, m.p. 74–74.5 °C, was prepared from 2,4,6-trimethylbenzyl chloride and silver nitrite in diethyl ether (14) and was characterized by its i.r. spectrum (1550 and 1367 cm^{-1}) and its p.m.r. spectrum (singlet 3.17 for 2 protons, singlet 4.60 for 2 protons, and two singlets 7.68 and 7.75 τ with total 9 protons).

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31. Found: C, 67.19; H, 7.35.

All the phenylnitromethanes were stored at −20 °C until used.

Deuteriosulfuric acid (99% D) of spectroscopic quality was obtained from Merck, Sharp and Dohme of Canada, Limited.

Phenylnitromethane-α,α-d_2 was prepared by the exchange of phenylnitromethane in alkaline deuterium oxide (16). After acidification with deuteriosulfuric acid, the deuterated phenylnitromethane was extracted out with carbon tetrachloride. The organic solution was dried and evaporated. Analysis for residual hydrogen in the deuterated phenylnitromethane by p.m.r. spectroscopy showed an isotopic purity of 97% D at the α-position.

Procedures for Kinetic Runs

(*A*) Sufficient phenylnitromethane was dissolved in water or 50% ethanol to give a 0.003 *M* solution. A 4 ml aliquot of this stock solution was added to 100.0 ml of dilute mineral acid in a stoppered flask. The flask was then immersed in a thermostatted water bath (±0.05 °C) and allowed to warm up for 45 min. (Separate experiments showed that thermal equilibrium was reached in less than this time.) Five milliliter aliquots were withdrawn at recorded time intervals, cooled in ice, and scanned with a Unicam SP800 spectrophotometer. The aliquot for "infinite" time was withdrawn after at least seven half-lives.

Alternatively, the reaction mixture was subdivided into screw-capped vials before heating to the reaction temperature.

The optical densities (*A*) at the wave length of λ_{max} for the (substituted) benzoic acid produced were measured. An exception to this general procedure was made for 2,4,6-trimethylphenylnitromethane, the reaction of which was followed at 244 nm, since mesitoic acid shows only end absorption in dilute acid.

The pseudo-first-order rate constants were calculated by a computer-assisted least-squares plot of ln $(A_\infty - A_t)$ *vs.* time.

The concentration of the mineral acid solutions was determined after the runs by titration with standard alkali.

(*B*) The runs in deuteriosulfuric acid were carried out by adding 10 µl of a 1 volume % solution of phenylnitromethane in ethanol to 10 ml dilute deuteriosulfuric acid and transferring, after mixing, to a u.v. cell. The cell was kept in a thermostatted cell block at the reaction temperature (±0.1 °C) for 1 h, and then removed at recorded time intervals for optical density determination at a fixed wavelength near λ_{max} for benzoic acid. The readings were made in the heated cell compartment of a Beckman DB spectrophotometer. The data were treated as above.

Comparative runs were made at the same time under the same conditions with protiosulfuric acid.

Determination of Distribution Coefficients

A stock solution of the phenylnitromethane to be studied was made in *n*-hexane, with optical density approximately 2.0 at a chosen wavelength near λ_{max}. A 10 ml aliquot of this solution was shaken with a measured aliquot of dilute sulfuric acid in a flask held at 25.0 °C in a water bath. The amount of dilute sulfuric acid used was varied to obtain approximately 50% partition. The hexane layer was withdrawn and scanned with a Unicam SP800 spectrophotometer to determine the concentration of the phenylnitromethane present. The distribution coefficient, *D*, was calculated (17) using the equation:

$$D = nA/(A_0 - A)$$

where A_0 is the optical density of the hexane solution before equilibration with the sulfuric acid solution, A is the optical density after equilibration, and n is the ratio of the volumes used (aqueous/organic).

An estimate of the distribution coefficient in pure water (D_{aq}) was made by extrapolation from dilute acid solutions, and used to calculate the aqueous activity coefficient (f_s) of the phenylnitromethane (18) in different concentrations of acid:

$$f_s = D/D_{aq}$$

Formation of Benzaldehyde from Phenylnitromethane

A mixture of 200 mg phenylnitromethane and 50 ml 11.5 *M* sulfuric acid was heated with frequent mixing to 80 °C for 3 h. A brown gas was visible over the reaction mixture during this time. After cooling, the reaction mixture was poured over 100 g crushed ice and extracted with carbon tetrachloride. The extract was dried with magnesium sulfate and evaporated. The i.r. and p.m.r. spectra indicated that the product was a mixture of 80% phenylnitromethane and 20% benzaldehyde.

Results and Discussion

Effect of Acid Concentration

The kinetics of the Meyer reaction of phenylnitromethane were studied in hot sulfuric, perchloric, and hydrochloric acids (Table 1). In each case, the rate profile passed through a maximum at an acid concentration far below that required to protonate most of the phenylnitromethane.

The rates of the rearrangement-hydrolysis of *p*-methylphenylnitromethane, *p*-chlorophenylnitromethane, and *m*- and *p*-nitrophenylnitromethane in sulfuric acid at 68.8 °C were also determined (Table 2 and Fig. 1). The rate profile for each of these compounds exhibited a maximum at a slightly different acid concentration.

The rate of the reaction of *o*-methylphenylnitromethane was considerably slower than that of *p*-methylphenylnitromethane (Table 2). The rate for 2,4,6-trimethylphenylnitromethane was even slower. Since the rate of reaction of the *aci*-form is actually increased by ortho substituents (4, 15), these steric effects must be operative in the transition state leading to the *aci*-form.

Reaction in Very Concentrated Acid

In sulfuric acid from 7–13 *M*, and in perchloric acid from 7–11 *M*, a different reaction of phenylnitromethane was observed at 78.6 °C: the formation of benzaldehyde. Within this acidity range, the rate of formation of benzaldehyde increased rapidly with increasing acid concentration. Above 11 *M* perchloric acid and 13 *M* sulfuric acid, undetermined brown reaction products were also formed.

The formation of benzaldehyde does not take place via the *aci*-form. The reaction of the sodium salt of *aci*-phenylnitromethane with acid in this concentration range produces only benzohydroxamic acid from a cold and benzoic acid from a hot solution.

Both hot perchloric acid and hot sulfuric acid in this concentration range are oxidizing agents (19, 20). The observation of a brown gas, probably nitrogen tetroxide, during the formation of benzaldehyde, lends support to the hypothesis that oxidation of the methylene group takes place as in eq. 9. This reaction was not studied further.

Activity Coefficient Changes

A decrease in substrate activity coefficient with increasing acid concentration ("salting-in") has been presented as part of the explanation for a maximum in the rate profile for the hydrolysis of some carboxylic anhydrides (21) and some aryl phosphates (22). The aqueous activity coefficients of phenylnitromethane and of some substituted derivatives were determined at room temperature in sulfuric acid solutions by partition between the acid solutions and *n*-hexane (18). It was found that the variation of log f_s with the molarity of sulfuric acid was not linear. An initial increase above zero ("salting-out") was followed by a later decrease ("salting-in") as the medium became more acidic. Similar behavior has been observed with many other organic compounds in sulfuric acid (17).

Phenylnitromethane and *p*-methylphenylnitromethane showed an increase in activity coefficient up to a maximum in 3 M sulfuric acid, followed by a smooth decrease. In 6M sulfuric acid, the activity coefficient had dropped below that in pure water. The nitro-substituted phenylnitromethanes were "salted-in" in 2 M sulfuric acid. Since the nitro-substituted phenylnitromethanes show a maximum in the rate profile for the Meyer reaction at a higher acidity than unsubstituted phenylnitromethane, we must conclude that "salting-in" of the substrate cannot account for the rate decrease observed after the maximum in the rate profile. Rodima and Haldna have reported that the formation of a hydrogen-bonded complex with nitro groups in acid does not cause an abnormal change in activity coefficients for these compounds (23).

Bunnett–Olsen Plot

Bunnett and Olsen (24) have tested a linear free energy relationship applicable to reactions of weakly basic substrates in acid. An estimate of the involvement of water in the transition state of such reactions is provided by the slope, ϕ, obtained from a plot of (log $k_\psi + H_0$) *vs.* (H_0 + log [H^+]). The parameter, ϕ, was shown to assume a value less than zero when water was not involved in the transition state, from 0 to 0.33 when water was acting as a nucleophile, and above 0.58 when water was taking part as a proton trans-

fer agent. The Bunnett–Olsen plots of our results for the rearrangement–hydrolysis of phenylnitromethane and *p*-methylphenylnitromethane are linear and give ϕ values greater than 0.58 (Table 3). The plots for the other substituted phenylnitromethanes are linear at high acidity, but show a deviation from linearity at low acidity. Bunnett predicted such deviations from linearity when a side-reaction competes with the reaction being studied. In paper I of this series (4), we reported a parallel reaction of phenyl-*aci*-nitromethanes in acid: the rearrangement to benzohydroxamic acid, which is the predominant reaction of phenyl-*aci*-nitromethane in concentrated acid (>3 *M*), is surpassed in rate in more dilute acid by the tautomerization to phenylnitromethane. It was also found that an electron-withdrawing group assisted the tautomerization and inhibited the rearrangement, until a higher acidity was reached. This predominance of tautomerization at low acid concentrations for phenylnitromethanes having electron-withdrawing substituents is the cause of the deviations from linearity in the Bunnett–Olsen plots.

The Nitro–Aci Tautomerization

In paper I of this series (4), the tautomerization rates and the rearrangement rates of phenyl-*aci*-nitromethane were determined over a range of acid concentration at 25.1 °C. In the Meyer rearrangement–hydrolysis of phenylnitromethane, phenyl-*aci*-nitromethane is formed slowly, then undergoes two fast competing reactions, as in eq. 10. A similar reaction scheme has been

$$10] \quad ArCH_2NO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ArCH{=}NO_2H \xrightarrow{k_2} \text{Products}$$

analyzed by Rocek and co-workers (25) who called the reaction characterized by k_2 the "rate-limiting" step, the last step in the reaction sequence that affects the overall rate. Although this step is faster than the initial step (k_1), the rate of the reaction depends on both k_1 and k_2, because of the very fast back-reaction (k_{-1}) that is competing.

In the case of phenylnitromethane, it was found that the ratio k_2/k_{-1} was relatively insensitive to temperature changes (4). Applying this ratio to the overall rate (k_ψ) observed for the Meyer reaction of phenylnitromethane at 68.8 °C, it is possible to determine the rate k_1 of the nitro–*aci* tautomerization (26), *i.e.* eq. 11. The results of

$$[11] \quad k_1 = k_\psi \times (k_2 + k_{-1}/k_2)$$

these calculations (Table 4) show the inhibiting effect of increasing sulfuric acid concentration in the range 0.85–7.18 *M* on the tautomerization of phenylnitromethane to phenyl-*aci*-nitromethane.

It has often been proposed that tautomerization between nitro and *aci* forms (like the tautomerization between keto and enol forms) is acid-catalyzed (5, 27, 28). However, there is much experimental evidence that dilute acids *inhibit* the tautomerization of the *aci* to the nitro form (eq. 2) (15, 29–31), and so, on the principle of microscopic reversibility, inhibit the reverse reaction 1.

Direct evidence for the effect of acid in inhibiting reaction 1 has been produced by Haldna *et al.* (8), and is confirmed by the present work. Haldna showed that the rate of bromination (k_r) of nitromethane in sulfuric acid up to 5.3 *M* decreased with decreasing water activity (a_{H_2O}) according to eq. 12, where k_0 is constant.

$$k_r = k_0 a_{H_2O}{}^4 \quad [12]$$

Our results for the tautomerization of phenylnitromethane (Table 4) follow a similar correlation with the fourth power of the water activity over the range 1.5–5.7 *M* sulfuric acid, indicating the involvement of water as a proton acceptor (8).

Further information about the tautomerization was obtained from a study of the Meyer reaction in an acidity range where the tautomerization alone is the rate-determining step ($k_1 \simeq k_\psi$). It is shown below that this condition is fulfilled at acid concentrations above those required for the maximum in the rate profile. In these concentrations the large negative entropy of activation (Table 5) indicates a mechanism in which there is a large increase in solvent ordering in the transition state (32), as would be required for the abstraction of a proton by water.

Explanation of Maxima in Rate Profiles

It now becomes possible to explain the maxima in the rate profiles shown in Fig. 1. We have seen previously (4) that in dilute acid $k_{-1} > k_2$, so that eq. 11 becomes eq. 13. Both k_1 (Table 4) and

$$k_\psi \simeq k_1 k_2 / k_{-1} \quad [13]$$

k_{-1} (ref. 4) decrease slowly with increasing concentration of acid, and their ratio remains about constant; however, k_2 increases rapidly, so that the net effect is an increase in k_ψ with increasing concentration of acid. But in acid concentrations beyond that required for the maximum rate, $k_2 > k_{-1}$, and eq. 11 becomes eq. 14, so that now k_ψ

$$k_\psi \simeq k_1 \quad [14]$$

decreases with increasing concentration of acid. Equation 14 shows that it is only in sulfuric acid more concentrated than about 4 *M* that the rate of the Meyer reaction of phenylnitromethane becomes equal to its rate of tautomerization to the *aci* form. This contrasts with the behavior of nitroethane (3) cited above.

Primary Isotope Effect

The reaction of phenylnitromethane-α,α-d_2 was studied in 2.92 and 4.68 *M* sulfuric acid (Table 6). In 2.92 *M* acid $k_2/k_{-1} > 10$ (from extrapolation of Fig. 2 in ref. 4), and so exchange of deuterium for protium cannot be important in the first few half-lives of the reaction; it must be even less important in the more concentrated acid. In both concentrations the reaction of the deuterated compound was found to be less than that of the undeuterated compound, as would be expected if the rate-determining step is the tautomerization (eq. 1), which involves stretching of a carbon–hydrogen bond. The maximum primary isotope effect (k_H/k_D) expected at 78 °C is 5, corresponding to a transition state with departing hydrogen symmetrically disposed between the carbon and the abstracting oxygen (33). The lower values observed for phenylnitromethane tautomerization indicate a transition state in which the departing hydrogen is bound more strongly to either the carbon or the oxygen. In view of the instability of the *aci*-phenylnitromethane in acid,

application of the Hammond postulate (34, 35) to this system would predict a transition state close to the *aci*-form or its anion: *i.e.* predict that the departing hydrogen is bound more strongly to oxygen.

Solvent Isotope Effect

The effect of carrying out the Meyer reaction of phenylnitromethane in deuteriosulfuric acid varies greatly, depending on the concentration of the acid (Table 7).

These isotope effects cannot be due to differential solvation of the initial state, since we have determined distribution coefficients of phenylnitromethane in isooctane/sulfuric acid and isooctane/deuteriosulfuric acid. The isotope effect ($f_s(H_2O)/f_s(D_2O)$) on the activity coefficient of the starting material in 4.0 M acid is 1.03. An isotope effect of 1.06 ($f_s(H_2O/f_s(D_2O)$) has been reported on the activity coefficient of nitromethane in water (36).

At high acid concentrations, the solvent isotope effect influences the rate-determining tautomerization of phenylnitromethane to phenyl-*aci*-nitromethane. Here the reaction is slowed in deuterated solvent by the lower basicity of deuterium oxide, which makes it less effective in proton abstraction (37). Swain and Rosenberg (38) pre-

For personal use only.

dicted values for the solvent isotope effect (k_{H_2O}/k_{D_2O}) on a proton abstraction from a carbon acid such as ketones and nitroalkanes: 1.0 for zero transfer of the proton in the transition state, 1.4 for half-transfer, and 2.0 for complete transfer of the proton to water in the transition state. Bunton and Shiner (35) calculated a solvent isotope effect of 1.4 for a symmetrical "free-proton" transition state for enolization of a ketone. The relatively large values (up to 1.96) obtained for the tautomerization of phenylnitromethane indicate a transition state with considerable proton transfer, close to hydronium ion and the *aci*-form or its anion.[3]

The reaction scheme is more complex in dilute acid. Here the *aci*-form is formed slowly, but is transformed back into the nitro-form more quickly than into the Meyer reaction products. The rate-limiting step now for the Meyer reaction is the loss of water from the protonated *aci*-form (eq. 4) (4). Reactions with a protonation equilibrium prior to the rate-limiting step are usually faster in deuterated solvent because of the increased acidity of deuteronium ion, and this is observed in the Meyer reaction, as shown in Table 7.[4] As the rate-limiting step changes over to tautomerization (eq. 1) in more concentrated acid, the value of the isotope effect changes to approach the value found for the tautomerization.

Conclusion

The Meyer rearrangement–hydrolysis of phenylnitromethane in acid proceeds through tautomerization to phenyl-*aci*-nitromethane. In dilute acid, the tautomerization is followed by a rate-limiting acid-catalyzed reaction of the *aci*-form (eq. 4), which causes the observed increase in rate with increasing acidity. As the medium is made more acidic, the rate-limiting step changes to the tautomerization (eq. 1), which is inhibited in acid, so that the rate decreases with increasing acidity. The tautomerization is not acid-catalyzed, and proceeds by proton abstraction from the α-carbon by water, through a transition state closely resembling the products.

We are grateful to a referee of this paper for several helpful suggestions.

[3]A referee has pointed out that if the reaction is not acid-catalyzed the intermediate close to the transition state must be the *aci* anion, unless water is acting simultaneously as an acid and a base in some cyclic transition state. Such a mechanism could account for the entropies of activation.

[4]In the three most dilute D_2SO_4 solutions of Table 7, exchange to form $PhCHDNO_2$ and $PhCD_2NO_2$ must be significant ($k_2 = k_{-1}$ in 1.5 *M* sulfuric acid). This exchange would contribute to an increase in the observed k_{H_2O}/k_{D_2O} ratio, so that the true values of k_{H_2O}/k_{D_2O} should be smaller than those recorded in Table 7. The argument of this paragraph, however, is not changed.

Reactions of Amine Oxides and Hydroxylamines with Sulfur Dioxide

J. T. Edward and Josephine Whiting[1]
Department of Chemistry, McGill University, Montreal, Quebec

Received January 15, 1971[2]

Strychnine *N*-oxide (**8**; X = H) reacts with sulfur dioxide in benzene to form the sulfitoamine **9** (X = H), which rearranges in boiling water to the substituted sulfamic acid **10** (X = H) by a free-radical mechanism. The sulfamic acid **10** (X = H) is also formed by reaction of strychnine *N*-oxide with cold aqueous sulfur dioxide, and may be an intermediate in the reduction of the amine oxide by sulfur dioxide in hot water. With aqueous sulfur dioxide at 0°, *N*,*N*-dimethylbenzylamine *N*-oxide gives tertiary amine by reduction and secondary amine and aldehyde by a Polonovski-type reaction; however, *N*,*N*-dimethylaniline *N*-oxide gives tertiary amine, *o*- and *p*-dimethylaminobenzene sulfonic acids, but no appreciable amount of secondary amine. The sulfonic acids are probably formed by a free-radical mechanism, since their formation is largely suppressed by the addition of hydroquinone. The reactions of hydroxylamine and of β-phenylhydroxylamine with sulfur dioxide in water have also been studied.

La réaction de l'oxide de strychnine (**8**; X = H) avec la dioxide de soufre en benzène fournit le composé **9** (X = H). En eau bouillante celle-ci réarrange a l'acide sulfamique **10** (X = H) par un mécanisme radicalaire. L'acide sulfamique est probablement l'intermédiaire quand l'oxide est réduit par la dioxide de soufre dans l'eau chaude. La dioxide de soufre réagit avec l'oxide de *N*,*N*-diméthylbenzylamine a 0° pour fournir en partie l'amine tertiaire, et en partie aldéhyde et une amine secondaire; avec l'oxide de *N*,*N*-diméthylaniline elle fournit en partie l'amine tertiaire, en partie les acides *o*- et *p*-diméthylaminobenzène sulfoniques, mais rien d'amine secondaire. Les acides sulfoniques sont probablement formées par un mécanisme radicalaire, parce qu'on peut les supprimer par l'addition de hydroquinone à la réaction. On a étudié aussi les réactions de hydroxylamine et de β-phénylhydroxylamine avec la dioxide de soufre dans l'eau.

Canadian Journal of Chemistry, **49**, 3502 (1971)

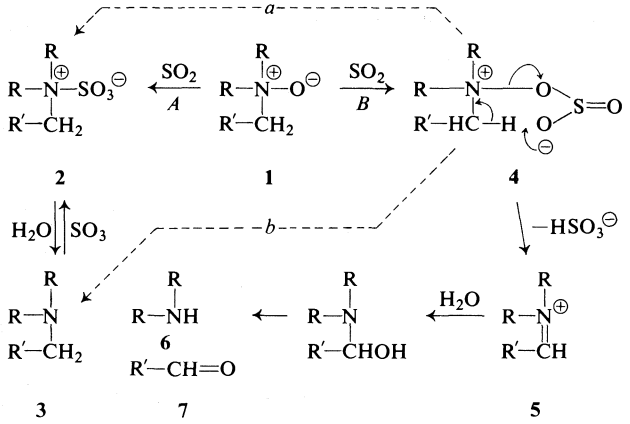
The reduction of amine oxides (**1**) to tertiary amines (**3**) has commonly been effected by aqueous sulfur dioxide (1–3), and has been assumed to take place by hydrolysis of an intermediate sulfamic acid[3] derivative **2** (route *A* in Scheme 1) (1). However, no mechanism has been advanced for the reaction **1** → **2**, in which an N—O bond becomes replaced by an N—S bond. Sometimes the reaction yields a secondary amine (**6**) and an aldehyde (**7**) (route *B*) in addition to products of route *A*. It has been postulated (5, 6) that route *B* products result from the decomposition of an intermediate sulfitoamine **4** via a Polonovski-type reaction (7) to give the iminium ion **5**, which would then be expected to hydrolyze rapidly to **6** and **7**. Thus Lecher and Hardy (5) found that the sulfitoamine **4** (R = Me, R′ = H), obtained by reaction of trimethylamine oxide (**1**; R = Me, R′ = H) with sulfur dioxide in dry benzene, decomposed in cold water to give dimethylamine (**7**; R = Me) and formaldehyde (**8**; R′ = H). The latter products were also obtained in more than 50% yield when trimethylamine oxide in aqueous solution was treated with sulfur dioxide, again presumably *via* the sulfitoamine **4** (R = Me, R′ = H), while route *A* products (**3**; R = Me, R′ = H: 15–20% yield, and **2**; R = Me, R′ = H: less than 5% yield) were obtained in smaller amounts. Wiewiorowski and Baranowski (6) found that reaction of sparteine N_{16}-oxide and lupanine *N*-oxide with aqueous sulfur dioxide went about 20% by route *A* and 80% by route *B*, while reaction of α-isosparteine *N*-oxide and sparteine N_1-oxide went 100% by route *A*. In the latter two cases the ring systems are such that the unsaturated intermediate **5** would be considerably strained, and the Polish authors suggested that for this reason route *B* was avoided and route *A* followed exclusively.

A possible route to sulfamic acids **2** and subsequent products would be by rearrangement of sulfitoamines **4** (reaction *a* of Scheme 1)

[1]Née Josephine Jaworska; holder of NRCC Studentship, 1966–1970.

[2]Revision received July 20, 1971.

[3]Sulfamic acid has the zwitterionic structure $H_3\overset{\oplus}{N}-\overset{\ominus}{SO_3}$ (4).



SCHEME 1

and we have investigated this possibility by studying the reactions of the sulfitoamines **9** (X = H and X = OMe), obtained by reaction of strychnine *N*-oxide (**8**; X = H) or brucine *N*-oxide (**8**; X = OMe) in benzene solution with sulfur dioxide. Because of the bridgehead position of the quaternary nitrogen atom, these sulfitoamines would not be expected to react by route *B*, and in fact in cold water they were stable. Furthermore, they showed no tendency to react with an excess of amine oxide to furnish the sulfatoamines **11** (X = H and OMe). In contrast, Lecher and Hardy (5) obtained triethylammonio sulfate (**13**) from the reaction of triethylamine oxide with sulfur dioxide in benzene, triethylammonio sulfite (**12**) presumably being an intermediate in the reaction (eq. 1). The sulfatoamines **11** (X = H and OMe) could be obtained by reaction of the amine oxides **8** (X = H and OMe) with pyridine – sulfur trioxide complex. They were hydrolyzed in water or in alkaline solution to sulfate ion and the amine oxide. (Under these conditions, **13** gave diethylamine, acetaldehyde, and sulfate ion (5) by a Polonovski-type reaction.)

In boiling water the sulfitoamine **9** (X = H) isomerized to the sulfamic acid **10** (X = H), m.p. 265–275°. This compound has been prepared previously (8), but by a route which left its structure uncertain; we have confirmed the

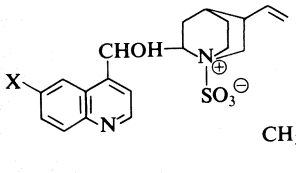
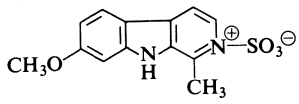
sulfamic acid structure by preparing it also by reaction of strychnine with pyridine – sulfur trioxide complex (a reaction of the type **3** → **2**). A third method of preparing **10** (X = H and OMe) was from the reaction of strychnine or brucine with sodium dithionate in boiling water. This reaction probably involved nucleophilic attack of the tertiary amines on sulfur (eq. 2).

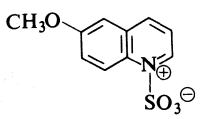
[2] 
Its generality was demonstrated by preparing also the derivatives **14** (X = H) from cinchonine, **14** (X = OMe) from quinine, **15** from harmine, **16** from 6-methoxyquinoline, and **17** from 2-phenyl[1, 2-*a*]imidazopyridine. All of these are



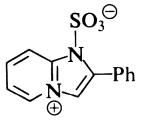
14



15



16



17

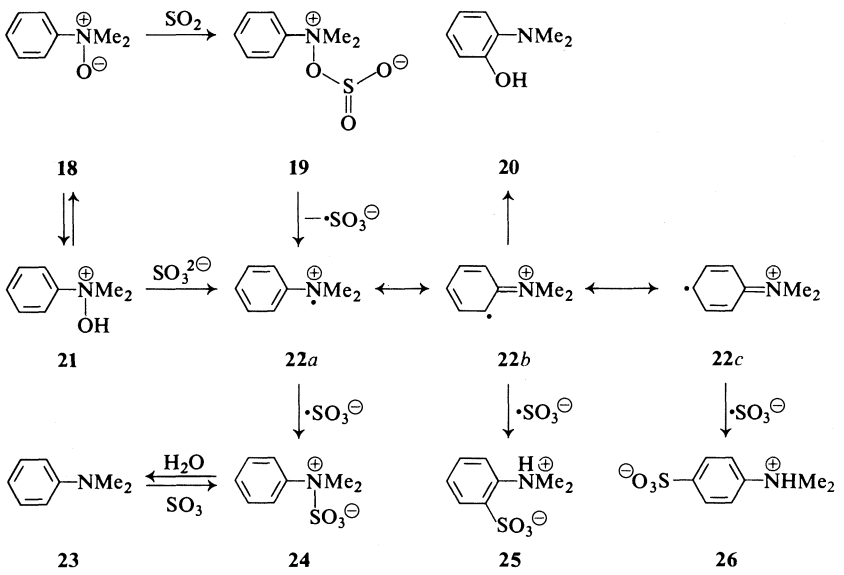
new compounds. Their sulfamic acid structures were demonstrated by preparing them also by reaction of the amines with pyridine – sulfur trioxide complex (used for **14** (X = H and OMe) and **15**), or with sulfur trioxide in 1,2-dichloroethane or chlorosulfonic acid in chloroform (used for **16** and **17**).[4]

The mechanism of the isomerization of the sulfitoamine **9** (X = H) into the sulfamic acid **10** (X = H) in boiling water may now be considered. After the rearrangement no sulfate ion can be detected in the solution, so that it is unlikely that the isomerization proceeds by eq. 3 (a route, furthermore, which would be disfavored by a polar solvent like water (10)). A more plausible route involves dissociation of the sulfitoamine into ion-radicals (11), followed by recombination (eq. 4). This mechanism is supported by the observation that in boiling water in the presence of the radical trap hydroquinone (11) only 25% of **9** (X = H) is isomerized to **10** (X = H), and 60% is reduced to strychnine and sulfite ion (eqs. 5 and 6).

We may now consider the confused literature on the reaction of strychnine *N*-oxide with sulfur dioxide in water. The reaction in hot water (exact temperature unspecified) was first reported by Pictet and Mattison (12), who obtained strychnine and sulfate ion. However, Polonovski and Polonovski (13) and Leuchs and Räck (14) claimed that the sulfamic acid **10** (X = H), m.p. > 330°, was also formed, while Leuchs and Boit (15) claimed a similar sulfamic acid from brucine *N*-oxide. Oesterlin (8) claimed to obtain exclusively the sulfamic acid **10** (X = H), m.p. 260–265°, from the reaction of strychnine *N*-oxide with sodium bisulfite in cold methanol, but exclusively strychnine and sulfate ion from its reaction with sodium bisulfite in water at 60°.

We have confirmed Oesterlin's observations on the effect of temperature: strychnine *N*-oxide reacts with an excess of sulfur dioxide in water at 60–65° to give strychnine (95% yield), but at 0° to give the sulfamic acid **10** (X = H),

[3] 
[4] 
[5] 
[6] 
[4]The structures **14** (X = H or OMe) for the products from cinchonine or quinine, expected on general grounds to be preferred over the alternative structures having sulfur trioxide complexed to the quinoline nitrogen (9), were supported by the u.v. absorption and n.m.r. characteristics of the compounds. The structure **15** for the product from harmine was supported by similar evidence, while the structure **17** for the product from 2-phenyl[1,2-*a*]imidazopyridine seemed most plausible because it allowed maximum delocalization of the positive charge.



SCHEME 2

m.p. 265–275° (85% yield). This compound is fairly stable in hot water, but is rapidly hydrolyzed in dilute acid or alkali to strychnine and sulfate ion. At 65° even sulfur dioxide in water is sufficiently acidic to effect rapid hydrolysis. The sulfamic acid is consequently a possible (though not a necessary) intermediate in the formation of strychnine from strychnine *N*-oxide. (Another possible intermediate is the sulfitoamine **9** (X = H) (reaction *b* of Scheme 1): in aqueous acid or alkali it also is hydrolyzed rapidly to strychnine and sulfate ion (eqs. 7 and 8).) Sulfur dioxide in water is able to effect complete hydrolysis of **9** (X = H) within 15–20 min at 65–70°).

[7] 
While we have demonstrated the isomerization in water of the sulfitoamine **9** (X = H) into the sulfamic acid **10** (X = H) (reaction *a* of Scheme 1), it proceeds too slowly to account for the formation of the sulfamic acid (85% yield in 15 min) from the reaction of strychnine *N*-oxide with aqueous sulfur dioxide at 0°; even at 100°, rearrangement of **9** (X = H) into **10** (X = H) is only about 50% complete in 15 min. Consequently, it seems likely that the sulfamic acid is formed from the *N*-oxide by the union of two radical ions produced by reaction 9. This one-electron oxidation–reduction reaction finds analogy in the reduction of amine oxides to aminium radical-ions by the one-electron reducing agent, iron(II) (16), and is supported by the observation that the formation of the sulfamic acid **10** (X = H) can be suppressed completely when strychnine *N*-oxide reacts with sulfur dioxide in water at 0° in the presence of hydroquinone.

Further evidence for free-radical intermediates was found in a study of the reaction of *N*,*N*-dimethylaniline oxide (**18**) with sulfur dioxide (Scheme 2). In benzene the unstable sulfitoamine **19** was formed; however, in water this decomposed to give no appreciable quantities of route *B* products, but only the products to be expected from eq. 4. These products are shown in Scheme 2, and their yields are given in Table 1.

TABLE 1. Yields (%) of products in Scheme 2

Reaction	Products			
	20	**23**	**25**	**26**
18 + aqueous SO_2 at 0° (ref. 18)	0.6	22	60	20
18 + aqueous SO_2 at 0° (this work)	0.5	20	56	18
N,N-Diethylaniline *N*-oxide + aqueous SO_2 at 0°	1.0*	30*	45*	15*
19 in water at 0–20°	0.5	20	58	20
19 in water at 70–80°	2.9	51	34	9.7

*Et in place of Me in products.

[10] $$\cdot SO_3^{\ominus} \leftrightarrow {}^{\ominus}O-\underset{\underset{O}{\|}}{S}-O\cdot \xrightarrow{22b} \text{(C}_6\text{H}_4\text{)}(NMe_2)(OSO_2H) \xrightarrow{-SO_2} \mathbf{20}$$

Besides the tertiary amine **23**,[5] the ortho- (**25**), and para-sulfonic (**26**) acids were obtained along with a trace of the *o*-aminophenol **20**. The latter may have come via an unstable sulfite ester (eq. 10). None of the sulfamic acid zwitterion **24** was isolated, because even at 0° this compound (unlike corresponding aliphatic zwitterions such as **10**) is extremely readily hydrolyzed by water alone.

The predominance of route *A* products from the reaction of this amine oxide is perhaps explained by the resonance stabilization of the aminium ion **22**, which makes homolytic fission of **19** according to reaction 4 much more facile than the competing reaction **4** → **5** of route *B*.[6] The facilitation of reaction 4 is further shown by the fact that in water the sulfitoamine **19** underwent reaction within a few hours at 0°, while during this time the sulfitoamine **9** had not isomerized completely even at 100°.

About the same yields of products **20**, **23**, **25**, and **26** were obtained by treating the amine oxide **18** with sulfur dioxide in water at 0° (a reaction studied by Bamberger and Tschirner (18) more than 70 years ago), as shown in Table 1. This may indicate that Bamberger's reaction also involves the sulfitoamine **19** as an intermediate, although the alternative pathway (**18** → **21** → **22** → products), based on eq. 9, cannot be excluded at the moment. Either pathway involves the intermediacy of the aminium ion **22**; this accords with the observation that in the presence of a radical scavenger, hydroquinone, the yields of **25** and **26** from the reaction of *N,N*-dimethylaniline oxide with aqueous sulfur dioxide are reduced about six-fold, with a corresponding increase in the yield of **23**.

The reaction of *N,N*-diethylaniline *N*-oxide with sulfur dioxide in water at 0 °C gave the same types of products, and their yields are given in Table 1. Again, there were no appreciable quantities of route *B* products. The reaction was followed by n.m.r. measurements to see if there was any evidence of chemically induced dynamic nuclear polarization (c.i.d.n.p.) (19) caused by free radical intermediates. No obvious emission or enhanced absorption could be observed in the ethyl signals of diethylaniline, which after 2 h made up roughly 20% of the reaction product. However, no evidence of c.i.d.n.p. from dialkylanilinium ion radical intermediates has yet been reported; it is possible that if the relaxation time for depolarization is fast no effect will be seen. Attempts to demonstrate by e.s.r. the presence of radicals in the reaction of *N,N*-dimethylaniline *N*-oxide with aqueous sulfur dioxide were also fruitless. However, to date most *N,N*-dialkylaniline cation-radicals have eluded physical detection because of their rapid

[5]A referee has pointed out that the tertiary amine could also arise by reduction of the aminium ion by SO_3^{2-}

$$\mathbf{22} + SO_3^{2\ominus} \rightarrow \mathbf{23} + \cdot SO_3^{\ominus}$$

[6]In contrast to the sulfitoamine **19**, the sulfatoamine **27** does not rearrange in water to the aminophenyl sulfate **28**, but hydrolyzes to the amine oxide and sulfuric acid.

$$\text{(C}_6\text{H}_4\text{)}(\overset{\oplus}{N}Me_2)(O-SO_3^{\ominus}) \not\rightarrow \text{(C}_6\text{H}_4\text{)}(NMe_2)(OSO_3^{\ominus})$$

27 **28**

This result disqualifies **27** as a possible intermediate in the Boyland–Sims reaction of dimethylaniline with alkaline persulfate to give **28** (*cf.* Discussions in ref. 17).

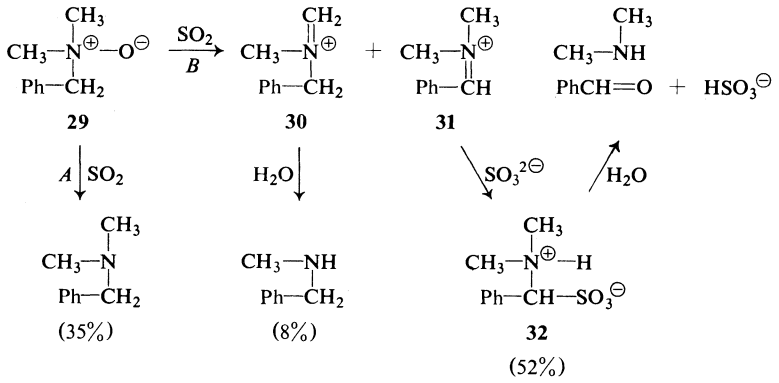

SCHEME 3

coupling reactions with themselves, solvent, or other radicals (20), and the negative results from c.i.d.n.p. and e.s.r. cannot be considered to exclude the possibility of radical intermediates.

While the reaction of *N*,*N*-dimethylaniline oxide with sulfur dioxide in water gave no route *B* products, the reaction of *N*,*N*-dimethylbenzylamine oxide (**29**) gave predominantly route *B* products, as shown by the yields indicated in Scheme 3.[7] The structure of the aminosulfonic acid **32** was inferred from its analysis, i.r. spectrum, and decomposition to benzaldehyde (and presumably dimethylamine and sulfurous acid) on attempts to crystallize it from water or 95% ethanol. The effect of the phenyl group would be expected to favor route *B* over route *A*, and to favor formation of the unsaturated intermediate **31** over **30**, in accordance with the results noted.

Finally, the reactions of β-phenylhydroxylamine and of hydroxylamine with aqueous sulfur dioxide were studied briefly. β-Phenylhydroxylamine is protonated in weakly acidic solution to give the ion **33**, analogous to protonated *N*,*N*-dimethylaniline oxide (**21**), and so might be expected to react with aqueous sulfur dioxide in similar fashion. In fact Illuminati

33

(21) has already reported the formation of orthanilic acid, aniline, and phenylsulfamic acid in varying amounts depending on the composition of the solvent (water, ethanol, and 60% ethanol). We have confirmed and extended Illuminati's results, as shown in Table 2. It is apparent that the course of the reaction is considerably more complex than that of dimethylaniline *N*-oxide; it is difficult, for example, to devise a plausible mechanism for the formation of metanilic acid. Furthermore, the failure of hydroquinone to affect the course of the reaction makes it unlikely that radicals are intermediates of any importance. On the other hand, it seems likely that the protonated form **33** of β-phenylhydroxylamine is required for reaction; when sodium bisulfite or sodium sulfite was used in place of sulfur dioxide, the rate of reaction became very slow.

In anhydrous ether sulfur dioxide reacted with β-phenylhydroxylamine to form the anilinium salt of phenylsulfamic acid in fairly good yield, instead of the expected sulfitoamine zwitterion. We have no plausible explanation for this result.

The reaction of hydroxylamine itself with sulfur dioxide in water gives sulfamic acid and small amounts of ammonium bisulfate (22–24). The rate of the reaction is maximal at about neutral p*H* values, but the ratio of sulfamic acid to ammonium bisulfate in the product is unaffected by p*H*. It has thence been concluded (22) that the transition complexes for both reactions have the same composition (SO_2, NH_2OH, ψH_2O); but these results are equally compatible with a transition complex made up of the ions of eq. 11. A possible route to sulfamic

[11] $NH_2OH + H_2SO_3 \rightleftarrows H_3\overset{\oplus}{N}—OH + HSO_3^{\ominus}$

acid and ammonium bisulfate would then be

[7]Hydroquinone had no appreciable effect on the yields of the different products, indicating that free radical intermediates are unlikely to be involved in the reactions of route *B*.

TABLE 2. Effect of solvent and of the presence of hydroquinone (S) on the yields (%) of the products from the reaction of phenylhydroxylamine with sulfur dioxide

Solvent	Aminobenzenesulfonic acids			Aniline	Phenylsulfamic acid
	ortho-	meta-	para-		
EtOH	35	5	10	45	1–2
EtOH (+S)	35	5	10	45	1–2
60% EtOH	20	3–5	15	40	10–15
60% EtOH (+S)	20	3–5	12	42	10–15
Water	15–20	1–3	12	20	40
Water (+S)	15–20	1–3	12	20	40

a reaction of these ions to give the radicals $H_3N^{\oplus}$ and $\cdot SO_3H$ (*cf.* reaction 9). However,

[12] $$H_3\overset{\oplus}{N}—OH + HSO_3^{\ominus} \rightarrow H_3\overset{\oplus}{N}\cdot + OH^- + \cdot SO_3H \rightarrow$$

$$H_2O + H_3\overset{\oplus}{N}\cdot + \cdot SO_3^{\ominus} \rightarrow H_3\overset{\oplus}{N}—SO_3^{\ominus}$$

Electron transfer ↓

$$NH_3 + SO_3 \xrightarrow{H_2O} \text{Ammonium bisulfate}$$

we have found the ratio of the products in this reaction to be unaffected by the presence of hydroquinone, which would have been expected to reduce the ion-radicals of eq. 12, and hence to favor the formation of ammonium ion at the expense of sulfamic acid. An intramolecular rearrangement of sulfitoammonium ion (*cf.* ref. 25) is accordingly indicated.

Experimental

The i.r. spectra were recorded with a Perkin–Elmer Model 337 spectrophotometer, n.m.r. spectra with a Varian A-60 spectrophotometer. Molecular weights were determined using a Mechrolab Model 301A osmometer. All melting points are uncorrected. Analyses were done by Dr. C. Daesslé of Montreal, Quebec, and Dr. Alfred Bernhardt of Elbach über Engelskirchen, West Germany.

(N_b-Strychninio) Sulfite[8] (**9**; *X = H)*

Strychnine *N*-oxide hydrate (26) was dehydrated by azeotropic distillation with benzene: m.p. 215–217° (lit. 216–217° (27)), ν_{max} (KBr) 958 cm^{-1} (ν N—O). Sulfur dioxide was bubbled through a stirred suspension of the anhydrous *N*-oxide (2.4 g) in benzene (100 ml) for 4 h, by which time all suspended solids had gone into solution. Concentration of the solution to 18–20 ml resulted in the separation of a white solid, which crystallized from absolute ethanol as white crystals (1.6 g, 60%), blackening at 194–196°, decomposed at 225°, ν_{max} (KBr) 1315, 1285, 1110, 1060, 990, 590 cm^{-1}.

[8]All nomenclature based on International Union of Pure and Applied Chemistry, Nomenclature of Organic Chemistry, Definitive Rules for Section *C*, Butterworths, London, 1965. p. 69.

Anal. Calcd. for $C_{21}H_{22}O_5N_2S$ (mol. wt. 414): C, 60.9; H, 5.3; N, 6.8; S, 7.7. Found (410 ± 10 (in benzene, by vapor pressure osmometry)): C, 61.0; H, 5.1; N, 6.8; S, 7.7.

*(N_b-Brucinio) Sulfite (**9**; X = OMe)*

The same procedure, applied to the anhydrous *N*-oxide of brucine (27), gave the sulfitoamine, blackening at 195 °C, decomposed at 220–225 °C, ν_{max} (KBr) 1315, 1284, 1110, 1060, 990, 590 cm^{-1}.

Anal. Calcd. for $C_{23}H_{26}N_2O_7S$: C, 58.2; H, 5.5; N, 5.9; S, 8.7. Found: C, 58.3; H, 5.4; N, 6.0; S, 8.8.

*Alkaline Hydrolysis of (N_b-Strychninio) Sulfite (**9**; X = H)*

(N_b-Strychninio) sulfite (0.12 g), swirled with 0.2 *N* sodium hydroxide (15 ml), went into solution, and in 1–2 min a white precipitate separated. This was removed by filtration, washed with cold water, and identified as strychnine (0.08 g, 88%), m.p. and mixed m.p. 284–287 °C. The filtrate, acidified with HNO_3 and treated with $BaCl_2$, gave a positive sulfate test.

*Acid Hydrolysis of (N_b-Strychninio) Sulfite (**9**; X = H)*

Sulfur dioxide was bubbled slowly for 15–20 min through a solution of (N_b-strychninio) sulfite (100 mg) in water (5 ml) at 65–70°. The solution, treated with sodium bicarbonate, deposited strychnine (76 mg, 90%), identified by m.p. and i.r. spectrum.

*(N_b-Strychninio) Sulfate (**11**; X = H)*

Pyridine – sulfur trioxide complex (0.27 g) was added to anhydrous strychnine-*N*-oxide (0.6 g) in dry pyridine (25 ml), and stirred for 5 min. The white solid (0.6 g, 83%) that separated was removed by filtration and freed from pyridine by pumping at 2 mm. It blackened at 200–202 °C, melted at 228–230 °C, ν_{max} (KBr) 1335, 1295, 1120, 1060, 710, 622 cm^{-1}.

Anal. Calcd. for $C_{21}H_{22}O_6N_2S$: C, 58.6; H, 5.2; N, 6.5; S, 7.4. Found: C, 58.6; H, 5.4; N, 6.5; S, 7.4.

*(N_b-Brucinio) Sulfate (**11**; X = OMe)*

The same procedure applied to brucine-*N*-oxide gave **11** (X = OMe), blackening 205–207 °C, melts at 235–236 °C, ν_{max} (KBr) 1334, 1295, 1129, 1060, 710, 622 cm^{-1}.

Anal. Calcd. for $C_{23}H_{26}O_8N_2S$: C, 56.3; H, 5.3; N, 5.7; S, 6.5. Found: C, 56.3; H, 5.4; N, 5.7; S, 6.3.

Alkaline Hydrolysis of (N_b-Strychninio) Sulfate

(N_b-Strychninio) sulfate (0.1 g), swirled with 0.2 *N*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sodium hydroxide (10–15 ml), went into solution. Repeated extraction with chloroform (10 × 25 ml) removed strychnine *N*-oxide hydrate (55 mg, 64%) (identified by m.p., i.r. spectrum, and t.l.c.). The aqueous phase, acidified with nitric acid and treated with barium chloride, gave a positive sulfate test.

Preparation of N-Ammonium Sulfonates

(a) By Reaction of the Amine with Sulfur Trioxide

A mixture of strychnine (0.5 g), dissolved in dry pyridine (40 ml), and pyridine – sulfur trioxide complex (0.24 g) was stirred for 15 min at room temperature. A white solid separated, which was removed by filtration, washed with pyridine, and dried under reduced pressure at room temperature. The solid **10** (X = H) (0.5 g) melted at 265–275 °C (dec.) (Oesterlin (8) reported m.p. 260–265 °C); ν_{max} (KBr) 1250, 1000, 700, 575 cm^{-1}.

By essentially the same procedure the complex **10** (X = OMe) was obtained from brucine, **14** (X = OMe) from quinine, **14** (X = H) from cinchonine, and **15** from harmine. The complexes **16** and **17** were obtained by the reaction of the parent amines with equivalent amounts of sulfur trioxide dissolved in 1,2-dichloroethane at 0° (*cf.* ref. 28) or by reaction of the parent amines with half-molar quantities of chlorosulfonic acid in chloroform at 0° (*cf.* ref. 29). The melting points and some i.r. peaks of these compounds are listed in Table 3 and their combustion analyses in Table 4. The u.v. absorption and n.m.r. spectra of these compounds were obtained, and did not differ essentially from the spectra of the analogous *N*-ammonium-*S*-thiosulfate compounds already reported (9).

(b) By Reaction of the Amine with Dithionate

A suspension of strychnine (1 g) in a solution of sodium dithionate (4 g) in water (90 ml) was refluxed for 5 h. The hot reaction mixture was filtered to remove unreacted strychnine and cooled. White crystals separated and were removed, washed with water and chloroform, and recrystallized from water or ethanol. The solid thus obtained (1.1 g, 95%), m.p. 265–275° (dec.), had an i.r. spectrum identical with that of material prepared above.

By essentially the same procedure, the following sulfamic acids were obtained from the free bases in the yields indicated: **10** (X = OMe), 83%; **14** (X = OMe), 80%; **14** (X = H), 95%; **15**, 80%; **16**, 60%; **17**, 96%.

The following amines failed to give any crystalline product after reaction with dithionate: triethylamine, *N,N*-dimethylaniline, imidazole, benzimidazole, 4-phenylpyridine, benzothiazole, and neostrychnine.

*Strychninium-N_b-sulfonate (**10**; X = H)*

(a) By Reaction of Strychnine-N-oxide with Sulfur Dioxide in Aqueous Solution

Sulfur dioxide was bubbled into a solution of strychnine *N*-oxide (1 g) in water (60 ml) at 0° for 15 min. A white solid (1 g, 85%), m.p. 265–275 °C (dec.), separated which proved identical (i.r. spectrum) with the product of the reaction of strychnine with sulfur trioxide.

*(b) By rearrangement of (N_b-Strychninio) Sulfite (**9**; X = H)*

The sulfitoamine **9** (X = H) (0.28 g) was boiled in water (40 ml) for 24 h. The solution was cooled and the precipitate that separated (0.23 g, 83%) was collected: m.p. 265–275° (dec.), ν_{max} (KBr) 1250, 1000, 700, 575 cm^{-1}. The product was shown to be identical with **10** (X = H) prepared above by m.p., i.r. spectral comparison, and combustion analysis.

Anal. Calcd. for $C_{21}H_{22}O_6N_2S$: C, 60.8; H, 5.3; N, 6.7; S, 7.7. Found: C, 60.6; H, 5.5; N, 6.7; S, 7.5.

When the time of the reaction was reduced to 15 min impure **10** (X = H), m.p. 260–268° (50% yield) crystallized from the solution on cooling, and impure **9** (X = H), blackening at 189–192°, decomposing at 210–220° (50% yield), was obtained by evaporation of the filtrate at reduced pressure.

Reaction of Strychnine N-Oxide with Aqueous Sulfur Dioxide at 60–65 °C

Sulfur dioxide was bubbled into a solution of strychnine *N*-oxide (100 mg) in water (50 ml) at 60–65 °C for 15 min. A white precipitate formed within the first 5 min and redissolved as the addition of sulfur dioxide was continued for 10 min. The solution, on treatment with sodium bicarbonate, precipitated strychnine (85 mg; 95%) identified by comparison of m.p. and i.r. spectrum with those of an authentic sample.

*Rearrangement of (N_b-Strychninio) Sulfite (**9**; X = H) in the Presence of Hydroquinone*

The sulfitoamine **9** (X = H) (0.60 g) was refluxed in water (100 ml) containing hydroquinone (0.17 g) for 24 h. The solution was cooled and extracted with ether (4 × 60 ml). The ether extracts were dried and evaporated to give residue *A* (0.14 g). The aqueous layer (p*H* ~ 5) was neutralized with sodium bicarbonate. A fine white solid separated and was extracted with chloroform (2 × 50 ml). The chloroform extract was dried and evaporated to give strychnine (0.29 g; 60%); after recrystallization from ethanol, m.p. 286–288° (dec.), undepressed by admixture with an authentic sample of strychnine. The aqueous layer was partially evaporated (25 ml). White needles separated and were collected (0.15 g, 23%), m.p. 265–275°, and were found to be identical with **10** (X = H) by mixed m.p. The aqueous filtrate gave a positive test for sulfite with $BaCl_2$ (0.17 g $BaSO_3$, 53%). Water (40 ml) was added to residue *A*, and the mixture was warmed on a steam bath for a few minutes, then cooled. The insoluble yellow material (90 mg) was removed by filtration and recrystallized from ethanol, giving slightly impure benzoquinone, m.p. and mixed m.p. 112–115°. The aqueous filtrate was evaporated and the solid residue (50 mg) recrystallized from ethanol to give needles of hydroquinone, m.p. and mixed m.p. 169–170°.

Reaction of Strychnine N-Oxide with Aqueous Sulfur Dioxide in the Presence of Hydroquinone

Sulfur dioxide was bubbled into a solution of strychnine *N*-oxide (0.34 g) and hydroquinone (0.10 g) in water (40 ml) at 0° for 10 min, during which time a white precipitate separated, redissolved, and then a yellow solid separated. The yellow solid after recrystallization from ethanol, had m.p. 113–115°, undepressed by admixture of the sample with an authentic sample of 1,4-benzoquinone. The aqueous solution was extracted with ether (3 × 25 ml) to remove a trace of hydroquinone, and then concentrated to 20 ml, and neutralized with sodium bicarbonate. White needles (0.26 g, 85%), separated; m.p. 286–288° (dec.) after recrystallization from ethanol, and identified by mixed m.p. as strychnine.

Strychnine *N*-oxide was not reduced to strychnine by hydroquinone in water at 0°.

*Acid Hydrolysis of Strychninium-N_b-sulfonate (**10**; X = H)*

(a) 6 N Hydrochloric Acid

Hydrolysis to strychnine (90% yield) and sulfate ion was complete within 2 min at room temperature.

(b) 0.5 N Hydrochloric Acid

Hydrolysis was complete in about 30 min at room temperature or 1 min at 100°.

(c) Aqueous Sulfur Dioxide

Hydrolysis was inappreciable after many hours at room temperature, but was complete (95% yield of strychnine) after 15 min at 65–70°.

*Alkaline Hydrolysis of Strychninium-N_b-sulfonate (**10**; X = H)*

Strychninium-N_b-sulfonate (0.15 g), swirled with 0.02 *N* sodium hydroxide (18.15 ml), deposited almost immediately strychnine (0.12 g); m.p. 286–288 °C (dec.) (identical by i.r. with an authentic sample of strychnine). The filtrate, acidified with nitric acid and treated with barium chloride, gave a positive sulfate test. Hydrolysis was almost instantaneous with aqueous ammonia and sodium carbonate but was inappreciable with aqueous sodium bicarbonate.

*N,N-Dimethylaniline N-Oxide (**18**)*

The following procedure is a modification of those in the literature (18, 30). Freshly distilled *N,N*-dimethylaniline (50 g) was stirred with 10% hydrogen peroxide (450 ml) at 60–70 °C for 10 h. The reaction mixture was cooled and extracted with ether (4 × 100 ml) to remove excess *N,N*-dimethylaniline. The aqueous layer was partially evaporated under reduced pressure at room temperature. A layer of benzene (100 ml) was added, and the mixture was treated with Linde Molecular Sieves Type 3A (250 g) until there was no positive peroxide test (15 h). The mixture was filtered and the benzene was evaporated. The pale-yellow solid residue was washed with cold benzene, removed by filtration, and dried at reduced pressure. It weighed 38 g (67%) and had m.p. 152–153 °C (lit. 152–153 °C (30)), ν_{max} (KBr) 965 cm^{-1} (ν N—O) (lit. 960 cm^{-1} (30)).

*(N,N-Dimethylanilinio-N) Sulfite (**19**)*

A solution of *N,N*-dimethylaniline oxide (3.02 g) in anhydrous benzene (100 ml) was saturated with sulfur dioxide. The solution turned yellow–orange, and a dark yellow gum precipitated on the walls of the flask. The benzene solution was decanted. Gradually (10 min) a white solid (18 mg) formed in the benzene solution and was removed by filtration. It had m.p. 95–98°, and an i.r. spectrum identical with that of an authentic sample of *N,N*-dimethylanilinium-*N*-sulfonate (24) prepared below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The benzene solution was evaporated under reduced pressure at room temperature. An acid wash of the benzene distillate removed *N,N*-dimethylaniline (0.75 g, 27%), having an i.r. spectrum identical with an authentic sample.

The oily residue in the flask (3.1 g, 70%) was identified as the sulfitoamine **19** by its characteristic i.r. spectrum (film between KBr plates: ν_{max} 1320, 1200, 1060, 1010, 780, 695, 580 cm^{-1}). It was very hygroscopic and was not analyzed.

*Rearrangement of the Sulfitoamine **19** in Water*

The sulfitoamine (3.1 g) was dissolved in water (80 ml) and the solution was kept in an ice-bath for 2 h, or was heated to 70–80° for 30 min. The solution was then worked-up by the procedure of Bamberger and Tschirner (18). Results are given in Table 1.

*N,N-Dimethylanilinium Sulfonate (**24**)*

Excess sulfur trioxide in 1,2-dichloroethane was added to dry *N,N*-dimethylaniline (2 g) in 1,2-dichloroethane (50 ml) at 0°. The reaction mixture was stirred for 1 h. The white solid was removed by filtration and dried under reduced pressure: 2.5 g, m.p. 95–99 °C, (lit. (31) m.p. 85–90°) ν_{max} (KBr) 1295, 1240, 1200, 1060, 1000, 750, 690, 575 cm^{-1}. The material was very hygroscopic and was hydrolyzed in cold water to *N,N*-dimethylaniline and sulfate almost instantaneously.

Reaction of N,N-Dimethylaniline Oxide with Aqueous Sulfur Dioxide

(a) Without Hydroquinone

Sulfur dioxide was bubbled for 45 min into a solution of the oxide (9.98 g) in water (75 ml) at 0°. The resultant emerald-green solution was stirred for 2 days and then worked-up according to Bamberger and Tschirner (18). Results are given in Table 1. Identity of the various products was confirmed by combustion analysis and by their i.r. and n.m.r. characteristics.

(b) With Hydroquinone

The reaction was carried out as above, except that hydroquinone (9 g) was added to the solution of the oxide in water before the introduction of sulfur dioxide. (In a separate experiment, it was shown that hydroquinone did not react with *N,N*-dimethylaniline oxide in water.) After 2 days reaction, the solution was acidified with 2 *N* sulfuric acid (4.7 ml), and benzoquinone and excess hydroquinone removed by extraction with ether. The solution was then worked-up according to the procedure of Bamberger and Tschirner (18), and gave *N,N*-dimethylaniline (80% yield), *N,N*-dimethylamino-*o*-benzenesulfonic acid (10%), *N,N*-dimethylamino-*p*-benzenesulfonic acid (3%), and *N,N*-dimethylamino-*o*-phenol (1.5%).

*(N,N-Dimethylanilinio) Sulfate (**27**)*

Pyridine – sulfur trioxide complex (0.68 g) was stirred for 30 min with anhydrous *N,N*-dimethylaniline *N*-oxide (0.6 g) dissolved in dry pyridine (30 ml). The t.l.c. on alumina then showed that no *N*-oxide (R_f 0.75 in $CHCl_3$/EtOH 80/20) remained. An oily gum formed on the walls of the flask. The solution was decanted, and the residual gum, dried under reduced pressure, set to a pale yellow solid (0.9 g), very hygroscopic. The i.r. spectrum (ν_{max} (KBr) 1340, 1275, 1110, 1030, 755, 685, 615 cm^{-1}) was similar to that of (strychninio-N_b) sulfate.

Anal. Calcd. for $C_8H_{11}O_4NS$: C, 44.2; H, 5.1; N, 6.4; S, 14.7. Found: C, 44.4; H, 5.3; N, 6.4; S, 14.5.

Hydrolysis of (N,N-Dimethylanilinio) Sulfate in Water

The sulfate (0.9 g) in water (25 ml) was heated on a steam bath for 10 min. The solution was neutralized with sodium bicarbonate, and was extracted with chloroform (10 × 40 ml). The extracts were dried and evaporated to give *N,N*-dimethylaniline-*N*-oxide (0.45 g) ν_{max} ($CHCl_3$) 965 cm^{-1}, R_f 0.75 by t.l.c. The acidified aqueous solution gave a positive test for sulfate (0.95 g $BaSO_4$; 98%). Picric acid added to the aqueous solution gave a yellow precipitate (0.17 g) of *N,N*-dimethylaniline oxide picrate, m.p. 136–138° (lit. m.p. 136° (18)).

Reaction of N,N-Diethylaniline Oxide with Aqueous Sulfur Dioxide

The monohydrate of *N,N*-diethylaniline *N*-oxide was obtained as a pale yellow solid, m.p. 89–92 °C (lit. 96° (32)), in 50% yield.

Sulfur dioxide was bubbled for 45 min into a solution of the *N*-oxide hydrate (10 g) in water (75 ml) at 0 °C. The resultant green solution was stirred for 2 days and then worked-up according to Bamberger and Tschirner (18). Yields are given in Table 1. *o-N,N*-Diethylaminophenol had m.p. < 20 °C (lit. 8–9 °C (33)), b.p. 216–219 °C (lit. 219–220 °C (33)), ν_{max} (KBr) 3400 (ν O—H), 1390 (δ O—H), 1220–1230 (ν C—O), 748 cm^{-1} (ortho-substituted). *o-N,N*-Diethylaminobenzenesulfonic acid darkened at about 275 °C and decomposed above 270 °C (34)), ν_{max} (KBr) 2650 (N^+—H), 1245 (ν_{asym} SO_3) 1080 (ν_{sym} SO_3), 765 (ortho-substituted), 590 cm^{-1} (δ SO_3); n.m.r. in D_2O: 1.20, 6H (CH_3, triplet), 4.02 4H(CH_2, quartet), 7.85 δ, 4H (aromatic, broad multiplet).

Anal. Calcd. for $C_{10}H_{15}NSO_3$: C, 52.4; H, 6.6; N, 6.1; S, 14.0. Found: C, 52.6; H, 6.7; N, 6.0; S, 13.9.

p-N,N-Diethylaminobenzenesulfonic acid darkened at 270 °C and decomposed at 285–300 °C (lit.: darkened at 250 °C, decomposed above 270 °C (34)), ν_{max} (KBr) 2650 (ν N^+—H), 1210 (ν_{asym} SO_3), 1035 (ν_{sym} SO_3), 832 (para-substituted), 590 cm^{-1} (δ SO_3); n.m.r. in D_2O: 1.20, 6H(CH_3, triplet); 4.02, 4H(CH_2, quartet); 7.85 δ, 4H (aromatic, broad multiplet).

Anal. Calcd. for $C_{10}H_{15}NSO_3$: C, 52.4; H, 6.6; N, 6.1; S, 14.0. Found: C, 52.0; H, 6.5; N, 6.0; S, 14.2.

In a second experiment, the reaction was followed by n.m.r. In acidified D_2O the n.m.r. spectrum of diethylaniline consists of a triplet at 1.45, 6H(CH_3), a quartet at 3.25, 4H(CH_2), and a broad multiplet at 7.85 δ, 5H (aromatic). The spectrum of the *N*-oxide in D_2O consists of a triplet at 1.20, 6H(CH_3), a quartet at 4.02, 4H(CH_2), and a broad multiplet at 7.85 δ. 5H (aromatic). The alkyl and aryl protons of the ortho- and para-sulfonic acids had virtually the same chemical shifts as those in the *N*-oxide.

Sulfur dioxide was bubbled into a solution of the *N*-oxide at 0 °C, and the spectrum was scanned every few minutes for the first hour and then intermittently for 2 days. There was no obvious emission or enhanced absorption in the alkyl resonances at any time. For the first 20 min the reaction was strongly exothermic so that thermal equilibrium was not established in the

probe, and mixing was imperfect (color not homogeneous), so that during this time the resonances were not well resolved. As the reaction proceeded a well-resolved quartet appeared at 3.25 and a triplet at 1.45 δ (slightly obscured by the CH_3 at 1.20 of the *N*-oxide). After 2 h the quartet at 3.25 integrated to approximately 20% of the quartet at 4.02 δ. The spectrum did not significantly change after this time.

*Reaction of N,N-Dimethylbenzylamine N-Oxide (**29**) with Aqueous Sulfur Dioxide at 0 °C*

Sulfur dioxide was bubbled into a solution of *N,N*-dimethylbenzylamine *N*-oxide (12 g of 50% solution) at 0° for 15 min. The reaction was strongly exothermic. A sticky white precipitate of **32** was removed, washed with ether, and dried at 80° and 1 mm: white powder, ν_{max} (KBr) 2660 (ν N^+—H), 1290 (ν_{asym} SO_3), 1200, 1055 cm^{-1} (ν_{sym} SO_3).

Anal. Calcd. for $C_9H_{13}NO_3S$: C, 50.2; H, 6.1; N, 6.2; S, 14.9. Found: C, 49.9; H, 6.1; N, 6.6; S, 14.4.

Attempts to recrystallize **32** from water or 95% ethanol resulted in decomposition, and a quantitative yield of benzaldehyde, ν_{max} (neat) 1695 cm^{-1}, was obtained; its 2,4-dinitrophenylhydrazone melted at 236–237°.

In a second experiment, the reaction mixture was diluted with water (25 ml) to keep **32** in solution. After reaction the solution was boiled for 5 min to remove sulfur dioxide, cooled, and extracted with ether (3 × 40 ml). The combined ether extracts were dried ($MgSO_4$) and distilled to give benzaldehyde (2.2 g, 52%). The aqueous solution was made strongly alkaline and extracted again with ether (3 × 40 ml). The combined extracts were dried ($MgSO_4$) and concentrated, and the residue chromatographed on alumina. Elution with benzene separated first *N,N*-dimethylbenzylamine (1.9 g, 35%); n.m.r. spectrum showing singlet (6H) at 2.9, and a singlet (2H) at 7.35 δ. Next came *N*-methylbenzylamine (0.4 g, 8%), ν_{max} ($CHCl_3$) 3300 cm^{-1} (ν N—H), forming a *p*-toluenesulfonamide, m.p. 93–95° (reported m.p. 95°).

When the reaction was carried out in the presence of hydroquinone (4.5 g), the yields of benzaldehyde (50%), *N,N*-dimethylbenzylamine (37%), and *N*-methylbenzylamine (8%) were almost unchanged.

Phenylsulfamic Acid

Phenylsulfamic acid was prepared by the procedure of Traube (35), and was isolated as the phenylammonium salt, melting with sublimation at 180°, ν_{max} (KBr) 2560 (ν NH_2^+), 1200 (ν_{asym} SO_3), 1010 (ν_{sym} SO_3), 750 and 690 (monosubstituted benzene), 695 (ν S—N), 575 cm^{-1} (δ SO_3); or as the barium salt, ν_{max} (KBr) 1200 (ν_{asym} SO_3), 1060 (ν_{sym} SO_3), 750 and 690 (monosubstituted benzene) 670 (ν S—N), 580 cm^{-1} (δ SO_3). Acidification of the barium salt resulted in hydrolysis to aniline bisulfate.

Reaction of Hydroxylamine with Aqueous Sulfur Dioxide

Sulfur dioxide was bubbled into 1 *M* aqueous hydroxylamine hydrochloride (50 ml) for 30 min at 0 °C, and the solution was stirred for another 60 min. Evaporation of the solution to dryness gave a white crystalline residue (4.9 g), ν_{max} (KBr) 3100–2600 (ν NH_4^+ and NH_3^+), 1540 (δ_{deg} NH_3^+), 1445 (δ_{sym} NH_3^+), 1300 (ν_{deg} SO_3) 1160 (ν_{asym} SO_3) in HSO_4^-), 1065 (ν_{sym} SO_3), 842 (ν S—O (H) in HSO_4^-), 688 cm^{-1} (ν S—N). The relative intensities of the sulfamic acid peak at 688 (36) and the bisulfate peak at 842 cm^{-1} (37), by comparison with those of known mixtures of sulfamic acid and potassium bisulfate, indicated an approximately 9:1 ratio of sulfamic acid:ammonium bisulfate, in agreement with results in the literature (22). The ratio was not affected when the reaction was repeated in the presence of hydroquinone (5.6 g), which was removed after the reaction by extraction with ether.

Reaction of Phenylhydroxylamine with Sulfur Dioxide

Through a solution of phenylhydroxylamine (5 g) in absolute alcohol (60 ml) at 10–25 °C, dry sulfur dioxide was passed for 1–2 h with stirring. A white crystalline solid was gradually formed and the color of the solution changed from light tan to brown. The flask was stoppered and allowed to stand for 3–30 h at 10° (different times caused no significant difference in yields). The mixture was filtered and the collected solid was found by i.r. examination to be a crude mixture of orthanilic and sulfanilic acids. This mixture was separated by fractional crystallization from water. The para isomer was crystallized first; it decomposed above 270° (lit. 288° (30)) and its i.r. spectrum (ν_{max} (KBr) 1220–1170 cm^{-1} (ν_{asym} SO_3) 1035 (ν_{sym} SO_3), 815 (para-substituted benzene), 565 cm^{-1} (δ SO_3)) was identical with that of an authentic sample of sulfanilic acid. The ortho isomer was obtained from the mother liquors by fractional crystallization; it decomposed above 180° (lit. 188° (33)) and its i.r. spectrum (ν_{max} (KBr) 1230–1180 (ν_{asym} SO_3), 1025 (ν_{sym} SO_3), 770 and 705 (ortho-substituted benzene), 560 cm^{-1} (δ SO_3)) was identical with that of an authentic sample of orthanilic acid.

The original mother liquor from the *o*- and *p*-isomers was made alkaline with potassium hydroxide and was extracted with ether (4 × 50 ml). The ether extracts contained aniline, which was identified by comparison of its i.r. spectrum and its chromatographic properties on alumina with those of an authentic sample. The extracted aqueous layer was neutralized with dilute hydrochloric acid and evaporated to give a brown solid, This was extracted with hot absolute alcohol (4 × 50 ml). then with hot 90–95% alcohol (4 × 50 ml), after which the residue consisted of inorganic material only. Evaporation of the absolute alcohol extracts gave a dark-colored solid which was recrystallized from water (charcoal) to give white crystals of metanilic acid, decomposing above 210°, ν_{max} (KBr) 1240–1150 (ν_{asym} SO_3), 1025 (ν_{sym} SO_3), 790 and 700 (meta-substituted benzene), 560 cm^{-1} (δ SO_3), identical with the spectrum of an authentic sample. From the 90–95% alcohol extracts, white crystals separated whose i.r. spectrum (ν_{max} (KBr) 1210–1160 (ν_{asym} SO_3), 1055 (ν_{sym} SO_3), 750 and 690 (mono-substituted benzene), 675 (ν S—N), 580 cm^{-1} (δ SO_3)) showed them to be potassium phenylsulfamate, by comparison with the spectrum of an authentic specimen of the barium salt. Potassium phenylsulfamate was readily soluble in cold water to give a neutral solution which gave no test for sulfate ion; when this solution was made acid and heated, complete hydrolysis of the product was effected, so that addition of barium chloride yielded an abundant precipitate of barium sulfate, and neutralization of the

aqueous phase with sodium bicarbonate and extraction with ether removed aniline quantitatively.

The same procedure was followed with other solvents (water and 60% ethanol) for the reaction. The yields of the various products are reported in Table 2.

Reaction of Phenylhydroxylamine with Sulfur Dioxide in the Presence of Hydroquinone

The same procedure as above was followed, except that hydroquinone (6 g) was added at the start of the reaction. Both the white solid formed initially and the filtrate from it were extracted with ether to remove a cream-colored solid (5.6 g, 93%), m.p. 169–171°, which was mainly hydroquinone (lit. m.p. 171–172°). A trace of benzoquinone (about 5%), was detected by comparing the chromatographic properties of the product on silica gel with the properties of known mixtures of hydroquinone and benzoquinone.

Reaction of Phenylhydroxylamine with Sulfur Dioxide in Anhydrous Ether

Dry sulfur dioxide was bubbled into a solution of phenylhydroxylamine (2.5 g) in anhydrous ether (50 ml) at 0 °C for 45 min. In the first few seconds a white precipitate formed, which then darkened to an orange oil and then (within a few minutes) to a black gum. The mixture was stirred for 8–10 h, by which time the black gum had solidified on the walls of the flask and a greyish powder was suspended in the ether. The grey powder (1.4 g, 42%), collected by filtration, sublimed at about 180°, and was identified as anilinium phenylsulfamate by comparison of its i.r. spectrum (ν_{max} (KBr) 2560 (ν NH_2^+), 1200 (ν_{asym} SO_3), 1010 (ν_{sym} SO_3), 750 and 690 (mono-substituted benzene), 625 (ν S—N), and 575 cm^{-1} (δ SO_3)) with the spectrum of an authentic specimen.

Anal. Calcd. for $C_{12}H_{14}N_2O_3S$: C, 54.1; H, 5.3; N, 10.5; S, 12.0. Found: C, 54.3; H, 4.9; N, 10.3; S, 12.4.

The powder (1 g) was heated with 2 *N* hydrochloric acid to 75° for 10 min and the resultant solution then neutralized with sodium bicarbonate and extracted with ether, removing aniline (0.55 g, 90%). The aqueous layer, acidified with nitric acid, gave a positive test for sulfate with barium chloride.

The ether filtrate was evaporated to give slightly impure aniline (25 mg, 1.5%), identified by comparison of i.r. characteristics and chromatographic properties on alumina with those of an authentic sample of aniline. The black sticky solid deposited on the walls (1.8 g, 54%) was identified by its i.r. spectrum as impure anilinium phenylsulfamate.

Reaction of Phenylhydroxylamine with Sodium Bisulfite in 60% Alcohol

A solution of sodium bisulfite (5 g) and phenylhydroxylamine (2.5 g) in 60% alcohol (80 ml) was stirred for 4 days at room temperature away from contact with air. Crystals gradually formed (0.3 g, 7.5%), and were identified as a mixture of orthanilic and sulfanilic acids by i.r. spectrum. Alcohol was removed from the filtrate by evaporation, and the aqueous layer was extracted with ether (4 × 75 ml). The combined ether extracts were dried and evaporated to give phenylhydroxylamine (2.2 g, 88%), m.p. 80–81°, and a trace of aniline.

Reaction of Phenylhydroxylamine with Sodium Sulfite in 60% Alcohol

A mixture of phenylhydroxylamine (2.5 g) and sodium sulfite (6 g) in 60% alcohol (100 ml) was stirred out of contact with air for 4 days at room temperature (sodium sulfite was not completely soluble). The reaction mixture was filtered, and the solid residue was extracted with hot alcohol (4 × 60 ml). Evaporation of the alcohol extracts gave a mixture of orthanilic and sulfanilic acids (0.2 g, 5%), contaminated by a trace of sodium sulfite. Alcohol was removed from the filtrate by evaporation, and the aqueous solution was extracted with ether (4 × 75 ml). The combined ether extracts were dried and evaporated to give a crude product (2.3 g) containing phenylhydroxylamine, aniline, azoxybenzene, and unidentified products, as shown by comparison of the chromatographic properties of alumina with those of authentic samples.

Preparation de quelques cyclohexène-2 diones-1,4 et de leurs dérivés

J. Y. Savoie et P. Brassard
Département de Chimie, Université Laval, Québec, Québec

Reçu le 2 septembre 1970[1]

Nous avons obtenu pour la première fois, à notre connaissance, les monomères des dihydroxy-5,6(*cis*) cyclohexène-2 diones-1,4 à partir de quinones lors d'oxydations catalysées par l'acide osmique. La toluquinone et l'*o*-xyloquinone donnent un mélange de deux isomères possibles. L'analyse des spectres de r.m.n. suggère qu'en général ces nouvelles substances ont une plus grande souplesse conformationnelle que les dihalogénures de quinones. La transformation de cyclohexène-2 diones-1,4 en oximes permet en outre de déterminer facilement toutes les constantes importantes de couplage.

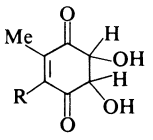
The osmic acid catalyzed oxidation of quinones has yielded for the first time to our knowledge the monomers of some *cis*-5,6-dihydroxycyclohex-2-ene-1,4-diones. Toluquinone and *o*-xyloquinone give mixtures of the two possible isomers. Observation of the n.m.r. spectra suggests that this new class of compounds are in general conformationally more mobile than quinonedihalides. The conversion of cyclohex-2-ene-1,4-diones into oximes allows the easy evaluation of all the important coupling constants.

Canadian Journal of Chemistry, **49**, 3515 (1971)

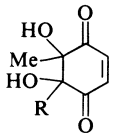
Grâce à la découverte récente de dihydro-2,3 quinones naturelles (1–4) et de leurs produits de réduction (5–7) on a réalisé des progrès considérables dans la synthèse de cyclohexène-2 diones-1,4 (8–13). Pour notre part, nous nous sommes intéressés tout particulièrement à leurs dérivés halogénés et hydroxylés en tant qu'intermédiaires de synthèse. On connaît depuis longtemps (14) les halogénures de quinones, mais leur configuration *trans* d'abord proposée (15), a ensuite été mise en doute (16), puis réaffirmée (17). En 1926, Terry et Milas (18) croyaient avoir préparé la première dihydroxy-5,6 cyclohexène-2 dione-1,4 par l'action du chlorate de sodium sur la *p*-benzoquinone en présence d'acide osmique. Cette substance a été reconnue depuis ce temps comme un dimère qui a fait l'objet de deux études de structure (19, 20).

Synthèse

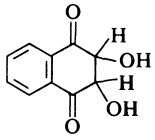
Appliquée à l'*o*-xyloquinone, la méthode originale n'a permis, après 10 jours, que de récupérer la substance de départ. Nous sommes maintenant en mesure de communiquer la première synthèse de cyclohexènediones hydroxylées en 5,6 à la suite de modifications apportées à ce procédé (voir tableau 1 et partie expérimentale). L'hydroxylation n'est d'ailleurs pas aussi spécifique que la plupart des réactions des quinones puisqu'on obtient parfois des mélanges des isomères *a* et *b* (sauf pour l'α-naphtoquinone et la phénylbenzoquinone). Par contre, les diols dérivés de la



1*a* R = H
2*a* R = CH_3



1*b* R = H
2*b* R = CH_3



3

toluquinone et de l'*o*-xyloquinone ne montrent déjà plus de tendance à se dimériser. La chloroquinone donne un mélange complexe de monomères et de dimères, mais à partir de la *p*-benzoquinone, en interrompant l'expérience avant la fin de la réaction, nous avons pu isoler et identifier le plus simple de ces diols. La formation de l'acétonide du composé **2***a* et le fait que les diacétates de **1***b*, **2***b*, et **3** et les produits d'acétolyse des époxydes correspondants sont différents, confirment la stéréospécificité de la réaction et démontrent que l'oxydation donne bien les diols *cis*.

Les dihydroxy-5,6 cyclohexène-2 diones-1,4 sont très solubles dans l'eau, mais s'isolent du milieu réactionnel par extraction répétée avec de l'éther. Les rendements relatifs des deux isomères **1***a*, *b* et **2***a*, *b*, varient quelque peu suivant les conditions expérimentales, mais en général ceux des isomères "*a*" sont respectivement de l'ordre de 60 à 70% et d'environ 80% pour la toluquinone et l'*o*-xyloquinone. La séparation des isomères **2***a* et *b* s'effectue facilement par chromatographie sur gel de silice. Il est par contre préférable d'isoler les isomères **1***a* et *b* sous la forme d'acétate par la même méthode après acétylation du mélange car ces isomères sont peu stables en présence de cet adsorbant.

Spectroscopie

Les études antérieures de r.m.n. sur un petit nombre de cyclohexène-2 ones naturelles et de cyclohexène-2 diones-1,4 semblent indiquer une nette prédominance d'un des conformères possibles (5, 7, 20–23). Norris et Sternhell (21) ont déduit la conformation des dibromures des méthyl-2 et bromo-2 benzoquinones et obtenu des résultats fragmentaires concernant quelques autres dérivés. Nous avons tenté d'obtenir directement des données plus générales par l'étude des monoximes correspondants (comme prévu, l'oximation d'un carbonyle ne semble pas perturber la situation conformationnelle).

Les dichloro- et dibromo-5,6 méthyl-2 cyclohexène-2 oximido-4 ones-1 donnent directement en première approximation des constantes de couplage vicinal ($J_{5,6}$) de 2.6 à 3.0 Hz et à longue distance ($J_{3,5}$) de 1.7 à 1.9 Hz, tout-à-fait comparables aux résultats antérieurs. Les spectres des mêmes dérivés de la *p*-benzoquinone elle-même permettent de plus d'évaluer toutes les constantes de couplage importantes ($J_{2,3}$, $J_{2,6}$, $J_{3,5}$, et $J_{5,6}$) et confirme l'orientation diaxiale des substituants (voir tableau 2). Dans cette partie de l'étude, nous nous sommes évertués à obtenir des échantillons purs et avons délibérément négligé les problèmes de l'isomérie *syn–anti* des substrats (le dichlorure de la toluquinonacétoxime en particulier se comporte comme un mélange d'isomères).

Il est bien connu que les époxy-5,6 cyclohexénones et cyclohexènediones adoptent de préférence la conformation "O-axiale" (5, 23, 24). Quoique Rashid et Read (11) n'aient observé que deux singulets dans le spectre de r.m.n. de l'époxybenzoquinone, nos spectres révèlent bien les deux triplets attendus pour une telle conformation (25). La valeur de $|J_{ax} + J_{a'x}|$ s'obtient donc directement et, puisque $J_{a'x}$ doit être très petit, nous obtenons une valeur de J_{ax} qui est en accord avec celle prédite. L'oxime de l'époxybenzoquinone permet encore une fois de mesurer les quatre constantes de couplage principales qui concordent bien avec les valeurs prévues pour le conformère O-axial.

Les dihydroxy-5,6 cyclohexènediones (*cis* et *trans*) présentent un problème conformationnel un peu plus délicat car, sous la forme monomère, elles montrent rarement, dans leurs spectres de r.m.n., de couplage à longue distance alors que ceux-ci sont très évidents dans le cas des dimères monohémiacétal (20). Les autres constantes de couplage peuvent parfois être mises en évidence par l'emploi de substituants convenablement situés (*i.e.* dans **1***b*) ou dans le cas de **2***a* par la formation d'un monoacétate.

Les résultats préliminaires obtenus à partir de la toluquinone et de l'*o*-xyloquinone semblaient confirmer que ces diols, comme beaucoup d'autres cyclohexènediones, adoptent une conformation particulière mais que celle-ci serait "bateau". En effet l'abaissement de la température à $-50°$ n'apporte aucune modification des spectres de r.m.n.

Le choix de substrats appropriés a toutefois permis de réjeter cette possibilité d'ailleurs peu probable. Ainsi les seuls diols, qui montrent un couplage à longue distance dans leur spectre de r.m.n. sont ceux qui dérivent des phényl et di-*t*-butyl-2,6 quinones. Dans ces deux cas, une conformation qui ne peut être que "chaise" prédomine et s'explique par des considérations élémentaires d'interaction de dipôles ou d'effets stériques. Dans les autres exemples, aucun facteur ne semble susceptible de stabiliser l'une des formes et on doit donc en conclure que l'on a affaire à des équilibres rapides de conformères "chaise".

Applications

L'énolisation de la dihydroxy-5,6(*cis*) diméthyl-2,3 cyclohexène-2 dione-1,4 dans l'éther saturé d'acide bromhydrique ou bien du diacétate correspondant dans le méthanol contenant de l'acide chlorhydrique a donné le tétrahydroxy *o*-xylène (avec un rendement de 70% à partir de l'*o*-xyloquinone). L'oxydation de cette hydroquinone par l'oxygène atmosphérique en milieu faiblement basique a aussi permis d'effectuer une synthèse de l'aurantiogliocladine beaucoup plus facile que celles publiées (26–28). D'ailleurs nous n'avons jamais pu répéter celle de Pettersson (28) en dépit de nombreuses tentatives; la réaction de Thiele sur l'hydroxy *o*-xyloquinone ne nous a jamais donné la moindre trace de tétraacétoxy *o*-xylène. De plus, cette dernière substance préparée par nous a un point de fusion de 174.0–174.5° au lieu de 97° que donne Pettersson (sans mention de rendement). D'autre part, toutes les tentatives en vue de transformer le tétrahydroxy *o*-xylène en dihydroxy-2,3 diméthyl-5,6(*trans*) cyclohexène-2 dione-1,4 (dont l'éther méthylique est la glioroséine) par les méthodes de Mayer et Weiss (29) se sont toutes soldées par des échecs.

Partie expérimentale

Les points de fusion ont été déterminés en tube capillaire à l'aide d'un thermomètre calibré (appareil Thomas–Hoover). Les spectres i.r. ont été réalisés sur un appareil Beckman, modèle IR-4. Les spectres de r.m.n. ont été enregistrés sur un appareil Varian A 60; les déplacements chimiques sont mesurés en δ par rapport au tétraméthyl silane (δ = 0) et ne sont pas corrigés.

(I) Méthodes générales de préparation des dihydroxy-5,6 (cis) cyclohexène-2 diones-1,4 à partir des p-benzoquinones correspondantes

Méthode A (Méthode principale)

A une solution de chlorate de sodium (10.0 g) dans l'eau (50 ml) contenant de l'acide osmique (1.3 ml d'une solution aqueuse à 1%), on ajoute de l'acide chlorhydrique concentré (1 ml) puis la quinone (0.1 mol) et on maintient le milieu réactionnel sous forte agitation à 25°. La fin de la réaction est généralement indiquée par la disparition de la couleur jaune caractéristique des quinones.[2] On sature alors la solution avec du chlorure de sodium et on extrait avec de l'éther de pétrole pour éliminer les dernières traces de quinone. On extrait ensuite les eaux-mères avec plusieurs portions successives d'éther (environ 2 l au total).

Méthode B (Méthode de Milas)

A une solution de chlorate de sodium (20.0 g) dans l'eau (50 ml) contenant de l'acide osmique (1.3 ml d'une solution aqueuse à 1%), on ajoute de l'acide chlorhydrique concentré (1 ml) puis lentement de l'hydroquinone (0.1 mol) en maintenant le milieu réactionnel sous forte agitation à 0°. L'addition trop rapide de l'hydroquinone empêche, par la formation de quinhydrone, une agitation suffisante, ce qui entraîne une élévation de température et la formation de produits de décomposition. Après la disparition de la quinhydrone (1 à 2 h), on laisse le milieu réactionnel se réchauffer à 25° et on procède comme par la méthode A.

Modifications des méthodes A et B

Voir tableau 1.

(II) Hydroxylation de la p-benzoquinone

On obtient par la méthode A, à partir de 10.8 g de *p*-benzoquinone dans 50 ml d'eau, après 48 h de réaction, 3.6 g du dimère.

Dihydroxy-5,6(cis) cyclohexène-2 dione-1,4

Le précipité obtenu du mélange réactionnel est lavé avec de l'eau froide (10 ml) et le filtrat est ajouté aux eaux-mères. On sature la solution avec du chlorure de sodium et on extrait avec de l'éther de pétrole jusqu'à disparition de la couleur jaune. On extrait alors avec de l'éther et on évapore sous vide à une température inférieure à 30°. On isole ainsi 3.2 g d'une huile jaune pâle très instable. Cette substance ne cristallise pas et ne résiste pas à la chromatographie sur gel de silice. Spectre de r.m.n. ($(CD_3)_2CO$): trois singulets d'égale intensité à δ 4.60, 5.93 et 6.85 (CH 5,6, OH 5,6, et CH 2,3 respectivement).

Diacétoxy-5,6(cis) cyclohexène-2 dione-1,4

L'acétylation immédiate de l'huile isolé dans l'extraction précédente par l'anhydride acétique en présence d'une trace d'acide sulfurique donne une huile incolore après hydrolyse, extraction à l'éther, séchage et évaporation. Le produit obtenu est aussi instable que le diol correspondant. Spectre de r.m.n. (CCl_4): un singulet à δ 2.07 correspondant à six protons ($OCOCH_3$ en 5,6), un singulet à 5.75 (CH 5,6), et un troisième singulet à 6.85 (CH 2,3).

(III) Hydroxylation de la toluquinone

On obtient par la méthode B, à partir de 25.0 g (0.2 mol) de toluhydroquinone dans 80 ml d'eau et 20 ml de dioxanne après 70 h de réaction, 15.2 g (50%) d'une huile incolore. L'huile est immédiatement chromatographiée sur gel de silice. Toutefois la séparation complète des isomères est beaucoup plus facile si l'on procède d'abord à une acétylation du mélange.

Dihydroxy-5,6(cis) méthyl-5 cyclohexène-2 dione-1,4 (1b)

L'élution au chloroforme donne dans les premières fractions une huile incolore (3.5 g) qui cristallise en aiguilles de l'éther de pétrole (p.é. 30–60°), p.f. 103–103.5°. Après deux recristallisations du benzène, la dihydroxy-5,6-(*cis*) méthyl-5 cyclohexène-2 dione-1,4 fond à 106.5–107.0°. Spectre i.r. ($CHCl_3$): bandes à 2.80 et 2.85 (OH), 3.30 (C═CH), et 5.85 μ (C═O). Spectre de r.m.n ($CDCl_3$): un singulet à δ 1.51 (CH_3 6), un singulet à 4.10 (OH 6), un doublet centré à 4.13 (OH 5), un doublet centré à 4.35 (CH 5) et un singulet (deux protons) à 6.90 (CH 2,3).

Anal. calc. pour $C_7H_8O_4$: C, 53.84; H, 5.16. Trouvé: C, 53.62; H, 5.16.

Diacétoxy-5,6 méthyl-5 cyclohexène-2 dione-1,4

L'acétylation du diol par l'anhydride acétique en présence d'une trace d'acide sulfurique ou d'acide perchlorique donne avec un rendement quantitatif la diacétoxy-5,6(*cis*) méthyl-5 cyclohexène-2 dione-1,4 qui, après deux cristallisations d'un mélange d'acétate d'éthyle et d'éther de pétrole (p.é. 66–70°), fond à 117–117.5°. Spectre i.r. ($CHCl_3$): bandes à 5.69 ($OCOCH_3$), 5.80 μ (C═O). Spectre de r.m.n. ($CDCl_3$): un singulet à δ 1.58 (trois protons; CH_3 6), un singulet à 2.02 (trois protons; $OCOCH_3$ 6), un singulet à 2.28 (trois protons; $OCOCH_3$ 5), un singulet à 5.47 (CH 5), et deux doublets centrés à 6.76 et 6.90, J = 10.2 Hz.

Dihydroxy-5,6(cis) méthyl-2 cyclohexène-2 dione-1,4 (1a) et diacétoxy-5,6(cis) méthyl-2 cyclohexène dione-1,4

Les fractions subséquentes de cette chromatographie donne une huile incolore contenant un mélange des deux diols isomères. Tous les essais de cristallisation sont demeurés infructueux même pour les dernières fractions contenant presqu'exclusivement de la dihydroxy-5,6(cis) méthyl-2 cyclohexène-2 dione-1,4 identifié par son spectre de r.m.n. ($CDCl_3$): un doublet centré à δ 2.05, J = 1.8 Hz (CH_3 2), plusieurs pics dans la région de 4.3 à 4.8 correspondant à quatre protons (CH 5,6; OH 5,6), et un multiplet à 6.71 (CH 3).

Une séparation plus efficace des deux isomères a été essayé par l'emploi d'éluants moins polaires ou par des

[2]Souvent la préparation n'est pas tout à fait reproductible et donne naissance à des produits secondaires fortement colorés qui empêchent de déceler la fin de la réaction. L'extraction avec le benzène devient alors nécessaire pour éliminer l'excès de la quinone. La perte en produit dihydroxylé causée par cette extraction est assez faible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

quantités d'absorbant plus grandes. Ces modifications n'améliorent pas le résultat car la décomposition des produits augmente avec le temps de contact sur gel de silice.

L'acétylation des dernières fractions par la méthode habituelle donne le diacétoxy-5,6(*cis*) methyl-2 cyclohexène-2 dione-1,4 qui cristallise de l'acétate d'éthyle, p.f. 105–105.5°. L'échantillon analytique, obtenu après deux recristallisations d'un mélange de benzène et de *n*-hexane fond à 105–105.5°. Spectre de r.m.n. ($CDCl_3$): un doublet centré à δ 2.10 (CH_3 2), un singulet à 2.14 (six protons; $OCOCH_3$ 5,6), un singulet à 5.83 (deux protons; CH 5,6), et un multiplet à 6.78 (CH 3).

Anal. calc. pour $C_{11}H_{12}O_6$: C, 55.00; H, 5.04. Trouvé: C, 55.37; H, 5.11.

Dans cette réaction d'oxydation on obtient donc 15.2 g de produits dihydroxylés contenant approximativement 35% de dihydroxy-5,6(*cis*) méthyl-5 cyclohexène-2 dione-1,4 et 65% de l'autre diol (**1***a*) (détermination faite par spectroscopie de r.m.n.). Du mélange 3.5 g (12%) du diol (**1***b*) et 7.2 g (15%) du diacétoxy-5,6(*cis*) méthyl-2 cyclohexène-2 dione-1,4 ont pu être isolé sous forme cristalline.

(IV) Hydroxylation de l'o-xyloquinone

On obtient par la méthode A, à partir de 13.6 g (0.1 mol) d'*o*-xyloquinone dans 70 ml d'eau et 20 ml de dioxanne après 50 h de réaction 15.3 g (93%) d'une huile incolore. L'huile cristallise en présence d'éther et fournit 7.8 g de cristaux incolores, p.f. 117–118°.

Le résidu (7.5 g) est chromatographié sur gel de silice.

*Dihydroxy-5,6(cis) diméthyl-5,6 cyclohexène-2 dione-1,4 (**2***b*)*

L'élution au benzène donne dans les premières fractions 3.0 g d'une huile qui cristallise en aiguilles de l'éther de pétrole (p.é. 30–60°), p.f. 82–84°. Ce produit a été identifié comme étant la dihydroxy-5,6(*cis*) diméthyl-5,6 cyclohexène-2 dione-1,4. Après trois recristallisations de l'éther de pétrole (p.é. 30–60°) il fond à 84–85°. Spectre i.r. ($CHCl_3$): 2.84 (OH), 3.29 (C═CH), 5.81 (C═O), 6.22 (C═C). Spectre de r.m.n. ($CDCl_3$): trois singulets à δ 1.35 (CH_3 5,6), à 3.52 (OH 5,6), et à 6.87 (CH 2,3).

Anal. calc. pour $C_8H_{10}O_4$: C, 56.46; H, 5.92. Trouvé: C, 56.92; H, 5.89.

Diacétoxy-5,6(cis) diméthyl-5,6 cyclohexène-2 dione-1,4

L'acétylation de ce diol (**2***b*) par l'anhydride acétique catalysée par une trace d'acide sulfurique donne avec un rendement quantitatif la diacétoxy-5,6(*cis*) diméthyl-5,6 cyclohexène-2 dione-1,4. Après trois recristallisations de l'acétate d'éthyle ce diacétate fond à 106–106.5°. Spectre i.r. ($CHCl_3$): 3.30 (C═CH), 5.69 ($OCOCH_3$), 5.80 C═O), et 8.18 μ (C—O). Spectre de r.m.n. ($CDCl_3$): trois singulets à δ 1.61 (six protons; CH_3 5,6), à 2.08 (six protons; $OCOCH_3$ 5,6), et à 6.73 (deux protons; CH 2,3).

*Dihydroxy-5,6(cis) diméthyl-2,3 cyclohexène-2 dione-1,4 (**2***a*)*

Lors de cette même chromatographie, le benzène élue dans les fractions subséquentes 4.1 g de dihydroxy-5,6(*cis*) diméthyl-2,3 cyclohexène-2 dione-1,4 qui cristallise facilement en présence d'éther. Ce produit est identique à celui (7.8 g) isolé directement de l'huile extraite du mélange réactionnel. On obtient ainsi un rendement total de ce diol de 11.9 g (70%). L'échantillon analytique, obtenu après deux recristallisations du benzène, fond à 119–119.5°. Spectre i.r. ($CHCl_3$): 2.86 (bande large, OH), 5.89 (C═O), 6.17 μ (C═C). Spectre de r.m.n. ($CDCl_3$): trois singulets à δ 2.07 (CH_3 2,3), à 3.50 (OH 5,6), et à 4.60 (CH 5,6).

Anal. calc. pour $C_8H_{10}O_4$: C, 56.46; H, 5.92. Trouvé: C, 56.17; H, 5.97.

Diacétoxy-5,6(cis) diméthyl-2,3 cyclohexène-2 dione-1,4

A une solution du diol **2***a* dans l'anhydride acétique (10 ml), on ajoute une trace d'acide sulfurique. On obtient de cette façon après hydrolyse, filtration, lavage avec de l'eau et séchage, la diacétoxy-5,6(*cis*) diméthyl-2,3 cyclohexène-2 dione-1,4 presque pure, p.f. 124–125°. Pour analyse élémentaire, un échantillon a été recristallisé trois fois d'un mélange d'éther et de *n*-hexane, p.f. 126.5–127.5°. Spectre i.r. (KBr): 5.65 ($OCOCH_3$), 5.82 et 5.93 (C═O), 6.18 (C═C), 8.13 et 8.26 μ (C—O). Spectre de r.m.n. ($CDCl_3$): trois singulets à δ 2.07 et 2.13 (CH_3 2,3; $OCOCH_3$ 5,6) et à 5.82 (CH 5,6).

Anal. calc. pour $C_{12}H_{14}O_6$: C, 56.68; H, 5.55. Trouvé: C, 56.72; H, 5.69.

Acétonide de la dihydroxy-5,6(cis) diméthyl-2,3 cyclohexène-2 dione-1,4

A une solution d'acétone anhydre (20 ml) contenant de l'acide *p*-toluènesulfonique (5 mg) et du sulfate de cuivre (500 mg) on ajoute la dihydroxy-5,6(*cis*) diméthyl-2,3 cyclohexène-2 dione-1,4 (**2***a*) (1 g) et on laisse reposer pendant 5 jours à l'obscurité. On traite ensuite le mélange réactionnel avec un excès de bicarbonate de sodium (solution aqueuse saturée) pour éliminer l'excès d'acide, le diol qui n'a pas réagi et les produits d'énolisation. Par extraction à l'éther, on obtient, après séchage sur sulfate de sodium anhydre et évaporation sous vide, une huile que l'on chromatographie sur gel de silice avec du benzène comme éluant.

On obtient ainsi 0.9 g de l'acétonide qui cristallise de l'éther de pétrole (p.é. 66–70°) en aiguilles jaune pâle, p.f. 98–99°. L'échantillon analytique est recristallisé deux fois de l'éther de pétrole (p.é. 66–70°) p.f. 98.5–99.0°. Spectre i.r. (KBr): 3.34 et 3.36 (—$C(CH_3)_2$), 5.90 (C═O), 6.18 μ (C═C). Spectre de r.m.n. ($CDCl_3$): des singulets à δ 1.41 et 1.46 (*gem*-diméthyles), à 2.07 (CH_3 2,3) et à 4.71 (CH 5,6).

Anal. calc. pour $C_{11}H_{14}O_4$: C, 62.84; H, 6.71. Trouvé: C, 62.65; H, 6.78.

Acétoxy-5 hydroxy-6(cis) diméthyl-2,3 cyclohexène-2 dione-1,4

On dissout 0.85 g (0.02 mol) de dihydroxy-5,6(*cis*) diméthyl-2,3 cyclohexène-2 dione-1,4 dans une quantité minimale d'acide acétique (2 ml) et on ajoute l'anhydride acétique (1.2 ml) et une trace d'acide sulfurique. On laisse réagir pendant 3 min, on hydrolyse et on extrait à l'éther. Le résidu après évaporation est chromatographié sur gel de silice. Le benzène élue une huile blanche que nous n'avons pas réussi à cristalliser. Le spectre de r.m.n. de cette substance correspond à celui de l'acétoxy-5 hydroxy-6 diméthyl-2,3 cyclohexène-2 dione-1,4. L'énolisation de ce produit par de l'acide chlorhydrique dans le méthanol donne le tétrahydroxy *o*-xylène.

(V) Hydroxylation de l'α-naphtoquinone et des diméthyl-2,6, ditertiobutyl-2,6 et phényl p-benzoquinones

*Dihydroxy-2,3(cis) dioxo-1,4 tétrahydro-1,2,3,4 naphtalène (**3**)*

On obtient par la méthode A, à partir de 15.8 g de naphtoquinone-1,4 dans 80 ml d'eau et 20 ml de dioxanne après 12 jours de réaction, 12.2 g d'un précipité blanc que

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

l'on filtre et lave avec de l'eau froide (20 ml). L'extraction du filtrat avec de l'éther (2 l) donne 4.2 g d'une huile incolore qui cristallise facilement (les deux produits sont identiques). On isole ainsi 16.4 g (85%) de dihydroxy-2,3(*cis*) dioxo-1,4 tétrahydroxy-1,2,3,4 naphtalène qui fond à 170–172° après deux cristallisations du chloroforme. Spectre i.r. (KBr): 2.96 (OH), 5.86 à 5.90 (C═O), 6.30 μ (C═C). Spectre de r.m.n. ($(CD_3)_2CO$): deux singulets à δ 5.0 et 2.9 respectivement (OH 2,3), un singulet à 4.83 (deux protons; CH 2,3), et un multiplet centré à 8.0 (quatre protons; CH aromatiques).

Anal. calc. pour $C_{10}H_8O_4$: C, 62.50; H, 4.20. Trouvé: C, 62.88; H, 4.22.

Diacétoxy-2,3 dioxo-1,4 tétrahydro-1,2,3,4 naphtalène

L'acétylation de ce diol de la façon habituelle donne quantitativement la diacétoxy-2,3 dioxo-1,4 tétrahydro-1,2,3,4 naphtalène, p.f. 116.0–116.5°. Après trois cristallisations de l'acétate d'éthyle, ce diacétate fond à 117.0–117.5°. Spectre i.r. ($CHCl_3$): 5.67 ($OCOCH_3$), 5.79 et 5.84 (C═O), 6.25 (C═C) et 8.30 μ (bande large, C—O). Spectre de r.m.n. ($CDCl_3$): un singulet à δ 2.14 (six protons; $OCOCH_3$ 2,3), un singulet à 6.01 (deux protons; CH 2,3), et un multiplet centré à 8.0 (quatre protons; CH aromatiques).

Dihydroxy-5,6(cis) diméthyl-2,6 cyclohexène-2 dione-1,4

On obtient par la méthode A, à partir de 6.8 g (0.05 mol) de diméthyl-2,6 *p*-benzoquinone dans 10 ml d'eau et 50 ml de dioxanne, après 72 h, 7.4 g (87%) de dihydroxy-5,6(*cis*) diméthyl-2,6 cyclohexène-2 dione-1,4, p.f. 140.5–141° (chloroforme). Spectra i.r. (KBr): 2.91 (OH), 5.90 à 5.97 (C═O), 6.15 μ (C═C). Spectre de r.m.n. ($(CD_3)_2CO$): un singulet à 1.44 (CH_3 6), un doublet à 2.01, J = 1.5 Hz (CH_3 2), un singulet à 4.37 (deux protons; OH 5,6), un singulet à 4.67 (CH 5) et un quadruplet à 6.78, J = 1.5 Hz (CH 3).

Diacétoxy-5,6(cis) diméthyl-2,6 cyclohexène-2 dione-1,4

Cette substance s'obtient à partir du composé précédent de la façon habituelle, p.f. 129.5–130° ($CHCl_3$). Spectre i.r. (KBr): 5.68 et 5.73 ($OCOCH_3$), 5.80 et 5.88 (C═O), et 6.18 μ (C═C). Spectre de r.m.n. ($(CD_3)_2CO$): un singulet à 1.54 (CH_3 6), un doublet à 2.03, J = 1.5 Hz (CH_3 2), deux singulets à 1.96 et 2.20 ($OCOCH_3$ 5,6), un singulet à 5.53 (CH 5), et un quadruplet à 6.61, J = 1.5 Hz (CH 3).

Dihydroxy-5,6(cis) ditertiobutyl-2,6 cyclohexène-2 dione-1,4

On obtient par la méthode A, à partir de 4.4 g (0.02 mol) de ditertiobutyl-2,6 *p*-benzoquinone dans 10 ml d'eau et 25 ml de dioxanne, après 72 h, le dihydroxy-5,6(*cis*) ditertiobutyl-2,6 cyclohexène-2 dione-1,4 avec un rendement presque quantitatif, p.f. 124.5–125° (eau–méthanol). Spectre i.r. (KBr): 2.89 (OH), 5.90 à 5.94 (C═O) et 6.24 μ (C═C). Spectre de r.m.n. ($CDCl_3$): deux singulets à 0.96 et 1.33 ($C(CH_3)_3$ 2,6), un doublet à 4.46, J = 2.0 Hz (CH 5), et un doublet à 6.75, J = 2.0 Hz (CH 3).

Diacétoxy-5,6(cis) ditertiobutyl-2,6 cyclohexène-2 dione-1,4

Par la méthode habituelle, p.f. 164.5–165° ($CHCl_3$). Spectre i.r. (KBr): 5.68 et 5.72 ($OCOCH_3$), 5.84 et 5.89 (C═O) et 6.21 μ (C═C). Spectre de r.m.n. ($CDCl_3$): deux singulets à 1.03 et 1.29 ($C(CH_3)_3$ 2,6), deux singulets à 2.08 et 2.17 ($OCOCH_3$ 5,6), un singulet à 5.79 (CH 5), et un singulet à 6.70 (CH 3).

Dihydroxy-5,6(cis) phényl-2 cyclohexène-2 dione-1,4

On obtient par la méthode A à partir de 9.20 g (0.05 mol) de phényl-*o*-benzoquinone dans 10 ml et 50 ml de dioxanne après 65 h, 7.7 g (72%) de dihydroxy-5,6 phényl-2 cyclohexène-2 dione-1,4, p.f. 123.5–124° ($CHCl_3$). Spectre i.r. (KBr): 2.89–3.04 (OH), 5.83 et 6.01 (C═O), et 6.07 μ (C═C). Spectre de r.m.n. ($(CD_3)_2CO + D_2O$): un doublet de doublets à 4.85, J = 3.0, 1.0 Hz (CH 5), un doublet à 5.04, J = 3.0 Hz (CH 6), un doublet à 7.07, J = 1.0 Hz (CH 3), et un multiplet à 7.45 (C_6H_5).

Diacétoxy-5,6(cis) phényl-2 cyclohexène-2 dione-1,4

Préparé de la façon habituelle (n'a pas cristallisé). Spectre de r.m.n. (CCl_4): deux singulets à 2.08 et 2.11 ($OCOCH_3$), un singulet à 5.80 (deux protons; CH 5,6), un singulet à 7.09 (CH 3) et un multiplet à 7.48 C_6H_5).

(VI) Tétrahydroxy o-xylène

Méthode A: à partir de la dihydroxy-5,6(cis) diméthyl-2,3 cyclohexène-2 dione-1,4

A une solution d'éther anhydre (100 ml) saturée d'acide bromhydrique, on ajoute le diol ***2a*** (1 g) et on laisse réagir pendant 1 h à 25°. On évapore ensuite le solvant à sec et on obtient de cette façon des cristaux blancs du tétrahydroxy *o*-xylène que l'on filtre et lave avec du chloroforme froid (25 ml). Les rendements sont quantitatifs. Le tétrahydroxy *o*-xylène fond à 177–179° après deux cristallisations du chloroforme. Spectre i.r. (KBr): 2.85 à 3.12 (bande très large, OH), 6.12, 6.61 et 6.66 (C═C), et 7.46 à 8.33 μ (bande très large, C—O). Spectre de r.m.n. ($(CD_3)_2CO$): un singulet à δ 2.08 (CH_3 5,6) et une bande très large de 3.5 à 6.7 correspondant à quatre protons et disparaissant par deutériation (OH 1,2,3,4).

Méthode B: énolisation et hydrolyse de la diacétoxy-5,6-(cis) diméthyl-2,3 cyclohexène-2 dione-1,4

On laisse reposer le diacétate (1 g) dans du méthanol (20 ml) contenant de l'acide chlorhydrique concentré (1 goutte) pendant 30 h à la température ambiante. On évapore alors l'alcool et on dissout l'huile résiduelle dans du chloroforme (10 ml) et on laisse cristalliser. On filtre les cristaux et on lave avec un peu de chloroforme froid (5 ml). On isole de cette façon 0.55 g du tétrahydroxy *o*-xylène (80%), p.f. 177–179°. Le point de fusion d'un mélange avec le produit obtenu par la méthode précédente est identique. Les spectres i.r. et de r.m.n. sont aussi identiques.

Tétraacétoxy o-xylène

Par acétylation de 0.9 g du tétrahydroxy *o*-xylène dans l'anhydride acétique contenant une trace d'acide sulfurique, on obtient après hydrolyse, extraction au chloroforme, séchage et évaporation 1.6 g du tétraacétoxy *o*-xylène, p.f. 173–174°.

L'échantillon analytique obtenu après deux recristallisations de l'acétate d'éthyle fond à 174.0–174.5°. Spectre i.r. (KBr): 5.62 ($OCOCH_3$) et 8.33 μ (bande large, C—O). Spectre de r.m.n. ($(CD_3)_2CO$): un singulet à δ 2.08 (CH_3 5,6) et deux singulets à 2.22 et 2.29 ($OCOCH_3$ 1,2,3,4). Les trois singulets sont d'égale intensité.

Anal. calc. pour $C_{16}H_{18}O_8$: C, 56.80; H, 5.36. Trouvé: C, 56.96; H, 5.39.

Dihydroxy-5,6 diméthyl-2,3 benzoquinone

Méthode A: à partir du tétrahydroxy o-xylène

On dissout 1 g de tétrahydroxy *o*-xylène dans 50 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

d'une solution faiblement basique (p*H* 8–9) et on y fait barboter de l'air pendant 1 h. On acidifie alors à p*H* 3 la solution refroidie dans la glace et on filtre le précipité rouge vin (0.7 g) de dihydroxy *o*-xyloquinone. L'extraction à l'éther des eaux-mères donne en plus 0.25 g de dihydroxy quinone (rendement total 95%). Si l'oxydation se fait à un p*H* supérieur à 9 elle est plus rapide mais les rendements sont beaucoup plus faibles.

La dihydroxy-5,6 diméthyl-2,3 benzoquinone cristallise de l'éthanol (95%) en feuilles rouge vin, p.f. 214–215° (rapide) (litt. 182, déc.). Spectre i.r. (KBr): 2.98 (OH), 6.11 (C═O), 7.75 et 8.26 μ (C—O). Spectre de r.m.n. ($(CD_3)_2CO$): deux singulets à δ 1.97 et 2.80 correspondant respectivement à six et deux protons. (CH_3 2,3; OH 5,6).

Anal calc. pour $C_8H_8O_4$: C, 57.14; H, 4.80. Trouvé: C, 57.21; H, 5.01.

Méthode B: à partir de la dihydroxy-5,6 diméthyl-2,3 cyclohexène-2 dione-1,4

On dissout 1 g du diol dans une solution de bicarbonate de sodium (p*H* 9) et on procède de la manière décrite dans la méthode A en laissant toutefois barboter le courant d'air pendant 3 h pour permettre une énolisation complète. On recueille ainsi 0.6 g (60%) de la quinone dihydroxylée identique à celle obtenue par la méthode A p.f. 213° (rapide), p.f. de mélange 213–215° (rapide). Cette méthode permet de passer directement de la dihydroxy-5,6 cyclohexène-2 dione-1,4 à la quinone dihydroxylée. Toutefois les rendements (60%) sont inférieurs à ceux de la méthode A précédente.

Diméthyl-2,3 diméthoxy-5,6 benzoquinone (aurantiogliocladine)

A une solution de dihydroxy *o*-xyloquinone (1.68 g) dans l'éther anhydre (10 ml) on ajoute 0.5 g de diazométhane. On laisse réagir jusqu'à la disparition de l'effervescence et on évapore l'éther. On chromatographie l'huile jaune orange sur gel de silice avec du benzène comme éluant. On obtient 1.85 g d'aurantiogliocladine (94%) qui cristallise en aiguilles (assez difficilement) de l'éther de pétrole (p.é. 30–60°), p.f. 61.0–61.5° (litt. 64° (30)). L'échantillon analytique a été obtenu après deux recristallisations dans le *n*-hexane suivies d'une sublimation à 40°, p.f. 62.0–62.5°. Spectre i.r. (KBr): 6.02 (C═O), 6.20 μ (C═C). Spectre de r.m.n. ($CDCl_3$): deux singulets d'égale intensité à δ 2.00 et 4.00 respectivement (CH_3 2,3; OCH_3 5,6).

Anal. calc. pour $C_{10}H_{12}O_4$: C, 61.21; H, 6.17. Trouvé: C, 61.20; H, 6.36.

(VII) Autres dérivés

Epoxy-5,6 cyclohexène-2 oximido-4 one-1

A une solution de chlorhydrate d'hydroxylamine (0.25 g) dans du méthanol (15 ml, solution aqueuse à 80%) on ajoute de l'acétate de sodium (0.23 g). Par addition d'acide chlorhydrique dilué, on ajuste le p*H* de la solution à 5. On ajoute alors 0.5 g d'époxy-5,6 cyclohexène-2 dione-1,4 et on laisse réagir pendant 2 h. On note l'apparition rapide d'une forte coloration rouge. La réaction terminée, on ajoute 10 ml d'eau et on évapore l'alcool sous vide à 40 °C. On isole ainsi 0.1 g de l'oxime qui cristallise très lentement dans les eaux-mères, p.f. 136° (déc.). Cet oxime, assez stable à l'état solide, se décompose rapidement en solution. Spectre de r.m.n. ($CDCl_3$): quatre quadruplets respectivement à δ 3.66, J = 3.7, 2.0 Hz (CH 6), 4.78, J = 3.7, 2.2 Hz (CH 5), 6.10, J = 10.0, 2.0 Hz (CH 2) et 6.97, J = 10.0, 2.2 Hz (CH 3), et un singulet à 11.89 (NOH).

Diacétoxy-5,6(trans) méthyl-5 cyclohexène-2 dione-1,4

A 0.5 g d'époxy-5,6 méthyl-5 cyclohexène-2 dione-1,4 dissous dans 5 ml d'acide acétique on ajoute 5 ml d'anhydride acétique et 1 ml d'acide sulfurique concentré et on chauffe sur un bain-marie pendant 5 min. On refroidit et on ajoute 15 g de glace. La diacétoxy-5,6(*trans*) méthyl-5 cyclohexène-2 dione-1,4 précipite du mélange réactionnel et on isole après filtration, lavage, et séchage 0.45 g de cristaux blancs, p.f. 197–198°. Après deux recristallisations de l'acétate d'éthyle ce diacétate fond à 198–199°. Spectre i.r. ($CHCl_3$): 3.28 (C═CH), 3.39 ($OCOCH_3$), 5.67 (C═O), 5.82 (C═C) et 8.00 avec épaulement à 8.26 μ (C—O). Spectre de r.m.n. ($CDCl_3$): cinq singulets à δ 1.43 (trois protons; CH_3 5), à 2.07 (trois protons; $OCOCH_3$ 5), à 2.25 (trois protons; $OCOCH_3$ 6), à 6.50 (un proton; CH 6), et à 7.02 (deux protons; CH 2,3).

Diacétoxy-5,6(trans) diméthyl-5,6 cyclohexène-2 dione-1,4

L'ouverture de 0.5 g de l'époxy-5,6 diméthyl-5,6 cyclohexène-2 dione-1,4 par la même méthode donne 0.55 g de la diacétoxy-5,6(*trans*) diméthyl-5,6 cyclohexène-2 dione-1,4, p.f. 185–187°. Ce produit cristallise de l'acétate d'éthyle en aiguilles blanches, p.f. 187.0–187.5°. Spectre i.r. (Nujol): 5.71 ($OCOCH_3$), 5.82 (C═O) et 8.28 μ (C—O). Spectre de r.m.n. ($(CD_3)_2CO$): trois singulets à δ 1.60 (six protons; CH_3 5,6), à 1.93 (six protons; $OCOCH_3$ 5,6) et 6.67 (deux protons; CH 2,3).

Diacétoxy-2,3(trans) dioxo-1,4 tétrahydro-1,2,3,4 naphtalène

Le dioxo-1,4 époxy-2,3 tétrahydro-1,2,3,4 naphtalène (1.0 g) donne par la même méthode 0.9 g de diacétoxy-2,3(*trans*) dioxo-1,4 tétrahydro-1,2,3,4 naphtalène, p.f. 211–212°. Un échantillon analytique, obtenu après deux recristallisations de l'acétate d'éthyle, fond à 215.0–215.5° (litt. 193–194° (21)). Spectre i.r. (KBr): 3.47 (acétates; vibration CH), 5.70 ($OCOCH_3$), 5.88 (C═O), 6.28 (aromatique), et 8.10 μ (bande large, C—O). Spectre de r.m.n. ($(CD_3)_2CO$): un singulet à 2.18 ($OCOCH_3$ 2,3), un singulet à 6.16 (CH 2,3) et un multiplet à 8.05 (quatre protons; CH aromatiques).

Anal. calc. pour $C_{14}H_{12}O_6$: C, 60.87; H, 4.38. Trouvé: C, 61.34; H, 4.33.

Bromo-2 dioxo-1,4 hydroxy-3 tétrahydro-1,2,3,4 naphtalène

A 10 ml d'une solution aqueuse d'acide bromhydrique à 48%, on ajoute 0.5 g de dioxo-1,4 époxy-2,3 tétrahydro-1,2,3,4 naphtalène et on agite pendant 10 min. On note alors l'apparition d'un précipité que l'on filtre aussitôt. On lave les cristaux avec 10 ml d'une solution diluée de sulfite de sodium (5%) puis avec 10 ml d'eau. On isole 0.45 g de bromo-2 dioxo-1,4 hydroxy-3 tétrahydro-1,2,3,4 naphtalène qui après deux recristallisations du chloroforme, fond à 190.00–190.5° (déc.). Cette bromohydrine est très instable, surtout en solution. Spectre i.r. (KBr): 2.86 (OH), 3.30 (CH), 3.44, 5.85 (C═O), 6.27 (C═C), et 7.91 μ (C—O). Spectre de r.m.n. ($(CD_3)_2CO$): un doublet à δ 4.81, J = 7.5 Hz, un doublet

à 5.16, J = 7.5 Hz, un multiplet à 8.00 (quatre protons: CH aromatiques).

Addition du brome ou du chlore aux oximes de quinones

L'addition du brome ou du chlore aux oximes (ou aux acétates correspondants) de quinones par les méthodes déjà décrites (17) donnent avec des rendements excellents les composés suivants dont les spectres r.m.n. sont décrits dans le tableau 2.

Dichloro-5,6 cyclohexène-2 acétoximido-4 one-1. Le p.f. 134° (déc.).

Dichloro-5,6 méthyl-2 cyclohexène-2 acétoximido-4 one-1. Le p.f. 154° (déc.).

Dibromo-5,6 cyclohexène-2 acétoximido-4 one-1. Le p.f. 135° (déc.).

Dibromo-5,6 méthyl-2 cyclohexène-2 acétoximido-4 one-1. Le p.f. 154° (déc.).

Dibromo-5,6 diméthyl-2,3 cyclohexène-2 oximido-4 one-1. Le p.f. 160° (déc.).

An Electron Spin Resonance Study of the 9,10-Dihydrophenanthrene Radical Anion

F. C. ADAM

Departments of Chemistry, University of Calgary, Calgary, Alberta and University of Sydney, Sydney, New South Wales, Australia

Received December 12, 1967[1]

The e.s.r. spectrum of 9,10-dihydrophenanthrene radical ion has been obtained in ether solvents at a number of temperatures between −106 and +51 °C. In dimethoxyethane–tetrahydrofuran mixtures below −80 °C, six triplet splittings are found with mean coupling constants of 5.36, 3.36, 2.66, 0.70, 0.26 and 0.15 oe. Above this temperature broadening occurs with some lines of the hyperfine spectrum due to motion resulting from the interconversion between the two equivalent conformers of the non-planar molecule ion. While the ring proton coupling constants are not strongly dependent on temperature, those due to the four methylene protons are, and interconversion between the conformers broadens the lines so that a 1:4:1 triplet is observed at low temperatures with a coupling of 2.97 oe. This is the sum of the axial and equatorial methylene proton splittings of a particular conformer. Near room temperature the motion is sufficiently rapid to give exchange narrowed lines and the process has an activation energy of 4.5 kcal/mol^{-1}. From these observations it was possible to assign the coupling constants to specific protons in the molecule and to determine the dihedral angle between the rings as 21°.

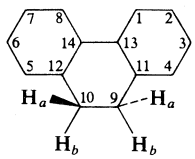
Le spectre de r.p.e. de l'ion radicalaire du 9,10-dihydrophénanthrène a été obtenu dans l'éther à différentes températures entre −106 et +51 °C. Dans un mélange diméthoxyéthane tétrahydrofuranne à une température inférieure à −80 °C, on observe six triplets avec des écarts hyperfins moyens de 5.36, 3.36, 2.66, 0.70, 0.26 et 0.15 oe. A température plus élevée, il se produit un élargissement de certaines raies du spectre hyperfin causé par une interconversion entre deux conformères équivalents de la molécule ion non-polaire. Même si les écarts hyperfins des protons des noyaux ne varient sensiblement pas avec la température, ceux dûs aux protons méthyléniques le sont, et l'interconversion entre conformères élargit les raies de telle sorte qu'à basse température on observe un 1:4:1 triplet avec un couplage de 2.97 oe. C'est la somme des écarts hyperfins des protons méthyléniques axial et équatorial de chaque conformère. Aux environs de la température ambiante, le mouvement moléculaire est suffisamment rapide pour que le phénomène d'échange produise un rétrécissement des raies et ce processus a une énergie d'activation de 4.5 kcal/mol. Grâce à ces observations, il a été possible d'assigner des écarts hyperfins à certains protons dans la molécule et de déterminer que l'angle dihèdre entre les noyaux est de 21°.

Canadian Journal of Chemistry, **49**, 3524 (1971)

Introduction

In the course of an investigation of a series of diphenyl radical anions, the spectrum of 9,10-dihydrophenanthrene reduced with different alkali me als was studied in a variety of solvents. The molecule has the carbon skeleton of diphenyl with two methylene groups bridging two of the ortho positions of the diphenyl rings. Molecular models show the molecule exists in two equivalent configurations in which the aromatic rings are held at approximately 20° relative to each other by the saturated bridge. In both conformers, each methylene group has an "axial" bond, which projects very nearly at right angles to the plane of the adjacent phenyl ring, while an "equatorial" bond lies very near to the phenyl plane. If one of the conformers is converted to the other, the equatorial proton and geminal axial proton of each methylene group exchange positions.

The numbering scheme used to identify the protons is as follows:



wherein H_a represents an axial proton and, H_b represents an equatorial proton.

Methyl (or methylene) groups attached to a carbon 2pπ orbital containing an unpaired electron spin have been shown (1) to give rise to isotropic proton hyperfine coupling constants

which follow a relationship given by

$$[1] \qquad a_{CH} = \rho(B_0 + B_2 \cos^2 \theta)$$

where $B_0 = 3.2$ oe, and $B_2 = 43.6$ oe, while θ is the dihedral angle that the C—H bond displays to the $2p\pi$ orbital axis as viewed down the C—C bond; ρ is the spin density in the $2p\pi$ orbitals. As a result of this angular dependence it is expected that the methylene protons in the axial and equatorial positions of the 9,10-dihydrophenanthrene anion will exhibit markedly different hyperfine coupling constants. Interconversion between the two conformers will result in modulation of these coupling constants with concomitant broadening at low interconversion rates, or with exchange-averaging of the hyperfine constants at higher rates (2).

The parent hydrocarbon species has been investigated using the technique of n.m.r. It is found that while 9,10-dihydrophenanthrene gives rise to a single narrow methylene proton absorption (3*a*), other derivatives give either a broadened methylene line, or a doublet when progressively larger groups are substituted in the remaining ortho positions of the diphenyl skeleton (3*b*) or in the bridge positions (3*c*). In particular, an activation energy of 23.1 kcal/mol is found for the 1,8-dimethyl 9,10-dihydrophenanthrene derivative, as estimated from the breadth of the n.m.r. lines observed as a function of temperature. The failure to observe line broadening in the case of 9,10-dihydrophenanthrene itself was taken to mean that the interconversion between the two conformers is extremely rapid (>100 Hz), due to a much lower barrier to conversion (<9 kcal/mol), even at the lowest temperature studied (-90 °C).

Although the diamagnetic compound studied by n.m.r. cannot be studied by e.s.r., the singly-reduced species can, and interconversion frequencies in the range 20 kHz to 100 mHz can be studied using analogous hyperfine line broadening techniques. It is not expected that the rotational energy barriers will be markedly different between the anion and the neutral hydrocarbon species, except that in the anion, the bond order of the central interannular bond is probably slightly higher. This would presumably decrease the energy required for interconversion so that an estimate of the activation energy obtained by e.s.r. would correspond to a lower limit for the neutral species. This paper describes a study of the temperature effects in the e.s.r. spectrum of the anion and an attempt to ascertain the rates of interconversion.

Experimental

9,10-Dihydrophenanthrene (DHP) was obtained from Aldrich Chemical Company, and repeated recrystallizations from ethanol were carried out followed by chromatography on alumina to make sure no phenanthrene or diphenyl remained. The purified compound was reduced by sodium metal in dimethoxyethane (DME) under high vacuum conditions. Potassium reduction gave essentially the same spectrum, and no metal splittings were observed with either metal in this solvent. Temperatures were reliable to about ± 2 °C. Cold nitrogen gas was transmitted through a conventional Dewar train to a quartz insert in the dual rectangular cavity of both a modified Strand-Labs X-band spectrometer employing a 12 in. Harvey–Wells magnet, and a Varian 4502 system. The field was calibrated with diphenyl reduced by potassium in dimethoxyethane wherein the para coupling constant of the diphenyl anion so obtained was taken to be 5.26 oe at room temperature.

Spectra of DHP anion were also taken using a 2:1 mixture of tetrahydrofuran (THF), with DME. Each solvent had been distilled from lithium aluminum hydride and stored over sodium–potassium alloy, under vacuum.

Results

Because of the similarity in structure one would expect the u.v. and e.s.r. spectra of the anion of 9,10-dihydrophenanthrene (DHP) to be analogous to biphenyl negative ion. The similarity in their u.v. spectrum has already been pointed out by Velhorst and Hoijtink (4). The solutions of DHP in DME are deep blue-green in color throughout the temperature range studied. Eloranta (5) has reported that these same green solutions are unstable and eventually lead to formation of an orange coloration. This was not the case with our preparations and both the blue-green color and the e.p.r. spectrum of solutions have remained unchanged in sealed sample tubes for a period of over three years. Biphenyl anion solutions are blue and phenanthrene, which appears to be the major impurity, produces olive green solutions. Each compound has its own characteristic e.p.r. spectrum and these have been well characterized over the temperature range of interest and in the various solvent compositions investigated. Only the spectrum of DHP exhibits the marked temperature dependence to be described. At the very lowest temperatures obtained before the onset of viscos-
